Fig. 4 T chromosome haplogroup phylogeny with arbitrary branch lengths. Labels outside terminal nodes describe the geographic origin of the majority of the individuals represented by the haplogroup (*Af* Africa, *Am* Americas, *As* Asia, *Eu* Europe, *Oc* Oceania) (Modified from van Oven et al. 2014)

The Y chromosome fulfills an analogous paternal role to maternally inherited mtDNA, as the majority of it does not recombine with regions of the X chromosome. This nonrecombining region (NRY) is also referred to as the male-specific portion (MSY) of the Y chromosome. While it was initially thought that little variation was present on the human Y chromosome, increasingly sophisticated molecular analytical techniques have allowed for the discovery of a wealth of variation and potential phylogenetically informative markers. Fortunately, unlike mtDNA, the naming of major lineages or haplogroups was regularized to unambiguously label the clades based upon their phylogenetic structure (The Y Chromosome Consortium 2002).

Early major research groups investigating human evolutionary history using Y chromosome markers inferred trees that have their deepest and next deepest roots within African populations (Underhill et al. 2000; Hammer et al. 2001; Jobling and Tyler-Smith 2003) (see Fig. 4). These studies also concurred in inferring a relatively recent African origin, around 100 Ka or younger with a more recent exodus into the rest of the Old World (Hammer et al. 1998; Underhill et al. 2000). This date is more recent than the mtDNA-derived estimate possibly because of the smaller effective population size of the human Y chromosome due to greater variation in reproductive success of males compared with females and the greater geographic structuring of Y chromosome variation. This apparent more recent common ancestry has been called into question by more recent studies involving more markers and more individuals. Cruciani et al. (2011) sequenced ~240 kb to better resolve the deeper lineages. Their study doubled the number of African-specific lineages and estimated the most recent common ancestor (MRCA) at 142 Ka.

Another study of 9 mega-base pairs (Mb) from over 1,200 males which using a rate of 0.53×10^{-9} bp^{-1} $year^{-1}$ (which is close to the estimates from triad de novo rates) found a MRCA of ~200 Ka (Francalacci et al. 2013). Mendez et al. (2013) discovered a new Y chromosome lineage in an African American individual that is also found in extremely low frequency in some Central Africans that they name A00. They inferred a MRCA date of 338 Ka and suggested either fundamental reassessment of the models for Y chromosome origins or the possibility of archaic hominin introgression. Elhaik et al. (2014) strongly critiqued Mendez et al.'s (2013) analyses on several grounds and recalculate the MRCA to 208 Ka. An analysis of 69 complete Y chromosome sequences estimates the MRCA between 120 and 156 Ka, in line with mtDNA estimates (Poznik et al. 2013). All these Y chromosome studies concur in the African origin of modern diversity, with the larger analyses placing the timing of this origin within the range of the estimated MRCA for mtDNA depending upon which evolutionary rates and fossil calibration points were used.

Pre-Second-Generation sequencing era studies were remarkably consistent. A study of over 10,000 base pairs on a region of the X chromosome with low levels of recombination also is compatible with the mtDNA and Y chromosome results. Kaessmann et al. (1999) found an approximately 535 Ka most recent common ancestor for the alleles of this region. This is broadly consistent with the mtDNA and Y chromosome dates, given that the effective population size of the X chromosome is three times that of the other two loci, so coalescent estimates will be approximately three times as old as well. A 3,000 bp region of the β-globin locus on chromosome 11 yielded an estimate of 750 Ka, which is again broadly consistent with being four times older then mtDNA and Y chromosome dates (Harding et al. 1997).

Nuclear loci such as the compound haplotype composed of an STR locus and an *Alu* deletion polymorphism on chromosome 12 at the CD4 locus demonstrate a similar pattern to the mtDNA and Y chromosome patterns of variation (Tishkoff et al. 1996). An African origin for the variation at this locus is estimated in the same time frame as that inferred from mtDNA and Y chromosome data with dramatically reduced variation found outside of Africa. Phylogenetic trees derived from numerous microsatellite (STR) loci similarly find their roots within Africa with reduced variation outside of it, though divergence date estimates cannot be easily calculated from such data (Bowcock et al. 1994). A similar pattern is found with SNPs (Yu et al. 2002) and polymorphic *Alu* insertions (Batzer et al. 1996).

Altogether, the majority of analyses of relatively short molecular sequences and markers suggest a recent African origin for the diversity of modern human genomes (Jorde et al. 2000; Takahata et al. 2001; Excoffier 2002; Satta and Takahata 2002). However, interpretations that contradict a scenario of a recent African origin have been put forth (Harris and Hey 1999; Hawks and Wolpoff 2001; Templeton 2005). Harris and Hey (1999), for instance, interpret PDHA1 (an X chromosome locus) sequence diversity as yielding a 1.86 Ma common ancestor, which would fall outside of the range of estimates derived from the above loci. The PDHA1 analysis has been called into question, due to the probability that the locus is under selection which makes inferences as to coalescence dates difficult (Disotell 1999). Nested clade analyses (Templeton 2002, 2005) suggest more than one major exodus from

Africa, an early one, approximately 1.9 Ma, one around 600–700 Ka, and a final one around 100 Ka with evidence for range expansion, long-distance dispersal, and isolation by distance complicating the picture. These analyses have generated a healthy skepticism, especially over the efficacy and accuracy of nested clade analysis (Cann 2002; Knowles and Maddison 2002; Satta and Takahata 2002; Panchal and Beaumont 2010).

Another approach to understanding our evolutionary history comes from examining the particular patterns of molecular variation found throughout the world. Several studies using microsatellite or short tandem repeat (STR) markers have found patterns that are best explained by a series of serial founder effects emanating from Africa outward to other regions of the world. Both Prugnolle et al. (2005) and Ramachandran et al. (2005) find the amount of genetic variation measured in a variety of ways linearly decreases the further populations are from Africa.

Analyses of the several thousandfold increase in amount of human molecular data collected with the advent of microarray SNP typing and Second-Generation (2ndGen) sequencing have corroborated most of the above findings. The Recent African Origin (RAO) model with important caveats discussed in detail below best explains the patterns of human molecular diversity observed today.

Neanderthals, Denisovans, and Other Archaic Hominins

Another opportunity for biomolecules to shed light on hominin phylogeny involves the direct characterization of DNA from fossils. While the earliest analyses of ancient hominin DNA focused on mtDNA, 2ndGen technologies now allow entire genomes to be sequenced. The presence of hundreds to thousands of copies of the mtDNA genome in most cells makes it an ideal candidate for extraction from poor or degraded sources of tissue, such as teeth and bone, including fossils. Ancient DNA (aDNA) analyses are however fraught with difficulties (Cooper and Poinar 2000; Mulligan 2005). Ancient DNA, when present, even under ideal preservation conditions is likely to be damaged and fragmented. More importantly, it is almost certainly contaminated with modern DNA from the environment, excavators, curators, scientists who have handled the material, and molecular laboratory personnel. Extraordinary precautions and techniques need to be carried out to lower the probability of mistakenly accepting such modern contaminants as the sequences from the ancient material (Cooper and Poinar 2000; Mulligan 2005). Despite these difficulties, aDNA provides a unique and important window in the evolutionary history and processes.

By the end of 2007, partial mtDNA sequences from around 18 Neanderthal individuals have been gathered (Krings et al. 1997; Ovchinnikov et al. 2000; Schmitz et al. 2002; Serre et al. 2004; Beauval et al. 2005; Lalueza-Fox et al. 2005; Caramelli et al. 2006; Lalueza-Fox et al. 2006; Orlando et al. 2006; Krause et al. 2007). These sequences form a reciprocally monophyletic clade with the thousands of modern human mtDNA sequences analyzed to date and are estimated to have diverged from modern humans somewhere between 365 and

853 Ka, with an average between 550 and 600 Ka. Even with this preliminary sampling of multiple individuals from different time periods and geographic locations, it is unlikely that a Neanderthal sequence that falls within the modern mtDNA gene pool will be discovered (Krings et al. 2000). Wolpoff (1998) suggested that because the original Feldhofer Neanderthal sequence is more similar to some modern human sequences than some other modern sequences are to other moderns, their mtDNA gene pools overlapped. This however was a misleading analysis as a cladistic analysis of the same data clearly demonstrates a complete separation of Neanderthals and moderns into reciprocally monophyletic clades (Disotell 1999). This observation has been further strengthened by all additional Neanderthal sequences and molecular analyses.

These Neanderthal sequences do not cluster among modern European sequences, as might be expected if they gave rise to the Europeans or extensively interbred with the new migrants into Europe as would be predicted under the multiregional model. However, both Nordborg (1998) and Relethford (2001) point out that different amounts of crossbreeding between Neanderthals and early moderns could have still been possible with the Neanderthal mtDNA lineages having gone extinct due to normal stochastic processes over the last 30 Ka. The Neanderthal sequences do show geographic and temporal structure however. The oldest sequences and eastern-most Neanderthals cluster together to the exclusion of western European samples younger than 48 Ka. Fabre et al. (2009) and Dalén et al. (2012) suggest that the western population may have experienced a bottleneck and population replacement while the eastern populations were more stable through time.

To further test hypotheses of modern human origins, several researchers have attempted to recover and sequence early modern human aDNA. One of these attempts provides a good illustration of the numerous difficulties of aDNA analysis. Adcock et al. (2001) claimed to have recovered an mtDNA sequence from an early modern human fossil skeleton from Australia, known as Lake Mungo III, then thought to date to approximately 60 Ka [this specimen has since been redated to 40 Ka (Bowler et al. 2003)]. The sequence fell outside of the range of modern human mtDNA diversity and clustered with a sequence located on chromosome 11 of the modern human genome, a known mitochondrial pseudogene (numt). Their interpretation was that early modern humans reached Australia before the most recent African exodus that gave rise to the rest of the world's mtDNA diversity less than 100 Ka. This analysis seems deeply flawed for several reasons. First, the standard protocols suggested to avoid contamination with modern DNA (Cooper and Poinar 2000; Mulligan 2005) were not rigidly followed (Cooper et al. 2001). The sequence is most likely in fact a contaminating numt or has been damaged to yield spurious nucleotide substitutions (Cooper et al. 2001). Smith et al. (2003) point out that it is extremely unlikely for aDNA to have survived at the Lake Mungo site due to the environmental conditions present. Finally, reanalysis with additional Australian and African sequences yields a tree very different from that originally put forth (Cooper et al. 2001). Caramelli et al. (2003) attempted to sequence several early modern specimens from Paglicci Cave in Southern Italy. Their sequences fully fall within the range of modern human sequences. These sequences are therefore either modern contaminants, or early modern mtDNA sequences indeed fall within the range of all modern mtDNA present today.

Serre et al. (2004) therefore took a different approach to investigating early modern human and Neanderthal mitochondrial diversity. They realized that demonstrating the presence of early modern mtDNA at that time was nearly impossible, so they tested five early modern fossil samples along with four Neanderthal samples for the presence of Neanderthal-specific mtDNA motifs. Included among the early human samples were fossils from Vindija, Croatia, and Mladeč (Czech Republic) that have been claimed to be transitional between Neanderthals and early moderns (Wolpoff 1999). Their reasoning was that, if interbreeding occurred between the two groups, the presence of Neanderthal mtDNA in early modern individuals would be more likely since it would not have had a great amount of time to go extinct as Nordborg (1998) and Relethford (2001) potentially proposed for the absence of Neanderthal mtDNA today. Serre et al. (2004) were able to amplify all four Neanderthal samples with "Neanderthal-specific" primers. None of the early modern human fossils yielded amplification products, though they did for more generalized "hominoid-specific" primers, suggesting DNA was present. Furthermore, faunal samples from the same sites all yielded DNA products, suggesting that the conditions at the sites were adequate for the preservation of aDNA.

Currat and Excoffier (2004) carried out a simulation study to model the conditions necessary to detect Neanderthal introgression with mtDNA. They extensively modeled different scenarios of modern human expansion into Europe with competition and admixture with Neanderthals. They found the mtDNA data at the time was only compatible with a less than 0.1 % interbreeding rate that would mean fewer than 120 matings over a 12,000-year period of overlap. One of the most important components of their model demonstrated that at the leading edge of an expanding population where interbreeding is most likely acts like a wave carrying new mutations and introgressed alleles to higher and higher frequencies. This iterative founder effect phenomenon is often referred to as "surfing the wave."

With development of 2ndGen sequencing methods, the potential of retrieving archaic hominin nuclear DNA improved dramatically. The first such studies (Noonan et al. 2006; Green et al. 2006) sampled a 38 Ka specimen (Vi-80) from Vindija Cave, Croatia, whose mtDNA analysis suggested contained 98 % endogenous Neanderthal DNA and only 2 % modern human contamination. Noonan et al. (2006) directly cloned DNA from the specimen (without amplification) and generated 62 kb of Neanderthal DNA. The sequences had the particular patterns of damage usually found in ancient DNA and were thus of presumed Neanderthal origin. They estimated an average divergence time between their sequences and those of modern humans at 706 Ka with the population split at 370 Ka.

Divergence time estimates for different loci within the genome will almost always be older than the population split, because nearly all populations have some level of variation within them. One test for the populations' divergence date is to look at variants within each population. For instance, if modern humans and Neanderthals separated a long time ago, Neanderthals would only rarely have the derived version of a modern human variant because if the variant appeared only in the modern lineage, and not in the common ancestor of modern humans and Neanderthals, the derived modern variant would not be found in Neanderthals. On the other hand, if Neanderthals and modern humans split recently or were significantly admixed, then derived modern human variants should be common in the Neanderthal genome. With only three derived modern human variants in their Neanderthal sample, Noonan et al. (2006) concluded that little to no interbreeding had occurred.

Green et al. (2006) using the same sample as Noonan et al. (2006) generated more than a million bases of sequence using a standard 2ndGen technique involving bead-based amplification. They estimated a divergence time of 516 Ka and found 30 % of the SNPs were identical to human-derived alleles. From this, they concluded significant admixture occurred. However, Wall and Kim (2007) demonstrated that much of Green et al.'s (2006) sequence was modern human contamination most likely introduced in the commercial facility utilized for the final sequencing. Thus, as of 2007, there was little evidence of any Neanderthal admixture with modern humans (Hodgson and Disotell 2008).

Using 2ndGen sequencing techniques, Green et al. (2008) generated a complete mtDNA genome from a Neanderthal from Croatia (Vindija 33.16). Briggs et al. (2009) sequenced five additional complete mtDNA Neanderthal genomes including Feldhofer 1 and 2, Vindija 33.25, El Sidrón in Spain, Mezmaiskaya 1, and Mezmaiskaya 2 (only a partial mtDNA genome) using a 2ndGen approach that targeted mtDNA. The younger individuals (38–70 Ka) had only about a third of the variation found in modern humans today, while the oldest sample was most divergent. The Mezmaiskaya 2 individual, despite only being 42 Ka, clustered with the younger western Neanderthals. A complete mtDNA genome from a 30 Ka modern human sample from Kostenki, Russia, was also sequenced using these techniques (Krause et al. 2010a). It clusters inside modern human haplogroup U2, which is common in North Africa, western Asia, and Europe.

With over two-dozen Neanderthal individuals sampled as of 2009, there was no evidence of mtDNA gene flow with modern humans (Currat and Excoffier 2004; Serre et al. 2004; Hodgson and Disotell 2008). With no sign of Neanderthal mtDNA in the tens of thousands of modern humans sampled to date, it was suggested that Neanderthal–human hybrids would have been rare while male hybrids might be sterile (Mason and Short 2011). According to Haldane's rule, the heterogametic sex in interspecific hybrids will be absent, rare, or sterile (Short 1997).

Improvements to 2ndGen sequencing techniques and new ways of avoiding or at least identifying contamination allowed Green et al. (2010) to successful produce a complete draft Neanderthal genome to 1.3-fold coverage. They generated 5.3 gigabases (Gb) of sequence from three Croatian female Neanderthal samples, using two different techniques that reduced microbial background and enriched the endogenous DNA present in the bones. They were able to cover about 60 % of the Neanderthal genome with less that 1 % error (Green et al. 2010). Along with the complete genomes of five diverse humans and small amounts of sequence from El Sidón, Feldhofer Cave, and Mezmaiskaya Neanderthals, they estimate the population split between humans and Neanderthals at occurred 270–440 Ka. Since modern human mtDNA coalesces around 200 Ka, the Neanderthal–human population split falls within the range of coalescence for nuclear genes (four times that of mtDNA). Therefore, it is expected that many alleles should be shared between humans and Neanderthals.

Green et al. (2010) found an excess of shared alleles between Neanderthals and the genomes they sampled from a French, Han Chinese, and Papua New Guinean individual but not two Africans (San and Yoruba). This suggests that non-African populations share more ancestry than African populations with Neanderthals, indicating some level of admixture. Interestingly enough, the Chinese and Papuan individuals share as much ancestry with Neanderthals as the French individual. By examining the extended haplotypes (regions of the genome that are similar between two individuals), they noted longer haplotypes in Neanderthals and non-Africans than in Africans. This suggests that the admixture was recent, since these regions were not broken up by recombination.

Green et al. (2010) estimated between 1 % and 4 % of non-African modern human alleles introgressed from Neanderthals. Furthermore, this gene flow was within the last 100 Kyr. They proposed two alternate scenarios to explain this admixture. Since the Neanderthal–human split occurred within the time frame in which modern human nuclear DNA diversity developed, if there was ancient substructure, the African modern human population, some African populations could be more closely related to Neanderthals than to others. If such a population or populations also later gave rise to the modern humans that exited Africa, non-Africans and Neanderthals would share more alleles than Neanderthals and other Africans. Given that only two African individuals were sampled, this could not be ruled out. Eriksson and Manica (2012) note that any analyses of potential admixture need to take such substructure into account. Yang et al. (2012) carried out simulations and compared them to data from the Complete Genomics Diversity Panel (Drmanac et al. 2010) and concluded that ancient African substructure does not explain Green et al.'s (2010) finding. Eriksson and Manica (2014) however argue that Yang et al.'s (2012) simulations were inadequate and ancient population substructure cannot be ruled out.

Green et al.'s (2010) favored scenario is that admixture occurred shortly after the modern human exodus from Africa carrying Neanderthal alleles both into western Asian and Europe as well as eastern and southeast Asia. One estimate of the timing of this potential gene flow is between 37 and 80 Ka (Sankararaman et al. 2012). Hodgson et al. (2010) suggested an alternative hypothesis in which limited admixture occurred slightly earlier, when African fauna and early modern humans expanded into western Eurasia around 100 Ka before retreating back into Africa due to climatic shifts. Neanderthal alleles would then be present in low frequency in northeast Africa. Populations from there later migrated out of Africa, either through the Sinai, the Arabian Peninsula, or both, carrying these alleles with them into Eurasia several tens of thousands of years later. These alleles would have become more common due to the iterative founder effect, surfing the wave to higher and higher frequencies in Europe and Asia (Currat and Excoffier 2004, 2011).

Updating their admixture models based on mtDNA (Currat and Excoffier 2004) to whole genomes, Currat and Excoffier (2011) found that under a wide variety of demographic scenarios, very low levels of interbreeding would be necessary to yield 1–4 % admixture. They further speculate that there would have been some kind of avoidance of interspecific mating or lower fitness in hybrids. They estimate that during the entire time and range of overlap, as few a few hundred matings may have occurred. Depending upon when and where those events occurred, different populations and different individuals are likely to share different Neanderthal alleles (Wills 2011). Vernot and Akey (2014) and Sankararaman et al. (2014) infer that up to 20–30 % of the Neanderthal genome is spread out among modern humans, a few nonoverlapping percent at a time.

With the continuing improving methodologies to extract and manipulate ancient DNA and higher and higher throughput 2ndGen sequencing technologies, an entire mtDNA genome followed by a 1.9× coverage full genome was generated from a 50 Ka partial juvenile distal phalanx and a single molar from Denisova Cave in the Altai Mountains of southern Siberia (Krause et al. 2010b; Reich et al. 2010). Using new techniques and remaining fragments of the phalange and some of the original extracted material, Meyer et al. (2012) generated a much higher coverage (31×) Denisovan genome which covers 99 % of the "mappable" genome. Despite being only 100 km from known Neanderthal sites, the Denisovan mtDNA genome is equally distantly related to both Neanderthals and modern humans, diverging around 1 Ma (Krause et al. 2010b). This date is too late to belong to *Homo erectus* and too early for the common ancestor of modern humans and Neanderthals. The Denisovan nuclear DNA on the other hand clusters with Neanderthals with an average divergence around 640 Ka.

The discrepancy between the mtDNA and nuclear divergence dates between Denisovans and Neanderthals could have two possible explanations. The Denisovans may have hybridized with an as yet unknown archaic hominin that migrated out of Africa after *Homo erectus* but before the common ancestor of Neanderthals and modern humans. Or, if the population that gave rise to Neanderthals and humans was quite variable and included the Denisovan haplotype, that haplotype may have gone extinct in both the modern human and Neanderthal lineages. This is known as incomplete lineage sorting. To date, neither of these hypotheses can be ruled out.

As interesting as the discovery of potential admixture between Neanderthals and Eurasians is the finding that up to 4.8 % Denisovan alleles are found in Melanesians (Reich et al. 2010). Along with 2.6 % Neanderthal ancestry, Melanesians may have up to 7.4 % of their genome composed of alleles found in archaic hominins. Denisovan alleles are also found in aboriginal Australians, near Oceanic, Polynesian, Fijian, and east Indonesian, but not south Asian or east Asian populations (Reich et al. 2011). Denisovans were also not very diverse, with only about 20 % of modern African and ~30 % of the variation found in Eurasians. There is also a reduced amount of admixed X chromosome alleles potentially suggesting it was mostly male-mediated gene flow. Unfortunately, all archaic genomes generated to date come from females, so we do not know what archaic Y chromosomes look like.

A toe phalanx discovered in 2010 in Denisova Cave has yielded an extremely high-quality (52× coverage) genome of a female Neanderthal (Prüfer et al. 2013b). With two high-quality archaic genomes now available, it was possible to estimate that the common ancestor of Denisovans and Neanderthals split from the modern human lineage between 553 and 589 Ka, while the two archaic lineages split approximately 381 Ka. The Altai Neanderthal was relatively inbred and probably derived from a population that went through a severe bottleneck. The higher-quality genomic data also reduce the amount of Neanderthal DNA thought to have introgressed into Eurasians to 1.5–2.1 %. Given that the branch length of the genome derived from the toe is shorter than the one derived from the finger, it is thought to be from slightly older sediments.

Further complicating the picture of admixture among the various hominins of the Middle Pleistocene is the observation that the mtDNA genome sequenced from a specimen from Sima de los Huesos in Spain is related to Denisovan mtDNA (Meyer et al. 2014). The Sima de los Huesos and Denisovan mtDNA genomes diverged around 700 Ka. The femur from which it was derived is classified as *Homo heidelbergensis* and is from sediments dated to over 300 Ka. Estimating the number of missing substitutions in the mtDNA genome, that is, those that would have occurred since the individual died, yields an expected age of 400 Kyr. Meyer et al. (2014) suggest that the most plausible evolutionary scenario is that the Sima de los Huesos hominins are broadly ancestral to both Denisovans and Neanderthals, which somehow maintained two deeply divergent mtDNA lineages.

Multiple scenarios are thus available to explain the complex patterns of relationships among the various Middle Pleistocene hominins and modern humans. The amounts, directions, and timings of introgression events are under healthy debate. There is still the possibility that what we are calling introgression may be the result of ancient population substructure (Eriksson and Manica 2014). Even the number of lineages involved is debatable. Does the Denisovan mtDNA haplotype represent another potential lineage? Hammer et al. (2011) infer approximately 2 % admixture from an unknown archaic population into some Africans population based on modern diversity in Africa. Similarly, based on whole-genome analyses, Lachance et al. (2012) infer introgression, from an unknown archaic population or populations, into Pygmy and click-speaking Hadza and Sandawe populations. Will east Asian fossils yield more surprises if or when molecular data is generated from them? Will the Flores Island specimens yield DNA with new and improved techniques, despite poor preservation?

Conclusions

Biomolecules have many advantages over morphological characters for phylogenetic analyses. The sheer volume of data potentially available is staggering. More importantly, nontrivial hypotheses regarding homology are generally more robust than those inferred for morphological characters and systems. The independence of characters and traits is more easily achieved at the molecular level, allowing multiple independent phylogenetic hypotheses to be generated and examined for concordance. On the other hand, all molecular phylogenies are necessarily gene trees, which can have different histories from the species or populations in which they reside. With whole-genome sequencing now available, including for a limited number of fossil taxa, the complexities of evolution are more readily apparent. Homoplasy and selection are more easily detectable at the molecular level. With high-quality ancient genomes, molecularly derived estimates of the ages of fossils are now possible. Fossils, on the other hand, can test hypotheses that have been put forth and suggest novel combinations of traits that we are not clever enough to have thought possible. A combination of approaches and techniques will provide us with the best insights into our evolutionary history.

The Miocene Hominoids and the Earliest Putative Hominids

Brigitte Senut

Contents

Abstract

For many years molecular studies suggested that the hominid family emerged during the Pliocene. But today we have good evidence of hominids in African Upper Miocene strata. Reconstructing our earliest history is a difficult task as the Miocene data is scanty and fragmentary. Furthermore, the tendency for

anthropologists to consider the modern chimpanzee as a good model for the last common ancestor of African apes and hominids has obscured our understanding of hominid evolution because the supposed distinctive apelike features are defined on the basis of a modern animal and not on those of Miocene hominoids. Taking into account detailed studies of Miocene apes and modern hominoids, it appears that bipedalism is probably the most reliable feature for defining hominids. Of the new hominoid taxa discovered in the Upper Miocene, only *Orrorin tugenensis* exhibits clear evidence of adaptation to bipedalism. Bipedalism in *Sahelanthropus tchadensis* and *Ardipithecus kadabba* still needs to be demonstrated. A long-lasting idea in hominoid evolution was that hominids emerged in dry, savanna-like environments; but the data obtained from the Upper Miocene levels in Baringo (Kenya) demonstrate that the environment of the earliest hominids was more forested and humid than expected. Finally, recent discoveries of modern-looking apes made in 12.5 Ma strata at Ngorora (Kenya), 10.5 Ma strata at Nakali (Kenya), 10 Ma strata at Chorora (Ethiopia), 11–5.5 Ma strata in Niger, and 6 Ma deposits at Kapsomin and Cheboit indicate that the dichotomy between African apes and humans could be much older than generally thought. Alternatively, one or more of these hominoids could represent early stages in the lineages of modern African apes.

Introduction

Identifying the earliest hominids remains a difficult task because the definition of the family varies widely from author to author. For some authors, the term hominid should be restricted to humans and their bipedal predecessors, whereas for others, it should include all extant and fossil great apes and humans; at its most extreme definition, all African apes should be included in the genus *Homo* (Czelusniak and Goodman 1998), or, in a slightly less extreme view, only chimpanzees and bonobos (with the exclusion of *Gorilla*) should be grouped with *Ardipithecus*, *Australopithecus*, and humans in this genus (Wildman et al. 2003). In the latter scenarios, the search for the oldest hominid leads to a strange situation where the quest becomes that of identifying the earliest ape rather than the earliest humans! This is definitely not what the theme of research on the origins of humans is today. The only consensus today among scientists (molecularists and anatomists) in ape evolution is that *Pongo*, *Pan*, and *Gorilla* do not belong to the same taxonomic group, a view that was widely accepted in the last century; the family Pongidae is now restricted to *Pongo* (Greenfield 1979). *Homo* is closely related to African apes and may be closer to *Pan* than to *Gorilla*. The modern tendency to use the term "hominines" is also misleading, as usage of the term varies: for some scientists, it gathers *Pan* and *Homo* and their ancestors, and for others, it is restricted to *Homo* and its forerunners. This is confusing, as the authors generally do not specify in which sense they use the term. This is why it is more appropriate to restrict the term Hominidae to humans and their fossil forerunners.

Whatever systematic scheme is considered, the focus is on understanding the ancestors of humans after their split from African apes. To understand the earliest hominids and ape cousins, we need to apply a geohistorical approach. The role of Asia as well as Africa in the history of our origins cannot be dismissed out of hand. However, today it seems clear from available field data that the development of the human lineage occurred in Africa.

Finally, we must consider the fact that, for the last 40 years, the history of research into the dichotomy between apes and humans has been dominated by the conflicting results obtained by paleontologists on the one hand and molecularists on the other. The debate has focused on two major aspects: chronology and the search for the closest relative. There was a heated debate in the 1970s concerning the molecular clock and its implications for hominid evolution versus paleontological evidence and geological time. But discrepancies in the time scales produced by various neontological studies have never been thoroughly debated, as pointed out by Arnason and coauthors in 2001. We have known for almost two centuries that the African apes are our closest relatives; but the research published in the last three decades has attempted to focus on the question in greater detail, and this has led to another major issue: Is the common chimpanzee the closest relative of humans? Or is it the bonobo? Or is it the group of African apes as a whole? At this point it has become widely accepted, almost without debate, that the closest human relative is the chimpanzee, frequently claimed to share 98 % or more of its genetic material with humans (or even 99.4 % for some authors such as Wildman et al. (2003)). General acceptance of these figures has occurred despite the fact that the problem is not yet definitively solved (Marks 2002).

It is within this complex framework that research on our oldest ancestors has taken place during the past three decades. In addition, preconceived ideas about our earliest relatives make it even more difficult to have a dispassionate discussion. A statement such as "the common ancestor of human and chimpanzees was probably chimpanzee-like, a knuckle-walker with small thin-enamelled teeth" (Pilbeam 1996) takes us back 200 years, being no different from the quest for the missing link. This widespread preconception is probably one of the reasons why many anthropologists have used modern chimpanzees as the basic comparative material when researching hominid origins and why the reconstructed late common ancestor was depicted as a bipedal chimpanzee.

This brings us to another aspect of the problem of defining the earliest hominid. Most anthropologists consider that apelike (i.e. chimpanzee-like) features are primitive and that humanlike ones are derived. However, chimpanzees are not primitive; they are in fact highly derived in their locomotor and dietary adaptations, and the use of their features as ancestral traits is a major error. Humans are also derived in their locomotion, but in a different way from chimpanzees. It is therefore not possible to define the polarity of these traits on the sole basis of some modern relict species; the Miocene apes were highly diverse, and this diversity has to be considered when reconstructing phylogenies. The neontological approach, which has been in favor in some scientific circles, turns out to be a total failure when dealing with the definition of the earliest hominids. This approach leads to a search for magic traits, such as flat face, small canines, and thick-enameled teeth, which are considered almost universally to be hominid features: for when only modern chimpanzees and humans are compared, these features seem to be obvious and clear. However, it is necessary to understand their meaning and their emergence before using them as a reference. When Miocene hominoids are included in the study, these same features are found to occur in many of them, suggesting that a flat face, small canines, and thick-enameled cheek teeth are plesiomorphic and that the elongated face of chimpanzees and their large canines and thin-enameled cheek teeth are apomorphies of the chimpanzee clade, rather than plesiomorphies of hominoids. Exclusion of the Miocene fossils from the comparisons of modern apes and humans erases the diversity of the past which is the raw material for understanding our evolution.

African or Eurasian Origins?

Determining a place for the origin of hominids (sensu stricto) has been widely debated for several decades, and some authors have suggested that Eurasia would be a better candidate than Africa (Begun 1992, 2002; Begun et al. 2012). However, these suggestions are based on biased data concerning Africa. The fact that hominoids were highly diverse in Eurasia between 13 and 8.5 million years does not mean that Africa was devoid of them in the Middle and Late Miocene. They have been recorded in Kenya, Ethiopia, Namibia, Chad, and Niger (Figs. 1 and 2). There is thus no reason to favor Eurasia in the origins of modern African hominoids

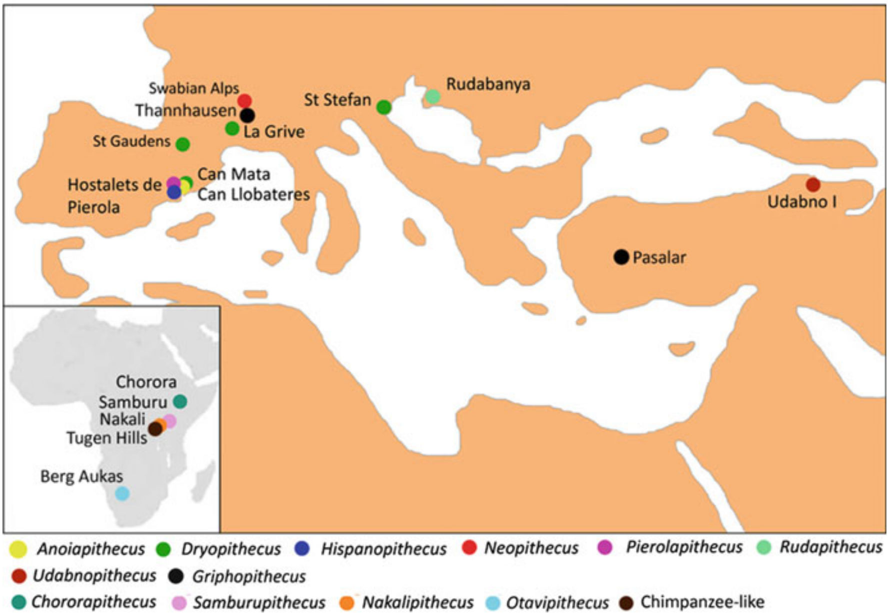

Fig. 1 Distribution of Late Middle Miocene and early Upper Miocene hominoids (Map modified from Begun et al. 2012)

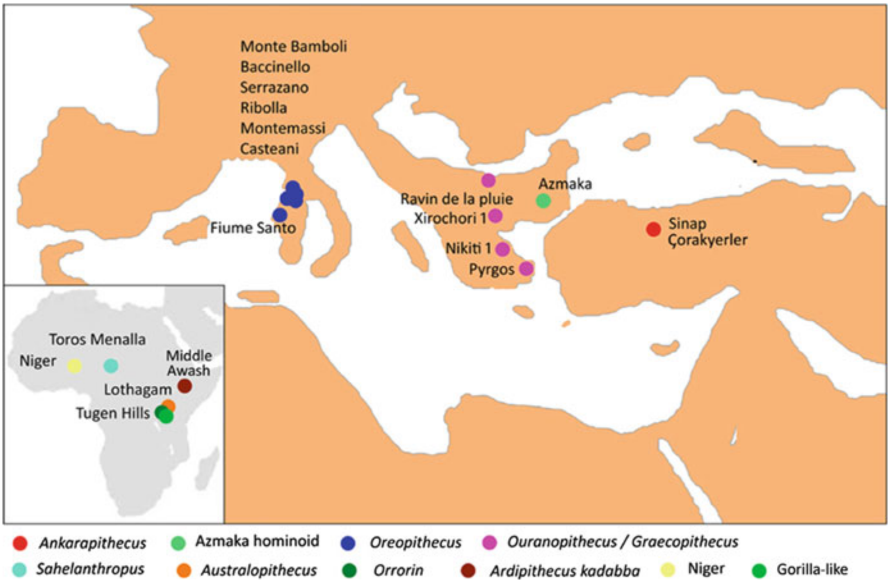

Fig. 2 Distribution of Upper Miocene hominoids (Modified from Begun et al. 2012)

(hominids included), and the "Back to Africa" hypothesis does not appear tenable today (Senut 2011a). However, does this necessarily mean that an African origin is the correct scenario? When climatic data are taken into account, it is possible to suggest yet another scenario. Nonhuman hominoids are basically tropical animals, and all through their 25 My-long history, they inhabited tropical areas, as indicated by floral and faunal data. Taking that into consideration, the most logical idea is to consider that their ancestors inhabited tropical regions and that faunal interchanges (including hominoids) occurred between Africa and Southern Eurasia throughout the Middle and Upper Miocene (the Tethys did not act as a permanent uncrossable barrier) (Senut 2011, and references therein). In the Early Miocene most of Africa was tropical, and the distribution of hominoids was Pan-African. When the Antarctic ice cap expanded to cover the entire continent at about 17 Ma, the Earth's climatic belts shifted northward such that midlatitude Eurasia became subtropical, allowing hominoids to disperse into vast areas of the Old World from Spain in the West to China in the East (Fig. 3). For several million years, faunal interchanges were possible between Eurasia and Africa, and hominoids could probably move freely between the continents in relation with paleogeography and the position of the tropical zones. This is why a precise geographic origin for African apes and humans cannot be proposed, although the paleoenvironment and paleoclimatic zone can be predicted with confidence (Fig. 4). However, for the moment the earliest modern-looking African apes and hominids are found only in Africa.

Still, the date of divergence between the different hominoids is not clear. Most biologists favor a young date for the split between humans and chimpanzees

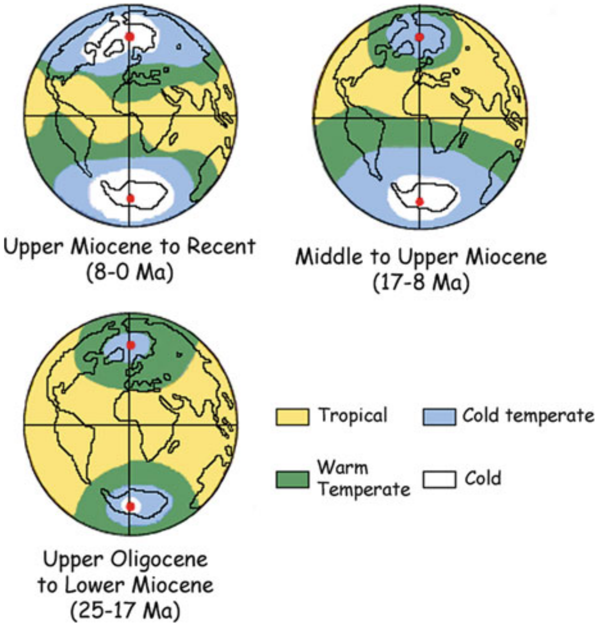

Fig. 3 Latitudinal shifts of the climatic belts during the Neogene. Being tropical mammals, hominoids followed these changes (From Senut 2011a)

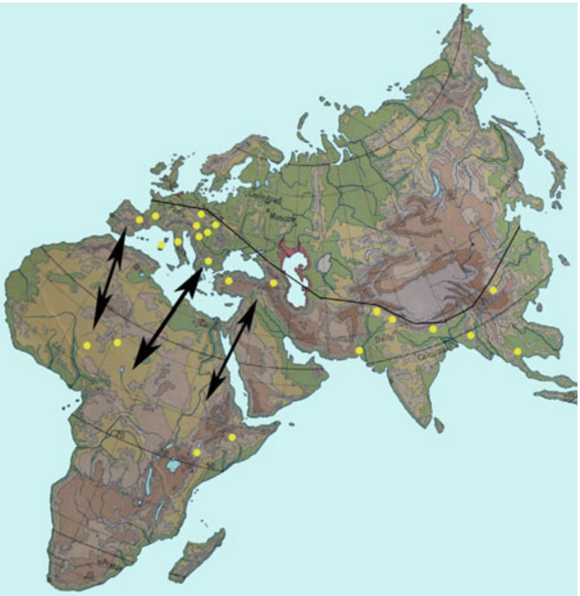

Fig. 4 Distribution of hominoids during the Upper Miocene. Even though a precise geographic origin for African apes and humans cannot be proposed, the extension of the tropical area reflects the zone of possible dispersals between Europe and Africa

(around 6 million years); but the calibration of the so-called molecular clock is not independent, as it needs an expected divergence date for some mammal lineages. However, some geneticists had already suggested other split times for hominoids (Arnason et al. 2001). In contrast, paleontologists usually tended to support older dates of 8–10 million years, or even older, for the split. But new dates of divergence, based on comparative generation time estimates in great apes compared with humans, and then using estimated mutation rates in humans provide a new look at the issue which accords better with the dates based on fossils (Langergraber et al. 2012). The split between chimpanzees and humans is now estimated to be 7–13 Ma, and the divergence between *Gorilla* and the lineage leading to the ancestor of chimpanzees and humans is between 8 and 19 Ma. Modern hominoid lineages are known from the Upper Miocene, indicating that their history was probably more ancient than previously thought.

The Rise and Fall of the *Ramapithecus-Kenyapithecus* Group

During the 1960s and 1970s, it was widely claimed that *Kenyapithecus* (sometimes considered to be an African relative of the Asian *Ramapithecus*) was a hominid, aged ca 15 Ma. This idea (Simons 1961; Simons and Pilbeam 1965; Leakey 1961/1962; Andrews 1971) was questioned by some morphologists (Genet-Varcin 1969; Greenfield 1978). The divergence between apes and humans was thus considered by these authors to be very ancient (about 16 Ma or even close to 20 Ma). But in the 1970s, the development of molecular biology and the application of the molecular clock led to the notion that the dichotomy was considerably more recent, and ages of divergences for the African great apes and hominids of about 2–4 Ma were proposed (Wilson and Sarich 1969). It was in this context, 30 years ago, that "Lucy" and the Afar australopithecines were discovered in more than 3 Myr-old deposits (Johanson and Taieb 1976). Considered at the time to be the earliest hominid, these fossils were later named *Australopithecus afarensis* (Johanson et al. 1978). This major discovery was widely acclaimed: for the first time, we could examine a quasi-complete fossil skeleton from an early time; the earliest stages of bipedalism (a key feature in the definition of hominids) could be seen, and we could get information on body proportions of the earliest members of our family Hominidae. Not least, "Lucy" was considered by many to occur in the range of dates estimated by the famous molecular clock, which at the time suggested that the dichotomy between apes and humans took place about 4 million years ago (Wilson and Sarich 1969).

Subsequently it was demonstrated that the molecular clock was not reliable, as it did not run at a constant rate in mammals and in particular in primates (Britten 1986; Pickford 1987; Stanyon 1989). In numerous papers a large variety of dates was advanced for the dichotomy between apes and humans, depending on the calibration ages accepted in the particular study and the type of protein used: these dates ranged from 2.5 Ma up to 4 Ma. But the fossils always seemed to give an earlier date. The question of an early or a late divergence was addressed by Greenfield (1980): he had already proposed that *Sivapithecus* (= *Ramapithecus) brevirostris* and *Sivapithecus* (= *Kenyapithecus*) *africanus* were size variants of *Sivapithecus*, and he suggested a late divergence for the group of *Homo*, *Pan*, and *Gorilla* from the pongid stock. However, the age of this dichotomy that he published (10–5 million years) was greater than the one proposed by geneticists.

Following general acceptance of the molecular evidence that supported a divergence between chimpanzees and humans around 4 Ma, the matter of chronology was thus thought to be solved and neither *Ramapithecus* nor *Kenyapithecus* was subsequently considered by many authors to be hominid. By the end of the 1970s, the *Kenyapithecus* material had been restudied, especially in the light of sexual dimorphism in modern and fossil apes (Greenfield 1978, 1979; Pickford 1986; Pickford and Chiarelli 1986). It transpired that the group of Ramapithecines-Kenyapithecines did not belong to Hominidae, and as a result the Middle Miocene estimates for the dichotomy between apes and humans were abandoned. Eventually, a meeting organized at the Vatican in 1982 led to a consensus between paleontologists and molecularists: the divergence occurred at around 7 Ma.

However, despite the fact that several isolated fossils of putative early hominid ancestors were already known at that time, such as the Lothagam mandible thought to be close to 7 million years old (Patterson et al. 1970), the 6 million year-old Lukeino lower molar (Pickford 1975), and the 4 million year-old Kanapoi humerus (Patterson 1966; Patterson and Howell 1967), these materials were too fragmentary to be taken seriously by most paleoanthropologists, and there was a tendency to avoid them in the phylogenies. Then Coppens (1983) reconsidered all the hominoids, some of which had been attributed to hominids. Taking into account environmental changes, chronology and geography, he formalized his "East Side Story." He suggested that around 7 Ma the ancestral population to African apes and humans was divided by the formation of the Great Rift Valley, which would have led a modification in the rainfall: which remained high in the West but was reduced in the East. The apes would have survived in the West in wooded and forested environments, while hominids became adapted to wooded grasslands and more open environments in the East. He later updated the theory and suggested an age of 10 Ma for the split between apes and hominids (Coppens 1986; Senut 2006b).

Until the end of the twentieth century, australopithecines were considered to be direct ancestors of humans, even though some scholars pointed out that more modern forms existed during the same period, implying that Plio-Pleistocene hominids were more diverse than expected, and that australopithecines might have been a side branch of human evolution (see Senut 1992 and Pickford 2012 for reviews). But by the end of the twentieth century, it was widely accepted that the earliest hominid ancestor was to be found in the early Pliocene.

Bipedalism and Its Impact on the Origins of Hominidae

Among living primates, facultative bipedalism is frequent; but even if most primates can sit with the back upright, stand on two feet, and walk bipedally for short distances, humans are the only ones that can move on two legs for long distances and for extended periods of time. This difference is reflected in the skeletal characters of extant humans, often defined in comparison with chimpanzees. While a suite of putatively bipedal features linked to femoral, pelvic, or sacral morphology appears to be soundly based, others are questionable. This is the case with the position of the foramen magnum. For the past 80 years, following Dart (1925), most scientists have considered that an anterior position of the foramen magnum indicates bipedality in hominids. Le Gros Clark (1950) used the anterior position of the occipital condyles to confirm the hominid nature of the australopithecines and proposed a "condylar position index," but he noticed that in modern humans this position varied between dolichocephalic and brachycephalic individuals. Later (Le Gros Clark 1972), the same author warned: "It has been assumed that the condylar-position index, by itself, is always correlated with the degree of postural erectness. The fallacy of this assumption is exposed by the fact that the index varies quite considerably even in modern *H. sapiens*." However, generic, specific, and/or populational studies remained limited before 1960, despite the fact that Schultz (1955) highlighted the variability of this feature. Since then it has been shown that an anterior position of the foramen is not linked exclusively with bipedalism, but could be related to the development of the brain (Biegert 1963). Several authors demonstrated that its position relative to the cranial foramina was variable (Dean and Wood 1981, 1982; Schaeffer 1999). It is difficult to discriminate individuals on these isolated features, as there is an overlap between apes and humans. Moreover, it appears that the foramen magnum is more anteriorly displaced in australopithecines than in humans, even though they were not better bipeds than we are. This feature is more complex than usually thought, and we must be cautious when using it.

Different forms of bipedalism have existed in the past. Of these, the most debated concerns *Oreopithecus bambolii*, discovered in the Late Miocene lignites of Tuscany (Hürzeler 1958; Schultz 1960; Straus 1963; Tardieu 1983; Sarmiento 1983; Senut 1989 and see review in Senut 2011b) and which was later demonstrated to be bipedal (Köhler and Moyà-Solà 1997; Rook et al. 1999). For the pedal features, these authors showed that this Miocene ape could move bipedally when on the ground but with a stabilization morphology that differed from those of humans and australopithecines. *Oreopithecus* lived in an island environment where the absence of large predators and limited trophic resources played an important role in the evolution of mammals (Köhler and Moyà-Solà 1997).

The most convincing bipedal evidence from the Upper Miocene remains *Orrorin* (Pickford et al. 2002; Galik et al. 2004; Richmond and Jungers 2008; Almecija et al. 2013) based on the femoral anatomy and morphometrics in different independent studies. Despite the fact that *Orrorin* is a biped, it is still moving in the trees as shown by other postcranial elements (Senut et al. 2001; Senut 2003). This ability is probably retained from older Miocene hominoids and is still present in australopithecines. This is also supported by the paleoenvironmental studies. Bipedalism and arboreality are major factors in our origins (Senut 2006b, 2012).

The Case of *Australopithecus afarensis* (= *antiquus*)

At one time or another, every single fossil older than *A. afarensis* from Afar in Ethiopia has been considered the earliest human ancestor; and this ancestor was almost always interpreted as being in the direct line leading to the genus *Homo* and thence to us. However, this approach ignored or underestimated the probable diversity of Pliocene hominids. In fact, in the late 1970s, several authors had already pointed out that there might be a taxonomic problem with the species *Australopithecus afarensis*: was it, as claimed, a single bipedal species? Did this species include two different taxa, one of which was a combination of a climber and a terrestrial biped and the other a more advanced species which was primarily a ground-dwelling biped? (See the review of *Australopithecus afarensis* locomotor adaptations in Stern (2000) and in Coppens and Senut (1991).) The difficulty derived mainly from the fact that before the 1970s scientists had built their phylogenetic trees almost exclusively on the basis of dental anatomy, whereas the incorporation of locomotor traits led to a modification of these phylogenies. The picture became more complex in subsequent years, with a crop of new species of australopithecines being created; several of these had specimens also included in other hypodigms. This was especially clear with *Praeanthropus africanus*, *Australopithecus afarensis*, and *Australopithecus anamensis*. The use of cladistic methods did not clear up the problem (Strait et al. 1997; Strait and Grine 1999, among others), as the *Praeanthropus* hypodigm of these authors does not include the same fossils as those proposed by Senut in 1996. The phylogenetic approach thus became more and more confused, various scholars using the same species names in different ways without defining them.

As discoveries became more and more numerous, several genera were resurrected or created: *Praeanthropus*, *Ardipithecus*, *Orrorin*, *Sahelanthropus*, and *Kenyanthropus*. New specimens of a Pliocene hominid, *Australopithecus prometheus*, were found in South Africa at Sterkfontein (Clarke 1995, 2013). But a major question remains unanswered: Is *Australopithecus afarensis* a direct ancestor or a side branch of our family?

The Upper Miocene Evidence

The majority of scenarios concerning the dichotomy of apes and humans, with the exception of the East Side Story of Coppens (1983), failed to take into account the environment. Coppens' hypothesis was ecogeographic in nature, the African Rift Valley constituting an ecological barrier between the apes in the West and early hominids in the East from about 7–8 Ma. But the most important elements of his hypothesis were chronological (the divergence took place between 10 and 7 Ma (Coppens 1986; Senut 2006b)) and ecological (climatic change engendering modifications in regional vegetation patterns, etc.); and, despite its name, the geographic element was subsidiary in the evolutionary scenario. As soon as we began to look for early and/or putative hominids in strata older than the Pliocene, we found them. In 2000, the discovery of early hominid remains (*Orrorin tugenensis*) in the Upper Miocene strata of Kenya, and subsequent finds in Middle to Upper Miocene sediments of the same country, shed new light on the question of our divergence from the African apes. The *Orrorin* discovery was subsequently followed by finds in Ethiopia (*Ardipithecus kadabba*) and then Chad (*Sahelanthropus tchadensis*). The debate mainly focused on the C/-P/3 complex and on adaptations to bipedalism. The status of the latter in the two last-named species is still a matter of debate, as the postcranial evidence is either poor or absent. But the main disagreement lies in the fact that in most studies comparisons were made basically with modern apes and later hominids and very little with Miocene apes. As pointed out above, structures or features supposed to be hominid apomorphies might well be retained from older Miocene apes; and some of the modern African ape features, usually considered to be primitive, might not be so.

Ardipithecus ramidus

In 1994 *Australopithecus ramidus* was published, and in 1995 it was attributed to the new genus *Ardipithecus*. This hominoid from Aramis localities 1–7 in the Middle Awash (Afar Depression in Ethiopia) (White et al. 1994, 1995) was pronounced to be the earliest-known hominid. All the specimens, except the humerus (which was found above the Daam-Aatu Basaltic Tuff), come from a level located between the Daam-Aatu Basaltic Tuff and the Gaala Vitric Tuff complex. The tuff complex, situated at the base of the section, has been dated at 4.39 ± 0.013 Myr, and an age between 4.2 and 4.5 Ma can be estimated for the fossil hominid (WoldeGabriel et al. 1994). At the time of the discovery, these fossils were among the few supposed hominids older than 4 Ma. Recently, a few more specimens have been described from the Early Pliocene at As Duma in the Gona Western Margin (Ethiopia). Their ages have been estimated at 4.51–4.32 Ma (Semaw et al. 2005). According to its discoverers, the new genus differed from *Australopithecus* by the reduced megadontia of the postcanine teeth; the greater width of the upper and lower incisors compared with postcanine teeth; a narrow and obliquely elongated lower dm1 with a large protoconid and a small, distally place metaconid without an anterior fovea; a small, low talonid with reduced cuspule development; absolutely and relatively thinner canine and molar enamel; and lower and upper P3s more strongly asymmetrical, with more dominant buccal cusps. With a canine that is not mesiodistally elongated, it is distinguishable from modern African apes. However, some of the cited features – including the thin enamel in the molars, asymmetrical upper and lower third molars, and the size relationships between the incisors and jugal teeth – place *Ardipithecus* closer to the chimpanzee than to any of the oldest hominids known (Pickford, 2012). The first deciduous molar shows resemblances to those of bonobos. But the morphology of the canine distances *Ardipithecus* from apes: it is more incisiform than in the latter group. Metric comparisons of the adult teeth were made with *Australopithecus afarensis* and underline the diminutive size of *Ardipithecus*. The upper canine/lower anterior premolar complex is typical of apes and was described as being "morphologically and functionally only slightly removed from the presumed ancestral ape condition" (White et al. 1994, p. 308) (though these authors also considered the modern ape morphology plesiomorphic). However, certain features taken as support for its hominid status occur in female apes, which have a reduced canine/premolar complex compared to those of males. Its postcranial bones reveal several apelike features, but the proximal humerus is more humanlike in the shallowness of the bicipital groove. However, this character occurs not only in hominids but also in other primates such as the cautious climber *Pongo* (Senut 1981). The fragment of occipital preserved would suggest that the foramen magnum is placed anteriorly relative to the carotid foramen, but for the reasons given above, we must be cautious with the interpretation of this feature. At the end of 1994, a skeleton (like a roadkill, according to the authors) was found in the Aramis strata. It was published in 2009 (White et al. 2009) and claimed to be the first representative biped of the human lineage. However, the traits proposed in evidence of bipedalism are not convincing. The reconstruction of the vertebral column is based on only two fragmentary vertebrae. And whereas the femur has been reconstructed to resemble a human one, only the shaft is preserved. This is very massive and robust and has nothing to do with the more gracile, elongated human femur. The humerus, which is not preserved, has been reconstructed like a human one. The bones of the forelimb are set wide apart, rather than close as in humans, and suggest massive forearm muscles as seen in modern African apes. The thumb is short, and its distal phalanx is not hominid-like in morphology. It is elongated and narrow, as in nonhuman hominoids, and lacks the hominid morphology seen in *Orrorin*, australopithecines, and *Homo*. The pelvis is strongly crushed, and the reconstruction appears more hominid-like, based on comparisons with *Australopithecus afarensis*. Despite the numerous papers on the functional anatomy, and given such weak evidence, it is difficult to accept bipedalism in *Ardipithecus ramidus*. The study suggests to me that *Ardipithecus* might be a fossil relative of the chimpanzee. Assuming that the features exhibited in modern chimpanzees were present in its forerunners has been a widespread theme among anthropologists, the bonobo long ago being considered a good model for the hominid ancestor (Zihlman 1984), although this was already criticized at that time (Senut 1988). The idea that the discovery of *Ardipithecus ramidus* led to the new idea that the chimpanzee is not a good model for the ancestor of hominids (Lovejoy et al. 2009) is thus actually not new. What is more, although the hypothesis appears to be right, it is based on wrong evidence.

Among other discoveries, Semaw et al. (2005) briefly described a proximal third of a pedal proximal phalanx from deposits of As Duma dated at 4.51–4.32 Ma. They wrote: “The transversely broad oval proximal facet is oriented dorsally, a character diagnostic of bipedality, and a trait also seen in Ardipithecus kadabba.” But Rose (1986) had already described the same feature in *Sivapithecus* from the Miocene of Pakistan, making it difficult to accept the proposed bipedalism in *A. ramidus*.

On the basis of the fauna and the botanical and sedimentological indications, the environment of *Ardipithecus ramidus* at Aramis is a forested one (WoldeGabriel et al. 1994). In the Gona sites, the faunal association, carbon isotopes, and sedimentology suggest a moderate rainfall woodland and woodland/grassland (Semaw et al. 2005).

Orrorin tugenensis

The discovery of *Orrorin* led to the elucidation of several aspects of early hominids (Senut et al. 2001). The specimens come from four sites: Cheboit, Kapsomin, Kapcheberek, and Aragai in the Lukeino Formation aged ca 6 Ma (6–5.8 Ma) (Bishop and Chapman 1970; Bishop and Pickford 1975; Chapman and Brook 1978; Kingston et al. 1994; Pickford and Senut 2001) (Fig. 5). The Lukeino Formation overlies the Kabarnet Trachyte dated by K/Ar, paleomagnetism, and biochronology

Fig. 5 Remains attributed to *Orrorin tugenensis* in 2000

at 6.1 Ma and is overlain by the Kaparaina Basalt the age of which is estimated to be 5.7 Ma (Sawada et al. 2002). In the section, Cheboit and Aragai are the oldest sites, followed by Kapsomin and then Kapcheberek which lies in the upper level of the formation. Up to now, 20 specimens of *Orrorin* have been found, consisting of the posterior part of a mandible in two pieces, a symphysis and several isolated teeth, as well as three femoral fragments, a partial humerus, a first phalanx, and a distal thumb phalanx. The genus is defined by its jugal teeth being smaller than those of australopithecines, an upper canine short with a shallow and narrow vertical mesial groove and a low apical height, a small triangular upper M/3, a lower p/4 with offset roots and oblique crown, small *Homo*-like squarish lower m/2 and m/3, thick enamel on the lower cheek teeth, a buccal notch well developed on the cheek teeth, no cingulum on the molars, a femur with a spherical head rotated anteriorly, the femoral neck elongated and oval in section, a medially salient lesser trochanter, a deep digital fossa, a humerus with a vertical brachioradialis crest, a curved proximal manual phalanx, and a dentition that is small relative to body size. *Orrorin* differs from *Australopithecus* in the morphology of the cheek teeth, which are smaller and less elongated mesiodistally. It differs from *Ardipithecus* by the greater thickness of enamel. It differs from both by the presence of a mesial groove on the upper canine. The upper and lower canines exhibit an apelike morphology, seen in female chimpanzees and Miocene apes; they are reduced in comparison with *Pan*. The apex of the upper canine is pointed and almost sectorial, and a poorly developed lingual wear facet is visible.

The femurs reveal that *Orrorin* was bipedal (Senut et al. 2001; Pickford et al. 2002; Galik et al. 2004). However, the other postcranial bones suggest that it could climb trees. The distal phalanx of the thumb exhibits features resembling hominids such as presence of a marked tuft (horseshoe shaped), deep depression for the *m. pollicis longus* with strongly asymmetrical edges, strongly asymmetrical basal tubercles, and a swelling at the base of the insertion of *m. pollicis longus* (Gommery and Senut 2006).

Some features of the hominid thumb are classically (but probably erroneously) associated with the manufacture of tools; these traits could be related to grasping abilities when climbing trees (Gommery and Senut 2006) (Fig. 6). At the time of its discovery, *Orrorin* was the first known bipedal hominid older than 5 Ma and indicated that the dichotomy between the African apes and the hominids had to be older than 6 million years and that the classic recent dates of divergences estimated by molecular biologists did not fit with the paleontological evidence. On the other hand, the locomotor and dental features suggest that *Orrorin* was different from *Australopithecus afarensis*. It was microdont with small postcanine teeth and a rather large body size, whereas *Australopithecus* was megadont with large postcanine teeth and small body size. Modern humans are microdont. Some morphometric studies have suggested that *Orrorin* is an ancestor of later australopithecines (Richmond and Jungers 2008). However, when checked in detail, it appears that their results could be interpreted either way, as *Orrorin* data fall close to australopithecines and *Homo*.

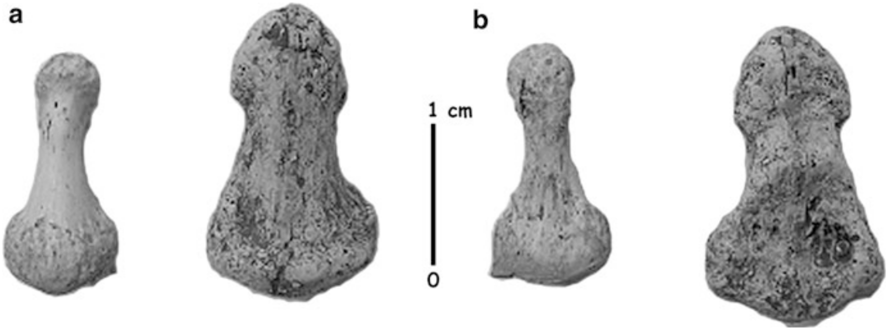

Fig. 6 Distal thumb phalanx of *Orrorin tugensis* (*right*) compared with an extant chimpanzee (*left*). (**a**) Dorsal view; (**b**) Palmar view (scale: 1 cm) (From Senut 2012)

Orrorin did not live in an open environment, but in a more forested one as suggested by faunal remains that include impalas, colobines, water chevrotains, arboreal civets, fruit bats and lorisids, and floral remains that contain large leaves with drip points (Pickford and Senut 2001; Senut and Pickford 2004; Senut 2006b), from which it is concluded that, in its early stages, bipedalism was not related to dry environments (Senut 2006b). Humid conditions persisted into the Lower Pliocene (Pickford et al. 2004). Stable isotope analyses of tooth enamel carbonate of large herbivores from the Lukeino and the Mabaget Formations are consistent with the first results (Roche et al. 2013) and refine them. They show that in the Early Pliocene and the latest Miocene, conditions were more humid than in the Upper Miocene. *Orrorin* inhabited a mixed C3–C4 environment comprised of thicket, woodland, and forest. Fossil leaves from the Lukeino Formation indicate the presence of woodland and dry evergreen forest, but some specimens suggest a more humid forest (Bamford et al. 2013).

Ardipithecus kadabba

Material discovered in Ethiopia (Haile-Selassie, 2001) from sediments aged between 5.2 and 5.7 Ma was identified as belonging to a subspecies of *Ardipithecus ramidus*, later raised to the specific rank *Ardipithecus kadabba* (Haile-Selassie et al. 2004). The material was collected at five different sites: Digiba Dora, Asa Koma, Alayla, Saitune Dora, and Amba East, from the Asa Koma Member of the Adu-Asa Formation. The first four are in the Asa Koma Member of the Adu-Asa Formation, and the deposits which have yielded the hominids are securely dated at 5.54–5.77 Myr by radiometric methods applied to underlying and overlying basalts. The Amba East material is slightly younger, being from the Kuseralee Member of the Satangole Formation dated 5.2–5.6 Ma (Renne et al. 1999). The morphology of the upper canine crown with a more rounded outline differs from *Orrorin*; but it also differs from *Ardipithecus ramidus* in the crest pattern of the same tooth as well as by a lower premolar that is more asymmetrical in outline and by the presence of a small anterior fovea. Moreover, the lingual cusps are more salient and sharp in the lower m/3 and the upper M3/ bears four cusps.

The species *Ardipithecus kadabba* differs from extant apes in its canines, which have a tendency to be incisiform as in *A. ramidus*, and by the presence of a clearly defined fovea on the lower p/3 which is isolated from the mesial marginal ridge by a fold-like buccal segment. However, some of the *Ardipithecus kadabba* dental specimens could belong to *Orrorin tugenensis*. It is difficult to know, as the material is not available for comparisons.

The postcranial morphology (Haile-Selassie 2001) indicates several similarities to African apes and selected specimens from the Hadar, but the shape of the ulnar olecranon differs from that of hominids. A proximal pedal phalanx resembles the ones from Hadar, and on the basis of the dorsal orientation of the proximal facet of the bone, it supposedly belonged to a biped. However, the curvature seen in the *Ardipithecus kadabba* phalanx might be linked with arboreal adaptations, as discussed by several authors (Susman et al. 1984; Stern and Susman 1983), and we must remain careful when assessing a locomotor complex on the basis of restricted material. *Ardipithecus kadabba* is associated with relatively wet and wooded environments as indicated by the fauna. However, the Amba East site seems to have been slightly drier (WoldeGabriel et al. 2001).

Sahelanthropus tchadensis

The discovery of *Sahelanthropus* in Chad was published in 2002 (Brunet et al. 2002). Announced as the earliest-known hominid, this status has been the subject of debate (Wolpoff et al. 2002, 2006; Wood 2002). It was found at Toros-Menalla (Chad) in deposits supposedly dated between 6 and 7 Ma, maybe closer to 7 Ma, by faunal comparison with the Lukeino Formation and Nawata Formation (Vignaud et al. 2002).

Recent Be/Al analyses performed on the levels hypothetically associated with the *Sahelanthropus* skull yielded a date between 7.2 and 6.8 Ma (Lebatard et al. 2008). However, some of the faunal remains found with the hominoid (discovered at the surface of the deposits), such as the Anthracotheriidae (Pickford 2008) and the fossil otters, could suggest the presence of two different biostratigraphic levels. In the latter case, data published on Dikika (Pliocene Australopithecine site in Ethiopia) (Geraads et al. 2011) based on results from Chad (Peigné et al. 2008) would suggest the presence of Pliocene fauna at Toros-Menalla. The age of the hominoid material remains uncertain.

The following diagnostic features of the species have been published: orthognathic face and weak subnasal prognathism; small ape-sized braincase; long and narrow basicranium; small canines; robust supraorbital torus; absence of supratoral sulcus; marked postorbital constriction; small, posteriorly located sagittal crest and large nuchal crest; wide interorbital pillar; low-crowned jugal teeth and enamel thickness between that of *Pan* and *Australopithecus*; and anterior position of the foramen magnum. It is considered to be different from all the living great apes because of the relatively small canines, the apical wear of the canines, and a probable non-honing C/-P/3 complex. The claimed hominid status is based on the small, apically worn canine and on the structure of the face. However, when these complexes are considered among all fossil and extant hominoids, it appears that they are more frequent than believed. The maxillofacial complex in extant apes varies according to sex, just as it does in Miocene hominoids (*Proconsul*, *Kenyapithecus*, *Ramapithecus*). It was this combination of features that originally led to *Ramapithecus* being proposed as a hominid, whereas it is today considered to be the female of *Sivapithecus*. Bipedalism in *Sahelanthropus* has been inferred from the position of the foramen magnum; but again, for the reasons expressed above, this feature can be misleading. The cranial base and nuchal area of *Sahelanthropus* (with its strongly developed nuchal crest and the flatness of the occipital) seem more apelike to some authors (Wolpoff et al. 2002, 2006), suggesting a quadrupedal posture and locomotion despite the reconstruction proposed by Zollikofer et al. (2005), which fails to contribute more evidence to the debate. The orientation of the plan of the foramen magnum falls within the range of variation of modern apes (Pickford 2005).

Whatever *Sahelanthropus* is, its status as a hominid is still debatable (Wood 2002), although it importantly fuels the debate on the origins of African apes and humans.

Sahelanthropus was found in perilacustrine sandstones, and the sedimentological context suggests a mosaic of environments between lake and desert, which have been compared with the modern Okavango delta. But the geological setting is different, as Lake Chad was much deeper in the Upper Miocene than the Okavango is today.

An Earlier Dichotomy?

During the past decade, several apelike fossils have been discovered in Africa that complete the data from the Samburu Hills (Ishida et al. 1984; Ishida and Pickford 1998). In the Baringo District of Kenya (Figs. 7 and 8), a lower molar in the 12.5 Ma Ngorora Formation and three fragmentary teeth from the Lukeino Formation are found in the same strata as *Orrorin tugenensis* (Pickford and Senut 2005); some isolated teeth at Chorora in Ethiopia are attributed to an ancestor of gorilla (Suwa et al. 2007). Also, a fragmentary mandible and isolated teeth come from Nakali (Kunimatsu et al. 2007), and a fragment of mandible of a proto-chimpanzee comes from Niger (Pickford et al. 2009). This new evidence sheds some crucial light on the dichotomy between African apes and humans.

Ngorora

In 1999, a lower molar was collected at Kabarsero, Ngorora Formation, Tugen Hills (Pickford and Senut 2005) 12.5 Ma (Bishop and Pickford 1975). This tooth, probably a lower m/2 (Pickford and Senut 2005), is close in morphology to *Dryopithecus* (Begun 2002) and chimpanzees and distant from similarly aged

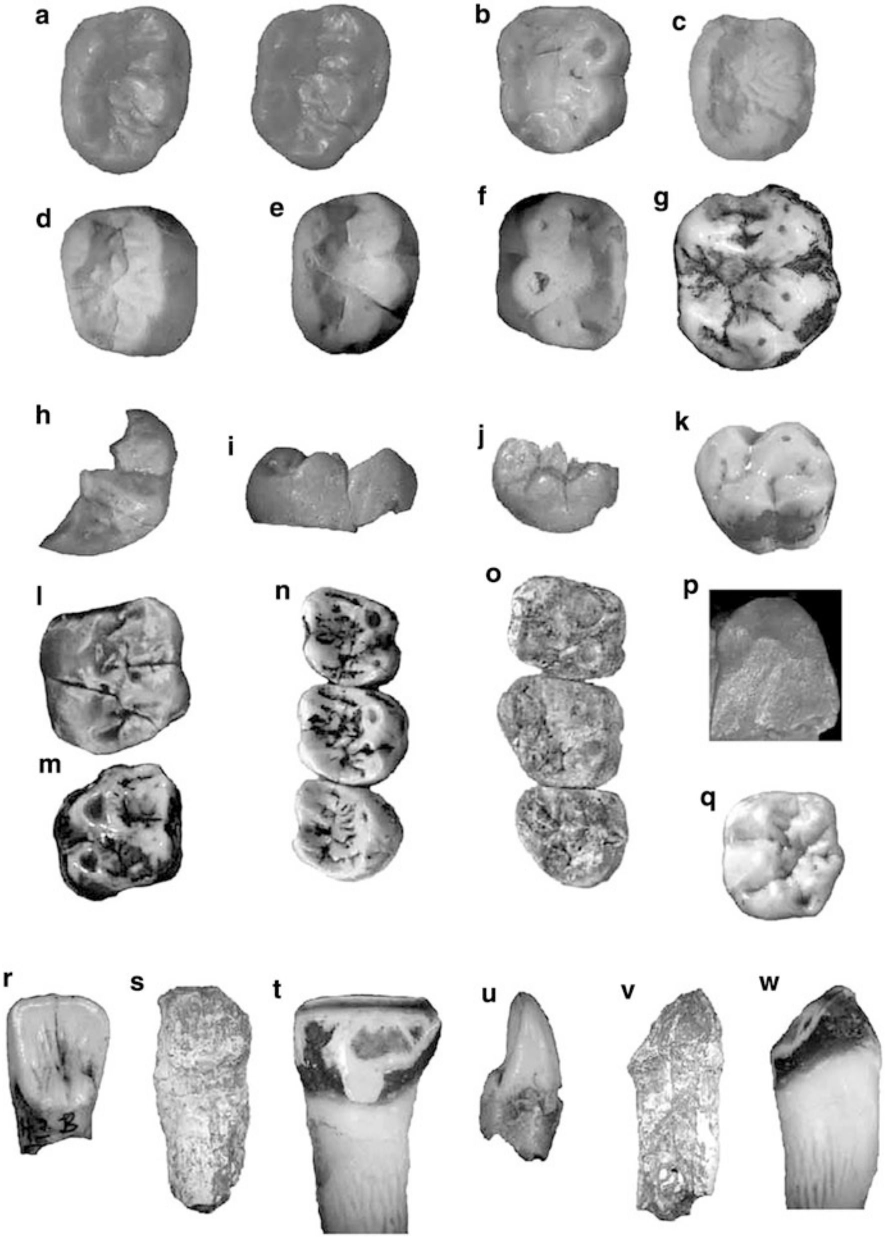

Fig. 7 (**a**) Bar 91'99, right lower molar, stereo occlusal view; (**b**) *Pan paniscus* right m/2, occlusal view; (**c**) *Pan troglodytes*, right m/2, occlusal view; (**d–f**) *Dryopithecus brancoi* lower molars from Europe, D = Trochtelfingen, E = Salmendingen, F = Ebingen; (**g**) *Gorilla gorilla* lower m/2, occlusal view; (**h–j**) Bar 1757'02, Kapsomin large ape, occlusal, lingual, and oblique views; (**k**) *Gorilla gorilla* lower m/2, oblique view; (**l**) *Australopithecus afarensis*, upper m/2, occlusal view; (**m**) *Gorilla gorilla* upper M2/, occlusal view; (**n**) *Pan troglodytes*, upper M1/–M/3 occlusal view;

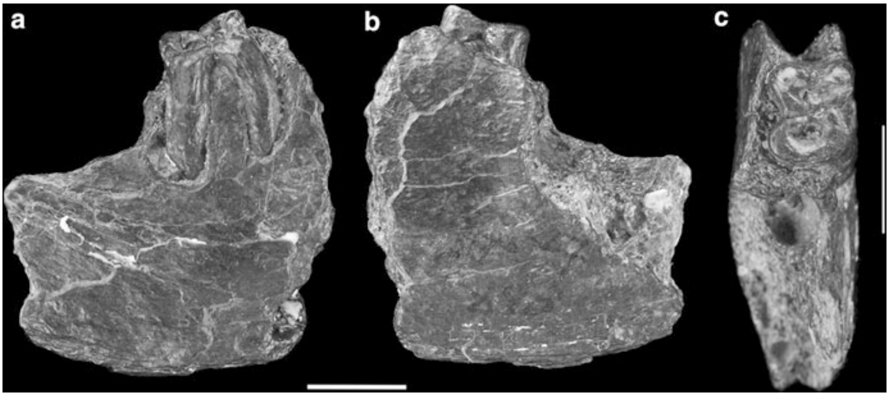

Fig. 8 Hominoid right mandibular fragment (1964-27-885) from Niger. (**a**) Buccal view; (**b**) Lingual view; (**c**) Occlusal view (scales: 1 cm)

Kenyapithecus and *Otavipithecus* (Conroy et al. 1992; Ward and Duren 2002). An upper molar had already been described from Ngorora (Bishop and Chapman 1970; Bishop and Pickford 1975; Leakey 1970), but it appears to be closer in morphology to *Kenyapithecus* (Ishida and Pickford 1998; Pickford and Ishida 1998; Senut 1998), and the thickness of the enamel and the more centralized cusps suggest that it belongs to a different hominoid from the lower molar. Two different kinds of hominoids would have coexisted at Kabarsero, a possibility which is also suggested in the lower (Napak) and middle (Moroto) Miocene sites of Uganda (Gommery et al. 1998, 2002).

If the derived characters of the Ngorora tooth are homologous to those of chimpanzees, then it would indicate that chimpanzees were already a separate lineage by the end of the Middle Miocene, a suggestion that accords with some interpretations of the molecular data (Arnason et al. 2001) and recent genetic studies (Langergraber et al. 2012). The resemblances between the Ngorora tooth and *Dryopithecus* indicate that the latter genus may have originated in Africa and migrated toward Europe about 12.5 Ma.

Chorora

Nine isolated teeth discovered in the Chorora area (site of Beticha) have been attributed to *Chororapithecus abyssinicus* (Suwa et al. 2007). They were found in

◄

Fig. 7 (continued) (**o**) *Orrorin tugenensis* upper molar row, occlusal view; (**p**) Bar 1757’02, detail of dentine-enamel junction at hypoconulid; (**q**) KNM LU 335, *Orrorin tugenensis*, left m/3, occlusal view; (**r**) *Praeanthropus africanus* cast of upper incisor from Laetoli, lingual view; (**s**) BAR 1001’01, Kapsomin large ape, I1/, lingual view; (**t**) *Gorilla gorilla* upper central incisor, lingual view; (**u**) *Praeanthropus africanus* cast of upper incisor from Laetoli, distal view; (**v**) Bar 1001’01, Kapsomin large ape, I1/, distal view; (**w**) *Gorilla gorilla* upper central incisor, distal view the upper part of the Chorora Formation dated at around 10.7–10.1 Ma. These teeth are close in size to, and resemble, those of *Gorilla gorilla*. They show clearly marked crests on the teeth, suggesting that they fed on fibrous plants that they sheared; but the cusps are less high and more peripheralized. The cingulum is weaker than in *Gorilla* and the thick-enameled molars are slightly larger. The faunal remains, rich in primates and poor in *Hipparion*, indicate that the environment of *Chororapithecus* was humid. Sedimentation suggests that *Chororapithecus* was living close to a lake shore and that there were alternating humid and more open spaces.

According to the authors, these teeth might represent a proto-*Gorilla*. If so, then, this find confirms the idea that the split between gorillas and chimpanzees and humans has to be at least 10 million years old.

Nakali

A few months after the discovery of the Ethiopian teeth, Kunimatsu and his team unearthed specimens belonging to another species of fossil hominoid from the Upper Miocene (9.88–9.80 Ma) at Nakali in Kenya: *Nakalipithecus nakayamai* (Kunimatsu et al. 2007). The reported material is composed of a posterior portion of a mandibular fragment and 11 isolated teeth. The teeth are close in size to females *Gorilla* or *Pongo*. The molars are thick-enameled, and their general morphology differs from other known hominoids in the canine and several premolar traits. It shares some similarities with the slightly younger *Ouranopithecus* from Greece but is more primitive. The authors suggest that it could be close to the last common ancestor to African apes and humans; but it could also belong to the lineage of the gorillas. Whatever it is, it evidences the fact that Africa was not devoid of large-bodied hominoids in the Upper Miocene.

Kapsomin

In 2002, half an upper molar of a large hominoid was found at Kapsomin, Lukeino Formation, aged 5.9 Ma (Pickford and Senut 2005). This tooth is larger than those of *Orrorin tugenensis* and the crown morphology is different. The trigon is wide, the distal fovea is broad, the main cusps are high and less inflated, and there is a deep buccal slit. Dentine penetration is also high. Most of these features occur in *Gorilla* and are different from *Pan*.

In 2000, an upper central incisor was found in the same strata as *Orrorin*. Originally assigned to *Orrorin tugenensis*, its morphology did not seem to fit with the early hominid. After a restudy of the specimen, it appears that it differs strongly from australopithecines and other hominids because of the lack of fossa on the lingual side of the tooth. Moreover, the crown is relatively low compared to root length, whereas in hominids the crown is higher with a scoop-shaped profile. In contrast, in *Gorilla* incisors, the lingual fossa is missing and the crown is wedge shaped as in the Kapsomin tooth.

In 2003, a lower molar was found at Cheboit, near the site of discovery of the first hominid tooth from the Lukeino Formation (Pickford 1975). The morphology of the tooth is compatible with the half upper molar from Kapsomin, and the specimens probably belong to the same taxon. As for Ngorora and the Ugandan sites, two different hominoids would have coexisted at Kapsomin in the same strata, 6 million years ago.

Niger

Discovered in 1964 in Niger, a right mandibular fragment with the roots of the lower M1 of a hominoid has been identified recently (Pickford et al. 2009). Comparisons with fossil and modern hominoids indicate similarities with *Pan troglodytes*. The faunal remains associated with the specimen suggest an Upper Miocene age between 11 and 5 million years. Furthermore, they suggest the presence of large river or a freshwater lake, indicating a more humid environment in the area than is the case today. This discovery is important, as it shows that hominoids were widespread in Africa in the Upper Miocene and it fills a gap in what is known of the distributions of African apes and their origins and sheds light on the dichotomy between humans and chimpanzees.

Conclusions

The debate about our earliest origins is probably not closed and is fueled by the poverty of fossils in the time period between 12 and 4 million years ago. This is why it is necessary to continue excavation and prospecting in different areas of Africa in order to fill the gaps and extend our knowledge of variation and diversity. As a matter of fact, recent surveys in Western Uganda led to the discovery of Upper Miocene and Pliocene faunas (including mammals) in an area supposed to be of Pleistocene age (Pickford et al. 2013). In Northern Namibia, new Upper Miocene and Pliocene deposits have been identified that have yielded mammals (Miller et al. 2010). One of the most troubling aspects of the research done to date on the origins of hominids relates to the comparative samples. Most scientists still focus on modern hominoids as a good reference for primitive morphologies. However, these animals are highly derived in their cranial and postcranial anatomy. As long as Miocene apes are not properly considered in these studies, we will remain trapped in the quest for a mythical missing link.

Of all the features used to define hominids, probably the least controversial is bipedalism. We know that in the past there have been several types of bipedalism, but there is definitely a basic one that is known in australopithecines, *Orrorin*, and *Homo*. In this group, adaptation to arboreality is variable: greater in some taxa, less in some others, and very little in *Homo*. There was probably a variety of early forms of hominids: the oldest widely accepted biped (supported by postcranial evidence) is *Orrorin*, and we await further data on *Ardipithecus* (arm, knee, and hip joints) and

Sahelanthropus to clarify their status (Fig. 3). What the evidence from the Upper Miocene tells us is that we cannot continue to support an origin of the earliest hominids in dry savanna-like conditions: in contrast, they inhabited humid to forested environments.

These early hominids cohabited with apes, and we are only just beginning to uncover the history of modern apes, of which we know only a small, emergent part of the iceberg: this is the challenge of the third millennium.

The Species and Diversity of Australopiths

William H. Kimbel

Contents

Abstract

In this chapter, the historical, systematic, and anatomical evidence for the diversity of the species within the australopith grade is reviewed. Given a strict evolutionary species definition, nominal taxonomic diversity and species-lineage diversity do not necessarily map onto one another in the fossil record. Species lineages entail statements of ancestry and descent that depend on the consistency of phylogenetic and stratophenetic data. The requirements for identifying species lineages in the fossil record are severe and in the early hominin

record are rarely met, most often owing to small sample size, underrepresented character data, nonrepresentation of rare or short-lived taxa, poor chronological resolution, gaps in the time-stratigraphic framework, or some combination of these factors. Because hypotheses concerning the "bushiness" of the hominin phylogenetic tree depend on the identification of lineages, not phenetically based "paleospecies," confidence with respect to this issue is not justified for the majority of the hominin fossil record. There are two cases in which an approach to this question can be attempted. In one, the evidence is consistent with the evolution of *Australopithecus anamensis* into *A. afarensis* via anagenesis. The other, the evolution of *A. boisei*, most likely entailed a speciation event that gave rise to southern African clade (represented by *A. robustus*) subsequent to the appearance of *A. aethiopicus*. The late Pliocene time period in which the latter events transpired (ca. 2.8–2.3 Ma) is one of substantial morphological diversity, high nominal taxonomic diversity, and high probability of synchronicity among known fossil samples. With the exception of the close phylogenetic relationship of *A. africanus* to *A. sediba*, it is not possible to connect the later Pliocene australopith taxa (*A. aethiopicus*, *A. garhi*) to particular descendants due to defects in the database. Nevertheless, this time period probably documents a previously (and subsequently) unmatched degree of lineage proliferation compared to other parts of the human evolutionary record. The challenge to paleoanthropologists is to devote resources to improving this part of the fossil record and then to create testable phylogenetic and adaptive hypotheses to explain it.

Introduction

The australopiths constitute a taxonomically and adaptively diverse group of extinct hominins that are currently known to have inhabited the African continent between approximately 4.2 and 1.4 million years ago (Ma). The documented geographical distribution of this group includes present-day South Africa, Malawi, Tanzania, Kenya, Ethiopia, and Chad but certainly may have been wider. Evidence from pelvic, knee, ankle, and foot morphology and, where available, trace fossils (i.e., the Laetoli footprint trails) indicates that these hominins were terrestrial striding bipeds, more similar, if not identical, in their locomotion to living humans (and extinct representatives of the genus *Homo*) than to any other known primate, living or extinct. The australopiths were impressively more variable in their skull and dental morphology than in their postcranial form, though the latter is poorly documented for some of the species included in the group. Our understanding of their taxonomic and adaptive diversity therefore reflects an historically important preoccupation with anatomical distinctions above the neck, particularly in the dentition and the bony structures thought to be associated with the masticatory system.

Many more characters distinguish the australopith species from one another than link them together as a group. Apart from bipedality, shared australopith characteristics include:

1. An approximately ape-size brain (range ca. 375–550 cm^3)
2. Inferosuperiorly short, vertical midface with massive zygomaticomaxillary region and strong subnasal prognathism
3. Short, wide basicranium with anteriorly positioned foramen magnum
4. Absolutely small, nonhoning canines
5. Large (in relation to body size) premolars and molars capped by variably thick enamel
6. Transversely thick mandibular bodies and tall ascending rami

Although these traits may, in combination, identify the australopiths, they do not diagnose them as a "natural" (i.e., monophyletic) group, as none of the listed features is unique to the group (i.e., they are not autapomorphies; they are either symplesiomorphies-shared with the great ape outgroup to hominins, such as small brain size and strong subnasal prognathism, or synapomorphies-shared with one or more species in the closest sister taxon, *Homo*, such as bipedal locomotion, reduced canines, short cranial base, and, at least in comparison to some early species usually attributed to *Homo*, postcanine megadonty). As such, the australopiths most likely constitute a paraphyletic group, identified by its unique adaptive grade among the hominins (small-brained, small-canined, megadont bipeds). This idea is reflected in the entrenched tendency to use the genus *Australopithecus* as a "waste basket" taxon for any and all of the extinct hominin species whose skeletal and inferred behavioral characteristics fit this adaptive pattern, notwithstanding the likelihood that one or more monophyletic groups, such as the so-called "robust" australopith species (sometimes attributed to genus *Paranthropus*), are thus subsumed within it.

Historical Perspective on Australopith Diversity

The first described australopith species was *Australopithecus africanus* Dart 1925, identified on the basis of a fossil juvenile skull and brain endocast from the site of the Buxton Limeworks at Taung, Orange Free State (now Free State), South Africa. During the 1930s–1940s, no fewer than four additional species (in three genera) were identified based on adult craniodental fossils recovered from brecciated sediments within collapsed and eroded karstic structures then being mined for lime in South Africa (Sterkfontein 1936; Kromdraai 1938; Makapansgat 1947; Swartkrans 1948). The early taxonomy of the australopiths was authored by paleontologist Robert Broom (1950), who conducted the excavations at Sterkfontein, Kromdraai, and Swartkrans and perceived a different species at

Table 1 The evolution of australopith taxonomy during the 1950s

Site	Broom (1950)	Robinson (1954)
Taung	*Australopithecus africanus* Dart 1925	*Australopithecus africanus*
Sterkfontein	*Plesianthropus transvaalensis* (Broom 1936)[a]	*Australopithecus africanus*
Makapansgat	*Australopithecus prometheus* Dart 1948	*Australopithecus africanus*
Kromdraai	*Paranthropus robustus* Broom 1938	*Paranthropus robustus*
Swartkrans	*Paranthropus crassidens* Broom 1949	*Paranthropus robustus*

[a] Broom initially assigned the species *transvaalensis* to *Australopithecus*

each site (Table 1). Broom's protégé John Robinson subsequently collapsed this taxonomy to one species within each of two genera (Table 1) based on his scenario of a dichotomous partitioning of dietary resources by these early hominins (Robinson 1954). Robinson's simplified taxonomy and hypothesis of a morphologically specialized herbivore *Paranthropus* and a more generalized omnivore (and presumptively meat-eating and toolmaking) *Australopithecus* has had a profound effect on subsequent australopith systematics. It remains the leading explanatory paradigm for the evolution of these hominins to the present day.

Much of the early debate about the australopiths' role in human evolution had less to do with their adaptations or diversity than with their suitability as human ancestors. The skepticism that greeted Dart's claims of human ancestral status for *A. africanus* is well known, and despite the subsequent demonstration by Broom (1939; Broom and Schepers 1946), Gregory and Hellman (1939), Le Gros Clark (1947), and others of uniquely human characteristics in adult australopith teeth, jaws, and basicrania, it was not until the identification of humanlike bipedal adaptations – and the absence of apelike quadrupedal ones – in a distal femur (TM 1513) and capitate (TM 1526) from Sterkfontein and a talus (TM 1517) from Kromdraai that the most ardent skeptics capitulated (e.g., Keith 1947, though his recantation began earlier: from Robert Broom (Broom and Schepers 1946, p. 22)) we learn that "In a letter I have recently received dated 11th May 1944, Sir Arthur writes: 'No doubt the South African anthropoids are much more human than I had originally supposed, and I am prepared to swallow plantigrade adaptations in their limb bones'."

Although australopith fossils had lurked unidentified in east African faunal collections as early as 1935 (i.e., the BMNH M 18773 lower canine from Laetoli, Tanzania (White 1981)), it was not until the discovery of the Garusi (Laetoli) maxillary fragment in 1939 that attention was directed (albeit fleetingly) toward the East African Rift Valley as a source of early hominin fossils. The particularly apelike upper premolar and palate morphologies of the Garusi specimen were overshadowed by the powerful appeal of Robinson's adaptive scheme in which the fossil was cast as an east African representative of *A. africanus* (Robinson 1953a), and thus the Garusi maxilla receded into relative obscurity until the recognition of the craniodentally plesiomorphic *A. afarensis*, based on new mid-Pliocene Hadar (Ethiopia) and expanded Laetoli collections in the late 1970s (Johanson et al. 1978; see below).

Mary Leakey's 1958 discovery of the megadont *Zinjanthropus boisei* cranium OH 5 at Olduvai Gorge, Tanzania, together with discoveries in the 1960s–1970s at Peninj, near Lake Natron in Tanzania, in the Omo River basin of southern Ethiopia, and at Koobi Fora, east of Lake Turkana, Kenya, populated the Plio-Pleistocene fossil record of eastern Africa with crania, jaws, and teeth of a hominin whose morphological pattern was easily accommodated in the adaptive mold of Robinson's vegetarian *Paranthropus* (Robinson 1960). Most workers have since upheld separate species status for these hominins (as *P. boisei* or *A. boisei*) on the grounds of morphological distinction and/or geographical separation (Tobias 1967; Howell 1978; Rak 1983).

The identification in 1964 of *Homo habilis* approximately contemporaneous with OH 5 at Olduvai Gorge (in Bed I, ca. 1.8 Ma) recalled the earlier discovery of "true man" (*Telanthropus capensis*) alongside *Paranthropus* in the pink breccia (later Member 1) at Swartkrans (Broom and Robinson 1949; Robinson 1953b; Leakey et al. 1964). Robinson (1965 et seq.) dismissed the Bed I *H. habilis* fossils as an east African variant of *A. africanus*, which he believed was ancestral to modern humans, while advocates of the "single species hypothesis" struggled to accommodate all southern and eastern African hominin morphological diversity within single evolving species (Brace 1967; Wolpoff 1970). However, the recovery of a cranium of *Homo erectus* (KNM-ER 3733) in the same radioisotopically dated horizon (ca. 1.75 Ma) of the Koobi Fora Formation (Kenya) that yielded *A. boisei* (e.g., KNM-ER 406) validated once and for all the idea that the pattern of early human evolution was, at least partly, the result of a process of diversification through speciation rather than a linear process of morphological advancement (Leakey and Walker 1976).

The Leakeys' argument for a geologically early appearance of genus *Homo*, bolstered by the 1972 recovery of the relatively large-brained, flat-faced KNM-ER 1470 (initially dated erroneously to >2.6 Ma but now known to be ca. 1.9 Myr old), strongly influenced the first interpretations of fossil hominin diversity in the collections made during the 1970s in pre-3.0-Myr-old sediments at Hadar and Laetoli. While the small Laetoli sample was thought to contain an early precursor of *Homo* (Leakey et al. 1976), as many as three hominin taxa, including one similar to the Laetoli form, were believed to inhabit the Hadar assemblage of teeth, jaws, and postcrania (Johanson and Taieb 1976). Such early diversity made sense given the Robinsonian view of an *A. africanus*-like ancestor for a geologically old *Homo* lineage, implying earliest Pliocene or even late Miocene hominin cladogenesis (Tobias 1973).

By the late 1970s, the correct allocation of KNM-ER 1470 to the latest Pliocene and the reinterpretation of the Hadar and Laetoli fossils as representing a single species (Johanson and White 1979) had refocused discussion around two different two-lineage models, both of which featured *A. afarensis* at the root of mid-Pliocene hominin diversity. One, a twist on Robinson's diet-driven diversity scenario, envisioned *A. africanus* as the basal taxon of a "robust" australopith clade, based on the view from the perspective of the craniodentally plesiomorphic *A. afarensis* of derived masticatory morphology in the hominins from Sterkfontein, Makapansgat, and Taung (White et al. 1981; Rak 1983; Kimbel et al. 1984). The other interpreted *A. africanus* as the better candidate for the common ancestry of *Homo* and "robust" australopiths by virtue of their shared derived morphology in the premolars and canines, mandible, and calvaria relative to more plesiomorphic states in *A. afarensis* (Kimbel et al. 1984; Skelton et al. 1986), but with implied reversals in derived states inferred to be related to heavy chewing in the transition to *Homo*.

Underscoring an emerging consensus on the importance of cladogenesis in the early record of human evolution, homoplasy became a dominant theme in paleoanthropological writings on australopith systematics during the 1980s. These focused in particular on the likelihood of independent evolution of skeletal responses to heavy mastication (see contributions in Grine 1988), an issue highlighted by the discovery of the 2.5-Myr-old KNM-WT 17000 cranium attributed to *A. aethiopicus* (Walker et al. 1986), whose startlingly plesiomorphic attributes within an otherwise fairly typical "robust" australopith anatomical milieu ensured a high degree of homoplasy (in the masticatory apparatus or cranial base) in any phylogenetic hypothesis that attempted to accommodate all australopith (and early *Homo*) species then known (Kimbel et al. 1988). *A. africanus*, more than any other species, continued to occupy a place of uncertainty in hominin phylogeny, which led to musings on whether the type species of the genus may actually comprise more than one species taxon (Clarke 1988, 1994; Kimbel and White 1988; Kimbel and Rak 1993) – a view that remains in the minority, despite the uncommon degree and type of cranial and dental morphological variation within the now 700+ specimen Sterkfontein sample.

The 1990s was a decade in which a great deal of paleoanthropological field work concentrated on extending the record of early hominins into the late Miocene, the period in which the evidence from DNA pinpoints the divergence of chimpanzee and human lineages. At least five hominin taxa predating *A. afarensis* have been recognized since 1994 (*Ardipithecus kadabba, A. ramidus, Orrorin tugenensis, Sahelanthropus tchadensis, A. anamensis*), aggregately spanning the period between ca. 4.2 and ca. 6–7 Ma. Relative to *A. afarensis*, all are more plesiomorphic in dental, mandibular, and cranial morphology. The youngest, *A. anamensis*, is by far the most similar morphologically to *A. afarensis* and subsequent australopiths (Leakey et al. 1995; Ward et al. 2001). For the purposes of this chapter, the australopiths will be taken to include *A. anamensis* as their earliest known representative.

Other recently proposed taxa in the 2–4-Myr time range, including *A. garhi* from Ethiopia (Asfaw et al. 1999), *A. bahrelghazali* from Chad (Brunet et al. 1996), *Kenyanthropus platyops* from Kenya (Leakey et al. 2001), and a so far undiagnosed form from Member 2 at Stertkfontein, South Africa (Clarke 2002), hint at as yet poorly understood aspects of hominin diversity and geographical distribution in the early to middle Pliocene of Africa. They will be mentioned in the survey of australopith species provided below, but relatively little is known about them compared to the other species included in the group. Table 2 lists the australopith species that will be discussed in this survey.

Table 2 Australopith species diversity according to nominal taxa

Taxon	Geographical distribution	Known age range (Ma)
Australopithecus africanus Dart 1925	South Africa	ca. 3.0–2.0
Australopithecus sediba Berger et al. 2010	South Africa	ca. 2.0
Australopithecus robustus (Broom 1938)	South Africa	ca. 1.5–2.0
Australopithecus boisei (Leakey 1959)	Tanzania, Kenya, Ethiopia, Malawi	≥2.3–1.4
Australopithecus afarensis Johanson et al. 1978	Ethiopia, Tanzania, Kenya	≥3.8–3.0
Australopithecus aethiopicus (Arambourg and Coppens 1968)	Ethiopia, Kenya, Tanzania	ca. 2.7–2.3
Australopithecus anamensis Leakey et al. 1995	Kenya	4.2–4.0
Australopithecus garhi Asfaw et al. 1999	Ethiopia	2.5
Kenyanthropus platyops M.G. Leakey et al. 2001	Kenya	3.5

Systematic Context of Australopith Diversity

Morphological diversity, taxonomic diversity, and species-lineage diversity do not neatly map onto one another in paleontology. This is largely due to the entrenched use of a phenetic species concept in this science, which tends to endorse the recognition of lineage segments as species. But the delineation of the "actors" in evolutionary processes over geological spans of time requires that we move beyond the recognition of "paleospecies" as static phenetic constructs, useful only as a formal catalogue of diversity, to rendering them as close to the entities that underpin the notion of the genetic species as lineages evincing signs of a unique network of gene exchange (see Kimbel and Rak 1993 for discussion and references). Substantial change can in principle accrue in such lineages under a model of anagenesis – amounts that would prompt many paleontologists to recognize distinct paleospecies at widely separated temporal cross sections of a lineage – but, in the absence of cladogenesis, no actual increase in lineage diversity would have resulted from this process. Therefore, to understand the diversity of australopiths, it is one thing to identify and name morphologically distinct taxa and quite another to delineate species lineages. Although a morphologically diagnosed species and a species lineage may exactly coincide, where fossil samples with different morphologies and temporal distributions are involved, the identification of species lineages entails a complex analytical process involving the comparison of phylogenetic hypotheses based on polarized morphological character states (cladistics) with data on the temporal distribution of form (stratophenetics). Where these approaches yield the same character transformations, with minimal stratigraphic gaps and no autapomorphies in temporally intermediate samples, the simplest explanation of the observed data may be the existence of a temporal sequence of samples representing ancestral and descendant populations within a single lineage (Smith 1994) even if two or more distinct nominal species are thereby joined in one *evolutionary species* (Simpson 1951; Wiley 1978; Krishtalka 1993). There is always the possibility that the evidence for an anagenetic lineage may mask a poorly resolved record of cladogenesis. Accordingly, a fairly densely sampled fossil record over a well-calibrated stratigraphic record and a reasonably complete sampling of taxa from the relevant time period are necessary for this kind of analysis. These requirements are rarely met in the hominin fossil record (but see Wood et al. 1994 and Kimbel et al. 2006 for exceptions).

In the following survey, I examine australopith diversity as a record of nominal taxa as well as attempting to characterize it in terms of species lineages. Because I am concerned with taxonomic diversity, my review focuses on craniodental morphology.

Species Diversity of Australopiths

Australopithecus anamensis (M. Leakey et al. 1995)

Known temporal distribution: ca. 4.17–3.95 Ma, based on radioisotopic age determinations on tephras (Leakey et al. 1995, 1998).

Known geographical distribution: Kanapoi, southwest of Lake Turkana, and Allia Bay, east of Lake Turkana, Kenya (Koobi Fora Formation); Asa Issie and Aramis sites, Middle Awash valley, Ethiopia.

Holotype: KNM-KP 29281, adult mandible with complete dentition and associated temporal bone fragment from Kanapoi.

Hypodigm: Seventy-eight catalogued fossils have come from the Kanapoi site (including the distal humerus reported by Patterson and Howells 1967); 31 specimens have come from Allia Bay (Ward et al. 2001, 2013). The combined sample comprises mostly dentognathic specimens, including, from Kanapoi, three adult mandibles, an adult maxilla, and deciduous and permanent teeth; from Allia Bay, an adult mandibular fragment, two fragmentary adult maxillae, and deciduous and permanent teeth. Postcranial material includes a distal humerus, a capitate, a proximal hand phalanx, and associated proximal and distal portions of a tibia from Kanapoi. Fragments constituting most of an adult radius from Sibilot Hill (Heinrich et al. 1993), ca. 20 km from the main fossil-bearing locality at Allia Bay, have been attributed to the species based on its inferred geological age (Ward et al. 2001). Additional teeth, a fragmentary maxilla, and a femoral shaft, representing no fewer than eight individuals, have been recovered from Asa Issie and Aramis, in the Middle Awash valley of Ethiopia (White et al. 2006).

Diagnostic morphology: Craniodentally, *A. anamensis* differs from extant African apes and Mio-Pliocene hominins (such as *Ardipithecus* and *Sahelanthropus*) chiefly in its expanded postcanine dental battery, including occlusally more complex premolars and thicker cheek tooth enamel, characteristics that are shared with later australopiths and early *Homo*. In morphology and functional wear, *A. anamensis* canines are less apelike than those of earliest known hominins (i.e., *Ardipithecus kadabba*; Haile-Selassie et al. 2004).

Differences from *A. afarensis* and later australopiths pervade the dentition, mostly in the anterior arcade, as well as in the symphyseal region of the mandible and the nasal region of the maxilla. The lower lateral incisors are mesiodistally expanded, as are the lower third premolars and maxillary canines. The P_3 is more asymmetric in occlusal form and is uniformly single-cusped, with an incipient metaconid expressed as a tiny pyramidal expansion of the transverse crest rather than a fully developed cusp, and it usually has a relatively large, mesiolingually "open" anterior fovea. Maxillary canine crowns are symmetric in lateral view, with basally positioned mesial and distal shoulders. Although canine crown size is approximately equivalent to that of *A. afarensis*, the canine roots in *A. anamensis* are considerably larger than in this younger australopith species (Ward et al. 2010, 2013). The buccolingually compressed and occlusally simple deciduous first molar crown differs from the more fully molarized dm_1 of subsequent australopiths and recalls the apelike form of this tooth in *Ardipithecus*.

Mandibles (KNM-KP 29281, KNM-KP 29287, KNM-KP 31713) feature an externally convex anterior corpus and a strongly inclined, retreating symphyseal cross section with a "cut away" basal segment, which is manifested in a marked inferomedial inflection of the lower lateral corpus in the canine/premolar region. The lower canine crown is set lateral to the long axis of the postcanine tooth row, giving the dental arch a long, rectangular shape that is reflected in the nearly parallel-sided maxillary dental arch. However, based on what little is actually preserved of the midline cross section, the reconstructed dental arch in the maxilla KNM-KP 28283 is too narrow and posteriorly convergent as depicted in published photographs (e.g., Leakey et al. 1995, Fig. 1b; partly corrected in Ward et al. 2001, Fig. 3). In the maxilla (KNM-KP 29283 from Kanapoi, ARA-VP 14/1 from the Middle Awash), large canine roots shape the morphology around the nasal aperture. The lateral margins of the aperture are rounded, not sharp as in *A. afarensis*, and the inferior margin is indistinct, with the subnasal surface arching smoothly into the nasal cavity.

A single fragmentary temporal bone (KNM-KP 29281) forms part of the holotype. From a small, evidently female individual, it has a flat mandibular fossa with an indistinct articular eminence and a horizontally disposed, shallow, and sagittally convex tympanic element that extends laterally to a small-diameter external auditory meatus. Although each of these features can be found individually among *A. afarensis* temporal bones from Hadar, their strong apelike expression in combination is not encountered in the Hadar sample.

The tibia and hand phalanx from Kanapoi, and the radius from East Turkana (granting its assignment to *A. anamensis*), are very similar to other australopith homologues, and the tibia constitutes the earliest known skeletal evidence for australopith bipedality. The capitate (KNM-KP 31724) is distinctive, however, in the relative orientation of the distal facets for the second and third metacarpals. As in great apes, but unlike the condition in later australopiths and humans, the facet for MC II is laterally directed and set at approximately 90° to the facet for MC III, implying little or no rotational capability at the carpal/MC II joint (Leakey et al. 1998).

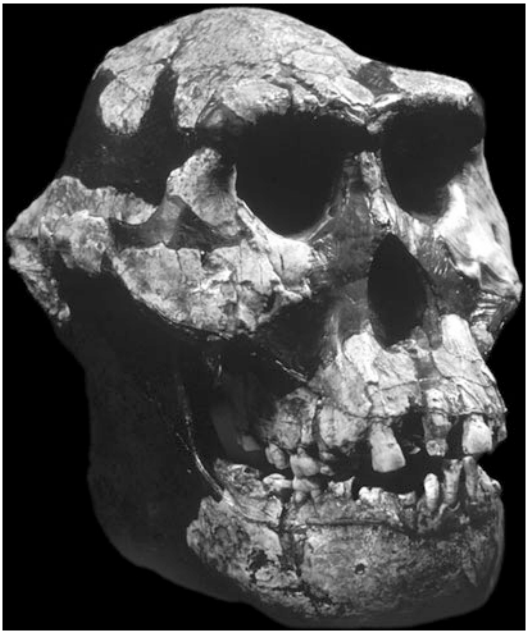

Fig. 1 Three-quarters view of the reconstructed skull of *A. afarensis* specimen A.L. 444-2 from Hadar, Ethiopia (Photo by W. Kimbel and Y. Rak)

Discussion: The *A. anamensis* hypodigm presents a distinctive and significantly more apelike anatomical package than those of subsequent australopith species. However, when the sample is separated into subsamples by site, a more complex picture emerges. Although the younger sample from Allia Bay is much smaller and less representative anatomically than the one from Kanapoi, in several of its morphological details, it stands out relative to conditions in the latter sample (Kimbel et al. 2006). The Allia Bay P_3 (in mandible KNM-ER 20432) has an expanded posterior fovea, and its anterior fovea is partly sealed by an elevated mesial marginal ridge. The mandible corpus fragment in which this tooth is preserved does not appear to possess the inferomedial inflection of the lateral corpus under the premolars, implying a less retreating symphyseal cross section. The Allia Bay lower canines ($n = 2$) show less development of the distal cingulum than in the Kanapoi sample ($n = 4$). These distinctions of the Allia Bay sample are the most common states in *A. afarensis* and bridge *A. anamensis* to that taxon. Moreover, as suggested initially by Leakey et al. (1995), the differences between *A. anamensis* and *A. afarensis* are not as pronounced when the geologically older Laetoli sample of *A. afarensis* is considered separately from the younger sample from Hadar (see below, under *A. afarensis*). In fact, the hypothesis of anagenetic change efficiently accounts for the observed morphological transformations across the four temporally ordered site samples, implying that *A. anamensis* and *A. afarensis* constitute a single evolutionary species (Kimbel et al. 2006; see also White et al. 2006).

Australopithecus afarensis (Johanson et al. 1978)

Known temporal distribution: ca. 3.8–3.0 Ma based on radioisotopic age determinations on tephras, supported by biochronology and paleomagnetic polarity.

Known geographical distribution: Laetoli, Tanzania (upper Laetolil Beds); Hadar, Ethiopia (Sidi Hakoma, Denen Dora, and Kada Hadar Members, Hadar Formation); Dikika, Ethiopia (Basal Member and Sidi Hakoma Members, Hadar Formation), Woranso-Mille, Ethiopia, Maka, Middle Awash, Ethiopia ("Maka Sands," Matabaietu Formation), East Turkana, Kenya (Tulu Bor Member, Koobi Fora Formation), possibly Koro Toro, Bahr-el-Ghazal, Chad.

Holotype: LH-4, mandible with dentition, from upper Laetoli Beds, Laetoli, Tanzania.

Hypodigm: Approximately 90 % of the hypodigm of *A. afarensis* comes from Hadar Formation sediments exposed at the Hadar site in Ethiopia ($n = 367$ specimens). The Hadar sample includes two partial skeletons with craniodental associations (A.L. 288-1, A.L. 438-1), two nearly complete (A.L. 444-2, A.L. 822-1) and one partial (A.L. 417-1) skull, 57 adult or subadult mandibular portions, 13 adult or subadult maxillae, 12 calvarial specimens (including a partial juvenile cranium, A.L. 333-105), and a wealth of upper limb, lower limb, and axial material, the majority of which comes from the A.L. 333 locality (see descriptive papers in the March 1982 *American Journal of Physical Anthropology* and Latimer et al. 1987; Latimer and Lovejoy 1989, 1990a, b; Kimbel et al. 1994, 2004; Drapeau et al. 2005). The Laetoli site sample consists of the holotype mandible (LH-4), several adult or subadult jaws (Garusi I, LH-2, LH-5), a fragmentary partial skeleton of a juvenile (LH-21), and an assortment of teeth (White 1977, 1980, 1981). Trace fossils in the form of the Laetoli bipedal hominin footprint trails, presumed to have been made by *A. afarensis*, are part of the species' hypodigm. From the Maka site in Ethiopia have come a proximal femur, a humerus, and several jaws, including a nearly complete mandible, at 3.4 Ma (White et al. 1993, 2000; Lovejoy et al. 2002). A partial calvaria (KNM-ER 2602; Kimbel 1988) is known from Koobi Fora. Although the 3.0–3.5-Myr-old mandible fragment (KT-12/H1) from Koro Toro, Chad, has been made the holotype of *A. bahrelghazali* by Brunet et al. (1996), its anatomy does not appear to distinguish it from the range of variation encompassed by the Hadar/Maka mandibular series, and so it is here tentatively interpreted to extend the geographical distribution of *A. afarensis* into north-central Africa. The Middle Awash frontal fragment from Belohdelie may also belong to *A. afarensis*, which would extend the time range of the species back to ca. 3.9 Ma (Asfaw 1987; Kimbel et al. 2004).

Diagnostic morphology (Fig. 1): *A. afarensis* can be distinguished from *A. anamensis* by a more molarized, symmetric P_3 crown with more frequent development of the second cusp (metaconid) and transverse orientation in the tooth row; an asymmetric upper canine with more apically positioned mesial crown shoulder; a molarized dm_1 with buccolingually expanded talonid; a straighter, commonly more upright anterior corpus profile, with a "filled out" basal segment and little to no inferomedial inflection of the lower corpus beneath the canine-premolars; lower canines set medial to postcanine row axis; a wider palate at equivalent palate lengths; a nasal aperture defined by sharp lateral margins and distinct inferior margin, with the canine jugum a distinct entity in the circumnasal topography; and a larger external auditory meatus. In all of these features, *A. afarensis* exhibits the derived condition for hominins.

Compared to all subsequent australopiths, a distinctive, predominantly plesiomorphic, anatomy pervades the *A. afarensis* skull and dentition. The calvaria testifies to an extensive posterior *m. temporalis* origin, with posteriorly extended sagittal crests and compound temporal/nuchal crests in both large (putatively male) and small (putatively female) specimens. The nuchal plane of the occipital bone is transversely convex and set at a steep angle to the Frankfurt plane, especially in less heavily crested small and subadult individuals, and it transitions to a relatively short occipital plane. In some individuals the nuchal plane extends superiorly to a very high position on the rear of the braincase. The cranial base features a shallow mandibular fossa bounded anteriorly by a weak to moderately developed articular eminence and posteriorly by an inflated postglenoid process that sits anterior to the tympanic element. The tympanic is a horizontally inclined tube, rather than a vertically oriented plate, and it usually lacks a distinct crista petrosa. Venous blood outflow was predominantly through the occipital-marginal rather than through the transverse-sigmoid sinus system. The frontal bone features a low, flat to mildly convex squama lacking a frontal trigone, coronally oriented, laterally thickened supraorbital bars, and broad postorbital breadth relative to other facial breadth dimensions. The midfacial axis (nasion-nasospinale) is upright, in contrast to the strongly projecting, convex subnasal plane (nasospinale-prosthion), which protrudes anteriorly beyond the bicanine line (also seen in *A. garhi*). Interorbital and nasal aperture breadths are narrow, contrasting with the broad, flat, and massive zygomatic region. The maxilla's zygomatic process root is located above M^1 or P^4-M^1, and its inferior margin is moderately to strongly arched. Within the nasal cavity, an elevated platform separates the inferior nasal margin from the anterior vomeral insertion. The palate is moderately deep in narrow jaws but is shallower in wider ones, and the upper dental arch is subparallel with slight convergence to moderate divergence posteriorly. The mandible has a deep but relatively thin corpus at the molars, and a moderately tall ramus originating high on the corpus and separated from it by a narrow extramolar sulcus. In individuals with an associated mandible and maxilla (i.e., A.L. 417-1, A.L. 444-2, A.L. 822-1), the mandibular corpus constitutes more than two-thirds of the orbitoalveolar height in the coronal plane of the orbits. The external contour of the anterior corpus is full and transitions to a vertical lateral corpus beneath the canines and premolars. Although the symphyseal axis is more vertical than in *A. anamensis*, it is, on average, less vertical than in subsequent australopiths. The lower anterior dental arch is pinched in small mandibles but widens into a U-shape in larger specimens, perhaps under the influence of moderate canine dimorphism.

Most of the distinctive dental features of *A. afarensis* are focused in the canines and premolars, which in this species are captured in evolutionary transition. Molarization of the P_3 is less advanced than in subsequent australopiths: the metaconid is variably expressed, with some individuals primitively lacking a distinct second cusp (e.g., A.L. 128-23, 277-1, 288-1, 417-1), though these are not necessarily those with a more "apelike" skewed occlusal outline and oblique orientation in the tooth row. Absolute canine size overlaps that of *A. africanus*, though relative to postcanine size the *A. afarensis* canines are larger. Some canines reveal ancestral traces of shearing wear (e.g., on the elongated distal crests of the lower), which is lost almost entirely in subsequent australopith species, but this is significantly less developed than in *A. anamensis* and especially *Ardipithecus*, and occlusal wear in *A. afarensis* canines and premolars is predominantly apical. Nevertheless, in some mandibles canine and mesial P_3 crowns stand tall even in the face of extreme occlusal molar wear, a remnant of the ancestral occlusal wear pattern.

Discussion: Well-documented variation in the large *A. afarensis* sample from Hadar indicates high levels of cranial polymorphism. Some of this variation is due to sexual dimorphism in size and shape, while some of it is due to anagenetic trends in craniodental morphology during the younger half (3.5–3.0 Ma) of the *A. anamensis* to *A. afarensis* species lineage (Lockwood et al. 2000). The Laetoli sample (ca. 3.8–3.6 Ma) figures prominently in this discussion. Although some dental metric differences between the Laetoli and Hadar samples have been cited in the past (White 1985), it now appears that the metric and morphological differences between the hominin populations represented at these sites are phylogenetically significant. Despite limited samples, the convex, retreating form of the adult anterior mandibular corpus (LH-4), mirrored in that of a juvenile (LH-2); the influence of the canine root on the curved lateral margin; the indistinct inferior margin of the nasal aperture (Garusi I); and the mesiodistally expanded lower canine and P_3 crowns recall conditions diagnostic of *A. anamensis* and occur in more derived states in the Hadar sample (Kimbel et al. 2006). The recently recovered sample of teeth and jaws from Woranso-Mille, dating to ca. 3.6–3.8 Ma, reinforces the hypothesis of dentognathic evolution along the *A. anamensis* to *A. afarensis* lineage (Haile Selassie et al. 2009).

Later in time, in the Kada Hadar Member at Hadar (ca. 3.0–3.1 Ma), there is evidence of an anagenetic increase in hominin skull size (and perhaps body size), which drove the *A. afarensis* mandibular corpus and facial skeleton to sizes rarely encountered in older strata (Lockwood et al. 2000). This trend was not accompanied by especially large postcanine teeth, more robust mandibular corpora (i.e., thicker in relation to depth), or by anteriorly shifted masticatory muscle blocks that are usually thought to signal diet-related morphological specializations in subsequent species of the australopith group. The causal processes underlying the observed increase in size are presently unclear, but it does roughly correspond to a change in the Hadar mammalian faunal community to more arid-adapted taxa (e.g., among the bovids).

The Burtele site, in the Woranso-Mille area of Ethiopia, has yielded a fossil partial foot skeleton from sediments contemporary with the Sidi Hakoma Member at Hadar and Dikika (ca. 3.4 Ma; Haile-Selassie et al. 2012). This specimen features a divergent hallux, which is universally present in arboreal catarrhines. However, derived features, including the dorsally “domed” heads of the lateral metatarsals and the anterior cant of the corresponding phalangeal bases, suggest toe off in terrestrial bipedality, as in *Australopithecus* and *Homo*. The mix of primitive and derived morphology in the Burtele foot, matching that of early Pliocene *Ardipithecus ramidus*, is strong evidence for a second species lineage contemporary with *A. afarensis* in eastern Africa (Haile-Selassie et al. 2012).

Kenyanthropus platyops (M.G. Leakey et al. 2001)

Known temporal distribution: ca. 3.3–3.5 Ma based on radioisotopic dating of tephra.

Known geographical distribution: Lomekwi (Nachukui Formation), west of Lake Turkana, Kenya.

Holotype: KNM-WT 40000, a crushed and distorted cranium with partial dentition.

Hypodigm: In addition to the holotype, a partial maxilla with dentition (KNM-WT 38350). (Other hominin fossils, including a partial temporal bone, a mandible fragment [formerly attributed to *A. afarensis* by Brown et al. (1993)], and some isolated teeth, were withheld from attribution to this taxon by Leakey et al. (2001).)

Diagnostic morphology: While enumeration of the diagnostic features of *K. platyops* is hampered by poor preservation of the holotype, taphonomy does not appear to account for all of the distinctive morphology of the type cranium relative to that of known specimens of *A. afarensis*, with which it was contemporary (Spoor et al. 2010). These differences reside mainly in the lower part of the face (Leakey et al. 2001) and include an anteriorly positioned root of the maxillary zygomatic process (above P^3-P^4, and seen in both the type specimen and KNM-WT 38350) and a transversely and sagittally flat subnasal plane with minimal projection beyond the canines. In addition, the dominant venous outflow track was via the transverse-sigmoid system, in contrast to the occipital-marginal system, which is very common in *A. afarensis* (though the Laetoli juvenile LH-21 also evinces the transverse-sigmoid drainage route). The size of the external auditory meatus is smaller than that of *A. afarensis*, despite the latter’s extensive variation in this feature (Kimbel et al. 2004), and approaches the tiny EAM of *Ardipithecus ramidus* and *A. anamensis*. The second molar in the type cranium is much smaller than that of other australopith M^2s, while the M^1 of KNM-WT 38350 is also very small.

Discussion: Along with the Burtele foot (see above), the specimens attributed to *K. platyops* currently constitute the best evidence for hominin lineage diversity prior to 3.0 Ma. On the basis of published information (Leakey et al. 2001), the material attributed to *K. platyops* shares only primitive characteristics with

A. afarensis (e.g., tubular tympanic element lacking a petrous crest, posteromedially angled temporal lines and an emphasis on posterior cranial crests, low and curved zygomaticoalveolar crest), but its facial configuration appears more derived than what is observed in the large cranial sample of that species. None of these derived characteristics are observed in the sample of one dozen adult maxillae in the Hadar sample of *A. afarensis*, or in the Garusi maxilla from Laetoli, which is demonstrably more primitive in the circumnasal region than the Hadar specimens (as discussed above and in greater detail in Kimbel et al. (2006)) yet is the more precise chronological match for the *Kenyanthropus* holotype. (KNM-WT 38350 is approximately contemporary with Hadar specimens A.L. 417-1, A.L. 200-1, and others from the middle Sidi Hakoma Member.) Therefore, *K. platyops* sits in phylogenetic isolation. There are no shared derived characters linking it to the *A. anamensis* to *A. afarensis* species lineage, and although favorable comparisons have been made directly with the lower facial morphology of *Homo rudolfensis* (i.e., KNM-ER 1470), at ca. 2.0 Ma (Leakey et al. 2001), it is unrealistic to link these two specimens via a meaningful phylogenetic hypothesis given 1.5 myr of no intervening data.

Key references: Leakey et al. 2001; Spoor 2010.

Australopithecus africanus (Dart 1925)

Known temporal distribution: ca. 3.0–2.0 Ma, based on U/Pb dating, paleomagnetic polarity and biochronological correlations with radioisotopically calibrated sequences in eastern Africa (Herries et al. 2013).

Known geographical distribution: Taung, Sterkfontein, and Makapansgat, South Africa.

Holotype: Juvenile skull, dentition, and endocast from Taung.

Hypodigm: In addition to the holotype, crania, jaws, teeth, and postcrania from Sterkfontein and Makapansgat. The Sterkfontein sample is by far the more extensive, consisting of some dozen nearly complete or partial crania (e.g., TM 1511, Sts 5, 17, 71, Stw 13, 505) and adult and juvenile mandibles plus hundreds of teeth, in jaws or isolated. Numerous postcranial remains are known, including at least three partial skeletons (Sts 14, Stw 431, Stw 573: Toussaint et al. 2003), but only one (Stw 573) is definitively associated with taxonomically diagnostic craniodental remains. The Makapansgat sample comprises roughly 40 specimens, including several jaws (MLD 2, 6/23, 9, 18, 40), two partial adult calvariae (MLD 1, MLD 37/38), and some fragmentary cranial and postcranial elements.

Diagnostic morphology (Fig. 2): Compared to *A. afarensis*, *A. africanus* has a higher, shorter braincase with rare sagittal cresting and no compound temporonuchal cresting. The supraorbital torus thins laterally from top to bottom and is occasionally divided into distinct supraorbital and superciliary components (Lockwood and Tobias 1999). The cranial base is a bit narrower in absolute terms, but in relation of calvarial size, it is broader and shorter than in apes. The occipital plane of the occipital bone is higher and the nuchal plane is flatter and more

Fig. 2 Oblique views of Sterkfontein *A. africanus* crania Sts 71 (*left*) and Sts 5 (*right*) (Photo by W. Kimbel and Y. Rak)

horizontally inclined. The mandibular fossa is deeper on average, with a stronger articular eminence. The tympanic element is more vertically oriented, usually bears a distinct crista petrosa, and tapers medially to a distinctive Eustachian process. Venous drainage from the endocranium is predominantly through the transverse-sigmoid system. Prominent anterior pillars border the nasal aperture, even in young individuals, and the subnasal plate is flat to slightly convex sagittally and much less projecting relative to the bicanine axis. Within the nasal cavity, the step-down to the nasal floor and anterior vomeral insertion occurs immediately posterior to nasospinale, usually without an intervening platform. The zygomatic bone features a variably prominent boss at the transition to the temporal process and a strong sagittal inflection across the frontal process/facial surface transition, which combine to create a central facial hollow in some individuals (e.g., MLD 6/23, TM 1511, Sts 71, Stw 505). Zygomatic process roots typically originate more anteriorly (above P^4/M^1 to P^4/P^3) and have a straight, superolaterally diverging inferior margin. The palate is, on average, deeper, with an inferiorly flexed premaxillary segment and posteriorly divergent tooth rows. The mandible corpus is more robust (breadth as a percentage of depth at M_1) and has a more inflated lateral surface beneath the premolars and a straighter, more vertical symphyseal profile. Dentally, compared with *A. afarensis*, *A. africanus* has absolutely larger (especially broader) postcanine teeth with centrally crowded molar cusp apices in some individuals. The P_3 is uniformly bicuspid, canine wear is exclusively apical, and the anterior-posterior adult occlusal wear gradient is weaker. C/P_3 and I^2/C diastemata are less frequent.

In its moderate (though impressively variable) upper midfacial prognathism (nasion-nasospinale), occasionally patent premaxillary suture in adult faces, and less topographically complex glenoid region of the temporal bone, *A. africanus* remains plesiomorphic in relation to *A. robustus* and *A. bosei* (but not *A. aethiopicus*). The mandibular corpus is less robust compared to states observed in *A. aethiopicus*, *A. robustus*, and *A. boisei*, and dental size and the anterior-posterior tooth row proportions remain relatively conservative (especially those involving the premolars, which are less expanded in relation to the molars). Facial breadths are narrower as a percentage of calvarial breadths, giving the impression that the cranium is less constricted postorbitally, though the minimum frontal breadth dimension is of similar absolute magnitude. The vertex of the braincase (in specimen Sts 5 at least) is higher in relation to the orbital roof when compared to crania of *A. aethiopicus, A. robustus*, and *A. boisei* (as well as *A. afarensis* and the great apes), but when size-standardized by calvarial length, vertex height is greater only than that of the "robust" species.

Discussion: The large *A. africanus* sample from the Sterkfontein Member 4 ("type site") fossil assemblage is notable for its unusually extensive range of craniodental variation (e.g., basal aspect of the temporal bone, facial topography and subnasal prognathism, postcanine tooth size), which has led to proposals that more than one hominin species may be contained within it (Clarke 1988, 1994, 1998; Kimbel and White 1988; Kimbel and Rak 1993; Moggi-Cecchi et al. 1998; Lockwood and Tobias 2002). However, because dividing the sample to create overlapping cranial and dental morphs has proven difficult (while different authors tend to disagree on such divisions in the first place), these proposals have not attracted much support (see Grine 2013 for a review). Still, appeals to normal sources of variation within a single geographically delimited biological species (chiefly sexual dimorphism) do not account for the variation, as much of this does not follow patterns of dimorphism observed within extant catarrhine species (Kimbel and White 1988; Kimbel and Rak 1993). The lack of chronological control within the Member 4 faunal assemblage leaves open the possibility that the hominin sample is time-transgressive. Kimbel (1986) offered as an explanation for the Sterkfontein Member 4 variation the temporal mixing of individual organisms' remains from morphologically distinct populations of *A. africanus* that had moved in and out of the Sterkfontein valley over a long period of time. Although Kuman and Clarke's (2000) revised stratigraphy implies a long and complex depositional history for Member 4, this idea is difficult if not impossible to test and does not in any event preclude the inclusion of fossils from more than one hominin species in the Member 4 sample. The basic systematics of the type species of *Australopithecus* remains a vexing issue, and the likelihood of being able to discern lineages is remote.

More recently, excavations in previously unexploited depositories in the Sterkfontein cave system have led to discoveries of hominin fossils originally said to be significantly older (ca. 4 Ma) than *A. africanus* of Member 4 (Clarke 1988, 2002; Partridge et al. 2003). These remains include a partial skeleton and skull (Stw 573) still being excavated in situ in the Silberberg Grotto and a small collection of specimens, including fragments of an adult cranium (Stw 578), from Jacovec Cavern. Published reports suggest general australopith affinities for these specimens. While their exact antiquity is uncertain, in part due to an extremely complex stratigraphic context, Herries et al. (2013) have presented evidence that these deposits are contemporaneous with Member 4 of the Sterkfontein site (ca. 2.0–2.6 Ma).

Australopithecus sediba (Berger et al. 2010)

Known temporal distribution: Faunal, paleomagnetic, and U/Pb dating methods combine to suggest a ca. 2.0 Ma age for the fossil-bearing sedimentary infill in the Malapa cave system, South Africa (Berger et al. 2010; Pickering et al. 2011; Herries et al. 2013).

Known geographical distribution: Malapa cave system, Gauteng Province, South Africa.

Holotype: MH1, a subadult partial skeleton and skull thought to be male (Berger et al. 2010).

Hypodigm: A subadult's partial skeleton and skull, reportedly male (MH1, the holotype), and an adult's partial skeleton and mandible, thought to be female (MH2). A tibia originally associated with the holotype is now said to represent a third individual (MH3) (Berger 2012).

Diagnostic morphology: The MH1 individual of *A. sediba* is small-brained, with an estimated endocranial volume (ECV) of ca. 420 cc, which must be close to the adult value given that the M^2s had achieved alveolar eruption (Carlson et al. 2011). This single value falls below the mean but within the ranges of *A. afarensis* and *A. africanus* ECV estimates (Holloway et al. 2004). Similarly, canine and postcanine tooth crown dimensions fall in the lower end of the range of size variation for these two australopith species (Berger et al. 2010). The face of MH1 is moderately prognathic with slight subnasal projection, but the latter feature, along with some other putatively diagnostic craniofacial characters, are subject to late growth-related changes. These ontogenetically labile characters include the widely spaced temporal lines, slight relative postorbital constriction, and mild relative lateral flare of the zygomatic arches (the latter two of which are expressed as a percentage of upper facial breadth in Berger et al. 2010). Thus, assessment of fully adult craniofacial shape in *A. sediba* would likely affect comparisons with other australopith species subtly but substantively.

In several respects the MH1 facial skeleton resembles that of *A. africanus* specimen Sts 52a, also a subadult (M3s unerupted). This specimen departs from characteristic *A. africanus* craniofacial anatomy (Rak 1983) in the absence of an anterior pillar, weak subnasal projection, a pronounced canine fossa, and mild eversion of the lateral nasal aperture margins superiorly with consequent slight prominence of the nasal bridge (enhanced by a median keel) – all features observed in MH1. MH1 shares several other craniofacial features with *A. africanus* adults and subadults (including Sts 52a), such as a superiorly placed anterior masseter origin associated with a straight, steeply angled (in anterior view) zygomaticoalveolar crest (Rak 1983; Kimbel et al. 1984).

At first glance, MH1 appears to bear a supraorbital torus separated from the frontal squama by a *sulcus supratoralis*, as in *Homo habilis* (sensu stricto; i.e., excluding fossils often attributed to *H. rudolfensis*). But in *H. habilis* the supraorbital torus is a distinct structure that bulges above the sulcus (with a topographic highpoint that divides the sulcus into lateral and medial sections on each side, as in KNM-ER 1813, OH 16 and OH 24), whereas in MH1 the squama passes onto a shelflike supratoral depression that extends, with little topographic disruption, directly onto the superior surface of the supraorbital structures. Perhaps this difference can be accounted for by the relative youth of MH1, although in hominoids juvenile supraorbital form is typically a good predictor of adult morphology. An alternative interpretation is that the MH1 morphology is one expression of the variable supraorbital form observed in *A. africanus* (as seen in the Sterkfontein Member 4 deposits). In this sample, the supraorbital elements are weakly defined topographically and are separated from the squama by a variably developed depression that ranges from virtually absent (in Sts 71, Stw 505) to mild (Sts 5) to pronounced (TM 1511, as revealed by the impression left in matrix by the specimen's now lost frontal squama; Kimbel and Rak, pers. obs.; see also Plate IV, Fig. 16 in Broom and Schepers 1946). MH1 is similar to the adult TM 1511 in the expression of this morphology (allowing for the effects of age-related differences in temporal line incursion), which is distinct from the *Homo habilis* morphology.

The Malapa mandibles (MH1 and MH2) are small and lightly built, but the extent to which the subadult status of MH1 and the presumptive female status of MH2 present a biased profile of mandibular size and shape variation (which is known to be considerable in other australopith taxa) can only be addressed with additional specimens. Rak et al. (in review) have concluded, however, based on the anatomy of the coronoid notch of the mandibular ramus, that the Malapa sample actually contains two hominin species, one of *Australopithecus* (MH1) and one of *Homo* (MH2) (see Rak et al. 2007).

As in all other australopith species, the *A. sediba* skeleton presents an amalgam of ancestral and derived features. MH2 features a nearly complete hand with a distinctive character mix relative to *A. afarensis*, *A. africanus*, and *H. habilis* (Kivell et al. 2011). The relatively long thumb and short fingers stand out in comparison even to the anatomy of modern humans. A similarly mosaic pattern is said to be found in the pelvis (MH 1 and MH2); it is similar to other australopiths in its large inter-acetabular breadth and long pubis, but distinct from *A. afarensis* and *A. africanus* in having more vertically disposed iliac blades and a shortened ischium (Kibii et al. 2011). Australopith taxonomy has for decades relied chiefly on skull and dental characters (in part because of the rarity of associated craniodental and postcranial remains), so it is noteworthy that the best evidence for the taxonomic distinctiveness of *A. sediba* may come from the postcranium.

Discussion: The case for the specific distinctiveness of the Malapa fossils has been conflated by their discoverers with arguments about its phyletic status (e.g., Berger 2012, p. 4). Neither is helped by the subadult status of the holotype and the fact that its cranium remains (at the time of this writing) partially encased in matrix, obscuring potentially informative portions of the external base (see Carlson et al. 2011). The bulk of the available craniodental evidence, however, argues for a close relationship with *A. africanus* as represented at Sterkfontein Member 4. The *A. sediba* to *A. africanus* relationship may constitute the best evidence for lineage continuity in the Plio-Pleistocene hominin record of southern Africa. If the young age (~2.6–2.0 Ma) of Sterkfontein Member 4 deposits suggested by Herries et al. (2013) is confirmed, then the age of some specimens of *A. africanus* (e.g., Sts 5) may fall within the error range of the age estimate for *A. sediba* at Malapa. Further support for chronological overlap would suggest a sister-group relationship, as opposed to an ancestor-descendant (anagenetic) relationship, between the populations represented by the two site samples.

Berger et al. (2010; Berger 2012) have argued that *A. sediba*, at 2.0 Ma, resided at the base of the *Homo* lineage. But if the unique phylogenetic link between *A. sediba* and *A. africanus* is substantiated, then for this argument to work, *A. africanus* itself would need to be rooted as a sister taxon to the *Homo* clade. Yet most comprehensive phylogenetic analyses of craniodental characters find *A. africanus* to be basal to a strongly supported “robust” australopith-*Homo* clade (e.g., Strait and Grine 2004; Kimbel et al. 2004). The Berger argument also hinges on a dismissal (rather than evaluation) of geologically contemporaneous or older (≥2.0 Ma) fossils from the genus *Homo* (*H. habilis*, *H. rudolfensis*, the A.L. 666-1 maxilla from Hadar, etc.) (Kimbel 2009; Spoor 2011).

Key references: Berger et al. 2010; Carlson et al. 2011; Pickering et al. 2011.

Australopithecus aethiopicus (Arambourg and Coppens 1968)

Known temporal distribution: ca. 2.3–2.7 Ma.

Known geographical distribution: Omo River basin, Ethiopia (Shungura Formation, Members C–F); West Turkana, Kenya (Nachukui Formation); Laetoli, Tanzania (Ndolanya Beds).

Holotype: Omo 18-1967-18, edentulous mandibular corpus (Member C, Shungura Formation, Ethiopia, ca. 2.7 Ma).

Hypodigm: The mostly complete and largely edentulous cranium KNM-WT 17000 from the Nachakui Formation, West Turkana, Kenya (2.5 Ma; Walker et al. 1986; Leakey and Walker 1988) is by far the most complete and well-preserved evidence for this relatively poorly known australopith species. Suwa et al. (1996) assigned to this species some 20 lower postcanine teeth (several in mandibles) from Omo Shungura Formation Members C–F, aggregately spanning ca. 2.7–2.3 Ma. An edentulous maxilla (EP 1500/01) from the Ndolanya Beds at Laetoli has also been assigned to *A. aethiopicus* (Harrison 2002).

Diagnostic morphology: Based on the single known cranium (KNM-WT 17000), *A. aethiopicus* can be distinguished from *A. afarensis* by its extreme midfacial prognathism (nasion-nasospinale); flat subnasal plane; smooth transition from subnasal surface to nasal cavity floor, with indistinct inferior margin of nasal aperture; anterior vomeral insertion and anterior nasal spine merged within nasal cavity; vertically thick palate; anteriorly positioned zygomatic process roots (over P^3/P^4); bulbous, forwardly sloping zygomatic facial surface, which leaves the nasal region in a central facial hollow; low calvarial height; frontal squama with frontal trigone delimited by strongly convergent temporal lines; vertically inclined tympanic element with distinct petrous crest; coronally aligned petrous element; and massive postcanine dentition (inferred from roots and fragmentary P^4 crown; Suwa 1989). Although the KNM-WT 17000 cranium features a very high sagittal crest, its diagnostic value is doubtful, as it was produced by the juxtaposition of enlarged temporalis muscles to a very small braincase (410 cm^3 cranial capacity) that may not have been typical for the species.

The majority of the characters discriminating the *A. aethiopicus* cranium from that of *A. afarensis* link the former species to classical "robust" australopith masticatory configurations. In addition, the dental remains attributed to the former species testify to postcanine size expansion and molarization seen in otherwise only in *A. robustus* or *A. boisei*, though with less premolar crown specialization than in the latter taxon (Suwa 1990; Suwa et al. 1996). However, *A. aethiopicus* retains a number of plesiomorphic characters, such as strong midfacial prognathism, posteriorly accentuated sagittal crest and extensive compound temporonuchal crest, flat mandibular fossa with low, indistinct articular eminence, and (as inferred from roots and alveolar dimensions) relatively large incisors and/or canines. While these characters set *A. aethiopicus* apart from both *A. robustus* and *A. boisei*, they also effectively discriminate it from *A. africanus*, which in several of these respects exhibits derived morphology (cranial vault shape, crest configuration, and mandibular fossa topography).

Discussion: As noted in the historical survey earlier, the discovery of the KNM-WT 17000 cranium provoked discussion about the role of homoplasy in early hominin phylogeny (see contributions in Grine 1988). The fact that aspects of this specimen's cranial morphology are strikingly more plesiomorphic than homologous states in *A. africanus*, combined with its obvious "robust" australopith masticatory signal, implies a high degree of convergent evolution in the australopith skull, the nature of which depends to a large extent on the phyletic position accorded *A. africanus*.

Does the temporal juxtaposition of the morphologically intermediate *A. aethiopicus* between *A. afarensis* and *A. boisei* support the identification of an evolving australopith lineage (evolutionary species) in the Middle to Late Pliocene of eastern Africa? Walker et al. (1986; Leakey and Walker 1988; Walker and Leakey, 1988) thought so and interpreted KNM-WT 17000 as an early, primitive, *A. boisei* specimen. Suwa's (1990; Suwa et al. 1996) detailed analysis of australopith postcanine dental evolution in the Shungura Formation found that in most respects the premolars and molars from Members C–F he attributed to *A. aethiopicus* more closely approximate the generalized condition of *A. robustus* than the highly derived condition of *A. boisei* (e.g., Olduvai Gorge, Koobi Fora, Peninj, etc.), but that the "*A. boisei* morphology emerge[d] in a mosaic fashion across Member G times [i.e., <2.3 Ma]" (Suwa et al. 1996, p. 274), implying in situ evolution of this morphotype. Even so, phylogenetic analyses of cranial morphology have usually identified a monophyletic *A. robustus* + *A. boisei* clade (Strait et al. 1997; Kimbel et al. 2004) whose last common ancestor would be expected to be cranially considerably more derived than the KNM-WT 17000 specimen of *A. aethiopicus*. Thus, given the still spotty fossil evidence in the 2.8–2.3 Ma time interval, the existence of a monophyletic east African "robust" lineage stemming anagenetically from *A. afarensis* remains weakly supported.

Key references: Walker et al. 1986; Leakey and Walker 1988; Grine 1988; Kimbel et al. 1988, 2004; Suwa et al. 1996; Harrison 2011.

Australopithecus garhi **(Asfaw et al. 1999)**

Known temporal distribution: ca. 2.5 Ma based on radioisotopic dating of tephra

Known geographical distribution: Bouri, Middle Awash, Ethiopia (Hata Member, Bouri Formation).

Holotype: BOU-VP 12/130 partial cranium, consisting of frontal, parietal, and maxilla with dentition.

Hypodigm: As for holotype.

Diagnostic morphology: The single specimen of *A. garhi* combines a largely plesiomorphic face and palate with a derived calvarial morphology and a highly unusual hominin dental configuration (Asfaw et al. 1999). It shares with *A. afarensis* a remarkable number of maxillary features including a strongly prognathic, convex subnasal surface; sharp lateral margins of the nasal aperture due to lateral placement of the canine root jugum and lack of anterior pillar; horizontal separation of the vomeral and septal insertions within the nasal cavity; low, arched root of the maxillary zygomatic process; and shallow palate. Although the parietal bones of this apparently male individual bear a fused sagittal crest, it does not exhibit the strong posterior emphasis seen in larger *A. afarensis* crania (e.g., A.L. 333-45, A.L. 444-2). The anterior part of the frontal squama features a depression bounded by the convergent temporal lines, said to be frontal trigone (Asfaw et al. 1999), which is otherwise observed only in *A. aethiopicus*, *A. robustus*, and *A. boisei*.

Dentally, the *A. garhi* cranium combines huge postcanine teeth with large incisors and especially canines. Although postcanine size falls above even the *A. boisei* range, neither enamel thickness nor occlusal form aligns these teeth with "robust" australopiths. The ratio of the calculated crown area of the *A. garhi* P^3 to that of M^2 (70 %, according to data in Asfaw et al. 1999) is greater than that of either *A. afarensis* (mean = 55 %, range = 51–61 %, $n = 5$ individuals with both teeth) or *A. africanus* (mean 54 %, range = 50–61 %, $n = 8$ individuals with both teeth) and even exceeds this ratio in the measurable sample of *A. robustus* specimens (mean = 59 %, range = 52–65 %, $n = 7$), one hallmark of which is relative premolar enlargement. Relative P^4 size (P^4/M^2 ratio = 70 %) is essentially identical to the *A. robustus* mean (69 %). Relative anterior tooth size (as measured by the I^1-C alveolar length as a percentage of the square root of various postcanine tooth crown areas) is smaller than in *A. afarensis* (and in early *Homo*), larger than in *A. robustus* or *A. boisei*, and most similar to that of *A. africanus* (Asfaw et al. 1999).

Discussion: The *A. garhi* cranium presents a unique amalgam of plesiomorphic (*A. afarensis*-like) and derived (*A. africanus*- or "robust" australopith-like) characters. It is similar in this respect to *A. aethiopicus*, although the character combinations are quite distinct in these two contemporary taxa (albeit each represented by only a single cranium). Whereas in *A. aethiopicus* facial and premolar crown forms are the most derived aspects of this species' anatomy (notwithstanding its unparalleled degree of midfacial prognathism), in *A. garhi* it is the morphology of the calotte (including the frontal) and premolar-molar proportions that are apomorphic-maxillofacial morphology remains primitive in this taxon. If we grant that *A. africanus* was approximately synchronic with these species, then this early interval of the late Pliocene presents an impressive and, up to this point in geological time unprecedented, array of hominin craniofacial and dental form, much of which appears related to the elaboration of postcanine megadonty subsequent to *A. afarensis*. While the relatively primitive masticatory system of *A. afarensis* makes it a *plausible* ancestor for any or all of these younger taxa, neither sample size, nor anatomical representation, nor stratigraphic density of the fossil record makes defining lineages across the 3.0- to 2.5-Ma time period a meaningful exercise. Nevertheless, by 2.8 Ma or so, we can perceive the diverse products of what can be hypothesized as a series of speciation events that laid the groundwork for the evolutionary events of the late Pliocene.

Australopithecus robustus (Broom 1938)

Known temporal distribution: ca. 1.5–2.0 Ma based on biochronologic correlation with radioisotopically calibrated east African sequences.

Known geographical distribution: Kromdraai, Swartkrans, Drimolen, South Africa.

Holotype: TM 1517 cranium, mandible, and purportedly associated talus from Kromdraai

Hypodigm: Approximately 250 specimens of jaws, teeth, crania, and postcranial elements from the Swartkrans cave (Brain 1993); a much smaller sample of teeth (approximately 30), in addition to the holotype, from Kromdraai (Thackeray et al. 2001); and more than 80 dentognathic specimens, including a cranium with associated mandible from Drimolen (Keyser 2000; Keyser et al. 2000).

Diagnostic morphology (Fig. 3) : Broom's (Broom and Schepers 1946) inference regarding the specific distinctiveness (from *A. africanus* sensu lato) of the Kromdraai skull and dentition was based on its disproportionately large postcanine dentition and unusual facial morphology, which features broad, anteriorly placed zygomatic bones and depressed infraorbital surfaces and nasal bridge between them (the so-called dished face). The large sample of teeth, jaws, and crania accumulated during postwar excavations at Swartkrans added significantly to the *A. robustus*

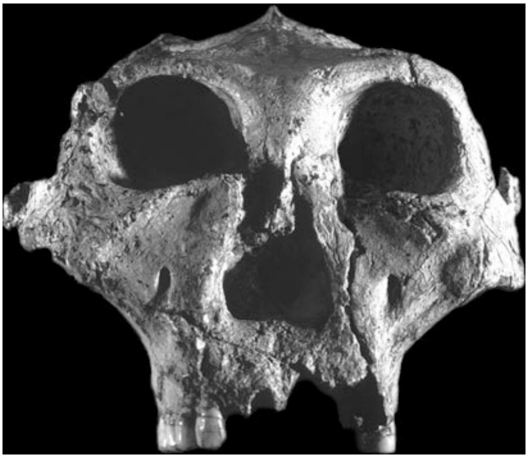

Fig. 3 Anterior view of Swartkrans *A. robustus* cranium SK 48 (Photo by W. Kimbel)

diagnostic profile, including buccolingually expanded and molarized premolars and lower deciduous first molars; premolar and molar crowns with convergent cusp apices and very thick enamel caps that wear to flat occlusal planes soon after eruption; mandibles with transversely thick and inflated bodies and vertically high rami; deep, posterosuperiorly sloping palatal roofs; a depressed posttoral frontal squama delimited by strongly incurving temporal lines ("frontal trigone"); and frequent frontoparietal sagittal crests. The large series of juvenile mandibles (with fully deciduous or mixed dentition) and a fragmentary, edentulous juvenile maxilla (SK 66), all from Swartkrans, demonstrate that many components of this pattern, especially postcanine megadontia and gnathic robusticity were manifested early in craniofacial ontogeny. Robinson (1953b) drew attention to the unusual nasal cavity configuration in *A. robustus*, which includes a smooth ("unstepped") transition from the subnasal surface to the nasal cavity floor, and a retracted position of the anterior nasal spine within the nasal cavity where it merges with the anterior insertion of the vomer (also observed in *A. boisei* and *A. aethiopicus*).

Rak's (1983) study of the australopith face identified a constellation of unique circumnasal (nasoalveolar gutter, maxillary fossula – the highly modified canine fossa, anterior pillar – less prominent than what is seen in *A. africanus*) and infraorbital traits (zygomaticomaxillary step, maxillary trigone) related to the posterior retraction of the palate and the anterior encroachment of the zygomatic bones (to originate above the premolars) on the midface. These antagonistic "shifts" lend the Swartkrans and Kromdraai crania their humanlike orthognathic appearance, and though the subnasal maxilla itself remained primitively prognathic, the facial aspect of the premaxillary suture fused prior to adulthood, again, as in humans.

Among the humanlike characteristics of the *A. robustus* type specimen that most impressed Broom (Broom and Schepers 1946) was the basal aspect of the temporal bone. The variably deep mandibular fossa with discrete articular eminence, small postglenoid process, vertically oriented, platelike tympanic element with prominent petrous crest and frequently well-developed vaginal process of the styloid, and the narrow or absent gap between the postglenoid process and tympanic are found with remarkable consistency in the now numerous cranial bases of *A. robustus* (e.g., SK 46, SK 47 [subadult], SK 48, SK 49, SK 52/SKW 18, SK 83, SKW 11, SKW 2581) and all converge on modern human morphology. Though elements of this pattern can be found in *A. africanus*, they are not presented in that taxon as a package. The single cranium of *A. aethiopicus* (KNM-WT 17000) presents notably less derived morphology in this area, sharing with *A. robustus* only the vertical tympanic with a strong petrous crest. The often dramatic lateral extension of the tympanic's inferior margin beyond the sagittal plane of porion and the coincident expansion of the diameter of the external auditory meatus are not seen in *A. afarensis*, *A. africanus*, or *A. aethiopicus*.

Discussion: The craniodental remains of *A. robustus* present a coherent and highly distinctive anatomical package across the three South African sites in which they are represented. Although a species-level distinction between the Kromdraai (*A. robustus*) and Swartkrans (*A. crassidens*) site samples has been proposed on the basis of metrical and morphological differences in the permanent and deciduous postcanine teeth – according to which the Kromdraai specimens appear less highly differentiated, and thus more similar to the teeth of *A. africanus* (Grine 1993) – reported variation within the Drimolen "robust" australopith sample spans the differences between the Kromdraai and Swartkrans dental collections (Keyser et al. 2000), making a site-based taxonomic split difficult to support.

With the proliferation of the east African hominin fossil record in the 1960s–1980s, there developed a tendency to see the South African australopiths as poised in morphological and adaptive transition between the generalized *A. afarensis* and the specialized *A. boisei*. Rak's (1983) morphocline of australopith craniofacial morphology was explicit in this regard, though when translated into a phylogenetic scenario, it allowed for cladogenesis between an *A. africanus* to *A. robustus* lineage and *A. boisei* on the basis of the overlap of the two "robust" species' temporal ranges. The recognition of the biological validity of *A. aethiopicus* rendered the *A. africanus* to *A. robustus* lineage unlikely due to the extensive character reversal it would entail given the former species' derived zygomaticomaxillary and postcanine dental morphology. While a polyphyletic origin for the "robust" morphology via separate eastern (*A. aethiopicus* to *A. boisei*) and southern (*A. africanus* to *A. robustus*) lineages is plausible, this scheme does not gain support from phylogenetic analyses of craniofacial characters, which strongly back a monophyletic "robust" clade to the exclusion of *A. africanus*. Thus, the potential for a single australopith species lineage in southern Africa is weak (and notwithstanding the poor chronological resolution within these hominin-bearing deposits).

***Australopithecus boisei* (Leakey 1959)**

Known temporal distribution: ca. 2.4–1.4 Ma, based on radioisotopic dating and tephrostratigraphy.

Known geographical distribution: Olduvai Gorge (Beds I and II), Tanzania; Peninj (Humbu Formation), Tanzania; Omo River basin (Shungura Formation, Member G), Ethiopia; Konso, Ethiopia; Koobi Fora (Koobi Fora Formation); West Turkana (Nachukui Formation), Kenya; Chesowanja, Kenya

Holotype: OH 5, cranium with full dentition, from Bed I, Olduvai Gorge

Hypodigm: Aside from the holotype, isolated teeth from Beds I and II, Olduvai Gorge (Tobias 1967); several mandibles, a partial cranium, and many isolated teeth from the Omo River basin (Shungura Formation, Member G); six complete or partial crania, more than 20 mandibles, and several maxillae with and without teeth from Koobi Fora (Wood 1991), a partial subadult cranium from West Turkana (Leakey and Walker 1988), two partial crania from Chesowanja (Carney et al. 1971; Gowlett et al. 1981), and a mandible with full dentition from Peninj (Leakey and Leakey 1964); a partial cranium with associated mandible, plus isolated teeth and jaw and cranial fragments from Konso, Ethiopia (Suwa et al. 1997).

Diagnostic morphology (Figs. 4 and 5): *A. boisei* presents one of the most easily recognized morphological patterns in the early hominin fossil record, due chiefly to uniquely derived states for many of its skull and dental characters. Tobias's (1967, pp. 232–233) study of the holotype cranium supported the specific distinctiveness (relative to *A. robustus*) of the Olduvai hominin, citing, among other features, the absolutely larger (especially broader) postcanine teeth, greater disproportion between the postcanine and anterior dentitions, stronger supraorbital torus, shorter foramen magnum, absence of "even the slightest trace of a canine fossa," structure of the zygomatic region, anterior flexion of the palate, and "evidences of marked

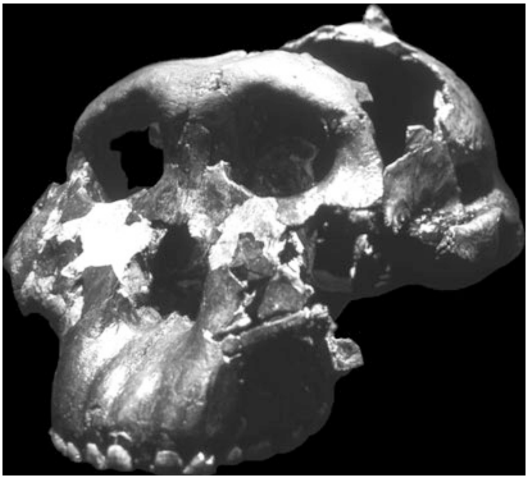

Fig. 4 Three-quarters view of the reconstructed cranium of *A. boisei* holotype specimen OH 5 (Photo by D. Johanson)

Fig. 5 Palate and maxillary dentition of *A. boisei* specimen OH 5 (Photo by D. Johanson)

parietal lobe and cerebellar expansion." Except for the foramen magnum and inference of brain expansion, these distinctions reside in the dentognathic complex, and it is here that most subsequent writing on the diagnostic morphology of *A. boisei* has been focused. In general terms, *A. boisei* has often been characterized as "hyper-robust," essentially an extreme version of *A. robustus*. Indeed, much of the specific craniofacial morphologies of *A. boisei* identified by Rak (1983), such as the elevated infraorbital "visor" (and its effects on the zygomatic arch), the (at least occasionally) inferolaterally sloping and "twisted" supraorbital bars, and the absence of an anterior pillar and maxillary fossula, were interpreted by him as signaling culminations of adaptive trends associated with masticatory specialization (retraction of the palate and advancement of the zygomatic region) that had already begun in *A. africanus*. The massiveness of *A. boisei* mandibular corpora (notwithstanding taphonomic effects on preserved dimensions among some of the largest of these; Silverman et al. 2001) surpasses even the most heavily built *A. robustus* jaws so far known (e.g., KNM-ER 3230 or KGA10-525 versus SK 12). There is, however, a high degree of variation in corpus size (but less so in corpus shape) among the mandibles of both species.

Discoveries made since OH 5 confirm that the postcanine dentition of *A. boisei* is substantially enlarged relative to that of *A. robustus* (White et al. 1981; Grine 1993). The mandibular P4 is particularly diagnostic of *A. boisei*, not only due to its larger size relative to the molars but also to its derived talonid expansion and molarization (Suwa 1988), also a tendency, though not as consistent, of the lower molars (Suwa et al. 1996). Whether measured as lower canine breadth or lower central incisor-canine alveolar length, the *A. boisei* anterior dentition is smaller relative to the cheek teeth than in *A. robustus* (Suwa et al. 1996). (Upper teeth of *A. boisei* remain poorly known relative to the lower, a phenomenon associated with the differential taphonomic attributes of the mandible versus the maxilla.)

The cranial base of *A. boisei* has received less attention than the dentognathic part of the skull but the morphology here is no less specialized (Kimbel et al. 2004). In lateral aspect, the mastoid process appears as an equilateral triangle, with an extensive, swollen lateral face that is sharply delimited from the posterior face, mostly hidden in this view, and the mastoid tip lies approximately midway between the projected horizontal line spanning asterion to porion. This configuration is unmatched in the large majority of other *Australopithecus* crania, in which the mastoid is dominated by an extensive posterolateral face with a long, straight posterior margin that converges with a shorter anterior margin to position the tip much closer to porion than to asterion. This is the generalized pattern common to the great apes, *A. afarensis* and *A. africanus*. Some *A. robustus* specimens approach the *A. boisei* anatomy (i.e., SKW 11), though most are more generalized, as is that of the *A. aethiopicus* cranium KNM-WT 17000.

The region around the mandibular fossa is also unique in *A. boisei* among australopith species. The articular fossa is very deep, with the highest point on the ceiling reaching above the Frankfurt plane, and the long steep articular eminence terminates at the posterior edge of the temporal foramen. The preglenoid plane is usually mediolaterally restricted. The articular eminence twists about its long axis such that medially it faces posteriorly, and the pyramidal entoglenoid process likewise points backward to create a flat "medial glenoid plane" at the medial end of the eminence. The platelike tympanic element is often flattened superiorly and inclined posteriorly, giving the external auditory meatus an oval shape with a diagonal long axis. In some specimens (e.g., KNM-ER 406, OH 5), this inclined tympanic forms more of the ceiling of the mandibular fossa than its posterior wall, and the petrous crest blends with the anterior face of the mastoid process, resulting in obliteration of the tympanomastoid groove. In all of these respects, the cranial bases of *A. robustus* and *A. aethiopicus* are more generalized.

Discussion: There is statistical backing for a trend (though not necessarily a gradual one) toward larger postcanine tooth size in *A. boisei* (sensu stricto) between 2.0 and 1.4 Ma (Wood et al. 1994; Lockwood et al. 2000). There is no evidence of change in mandibular corpus size over this interval. Prior to 2.0 Ma, the east African "robust" australopith fossil record is not well documented, but evidence for a species lineage that extends back in time from *A. boisei* focuses on specimens that lack the full suite of derived craniodental characters enumerated above. "Robust" australopith dental remains, especially the lower premolars, from Members D–F of the Shungura Formation (ca. 2.5–2.3 Ma) are less derived than those of post-2.0 Ma *A. boisei* (Suwa et al. 1996), as reviewed above (see discussion of *A. aethiopicus*). Cranial specimens of the "robust" morphotype from the pre-2.0-Ma period are rare, but the lower Member G partial cranium Omo 323-1976-896 (ca. 2.1 Ma), attributed by Alemseged et al. (2002) to *A. boisei*, lacks a number of the cranial autapomorphies that characterize the post-2.0-Ma skulls of this species, including mastoid, tympanic, articular eminence, preglenoid, and entoglenoid characteristics (Kimbel et al. 2004; see also Alemseged et al. 2002). In these respects, the Omo cranium resembles the more generalized *A. robustus*, yet it is less similar to *A. aethiopicus* – the Omo specimen has a deeper mandibular fossa and probably, based on the preserved maxillary fragment, less midfacial prognathism compared to KNM-WT 17000 (2.5 Ma) – which implies an immediate predecessor of *A. boisei* in eastern Africa that was cranially more like southern African *A. robustus* than like eastern African *A. aethiopicus*. Suwa (1988; Suwa et al. 1996) reported a mix of derived and generalized "robust" australopith postcanine crown morphologies in Member G of the Shungura Formation (ca. 2.3–2.0 Ma), which is consistent with the relatively generalized anatomy of the Omo 323 cranium at ca. 2.1 Ma. This evidence has been used to support an anagenetic derivation of *A. boisei* from a chain of progressively less derived "robust" populations leading back to *A. aethiopicus* at ca. 2.5 Ma or older (Kimbel et al. 1988; Leakey and Walker 1988; Suwa et al. 1996; Alemseged et al. 2002). If true, this would argue for the existence of a single-species lineage of over 1-Myr duration, which is about the documented span of the hypothesized *A. anamensis* to *A. afarensis* species lineage of the earlier Pliocene (Kimbel et al. 2006). However, given the demonstrated morphological links of the eastern African "robust" specimens between 2.0 and 2.3 Ma to *A. robustus*, and the report of otherwise unique *A. robustus* characters within a diagnostic *A. boisei* morphological milieu in the late (1.4 Ma) partial skull from Konso, Ethiopia (Suwa et al. 1997), reconstructing a direct phyletic link between *A. aethiopicus* and *A. boisei* would require positing a cladogenetic event giving rise to a southern African "robust" branch within the 2.3–2.0-Ma interval. Thus, an unbroken, anagenetically evolving "robust" australopith species lineage in the eastern African middle-late Pliocene is unlikely.

Key references: Tobias 1967; Grine 1988; Wood 1991; Wood et al. 1994; Suwa et al. 1996, 1997; Alemseged et al. 2002; Kimbel et al. 2004; Wood and Constantino 2007.

Conclusion

Given a strict evolutionary species definition, nominal taxonomic diversity and species-lineage diversity do not necessarily map onto one another in the fossil record. Species lineages entail statements of ancestry and descent that depend on the consistency of phylogenetic and stratophenetic data. The requirements for identifying species lineages in the fossil record are severe and rarely met in the early hominin record, most often owing to small sample size, underrepresented character data, nonrepresentation of rare or short-lived taxa, poor chronological resolution, gaps in the time-stratigraphic framework, or some combination of these factors. Because hypotheses concerning the "bushiness" of the hominin phylogenetic tree depend on the identification of lineages, not phenetically based "paleospecies," confidence with respect to this issue is not justified for the majority of the hominin fossil record.

The fossil record of australopith evolution in eastern Africa offers two cases in which an approach to this question can be attempted. In one, the evidence, though still imperfect, is consistent with the evolution of *A. anamensis* into *A. afarensis* via anagenesis (i.e., without an increase in lineage diversity). The other, the evolution of *A. boisei*, is almost certain to have entailed a speciation event that gave rise to southern African clade (represented by *A. robustus*) subsequent to the appearance of *A. aethiopicus*. The late Pliocene time period in which the latter events transpired (ca. 2.8–2.3 Ma) was one of substantial morphological diversity, high nominal taxonomic diversity, and high probability of synchronicity among known fossil samples. Although it is not possible to connect these australopith taxa (*A. aethiopicus, A. africanus, A. garhi*) to particular descendants due to the aforementioned defects in the database – and indeed, it is not unlikely that some or all of these species are terminal taxa – once it is better known, this period will most likely be seen to have witnessed a previously (and subsequently) unmatched degree of lineage proliferation compared to other parts of the human evolutionary record. The challenge to paleoanthropologists is to devote resources to improving this part of the fossil record and then to create testable phylogenetic and adaptive hypotheses to explain it.

Defining the Genus *Homo*

Mark Collard and Bernard Wood

Contents

Abstract

The definition of the genus *Homo* is an important but under-researched topic. In this chapter we show that interpretations of *Homo* have changed greatly over the last 150 years as a result of the incorporation of new fossil species, the discovery of fossil evidence that changed our perceptions of its component species, and reassessments of the functional capabilities of species previously allocated to *Homo*. We also show that these changes have been made in an ad hoc fashion. Criteria for recognizing fossil specimens of *Homo* have been outlined on a

number of occasions, but these criteria have generally not been explicitly derived from a genus concept. Rather, the course of action followed by most researchers has been to assign new specimens to *Homo* on the basis of a subset of the diagnostic traits that are considered to be key, and to then redefine the other traits of the genus in the light of the morphological and functional attributes of the new specimens. With a view to moving beyond this approach, in the next section of the chapter we outline six competing proposals for how genera should be defined, and consider their impact on the species assigned to the genus *Homo*. Subsequently, we consider the pros and cons of the six genus concepts. We argue that three of them are impractical and/or internally inconsistent, and that three are useful. We go on to suggest that, while there is little to choose between the latter three concepts on theoretical grounds, the one put forward by Wood and Collard (Science 284: 65–71, 1999) has practical advantages. In the last part of the chapter, we update Wood and Collard's review of genus *Homo* in the light of research published since their study appeared. We find that, on balance, the available evidence still supports their suggestion that *Homo* should be reconfigured such that it includes *H. ergaster*, *H. erectus*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens* but excludes *H. habilis* and *H. rudolfensis*. We also find that the proposed inclusion of the collection of Late Pleistocene specimens from the site of Liang Bua, Flores, in the genus *Homo* as a new species, *H. floresiensis*, is not compatible with Wood and Collard's definition of the genus *Homo*.

Introduction

It is obvious – indeed it is so obvious that it bears repeating – that an understanding of the evolution of genus *Homo* depends, to a considerable extent, on the proper definition of the classificatory categories "genus" and "species," and the correct evaluation of the taxa that are assigned to these categories. In recent years, the species category has received considerable attention from paleoanthropologists (e.g., Tattersall 1986; Turner and Chamberlain 1989; Kimbel and Martin 1993) and there has been a taxonomic rationalization of material previously grouped as "early *Homo*" and "archaic *Homo sapiens*" into reasonably robust species groups (e.g., Tattersall 1986, 1992; Lieberman et al. 1988; Wood 1991, 1992; Wood et al. 1991; Rightmire 1993, 1996, 1998). In contrast, both the definition of the genus category and the demarcation of the genus *Homo* remain contentious. In this chapter, we outline the main events that have taken place in the taxonomic history of the genus *Homo*. We then evaluate several recent proposals to amend the criteria that are used to assign species to genus *Homo*, and show that the criteria we outlined in the late 1990s (Wood and Collard 1999) are the least problematic. Lastly, we discuss the effect of recent work on the main conclusion we reached when we applied our criteria to the species then assigned to genus *Homo*, namely that *Homo habilis* and *Homo rudolfensis* should be assigned to a different genus or pair of genera (Wood and Collard 1999).

Changing Interpretations of Genus *Homo*

The genus *Homo* was established by Carolus Linnaeus in the 10th edition of his *Systema Naturae*, published in 1758. As conceived by Linnaeus, the genus incorporated two species. The name *Homo sapiens* was attached to what Linnaeus described as the more diurnal of the two species. Within *H. sapiens*, Linnaeus recognized six groups. Four of these are geographical variants drawn from the four continents known to Linnaeus, namely Africa, America, Asia and Europe. The other two groups, which Linnaeus called "wild men" and "monstrous men" respectively, are of historical rather than biological interest. A similar conclusion probably also applies to Linnaeus' second species of *Homo*, *Homo sylvestris*, also called *Homo troglodytes* or *Homo nocturnes*, which he suggested is a nocturnal cave-dwelling form of human from Java. *H. sylvestris* is widely regarded as mythical, although the recent discovery of *Homo floresiensis* (see below) raises the possibility that it may have had some basis in fact.

The first fossil species was assigned to *Homo* in 1864. In this year the Irish geologist William King referred a partial skeleton that had been recovered in 1856 from the Feldhofer cave in the Neander Valley in Germany to *Homo neanderthalensis*. King considered naming a new genus for the Feldhofer skeleton, but eventually decided that it was sufficiently similar to *H. sapiens* to warrant its inclusion within *Homo*. In the same year George Busk reported to the British Association for the Advancement of Science what we now know to be a Neanderthal cranium from Gibraltar (Busk 1865). Although Busk acknowledged the strength of the resemblance between the Gibraltar cranium and the one from the Neanderthal Cave, he judged the former to belong to *H. sapiens*, albeit a member of the species that was more similar to living Tasmanians and Australians than to contemporary Europeans. The inclusion of the Neanderthal skeleton within *Homo* expanded the ranges of both the cranial and postcranial morphology of the genus. The morphology of the type specimen, together with evidence gleaned from discoveries made prior to 1856 and thereafter in Western Eurasia, show that Neanderthal crania differ from those of *H. sapiens* in several respects. Typically, they have discrete and rounded supraorbital ridges, faces that project anteriorly in the midline, laterally-projecting and rounded parietal bones, a rounded, posteriorly projecting, occipital bone, a derived nasal morphology (Schwartz and Tattersall 1996; but see Franciscus 1999), large incisor teeth, and postcanine teeth with large root canals. Their brains were as large, if not larger, in absolute terms than the brains of modern humans. Postcranial peculiarities of the Neanderthals include limb bones with stout shafts and relatively large joint surfaces, especially well-marked areas for the attachment of a muscle that helps to control movement at the shoulder, and an elongated pubic ramus of the pelvis (Pearson 2000).

The morphological variability of genus *Homo* was further extended between 1908 and 1933 by the addition of a group of specimens that was initially referred to as "archaic *Homo sapiens*" but is now more often called *Homo heidelbergensis* (Tattersall 1986, 1992; Rightmire 1996, 1998). The type specimen of *H. heidelbergensis* is a mandible that was found in 1907 during excavations to extract sand from a quarry at Mauer, near Heidelberg, Germany (Schoetensack 1908). The next evidence within Europe came in 1933 from a gravel-pit at Steinheim in Germany, but in the meantime evidence had also been found at the site of Kabwe in what was then Rhodesia (Woodward 1921). The brain cases of *H. heidelbergensis* are often, but not always, smaller than those of modern humans (e.g., Steinheim), but they are always more robustly built, with large rounded ridges above the orbits and a thickened occipital region. The Mauer mandible has no chin, and the corpus is substantially larger than those of modern Europeans. Postcranially, the shapes of the limb bones are much like those of *H. sapiens*, except that the shafts of the long bones are generally thicker, with higher robusticity indices. Schoetensack's (1908) decision to refer the Mauer mandible to *H. heidelbergensis* altered the interpretation of *Homo* in that it added a taxon with a mandible more primitive than those of either *H. sapiens* or *H. neanderthalensis*. The subsequent addition of the Kabwe specimen to *Homo* meant that the genus now included a species with a more heavily built cranium than either *H. sapiens* or *H. neanderthalensis*.

The range of morphology within *Homo* was widened again in 1940 when Franz Weidenreich formally proposed that two existing hypodigms, *Pithecanthropus erectus* and *Sinanthropus pekinensis*, should be merged into a single species and transferred to *Homo* as *Homo erectus* (Weidenreich 1940). Subsequently the hypodigms of *Meganthropus* (Mayr 1944, p. 14; Le Gros Clark 1955, pp. 86–87), *Atlanthropus* (Le Gros Clark 1964, p. 112) and *Telanthropus* (Robinson 1961; Howell 1978, p. 198) were also sunk into *H. erectus*. Compared with *H. sapiens*, *H. neanderthalensis* and *H. heidelbergensis*, most fossils attributed to *H. erectus* have a smaller neurocranium, a lower vault, a broader base relative to the vault, and more complex premolar roots. They also have a substantial and essentially continuous torus above the orbits, behind which is a sulcus. There is usually a sagittal torus, and also an angular torus that runs towards the mastoid process. The occipital region is sharply angulated, with a well-marked supratoral sulcus, and the inner and outer tables of the vault are thickened. Despite the relatively large numbers of crania that had been recovered from Java, China and elsewhere, relatively little was known about the postcranial morphology of what was to become *H. erectus*. Discoveries from East African sites provided crucial evidence in the form of a from pelvis and femur Olduvai Gorge (OH 28), two fragmentary partial skeletons from and a pelvis East Turkana (e.g., KNM-ER 803, 1800 and 3228), and the unusually well-preserved skeleton from West Turkana (KNM-WT 15000). The cortical bone of the postcranial skeleton is generally thick. The long bones are robust, and the shafts of the femur and the tibia are flattened from front to back relative to those of other *Homo* species; these conditions are referred to as platymeria and platycnemia, respectively. However, all the postcranial elements are consistent with a habitually upright posture and long-range bipedalism.

In 1964, Louis Leakey, Phillip Tobias and John Napier announced the discovery at Olduvai Gorge of specimens that they believed belonged to a previously unknown species of *Homo*, which they called *Homo habilis* (Leakey et al. 1964). These specimens (OH, 4, 6, 7, 8, 13, 14 and 16) were found between 1959–when a new genus and species, *Zinjanthropus boisei*, had been created for the famous "Nutcracker Man" cranium, OH 5–and 1963. The type specimen of *H. habilis*, OH 7, recovered in 1960, consists of substantial parts of both parietal bones, much of a mandible and several hand bones of a juvenile skeleton. In the next three years further evidence of a "non-robust" fossil hominin was unearthed in Bed I of Olduvai Gorge (OH 8 – an adult foot; OH 14 – juvenile cranial fragments, and OH 16 – the fragmented cranial vault and maxillary dentition of a young adult) as well as in Bed II (OH 13 – the incomplete skull of an adolescent). The inclusion of this group of specimens in *Homo* substantially widened the range of morphology within the genus, and meant that Le Gros Clark's 1955 diagnosis needed to be amended. In particular, in order to accommodate *H. habilis* in the genus, Leakey et al. (1964) reduced the lower end of the range of brain size to 600 cm^3. They claimed that other criteria, such as dexterity, an erect posture and a bipedal gait, did not need to be changed because their interpretation of the functional capabilities of the *H. habilis* remains from Olduvai was such that the type specimen and the paratypes complied with these functional criteria (Leakey et al. 1964). Ultimately fresh evidence, and the reinterpretation of existing evidence, has led others to offer rather different functional assessments of the same material (see below).

The systematic interpretation of *Homo* was further complicated in 1972 by Richard Leakey and colleagues' discovery of KNM-ER 1470. Recovered from the Upper Burgi Member of the Koobi Fora Formation, KNM-ER 1470 is now reliably dated to between 1.945 ± 0.004 and 2.058 ± 0.034 Ma (Joordens et al. 2013). Morphologically, it presents a unique mixture of a relatively large, *Homo*-like neurocranium and a large, broad *Paranthropus*-like face. The presence of these two morphologies in the same cranium posed a difficulty for researchers. Which was the homoplasy – the large brain or the large face? Alone among the early commentators, Alan Walker (1976) cautioned that KNM-ER 1470 may represent a large-brained australopith. Most researchers chose the face as the site of homoplasy and argued that the large neurocranium allied the specimen with *Homo* (e.g., Leakey 1973; Rak 1987; Bilsborough and Wood 1988). As a consequence, *Homo* subsumed a substantially wider range of facial morphology than it did prior to the discovery of KNM-ER 1470 (Wood 1991).

In due course, additional specimens from Koobi Fora (e.g., KNM-ER 1590, 1802, 1813, 3732, 60000, 62000, 62003) (Wood 1991; Leakey et al. 2012), and Olduvai (e.g., OH 62, 65) (Johanson et al. 1987; Bermudez de Castro et al. 2003; Clarke 2012) were added to the early *Homo* hypodigm, as was fossil evidence from Members G and H of the Shungura Formation (Howell and Coppens 1976; Boaz and Howell 1977; Coppens 1980), A.L. 666-1 from Hadar (Kimbel et al. 1997), a temporal bone from the Chemeron Formation (Hill et al. 1992), a mandible from Uraha in Malawi (Bromage et al. 1995), and an isolated tooth from the Nachukui Formation, West Turkana (Prat et al. 2005). Fossils from southern African sites, Member 5 at Sterkfontein (Hughes and Tobias 1977; Clarke 1985), and Member 1 at Swartkrans (Clarke and Howell 1972; Grine and Strait 1994; Grine et al. 1993, 1996) and Drimolen (Curnoe and Tobias 2006), were also added. This additional material subsumes a wide range of cranial morphology. For example, the endocranial volumes of the specimens range from just less than 500 cm^3 to around 850 cm^3. The mandibles also vary in size, with those from the larger individuals having robust bodies and premolar teeth with complex crowns and roots. The discovery of OH 62 was particularly significant with regard to the postcranial anatomy of *H. habilis*. Although the preservation of this specimen is poor, its skull is sufficiently well preserved to be confident that it does not belong to *Paranthropus boisei*. Thus, unless it is the first evidence from Bed I of a novel taxon, then OH 62 must belong to *H. habilis*, the only other hominin species known from that time range at Olduvai Gorge. Although several isolated postcranial specimens from Bed I had been attributed to *H. habilis* (Leakey et al. 1964), it was subsequently pointed out that it is at least equally likely that this postcranial evidence belongs to *P. boisei* (Wood 1974). The discovery of OH 62 provided the first unequivocal postcranial evidence of *H. habilis*. It is significant therefore that OH 62 has been interpreted as having limb proportions that are at least as ape-like as those of individuals attributed to *Australopithecus afarensis* (Johanson et al. 1987; Hartwig-Scherer and Martin 1991; Richmond et al. 2002).

The morphological limits of genus *Homo* were expanded once again in 2004 with the announcement of the species *Homo floresiensis* (Brown et al. 2004). The specimens initially attributed to this species were recovered from deposits in the Liang Bua cave on the Indonesian island of Flores, and are dated to between approximately 74,000 and 18,000 years ago (Brown et al. 2004; Morwood et al. 2004), but they may be closer to 100 Ka. They include a well-preserved skull and partial skeleton of an adult female as well as several more fragmentary specimens (Brown et al. 2004). Since 2004 additional upper limb evidence of the type specimen, LB1, has been recovered, together with a second adult mandible (LB6), and postcranial remains belonging to other individuals (LB4, 5, 7, 8-9) (Morwood, et al. 2005). *H. floresiensis* is a particularly significant addition to *Homo* because of its brain size. The endocranial volume of the partial associated female skeleton, LB1, was initially reported to be 380 cm^3 (Brown et al. 2004). Subsequently, Falk et al. (2005) increased this figure to 417 cm^3. Even at 417 cm^3, the endocranial volume of *H. floresiensis* is considerably smaller than those of the other species assigned to *Homo*. Among the latter, *Homo habilis*, *Homo rudolfensis*, and *Homo erectus* (including *Homo ergaster*) have the smallest endocranial volumes. Adult endocranial volume in *H. habilis* presently ranges between 509 and 674 cm^3 (Tobias 1991; Kappelman 1996). Only one of the specimens assigned to *H. rudolfensis* is sufficiently complete to provide an adult endocranial volume for this species. The specimen in question, KNM-ER 1470, is estimated to have an endocranial volume of 752 cm^3 (Kappelman 1996). Currently the upper limit of adult endocranial volume in *H. erectus* is 1,251 cm^3 (Rightmire 2004); the lower limit is either 775 cm^3 or ~600 cm^3 depending on the taxonomic status of the D2700 cranium from Dmanisi (Vekua et al. 2002; Rightmire 2004). Thus, the assignment of the Late Pleistocene Liang Bua specimens to *Homo* greatly increases brain size variation in the genus. The body of *H. floresiensis* has been suggested to be small compared to other species of *Homo* (Lahr and Foley 2004). However, the stature estimates of 106 cm for LB1 (Brown et al. 2004) and 109 cm for LB8

(Morwood et al. 2005) are only slightly smaller than McHenry's (1991) stature estimate of 118 cm for the *H. habilis* partial skeleton OH 62.

Interpretations of *Homo* have also changed as a result of researchers reassessing the functional implications of the postcranial remains from Olduvai Gorge that are conventionally attributed to *H. habilis*. The type and paratypes of *H. habilis* include fossil evidence from both the forelimb (OH 7) and the hindlimb (OH 8, 10 and 35) (some have argued that OH 8 and 35 are from the same individual [Susman and Stern 1982], but an analysis of the shapes of the reciprocal joint surfaces suggests otherwise [Wood et al. 1998]). The initial assessment of the functional implications of the evidence from the leg and foot stressed the ways in which the Olduvai material resembled *H. sapiens* (Napier 1964). However, the authors of papers in which these specimens have been considered in more detail have been more cautious. For example, they have stressed that the knee was imperfectly adapted to bipedalism (Davis 1964), and that the foot may not have been from an individual capable of modern human-like striding bipedalism (Day and Napier 1964). Functional morphological studies of the OH 8 foot have also stressed its potential for climbing, and its retention of several of the features seen in living non-human primates (Lewis 1983, 1989; Susman and Stern 1982; Kidd et al. 1996; Gebo and Schwartz 2006). Researchers have suggested that, while OH 8 possesses the articular mechanisms that convert the foot into a rigid lever during the support phase of walking (Lewis 1989), it lacks some of the functional elements that are present in *H. sapiens* such as the lateral deviation of the heel and the propulsive great toe (Lewis 1972). Similarly, considerations of the OH 7 hand have suggested that earlier functional interpretations may need to be revised in the light of evidence that it displays a mosaic of features, ranging from ape-like phalanges and carpus to a thumb that some have interpreted as compatible with pulp-to-pulp opposition (Susman and Creel 1979; Marzke 1997; Susman 1998).

Today, as a result of the developments outlined above, the genus *Homo* subsumes considerably more variation than it did when it was first established 250 years ago. This variation is particularly obvious in relation to cranial capacity. The adult *Homo* specimen with the largest recorded cranial capacity is the Neanderthal skeleton Amud 1 at an estimated 1,750 cm^3. At the other end of the spectrum lies the type specimen of *H. floresiensis*, Liang Bua 1, with a cranial capacity of 417 cm^3. To put this in perspective, at 1750 cm^3 the braincase of Amud 1 is almost 100 cm^3 larger than the largest *H. sapiens* specimen included in one of the most comprehensive studies of human brain size published to date (Beals et al. 1984), while the braincase of Liang Bua 1 is slightly smaller than that of an average-sized adult male chimpanzee (Kappelman 1996). Variability is also conspicuous in relation to masticatory morphology. For example, the lower first molars of the *Homo* species with the largest M_1s, *H. rudolfensis*, are 32 % larger mesiodistally than those of the *Homo* species with the smallest M_1s, *H. neanderthalensis* (Wood and Collard 1999). Likewise, average mandibular corpus width at M_1 in *H. rudolfensis*, the *Homo* species with the widest mandibular corpus, is 77 % greater than it is in *H. sapiens*, the *Homo* species with the narrowest mandibular corpus (Wood and Collard 1999). Noteworthy variability in locomotor strategies exists as well. Most of the fossil species assigned to *Homo* are interpreted as having been obligate bipeds like *H. sapiens*. However, as noted earlier, in recent years the postcranial specimens assigned to *H. habilis* have come to be viewed by most researchers as being consistent with bipedalism combined with an ability to climb proficiently (McHenry and Coffing 2000; Wood and Richmond 2000; Ruff 2009). Thus, there would seem to be at least two distinct modes of locomotion represented within *Homo*.

Is Genus *Homo* a "Good" Genus?

In view of the conspicuous variation incorporated within the hypodigm of *Homo*, it seems reasonable to ask whether it is a "good" genus as it is currently construed. Needless to say, in order to determine whether or not *Homo* is a "good" genus there must first be agreement about what it is that genera represent.

Surprisingly, the genus concept has received relatively little attention from taxonomists. It certainly has received much less consideration than the species concept even though as Simpson (1963, p. 199) notes "it frequently appears that the genus is a more usable and reliable unit for classification than the species." In the paleoanthropological literature, discussion of the genus as a concept has been very limited indeed. Criteria for recognizing fossil specimens of *Homo*, *Australopithecus* and other hominin genera have been outlined on a number of occasions (e.g., Le Gros Clark 1955; Howell 1978). But these criteria have generally not been explicitly derived from a genus concept. Rather, the course of action followed by most researchers appears to have been to assign new specimens to a fossil hominin genus on the basis of a subset of the diagnostic traits that the researchers in question deem to be key, and to then redefine the other traits of the genus in the light of the morphological and functional attributes of the new specimens. This is seen most clearly in relation to Leakey, Tobias and Napier's (1964) proposal to recognize *H. habilis*. As noted earlier, Leakey et al. (1964) assigned the *habilis* specimens from Olduvai Gorge to *Homo* on the grounds that, according to their interpretation of the available postcranial evidence, *H. habilis* stood upright and moved around using a bipedal gait, and was capable of modern human-like dexterity. They then amended the diagnosis of *Homo* presented by Le Gros Clark (1955) to take into account the 638–674 cm^3 brains of the Olduvai specimens. At no point in their paper do Leakey et al. (1964) discuss the pros and cons of assigning the Olduvai *H. habilis* specimens to *Homo* in terms of the genus as a concept.

If we wish to move beyond this ad hoc approach to assigning fossil hominin specimens to genera, what options are available? Currently, there are six competing proposals for how genera should be defined. We present them in chronological order of the main publication associated with each proposal. The first is associated with Ernst Mayr and the evolutionary systematic school of taxonomy. Mayr (1950, p. 110) suggested that "a genus consists of one species, or a group of species of common ancestry, which differ in a pronounced manner from other groups of species and are separated from them by a decided morphological gap." He went on to state that the genus "has a very distinct biological meaning. Species that are united in a given genus occupy an ecological situation which is different from that occupied by the species of another genus, or, to use the terminology of Sewall Wright, they occupy a different adaptive plateau" (Mayr 1950, p. 110). Thus, according to Mayr, a genus is a group of species of common ancestry that is adaptively both homogeneous and distinctive. Mayr et al. (1953, p. 50) acknowledged the phylogenetic and functional evidence may be in conflict if "unrelated species acquire a superficial similarity owing to parallel adaptations to similar environments," and in such cases they recommended that the phylogenetic evidence should be given precedence. However, it is implicit in Mayr's (1950) definition that "common ancestry" subsumes both monophyletic and paraphyletic groups.

The second concept of the genus is associated with Willi Hennig and the phylogenetic systematic or cladistic school of taxonomy. In his 1966 volume "Phylogenetic Systematics," Hennig outlined not only what has come to be known as the cladistic method of phylogenetic reconstruction, but also an approach to biological classification. With regard to the latter, Hennig (1966) suggested that only monophyletic groups should be accepted as valid taxa, and that the ranks assigned to taxa should be based on their time of origin so that taxa arising at the same time are assigned the same rank. Hennig (1966) recognized that strict application of the time of origin criterion for delineating ranks is impractical. This is because it would involve massive reorganization of current classifications of the living world, with some groups being lumped to a much greater extent and others being split much more finely. For example, as Hennig (1966) noted, if the time of origin criterion were to be applied strictly, then the first appearance date of Mammalia is such that the class would have to be downgraded to an order, and the orders that are assigned to it, such as Primates, would have to be downgraded to tribes. Conversely, the first appearance dates of some ostracod genera are such that they would have to be elevated to the class rank. Accordingly, Hennig proposed a compromise in which different time scales are employed for different animal groups, with the time scales being selected with a view to minimizing the number of changes in rank of subgroups.

The third genus concept focuses on hybridizability as the criterion for grouping species into genera. Although it has not been widely used by systematists to date, the origins of the concept can be traced back at least as far as the middle of the nineteenth century. Flourens (1856), for example, argued that two species whose members are able to produce hybrids, such as horses and donkeys, and jackals and dogs, should be placed in the same genus. More recently, the concept has been discussed by Hubbs and Drewry (1959), Van Gelder (1977, 1978), and Dubois (1988). The most comprehensive exposition of the hybridizability-based genus concept published to date is to be found in Dubois (1988). According to this author, when two species are able to produce viable adult hybrids both species should be included in the same genus. This is the case, Dubois (1988) suggested, regardless of whether the hybrids are fertile or infertile. If the two species in question had previously been attributed to distinct genera then they should be merged together even if other criteria for separating them are valid. In other words, Dubois (1988) argued that the ability to give birth to viable adult hybrids should be the primary criterion for grouping species into genera. Dubois (1988) stressed two additional points. One is that hybridization need not take place only in the wild to be admissible as evidence of the congeneric status of two species; the results of experimental studies are also acceptable. The other point he emphasized is that the criterion of hybridizability must only be used to group species together. A negative result – i.e., one where hybridization does not occur or where the hybrid is not viable – cannot be used to place two species in different genera.

The fourth genus concept was proposed by Wood and Collard (1999). These authors suggested that a genus should be defined as a species or monophylum whose members occupy a single adaptive zone. This definition, which is a revised version of Mayr's (1950) concept, differs from the latter in that it excludes paraphyletic taxa. It also differs from Mayr's (1950) concept in that it does not require the adaptive zone to be unique or distinct (*contra* Leakey et al. [2001] and Cela-Conde and Altaba [2002]). Rather, it simply requires the adaptive zone to be consistent and coherent across the species in the putative genus. That is, in contrast to Mayr (1950), Wood and Collard's (1999) proposal allowed for the possibility that species assigned to different genera will occupy the same adaptive zone, but it prevented species in the same genus from occupying different adaptive zones. Wood and Collard (1999) suggested two criteria for assessing whether or not a group of species has been correctly assigned to a genus. First, the species should belong to the same monophyletic group as the type species of that genus. Second, the adaptive strategy of the species should be closer to the adaptive strategy of the type species of the genus in which it is included than to the type species of any other genus.

The fifth approach to recognizing genera was outlined by Watson et al. (2001). These authors suggested that species should be grouped into genera on the basis of genetic distance. Specifically, Watson et al. (2001) argued that, if the genetic distance between a pair of species is the same as or less than the genetic distance that is typical for congeneric pairs of species in other animal groups, then the species in question should be assigned to the same genus.

The sixth and final approach to the genus concept was outlined by Cela-Conde and Altaba (2002; see also Cela-Conde and Ayala 2003). Their concept is similar to the one advocated by Wood and Collard (1999) in that it holds that a genus should be monophyletic and uses inferences about adaptation to determine which monophyla should be designated genera. However, it differs from Wood and Collard's (1999) concept in that it allows for the species assigned to a genus to occupy more than one adaptive zone. Specifically, Cela-Conde and Altaba (2002) suggested that one species in each genus should be designated as the *species germinalis*. This species is the one that is considered to have given rise to the other species in the genus. Because of its ancestral status, the *species germinalis* is allowed to occupy a different adaptive zone from the other species in the genus.

Several of these concepts have been applied to genus *Homo* in recent years. Hennig's (1966) approach to delineating supraspecific taxa has been applied to

Homo in a series of papers and books produced by a team of researchers led by Morris Goodman (e.g., Goodman et al. 1998, 2001; Wildman et al. 2003). Goodman et al. (1998) averred that, at least among the primates, monophyla should be deemed to be genera if they originated 11–7 Ma before present (Ma BP). Goodman et al. (1998) selected this criterion on the basis of local molecular clock analyses, which suggested that the majority of extant primate genera arose between 11 and 7 Ma BP. Subsequently, Wildman et al. (2003) further justified the selection of 11 to 7 Ma BP as the criterion for recognizing primate monophyla as genera on the grounds that the majority of genera in other mammalian orders arose between 11 and 7 Ma BP. Significantly for present purposes, as Goodman and coworkers have noted on a number of occasions (Goodman et al. 1998, 2001; Wildman et al. 2003), their definition of the genus implies that *Homo* should be broadened to include not only the australopiths and other early hominins, but also chimpanzees and bonobos, which are conventionally assigned to the genus *Pan*. This is because molecular clock studies suggest that humans, chimpanzees and bonobos last shared a common ancestor around 6 Ma BP, and the nomen *Homo* has priority over the nomen *Pan*, the former being proposed by Linnaeus in 1758, as noted earlier, and the latter by Oken in 1816. Subsequently, one of the authors of the Goodman et al. (1998) study, Colin Groves, proposed at least two other time depth-based criteria for recognizing monophyla as genera (Groves 2001a, 2001b; Cameron and Groves 2004). For example, in his widely-cited monographic treatment of primate taxonomy Groves reviewed evidence pertaining to the chronological origin of genera in several mammalian families, including Ursidae, Canidae, Elephantidae, Rhinocerotidae, Hippopotamidae, and Bovidae, and concluded on the basis of this evidence that an origin time of between 7 and 4 Ma BP should be used as the criterion for delineating extant mammalian genera (Groves 2001a). This led him to retain *Homo* and *Pan* as separate genera in contrast to Goodman et al. (1998). More recently, Groves proposed that primate monophyla should be recognized as genera if they originated between 6 and 4 Ma (Cameron and Groves 2004). The corollary of this, he suggested, is that all extinct hominin genera and perhaps also the chimpanzee genus, *Pan*, should be assigned to *Homo*.

In the paper in which Wood and Collard outlined their genus concept (Wood and Collard 1999), they applied the criteria derived from it to the species that most researchers then assigned to genus *Homo*, namely *H erectus*, *H. ergaster*, *H. habilis*, *H. heidelbergensis*, *H. neanderthalensis*, *H. rudolfensis*, and *H. sapiens*. They examined a range of phylogenetic and functional evidence in order to determine whether or not the fossil species assigned to *Homo* form a monophylum with *Homo sapiens* and also share its adaptive strategy. They found that the only fossil *Homo* species that form a robust clade with *H. sapiens* are *H. neanderthalensis*, *H. heidelbergensis*, *H. erectus* and *H. ergaster*. They also found that when evidence about body size, body shape, relative brain size and development is combined with inferences about locomotion and diet, these species are the only *Homo* taxa whose adaptations are closer to those of *H. sapiens* than they are to those of *Au. africanus*, the type species of *Australopithecus*. The phylogenetic relationships of *H. habilis* and *H. rudolfensis* were found to be equivocal, and the available evidence regarding the adaptive strategies of *H. habilis* and *H. rudolfensis* was interpreted as indicating that they were at least as similar, and probably more similar, to the australopiths than they are to *H. sapiens*. Wood and Collard (1999) concluded from this that a genus *Homo* that includes them is not a "good" genus, and that *H. habilis* and *H. rudolfensis* should be removed from *Homo* and placed in *Australopithecus* until such time as their phylogenetic relationships are clarified. Recently, Cameron has employed the concept proposed by Wood and Collard (1999), but reached different conclusions regarding the fossil species that should be assigned or excluded to *Homo* (Cameron and Groves 2004). Most notably for present purposes he argued that the *H. habilis* hypodigm should be retained in *Homo*, and suggested that the *H. rudolfensis* hypodigm should be removed from *Homo* and assigned to *Kenyanthropus*. The latter proposal is based on cladistic analyses that link the *H. rudolfensis* hypodigm with *Kenyanthropus platyops* (Cameron and Groves 2004). Cameron does not explain how retaining the *H. habilis* hypodigm within *Homo* is consistent with the notion that a genus should be a species or monophylum whose members occupy a single adaptive zone. However, the implication is that he does not accept Wood and Collard's (1999) contention that the adaptive strategy of *H. habilis* was more similar to that of *Au. africanus* than to the adaptive strategy of *H. sapiens*.

In the 2001 paper in which Watson and colleagues outlined their genetic distance-based concept of the genus they also applied the concept to previously published mtDNA sequence and DNA hybridization data for humans, chimpanzees, gorillas and a range of other mammalian groups with a view to classifying the living hominoids (Watson et al. 2001). They found that the genetic distances between chimpanzees and humans are equivalent to the distances between many mammalian species within the same genus. They also found that the genetic distances between gorillas and chimpanzees, and between gorillas and humans, are similar to the distances between congeneric mammalian species. These observations, Watson et al. (2001) suggested, indicate that the genus *Homo* should be expanded to include chimpanzees and gorillas as well as humans. Watson et al.'s (2001) approach has also been applied to DNA distance data for humans and chimpanzees by Curnoe and Thorne (2003). These authors also concluded that the human and chimpanzee genomes are sufficiently similar for the species to be considered congeneric. Accordingly, they recommended transferring chimpanzees to genus *Homo*.

In 2002, Cela-Conde and Altaba revised the taxonomy for the hominins proposed by Wood and Collard (1999) in the light of their *species germinalis* concept and fossil specimens recovered in the intervening period (Cela-Conde and Altaba 2002). Most significantly for present purposes, Cela-Conde and Altaba (2002) agreed with Wood and Collard (1999) that *H. rudolfensis* should be removed from genus *Homo*, but disagreed with them regarding the generic attribution of *H. habilis*. They suggested that *H. rudolfensis* should be transferred to the genus *Kenyanthropus*, which had been erected in 2001 to accommodate the newly discovered species *K. platyops*, and that *H. habilis* should be included in *Homo* as the *species germinalis* of the genus. In 2003, Cela-Conde and Ayala revised the taxonomy proposed by Cela-Conde and Altaba (2002) (Cela-Conde and

Ayala 2003). They argued not only that *H. habilis* and *H. rudolfensis* should be included in *Homo*, but also that the hypodigm of *K. platyops* should be transferred to *Homo* as the *species germinalis* of the genus. Cela-Conde and Ayala (2003) included the *H. habilis* and *H. rudolfensis* hypodigms in *Homo* on the grounds that they share the morphological traits that Leakey et al. (1964) suggested define *Homo*. The inclusion of the *K. platyops* hypodigm in *Homo* is justified, Cela-Conde and Ayala (2003) argued, because it is similar to *H. habilis* and especially *H. rudolfensis* in certain features of its face and dentition. Cela-Conde and Ayala (2003) designated *platyops* as the *species germinalis* of *Homo* because it lacks "the more advanced features of *Homo* that appear with *Homo erectus* and *Homo ergaster*" (p. 7686).

Table 1 presents a comparison of the definitions put forward by Goodman et al. (1998), Wood and Collard (1999), Watson et al. (2001) and Cela-Conde and Ayala (2003). The first column in the table lists the names of the genera and species recognized in a typical taxonomy covering the hominins and the extant African apes (Stanford et al. 2005). The other columns in the table record the names of the species and genera that would be recognized among the hominins and African apes if the conventional taxonomy were revised in line with the proposals of Goodman et al. (1998), Collard and Wood (1999), Watson et al. (2001) and Cela-Conde and Ayala (2003). The table shows that the four definitions have different implications for not only the composition of genus *Homo* but also the taxonomy of hominins and extant African apes. The conventional taxonomy recognizes 21 species and assigns these to nine genera. Revising the conventional taxonomy in line with Wood and Collard's (1999) and Cela-Conde and Ayala's (2003) proposals results in relatively few changes. Wood and Collard's (1999) scheme leads to species being moved between genera but no reduction in the number of genera, while the one put forward by Cela-Conde and Ayala (2003) requires species to be moved between genera and the elimination of a genus, *Kenyanthropus*. Goodman et al.'s (1998) and Watson et al.'s (2001) proposals have more radical implications. If the conventional taxonomy were to be reorganized in line with Goodman et al.'s (1998) definition of *Homo*, then the 21 species would be assigned to just two genera, *Homo* and *Gorilla*; *Homo* would have 20 species assigned to it, and *Gorilla* a single species. If the conventional taxonomy were reorganized in line with the definition of *Homo* offered by Watson et al. (2001), then the 21 species would be assigned to a single genus. Thus, some proposals to redefine *Homo* have little or no impact on the current consensus regarding generic diversity among the hominins and African apes, while others have a major impact.

The definitions of genus *Homo* presented by Goodman et al. (1998), Wood and Collard (1999), Watson et al. (2001), Cela-Conde and Altaba (2002), and Cela-Conde and Ayala (2003) have other implications for how *Homo* is interpreted. One of the most obvious is the time of its origin. Conventional taxonomies such as the one outlined in Table 1 suggest that the genus arose in the late Pliocene, since the current first appearance dates of *H. habilis* and *H. rudolfensis* are c. 2.35 and c. 2.5 Ma, respectively. Collard and Wood's (1999) definition, which excludes *H. habilis* and *H. rudolfensis* from the genus, implies that *Homo* appeared about 2.0 Ma BP.

Table 1 Illustrative comparison of the impact of four recent proposals to revise genus *Homo* on the taxonomy of hominids and the African apes. A conventional splitter's taxonomy (CST) taken from Stanford et al. (2005) is used as the baseline

In contrast, the other three definitions push back the date of origin. Cela-Conde and Ayala's (2003) definition implies that the genus appeared around 3.5 Ma, which is the date of the *species germinalis* they propose for *Homo*, *H. platyops* (Leakey et al. 2001). The definitions put forward by Goodman et al. (1998) and Watson et al. (2001) imply that the genus originated even earlier. The timing of the spit between the lineage leading to chimpanzees and the lineage leading to modern humans split is still under investigation, as is the timing of the split between the lineage leading to gorillas and the lineage leading to chimpanzees and modern humans. But it is generally accepted that both events occurred long before 3.5 Ma. Estimates in the range of 5.5–8 Ma for the chimp-human split and 8.5–12 Ma for the gorilla-chimp/human split are typical (e.g., Scally et al. 2012). Thus, if we accept Goodman et al.'s (1998) definition genus *Homo* originated by at least 5.5 Ma, while if we accept Watson et al.'s (2001) definition it originated by at least 8.5 Ma.

Another aspect of the genus that varies considerably depending on the definition employed is its mode of locomotion. Conventional taxonomies incorporate at least two forms of locomotion, facultative bipedalism and obligate bipedalism. The extinct hominin species Wood and Collard (1999) assign to *Homo* are all reconstructed as being obligate bipeds, while Goodman et al.'s (1998) and Watson et al.'s (2001) definitions incorporate obligate bipeds, facultative bipeds and knuckle-walkers within genus *Homo*. Most of the other adaptive characteristics that are of interest to paleoanthropologists, such as the size of the masticatory system, brain size and developmental schedule are affected in a similar manner.

Given that these various genus concepts evidently have markedly different implications for the composition, and therefore the interpretation, of *Homo*, which of them should be preferred? In our view, the approach to delineating genera proposed by Watson et al. (2001) is not convincing. The notion that genetic distances among congeneric species in one animal group should be used as a criterion to cluster species into genera in another animal group is problematic. First, given that there does not seem to be a straightforward relationship between genetic distance and morphological distance among living taxa (Lambert and Paterson 1993), it is doubtful that Watson et al.'s (2001) suggestions can be applied to fossil taxa. Second, even if it were possible to obtain reliable estimates of the genetic distances among pairs of fossil species, there is no reason to believe that interspecific genetic distances are distributed in such a way as to justify designating any particular distance or range of distances as the criterion for clustering species into genera. This course of action might be appropriate if interspecific genetic distances were discontinuously distributed or if there were sound theoretical reasons why genera should correspond to a given genetic distance. However, neither of these conditions appears to be the case. The available evidence suggests that genetic distances are more or less continuously distributed (Lambert and Paterson 1993), and Watson et al. (2001) do not provide any theoretical justification for the approach they advocate. Accordingly, there is no reason to prefer one particular genetic distance or range of distances as the criterion for delineating genera over any other genetic distance or range of distances.

We are also skeptical about the utility of the hybridizability-based concept for assigning species to genus *Homo*. Given that many of the relevant species are known only from fossilized bones, application of this concept requires skeletal variation among hominins to be a reliable proxy for hybridizability. This assumption is only valid if skeletal variation has been found to accurately predict hybridizability in a range of appropriate model taxa such as the living primates. The relationship between skeletal variation and hybridizability has been investigated in a few animal groups (Ackermann 2010; Ackermann and Bishop 2010), but there is good reason to doubt that the relationship between these parameters in primates is such that the hybridizability-based concept can be used to assign species to genus *Homo*. In the last 20 years a number of studies have demonstrated that there is considerable overlap between intraspecific and interspecific skeletal variation in living primates (Tattersall 1986; Kimbel 1991; Aiello et al. 2000). Given that species status has been conferred on most extant primate species on the basis of failure to produce fertile offspring in the wild, this overlap suggests that skeletal morphology is a poor guide to reproductive biology in primates. Accordingly, it seems unlikely that skeletal morphology can be used to assign fossil hominin species to *Homo* on the basis of their likely ability to produce viable hybrids.

Hennig's (1966) approach to delineating genera and other supraspecific taxa has the advantage that it is relatively easy to implement. Another advantage of Hennig's approach for paleoanthropology, at least in the way it has been implemented by Goodman et al. (1998), is that the genera it produces can be expected to be relatively stable. Given that, as discussed earlier, the consensus is that the split between the human and chimpanzee lineages occurred no earlier than 8 Ma, Goodman et al.'s (1998) proposal that monophyla should be recognized as genera if they originated between 11 and 7 Ma means that new fossil hominin finds and fresh phylogenetic analyses will rarely require the creation of new genera.

However, the time-based approach also has a number of shortcomings. One of these concerns the manner in which the time ranges that correspond to different taxonomic ranks are chosen. As noted earlier, the approach that is most defensible on theoretical grounds – strict application of the time of origin criterion across all groups – was considered to be impractical even by Hennig. Unfortunately, the alternative approach proposed by Goodman et al. (1998) and Groves (2001a) – assigning taxa in one group of organisms (e.g., primates) to ranks on the basis of the age of origin of taxa within another group of organisms (e.g., bears) – is problematic. One problem is that the approach is sensitive to the choice of comparator groups. For example, Goodman et al. (1998) review one set of first appearance dates and conclude that monophyla should be recognized as genera if they originate between 11 and 7 Ma, while Groves (2001a) reviews another set of first appearance dates and concludes that the relevant time span should be 6–4 Ma. It is difficult to see how this can be avoided given that phylogenetic relationships are relative phenomena. How do we defend a given degree of relatedness as the criterion for deciding which taxa to include in our comparator group and which to exclude?

A second and perhaps even more profound problem with the approach proposed by Goodman et al. (1998) and Groves (2001a) is that it is not internally consistent.

Again, the problem lies with the comparator taxa. Given that, as we noted earlier, strict application of the time of origin across all groups is impractical, at least one of the comparator taxa must be defined in relation to a criterion other than time, such as adaptive coherence. For example, as noted earlier, Groves (2001a) assigns primate species to genera in the light of the first appearance dates of genera in Ursidae, Canidae, Elephantidae, Rhinocerotidae, and Hippopotamidae, but it is evident from the references he cites in relation to the latter that they have been defined on the basis of anatomical evidence. Thus, the approach advocated by Goodman et al. (1998) and Groves (2001a) essentially entails reorganizing the taxonomy of one group of organisms on the basis of prior taxonomic analyses of another group of organisms that employed a different approach to delineating taxa. We recognize that, in the absence of a strict application of the time of origin across all groups, this is unavoidable, but it is still a major flaw. It means that the approach is not only contradictory (time of origin is the preferred criterion for assigning taxa to ranks *except* in the case of the comparator taxa, which are defined in relation to some other criterion), but it also effectively requires paleoanthropologists to subjugate their own taxonomic philosophies in favor of those used by researchers working on other groups of organisms.

The differences between the remaining approaches are subtle. To reiterate, for Mayr (1950) a genus is a species or group of species of common descent that occupies an ecological situation that is different from those occupied by the species of another genus, while for Wood and Collard (1999) a genus is a species or monophylum whose members occupy a single adaptive zone. Cela-Conde and Altaba's (2002) concept is similar to the one proposed by Wood and Collard (1999) in that it holds that the species assigned to a genus should be monophyletic and uses inferences about adaptation to determine which monophyla should be designated genera. However, it differs from Wood and Collard's (1999) concept in that one species, the *species germinalis*, is allowed to occupy a different adaptive zone from the other species in the genus. Thus, the approaches differ regarding whether phylogeny should be given priority over adaptation or vice versa. Mayr's (1950) approach prioritizes species' adaptive characteristics over their phylogenetic relationships; Wood and Collard's (1999) approach prioritizes species' phylogenetic relationships, but also takes into account their adaptive characteristics; Cela-Conde and Altaba's (2002) approach prioritizes species' phylogenetic relationships over their adaptive characteristics. One important consequence of these differences is that Mayr's (1950) approach allows genera to be either monophyletic or paraphyletic, whereas the approaches favored by Wood and Collard (1999) and Cela-Conde and Altaba (2002) hold that genera must be monophyletic. Another important consequence is that Wood and Collard's (1999) approach makes allowance for the possibility that species in different genera will occupy the same adaptive zone, whereas Mayr's (1950) approach demands that species assigned to different genera must have different adaptive strategies. In contrast to both Mayr's (1950) approach and the one put forward by Wood and Collard (1999), Cela-Conde and Altaba's (2002) approach anticipates that the species assigned to a genus may subsume two adaptive strategies – the ancestral adaptive strategy, which will be displayed by the *species germinalis*, and the derived adaptive strategy, which will be exhibited by the remaining species.

Choosing between the genus concepts proposed by Mayr (1950), Wood and Collard (1999) and Cela-Conde and Altaba (2002) is not straightforward. It is especially difficult for paleoanthropologists, given that we often need to classify taxa based on a few specimens, and occasionally just a single specimen. The dilemma with which we are confronted was outlined particularly clearly by Alan Walker in a paper titled "Remains attributable to *Australopithecus* in the East Rudolf succession," published in 1976. Walker pointed out that while classifying fossil hominins on the basis of their adaptive characteristics is problematic, so too is classifying them on the basis of their phylogenetic relationships. The former is problematic because, if the approach is followed to its logical conclusion, there will come a point where one generation is in one taxon and the next in another. The latter is problematic because, if its logic is followed, there will come a point where part of a single population will be in one taxon and another part of the same population will be in a different taxon. None of three remaining genus concepts avoids this dilemma. Ultimately, they all force researchers to choose to err in one direction or the other. Indeed, given that evolution involves both descent and modification, it is difficult to see how it could be otherwise. Thus, it is not easy to choose between the three concepts on theoretical grounds.

Choosing between the concepts on practical grounds is also difficult. Given that one of the main purposes of a biological classification is to communicate information about taxa (Harrison 1993), the key practical issues would seem to be stability, minimizing the number of genera, and the transparency and utility of the criteria used for delineating genera. Mayr's (1950) approach can be expected to be more stable than the approaches put forward by Wood and Collard (1999) and Cela-Conde and Altaba (2002). This is because Mayr's (1950) approach allows genera to be either monophyletic or paraphyletic, whereas the approaches of Wood and Collard (1999) and Cela-Conde and Altaba (2002) require genera to be monophyletic. The ability of Mayr's (1950) approach to take into account paraphyletic taxa means that the genera it produces are less likely to need revising in the light of new fossil finds or fresh phylogenetic analyses than the genera produced by Wood and Collard's (1999) and Cela-Conde and Altaba's (2002) approaches. The ability of Mayr's (1950) approach to take into account paraphyletic taxa also means that it can be expected to result in fewer genera than the approaches of Wood and Collard (1999) and Cela-Conde and Altaba (2002). Cela-Conde and Altaba's (2002) approach can also be expected to result in fewer genera than the approach put forward by Wood and Collard (1999), because the species that Cela-Conde and Altaba (2002) designate as the *species germinalis* would be assigned to a new genus in Wood and Collard's (1999) approach. Thus, in terms of stability and minimizing genera, Mayr's (1950) approach is to be preferred over the approaches put forward by Cela-Conde and Altaba (2002), which in turn is to be preferred over Wood and Collard's (1999) approach.

However, Wood and Collard's (1999) approach has the advantage with respect to the explicitness of the criteria for delineating genera. As noted earlier, Wood and

Collard (1999) suggest that the fossil species assigned to genus *Homo* should be (1) more closely related to the type species of the genus, *H. sapiens*, than to the type species of any other genus, and (2) more similar to *H. sapiens* than to the type species of any other genus in terms of key adaptive variables. The ones they proposed – body mass, body shape, locomotion, size of the teeth and jaws, relative brain size, and developmental schedule – are all capable of being inferred with a reasonable degree of reliability from the fossil record. In contrast, neither Mayr (1950) nor Cela-Conde and Altaba (2002) provided workable criteria for delineating genera. Mayr (1950) suggested that the species assigned to a genus should be separated from other groups of species by a "decided morphological gap" and also occupy a "different ecological situation," but he did not specify what constitutes a decided morphological gap or a different ecological situation. Cela-Conde and Altaba (2002) proposed that a genus should be a monophylum whose members are adaptively distinct apart from the *species germinalis*, which is allowed to have the same adaptive strategy as another genus. But they did not provide criteria for determining that a group of species is adaptively distinct from another group of species. They also did not provide criteria for identifying the *species germinalis*. Needless to say, the lack of adequate criteria for delineating genera makes it difficult to implement the approaches put forward by Mayr (1950) and Cela-Conde and Altaba (2002). It also makes the resulting taxonomies difficult to defend. For example, Cela-Conde and Ayala (2003) revise Cela-Conde and Altaba's (2002) taxonomy without recourse to analysis. Accordingly, for the time being (i.e., until Mayr's [1950] and Cela-Conde and Altaba's [2002] approaches are operationalized satisfactorily) our preference is to use the approach outlined by Wood and Collard (1999).

Updating Wood and Collard's (1999) Review of Genus *Homo*

With the last point of the foregoing section in mind, the remainder of this chapter is devoted to updating Wood and Collard's (1999) review of genus *Homo* in the light of developments since their study appeared. To reiterate, Wood and Collard (1999) applied their genus concept to the species that most researchers assigned to genus *Homo* in the late 1990s, namely *H. erectus*, *H. ergaster*, *H. habilis*, *H. heidelbergensis*, *H. neanderthalensis*, *H. rudolfensis*, and *H. sapiens*. They examined a range of phylogenetic and functional evidence in order to determine whether or not the fossil species assigned to *Homo* form a monophylum with *Homo sapiens* and also share its adaptive strategy. They suggested that the only fossil *Homo* species that form a robust clade with *H. sapiens* are *H. neanderthalensis*, *H. heidelbergensis*, *H. erectus* and *H. ergaster*. They also found that when evidence about body size, body shape, relative brain size and development is combined with inferences about locomotion and diet, these are the only *Homo* species whose adaptations are closer to those of *H. sapiens* than they are to *Au. africanus*, the type species of *Australopithecus*, or *P. robustus*, the type species of *Paranthropus*. Wood and Collard (1999) found the phylogenetic relationships of *H. habilis* and

H. rudolfensis to be equivocal, and interpreted the available evidence regarding the adaptive strategies of *H. habilis* and *H. rudolfensis* as indicating that they are more similar to *Au. africanus* than they are to *H. sapiens*. Wood and Collard (1999) concluded from this that *Homo* as thus constituted is not a "good" genus, and that *H. habilis* and *H. rudolfensis* should be removed from genus *Homo* and placed in *Australopithecus* until such time as their phylogenetic relationships are clarified.

Wood and Collard's (1999) conclusions regarding their phylogenetic criterion were based on the results of the six studies that had, at the time of writing, included enough fossil hominin species to adequately test the monophyly of *Homo* (Chamberlain 1987; Chamberlain and Wood 1987; Wood 1991, 1992; Lieberman et al. 1996; Strait et al. 1997) as well as re-analyses of the datasets used in three of the studies (Wood 1991, 1992; Strait et al. 1997). Since Wood and Collard's (1999) study appeared, a further six phylogenetic studies have included sufficient fossil hominin species to assess the hypothesis that the species assigned to genus *Homo* form a monophyletic unit (Curnoe 2001; Cameron and Groves 2004; Strait and Grine 2004; Gonzalez-Jose et al. 2008; Argue et al. 2009; Irish et al. 2013).

Curnoe (2001) focused on the phylogenetic relationships of three specimens from South Africa, SK 847, SK15 and Stw 53, all of which are usually considered to represent early *Homo*. His analysis employed 47 cranial characters recorded on SK 847, SK15, Stw 53 plus specimens assigned to *Australopithecus afarensis*, *Au. africanus*, *H. erectus*, *H. habilis*, *H. rudolfensis*, *Paranthropus aethiopicus*, *P. robustus*, and *P. boisei*. He used the same data set in six analyses, in which methodological choices were varied in order to avoid bias. The common chimpanzee, *Pan troglodytes*, was used as the outgroup in all the analyses. The results of Curnoe's analyses do not support the hypothesis that *Homo* is a monophylum. Both the most parsimonious cladogram and the consensus cladogram presented by Curnoe (2001) suggest that *H. habilis*, *H. erectus* and the three South African early *Homo* specimens form a clade to the exclusion of the other taxa in the sample. However, *H. rudolfensis* is not linked exclusively to the other *Homo* taxa in any of the cladograms presented by Curnoe (2001). In two of them (A and D in Curnoe's [2001], Fig. 1), it is the sister taxon of a clade comprising *Au. africanus* and the other *Homo* taxa. In another two (B and C in Curnoe's [2001], Fig. 1) it is part of a large polychotomy that also contains *Au. africanus*. In the remaining cladogram (E in Curnoe's [2001], Fig. 1), *H. rudolfensis* forms a clade with *P. boisei* and *P. robustus*.

Cameron and Groves (2004) examined the phylogenetic relationships of 14 hominin species, including *H. ergaster*, *H. habilis*, *H. rudolfensis* and *H. sapiens*. They carried out two sets of analyses. One employed 92 characters; the other utilized only the characters that were present in *Sahelanthropus tchadensis* or *K. platyops*, of which there were 52. In both sets of analyses, three Miocene ape species were employed as outgroups. A parsimony analysis of the 92 characters returned eight equally parsimonious trees. The consensus of these clustered *H. ergaster*, *H. habilis* and *H. sapiens* in a clade to the exclusion of the other taxa, and grouped *H. rudolfensis* in a clade with *K. platyops*. A bootstrap analysis of the 92 characters supported a sister group relationship between

H. ergaster and *H. sapiens*, but was unable to resolve the relationships of the other *Homo* taxa at the 70% level of support that is commonly used to identify statistically significant clades in such analyses (Hillis and Bull 1993). *Homo habilis* and *H. rudolfensis* formed a multichotomy with *K. platyops*, *Au. africanus*, a clade comprising *P. aethiopicus*, *P. boisei* and *P. robustus*, and the aforementioned (*H. ergaster*, *H. sapiens*) clade. The results of the 52 character analyses were similar. Twenty equally parsimonious cladograms were returned by a parsimony analysis. The consensus of these grouped *H. ergaster*, *H. habilis* and *H. sapiens* in a clade to the exclusion of the other taxa, and clustered *H. rudolfensis* in a clade with *K. platyops*. A bootstrap analysis supported a sister group relationship between *H. ergaster* and *H. sapiens*, but was unable to resolve the relationships of the other *Homo* taxa at the 70% level. Thus, neither set of analyses supported the hypothesis that the fossil species assigned to *Homo* form a monophyletic group with *H. sapiens*. They suggest that *H. ergaster* is more closely related to *H. sapiens* than to any other fossil hominin species, but are equivocal regarding the relationships of *H. habilis* and *H. rudolfensis*.

Strait and Grine (2004) carried out a series of maximum parsimony and bootstrap analyses to examine the relationships of several hominin species including *H. ergaster*, *H. habilis*, *H. rudolfensis* and *H. sapiens*. Their dataset comprised 109 qualitative craniodental characters and 89 craniometric characters recorded on 14 hominin species plus seven extant non-human primate taxa. The consensus of the most parsimonious cladograms obtained by Strait and Grine (2004) suggests that *H. ergaster*, *H. habilis*, *H. rudolfensis* and *H. sapiens* form a clade to the exclusion of the other species in the sample. Within the (*H. ergaster*, *H. habilis*, *H. rudolfensis*, *H. sapiens*) clade, *H. ergaster* and *H. sapiens* form a clade to the exclusion of *H. habilis* and *H. rudolfensis*. The relationships among the (*H. ergaster*, *H. sapiens*) clade, *H. habilis* and *H. rudolfensis* are unresolved. The results of Strait and Grine's (2004) bootstrap analyses were inconsistent with regard to the relationships of the *Homo* species. When all the characters and taxa were analyzed together, a (*H. ergaster*, *H. sapiens*) clade was supported by 86% of the bootstrap replicates, but the relationships of the other *Homo* taxa were not resolved at the 70% level. A similar result was obtained when all the taxa but only the 109 qualitative characters were included. When *K. platyops* was dropped from the all-characters analysis, both a (*H. ergaster*, *H. sapiens*) clade and a (*H. ergaster*, *H. habilis*, *H. rudolfensis*, *H. sapiens*) clade were supported by more than 70% of the replicates. Again, a similar result was obtained when only the qualitative characters were included. Thus, Strait and Grine's (2004) parsimony analyses support the hypothesis that *Homo* is a monophylum, but this hypothesis is not consistently supported by their bootstrap analyses. Smith and Grine (2008) reanalyzed Strait and Grine's (2004) dataset to assess the relationships of some controversial early *Homo* specimens from southern Africa, and obtained similar results.

The study reported by Gonzalez-Jose et al. (2008) sought to recover a phylogenetic signal from three-dimensional geometric morphometric data recorded on 18 hominin crania and two great ape crania. The shape data were subjected to principal components analysis, and then the principal component scores were included as variables in a maximum parsimony analysis and a maximum likelihood analysis. Only the first of these analyses included sufficient hominin species to assess the monophyletic status of genus *Homo*. This analysis returned a single most parsimonious cladogram in which the various *Homo* specimens were shown as more closely related to each other than any of them is to specimens assigned to other genera.

Argue et al.'s (2009) study focused on the phylogenetic position of the controversial fossil hominin taxon, *Homo floresiensis*. Their dataset consisted of states for 60 cranial characters scored on specimens assigned to ten hominin taxa and three outgroup species. In addition to *H. floresiensis*, the hominin taxa included *Au. afarensis*, *Au. africanus*, *H. habilis*, *H. rudolfensis*, *H. ergaster*, *H. erectus*, *Homo rhodesiensis* (a junior synonym of *Homo heidelbergensis*), a sample of early *Homo* fossils from Dmanisi, and *H sapiens*. Argue et al. (2009) subjected their dataset to maximum parsimony analysis and bootstrapping. The maximum parsimony analyses returned two most parsimonious cladograms. Both of these suggested that the *Homo* taxa in their sample are more closely related to each other than any of them is to the other species in their sample, *Au. afarensis* and *Au. africanus*. However, none of the bootstrap support values for the clades of the most parsimonious cladograms exceeded or even equaled 70%. This indicates that the dataset contains a large number of homoplastic similarities and does not support any of the relationships suggested by the most parsimonious cladograms. Thus, Argue et al.'s (2009) study does not support the hypothesis that the species assigned to *Homo* form a monophyletic unit.

The goal of Irish et al.'s (2013) study was to elucidate the phylogenetic relationships of the relatively new fossil hominin species *Australopithecus sediba*. Their dataset comprised 23 dental traits recorded on ten hominin species plus an outgroup, *Gorilla gorilla*, and they subjected the dataset to both maximum parsimony analysis and 10,000-replication bootstrap analysis. Irish et al.'s (2013) most parsimonious cladogram supports the monophyly of genus *Homo*, because the four *Homo* taxa in their sample (*H. habilis/rudolfensis*, *H. erectus*, sub-Saharan *H. sapiens*, north African *H sapiens*) are grouped together to the exclusion of all the other fossil hominin species in their sample. However, none of the bootstrap support values for the clades of the most parsimonious cladogram exceeds 50% let alone 70%. So, the Irish et al. (2013) study also cannot be counted as supporting the hypothesis that the species assigned to *Homo* form a monophyletic unit.

Collectively, the studies of Curnoe (2001), Cameron and Groves (2004), Strait and Grine (2004), Gonzalez-Jose et al. (2008), Argue et al. (2009), and Irish et al. (2013) present a similar picture regarding the monophyletic status of *Homo* to the studies reviewed by Wood and Collard (1999). They provide reasonably strong to strong support for considering *H. ergaster*, *H. erectus*, *H. heidelbergensis*, and *H. neanderthalensis* to be more closely related to *H. sapiens* than to the types species of any other genus, but only weak support for the hypothesis that *H. habilis* and *H. rudolfensis* are more closely related to *H. sapiens* than to the types species of any other genus. *Homo rudolfensis* clustered exclusively with the other *Homo* species in Strait and Grine's (2004) parsimony analyses and also in some of their bootstrap analyses, but it did not cluster exclusively with the other *Homo* species in the parsimony and bootstrap analyses reported by Curnoe (2001) and Cameron and Groves (2004). The results of the parsimony analyses carried out by Curnoe (2001), Cameron and Groves (2004), and Strait and Grine (2004) offer support for the hypothesis that *H. habilis* is a member of the *Homo* clade. However, the bootstrap analyses carried out by Cameron and Groves (2004) and some of the bootstrap analyses conducted by Strait and Grine (2004), failed to support a link between *H. habilis* and later *Homo* species at the 70% level. This suggests that little confidence can be placed in this hypothesis. Argue et al.'s (2009) and Irish et al.'s (2013) results also do not support the idea that *H. habilis* and *H. rudolfensis* are more closely related to the other species assigned to *Homo* than to species assigned to other genera. Their maximum parsimony analyses linked *H. habilis* and *H. rudolfensis* taxon with *H. sapiens*, but their bootstrap analyses indicated that this grouping is not supported by their datasets. Thus, on balance, the results of the six new studies have not increased confidence in the hypothesis that the species assigned to *Homo* form a monophyletic unit.

Other developments have challenged Wood and Collard's (1999) conclusions regarding the status of *H. habilis* and *H. rudolfensis* as members of genus *Homo*. Probably the most significant of these was presented in Lordkipanidze et al. (2013). In this paper, David Lordkipandze and his collaborators describe an adult hominin cranium, D4500, recovered from layer B1y in Block 2 at the site of Dmanisi, Georgia. They also report a geometric morphometrics-based analysis that they claim demonstrates that the variation in the sample of fossil hominin crania from Dmanisi exceeds that of *H. habilis*, *H. rudolfensis*, *H. ergaster*, and *H. erectus* combined. The corollary of this, they contend, is that *H. habilis*, *H. rudolfensis*, *H. ergaster*, *H. erectus*, and the Dmanisi specimens should be treated as a single early *Homo* species, the name of which should be *H. erectus*, according to the rules of zoological nomenclature. Obviously, if the hypodigms of *H. habilis* and *H. rudolfensis* are lumped together with those of *H. ergaster* and *H. erectus*, the issue of whether *H. habilis* and *H. rudolfensis* should be assigned to *Homo* or some other genus is rendered null and void. However, Lordkipanidze et al.'s (2013) claim is not defensible. Even if one accepts that their methods of data capture are sound – which we do not – their conclusions are based on a flawed analysis and a logical fallacy. The analytical flaw is that their method fails to distinguish between a morphologically very distinctive and large-brained Neanderthal cranium and the small-brained Dmanisi Skull 4. These specimens are separated by close to two million years of evolutionary history, and are widely accepted to belong to distinct species. That the landmarks Lordkipanidze et al. (2013) employ are unable to distinguish them strongly suggests that the landmarks are inadequate for assessing the limits of fossil hominin species. The logical fallacy is that they take three-dimensional cranial shape to be the arbiter of early hominin taxonomy, yet many of the features that have been used to distinguish *H. habilis*, *H. rudolfensis*, *H. ergaster*, and *H. erectus* (e.g., detailed basicranial morphology, bony labyrinth morphology, foot morphology, long bone strength, life history, relative tooth size) are not captured in such an analysis. There is no justification for claiming to refute a taxonomic hypothesis when the grounds for doing so are so limited.

Wood and Collard's (1999) conclusions regarding the status of *H. habilis* and *H. rudolfensis* as members of genus *Homo* have also been challenged by Antón and Snodgrass (2012). These authors contend that recent work has shown that relative hind-limb length is more similar in *Australopithecus* and *Homo* than appeared to be the case when Wood and Collard (1999) carried out their review. The corollary of this, Antón and Snodgrass (2012) suggest, is that the difference Wood and Collard (1999) identified between *H. ergaster*, *H. erectus*, *H. heidelbergensis*, *H. neanderthalensis* and *H. sapiens* on the one hand, and *Australopithecus* and *Homo habilis* on the other hand, is no longer tenable. Again, this obviously represents a potentially serious problem for the hypothesis that *H. habilis* and *H. rudolfensis* should be assigned to a different genus or pair of genera from the other species currently assigned to *Homo*. However, the problem is more apparent than real.

Antón and Snodgrass (2012) base their argument on analyses reported by Pontzer (2012). It is certainly the case that Pontzer (2012) concludes that there is no difference between *Australopithecus* and *Homo* in relation to relative hind-limb length. But this conclusion is based on questionable data. The finding that *Australopithecus* and *Homo* do not differ in relative hind-limb length is primarily based on estimates for putatively large-bodied specimens assigned to *Australopithecus afarensis* (KSD-VP-1/1), *Au. sediba*, and *Au. garhi*. All of the estimates in question are problematic. The *Au. afarensis* specimen KSD-VP-1/1 does not have a femur. It only has a tibia, which means the hind-limb length estimate is not secure. In addition, as the describers of KSD-VP-1/1 make clear (Haile-Selassie et al. 2010), the state of preservation of the specimen's remaining acetabulum is such that its diameter is consistent with a wide range of body mass estimates, some of which can be expected to be much smaller than the estimate utilized by Pontzer (2012). Relative hind-limb length in *Au. sediba* is no more secure. Pontzer (2012) cites body mass estimates of 31.5 kg for MH1 and 35.7 kg for MH2. He indicates that Trenton W. Holliday provided the MH 1 estimate, while the MH 2 estimate was taken from Berger et al. (2010). Neither of these estimates can be relied on. While Holliday is apparently willing to offer a body mass estimate for MH 1, the specimen's femoral head is sufficiently badly damaged that other members of the team involved in the analysis of the Malapa specimens think it is too soon to offer a body mass estimate for the specimen (S. Churchill, personal communication). The body mass estimate for MH 2 that Pontzer (2012) suggests he obtained from Berger et al. (2010) is not in fact included among the data reported by Berger et al. (2010). All Berger et al. (2010) say about body size in *Au. sediba* is that it is "small" (their Table S2). Lastly, the body mass estimate for *Au. garhi* has to be treated with considerable caution because the relevant specimen, BOU-VP-12/1, does not include diagnostic cranial remains and therefore cannot be confidently allocated to a species (Asfaw et al. 1999). Given these problems, plus his uncritical inclusion of KNM-ER 1471 and 1482 in H. habilis, we suggest Pontzer's (2012) claim that there is no difference in relative hind-limb length between *Australopithecus* and

Homo does not hold water. The corollary of this is that there is no basis for Antón and Snodgrass (2012) to challenge Wood and Collard's (1999) conclusions.

The proposed inclusion of the collection of Late Pleistocene specimens from the site of Liang Bua, Flores, in genus *Homo* as a new species, *H. floresiensis* (Brown et al. 2004) represents a third important challenge to Wood and Collard's (1999) conclusions. In justifying the inclusion of the Liang Bua material in *Homo*, Brown et al. (2004) cited Wood and Collard's (1999) study in such a way that it appears that incorporating the *H. floresiensis* hypodigm in *Homo* is compatible with the latter authors' proposals regarding the definition and composition of the genus. However, it is not clear that this is in fact the case.

To begin with, it is not possible to determine whether or not *H. floresiensis* fulfills Wood and Collard's (1999) first criterion for including a species within the genus *Homo*, namely that it is more closely related to *H. sapiens* than to the type species of any other genus. So far, *H. floresiensis* has been the focus of a single phylogenetic study (Argue et al. 2009). The results of this study were, as discussed earlier, ambiguous. To reiterate, the two most parsimonious cladograms obtained by the authors grouped *H. floresiensis* with the other *Homo* species, but none of the bootstrap support values for the clades of the most parsimonious cladograms exceeded or even equaled 70%. This indicates that the dataset contains a large number of homoplastic similarities and does not support any of the relationships suggested by the most parsimonious cladogram. Thus, the phylogenetic relationships of *H. floresiensis* are unclear at the moment.

Some evidence relevant to Wood and Collard's (1999) second criterion – that the adaptive strategies of fossil species assigned to *Homo* should be more similar to that of *H. sapiens* than to the adaptive strategies of the type species of other genera – is available for *H. floresiensis*, but this evidence is difficult to interpret. The individual represented by the partial associated skeleton LB1 has been estimated to have been around 106 cm in height and to have weighed between 16 and 36 kg, depending on the body mass proxy employed (Brown et al. 2004). A tibia belonging to another individual (LB8) is consistent with a stature of 109 cm (Morwood et al. 2005). These figures suggest that *H. floresiensis* was more similar in size to the australopiths than to *H. sapiens*. It also appears that *H. floresiensis* had a relatively small brain. When Wood and Collard's (1999) approach to computing relative brain size (cube root of brain size divided by square root of orbital area, product multiplied by 10) is employed, *H. floresiensis* has a relative brain size that is smaller than those of *Au. africanus*, *P. aethiopicus*, and *P. boisei* (Table 2). Initially, the postcranial anatomy of *H. floresiensis* was suggested to be consistent with the type of obligate bipedalism seen in modern humans as opposed to the form of facultative bipedalism that most researchers believe the australopiths employed (Brown et al. 2004). However, new specimens from Liang Bua, including additional elements of the LB1 associated skeleton, have cast doubt on this hypothesis (Morwood et al. 2005). It now appears that the humerofemoral index of *H. floresiensis* is more similar to that of *Au. afarensis* than it is to that of *H. sapiens* (Morwood et al. 2005). Likewise, Morwood et al. (2005) have suggested that the ilium of LB1 is consistent with a teardrop-shaped thorax rather than the

Table 2 Relative brain size

Taxon	Absolute/cm^3	Orbital area/cm^2	Relative
P. aethiopicus	410	968	2.39
P. boisei	513	1114	2.40
Au. africanus	457	839	2.66
H. habilis	552	908	2.72
H. ergaster	854	1180	2.76
H. rudolfensis	752	1084	2.76
H. heidelbergensis	1198	1403	2.84
H. erectus	1016	1225	2.87
H. neanderthalensis	1512	1404	3.06
H. sapiens	1355	1289	3.08
H. floresiensis	417	992	2.37

Values taken from Wood and Collard (1999) apart from those for *H. floresiensis*. The brain size figure for *H. floresiensis* was taken from Falk et al. (2005). The orbital area figure for this species was obtained by multiplying the values for orbital height and width provided by Brown et al. (2004). Relative brain size was computed by dividing the cube root of absolute brain size by the square root of orbital area and multiplying the product by 10, as per Wood and Collard (1999)

barrel-shaped thoracic region found in modern humans. Morwood et al. (2005) also report that LB1's femoral robusticity falls in the chimpanzee range, and that its humeral robusticity is midway between the chimpanzee range and the human range. These observations suggest that the locomotor behavior of *H. floresiensis* may have been more like that of the australopiths than that of modern humans. However, LB1 apparently differs from all other known hominin species in humeral torsion and aspects of ulna morphology (Morwood et al. 2005), which suggests that this hypothesis may also need to be revised in future. Thus, in terms of body size, relative brain size and inferred locomotor behavior *H. floresiensis* appears to be more similar to the australopiths than to the species that Wood and Collard (1999) assign to genus *Homo*.

The available data pertaining to masticatory morphology presents a different picture. Wood and Collard (1999) assessed masticatory system similarities among the hominins on the basis of Euclidean distances derived from 11 size-corrected dental and mandibular variables. So far, data for only six of these variables have been published for *H. floresiensis* (Brown et al. 2004). When Wood and Collard's analysis is replicated with the six variables, the Euclidean distance between *H. floresiensis* and *H. sapiens* is 1.77, while the comparable distances between *H. floresiensis* and *Au. africanus* and between *H. floresiensis* and *P. robustus* are 4.97 and 5.72, respectively (Tables 3 and 4). Thus, this aspect of the masticatory apparatus of *H. floresiensis* is more similar in size to that of *H. sapiens* than it is to the type species of the other two hominin genera for which Wood and Collard (1999) provide data.

While the lack of clarity about the phylogenetic relationships of *H. floresiensis* precludes a satisfactory assessment of its attribution to *Homo* as per Wood and

Table 3 Masticatory system relative size

Taxon	1	2	3	4	5	6	OA
Au. africanus	41	20	33	23	12.9	14.1	838.95
P. boisei	51	29	42	29	15.7	18.5	1114.26
P. robustus	50	28	39	27	14.1	15.7	1066.42
H. erectus	37	19	36	22	12.0	12.7	1225.33
H. ergaster	33	20	31	19	11.6	12.3	1180.20

H. rudolfensis	36	23	36	23	13.2	13.7	1084.16
H. sapiens	34	14	29	13	10.5	10.5	1289.37
H. floresiensis	28	15	20.5	15.5	11.4	10.0	992.00

Values taken from Wood and Collard (1999) apart from those for *H. floresiensis*. Figures for the mandibular and dental characters for *H. floresiensis* were obtained from Brown et al. (2004). The orbital area value for this species was obtained by multiplying the values for orbital height and width provided by Brown et al. (2004)

1 symphyseal height, *2* symphyseal breadth, *3* corpus height at M_1, *4* corpus width at M_1, *5* M_1 buccolingual diameter, *6* M_2 buccolingual diameter, *OA* orbital area

Table 4 Normalized Euclidean distances between fossil *Homo* species and *H. sapiens*, *Au. africanus* and *P. robustus* based on the masticatory system variable values given in this table

	H. sapiens	*Au. africanus*	*P. robustus*
H. rudolfensis	3.96	1.75	**1.17**
H. habilis	3.45	**2.63**	3.40
H. erectus	**2.81**	2.91	3.59
H. ergaster	**1.98**	3.57	4.22
H. neanderthalensis	**1.19**	4.54	5.19
H. floresiensis	**1.77**	4.97	5.72

The figure in bold in each row is the shortest distance

Collard's (1999) definition of the genus, the available data on its adaptive strategy clearly suggest that there is a problem. Given that some of its adaptive characteristics are consistent with those seen in the other species assigned to genus *Homo* by Wood and Collard (1999) while others are not (Table 5), either Wood and Collard's (1999) approach to defining *Homo* needs to be amended, or *H. floresiensis* needs to be assigned to a different genus. In our view, the latter course of action is preferable until the phylogenetic relationships and adaptive strategy of the species have been more fully evaluated.

There also have been developments in two areas that impact Wood and Collard's (1999) conclusions regarding the adaptive strategies of *H. erectus*, *H. ergaster*, *H. habilis*, *H. heidelbergensis*, *H. neanderthalensis*, *H. rudolfensis*, and *H. sapiens*. One of these concerns the life history strategies of the fossil species. The period of maturation of *H. sapiens* is nearly twice as long as those of the *G. gorilla* and *P. troglodytes* (Dean et al. 1986; Smith 1994). This extended ontogeny has been linked with the transmission of the numerous additional learned behaviors that

Table 5 Summary of results of adaptive strategy analyses

Taxon	1	2	3	4	5	6
H. rudolfensis	?	?	?	A	A	A
H. habilis	A	A	A	A	A	A
H. ergaster	H	H	H	H	A	A
H. erectus	H	?	H	H	A	I
H. heidelbergensis	H	?	H	H	?	A
H. neanderthalensis	H	H	H	H	H	H
H. floresiensis	A	A	A	H	?	A

This is a revised version of Wood and Collard (1999)'s Table 7. *1* body size, *2* body shape, *3* locomotion, *4* jaws and teeth, *5* development, *6* brain size, *H* modern human-like, *A* australopith-like, *I* Intermediate

modern humans exhibit compared to the African apes. Wood and Collard's (1999) review of the literature led them to conclude that the developmental schedules of *H. ergaster* and *H. neanderthalensis* were more similar, if not identical, to that of *H. sapiens*, whereas the developmental schedules of *H. habilis* and *H. rudolfensis* were more like those of living chimpanzees and gorillas. Wood and Collard (1999) did not discuss the developmental schedules of *H. erectus* and *H. heidelbergensis* because at the time their paper went to press no comparative analysis of hominin development had included specimens of these species.

It is now clear that Wood and Collard's (1999) conclusions regarding the life history strategies of the fossil *Homo* species need to be modified. While there are differences between what can be determined about the growth trajectory of Neanderthals and the growth trajectory of modern humans (Thompson and Nelson 2000; Ramirez Rozzi and Bermudez de Castro 2004; Smith et al. 2010), the developmental schedule of *H. neanderthalensis* appears to have been more modern human-like than ape-like (Dean et al. 2001). In contrast, the developmental schedules of *H. habilis* and *H. rudolfensis* appear to have been more ape-like than modern human-like (Dean et al. 2001). However, the hypothesis that the maturation period of *H. ergaster* was modern human-like no longer appears tenable. Dean et al.'s (2001) comparative analysis of fossil hominin dental incremental markings suggests that while the pattern of development in *H. ergaster* is similar to the pattern of development in *H. sapiens*, the rate at which *H. ergaster* developed was more ape-like than modern human-like. In addition to altering the assessment of the developmental schedule of *H. ergaster*, work published since Wood and Collard's (1999) study appeared has shed light on the life history strategy of *H. erectus*. Dean et al. (2001) included a specimen assigned to *H. erectus* in their study. They concluded from this specimen, Sangiran S7-37, that *H. erectus* reached maturity relatively rapidly. *Homo erectus* was also found to have had an ape-like pattern of brain growth in a study reported by Coqueugniot et al. (2004) in which the infant *H. erectus* specimen from Java, Perning 1, was compared with a sample of modern humans and chimpanzees. A number of recent studies have examined development in *H. heidelbergensis* (Bermudez de Castro and Rosas 2001; Ramirez Rozzi and

Bermudez de Castro 2004; Bermudez de Castro *et al*. 2003). Unfortunately, these studies have been carried out in such a way that it is difficult to assess with confidence whether the developmental schedule of *H. heidelbergensis* was more like that of *H. sapiens* than those of the great apes, or vice versa. Nonetheless, the fact that Ramirez Rozzi and Bermudez de Castro (2004) find enamel extension rates to be slower in *H. heidelbergensis* than in Neanderthals suggests that *H. heidelbergensis* was more modern human-like than ape-like in its developmental schedule. Thus, it now appears that the developmental schedules of *H. heidelbergensis* and *H. neanderthalensis* were more similar to the developmental schedule of *H. sapiens* than to those of chimpanzees and gorillas, whereas the developmental schedules of *H. erectus*, *H. ergaster*, *H. habilis*, *and H. rudolfensis* were more like those of chimpanzees and gorillas.

The other area in which there have been developments that affect Wood and Collard's (1999) conclusions regarding the adaptive strategies of the species conventionally assigned to genus *Homo* is locomotor behavior. Their case for removing *H. habilis* from genus *Homo* was based, in part, on the fact that they considered it to have been a facultative biped like the australopiths rather than an obligate biped like *H. ergaster*, *H. erectus*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*. The locomotor behavior of *H. rudolfensis* was not considered because in the absence of an associated skeleton nothing is known for certain about its postcranial morphology. Wood and Collard (1999) cited three lines of evidence in support of their claim about H. habilis. One of these was the morphology of the hand bones associated with OH 7, the type specimen of the species, which have been interpreted as being consistent with an apelike climbing ability (Susman and Creel 1979). Another was the configuration of the semi-circular canals in the southern African *H. habilis* specimen Stw 53. This is so markedly different from the configuration in *H. sapiens* (Spoor et al. 1994) that it is likely the two taxa had different balancing requirements. The third line of evidence Wood and Collard (1999) cited in support of the hypothesis that *H. habilis* was a facultative biped was the limb proportions of the two associated skeletons, OH 62 and KNM-ER 3735, that have been assigned to *H. habilis*. These had been reconstructed as being more primitive than those of *Au. afarensis* (Hartwig-Scherer and Martin 1991). Humerus length is similar in modern humans and living chimpanzees, but the former have shorter forearms than the latter. They also have markedly longer femurs. These differences in limb proportions are thought to be related to the contrasting locomotor strategies of the two species: the long femurs of modern humans being adaptive for bipedalism, and the long forearms of living chimpanzees being adaptive for climbing. The available evidence pertaining to limb proportions in australopiths suggests that their forearms were comparatively long while their femora were intermediate in length between those of humans and chimpanzees. This is consistent with the hypothesis that australopiths combined facultative terrestrial bipedalism with proficient climbing. Thus, Hartwig-Scherer and Martin's (1991) finding that the limb proportions of OH 62 and KNM-ER 3735 were more primitive than those of *Au. afarensis* reinforced the hypothesis that *H. habilis* was a facultative biped.

Since Wood and Collard's (1999) study went to press, a number of analyses have been published that challenge the hypothesis that the limb proportions of *H. habilis* were more primitive than those of the australopiths. For example, in 2002 Brian Richmond, Leslie Aiello and Bernard Wood reported the results of a randomization-based study designed to examine the significance of the limb proportion differences among several early hominins, including OH 62 and the only *Au. afarensis* associated skeleton, AL 288-1. They found that the limb proportions of OH 62 are not statistically significantly different from those of AL 288-1. Thus their analyses did not support the hypothesis. More recently, Reno et al. (2005) have argued that the humerofemoral index of OH 62 cannot be calculated because the portion of femur it retains – the proximal part – is a poor predictor of maximum femur length. This claim is supported by an analysis of the relationship between proximal and maximum femur length in extant hominoids, which suggests that the two lengths are not significantly correlated. Although some researchers have taken issue with the methods and assumptions used by Reno et al. (2005), the lack of association between proximal and maximum femur length in their sample of humans and apes certainly suggests that current estimates of the length of OH 62's femur or of its humerofemoral index must be treated with caution. Thus, there is no longer any support for the claim that the limb proportions of OH 62 are more primitive than those of the australopiths; the most that can be said is that they are australopith-like.

The developments that have taken place over the last few years in relation to fossil hominin life histories and locomotor abilities have certainly challenged Wood and Collard's (1999) conclusions regarding the adaptive strategies of some of the species conventionally assigned to genus *Homo*. Most notably, they suggest that *H. erectus* and *H. ergaster* were less modern human-like than Wood and Collard's (1999) analyses suggested. However, on balance, the available evidence still suggests that the adaptive strategies of *H. habilis* and *H. rudolfensis* were different from those operated by *H. erectus*, *H. ergaster*, *H. heidelbergensis*, *H. neanderthalensis* and *H. sapiens* (Table 5). Taken together with the results of the phylogenetic studies that have been published in the last 7 years, this suggests that Wood and Collard's (1999) proposal to remove *H. habilis* and *H. rudolfensis* from *Homo* and assign them to a different genus or pair of genera remains valid.

Conclusion

There is a widespread belief that hominin systematics is arcane and irrelevant, but in our view this notion is ill-founded. Sound taxonomic units are a prerequisite for progress in evolutionary biology (Crowson 1970; Panchen 1992). Thus, *more* attention should be paid to the systematics of the hominins, not less. With this in mind, we hope that the points we have made in this chapter stimulate further work on the definition and composition of the genus *Homo*. In particular, there is a pressing need for Mayr's (1950) and Cela-Conde and Altaba's (2002) approaches to defining genera to be operationalized satisfactorily. We also badly need reliable information about both the phylogenetic relationships of the early *Homo* species and their postcranial morphology, especially as it relates to locomotion. Lastly, it would be helpful for the systematic comparative approach to analyzing dental development employed by Dean et al. (2001) to be extended to the fossils assigned to *H. heidelbergensis* and to the taxon that, for the time being at least, is referred to as *H. floresiensis*.

The Earliest Putative *Homo* Fossils

Friedemann Schrenk, Ottmar Kullmer, and Timothy Bromage

Contents

Abstract

The earliest fossil remains of the genus *Homo* have been discovered in eastern, southeastern, and southern Africa. The sample comprises about 200 skeletal fragments attributable to about 40 individuals and assigned to two species: *Homo rudolfensis* (2.5–1.8 Ma) showing a combination of primitive dentition with *Homo*-like locomotion and *Homo habilis* (2.1–1.5 Ma) exhibiting a progressive reduction of tooth roots but resembling great apes rather than humans in the postcranial skeleton. Another significant difference between early *Homo* and the australopithecines is brain size, which was larger in early *Homo* than in *Australopithecus* but smaller than in *Homo erectus*. Endocasts of *H. habilis* from

Olduvai Gorge and Koobi Fora reveal a number of distinctive features, some of which are recognized as *Homo* autapomorphies. Differences in tooth wear between *H. rudolfensis*, with megadont teeth and more horizontal tooth abrasion, and *H. habilis*, with more gracile molars and higher relief in worn teeth, indicate significant differences in diet and ecology of early *Homo* species. The origin of the genus *Homo* coincided with the onset of material culture. Between ca. 2.8 and 2.5 Ma, extensive open habitats comprising more arid-tolerant vegetation developed in Africa. The selective pressures of this habitat change resulted in the increased survival of more megadont species varieties. Megadonty allowed these species to feed on harder open woodland-open savannah food items (chapter "▶ Dental Adaptations of African Apes," Vol. 2) resulting in the phyletic splitting of *Australopithecus afarensis* into *Paranthropus* and *Homo* lineages by ca. 2.5 Ma. An evolutionary scenario that complies with both the Habitat Theory and early hominid biogeography is provided. It delineates the association between faunal turnover and climate change and suggests a single origin for the *Paranthropus* lineage but separate origins for *H. rudolfensis* and *H. habilis* from *A. afarensis*, *A. africanus*, or *A. sediba* ancestors, respectively.

Introduction

The search for the roots of the genus *Homo* is of particular interest in the field of paleoanthropology. The taxonomic determination of the earliest putative *Homo* fossils provides the basis for the definition of the taxon *Homo* to which all modern humans belong.

Carolus Linnaeus (1758) established the genus *Homo* in the tenth revision of his *Systema Naturae* (chapter "▶ Historical Overview of Paleoanthropological Research," Vol. 1). In his opinion, *Homo* subsumed six groups: *H. sylvestris*, *H. troglodytes* (a mixture of orangutan and myths), *H. sapiens*, and four geographical variants from Africa, America, Asia, and Europe. In the two centuries that followed, *H. neanderthalensis* (King 1864), *H. heidelbergensis* (Schoetensack 1908), *H. erectus* (Dubois 1892; Mayr 1944), *H. habilis* (Leakey et al. 1964), *H. ergaster* (Groves and Mazák 1975), *H. rudolfensis* (Alexeev 1986), *H. antecessor* (Bermudez de Castro et al. 1997), and others were all included in the genus *Homo* (overview in Henke and Hardt 2011).

The history of research, the order of discoveries, and the existing paradigms heavily influence the formation and change in the interpretations of human evolution. This holds true especially regarding ideas on the origin of the genus *Homo* since the 1960s. Debates on the attribution of fossil specimens and the definition of the genus *Homo* continue, and up to date, the taxonomic interpretation of earliest *Homo* is highly controversial (Wood and Collard 2001; Wood and Lonergan 2008; Lordkipanidze et al. 2013).

Opinions differ regarding the number of species and also the specimens included in the genus. Some even assign all putative *Homo* specimens to living humans

(*H. sapiens*). In practical terms, species names in paleoanthropology are labels rather than natural species, and the taxonomic determination of fossils is more or less a question of the philosophy followed by the authors. There are both theoretical and practical reasons to erect taxa, as chronospecies for time equivalent appearance or morphospecies for a complex of shared anatomical features, and in the worst case, there are political reasons for the allocation of species (chapters "▶ Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms," "▶ Species Concepts and Speciation: Facts and Fantasies," Vol. 1, "▶ Defining Hominidae," "▶ *Homo ergaster* and Its Contemporaries," and "▶ Defining the Genus *Homo*," Vol. 3).

Fossil Evidence

Early research on the origin of the genus *Homo* is closely related to the African fieldwork of Louis S. B. Leakey (1903–1972). He strongly believed in Africa as the cradle of humankind and in 1932 discovered the first evidence of early *Homo* at Kanam (Kenya), east of Lake Victoria – a specimen, which today is attributed to *H. erectus*. He also undertook archaeological surveys in Olduvai Gorge, Tanzania (Fig. 1), where later he discovered early pebble tools in Bed I (ca. 1.8 Ma) – remains of what he termed the "Oldowan" industry. The search for the artifact creator led to the discovery of robust australopithecine remains (*Zinjanthropus boisei*) (Leakey 1959). However, due to its small brain size, this specimen Olduvai Hominid 5 (OH 5) was not a convincing candidate for the first toolmaker.

A year later, Louis' son Jonathan Leakey discovered two fragments of a relatively gracile skull, a lower jaw (Fig. 2), and several hand bones of OH 7 (Leakey 1961), deriving from the same stratigraphic level (Bed I) at Olduvai. Brain volume was estimated at around 680 cm^3, a significantly higher value than in robust australopithecines. Consequently, this fossil was interpreted as representing a progressive hominid type of unknown species affiliation. Later Leakey et al. (1964) decided on the new species *H. habilis*. Raymond A. Dart, the founder of modern paleoanthropology in Africa, who in 1925 had introduced the genus *Australopithecus*, had suggested this name to them (chapter "▶ The Species and Diversity of Australopiths," Vol. 3). The Latin term "habilis" means "handy, skillful, able": finally, the producer of the Oldowan culture seemed to have been identified.

Apart from OH 7, the species description of *H. habilis* included skull fragments and teeth (OH 4 and OH 6), part of an adult foot (OH 8), and the incomplete skull of an adolescent (OH 13). Further, Leakey et al. (1964) referred a collection of juvenile cranial pieces (OH 14) and the fragmented cranial vault and dentition (OH 16) of a young adult to the new species.

Since then, numerous additional fossils assigned to *H. habilis* have been discovered at Olduvai Gorge: nine fragmentary skulls, four mandible fragments, 19 teeth, and eight postcranial fragments. Among these fragments was the squashed skull OH 24 ("Twiggy"), which was found in 1968. In 1986, a partial female skeleton

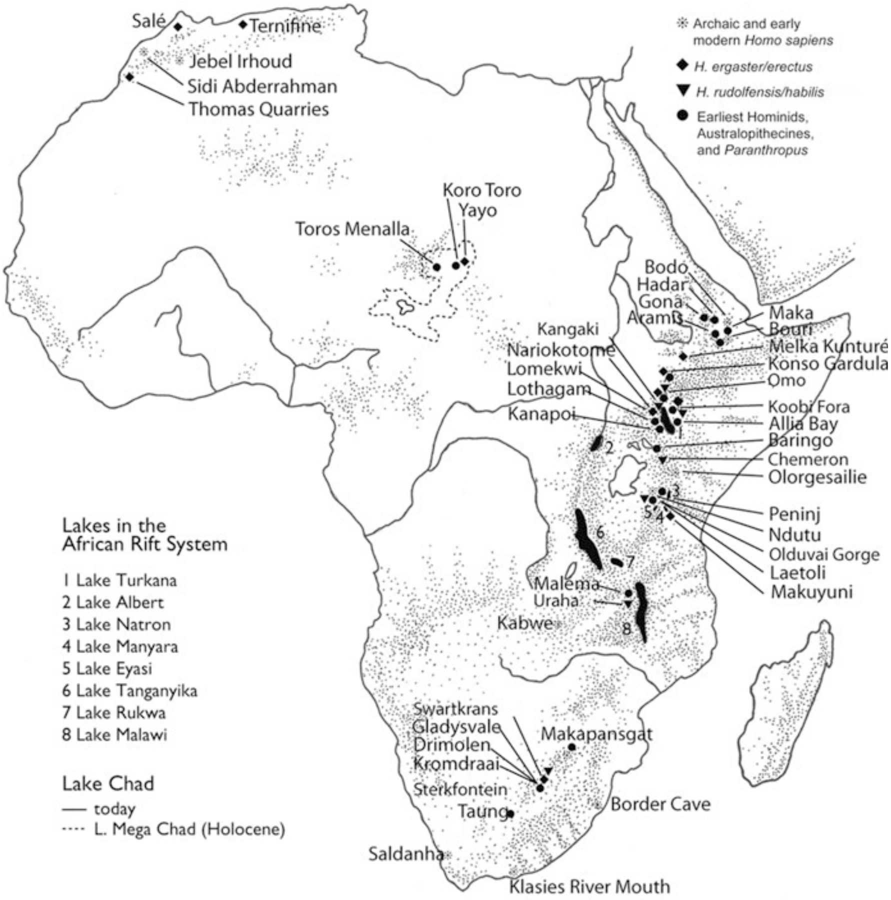

Fig. 1 African early hominid sites. *Homo rudolfensis* and *Homo habilis* sites (▼)

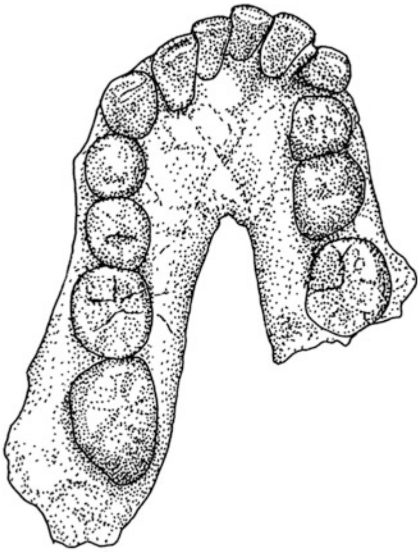
(OH 62) was assembled from a number of fragments (Johanson et al. 1987). This specimen showed that *H. habilis* was fully bipedal and had a brain larger than all australopithecines. For many years, the *H. habilis* remains from Olduvai Gorge were seen as the most important early *Homo* specimens and consequently played the leading role in most hypotheses regarding the origin of genus *Homo* (chapters "▶ Analyzing Hominin Phylogeny: Cladistic Approach," "▶ Defining the Genus *Homo*," Vol. 3).

Leakey et al. (1964) originally discussed cranial and mandibular traits to distinguish the *Homo* specimens of Olduvai from australopiths and *H. erectus*. Maxillary and mandibular size is smaller than in *Australopithecus* and tends in size to *H. erectus* and *H. sapiens*. The surface of the skull shows slight to strong muscular markings, and the parietal curvature in the sagittal plane varies from slight to moderate. The frontal bone is more vertical and the torus supraorbitalis is less

Fig. 2 Type specimen of *Homo habilis*: mandible OH 7, Olduvai Gorge, Tanzania



developed than in australopithecines. In the occipital region, the relatively open-angled external sagittal curvature differs markedly from *Australopithecus*.

In 1970 the picture of earliest *Homo* began to change significantly with the success of the Koobi Fora Research Project in northern Kenya led by Richard Leakey, Louis' son. In just a few years on the eastern shores of Lake Turkana, his team recovered nine skulls, ten mandibles, six isolated teeth, and five postcranial fragments (Leakey 1973a, b). Originally, all the early *Homo* finds from East Turkana, with an age similar to those from Olduvai (1.9–1.8 Ma), were interpreted as bearing similarities to *H. habilis* – then the only early species of *Homo* known. One cranial fragment from the Nachukui Formation on the western shores of Lake Turkana was also assigned to *H. habilis*. However, two of the best preserved skulls from Koobi Fora (KNM-ER 1470, Fig. 3a; KNM-ER 1813, Fig. 3b) later gave rise to an extended debate among researchers about the heterogeneity of the *H. habilis* hypodigm and finally led to the recognition of a new species, *H. rudolfensis* (Alexeev 1986; Wood 1992).

In the 1970s a large number of isolated *Homo* teeth were discovered north of Koobi Fora, near the Omo River in southern Ethiopia, in Members G and H of the Shungura Formation. From these it became clear that the origin of the genus *Homo* extended well beyond 2 Ma. In 1965 a temporal bone was discovered by John Martyn at Chemeron, Kenya, and nearly two decades later, it was described by Hill et al. (1992) as a very early member of the genus *Homo*, dated to around 2.4 Ma.

In 1976, an early *Homo* fossil was found at Sterkfontein, South Africa (Stw 53), that belonged neither to *H. erectus* nor to *Australopithecus* (Hughes and Tobias 1977). A partial facial skull (SK 847 from Swartkrans), assembled from several fragments, originally attributed to a different species, is further evidence for *H. habilis*, which probably migrated into southern Africa around

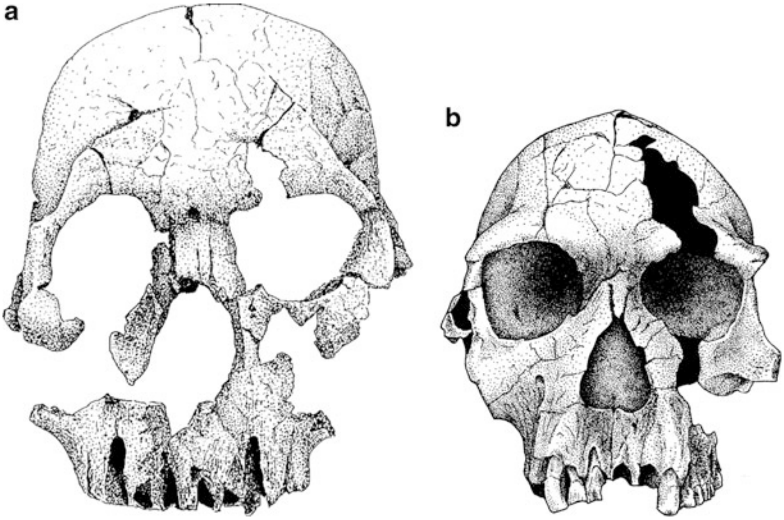


Fig. 3 (**a**) (*left*) KNM-ER 1470 from Koobi Fora, Kenya (ca. 1.9 Ma) *Homo rudolfensis*. (**b**) (*right*) KNM-ER 1813 from Koobi Fora, Kenya (ca. 1.9 Ma) *Homo habilis*. (Scale ca. 1 : 2) (Drawing: Claudia Schnubel)

2 Ma (see below). A new species, *Homo gautengensis*, was established by Curnoe 2010, encompassing finds from Sterkfontein, which earlier had been classified as *Homo habilis* (Curnoe 2010).

The geographical gap between the southern and eastern African early hominid sites was filled in the early 1990s through discoveries in the "Hominid Corridor" of the northern Malawi Rift (Schrenk et al. 1993; Bromage and Schrenk 1995). In 1992, at Uraha, the Hominid Corridor Research Project (HCRP) recovered a mandibular corpus, UR 501 (Fig. 4), containing third and fourth premolars and first and second molars in variable states of preservation (Schrenk et al. 1993). Many absolute and relative measures defining molar and premolar crown shape indices, relative cusp areas, fissure patterns, and enamel microanatomical features, as well as overall crown morphology, are within the sample range of early *Homo*, although some may also be subsumed within the limits of variation represented by *Australopithecus* (*A. africanus* and *A. afarensis*). However, UR 501 has absolutely large molar crown areas, relative expansion of the P_3 talonid, platelike P_3 and P_4 roots, and some enamel microanatomical features correspond more closely to the *Paranthropus* condition. UR 501 corresponds closely to the subset of Late Pliocene fossils from East Turkana, Kenya, which have relatively large brains and robust jaws and teeth and based on the above were assigned to *H. rudolfensis* by Alexeev (1986) and Wood (1992). UR 501 was also referred to this group (Bromage et al. 1995). This Malawi specimen has been dated by biostratigraphic correlation of suid material with well-dated sites in southern Ethiopia (Omo Shungura) and northern Kenya (Koobi Fora), indicating an age of about 2.3–2.5 Ma (Kullmer 2008), whereas most early *Homo* fossils are around 2 Myr old.

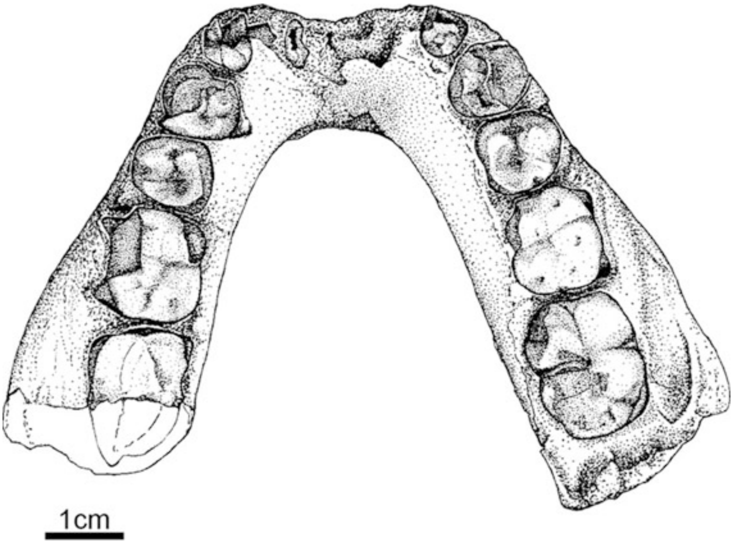

Fig. 4 UR 501 from the Chiwondo Beds, northern Malawi (ca. 2.5–2.3 Ma), *Homo rudolfensis* (Drawing: Claudia Schnubel)

It is important to note that the appearance of earliest *Homo* is contemporaneous with the origin of hyperrobust australopithecines (*Paranthropus*) (chapters "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1 and "▶ Origins of Homininae and Putative Selection Pressures Acting on the Early Hominins," Vol. 3). The earliest evidence for this co-existence is based on further hominid discoveries in the Chiwondo Beds of northern Malawi (Kullmer et al. 1999, 2011). A maxillary fragment (RC 911) preserves part of the left alveolar process, with badly damaged M^1 crown and fragmentary M^2 crown. Size, morphology, and abrasion occlusal pattern on the surface suggest that RC 911 should be assigned to *Paranthropus boisei* (Kullmer et al. 1999; Alt et al. 2000).

The biogeographic significance of these Malawi Rift hominids lay in their association with the eastern African endemic faunal group. The associated bovid and suid faunas show a small amount of overlap with southern African animals and a greater overlap with eastern African faunal elements. Biogeographic variation in the Malawi Rift may be linked to habitat changes occurring due to climate shifts, with maximum change occurring around 2.5 Ma.

Changing Taxonomy

Hominid fossils have been assigned to the genus *Homo* if they fulfilled four main perceived criteria (Keith 1948; Tobias 1991; Wood and Collard 2001): a brain size above 600 cm^3, putative ability for speech and toolmaking, and an opposable

Table 1 Significant morphological differences between *H. habilis* and *H. rudolfensis*

	Homo habilis sensu stricto	*Homo rudolfensis*
Skull and teeth		
Absolute brain size (cm^3)	An average volume of 610	An average volume of 650–675
Overall cranial vault morphology	Enlarged occipital contribution to the sagittal arc	Primitive condition
Endocranial morphology	Primitive sulcal pattern	Frontal lobe asymmetry
Suture pattern	Complex	Simple
Frontal	Incipient supraorbital torus	Torus absent
Parietal	Coronal > sagittal chord	Primitive condition
Face overall	Upper face > midface breadth	Midface > upperface breadth
Nose	Margins sharp and everted; evident nasal sill	Less everted margins; no nasal sill
Malar surface	Vertical or near vertical	Anteriorly inclined
Palate	Foreshortened	Large
Upper teeth	Probably two-rooted premolars	Premolars three rooted; absolutely and relatively large anterior teeth
Mandibular fossa	Relatively deep	Shallow
Foramen magnum	Orientation variable	Anteriorly inclined
Mandibular corpus	Moderate relief on external surface; rounded base	Marked relief on external surface; everted base
Lower teeth	Buccolingually narrowed; postcanine crowns; reduced talonid on P_4; M_3 reduction; mostly single-rooted mandibular premolars	Broad postcanine crowns; relatively large P_4 talonid; no M_3 reduction; twin, platelike P_4 roots, and bifid, or even twin, platelike P_3 roots
Postcranium

pollux. To date, the hypodigm of earliest *Homo* attributed to *H. habilis sensu stricto* and *H. rudolfensis* contains about 200 skeletal fragments attributable to about 40 individuals (Tables 1 and 2). Despite or maybe due to the large number of specimens, the taxonomic interpretation of earliest *Homo* is highly controversial (e.g., Wood 2000).

Originally, the interpretation of the early *Homo* hand as "modern" (Leakey et al. 1964) supported the view of *H. habilis* as an early but "able" human as opposed to the rather "clumsy" australopithecines. However, later skeletal finds at Olduvai Gorge (OH 62) (Johanson et al. 1987) demonstrated that the postcranial skeleton of *H. habilis* indeed resembled *Australopithecus africanus* rather than *Homo*. Yet the most distinctive character of *H. habilis* remains its relatively and absolutely higher brain volume compared to that of *Australopithecus*. The forehead of *H. habilis* is more vertical and a weak supraorbital torus is present. Whereas the morphological characters are quite uniform in the Olduvai sample, the discussion started to heat up mainly over two very distinct fragmentary skulls from Koobi Fora: KNM-ER 1470 (Fig. 3a) (Leakey 1973a) and KNM-ER 1813 (Fig. 3b) (Leakey 1973b).

In a comprehensive character analysis of all available putative *H. habilis* fossils from Koobi Fora, Wood (1991) concluded that the variability exhibited by the sample was not only the result of sexual dimorphism, as was suspected at the time, but that highly significant differences exist throughout the entire skeleton. There is a mosaic of *Australopithecus* and *Homo* characters in both early species: Whereas *H. rudolfensis* exhibits a combination of ancestral dentition with *Homo*-like

locomotion, *H. habilis* shows a progressive reduction of tooth roots and resembles great apes rather than humans postcranially.

Based on the work of Wood (1991) and subsequent re-evaluation of fossils, it is evident that two distinct types can be separated. Whereas one group, represented by KNM-ER 1813, follows the original description of *H. habilis* from Olduvai Gorge, a new group is represented by KNM-ER 1470, for which no comparison existed in Olduvai at the time. Although the subsequent find of OH 65 at Olduvai (Blumenschine et al. 2003) showed a mixture of *H. habilis sensu stricto* and KNM-ER 1470 features, it is still a valid conclusion that about half the early *Homo* material from Koobi Fora belongs to *H. habilis sensu stricto*, with an age of 2.1–1.5 Ma, which includes also specimens from Koobi Fora, West Turkana, Omo, Olduvai Gorge, and southern Africa (Table 2). Hominid remains from Ubeidiya in Israel (Leakey et al. 1964) and *Meganthropus palaeojavanicus* from Java, Indonesia, which at one stage were tentatively assigned to *H. habilis* (Tobias and von Koenigswald 1964), are not considered as such today.

The Koobi Fora early *Homo* material not assigned to *H. habilis* is allocated to the more recently named species *H. rudolfensis*, with an age of 2.5–1.8 Ma, which also includes specimens from Chemeron, West Turkana (Prat et al. 2005), and Omo (Suwa et al. 1996; Ramirez Rozzi 1997), as well as northern Malawi (Schrenk et al. 1993) (Table 3).

The species name *rudolfensis* was coined by Russian paleontologist Valerij Pavlovič Alexeev, who in 1986 described KNM-ER 1470 as "*Pithecanthropus rudolfensis*," after Lake Rudolf, the name of Lake Turkana prior to Kenyan independence in 1963.

Postcranial Skeleton

The postcranial skeleton of *H. habilis* was characterized by Leakey et al. (1964) using a number of characteristics: the clavicle resembles that of *H. sapiens*, the hand shows broad terminal phalanges, and capitate and MCP articulations also resemble *H. sapiens*, but differ in respect to the scaphoid and trapezium, attachments of the superficial flexor tendons, and the robusticity and curvature of the phalanges. The foot bones resemble *H. sapiens* in the stout and adducted hallux and well-defined foot arches, but differ in shape of the talar trochlea surface and the relatively robust third metatarsal.

All these features indicate an affinity toward *H. sapiens* and underline that the early postcranial material from Olduvai seems to be different from that of the australopiths. Functional implications based on more detailed descriptions of the foot (OH 8, OH 10) and leg (OH 35), both of which are probably from the same individual (Stern and Susman 1983), were generally more cautious (Wood 1992). According to Stern and Susman (1983), *H. habilis* had not reached the characteristic bipedal gait of *H. sapiens*, since the functional morphology of the knee joint was not well adapted for striding. Further analysis of the OH 8 foot demonstrated that some features, common in nonhuman hominoids, are also present in the foot bones (Lewis 1989). As more postcranial material was uncovered at Koobi Fora, interpretation of hind limb function of early *Homo* became more complex. However, some specimens, such as the femur KNM-ER-1472A and the talus KNM-ER-813, may belong to *H. erectus* or *H. ergaster* rather than to *H. habilis* (Tobias 1991). Although the partial skeleton OH 62 from Olduvai Gorge was interpreted as evidence for fully upright human bipedal locomotion, Haeusler and McHenry (2004) demonstrated that there is little evidence in support of ancestral body proportions with short legs and long arms in *H. habilis*. Their results suggest that it is more likely that earliest *Homo* possessed an elongation of the legs relative to *A. africanus* and *A. afarensis*, whereas long forearms were still retained (Johanson et al. 1987). With its upper-to-lower limb shaft length proportions, OH 62 falls within the upper range of modern humans and the lower range of chimpanzees due to the partial overlap between these taxa at small body sizes. KNM-ER 3735, the larger-bodied early *Homo* from Koobi Fora, falls well outside the chimpanzee range and reflects the average proportions of modern humans. Comparison of the Koobi Fora and Hadar postcranial remains has led to the interpretation that *H. habilis* did probably possess a modern pattern of limb shaft proportions, and the body proportions of OH 62 are in agreement with other available evidence of *H. habilis* postcranial material (Johanson et al. 1987), but Jungers (2009) judges OH 62 interlimb proportions as indeterminate. The change in the proportions of limb length toward the development of long legs may be indicative of long-distance terrestrial running in early *Homo* and probably implies a shift in hominid ecology (Bramble and Lieberman 2004).

Brain and Language

A significant difference between early *Homo* and australopiths exists in brain size, which was larger in early *Homo* than in *Australopithecus* but smaller than *H. erectus*. Endocasts of *H. habilis* from Olduvai and Koobi Fora reveal a number of distinctive features, some of which are recognized as autapomorphies of the genus *Homo*. Tobias (1987) defined the principal morphological trait to distinguish *H. habilis* from *Australopithecus* as a larger mean endocranial capacity in the former (640 cm^3) than in *A. africanus* (441 cm^3), *A. boisei* (513 cm^3), and *A. robustus* (530 cm^3) (chapters "▶ The Evolution of the Hominid Brain," Vol. 3 and "▶ The Evolution of Speech and Language," Vol. 1). This suggests that the evolutionary trend toward brain expansion was already well under way more than 2 Ma. The *H. habilis* mean (640 cm^3) is close to the lower limit (647 cm^3) of the 95 % population range of *H. erectus* but well above the upper limit of the *A. africanus* range (492 cm^3). The brain capacity of the *H. rudolfensis* type specimen, originally reconstructed to give 752 cm^3, is larger than the known range for *H. habilis* from Olduvai Gorge and Koobi Fora and falls within the lower range of *H. erectus*. However, the relationship between prognathism and cranial capacity in primates results in an estimate of KNM-ER 1470 cranial capacity of 625 cm^3 (1 SD = 49 cm^3), and together with other considerations, a ca. 700 cm^3 estimate is more realistic (Bromage et al. 2008). This revision is not inconsistent with other Late Pliocene *Homo* prior to the appearance of Early Pleistocene *Homo erectus/ergaster* (Holloway 1996).

A prominent feature of the *H. habilis* brain is the bilateral transverse expansion of the cerebrum, especially in the frontal and parieto-occipital areas, and a posterior heightening. The increased bulk of cerebral frontal and parietal lobes and the sulcal and gyral patterns of the lateral frontal lobe have been interpreted as derived features for the genus *Homo* (Tobias 1987). The *H. habilis* brain showed a well-developed left superior parietal lobule and a prominent development of the inferior parietal lobule.

The endocast of KNM-ER 1470 shows a left frontal lobe sulcal pattern that is associated with Broca's area in living people (Falk 1987), a finding that has led to the conclusion that *H. rudolfensis* may have been capable of speech. This conclusion is in accordance with Holloway's observation of a pronounced left-occipital-right-frontal petalia pattern in the KNM-ER-1470 endocast that may indicate functional cortical asymmetry (Holloway 1983). Surprising corroborative evidence has been provided by Toth's analyses (chapters "▶ Overview of Paleolithic Archaeology," Vol. 3 and "▶ Modeling the Past: Archaeology," Vol. 1) of stone flakes, which indicate that hominids were predominantly right-handed by 2 Ma (Toth 1985). Adjacent areas in the left frontal lobe control the speech organs and the right hand. Tobias (1991) stated that *H. habilis* is the earliest hominid to show prominent enlargement of Broca's and Wernicke's areas. If so, the same should be seen in *H. rudolfensis*. *Australopithecus* endocasts show Broca's area, but not Wernicke's region, while anthropoid apes display neither of the two. The prominent development of the two speech areas may thus be seen as an important autapomorphy of the genus *Homo* (Tobias 1991). Even if *H. habilis* and

H. rudolfensis possessed the neurological bases of speech, there is no evidence that either of them used spoken language. The areas of the brain that control spoken (chapter "▶ The Evolution of the Hominid Brain," Vol. 3) communication probably manifested themselves only when brain enlargement occurred and marked encephalization started.

Material Culture and Food Processing

Around 2.5 Ma, simultaneously with an increase in drier and harder food stuffs due to increasing aridity in eastern Africa (de Menocal 2004), there occurred the first hyperrobust australopithecines (*Paranthropus*) and the first specimens identified as genus *Homo* in the fossil record (Bromage et al. 1995). This demonstrates an evolutionary alternative to the massive masticationary system of *Paranthropus*, which was capable of dealing with hard foods. There was a reduction in molar size in *Homo rudolfensis* relative to *Paranthropus*, but earliest *Homo* was nevertheless comparatively megadont, illustrating that while a larger and more possibly more cognitively complex brain may have helped early *Homo* to respond to changing environmental conditions, they must still have been somewhat dependent on hard and tough vegetative resources (Wood and Strait 2004).

The evolutionary alternative to megadonty was the manufacturing and use of stone tools. The oldest chopper tools are known from Ethiopia (Hata, Bouri Formation) and from Tanzania, approximately 2.5 Ma (Kaiser et al. 1995). From Gona, east of Hadar in the Afar Triangle, primitive pebble tools are dated to 2.6 Ma (Harris 1986), and discoveries from west of Lake Turkana confirm the existence of an early tool culture around 2.5 Ma (Roche et al. 2003). Earliest cutmarks on bone fragments are reported from a 3.4-Ma-old site at Dikika in Ethiopia (McPherron et al. 2010) but have been interpreted as trampling marks by others (Domínguez-Rodrigo et al. 2010). The oldest stone tools associated with early *Homo* were found in the Hadar area of Ethiopia (Kimbel et al. 1996). At many sites the presence of more than one hominid species, occurring in the same horizon as early Oldowan pebbles, does not give clear evidence of who were the first toolmakers. However, distinct specialization of the skull and dental morphology in robust australopithecines and brain expansion in early *Homo* point to the latter as the most likely tool manufacturer (chapters "▶ Modeling the Past: Archaeology," Vol. 1 and "▶ Over view of Paleolithic Archaeology," Vol. 3).

Implements are widely used by higher primates (Boesch and Boesch 1990) (chapters "▶ Great Ape Social Systems," "▶ Cooperation, Coalition, Alliances," and "▶ Theory of Mind: A Primatological Perspective," Vol. 2). Yet during marked habitat shifts, which led to pronounced changes in food resources, it probably was the invention of stone tools which supported the origin of the genus *Homo* around 2.5 Ma. Increasing independence from the environment led to an increase in the dependence on culture.

If early *Homo* utilized stone tools to prepare food, the dentition might actually reflect these behavioral changes in food acquisition. However, the morphology of early *Homo* teeth does not seem to suggest extensive food preparation before ingestion. The incisors are large compared to those of *Australopithecus* and *H. erectus*, and the canines are large relative to the premolar crown surfaces. The premolars are narrower than in *Australopithecus* and fall within the range of *H. erectus*. Molar size overlaps the ranges for *Australopithecus* and *H. erectus*. The cheek teeth of *H. rudolfensis* are enlarged and show affinities to *Paranthropus* molars. All teeth are relatively narrow buccolingually and elongated mesiodistally, especially the mandibular molars and premolars. In *H. habilis* we see well-developed third molars, while in *H. rudolfensis*, the third molar has a smaller crown than the second molar. The occlusal surface of the cheek teeth is not as broad as in australopithecine molars and indicates differences in chewing. Tobias (1987) states that the crown's cusp relief is still present even when the teeth show advanced wear and dentine is visible. This means that the attrition of the enamel is less pronounced than in earlier hominids. Differences in tooth wear between *H. rudolfensis*, with megadont teeth and a more horizontal tooth abrasion, and *H. habilis*, with its more gracile molars and higher relief in worn teeth, are clearly visible. This indicates significant differences in diet and ecology of early *H.* species. *H. rudolfensis* and the robust australopithecines share some cranial and dental features in the morphology of the masticatory apparatus (Wood 1992), which indicates that these hominids were able to cope with hard fruits and plants. Since those features are judged as an adaptation to drier climatic conditions, they also show that *H. rudolfensis* was relatively conservative nutritionally and probably less versatile in his food choice than *H. habilis* and certainly *H. erectus* (Ungar et al. 2006).

Biogeographic Scenario

The scenario presented here is derived mainly from hypotheses about early hominid evolution in the context of environmental change and faunal biogeography. It is thus a biogeographic perspective against which we understand the relevance to studies of early *Homo* systematics in general and morphology and character transformation more specifically.

The behavioral inclination of the earliest hominids, distributed along the margins of the tropical rain forest, was to maintain a connection to, and remain near, the borders between broad riparian habitats and open woodlands during the ascendancy of more warm and humid times. Over short geological timescales, this typically involved a local, nondispersing tendency, but by approximately 4 Ma, several species of *Australopithecus* had successfully dispersed throughout the reaches of the African Rift Valley and into western Africa (Fig. 6). Over longer time frames, this included dispersal through the riparian "corridor" connecting eastern and southern Africa, permitting population dispersal into southern Africa by 3 Ma. This dispersing population maintained habitat specificities to forested environments (Rayner et al. 1993), though in more environmentally temperate climes and in relative geographical isolation at the extreme distal edge of its distribution.

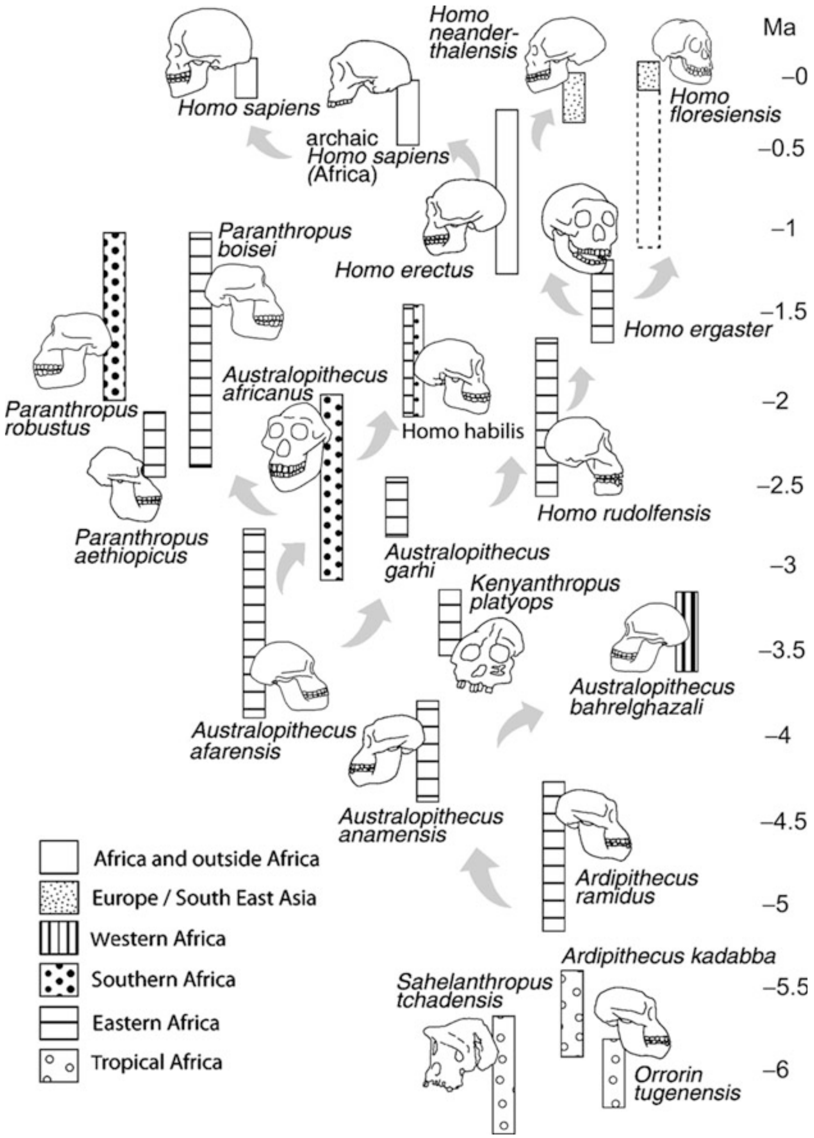

Fig. 5 Hominid chronology

The dispersion along changing latitudinal circumstances covaried with its transformation into, first, a geographic variant and, subsequently, into *A. africanus*, joining ranks with other southern African endemic faunas. Thus, *A. afarensis* was essentially an eastern African endemic form, and it follows that no typical representatives are likely to be recovered from southern African deposits older than 3.5 Ma. (Figs. 5 and 6).

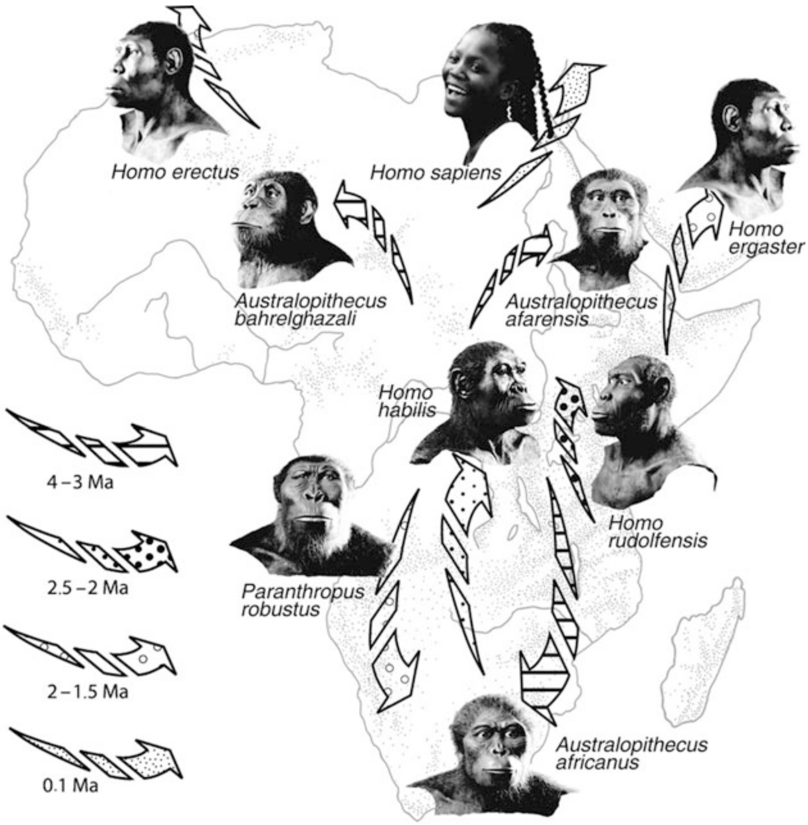

Fig. 6 Early hominid biogeography, dispersal and migration in Africa

By approximately 2.8 Ma, the initiation of cooler and drier conditions prevailed upon the African landscape, its vegetation, and its faunas, until climaxing ca. 2.5 Ma (chapters "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3 and "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1) (Bonnefille 1980; Vrba 1985, 1988; Prentice and Denton 1988; de Menocal 2004). During this time, *A. afarensis* in eastern Africa and *A. africanus* in southern Africa were each subject to unique paleobiogeographic consequences of this global aridification, reflected in the "Habitat Theory" of Vrba (chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3) (1992).

For *A. afarensis*, then, the changing climate meant vicariance of its habitat and its distribution into more distant ecotonal riparian and closed lake margin environs. During the interim between ca. 2.8 and 2.5 Ma, these changing conditions engendered more extensive open habitats, comprising more resistant arid-tolerant vegetation around the remaining relatively lush but narrowed "ribbons" of tree-lined riverine forest. The selective pressures of this habitat change resulted in the increased survival of more megadont varieties capable of feeding on harder fruit and open woodland-open savanna food items. This was so for early hominid as well as numerous eastern and southern African large terrestrial vertebrate lineages ca. 2.5 Ma (Turner and Wood 1993). These pressures were likewise sufficient to result in the phyletic splitting of *A. afarensis* into *Paranthropus* and *Homo* lineages by ca. 2.5 Ma (Vrba 1988) (Figs. 5 and 6).

Ensuing cooler and drier conditions favored a savanna vegetation composed of plant species better able to retain their moisture under such conditions. Selection favored more facially robust and large molar-toothed mammals, including early hominids, capable of efficiently processing harder, more durable vegetation of the savanna. Our evidence suggests that the tropical equatorial animals, including the hominids, of eastern Africa stay in the tropical African ecological domain, while during the drying and cooling of global climates ca. 2.5 Ma, the southern and more temperate African faunas follow their northward-drifting vegetation zones. Thus, *Homo* and *Paranthropus* may have emerged in tropical Africa as a result of the ca. 2.5-Ma climatic cooling event and remained endemic to tropical latitudes during this time (Bromage et al. 1995). The eastern African tropical faunas, having habitable alternatives, remained within their biogeographic domains rather than braving the relative deterioration and paucity of habitats south of the African Rift Valley.

The faunas of southern Africa were subject to a different set of environmental stimuli during the ca. 2.5-Ma cooling event. Waning of the forests and woodlands and expansion of more open arid grasslands not only invigorated evolutionary adaptations to savanna life in tropical eastern Africa but also resulted in the distribution drift northward of faunas that tracked the equatorial shift of grassland and woodland biomes into eastern Africa from the south, ca. 2.5 Ma (Bromage et al. 1995). The temperate zone ca. 2.5 Ma experienced more seasonal extremes, and many organisms unwittingly maintained their inherited preference for moderate seasonal climes and temperate vegetation by moving northward with the shrinking of this biome toward the equator, effectively transgressing the Zambezi Ecozone. Among these migrants was *A. africanus* which, having been adapted to a modest temperate ecology, now found its suitable habitats shifted to the north toward the East African Rift Valley. While dispersing toward the eastern African tropical domain, selection for increased behavioral flexibility was related to the habitat diversity of the tropics and the presence of other non-vegetative food resources available in their new region. This emerging taxon, *H. habilis*, rapidly established itself as a categorical omnivore and found that it could buffer itself more resolutely from environmental changes (Ungar et al. 2006). This enabled it to cross habitat boundaries more easily and also to advantage itself of more resources with its material culture.

By approximately 2 Ma, Africa was rebounding from its relatively cool and dry climate to return to slightly more warm and humid conditions (Bromage et al. 1995). A phase of biome expansion ensued, which facilitated dispersions away from the equator, ending nearly 1 Myr of relative endemism dominated by tropical equatorial speciations. *P. boisei* dispersed southward, along reestablished ecotonal habitats, into southern Africa, became a geographic variant under more temperate conditions, and evolved into *Paranthropus robustus* (Fig. 5). *Homo habilis* expanded southward into the southern African temperate domain, but it maintained a very much broader niche and increased its distributional area as a single species. *Homo rudolfensis* remained endemic to the eastern African tropical domain due partly to its preference for more open habitats around the rain shadows of the African Rift Valley and partly, perhaps, to some small measure of competitive exclusion from geographic realms occupied by *H. habilis*.

Whereas our model suggests the origin of early *Homo* in tropical (eastern) Africa, recent fossil discoveries from Malapa Cave South Africa (Berger et al. 2010), described as *Australopithecus sediba*, have been interpreted as potential evidence for a Southern African origin of *Homo*. The hip structure of this species seems more closely related to *Homo erectus* than to *Homo rudolfensis* or *Homo habilis*. However, with an age of less than 2 Ma, it seems more likely that these late australopiths were convergently adapted with rather than ancestral to the earliest *Homo*.

Conclusions

The origin of the genus *Homo* is highly debated. Earliest fossil evidence dates to around 2.5 Ma and is in temporal co-existence with the appearance of *Paranthropus* in eastern Africa. The beginning of the *Homo* lineage, represented by *H. rudolfensis*, was an endorsement of its recency of common ancestry with *A. afarensis*, a distinction it shared with *Paranthropus*. However, while *Paranthropus* was principally adapted by means of a robust masticatory system to abrasive diet, early *Homo* exhibited an increased behavioral and dietary flexibility as its adaptation included a larger and more provoking, inquiring, and capable brain, which led to a large diversification represented by later *Homo* species, such as *H. habilis/ergaster/erectus*. This included a shift to proportionately less abrasive foodstuffs and more omnivorous habits. Increasing cultural abilities and the beginnings of a stone tool culture ameliorated the effects of changing habitats and food resources to the degree that it enabled early *Homo* to take advantage of diverse resources more efficiently than was ever possible before.

Homo ergaster and Its Contemporaries

Ian Tattersall

Contents

Abstract

On the basis of their strong morphological differences from the Javan type materials, many authorities now consider the diverse East African fossils initially classified as "African *Homo erectus*" to be more properly allocable to the species *H. ergaster*. However, while this separation at the species level of the African and Indonesian hominids is certainly justified, the species *H. ergaster* as thus constituted still embraces a significant morphological variety. Indeed, although this grouping of African fossils seems to form a fairly coherent clade, it also appears quite diverse. The East Turkana type mandible of *H. ergaster* is matched by other specimens from Kenya and Tanzania, but not by the mandible of the iconic WT 15000 skeleton, and in its turn this specimen fails to match either in its cranial construction or its upper dentition most of the other comparable specimens usually referred to *H. ergaster*. Clearly there is a need for a systematic reappraisal of the entire "African *Homo erectus*" = *Homo ergaster* group, and equally clearly the hominid evolutionary story throughout the Old

World in the Early–Middle Pleistocene was more complex than is implied by the extension of the species *H. erectus* to cover the entire miscellaneous assemblage of hominid fossils from this time period.

Introduction

There is probably no area of paleoanthropology in which disagreement is more profound than in the systematics and taxonomy of the genus *Homo* in the Early to Middle Pleistocene. This discord has a long and, dare one say it, illustrious pedigree, dating right back to the initial discovery and description of the Javan species *Pithecanthropus* (=*Homo*) *erectus* by Eugène Dubois in the early 1890s. At that time the only extinct hominid known was the European *H. neanderthalensis*, a form that, though peculiar in morphology, possessed a brain of modern human size. The new and more ancient hominid announced by Dubois as an intermediate between modern humans and apes (a status reflected in his initial choice of name, which translates as "upright ape-man") was thus the first known human fossil relative to display a brain cavity that was significantly larger than those of modern-day great apes while lying below the range of *H. sapiens*. Dubois's discovery unleashed an immediate furor. The key to Dubois's interpretation of this specimen as a human relative (though he stopped short of placing his find in the human family Hominidae) was the association of the type Trinil skullcap with a femur whose morphology was without doubt that of an upright biped in the modern fashion. This association was immediately attacked (and has continued to be periodically questioned), initially by those who preferred to see the cranium as that of a specialized ape, maybe related to the gibbons. At the same time, many of those who accepted the association between the cranium and femur wrote off the former as deriving from an aberrant modern human (see discussion in Tattersall 1995, 2008).

Still, some paleoanthropologists (Cunningham 1895) did seize immediately upon the Trinil specimen as an evolutionary intermediate between great apes and humans, and were willing to view the Javan hominid as an early member of a lineage that had given rise to *H. sapiens* via the Neanderthals. This interpretation rapidly gained ground (Theunissen 1988), and by early in the twentieth century, not least through the efforts of Schwalbe (1899) – and despite those of Boule (1911–1913) – the place of *H. erectus* as the "hominid in the middle" had effectively been secured. Given the tiny size of the hominid fossil record at that time, and that the apparent rudiments of a transformation series in brain size were present in what was known, this interpretation was hardly surprising: indeed, it was a good story that was hardly contradicted by the few facts then available. And, in the decades before the Second World War, two additional developments conspired to keep *H. erectus* at the front and center in scenarios of human evolution.

The first of these was the discovery of the huge trove of *Sinanthropus pekinensis* fossils at Zhoukoudian near Beijing during the late 1920s and the 1930s, and of the similarly impressive series of *H. soloensis* crania at Ngandong in Java in

1931–1932. The hominids from both sites were reckoned to be very close to Javan *H. erectus*, if not exactly the same thing; and at a time when most hominid fossil sites produced a specimen here and there, both discoveries were overwhelming by virtue of the sheer volume of material produced. At the same time geneticists, systematists, and paleontologists in the USA and Europe were busily constructing the outlines of what came to be known as the Evolutionary Synthesis, which saw the gradual modification of continuous lineages as the central feature of the evolutionary process (see discussion in Tattersall 1995). And at mid-century, the ornithologist Ernst Mayr (1950), one of the principal architects of the Synthesis, bluntly told the paleoanthropological profession that *S. pekinensis*, *H. soloensis*, and other Middle Pleistocene hominids all belonged to *H. erectus*, the species that occupied the middle part of a direct and gradually transforming lineage running from *H. transvaalensis* (the australopiths) at the beginning to *H. sapiens* (which embraced the Neanderthals) at the summit.

Mayr's short article was perhaps the most influential contribution ever in paleoanthropology, and effectively set its agenda for the next half-century. The rapidly increasing size of the human fossil record eventually forced even Mayr to relent, and to admit a little more complexity into the picture; but for decades, paleoanthropologists labored steadfastly under the notion that the evolutionary history of our kind had largely involved the gradual modification through time of a central lineage that eventually culminated in *H. sapiens*. Of course, it was admitted that at any one point in time such a lineage, widely distributed across the Old World, would have harbored a variety of local variants (see Baab, chapter "▶ Defining *Homo erectus*," Vol. 3); but throughout the second half of the twentieth century, the emphasis was principally on within-species variation, rather than on the question of whether a signal of systematic (species) diversity might be detectable in the variety of morphologies that emerged as the hominid fossil record steadily enlarged. Against this background, the category *H. erectus* became a catchall for a huge and unwieldy assortment of fossils of substantially differing morphologies.

Such hominids came from widely scattered localities. First, the probably 1.0- to 0.7-million-year (myr)-old Trinil specimens from Java were joined by a steady stream of discoveries in the nearby Sangiran Dome, not far away, that probably date in the 1.5- to 1.0-myr range, most of them closer to its younger end. Then the sample was augmented by the Chinese Peking Man fossils, now thought to be probably between about 500 and 300,000 years (kyr) old, followed by the Ngandong specimens (which may be as young as 50–30 kyr old), and ultimately by other Javanese fossils from localities such as Sambungmacan and Ngawi, both uncertainly dated but unlikely to be more than 200 kyr old, and most probably younger. In China, later finds attributed to *H. erectus* came from sites including Lantian (Gongwangling and Chenjiawo, both perhaps around 1.0 myr), Hexian (maybe 400 kyr), Nanjing (ca. 350 kyr), and even Longgupo, a site that may possibly be as much as 1.8 myr old. Some European specimens in the 400–300 kyr range, such as those from Vértesszöllös (Hungary), Arago (France), and Bilzingsleben (Germany), have been referred by some authors to *H. erectus*, as has the 900- to 800-kyr-old calvaria from Ceprano in Italy. Further east, in the Caucasus, the 1.8-myr-old Georgian site of Dmanisi has yielded fossils that have also been attributed to *H. erectus*. In Africa practically anything from the earlier Middle Pleistocene, and soon many older specimens as well, found themselves identified as *H. erectus*, so that the species came to include such motley fossils as the 1.4-myr-old Olduvai Hominid (OH) 9 calvaria from Tanzania; the 700-kyr-old mandibles from Tighenif (Ternifine) in Algeria; the 400-kyr-old Salé partial braincase from Morocco; the 1.6-myr-old WT 15000 "Turkana Boy" skeleton from Nariokotome on the western side of Lake Turkana in Kenya, and several crania and mandibles in the 1.9–1.5-myr range from Koobi Fora and Ileret on the eastern side of the same lake; also from Kenya, the fragmentary Olorgesailie hominid at 1.0–0.9 myr; the 1-myr-old Daka calvaria from Ethiopia; a cranium of apparently similar age from Buia in Eritrea; and even, from South Africa, the perhaps 1.6-myr-old Swartkrans Member 1 SK 847 partial cranium.

Not only do these fossils cover an enormous span of time (ca. 1.8–0.03 myr), but they also embrace a huge range of morphologies, and taken together they hardly suggest a neat chronological series of the kind the Synthesis had predicted. Clearly, there is a systematic signal of some kind in the assemblage of hominid fossils that have at one time or another been allocated to *Homo erectus*: a signal of diversity at the species as well as the morphological level. But it was not until the beginning of the final quarter of the twentieth century that this possibility began to be seriously investigated.

Enter *Homo ergaster*

The existence of *H. erectus* as a convenient catchall for a remarkable variety of hominids certainly facilitated the telling of a relatively simple and straightforward human evolutionary story that could be told in terms of consistent long-term selection pressures for such things as more perfect thermoregulation, more efficient digestion, and above all greater intelligence. However, this story of the gradual honing over time of an ever more effective human machine was contradicted by the growing post-Synthesis realization that the evolutionary process consists of a great deal more than simple natural selection (Tattersall 1995, 1998). It also sat rather uneasily with the fact that the Pleistocene was increasingly being seen as a period of extraordinary short-term climatic oscillations as well as of longer-term fluctuations (see Van Couvering, chapter "▶ Quaternary Geology and Paleoenvironments," Vol. 1). And, most significantly of all, it was not the story that the growing assemblage of *Homo* fossils seemed to be telling.

The first shot across the bows of the all-encompassing notion of *H. erectus* came from work on fossils found at the classic African localities on the eastern shores of Lake Turkana. During the 1970s, several fossils, notably the partial crania KNM-ER 3733 and KNM-ER 3883, were discovered at Koobi Fora that their

Fig. 1 Lateral view of the KNM-ER 992 holotype mandible of *H. ergaster*. Scan of cast by Ken Mowbray

describers (Leakey and Walker 1976; Walker and Leakey 1978) ascribed to the species *H. erectus*. With cranial volumes of 848 and 804 ml respectively (these and most of the other endocranial volumes cited here come from Holloway et al. 2004), these 1.8- and 1.6-myr-old individuals had possessed brains almost as large as that of Dubois's much younger (1.0–0.7 myr) Trinil type specimen of *H. erectus*, at about 950 ml. Another significant specimen was a well-preserved mandible, KNM-ER 992 (Fig. 1), about 1.5 myr old, which was recovered at Ileret and described simply as *Homo* of indeterminate species (Leakey 1972). Soon thereafter, Groves and Mazák (1975) jumped into the fray and made ER 992 the type specimen of a new species, *H. ergaster*. Although this innovation was disdainfully dismissed by the Koobi Fora team, and some other influential workers (Rightmire 1990) also continued to prefer the more comprehensive concept of *H. erectus*, this move finally opened the door to a reappraisal of the tradition of automatically assigning to *H. erectus* any and all African fossils with measured or assumed brain sizes in the general range of those noted above. In short, it became possible to entertain the notion that *H. erectus* is a terminal eastern Asian hominid species, and that hominid evolution throughout the Early and Middle Pleistocene continued in the pattern already established, with a vigorous exploration of the many different ways in which it was possible to be a hominid in the shifting and highly varied habitats of the Ice Age Old World. The next section, on "Cranial Morphologies in *Homo* of the Early to Middle Pleistocene," will examine the morphological evidence for diversity within the immediate group to which both *H. ergaster* and *H. erectus* belong.

Cranial Morphologies in *Homo* of the Early to Middle Pleistocene

General Considerations

Nobody doubts that the *H. erectus*/*H. ergaster* group represents a relatively cohesive subset of the family Hominidae. The question, clearly, is whether in this group of fossils we are looking at a radiation of species or at a single hugely variable species that may or may not have evolved directionally over the entire expanse of time (about 1.9–1.8 to 0.03 myr) and space (virtually the entire habitable Old World) it occupied. The distinction here is an important one, for species (even if not greatly differentiated morphologically from their closest relatives) are historically individuated entities which can compete with one another for ecological space and become extinct, whereas within species even demes that are significantly differentiated morphologically remain ephemeral entities that can disappear simply by absorption into ongoing conspecific populations. The twin processes of speciation and genetic/morphological differentiation are not linked, so that speciation may take place in the absence of significant morphological divergence, while the latter can occur without speciation intervening. This, of course, often makes unequivocal species recognition difficult in fossil assemblages (Tattersall 1986). However, it seems generally to be the case among living primates that, where substantial osteological differences are present among populations, those populations tend to act in nature as distinct species (i.e., as effectively independent reproductive entities). If we apply this criterion very conservatively to species recognition in the fossil record, demanding that the fossil species we recognize consistently bear distinctive osteological differences from related forms, we will probably underestimate the number of species in that record. However, we will not distort its overall pattern (Tattersall 1986, 1992). It is important to bear in mind that not all "morphs" (distinctive morphological entities) that we recognize in the fossil record will necessarily correspond to species in the reproductive sense; but it is equally evident that, given the nature of the fossil record, morphology must be the starting point in our analyses of it. After all, neither geological age nor geographical provenance, the other two attributes of any fossil, is *necessarily* linked to species identity, while its morphology is the only feature that makes a fossil species recognizable at all. It is in this spirit that the remainder of this survey is offered, with the proviso that we will clearly not learn much that is useful about the pattern of events in hominid evolution during the Pleistocene if we do nothing more than replace the term "African *Homo erectus*" with the equally sweeping *H. ergaster*.

Eastern Asia

Given the established conventions of nomenclature and systematics, when we begin to consider the mass of material that has at one time or another been allocated to *H. erectus*/*H. ergaster* we must necessarily begin with Dubois's holotype material

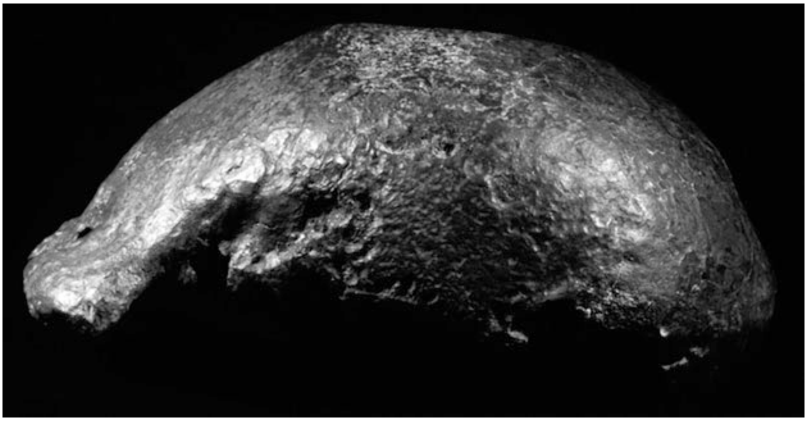

Fig. 2 Lateral view of the Trinil holotype calotte of *H. erectus* (Photo courtesy of © Jeffrey H. Schwartz)

(Fig. 2) from Trinil in Java (Schwartz and Tattersall 2003, 2005). It is the morphology of the Trinil skullcap that defines the species *H. erectus*, and the allocation of other fossils to this named entity must be done on the basis of their morphological similarities to it. The problem lies, of course, in deciding just how close those similarities should be, and it has to be admitted that there is no quantifiable answer to this question.

The Trinil 2 holotype is highly derived among hominids in a number of characteristics, especially of the brow region and the rear of the skull (Schwartz and Tattersall 2000, 2005). It is a smallish, long, thin-boned calotte with a narrow, shelflike, and laterally flaring postorbital region that flows onto the long, gently sloping, and flattish frontal plane with an almost imperceptible midline keel defined by shallow depressions bilaterally. The lateral walls of the low braincase are short and are markedly tilted inwardly above faint, low-set temporal lines; and the rather acute nuchal angle is distended posteriorly into a well-defined horizontal torus. Although the hominid sample from the adjacent Sangiran region is quite variable, especially in robusticity, the basic Trinil braincase morphology is repeated in most of the crania, the major exception being the quite complete if somewhat distorted cranium Sangiran 17 (Fig. 3). The Sangiran sample of upper and lower dentitions is also heterogeneous, suggesting that a second hominid morph may be present in addition to the Trinil one.

The two (now three) crania known from the Sambungmacan region, to the northeast of Sangiran, are substantially younger than the Trinil/Sangiran assemblage and share a contrasting brow structure in which the quite horizontal supraorbital tori thicken laterally and appear to be continuous across glabella. The braincase itself has the appearance of being rather better inflated than typical of the Trinil form (the two published brain volumes are 1,035 and 917 ml), and the coronal profile is tent-shaped rather than having a squat and rounded outline. The nuchal plane undercuts the occiput to produce a horizontal torus that is well defined

Fig. 3 Lateral views of crania from Africa and Eurasia in the "*Homo erectus*/*Homo ergaster*" group. *Left column*, *top* to *bottom*: Sangiran S17; Koobi Fora KNM-ER 3733; Koobi Fora KNM-ER 3732; West Turkana KNM-WT 15000; Dmanisi D 2282. *Right column*, *top* to *bottom*: Zhoukoudian cranial reconstruction (Sawyer and Tattersall version); Koobi Fora KNM-ER 3883; Olduvai OH 9; Koobi Fora KNM-ER 1813 (scale = 1 cm) (From Schwartz and Tattersall (2005). below, but has much poorer definition above. Together these specimens, along with another calvaria from Ngawi (870 ml), produce a morph that generally resembles the Trinil type but is readily distinguishable from it. The Ngandong crania are similarly distinctive. Larger and more robust than the others, with endocranial volumes that range from 1,015 to 1,250 ml, they differ from the Trinil form in the ways in which the Sambungmacan ones do. However, in addition they present yet more capacious braincases that have more or less vertical side walls with quite aggressively raised temporal lines; and they show a greater rearward projection than the Sambungmacan forms do of the occipital torus, a feature with a well-defined superior border. Nonetheless, this entire group is united, in particular, by a set of derived supraorbital and nuchal morphologies, and it presents itself as a relatively cohesive whole. Clearly, these Javan forms are part of the same eastern Asian hominid clade and, if it is not divided up (basically, at this point, a matter of taste), it is this assemblage that must provide the core identity of the species *H. erectus*.

The hominid fossils from Locality 1 of Zhoukoudian, in China (Fig. 3), have generally been considered classic exemplars of *H. erectus*. But it is still worthwhile noting that as a group they do differ fairly markedly from the Trinil type material, though mostly in ways that recall the Sambungmacan/Ngandong series. The crania from this site (with brain volumes ranging from 850 to 1,140 ml) are most distinctive in their supraorbital morphology, with a low-set glabella, supraorbital tori having a strong vertical component, and a continuous posttoral sulcus. In addition, there are marked dental differences between the Zhoukoudian and Sangiran samples (Schwartz and Tattersall 2005). Chinese specimens closely resembling the Peking Man materials include the Nanjing crania (Lü and the Tangshan Archaeological Team 1996). Other materials sometimes associated with them, such as those from Lantian, Hexian, Yunxian, and Longgupo, show a variety of differences both from Zhoukoudian and among themselves. These differences are discussed by Schwartz and Tattersall (2005) and Tattersall and Schwartz (2009).

Africa

As already noted, at one time or another many African fossils in the 1- to 2-myr time range have been referred to the species *H. erectus*. Among them, the classic exemplars are fossils from the Turkana Basin of northern Kenya, notable among these being the cranium KNM-ER 3733 and the calvaria ER 3883 from sediments at Koobi Fora to the east of Lake Turkana, and the fairly complete skeleton KNM-WT 15000 from deposits to its west at Nariokotome. The mandible KNM-ER 992, initially allocated simply to *Homo* sp., comes from Ileret, to the north of Koobi Fora. All the specimens concerned date within the 1.9- to 1.5-myr range. The widely used term "African *Homo erectus*" was a convenient designation for these fossils and a host of others, but it disguises the fact that a substantial variety of morphologies is involved.

Fig. 4 Occlusal views of mandibles. *Top left*: left side of Koobi Fora KNM-ER 992. *Top right*: Koobi Fora KNM-ER 3734. *Middle left*: Olduvai OH 22; *Middle right*: left side of West Turkana KNM-WT 15000. *Bottom*: left side of Dmanisi D 211 (scale = 1 cm) (From Schwartz and Tattersall (2005). This reality was first acknowledged in 1975 by Groves and Mazák who, as noted, made the ER 992 mandible (Figs. 1 and 4), the holotype of the new species *H. ergaster* ("work man"). Subsequently, many authors have begun to use the new name in place of "African *Homo erectus*," to the extent that it is now *H. ergaster* that is the standard-issue *Homo* of the 2- to 1-myr period. Still, all this change has achieved is to remove the assortment of Asian morphologies from the African equation, and it does nothing to address the morphological variety found within the continent in this period. In coming to grips with this, the best place to start is with the iconic example, the KNM-ER 3733 cranium (Fig. 3), which has an endocranial capacity of 848 ml. In this individual, the supraorbitals arc separately over each orbit and project forward as well as upward. There is thus a distinct posttoral sulcus in front of the quite steep frontal rise, which rapidly peaks before the profile descends more gradually rearward. Seen from behind, the braincase is rather tall compared to its breadth, and its side walls are curving. The raised temporal lines start quite far medially. It is unsurprising that these characteristics distinguish this specimen sharply from any Asian *Homo*; more remarkable are its differences from the ER 3883 cranium (Fig. 3), which has an endocranial volume of 804 ml. This individual has very thickened supraorbital margins that protrude outward but slightly down, overhanging nasion and the (mostly missing) face beneath. Further, in this specimen the frontal slopes strongly up and back, reaching its maximum height rather far back. Unlike in ER 3733, the mastoid is large and protruding, and in what is preserved of the face the zygoma flares outward from top to bottom. That this morphology is no freak is shown by its close repetition in preserved features of the ER 3732 partial cranium (Fig. 3).

Interestingly, all the specimens just mentioned are distinctly different from the skull of the KNM-WT 15000 skeleton (Fig. 3), exhaustively described in the monograph edited by Alan Walker and Richard Leakey (1993). This 1.6-myr-old skeleton is remarkable both for its degree of completeness and for being the earliest good evidence we have in the human fossil record of the arrival of essentially modern stature and postcranial proportions. Frustratingly, we cannot yet be certain that this was the case for the possessors of the ER 3733 and ER 3883 crania. The adolescent WT 15000 individual died at about 8 years of age, but was at a stage of development approximating that of a modern 12-year-old. This presumed male stood about 160 cm tall, but had he survived to adulthood, it is estimated that he would have topped 180 cm. He was long limbed and slender, with efficient heat-shedding proportions that would have served him well in the heat of the open tropical savanna. In contrast to the relatively long crania just described, the braincase of WT 15000, with a capacity of about 900 ml, was quite short and had a well-rounded profile. To the extent that it is possible to judge, the badly damaged supraorbital surfaces amounted to little more than substantial thickenings of the superior orbital margins, lacking either the aggressive projection seen in ER 3733 or the vertical thickening noted in ER 3883. The structure of the face contrasts with that seen in both ER 3733 and ER 3883; it is longer and narrower, with much more alveolar prognathism, a higher and narrower nasal aperture, and preserved portions of the nasal bones that suggest a flatter profile of the upper face. It is often claimed that these differences from the East Turkana specimens are due to the subadult status of WT 15000, but this appears rather dubious since differences of this kind would, if anything, probably have become more marked with age.

Cranial differences are backed up by dental comparisons to the extent that these are possible. ER 3883 has no associated teeth, and ER 3733 has only one, an M^2. But this tooth, though unfortunately quite heavily worn, is nonetheless distinctly different from its counterpart in WT 15000. The M^2 of ER 3733 has smooth enamel and well-defined trigon cusps, with the paracone much larger than the metacone. The hypocone is distally placed, the cristae are sharp, and both basins are well excavated. In WT 15000, in contrast, the M^2s are high-crowned, with fairly flat but wrinkled occlusal surfaces. The cusps of the trigon are subequal in size, and the basins are quite shallow. In both ER 3733 and WT 15000, the M^2s contrast with their homologues in the best-preserved upper dentition from Java, the Sangiran

4 palate, in which there are low cusps, a massive hypocone, and a very large postprotocrista that is not a feature of either African specimen.

The ER 992 type specimen of *H. ergaster* is a lower jaw, so comparisons to ER 3733 and ER 3883 are not possible. However, uniquely, the WT 15000 skull has a definitively associated lower jaw (Fig. 4), allowing direct comparison to ER 992. When this comparison is made, clear differences become apparent. In ER 992 (Fig. 4), the lower canines are quite high and are compressed buccolingually. In the anterior lower premolar, there are distinct anterior and posterior foveae, and the protoconid is the clearly dominant cusp. In the posterior premolar the protoconid and metaconid are subequal, and the basins are shallow. The elongated lower molars bear rounded and protruding hypoconulids, their basins are shallow, and their enamel is wrinkled. In contrast, the lower canines of WT 15000 are short crowned, with distinct mesial and distal foveae that bound a strong lingual pillar that swells out the tooth at its base. Both premolars have deep mesial and distal basins. The first molar is distended mesially, and both erupted molars have large and lingually placed hypoconulids and narrow but deep talonid basins that are surrounded by well-defined but rather bulbous cusps. Here, again, we have two distinctly different lower dental morphologies, both of which also differ from their homologues known from Sangiran. Morphologically, at least, the lower dentitions of ER 992 and WT 15000 are not “the same thing,” and both are at variance with Javan *H. erectus* (Schwartz and Tattersall 2000, 2005).

Interestingly, the 1.5-myr-old ER 992 from Ileret makes a fairly good match for the mandible OH 22 (Fig. 4) from Olduvai Gorge in Tanzania, as well as for its rather older (1.9 myr) neighbor ER 3734 (Fig. 4) from Koobi Fora. As for WT 15000, its lower teeth compare quite closely with those of OH 13, one of the paratypes of *H. habilis* from Bed II of Olduvai Gorge, and of similar age. Both show mesially tapering premolars, with small metaconids lying opposite the protoconids, and smaller foveae in front of these cusps than behind. The degree of wear on the molars is very different, but both show an oblique groove that runs between the hypoconulid and hypoconid to the base of the metaconid; and in both the hypoconid lies buccally and the M_1s taper slightly distally, while the M_2s are more broadly rounded at the rear. In the cranium and upper dentition, WT 15000 shows substantial similarities with the East Turkana cranium ER 1813 (Fig. 3). Although the latter boasts a substantially smaller intracranial volume of 510 ml, both specimens share a short, high cranial vault (rather like that of OH 13) with rounded brows that arc over each orbit and a frontal that rises behind a very short posttoral plane. In both the nasal apertures are tall, are relatively narrow, and taper strongly upward, while the nasoalveolar clivuses are long and slope forward.

Even more telling are upper dental similarities among WT 15000, ER 1813, and OH 13. All have a high-crowned but flat-surfaced M^1, with the mesiodistally long hypocone as high as the protocone, and separated from it by a lingual notch. In all, the M^2s are basically similar to the M^1s, but show reduction of the metacone and a smaller notch between the hypocone and protocone. In all, M^1 and M^2 both have thick postcingula. In WT 15000 and ER 1813, the P^2s are very similar in having a bulbous and centrally placed paracone and a continuous crista running mesially from the paracone and swinging right around the side of the tooth. Further, although it has a very worn dentition, the recently described palate OH 62 seems to present an upper dental morphology similar to those of the three specimens just described. In sum, the evidence seems to be quite compelling for the existence of an upper dental morph, most spectacularly represented by the fairly complete individual WT 15000, that is found almost a thousand kilometers away at Olduvai as well as around Lake Turkana at Koobi Fora and Nariokotome. The available name for this morph, should anyone wish to designate it a species, is *H. microcranous* (Ferguson 1995).

Other "African *Homo erectus*" specimens include the 1.4-myr-old OH 9 calvaria (Fig. 3: 967 ml) from Olduvai Gorge, but it does not compare any better to the material from eastern Asia than it does to the Turkana fossils; and though it has been compared to the purportedly *H. erectus* Daka cranium from Ethiopia (~1.0 myr, 995 ml; Asfaw et al. 2002), resemblances between the two, other than in endocranial volume and its correlates, are not particularly striking (Schwartz and Tattersall 2005). In sum, there is considerable morphological diversity among African *Homo* of the 2.0- to 1.0-myr period; and this diversity does seem to be organized into a number of distinctive morphs. Some of these are represented by individual fossils such as OH 9 that are clear outliers in terms of other known material; others seem to be represented by multiple individuals and even at multiple sites. Definitive systematic organization of this variety will clearly have to await a more comprehensive fossil record, but it is already evident that we are not looking here at a chronological transformation series, even one that is represented by high diversity at all time points. Somewhere in all of this there is a systematic signal, and it is evident that the blanket appellation *H. ergaster*, while a useful device for distinguishing the African hominid radiation of this period from the Asian one, is an inadequate expedient for describing diversity in the African record.

Some paleoanthropologists are beginning implicitly to recognize this, but apparently without wishing to abandon old paradigms. Thus Spoor et al. (2007) reported new fossils from East Turkana that they concluded were evidence for two contemporaneous lineages of *Homo* in the Turkana Basin at around 1.5 million years ago. One of these was the calvaria KNM-ER 42700. Spoor and colleagues cited a handful of trivial features that they claimed allied this specimen with *Homo erectus*; but in reality it bears none of the classic hallmarks of that species such as the long, low, posteriorly sharply angled lateral profile, the shelflike and protruding supraorbital surfaces, and the ovoid posterior profile. Indeed, in these diagnostic features the Turkana specimen is the very antithesis of the Javan type specimen. In contrast, the partial maxilla KNM-ER 42703, though hardly comparable to the calvaria, was considered to represent another lineage and was allocated to the exceedingly poorly defined species *Homo habilis*. Whether or not that species assignment is appropriate, or even means anything at all, the allocation of ER 42700 to *Homo erectus* is extremely telling. For while Spoor and colleagues evidently accept diversity among 1.5-myr-old hominids at Turkana, the assignment of the calvaria to *Homo erectus* only makes any sense at all in the context of the notion that *Homo erectus* is the middle "grade" of a single comprehensive, worldwide, variable, and gradually evolving *Homo* lineage.

Europe

It is now fairly widely accepted that most of the western European forms that have at one time or another been described as *H. erectus* (see above) are better allocated to *H. heidelbergensis*, a move that takes these fossils out of the scope of the current discussion. And while some still view the Italian Ceprano calvaria (ca. 800–900 kyr; 1,165 ml), recently designated the holotype of *H. cepranensis* by Mallegni et al. (2003), as a representative of *H. erectus*, nobody has claimed that it represents *H. ergaster*. Indeed, Mounier et al. (2011) have suggested that it is a primitive *Homo heidelbergensis*.

To the east, however, in the Caucasus at the Georgian site of Dmanisi (1.8 myr), there exists a very important and early hominid fossil assemblage with claimed African affinities (Figs. 3, 4, 5, 6, and 7). The first find, the mandible D 211 (Fig. 4) discovered in 1991, was assigned by its describers to "archaic African *Homo erectus*" (Gabunia and Vekua 1995). It was more generally attributed to

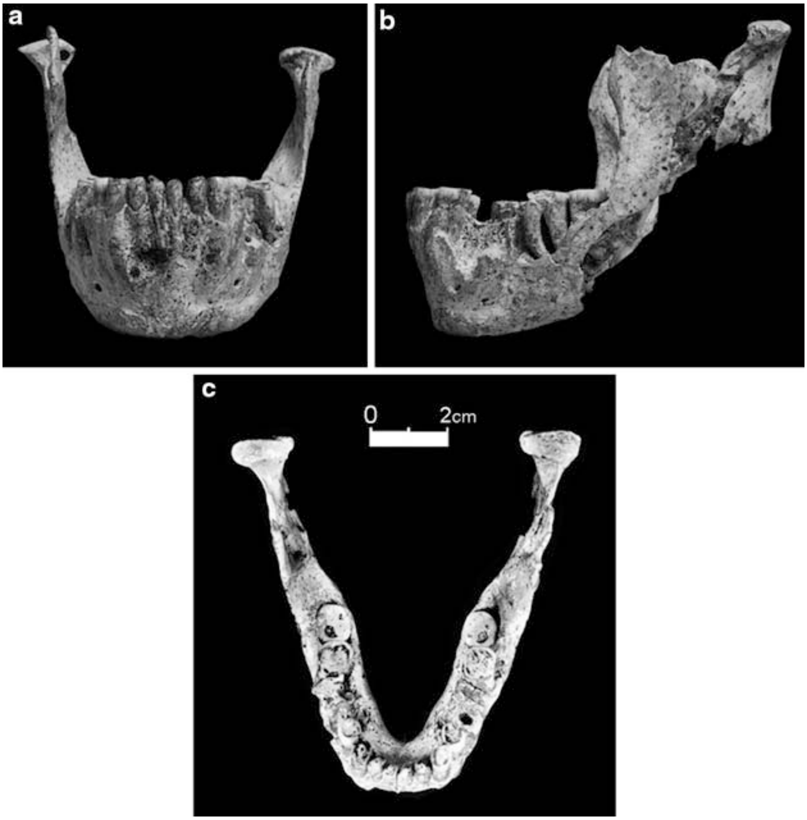

Fig. 5 The D 2600 mandible from Dmanisi. (**a**) Front view, (**b**) left lateral, and (**c**) occlusal (Photos courtesy of David Lordkipanidze)

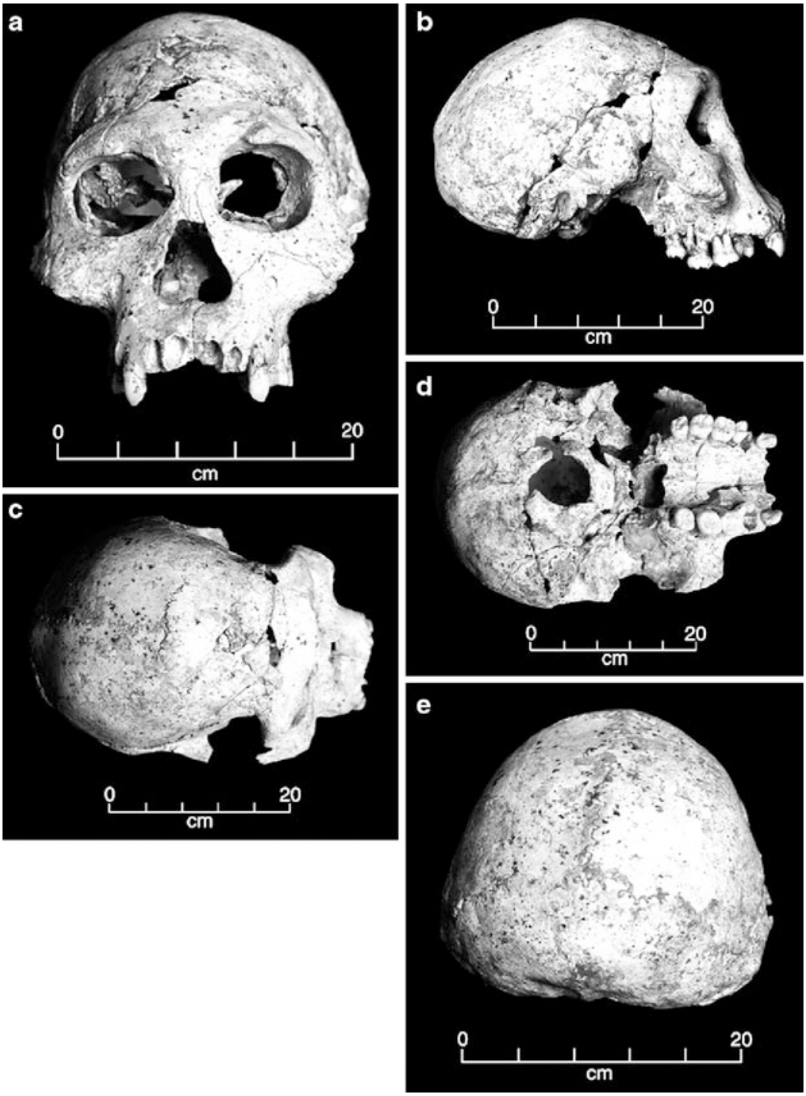

Fig. 6 Five views of the D 2700 cranium from Dmanisi (From Vekua et al. (2002), supplemental web data; Photos courtesy of David Lordkipanidze)

H. erectus by Henke (1995) and also by Bräuer and Schultz (1996), although these latter authors remarked that, oddly, this early mandible showed "progressive" features seen in geologically younger *H. erectus*. These early differences in interpretation foreshadowed a fairly wild taxonomic ride. Gabunia et al. (2000) reported the discovery of two crania (D 2280 and 2282; Fig. 3) close to the original site; they considered these comparable in size and morphology to Koobi Fora *H. ergaster*, although cranial volumes were somewhat smaller: 780 and 650 ml, respectively.

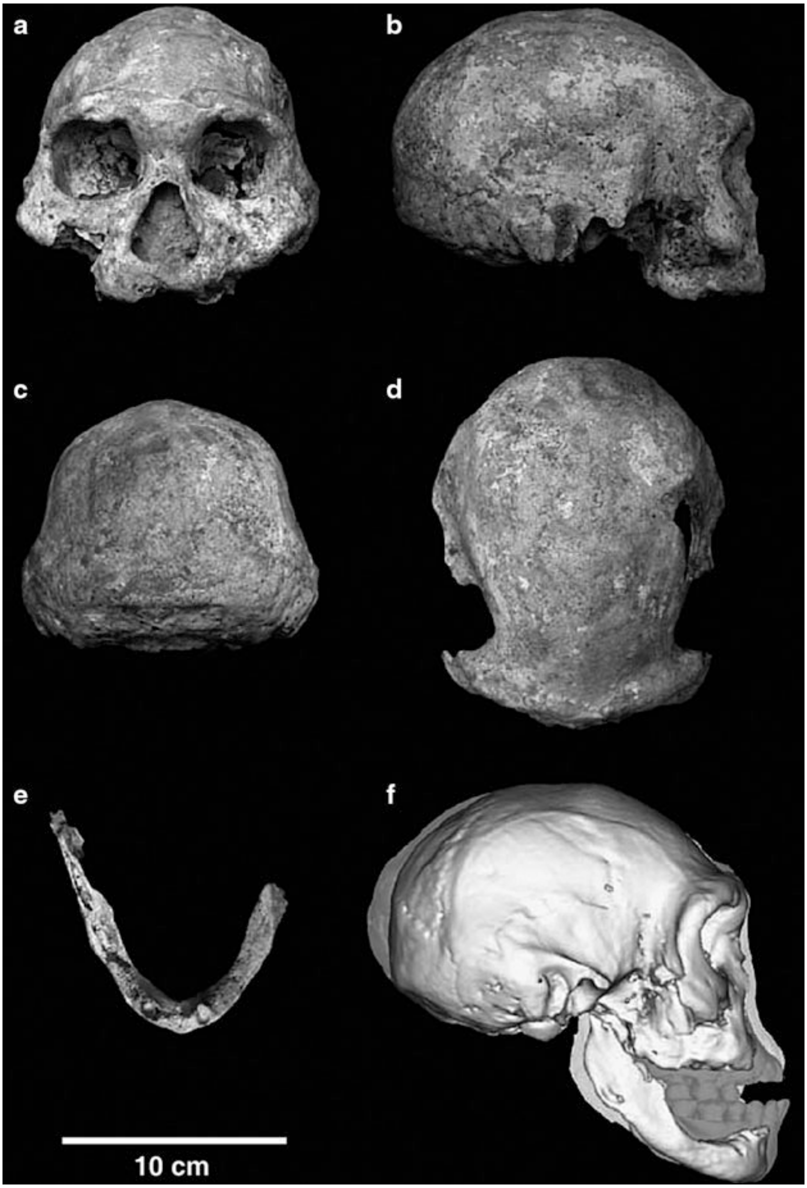

Fig. 7 The edentulous D 3444 cranium from Dmanisi. *Lower left*: mandible D 3900. *Lower right*: CT-based superimpositions by C. Zollikofer and M. Ponce de León of the Dmanisi skull D 3444/D 3900 on the D 2700/D 2735 and D 2282/D 211 specimens, to show contrasting silhouettes (From Lordkipanidze et al. (2005). Photos courtesy of David Lordkipanidze. Scale: 10 cm)

With the discovery in September 2000 of a very large and long mandible with highly worn teeth (D 2600; Fig. 5), the picture changed again. This mandible presented a marked contrast to D 211, but the Dmanisi team nonetheless concluded that all of the specimens belonged to a single highly sexually dimorphic species which they named *H. georgicus*, with D 2600 as its holotype (Gabounia et al. 2002). The gracile specimens D 211, D 2280, and D 2282 were considered to be female; and the robust D 2600 lower jaw was viewed as a male representative of this species. The group concluded that *H. georgicus* "preserves several affinities with *Homo habilis* and *Homo rudolfensis* … foretelling the emergence of *Homo ergaster*" (Gabounia et al. 2002, p. 245). But things did not stop there. Almost simultaneously, the team announced the discovery of an associated cranium and mandible, D 2700/D 2735 (Vekua et al. 2002; Fig. 6). Strikingly different from the crania discovered earlier, though also notably small-brained (600 ml), this excellently preserved specimen was said by its describers to bear resemblances to penecontemporaneous East African fossils. Abandoning the species *H. georgicus*, as well as the notion of *H. ergaster* as a separate entity, the Dmanisi team allocated D 2700/D 2735, and the rest of the hominid assemblage along with it, to *H. erectus*, while noting that they "are among the most primitive individuals so far attributed" to that expanded species (Vekua et al. 2002, p. 88).

During the 2002/2004 field seasons yet another associated cranium and mandible (D 3444/D 3900) were recovered at Dmanisi. The most remarkable aspect of this aged presumed male (Fig. 7) is that he had possessed just a single tooth at death and had evidently been largely edentulous for many years (Lordkipanidze et al. 2005). Although at least one recent chimpanzee is known to have survived a long time in an edentulous state, the Dmanisi team surmised that the individual must have "survived for a lengthy period without consuming foods that required heavy chewing … and/or by virtue of help from other individuals" (Lordkipanidze et al. 2005, p. 718), and suggested that this had significant implications for early hominid social structure. They also noted that the cranium had been found in close proximity to Mode 1 stone artifacts and to cut-marked animal bones. The authors refrained from commenting on the systematic implications of the new find; but in a review published soon afterward, Rightmire et al. (2006) reaffirmed their belief that the Dmanisi assemblage as a whole was a single "paleodeme" best placed within *H. erectus* (which to them subsumed *H. ergaster*), despite resemblances to *H. habilis* in brain volume and in some aspects of craniofacial morphology. Yet while they (Rightmire et al. 2006, p. 140) noted that, if the large D 2600 mandible could be accommodated within the rest of the Dmanisi hominid population, then "the appropriate nomen is *H. erectus georgicus*," they also pointed out that should the separate species status advocated by Gabounia et al. (2002) for the large jaw be "verified by new discoveries, then a subspecies other than *H. erectus georgicus* will have to be selected [for the remainder of the sample]."

The hoped-for new discovery, of the cranium matching the D 2600 jaw, was duly made at Dmanisi in 2005. Following a long agony of indecision, this complete and beautifully preserved specimen (D 4500) was finally published in 2013 (Lordkipanidze et al. 2013). The delay is quite understandable, for this fossil is quite unlike anything ever seen before. As one would have predicted from the large teeth and long tooth rows of the mandible, the new cranium possesses a large and highly prognathic face, which is hafted on to a remarkably small braincase with a volume of fractionally less than 550 ml. But while these attributes generally recall those of australopiths, Lordkipanidze and colleagues probably wisely refrained from associating their new specimen with any previously known early hominid taxon. Instead, they crammed it into *Homo erectus*, an assignment for which there is less than scant morphological justification. Declaring that the extraordinarily distinctive morphology of D 4500 "reflects variation between demes of a single evolving lineage" (Lordkipanidze et al. 2013, p. 330), the group concluded that "specimens previously attributed to *H. ergaster* are thus sensibly classified as a chronosubspecies, *H. erectus ergaster*" (Lordkipanidze et al. 2013, p. 330). And finally they took the astonishing step of reducing the entire Dmanisi hominid sample to the previously unknown status of a sub-subspecies, *Homo ergaster erectus georgicus*. If there is any substance whatever to this convoluted taxonomic judgment, systematists everywhere should be in mourning, because it effectively deprives morphology of any utility in systematics – and where are we left to go from there?

In any event, the contorted taxonomic journey of the Dmanisi hominids reflects the unusual morphologies that make it hard to fit them into established categories. And this journey is certainly not yet at an end. Even before the initial discovery of D 4500, Schwartz and Tattersall (2005) had already noted that the morphological heterogeneity in the Dmanisi assemblage made it difficult to recognize a single consistent morph at the site, irrespective of what this might have implied about species status. What is more, the lead geologist at Dmanisi, Reid Ferring (personal communication), reports that accumulation of the Dmanisi hominids might have taken place over the span of as much as a few hundred years. And if this is the case, there is no compelling reason (as there might be in the case of a catastrophic assemblage) to believe that only one hominid species is necessarily implicated in the fossil assemblage. Additionally, Schwartz and Tattersall observed that none of the Dmanisi material appeared to bear very close, i.e., systematically suggestive, resemblances either to any Asian fossils that had been described as *H. erectus* or to any African specimens allocated to *H. erectus* or to *H. ergaster*. Exactly how much systematic variety there is in this assemblage clearly awaits more study; but although the Dmanisi hominids most plausibly represent one or possibly more early departures from Africa hard on the heels of the origin of *Homo*, it is hard at present to point to craniodental morphologies that specifically unite them with any latest Pliocene or earliest Pleistocene African hominids yet known.

It is unknown with any certainty exactly what it was that allowed hominids to spread, for (presumably) the first time, out of the ancestral continent of Africa as far as Dmanisi. But since the Mode 1 stone tool assemblage at Dmanisi is remarkably primitive, and the brains of the hominid(s) there remained small, it seems most likely that the factor responsible was the acquisition of striding bipedality. As exemplified by WT 15000, this locomotor style was already present in *Homo ergaster*; and a partial postcranial skeleton from Dmanisi (putatively associated with the D 2700/D 2735) and postcranial bones from three other individuals are said to show “modern-human-like body proportions” (Lordkipanidze et al. 2007, p. 305). Still, the scientists who described these elements also noted a “surprising mosaic of primitive and derived features” (Lordkipanidze et al. 2007, p. 305); and it is clear that the last word on the Dmanisi postcranials–and indeed, on the assemblage as a whole–has yet to be written.

Conclusions

Homo ergaster is the designation of choice for the growing number of paleoanthropologists who believe that the fossils previously allocated to “African *Homo erectus*” are sufficiently different from the Asian type material of *H. erectus* to warrant assignment to a distinct species. Adoption of this nomenclature is a considerable improvement on our older understanding, certainly to the extent that it emphasizes that the Trinil fossil and others like it are quite highly autapomorphic and that Javan or at least eastern Asian *H. erectus* is thus most appropriately viewed as an indigenous and terminal regional species (or maybe even clade), rather than as an Old World-wide stage or grade in hominid evolution. Nonetheless, it remains true that to call the entire African rump of this Old World “*Homo erectus* grade” *H. ergaster*, is to brush a huge diversity of morphologies under the rug of one single species. Close examination of the morphologies displayed by the diversity of fossils that have at one time or another been referred to as “African *Homo erectus*” makes it evident that, while it is likely that all may be legitimately regarded as members of a single hominid clade, there is some diversity within it.

The KNM-ER 992 holotype mandible of *H. ergaster* appears to be matched morphologically by the OH 22 mandible from Olduvai as well as by another mandible (ER 3734) from Koobi Fora. But there seems to be no compelling reason to match these lower jaws with any of the cranial materials available, and certainly none to associate them with the iconic KNM-WT 15000 skeleton, the lower dentition of which is distinctly different in a whole host of characteristics. Clearly, there is a need for a detailed systematic reappraisal of the entire “African *Homo erectus*” = *Homo ergaster* group. Meanwhile, the recognition of a distinct *H. ergaster* clade at least serves to highlight the fact that the complexity of the hominid evolutionary story throughout the Old World in the Early–Middle Pleistocene was far greater than is implied by the inclusion of the entire group of fossils involved within the single hugely variable species *H. erectus*.

Defining *Homo erectus*

Karen L. Baab

Contents

Abstract

Pithecanthropus (now *Homo*) *erectus* was first recognized as a species by Eugène Dubois in the 1890s from fossils at the Indonesian site of Trinil. Additional finds from Indonesia and then China expanded the morphological, geographic, and temporal bounds of this species, but it was not until 1960 that *H. erectus* was recognized in Africa. Since that time, *H. erectus* has become among the best sampled species in human evolution and has also come to include fossils from Eurasia and possibly South Africa. These fossils are united by a shared neurocranial shape and the presence of a large number of discrete traits. Yet, there is considerable variation among and within fossil assemblages, which has been interpreted within the framework of a long-lived and polytypic species

by some, and as indicative of multiple species by others. This chapter reviews the morphological features of the skull that serve to define *H. erectus*, as well as the extent and implications of variation across the fossil hypodigm. Sometimes the smaller and less derived African and Georgian fossils have been assigned to a separate species, *H. ergaster*. Yet, geometric morphometric analysis indicates that the degree of cranial shape variation for the entire sample (including African, Georgian, Indonesian, and Chinese fossils) is within the range of many single primate species, and the variation between Indonesian and Chinese fossils is of the same magnitude as that between African/Georgian and Asian fossils. Therefore, the single-species model for *H. erectus* cannot be rejected on the basis of cranial shape. However, not every fossil assigned to this species is a perfect fit, and some of the most recent additions to *H. erectus* expand the range of variation in directions that are unexpected based on established patterns of intraspecific variation. The analysis of shape has further confirmed that much of the cranial shape variation present within the species is partitioned among circumscribed temporo-geographic groups. Additional work is necessary to better understand the utility of discrete traits for systematic research and their distribution in the expanded Pleistocene *Homo* fossil record.

Introduction

Fossils assigned to *Homo erectus sensu lato* (*s.l.*) (including fossils from Indonesia, China, Africa and Georgia; Antón 2003; Rightmire et al. 2006; Baab 2008b) retain a broadly homogeneous cranial and postcranial *Bauplan* across an impressive geographic and temporal range. Yet, variation within this hypodigm is evident at both the population and individual levels. Disagreement concerning how this variation is interpreted is at the heart of the long-standing debate regarding whether the *H. erectus s.l.* fossil hypodigm represents a single species or multiple species. This chapter first outlines the geographic and temporal range of *H. erectus s.l.* with a particular emphasis on the historical development of this debate concerning alpha taxonomy. The three main hypotheses concerning *H. erectus s.l.* alpha taxonomy (the multiregionalism, the single-species model, and the multiple-species model) are then described. This is followed by a discussion of cranial discrete characters and aspects of cranial shape that have figured prominently in species definitions for *H. erectus s.l.*. Both the magnitude of cranial variation and the spatiotemporal patterns of variation are discussed, and the attribution of recently described fossils to *H. erectus* is examined against this background of variation.

Survey of Fossils Assigned to *Homo erectus sensu lato*

Many historical and geochronological surveys of *H. erectus s.l.* exist in the literature (e.g., Rightmire 1990; Antón 2003). For this reason, this chapter will briefly summarize the geographic and temporal span of this species, broadly defined, with particular emphasis on those fossils that are especially well preserved (and therefore morphologically informative), have played a key role in taxonomic and phylogenetic hypotheses, or are recent discoveries that are likely to be less well known to the reader.

Homo erectus was first discovered by Eugène Dubois on the Indonesian island of Java, which subsequently became a source of many additional fossils usually assigned to this species. Many of the best-known *H. erectus* fossils derive from the sites of Trinil (including the type specimen, Trinil 2; Dubois 1894) and the Sangiran Dome (including the most complete cranium of Asian *H. erectus*, Sangiran 17). A series of lesser-known fossil calvaria and fragments of faces have also been recovered since the late 1970s from Sangiran Dome localities, including some of the oldest Indonesian fossils (Sangiran 27 and 31, Bpg 2001.04) (Jacob 1980; Sartono 1982; Indriati et al. 2008; Zaim et al. 2011) and the remarkably well-preserved Skull IX (Tjg-1993.05) calvarium (Arif 2005; Kaifu et al. 2011). The *H. erectus* fossils from these two sites range in age from more than 1.5 to ~1.0 Ma (Larick et al. 2001). Further east, the juvenile cranium from Modjokerto was recently confirmed to be from the Sangiran Formation (Huffman 2001; Huffman et al. 2005, 2006), which was dated at Sangiran to >1.5 Ma by Larick et al. (2001). The sites of Ngandong, Sambungmacan, and Ngawi together have yielded more than a dozen complete or partial calvaria, the most recent of which was discovered in 2001 (Sambungmacan 4), (Baba et al. 2003b). The dating of Ngandong has been controversial, and estimates have ranged from Early to Late Pleistocene. The very young ages of 35–50 ka for the Ngandong and Sambungmacan 1 locality (Swisher et al. 1994) appear to be inaccurate, and a more recent estimate for Ngandong is a Middle Pleistocene age of ~546 Ma (Indriati et al. 2011). The lack of provenance for the Sambungmacan and Ngawi fossils precludes accurate date estimates, but they are morphologically closer to Ngandong than to the Sangiran/Trinil series (Baab 2010). The geographic range of Indonesian *H. erectus* was recently expanded westward to the site of Cisanca where a single incisor was recovered (Kramer et al. 2005).

The most productive of the Chinese sites is the famous Zhoukoudian Cave, from which a series of well-preserved calvaria were recovered, mostly in the 1930s. The consensus during the 1980s was that hominin activity at Zhoukoudian Cave Locality 1 was from ~500 to 230 ka (Zhao et al. 1985). Recent estimates are older: analysis of radioactive ^{26}Al and ^{10}Be in the cave sediments indicated an age of ~770 ka for the oldest hominin fossil-bearing stratum (Shen et al. 2009), while the youngest fossil was probably 400–500 ka based on ^{230}Th/^{234}U dating of cave speleothems (Shen et al. 2001). Additional Chinese *H. erectus* fossil sites include Yiyuan, Nanjing (Tangshan), Hexian, Gongwangling (Lantian), Chenjiawo, Yunxian, and Yuanmou (Li and Mei 1983; Wu et al. 1989; An et al. 1990; Yan 1993; Chen et al. 1997; Grün et al. 1998; Zhao et al. 2001; Liu et al. 2002; Wang et al. 2002). Many of these sites appear to be of Middle Pleistocene age, although ages in excess of 0.9 Ma have been proposed for Yunxian (0.936 Ma; de Lumley et al. 2008), Gongwangling (~1.15–1.2 Ma; An and Ho 1989; An et al. 1990; Zhu et al. 2003), and Yuanmou (~1.7 Ma; Li et al. 1976; Qian and Zhou 1991;

Huang and Grün 1998; but see Hyodo et al. 2002; Zhu et al. 2003). Both the Yiyuan and Nanjing fossils bear strong similarities to the Zhoukoudian sample, but the Hexian cranium is distinct from this group (Lu et al. 1989; Etler 1996; Kidder and Durband 2004a; Liu et al. 2005). The Gongwangling and Yunxian cranial fossils suffered considerable postmortem damage, and while both are usually allied with *H. erectus*, the latter are sometimes grouped with later archaic *Homo* (Li and Etler 1992; Wu and Poirier 1995; Zhang 1998; Brown 2001).

Both cranial and postcranial fossils attributed to *H. erectus* have been recovered from East, South, and North Africa. Significant fossil discoveries from East Africa were made at Olduvai Gorge, including the robust OH 9 skull and the smaller OH 12, and in the Turkana Basin of Kenya, including the type specimen of *H. ergaster* (the mandible KNM-ER 992), two crania often assigned to *H. ergaster* (KNM-ER 3733, 3883), and the remarkably complete juvenile skeleton, KNM-WT 15000. Fossils from Olduvai Gorge and the Turkana Basin fall between 1.9 and 1.2–1.02 Ma (Feibel et al. 1989; Hay 1990; Brown and McDougall 1993; Tamrat et al. 1995). The oldest fossil assigned to *H. erectus* is a fragment of occipital bone (KNM-ER 2598) dated to 1.88–1.9 Ma (Feibel et al. 1989; but see White 1995) and attributed to *H. erectus* on the basis of the thickness of the bone and the presence of an occipital torus (Wood 1991). This time range overlaps the Indonesian time frame but also extends it further into the past. More recent East African discoveries include two small specimens, an older subadult from Ileret, Kenya (KNM-ER 42700), and a fragmentary calvarium from Olorgesailie, Kenya (KNM-OL 45500), dated to 1.5–1.6 and 0.90–0.97 Ma, respectively (Leakey et al. 2003; Potts et al. 2004). If correctly assigned, these extend the size range of *H. erectus* in Africa. Isolated postcrania are often referred to *H. erectus*, such as the KNM-ER 3228, OH 28, and BSN49 pelves from Kenya, Tanzania, and Ethiopia, respectively, but these attributions are hard to confirm. Two younger fossils from Bouri, Ethiopia (the Daka cranium), and Buia, Eritrea (the Buia cranium) span the time period of 0.8–1.0 Ma and exhibit more derived traits than other African *H. erectus*. In fact, doubts have been raised about the inclusion of Buia in *H. erectus* (Antón 2003). A pelvis recovered from Gona, Ethiopia, dated to 1.4–0.9 Ma has been assigned to *H. erectus*, and the SK 847 (~1.7 Ma; Brain 1993) partial cranium from South Africa is also sometimes assigned to this species (originally *Telanthropus capensis*).

A series of sites in Middle Pleistocene North Africa, Tighinif (Ternifine), Salé, Thomas Quarries, and Sidi Abderrahman, have yielded mandibular and cranial fossils sometimes assigned to *H. erectus*. The Tighenif fossils were initially assigned to *Atlanthropus mauritanicus* (Arambourg 1954) but later to *H. erectus*. However, these fossils are now more often attributed to later *Homo*. Other African fossils previously assigned to *H. erectus*, including Salé, Ndutu, Bodo, and Kabwe (Broken Hill), are now considered part of the *H. heidelbergensis* hypodigm (sensu Rightmire 1998b; 2008; 2013).

Five crania, some associated with mandibles, and many postcranial elements have been recovered at the Eurasian site of Dmanisi, Georgia, from 1.77 Ma deposits (Gabunia et al. 2000; Simpson et al. 2008), but artifacts have been found in deposits as old as 1.85 Ma (Ferring et al. 2011). A combination of *H. erectus*-like traits as well as plesiomorphic features more often observed in earlier taxa like *H. habilis* led some to classify these fossils as *H. erectus* (e.g., Rightmire et al. 2006), but others to create a new taxon, *H. georgicus* (Gabounia et al. 2002; de Lumley et al. 2006). A partial calotte from Kocabaş, Turkey, was recently assigned to *H. erectus*, mostly on the basis of its frontal bone anatomy (Kappelman et al. 2008; but see Stringer 2012). Additional European fossils previously considered to be *H. erectus* are now more commonly assigned to later *Homo* taxa: Ceprano, Petralona, Arago, Bilzingsleben, and Vértesszöllös.

Homo erectus sensu lato Alpha Taxonomy

A Historical Overview

The early discoveries of *H. erectus* in Asia initially included several distinct genera: *Pithecanthropus*, *Meganthropus*, and *Sinanthropus*, many of which included multiple species. This early plurality was followed by compression of these taxa into fewer, more inclusive taxa. For example, von Koenigswald and Weidenreich (1939, p. 928) concluded that the remains from Java (specifically Trinil, Sangiran, and Kedung Brubus) and China (Zhoukoudian) "were related to each other in the same way as two different races of present mankind" and Weidenreich (1940) included them as subspecies within *H. erectus*. Similarly, Mayr (1950) sunk both *Pithecanthropus* and *Sinanthropus* into *H. erectus* in his highly influential 1950 publication. Similar concatenations occurred with the South and North African material. *Telanthropus capensis* was first moved into *Pithecanthropus capensis* (Simonetta 1957) and then *H. erectus* (Robinson 1961). *Atlanthropus mauritanicus* was sunk into *H. erectus* as early as 1964. Leakey, Walker, and colleagues assigned African fossils from Olduvai Gorge and the Turkana Basin to *H. erectus* throughout the 1960s–1980s (Leakey 1961, 1976; Walker and Leakey 1978; Brown et al. 1985; Leakey and Walker 1985). Detailed morphological analysis led Santa Luca (1980) to conclude that the fossil assemblage from Ngandong (originally *Javanthropus soloensis*) should be subsumed within the *H. erectus* species. Therefore, by the mid-1980s *H. erectus s.l.* was a broadly configured species that included representatives as old as 1.9 Ma and as young as 0.5 or 0.4 Ma and occupying sites as far south as South Africa and as far east as Indonesia and China. Additional fossils from these major regions have been added subsequently, and the geographic range was expanded with the addition to *H. erectus s.l.* of the fossils from Dmanisi and possibly Turkey. A small minority of workers have gone even further, moving all of these *H. erectus s.l.* specimens into *H. sapiens*, which would also include mid-Pleistocene *Homo* fossils and early and recent modern humans, and a recent study questioned whether early *Homo* species might also be subsumed within *H. erectus* (Lordkipanidze et al. 2013). However, many workers have continued to recognize a multiplicity of species and even genera for the same fossil sample.

Systematics Controversy

This debate is not simply a matter of semantics as alpha taxonomies provide the raw material for analyses of species diversity and rates of diversification, and influence views of intraspecific, including sexual, variation. The widespread disagreement regarding Pliocene–Pleistocene *Homo* systematics is related to many factors, including fundamental differences in how species are defined theoretically and operationally and the underlying phylogenetic scenarios to which they are inextricably linked (e.g., compare Tattersall 1986; Wolpoff et al. 1994). Evolutionary/taxonomic scenarios range from the well-known regional continuity model at one extreme to the "bushy tree" model at the other. Most workers adhere to one of two intermediate positions, which correspond to a single, polytypic species model or a two-species model. Each will be described briefly below, followed by a discussion of how morphology is interpreted under these different models.

Weidenreich (1943, 1951) argued for a more or less unilinear view of hominin evolution which recognized successive evolutionary stages or grades, defined morphologically by shared set of features. He further viewed "racial" or geographic groups of modern humans as having their roots in the archaic taxa that preceded them in those same regions. Weidenreich's early application of multiple genus and species names represented a convenient way to refer to different samples of fossils rather than a formal taxonomy that reflected his phylogenetic hypothesis (Mayr 1950). This is particularly clear in his 1951 monograph on the Ngandong fossils where he states:

> As to nomenclature, in general, I believe that all the hominids now known belong morphologically to a single species, and therefore I regard subdivisions expressed in terms of fixed taxonomy as a matter of secondary concern. (Weidenreich 1951, p. 226)

More recent standard bearers for this multiregional evolutionary scenario still adhere to a gradistic view of human evolution but place more emphasis on gene flow among regions (Thorne and Wolpoff 1981; Wolpoff et al. 1984, 1994; Hawks et al. 2000). The gradual nature of morphological transitions among grades has led to the proposal that fossils traditionally assigned to *H. erectus s.l.* should instead be subsumed into a single evolving *H. sapiens* species (Jelínek 1982; Wolpoff 1984; Wolpoff et al. 1984, 1994; Curnoe 2006).

A contrasting perspective is that *H. erectus* is a "real" species (including all or nearly all of the fossils described above) that is morphologically distinct from other species (Howell 1978; Howells 1980; Rightmire 1984, 1986, 1990, 1998a, 2006; Harrison 1993; Antón 2003; Baab 2008b). In this context, *H. erectus* is morphologically differentiable from both early *Homo* (Rightmire et al. 2006) and later *Homo* (Rightmire 2013). Under the single-species model, variation is viewed as the norm for a widespread polytypic species. In the words of Rightmire (1998b, p. 220):

> . . .it is interesting that the Asian populations apparently are more specialized in the sense of exhibiting a higher incidence of some morphological characters associated with cranial robusticity. These traits are subject to geographic variation and do not mark a species boundary, but they may nevertheless delimit groups that had different evolutionary fates.

Antón (2003), adopting Jolly's (2001) suggestion, proposed that anatomically distinct geographic variants be viewed as parapatric allotaxa – neighboring populations that are at once in possession of the same basic anatomy and able to hybridize, yet distinguishable from one another. Phylogenetically, Rightmire (1998b) proposed that some populations of *H. erectus* in Africa or western Asia were ancestral to later *Homo* species, a speciation event that occurred by the Early Pleistocene. Other populations, particularly in eastern Asia, survived until more recently but eventually went extinct and were replaced by dispersals of more derived species.

The rise of cladistic thinking in anthropology encouraged a focus on autapomorphies in species definitions (Andrews 1984; Stringer 1984; Wood 1984, 1991; Tattersall 1986; Groves 1989). The higher frequency of autapomorphic traits in the Asian fossils, such as thicker cranial bones, midline and coronal keeling, an angular torus, and a fissure between the mastoid process and the petrosal crest of the tympanic, provided the basis of a species definition for *H. erectus sensu stricto* (*s. str.*) that excluded either all African fossils (Andrews 1984; Stringer 1984) or at least the Koobi Fora portion of the African record (Wood 1984, 1991, 1994) (Note that the African record at that time did not yet include fossils such as KNM-ER 42700, KNM-OL 45500, and Daka.). Moreover, synapomorphies were identified in the Koobi Fora remains and *H. sapiens* that were lacking in *H. erectus* (Wood 1992). This distribution of autapomorphies and synapomorphies suggested the following phylogenetic scenario to Andrews (1984, p. 172):

> . . .my provisional interpretation of the evidence would be that the African skulls formerly attributed to *erectus* would have been close to the line leading to *sapiens* and that the Asian *erectus* was some way removed from this lineage.

Hence, *H. ergaster* was embraced as a species comprised Pliocene–Early Pleistocene African fossils possibly ancestral to both a lineage of more derived *Homo* (*H. heidelbergensis s.l.*) and to *H. erectus s. str.*, itself an evolutionary dead end.

Even more speciose taxonomies assume a greater number of cladogenic events. For example, a three-species model comprised *H. erectus s. str.*, *H. ergaster*, and *H. georgicus* is premised on the latter having diverged from early *Homo* prior to the emergence of *H. ergaster* (Gabounia et al. 2002; de Lumley et al. 2006; Martinón-Torres et al. 2008). The relationships among these three species, however, remain unclear. Other researchers embrace an even bushier tree during this time period, arguing that closely related species are often hard to distinguish on the basis of hard tissue anatomy alone, and therefore diagnosable units in the fossil record most likely represent distinct species (Tattersall 1986, 1992). Tattersall and Schwartz have identified many "morphs," which Tattersall (1992, p. 345) has previously equated with "at the very least. . .genetically disjunct species," even within single sites and restricted time periods (e.g., Koobi Fora, Schwartz and Tattersall 2003; Dmanisi, Schwartz and Tattersall 2005). However, true species diagnoses and nomenclature are lacking, and a phylogenetic hypothesis linking these taxa together has not yet been articulated.

Defining *Homo erectus sensu lato*

The morphological definition of *H. erectus s.l.* offered below is a combination definition (sensu Wood 1984) that includes plesiomorphic, synapomorphic, and possibly autapomorphic characters that together are found only in this species, even if individual features evince a broader taxonomic distribution. This list is general in nature, and there is a well-documented variation across populations and individuals in the expression of these traits (see below), consistent with a polymorphic species (Rightmire 1986, 1990; Turner and Chamberlain 1989; Antón 2003). Cranial features have weighed most heavily in taxonomic debates because cranial remains dominate the *H. erectus* fossil sample. This discussion will therefore be biased in favor of cranial morphology. There are a number of traits which are common (but not necessarily ubiquitous) in the broadly defined *H. erectus* species, which can be roughly divided into discrete characters and shape characters. For this discussion, "discrete" traits are locally restricted features not easily measured with standard morphometric tools, whereas shape traits refer to large-scale features that are more amenable to measurement ("metric" traits). Some characters could be accommodated in either category (e.g., form of the supraorbital region), and their categorization is arbitrary.

Many of the discrete characters that serve to define *H. erectus s.l.* are termed cranial superstructures and represent localized hypertrophies of the cranial bones in the form of keels, tori, and crests. Keeling often occurs along the midsagittal suture, the median plane of the frontal bone, and the coronal sutures, and may be associated with a bregmatic eminence (Fig. 1). Among the most prominent of the cranial superstructures are the occipital torus and the supraorbital torus. The first traverses the occipital bone at the junction of the occipital and nuchal squamae, and its inferior surface is sometimes excavated by nuchal musculature such that it overhangs the nuchal plane. The latter is anteriorly projecting, may be straight along both its anterior and superior borders, and is usually found in conjunction with a supratoral sulcus. The angular torus is located at the posterior extent of the temporal lines as a raised arc of bone on the parietal near the mastoid notch. Mastoid, supramastoid, and suprameatal crests may be present on the lateral aspect of the temporal bone, a juxtamastoid eminence may form medial to the mastoid process, and there are sometimes postcondylar tuberosities posterior to the occipital condyles.

Additional discrete traits that are not superstructures include a mastoid fissure (a fissure between the mastoid process and the tympanic tube) and a narrowing of the glenoid cavity into a fissure between the entoglenoid pyramid and the tympanic plate. There is no sphenoid spine. The petrotympanic crest is often thick with a petrous crest anterior to the stylomastoid foramen and styloid pit and a projecting processus supratubarius located at its medial end near the carotid canal. *H. erectus* is frequently described as lacking both a styloid process and a vaginal sheath, though this is variable. The petrous pyramid is more sagittally oriented than in modern humans. The mastoid process is often described as small, and the tip may be inclined medially with a flattened posterior surface

Fig. 1 *Homo erectus* cranial morphology and variation. *Homo erectus* cranial morphology from several perspectives (from *top* to *bottom* and *left* to *right*): *left lateral* (Sangiran 2), posterior (Dmanisi 3443 – cast), superior (Zhoukoudian 3 – cast), inferior (OH 9), and anterior (KNM-ER 3733). Note many of the key *H. erectus* cranial traits discussed in the text, including the long and low midsagittal profile, angled occipital bone, flat frontal bone, postorbital constriction, well-developed supraorbital torus with a posttoral sulcus, occipital torus, midline keeling, maximum breadth positioned low on the vault, a heavily constructed cheek region, a fissure between the tympanic tube and the entoglenoid process, and the processus supratubarius at the medial end of the tympanic plate. Photographs by K.L. Baab (Turkana image with permission of the National Museum of Kenya)

(Rightmire and Lordkipanidze 2009), but again, this is not universal. Inion and endinion are often vertically separated, and inion and opisthocranion are coincident (or nearly so) (Dubois 1924; Weidenreich 1943, 1951; Howell 1978; Howells 1980; Santa Luca 1980; Rightmire 1984, 1990; Wood 1984, 1991; Antón 2002, 2003). A final *H. erectus* feature that is not easily classified as either a cranial shape or a discrete trait is that of thickened cranial vault bones (Kennedy 1991; Brown 1994; but see Balzeau 2006).

Aspects of cranial shape traditionally used to define *H. erectus* include a low and elongated cranial vault when viewed laterally, marked postorbital constriction, maximum cranial breadth across the angular torus or supramastoid crests, a high occipital/parietal arc ratio, flattened frontal squama and parietal bones, a low and flat temporal squama (in contrast to an arched squama), an acutely angled occipital bone in the sagittal plane, a longer nuchal than occipital plane, an unflexed cranial base, and a more sagittally oriented petrous temporal (Fig. 1) (Dubois 1924;

von Koenigswald and Weidenreich 1939; Weidenreich 1943, 1951; Le Gros Clark 1964; Howells 1980; Maier and Nkini 1984; Wood 1984; Rightmire 1990; Antón 2003). *Homo erectus* is described as having a wide midface, a massive cheek, a prominent nasal saddle, and a wide nasal aperture (Rightmire and Lordkipanidze 2009).

Do the preceding characteristics of *H. erectus s.l.* serve to delineate this species from other closely related species? In general, workers have focused on differentiating early African *H. erectus* (*H. ergaster*) from Asian *H. erectus* (*H. erectus s. str.*) rather than delineating *H. erectus* from early *Homo* (*H. habilis* and *H. rudolfensis*). That said, early *Homo* may have thinner cranial bones and fewer cranial superstructures than *H. erectus*, although their low frequency in the Koobi Fora *H. erectus* diminishes this distinction. Of the rather large number of traits that characterized *H. erectus s.l.* listed above, Rightmire (1990) singles out nine that are derived in *H. erectus s.l.* relative to earlier species, including a midline keeling on the frontal bone, an angular torus, a fissure between the entoglenoid process and the tympanic tube, and a prominent petrotympanic crest with a processus supratubarius. Turner and Chamberlain (1989) identified five additional features that differentiate *H. erectus* from early *Homo*, including broader nasal bones with a distinct nasal spine and a shorter temporal fossa. Antón (2004) highlighted derived features of the *H. erectus s.l.* face, such as a broad interorbital region that is convex side to side and a more convex lateral malar.

At the other end of the phylogenetic bracket, many classical systematic treatments focused on differentiating *H. erectus* from *H. sapiens* rather than taxa now recognized as morphologically and chronologically intermediate, such as *H. heidelbergensis*, *H. rhodesiensis*, and *H. antecessor*. Modern human crania are easily differentiable from *H. erectus* because of their globular neurocrania (including a vertical forehead, parallel vault walls, separation of inion and opisthocranion, and greatest breadth across the parietals), thin cranial bones, smaller and more orthognathic faces, and distinct chins. Fossils assigned to the Middle Pleistocene taxa mentioned above are more difficult to distinguish from *H. erectus* because they often express traditional *H. erectus* traits, such as sagittal keeling, angular tori, thick cranial bones, and an occipital torus. However, these fossils generally have larger endocranial volumes, higher vaults, more vertical cranial vault walls, less sharply angled occipitals, and even more pronounced supraorbital tori than *H. erectus*. Additional features identified by Rightmire (2008) include a thinner tympanic plate and the presence of a sphenoid spine as well as a more arched temporal squama and longer occipital scale in *H. heidelbergensis s.l.* Some European *H. heidelbergensis* specimens also exhibit incipient Neanderthal traits.

Cranial shape can also be characterized and analyzed via geometric morphometric analysis of three-dimensional (3D) landmark data. Fifty-five landmarks, capturing overall neurocranial shape, were analyzed via principal components analysis (PCA) after superimposing all landmark configurations using standard Procrustes-based procedures (Gower 1975; Rohlf and Slice 1990) (chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1). The superimposition process scales all individuals to the same overall size, so that only shape is analyzed. Unfortunately, preservation issues limited the sample of early *Homo* to

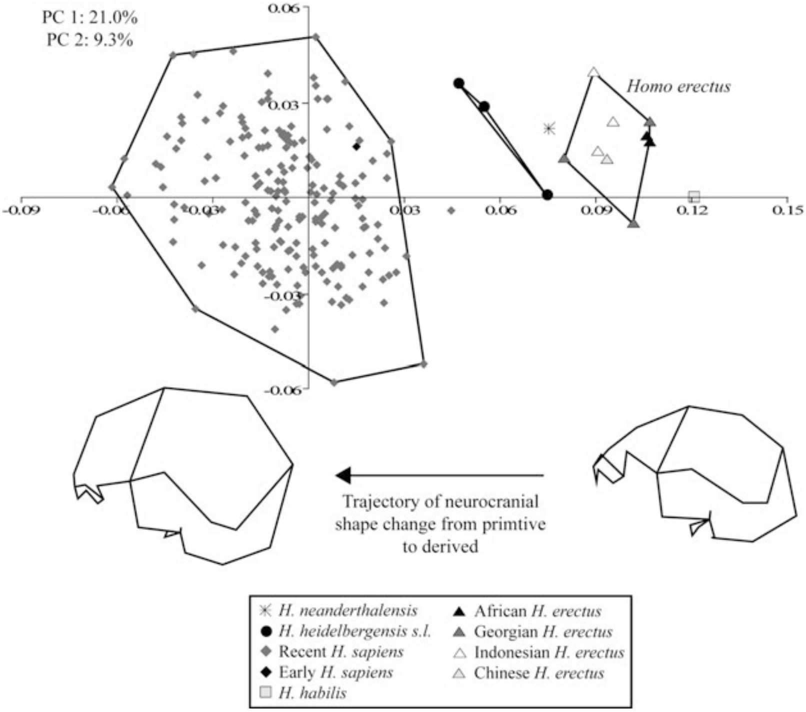

Fig. 2 *Homo erectus* neurocranial shape in a broader comparative context of extinct and extant *Homo* species. A comparative analysis of cranial shape using principal components analysis of 3D cranial landmarks from *Homo erectus* and other closely related *Homo* species. The first two principal components are figured. The first component captures the contrast in neurocranial shape between archaic *Homo* species and *H. sapiens*. *Homo erectus* is intermediate between the two extremes, represented by *H. sapiens* and *H. habilis*, but closer to the latter. Its distribution in morphospace also borders on mid-Pleistocene *Homo*. The wireframes illustrate shape differences along the first component: the high-scoring archaic taxa have a low neurocranial profile in contrast to the more globular shape of the cranial vault in modern humans. Other differences include the low position of greatest cranial breadth, more marked postorbital constriction, and pronounced browridge in the extinct species, whereas modern humans have more vertical cranial vault walls, reduced constriction, and a gracile supraorbital region

a sole *H. habilis* cranium (KNM-ER 1813). The *H. erectus* sample includes representatives of most major geographico-temporal groups (Sangiran, Ngandong, Sambungmacan, Zhoukoudian, Koobi Fora) but excludes some fossils due to incomplete preservation (e.g., KNM-WT 15000 and OH 9) or because their status as *H. erectus* remains unclear (e.g., KNM-ER 42700 and Daka). The first axis preserves a basic archaic to derived trajectory anchored on one end by *H. habilis* and on the other by *H. sapiens*, with *H. erectus s.l.* and Middle Pleistocene *Homo* specimens, including Neanderthals and what has been broadly referred to as *H. heidelbergensis*, arrayed between them (Fig. 2). The *H. erectus* sample overlaps or abuts the early end of the time range for *H. heidelbergensis*, but the two samples

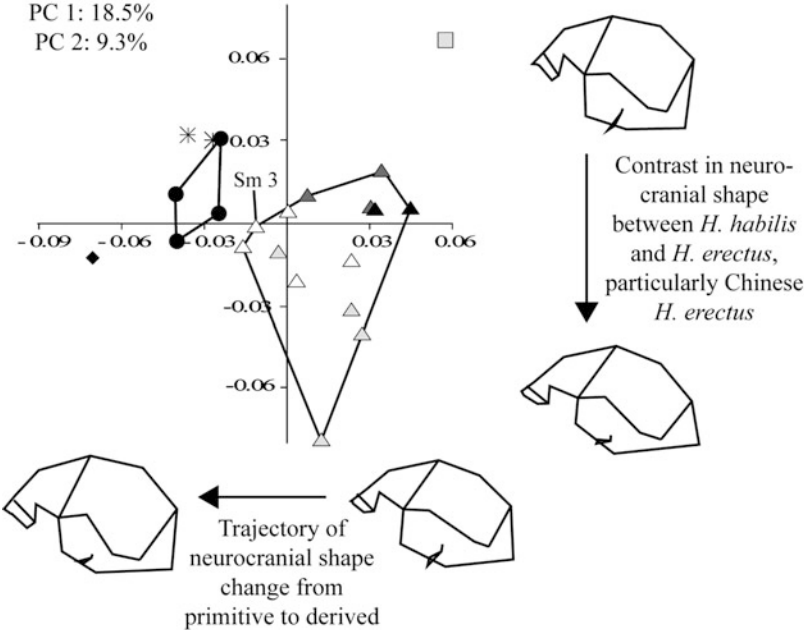

Fig. 3 *Homo erectus* neurocranial shape compared to fossil *Homo* species. A comparative analysis of neurocranial shape using principal components analysis of 3D cranial landmarks from *Homo erectus* and other closely related *Homo* species, excluding recent *H. sapiens*. This analysis features a more restricted set of landmarks but larger fossil sample than Fig. 2, but a similar pattern of archaic to derived neurocranial shape differences is apparent on PC 1 as seen in Fig. 2. The second component emphasizes how *H. habilis* (KNM-ER 1813) and Chinese *H. erectus* contrast with one another and with the remainder of the sample. *Homo erectus* again occupies a unique region of morphospace compared to its congeners. Sambungmacan 3 is labeled to emphasize how its more globular cranial vault converges on more derived *Homo* species. Legend is the same as in Fig. 2

analyzed here are distinct from one another in their cranial vault morphology. A similar pattern is evident in an analysis of a more restricted set of 39 neurocranial landmarks limited to just fossils but also demonstrates that the Chinese sample (PC 2) (Fig. 3) and the Indonesian sample (PC 3; not illustrated) are divergent from this main branch. The lack of overlap between *H. erectus* and closely related *Homo* species suggests that this species is distinct in terms of cranial shape, although larger samples of both earlier and later *Homo* are necessary to confirm this.

Variation in *Homo erectus sensu lato*

The preceding description of *H. erectus* obfuscates geographic, temporal, allometric, and interindividual (including sexual) variation within the sample. Indeed, many of the features described are not present in all members of the species and may in fact serve to delineate among samples from different regions or from different time periods. Perhaps the biggest stumbling block in studying *H. erectus* systematics is distinguishing between intra- and interspecific variations. Are differences between fossils from Koobi Fora and West Turkana (and perhaps Olduvai Gorge and Dmanisi) and those from Asia indicative of a cladogenic event? Or could this variation be attributed to temporal and spatial variation in a widespread and temporally deep species?

Magnitude of Variation

While many workers adhere to some version of the biological species concept, this cannot be directly applied to the study of paleospecies. A common "work-around" is to use extant species as a yardstick against which to gauge the degree of morphological variability in a fossil sample. The underlying assumption is that morphological variability is the outcome of a shared gene pool and membership in a single evolving lineage. Therefore, a fossil sample exhibiting more variation than the extant analogs may contain members of multiple species. However, this alone is insufficient to falsify the null hypothesis of a single species as issues unique to the fossil sample, such as greater temporal depth or greater sexual dimorphism, may give a false signal of excessive variation (Kelley and Plavcan 1998).

Explicit tests of the single-species hypothesis based on the degree of metric variability in *H. erectus s.l.* have generally supported a single-species model (Kramer 1993; Bilsborough 2000; Villmoare 2005), but this result is not universal (Terhune et al. 2007). Interestingly, analyses confined to just the Dmanisi sample have also come to contrasting conclusions: variations in cranial dimensions and endocranial capacity were within the range of a single species (Macaluso et al. 2004; Lee 2005), but size and shape dimorphisms of the mandibles were excessive for a single species (Skinner et al. 2006). A recent analysis which includes all five skulls found that variation was within expectations for demes of chimpanzees and bonobos and for a worldwide modern human sample (Lordkipanidze et al. 2013). The borderline nature of this result was reinforced by Baab (2008b) who found that variation in the neurocranial shape of *H. erectus* (captured by 16 3D landmarks) was more variable than *H. sapiens* and both chimpanzee species, less variable than *Pongo* and *Gorilla* species, and most comparable to the geographically disperse *Papio hamadryas* species (including representatives of six subspecies) and the *Macaca fascicularis* species group (including four species). Although the results were somewhat ambiguous, a single-species model was not rejected given the overlap in cranial vault variability between *H. erectus s.l.* and several extant primate species (or even species groups), especially in light of the greater geographic and temporal depth in the fossil sample.

The degree of variation among regional/temporal subsamples can also be assessed and compared to variation documented within and between extant species.

The degree of neurocranial shape differentiation observed between *H. ergaster* and *H. erectus s. str*. as defined by Wood (1991) (where the former is restricted to the Koobi Fora fossils and the latter includes both Asian fossils and OH 9) is less than the distance between strictly geographic or temporal subsets of fossils (Baab 2008b). Although not reported in the original study, the distance between Chinese and Indonesian samples exceeds that seen in the African/Georgian vs. Asian comparisons. Villmoare (2005) also evaluated distances between African and Asian *H. erectus s.l.* based on craniometrics and discrete traits relative to distances between regional groups of *H. sapiens*. He found that metric variation in the fossil sample did not exceed that found in modern humans but that variation in discrete characters did exceed that observed among regional groups of modern humans.

Pattern of Variation

A second and equally crucial piece of the puzzle is understanding how variation is patterned within this sample. One current challenge is parsing out variation due to different sources. For example, temporal trends in cranial shape evolution run largely parallel to allometric variation in this taxon as cranial capacity has increased over time in *H. erectus s.l.*, resulting in changes to cranial form. Therefore, to a large extent the effects of time and size are confounded in this sample. Despite these caveats, some generalizations can be made, and certain patterns are apparent. In addition to the discussion of variation below, readers are also referred to Antón (2003) and Baab (2007) for additional details pertinent to variation in *H. erectus s.l.* cranial morphology.

It was the higher frequency of certain discrete traits in the Asian fossils that initially prompted researchers to question the inclusion of the early African fossils in *H. erectus s. str*. Traditionally, these traits include thicker cranial bones, an occipital torus that is continuous with the angular torus and mastoid crest laterally, a supramastoid crest, a straighter frontal torus in anterior and superior views with a continuous posttoral sulcus, a midline keeling on the frontal bone and sagittal suture, a mastoid fissure, and a fissure between the tympanic plate and the entoglenoid pyramid (e.g., Andrews 1984; Stringer 1984; Wood 1984; Antón 2003; Villmoare 2005). The general lack of cranial superstructures in the African fossils is mirrored in the Georgian fossils (Antón 2003).

However, two objections have been raised to this observation of geographic differentiation: (1) many of these features appear to have a broader distribution in African and Georgian *H. erectus* and even outside of *H. erectus* (Rightmire 1986; Turner and Chamberlain 1989; Bräuer 1990; Kennedy 1991; Bräuer and Mbua 1992; Brown 1994; Villmoare 2005; Rightmire et al. 2006), and (2) these traits more accurately describe the Zhoukoudian (and other Chinese) fossils than the Indonesian fossils (Antón 2002). A further complication relates to the subjectivity of describing complex and often continuously varying morphology. For example, Antón (2004) describes KNM-ER 3733 as having "an apparently continuous, concave supratoral sulcus that rises relatively steeply to meet the frontal squama" (see also Rightmire 1990), whereas Wood (1984, 1991) argues that this same specimen lacks a well-defined supratoral sulcus.

Questions have been raised regarding the independence of these traits. Hublin (1986, 1987) put forth the interesting proposal that cranial superstructures (which comprise the majority of the proposed *H. erectus* autapomorphies) are developmentally integrated and are not therefore independent from one another. He specifically ties their development to thick cortical bone as cranial superstructures are localized hypertrophies of the outer layer of cortical bone (with the exception of the supraorbital torus which also involves the diploe). The endocrine factors responsible for cortical bone deposition may therefore also influence the development of these superstructures. Empirical evidence has been garnered both in support (Hublin 1987) and opposition of this idea (Balzeau 2013). In addition, both Lahr and Wright (1996) and Baab et al. (2010) found that cranial robusticity was integrated with cranial form in modern humans, and cranial superstructure expression may therefore relate to cranial size and shape in *H. erectus*. If cranial superstructures are in fact highly integrated, then they would not constitute separate lines of evidence in favor of restricting *H. erectus* to just the Asian part of the hypodigm.

While the focus is typically on discrete characters, differences in cranial shape have also been described, including a more angled occipital, shorter upper scale of the occipital, wider interorbital breadth, and shorter, wider face in the Asian specimens. The Asian fossils also have a higher ratio of posterior to anterior vault breadth (Antón 2003) and narrower and anteroposteriorly longer temporomandibular fossae (Bräuer 1994). In contrast, the East African sample has the greatest degree of postorbital constriction and a shorter parietal sagittal chord and arc (Andrews 1984; Stringer 1984; Wood 1984, 1991; Bräuer 1994; Bilsborough 2000). The Zhoukoudian population is characterized by a narrower biasterionic breadth and a wider biauricular breadth (Weidenreich 1943; Bilsborough 2000; Antón 2002; Kidder and Durband 2004b; Baab 2010). Yet, the scale of metric differences among temporo-geographic groups is relatively minor and broadly comparable among groups (Bilsborough 2000).

Geometric morphometric analysis of cranial vault variation within *H. erectus* found consistent differences between the African/Georgian and Asian samples but also indicated that the Zhoukoudian and Indonesian samples were at least as distinct from one another as either was from the African/Georgian fossils (Baab 2008b and Fig. 4). A more focused study of intra-Asian cranial shape variation also supported a basic Zhoukoudian–Indonesian dichotomy (although Sangiran 2 sometimes overlapped the Chinese distribution) while also identifying two main clusters within the former grouping: those from the Sangiran Dome and those from Ngandong, Sambungmacan, and Ngawi (Baab 2010), possibly reflecting phyletic change if the Sambungmacan and Ngawi fossils are as young as the Ngandong fossils.

It is possible to detect anagenetic changes in addition to regional differentiation as there is some chronological overlap among sites. Perhaps the most notable temporal trend is that of increasing endocranial volume through time (Fig. 5),

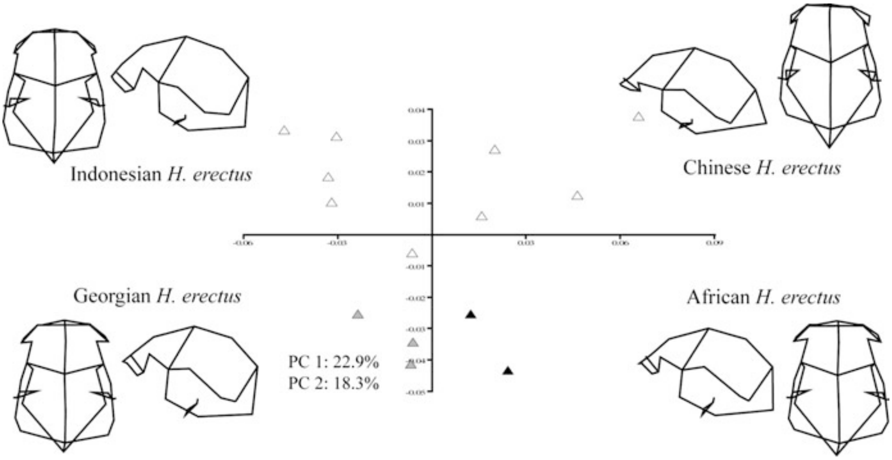

Fig. 4 Intraspecific variation in *Homo erectus* neurocranial shape. An intraspecific analysis of neurocranial shape variation in *Homo erectus s.l.* using principal components analysis of 3D cranial landmarks. This analysis uses the same landmark set as Fig. 3. There is clear geographic and temporal partitioning of cranial shape variation (wireframes represent the centroids for each geographic grouping). The first component separates the Indonesian and Chinese samples and the Georgian from African samples. The second component separates the Afro-Georgian and Asian samples. Shape differences include the narrower frontal bone and more posteriorly projecting inion of the Chinese fossils and the greater postorbital constriction of the older African and Georgian fossils. The lowest-scoring Indonesian fossil on PC 2 is also the oldest Indonesian fossil in the analysis (Sangiran 17). Legend is the same as in Fig. 2

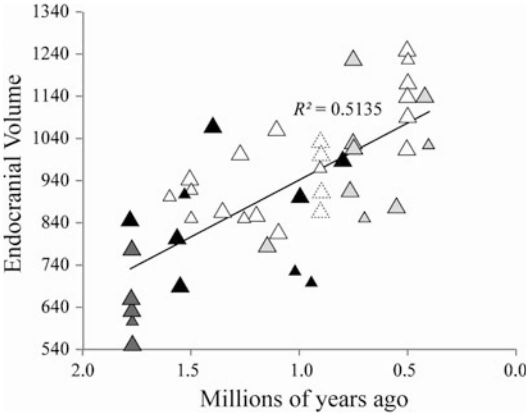

Fig. 5 Change in brain size over geological time in *Homo erectus s.l.* Bivariate plot of endocranial volume (EV) against geochronological age in a broadly defined sample of *Homo erectus*. The result indicates an increase in EV through time, but with considerable variation any given time slice. Legend is the same as in Fig. 2; the least secure estimates of EV from incomplete specimens or adult estimates based on juvenile/subadult specimens are indicated by smaller symbols, while the estimates for Sambungmacan and Ngawi have a dashed outline due to uncertainties in their provenance and therefore dating. The R^2 value shown on the plot is for the entire sample

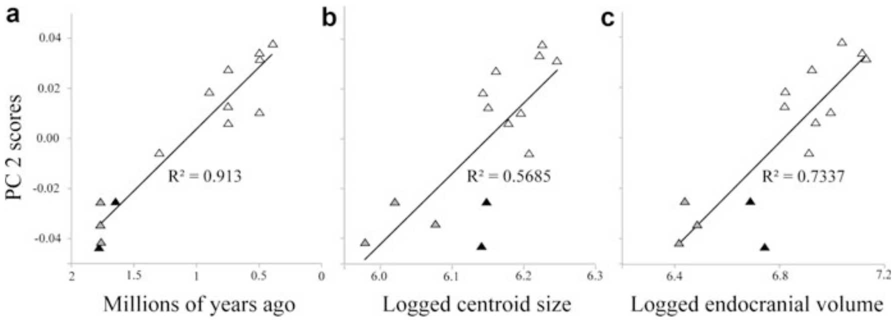

Fig. 6 The relationship between neurocranial shape and time, neurocranial size, and brain size. Bivariate plots relating principal component 2 scores (from Fig. 4) to (**a**) geochronological age of the fossils, (**b**) overall neurocranial size (natural logarithm of centroid size), and (**c**) natural logarithm of endocranial volume. Taken together, it is clear that there is phyletic change in neurocranial shape through time in *Homo erectus*, which is related in part to increasing brain size. The decrease in constriction behind the orbits observed on PC 2 makes intuitive sense when viewed in this light. Differences between endocranial volume and overall neurocranial size relate to differential cranial bone thickness and expression of ectocranial morphology, including cranial superstructures

a pattern that also holds within some regions, but not others (e.g., compare the distribution of Indonesian and African specimens on Fig. 5). Endocranial volume ranges from 646 to 1,251 cm^3. This pattern has been documented by previous workers (Leigh 1992; Rightmire 2004; Lee and Wolpoff 2009) and is confirmed here using a more complete set of *H. erectus* fossils and revised dates ($R^2 = 0.5135$). The results remain significant (and the R^2 value increases to 0.6014) when several questionable estimates from incomplete fossils (Sangiran 3, 4, and 38, Bukuran, Grogol Wetan, Ng 11, Hexian, Zkd 6, OH 12, KNM-OL 45500) and adult estimates for two juveniles (D2700, KNM-WT 15000) are excluded. As presented, the Sambungmacan and Ngawi fossils were assigned a (somewhat arbitrary) date of 0.9 Ma, but excluding them from the analysis has a negligible effect on the result ($R^2 = 0.5193$). Assigning them a younger age equivalent to Ngandong (0.5 Ma) reduces the R^2 value slightly to 0.4760. Excluding the 12 fossils with the most problematic EV estimates in addition to the Sambungmacan and Ngawi specimens strengthens the association ($R^2 = 0.6156$).

Cranial shape also varies as a function of time, although many fewer specimens can be examined (Baab 2007). For example, the position of fossils along the second principal component shown in Fig. 4 is strongly correlated with geological age (Fig. 6a). While some of this shape change is attributable to the underlying increase in cranial capacity, the fit between geological age and PC 2 scores is better than between cranial size and PC 2 scores (Fig. 6b) or between endocranial volume and PC 2 scores (Fig. 6c). Additional temporal trends have been documented by Kaifu and colleagues within Sangiran and across Indonesia more broadly (Kaifu et al. 2005, 2008).

Implications of Newly Described Fossils for *Homo erectus* Systematics

Since the 1980s, a number of fossils were recovered from China, Indonesia, Africa, and Georgia that compare favorably with other *H. erectus*. Some of these have been evaluated in a comparative context and appear to fall within the boundaries established previously for the species, including the Chinese Nanjing I cranium (Liu et al. 2005) and the Indonesian fossils Skull IX (Tjg-1993.5) (Arif 2005; Kaifu et al. 2011), Bukuran (Grimaud-Hervé et al. 2005; Grimaud-Hervé et al. 2012), Grogol Wetan (Widianto and Grimaud-Herve 2000), Sambungmacan 4 (Baba et al. 2003a), and Bpg 2001.04 (Zaim et al. 2011).

Other recently described fossils attributed to *H. erectus* differ in some way from the average configuration. The two Yunxian crania from China resemble other *H. erectus* in their overall low and elongated cranial vaults, but exhibit more derived facial features, in common with *H. antecessor* or *H. sapiens* (Li and Etler 1992; Etler 1996, 2004; Vialet et al. 2010), although Zhang (1998) raised concerns about the accuracy of character evaluations due to deformation of the fossils. Sambungmacan 3, while sharing many detailed anatomical resemblances to other Sambungmacan and Ngandong fossils, lacks an angular torus (Márquez et al. 2001), and geometric morphometric analysis indicates that its rounded frontal bone and less sharply angled occipital create a midsagittal profile that is intermediate between fossil *Homo* and *H. sapiens* (Delson et al. 2001). Sambungmacan 3 is more closely affiliated with *H. erectus* than modern humans based on its overall vault shape (rather than just the midsagittal profile), but its globular neurocranium positions it at the periphery of the *H. erectus* distribution, closer to more derived *Homo* (labeled in Fig. 3). The overall pattern of metric and nonmetric similarity between Sambungmacan 3 and other Indonesian *H. erectus* supports its inclusion in the species. Some fossils that have been known for a longer time also remain enigmatic, such as SK 847 from Swartkrans (e.g., Grine et al. 1996).

Among the most noteworthy potential additions to the *H. erectus s.l.* hypodigm since the 1980s are the fossils from Dmanisi. Descriptions of four crania and four mandibles, as well as numerous postcranial bones, were published between 1992 and 2007 (Gabunia 1992; Gabunia and Vekua 1995; Gabunia et al. 1999, 2000; Vekua et al. 2002; Lordkipanidze et al. 2005, 2007). Their cranial vault profiles are typical of *H. erectus* in being long and low with prominent supraorbital tori. Some individuals also exhibit midline keeling, occipital tori, and other discrete traits common to *H. erectus*. However, the cranial capacities of these individuals are smaller than any of the Asian fossils and the KNM-ER 3733 and 3883 and OH 9 fossils from Africa. A description of the fifth cranium (D4500) from this site was published in 2013 and diverges from the other four in having an even smaller endocranial volume (546 cm^3) but a large and prognathic face. It also exhibits the most well-developed cranial superstructures of any of the Georgian fossils, including a large supraorbital torus, occipital torus, and supramastoid crests, although midline keeling is restricted to the posterior sagittal suture and a “lambdoid hump” creates a more vertical occipital squama that is typical in

H. erectus (Lordkipanidze et al. 2013). This individual, as well as D3444, may well represent males while the others were females, possibly providing the best glimpse currently available into sexual variation in this species.

Although extensive, the degree of cranial shape variation (particularly in terms of facial rather than neurocranial morphology) within the Dmanisi sample is comparable to populations of chimpanzee species as well as humans. The authors interpret this variation as indicative of higher levels of intraspecific variation than normally recognized for fossil hominins (at least partially due to sexual dimorphism) and use this observation to argue for a single, geographically widespread *H. erectus* species ranging from East and South African north to Georgia and east to China and Indonesia (Lordkipanidze et al. 2013). Yet, the description also emphasizes morphological affinities between the new Georgian cranium and African fossils attributed to *H. habilis*/*rudolfensis*, and the authors hint at subsuming these taxa within *H. erectus s.l.* (but see Spoor et al. 2008; (chapter "▶ Defining Hominidae," Vol. 3). Other Dmanisi fossils also exhibit aspects of facial form and dentition that are more primitive than KNM-ER 3733 and 3883 (Vekua et al. 2002; Martinón-Torres et al. 2008; Rightmire and Lordkipanidze 2009). Given their antiquity, this pattern could be reconciled by positing an early migration of this population soon after the origin of the species (or even a Eurasian origin for *H. erectus s.l.*) and does not require the recognition of a distinct species. Yet, it must also be acknowledged that this "solution" does blur the morphological boundaries between *H. habilis*, *H. rudolfensis*, and early *H. erectus* (Rightmire and Lordkipanidze 2009; Lordkipanidze et al. 2013), a similar concern noted by Wood (1984) in reference to the inclusion of KNM-ER 3733 and 3883 in *H. erectus*.

One European fossil was recently assigned to *H. erectus* from Kocabaş, Turkey, and dated to the Middle or possibly Lower Pleistocene. This fossil is quite incomplete, but both the initial description (Kappelman et al. 2008) and a subsequent linear morphometric comparative analysis of the reconstructed specimen (Vialet et al. 2012) emphasized its affinities with *H. erectus* fossils. The comparative analysis was not complete, however. For example, it did not include any of the Ngandong specimens which may be of similar Middle Pleistocene age, but which are likely to be much larger in overall size, or the small *H. heidelbergensis s.l.* fossil from Ceprano, Italy. The Kocabaş fossil also lacks a midline keel on the parietal bones. Therefore, while this fossil may represent a second Eurasian *H. erectus* site, its incomplete nature and the limited comparative analyses leave open other possibilities.

Two fossils described from Kenya in the 2000s are separated geologically by ~0.6 Myr but share an important feature – both are quite small. KNM-ER 42700, with an estimated cranial capacity of 691 cm^3 (Spoor et al. 2007), is smaller than other similarly aged fossils, but within the range of the Georgian fossils. This calvarium exhibits some discrete traits typical of *H. erectus*, such as keeling on the frontal and parietals and a supratoral sulcus, but not others, including thick cranial vault bones, a prominent supraorbital torus, and an occipital torus (Spoor et al. 2007), and its cranial shape is outside of the bounds of *H. erectus*, including the Dmanisi fossils (Baab 2008a). The interpretation of these results is complicated somewhat by the older subadult or young adult status of this fossil, but a subadult from Dmanisi, D2700, is much more similar to other *H. erectus*. KNM-ER 42700 also suffered some postdepositional deformation, primarily affecting the position of the frontal bone (Spoor et al. 2008). Reanalysis without frontal bone landmarks yields the same result as the original analysis (i.e., KNM-ER 42700 is quite distinct in its posterior cranial vault shape from *H. erectus*; unpublished data). KNM-OL 45500 from Olorgesailie is a more fragmentary specimen but is clearly a small individual (Potts et al. 2004). Its frontal bone shape is most similar to other *H. erectus*, falling outside of the previously documented range of variation, but not in the direction of any other *Homo* species (Baab 2007). The shape analysis may be affected by preservation issues, but its basic patterns of a distinct supraorbital torus with a continuous supraorbital sulcus and marked postorbital constriction are all consistent with attribution to *H. erectus*. Its inclusion does, however, increase both size and shape variation during this time period (0.9 Ma) and possibly for the species as a whole since it exhibits very small dimensions of the frontal and temporal bones.

Two other African crania have been described from a similar time period, one of which was explicitly attributed to *H. erectus* (the Daka calvarium from Ethiopia, 1 Ma) and one of which was compared favorably to *H. erectus*, although the authors fell short of actually assigning it to this species (the Buia cranium from Eritrea, 0.8 Ma). These specimens are of average size for this time period, but much of their morphology is clearly derived relative to other *H. erectus*, particularly the more vertical cranial vault sides and higher, more rounded vaults. Both fossils also have very tall supraorbital tori, a feature common to *H. heidelbergensis s.l.* Neither fossil has a well-developed occipital torus or an angled occipital bone. Yet the two fossils are not identical – the Buia fossil is much narrower for its length and height than the Daka fossil, and there is a marked glabellar depression in the Daka fossil absent in the Buia fossil. Two reasonable explanations for the derived morphology seen in the Daka and Buia fossils are that each may represent either an "advanced" *H. erectus* on the lineage leading to later *Homo* or an early member of a more derived *Homo* species. Thus, the Daka and Buia fossils present a situation similar to the Dmanisi fossils in that their inclusion in *H. erectus* serves to blur the distinction between *H. erectus* and later *Homo* taxa. However, if the Dmanisi fossils are included in *H. erectus* due to the presence of derived *H. erectus* characters, then, by the same logic, the Daka and Buia fossils should be assigned to a later taxon based on the presence of traits derived with respect to the rest of the *H. erectus* hypodigm.

Discussion

Clearly much of the variation in cranial shape and discrete cranial features is structured along geographic and temporal lines. This raises the question of whether differences among geographically and possibly temporally restricted samples should be read as support for a single, polytypic species or for multiple species.

In support of the former, members of *H. erectus s.l.* are united by a remarkably consistent cranial *Bauplan* with more minor geographic and temporal variations superimposed on this basic form (e.g., Rightmire 1990; Antón 2003). Furthermore, variation between African/Georgian and Asian fossils is comparable to that seen within the Asian sample. A variety of factors can contribute to interpopulation variation, including adaptation to local environments, genetic drift (Antón 2002, 2003), species-wide temporal trends (e.g., increasing brain size; Rightmire 2004; Lee and Wolpoff 2009), and in situ evolutionary change (Kaifu et al. 2008, 2011). In support of a multiple-species model, a few studies have found morphological variation to be in excess of single primate species (Villmoare 2005; Skinner et al. 2006) and, more importantly, autapomorphic features are more heavily concentrated in the Asian fossil record (e.g., Wood 1984).

Paleontological species are defined based on morphological characters that are themselves implicitly believed to signal the boundaries of a gene pool. Given that species are descended from preexisting species and that some will also give rise through speciation events to additional species, the characters that form the basis of this definition will in many cases be a combination of both plesiomorphic and synapomorphic traits. Species with no descendants may also be delineated by autapomorphic characters. However, speciation events rarely entail the entirety of a species but rather a subsample of that species (i.e., allopatric speciation). It is therefore conceivable that a species which gave rise to one or more daughter species could still have contained populations that exhibit autapomorphies. Therefore, although the arguments are finely balanced, the evidence from morphology is insufficient to overturn the null hypothesis of a single species for the core *H. erectus* hypodigm (those found in Africa and Asia through the 1980s). The position of more recently described fossils from Asia, but more importantly from Africa, needs to be assessed relative to these established patterns to evaluate whether these fossils expand the morphological range of *H. erectus*, and if so, whether this expansion is consistent with expectations for a single species. In other words, accepting a polytypic species model for *H. erectus* does not imply that this species must or should become a “wastebin” taxon.

The location of the oldest fossils attributed to *H. erectus* in East Africa is most consistent with an origin of *H. erectus* in East Africa, likely from an ancestor similar to *H. habilis*. However, this hinges on the correct identification and dating of KNM-ER 2598 as *H. erectus* at 1.9 Ma in the Turkana Basin (Wood 1991). Otherwise, *H. erectus* appears more or less simultaneously in East Africa and Eurasia, and the possibility of a Eurasian origin of *H. erectus* has been raised (White 1995; Asfaw et al. 2002; Dennell and Roebroeks 2005). On the one hand, the presence of a potential ancestral species, *H. habilis*, in East Africa is further support for an African origin. On the other hand, the presence of *H. floresiensis* in Indonesia with its *H. erectus*-like cranial morphology but unexpectedly primitive postcranial and dentognathic morphology (Brown and Maeda 2009; Jungers 2009; Jungers et al. 2009; Baab et al. 2013) may imply the presence of a more ancient dispersal through mainland Asia. In either case, origin was followed by rapid dispersal (to either Eurasia or East Africa, depending on the location of the origin).

What happened subsequent to this migration is less clear. Kaifu and colleagues suggest a similarly early migration to Java on the basis of primitive dentognathic fossils in the early Sangiran hominin fossil record (Kaifu et al. 2005). Certainly, there was at least one, but possibly more than one, migration to East Asia and possible back migration from Asia to Africa (Dennell and Roebroeks 2005; Zaim et al. 2011), and the degree of gene flow among populations remains obscure. Populations in China and Indonesia survived into the Middle Pleistocene, and, at least in Indonesia, there is evidence of additional in situ evolutionary change from the Lower to Middle Pleistocene (Kaifu et al. 2008). Most researchers view the Asian populations as evolutionary dead ends, although some see links between Chinese *H. erectus* and *H. antecessor* (Carbonell et al. 2005). In contrast, many workers see portions of the African *H. erectus* fossil sample as potential ancestors to later species, such as *H. antecessor* (Bermúdez de Castro et al. 1997, 1999) or *H. heidelbergensis s.l.* (Andrews 1984; Rightmire 1990, 2008; Wood 1994; Asfaw et al. 2002).

Not surprisingly, both early and late members of the species present a challenge because they may resemble more primitive or derived species, respectively. At the early end of the time range, the Dmanisi fossils further blur the distinction between *H. habilis*, *H. rudolfensis*, and *H. erectus*, while at the more recent end, Daka and Buia exhibit cranial traits that overlap *H. heidelbergensis s.l.* The latter case is particularly interesting as it signals a divergence between the African and Asian fossils in regard to cranial evolution in response to increased brain size since more recent (and larger-brained) fossils from Indonesia (e.g., Ngandong) do not converge on the *H. heidelbergensis* morphotype as strongly. This creates a situation familiar from the European Middle Pleistocene: Daka and Buia could be interpreted as "pre-*H. heidelbergensis s.l.*" or "pre-*H. rhodesiensis*," much as the Sima de los Huesos (and some other European fossils) are characterized as pre-Neanderthals. The controversy over how to treat a chronospecies from a taxonomic perspective would then also apply here (e.g., Bermúdez de Castro et al. 1997; Hublin 2001; Stringer 2012).

More generally, the increase in the size of the fossil sample has created a new set of challenges for *H. erectus* systematics. As Antón (2003, p. 162) argued:

> . . .the greater the fossil data set, the less clear the boundaries between taxa appear to be, and the more critical it becomes that we understand the structure, function, and development of the characters that appear to separate or unite our fossil groups. Understanding the function, developmental origins, and underlying variability of these features in extinct and extant primates remains an imperative task.

The expression of discrete traits across geographic regions and through time needs to be systematically reevaluated given the expansion of the fossil hypodigm assigned to *H. erectus*. The accessibility of technologies such as laser surface scanning and computed tomography also opens the door to better options for quantifying discrete traits that have traditionally been assessed visually and described qualitatively. Furthermore, a fruitful direction for future research is the clarification of the etiology of discrete traits used to define and differentiate among

Pliocene–Pleistocene *Homo* taxa. Do these traits have a genetic basis? Are they adaptive or do they retain a primarily stochastic signal? Are these traits independent or is their expression integrated with other aspects of morphology? A diverse range of tools can be used to address these questions, including quantitative genetics, animal models, correlative approaches using modern humans, and analysis of integration.

Conclusion

This review highlights that one of the most consistent features tying together different fossils assigned to *H. erectus s.l.* is cranial vault shape which is generally low and elongated with greatest width across the supramastoid or mastoid crests, a sloping frontal bone with marked postorbital constriction, and an angled occipital bone. While less commonly preserved, the facial skeleton may be more variable. Cranial superstructures, along with a handful of other discrete traits of the cranial vault, also serve to unite many of the fossils but are less consistently expressed across individuals. While the overall frequency may be higher in the Asian fossils, they do not serve to clearly distinguish among subsets of the larger hypodigm. Phyletic change in *H. erectus* through time is due in part to an increase in brain size, but both geographic and temporal variations also likely reflect microevolution and local adaptation.

Morphological evidence supports the interpretation of *H. erectus* as a polytypic species comprising fossils primarily from Lower to Middle Pleistocene sites in China, Indonesia, East Africa, Eurasia, and possibly South Africa. Current evidence suggests that the origins of this species lie in Eurasia or East Africa, and this species likely contains the population ancestral to more derived *Homo* species, such as *H. antecessor* or *H. heidelbergensis*. Yet, the recognition of a geographically and temporally widespread species should not encourage incautious attribution of fossils to this species, lest we create another “wastebin” species. Proposed additions that do not fit the established morphological bounds of the species should be evaluated in terms of how much they extend the magnitude of variation relative to extant analogs and whether they extend the range in a way which is consistent with intraspecific patterns of variation documented for this species. Geometric morphometric analysis of cranial shape has helped to clarify how the cranial shape of *H. erectus* fits into a broader *Homo* context, as well as identifying differences among spatiotemporal groups (perhaps equivalent to paleodemes). Additional work quantifying discrete traits, establishing their distribution in the expanded Pleistocene *Homo* fossil record, and establishing the utility of these traits in systematic applications will further clarify the boundaries of *H. erectus* as a species.

Acknowledgement I gratefully acknowledge the following individuals and institutions for permission to study their collections: Ian Tattersall, Ken Mowbray, and Gisselle Garcia, American Museum of Natural History; Marta Lahr and Maggie Bellati, University of Cambridge; Teuku

Jacob and Etty Indriati, Gadja Mada University; Dominique Grimaud-Hervé, Institut de Paleontologie Humaine; Philippe Mennecier, Musée de L'Homme; Mamitu Yilma, National Museums of Ethiopia; Emma Mbua and Idle Omar Farah, National Museums of Kenya; Rob Kruszynski and Louise Humphrey, Natural History Museum; Michele Morgan, Peabody Museum, Harvard University; Alan Morris, University of Cape Town. Grant support was provided by NSF (BCS 04-24262, DGE 03-33415, and DBI 96-02234), and the Leakey and Sigma Xi Foundations; this is NYCEP Morphometrics contribution 90.

Later Middle Pleistocene *Homo*

G. Philip Rightmire

Contents

Abstract

Hominin fossils are known from Middle Pleistocene localities in Africa, Europe, South Asia, and the Far East. It is recognized that these individuals display traits that are derived in comparison to the condition in *H. erectus*. However, the skulls retain numerous primitive features that set them apart from modern humans.

DOI 10.1007/978-3-642-39979-4_55

Faces are massively built with strong supraorbital tori, frontals are flattened, and vaults remain low with less parietal expansion than in *Homo sapiens*. The hominins from Bodo, Broken Hill, and Elandsfontein in Africa are quite similar to their Middle Pleistocene contemporaries in Europe. Crania and jaws from Arago Cave and Petralona, and the spectacular assemblage from Sima de los Huesos, are particularly informative. In sum, this evidence suggests a speciation event in which *H. erectus* gave rise to a daughter lineage. At or before the beginning of the Middle Pleistocene, new populations spread through Africa and western Eurasia and perhaps also to the Far East. How the fossils should be treated taxonomically is currently uncertain. One view emphasizes gradual anagenetic change, while others advocate speciation occurring repeatedly throughout the Pleistocene. In the perspective favored here, differences between the Middle Pleistocene hominins can be attributed to geography, time, or intragroup variation. Many, if not all, of the European and African specimens can be accommodated in one species distinct from Neanderthals and modern humans. If the Mauer mandible is included in this hypodigm, then the appropriate name is *H. heidelbergensis*. This species is probably ancestral to both the Neanderthals in Europe and the earliest representatives of *H. sapiens* in Africa.

Introduction

Humans evolved in Africa and were confined to that continent for much of their early history. The first dispersals from Africa into Eurasia occurred near 2 million years ago (Ma). These migrants were probably representatives of *Homo erectus* (sometimes called *Homo ergaster*). Traces left by these hominins have been recovered from the site of ‘Ubeidiya in the central Jordan Valley and at Dmanisi in the Georgian Caucasus. Some early occupations were likely transitory and did not result in permanent settlements. However, groups of *H. erectus* were able to travel relatively quickly across southern Asia to the Far East, where they were established both in Java and in China by 1.7–1.6 Ma. The first penetration westward into Europe apparently came much later. There are indications that humans were moving into the Mediterranean region prior to 1 Ma, but the initial populating of Europe north of the major mountain barriers is documented only after about 700 thousand years ago (Ka). The biological identity of the first Europeans is unclear, but it is agreed that these hominins differ from *H. erectus*. Many of the ancient fossils are presently assigned to the species *H. heidelbergensis* (named originally from a mandible found near Heidelberg in Germany). *Homo heidelbergensis* or perhaps other closely related species are known also from Middle Pleistocene localities in Asia and Africa (Fig. 1). These people seem to have been more advanced in behavior than their predecessors, and there is evidence that *H. heidelbergensis* was able to make relatively sophisticated stone tools, hunt larger and more dangerous game animals, and perhaps engage in cooperative social activities.

Fig. 1 Map giving the locations of Middle Pleistocene localities where important hominin fossils have been discovered

The Middle Pleistocene of Africa

In Africa, fossils from the early Middle Pleistocene are clearly different from *H. erectus* in cranial capacity (approximately equal to brain size), width of the frontal bone, proportions of the occipital region, and anatomy of the underside of the skull. Where it is preserved, the face is still heavily constructed, but the brows, nasal profile, and bony palate more closely resemble the condition seen in later humans. In many instances, the hominins are found with stone tools that are more carefully shaped than the choppers and relatively crude hand axes associated with *H. erectus*. From Bodo in Ethiopia to Elandsfontein in South Africa, a shift toward the manufacture of thinner, more finely flaked bifacial tools is documented in the Middle Pleistocene, and it is reasonable to link this change in behavior to a speciation event in which *H. erectus* gave rise to a daughter lineage exhibiting increased relative brain size (encephalization).

Bodo

One important specimen came to light in 1976 at Bodo, in the Middle Awash region of Ethiopia (Fig. 1). The Bodo cranium and later a broken parietal from a second

Fig. 2 Facial and oblique views of the cranium from Bodo, Ethiopia. The projecting glabellar region, wide interorbital pillar, and massive zygomatic (cheek) bones give the face an archaic appearance similar to that of *H. erectus*. Other traits including the vertical border of the nasal aperture are interpreted as apomorphies shared with later humans

individual were found in conglomerates and sands containing mammalian bones and Acheulean tools (Kalb et al. 1980; Clark and Schick 2000; Gilbert et al. 2000). Fauna from the Bodo site has been compared to that from Bed IV at Olduvai Gorge and Olorgesailie in Kenya, and an early Middle Pleistocene date is indicated. ^{40}Ar/^{39}Ar measurements reported by Clark et al. (1994) support this biochronology, and the evidence points to an age of about 600 Ka for the Bodo hominins.

The face and the anterior part of the Bodo braincase are preserved (Fig. 2). There are some cut marks on the facial bones, and these indicate intentional postmortem defleshing, as documented by White (1986). It can be established that Bodo is like *H. erectus* in some features. The massive facial bones, projecting brow, low frontal with midline keeling, parietal angular torus, and thick vault give the specimen a pronounced archaic appearance. In other respects, the cranium is more specialized (derived) in its morphology. Brain size is close to 1,250 cm^3 and is thus substantially greater than expected for *H. erectus*. Frontal bone proportions, the high-arched shape of the squamous temporal, and some traits of the cranial base are like those of more modern humans. Although the face is very broad and heavily constructed, the supraorbital tori are divided into medial and lateral segments, the margin of the nose is vertical rather than forward sloping, and the incisive canal opens into the front of the hard palate (Rightmire 1996). These are derived (apomorphic) conditions present in the face of recent *Homo*.

Broken Hill and Elandsfontein

Another African specimen is the cranium from Broken Hill (now Kabwe) in Zambia, discovered by miners in 1921. Quarrying for lead and zinc ore had already removed most of a small hill, when the miners broke into the lower part of an extensive cavern. Published reports do not all agree on this point, but apparently the cranium was picked up by itself, not in clear association with other hominin remains. The fossil is in remarkably good condition. The face is massive, with some of the heaviest brows on record. The frontal is flattened with slight midline keeling, and the vault is low in profile. Shortly after it was found, the fossil was attributed to the (new) species *H. rhodesiensis* (Woodward 1921). In its overall morphology, however, Broken Hill resembles *H. erectus*, and indeed, it has been classified this way on more than one occasion. At the same time, there are apomorphic features shared with later humans. The temporal squama is high and arch shaped, and the upper scale of the occipital is expanded relative to its lower nuchal portion (where the neck muscles are attached). Several discrete characters of the temporomandibular joint region are specialized. These include a raised articular tubercle and a sphenoid spine. More changes are apparent in the face, where the lateral border of the nasal aperture is set vertically, and the palatal anatomy is like that of later people (Rightmire 2001).

Another cranium quite similar to that from Broken Hill comes from the farm Elandsfontein, near Saldanha Bay on the Atlantic coast of South Africa. At Elandsfontein, there is an expanse of sandveld that has long been a focus of attention for paleontologists. Dunes migrate across this area, and in between the dunes, there are swales resulting from deflation. Whether the ancient horizons exposed in these “bays” are stratified land surfaces or simply mark the (seasonal) fluctuations of the water table is unclear. Given either of these interpretations, it is evident that during the mid-Quaternary, the region supported wetlands and water holes, with plenty of grass (Deacon 1998). Animals, many of them bovids or other large herbivores, were attracted to the water. The fauna includes numerous archaic elements such as a dirk-toothed cat, a sivathere, and a giant buffalo. Altogether, some 15 of 48 mammalian species collected at the site have no historic descendants. Comparisons conducted by Klein and Cruz-Uribe (1991) imply that the bones were accumulated between 700 and 400 Ka, but more recent sorting of the fauna suggests an older interval, between 1 Ma and 600 Ka (Klein et al. 2006).

Much of the work at Elandsfontein has been surface prospecting, and it was during one such visit in 1953 that investigators picked up pieces of a human skullcap. The reconstructed Elandsfontein cranium is composed of the frontal and parietal walls and some of the occiput. The bones are cracked and heavily weathered, but the braincase is not distorted. There are some similarities to *H. erectus*, but certainly the better match is with Broken Hill. These two Middle Pleistocene specimens are alike not only in overall proportions but also in many anatomical details. The Elandsfontein brow is almost as thick as that of Broken Hill, and the frontal contours are the same. Radiographs show that the frontal sinus is large and complex, reaching well up into the squama in both cases (Seidler et al. 1997; Rightmire unpublished observations). The South African frontal bone gives a breadth index of 91.9 and is thus slightly less constricted than that of Broken Hill, for which the ratio of least width to greatest breadth is 83.0. Sagittal and coronal measurements of the parietal are similar in the two individuals as is the length and orientation of the upper scale of the occipital. Unfortunately, the Elandsfontein base is missing, and there is no face. These are just the regions where one would expect to find additional apomorphies setting the South African hominin apart from *H. erectus*.

Lake Ndutu

A fourth Middle Pleistocene specimen is known from Lake Ndutu. This seasonal soda lake is located at the western end of the Main Gorge at Olduvai, in northern Tanzania. Excavations conducted near the lake margin in 1973 produced an encrusted human cranium, along with other fossils and numerous artifacts (Mturi 1976). Initially, the stone assemblage included mostly spheroids, cores, and flakes, but hand axes were picked up during later visits to the site. All of this material is thought to be derived from archaeological horizons in a greenish sandy clay, tentatively correlated with the upper Masek Beds at Olduvai.

When it was found, the cranium was severely damaged and encased in a clay matrix. The process of cleaning and reconstructing the fossil has been described by Clarke (1990). These efforts were generally successful, but the face is quite incomplete, as is the frontal bone. There are gaps in the parietals as well. The braincase is relatively small, with a capacity of only about 1,100 cm^3. Just a fragment of the supraorbital region is preserved, and the torus is projecting, if not especially thickened. Bossing of the parietals is emphasized in Clarke's reconstruction. This has perhaps been overdone with plaster, but the walls of the vault appear to be more convex than would be the case for *H. erectus*. Also, the upper plane of the occiput is vertical, above the moundlike transverse torus. The morphology of this torus is in keeping with other characters suggesting that Ndutu could be female, in comparison to males such as Bodo or Broken Hill.

Florisbad

Several additional fossils are more fragmentary and therefore somewhat less informative. An example is the cranium from spring deposits at Florisbad in South Africa, consisting only of facial parts, the frontal bone, and pieces of the parietals. Early studies compared the hominin to recent populations, but it is important to emphasize that Florisbad is far from modern in its morphology. Glabella (in the midline above the nasal root) is projecting, as is the brow on either side. The facial bones as repositioned by Clarke (1985) suggest that the nasal cavity is large and the cheek is flattened, without obvious infraorbital hollowing. The face is less heavily constructed than that of Broken Hill but otherwise not dissimilar. A human upper molar tooth from Florisbad has been dated by ESR to 259 Ka (Grün et al. 1996).

The Omo Localities and Herto

Several sites in the Omo region of southern Ethiopia, explored initially in 1967, have recently been revisited. Human remains are known from Member I of the Kibish Formation, now considered to be 200–100 Ka in age (Assefa et al. 2000). Omo 2 is an isolated surface find from PHS, lacking archaeological associations. This partial cranium is low in contour and decidedly massive in its construction, with a blunt frontal keel and a strongly angled occiput. Other likely primitive features include the shape of the deep mandibular cavity lacking any distinct articular tubercle and the absence of a sphenoid spine. Nevertheless, the vault is large overall. The frontal bone is broad and relatively unconstricted, and the parietal walls show some outward curvature (limited to the regions below the temporal lines). The supraorbital torus is extensively damaged, and none of the face is preserved.

Omo 1 was excavated at the KHS site, dated to 195 Ka (McDougall et al. 2005), from which there is now a large collection of Middle Stone Age artifacts. This individual is represented by only small portions of a skull, but much more of the postcranial skeleton is present. The cranium as reconstructed by several workers is globular in form, with expanded parietals and an occipital that is more rounded than that of Omo 2. To the limited extent that these can be checked, cranial superstructures (crests and tori) are not strongly expressed. The anterior part of the mandible shows clear signs of chin formation. Given these important markers of modern morphology, there is general agreement that Omo 1 should be regarded as early *H. sapiens*.

An important question, still not firmly resolved, is whether the Omo 1 skeleton can be grouped with the more archaic Omo 2 remains or whether these individuals should be placed in separate populations. The morphological differences between the two crania are very substantial. Indeed Omo 2 has been compared to specimens such as Broken Hill or Elandsfontein, even though the frontal is rather less narrowed behind the orbits. If the Omo fossils are approximately the same age, then there are two possibilities. Omo 2 may be a remarkably robust individual, within a highly variable but essentially modern population. Alternatively, this specimen can be regarded as representative of an archaic, late-surviving lineage, present alongside anatomically modern humans. However, if Omo 2, picked up on the surface, is actually older than implied by recent dating for the PHS site, then it is easier to argue that the cranium is sampled from an earlier portion of the lineage ancestral to *H. sapiens*.

Specimens from Herto in the Middle Awash region confirm the presence of *H. sapiens* in northeastern Africa late in the Middle Pleistocene. Three fossilized crania recovered in 1997 show cut marks associated with postmortem defleshing and are associated with a stone tool assemblage that can be characterized as late Acheulean or Middle Stone Age. The bones and artifacts are dated radioisotopically to between 160 and 154 Ka (Clark et al. 2003). One of the adult crania

(BOU-VP-16/1) is intact, with a brain size estimated as 1,450 cm^3 (White et al. 2003). This individual is ruggedly built, with a very prominent, bilaterally arched glabella, a long vault, and a distinctly flexed occipital. The parietal walls are convex rather than inward sloping, and the index of neurocranial globularity (Lieberman et al. 2002) calculated as ca. 0.54 for BOU-VP-16/1 is high enough to be within the range expected for anatomically modern humans. A second adult cranium is less complete, and there is a child estimated as 6–7 years in age. As a group, the Herto individuals are very robust but display morphologies that place them close to recent populations. White et al. (2003) have referred the fossils to a new subspecies of *H. sapiens*.

Middle Pleistocene Hominins from Europe

Skulls very similar to those from Africa have been found in western Eurasia. Several of the principal localities lie close to the Mediterranean Sea, but it is apparent that humans were also able to reach Britain and central Europe, relatively early in the Middle Pleistocene (Fig. 1).

The Cranium from Petralona

Petralona lies near the city of Thessaloniki in northern Greece. The exact provenience of the hominin fossil found within cave deposits containing the bones of numerous extinct animals is uncertain, but the Middle Pleistocene antiquity of this material is not in doubt. The cranium itself is exceptionally well preserved (Fig. 3)

Fig. 3 Lateral and facial views of the cranium from Petralona, Greece. This European hominin resembles Middle Pleistocene specimens from Africa. The Petralona and Broken Hill individuals are especially similar in measurements relating to facial proportions and vault shape

and would have enclosed a brain close to 1,230 cm^3 in volume (Stringer et al. 1979). Supraorbital tori are about as massive and projecting as in Broken Hill, while CT scans show that the frontal sinuses are greatly expanded. These air cavities extend posteriorly toward bregma and also laterally, where they are separated from the sphenoid sinuses only by thin bony partitions (Seidler et al. 1997). The frontal bone itself is relatively shorter and broader than in Broken Hill. The ratio of least to greatest frontal breadths is 91.6; postorbital constriction is thus less pronounced than in Broken Hill but comparable to that estimated for the Elandsfontein specimen. Petralona also differs from Broken Hill in having a wider cranial base and a less prominent torus crossing the occipital bone. However, the two hominins are alike in many other aspects of vault shape, in orientation of the infraorbital region, and in several measures of facial projection (Rightmire 1998, 2001; Friess 2010; Harvati et al. 2010, 2011).

Arago Cave

Much the same conclusion applies to the less complete cranium from Arago Cave in France dated to about 450 Ka. The partial cranium numbered Arago 21 has a face that is largely intact but damaged as a result of its long interment in compacted cave sediments. The frontal bone, interorbital pillar, nose, and cheeks show numerous cracks, and areas of localized crushing are present. The discoverers have been able to correct some of this damage in a reconstruction, but significant distortion remains. Nevertheless, it is evident that Arago 21 is somewhat smaller than Petralona or Broken Hill in brow thickness, upper facial width, and facial length. Height of the bony orbit and the subnasal part of the maxilla are especially reduced, and the nasal saddle seems to be less elevated relative to the orbital margins. Apart from these differences, Arago 21 is similar in its proportions to the Broken Hill cranium from Africa (Rightmire 2001).

Some workers discern resemblances to Neanderthals. Hublin (1996) and Arsuaga et al. (1997) note that the infraorbital surface of the Arago 21 maxilla is flattened and the cheek bones are obliquely oriented, as in Neanderthals. Also, there is forward protrusion of the face at subspinale (in the midline, just below the nasal opening), and the nasal aperture is bounded inferiorly by a sharp rim. These observations must be tempered by the fact that cracking and plastic deformation make it difficult to assess key aspects of morphology. The wall of the Arago 21 maxilla is generally flattened or even inflated in the manner characteristic of Neanderthals, but the cheek is slightly hollowed laterally, below the orbit. This feature cannot be due entirely to damage. Also, it is not clear that the zygomatic bone is swept back (obliquely oriented) so noticeably as in later European populations. In facial forwardness at subspinale [as measured by the zygomaxillary angle of Howells (1973)], Arago 21 at 113° is in the Neanderthal range, and Petralona at 118° shows almost as much protrusion. But the value for Broken Hill is only 116°, so a low zygomaxillary angle does not align Arago 21 and Petralona with Neanderthals rather than with other Middle Pleistocene specimens. The sharp inferior margin of the Arago nose is indeed reminiscent of that in Neanderthals. However, there is variation in this feature. Petralona is rather less like the Neanderthals, while some later Europeans including the Sima hominins (section "Sima de los Huesos, Atapuerca") have a pattern of cresting on the nasal floor resembling that in Broken Hill or Bodo.

In addition to the partial cranium, the cave at Arago has yielded several mandibles, of which two have been described. Arago 2 is the more complete, missing only the angle and ascending portion from the left side. This specimen has sustained damage anteriorly, where the symphysis and left corpus are cracked. Arago 13 is a large hemimandible (right side), in relatively good condition. Both specimens present a mix of archaic and more modern characters. Development of the lateral prominences, marginal tori and tubercles, and internal symphyseal buttresses is comparable to that observed in *H. erectus*, although the alveolar planum is steeper and less shelflike in the Arago individuals. Arago 2 displays definite incurving of the symphyseal face below the alveolar border. Here, the elements of a mental trigone are present, while in Arago 13, signs of "chin" formation are less clear. Both jaws have retromolar fossae. However, in Arago 13, this fossa is restricted, and the crown of M_3 is partly obscured by the leading edge of the ramus when the specimen is viewed from the side.

The Arago mandibles are important not only because they reveal information about a Middle Pleistocene hominin population but also because they can be compared to the jaw from Mauer, near Heidelberg in Germany. Assigned a radiometric age of 609 Ka (Wagner et al. 2010), the Mauer fossil is likely to be one of the oldest recovered in Europe. It has often been described as primitive, with a massive body and very thick symphysis lacking any mental eminence. At the same time, the broad ramus, increased symphyseal height, and moderate size of the teeth suggest a morphological pattern different from that of *H. erectus*. The mandible was referred to the (new) species *H. heidelbergensis* by Schoetensack (1908). As the Arago jaws resemble the Mauer specimen, it is possible to link the French assemblage with the same taxon. Similarities of the Arago 21 face to Petralona (or Broken Hill) in turn provide a formal basis for including other European (or African) individuals in *H. heidelbergensis*.

Sima de los Huesos, Atapuerca

The species *H. heidelbergensis* is increasingly well documented by the spectacular finds from Atapuerca in northern Spain. Excavations in the Sima de los Huesos have produced hominin remains, representing virtually all parts of the skeleton, that their describers have attributed to *H. heidelbergensis*. In addition to skulls, there are many postcranial bones, and it is clear that at least some of the Sima (male) individuals were tall and robust (Arsuaga et al. 1999a). Somewhat surprisingly, sexual dimorphism is comparable to that expressed in recent populations. The cave also contains the bones of bears and a few other carnivores, but there are no herbivores that might represent food waste. With one exception, there are no stone artifacts. A single hand axe fashioned from red quartzite was discovered in 1998. Investigators working at the Sima have argued that the skeletons were deposited in this pit by other humans and that the unique hand axe documents symbolic behavior (Carbonell and Mosquera 2006). First application of U-series dating to a speleothem present in the lower part of the stratigraphic sequence suggested a date of >350 Ka (Bischoff et al. 2003). More recent sampling from the same speleothem points to an age for the fossils of ca. 530 Ka (Bischoff et al. 2007).

Two of the Sima adults provide estimates for brain size. At close to 1,100 cm^3, SH 5 is rather small, but SH 4 with a capacity of 1,390 cm^3 is one of the largest of all Middle Pleistocene specimens. The crania are primitive in some respects, and the massive face of SH 5 is surmounted by a prominent browridge. Vault bones are thickened, and both sagittal keeling and an angular torus are variably developed. The braincase is broadest in the supramastoid region or just above the ear openings. As do their European and African contemporaries, the Sima hominins also exhibit derived traits in the face, shape of the squamous temporal, proportions of the occipital bone, and structure of the cranial base.

An important question is the extent to which these people resemble the later Neanderthals of Europe. As described by Arsuaga et al. (1997), the midface of SH 5 seems to anticipate the distinctive morphology associated with Late Pleistocene Europeans. The infraorbital surface and the side wall of the nose meet at a shallow angle, so as to produce a slight concavity. The cheek region is thus not “inflated” in the extreme manner of Neanderthals, but it can be interpreted as intermediate in form. Also in the Sima sample, continuity of the supraorbital tori at glabella is said to be reminiscent of Neanderthals, and the broad nasal bones are set in a relatively horizontal orientation. At the rear of the cranium, the suprainiac area is large but not very depressed. This trait and the shape of the occipital torus may also foreshadow the Neanderthal condition. How these features are evaluated (whether any of them can be judged to be true Neanderthal apomorphies) will determine how the Sima hominins as well as Arago and Petralona are related to populations outside of Europe and how these regional paleodemes should be treated in phylogenetic schemes.

The TD6 Assemblage from Gran Dolina, Atapuerca

Additional evidence bearing directly on the first peopling of Europe is accumulating from another site in the Atapuerca region. Excavations at Gran Dolina have uncovered stone core-choppers and flakes, animal bones, and human remains dating to the end of the Early Pleistocene. An age slightly in excess of 780 Ka for the TD6 level containing the fossils now seems to be established (Falguères et al. 1999). Cranial specimens include a juvenile face, an adult cheek bone, part of a subadult frontal with some of the brow, and a piece of the cranial base on which most of the joint cavity for the mandible is preserved. There are also broken lower jaws with teeth, along with vertebrae, ribs, and bones of the hand and foot.

Arsuaga et al. (1999b) argue that the TD6 people are not *H. erectus*. Morphology of the hollowed cheek region, vertical orientation of the nasal aperture, features of the hard palate, form of the developing (but already substantially thickened) brow, a wide frontal, the shape of the temporal bone at the side of the vault, and the apparently modern mandibular joint all suggest that the Gran Dolina fossils are different from *H. erectus* and more like later humans. Also, there can be little doubt that this population is distinct from the later Neanderthals. The hollowed cheek (bearing a "canine fossa") points toward this conclusion, and neither in the juvenile nor in the adult faces is there much sign of the specialized Neanderthal condition. One partial mandible is generalized in its morphology, while the teeth resemble those of European and African Middle Pleistocene hominins.

Given this complex of traits, the Gran Dolina material may represent a new species. The name *H. antecessor* was proposed by Bermúdez de Castro et al. (1997). However, the number of fossils is still quite small, and several of the craniodental remains are fragmentary and/or subadult. A fair question is whether there is presently enough evidence to separate the TD6 assemblage from other penecontemporary fossils already on record. In particular, it must be asked whether the Gran Dolina bones and teeth differ from those of other early Europeans such as Mauer, Arago, and the Sima de los Huesos. Much attention has been focused on the development of a "canine fossa" in the midface. Hollowing is indeed apparent in the cheek of the TD6 juvenile, but a fossa is less obvious in the TD6 adult. This feature is variable in its expression in other populations, and the significance of this pattern is unclear. In the mandible, teeth, and postcranial bones, there seem to be few traits that differentiate the Gran Dolina hominins from Europeans of the Middle Pleistocene.

South Asia and the Far East

One South Asian locality deserving mention is the Narmada Valley in central India (Fig. 1). Part of a cranium was found there in 1982, embedded in a conglomerate containing animal bones and a scattering of Acheulean artifacts. Dates for this material are poorly constrained, but it is probably of Middle Pleistocene age (Sonakia and Biswas 1998). Unfortunately the skull is damaged and lacks most of the face. Narmada has been described by its finders as *H. erectus*, but it is better compared to *H. heidelbergensis* (Kennedy et al. 1991). In its overall morphology, the cranial vault is not very different from the African and European hominins already discussed.

Early humans occupied China before 1.6 Ma (Zhu et al. 2004). This part of Asia has been a focus of research in paleoanthropology for quite a long time. Apart from the famous discoveries of *H. erectus* at Zhoukoudian, there are important sites dating to the later Middle Pleistocene. One is Dali and another is Jinniushan, both of them in northern China. The Dali cranium was found in river terrace deposits with stone flakes and fauna. The Jinniushan skeleton was recovered from cave fill containing animal bones but no artifacts. ESR and U-series dates obtained from animal teeth suggest ages of perhaps 300–200 Ka.

Dali is much of a cranium, damaged on the right side and at the base. The alveolar process and palate have been crushed upward. The specimen is otherwise undistorted and carries a lot of information. It has most often been described as "archaic" *H. sapiens*, intermediate in form between *H. erectus* and recent humans. Indeed, there are similarities to *erectus*, and these include the heavy brow, a long low vault that is broad across the base, and the sharply angled occiput. The temporomandibular joint cavity is offset laterally, and the cranial bones are thickened. These traits are best described as primitive retentions. At the same time, Dali exhibits other advanced features that link it to later populations. There is not much postorbital constriction, and the parietal walls are vertical rather than inward sloping. Both the high temporal squama and the proportions of the occiput depart from the *erectus* condition. The face is particularly short and non-prognathic (Wu and Athreya 2013).

The Jinniushan cranium has been reconstructed several times, and there are gaps in the face, the frontal region, and the base. The brow is somewhat less massive than in Dali, but there is an eminence behind bregma, and the occiput is flexed. In other respects, the specimen differs from *H. erectus*. Brain volume is close to 1,300 cm^3. The border of the nasal aperture is vertical (rather than angled forward), and the nasal sill is crested. On the palate, the incisive canal opens anteriorly (just behind the incisor roots) as in recent humans.

In many anatomical details, both Dali and Jinniushan are like other Middle Pleistocene hominins from Africa or Europe. Comparisons based on facial measurements show that the Chinese specimens resemble Broken Hill to about the same extent as does Arago 21 (Rightmire 2001). There are some differences relative to Broken Hill, particularly in upper facial height (reduced in Dali and Jinniushan) and flattening below the nose (more pronounced in Jinniushan). Also, the Dali cheek exhibits a "canine fossa." This feature has been taken as a basis for regarding the Chinese fossil(s) as distinct from western populations, but in fact hollowing of the infraorbital surface can be documented for faces outside of the Far East. Finds from Gran Dolina suggest that this feature may appear in Europe at the beginning of the Middle Pleistocene (section "The TD6 Assemblage from Gran Dolina, Atapuerca"). The recognition of such variation will make it harder to argue for isolation of the major Old World geographic provinces.

Brain Size, Encephalization, and Speciation

Many of the Middle Pleistocene hominins have brains that are enlarged relative to those of *H. erectus*. For 10 of the more complete crania including Bodo, Broken Hill, Petralona, two of the Sima de los Huesos adults, Dali and Jinniushan, average capacity is 1,206 cm^3. For 30 *H. erectus* individuals, the mean volume is only 973 cm^3. This difference is substantial, and it can be determined that a number of the Middle Pleistocene specimens actually lie beyond the limits predicted for an average *H. erectus* of comparable antiquity. Apparently, the change in brain size is not simply a consequence of larger body mass (Rightmire 2004).

Encephalization quotients (EQ) can also be obtained for a number of the specimens. This entails first estimating body mass from orbital height (following Aiello and Wood 1994) and then deriving EQ from the relationship of brain weight to body mass established for mammals by Martin (1981). Here, there are various complications. Apart from the error associated with any weight estimate, there is the fact that the regression equations of Aiello and Wood (1994) are based on several species. Because EQ is a function of body mass predicted for individuals using an interspecific equation, comparisons of the EQ values determined for fossils may be misleading (Smith 2002). In any event, six *H. erectus* crania from Africa and Asia are complete enough to supply the necessary measurements, and the average EQ is 3.61 (Rightmire 2004). This result is comparable to that reported by Ruff et al. (1997), who employ mean estimates of brain and postcranially based body masses to compute EQ values of 3.40 and 3.46 for temporally defined (Early Pleistocene to early Middle Pleistocene) assemblages.

During the balance of the Middle Pleistocene, a rise in EQ is apparent. Bodo and Broken Hill remain within the range observed for *erectus*, but other individuals have higher values and the average for eight specimens is 5.26. The magnitude of this increase is greater than that determined by Ruff et al. (1997) for humans of mid-Quaternary age. These authors use unmatched brain and body weights (means for samples of disassociated crania and postcrania) as a basis for their EQ calculations, and this may account for some of the difference in results. Also, orbit height may tend to underestimate body mass in comparison to predictor variables drawn from the postcranial skeleton. Nevertheless, there is evidence for a shift in brain size at or just before the onset of the Middle Pleistocene.

This increase in encephalization seems to be linked to an episode of speciation. It is generally assumed that the larger brain and accompanying changes to the vault and face distinguish *H. heidelbergensis* from *H. erectus*. Here, an important question must be raised. Differences in frontal proportions, the parietal arc, form of the temporal squama, and rounding of the occiput may be related to the expanding brain, as may the increase in cranial height. As a consequence, traits such as parietal length and occipital curvature are not independent, and it will be incorrect to claim that each of these measurements adds new information useful in phylogenetic analyses. If this is the case, it may not be reasonable to recognize one or more new species, primarily on the strength of an increase in cranial capacity. Examined critically, the morphological evidence may not justify the recognition of so many taxa within *Homo* (Lieberman and Bar-Yosef 2005).

Correlation analysis provides information about the interactions of brain volume with vault form in Pleistocene *Homo* (Rightmire 2012, 2013). It can be determined that the expanding brain influences vertex height and probably also parietal sagittal length. However, brain size fails to influence vault breadth within either *H. erectus* or the Middle Pleistocene hominins. Instead, the cranial base has a major effect on variations in width. Endocranial volume is not associated with the frontal flattening that is so characteristic for *H. erectus*. In *H. erectus*, and in individuals such as Bodo and Petralona, the massive face seems to override the brain as a determinant of frontal form. Encephalization does not explain the occipital rounding that distinguishes Broken Hill, Omo 2, and the Sima crania. Evidently, apart from greater vertex height, few of the vault characters considered diagnostic for *H. heidelbergensis* can be attributed directly to changes in the brain. Traits that are independent can be used to document speciation.

Phylogenetic Hypotheses

Discoveries of new fossils, reassessments of specimens found earlier, and advances in the application of dating techniques show that hominins differing from *H. erectus* appeared in southern Europe before 780 Ka and in Africa at about the same time. One reading of the record suggests that these European and African groups share a number of derived features of the cranial base and vault. Other similarities to later humans are apparent in the facial skeleton (orientation of the nasal aperture, location of the palatal incisive canal) and perhaps the mandible (symphyseal height increased relative to the posterior corpus, incipient mental eminence). Postcranial bones known principally from the Sima de los Huesos in Spain suggest that the European hominins were heavily built, perhaps reflecting adaptation of body form to a temperate environment. In sum, the anatomical evidence can be interpreted as supporting a claim that all of the earlier Middle Pleistocene fossils belong to a single lineage (Fig. 4a). This species can be called *H. heidelbergensis*. Later in the Middle Pleistocene, some populations dispersed northward within Europe, where they were subject to long episodes of extreme cold. During glacial advances and retreats occurring over several hundred thousand years ago, these hominins continued to adapt to harsher (cold/dry) conditions and evolved the specialized craniofacial characters and body build of the Neanderthals. In this same interval of time, other representatives of *H. heidelbergensis* in Africa were becoming more like modern humans. Fossil finds from Irhoud in Morocco, the Omo in southern Ethiopia, Herto in the Middle Awash region, and Laetoli in Tanzania document this evolutionary progression toward *H. sapiens*.

Alternatively, it can be argued that *H. antecessor* is the ancestor to all later humans (Fig. 4b). This species is considered to be descended from (African) *H. erectus* (Bermúdez de Castro et al. 1997). Rather soon after its first appearance in Spain, *H. antecessor* must have given rise to *H. heidelbergensis*. In this scenario, the *heidelbergensis* lineage was confined exclusively to Europe, where its members gradually acquired the large nose, more projecting facial skeleton, and other morphology of the Neanderthals. This is the accretion hypothesis of Dean et al. (1998). Also, *H. antecessor* is presumed to have evolved an African offshoot, represented at localities such as Bodo, Broken Hill, and Elandsfontein. Although these Middle Pleistocene hominins are acknowledged as morphologically similar to (perhaps even capable of exchanging genes with) their European contemporaries, they are not assigned to *H. heidelbergensis*. Instead, the African fossils are lumped

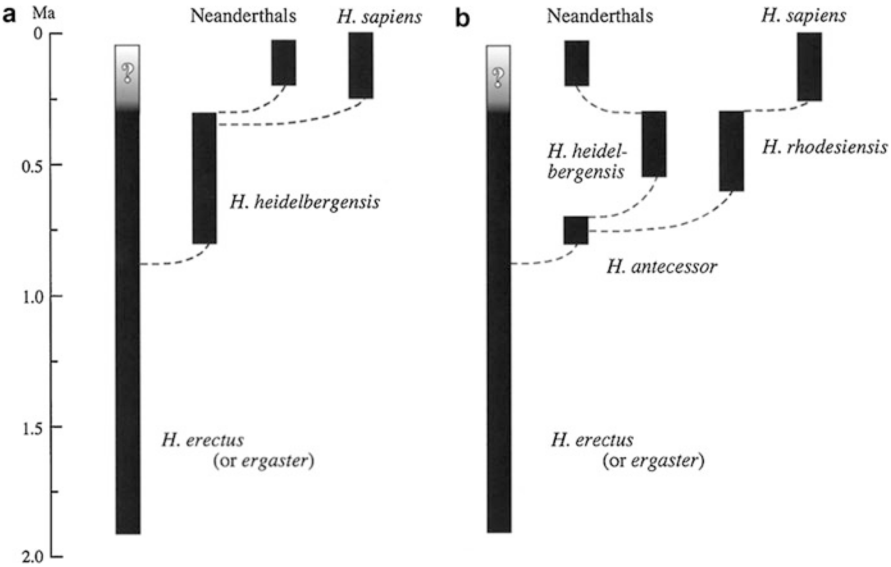

Fig. 4 Alternative evolutionary trees showing the relationships among *H. erectus*, Middle Pleistocene hominins, Neanderthals, and modern humans. Bars depict the time range estimated for each species. Broken lines indicate likely links of ancestors with descendants. Hypothesis (**a**) shows *H. heidelbergensis* to be descended from *H. erectus*. This species must have dispersed widely across Africa and western Eurasia at the beginning of the Middle Pleistocene, and some populations may also have reached the Far East. Here *H. heidelbergensis* is depicted as the antecedent to both Neanderthals in Europe and recent humans all across the old World. In a different interpretation (**b**), *H. antecessor* is recognized as the direct descendant of *H. erectus*. In turn, *H. antecessor* evolved into European *H. heidelbergensis*, and this species gave rise (only) to the Neanderthals. African *H. rhodesiensis* is considered to be ancestral to *H. sapiens*

in a separate species, for which the nomen *H. rhodesiensis* is available. Whether this taxonomic view can be accepted will depend largely on the outcome of excavations that are continuing in the TD6 levels at Gran Dolina. It will be important to expand the sample of fossils documenting the earliest European settlers.

Another question is whether the far eastern specimens can be accommodated within one of these systematic frameworks. The answer is a tentative yes, although the evidence is sparse. Dali and Jinniushan do share a number of apomorphic traits with the western hominins. But there are some differences, and the face has been a focus of contention. Dali has a short face, and this would be true even if damage to the maxilla were corrected. Jinniushan also has a short clivus (the subnasal portion of the maxilla), and it is oriented vertically. In Dali, there is hollowing of the cheek below the orbit, and such excavation is not present in the African crania. Much has been made of this facial morphology, but in fact there is individual variation (see section "Brain Size, Encephalization, and Speciation"). The significance of the Dali “canine fossa” should not be overemphasized. It is possible to argue that the later Middle Pleistocene hominins of China document an eastward excursion of *H. heidelbergensis*, where this species is taken to be the link between *H. erectus* and all later humans. Dating is not very firm, but probably fossils such as Dali and Jinniushan are younger than those in Africa. This may suggest that *H. heidelbergensis* was a late arrival in the eastern part of Asia.

Current Debates

A differing interpretation arises from ongoing analyses of the discoveries at the Sima de los Huesos. As noted above, the Sima skulls exhibit traits expected to occur (very) early in the evolution of the Neanderthal lineage (Arsuaga et al. 1997). Recently, it has been emphasized that the Sima de los Huesos teeth are remarkably like those of “typical” Neanderthals (Martinón-Torres et al. 2012). The upper incisors display conspicuous labial convexity and a distinctive shovel shape, while the upper premolars present a bulging of the buccal aspect of the crown. The M^1s possess an enlarged hypocone, giving the crown a rhomboidal outline characteristic of Neanderthals. The P_3s have a symmetrical contour. Here, the talonid is reduced or absent, so that the remaining cusps occupy a small area near the lingual border of the crown. This Neanderthal-like morphology is more pronounced in the Sima sample than in other Middle Pleistocene hominins. Indeed, Martinón-Torres et al. (2012) claim that the Sima specimens are “more Neanderthal” in form than the Mauer or the Arago dentitions. They suggest that the Sima may constitute a source population for Neanderthals, while Mauer and Arago document the presence of a morphologically distinct lineage. Such a conclusion is favored by Stringer (2012), who envisions two species coexisting in the European Middle Pleistocene. The second species (*H. heidelbergensis*) includes fossils presumed to predate the evolutionary emergence of *H. neanderthalensis*, as well as specimens such as Petralona from later time periods.

Archaeology and Behavior in the Middle Pleistocene

Controversy over the number of Middle Pleistocene lineages in Eurasia and Africa will likely continue. Nevertheless, it is becoming clear that the hominins were more encephalized than *H. erectus*. Also, there is evidence from archaeology that these people were developing new behavior. Later Acheulean artifacts are known from numerous African sites, including Bodo, Olorgesailie, Isimila, Lake Ndutu, the Cave of Hearths, Elandsfontein, and Duinefontein 2. In general, later Acheulean hand axes can be characterized as thinner, more symmetrical, and bearing many more flake scars than their earlier counterparts. In some sites, relatively small hand axes are accompanied by flake tools resembling those of the Middle Stone Age (Klein 2000). While it is dangerous to expect universal associations of *Homo* species with particular industrial traditions, informative patterns may be uncovered (Foley and Lahr 1997). In virtually all mid-Quaternary African contexts, where diagnostic human bones are found with later Acheulean artifacts, the maker is *H. heidelbergensis* (or *H. rhodesiensis*). One may conclude that this species was capable of producing a tool kit more sophisticated than that utilized routinely by *H. erectus*.

In western Eurasia, hominins equipped with Acheulean tools were present by the onset of the Middle Pleistocene (780 Ka) at Gesher Benot Ya'aqov in Israel (Goren-Inbar et al. 2000). Farther to the west in Europe, there are no Acheulean sites from the beginning of the Middle Pleistocene, but Boxgrove in Britain is likely to be 500 Ka in age. This locality has yielded thin, extensively flaked flint bifaces, along with bones of horses and rhinoceroses bearing cut marks. The animals may well have been hunted and butchered. In addition, there is the shaft of a human tibia. The dimensions of this bone at midshaft are large, and the Boxgrove individual was probably quite massive. This hominin has been attributed to *H. heidelbergensis* by Roberts et al. (1994). Signs of later Acheulean toolmakers are known from Torralba and Ambrona in Spain, where the artifacts are again found with large herbivores, including elephants and horses (Freeman 1994). Acheulean artifacts occur also at several sites in France and Italy. At Castel di Guido in central Italy, finely flaked bifacial tools were produced from elephant bone (Villa 1991). At some other earlier Middle Pleistocene localities, including Arago Cave, the stone industries contain small chopping tools and flakes but no hand axes (De Lumley et al. 1984). The reasons for this difference are unclear, but the availability of suitable raw materials, the constraints imposed by different types of stone, and the context in which tools were manufactured must all be considered, along with the possibility that distinct cultural behaviors or styles are represented.

An isolated but particularly significant example of the skills acquired by mid-Quaternary Europeans comes from Schöningen in Germany. Eight carefully crafted wooden throwing spears have been uncovered near a former lake, where they are associated with flint tools and chips (Thieme 1997, 2005, 2007). Scattered through the same horizon are the remains of numerous horses. Many of the bones are cut-marked, and some of the animals must have been processed for meat and marrow extraction (Roebroeks 2001). More convincingly than other early European assemblages, the Schöningen discovery points to systematic hunting of large animals. Stalking and killing of agile or dangerous prey requires experience and practice, and it is reasonable to hypothesize that the people were cooperating with one another in these efforts. Increased levels of social cooperation and exchange of knowledge would have become the norm. And if the hunters at Schöningen (also at sites such as Boxgrove and Arago) were able to obtain large amounts of meat, they would likely have shared or exchanged food with other groups, perhaps at established meeting places (Roebroeks 2001). Certainly our understanding of the behavior of the early Europeans remains quite incomplete, but it is apparent that bands of *H. heidelbergensis* were not only skilled at flaking stone but also capable of interacting regularly in the pursuit of game and other social activities.

Conclusion

Middle Pleistocene crania from Bodo, Broken Hill, Elandsfontein, and Lake Ndutu in Africa are quite similar to penecontemporaneous fossils from Europe. Craniodental remains and jaws from Petralona and Arago Cave are particularly informative, and the assemblage from Sima de los Huesos is spectacular. If this grouping is expanded to include the Mauer mandible, then it can be argued that *H. heidelbergensis* was a geographically dispersed paleospecies.

A question is whether additional specimens from China can be accommodated within this taxon. Dali and Jinniushan share a number of apomorphic traits with the western hominins, but there are differences, and the face has been a focus of contention. Dali has a short face, and there is hollowing of the cheek below the orbit. Probably the significance of the Dali "canine fossa" should not be overemphasized. Later Middle Pleistocene populations of China may document an eastward excursion of *H. heidelbergensis*, where this species is taken to be the link between *H. erectus* and all later humans.

Homo heidelbergensis differs from *H. erectus* in absolute as well as relative brain size. Correlation analysis provides information about the interactions of brain volume with vault form. It can be determined that the expanding brain influences vertex height and probably also parietal sagittal length. Traits that vary independently from brain volume have greater taxonomic utility and include anterior frontal broadening, perhaps the high, arched outline of the temporal squama, and lateral expansion of the parietal vault. Encephalization does not explain the occipital rounding that distinguishes Broken Hill, Omo 2, and the Sima crania, nor does it account for the greater elevation of the lambda-inion chord. Traits of the cranial base also serve to diagnose *H. heidelbergensis* in relation to *H. erectus*. Morphology of the temporomandibular joint generally resembles that in *H. sapiens*, as is the case for the tympanic and petrous portions of the temporal bone. There is no reduction in overall face size in comparison to *H. erectus*, and the facial skeleton seems to be "hafted" to the braincase in such a way as to accentuate anterior projection. But reorientation of the nasal aperture and forward placement of the incisive canal within the palate suggest that the face of *H. heidelbergensis* may be more nearly vertical, as in *H. sapiens*.

Later Acheulean artifacts are known from many mid-Pleistocene African localities, and in general, the hand axes can be characterized as thinner and more symmetrical than earlier examples. In some sites, relatively small hand axes are accompanied by flake tools resembling those of the Middle Stone Age. While it is dangerous to expect universal associations of *Homo* species with particular industrial traditions, in virtually all African contexts where diagnostic human bones are found with later Acheulean artifacts, the maker is *H. heidelbergensis*. One may conclude that these people were more advanced in behavior than their predecessors. There is evidence that *H. heidelbergensis* was able to make relatively sophisticated stone tools, hunt larger and more dangerous game animals, and perhaps engage in cooperative social activities.

Abstract

Neanderthals are the group of fossil humans that inhabited Western Eurasia from the mid-Middle Pleistocene until ca. 40 Ka ago, when they disappeared from the fossil record, only a few millennia after the first modern humans appear in Europe. They are characterized by a suite of morphological features that in combination produce a unique morphotype. They are commonly associated with the Mousterian lithic industry, although toward the end of their tenure they are sometimes found with assemblages resembling those produced by early modern humans. Although there is still discussion over their taxonomic status and relationship with modern humans, it is now commonly recognized that they represent a distinct, Eurasian evolutionary lineage sharing a common ancestor with modern humans in the Middle Pleistocene. This lineage is thought to have been isolated from the rest of the Old World, probably due to the climatic conditions of the glacial cycles. Glacial climate conditions are often thought to have been at least in part responsible for the evolution of some of the distinctive Neanderthal morphology, although genetic drift was probably also very important. The causes of the Neanderthal extinction are not well understood. Worsening climate and competition with modern humans are implicated.

The Discovery of Neanderthals: Historical Background

Although the first Neanderthal remains were discovered in the early nineteenth century (Engis child in 1830, Forbes Quarry adult in 1848), it was not until the discovery of the skeleton from the Neander Valley in 1856, roughly coinciding with the publication of Darwin's "The Origin of Species" in 1859, that the existence of an extinct kind of archaic humans was recognized. It is this locality that lends its name to the group, and it is there that the debate surrounding the relationship of Neanderthals with modern humans began.

The antiquity of the Neanderthal skeleton and its status as an archaic human was not immediately accepted. Instead, its peculiar anatomical attributes were considered the result of various pathologies, including rickets. Its antiquity was only firmly established with the eventual discovery of additional skeletons of similar morphology associated with lithic artifacts and extinct fauna.

Neanderthals were assigned to the species *H. neanderthalensis* as early as 1864 (King 1864). However, once their status as archaic predecessors of modern humans was accepted, their relationship with modern humans, and particularly modern Europeans, began to be intensely debated. The predominant view in the 1910s and 1920s was represented by scientists like Marcellin Boule and Sir Arthur Keith, who were among the most influential scholars of their day. They placed Neanderthals in their own species and rejected any ancestral role for them in the evolution of modern people, pointing out their "primitiveness" and presumed inferiority (Boule 1911/1913; Boule and Vallois 1957).

This perception of Neanderthals began to change during the 1930s. A rearrangement and "pruning" of the tangled hominin taxonomy was undertaken in the 1940s and 1950s by Mayr, Simpson, and Dobzhansky, who placed Neanderthals and other Middle Pleistocene fossil specimens within our own species, *Homo sapiens*. According to this view, Neanderthals were thought to have evolved into modern people through anagenetic evolution (Trinkaus and Shipman 1992, 1993; Tattersall 2000). This view has been reexamined in more recent years, with new evidence coming from modern human and fossil genetic studies, the development of better dating techniques and new approaches to the analysis of morphology. Currently, Neanderthals are commonly viewed as a distinct, Western Eurasian evolutionary lineage, which probably did not contribute significantly to the evolution of modern people.

Chronological Distribution

The earliest human skeletal remains found in Europe have been recovered from Sima del Elefante in Atapuerca, Spain, dated to ca. 1.2 Ma (Carbonell et al. 2008) and from Barranco León, with a possibly even earlier date (up to 1.4; Toro-Moyano et al. 2013; but see Muttoni et al. 2013). Human remains dated to ca. 800 Ka have been recovered from Gran Dolina (Atapuerca, Spain; Bermúdez de Castro et al. 1997; Falguères et al. 1999), and lithic artifacts dated to ca. 700 and possibly up to 950 Ka have recently been discovered in England (Parfit et al. 2005, 2010) documenting an early human presence also in Northern Europe. These early European populations are considered by some to have been ancestral to the later, Middle Pleistocene Europeans and to Neanderthals (e.g., Bermúdez de Castro et al. 1997), but may also represent unsuccessful early episodes of colonization that ended in local extinctions. A calvaria from Ceprano, Italy, previously thought to date to ca. 780–800 Ka (Manzi et al. 2001) has recently been redated to ca. 450 Ka (Muttoni et al. 2009) and is now referred to *Homo heidelbergensis* (Mounier et al. 2011).

The first appearance of Neanderthals in the fossil record is not clear-cut. Neanderthal-like features appear for the first time in a mosaic fashion in Middle Pleistocene European humans, as, e.g., in the large assemblage from Sima de los Huesos (Atapuerca), Spain (Arsuaga et al. 1997), recently dated to between 400 and 600 Ka (Bischoff et al. 2003, 2007; Arnold et al. 2014; but see Stringer 2012 for criticisms of this age estimate). Different Neanderthal-like traits appear at different times and places and in different combinations, but their presence in the European Middle Pleistocene fossil specimens suggests that the latter were early representatives of the Neanderthal lineage (Fig. 1).

A progressively stronger expression of Neanderthal morphology is perceived through time, with specimens from the late Middle Pleistocene/early Late Pleistocene ($\sim$200–100 Ka) showing clear, albeit still not fully expressed, Neanderthal morphology. The full suite of Neanderthal features appears with the "classic" Neanderthals, in the Late Pleistocene, dated from approximately 70–30 Ka. This group includes

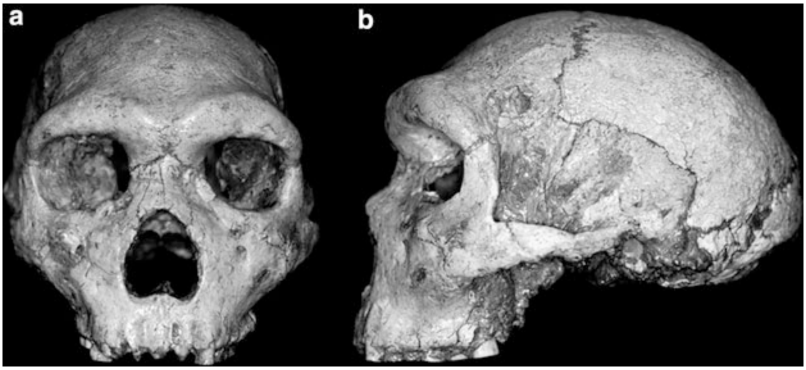

Fig. 1 Frontal (**a**) and lateral (**b**) views of the Middle Pleistocene cranium from Petralona, Greece, showing incipient Neanderthal morphology in its facial region (Courtesy of Eric Delson and © Eric Delson, Photo by K. Harvati)

among others the famous "Old Man" of La Chapelle-aux-Saints, as well as the type specimen from the Neander Valley, Feldhofer 1.

The last date of appearance of Neanderthals, and thus the potential coexistence of Neanderthals and modern humans in Europe, has also been controversial due to methodological issues affecting radiocarbon dating of this period (see Conard and Bolus 2008; Blockley et al. 2008). The radiocarbon chronology of the late Neanderthals throughout Europe has been recently extensively revised using the latest methodological advances. Radiocarbon dates reported here are uncalibrated, unless otherwise specified.

The Neanderthal specimens from Layer G1 at Vindija, Croatia, were recently directly redated to ca. 33–32 radiocarbon Ka BP through direct accelerator mass spectrometry (AMS) using collagen ultrafiltration (Higham et al. 2006), revising previously published younger dates of ca. 29 radiocarbon Ka BP (Smith et al. 1999).

Two sites in France, both associated with the Châtelperronian lithic industry (see below), have been associated with Neanderthal remains. The partial skeleton from Saint-Césaire was originally dated to ca. 36 Ka BP using the thermoluminescence (TL) dating method (Mercier et al. 1991). A recent direct AMS ultrafiltration radiocarbon date on the skeleton produced a somewhat older date of ca. 36 radiocarbon Ka BP (between 41,950 and 40,660 years BP calibrated; Hublin et al. 2012). The Châtelperronian layers containing a subadult Neanderthal temporal bone (Hublin et al. 1996), as well as several Neanderthal isolated teeth (Bailey and Hublin 2006) at Arcy-sur-Cure (Grotte-du-Renne), were originally dated by AMS radiocarbon to ca. 34 Ka (David et al. 2001). Hublin et al. (2012) redated the Châtelperronian and Late Châtelperronian layers at Arcy to between ca. 40 and 35.5 radiocarbon Ka BP using accelerator mass spectrometry radiocarbon dates on ultrafiltered bone collagen (calibrated to between 41,620 and 40,570 years BP).

A very late direct radiocarbon date for one of the Mezmaiskaya (Russia) Neanderthal infants (~29 Ka; Ovchinnikov et al. 2000) is now thought to have resulted from modern carbon contamination. Recent work on this site has produced much older ESR dates (~70–60 Ka for the first infant and ~40 Ka for the second; Skinner et al. 2005), as well as a direct ^{14}C AMS ultrafiltration date on the second infant of ca. 39.7 Ka BP (calibrated to between 42.3 and 45.6 Ka cal BP; Pinhasi et al. 2011).

Several sites in Spain have been proposed as showing late Neanderthal occupation. Zafarraya was until recently considered to be among the youngest Neanderthal sites in Europe. The Neanderthal-bearing layers there had been dated to between ca. 33.4 and 28.9 Ka BP using conventional ^{14}C and uranium series dating (Hublin et al. 1995). The age of these Neanderthal layers has most recently been revised (using ultrafiltration and AMS ^{14}C) to be much older and close to the radiocarbon limit (Wood et al. 2013). A relatively late date for Neanderthal layers at Las Palomas (ca. 34.5 and 35 Ka BP, both AMS ^{14}C on burnt faunal bone; Walker et al. 2008) has been criticized as unreliable due to the difficulties in dating burnt material (Wood et al. 2013). Finally an exceptionally recent date of 24 Ka BP as the date of last appearance of Neanderthals in Iberia based on redating of a Mousterian lithic assemblage (Finlayson et al. 2006) is considered questionable due to stratigraphic inconsistencies (Delson and Harvati 2006) as well as methodological concerns (Wood et al. 2013).

Geographic Distribution

Neanderthals are commonly thought of as European hominins, and Europe is often considered as their geographical area of origin, with specimens outside the continent representing later range expansions (Hublin 1998, 2000). Within Europe, Neanderthals range from Iberia to Russia and from the Mediterranean to Northern Europe. Outside of the continent, their presence has been documented in the Near East and in Western Asia as far east as Uzbekistan (Fig. 2) and Siberia (Krause et al. 2007b).

Eastern Neanderthals are often juxtaposed with those from Western Europe in that their morphology is mosaic in pattern and not fully “Neanderthal” (Vandermeersch 1989; Smith 1991; Rak 1993). In some of their features, Eastern Neanderthals show conditions that have sometimes been perceived as more modern (though not all specimens show the same conditions for the same features), leading some to question the Neanderthal identity of these fossils (Arensburg and Belfer-Cohen 1998). A more widely accepted view is that the weaker expression of Neanderthal traits in these specimens reflects primitive retentions rather than affinities with modern humans (Stringer 1990). Similarly, weakly expressed Neanderthal morphology is found in early Neanderthals, such as those from Saccopastore, again interpreted as retentions of primitive morphology (Condemi 1992).

Morphology

Neanderthals are characterized by a suite of distinctive cranial, mandibular, dental, and postcranial anatomical features (Figs. 3 and 4), some of which represent retentions of ancestral conditions but many of which are derived for this group.

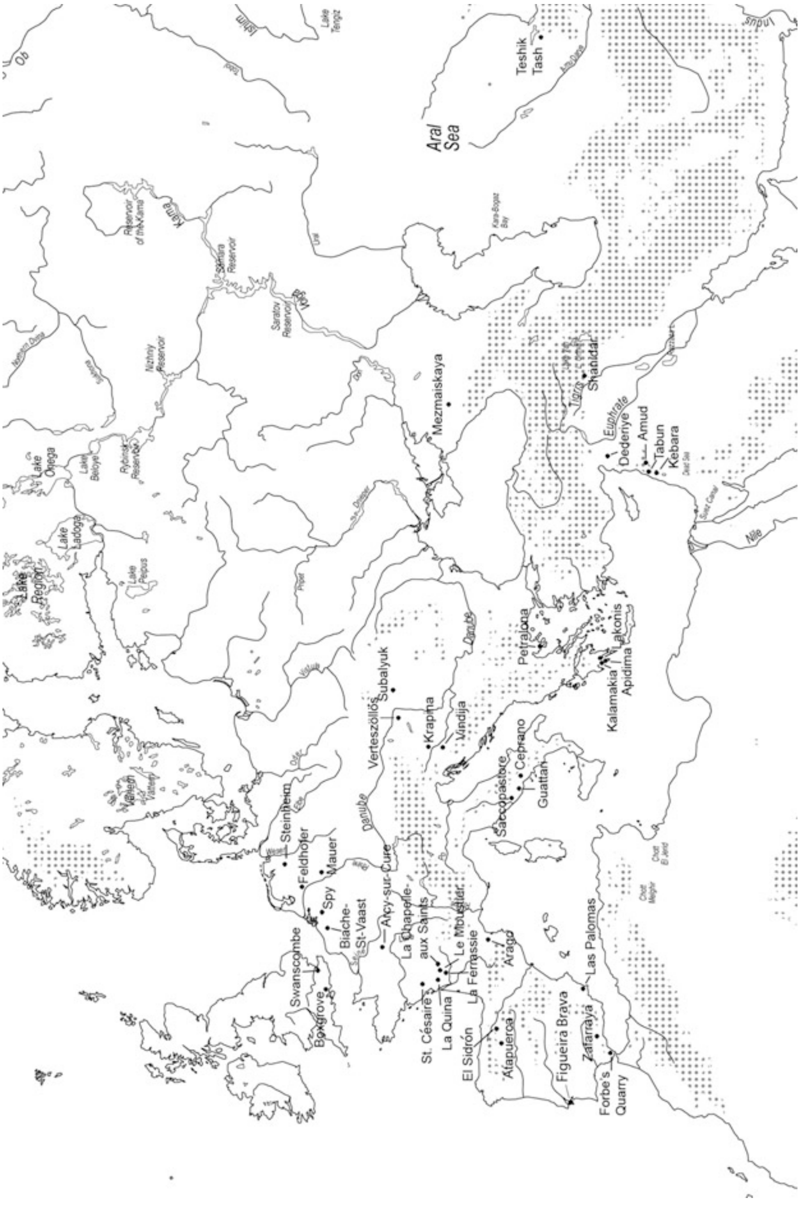

Fig. 2 Map of the geographic distribution of Neanderthals, showing several sites preserving Neanderthal and pre-Neanderthal skeletal remains discussed in the text

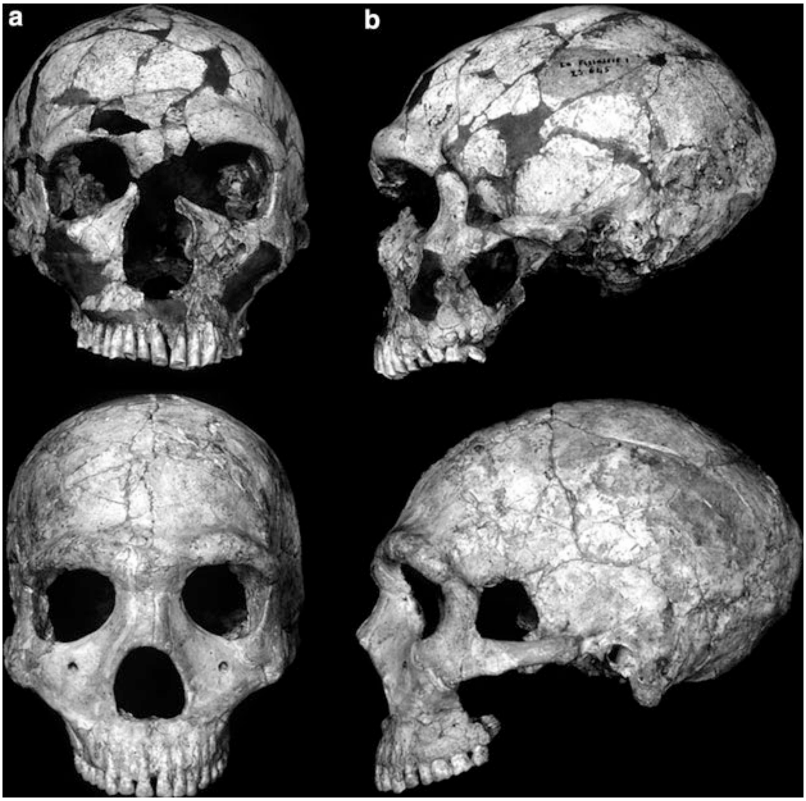

Fig. 3 Frontal (**a**) and lateral (**b**) views of the La Ferrassie 1 (*top*) and Amud 1 (*bottom*) Neanderthal crania (Courtesy of Eric Delson, © Musée de l' Homme and Rockefeller Museum, Photo by C. Tarka for Ancestors)

Primitive traits, shared with the common ancestor of both Neanderthals and modern humans, include their low and elongated crania, heavy brow ridges, large faces with large nasal apertures, and the lack of a chin. Neanderthals share some derived features with modern humans, including enlarged brains, reduced prognathism, a weak occipital torus, and a longer and more rounded occipital. A list of proposed deriver traits is provided in Table 1.

A detailed morphological description of the various anatomical areas follows.

Cranium

Face

The Neanderthal face is characterized by a heavy, double-arched supraorbital torus which does not show distinct elements and grades smoothly onto the frontal squama. The orbits are large and rounded. The nasal aperture is very large and

Fig. 4 Complete Neanderthal skeleton (*left*) reconstructed using elements from five partial skeletons (principally La Ferrassie 1 and Kebara 2) compared to a modern human skeleton (*right*) (Courtesy of Ian Tattersall and Gary Sawyer, Photo by Ken Mowbray)

broad. The nasal cavity is voluminous and displays large medial projections and a bilevel internal nasal floor. Neanderthals show pronounced midfacial prognathism and an oblique and inflated infraorbital plate with no canine fossa, which obliquely recedes into the zygomatic bone. The inferior root of the zygomatic is oblique, and not sharply angled, and the zygomatic processes are elongated and thin. Internally, the maxillary sinuses are large, while the frontal sinus is expanded laterally to fill most of the supraorbital torus (up to midorbit) but does not extend upward into the frontal squama (Heim 1974, 1976; Stringer et al. 1984; Rak 1986; Trinkaus 1987, 2003; Schwartz and Tattersall 1996a; Arsuaga et al. 1997; Franciscus 1999, 2003).

Several alternative hypotheses have been proposed to account for the distinctive Neanderthal facial morphology. The large nasal aperture and associated structures have been proposed to relate to cold-climate adaptation and to function in warming and humidifying inspired air, as well as to dissipate heat (Coon 1962; Dean 1988). Another interpretation sees the Neanderthal facial features as biomechanical consequences of intense paramasticatory behavior evidenced by the unusual anterior tooth wear pattern exhibited in this fossil group (Heim 1976; Rak 1986; Trinkaus 1987). Among recent humans, the shape of the nasal cavity has been shown to be affected by climatic factors such as temperature and humidity (Noback et al. 2011).

Table 1 Some proposed derived Neanderthal features (Adapted from Hublin (1998))

Cranium
Midfacial prognathism
Medial nasal projections above a spinoturbinal crest delineating a prenasal fossa
Double-arched supraorbital torus with no distinct elements
Horizontally flat or convex infraorbital area, obliquely receding in alignment with the anterolateral surface of the zygomatic bone
Secondarily increased relative platycephaly
"En bombe" cranial shape
Highly convex occipital plane (chignon or occipital "bun")
Pitted suprainiac fossa associated with a bilaterally protruding occipital torus
External auditory meatus at the level of the posterior zygomatic arch, with a strong inclination of the basal groove of this process
Flat mandibular fossa
Long and narrow foramen magnum
Laterally flattened, small mastoid process and large juxtamastoid eminence
Anterior mastoid tubercle
Small and inferiorly positioned posterior semicircular canal
Mandible
Mental foramen below the M_1
Retromolar gap
Asymmetric mandibular notch, coronoid process higher than the condyle
Laterally expanded condyle
Oval/horizontal shape of the mandibular foramen
Large pterygoid tubercle
Dentition
Expanded anterior dentition
Taurodontism
Mid-trigonid crest on mandibular molars
Markedly skewed upper molar crowns
Asymmetric mandibular fourth premolar crown

However, large noses and nasal cavities are characteristic of warm-climate populations, although tall nasal apertures characterize arctic populations (Hubbe et al. 2009), making the climatic adaptation hypothesis difficult to evaluate. On the other hand, several studies have rejected the proposed biomechanical advantages of the Neanderthal face (Antón 1994, 1996). A third interpretation considers Neanderthal facial morphology as primarily the result of stochastic processes (Hublin 1998; Weaver et al. 2007).

Vault

Neanderthals show a particularly flat and elongated vault in lateral profile and an "en bombe," rounded profile in posterior view, with the widest point at the mid-parietals. The occipital region shows a highly convex occipital scale, with a flattening above lambda, termed occipital "bun" or "chignon." The occipital torus is weak with no external occipital protuberance. It is inferiorly undercut by the nuchal plane, but not clearly defined superiorly, and shows a pitted oval depression above it (suprainiac fossa). The temporal squama is superoinferiorly low, anteroposteriorly short, and symmetrically arched. The external auditory meatus is elevated relative to the zygomatic process and the floor of the glenoid fossa. The parietomastoid suture is relatively long and straight (Boule 1911/1913; Hublin 1978, 1988a, b, 1998; Stringer et al. 1984; Condemi 1988; Lieberman 1995; Schwartz and Tattersall 1996b; Dean et al. 1998; Harvati 2003b).

Neanderthal endocasts show similar features to those of modern humans (Holloway 1985), but their average cranial capacity is larger measuring approximately 1,520 cm^3 (from 1,200 to 1,700 cm^3). Large brains might be related to cold-climate adaptation in these hominins (Churchill 1998). Even though absolute brain size was larger on average in Neanderthals relative to modern humans, their relative brain size may have been smaller due to their greater body mass (Ruff et al. 1997). The brain enlargement characteristic of both Neanderthals and modern humans appears to have followed distinct evolutionary trajectories in the two lineages, with Neanderthals retaining an archaic endocranial shape despite larger size, and modern humans exhibiting distinct shape, as well as size, changes (Bruner et al. 2004). Modern human endocasts show enlarged parietal lobes, as well as expanded temporal lobes and enlarged cribriform plates compared to Neanderthals (Bruner et al. 2004; Bastir et al. 2011). The distinctive globular shape of the human endocast appears to be achieved early in development, through the addition of a distinct "globularization" phase (Gunz et al. 2010).

Basicranium

The mastoid process is small and equal in size to or smaller than the juxtamastoid eminence. It often shows a mastoid tubercle. The petrotympanic crest originates at the most inferiorly projecting part of the tympanic, and the tympanic plate is coronally oriented. The mandibular fossa is wide, shallow, and medially closed off. The foramen magnum is long, narrow, and ovoid in shape. The cranial base is relatively flattened. Recent examination of the internal morphology of the inner ear using computer tomography (CT) scans has revealed a distinctive shape for the Neanderthal bony labyrinth, most significantly characterized by an inferior placement of the posterior semicircular canal (Vallois 1969; Santa Luca 1978; Laitman and Heimbuch 1982; Trinkaus 1983; Stringer et al. 1984; Stringer 1985; Vandermeersch 1985; Hublin 1988; Condemi 1991, 1992; Elyaqtine 1995; Hublin et al. 1996; Schwartz and Tattersall 1996b; Harvati 2003b; Spoor et al. 2003).

Mandible

Neanderthal mandibles show a receding symphysis resulting in the absence of a mental eminence or chin. There is a space between the third molars and the ascending ramus, termed the retromolar gap. Recent analyses have shown this trait to be related to increased size in modern humans, great apes, and Middle-Late Pleistocene

European fossils, suggesting caution in the interpretation of its derived status. The Neanderthal mental foramen is positioned posteriorly below the first mandibular molar rather than the premolars, unlike modern humans. The gonial area is rounded. The mandibular (sigmoid) notch is shallow and asymmetric with a coronoid process that is higher than the condyle. The mandibular notch meets the condyle in a medial position, and the condyle is laterally expanded. The submandibular and pterygoid fossae are very deep, and the mandibular foramen shows an oval-horizontal shape (Boule 1911/1913; Vandermeersch 1981; Stringer et al. 1984; Tillier et al. 1989; Condemi 1991; Franciscus and Trinkaus 1995; Hublin 1998; Rak 1998; Rosas 2001; Jabbour et al. 2002; Rak et al. 2002; Trinkaus et al. 2003; Rosas and Bastir 2004; Nicholson and Harvati 2006).

Dentition

The dimensions of the Neanderthal posterior dentition completely overlap with those of modern humans. However, Neanderthal anterior teeth, and particularly the incisors, are larger. Neanderthal teeth show enlargement of the pulp chambers (taurodontism), although this trait is variable in its degree of expression and seems to be more weakly expressed in Eastern Neanderthals. Several morphological dental features appear at very high frequencies in Neanderthals compared to modern humans. These include shoveling of the incisors and the presence of a tuberculum dentale; asymmetric lower fourth premolars with transverse crests and distolingual cusps; markedly skewed upper molars; lower molars with mid-trigonid crests; and the absence of four-cusped lower third molars. Finally, the Neanderthal dentition is distinctive in its wear patterns, showing markedly greater wear anteriorly. Although this is not a heritable trait, it has been used to infer behavioral practices (Keith 1913; Trinkaus 1983; Bytnar et al. 1994; Bailey 2002, 2004; Bailey and Lynch 2005; Bailey and Hublin 2006).

Postcranium

The Neanderthal postcranium (Fig. 4) is overall robust, with markedly curved shafts of the femur and radius, thick cortical bone, and strong muscle and ligament markings. Neanderthals were short relative to early modern humans and probably also to earlier *H. ergaster* populations. Estimated stature averages ~169 cm for males and ~160 cm for females. Body mass is estimated at ~78 kg for males and ~66 kg for females. Additional Neanderthal postcranial features include a broad and deep ribcage, with large thoracic volume, especially inferiorly; relatively short distal limb segments; large articular heads of the tibia and femur; a relatively low angle between the femoral neck and shaft; the absence of a pilaster on the femur and a more rounded (in cross section) femoral shaft; a dorsal, rather than ventral, sulcus on the axillary border of the scapula; large and round apical tufts of the manual phalanges and a relatively short proximal thumb phalanx; clavicles showing two curvatures in dorsal view; and an elongated and thin pubic ramus (Boule 1911/1913; Trinkaus 1983; Ruff 1991, 1993, 1994; Holliday 1997a, b; Ruff et al. 1997; Churchill 1998; Rosenberg 1998; Trinkaus and Ruff 1998; Pearson 2000; Voisin 2000; Niewoehner 2001; Franciscus and Churchill 2002; Weaver 2003; Sawyer and Maley 2005).

Several of these traits have been linked to high activity levels and/or cold-climate adaptation. Others could represent Neanderthal-derived features, but since very little is known about their ancestral conditions, no definitive assessments can be made at present. Neanderthal body proportions are commonly viewed as "hyperarctic." It has been suggested that the short stature and short distal limb proportions represent a cold-climate adaptation following Bergmann's and Allen's rules, as seen also in some modern human populations (Trinkaus 1981; Holliday 1997a, b; Steegmann et al. 2002). Overall robusticity, wide trunks, and features of the Neanderthal femur and pelvis have also been linked to climate adaptation (Ruff 1994; Pearson 2000; Weaver 2003). As improved paleoclimatic information suggests that Neanderthal ranges followed favorable climatic conditions, the designation of Neanderthals as "hyperarctic" has been challenged (Finlayson 2004). A recent estimate of the ability of the Neanderthal body shape to withstand cold temperatures showed only a small advantage over early modern humans with a less "cold-adapted" body form (Aiello and Wheeler 2003), indicating that Neanderthals could not have inhabited their high-latitude habitats without substantial cultural insulation.

Life History, Pathology, and Trauma

Neanderthal growth seems in many ways similar to modern humans, although there are indications that some aspects of their development, including brain and dental growth, were accelerated (Dean et al. 1986, 2001; Ramírez Rozzi and Bermúdez de Castro 2004; Smith et al. 2007, 2009, 2010). The age-mortality profile observed among Neanderthals has been found to differ from that of recent human and other mammals in having a low percentage of older adults and infants and a high percentage of adolescents and prime-age adults (Trinkaus 1995). A similar pattern was found in the Atapuerca Sima de los Huesos and Krapina human assemblages (Bocquet-Appel and Arsuaga 1999). Although there are problems associated with such paleodemographic analyses, the observed mortality profile suggests very low adult life expectancy, probably associated with high levels of stress and trauma (Trinkaus 1995). Increased survivorship of adults resulting in a longer lifespan may have appeared very late in human evolution and not until the advent of early modern humans (Caspari and Lee 2004).

Indications of trauma and stress are ample in the Neanderthal skeletal record, so much so that it has been remarked that posttraumatic lesions can be found on almost every well-preserved adult Neanderthal skeleton (Trinkaus 1983; Berger and Trinkaus 1995; Jelinek 1994). An analysis of traumatic lesion patterns in Neanderthals found them to be concentrated in the head and neck region, an uncommon pattern of injury that was argued to result from hunting strategies requiring proximity to large prey animals (Berger and Trinkaus 1995). On the other hand, some injuries have been argued to originate from interpersonal aggression (Trinkaus 1983; Zollikofer et al. 2002; Churchill et al. 2009). As the majority of traumatic lesions in Neanderthals are healed or partially healed, they have also been seen as evidence for social assistance in these hominins, as have the multiple incidents of highly worn or otherwise nonfunctional dentition (Trinkaus 1983, 1985; Lebel et al. 2001; Lebel and Trinkaus 2002).

In addition to trauma, Neanderthal remains show elevated developmental stress (Molnar and Molnar 1985; Ogilvie et al. 1989; Jelinek 1994; Berger and Trinkaus 1995). However, the degree to which this differs from stress levels in recent foraging groups is debated (Hutchinson et al. 1997; Guattelli-Steinberg et al. 2004).

Neanderthal Genetics

Neanderthals are the first extinct human species to yield genetic information. The first glimpse of their mitochondrial DNA came with the publication of the seminal article by Krings et al. (1997). These researchers were able to recover mtDNA from the Neanderthal (Feldhofer 1) type specimen and to compare it to the homologous sequence from diverse modern human populations. The Neanderthal sequence was outside the range of modern human variation and was equally dissimilar to modern human sequences from different geographic regions. It pointed to a last common ancestor for the mitochondrial genome of Neanderthals and modern humans at approximately 500 Ka (between 317 and 741 Ka).

mtDNA has now been sequenced partially or in whole for several Neanderthal specimens from diverse geographic origin (Krings et al. 1997, 2000; Ovchinnikov et al. 2000; Schmitz et al. 2002; Serre et al. 2004; Beauval et al. 2005; Lalueza-Fox et al. 2005, 2006; Caramelli et al. 2006; Orlando et al. 2006; Krause et al. 2007a; Green et al. 2008). All have yielded similar, Neanderthal-like sequences, which group together as a distinct clade, albeit with some geographic patterning (Fabre et al. 2009). On the other hand, all of the earliest Eurasian modern human specimens so far tested have yielded only modern humanlike and no Neanderthal-like mtDNA sequences (Caramelli et al. 2003; Serre et al. 2004; Krause et al. 2010; Fu et al. 2013). A recent analysis of five Neanderthal mtDNA genomes estimated the date of divergence of the Neanderthal and modern human ancestral populations in the mid-Middle Pleistocene (starting at ca. 410–440 Ka BP; Endicott et al. 2010).

More recently it has been possible to investigate also the nuclear DNA of Neanderthals. Nuclear DNA analysis has shown that Neanderthals share with modern humans the FOXP2 gene variant, one of the genes affecting language abilities, which was previously thought to be unique to modern humans (Enard et al. 2002; Krause et al. 2007a). Analysis of the nuclear DNA of an Italian Neanderthal showed that at least that individual did not share the derived allele for microcephalin with modern humans, a gene previously suggested to derive from Neanderthal ancestry (Lari et al. 2010). Ancient DNA analysis has also offered a glimpse of what Neanderthals may have looked like in the flesh: pale skin and red hair have been suggested for two Neanderthal specimens from Italy and Spain on the basis of their melanocortin 1 receptor variant (Lalueza-Fox et al. 2007). A subsequent analysis of the published genomic data from three Neanderthal individuals from Vindija, Croatia, however, indicated that they carried alleles consistent with darker skin and eyes and brown or red hair color (Cerqueira et al. 2012). These results suggest that phenotypic variability was likely high among Neanderthals.

The sequencing of the Neanderthal genome has also indicated a limited contribution [1–4 % (Green et al. 2010), recently reestimated to 1.5–2.1 % (Prüfer et al. 2014)] of Neanderthals to modern people from Eurasia. Admixture is thought to have likely occurred in the Near East and before the spread of early modern humans into the rest of Eurasia (Green et al. 2010), although other models have also been proposed (e.g., Currat and Excoffier 2011), in part to account for the observed higher admixture levels in Asia compared to Europe (Sankararaman et al. 2014; Vernot and Akey 2014). By measuring the extent of linkage disequilibrium among modern European genomes, Sankararaman et al. (2012) dated the last interbreeding between Neanderthals and modern Europeans to between 37,000 and 86,000 years BP and likely between 47,000 and 65,000. There is still discussion on whether the observed similarities can be at least in part explained by population substructure of the ancestral modern human population rather than by admixture (Eriksson and Manica 2012; Lowery et al. 2013). Nevertheless, it has been argued that such archaic interbreeding had important health consequences for modern humans (Abi-Rached et al. 2011; Sankararaman et al. 2014; The Sigma Type Diabetes Consortium in press). Some of the identified Neanderthal-derived alleles are connected with modern diseases, such as diabetes, lupus, Crohn's disease, and other conditions (Sankararaman et al. 2014). Others, however, mainly alleles relating to skin and hair, appear to have been selected for in modern humans and therefore likely provided some evolutionary advantage (Sankararaman et al. 2014; Vernot and Akey 2014). Strikingly, the modern human genome is depleted from Neanderthal-derived alleles in the X chromosomes and in genes that are expressed in the testes (Sankararaman et al. 2014). This evidence strongly suggests male infertility for Neanderthal-modern human hybrids and indicates a high level of genetic incompatibility among the two sister taxa (Sankararaman et al. 2014; Vernot and Akey 2014). This finding is compatible with the high level of morphological differentiation between Neanderthals and modern humans and accounts for the very low observed levels of admixture.

One of the unexpected results of the Neanderthal genome project has been the genetic identification of a hitherto unknown hominin lineage, dubbed the Denisovans (Krause et al. 2007b; Reich et al. 2010), first recognized through the mtDNA analysis of a phalanx from Denisova cave, in the Altai Mountains, Siberia, dating to ca. 50–30 Ka BP. The mtDNA retrieved differs from that of either modern humans or Neanderthals, and appears to belong to a hominin that shared a common mtDNA ancestor with both groups at ca. 1 Ma BP (Krause et al. 2007b). Reich et al. (2010) were able to retrieve nuclear DNA from the same bone, as well as to identify another fossil carrying the same mtDNA type. The genomic analysis showed that, contrary to the mtDNA results, the Denisovan individual likely represents a sister taxon to Neanderthals. Unlike Neanderthals, Denisovans seem to not have contributed genetically to all Eurasians, but instead to have admixed with modern Melanesian populations, which show Denisovan contribution of 4–6 % to their genetic material. On the basis of these results, it was suggested that this taxon was very widespread in Asia during the Late Pleistocene (Reich et al. 2010).

There is little understanding of what fossil taxon may correspond to the genetically identified Denisovans. A tooth from the same cave yielded the same type of mtDNA, providing a narrow glimpse on the morphology associated with this lineage (Reich et al. 2010). This specimen is a very large upper molar, likely a third molar or possibly second molar. If considered a third molar, this specimen is outside the range of variation in its crown dimensions of any taxa of the genus *Homo*, except *H. habilis* and *H. rudolfensis*. If considered a second molar, its dimensions also overlap with those of *H. erectus*. The specimen does not present any derived Neanderthal or modern human features. This question has become even more complicated by the recent discovery of Denisovan-like mtDNA in the Sima de los Huesos material (Meyer et al. 2014). These findings suggest that the Sima population may have been related to the ancestors of both Neanderthals and Denisovans or, alternatively, that gene flow between these two lineages contributed the Denisovan-like DNA to the Sima group.

Behavior

Technology

Neanderthals are most commonly, though not exclusively, associated with the Mousterian lithic technology, named after the site of Le Moustier in the Dordogne, France. Typical of Mousterian industries was the use of both Levallois and discoidal flaking techniques for the production of flakes that could be converted to a wide range of shapes, including various kinds of side scrapers, retouched points, denticulates, notches, and sometimes small handaxes (Debénath and Dibble 1994; Mellars 1996; Shea and Brooks 2000). In addition to Europe, the Mousterian is found in the Caucasus, the Near East (where it is associated with both Neanderthals and early modern humans) and North Africa (where it is not associated with Neanderthals). Mousterian industries appear in Europe as early as ~200–150 Ka and possibly earlier in the Near East, but most sites are dated to the interval from ~130 to 30 Ka.

The lithic raw material used for the production of tools in most Mousterian sites tends to be locally available. Most raw materials derive from within a 5–6 km range, and only a very small component derives from distant sources (Mellars 1996). These are mostly transported as finished tools. There is a lack of specialized use of different types of raw materials in the Mousterian, as well as a lack of specialized quarries. Very few bone tools are known (but see Soressi et al. 2013). Some points appear to have been hafted and were probably used as spear points

(Mellars 1996; Shea and Brooks 2000). Wooden tools were probably also made, as is evidenced by several well-preserved wooden spears discovered in Schöningen and dated to approximately 400 Ka (Thieme 2000) and by parts of similar implements from Clacton-on-Sea (possibly ca. 350 Ka) and Lehringen (ca. 130–110 Ka; Mellars 1996).

Neanderthal sites show relatively little structure compared to later Upper Paleolithic sites. The living areas are small and exhibit no clear focus of activity. Artificial structures are rare, although exceptions are known. Hearths are well defined and were probably central in tool production and bone processing but are not consistent in their location (Mellars 1996). Controlled use of fire appears widespread in Europe from the Middle Pleistocene Oxygen Isotope Stage (OIS) 11 (~400 Ka) onward and possibly earlier (Gowlett 2006).

Until recent years, the Mousterian was commonly thought to represent a static culture. However, redating of Mousterian sites has shown changes with time in regional industries from Europe and the Near East (Shea and Brooks 2000). Additionally, reanalysis of some Mousterian sites has shown technological responses to climatic changes (Kuhn 1995; Shea and Brooks 2000). Some "transitional" Middle-Upper Paleolithic industries, like the Châtelperronian industry in France, the Uluzzian in Italy, and the Szeletian in East-Central Europe, also show strong affinities with the Mousterian. These were originally thought to have been made by early modern humans, also generally considered responsible for the Aurignacian industry. Since the Châtelperronian has been found associated with Neanderthal skeletal remains in two sites in France, St. Césaire, and Arcy-sur-Cure (Lévêque and Vandermeersch 1980; Hublin et al. 1996), it has been widely held that at least some of these transitional industries were produced by late Neanderthal populations. This in turn has prompted intense debate over the identity of the makers of these industries, the possibility of Neanderthal acculturation by, or trade with, early modern humans, and the cognitive capacities and ability for symbolic thought in Neanderthals (d'Errico et al. 1998; Zilhão and d'Errico 1999; Mellars 1999, 2005; Klein 2000; Harvati et al. 2003; Bar-Yosef 2005; Gravina et al. 2005; Svoboda 2005; Hublin et al. 2012). Recently Benazzi et al. (2011) identified the only known human remains associated with the Uluzzian (two milk molars from Grotta del Cavallo, Italy) as representing modern human, rather than Neanderthal, children. These remains furthermore represent the earliest known modern human remains in Europe (dated to between ca. 42 and 45 Ka calibrated BP through AMS ^{14}C dating on shell). This discovery suggests that at least the Uluzzian was produced by modern humans and further complicates our understanding of the transitional industries in Europe.

Subsistence

Neanderthal sites abound in faunal remains of various taxa, indicating a high reliance on meat in their diet. Large palearctic mammals are most commonly found in these assemblages, including bison, wild cattle, horse, reindeer, red and fallow deer, ibex, wild boar, and gazelle (Shea and Brooks 2000). Sites from the high latitudes of Northern and Central Europe indicate an almost exclusive reliance on large- to medium-sized mammals, with very little small game and low diversity of animals consumed (e.g., very few bird or fish remains; Hockett and Haws 2005). Middle-latitude Neanderthal sites (Southwestern France and Northern Spain) also show low diversity and a focus on terrestrial mammals but indicate a somewhat greater reliance on medium-sized mammals. Sites from the Mediterranean region still show reliance on large- and medium-sized terrestrial mammals but also preserve evidence for consumption of other food sources, such as shellfish, birds, tortoises, and marine mammals (Stiner 1994; Barton 2000; Currant 2000; Hockett and Haws 2005; Stringer et al. 2008; Harvati et al. 2013). Plant remains in Neanderthal sites are rare, likely due to their poor preservation. Phytoliths and other vegetal remains known primarily from Mediterranean sites point to a plant component in Neanderthal diet which probably included wild legumes and grasses as well as seeds and fruit (e.g., Gale and Carruthers 2000; Madella et al. 2002; Lev et al. 2005). Recent work on dental calculus recovered from Neanderthal teeth has confirmed such strong plant components in Neanderthal diets and has also pointed to cooking and potentially medicinal use of plants (Henry et al. 2011; Hardy et al. 2012).

In addition to direct evidence of faunal and plant remains from archaeological sites, Neanderthal diets can be assessed using the isotopic signature of the Neanderthal skeletons themselves. Analysis of the stable isotopes of carbon and nitrogen has now been undertaken for a number of Neanderthal specimens from a wide time range (~130–30 Ka) and so far has invariably indicated a very strong reliance on herbivore meat (Fizet et al. 1995; Bocherens et al. 1999, 2005; Richards et al. 2000). All Neanderthal bones so far analyzed are similar to top predators in their isotopic composition. Furthermore, some of the isotopic studies suggest a much greater reliance on very large herbivores, such as wholly rhinoceros or wholly mammoth, than had been previously thought based on the faunal archaeological evidence (Bocherens et al. 2005). The isotopic analyses agree with zooarchaeological studies in suggesting a very small component of marine foods in Neanderthal diets, in sharp contrast with later, Upper Paleolithic modern humans (Richards et al. 2001, 2005).

The degree to which Neanderthals obtained meat through hunting as opposed to scavenging has been a subject of debate (Binford 1983; Chase 1986; Stiner 1990). Some have suggested that the relative significance of these two activities probably varied seasonally and from region to region (Shea and Brooks 2000). Among the arguments brought forth to support scavenging as the primary Neanderthal activity is the high proportion of cranial faunal remains in Neanderthal sites and the age profile of the remains, thought to be for the most part old individuals rather than prime-age adults (Binford 1983). However, a bias toward cranial remains may simply represent a bias in the butchering and transportation of large carcasses (Mellars 1996). The age-mortality profile is now known to vary, with several French Middle Paleolithic sites showing a catastrophic mortality profile inconsistent with hypotheses of scavenging (summarized in Mellars 1996).

Further evidence in support of hunting comes from the wooden spears from Schöningen dated to 400 Ka (Thieme 2000), although there is disagreement as to whether these represent throwing or thrusting spears. Finally, the Neanderthal stable isotopic signature suggests active predation on the part of the Neanderthals and is difficult to reconcile with a subsistence strategy consisting primarily of scavenging (Richards et al. 2000).

Symbolic Thought and Language

The Neanderthal ability for symbolic thought and language is hotly debated. The archaeological record shows a dearth of "symbolic" objects, such as objects of art or personal ornamentation, in Mousterian assemblages, compared not only with later Upper Paleolithic industries (Mellars 1996) but also with some penecontemporaneous African sites (McBrearty and Brooks 2000; Henshilwood et al. 2001; but see Zilhão et al. 2010; Peresani et al. 2011). The relative scarcity of such objects has been argued to indicate a lack of human cognitive abilities and language. However, it has also been pointed out that the archaeological record is a very limited and imperfect record of behavior, perhaps in this case resulting in a biased documentation (or lack thereof) of Neanderthal symbolic activities. The discovery of Neanderthal remains associated with transitional industries, and, in the case of Arcy-sur-Cure, with lavish personal ornaments, has raised tremendous discussion over the identity of the makers of these objects, as well as the processes that would have led to their association with Neanderthals (i.e., trade, acculturation, or endogenous development; see, e.g., Hublin et al. 1996, 2012; d'Errico et al. 1998; Zilhão and d'Errico 1999; Mellars 1999, 2005; Klein 2000; Harvati et al. 2003; Bar-Yosef 2005; Benazzi et al. 2011).

Evidence in support for Neanderthal ability for some symbolic thought is the occurrence of ochre and manganese "crayons" in Neanderthal sites and the burial of at least some Neanderthal skeletal remains. Although the apparent Neanderthal burials have been argued to be simply the product of natural processes (Gargett 1999), the recovery of a number of largely complete skeletons from diverse sites found in articulation and placed in shallow pits is strongly indicative of intentional burial. Nevertheless, evidence for grave goods and other burial practices is scant and controversial (Mellars 1996; Shea and Brooks 2000).

In terms of the anatomical evidence for language and cognition, Neanderthals possessed cranial capacities as large as or larger than modern humans. Their endocasts show similar features to those of modern humans and similar left-right asymmetries (Holloway 1985) although they retain an "archaic" overall shape (Bruner et al. 2004; see also Gunz et al. 2010; Bastir et al. 2011). The relatively flat Neanderthal cranial base was long considered to indicate a larynx positioned so high that it would preclude the production of certain speech sounds and particularly of vowels crucial to speech perception (Lieberman and Crelin 1971; Laitman and Heimbuch 1982; Lieberman 1989). This hypothesis was most recently tested by Barney et al. (2012) who used extensive modern human reference series and a large number of fossils to reconstruct the Neanderthal vocal tract and to simulate its articulatory potential. This study found that, although Neanderthals probably had a limited production of vowels compared to modern humans, this limitation would likely not have affected the/i/and/u/vowels that are critical for speech. A further attempt to infer language capabilities from the bony morphology focused on the hypoglossal canal, which transmits the nerves to the exceptionally large human tongue musculature. The size of the hypoglossal canal was found to be similar in Neanderthals and modern humans and larger than in earlier hominins (Kay et al. 1998), suggesting a similar function for the Neanderthal tongue in speech production. More recent work, however, has questioned this evidence (DeGusta et al. 1999). Neanderthals are also similar to modern humans and unlike earlier hominins in their enlarged thoracic vertebral canals, which could indicate an expansion of thoracic innervation (MacLarnon and Hewitt 1999). The resulting greater control of the intercostal musculature would enhance breathing control and could indicate the ability for speech. Finally, the anatomy of the outer and middle ear in the Middle Pleistocene pre-Neanderthal fossils from Sima de los Huesos (Atapuerca, Spain) was found to be similar to that of modern humans and specialized for speech perception (Martínez et al. 2004), supporting speech capabilities for Neanderthals and their ancestors.

Evolution and Classification

The “Accretion Hypothesis”

The “Accretion Model” for the evolution of Neanderthals (Dean et al. 1998; Hublin 1998) accounts for the progressive appearance of Neanderthal morphology through time, beginning around 450 Ka (OIS 12). According to this hypothesis, the Neanderthal lineage became isolated in Europe due to the severe glacial conditions prevailing in the Balkans at this time, in combination with enlarged Caspian and Black seas and increased aridity in North Africa and the Levant (Stringer 2012). In these conditions of isolation, the Neanderthal morphology is thought to have become gradually fixed, partly through natural selection as an adaptation to cold-climate conditions but perhaps primarily through the process of genetic drift (Hublin 1998; Stewart and Stringer 2012).

Although the accretion process of Neanderthal features is mosaic in nature, facial and mandibular features have been argued to be established first, followed by features in the occipital region and finally in the temporal bone and vault (Dean et al. 1998; Hublin 1998; Rightmire 1998). This pattern, however, is complicated by uncertainties in the chronology of the skeletal material (especially the very old ages proposed for the Sima de los Huesos remains; see Stringer 2012) and in the polarity of some of the relevant features (see Harvati et al. 2010; Freidline et al. 2012). Four broad stages of Neanderthal evolution have been described (Dean et al. 1998; Hublin 1998). Stage 1 includes “early pre-Neanderthals,” i.e., the Middle Pleistocene archaic specimens, such as Petralona, Arago, and Mauer, dating from before

OIS 12. These hominins are considered to show incipient Neanderthal features mainly in the facial region (although some of these features may represent primitive retentions; Harvati et al. 2010). They also show strong similarities with African and Asian contemporaries (e.g., Stringer 1974; Mounier et al. 2009; Harvati et al. 2010; Schwartz and Tattersall 2010). Stage 2 (OIS 11-9) specimens are termed "pre-Neanderthals" (e.g., Steinheim, Swanscombe). They are thought to exhibit Neanderthal morphology more clearly, showing Neanderthal features also in the occipital area. Stage 3 (OIS 7-5, Biache, Krapina, Saccopastore) "early Neanderthal" specimens show most Neanderthal traits in the posterior cranium and some also in the temporal region. Finally, Stage 4 comprises the "classic Neanderthals" of OIS 4 and 3 (Neanderthal, La Chapelle-aux-Saints, Amud), showing fully expressed Neanderthal morphology.

Classification of Middle Pleistocene Humans

According to the accretion hypothesis, Neanderthal evolution was an anagenetic process with no speciation event resulting in the appearance of this taxon. Within the framework of this model, Neanderthals can be viewed either as a subspecies of *H. sapiens* or as a full, distinct species, *H. neanderthalensis*. If the latter classification is accepted, then the position of the Middle Pleistocene specimens from Europe must be clarified. Traditionally, these have been included in the species *H. heidelbergensis* in which African Middle Pleistocene humans have also been placed, due to extensive observed morphological similarities between the European and African Middle Pleistocene human fossils (e.g., Stringer 1974, 1984; Arsuaga et al. 1997; Rightmire 1998, 2007, 2008; Harvati 2009; Mounier et al. 2009; Harvati et al. 2010). This taxon is viewed by some as ancestral to both Neanderthals and modern humans (e.g., Rightmire 1998, 2008, 2009; Stringer 2012). If the European *H. heidelbergensis* was exclusively ancestral to Neanderthals, this sample could be placed within the Neanderthal lineage and within the taxon *H. neanderthalensis* (e.g., Stringer 1995, 2012; Hublin 1998, 2009). Alternatively, the European lineage could be arbitrarily split into two paleospecies, the earlier segment retaining the nomen *H. heidelbergensis* and the later *H. neanderthalensis* (e.g., Arsuaga et al. 1997; Manzi 2004; but see Wolpoff et al. 1994; Rosas et al. 2006; Tattersall and Schwartz 2006; Bräuer 2008). In either case, the African Middle Pleistocene specimens would have to be placed into another taxon, possibly *H. rhodesiensis* or *H. helmei* (Stringer 1995, 2012). The position of the Sima de los Huesos in this scheme is crucial, as these specimens exhibit very strong Neanderthal similarities (e.g., Rak et al. 2011; Gomez-Robles et al. 2012; Martinón-Torres et al. 2012) while argued to be >530 Ka old (Bischoff et al. 2007), thus providing a very strong link between European *H. heidelbergensis* and later Neanderthals. Recently Stringer (2012) questioned this age estimate due to taphonomic considerations and proposed that the Sima de los Huesos specimens can be considered early Neanderthals instead of *H. heidelbergensis*.

Neanderthal Taxonomy and the Neanderthal Role in Modern Human Evolution

Ever since their assignment to the distinct species *Homo neanderthalensis* (King 1864), the classification of Neanderthals and their role in human evolution have been the subject of intense discussion. Current consensus sees Neanderthals and earlier Middle Pleistocene European extinct humans as a separate evolutionary lineage, at least partly geographically isolated in Western Eurasia. What is still unclear, however, is the nature of the interaction between Neanderthals and modern humans arriving in Europe ca. 45 Ka BP (Benazzi et al. 2011; Higham et al. 2011a, b). Since the two taxa likely overlapped in Europe for some millennia, it is widely thought that they would have met at least on some occasions (although the duration of their coexistence is debated, as is contact between them; e.g., Finlayson 2004; Pinhasi et al. 2011, 2012). The nature of their interaction and the possibility and extent of interbreeding during these encounters are central points of discussion.

Although there is no doubt that Neanderthals were our closest relatives, the magnitude of anatomical differences between Neanderthals and modern humans is such that several authors recognize the former as a distinct species under species definitions that use morphological criteria (e.g., Stringer 1974; Tattersall 1992; Stringer and Andrews 1988; Hublin 1998; Harvati 2003b; Harvati et al. 2004). The long list of uniquely derived Neanderthal features, many of which appear early in ontogeny (e.g., Maureille and Bar 1999; Ponce de León and Zollikofer 2001), points to distinct species status under the phylogenetic species concept (e.g., Hublin 1978; Santa Luca 1978; Stringer et al. 1984; Tattersall 1986, 1992, 2000; Stringer and Andrews 1988; Schwartz and Tattersall 1996a, b). Furthermore, the cranial morphological distance between Neanderthals and modern humans is more similar to interspecific than to intraspecific distances observed among primate species and their subspecies, suggesting a distinct species status as appropriate for Neanderthals (Harvati 2003a; Harvati et al. 2004).

Some paleoanthropologists see evidence for admixture in the fossil record and have therefore argued for subspecific status for Neanderthals following the biological species concept. These authors have pointed out Neanderthal-like features in early modern European specimens and trends of morphological "modernization" in some late Neanderthal samples, as well as proposed individual specimens as potential hybrids (e.g., Smith 1982, 1992; Wolpoff 1989; Frayer 1992; Frayer et al. 1993; Duarte et al. 1999; Ahern et al. 2002; Trinkaus et al. 2003; Soficaru et al. 2007). However, others have rejected these claims (e.g., Lahr 1996; Bräuer and Broeg 1998; Tattersall and Schwartz 1999; Bräuer et al. 2004, 2006; Bailey 2002; Harvati 2003a, 2009; Harvati et al. 2004, 2007).

From a genetic perspective, the mtDNA of Neanderthals and Upper Paleolithic Europeans shows no evidence for admixture between the two groups (Wolpoff et al. 2001; Serre et al. 2004; Green et al. 2008), although demographic modeling indicates that a small contribution of Neanderthals to the modern human gene pool is consistent with this result (<1–2 %; Currat and Excoffier 2004; Weaver and Roseman 2005). The recent publication of Neanderthal genomic data, however (Green et al. 2010; Prüfer et al. 2014), showed the Neanderthal genome was more similar to that of Eurasians than Africans. This evidence suggests that limited interbreeding may have occurred during the earliest dispersal of modern humans out of Africa. Green et al. (2010) estimated the proportion of Neanderthal-derived DNA in modern Eurasians to be ca. 1–4 %. This estimate was further refined to 1.5–2.1 % by Prüfer et al. (2014). Demographic modeling of admixture combined with territorial expansion under this level of introgression has pointed to very low (<2 %) interbreeding rates and was interpreted as showing strong reproductive barriers between Neanderthals and modern humans (Currat and Excoffier 2011). Nonetheless, discussion is ongoing on whether population substructure in ancestral modern humans can also account for at least part of the observed patterns (Eriksson and Manica 2012; Lowery et al. 2013).

The inability to reproduce successfully is the criterion for species recognition under the commonly applied biological species concept. Nonetheless, closely related mammal species, including primates (see Jolly 2009), are known to hybridize. (Indeed recent genetic evidence indicates that such interbreeding may have been the case among several hominin species: Denisovan DNA was found at frequencies up to 6 % in modern Melanesians, suggesting an admixture event between modern humans and this extinct taxon (Reich et al. 2010), and archaic admixture has been proposed for some Central African modern human populations (Hammer et al. 2011; see also Harvati et al. 2011). Furthermore, interbreeding has been suggested between Neanderthals and Denisovans, as well as between the latter and an unknown, older species, possibly *Homo erectus* (Prüfer et al. 2014). Therefore, a low level of interbreeding between Neanderthals and modern humans is not necessarily inconsistent with a separate species assignment of Neanderthals (see Hofreiter 2011; Stringer 2012). This is especially true if there was strong reproductive isolation between the two taxa, possibly related to reduced hybrid fitness, as suggested by Currat and Excoffier (2011). Recent genomic analysis in modern humans showed that entire genome regions are depleted of Neanderthal-derived alleles, including most importantly the X chromosome and genes expressed in the testes (Sankararaman et al. 2014). This pattern is consistent with male hybrid sterility and strongly suggests post-zygotic isolating mechanisms between Neanderthals and modern humans. The two taxa were therefore likely largely genetically incompatible and in the process of speciation. This genomic evidence agrees with the great morphological differences described between the two taxa. It also accounts for the very low interbreeding rates observed, as well as for the ambiguous evidence for admixture in the fossil record. Partial reproductive isolation, if supported by future analyses, would also be consistent with the recognition of Neanderthals as a distinct species under the biological species concept.

The Neanderthal Extinction

The last appearance date of Neanderthals is not well dated. The most recent radiometric evidence points to their disappearance around or soon after 40 calendar Ka BP (e.g., Pinhasi et al. 2012; Wood et al. 2013) and to the first appearance of modern humans in Europe as early as approximately 45 calendar Ka BP (Benazzi et al. 2011; Higham et al. 2011a, b). These results suggest that Neanderthals and early modern humans probably overlapped in Europe for some millennia (e.g., Pinhasi et al. 2012). For some researchers, the last appearance of Neanderthals simply signifies their assimilation into the modern human gene pool (Smith et al. 2005; Svoboda 2005). Although genomic research is ongoing, the evidence recovered as yet suggests minimal admixture on the order of 1.5–2.1 % (Prüfer et al. 2014), which is likely not compatible with a full assimilation scenario. Most researchers view the Neanderthal demise as a true extinction, even if limited genetic exchanges with modern humans took place.

Several scenarios for the Neanderthal extinction have been proposed, and often they invoke some direct or indirect competition with early modern humans arriving in Europe shortly before Neanderthals disappear. Proposed modern human competitive advantages range from demographic factors, such as small differences in birth and mortality rates or in interbirth spacing (Zubrow 1989; Skinner 1997; Flores 1998), to larger group sizes and higher population density among Upper Paleolithic modern humans (Gat 1999; Mellars and French 2011), to greater dietary diversity in Upper Paleolithic modern humans (Richards et al. 2001; Hockett and Haws 2005). The role of climate was until recently not emphasized, as Neanderthals disappeared in OIS 3, during what was thought to be relatively stable conditions preceding the last glacial maximum (Stringer et al. 2003). Some recent hypotheses, however, consider climatic and environmental factors to be major driving forces. It has been proposed that habitat degradation and fragmentation led to the disappearance of Neanderthal populations, with modern humans arriving in areas previously occupied by Neanderthals after the latter were already extinct (Finlayson 2004). The Neanderthal demise has also been viewed as one of the many Late Pleistocene megafauna extinctions caused by the loss of an environment with no modern analogue (Stewart et al. 2003; Stewart 2005).

Available paleoclimatic records have shown that OIS 3 was dominated by much more unstable climatic conditions than previously thought, possibly precipitated by unusually intense volcanic activity (Golovanova et al. 2010), leading to a reexamination of the role of climate deterioration in the Neanderthal demise (van Andel and Davies 2003; but see Lowe et al. 2012). The argument has also been made that no two cooling episodes are the same and that taxa surviving one cooling episode may not persist through the next (Stewart 2005). An alternative interpretation, however, sees the advent of modern humans, perhaps with better cultural buffeting and more effective social networks, as providing the *coup de grâce* to the highly stressed Neanderthal populations through competition for severely limited resources during the critical time interval of their coexistence in Europe (Stringer et al. 2003; see also Lahr and Foley 2003). In this view, it is the interaction between the effects of fluctuating climate and environment and of competition with modern humans that led to the eventual Neanderthal extinction.

Conclusions

The most striking advances in Neanderthal research since the publication of the first edition of this volume come undoubtedly from the realm of ancient DNA. In the last few years, aDNA analyses, and particularly genomic analyses, have made it possible to gain insight on diverse aspects of Neanderthal paleobiology, from their phenotypic appearance to their population structure. They have also shed light on the genetic interactions between Neanderthals and modern humans, as well as, most recently, on the evolutionary advantages and disadvantages that such genetic interactions conferred to our ancestors. Methodological advances have now made it possible to recover DNA from even more ancient remains, as evidenced by the recently published mtDNA from the Sima de los Huesos, renewing hope that other limitations may be overcome in the future. A major achievement would be the retrieval of aDNA from early modern human fossils from the Near East and Africa.

A second set of methodological advances has come from the realm of dating, particularly the dating of the late Neanderthal and early modern European sites. Refinements in radiocarbon dating, as well as the implementation of the dating of volcanically derived sediments, have made a major impact in our understanding of the chronology of coexistence, which provides the framework for Neanderthal-modern human interactions and for the Neanderthal extinction. Ongoing paleoclimatic analyses will help pinpoint the still unresolved role of changing environmental conditions in these processes. Finally, the advent of powerful imaging and morphological analysis of fossils has enabled the retrieval of crucial information even from fragmentary and previously uninformative specimens, in some cases overturning previous hypotheses, as well as further illuminated the paleobiology of Neanderthals and our own ancestors. The combined efforts of these approaches promise an exciting era of breakthroughs in the coming years.

Homo floresiensis

Leslie C. Aiello

Contents

Abstract

Homo floresiensis was announced in 2004 as a new, late surviving hominin species that lived between ~74 and 17 ka on the Indonesian island of Flores. Since then, there has been considerable controversy over its evolutionary position. *H. floresiensis* is a small-bodied and small-brained hominin that has a unique mosaic morphology which, taken at face value, suggests that its closest evolutionary affinity is with early *Homo*. Various analyses have suggested either *H. habilis*, *H. georgicus*, or *H. erectus* from Africa or Asia as the most probable ancestor. The alternative to this "new species" hypothesis is that *H. floresiensis*, and particularly the LB1-type skeleton, represents a pathological modern human suffering from one or a combination of syndromes, which produce disordered growth (dwarfism) and microcephaly. Both hypotheses have compelling aspects, but the "pathological modern human" hypothesis has yet to account for the total

morphological pattern observed in *H. floresiensis*. At present this is a less convincing hypothesis than the "new species" hypothesis. Recent research is pointing to a *H. erectus* as the most plausible *H. floresiensis* ancestor. It is known from Island Southeast Asia in the proper time frame and would avoid the paradigm changing necessity of postulating an unknown Asian pre-*erectus* ancestor. However, many questions remain and the issues surrounding *H. floresiensis* will not be resolved without further analysis and discovery.

Introduction

Homo floresiensis is a hominin taxon erected by Brown et al. (2004) on the basis of a partial skeleton (LB1) (holotype) and a single tooth (LB2) (paratype) discovered in 2003 at the cave site of Liang Bua on the island of Flores, Indonesia (Figs. 1 and 2). Further hominin material was recovered in 2004 (Morwood et al. 2005), and the hypodigm now includes over 100 numbered specimens representing 9–14 individuals (Morwood et al. 2005, 2009). The majority of the material, including the LB1-type skeleton, dates between ~18 and 16 ka and was found by the east wall of the cave (Morwood et al. 2004; Roberts et al. 2009; Westaway et al. 2009a). Other material dates between ~74 and 61 ka and is located near the west wall in the center of the cave.

The hominin remains are variously associated with stone tools that have been described as relatively advanced. They are also variously associated with a dwarfed

species of *Stegodon* (*Stegodon florensis insularis*), the only other large mammal on the island; the Komodo dragon; giant rats; bats; and birds including the giant, 1.8 m tall, carnivorous marabou stork, *Leptoptilos* sp. (Van den Bergh et al. 2009). Some of *Stegodon* bones show cut marks (Morwood et al. 2005). The LB1-type skeleton was found in a situation suggesting that it was rapidly covered in a standing pool of water. Other *H. floresiensis* material was found in association with charred bone and reddened fire-cracked rocks suggesting the use of fire. There is no evidence of high-level cognition such as the burials, personal ornamentation, or ocher found with contemporaneous hominins elsewhere in the world.

General Description

The material represents individuals that were relatively small in stature. The LB1-type skeleton (Fig. 3) has been estimated to have stood ~106 cm tall (Brown et al. 2004), and the other adult material has been estimated to have been smaller. There is only one known cranium (LB1), and this has a cranial capacity of 380–426 cm^3, with 426 cm^3 being the most recent and accurately determined estimate (Brown et al. 2004;

Fig. 3 The LB1 *Homo floresiensis* skeleton (Photo: Bill Jungers)

Falk et al. 2005a; Holloway et al. 2006; Kubo et al. 2013). The *H. floresiensis* cranium is reminiscent of *Homo erectus* (Brown et al. 2004; Baab and McNulty 2009; Baab et al. 2013) (Fig. 4), while the LB1 skeleton has limb proportions that resemble *Au. afarensis* with short legs relative to arms and other postcranial features that individually are most similar either to apes, to australopithecines, or to *Homo erectus* or are totally unique such as its unusually large feet (Jungers et al. 2008, 2009a).

The Context of *Homo floresiensis*

Current evidence suggests that *H. floresiensis* spans the period from ~74 to ~17 ka, and during this time, the environment around the Liang Bua cave fluctuated from humid forest to grassland, influenced by the glacial phases (Westaway et al., 2009b). The uppermost *H. floresiensis* deposits are capped by volcanic layer reflecting a massive eruption, although it is unclear whether the disappearance of *H. floresiensis* was directly related to this eruption or was related to climate change,

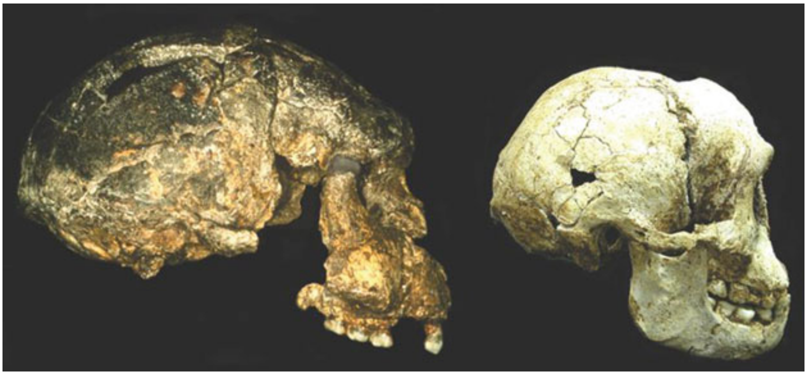

Fig. 4 Javanese *Homo erectus* (Sangiran 17) (*left*) and *Homo floresiensis* (LB1) (*right*) (Photo: Peter Brown)

to the arrival of modern *H. sapiens*, or to a combination of events (Morwood et al. 2009). Modern humans and their cultural remains are found in higher levels of Liang Bua, dating to ~11 ka (see Moore et al. 2009).

There is evidence from stone tools that there were hominins in the vicinity of the cave at the earlier period of ~190 ka (Westaway et al. 2009a, b). Elsewhere on Flores in the Soa Basin, there is archaeological evidence that hominins were present at other sites such as Mata Menge at 800–880 ka (Morwood et al. 1998; Brumm et al. 2006; Moore and Brumm 2007) and at Wolo Sege at 1.02 ± 0.02 Ma (Brumm et al. 2010). It is unknown who these hominins were, and it is possible that hominin occupation on Flores predates the oldest Soa Basin deposits.

What Is *Homo floresiensis*?

There are two competing hypotheses to explain the existence of *H. floresiensis*. The first is supported by the discovery team as well as many other paleoanthropologists and posits that *H. floresiensis* represents a new species of hominin that survived into relatively recent times in an island refugium environment (e.g., Argue et al. 2006, 2007, 2009; Brumm et al. 2006; Falk et al. 2005a, b, 2006, 2007a, b, c; Larson 2007; Larson et al. 2007a, b; Tocheri et al. 2007; Zeitoun et al. 2007; Van Heteren and de Vos 2007; Morwood and van Oosterzee 2007; Gordon et al. 2008; Jungers et al. 2008, 2009a; Lyras et al. 2009; see also Morwood and Jungers 2009a and the papers therein). The original interpretation was that it represents a dwarfed island descendant of the larger-bodied *Homo erectus*, which is well known from other sites in Indonesia (e.g., Brown et al. 2004). Others suggest that it was a pre-*erectus* hominin that arrived on Flores with both a small body and a small brain (Brown and Maeda 2009; Morwood and Jungers 2009b).

The alternative major hypothesis is that the LB1 skeleton represents a modern individual suffering from one of the many syndromes which, either individually or in combination, result in microcephaly and disordered growth (e.g., Weber et al., 2005; Martin et al. 2006a, b; Martin 2007; Richards 2006; Henneberg 2007; Hershkovitz et al. 2007; Tuttle and Mirsky 2007; Henneberg and Schofield 2008; Rauch et al. 2008; Obendorf et al. 2008; Oxnard et al. 2012). The LB6 mandible, which is more recent that the LB1 skeleton, is considered to represent another afflicted individual, while the other material is too fragmentary to determine whether individuals were healthy or not. Indriati (2007) has observed that scientists with broad backgrounds dealing with modern human variation (e.g., geneticists, clinicians, and human biologists) tend to favor a pathological explanation in contrast to the paleoanthropologists who tend to favor the "new species" hypothesis.

Both major hypotheses have compelling aspects. The "new species" hypothesis in either of its variants foregrounds *H. floresiensis* cranial and postcranial anatomy, which is not known to be mimicked by the various pathological conditions put forward to support the "pathological modern human" hypothesis. However, this second hypothesis is considered by its supporters to be a more parsimonious explanation for the occurrence of *H. floresiensis*, who was living contemporaneously with anatomically modern humans in Island Southeast Asia (e.g., Oxnard et al. 2012). In addition to arguments for a number of syndromes in modern humans that can produce short stature and microcephaly, these scholars point to major questions about insular dwarfism as an explanation for the small *H. floresiensis* brain and ask whether a small-brained hominin would be capable of the level of cultural complexity suggested by the archaeological context or could have survived in a small island environment when contemporaneous modern humans are known from the area from ~50 ka (O'Connor 2007).

Morphology of *H. floresiensis*

One of the main arguments against the "new species" hypothesis for *H. floresiensis*, particularly if its antecedent was a relatively large *H. erectus*, has been that the degree of brain size reduction in *H. floresiensis* is simply too great to be explained by insular dwarfism (Martin et al. 2006a, b; Martin 2007). Dwarfed animals, including humans, generally have larger brains relatively to their body sizes (higher encephalization quotients) than their larger antecedents (Schoenemann and Allen 2006). This is because, in insular dwarfism, bodies reduce along a steeper curve than brains. But recently Kubo et al. (2013) have argued that up to 50 % of the brain size reduction in *H. floresiensis* may be explained by body size reduction alone. The remaining reduction could be accounted for by a number of factors. For example, in altricial animals, dwarfing along an ontogenetic rather than the adult allometric curve may be a more appropriate model. If this was true for *H. floresiensis*, it is conceivable that an *H. erectus* ancestor could have given rise to *H. floresiensis*, particularly if the ancestor was relatively small brained like early *H. erectus* from Java (Weston and Lister 2009; Kubo et al. 2013). Another factor may be adaptation to conditions where energetic concerns are important, and a small and energetically less expensive brain would be an advantage (Taylor and van Schaik 2007; Kubo et al. 2013; see also Köhler and Moyà-Solà 2004). However, the smaller the brain size of the ancestor, the more likely that insular dwarfism may have been a factor, and this is one reason why many paleoanthropologists favor a smaller-brained pre-*erectus* ancestor for *H. floresiensis*.

Brain shape (endocranial cast shape) has been used in support of the "new species" hypothesis (Falk et al. 2005a, 2007a, 2009b), which argues that it is different from modern microcephalic endocasts and resembles most closely *H. erectus* endocasts. However, critics point out that microcephalic endocranial casts are highly variable and that the *H. floresiensis* endocranial cast can be matched in some microcephalics (Weber et al. 2005; Martin et al. 2006a, b; Martin 2007). The most recent analysis in a long debate on this issue is based on craniometric ratios and suggests that the LB1 endocranial cast falls within the range of the microcephalics and outside the range of modern normal human and *H. erectus* endocasts (Vannucci et al. 2011). However, these authors caution that this analysis does not necessarily prove that *H. floresiensis* is a microcephalic. They call for more comprehensive 3D morphometric analyses and ideally the discovery of more fossils or DNA evidence that would definitively settle the issue one way or another.

Evidence from the cranium and mandible is less ambiguous. In the original publication, the small LB1 cranium was described as being similar in shape to *H. erectus* (Brown et al. 2004). The cranium is broad in relation to its height, and the greatest breadth is at the level of the inflated supramastoid region. Both facial height and prognathism are reduced in relation to pre-*Homo* hominins, and in lateral view the infraorbital region is oriented posteriorly. The mandible lacks a chin and has a developed alveolar planum, with a robust superior transverse torus, a deep digastric fossa, and a low, rounded inferior transverse torus.

Detailed metric analyses have confirmed similarity to early *Homo* (variously *H. habilis*, *H. georgicus*, or *H. erectus* from Africa and Asia) (Argue et al. 2006; Zeitoun et al. 2007; Gordon et al. 2008; Martinez and Hamsici 2008; Lyras et al. 2009; Baab and McNulty 2009; Baab et al. 2013). Baab et al. (2013) point out some similarity in shape between LB1 and modern human microcephalic specimens, although they emphasize that in features that distinguish microcephalics from *H. erectus*, LB1 is most similar to the fossils. They also note that because of the small size of LB1, the allometries in facial morphology converge on what has been interpreted as a more modern face (Baab and McNulty 2009). 3D morphometric analysis of the LB1 mandible also confirms morphological similarity to fossil hominins and difference from modern humans, including microcephalics (Viterbo et al. 2012).

The postcrania also has many features reminiscent of fossil hominins, particularly in the hand, foot, and shoulder (Tocheri et al. 2007, 2008; Larson 2007; Larson et al. 2007a, b, 2009; Jungers et al. 2008, 2009a, b). The wrist bones (trapezoid, scaphoid, and capitate) have a primitive morphology for the African ape-human clade, which is more primitive than the morphology represented in *H. antecessor* and the Neanderthals (Tocheri et al. 2007, 2008), although aspects of the proximal and distal pollical (thumb) phalanges are more similar to modern humans (Crevecoeur et al. 2012).

The shoulder is also primitive in form, with a short clavicle and a humerus with a low degree of torsion (Larson 2007; Larson et al. 2007a). This morphology predates *H. antecessor* and is shared with earlier hominins (early *Homo erectus* (Nariokotome) and *H. georgicus*).

The foot is also unusual in a number of features. In particular, the navicular appears to have been weight bearing, suggesting that *H. floresiensis* lacked a transverse arch. The pedal phalanges are moderately curved, resembling some australopithecines, and the forefoot is long in relation to the tarsal skeleton. The entire foot is also long in relation to the length of the femur and the tibia (Jungers et al. 2009a, b).

Other aspects of the skeleton show a mixture of features. For example, the femur resembles australopithecines in being relatively short with a small head and anteriorly-posteriorly compressed neck. However, it differs from them in having a laterally expanded greater trochanter and a well-developed intertrochanteric crest (Jungers et al. 2009b; Richmond and Jungers 2008). The pelvis is also a mosaic, with an australopithecine-like laterally flaring iliac blade and a small acetabulum. However, the acetabulum is distinguished from these earlier hominins in having a superior portion of the acetabular lunate surface that is broader than the posterior horn.

Taken together, the postcranial morphology suggests a different locomotor and manipulative functionality than found in modern humans. For example, the absence of a transverse arch in the foot and the long, moderately curved pedal phalanges suggest a non-modern pattern of weight transfer through the foot during the stance and toe-off phases of walking. The long foot would also suggest clearance problems during the swing phase, and the conclusion would be that the kinematics of both walking and running would be different from modern humans (Jungers et al. 2009a, b). This, together with the relatively short clavicle and resulting narrow upper thorax, would be inconsistent with endurance running (e.g., Bramble and Lieberman 2004), while the shoulder morphology in itself would not be compatible with modern human throwing ability (Larson 2007; Larson et al. 2007a). The wrist morphology would also be inconsistent with more advanced tool making and manipulative behaviors (Tocheri et al. 2007, 2008).

The Anatomically Based "New Species" Conclusion

Taken at face value, these morphologies suggest that *H. floresiensis* may have its closest affinity with a small-bodied hominin retaining aspects of anatomy that are primitive for the genus *Homo* (e.g., Morwood and Jungers 2009b). Cladistic analyses of 60 cranial, mandibular, and postcranial character states support a pre-*erectus* ancestor and result in two equally parsimonious cladograms (Argue et al. 2009). One places *H. floresiensis* between *H. rudolfensis* and the clade including *H. habilis* and all later hominins. The second places *H. floresiensis* between *H. habilis* and the clade including *H. georgicus* (Dmanisi) and all later hominins. If either variant is correct, it would suggest that *H. floresiensis* is most closely related to hominins that lived more than 1.5 Ma. It would also suggest that pre-*erectus* hominins were the first to leave Africa, and this would challenge the traditional "Out-of-Africa 1" model for the first colonization of Eurasia by early African *Homo erectus*. However, cladistics is only one analytical technique, and an increasing number of recent analyses support *Homo erectus* as the ancestor of *H. floresiensis* (e.g., Baab et al. 2013; Kubo et al. 2013) and insular dwarfism over ~1 Ma as the evolutionary process responsible for its unique mosaic morphology (see below).

Could *Homo floresiensis* Be a Pathological Modern Human?

The alternative major hypothesis that *H. floresiensis* is a pathological modern human suffering microcephaly and disordered growth appeared shortly after the introduction of the taxon in 2004. Henneberg and Thorne (2004) argued that such pathologies could not be rejected as an explanation, particularly in view of the fact that this explanation was more consistent with the age of the site and the associated artifacts, which are found elsewhere in Island Southeast Asia in association with modern humans (see also Brown and Morwood 2004). This work was followed by a more extensive analysis by Jacob et al. (2006), which has been largely discredited based on the extensive morphological analyses of *H. floresiensis* (e.g., thin-walled, "tublated bone" or weak muscles). Some features have also been shown to fall within the range of variation of normal humans or apes (e.g., asymmetry) (Baab and McNulty 2009; Larson et al. 2009; Kaifu et al. 2009). There is, however, a relatively large literature supporting a pathological interpretation for *H. floresiensis* (e.g., Weber et al. 2005; Martin et al. 2006a, b; Martin 2007; Richards 2006; Henneberg 2007; Hershkovitz et al. 2007, 2008; Tuttle and Mirsky 2007; Rauch et al. 2008; Obendorf et al. 2008; Oxnard et al. 2012).

The various syndromes that have been proposed to explain *H. floresiensis* include (1) a combination of growth hormone-insulin-like growth factor I axis modification and mutation of the MCPH (microcephalin) gene family (Richards 2006), (2) Laron syndrome (Hershkovitz et al. 2007, 2008), (3) microcephalic osteodysplastic primordial dwarfism type II (MOPD II) (Rauch et al. 2008), and (4) myxedematous endemic (ME) cretinism (Obendorf et al. 2008; Oxnard et al. 2012). All these can produce short stature and/or microcephaly, but the majority have been rejected on the basis that they do not account for the total morphological pattern observed in *H. floresiensis* (e.g., Falk et al. 2008, 2009a; Brown and Maeda 2009).

The most recent debate surrounds ME cretinism (Obendorf et al. 2008; Oxnard et al. 2012; Brown 2012). ME cretins are born without a functioning thyroid due to environmental factors including iodine deficiency, selenium deficiency, and raised serum thiocyanate (Oxnard et al. 2012). These authors argue that ME cretinism is known in Island Southeast Asia, on Bali, Java, Sumatra, and Borneo, and can be found in modern populations living as close as 18 km to the ocean and iodine-rich marine resources. They also note that this condition results in extreme dwarfism and a mosaic of skeletal features, particularly in younger individuals, that is "rather like" the mosaic found in *H. floresiensis*.

Proponents of this hypothesis, although vigorous in its support, have not had the opportunity to study the original *H. floresiensis* material, and equally vigorous critics argue that many of the features used in its support, such as a persisting bregmatic fontanel, a depressed nasal bridge, absence of a frontal sinus, and a bipartite trapezoid, do not hold up to scrutiny (Falk cited in Dalton 2008; Jungers et al. 2009a; Brown 2012). Brown (2012) notes that out of the large number of skeletal and dental traits associated with ME cretinism in the clinical literature, only very short stature and the degree of humeral torsion are shared with *H. floresiensis*, and a similar humerus torsion angle is also found in earlier members of the genus *Homo* (see also Larson, 2007). Brown (2012) emphasizes that there is no evidence in *H. floresiensis* of delayed linear growth and development characteristic of ME cretins and that the average brain size of cretins is within the normal human range.

As emphasized by Aiello (2010), the fact that existing hypotheses for pathological explanations for LB1 cannot explain the evidence does not falsify all potential hypotheses. Knowledge of the skeletal manifestations of the various syndromes resulting in dwarfism and microcephaly has increased in recent years, but without more conclusive comparative information, and wider access to the original *H. floresiensis* fossils, definitive DNA analyses, and/or additional discoveries, the weight of the current evidence continues to support the hypothesis that *H. floresiensis* is a surviving species of early *Homo*.

Questions Raised by the "New Species" Interpretation of *Homo floresiensis*

In many ways the "new species" interpretation of *H. floresiensis* is inconvenient. This is because it raises more questions about *H. floresiensis* and human evolution in Island Southeast Asia than it answers, some of which are summarized in Aiello (2010). It would be much easier to write off *H. floresiensis* as an interesting pathological modern human.

One major question is the relationship of *H. floresiensis* to other Asian hominins such as the Denisovans and modern humans. Genetic evidence suggests that the Denisovans were once a large, widespread population, and Stringer (2012) speculates that perplexing Asian hominins such as Maba, Xujiayao, Dali, and Jinniushan in China and Narmada in India may be Denisovans. These hominins are probably too recent in time to be ancestors of *H. floresiensis*, but the presence of Denisovan DNA in indigenous Australians, Papua New Guineans, and other Island Southeast Asian populations suggests that the Denisovan range extended across Wallace's Line (Reich et al. 2011; Pennisi 2013; Cooper and Stringer 2013). This also suggests that *H. floresiensis* could have been contemporaneous in this region at various times with both the Denisovans and modern humans (see O'Connor 2007, for modern human occupation in Island Southeast Asia). Their isolation on Flores may have been due to the strong currents between islands, and non-endemic faunal evidence suggests that modern humans were not moving freely among the islands until well into the Holocene (Van den Bergh et al. 2009).

This raises the issue of when and how *H. floresiensis* could have arrived on Flores. The archaeological evidence from Wolo Sege at 1.02 ± 0.02 Ma (Brumm et al. 2010) and Mata Menge at 800–880 ka (Morwood et al. 1998; Brumm et al. 2006; Moore and Brumm 2007) in the Soa Basin suggests that the island had been occupied for at least a million years. Archaeological continuity between these sites and Liang Bua also implies population continuity. However, the best evidence may come from the fauna (Van den Bergh et al. 2009; Meijer et al. 2010; Dennell et al. 2013). Throughout the majority of this period, the fauna is described as an impoverished endemic island fauna, lacking evidence of new colonizers. Van den Bergh et al. (2009) report a faunal turnover at approximately 900 ka, after which time the fauna remains endemic until ~17 ka and the volcanic event associated with the disappearance of *H. floresiensis* and the dwarfed *Stegodon* (*Stegodon florensis insularis*). The consensus is that the ancestor of *H. floresiensis* must have arrived on Flores via a sweepstakes event (such as a tsunami) and the prevailing currents suggest Sulawesi as a probable source (Van den Bergh et al. 2009; Meijer et al. 2010; Dennell et al. 2013). Dennell et al. (2013) also concludes on the basis of energetic modeling that a small-bodied, energetically efficient hominin could have survived on an island of the size of Flores throughout this period (see also Meijer et al. 2010).

But who was the ancestor of *H. floresiensis*? There is currently no clear evidence to indicate whether it was *Homo erectus* or an unknown pre-*erectus* hominin. Meijer et al. (2010) agree with the original interpretation (Brown et al. 2004) and argue that the only plausible ancestor would have been *Homo erectus*, who is the sole currently known hominin that was present in Island Southeast Asia prior to a million years ago. Meijer et al. (2010) explain the mosaic morphology of *H. floresiensis* as a consequence of insular evolution, and these authors suggest that it follows evolutionary pathways similar to those of other terrestrial vertebrates in island environments. They specifically invoke pedomorphosis to explain the presence of features in *H. floresiensis* that are primitive for *Homo erectus*. They also agree with Taylor and van Schaik (2007), Weston and Lister (2009), and Kubo et al. (2013) in arguing that the degree of brain size reduction in *H. floresiensis* would be possible, and might even be expected, under conditions of resource limitation in an island environment (see also Migliano et al. 2007; Bromham and Cardillo 2007 for body size reduction).

This is a parsimonious explanation, but at present, much needs to be taken on faith. It is unknown whether insular dwarfing of *Homo erectus* would result in the unique mosaic of features recognized in *H. floresiensis*. However, the alternative "new species" hypothesis involving a pre-*erectus*, smaller-brained antecedent has its own difficulties. It would be paradigm changing in postulating the existence of an unknown pre-*erectus* hominin in eastern Asia prior to one million years ago. However, the history of human evolutionary research has shown that anthropologists are naive to believe that all of the hominin species that have ever existed are known today (Aiello 2010). Based on the morphology of *H. floresiensis*, the alternative "new species" hypothesis that postulates an unknown pre-*erectus* ancestor must continue to be entertained as a plausible explanation for *H. floresiensis* evolution. As Dennell and Roebroeks (2005) suggest, it is possible that *H. floresiensis* will result in a major transformation in our understanding of the course of human evolution in Asia. A resolution to this issue awaits further research and discovery.

Conclusion

The controversies surrounding *Homo floresiensis* have focused attention on a variety of issues relevant to the interpretation of the fossil evidence for human evolution. Prime among these is the evidence necessary to separate normal from pathological morphology and conclusively decide whether particular fossil material merits recognition of a new species. This is particularly important in cases where the new species appears to be out of either time or place. The case of *Homo floresiensis* is particularly perplexing because the morphology suggests affinities with Pliocene or early Pleistocene hominins from Africa (e.g., *Au. afarensis*, *H. habilis*), but the species persists on Flores at a time that is contemporaneous with modern humans and long after other hominin species went extinct. This is not the first time in the history of human origins research that new discoveries have raised such questions. For example, the discovery of the Neanderthals, *Pithecanthropus*, and the Taung child (*Au. africanus*) raised similar debates in their day (Aiello 2010). In these cases, additional fossil material and analytical research ultimately settled the debate in favor of new species and radical changes in our understanding of the course of human evolution.

The question is whether the same will happen in the current case of *H. floresiensis*? There is only one cranium (LB1) giving evidence of the relatively small brain size and one skeleton (LB1) that is complete enough to determine body proportions and the other features making up the unique *H. floresiensis* mosaic of primitive and derived features. There is a second partial skeleton (LB6), including a mandible, which confirms that at least some of the morphology is found in more than one individual. The remaining *H. floresiensis* hypodigm is largely fragmentary, and although it does document some of the unique *H. floresiensis* features, it is largely ignored by recent proponents of the "pathological modern human" hypothesis. One reason for this may be that they have not had the opportunity to study the original fossil material.

At present, the various syndromes that have been evoked to explain *H. floresiensis* as a pathological modern human have not been able to account for its total morphological pattern. As a result, the "pathological modern human" hypothesis cannot be supported. The weight of the evidence currently supports the "new species" hypothesis, and of the alternative possible *H. floresiensis* ancestors, currently the most parsimonious is an early Asian *Homo erectus* that would have been present at the right time and place in Island Southeast Asia (Meijer et al. 2010). The major obstacle to the idea that *H. floresiensis* is a dwarfed descendant of *H. erectus* has been brain allometry, although based on recent research, this obstacle may be receding (Kubo et al. 2013). However, major questions still remain in relation to whether the total pattern of *H. floresiensis* morphology is consistent with this hypothesis and whether *H. floresiensis* could have survived on Flores for over 1 Ma. There are also concerns over its relationship to other contemporaneous hominins, including modern humans. We also know little about its physiology, life history, locomotion, and lifestyle, and there remain many questions about its cognitive capabilities in relation to the associated material culture (see Aiello 2010). Resolution to all of these questions will not happen until conclusive evidence appears in the form of additional fossil material, analytical advances, and ideally ancient DNA evidence. The *H. floresiensis* story does not yet have an ending.

Origin of Modern Humans

Günter Bräuer

Contents

Abstract

In the early 1980s, a new period in the debate on modern human origins began, focusing on two alternatives: the Multiregional Evolution model and the Out-of-Africa hypothesis. Over the last few decades, new hominin discoveries, absolute dating, and other evidence have supported the latter view, which proposes a recent common origin of modern humans in Africa. The increasing evidence made the idea of long-term regional evolution up to modern humans in Europe and Asia, following the first expansion out of Africa at nearly 2 Ma, more and more unlikely. Only the African fossil record documents a continuous early modernization process. In contrast, the European evidence shows a replacement of the Neanderthals by modern humans. Also, the claimed evidence for regional continuity in China and Australasia has turned out to be unsubstantiated. Major questions in the current discussion of modern human origins refer to the fossil and molecular evidence for gene flow during the replacement period and to the number of species involved in Middle Pleistocene evolution.

Early and Current Controversies

The origin of modern humans has always been a controversial topic in paleoanthropology. Already at the beginning of the twentieth century and based on a very sparse – mainly European – fossil record, alternative phylogenetic scenarios were suggested. Schwalbe (1906) proposed a unilinear concept in which Neanderthals were an intermediate form between Dubois' *Pithecanthropus* and modern humans. Boule (1913), on the other hand, saw the Neanderthals as an evolutionary cul-de-sac postulating a parallel "presapiens" lineage to modern humans. Although the Presapiens hypothesis became widely accepted in the subsequent decades, some researchers, especially Hrdlička (1927) and Weidenreich (1943), supported unilinear concepts. Weidenreich (1943), after examining the newly discovered Chinese and Javanese hominin fossils, proposed his Polycentric Evolution Theory, which suggested different evolutionary lines in North Asia, Southeast Asia/Australasia, Europe/Near East, and eastern/southern Africa. He regarded the regional sequences as an interconnected web evolving in a single common direction. Yet Weidenreich's (1947) explanation of orthogenesis as the driving factor of such a polycentric evolution was rejected by the new synthetic theory of evolution. In addition, Coon's (1962) later model of largely isolated parallel evolution in different parts of the world was eventually dismissed.

In the 1950s, new support emerged for the Presapiens hypothesis, in particular by the cranial remains from Fontéchevade in connection with the specimens from Swanscombe and Steinheim (Vallois 1954). However, later research on the critical presapiens specimens revealed their affinities to Neanderthals and Preneanderthals (Trinkaus 1981; Hublin 1982). In addition, new hominid discoveries, such as the partial crania from Arago and Biache St. Vaast, demonstrated that the idea of a separate lineage to modern humans in Europe was no longer tenable. It became clear that there was only one lineage in Europe leading to Neanderthals (Bräuer 1984a). During the 1950s, another model was proposed (Howell 1951) – the Preneanderthal hypothesis – which assumed that the lineages to Neanderthals and modern humans only split during the Eem Interglacial. Following this event, the southwest Asian "progressive" Preneanderthals evolved into modern humans, while the European Preneanderthals developed into the robust "classic" Neanderthals. However, this concept was also not supported by later research. No diachronic trends of reduction in size could be observed in the Near Eastern Neanderthals, and later dating revision revealed that early modern humans and Neanderthals were nearly contemporaneous in this region. Thus, by the late 1970s, the question of the origin of modern humans was again largely open. A few researchers such as Wolpoff (1980) continued to favor evolutionary continuity in Europe and elsewhere, whereas others like Howells (1976) assumed a recent common origin of modern humans.

In the early 1980s, a new period in the controversy on modern human origins began, mainly focusing on two alternatives: the Multiregional Evolution model and the Out-of-Africa hypothesis (Fig. 1). Wolpoff et al. (1984) proposed the Multiregional Evolution model, which was largely based on Weidenreich's theory

Fig. 1 (**a**) Multiregional evolution (After Thorne and Wolpoff 2003, p. 52) and (**b**) Out-of-Africa models

of Polycentric Evolution. In contrast to Weidenreich's (1947) explanation of orthogenesis, the supporters of the new multiregional concept see a balance of evolutionary forces, such as gene flow, local selection, and drift, as explanations for the assumed long-term regional continuities (Wolpoff 1992). Yet they accepted and used most of Weidenreich's morphological observations for regional continuity that had been collected in the 1930s and 1940s (Wolpoff et al. 1984; Frayer et al. 1993). Although assuming interregional gene flow, multiregionalists have emphasized the regional pattern of evolution as stated, for example, by Frayer et al. (1993, p. 41): "Each geographic region we examined contains a wealth of information that shows the continuous evolution of *Homo* populations over time. We find neither specimens nor traits that could reflect an infusion of any African genes and their so-called more-modern morphology." Frayer (1992, p. 49) considered the "Neandertals as the probable ancestors of the people in the Upper Palaeolithic," and Thorne (1993, p. 173) is convinced that the "descendants of the Java and Peking people do not become extinct but give rise, without African influence, to the modern people of their region."

The roots of the alternative Out-of-Africa model can be traced back to the early 1970s. Although at that time practically all evidence from archaeology and paleoanthropology pointed to the presence of archaic hominins – the so-called "Rhodesioids" (named after the Kabwe cranium from Zambia) – in eastern and southern Africa from only 30 or 40 Ka (Clark 1970), new skeletal remains from Omo Kibish, Ethiopia, and new dates for the South African Border Cave specimens indicated the early presence of modern humans at about 100 Kyr bp, or even slightly earlier (Leakey et al. 1969; Protsch 1975). Yet it remained puzzling how such early moderns fit in with the much later presence of the archaic humans. Further research on the dating of the African Stone Age during the 1970s led to a drastic extension in time of the Middle and Later Stone Age and thus to older dates of the associated hominins (Clark 1979). It also turned out that the archaic "Rhodesioids" were considerably older than had been thought.

In the late 1970s, I started a new analysis of the Middle and Late Pleistocene hominin material from Africa. This research provided a new framework of *Homo sapiens* evolution, suggesting a mosaiclike, continuous anatomical process of modernization leading to an early emergence of modern humans. Based on this framework and a review of the fossil evidence from Europe and the Far East, I proposed an Out-of-Africa model initially dubbed the "Afro-European *sapiens*" hypothesis (Bräuer 1982) because the best evidence for replacement came from Europe. Yet the model was a global one, regarding replacement as the most likely process for the Far East as well (Bräuer 1984b). The Out-of-Africa model suggested an evolution to modern humans only in Africa and subsequent dispersals into Asia and Europe that replaced the resident archaic populations, including the Neanderthals. "Replacement" was assumed to also allow for interbreeding. In fact, a "Hybridization and Replacement model" was regarded to be in best agreement with the facts (Bräuer 1984b, p. 162). It could explain possible indications of regional archaic features among early modern humans, and it upheld the widely agreed upon view that the replaced archaic and the early modern humans belonged to the same species *H. sapiens*. A few years later, Cann et al. (1987) provided important support for a recent common origin of modern humans in Africa based on human mitochondrial DNA (mtDNA). Although no strongly divergent mtDNA lineages could be found among extant humans, Cann (1992, p. 71) did not assume reproductive isolation between the archaic and the dispersing modern populations, but rather concluded that we are about 30 Kyr too late to see the persistence of Neanderthal maternal lineages.

These and additional results from molecular biology and paleoanthropology during the 1980s supporting a Recent African Origin (RAO – a term also used for Out-of-Africa) did not lead to the dismissal of the alternative Multiregional Evolution model, but instead to a heated debate and an artificial polarization. The multiregionalists now claimed that the mtDNA results must be interpreted as excluding any gene flow and that this is an essential assumption of the Out-of-Africa model (Wolpoff and Thorne 1991). Although this view was rejected (Bräuer 1989, 1992; Stringer 1992), the multiregionalists focused on the criticism of the extreme "Eve Theory," assuming that by excluding gene flow, any possible indication of regional continuity outside Africa would be sufficient to disprove the Out-of-Africa model (Frayer et al. 1993). This argument, however, was misleading, as the "Eve" concept is based on a particular interpretation of the mtDNA data and cannot be equated with the Out-of-Africa model, which includes the evidence from fossils and nuclear DNA as well (Stringer and Bräuer 1994, p. 416). In fact, the Out-of-Africa replacement view allows for the possibility of gene flow between archaic and modern humans and is ready to accept any convincing evidence for it that might be found in the fossil record (Bräuer and Stringer 1997; Bräuer 2001a). Although subsequent research on the mtDNA did not provide any unequivocal evidence for interbreeding (Currat and Excoffier 2004), researchers like Serre and Pääbo *(*2006) were cautious and did not regard the extreme interpretation of complete replacement as proven. Only as recently as 2010 was the most relevant progress on the gene flow debate made. Sequencing of more than four billion nucleotides of the Neanderthal genome and comparisons to recent human genomes suggest that between 1 % and 4 % of the genomes of the people in Eurasia are derived from Neanderthals (Green et al. 2010, p. 721). Thus, not only fossil but also the molecular evidence supports such an "Out-of-Africa and hybridization" model (Stringer 2011), as was basically suggested about three decades ago (Bräuer 1984b, 2006; Stringer 2001a).

Another view on modern human origins is the so-called Assimilation model first proposed by Smith et al. (1989) that long held an intermediate position between the Out-of-Africa and Multiregional Evolution models by strongly emphasizing regional continuity in Central Europe and other peripheries (Aiello 1993; Frayer et al. 1993). More recently, this view has leaned toward the Out-of-Africa model but still assumes a more significant assimilation of the Neanderthals (Churchill and Smith 2000) than does the "Out-of-Africa and hybridization" model (Bräuer and Broeg 1998; Bräuer 2006). Most recently, the Assimilation model is said to even agree with a level of only 1–4 % of non-African contribution to extant Eurasians (Smith et al. 2012, p. 386). This would in fact mean that this latest perspective is now hardly distinguishable from the Out-of-Africa and hybridization model (Stringer 2011; Gibbons 2011). In the following paragraphs, the origin of modern humans in Africa and the controversy on the evolutionary pattern in the other parts of the Old World will be considered.

African Emergence of Modern Humans

Over the last few decades, the evolutionary framework of anatomical modernization and the early appearance of modern humans in Africa as basically suggested in the early 1980s (Bräuer 1984c) have gained increasing support (Klein 1999, 2009; Bräuer 2001b, 2012; Smith 2002; Stringer 2002a; Mbua and Bräuer 2012). Absolute dating evidence for several hominin specimens contributed to the current chronological framework of the process (Clark et al. 1994; Grün et al. 1996; Bräuer et al. 1997; McDougall et al. 2005; Brown et al. 2012). The evolutionary scheme presented here (Fig. 2) is based on quite a number of diagnostic as well as absolutely dated specimens that support a mosaiclike, continuously evolving lineage from archaic to modern humans. In spite of broad agreement on the African sequence (Klein 1999, 2009), there is some controversy on whether the different evolutionary groups or morphs should be distinguished on the species or, as suggested here, on the intraspecific level (Bräuer 2008).

The anatomical modernization process can be divided into three groups or grades of *H. sapiens*, each of which includes hominin specimens of a similar evolutionary level (Bräuer 1989, 2008, 2012). The specimens grouped within the early archaic *H. sapiens* category are derived relative to *H. erectus*, especially regarding their enlarged cranial capacity, more vertically oriented lateral walls, expanded frontal bone, less strongly angulated occipital bone, more vertically oriented upper scale of the occipital, higher temporal squama, and reduced development of the supraorbital and occipital tori. The late archaic *H. sapiens* is clearly more derived compared to the morphological pattern of the early archaics, especially evident in the large cranial capacity, the more reduced supraorbital torus, and the near-modern or modern face, including the canine fossa and inframalar incurvature. This grade of evolution is followed by anatomically modern *H. sapiens* with a fully modern morphology of vault and face. There is obvious continuity between the grades, which are best seen as a way of describing the levels of the modernization process. In this respect, the late archaics have also been designated as the transitional group (Smith 2002). This approach suggests neither anything about the underlying factors of anatomical modernization nor whether there are parts of the lineage that show more relevant changes toward the modern morphology than others. Thus, the identification of major structural elements in this process, such as neurocranial globularity and facial retraction (Lieberman et al. 2002), is relevant. Indeed, many of the features and aspects characterizing the grades are connected with such general changes (Mbua and Bräuer 2012).

A key specimen of early archaic *H. sapiens* is the Bodo hominin from Ethiopia, dated by Ar/Ar to ca. 600 Kyr bp (Clark et al. 1994). The large cranial capacity of

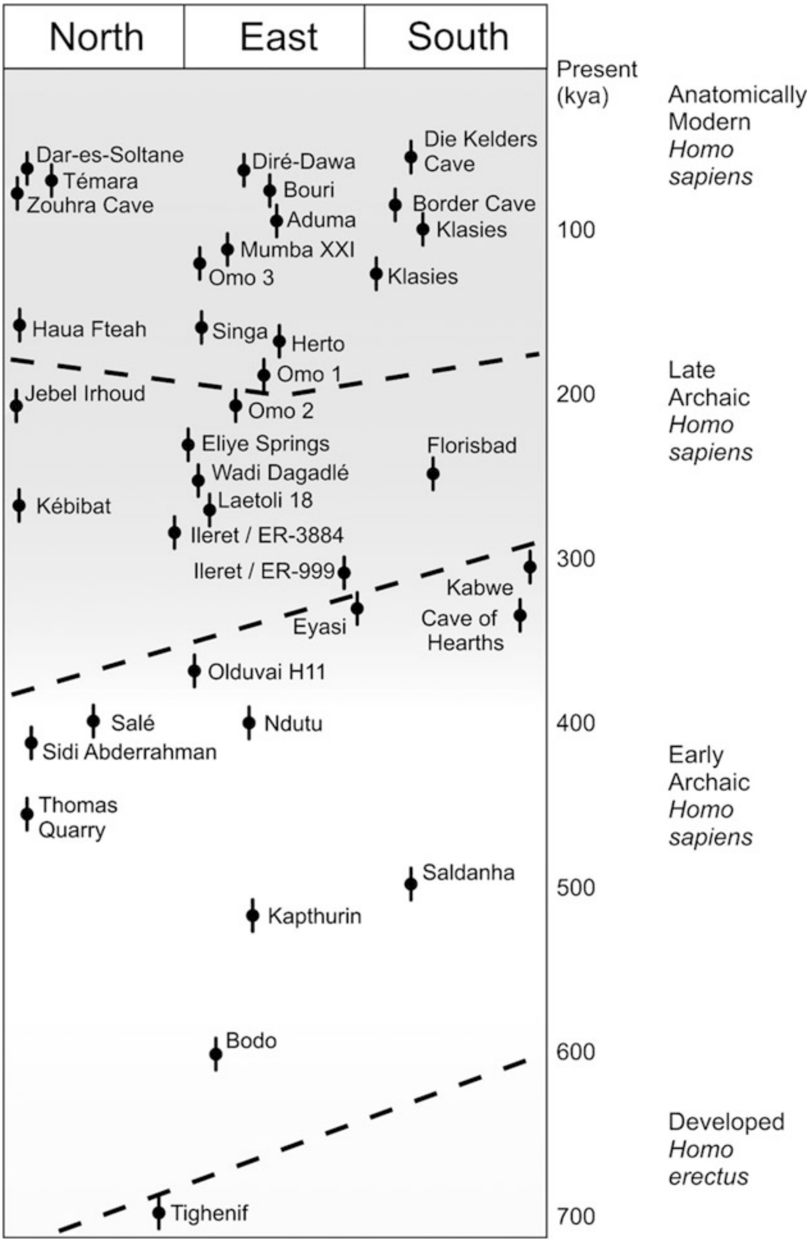

Fig. 2 Fossil record of *Homo sapiens* evolution in Africa

nearly 1,300 cm^3 is associated with some parietal bossing, a coronally expanded frontal, and derived features of the temporal. The supraorbital torus even shows some division into a medial and lateral portion. In the still massive face, there are several characteristics shared with modern humans (Rightmire 1996). Another specimen of similar or slightly younger age (Klein 2009) is the Saldanha (or Elandsfontein) cranium from South Africa. Having an estimated cranial capacity of around 1,225 cm^3, the parietals are well arched and show some bossing. Also, the frontal squama is coronally enlarged and the supraorbital torus attenuates laterally. The occipital is less angulated than generally seen in *H. erectus* and the transverse torus is reduced. The other well-preserved early archaic specimens, such as the crania from Kabwe, Zambia; Eyasi and Ndutu, Tanzania; and Salé, Morocco, date from the same time period between 600 and 300 Ka and exhibit similar derived *sapiens*-like conditions in spite of obvious individual variation (Bräuer 2008, 2012; Mbua and Bräuer 2012).

The late archaic transitional group also comprises specimens spreading from northern to southern Africa. A good example of these near-moderns is the cranium KNM-ER 3884 from Ileret, East Turkana (Fig. 3) directly dated by U/Th gamma-ray spectrometry to ca. 270 Kyr bp (Bräuer et al. 1997). A previous analysis showed that most of the cranial vault falls close to the range of Holocene Africans (Bräuer et al. 1992a). However, the cranium also exhibits a continuous but moderately developed supraorbital torus that deviates from the generally rather modern impression of the specimen (Bräuer 2001b; Schwartz and Tattersall 2003). Further support for such an early presence of near-modern late archaics came from absolute dates

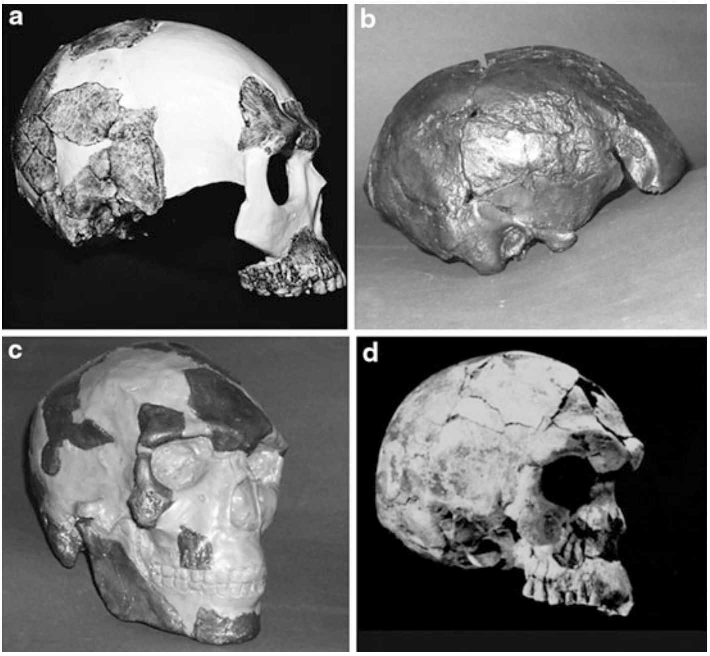

Fig. 3 Late archaic and early modern *Homo sapiens*: (**a**) KNM-ER 3884, Ileret; (**b**) Omo Kibish 2; (**c**) Omo Kibish 1; (**d**) BOU VP-16/1, Herto (After White et al. 2003, p. 734)

for the Florisbad hominid from South Africa and for the Laetoli Hominid 18 from the Ngaloba Beds in Northern Tanzania (Manega 1995; Grün et al. 1996). The Florisbad specimen directly dated by ESR to ca. 260 Kyr bp has a coronally greatly expanded frontal bone associated with a continuous but only slightly projecting supraorbital torus and a modern facial shape with a well-developed canine fossa. The LH 18 cranium, with an age of more than 200 up to 300 Kyr, exhibits a modern-looking face with a canine fossa and a near-modern braincase with a capacity of about 1,350 cm^3, a more or less rounded occipital bone, and well-developed parietal bossing. Archaic features mainly include the flat and narrow frontal squama and the supraorbital torus (Bräuer 1989). However, the relatively thick torus shows an incipient division in the midorbital region, which might be a tendency toward the fully modern pattern. Based on its combination of ancestral and derived conditions, the cranium from Eliye Springs, West Lake Turkana, might also belong to this grade (Bräuer and Leakey 1986; Bräuer et al. 2004a). Important late archaic crania also come from Jebel Irhoud, Morocco, dated to about 170 Kyr bp (Grün and Stringer 1991; Hublin 1992; Bräuer 2012).

The mosaic-like transition from late archaic to early anatomically modern *H. sapiens* is also obvious in the available specimens from Ethiopia such as the Omo Kibish remains (Fig. 3). Recent fieldwork at the sites and Ar/Ar dating has suggested that both the Omo 1 skeleton and the Omo 2 cranium date to 195 ± 5 Kyr bp (McDougall et al. 2005; Brown et al. 2012). Whereas the Omo 1 specimen is by most accounts fully anatomically modern and according to the new dating evidence the oldest known modern human, the Omo 2 cranium shows a mosaic of modern and archaic features. It exhibits a robust yet basically modern supraorbital morphology along with strong midsagittal keeling and an angulated occipital bone. Recently discovered cranial remains from Herto in the Middle Awash, Ethiopia, dated by Ar/Ar to ca. 154 – 160 Kyr bp, further illustrate this transitional process (White et al. 2003). The large robust Herto cranium BOU VP-16/1 (Fig. 3) apparently exhibits a modern supraorbital morphology and modern face combined with a rather angulated occipital bone similar to the condition seen in Omo 2. The variability of this occipital trait, however, is evident in the less angled condition of the more fragmentary adult specimen BOU VP-16/2 (White et al. 2003). With an age of around 150 Kyr bp, the Singa cranium from Sudan also belongs to this earliest modern human spectrum (Bräuer 2012).

More early moderns come from South Africa, especially from the Klasies River Mouth Caves. Here, the oldest human remains date to ca. 120 Kyr bp. These maxillary fragments fall within the range of variation of Holocene Africans (Bräuer et al. 1992b). A nearly complete mandible with an age of about 100 Kyr is anatomically modern, as are the other slightly more recent cranial fragments from the site (Bräuer 2001b, 2008). Regarding the postcranial specimens, the conditions seen in the Klasies remains can be matched with recent population samples from southern Africa (Rightmire and Deacon 1991; Churchill et al. 1996). Some features, such as the relatively low coronoid height of the ulna, could be retained archaic features reflecting the mosaic pattern of evolution in the postcranial skeleton (Churchill et al. 1996). But it is also possible that such postcranial conditions simply belong to the range of variation of these early modern humans (Pearson 2000). Another early modern specimen from South Africa is the Border Cave 1 partial cranium, which is about 90 Kyr old or perhaps somewhat older (Grün and Beaumont 2001).

Considering the complete evidence from the fossil record, of which I can discuss only a few specimens here in some detail, it is obvious that there is good documentation of the modernization process in Africa. This process recently gained further support from a new analysis of the Middle Pleistocene hominins showing clear trends from early archaic up to modern *H. sapiens* in many metrical and nonmetrical cranial features (Mbua and Bräuer 2012). The current fossil record of the African Middle Pleistocene allows subdivision into the three suggested groups, regardless of whether they are termed "grades" of an evolving species *H. sapiens* or different "morphs." Foley (2001), however, distinguishes these groups on the species level, as *H. heidelbergensis*, *H. helmei*, and *H. sapiens*. Yet he concedes that the derived descendant taxa of *H. heidelbergensis* are problematic because of the continuity that can be found between them and their presumed ancestor:

> These seem to be species in the sense that Simpson meant – lineages with independent trajectories – but both the details of the fossil record and the scale of the process seem to rule out any punctuated events. Indeed, continuity between them, rather than discontinuity, is the reason for the persistent problem of delimiting the taxonomic units in the later stages of human evolution and gives rise to the question of whether the species concept, which lies at the heart of macroevolutionary theory, is sufficiently fine-tuned to cope with evolution at this scale. (Foley 2001, pp. 9–10)

However, problems already exist with regard to *H. heidelbergensis*. Shortly after Adefris (1992) classified the Bodo cranium as "archaic *Homo sapiens*" based on a detailed study, Rightmire (1996) considered it more reasonable to refer to Bodo as a *H. heidelbergensis*. Rightmire (1998) suggested speciation between *H. erectus* and *H. heidelbergensis* in Africa at around 800 – 700 Ka, instead of a speciation between *H. erectus* and (archaic) *H. sapiens* (Bräuer 2001b). While this difference appears to mainly involve names, especially since Rightmire also favors a single polytypic species *H. erectus* in Asia and Africa, his scheme also suggests two further speciations: one in Europe from *H. heidelbergensis* to *H. neanderthalensis* at ca. 300 Ka and another in Africa from *H. heidelbergensis* to *H. sapiens* at ca. 150 Ka. However, due to the mosaic nature of the accretion process in Europe, it is hardly possible to define any clear divisions along the Preneanderthal/Neanderthal lineage (Hublin 1998, p. 302; Klein 2009). Thus, there appears to be little convincing evidence for such a speciation within the European record. In Africa, there is a similar process with regard to the mosaiclike modernization, which also does not justify any subdivisions at the species level (Smith 2002; Turbón 2006; Bräuer 2008). I think it is more likely that we are dealing with one evolving biological species and several subspecies (Jolly 2003). Further splitting of the African sequence as suggested by Foley and Lahr (1997) into three species (*H. heidelbergensis*, *H. helmei*, and *H. sapiens*), which largely include the same African specimens as the three proposed grades, can only mean that these are artificially defined morphs or paleospecies. Yet it is problematic that Foley and

Lahr (1997) also included European fossils in *H. helmei*, as outlined by Stringer (2002a, p. 567).

First, Neanderthal characteristics were already evolving in Europe prior to the hypothesized appearance of "*H. helmei*," e.g., in the Swanscombe specimen, dated to ca. 400 Kyr bp. Second, African specimens such as Florisbad and Jebel Irhoud make unparsimonious ancestors for the Neanderthals, since not only do they post-date the appearance of Neanderthal clade characters in Europe, but they appear to lack Neanderthal morphological characteristics that might be expected in a common ancestor.

Recently, Weaver (2012) demonstrated that models based on theory of population and quantitative genetics are well in agreement with a lengthy process of modern human origins that lasted from the divergence of the modern human and Neanderthal evolutionary lineages more than 400 Ka to the expansion of modern humans out of Africa, without speciation events. In spite of the current discussion on the number of taxa involved (Bräuer 2008, 2012), there is nearly general agreement on a post-*erectus* evolutionary process in Africa leading to an early origin of modern humans during the late Middle Pleistocene. This is in agreement with the fact that in the Near East, anatomically modern humans appeared as early as about 100–130 Ka. These early moderns from Skhūl and Qafzeh might not only have an African origin but may also represent the oldest, well-documented evidence of modern humans outside of Africa. Interestingly, and not yet fully understood, these moderns might have coexisted in the Near East with Neanderthals for some tens of thousands of years until the latter disappeared at around 45 Ka. According to both morphological and the recent molecular evidence, gene flow occurred during this period of coexistence (Bräuer and Rimbach 1990; Green et al. 2010).

Replacement of European Neanderthals

Largely parallel to the anatomical modernization process in Africa, the evolution of the Neanderthals took place in Europe. It is widely agreed that the development of the Neanderthal morphology mainly resulted from an accretion process, which began about 400–530 Ka (Hublin 1998; Bischoff et al. 2003; Stringer 2012). Studies on whole Neanderthal mtDNA genomes support such a long, separate evolution in Africa and Europe (Briggs et al. 2009; Endicott et al. 2010). Recent estimations of the human-chimpanzee split using generation times in great apes could also point to a somewhat earlier population split between Neanderthals and modern humans (Langergraber et al. 2012). This does not necessarily indicate that two different biological species originated since the taxonomic significance of the genetic differences is ambiguous (Hublin 1998; Jolly 2003), and as Hofreiter (2011, p. 7) put it: ". . ., given that humans and Neanderthals are large-bodied mammals with long generation times, the recent divergence time of humans and Neanderthals argues against species-level distinction." In view of the increasing evidence for widespread interbreeding between modern and different archaic humans (see below), Stringer (2011, p. 261, 2012) also pointed to the possibility of abandoning the different species names and lumping all these post-*erectus* fossils together as *H. sapiens*. So, whether one prefers to regard the Neanderthals as a subspecies of *H. sapiens* (Turbón 2006; Bräuer 2008) or as a different species or paleospecies (Tattersall and Schwartz 2000; Harvati 2003), the Neanderthals were clearly very closely related to us (Stringer 2001b). Of special relevance in this respect is also the research on possible Neanderthal-modern differences in life history. Current evidence, however, points to great overlap between dental development in Neanderthals and modern populations from different regions of the world and to great difficulties in gauging Neanderthal life histories from dental growth (Guatelli-Steinberg 2009). Nevertheless, the long, separate evolution of the Neanderthals led to an accumulation of a large number of derived features in the skull and postcranial skeleton that are either unique or most frequent in this group (Trinkaus 1988; Hublin 1998).

In spite of the numerous differences between the Neanderthal morphology and that of early modern Europeans, multiregionalists have long regarded Central Europe as a possible region of evolutionary change from Neanderthals to modern humans (Smith 1982; Frayer et al. 1993). In particular, the Neanderthal remains from Vindija, Croatia, were considered to demonstrate evolutionary continuity to early modern humans of the region, as, e.g., from Velika Pećina. However, direct AMS radiocarbon dating has shown that the frontal fragment from Velika Pećina once regarded to be ca. 34 Kyr old is only 5 Kyr old (Smith et al. 1999) and the most recent Vindija Neanderthal sample (G1) has an age of ca. 32 Kyr bp, based on a new ultrafiltration technique for bone radiocarbon samples (Higham et al. 2006). AMS dating has led to further drastic revisions regarding some presumably early modern Europeans. The frontal bone from Hahnöfersand near Hamburg, which was dated to ca. 36 Kyr bp (Berger and Protsch 1989, p. 64), has been redated to only 7,500 years bp (Terberger et al. 2001). For the fragmentary crania from Zlatý Kůn and Svitávka, Czech Republic, for which ages of at least 30 Kyr were suggested, new dates of 12,870 and 1,180 years bp, respectively, were obtained (Svoboda et al. 2002). Also, the human remains from the Vogelherd Cave in southwestern Germany, which have long been thought to derive from Aurignacian deposits, turned out to be only 5 Kyr old (Conard et al. 2004).

In spite of the exclusion of several presumably early modern Europeans, there are still a number of specimens that date to more than 30,000 and even somewhat more than 40,000 radiocarbon years bp (Mellars 2011). Among these are the remains from Mladeč, Czech Republic, for which direct AMS dating on several specimens provided ages of about 31 Kyr bp, i.e., 36 Kyr bp based on new calibration curves, which are in agreement with the Aurignacian artifacts as well as previous AMS dates for associated calcite deposits (Svoboda et al. 2002; Wild et al. 2005; Higham et al. 2011). Further early modern cranial and mandibular remains have recently been discovered in the Peștera cu Oase, Romania, for which direct AMS dating of a mandible yielded ages of 34–36 Kyr bp (Trinkaus et al. 2003) and recent redating using the ultrafiltration technique resulted in a calibrated date of ca. 40 Kyr bp (Higham et al. 2011). Ultrafiltrated collagen radiocarbon dating on animal bones associated with the presumably modern maxillary fragment Kent's Cavern 4 from England has even suggested calibrated dates between 42 and 44 Kyr bp (Higham et al. 2011; Stringer 1990). In spite of the recent use of the improved cleaning techniques of bone collagen to reduce contaminations, there is still good evidence for several thousand years of Neanderthal-modern coexistence. The question of a Neanderthal contribution to the early modern European gene pool has been strongly debated between supporters of the Multiregional Evolution, Assimilation, and Out-of-Africa models for many years.

Based on the current dates, the Mladeč remains represent the best preserved early modern material from the time at which Neanderthals were still around in Central Europe (Teschler-Nicola 2006). Thus, it is key material for examining the question of Neanderthal-modern gene flow. Multiregionalists have long used the Mladeč material to demonstrate regional evolution. Frayer (1986, p. 254) saw here "good evidence in support of a gradualist model," and Wolpoff (1999, pp. 762–763) described the Mladeč specimens 4, 5, and 6 as Neanderthal-like. In testing the similarities of Mladeč 5 and 6 to their potential ancestors – European Neanderthals and early moderns from Skhūl/Qafzeh – Wolpoff et al. (2001, p. 293; Wolpoff 2009) even found a predominance of Neanderthal resemblances for several sets of variables, which are said to separate the Neanderthal and Skhūl/Qafzeh samples.

In order to determine the hard evidence for the Neanderthal contribution to these early moderns, analyses of the Mladeč material were carried out (Bräuer and Broeg 1998; Bräuer 2006; Bräuer et al. 2006). These studies included the most relevant and well-preserved crania, the females Mladeč 1 and 2 and the males Mladeč 5 and 6 (Fig. 4) as well as the maxilla fragment, Mladeč 8. A set of nonmetrical Neanderthal

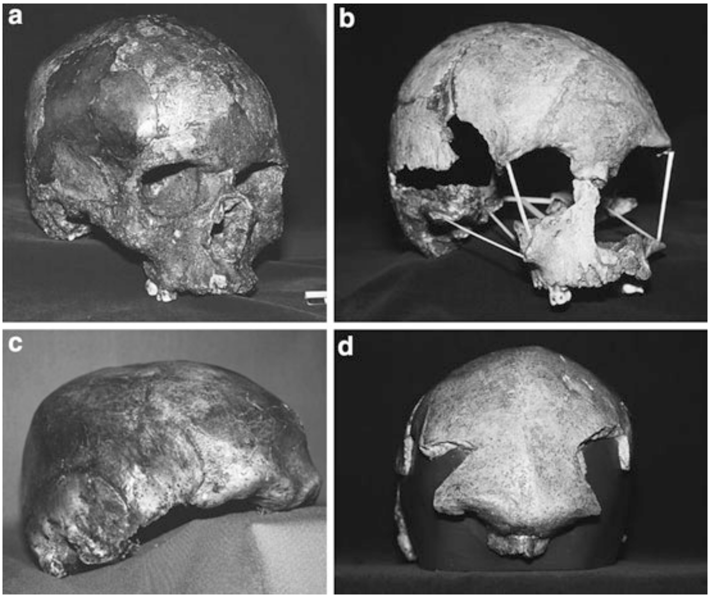

Fig. 4 Early modern crania from Czech Republic: (**a**) Mladeč 1; (**b**) Mladeč 2; (**c**) Mladeč 5; (**d**) Mladeč 6 (Photos **c**, **d**: H. Broeg)

features was used as well as measurements of the frontal shape and facial morphology and projection. The results were rather unexpected. Regarding the common nonmetrical Neanderthal features studied, not a single condition could be found in the Mladeč specimens that can be said to have been unequivocally derived from Neanderthals. On the contrary, the respective regions, such as the supraorbitals, the shape of the vault, the face, the occipital, and mastoid regions, are all anatomically modern and do not exhibit any derived Neanderthal morphology. Also, the metrical analysis revealed great deviations in the frontal curvature of the Mladeč specimens from both European and Near Eastern Neanderthals. Among the Upper Paleolithic sample ($n = 18$), Mladeč 1 and 5 show the greatest divergence from Neanderthals ($n = 10$). No indication of a midfacial projection could be found in these early Czech specimens. Mladeč 1, 2, and 5 diverge strongly from Neanderthals with regard to their Nasofrontal Angle (NFA), and Mladeč 1, the only specimen for which the Zygomaxillary Angle (SSA) could be determined, shows a large disparity when compared to the Neanderthal range of variation.

Major reasons for these contradictory results lie in the assessment as well as the selection of the features. For example, one of the commonly used features is the "occipital bun" (chignon), which exhibits a derived morphology in Neanderthals. In early modern Europeans, the occipital projections are not only placed "in the context of a rather different cranial shape" compared to that of Neanderthals (Churchill and Smith 2000, p. 97), but they also differ in a number of special details such as the extent of lambdoidal flattening, the angulation between the nuchal and occipital planes, and the height of the vertical face of the posterior occiput (Caspari 1991). These differences led Smith (1982) to suggest the term "hemibun" for the occipital projections in Upper Paleolithic specimens. Lieberman et al. (2000, p. 291) even raised the possibility that the specialized Neanderthal bun and the projections in early modern Europeans may not be homologous. In addition, these more moderate projections are rather variable and occur practically all over the world as, e.g., in Africa or East Asia (Bräuer and Broeg 1998; Wu 1998, p. 282). Thus, to label as an "occipital bun" anything different from the derived and well-defined Neanderthal bun leads to confusion, as can be well demonstrated in the case of the Mladeč specimens.

Wolpoff (1999, p. 762) classifies the occipital projections in Mladeč 5 and 6 as a "Neanderthal-like occipital bun," a view shared by Frayer (1992, p. 21). However, the midsagittal curvatures of Mladeč 5 and La Chapelle-aux-Saints are in fact more different than those of, e.g., Mladeč 5 and late Middle Pleistocene archaic *H. sapiens* specimens like Jebel Irhoud 1 or Laetoli H18 (Bräuer and Broeg 1998; Bräuer 2006). Smith et al. (1995, p. 201) had also emphasized that "the occipital buns in Jebel Irhoud are more similar to those in early modern Europeans (like Mladeč, Zlatý Kůn, or Predmosti) than to Neanderthals because of the greater similarity in posterior cranial vault morphology between them." Thus, there should be little reason to suggest that the more African-like hemibuns in Mladeč were derived from European Neanderthals. However, Frayer (1992, p. 21) argued that the morphology in the early modern Europeans must have derived from Neanderthals because occipital buns are not present in the Near Eastern early moderns. Yet, in regard to the bunning in Jebel Irhoud and other circum-Mediterranean specimens, Wolpoff (1999, p. 613) considers the bunning similar to Skhūl/Qafzeh. And indeed, comparisons of the midsagittal curvatures demonstrate close similarities between the occipital profiles of Qafzeh 6 and those of all three Mladeč crania in which the occipital is preserved (Bräuer 2006). Thus, the predominant multiregionalist assessment of the bun morphology in Neanderthals and Mladeč as present and in Skhūl/Qafzeh as absent is inaccurate.

Another example of problematic assessment concerns the "suprainiac fossa," which also has a clearly defined morphology in Neanderthals. It is a generally large, wide resorptive depression which is either rectangular or triangular in shape with a horizontal base formed by the transverse occipital torus (Nara 1994; Hublin 1998). Yet, as Caspari (1991, p. 184) pointed out, "it is unclear if all resorptive pitting in this area that could be referred to as fossae (or incipient fossae) can be validly compared with the Neandertal condition. Perhaps only the Neandertal pattern should be considered true suprainiac fossae, or alternatively some intermediate forms might also be considered suprainiac fossae." Quite obviously, not all pitting in this region can be regarded as a Neanderthal suprainiac fossa. Smaller or larger resorptive depressions that do not match the Neanderthal condition can be found in modern humans nearly everywhere in the world. They are frequently present, e.g., in terminal Pleistocene material from North Africa and occur in recent crania from New Guinea (Bräuer and Broeg 1998). These depressions normally have an inverted triangular shape with the apex pointing to the nuchal plane. Mladeč 5 shows such a small pitting, which can hardly be regarded as Neanderthal suprainiac fossa, and also Mladeč 6 exhibits a tiny non-Neanderthal-like depression. This had also been contended by Frayer (1986, p. 251), when he concluded that "neither Mladeč 6 nor 5 have a distinct suprainiac fossa." However, later Caspari (1991) felt that there was a suprainiac fossa in Mladeč 6, and Frayer (1992, p. 22), although emphasizing the differences between the Neanderthal and Upper Paleolithic conditions, recognized the structure in Mladeč 6 as a possible exception. This example also highlights the problematic use of character states in order to support the idea of continuity.

Wolpoff et al.'s (2001) finding of a great number of Neanderthal resemblances in two of the Mladeč specimens – which he recently repeated in more detail (Wolpoff 2009) – is largely based on features which are problematic with regard to both their assessment and phylogenetic relevance. Many of the nonmetrical features used are, in fact, metrical traits that were arbitrarily divided into two alternative conditions without any recognizable justification such as thick parietal at asterion (>9 mm), broad frontal (>125 mm), long frontal (glabella-bregma length >113 mm), or long occipital plane (>60 mm). With regard to other features used, it is unclear how they can be properly scored as present or absent without a clear scoring system. Among these are as follows: mastoid-supramastoid crests well separated, frontonasal suture arched, glabellar depression, glenoid articular surface flattened, and paramastoid crest prominent. In addition, many of the features used can hardly be regarded as distinguishing between Neanderthals and modern humans. Thus, it is not surprising that Wolpoff et al. (2001) found the most divergent numbers of differences between

Mladeč 5 and two closely related early modern specimens from Skhūl, i.e., only 8 differences to Skhūl 4, but 23 to Skhūl 5. Yet there are further problems with this study, such as the morphological representativeness of using only the male specimens, the lack of relevant features, and the inappropriate method of pairwise difference analysis (Collard and Franchino 2002; Bräuer et al. 2004b). Thus, critical reexamination of the claimed evidence for a considerable Neanderthal contribution in the Mladeč material cannot be supported.

Another early modern specimen claimed to show evidence for gene flow from Neanderthals is the mandible from Peştera cu Oase. However, according to Trinkaus et al. (2003, p. 11235), "the only feature that suggests Neandertal affinities is the lingual bridging of the mandibular foramen, a feature that is currently unknown among humans preceding Oase 1 other than the late Middle and Late Pleistocene members of the Neandertal lineage." Yet how reliable is this so-called H-O foramen for demonstrating Neanderthal-modern gene flow? As Smith (1978, p. 327) found, there are neither individuals under 18 years of age from any modern sample examined nor any juvenile Neanderthal exhibiting the H-O type. This makes it likely that, as Smith (1978) mentioned, factors developing during the individual's lifetime could also be responsible for the occurrence of the trait. Since the morphology at the mandibular foramen can change during a lifetime, the feature cannot be regarded as a good genetic trait (Lieberman 1995, p. 175). Moreover, its occurrence does not clearly signal continuity. According to Frayer (1992, p. 31), the H-O type appears in 10 out of 19 Neanderthals (52.6 %), in 4 out of 22 early Upper Paleolithic specimens (18.2 %), and in 2 out of 30 late Upper Paleolithic specimens (6.7 %). The four early Upper Paleolithic specimens, however, include the Neanderthal Vindija 207 and Stetten (Vogelherd) 1, which no longer belong to this group. Thus, there is no relevant occurrence of this feature in the early Upper Paleolithic. Moreover, most important in this respect is a study of terminal Pleistocene North African samples. Groves and Thorne (1999, p. 253) found the bilateral H-O foramen in 22.2 % of the Nubian material from Tushka and Jebel Sahaba, further showing that this trait is not necessarily derived from Neanderthals. Finally, the H-O foramen already occurred outside of Europe in *H. erectus* such as in OH 22 and Zhoukoudian H1. Thus, though it cannot be excluded, it is far from clear that this single possible Neanderthal trait present on one ramus of the Oase mandible really indicates gene flow from Neanderthals. There is also no unequivocal evidence for a Neanderthal contribution in the adolescent cranium Oase 2 that might be contemporaneous with the mandible. This specimen exhibits a whole set of derived modern features in the vault and face, combined with M3s that are unusually large and have a complex cusp pattern (Rougier et al. 2007). Specimens from two further Romanian sites have also been regarded as relevant to the gene flow debate. The mandible from the Peştera Muierii with an ultrafiltrated and calibrated AMS date of 34 Kyr bp (Higham et al. 2011) exhibits an asymmetrical mandibular notch which occurs most frequently in Neanderthals (Rak 1998; Soficaru et al. 2006). Yet it is also found in modern and recent humans as, e.g., in the Holocene Vogelherd mandible and shows great individual variability. Nevertheless, a possible indication to Neanderthal gene flow cannot be excluded here. This, however, appears less likely, regarding the nuchal morphology of the slightly younger calvaria from Cioclovina. Rather, this specimen shows a robust modern morphology and no typical Neanderthal suprainiac fossa (Bräuer 2010).

Finally, the juvenile Gravettian skeleton from Lagar Velho, Portugal, has been suggested to exhibit aspects indicating Neanderthal ancestry (Zilhão and Trinkaus 2002). Yet the major feature that has been suggested to show a Neanderthal-like condition – the relatively short lower legs – is not unequivocal. It cannot be excluded that the condition also reflects some adaptation among these early modern populations to cold conditions before the Last Glacial Maximum (Stringer 2002b) or individual variation within this modern population (Tattersall and Schwartz 1999). In addition, the occurrence of Harris lines points to periods of disease or malnutrition. Moreover, if one takes the estimated adult crural index for Lagar Velho of 80.7 % and the 95 % confidence intervals (77.5–83.9) as provided by Ruff et al. (2002, p. 380), there appears to be considerable overlap with early Upper Paleolithic Europeans as well. No matter whether some Neanderthal genes were involved in the specimens discussed here or not, it is difficult to escape the conclusion that the hard evidence points to only small traces of interbreeding between Neanderthals and modern humans. A Neanderthal contribution to early modern Europeans of up to 50 % as assumed by Wolpoff et al. (2004) has no support. Thus, a replacement process accompanied by a small amount of gene flow as suggested by the Out-of-Africa and hybridization model appears to be in good agreement with the current evidence from Europe (Bräuer 2010; Stringer 2011).

Continuity or Discontinuity in the Far East

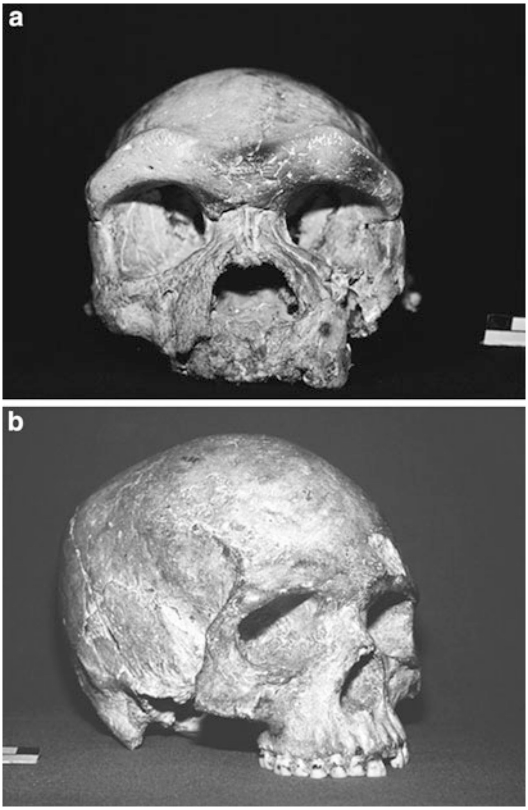
The assumption of regional evolution in China and Australasia is mainly based on morphological features or sets of features. Weidenreich (1943) published a list of 12 so-called Mongolian traits that he regarded as clear evidence for a close relationship between Chinese *H. erectus* and living north Chinese. Among these are midsagittal crest and parasagittal depression, metopic suture, Inca bone, certain "Mongolian" features of the nasal bridge and cheek region of the maxilla and zygomatic bone, shovel-shaped upper lateral incisors, and horizontal course of the nasofrontal and frontomaxillary sutures. Coon (1962, p. 458) was also convinced that many common features existed between Peking Man and living northeast Asians. Finally, the multiregionalists, as well, see strong support for their model in North Asia. Accepting most of the features suggested by Weidenreich and some other authors, multiregionalists presented a rather long list of assumed regional Chinese traits (Wolpoff et al. 1984; Pope 1992; Wu 1992). Although some features are said to have changed over time, Wolpoff et al. (1984, p. 435) were convinced that "all of these characteristics have much lower frequencies and are distributed discontinuously in regions other than China."

Weidenreich (1943) also saw an evolutionary line leading from *Pithecanthropus* via *H. soloensis* to the Australian aborigines of today. Some years before, Keith (1936) had already regarded the recently discovered Solo hominins as representing the evolutionary stage linking *Pithecanthropus* to the Australian aborigine. Wolpoff et al. (1984, pp. 443–444) mentioned about 20 continuity features of the cranium, including flatness of the frontal in sagittal plane, distinct prebregmatic eminence, marked prognathism, persistence of the zygomaxillary ridge, eversion of the lower border of the malar, rounding of the inferolateral border of the orbit, prelambdoidal depressions, and lambdoidal protuberance. Most of the features are from Weidenreich (1943), Larnach and Macintosh (1974), and Thorne and Wolpoff (1981). Based on these assumed regional features, multiregionalists are convinced that Australasia shows a clear anatomical sequence between the earliest Indonesian *H. erectus* and the recent and living Australians uninterrupted by African migrants at any time (Frayer et al. 1993, p. 21).

Since many of the regional features for the Far East were suggested in the first half of the twentieth century, reexaminations have been carried out by several authors over the last two decades. With regard to the suggested East Asian traits, Groves (1989, p. 279) arrived at the conclusion that there is "little evidence for special likeness of modern 'Mongoloids' to *Homo erectus pekinensis*" and identified many of the features as primitive retentions also found outside the region. According to Habgood (1992, p. 280) "none of the proposed 'regional features' can be said to be documenting 'regional continuity' in east Asia as they are commonly found on modern crania from outside of this region . . ., and are consistently found on archaic *Homo sapiens* and/or *Homo erectus* crania throughout the Old World." In her analysis of 11 proposed East Asian continuity features, Lahr (1994) found that almost all of them occurred *more frequently* in recent samples from other parts of the world. Facial flatness was found to be most pronounced in final Pleistocene populations from Northern Africa. A later detailed study by Koesbardiati (2000) focused on the middle and upper facial regions especially regarded as showing a great number of East Asian continuity features (Pope 1992; Frayer et al. 1993). The results, however, revealed that no variable showed a distribution as would be predicted by the Multiregional Evolution model. Instead, most of the features occur more frequently or are more pronounced among population samples from Africa, Europe, and Australia than in the Chinese sample. Some of the features show the highest frequencies among the Inuit of Greenland who, however, represent a relatively young population showing adaptations to extreme conditions (Howells 1993; Lahr 1995).

Also, the fossil record from China hardly supports regional continuity from *H. erectus* to modern people of the area. Even the problematic continuity features are lacking in archaic *H. sapiens* specimens. For example, the 200 Kyr old cranium from Jinniushan does not exhibit any of the following: midfacial flatness, a marked angulation of the maxilla and zygomatic bones when viewed from beneath, a flattened nasal saddle, a nondepressed nasal root, or lack of wisdom teeth. Based on further features, even Pope (1992) has raised doubts whether this hominin along with the Maba specimen fits into the picture of regional evolution in China and suggested strong genetic influence from the West into China in the terminal Middle or Late Pleistocene. Moreover, the 150–200 Kyr old cranium from Dali (Fig. 5) with its heavy supraorbital torus and other archaic features hardly reveals clear

Fig. 5 Archaic and early modern crania from China: (**a**) Dali; (**b**) Liujiang



similarities to modern Chinese. Because of the discontinuity between Chinese *H. erectus* and this East Asian archaic *H. sapiens* group and the similarities of the latter to archaic *H. sapiens* from Europe, it has been suggested that the Dali-Maba-Jinniushan morph has its roots in the archaic *sapiens* of the western part of the Old World. Recent sequencing of the genome of a 40 Kyr old finger bone from the Denisova Cave in the Altai Mountains, southern Siberia, identified a new archaic hominin group that shared some of its history with Neanderthals and might have split from the common Preneanderthal lineage some 200–300 Ka (Reich et al. 2010). Moreover, it has been shown that these so-called Denisovans interbred with the modern ancestors of present-day Melanesians and Australians, most likely in Southeast Asia. These populations exhibit about 5 % of Denisovan DNA (Reich et al. 2010, 2011). Perhaps – but this is still a hypothesis – the Dali-Maba-Jinniushan group could belong to this archaic Denisovan lineage that lived in wide parts of East Asia.

Further relevant evidence contradicting the idea of regional evolution in China comes from the earliest modern humans of the area. For a long time, the specimens from the Upper Cave at Zhoukoudian and from Liujiang in southern China were regarded to be among the earliest moderns, probably dating to ca. 25–30 Kyr bp

(Hedges et al. 1995; Etler 1996). Due to more recent Uranium-series dates, Shen et al. (2002) have argued that the Liujiang specimen could be much older (>60 Ka or ~100 Ka), but there remain basic uncertainties as to the stratigraphic position of the human remains and thus to their age (Demeter et al. 2012; Keates 2010). In spite of some deviations from present-day Chinese population samples (Howells 1995; Stringer 1999), a multivariate analysis of these early modern Chinese crania (Bräuer and Mímisson 2004) demonstrated that the Upper Cave 101 specimen exhibits the closest affinities with Upper Paleolithic Europeans and also Australians and recent Europeans. For the Liujiang cranium (Fig. 5), the greatest similarity was found with recent North Africans and Europeans as well as with Upper Paleolithic Europeans, terminal Pleistocene North Africans, and sub-Saharan Africans. These similarities appear to support a more recent date for Liujiang. Yet, even if this fully modern specimen would indeed be about 100 Kyr old, it would still clearly contradict any regional evolution from the archaic Dali-Maba-Jinniushan group.

The discussion on the date of the earliest presence of modern humans in East Asia continues, since more human remains have been reported to date between >40 and 100 Ka. These comprise an anterior mandibular fragment from Zhirendong, South China, dated to about 100 Ka (Liu et al. 2010), and a partial adult cranium from the Tam Pa Ling, a cave in Laos, with an age of ca. 46 Ka (Demeter et al. 2012). Because of extant uncertainties on the dating of Liujiang and the fully modern condition of Zhirendong, Demeter et al. (2012) regard the rather well-preserved specimen from Laos as the earliest definitively modern fossil in East Asia. Yet, even with this specimen some questions on the dating and stratigraphy exist (Pierret et al. 2012).

Regarding Australasia, the central assumptions of the multiregionalists have also proven to be no longer tenable. In spite of the huge gap in time between the only *H. erectus* specimen with a well-preserved face, Sangiran 17, and the earliest Australians, Wolpoff et al. (1984, p. 443) saw, especially in the face, a number of continuity features such as the marked prognathism, the maintenance of large posterior dentitions throughout the Middle and Late Pleistocene, an eversion of the lower border of the malar, the persistence of a zygomaxillary ridge, and rounding of the inferolateral border of the orbit. Yet the assumption of interregional gene flow as emphasized by multiregionalists would make it very unlikely that such combinations of features could have been maintained over a period of more than 1 Myr and during the claimed transformation process from the massive facial morphology of *H. erectus* toward that of modern humans (Nei 1998). In addition, Aziz et al. (1996) demonstrated that the earlier reconstruction of the Sangiran 17 cranium done by Wolpoff (Thorne and Wolpoff 1981) is incorrect in several respects. In the revised reconstruction (Fig. 6), the degree of facial prognathism is not marked, but only moderate, and there is no eversion of the lower border of the zygomatic bone, which as a whole bulges laterally. Moreover, the zygomaxillary ridge could not be detected by Aziz et al. (1996, p. 20), nor by myself, on the

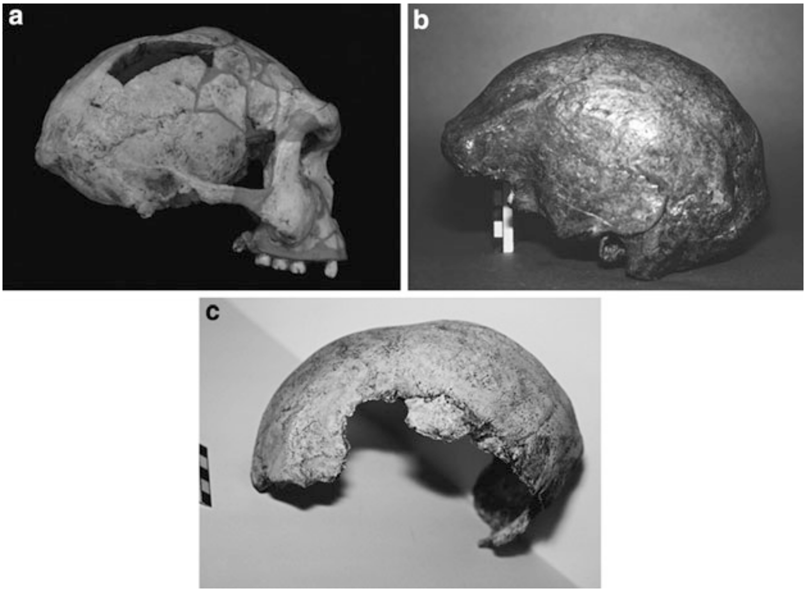


Fig. 6 *Homo erectus* from Indonesia and an early modern Australian: (**a**) Revised reconstruction of Sangiran 17 by Aziz et al. 1996 (Photo: F. Aziz/H. Baba); (**b**) Ngandong; (**c**) Lake Mungo 3

original. There is also no rounding of the inferolateral border of the orbit (Baba et al. 2000, p. 61). Finally, Baba et al. (2000, p. 62) demonstrated that "it does not make sense to compare the degree of facial and dental reduction between Sangiran 17 and Australians, because masticatory adaptation pattern is completely different from each other." Thus, relevant continuity features which have been said to be present on Sangiran 17, dated to ca. 1.3 Ma (Antón 2003), are simply not there or are the result of incorrect reconstruction. Also, in her comprehensive analysis of 20 assumed Australasian cranial features, Lahr (1994) arrived at the conclusion that most of the traits did not show the pattern proposed by the Multiregional Evolution model and quite a number of them occur with high frequency in a robust terminal Pleistocene sample from North Africa, thereby supporting a functional interpretation of these traits.

Detailed analyses of the cranial morphology of Indonesian *H. erectus* show a continuous gradual evolution from the early Pleistocene specimens to the late *H. erectus* from Ngandong (Fig. 6) and Sambungmacan, but no further evolutionary continuity to early modern Australasians (Kaifu et al. 2008). Until recently, the ages of Ngandong and of Sambungmacan, which have long been controversial, ranged between a few hundreds of thousands of years (e.g., Bartstra et al. 1988) to only 30–50 Ka (Swisher et al. 1996). New redating by Ar/Ar and ESR/U-series also arrived at divergent results that nevertheless narrow the age of the Ngandong hominins to between 140 and 540 Ka (Indriati et al. 2011). Thus, it now seems that the Ngandong *erectus* is older than 100 Ka and not contemporaneous with the earliest Australians, such as the fully modern skeleton Lake Mungo 3, southern Australia (Fig. 6), for which several dating approaches have yielded an age of more than 40 Kyr bp and perhaps even up to 60 Kyr bp (Thorne et al. 1999; Bowler and Magee 2000).

Although no conclusive indications for a regional evolution from *H. erectus* to modern Australians appear to exist, the human fossil and subfossil material from Australia as a whole exhibits considerable variability with regard to robusticity. Among these anatomically modern humans, there are very robust as well as gracile specimens as, for example, present in the Kow Swamp material which dates to ca. 22–19 Kyr bp or somewhat more recent (Bräuer 1989; Stone and Cupper 2003). One of the most robust crania is WLH-50 from the Willandra Lakes, which has been absolutely dated to 14 Kyr bp (Simpson and Grün 1998). The cranial vault of this specimen has also been modified by severe pathological alterations (Webb 1990). Notwithstanding the young age and pathology of WLH-50, Wolpoff et al. (2001) chose this cranium instead of the much more appropriate one from Lake Mungo in order to demonstrate regional evolution in Australasia. However, their approach also suffers from fundamental problems with the characteristics used as well as their assessments (Bräuer et al. 2004b). Robust specimens also date from the early Holocene. Possible explanations for the great range of variation might be drift effects in the course of the occupation of the continent but may also include adaptation to an increasingly arid environment toward the peak of the last glacial period (Klein 1999; Baba et al. 2000). As the recent genome sequencing showed, populations of Australia and New Guinea not only exhibit up to 5 % of their DNA from the archaic Denisovans but also 1–4 % of Neanderthal DNA (Reich et al. 2011). Yet, in view of the fact that the earliest fully moderns in Australia are rather gracile, it remains controversial whether this archaic DNA component also contributed to the greater robusticity among the later terminal Pleistocene Australians.

Conclusions

Over the last two and a half decades, the accumulating fossil and molecular evidence has strongly supported the "Out-of-Africa and hybridization" model. Claims by multiregionalists for a larger contribution of Neanderthals to the early modern Europeans cannot be supported by the current evidence. Instead, the most likely scenario appears to be a replacement of the Neanderthals accompanied by only a small amount of gene flow. For the Far East, it is more difficult to examine possible indications of interbreeding since the fossil record of the replacement period is rather poor. Nevertheless, in view of the serious problems regarding the claimed continuity features for China and Australasia and the fact that the earliest modern humans in both areas are fully anatomically modern and do not fit into the concept of regional evolution, no convincing evidence can be seen for long-term regional evolution up to modern humans.

The anatomical modernization process in Africa now appears to be well established by quite a number of diagnostic and reliably dated hominid specimens. To describe the obvious morphological changes of this continuously evolving lineage, three grades or groups of *H. sapiens* have been suggested. This evolutionary sequence led to an early emergence of anatomically modern humans nearly 200 Ka. In view of the obvious continuity from archaics to early moderns and the near-modern morphology of the premoderns, it appears unlikely that anatomically modern humans differ from their direct ancestors on the species level (Stringer 2002a; Bräuer 2008). Instead, during the major part of the Middle Pleistocene, the African fossil record documents a diachronic increase of more derived modern-like conditions. Therefore, it appears adequate to assign the post-*H. erectus* humans to one biological species *H. sapiens* (Klein 2009; Hofreiter 2011). This view is also supported by the fact that the Preneanderthal/Neanderthal lineage which goes back to around 500 Ka bp cannot reasonably be split into different species. It might thus be in agreement with the current evidence (Fig. 7) from Africa and Europe to only assume a speciation between *H. erectus* and (archaic) *H. sapiens* at around 700 or 800 Ka in Africa. Later, early archaic *sapiens* populations spread into Europe evolving toward the Neanderthals. Regarding China, it appears likely that the late Middle Pleistocene humans derived from an eastward dispersal of archaic *H. sapiens* populations, possibly representing the Denisovan lineage, although some regional gene flow from *H. erectus* cannot be excluded as well.

As discussed in this and other chapters, various alternative phylogenetic scenarios have been suggested to describe Middle and Late Pleistocene human evolution. *H. sapiens* is often restricted to modern humans, and its ancestral group (largely equivalent to late archaic *H. sapiens*) has been assigned either to the same species (Stringer 2002a) or to a separate species, *H. helmei* (McBrearty and Brooks 2000). Alternatively, *H. helmei* is regarded as ancestral not only to modern *H. sapiens* but also to *H. neanderthalensis* (Foley and Lahr 1997). These various possibilities, however, have their own problems. For example, the latter phylogeny does not consider that Neanderthal features had long existed in Europe prior to the hypothesized appearance of *H. helmei*. Moreover, suggesting several species within the continuously evolving lineages of later human evolution causes problems in delimiting the taxonomic units (Foley 2001). Such units are rather arbitrarily defined entities without any clear relation to biological species. Studies on extant primates led Jolly (2003, p. 662) to conclude that Neanderthals, Afro-Arabian "premodern" populations, and modern humans are, roughly speaking, biological subspecies, comparable to interfertile allopatric taxa or phylogenetic species of baboons. Thus, it appears well supported from different lines of evidence, including the recent results from nuclear DNA sequencing for widespread archaic-modern hybridization, to regard the European Preneanderthals/Neanderthals and the African Middle Pleistocene lineage to modern humans and the late archaic group in China as belonging to one polytypic species *H. sapiens*. "Speciation remains the special case, the less frequent and more elusive phenomenon, often arising by default" (Grubb 1999, p. 164).

Population Biology and Population Genetics of Pleistocene Hominins

Alan R. Templeton

Contents

Abstract

The population genetics of Pleistocene hominins is deduced from three types of data: coalescent processes and haplotype trees estimated from surveys of genetic variation in present-day human populations, ancient DNA extracted from fossils, and overlays of current quantitative genetic variance/covariance matrices upon hominin fossils. The haplotype trees are subjected to nested clade phylogeographic analyses. These analyses show that there were three major expansion events of hominins out of Africa during the last 2 Myr. The first expansion event marked the original dispersal of *Homo erectus* out of Africa into Eurasia. The quantitative genetic analysis of hominin fossils indicates that there was relaxed selection upon at least some morphological features at this time,

perhaps due to an increased use of cultural inheritance in dealing with the environment. Coalescent analyses indicate that the colonization of Eurasia was marked by strong selection at many loci, so although morphological selection may have been relaxed, adaptive processes were still proceeding as humans colonized this new geographical area. A second expansion out of Africa was marked by the spread of the Acheulean culture, implying that the spread of this culture was due to a spread of peoples and not just ideas. The expanding Acheulean populations interbred with existing Eurasian populations, and recurrent gene flow between Eurasian and African populations was established although restricted by isolation by distance after the Acheulean expansion. A third expansion out of Africa marked the spread of many anatomically modern traits that had earlier appeared in Africa. This expansion was also marked by interbreeding, so regional continuity persisted for some traits. Total replacement of Eurasian populations is rejected with a $p < 10^{-17}$, under nested clade phylogeographic analysis, and this strong conclusion has been confirmed by subsequent phylogeographic analysis using Approximate Bayesian Computation after correcting for some statistical errors. Direct studies on ancient DNA also support limited admixture rather than total replacement. Coalescent studies are inconclusive and contradictory both about the size of hominin populations before this last out-of-Africa expansion and the degree of population growth during the expansion phase. Because of admixture and gene flow, humanity evolved into its modern form as a single evolutionary lineage but with geographical differentiation at any given time due to isolation by distance and local adaptation.

Introduction

Population genetics is concerned with the origin, amount, and distribution of genetic variability present in populations of organisms and the fate of this variability through space and time. Variation in genes through space and time constitutes the fundamental basis of evolutionary change, so population genetics can be thought of as the science of the mechanisms responsible for evolution within a species or within a continuous lineage of species through time. The fate of genes through space and time is strongly influenced by a population's demography, so genetic studies can also be used as a powerful tool to investigate past demography.

Most population genetic studies of natural populations involve surveying a sample of individuals from one or more demes (local subpopulations), followed by analyses to infer population structure, demography, and/or the impact of various evolutionary forces such as genetic drift, gene flow, and natural selection. But how does one study the genetics and demography of populations from the distant past, such as hominin populations from the Pleistocene? The most common approach to the study of past populations arises from the subdiscipline of population genetics known as coalescent theory. Because DNA can replicate and pass on copies of itself to the next generation, contemporary DNA contains information from past generations. One can therefore genetically survey contemporary populations and then use phylogenetic techniques to estimate the pattern of past DNA replication events. A DNA replication event produces two copies of DNA from one ancestral molecule, so when looked at backward in time, a DNA replication event corresponds to two molecules of DNA coalescing into a single ancestral molecule. Our ability to infer coalescent events with phylogenetic methods depends on the descendant DNA lineages being distinguishable from one another, so the only coalescent events that can be inferred are those that are also associated with a mutation in one of the DNA lineages.

The distinguishable DNA lineages are called haplotypes, and we can only reconstruct the haplotype tree of a DNA region, that is, the pattern of coalescent events marked by mutational changes. Thus, the rate of mutation in a DNA region places a limit on our ability to infer the evolutionary history of that region. Because of the Mendelian properties of genetic recombination and assortment and because different DNA regions can display different patterns of inheritance (e.g., the DNA on the Y chromosome is paternally inherited but autosomal DNA is inherited through both sexes), different regions of DNA can have different evolutionary histories and can be influenced by different subsets of past demographic events and processes. Moreover, population genetic inference requires genetic variation, so once all the contemporary copies of a gene or DNA region have coalesced back to a single ancestral molecule of DNA, all population genetic information is lost. Because different DNA regions can coalesce to their common ancestral molecule at different times in the past, different genes are informative of different time periods in the past. Natural selection can also affect the coalescent dynamics of a particular gene region, either by increasing the frequency and geographical range of a new, favored haplotype, by maintaining locally adaptive haplotypes, or favoring the maintenance of multiple DNA lineages. In this case, the haplotype tree does not just reflect the impact of past demography, but also past and ongoing natural selection. Populations generally contain much variation in their gene pools. Hence, when a population splits into two or more isolates, those isolates at first share much of their genetic variation. As time proceeds, genetic drift insures that some DNA lineages are lost, and one will eventually become the common ancestral form for a particular isolate. Because of the randomness of genetic drift, this process of DNA lineage sorting can sometimes produce haplotype trees with different topologies than the evolutionary tree of population splits. Finally, populations can differentiate under restricted gene flow, never experiencing true splits followed by isolation. Indeed, if gene flow is sufficiently strong, the entire species may represent a single panmictic population. In these cases there is no evolutionary tree of populations at all, but there are still haplotype trees for specific regions of the genome. For all of these reasons, any one gene or DNA region captures only a portion of a population’s evolutionary history, and the haplotype tree of a gene or DNA region should *never* be equated to the evolutionary history of populations. Many different haplotype trees are required to overcome these difficulties in order to yield a reconstruction of population history. Fortunately, such multi-locus, coalescent analyses are now feasible.

The coalescent approach starts in the present and looks into the past. An opposite approach is to start in the past with some set of assumed conditions and then project into the present using a detailed evolutionary model. This projection is typically accomplished through computer simulation. The parameter space of the assumed model is explored to find the set of parameters that best fits the current genetic observations. Often qualitatively different models are also simulated to find the model that best fits the current genetic observations. This approach does not require haplotype trees, but rather can be applied to wide variety of genetic data sets.

One limitation of both the coalescent and simulation approaches is not easily overcome. Both types of analyses are based upon current genetic variation and therefore are limited to inferences on past populations or subpopulations that have left genetic descendants in present-day populations. Any population that left no descendants is outside the domain of coalescent analyses. DNA from fossils can overcome this limitation, so ancient DNA studies can extend coalescent and simulation analyses. But because evolution is a population process, accurate evolutionary inferences often depend upon having large sample sizes, and the number of fossils that retain useful DNA severely limits ancient DNA approaches. As a result, ancient DNA surveys usually involve limited sample sizes, even when fossils from diverse geographical locations and separated by tens of thousands of years are pooled together as a single "population." Extremely small sample sizes often preclude precise population genetic inference. However, some population genetic inferences depend more on the number of genes sampled than the number of individuals, and since ancient DNA studies on hominins can now span the entire genome, some types of inferences can be made with a high degree of confidence. Hence, ancient DNA studies can now address at least some of the questions addressed by studies based on current variation. This allows a direct cross-validation between the present and the past.

Coalescent approaches and patterns found in current genetic variation can also be used to infer the presence and type of natural selection operating upon specific genes. Hence, some aspects of adaptive evolution in hominin populations can be addressed from surveys of present-day genetic variation. Additional adaptive insights can be achieved by combining genetic surveys on living populations with ancient genomes from fossils. Another approach to studying past adaptive evolution is to use genetic studies on morphological variation in present-day populations to model the evolutionary forces that created morphological change in the fossil record. All four approaches – coalescence of haplotypes, ancient DNA, simulation, and quantitative genetics – will be considered in this chapter with respect to two major aspects of hominin evolutionary history: (1) hominin population structure and historical demographic events and (2) natural selection and adaptive evolution in past hominin populations.

Hominin Population Structure and Historical Demographic Events

Nested Clade Phylogeographic Analyses

Nested clade phylogeographic analysis (NCPA) is a coalescent-based approach to extract information from haplotype trees to infer the qualitative nature of past population structure (patterns of gene flow among geographical areas) and historical demographic events (population range expansions, colonization events, and fragmentation events) (Templeton et al. 1995). NCPA first defines a series of hierarchically nested clades (branches within branches) from the haplotype tree using a set of explicit nesting rules (Templeton et al. 1987; Templeton and Sing 1993). Most human haplotype trees are rooted, so the oldest clade is known in any given nested category. The relative temporal orderings are used to analyze the spread of haplotypes and clades through space and time. NCPA next quantifies the spatial distribution of haplotypes and clades by measuring how widespread a clade is spatially and how far away a clade is located from those clades with which it is nested into a higher-level clade (Templeton et al. 1995). To adjust for sampling, the nested clade analysis uses a random permutation procedure to test the null hypothesis that the clades nested within a higher-level clade have no geographical associations. Because the nested clades are asymptotically independent (Templeton et al. 1995), the Bonferroni procedure is used to correct for multiple testing. All subsequent inferences are limited to those clades associated with a statistically significant rejection of the null hypothesis of no geographical association.

Statistical significance tells us that geographical associations exist within the haplotype tree, but they do not tell us how to interpret those geographical associations. Indeed, no single test statistic discriminates between recurrent gene flow, past fragmentation, and past range expansion in NCPA. Rather, it is a pattern formed from several statistics that allows discrimination. Also, many different patterns can sometimes lead to the same biological conclusion, and sometimes a statistically significant pattern has no clear biological meaning because of inadequate geographical sampling or a lack of genetic resolution. Finally, NCPA searches out multiple, overlaying patterns within the same data set. In light of these complexities (which reflect the reality of evolutionary possibilities and sampling constraints), an inference key was provided as an appendix to Templeton et al. (1995), with the latest version being available at http://darwin.uvigo.es/ along with the program GEODIS for implementing the nested clade analysis.

Although NCPA has many strengths, it does have limitations. In particular, inference is limited by (1) sample size and sample sites, (2) insufficient genetic resolution to detect an event or process that actually occurred, and (3) false inferences arising from the evolutionary stochasticity of the coalescent process or by the haplotype tree being skewed or otherwise altered by natural selection. In light of these limitations, the inference key has been extensively validated by applying NCPA to actual data sets with 150 a priori expectations (Templeton 2004b). The inference key did well, with the most common error being the failure to detect a known event. Only rarely did NCPA result in a false positive. The failure to detect known events was due to the fact that an appropriate mutation had not occurred in the right place and time to mark the event. This shows that no one locus or DNA region can capture the totality of a species' population structure and evolutionary history. Concerning false positives, the processes of mutation and genetic drift, which shape the haplotype tree upon which the NCPA is based, are both random processes. Therefore, the expected pattern for a particular event or process can sometimes arise by chance alone, leading to a false biological inference. Moreover, natural selection can lead to false biological inferences by skewing the shape of the haplotype tree and the geographical distribution of certain haplotypes.

The occurrence of false negatives and false positives can be reduced by performing NCPA upon many loci or gene regions (Templeton 2002). Using multiple DNA regions reduces the danger of missing an event or process due to the lack of an appropriately placed mutation in time and space for any one DNA region. The chance of making a false inference is reduced by cross-validating inferences across DNA regions. Templeton (2002) used a multi-locus NCPA based on the human mitochondrial genome and nine nuclear genome regions to infer recent human evolutionary history. What was most remarkable about the cross-validated inferences in this case was the incompleteness found in any one DNA region. This illustrates that failure to detect events or processes with a single DNA region is a common phenomenon. Interestingly, most inferences that were made with one gene were cross-validated by other DNA regions, thereby indicating that false positive inferences are rare in NCPA. This is the same pattern observed when validating the inference key with real data with a priori expectations (Templeton 2004b).

The power and low false positive rate of multi-locus NCPA was confirmed by the simulations of Knowles and Maddison (2002). Knowles and Maddison simulated an evolutionary history of micro-vicariance, in which each local population was a genetic isolate due to past fragmentation events. Moreover, the time between population splits was less than the expected coalescent times and the population sizes were large, thereby insuring the sharing of much ancestral polymorphism across isolates. This is a difficult inference problem, and indeed their own simulation procedures fared poorly (Knowles and Maddison 2002). Although the multi-locus version of NCPA had been published 9 months earlier (Templeton 2002), Knowles and Maddison chose to apply only the 1998 single-locus version of NCPA to their simulated data, despite the fact that micro-vicariance had been explicitly excluded from the single-locus version (Templeton et al. 1995). Accordingly, it is not surprising that single-locus NCPA fared poorly when used to analyze these simulated data sets. However, when the 2002 version of multi-locus NCPA was applied to these same simulated data sets, a 100 % accurate reconstruction of the population's evolutionary history was made with no false inferences (Templeton 2009a). These simulations therefore demonstrate the power of multi-locus NCPA to reconstruct difficult evolutionary histories even when no single locus could yield accurate inferences and the low false positive rate of multi-locus NCPA.

Cross-validation in Templeton (2002) was based upon concordance across DNA regions of NCPA inferences by type and geographical location. Assessing concordance of inference type and locality is straightforward as these are categorical variables, but inferences should also be temporally concordant. Estimated times of events are quantitative variables with considerable error due to the high stochasticity associated with the coalescent process (Templeton 2004b). Therefore, Templeton (2004a) developed log-likelihood ratio tests of temporal concordance. Panchal and Beaumont (2010) performed simulations to determine the false positive rates under a variety of scenarios using this triple cross-validation of inference type, geographical location, and a formal statistical test of temporal concordance. In general, they found low rates of false positives that were below the nominal rate of 5 %. The one exception was for inferences involving gene flow. Panchal and Beaumont claimed that gene flow inference is subject to a high false positive rate "because there is no stipulation that the inferences should be concordant across time" (Panchal and Beaumont 2010, p. 418). This claim is false. Gene flow is a recurrent event, so temporal concordance does not mean that all gene flow inferences must have occurred at exactly the same time. Therefore, likelihood ratio tests were designed for temporal concordance across a *time interval* for gene flow (Templeton 2004a, Eq. 12; Templeton 2009b, Eq. 2). The 2009 test specifically tests the null hypothesis of no gene flow between two areas in a specific time interval. Panchal and Beaumont (2010) are correct in concluding that their reported high false positive rate for gene flow inferences was due to *their* failure to test for temporal concordance, but Panchal and Beaumont made an egregious misrepresentation of NCPA by claiming that such a test did not exist. Whenever Panchal and Beaumont actually implemented multi-locus NCPA, the false positive rates were always below the nominal rate. These simulations therefore demonstrate that multi-locus NCPA is a powerful and accurate method for reconstructing past evolutionary histories from current genetic data.

Because multi-locus NCPA uses haplotype trees, only those gene regions that have little to no recombination can be used. Recombination can place together in a single DNA molecule different segments that may have had different evolutionary histories, thereby undermining the very idea of an evolutionary tree of haplotypes. This is why the initial studies using NCPA for human evolution were limited to the nonrecombining molecules of mitochondrial DNA (mtDNA) and the Y chromosome (Y-DNA). However, recombination in the human genome is not evenly distributed, but rather is concentrated into hotspots with little to no recombination in many of the regions bounded by hotspots (Templeton et al. 2000a). Hence, with modern genomics it is not difficult to find many regions in the human genome that are amenable to multi-locus NCPA. These nonrecombining regions are the ones upon which human evolutionary history is most clearly and cleanly written.

Multi-locus NCPA was first applied to infer recent human evolution with 10 gene regions (mitochondrial DNA, Y chromosomal DNA, and 8 nuclear gene regions) (Templeton 2002) and was later expanded to include 15 additional nuclear gene regions (Templeton 2005, 2008). The *MX1* data used in Templeton (2002) was later

Table 1 The times to the most recent common ancestor (TMRCA) in millions of years ago for the 24 loci subjected to NCPA

Gene region	TMRCA

FUT2	5.04

found to contain some paralogous copies, so it was subsequently excluded, leaving a total of 24 gene regions. Interestingly, the inferences from *MX1* had already been excluded from the earlier analysis on the basis of the cross-validation procedure (Templeton 2005, 2008). Coalescent theory predicts that there will be a large variance in coalescent times to the most recent common ancestor (TMRCA) among the various gene regions, with the unisexual, haploid regions (mtDNA and Y-DNA) having an expected coalescence time of N_{ef} generations (the long-term inbreeding effective size of humanity), the X-linked loci having an expected coalescence time of $3N_{\mathrm{ef}}$, and the autosomal loci having an expected coalescence time of $4N_{\mathrm{ef}}$ (Templeton 2002). Table 1 gives the TMRCAs for the 24 loci used in this analysis. The average coalescence times do indeed fit the expected ranking, and there is also the large expected variance within each category. Table 1 further shows that there is a rather continuous temporal coverage up to about 2.5 Ma. Thus, with these 24 loci, events going back to around 2 Ma can be inferred with potential cross-validation, which represents a significant improvement in the informative temporal range over that of the original 10 loci (Templeton 2002).

Table 2 The NCPA inferences and their estimated times (in Ma) from the 24 gene regions that yielded significant and interpretable results. Time is indicated only as "recent" for events too young to be reliably dated by phylogenetic means. Only gene flow inferences between Africa and Eurasia are shown

Gene region	Range expansion events	Restricted gene flow between Africa and Eurasia
mtDNA	Out of Africa, $t = 0.1308$	Isolation by distance, recent
	To N. Eurasia, recent	
	To Siberia, recent	
	To the Americas followed by fragmentation, recent	Isolation by distance, recent

Table 2 (continued)

Gene region	Range expansion events	Restricted gene flow between Africa and Eurasia
MSN/ ALAS2	–	Isolation by distance, $t = 0.164$
PDHA1	–	Isolation by distance, $t = 0.8597$
RRM2P4	Out of Africa, $t = 0.14$	With some long-distance dispersal, $t = 0.6$
TNFSF5	To the Americas, recent	–
Xq13.3	–	Isolation by distance, $t = 0.48$

Table 2 shows the inferences made from the 24 gene regions along with their estimated times of occurrence. Some events could not be timed because there were too few or no mutations available to obtain a reliable estimate. The inferences shown in Table 2 span most of the Pleistocene.

Table 2 reveals 15 different identifications of out-of-Africa range expansion events or Africa/Eurasian range expansion events of ambiguous origin. These 15 events are concordant by type (range expansion) and geographical location (expansion events involving both African and Eurasian populations, and when geographical resolution of the origin is possible, it is always out of Africa). To test temporal concordance of these 15 inferences, their estimated times are regarded as random variables with a mean given by a standard phylogenetic estimator (Takahata et al. 2001) of the age of the youngest clade contributing in a statistically significant fashion to the inference, with a calibration point of 6 Ma for the divergence between humans and chimpanzees (Templeton 2004a). The variance of this time is given by Tajima (1983).

$$\sigma^2 = \frac{T^2}{(1 + k)} \tag{1}$$

where T is the standard phylogenetic estimator of age and k is the pairwise divergence among present-day haplotypes as measured by the number of mutations that have accumulated in the descendants of the haplotype or node whose age is estimated to be T. Equation 1 incorporates two sources of error into the variance associated with estimator T. First, the numerator of Eq. 1 is T^2, reflecting the evolutionary stochasticity of the coalescent process itself in which the variance is proportional to the square of the mean (Donnelly and Tavare 1995; Hudson 1990). The other factor that influences the variance is k, which depends upon the number of mutations that have accumulated in the DNA lineages from T to the present. This can vary considerably from locus to locus, depending upon the local substitution rates and upon the amount of DNA being sequenced. Because k is generally very small for recent events, phylogenetic dating procedures are often unreliable for recent events (Rannala and Bertorelle 2001).

If the population under study has not been significantly fragmented into subpopulations and evolution is neutral, then the distribution of t_i, the time of a phylogeographic event or process inferred from DNA region i, can be approximated by a gamma distribution (Kimura 1970):

$$f(t_i|T_i, k_i) = \frac{t_i^{k_i} e^{-t_i(1+k_i)/T_i}}{\left(\frac{T_i}{1+k_i}\right)^{1+k_i} \Gamma(1+k_i)} \tag{2}$$

where k_i is the average pairwise nucleotide diversity among the haplotypes in DNA region i in the youngest monophyletic clade that contributed in a statistically significant fashion to the NCPA inference of interest, and T_i is the age obtained by the phylogenetic estimator (Templeton 2004a). Given that the NCPA did not reveal any cross-validated fragmentation events except perhaps very early in the Pleistocene between Africa and Eurasia (the exclusive focus of this chapter) that were subsequently mostly erased by range expansions and admixture, the gamma distribution assumption is justified for the human data.

Templeton (2004a) used these gamma distributions to derive maximum-likelihood estimators of the time of an event based on multi-locus data and to derive a log-likelihood ratio test of the null hypothesis that n separate inferences of a geographically concordant event are also temporally concordant; that is, they are the same event. Figure 1 shows the gamma distributions for the 15 inferences of range expansion involving African and Eurasian populations. The log-likelihood ratio test rejects the null hypothesis that all 15 events are temporally concordant with a probability value of 3.89×10^{-15}. Thus, the genetic evidence is overwhelming that there were multiple range expansion events out of Africa during the last 2 Myr (million years) of human evolution. An inspection of Fig. 1 reveals that the time distributions for the 15 events cluster into three distinct groupings. Accordingly, the null hypotheses of temporal concordance within each of these three groupings were tested, and in all cases there was strong concordance within ($p = 0.95$ for the most recent expansion out of Africa, $p = 0.51$ for the middle expansion, and $p = 0.62$ for the oldest expansion). Pooling together the inferences from j homogeneous loci also results in a gamma distribution with mean and variance (Templeton 2004a):

$$\text{Mean} = \hat{T} = \frac{\sum_{i=1}^{j} t_i(1+k_i)}{\sum_{i=1}^{j} (1+k_i)} \tag{3}$$

$$\text{Var}\left(\hat{T}\right) = \frac{\sum_{i=1}^{j} (1+k_i)^2 \text{Var}(t_i)}{\left(\sum_{i=1}^{j} (1+k_i)\right)^2} = \frac{\sum_{i=1}^{j} (1+k_i) t_i{}^2}{\left(\sum_{i=1}^{j} (1+k_i)\right)^2} \tag{4}$$

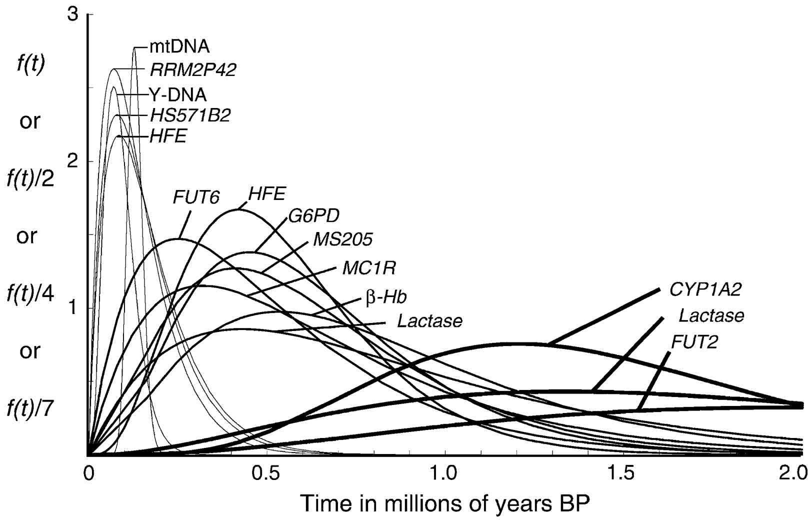

Fig. 1 The distributions for the ages of range expansion events involving Africa and Eurasia, all of which are out-of-Africa events when the geographical origin is unambiguous. The x-axis gives the age in millions of years before present, and the y-axis gives the gamma probability distribution $f(t)$ that was fitted to the data from a particular locus or DNA region. Because the probability mass is so concentrated close to the y-axis for several genes, the gamma distribution was divided by 7 for mtDNA, by 4 for Y-DNA, and by 2 for HFE, HS571B2, and RRM2P4 to yield a better visual presentation. The age distributions fall into three clusters, shown by *thin black lines*, *medium colored lines*, and *thick dashed lines*, respectively

Combining Eq. 1 with Eq. 4, the effective number of informative mutations about the age of the event based on pooled data, k_{eff}, is given by

$$k_{\text{eff}} = \frac{\hat{T}^2}{\text{Var}(\hat{T})} - 1 \tag{5}$$

The standard log-likelihood ratio test given in Templeton (2004a) can be used to test the null hypothesis that two or more times based on pooled data are the same by using Eqs. 3 and 5. The log-likelihood ratio test of temporal homogeneity of the most recent and middle out-of-Africa expansion events yields a chi-square statistic of 40.84 with 1° of freedom with a p-value of 1.66×10^{-10}. Hence, the null hypothesis of temporal concordance is strongly rejected, and the first two clusters shown in Fig. 1 define two distinct out-of-Africa expansion events. The log-likelihood ratio test of homogeneity of the middle and oldest out-of-Africa expansion events also rejects temporal concordance with a chi-square statistic of 8.85 with 1° of freedom and a p-value of 0.0029. Hence, all three clusters shown in Fig. 1 identify separate events that are all cross-validated by multiple loci. The estimated times and 95 % confidence intervals for these three out-of-Africa range expansions are shown in Table 3.

Table 3 The estimated times and 95 % confidence limits of the NCPA inferences of out-of-Africa range expansions when multiple loci are pooled according to the results of log-likelihood ratio tests

Time of expansion (Ma)	More recent age limit	Older age limit
0.1304	0.0965	0.1693
0.6508	0.3917	0.9745
1.9007	0.9937	3.0969

These NCPA inferences from molecular genetic data are consistent with the fossil and archaeological record. The oldest expansion, genetically dated to 1.9 Ma, corresponds well to the fossil dating of the original expansion of *Homo erectus* (which includes *ergaster* in this chapter) from Africa into southern Eurasia at 1.85 Ma (Ferring et al. 2011) and far East Asia by 1.7 Ma (Zhu et al. 2008). Dennell (2003) has argued that these early Pleistocene fossil finds in Eurasia may not have represented permanent settlement but also acknowledges the difficulty of inferring (or rejecting) regional continuity over a long-time period from temporally sporadic fossil and archaeological finds from a single geographical area. Genetics can offer an important tool that complements the fossil and archaeological data. Recall that the NCPA can only detect the genetic signatures of past populations that have made at least some genetic contribution to current populations. This statistically significant signal of an expansion into Eurasia in the late Pliocene to early Pleistocene, cross-validated by three genes, would not exist at all if these initial Eurasian colonies had not left some descendants in present-day Eurasian populations. Hence, the initial colonization of Eurasia by *Homo erectus* was a successful one that resulted in the permanent settlement of at least parts of Eurasia.

The middle expansion out of Africa shown in Table 3 is consistent with the spread of the Acheulean stone-tool culture out of Africa and into Eurasia. Evidence for this culture is found first in Africa at 1.76 Ma (Beyene et al. 2013; Lepre et al. 2011), with the earliest non-African sites being older than 1 Ma (Pappu et al. 2011). However, Acheulean sites are not widespread in Eurasia until about 0.6–0.8 Ma, particularly eastern Asia (Hou et al. 2000). This has led to the suggestion by some that there were two Acheulean expansions out of Africa: the first at about 1.4 Ma and the second at 0.6–0.8 Ma (Aguirre and Carbonell 2001; Bar-Yosef and Belfer-Cohen 2001; Goren-Inbar et al. 2000). As outlined above, the current analysis indicates a statistically significant out-of-Africa expansion at 0.65 Ma (0.3917–0.9745 Ma), which corresponds well with the second, more widespread, Acheulean expansion. However, this genetic analysis does not falsify the hypothesis that there was an earlier Acheulean expansion at 1.4 Ma. Indeed, the out-of-Africa expansion detected by *CYPA2* dates to 1.43 Ma. However, because of the large variances associated with older coalescent-based estimates of age (Eq. 1), this event at 1.43 Ma could not be distinguished from the older out-of-Africa events detected by *FUT2* and *Lactase* with the likelihood ratio tests described above. Thus, there may well have been an Acheulean expansion at 1.4 Ma, but because this event is between the original out-of-Africa expansion by *Homo erectus* and the much stronger (in terms of both archaeological and genetic evidence) Acheulean expansion between 0.6 and 0.8 Ma, it will take a much larger data set to achieve statistical discrimination. Another explanation is that the Acheulean expansion at 1.4 Ma may have been very limited geographically, perhaps confined to the Middle East and southern India. A limited range expansion from Africa would not be detectable by most of the loci analyzed here because of sparse geographical sampling in the Middle East and India. Finally, it is also possible that the 1.4 Ma Acheulean expansion was only a cultural expansion, in which case it would be invisible to NCPA.

It is not clear from the archaeological evidence whether the 0.6–0.8 Ma Acheulean expansion was solely the diffusion of ideas from Africa or also involved movement of populations or individuals (Saragusti and Goren-Inbar 2001). Here, the genetic data can complement the archaeological data. NCPA can only detect movements of reproducing populations and individuals, not ideas. By combining NCPA with archaeology, it is likely that the 0.6–0.8 Ma Acheulean expansion represented a movement of both people and ideas. Another question that cannot be answered by the archaeological data alone is what happened when these Acheulean peoples coming out of Africa encountered the Eurasian populations? Perhaps the Acheulean peoples drove the earlier inhabitants to extinction, completely replacing them. Alternatively, the expanding Acheulean peoples could have interbred with the Eurasian populations. The Acheulean replacement hypothesis can be tested by noting that if complete replacement had occurred, there would be no genetic signatures of events or genetic processes in Eurasia that would be older than this expansion event (Templeton 2004a). This prediction stems from the simple fact that NCPA can only detect events and processes that affected past populations that left genetic descendants in present-day populations. The Acheulean replacement hypothesis can therefore be tested by testing the null hypothesis that the gamma distribution marking the Acheulean expansion has a mean time that is not significantly older than other Eurasian events or processes with older estimated times. To be conservative in the definition of "older," an event or process will only be regarded as older than the Acheulean expansion if its estimated age falls in the older 1 % tail of the pooled gamma distribution that describes the Acheulean expansion. This 1 % cutoff is calculated from the pooled Acheulean gamma distribution to be 1.0476 Ma. NCPA identified four events or processes with estimated times older than 1.0476 Ma: the first out-of-Africa expansion at 1.9 Ma and three inferences of restricted gene flow dating from 1.25 Ma to 1.9844 Ma (Table 2). The log-likelihood ratio test of the null hypothesis that these four other events and processes involving Eurasian populations are no older than the Acheulean expansion yields a chi-square of 10.37 with 4 degrees of freedom, which is significant at the 5 % level ($p = 0.0346$). Hence, the null hypothesis of Acheulean replacement is rejected. The expansion of people from Africa about 0.6–0.8 Ma was therefore marked both by bringing a new culture to and by interbreeding with Eurasian populations.

The Acheulean range expansion from Africa dated to 0.65 Ma (Table 3) is also compatible with the fossil record. After the initial expansion of *Homo erectus* out of

Africa about 1.9 Ma (Table 3), there was little change in average brain size up to 0.7–0.6 Ma, after which cranial capacities show a substantial increase (Lepre et al. 2011; Relethford 2001b; Rightmire 2004; Ruff et al. 1997). Hence the fossil record, the archaeological record, and the genetic analysis presented here all imply that an important transition in human evolution occurred about 0.65 Ma.

The final out-of-Africa expansion is genetically dated to 130,000 years ago (Table 3). Many anatomically modern traits first appeared in sub-Saharan Africa around 200,000 years ago (McDougall et al. 2005), then appeared outside of sub-Saharan Africa in northern Africa, the Arabian Peninsula, and Levant between 130,000 and 125,000 years ago (Armitage et al. 2011; Grun et al. 2005; Vanhaeren et al. 2006), and finally reached far eastern Asia no later than 110,000 years ago (Jin et al. 2009; Liu et al. 2010). Once again, the genetic date from NCPA agrees remarkably well with the fossil and archaeological records.

There has been considerable controversy over whether or not this most recent out-of-Africa expansion event was also a replacement event. This recent replacement hypothesis can be tested in the same manner as the Acheulean replacement hypothesis. The older 1 % tail of the gamma distribution that describes this recent out-of-Africa expansion occurs at 0.1774 Ma. Two older out-of-Africa expansion events occurred, as previously discussed, as well as an expansion event within Eurasia dated to 0.2535 Ma (Table 2). However, this within-Eurasia expansion event is not cross-validated by any other locus, so it will be ignored in this and all subsequent analyses. In addition to the two expansion events, there are 15 inferences of restricted gene flow involving Eurasian populations that have estimated ages older than 0.1774 (Table 2). The log-likelihood ratio test of the null hypothesis that all 17 of these times are no older than the most recent out-of-Africa expansion event yields a chi-square statistic of 118.18 with 17 degrees of freedom, which yields a p-value of less than 10^{-17}. Hence, the genetic data overwhelmingly reject the out-of-Africa replacement hypothesis. There is no doubt from NCPA that this spread of humans with many anatomically modern traits resulted in interbreeding with at least some Eurasian populations.

Several more range expansions were detected by NCPA: expansions within Eurasia, including the colonization(s) of new areas in Northern Eurasia and colonizations of the Pacific and the Americas. These expansions were marked by genetic regions with too few mutations to date, but they were inferred to have occurred after the most recent out-of-Africa expansion. More extensive data on the Y chromosome has allowed the dating of an expansion originating in Eurasia to 41,000–52,000 years ago (Wei et al. 2013). As this expansion was marked by both Y-DNA and nuclear DNA in the NCPA but not mtDNA, even though mtDNA had the best sampling and genetic resolution, this Paleolithic expansion was most likely male-mediated and therefore must have involved interbreeding with previously established populations.

The NCPA results indicate that expansions coupled with interbreeding or admixture were not the only source of genetic contact between African and Eurasian populations during much of the Pleistocene. Figure 2 shows the gamma distributions for all the inferences of restricted gene flow among African and

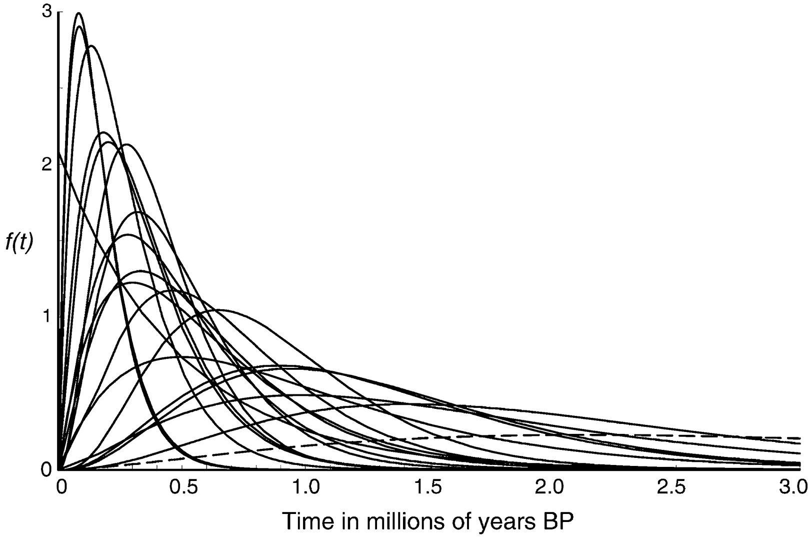

Fig. 2 The distributions for the ages of the youngest clade contributing to a significant inference of restricted gene flow, primarily with isolation by distance. The x-axis gives the age in millions of years before present, and the y-axis gives the gamma probability distribution, $f(t)$. The genes or DNA regions yielding these distributions are, as ordered by their peak values of $f(t)$ going from left to right: Xq13.1, *MSN/ALAS2*, *HFE*, *FIX*, *HFE*, *G6PD*, *βHb ECP*, *RRM2P4*, *EDN*, *PDHA1*, *CYP1A2*, *FUT2*, *FUT6*, *FUT6*, *FUT2*, *CYP1A2*, *CCR5*, and *MX1*. The curve for *MX1* is shown in a *dashed line* to emphasize its outlier status (Templeton 2002). Several other inferences of restricted gene flow that were too recent to date phylogenetically are not shown and not used in the analyses

Eurasian populations from Table 2. Almost all of the older inferences of gene flow indicate that it was restricted by isolation by distance, but some of the more recent inferences (often not datable by phylogenetic techniques) indicate some long-distance dispersal as well. This means that this genetic interchange was mostly due to short-distance movements to neighboring demes (other than the three major population-level expansions), but copies of genes could have spread throughout Africa and Eurasia via gene flow, using local demes as stepping stones to cross vast distances over many generations.

A glance at Fig. 2 versus Fig. 1 reveals a dramatic difference; the inferences of range expansion are clustered, but the inferences of restricted gene flow form a continuum across much of the Pleistocene. The continuum defined by the genes is expected if gene flow restricted by isolation by distance were a recurrent evolutionary force throughout much of the Pleistocene, with no lengthy interruptions.

Because gene flow is a recurrent evolutionary force, there is no expectation of different inferences of restricted gene flow from the various genes to be temporally concordant, in contrast to historical events such as rapid range expansions. But it is possible to test the null hypothesis of isolation (no gene flow) between two areas in the time interval l to u. In particular, if j is the number of loci that yield an inference of gene flow within the time interval l to u between the two areas of interest, the likelihood ratio test (*LRT*) of the null hypothesis of isolation between the two areas in the time interval l to u is

$$LRT\big(\text{isolation in } [l,u] = -2\sum_{i=1}^{j}\ln\left[1-\int_{l}^{u}\frac{t_i^{k_i}e^{-t_i(1+k_i)/T_i}}{\left(\frac{T_i}{1+k_i}\right)^{1+k_i}\Gamma(1+k_i)}dt_i\right] \tag{6}$$

with the degrees of freedom being j (Templeton 2009a).

During the early Pleistocene in the time interval between the first out-of-Africa expansion (1.9 Ma) and the Acheulean expansion (0.65 Ma), there were seven inferences of gene flow with isolation by distance between Africa and Eurasia (Table 2). The likelihood ratio test of the null hypothesis of isolation (no gene flow) between Africa and Eurasia given by Eq. 6 yields a log-likelihood ratio statistic of 11.86 with 7 degrees of freedom, which is not significant at the 5 % level. Hence, after the first expansion of *Homo erectus* into Eurasia, there was no significant gene flow between Eurasian and African populations up to the time of the Acheulean expansion. In the time interval between the Acheulean expansion (0.65 Ma) and the expansion of anatomically modern humans out of Africa (0.13 Ma), there are 11 inferences of gene flow between Africa and Eurasia, with Eq. 6 yielding a log-likelihood ratio statistic of 23.94 with 11 degrees of freedom, which yields a p-value of 0.013. Hence, the null hypothesis of isolation between Africa and Eurasia is rejected during this time interval. Humans by 650,000 years ago had the capability of moving both in and out of Africa and did so on a recurrent basis.

Figure 3 summarizes the cross-validated, statistically significant conclusions from the NCPA based on 24 genes or DNA regions. The inferences in Fig. 3 of ancient and recurrent gene flow punctuated by major population movements out-of-Africa coupled with interbreeding are consistent with the fossil record. Many fossil traits display a pattern of first appearing in Africa and then spreading throughout Eurasia (Stringer 2002), whereas other traits display a pattern of regional continuity (Wolpoff et al. 2000; Wu 2004). These two patterns are often regarded as mutually exclusive alternatives, but they are not under a model of genetically interconnected populations and no total replacement. As long as there is genetic interchange among populations, the Mendelian mechanisms of recombination and assortment allow different traits influenced by different genes to have different evolutionary fates. Some traits could have spread due to the joint actions of gene flow, admixture, and natural selection, whereas other traits may not have spread as rapidly or not at all due to a lack of selection or due to local selective pressures. Recurrent gene flow and admixture therefore provide the genetic interconnections that explain *all* of the fossil trait patterns during this time period, as well as current distributions of genetic variation in humans (Dugoujon et al. 2004; Eller 1999; Eswaran 2002). This model of gene flow and interbreeding also explains why current genetic variation in human populations does not fit an evolutionary tree model in which different human populations are treated as distinct “branches” on an evolutionary tree. Although the

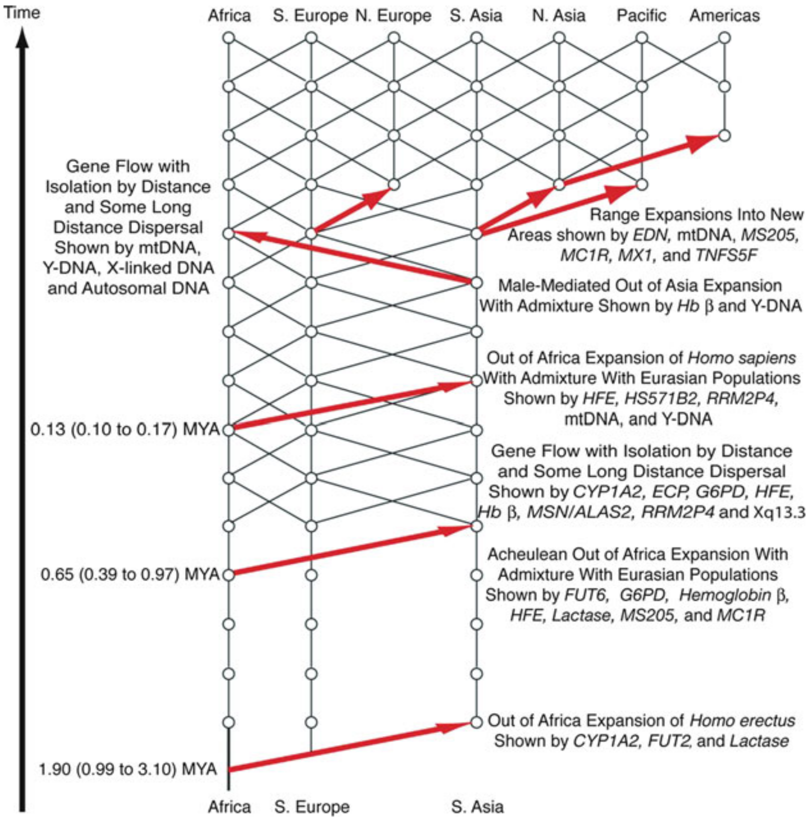

Fig. 3 A model of recent human evolution as inferred from NCPA. All inferences are cross-validated by two or more genes and are statistically significant at least at the 5 % level. Major expansions of human populations are indicated by *arrows*, and the time periods for the out of Africa are the 95 % confidence limits given in Table 3. Genetic descent is indicated by *vertical lines* and gene flow by *diagonal lines*

human evolutionary genetic literature is filled with portrayals of human populations as branches on a tree, none of these population evolutionary trees actually fit the genetic data when tested (Templeton 1998, 2003, 2013). Instead, patterns of genetic differentiation among current human populations fit an isolation-by-distance model much better than a tree model (Eller 1999, 2001; Templeton 1998, 2003, 2013).

Ancient DNA Analyses

The NCPA overwhelmingly indicates that the most recent out-of-Africa range expansion event was not a total replacement event. This does not mean, however, that there was interbreeding with all Eurasian populations. The possibility of some local replacement is compatible with the NCPA, but that possibility is not testable with NCPA because its inference is limited to historical populations that have left some genetic descendants in present-day populations. One way of addressing this possibility is to extract DNA from hominin fossils.

Working with ancient DNA is difficult. Because mtDNA is much more abundant than nuclear DNA, the initial ancient DNA studies focused on mtDNA (Caramelli et al. 2003; Currat and Excoffier 2004; Knight 2003; Krings et al. 2000; Serre et al. 2004). These studies revealed that Neanderthal mtDNA represents a unique mitochondrial lineage that is distinct both from present-day human mtDNA and from the mtDNA found in fossil but anatomically modern specimens from comparable time periods. This pattern has been interpreted to mean that there was no or extremely little interbreeding between Neanderthals and their more anatomically modern contemporaries. However, there are difficulties with these conclusions from ancient DNA studies.

First are the technical difficulties. Ancient DNA is subject to damage over time, and resulting lesions can create artifactual substitutions (Caldararo and Gabow 2000; Hansen et al. 2001). One test for artifactual substitutions makes use of the considerable age range found in the Neanderthal fossils used as sources for DNA. If the apparent divergence is real, then the oldest Neanderthal samples should tend to be closest to current human mtDNA because they are temporally closer to the common ancestral sequence for Neanderthal and modern human mtDNA. In contrast, if DNA damage has made a large contribution to the apparent divergence, then the oldest Neanderthal sequences should be the farthest from that of modern humans. The later pattern is true (Gutierrez et al. 2002). Because the samples are small, one could argue that just by chance the oldest Neanderthal sequences just happened to come from an abnormally highly divergent lineage of Neanderthal mtDNA; but these results indicate that DNA damage cannot be discounted as a significant source of error in these early studies. In addition, ancient DNA extracts induce artifactual mutations, both nucleotide substitutions and insertions/deletions, in a nonrandom fashion such that the same artifacts are independently created in controlled experiments (Pusch and Bachmann 2004). Moreover, many of the sites at which these artifacts repeatedly occur are the same sites observed in Neanderthal mtDNA divergence (Pusch and Bachmann 2004). These results indicate that great caution should be exercised in interpreting these early ancient mtDNA sequence data.

Second, these initial ancient DNA studies on human fossils were confined to mtDNA, a molecule that has some unusual patterns of mutation and nucleotide substitution. Most of the analyses of Neanderthal mtDNA have ignored this fact. When the best-fitting maximum-likelihood model of mtDNA evolution is used, there is **no** statistically significant support for a branch separating the Neanderthal sequences from modern human sequences even when all the sequences are assumed to be completely valid (Gutierrez et al. 2002).

Third, mtDNA is incapable biologically of completely reflecting a population's evolutionary history and of rejecting the hypothesis of admixture. MtDNA is sensitive only to female-mediated gene flow and can totally miss even extensive interbreeding mediated through males.

Fourth, as mentioned in the introduction, the evolutionary history of a single gene or DNA region should never be equated to the evolutionary history of a population. A glance at Fig. 3 reveals that much of humanity's recent evolutionary history is not detected at all by mtDNA. One needs multiple loci to obtain an accurate reconstruction of evolutionary history (Wall 2000) and to protect against false inferences due to evolutionary stochasticity and natural selection skewing the results of a particular gene (Templeton 2002, 2004b).

Fifth, the small sample sizes preclude the ability to dismiss significant amounts of gene flow between Neanderthals and moderns (Currat and Excoffier 2004; Nordborg 1998; Pearson 2004; Relethford 2001a; Wall 2000).

Technological advances have overcome many of these problems, as it is now possible to examine much of the nuclear genome with increasing accuracy and coverage (Green et al. 2010; Mendez et al. 2012; Meyer et al. 2012; Reich et al. 2010; Skoglund and Jakobsson 2011; Wall and Slatkin 2012; Yotova et al. 2011). These newer studies on ancient DNA clearly document low levels of admixture with the two archaic populations examined so far: Neanderthals from Europe and Denisovans from Siberia. The fact that two out of two studied archaic populations have contributed to modern human genetic diversity through admixture implies that low levels of admixture between the expanding populations of modern humans with the earlier Eurasian resident populations were both spatially widespread and common. Moreover, ancient DNA studies on an anatomically modern human fossil from China dated to 40,000 years ago revealed admixture levels that were similar to those found in current human populations (Fu et al. 2013). This indicates that admixture was essentially completed before 40,000 years ago. As discussed earlier, modern human fossils are found in China by 110,000 years ago, so the admixture event or processes in China occurred in the time interval between 40,000 and 110,000 years ago. Similarly, a linkage disequilibrium analysis indicates that the last gene flow from Neanderthals into Europeans likely occurred 37,000–86,000 years ago (Sankararaman et al. 2012). These ancient DNA studies confirm the strong rejection of the out-of-Africa replacement model in favor of limited admixture with Eurasian populations made by multi-locus NCPA (Templeton 2002; Templeton 2005).

Demographic Inferences from Coalescent and Simulation Analyses

The definitive rejection by multi-locus NCPA of the null hypothesis of the out-of-Africa replacement hypothesis in favor of a limited amount of admixture (Templeton 2002, 2005) was extremely controversial at the time because the replacement hypothesis had become the standard model of Pleistocene human evolution. The almost universal acceptance of the replacement model by geneticists was all the more remarkable because not a single genetic data set or analysis had resulted in a statistically significant hypothesis test favoring replacement (Templeton 2007). The support for replacement was not based on the standard scientific standard of hypothesis testing, but rather on the weaker argument of hypothesis compatibility with genetic data sets incapable of discriminating among the alternatives (Templeton 2007). The only analysis prior to the ancient DNA studies that claimed a statistically significant rejection of even small amounts of admixture was that of Fagundes et al. (2007) who used computer simulations of several models of human evolution followed by a comparison of how well the specific models fit the genetic data. Such simulation approaches had been frequently used to assess various models of human evolution, but the best-fitting models varied from simulation to simulation, sometimes favoring replacement and sometimes favoring other models (Templeton 2007). The basic problem with these simulations was that there was no rigorous statistical assessment of the goodness of fit, making it impossible to objectively measure how well a particular model fit the data compared to an alternative model. Fagundes et al. (2007) solved this problem by using an approach called approximate Bayesian computation (ABC). The simulation of a model of human evolution requires the specification of a large number of parameters (population sizes, times of range expansions, gene flow rates, degree of admixture, etc.). With ABC, these parameters are regarded as random variables drawn from probability distributions called "priors." After a specific set of parameter values are drawn from the priors, the simulation is executed followed by a comparison of how close a set of summary genetic statistics calculated from the simulation are to the summary statistics calculated from the actual genetic data. This process is repeated multiple times, and from the subset of simulations that result in summary statistics closest to the observed results, it is possible to calculate a localized approximation to the "posterior" distribution of the parameters given the genetic data. Rigorous statistical inference can then be drawn from these posterior distributions. Fagundes et al. (2007) concluded that the replacement model had the highest posterior probability of 0.8 and that any model that included even small amounts of admixture had a posterior probability of only 0.001. These statistically significant results were the opposite of those arising from multi-locus NCPA and are contradictory to the findings of ancient DNA studies.

Egregious statistical errors were made in the analysis by Fagundes et al. (Templeton 2010). The great strength of a Bayesian approach is that prior information can be incorporated into the prior probability distributions. However, Fagundes et al. (2007) did not just ignore prior information, they constructed priors that were contradictory to prior information. For example, as mentioned earlier, already by 2007 there were fossil and archaeological data showing that the expansion of anatomically modern humans out of sub-Saharan Africa had commenced by 125,000–130,000 years ago. Despite this prior information, Fagundes et al. (2007) used a prior that assigned zero probability to any date older than 4,000 generations (80,000 years ago assuming a generation time of 20 years), thereby ensuring a more recent estimated date then indicated by the fossil and archaeological data regardless of the genetic data. Other priors likewise were incompatible with prior studies (Templeton 2010). Much more seriously, Fagundes et al. (2007) used the posterior probabilities in a manner that violated fundamental probability measure theory. In particular, they had a parameter *M* that measured the degree of admixture.

The model with no admixture ($M = 0$) is a special case of the general model in which M can take on any value between 0 and 1. Hence, the $M = 0$ model is nested within the general model. Fagundes et al. (2007) treated the special case and general models as if they were mutually exclusive rather than nested, resulting in posterior model probabilities that were mathematically and logically impossible (Templeton 2010). It is possible to reformulate nested models as mutually exclusive models in a Bayesian framework by performing a Jordon decomposition in which the special case is assigned an atom of probability mass, and the remaining parameter values are assigned a continuous probability measure. No such decomposition was made, so the model probabilities given by Fagundes et al. (2007) have no validity. By using a standard Bayesian procedure that treats nested models as nested models (Lindley 1965), the hypothesis of replacement is rejected in favor of the admixture model with a probability <0.025 (Templeton 2010). This reversal of relative model probabilities by 5 orders of magnitude illustrates the serious nature of the statistical errors committed by Fagundes et al. (2007). Note also that this reversal of inference was made using the *same* posterior distributions generated by Fagundes et al. (2007). Hence, this is not an error of Bayesian statistics in general nor even of ABC in particular. Rather, Fagundes et al. (2007) used their posterior probabilities incorrectly relative to the models being tested. Once this error is corrected, NCPA, ancient DNA, and ABC all result in the rejection of the out-of-Africa replacement model in favor of a model with limited admixture.

ABC and other simulation approaches have the serious disadvantage relative to NCPA that the models of human evolution have to be fully pre-specified rather than having the models emerge naturally from the hypothesis testing framework. However, ABC and other simulation approaches do have the advantages over NCPA that a broader range of genetic data can be used for inference and that they can estimate many important demographic parameters. Because the coalescent process is influenced by basic demographic parameters such as population size and population growth rates, coalescent and simulation analyses have been extensively applied to reconstruct past human demography. These analyses can both reinforce and complement the inferences made from NCPA. For example, NCPA infers a population range expansion out of Africa starting around 130,000 years ago, but it only identifies this as an expansion in geographical range and not necessarily as an expansion in population size. One of the first molecular genetic studies that indicated that this time period was also marked by a population size expansion was the work of Rogers and Harpending (1992). They showed that a sudden increase in population size induces a distinct peak (wave) in the distribution of pairwise nucleotide differences (the mismatch distribution) under a neutral model of evolution in a DNA region, with little to no recombination and with each new mutation occurring at a distinct nucleotide site (the infinite-site model) and uniformly across sites. They found such a distinct peak in human mtDNA, which apparently marks a rapid increase in human population size. Computer simulations of the coalescent under an infinite-site model revealed a good fit to the empirical curve with a population size expansion between 60,000 and 120,000 years ago (later revised to 30,000–130,000 years ago (Harpending and Rogers 2000)), which corresponds well to the most recent out-of-Africa range expansion shown in Fig. 3. They also showed that Tajima's D statistic (Tajima 1989a), an infinite-site model statistic that is sensitive to past population bottlenecks, was consistent with their conclusions of growth from a much smaller population size in the past.

Rogers (1992) recognized that the mismatch analysis and accompanying computer simulations were based upon a highly unrealistic model for mtDNA evolution: the infinite-site model. Rogers (1992) showed that the error introduced by this assumption was only about 3 % and perhaps less than 1 %, a conclusion reinforced by subsequent work (Rogers et al. 1996). In contrast, Yang (1997) and Schneider and Excoffier (1999) found that the estimates of ancestral population sizes are very sensitive to mutational assumptions, with the infinite-site model underestimating past population size. The reason for this discrepancy in how much error is induced is that there are multiple alternatives once one leaves the model of infinite sites and uniform mutation rates. Depending upon the alternative chosen, one can obtain trivial to substantial errors from infinite-site, uniform mutation-based statistics. Unfortunately, our knowledge of the appropriate model for DNA evolution is limited at present; and moreover, different DNA regions normally deviate from the uniform infinite-site model in region-specific ways (Fullerton et al. 2000; Templeton et al. 2000a), so there is no single alternative. We do know now that the deviations from the uniform infinite-site model are much more extreme than those taken into account by Rogers (1992) and Rogers et al. (1996). To illustrate how misleading the infinite-site model can be in a case where the answer is known, Templeton et al. (2000a) applied a standard, infinite-site estimator of recombination to human mtDNA. The infinite-site statistic detected 413 recombination events uniformly distributed over the mtDNA genome. The problem is mtDNA does not recombine! Thus, the conclusions based on infinite-site statistics can be egregiously wrong. Such discrepancies can also be found in human nuclear DNA (Templeton et al. 2000a). Unfortunately, infinite-site statistics still dominate the human (and nonhuman) literature. Until we have a greater knowledge of appropriate DNA models and the development of more statistics and simulation packages that do not assume an infinite-site model (and the willingness of investigators to thoroughly examine their data in order to choose an appropriate mutational model for their specific DNA region, including multi-nucleotide models), demographic conclusions should be regarded as subject to an unknown but potentially substantial degree of error. In contrast, NCPA is based on haplotype trees that use a phylogenetic estimator that does not assume the infinite-site model (Templeton et al. 1992), and as a result such haplotype trees can be used to test hypothesis about the underlying mutational models, including multi-nucleotide models of nonrandom mutagenesis (Templeton et al. 2000b).

The statistics used for demographic inference are also sensitive to natural selection (Harpending and Rogers 2000; Tajima 1989a, b). A dramatic indicator of the potential of selection to bias results can be seen in a coalescent analysis to estimate the amount of population size expansion in recent human evolution based on 612 single-nucleotide polymorphisms (SNPs) (Wooding and Rogers 2002). The SNPs were subdivided into three categories: coding nonsynonymous, coding synonymous, and noncoding DNA regions. The coding nonsynonymous SNPs are generally regarded as the ones most likely to be subject to natural selection. Wooding and Rogers (2002) obtained maximum-likelihood estimates of the ratio of the human population size in the most recent epoch to the population size in an earlier epoch for all three SNP categories. The coding nonsynonymous SNPs yield a ratio of 9900, implying massive population growth. In contrast, the ratios were 0.4 for coding synonymous and 0.6 for noncoding SNPs, implying little or no change in population size. Thus, dramatically different inferences arose among these categories of SNPs that should be differentially sensitive to natural selection. Note also that the inferences least likely to be affected by selection indicated little or no change in population size.

Because selection and demography are confounded in the coalescent-based statistics used for demographic inference, it is important to use cross-validation across multiple loci, just as was done in NCPA. However, cross-validation is probably less effective in protecting against false demographic inferences than in protecting against false phylogeographic inferences using NCPA. At the molecular level, the two most common patterns of selection that are reported in the literature are negative (purifying) and positive (directional) selection (Fay et al. 2001; Miller et al. 2004). Negative selection occurs when mutations at a locus or DNA region are primarily a mixture of neutral and deleterious mutations such that the role of natural selection is to eliminate the deleterious mutations, thereby preserving the important structural features controlled by the gene. About 70 % of all nucleotide substitutions leading to amino acid changes are deleterious in humans and chimpanzees (Enard and Pääbo 2004), and 48 % of the single-nucleotide polymorphisms (SNPs) found in a single genome are deleterious (Subramanian 2012). Because deleterious mutations are eliminated by natural selection, they play little if any role in shaping the haplotype tree (Barton and Etheridge 2004). The NCPA inferences arise from the haplotype tree, and therefore purifying selection does not confound NCPA inferences. The same is not true for population size inferences. The selective elimination of deleterious mutations in a DNA region with little or no recombination (such as mtDNA, and now, much of the human nuclear genome as well (Reich et al. 2002)) mimics the effects of a simple reduction in population size in the past (Charlesworth et al. 1995). Unfortunately, the other most common form of selection, directional or positive selection, also mimics a past reduction in population size (Tajima 1989a). Directional selection causes a selective sweep, eliminating all previous variation within the DNA region that does not recombine with the selected mutation. Since NCPA makes inferences only on the variable part of the haplotype tree with no inferences possible past the coalescent time to a common ancestral molecule, the actual inferences made by NCPA are not affected by selective sweeps except in the rare case of actually sampling a locus in the middle of such a sweep. Thus, while NCPA is expected to be robust to both negative and positive selection, population size inferences are affected by both and *in the same direction*. This shared bias from the two most common forms of reported selection diminishes the effectiveness of cross-validation for demographic inferences. Recall from above that deviations from the infinite-site model also result in underestimates of time and population size (Schneider and Excoffier 1999). Hence, many estimates of past population sizes and their ages are probably underestimates, even when based upon multiple loci.

Two other forms of selection can cause a demographic bias in the opposite direction. The first is balancing selection in which natural selection maintains two or more haplotype lineages or alleles in a polymorphic state. Balancing selection can extend coalescence times into the past, which inflates apparent population size. The coalescent processes within each selected haplotype lineage obey neutral coalescent theory (Hudson 1990), so balancing selection has only a limited impact on the haplotype tree (Barton and Etheridge 2004). Because of the nested clade design used in NCPA, most clades would be unaffected by balancing selection, with only those clades containing different selective lineages (typically only those at the highest level of nesting) being influenced. Hence, NCPA inferences are mostly robust to balancing selection but with some exceptions that should be dealt with via cross-validation. The final type of selection is diversifying selection due to local adaptations in a spatially heterogeneous environment. Such selection also maintains polymorphism in the species as a whole and hence mimics the biases seen with balancing selection. However, unlike balancing selection, this type of selection can create strong geographical correlations and thereby lead to false inferences for NCPA. Multi-locus cross-validation is therefore important in both demographic inference and NCPA to protect against the effects of balancing and spatially diversifying selection.

Cross-validation was used for the mtDNA inference of a population size expansion between 30,000–130,000 years ago. Although some nuclear loci do indeed cross-validate this result (Marth et al. 2003, 2004), others do not (Harpending and Rogers 2000). Recall also that the coalescent analyses of the SNPs least likely to be subject to selection did not indicate a Pleistocene population size expansion (Wooding and Rogers 2002). Similarly, an analysis of 10 noncoding DNA regions (to minimize selection) found no evidence for significant population size expansion in Africa and only nominal significance (without correcting for multiple testing) in Eurasian samples (Pluzhnikov et al. 2002). Harpending and Rogers (2000) attempt to salvage the idea of a Pleistocene population size expansion by arguing that balancing selection is pervasive in the human nuclear genome which, as discussed above, inflates the apparent population sizes of the past and thereby reduces the apparent amount of population growth. This assumption is inconsistent with recent surveys of natural selection that found evidence for positive or balancing selection in only 8 of 132 genes in Eurasians, and 0 out of 132 in Africans (Akey et al. 2004). This explanation is also inconsistent with studies indicating little population size expansion that use noncoding or silent variation that is unlikely to be subject to balancing selection (Pluzhnikov et al. 2002; Wooding and Rogers 2002). More recently, analyses based on whole genome data indicate large effective population sizes going back to at least 250,000 years ago (Li and Durbin 2011). Thus, the evidence for a small ancestral human population size is mixed and a coherent picture has yet to emerge (Pluzhnikov et al. 2002; Wooding and Rogers 2002).

A separate demographic issue concerning the most recent out-of-Africa range expansion shown in Fig. 3 was whether or not it involved a large population coming out of Africa, or a small one. Many genetic surveys show that haplotype diversity is generally much lower in Eurasian populations than in African and that Eurasian populations show more linkage disequilibrium (nonrandom associations between polymorphic sites that can be induced by both small population size and admixture) than African populations. These patterns indicate that the African population coming into Eurasia was relatively small initially (Tishkoff and Verrelli 2003) yet dominated in the subsequent interbreeding with Eurasian populations. These patterns could also mean that the Eurasian population was smaller than the African population during most of the Pleistocene (Relethford 1998), rather than an initial extreme bottleneck. Indeed, studies having a large sample of Africans tend to have much larger estimates of ancestral human population size (Tishkoff and Verrelli 2003), even to the extent to showing no significant or moderate population size growth from the past to the present within Africa (Adams and Hudson 2004; Pluzhnikov et al. 2002). However, an ABC analysis using 20 autosomal regions inferred a strong bottleneck as modern humans expanded out of Africa (Laval et al. 2010). In contrast, an ABC analysis based on 61 loci indicated that there was no major bottleneck in modern humans 130,000 years ago, with at most a 3-fold reduction in population size (Sjodin et al. 2012). Thus, the evidence for a strong bottleneck as modern humans expanded out of Africa is mixed, and a coherent picture has yet to emerge.

A major limitation of many of the coalescent estimators relative to NCPA is that they are based on simulating various demographic models and measuring the fit to the data. Thus, the inference universe is limited to the scenarios that were simulated. Even an excellent fit to the data does not insure that the simulated model is the right one because often several models can fit the data well. For example, Adams and Hudson (2004) pointed out that one of the African populations they studied fit both models of constant population size *and* a variety of growth models, including fivefold growth beginning no earlier than 36,000 years ago. The real weakness of the simulation approach is that it is never possible to simulate all possible scenarios, so many alternative hypotheses are never evaluated at all. For example, few of the simulations performed in the papers referred to in this section take into account the fact that the expanding populations out of Africa interbred with Eurasian populations (recall that the hypothesis of total replacement was rejected with a p-value of less than 10^{-17} and admixture has now been confirmed by ancient DNA studies) nor the long history of gene flow constrained by isolation by distance between African and Eurasian populations that has occurred in the last 650,000 years (Fig. 3). What a simulation includes or excludes can make a large difference. For example, most of these simulations also estimate the time of out-of-Africa expansion around 60,000 years ago – a figure incompatible with the date inferred by NCPA and with the fossil and archaeological record summarized earlier. However, when similar simulation models include the effects of migration and gene flow (as suggested by NCPA, Fig. 3), the estimated date of expansion goes back to 100,000 years ago (Gutenkunst et al. 2009) – a figure now compatible with the confidence interval from NCPA (Table 3). Analyses based on whole genome data also indicate a date between 120,000 and 100,000 years ago (Li and Durbin 2011), further supporting the older date estimated from NCPA.

Based on the literature from the early 1990s (reviewed in Hawks et al. 2000), it is commonplace to find many papers citing a figure of 10,000 for the ancestral human population size and even regarding this population size as a well-established constraint in interpreting human evolution (Pearson 2004). Given that inappropriate DNA models, positive and negative selection, and sampling biases all conspire to underestimate this ancestral human population size, it is now obvious that 10,000 is an underestimate. Indeed, the more recent studies that most thoroughly try to eliminate these biases as mentioned above usually detect no significant to moderate population growth during much of the Pleistocene, particularly in Africa, implying that the human ancestral population size was much greater than 10,000.

The error of regarding the figure of 10,000 as a given constraint on recent human evolution is sometimes amplified by regarding this figure as an estimate of the census size of the human population at that time (Pearson 2004). No coalescent estimator of population size estimates census size; rather, they all estimate the inbreeding effective size. A coalescent event establishes a relationship known in population genetics as identity by descent. Population genetics also makes frequent use of an idealized population characterized by self-compatible hermaphrodites that are randomly mating in an un-subdivided population, all with the same average number and variance of offspring (as described by a Poisson distribution), no selection, discrete generations, and constant population size. These assumptions allow one to derive formulae that describe how a variety of population genetic parameters evolve under genetic drift, including the probability of identity by descent. Of course, real populations, and humans in particular, deviate from this idealized population. Population genetics uses the concept of an effective population size to create a common reference for all real populations. One chooses a particular genetic parameter, such as the probability of identity by descent or the variance in allele frequency from one generation to the next, and observes how this parameter evolves in the real population. Then, one calculates the size of an idealized population that would yield the same parameter values as observed in the real population. The calculated size of the idealized population that mimics the evolution of the parameter of interest in the real population is known as an effective population size (Templeton 2006). It has long been known that deviations from the idealized population can create quantitatively and qualitatively different deviations from census size for different population genetic parameters. For example, an expanding population size tends to decrease the inbreeding effective size (the effective size for the genetic parameter of probability of identity by descent) but increase the variance effective size (the effective size for the genetic parameter of the variance in allele frequency from one generation to the next) (Crow and Kimura 1970). It is incorrect to define "the" effective size as the number of breeding individuals, as done for example by Pearson (2004). Rather, there are many different effective sizes, depending upon the genetic parameter of interest. The effective size estimated from coalescent-based approaches is the inbreeding effective size.

There is no expectation for the inbreeding effective size to equal the census size, nor to equal other effective sizes. The absurdity of equating an inbreeding effective size to a census size is shown by the fact that the inbreeding effective size of Africans alone is larger than the inbreeding effective size of Africans and Eurasians together, as pointed out above. Hence, if we equated these effective sizes to census sizes, we would conclude that more people lived in Africa alone than in Africa plus Eurasia combined! Under realistic circumstances, these effective sizes can differ from one another and from census sizes by orders of magnitude (Braude and Templeton 2009; Templeton and Read 1994). For example, models of demes interconnected by gene flow but with some local extinction and recolonization are applicable to many species, including humans. Such "meta-population" models can greatly reduce inbreeding effective size relative to census size (Wakeley 2004). Indeed, Eller (2002) showed that such a demographic model allows the human census size to be approximately 300,000 through the Pleistocene and still be compatible with an inbreeding effective size of 10,000. Consequently, arguments that a population size of 10,000 is too small to support an African and Eurasian distribution (e.g., Pearson 2004) are without substance even if one accepts an inbreeding effective size of humans of 10,000 – a conclusion itself that is highly questionable. Thus, no coherent picture has emerged from genetic studies concerning the size of Pleistocene hominin populations, but a non-genetic estimate of around half a million individuals (Weiss 1984) is consistent with many of the latest genetic results and the calculations of Eller (2002).

Natural Selection and Adaptive Evolution in Hominin Populations

Adaptive Evolution at the Molecular Level

Coalescence theory and phylogenetics provide a variety of tests to infer the presence and type of natural selection operating at the molecular level, particularly in protein-coding genes (Bamshad and Wooding 2003; Enard and Pääbo 2004; Tishkoff and Verrelli 2003). Indeed, the great abundance of sequence data, not only in humans but in closely related species (outgroup data are frequently required for many of these tests of selection), has allowed massive screening throughout the human genome to identify those genes and DNA regions that were specifically subjected to positive, directional selection in the lineage leading to modern humans and thus were involved in the adaptive transformation of the human species.

Purifying selection that maintains an adaptive genetic state is the most common selective pattern identified, affecting at least 5.5 % of the human genome and millions of elements, including protein-coding exons, RNA structural families, and potential promoter, enhancer, and insulator regions (Lindblad-Toh et al. 2011; Ward and Kellis 2012).

Positive selection, in which natural selection favors a rare preexisting variant as the environment changes or a de novo mutation, is of more interest in understanding the evolutionary changes leading to modern humans. Clark et al. (2003) found 178 genes out of 7,645 protein-coding genes that had significant ($p < 0.01$) evidence of positive selection with standardized ratios of nonsynonymous to synonymous nucleotide substitutions with a model that allowed the amino acid sites to be either neutral, under negative selection, or under positive selection specifically on the branch of the gene tree leading from the common ancestor of humans and chimpanzees to present-day humans. Many of the genes that were under positive selection in the human lineage involved sensory perception, particularly olfaction and hearing. Several other genes under positive selection were involved in amino acid catabolism and may have been selected as the dietary habits of the human lineage diverged from the human/chimp ancestral state. Many developmental genes were also under positive selection in the human lineage, and these fell into two main categories: skeletal development and neurogenesis. Using a more extensive genomic database, Grossman et al. (2013) identified 412 candidate regions for positive selection, including 35 high-scoring nonsynonymous variants, 59 variants associated with expression levels of a nearby coding gene or lincRNA, and numerous variants associated with susceptibility to infectious disease and other phenotypes. Looking specifically at genes involved in the nervous system, Dorus et al. (2004) found accelerated rates of amino acid substitutions in the primate lineages leading to humans, with the highest rate being found in the branch leading from the common ancestor of humans and chimpanzees to humans. Vallender and Lahn (2004) reviewed the literature on those genes showing positive selection in the lineages leading to humans and found that the vast majority of them fell into just a few functional categories: host-pathogen interactions, reproduction, dietary enzymes, sensory perception, central nervous system functioning, and brain anatomy.

The above studies indicate that positive selection played an important role in the adaptive evolution of the human lineage, but these studies only localize that selection into the time period between the common ancestor of humans and chimpanzees to the present. One way of localizing the positive selection to the Pleistocene is to look for evidence of a selective sweep and genomic segments of identity by descent that are shared by diverse individuals and populations. As mentioned in the previous section, positive selection induces a selective sweep of the genetic variation linked to the favored mutation. This in turn leaves a signature in the haplotype tree that is gradually lost over time, limiting this approach to only the latest stages of human evolution (Przeworski 2002). Such selective sweeps have been found for the *monoamine oxidase A* gene (Gilad et al. 2002), involved in the functioning of the central nervous system, and in *FOXP2*, a gene coding for a transcription factor involved in speech and language development (Zhang et al. 2002). Another region of accelerated evolution in the human lineage is a novel RNA gene that is expressed in the developing human neocortex from 7 to 19 gestational weeks, a crucial period for cortical neuron specification and migration (Pollard et al. 2006). The HLA region shows the most extreme signal, suggesting that much of the strong recent selection acting on the human genome has been immune related (Albrechtsen et al. 2010).

A second approach to identifying recent selection is to look for evidence of positive selection confined to Eurasian populations. This would not only imply some sort of local selection involved with the colonization of Eurasia but also confine the time period to the last 2 Myr. Akey et al. (2004) surveyed 132 genes and found evidence for positive or balancing selection in eight of them in Eurasian populations, but none in African populations. Similarly, a survey of 624 autosomal loci found evidence of positive selection in 13 genes, and of these 12 exhibited only a Eurasian signature of positive selection (Storz et al. 2004). A contrast of East Asian populations identified positive selection resulting in a north-south cline in the HLA region (Suo et al. 2012). A genome scan of human populations of African, European, and Asian origin found evidence of selection related to population-specific traits, such as skin pigmentation, immune response, senses, and dietary adaptations (de Magalhães and Matsuda 2012), and another study indicated selection related to cold tolerance (Hancock et al. 2011). Specific to dietary adaptations, the enamelin gene that influences enamel formation has been shown to undergo bursts of positive selection in primates inferred to have undergone dietary change, and similarly it shows evidence for selective sweeps in non-African populations (Kelley and Swanson 2008). With respect to immune response, 11 out of 26 blood group antigen genes show significant correlations with local pathogen richness, and 3 show evidence of balancing selection in which selection favors the maintenance of multiple allelic lineages, a type of selection also found in HLA (Fumagalli et al. 2009) and the TRIM5 gene that encodes a retroviral restriction factor that influences risk of certain viral infections (Cagliani et al. 2010). A subsequent genome screen demonstrated that selection on pathogens is the primary driver of local adaptation and affects the distribution of genetic variation at a large number of genes (Fumagalli et al. 2011). These studies indicate that human populations had to adapt to novel selective features associated with the Eurasian continent. Thus, the expansions out of Africa shown in Fig. 3 were also associated with altered selective regimes that influenced human adaptive evolution.

A third approach to identifying genes under positive selection is to make use of the genome data available from ancient DNA studies. Paixao-Cortes et al. (2012) performed an extensive comparison of the complete genomes of chimpanzee (*Pan troglodytes*), extant *Homo sapiens*, Neanderthals, and the Denisova specimen. They focused on nonsynonymous mutations in protein-coding genes and found 10,447 nonsynonymous substitutions in which the derived allele is fixed or nearly fixed in humans as compared to chimpanzee. By restricting their study to derived alleles that were fixed or near fixed in humans, this study focuses only on those genes that were selected in the entire human lineage and that were not involved in local adaptation. The presence of the derived alleles was then searched for in the two archaic genomes, and in most cases it was found. This indicates that the selective sweeps that gave rise to modern humans were initiated before the divergence of archaic and modern humans and/or there was sufficient gene flow between archaic Eurasian and African populations that selectively favored alleles could spread between them.

Adaptive Evolution of Hominin Facial Morphology

When selection operates upon a morphological trait, it generally alters other traits as well, due to shared underlying developmental process and genes. These correlated responses to selection can be captured by a quantitative genetic variance/covariance matrix (Ackermann and Cheverud 2004). If a set of morphological traits is evolving neutrally or are neutral correlates of another, unmeasured trait under selection, then their coordinated change should reflect the variance/covariance matrix (Lande 1980). Deviations from this expected correlational structure indicate the action of natural selection. Ackermann and Cheverud (2004) estimated the variance/covariance matrices for several facial features from living human, chimpanzee, and gorilla populations and used all three of these living models to detect selection on facial features in hominin fossils. The results within the *Homo* fossils were robust to all three models, showing that between 1 and 2 Ma, most facial evolution was neutral. In contrast, selection was necessary to produce the *Homo* face from that of a gracile australopith, with selection being exerted to increase the relative portions in the upper face and orbit, weak to no selection to increase the midface/nasal region, and selection to reduce the lower orbits and zygomatics. Hence, in terms of the human face, the most important adaptive evolution occurred leading up to *Homo*, with little evidence for selection during the Pleistocene. This is consistent with the idea that the development of cultural inheritance could have released many morphological traits of humans from the effects of selection (Ackermann and Cheverud 2004; Lynch 1990). If this explanation is true, it would imply that hominins increasingly relied on technology near the time of the spread of *Homo erectus* out of Africa.

Conclusions

The first major event in hominin evolution over the past 2 Myr was a range expansion out of the African homeland into Eurasia. This expansion event may have been triggered by an increase in the importance of cultural inheritance as a means of adapting to the environment. Regardless, the time of this expansion marked an era of relaxed selection on some morphological features. Although some morphological selection may have been relaxed as hominins expanded into Eurasia, natural selection nevertheless operated strongly and swiftly upon many genes as hominins adapted to novel environmental circumstances in Eurasia and underwent multiple global selective sweeps.

Because this initial colonization of Eurasia left detectable genetic signatures in present-day Eurasian populations, there has been a continuous Eurasian hominin presence for at least the last 1.9 Myr. Africa still remained the center of hominin evolution, however, with the next major Pleistocene event being the development of the Acheulean culture and its subsequent spread out of Africa. This spread was both cultural and demic, with the expanding peoples from Africa interbreeding with at least some of the Eurasian populations with whom they came into contact.

Recurrent gene flow with isolation by distance was established between African and Eurasian populations after the Acheulean expansion 650,000 years ago. Such a population structure would have allowed some traits to spread throughout all of humanity, while other traits were locally restricted. Indeed, those derived alleles that went to fixation or near fixation in modern humans are for the most part shared with archaic Eurasian populations. For other genes, there is evidence of local selective sweeps, often confined to Eurasia despite recurrent gene flow. No coherent picture has emerged from genetic studies concerning the size of the middle Pleistocene hominin population, but a non-genetic estimate of half a million individuals (Weiss 1984) is consistent with many of the latest genetic results.

Many anatomically modern traits first evolved in Africa, and then populations with these traits spread out of Africa starting 130,000 years ago. As with the Acheulean expansion, this expansion involved interbreeding with at least some archaic Eurasian populations and was overlaid upon a recurrent pattern of genetic interchange. Modern traits could spread by this demic expansion coupled with admixture and gene flow with isolation by distance. As before, this population structure allows locally adaptive traits to maintain their regional continuity.

After this last major out-of-Africa expansion event, humans expanded into previously unoccupied parts of the world: northern Eurasia, Australia and the Pacific, and the Americas (Fig. 3). There was also a major expansion of humans out of Asia back toward Europe and Africa that was primarily male-mediated (Fig. 3). Wherever humans spread, genetic interconnections were maintained with other human populations, at least on a time scale of several thousands of years. These connections of gene flow were restricted through isolation by distance, although long-distance dispersal becomes more important in very recent times (Table 2). Even today geographical distance remains the primary indicator of the degree of genetic differentiation between local human populations (Eller 1999). The relationships among current human populations therefore cannot be represented as a tree of populations, but rather an intertwined trellis (Fig. 3). As a result, humanity evolved into its modern form as a single evolutionary lineage but with some geographical differentiation at any given time.

Acknowledgments I am grateful for the support by NIH grant GM065509. I also want to thank Rebecca Ackermann and James Cheverud for kindly making their manuscript on hominin evolution available to me prior to its publication.

Dispersals of Early Humans: Adaptations, Frontiers, and New Territories

Michael Bolus

Contents

Abstract

Fossils of early hominins have been found exclusively in Africa. While the australopiths only spread within Africa, members of the genus *Homo* were the first to leave their home continent, roughly 2 million years ago, thus expanding their settlement area considerably. Once "out of Africa," groups of *Homo ergaster*, *Homo erectus*, or other early *Homo* species moved in several waves to East and Southeast Asia, while other groups, possibly through the Levantine Corridor and crossing the Caucasus, entered Europe. The oldest artifact assemblages outside of Africa are of Oldowan type, while in Africa at the same time the techno-complex of the Acheulean had begun to evolve, which came to

Eurasia much later. In Europe, the Neanderthals, the only indigenous European hominins, evolved out of later populations of *Homo heidelbergensis*. At the end of the last glacial period, the Neanderthals enlarged their originally exclusive European settlement area, expanding into the Near East, parts of Central Asia, and even as far as the Altai region in Siberia. While the Neanderthals apparently never entered Africa, they started their movement "out of Europe" and into Asia at about the same time that anatomically modern humans (AMH), who originated in Africa, started their movement "out of Africa," also heading first into Asia. Sahul was colonized by AMH earlier than Europe, which was first entered about 45,000 years ago, when the Neanderthals were still living there. Today, modern humans are the only existing hominin species, inhabiting nearly every part of the world. During their expansions, the Neanderthals and AMH not only mixed with each other – at least in the Near East – but apparently both interbred with a third hominin group, the Denisovans, who seem to have moved specifically into East and/or Southeast Asia.

Introduction

Broad agreement exists on the fact that the human lineage originates from Africa. All hominin species which are potentially direct ancestors of the genus *Homo* have been found exclusively on this continent. Similarly, the first known stone tools, with an age of about 2.6 million years, have been found in East Africa. It seems plausible that this cultural "quantum leap," which represents a very specific type of adaptation, enabled early humans – most probably the earliest representatives of the genus *Homo* (for an overview of the genus *Homo* see, e.g., Wood and Baker (2011) and Henke and Hardt (2012)) – to become increasingly independent from climates and environments and to colonize new territories. The question of when, why, and how early hominins started to leave their original home ranges has been and still is a topic of vivid discussion within paleoanthropology, archaeology, and related scientific fields. While the australopiths only spread within Africa (Schrenk et al. 1993, 2002; Vrba 1995), early *Homo* left his home continent to settle large parts of the Old World in several waves (see Tattersall 1997). The Neanderthals, originating from Europe, widened their settlement area considerably while it was left to anatomically modern humans (AMH), rooted in Africa once more, to colonize nearly all parts of both the Old World and the New World.

Prelude: African Origins

As far as is known, the earliest ancestors of humans evolved in tropical Africa. A group of Late Miocene fossils, *Sahelanthropus tchadensis* (Chad), *Orrorin tugenensis* (Kenya), *Ardipithecus kadabba*, and *Ardipithecus ramidus* (both Ethiopia), with ages between about 7 and 4.4 million years, is probably ancestral to the Australopithecines (Brunet 2009) and was able to walk at least occasionally upright (see Harcourt-Smith, chapter "▶ Origin of Bipedal Locomotion," Vol. 3).

Starting with *Australopithecus anamensis* from East Africa about 4 million years ago, the genus *Australopithecus* developed as the earliest known undoubted hominins. Today, several species of these gracile hominins are known, among them *Australopithecus afarensis* and *Australopithecus africanus*. The famous 3.5-million-year-old partial skeleton known as "Lucy" belongs to the former group, whereas the somewhat younger Taung Child is a representative of the latter (for an overview, see Klein (2009); Kimbel, chapter "▶ The Species and Diversity of Australopiths," Vol. 3). Another genus, *Paranthropus*, evolved shortly after 3 million years ago in East Africa, with members of the genus *Australopithecus* as their ancestors. Later representatives of *Paranthropus* existed in East and South Africa 1.4 million years ago. Isotopic analyses have shown that *Australopithecus* and *Paranthropus* consumed different types of diet (Sponheimer et al. 2013), which most probably reflects different modes of living and different patterns of adaptation.

From an anthropological point of view, it is difficult to distinguish clearly between late australopiths and early representatives of the genus *Homo*. The challenge has been highlighted by the recent discovery of two approximately 2-million-year-old skeletons in the South African cave site of Malapa named *Australopithecus sediba* (Berger et al. 2010), which combine features of australopiths with those of early *Homo*.

It can be shown that australopiths and *Paranthropus* already left their home areas to colonize new territories (see, e.g., Schrenk et al. 2002), but they stayed within their continent. Until now, there is no unambiguous indication that representatives of the genus *Australopithecus* (and of the genus *Paranthropus*) ever moved out of Africa. The possibility cannot, however, be completely ruled out.

Out of Africa: Early *Homo*

The oldest known *Homo* fossil so far was discovered in the "Hominid Corridor" in northern Malawi. It is the mandible UR 501 from Uraha, attributed to *Homo rudolfensis* and dated to an age of about 2.5 million years (Schrenk et al. 1993). Together with the discovery of *Paranthropus*, probably *P. boisei*, of more or less the same age in Malema, also in northern Malawi, this has high biogeographic significance, and it has been suggested (Bromage et al. 1995, p. 71) that "early hominids arose successively in the eastern African tropical ecological domain. During favorable periods, some early hominids dispersed southward beyond the Zambesian Ecozone, evolved there, perhaps due to relative isolation and/or due to factors associated with its temperate ecology, and became endemic there."

The earliest *Homo* appeared at about the same time as the oldest stone tools. They come from Gona in Ethiopia and have an age of about 2.6 million years (Semaw et al. 2003). The assemblage consists of cores, flakes, and pebble tools which can be attributed to the early Oldowan complex (named after the Olduvai Gorge in Tanzania). Some bones of the associated fauna show unambiguous cut marks made by humans processing the bones. Only slightly younger are early Oldowan assemblages from Lokalalei 2C in West Turkana (Kenya) with an age of about 2.34 million years. The choice of raw materials and the level of knapping skills these early humans mastered demonstrate a high degree of planning and foresight at that early date (Delagnes and Roche 2005). It is still not definitely clear which hominin species was responsible for the earliest stone tools. A first lower molar germ attributed to early *Homo* found near Lokalalei 2C makes early members of our genus possible candidates for making the artifacts, but *Paranthropus/ Australopithecus aethiopicus* was also present in West Turkana about 2.5 million years ago. As far as the Gona artifacts are concerned, *Australopithecus garhi*, known from Bouri (Ethiopia), may be another possible candidate. While no stone artifacts have been found in direct association with *H. rudolfensis* fossils, *H. habilis* has securely been identified as toolmaker.

In any case, stone tools and cut marks on large mammal bones suggest that early *Homo* had a dietary spectrum different from that of other early hominins. Isotopic analyses (Balter et al. 2012) have confirmed that *Paranthropus robustus* relied more on a plant-based diet than early *Homo*, which in turn means that early *Homo* consumed more meat than contemporary *Paranthropus*, thus occupying a different ecological niche. Tool use may also have been crucial in enabling early *Homo* to colonize new territories – ones never settled before by hominins. Another factor could be the use of fire. Although the oldest secure evidence for the controlled use of fire dates no earlier than about 1 million years ago (Wonderwerk Cave in South Africa: Berna et al. 2012), it is imaginable that early *Homo* already had at least the ability to use fire started by natural processes such as lightning. This might have helped him, a carnivore himself, to keep other large carnivores away, thus gaining access to carcasses of mammals hunted by others and, ultimately, to win and defend territories occupied by other large carnivores.

About 2 million years ago, or perhaps a bit earlier, early *Homo* left the African continent for the first time. The exact timing and circumstances of that first wave(s) out of Africa are still unclear. It may be that they were pushed out by climatic conditions. Helmut Hemmer regards coevolution with felids and canines (predators) as the essential trigger. According to him, early *Homo* as a member of the guild of larger terrestrial carnivores, and as such dependent on animal food resources, followed large herds, in competition with other larger terrestrial carnivores and finally left Africa (Hemmer 2000). The role that fire use may have played in this process has just been mentioned. Another question that is still unsolved is which species of *Homo* took the first step. It is even possible that different species found their way out of Africa.

Roughly contemporaneously with this first wave of dispersal, a new lithic technology developed in Africa. First and foremost, it is characterized by bifacially worked hand axes. After the site of St. Acheul in northern France, this new techno-complex is named Acheulean. While until recently it was thought that this technology started at about 1.6 million years ago, excavations at the site of Kokiselei 4 in Kenya have yielded evidence for an earlier origin at about 1.8 million years ago (Lepre et al. 2011).

The oldest human fossils outside Africa are those from Dmanisi in the Caucasus in Georgia, associated with faunal remains and stone artifacts and about 1.8–1.7 million years old (Ferring et al. 2011). There has been some debate about the exact taxonomic position of these fossils (see Tattersall, chapter "▶ *Homo ergaster* and Its Contemporaries," Vol. 3); both similarities and differences with *H. ergaster* and *H. erectus* have been suggested. In earlier publications (e.g., Gabounia et al. 2002), the fossils were ascribed to a new *Homo* species: *H. georgicus*; however, in the context of the detailed analysis of skull 5, the denomination *H. erectus ergaster georgicus* was suggested (Lordkipanidze et al. 2013). The lithic industry is dominated by pebble tools, cores, and flakes, whereas retouched pieces are rare; it thus represents a typical Oldowan. This clearly proves that intercontinental dispersals were possible with such a relatively simple tool kit and that no (Acheulean) hand axes were needed. Since the earliest Oldowan tools are almost 1 million years older than the Dmanisi tools, this also suggests that lithic technology alone was not sufficient for *Homo* to leave Africa; the earliest toolmakers must have faced other obstacles that hindered them from crossing the continental frontier. Given the fact that hand axes already existed 1.8 million years ago in Africa, the first wave of dispersal is obviously not linked with hand axe-producing humans. According to a hypothesis proposed by Helmut Hemmer (e.g., Hemmer 2000), this could mean that the earliest *Homo* populations out of Africa relied completely on scavenging to cover their meat requirements and that they were in constant competition with larger predators, since the Oldowan tool kit does not include the unambiguous weapons that seem necessary to enable hominins "to enjoy nearly unlimited large mammal food resources" (Hemmer 2000, p. 99).

The implications of an early origin of the Acheulean are discussed in some detail by Lepre et al. (2011, pp. 84–85). They argue that "the difference between the ages for the oldest known Acheulian artefacts in the world from Africa and the oldest known Acheulian artefacts from Eurasia raises the likelihood that the first Eurasian hominins derived from an African population lacking Acheulian culture. Potentially, two hominin groups coexisted in Africa at 1.76 Myr ago. One of these groups could have developed the Acheulian technology but remained in Africa. The other could have lacked the cognitive ability and/or technological knowledge to manufacture the Acheulian technology and did not carry it into Eurasia. This division may indicate different behavioral aptitudes for separate African species (for example, *H. erectus sensu lato* versus *Homo habilis sensu lato*) or a within-species cultural disparity. In any event, it seems that a second hominin dispersal with Acheulian technology or a diffusion of this technology took place later, leading to the widespread occurrence of this Early Stone Age tradition in the circum-Mediterranean area and elsewhere after ~1 Myr ago."

Some sites in China and Java are only a bit younger than Dmanisi and may also be part of the first wave(s) of dispersal. They include several 1.6- to 1.5-million-year-old sites in the Nihewan Basin in northern China with faunal remains and Oldowan-type stone artifacts (Keates 2010; Ao et al. 2013), as well as the oldest *H. erectus* fossils from the Sangiran Dome, found without archaeological context and also with ages of ca. 1.6–1.5 million years (Larick et al. 2001).

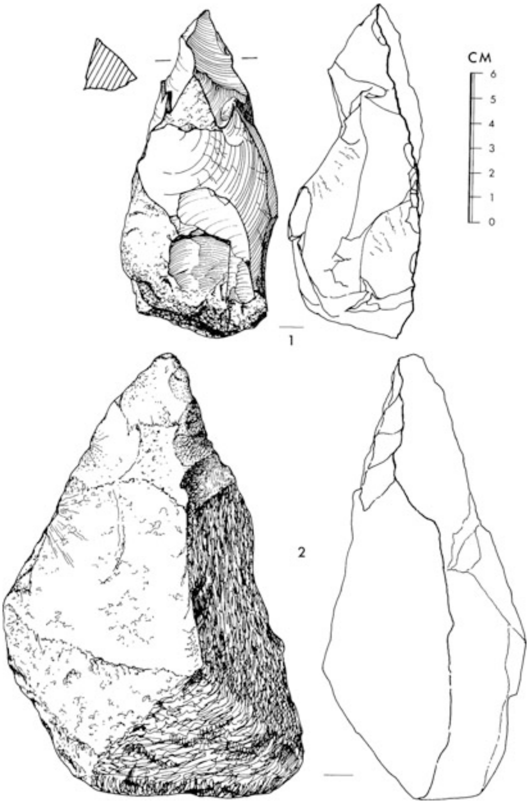

Fig. 1 ‘Ubeidiya. Acheulean hand axes from layer I-26d (After Bar-Yosef and Goren-Inbar 1993. Reproduced with kind permission from O. Bar-Yosef and N. Goren-Inbar)

A late witness of the first wave(s) of expansion of early *Homo*, or maybe an early witness of the next wave, is the site of ‘Ubeidiya in the Jordan Valley in Israel, which is situated along one of the possible dispersal routes out of Africa, the so-called Levantine corridor. Paleomagnetic studies at the multilayered site indicate a sequence spanning between around 1.5 and 1.2 million years. Early *Homo* remains associated with rich lithic artifact assemblages, and faunal remains have been uncovered (see, e.g., Belmaker et al. 2002). The lithic assemblages combine elements of the Developed Oldowan with hand axes as markers of the early Acheulean (Bar-Yosef and Goren-Inbar 1993) (Fig. 1). Recently, evidence has been published that already during the same period, the Acheulean may have reached the Indian subcontinent (Pappu et al. 2011). Assuming that the early date will be confirmed, this Acheulean presence in South Asia may be due to a rapid dispersal of early humans from ‘Ubeidiya, but there is also the possibility of another direct dispersal wave from Africa (see Dennell 2011).

It is interesting to note that the first human settlement of Europe is obviously not linked with the first dispersal wave out of Africa, but that nevertheless no Acheulean assemblages akin to those already present in the Near East have been found in the earliest European sites. If the dates of down to 1.4–1.3 million years for the

Spanish sites of Barranco León D and Fuente Nueva 3 in the Orce region are correct, these range among the sites providing the earliest evidence for human presence in Europe. The lithic assemblages from these sites do not show any Acheulean influence but clearly are of Oldowan type (Barsky et al. 2010). With an age of older than 1.2 million years – probably close to 1.4 million years – an early *Homo* molar found at Barranco León D seems to be the oldest human fossil in Europe today (Toro-Moyano et al. 2013). Of apparently similar age are the Oldowan assemblages from Pirro Nord in southern Italy (e.g., Arzarello et al. 2012).

As far as Europe is concerned, Oldowan-type assemblages remain the only assemblages to be found with the sites following chronologically, the long existence of the Oldowan being a demonstration of the effectiveness of this technology. This is, for instance, true for the 1.2-million-year-old Sima del Elefante site in Atapuerca and still true for the 0.8-million-year-old Gran Dolina site in the same Atapuerca complex. Both sites have yielded human fossils, with those from the latter site often attributed to a separate species: *Homo antecessor* (see, e.g., Bermúdez de Castro et al. 1997).

The sites mentioned above are clear indications of a relatively early settlement of Europe, at least as far as the southern part of the continent is concerned – a settlement taking place at a much earlier time than the supporters of a "short chronology" for the settlement of Europe had suggested (for an overview, see Roebroeks 2006).

One of the next dispersal waves may be represented by the site of Gesher Benot Ya'aqov in Israel. About 780,000 years old, the assemblages of this site are clearly Acheulean (Sharon et al. 2011). Having yielded the oldest secure evidence for the controlled use of fire outside Africa, this site indicates that at least some 800,000 years ago, continual fire control was part of the capabilities of early hominins in Eurasia. Given the fact that the earliest evidence in Africa seems to be older than 1 million years, it seems plausible that both the Acheulean technology and the controlled use of fire mark important developments needed for early humans to conquer new territories during further dispersals. Acheulean-like hand axes found in the Bose Basin in China (Yamei et al. 2000) are of about the same age as the assemblages from Gesher Benot Ya'aqov. With a possible early appearance of the Acheulean in India, as mentioned above, these tools might not be the result of an indigenous development but may well be due to the "movement of hominins (or ideas) from either East Africa or the Levant. This raises the possibility that the Acheulian-like bifaces from China indicate subsequent dispersal from India" (Dennell 2011, p. 1532).

An early appearance of Acheulean hand axes has been claimed for the Spanish sites of Cueva Negra del Estrecho del Río Quípar and Solana del Zamborino (Scott and Gibert 2009). However, the early dates of 0.9 million years for the Quípar site and 0.78 million years for the Zamborino site have been plausibly questioned by other scientists (Jiménez-Arenas et al. 2011) and thus cannot be taken as proof for such an early presence of the Acheulean in Europe. Acheulean hand axes from fluvial deposits in the Middle Loire River Basin in France may date back to

700–600,000 years ago (Despriée et al. 2011), but with the possible exception of the 650,000-year-old Notarchirico site in southern Italy (Lefèvre et al. 2010) and of a single hand axe from Sima de los Huesos at Atapuerca, the earliest securely dated in situ Acheulean levels from Europe are not considerably older than 500,000 years (Antoine et al. 2010; Falguères et al. 2010). Again, it is noteworthy that between about 800,000 and 600,000 years ago, dispersal waves into the Near East (and to East Asia?) seem to be associated with Acheulean technology, whereas it is questionable if these waves ever reached Europe.

While the earliest secure evidence for the Acheulean in Great Britain is about 500,000 years old (McNabb 2013), the stone artifacts from the Happisburgh 3 site seem to be of Oldowan type rather than representing the Acheulean (Parfitt et al. 2010). In any case, sites such as Happisburgh 3 strengthen the evidence that early humans peopled large parts of Europe rather quickly and even reached regions as far north as Britain nearly 800,000 years ago – again arguing against a short chronology. This remarkable expansion of their settlement area proves that the potential of early hominins to thrive in different landscapes and environments had enormously increased.

Claims have been made in several publications that the Acheulean presence outside of Africa could be seen as an indication of hominin dispersals from Africa into Eurasia. This assumption was strengthened by model-bound approaches and a phylogeographic analysis (Lycett and von Cramon-Taubadel 2008; Lycett 2009). Other studies, however, point to the possibility of local invention and evolution of bifacials in the European Acheulean (e.g., Nicoud 2013).

From the anthropological point of view, the European fossils associated with the Middle Pleistocene Acheulean belong to *H. heidelbergensis*. While the famous mandible from Mauer with an age of about 600,000 years was found without any archaeological context, the fossils from Sima de los Huesos/Atapuerca, Boxgrove, and other sites are secure evidence of this association. The European fossils of *H. heidelbergensis* may be representatives of one of the last (if not the last) expansion wave(s) of archaic humans out of Africa.

Out of Europe: The Neanderthals

Based on the present fossil evidence, the Neanderthals were indigenous European hominins (the only ones) whose origins can be seen exclusively on this continent. They probably evolved from late populations of *H. heidelbergensis* or archaic *Homo sapiens* (see, e.g., Hublin 1998; Rightmire 1998; Bräuer 2008; Harvati, chapter "▶ Neanderthals and Their Contemporaries," Vol. 3). Following the high age estimate for the human remains from Sima de los Huesos in Atapuerca (Spain) (Bischoff et al. 2007), first fossils with diagnostic Neanderthal traits – and thus, the Neanderthal lineage – may be tracked as far back as around 500–600,000 years. During a process that might be called "neanderthalization" and which is described within the "accretion model" (see, e.g., Dean et al. 1998 and Hublin 1998), more and more Neanderthal traits accumulated until during the last glacial the Classic Neanderthals appeared. Based on the accretion model, three categories have been established (see also Serangeli and Bolus 2008):

1. *Pre-Neanderthals* are fossils of *H. heidelbergensis* or archaic *H. sapiens* which show first distinct Neanderthal features. While they are not Neanderthals themselves, they stand at the threshold of what might be referred to as Neanderthals. Besides Sima de los Huesos, sites with pre-Neanderthal remains include Arago (Tautavel) in France, Petralona in Greece, and Steinheim in Germany.
2. *Early Neanderthals* appear around 250,000 years before present (BP) and can clearly be distinguished from *H. heidelbergensis*/archaic *H. sapiens*. The term Early Neanderthals is used for all pre-Weichselian/pre-Würmian Neanderthal fossils. Among the earliest are the fossils from Grotte du Lazaret near Nice (France) and from Pontnewydd in Wales. Similarly, all fossils from the Eemian interglacial, such as the human remains from Krapina in Croatia, are regarded as Early Neanderthals.
3. *Classic Neanderthals* appear starting with the last glacial, some 115,000 years ago. Among the best known and studied is the type specimen discovered in the German Neander Valley (Neandertal) in 1856. Fossils of Classic Neanderthals are spread over larger parts of Europe and can also be found in the Near East, in the western part of Central Asia, and even in the Siberian Altai region.

For the purpose of this chapter, it is sufficient to equate the time of the Neanderthals with the Middle Paleolithic, although this is problematic for some regions. In the Near East, for instance, both Neanderthals and early AMH produced artifact assemblages classified as Middle Paleolithic. But on the other hand, no unambiguous Neanderthal fossils have been found in fully Upper Paleolithic assemblages yet. According to the approach suggested by Alain Tuffreau (1979), Gerhard Bosinski (1986), and others, the Middle Paleolithic started about 300,000 years ago and lasted until about 30,000 BP, at which point its end overlaps with the beginning of the Upper Paleolithic.

Stone tools produced by Neanderthals show a broad variety and include hand axes and other bifacial tools, such as wedge-shaped knives (*Keilmesser*) and leaf points (*Blattspitzen*), different types of side scrapers, variable point types, and many others (Bordes 1961; Bosinski 1967; Fig. 2). Formal organic tools are much rarer. In most cases they are represented by points. While pigment use by Neanderthals is observed relatively often and can be traced backed to Early Neanderthals, personal ornaments are restricted to a small number of late Neanderthal sites. Neanderthal burials which appear just a bit later than the oldest AMH burials give insight into the spiritual world of the Neanderthals.

A map showing all sites with Neanderthal fossils known from the literature highlights the core area of Neanderthals in southern and southwestern Europe (Fig. 3). As indicated by this core area, Neanderthals originally were adapted to a temperate rather than cold, or even extremely cold, climate. However, under

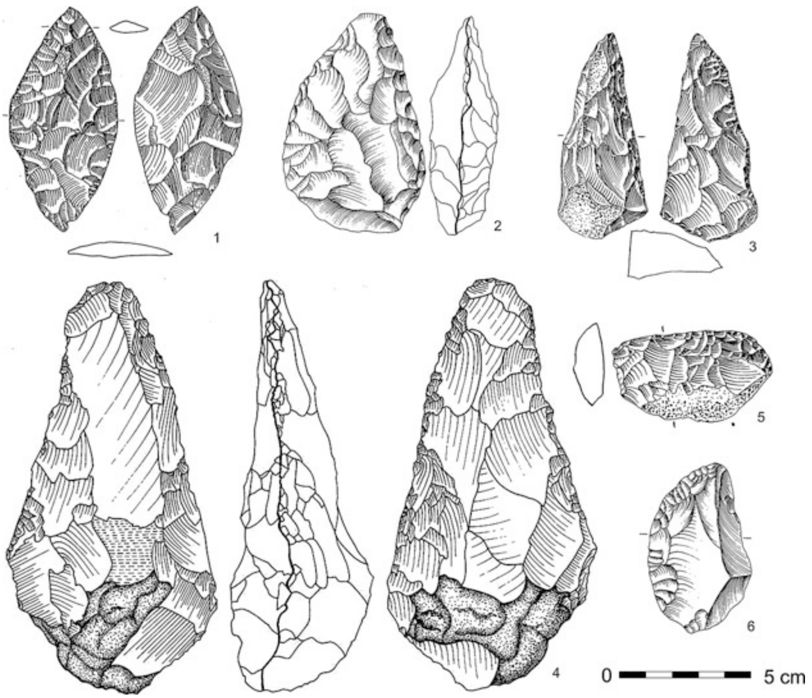

Fig. 2 Middle Paleolithic tools made by Neanderthals from sites in the Swabian Jura, southwestern Germany. *1* Leaf point (*Blattspitze*); *2*, *4* hand axes; *3* wedge-shaped knife (*Keilmesser*); *5*, *6* side scrapers (After Conard et al. 2012)

favorable climatic and environmental conditions, they repeatedly left their core area to move into areas of temporary occurrence *sensu* von Koenigswald (2003) and even "learned" to cope with harsher environmental and climatic conditions. During the last glacial, Classic Neanderthals enlarged their originally exclusive European settlement area, expanding into the Near East, parts of Central Asia, and even as far as the Altai Mountains in Siberia – a dispersal that has been called the "Out of Europe Movement" of Neanderthals (Serangeli and Bolus 2008).

It is remarkable that, on the one hand, Neanderthals were able to settle new territories, but that, on the other hand, there is no unambiguous evidence that they ever moved to Africa, the home continent of AMH (although some anthropologists think there are Neanderthal influences, however slight, in North Africa: Simmons and Smith 1991). The reasons why Neanderthals did not enter Africa once they had reached the Near East about 80–90,000 years ago are not yet clear; they represent one important topic of the research project "The role of culture in early expansions of humans" (ROCEEH) of the Heidelberg Academy of Sciences and Humanities

(Haidle et al. 2010). It is obvious that AMH lived in northern Africa when Neanderthals settled Europe and moved "out of Europe." Hence, it might be possible that some sort of "cultural barrier" plays an important role in the lack of Neanderthals in northern Africa and in Africa in general.

As remarkable as the extensive expansion(s) of Neanderthals is their disappearance as an independent hominin lineage some 30–35,000 years ago or, according to other scientists, some 40,000 years ago (see Pinhasi et al. 2011). It is even more striking given the fact that at the same time when Neanderthals reached their largest geographic distribution in the Siberian Altai Mountains (Fig. 4), their demise had already started in their home continent, Europe. Their distribution area contracted further and further, until finally Neanderthals only existed in some refuge areas such as the Iberian Peninsula and the Crimea.

There have been vivid discussions and speculations about the reasons for the extinction of the Neanderthals, but it must be admitted that these reasons are not yet fully understood. It is most probable that the answer lies in an interaction of several factors. One of these factors might be the appearance and rapid expansion of AMH in Europe starting some 45,000 years ago.

Out of Africa Again: Anatomically Modern Humans

Unambiguous evidence for the lineage eventually leading to anatomically modern humans (AMH) comes exclusively from Africa (for an overview, see Bräuer (2008); "▶ Origin of Modern Humans," Vol. 3). According to Günter Bräuer, a long line of evolution becomes apparent on that continent starting some 600,000 years ago with Early Archaic *H. sapiens* (*sensu* Bräuer; most of these fossils, such as Bodo, Ndutu, and Kabwe/Broken Hill, are included by Stringer (2012) and Rightmire (2009) in *H. heidelbergensis*), followed by Late Archaic *Homo sapiens* (*sensu* Bräuer; some of these fossils, such as Florisbad, Laetoli 18, and Irhoud 1 and 2, are included by Rightmire (2009) in a "Florisbad group" of Middle Pleistocene African hominins). First fossils of anatomically modern *H. sapiens* have been found in Ethiopia in the sites of Omo Kibish (McDougall et al. 2005) and Herto (White et al. 2003), with ages of about 195,000 and 160,000 years BP, respectively. These humans produced Middle Stone Age industries with Acheulean elements. Later fossils from Africa include, among others, those from Singa (Sudan), Mumba (Tanzania), Klasies River Mouth, and Border Cave (both South Africa).

Asia

The exact date when AMH left Africa for the first time, often called the "Out of Africa II" movement, remains as unclear as the exact dispersal route(s). The oldest

AMH fossils outside Africa have been found in burials from two caves in Israel: Skhūl in the Carmel Mountains and Qafzeh near Nazareth. These fossils have ages of about 90–100,000 BP, making them the oldest burials known so far. At the same time, these finds mean that there is a temporal gap of about 100,000 years between the oldest AMH fossils from Africa and those from outside Africa. The AMH from Skhūl and Qafzeh both produced Middle Paleolithic assemblages similar to the ones contemporaneous Neanderthals produced in Europe, which shows that biological evolution does not necessarily run parallel with cultural evolution.

After the Skhūl and Qafzeh people, only Neanderthals seem to have settled the Near East for several tens of thousands of years. Coming from the site of Ksar Akil in Lebanon, the next AMH in that region are no older than about 42,000 years and seem to represent another dispersal wave of AMH out of Africa (Douka et al. 2013). These fossils have been found within Initial and Early Upper Paleolithic contexts which clearly differ from the European Aurignacian to be discussed below.

Due to the overall weak fossil record, no clear dispersal route of AMH from eastern Africa (or southern Africa, since genetic evidence seems to indicate a southern African origin for AMH; Henn et al. 2011) can be traced to the Levant. Due to its intermediate geographic position between southern and eastern Africa on the one hand and the Levant on the other, the Egyptian site of Taramsa, which has yielded a probable AMH burial from Middle Paleolithic context (Van Peer et al. 2010), may indicate movements of AMH along the Nile Valley. The burial, however, is dated to about 68,000 BP, so that it is much younger than the earliest AMH fossils from the Levant.

Whether the site of Jebel Faya in the United Arab Emirates (Armitage et al. 2011) falls into the temporal gap remains to be proven. The oldest assemblage of the site dates to about 125,000 BP. Unfortunately, the site has not yielded any human remains so far, but comparisons of the lithic artifacts show similarities with contemporaneous African Middle Stone Age assemblages that are definitely produced by AMH, whereas the site seems to lie outside the Neanderthal range. Given this, Jebel Faya could provide evidence for an expansion of AMH into Arabia earlier than the burials from Skhūl and Qafzeh.

Theoretically, even an independent evolution of AMH in the Near East or in other parts of Asia cannot completely be ruled out, but a record of archaic *H. sapiens* fossils, transitional groups, and early AMH cannot be put together for this region the way it was for Africa. The phylogenetic position of the Zhirendong fossils from South China is still under discussion, and the same is true for the exact ages of other earlier Late Pleistocene human fossils from both continental and insular regions of East Asia (Kaifu and Fujita 2012). With an age of about 40,000 years, the AMH skeleton from Tianyuan Cave in North China (Shang et al. 2007) ranks among the oldest securely dated AMH remains from eastern Eurasia.

The colonization of southern Asia apparently did not happen before the “supereruption” of the Mount Toba volcano on Sumatra (ca. 74,000 years ago). Based on archaeological and genetic evidence, a dispersal scenario has recently been published which suggests a coastally oriented dispersal of AMH from eastern Africa to southern Asia (Mellars et al. 2013). Provided this holds true, dispersals of AMH from southern Asia both to eastern Asia and to Sahul are possible.

Sahul

The colonization of Sahul – the landmass which during the last glacial comprised mainland Australia, New Guinea, Tasmania, and some other neighboring islands – was definitely not possible without crossing water; in this it differs from all earlier dispersals of humans. Even with the water level being about 100 m lower than today, the water barrier to be crossed to enter Sahul measured at least 70 km (Balme 2013). Several routes are conceivable by which AMH may have reached the new territory, most probably by boats or rafts (Birdsell 1977), although none of these routes have been definitely proven yet. In any case, Sahul was the first continent to be colonized exclusively by AMH. Sites with the earliest evidence for human presence in Sahul include Malakunanja 2 and Nauwalabila 1 in Arnhem Land with Optically Stimulated Luminescence (OSL) ages of about 53,000 BP, while the famous Lake Mungo burials in New South Wales date to about 41,000 BP (see Davidson 2010). A couple of other sites have also yielded reliable age estimates around 40,000 BP, whereas ages down to more than 100,000 BP could not be verified. It is noteworthy that sites with ages greater than 35,000 BP are not only to be found near the coastal areas but also inland, which indicates that early AMH in Sahul were able to settle very different environments more or less contemporaneously, thus showing a high degree of adaptive capabilities.

Europe

From the dates given, it is evident that the colonization of Sahul took place prior to the colonization of Europe. But in light of new dates and the reanalysis of human fossils, the first presence of anatomically modern humans in Europe has also been dated back. Different routes are imaginable, and since the fossil record for the earliest Europeans is still sparse, it is essential to consider the archaeological record as well.

The site of Üçağızlı Cave I, located on the Mediterranean coast in the Hatay province of south-central Turkey – that is, positioned at the gates of Europe though not, geographically speaking, quite part of it – yielded important data. A multilayered stratigraphy was excavated, with an Initial Upper Paleolithic (IUP) sequence followed by an Early Upper Paleolithic Ahmarian sequence (Kuhn et al. 2009). Both the IUP and the Ahmarian yielded teeth attributed to AMH, the oldest of them coming from levels with calibrated radiocarbon ages of down to 45,000 calBP (for the dates, see Douka 2013). Archaeologically, the assemblages stand out for a variety of organic tools and personal ornaments coming from all parts of the IUP and Ahmarian sequence.

Recently, two teeth from Grotta del Cavallo (Italy), found in an Uluzzian context, have been reanalyzed (Benazzi et al. 2011). This reanalysis shows them to be from AMH, and not from Neanderthals as supposed earlier. New chronometric data obtained from associated shell beads give (calibrated and modeled) ages of 43–45,000 calBP, making the Cavallo teeth the oldest known European AMH. These fossils have about the same age as the oldest AMH teeth from Üçağızlı. The Uluzzian, in which the Cavallo teeth were found, belongs to the so-called transitional industries, which combine elements of the Middle Paleolithic and the Upper Paleolithic. Since the term "transitional industries" is somewhat misleading, insofar as it implies that one techno-complex (Middle Paleolithic) developed into another (Upper Paleolithic), assemblages of this kind, though still bearing some Middle Paleolithic characters, might more neutrally be termed Initial Upper Paleolithic (IUP). It should be noted, however, that IUP assemblages such as the Uluzzian, the IUP of Üçağızlı, and others differ considerably from each other and should not be attributed to one and the same dispersal wave of AMH into Europe.

The problem of assigning all "transitional industries" jointly to either AMH or Neanderthals is illustrated by the Châtelperronian techno-complex, distributed in larger parts of France and small parts of Spain. Despite ongoing controversy (see, e.g., Bailey and Hublin 2006 and Bar-Yosef and Bordes 2010; Higham et al. 2010), it seems that this techno-complex was created by Neanderthals, whereas, as just mentioned, the Uluzzian was produced by AMH. Both the Châtelperronian and the Uluzzian stand out for the fact that some of the assemblages have yielded bone tools as well as personal ornaments (White 2001; d'Errico et al. 2003; Benazzi et al. 2011). In most cases, the presence of personal ornaments in an assemblage is regarded as a "modern" trait. That is why there is vivid discussion over the notion, advocated by some scientists, that the creators of the Châtelperronian, assuming they were Neanderthals, had been acculturated by incoming AMH (e.g., Mellars 1989). The alternative, argued for by other researchers, is that the Neanderthals themselves had the capability to produce personal ornaments, without any contacts with AMH (e.g., Zilhão 2007). The dispute remains unresolved.

For still another IUP complex, the Bohunician from eastern-central Europe, an authorship of AMH, has been suggested for reasons of lithic technology, which to some extent resembles that of the Ahmarian from the Near East (Škrdla 2003). This suggested authorship, however, remains to be confirmed, since new Thermoluminescence (TL) dates place the Bohunician-type site Brno-Bohunice (Czech Republic) at about 48,000 BP (Richter et al. 2008) – which would imply a much earlier presence of AMH in Europe than previously thought. Unfortunately, no human fossils have been found in a Bohunician context.

Some of the oldest AMH fossils from Europe have either been found without any archaeological context, such as those from Peştera cu Oase in Romania (Zilhão et al. 2007), or with unclear context, such as the maxilla from Kent's Cavern in England (Higham et al. 2011). While for Kent's Cavern calibrated ages of 43–42,000 calBP were obtained from faunal remains (which need not necessarily stem from direct association with the fossil), direct dating of the Oase 1 mandible

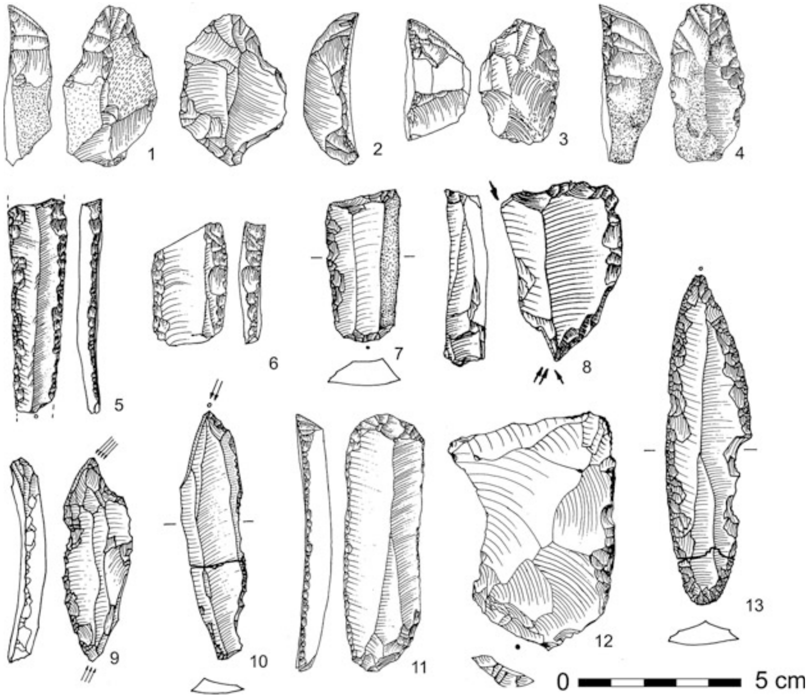

Fig. 5 Stone tools from Aurignacian sites in the Swabian Jura, southwestern Germany. *1*, *2* nosed end scrapers; *3*,*4* carinated end scrapers; *5*,*6* laterally retouched blades; *7* truncated blade; *8–10* burins; *11* end scraper; *12* knifelike flake with lateral retouch and faceted platform remnant; *13* pointed blade (*Spitzklinge*) (After Bolus 2011)

has yielded calibrated radiocarbon ages of 40–38,000 calBP. Looking further to the east of Europe, the Russian site of Kostenki XIV in the Don region yielded two AMH teeth with an Initial or Early Upper Paleolithic assemblage dated to (calibrated) 40–36,000 calBP (Sinitsyn and Hoffecker 2006). The fossils mentioned, even those without clear archaeological context, confirm a rapid dispersal of modern humans across the continent from east to west before the disappearance of Neanderthals.

The archaeological record from early Upper Paleolithic sites in Europe without human fossils adds to this picture, though at first glance the general rarity of human fossils from that time period seems problematic. The Aurignacian is the first fully Upper Paleolithic techno-complex to be present in larger parts of Europe (Fig. 5). Roughly speaking, it can be found from the Don region in the east to the Atlantic coast in the west, though regional differences cannot be ignored. The Aurignacian sensu stricto seems to be an indigenous European techno-complex (Bolus 2004).

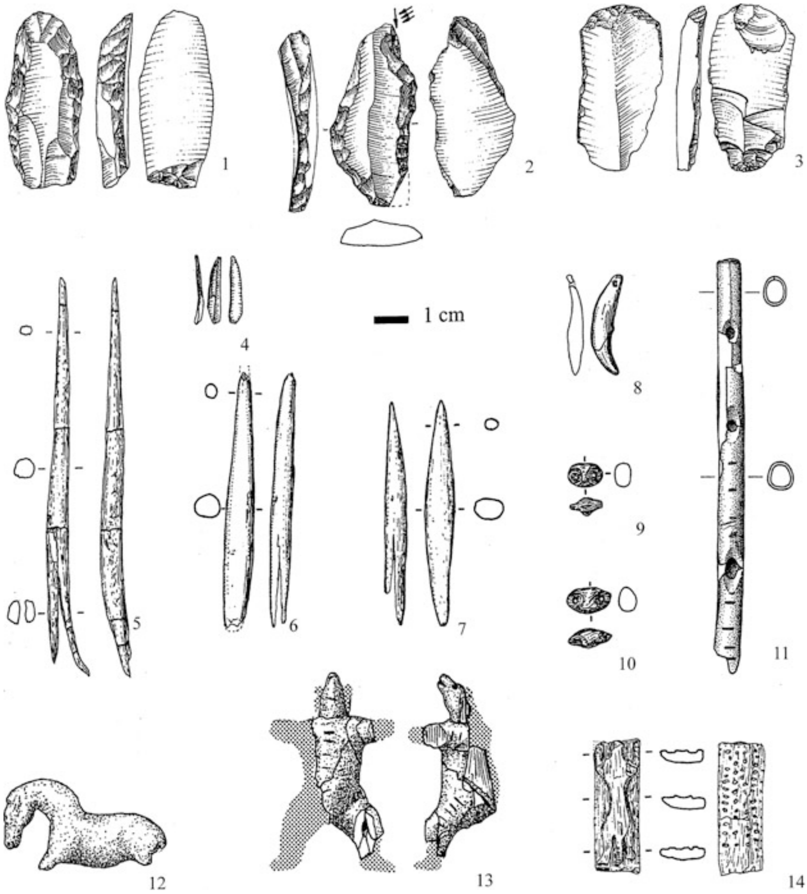

Fig. 6 Stone and organic tools, personal ornaments, art objects, and a musical instrument from Aurignacian sites in the Swabian Aurignacian of southwestern Germany. *1* end scraper; *2* busked burin; *3* splintered piece; *4* Dufour bladelet; *5–7* split-based antler points; *8* perforated fox canine; *9–10* double-perforated ivory beads; *11* bone flute; *12–14* ivory figurines (After Bolus 2011)

The oldest known Aurignacian assemblage comes from archaeological horizon III of the Geißenklösterle Cave in the Swabian Jura of southwestern Germany, with calibrated and modeled ages of down to 43,000 calBP (Higham et al. 2012). Another cave site from the Swabian Jura, Hohle Fels, less than 3 km away from Geißenklösterle, yielded only slightly younger ages from the lowest part of the Aurignacian sequence (Conard 2009). Both sites stand out for their variety of personal ornaments, figural artworks, and musical instruments (Fig. 6). With the ages mentioned, these objects range among the oldest examples of their kinds and thus of what might be called cultural or behavioral modernity (for a definition, see Conard 2008; (see Haidle, chapter "▶ Modeling the Past: Archaeology," Vol. 1 and

Conard, chapter "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," Vol. 3).

Assemblages of similar ages can be found in Bavaria and in Lower Austria. But while the assemblage from layer 2 of Willendorf II in Lower Austria, dated older than 40,000 BP, can only be attributed to an unspecific Early Upper Paleolithic, layer 3 of the same site, which yielded ages around 39,000 BP, clearly belongs to the Aurignacian (Nigst and Haesaerts 2012).

These sites in the Swabian Jura and in Lower Austria are in full accordance with the "Danube Corridor" hypothesis, which states that groups of AMS entered central Europe following the Danube Valley (Conard and Bolus 2003) and from there dispersed further to the west and northwest.

Calibrated age estimates for the oldest French Aurignacian strengthen the argument, since they are somewhat younger than those for the Swabian sites. The oldest French Aurignacian sensu stricto comes from Abri Pataud in the Dordogne and is younger by about 2,000 years than the oldest Aurignacian from Geißenklösterle (Higham et al. 2012). Assuming a high dispersal speed, these dates would be well compatible with the scenario of the "Danube Corridor."

Unfortunately, neither Geißenklösterle nor Hohle Fels nor any other early Aurignacian sites of similar age have yielded human fossil remains. The oldest example from secure Aurignacian context comes from the site of La Quina-Aval in France, with a calibrated age of about 38,000 calBP (Verna et al. 2012). Other, somewhat younger sites include Brassempouy and Les Rois, both in France as well. Since in every case when human remains have been found in secure Aurignacian context, the remains were identified as AMH (see also Bailey et al. 2009), and since the Aurignacian assemblages from Geißenklösterle and Hohle Fels represent full Aurignacian assemblages, it seems plausible to see AMH as the hominins responsible for the Swabian Aurignacian in particular and, by extension, for the European Aurignacian in general. This line of argument offers an illustration of how archaeology can provide valuable information on the dispersal of early AMH within Europe where human fossils are lacking.

From the northern Mediterranean region, a similar techno-complex is known: the archaic Aurignacian, also called Proto-Aurignacian or Fumanian. It is not necessary here to discuss the differences and the similarities with the Aurignacian sensu stricto. In all sites where both techno-complexes are present, the archaic Aurignacian underlies the Aurignacian sensu stricto. This does not mean, however, that the archaic Aurignacian is automatically older. Instead, the oldest archaic Aurignacian sites from Fumane and Riparo Mochi in Italy, Abric Romaní in Spain, and Arcy-sur-Cure and Les Cottés in France have yielded calibrated radiocarbon ages between about 42,000 and 40,000 calBP (Higham et al. 2012), thus being slightly younger than the oldest Geißenklösterle dates and contemporaneous with other dates for the Aurignacian sensu stricto. Uncalibrated ages of down to 40–39,000 BP have been obtained for archaic Aurignacian assemblages from northeastern Spain (Arbreda and Reclau Viver: Soler Subils et al. 2008).

The human fossil record for the archaic Aurignacian is even worse than it is for the Aurignacian sensu stricto. Either there are no fossils from the assemblages at all, or the fossils are not unambiguously from the archaic Aurignacian levels, or they are not attributable to specific hominins. Hence, though the suggestion to attribute the archaic Aurignacian to AMH is the most plausible one, it is just that – a suggestion.

Nevertheless, this question is of particular importance since, on the assumption that AMH were responsible for the assemblages of archaic Aurignacian type, those assemblages would be indicative of another dispersal route of early AMH into and through Europe – a route which did not run along the Danube Valley but along the northern Mediterranean coast and from there, as the sites of Arcy-sur-Cure in Burgundy and Les Cottés in Auvergne show, further inland.

This returns us to the question from where and how AMH came into Europe. The first dispersal wave of AMH out of Africa, about 100,000 years ago, does not seem to have reached Europe. The fossils from Üçağızlı at the gates of Europe as well as the oldest AMH fossils found in Europe, and the European archaeological record leave a clear temporal gap between the earliest AMH presence outside Africa – in the Near East and even in Sahul – and the colonization of Europe. The scenario of a second wave of dispersal of AMH into Europe from Africa, crossing the Levantine Corridor, is put into question by the relatively young dates for the Ksar Akil fossils. The Aurignacian sensu stricto as well as the archaic Aurignacian had already been fully established at the time of the Initial/Early Upper Paleolithic in the Near East. On the other hand, further research is needed to strengthen the possibility of a dispersal of AMH from East and Central Asia into Europe. The oldest securely dated AMH fossils from East Asia, all found in Early Upper Paleolithic contexts but in neither case within Aurignacian contexts, do not seem to be older than the oldest AMH fossils from Europe.

This leads back to the archaeological evidence and the suggestion of a genuine European origin of both the archaic Aurignacian and the Aurignacian sensu stricto. Based on the archaeological and the fossil evidence, a scenario is imaginable where AMH entered Europe from the Near East and/or Central Asia moving both through the Danube Corridor and along the northern Mediterranean rim, finally reaching the western and northwestern ends of the continent. It seems that the earliest colonizers of Europe had some sort of Initial or Early Upper Paleolithic industry with them, but no Aurignacian. During their spread across Europe, numerous innovations evolved within the material culture, and most probably changes in the social/behavioral realm appeared as well. It is noteworthy that the earliest evidence for the full development of these features comes from the Swabian Jura in southwestern Germany. This leads to the hypothesis that early AMH entered Europe showing some, but not all, characteristics of fully modern behavior. These were developed somewhere in (central) Europe with the Aurignacian sensu stricto and along the northern Mediterranean rim with the archaic Aurignacian. At least two different routes can be traced following the archaeological record; what it confirms very

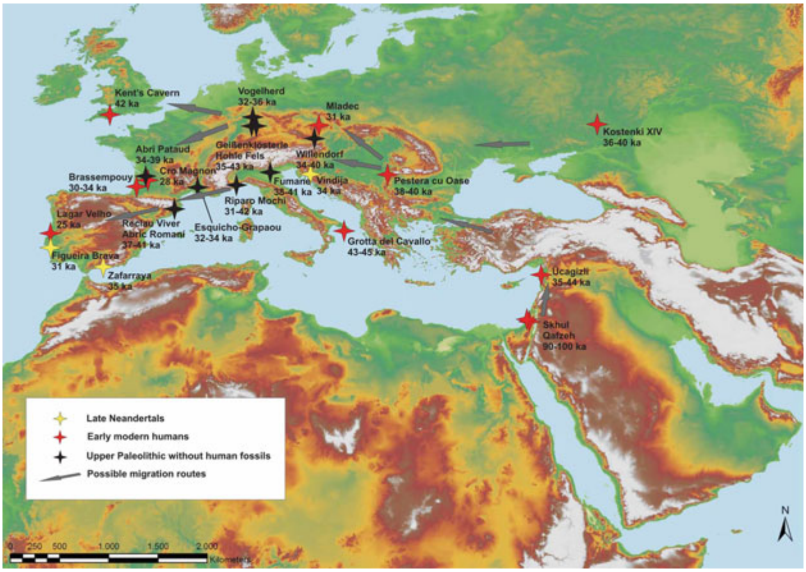

Fig. 7 Sites with late Neanderthal fossils, with early AMH fossils, with early Upper Paleolithic assemblages (but without human fossils), and possible dispersal routes of AMH into and through Europe

clearly is that AMH, once having entered Europe, spread rapidly through the continent (Fig. 7).

The New World

The last major dispersal steps were made when at the end of the last glacial, about 15–14,000 years ago, AMH started to colonize the Americas until, finally, they had entered most parts of the habitable world. From where exactly the colonization of the New World took place is still open to debate (see Davidson (2013) and the references given therein) and shall not be further discussed here.

Third Party: The Denisovans

Until about a decade ago, Neanderthals and AMH were the only known hominins during what is archaeologically defined as the late Middle Paleolithic and Upper Paleolithic. The discoveries from Liang Bua Cave and other sites on Flores, Indonesia, however, demonstrated that it is better to be cautious with preconceptions. The exact taxonomic position of the Liang Bua fossils is still under debate (see Aiello, chapter "▶ *Homo floresiensis*," Vol. 3). The implications of these fossils and of stone artifacts from sites such as Mata Menge on Flores, with a possible age of down to 0.8 million years (Brumm et al. 2010), shall not be discussed here.

Fig. 8 Denisova Cave in the Russian Altai Mountains. A Neanderthal pedal phalanx as well as fossils of a new hominin group, the Denisovans, have been found here (Photo: Michael Bolus)

Another discovery of the recent past must at least be touched on, though the various implications of this discovery are not yet fully understood. In 2010, geneticists announced the discovery of a new, hitherto unknown human group (Krause et al. 2010; Reich et al. 2010). A human finger phalanx excavated in the Denisova Cave in the Russian Altai (Fig. 8) in 2008 yielded an mtDNA sequence belonging neither to Neanderthals nor to AMH. According to the site where the bone had been found, the new lineage was named the Denisovans. However, geneticists cautioned that it might be premature to apply "any formal Linnaean taxonomic designation that would indicate species or subspecies status for either Neanderthals or Denisovans" (Reich et al. 2010, p. 1059). Until now the new hominin group is only known from the phalanx mentioned and two molars, all excavated at Denisova Cave. In the meantime, a draft nuclear genome sequence has been retrieved from the phalanx. It "revealed that Denisovans are a sister group to Neandertals, with the Denisovan nuclear genome sequence falling outside Neandertal genetic diversity, which suggests an independent population history that differs from that of Neandertals. Also, whereas a genetic contribution from Neandertal to the present-day human gene pool is present in all populations outside Africa, a contribution from Denisovans is found exclusively in island Southeast Asia and Oceania" (Meyer et al. 2012). Further genetic data suggest that Denisovan gene flow occurred in Southeast Asia and not mainland East Asia. This leads to the conclusion that archaic Denisovans "must have lived over an extraordinarily broad geographic and ecological range, from Siberia to tropical Asia" (Reich et al. 2011, p. 516). Most recently, a mitochondrial genome sequence gained from a hominin femur from Sima de los Huesos has revealed a close relationship to the lineage leading to the mitochondrial genomes of Denisovans (Meyer et al. 2014).

It is obvious that further research, in particular analysis of more fossils belonging to the Denisovans, is needed to better understand the dispersals of these newly discovered hominins.

Three or Four Different Hominin Lineages: Did They Meet?

In light of the possibility that at least three (or perhaps four, including the Liang Bua fossils) different hominin lineages existed during the later Middle Paleolithic and the Upper Paleolithic, the question may be raised whether these different hominins met during their dispersals or not. From an archaeological point of view, the situation is still not clear. As far as the so-called transitional industries between Middle and Upper Paleolithic are concerned, so far no unambiguous proof has been established that they are the result of contacts between Neanderthals and AMH. The possible case of the Châtelperronian has been discussed above. The fact that up to 4 % of Neanderthal DNA has been detected in the AMH genome, however, is proof of interbreeding, and the fact that this Neanderthal DNA has been found in all living non-African AMH while it is lacking in all Africans demonstrates that this interbreeding must have occurred outside of the African continent. Most probably, it happened in the Near East, but the exact date of the admixture is still open to discussion (Green et al. 2010).

AMH also mixed with Denisovans, most probably in Southeast Asia (Reich et al. 2011). And very recent genetic data suggest an even more complex scenario of admixtures. The Denisovans clearly interbred not only with AMH but also with Neanderthals, most probably in the Middle East. Finally, the genetic results hint at the possibility that Denisovans also mixed with still another, more ancient hominin (Prüfer et al. 2014). If so, this would open a completely new chapter of human history and dispersals.

Conclusion

At the moment, it seems most probable that representatives of the genus *Homo* were the first hominins to leave their African home continent. In contrast, for the genera *Australopithecus* and *Paranthropus*, only dispersals within Africa can be traced. The dispersals of *Homo* out of Africa happened during several waves over a time span of about 1 million years. The first humans outside of Africa, with an age of about 1.8 million years, have been found in Dmanisi in the Georgian Caucasus. Only slightly younger evidence from Southeastern and eastern Asia belongs to the same first wave of expansion. Sites and fossils in the Levantine Corridor with an age of 1.5–1.2 million years may be late witnesses of the same wave or early witnesses of one of the next. The Levantine Corridor is regarded as one of the major dispersal routes for early humans at that time. A southern route crossing the Arabian

Peninsula has also been discussed, but archaeological and fossil evidence for that early time is still lacking for that region.

The earliest material culture of humankind, with an age of around 2.6 million years, is named Oldowan. The first human fossils outside of Africa, although considerably younger, are still associated with this techno-complex. Even humans belonging to later expansion waves, such as those from Atapuerca (Sima del Elefante and Gran Dolina), still produced Oldowan tools. In Africa, a new technological tradition, the Acheulean, started to evolve some 1.8 million years ago. The Acheulean seems to have reached southern Asia much earlier than Europe, where the earliest secure appearances are no older than 700–600,000 years, while evidence from East Asia and the Near East is somewhat older. The European fossils assigned to *H. heidelbergensis* may be representatives of one of the last (if not the last) expansion wave(s) of archaic hominins out of Africa.

The Neanderthals, genuine European hominins, evolved probably out of later representatives of *H. heidelbergensis*/archaic *H. sapiens*. They repeatedly left their core area in southeastern and southern Europe to move into areas of temporary occurrences. During the last glacial period, they started their dispersal "out of Europe" and finally reached an area as far away from their original core area as the Russian Altai Mountains in southern Siberia.

While Neanderthals inhabited Europe and later moved out of Europe, AMH evolved in Africa nearly 200,000 years ago. First AMH fossils outside of Africa with an age of about 100,000 years have been found in the Levantine Corridor, but there is archaeological evidence for an even earlier presence of AMH in the Arabian Peninsula. A considerable temporal gap exists between these appearances and the next evidence for AMH outside of Africa. With the Arabian Peninsula serving as some sort of bridge, it seems plausible that early AMH followed a southern route until finally reaching Sahul some 50,000 years ago.

The colonization of Europe started no earlier than about 45,000 years ago. Only slightly later, by about 43,000 years ago, a new techno-complex, the Aurignacian, evolved in Europe and gradually spread over larger parts of the continent. The archaeological evidence suggests a dispersal of early AMH through the Danube Corridor. Another dispersal route of early AMH is suggested by sites around the northern Mediterranean rim which are attributed to the archaic Aurignacian and which are more or less contemporaneous with the Aurignacian sites. With a broad variety of organic tools, personal ornaments, figurative art, and musical instruments, the makers of the early Aurignacian and archaic Aurignacian, most probably AMH, show the full package of what is called fully modern behavior. Once in Europe, AMH spread rapidly across the continent.

While the archaeological evidence is not that clear, genetic data show that AMH mixed both with Neanderthals and with a recently discovered, new hominin group, the Denisovans, which in turn also mixed with Neanderthals.

At about 15–14,000 years ago, AMH finally started to colonize the New World.

Today, much is known about adaptations, traces, frontiers, and new territories during the several repeated dispersal waves of early hominins. But it is also clear, as evidenced by the ongoing discovery of surprising finds, such as the Liang Bua fossils from Flores, the Denisovans, and yet another possible hominin lineage, that researchers are far from understanding the whole scenario of inter- and intracontinental dispersals of early humans.

The Dentition of American Indians: Evolutionary Results and Demographic Implications Following Colonization from Siberia

Christy G. Turner II and G. Richard Scott

Contents

Abstract

This chapter uses dental morphology to make inferences about how the New World was first colonized. The major emphasis is on the initial Macro-Indian migration based on dental traits observed in Paleo-Indian, Archaic, and more recent prehistoric crania. The major results are as follows: (1) Arctic and Subarctic

---

Christy G. Turner II passed away on July 27, 2013. This chapter has subsequently been updated by his coauthor.

native dentitions differ enough from those of Macro-Indians to indicate separate migrations. (2) Clustered MMD values show three Macro-Indian branches of North Americans, South Americans, and mixed North and South. (3) There is no marked branching depth for these three dental divisions, which fits the hypothesis of a single rapid Paleo-Indian colonization event. (4) The minimally divergent North and South American dental divisions are most likely the microevolutionary result of dispersal-dependent population structure and lineage effects. (5) No genetic bottlenecking can be identified at Panama. (6) The small amount of New World internal dental divergence favors colonization of South America soon after the settlement of North America. (7) There are no obvious clines, frequency trends, or geographic groupings for individual dental traits. This suggests little or no selection and that after leaving Siberia, population size increased sufficiently to limit genetic drift. (8) There is no sign of any Old World or Oceanic dental pattern other than Northeast Asian Sinodonty. All things considered, including New World and Siberian linguistics, archaeology, genetics, route considerations, and relevant natural history, dental analysis supports the Late Pleistocene ice-free corridor, Clovis or epi-Clovis settlement hypothesis, and the Greenberg Amerind or Macro-Indian language evolution model.

Introduction

This chapter reviews the dental morphological evidence for the pre-Columbian colonization of the New World. This evidence, in conjunction with genetic information, is used to challenge colonization scenarios based on measurements of prehistoric skulls. There are two main anthropological questions for which answers have been sought using the variation of New World dental morphology and comparative information from Old World and Pacific basin populations. First, how many colonizing migrations can be postulated on the basis of New World dental variation? To answer this question, analysts have tried to determine if there are any dental correspondences with modern or ancient New World culture areas (yes), environmental types (no; however, Jantz et al. 1992 found that anthropometric variation was correlated with geography), or linguistic families (yes) (Greenberg et al. 1986). These findings suggest that New World dental variation is more closely linked to ethnicity (i.e., migration) than to environment (natural selection or physiological adaptation). Roughly put, dental variation is strongly caused by nature, whereas cranial variation has a significant nurture component (Kohn 1991, p. 273) notes that "environmental factors contribute a significant amount to the observed variability in craniofacial morphology and growth"). Because of linguistic and ethnic correspondences with dentition, Arctic and western Subarctic dental variation is most parsimoniously interpreted as due to two migrations of people dentally differentiated to a slight degree from an earlier migration (Clovis or epi-Clovis). All three inferred migrant groups exhibit minor variants of the Sinodont dental pattern and, as such, are closely related and share a common Northeast Asian ancestor sometime in the relatively recent past. Presumably, each originated in different geogenetic regions of Northeastern Asia (Turner 1985) after separating from the common ancestral stock that presumably lived further to the south, say, central China. As will be shown, the earliest colonizers must have given rise to all modern North and South American populations except for Arctic and Subarctic groups. This first migrant group is referred to as Macro-Indian or Amerind, linguistic names (Ruhlen 2000), and Paleo-Indian or Clovis, synonyms used by archaeologists (Haynes 1987). The term epi-Clovis has been recently proposed to denote the Late Pleistocene ancestral cultural condition in Beringia prior to the development of the fluted points that are the hallmark of the Clovis big-game hunters (Turner 2002). Another name used in Alaska to denote epi-Clovis is Nenana complex (Hoffecker et al. 1993). In addition to the just-cited articles, other major reviews of the archaeological evidence for the peopling of the Americas can be found in Carlson (1991), Fiedel (2004), Haynes (2002a, which contains an immense bibliography, 2002b), Hoffecker and Elias (2003), Madsen (2004), Meltzer (1993), Rogers et al. (1992), West (1996), Yesner (2001), Yesner and Pearson (2002), Graf et al. (2013), and many others. The emphasis here is on the importance of archaeology and archaeologically derived teeth since both provide direct diachronic evidence for human biocultural prehistory.

In the Old World, the Sinodont dental pattern occurs in modern and prehistoric Northeast Asians of China, Tibet, Mongolia, post-Jomon Japan, Korea, and eastern Siberia (Hanihara 1968; Zoubov and Haldeyeva 1979; Hanihara 1991; Scott and Turner 1997). In contrast, Late Pleistocene and recent peoples of mainland and island Southeast Asia (Thailand, Indonesia, Borneo, Philippines, Taiwan, Jomon Japan, etc.), as well as Polynesians, Micronesians, and early Sri Lankans, possess a dental pattern called Sundadonty, which is simpler and retains more of the character of a hypothesized earlier pattern (proto-Sundadonty) than does the more specialized Sinodonty (Turner 1983, 1990a; Scott and Turner 1997). Modern and recent Europeans, as well as the earlier Cro-Magnons, possess a simplified dental pattern, which is similar to that found in modern India, North Africa, and western and central Asia (Irish 1993; Haeussler 1996; Hawkey 1998). The simplest of modern human dental patterns is found in Europe (Scott et al. 2013). It more closely resembles the dental pattern of modern Africans and Australians than Sinodonty.

The second question involves claims using controversial archaeological and craniometric evidence that proposes the New World was initially colonized by a pre-Clovis, Sundadont population that was less Mongoloid cranially than modern Indians. These claims presume an earlier entry into the New World than the classic Clovis-first model. Claims for pre-Clovis range widely, from 15,000 to more than 50,000 years BP.

To put the peopling of the New World into a broad framework of dental pattern evolution, a phylogenetic reconstruction is offered that seems to have the best general concordance with other lines of evidence derived from archaeology, linguistics, genetics, and natural history. In this context, dental pattern refers to a standardized set of independent discrete crown and root morphological traits whose occurrence (presence or absence) and expression (small, moderate, large, very large; shape variation; etc.) in one major geographic region, such as Northeast Asia, differ considerably from what is found in other major natural regions, such as Europe (cf. Scott et al. 2013). The authentication of these patterns has been based on repeated dental sampling of the geographic regions, which produces trait frequencies like those originally used to define the regional patterns. On dental grounds, prehistoric Europeans and Africans are excluded as having anything to do with the peopling of the New World until the Christian era. Similarly, teeth indicate that peoples of Oceania and Southeast Asia played no role in the colonization of the New World. Long before Siberians reached Alaska, human populations had evolved their major modern dental patterns. Scott and Turner (1997) identify these as belonging to five groups: Africa south of the Sahara, western Eurasia (Europe, Middle East, North Africa, India), Sahul-Pacific (Australia, New Guinea, Melanesia), Sunda-Pacific (mainland and insular Southeast Asia, Polynesia, Micronesia), and Sino-American (Northeast Asia and the Americas). Finally, all claims for an autochthonous creation of Native Americans, as based on some religious beliefs, as well as on flawed reasoning, are excluded from consideration (Tyler 1998).

To put the peopling of the New World into a broader human evolutionary context, it is necessary to first consider what is known about human evolution in Asia during the Upper Pleistocene. Sometime before 50,000 BP, there were anatomically modern humans living in Southeast Asia, although among complete specimens only the south China Liujiang skull may be this old or older (Pope 1992, p. 275). However, the 50,000 BP date approximates the earliest archaeological appearance of human-made stone artifacts in Australia (Roberts et al. 1994). All human skeletal remains found in Australia, some dating as far back in time as 30,000 BP, are anatomically modern. Australia could only have been colonized from Southeast Asia, at a few locations along the route and only with the aid of some form of watercraft. Early Southeast Asians and Australian colonists are hypothesized to have possessed a dental pattern similar to that of modern Australians. Turner (1992c) has called this hypothetical pattern proto-Sundadonty, which was estimated by averaging the dental trait frequencies obtained from archaeologically and ethnographically derived skeletal samples collected in several localities throughout Australia. In their early terrestrial and oceanic dispersal eastward out of Southeast Asia, proto-Sundadonts, in time, became ethnic Melanesians and Australians. Their dental pattern is much like that found in modern and recent Southeast Asians as well as modern sub-Saharan Africans, suggesting proto-Sundadonty and the African dental pattern were derived from an as yet unidentified common ancestral pattern. Before the end of the Pleistocene 10,000 years ago, Southeast Asian teeth had evolved into the slightly more specialized Sundadont pattern as part of the general drift toward dental complexity in eastern Eurasia, in contrast to the Late Pleistocene drift toward increased simplicity in western Eurasia. The areal extent of Sundadonty increased with the northward coastal expansion of these modern humans into Taiwan and Jomon Japan, where Sundadonty remains to the present day in unadmixed Taiwan aborigines and the Ainu of northern Japan. In the more interior part of the East Asian mainland, probably north China, Sundadonty evolved into the more complex and specialized Sinodont pattern. In time, nomadic groups possessing Sinodonty expanded into Mongolia, eastern Siberia, and eventually the New World. In the later Holocene, Southeast Asians traveled the Pacific by large sailing watercraft to become island populations of Polynesians and Micronesians, retaining their Sundadont pattern. Thus, all around the Pacific basin, there are three distinctive dental morphological patterns: proto-Sundadonty (Sahulland: Australia and Melanesia), Sundadonty (Sundaland: mainland and island Southeast Asia; island East Asia), and Sinodonty (Sino-America). At least 50,000 years are involved in the evolution of this Asian-Pacific dental patterning. In terms of time involving only several thousands of years, these patterns are evolutionarily quite stable and remarkably consistent in ethnically related groups living in strongly dissimilar ecological settings. Such demonstrable stability is part of what makes dental morphology eminently useful for evaluating long-term diachronic and synchronic affinities, population origins, and microevolutionary processes.

New World Arctic and Subarctic Dental Variation

While all New World teeth conform to the Sinodont dental pattern, first defined on the basis of prehistoric Chinese teeth, those of Arctic and Subarctic Eskimos, Aleuts, and speakers of Na-Dene languages differ slightly from those of Macro-Indians (Scott and Turner 1997, 2008). For example, pronounced upper incisor shoveling is less frequent in Eskimos and Aleuts than it is in Macro-Indians. It tends to be intermediate in Subarctic Indians. Eskimos and Aleuts have greater frequencies of three-rooted lower first molars than do Macro-Indians, while western Subarctic tribes are intermediate. When the three New World groups – (1) American Arctic, (2) Northwest North America, and (3) North and South America – were graphed for mean trait frequencies and standard errors of 23 crown and root traits, ten of the traits show the intermediate nature of Northwest North America, viz., Eskimo-Aleuts and American Indians in general, while 11 traits showed similar frequencies across the three groups (Scott and Turner 1997). The only two traits that failed to exhibit intermediary or similarity were incisor interruption grooves and odontomes, but the differences were not dramatic in either instance. The intermediacy of Northwest North American natives was addressed by Scott and Turner (2008) who suggest it is likely due to ancient gene flow between groups ancestral to modern Na-Dene and Algonquian speakers.

Multivariate and univariate analyses and comparisons show that all New World groups are dentally more like Northeast Asians than any other major geographic group in the world. Nevertheless, the teeth of New World Arctic and Subarctic peoples are generally more like those of Northeast Asians than are the Macro-Indian populations, which, as archaeological evidence suggests, means that the Macro-Indian colonization occurred before or separated from that of the modern Arctic and Subarctic populations. It has been inferred that the concordances between New World archaeological groups and biological populations likely are big-game hunting Clovis fluted point makers = Paleo-Indian Sinodonts; smaller-game hunting Paleo-Arctic biface and microblade makers = Na-Dene/Greater Northwest Coast Sinodonts; and Maritime Anangula blade makers = Aleut-Eskimo

Sinodonts. What holds these concordances together are their individual geographic distributions for artifact types, dental divisions, and language families.

Macro-Indian Dental Variation

Comparative analyses of Native American dentitions by Haeussler and Turner (1992), Hanihara (1979), Perzigian (1984), Powell (1993), Scott (1973, 1991), Scott et al. (1983, 1988), and Turner (1983, 1985, 1986, 1990a, 1992a, b, 1993, 2002), as well as contemporary genetic studies by Callegari-Jacques et al. (1993), Cavalli-Sforza et al. (1988, 1994), Horai et al. (1991), Laughlin and Harper (1988), Stone and Stoneking (1993), Szathmary (1979, 1993), Torroni et al. (1992), and others reviewed herein, and most osteological studies by Alekseev (1979), Kozintsev (1995), Steele and Powell (1992), and Brace et al. (2001) are in good agreement that the ancestors of Native Americans originated in Northeast Asia. However, a few osteological studies are not in full accord with this general inference. Howells' (1989) worldwide craniometric analyses showed male Peruvians and Californians clustering with males from Europe, while his male Arikara Indians clustered with male New Zealand Moriori. Neves and Pucciarelli (1991) argued on multivariate grounds that early South American crania are morphometrically closer to Australians even though their principal component plots show early South Americans equally similar to East Asians and Europeans. Owsley (2013) analyzed Paleo-Indian skulls from the Americas and found they were most similar to and clustered with recent Polynesians. Inasmuch as archaeology (West 1981, 1990; Dillehay and Meltzer 1991; Stanford and Day 1992; Meltzer 1993), linguistics (Greenberg et al. 1986; Greenberg 1990; Greenberg and Ruhlen 1992), and paleo- and neo-geography (Hopkins 1982; Laukhin 1997), as well as dentition, genetics, and most osteology, strongly support a Northeast Asian origin for all Native Americans, the cited craniometric studies are notable exceptions to the Northeast Asian-American anthropological and other correspondences as well as the Sino-American dental correspondences (Scott and Turner 1997). Nevertheless, in recent years there has been a concerted effort to resuscitate the notion of a pre-Clovis occupation of the Americas (Hall 2000; many papers in Graf et al. 2013).

A Brief History of the Pre-Clovis Revival as It Bears on Dental Variation

There has long been disagreement between Americanist scholars who line up with the late Aleš Hrdlička (1925) by arguing that the colonization of the New World was late compared to the amount of human evolution in the Old World, in contrast to scholars who believe there is evidence for much older human occupation in the New World. For example, Krieger (1964) (pre-projectile occupation), Carter (1957) (very ancient occupation), Müller-Beck (1967) (Mousteroid element in Americas), and others posit very early migrations (>20,000 BP) of peoples from the Old to the New World. There have been any number of archaeological claims for pre-Clovis occupation of the New World, but as Meltzer (1993) noted, the claims usually have a "shelf life" of about 5 years. Among modern physical anthropologists, several revivalists of the pre-Clovis and/or non-Mongoloid origins include Neves and Pucciarelli (1991, and several similar articles), Crawford (1992), Lahr and Haydenblit (1995), Steele and Powell (1992), and Owsley (2013).

Lahr and Haydenblit (1995) proposed that Sundadonty was present in a series of South American crania from Patagonia and Tierra del Fuego. In a lengthy review article, Lahr (1995) proposed that either Sinodonty evolved in parallel in Asia and the Americas or there were two migrations ancestral to Native Americans, i.e., a Sundadont group followed by a Sinodont group. Based on a dental morphological analysis of Peruvian and Chilean samples, Sutter (2004) arrived at a similar conclusion. He notes that older samples exhibit dental morphology more in line with the simplified Sundadont pattern, while later groups exhibit the more complex features associated with Sinodonty.

These proposals are inconsistent with dental observations on South Americans. The senior author has never observed a South American series or individual skull that could be considered as having the Sundadont pattern. This includes the Lagoa Santa remains housed in Brazil and those curated in Denmark, as well as Archaic samples from coastal Brazil, Chile, Ecuador, and Peru. The observations of Lahr and Haydenblit on degree of trait expression may have been impacted by dental attrition. Wear most likely caused the underscoring of crown traits that led them to propose the presence of Sundadonty (Burnett et al. 1998). Tooth wear might also have misled Powell and his associates in their observations on small Paleo-Indian samples. The observation of Stojanowski et al. (2013) that some South American samples exhibit root trait frequencies that would not be impacted by crown wear and yet are in line with the Sundadont pattern has not been fully evaluated.

When Steele and Powell (1997) evaluated craniometric data of two ancient skulls from Nevada (Spirit Cave, Pyramid Lake) that dated ca. 9,500 BP, they found that they failed to cluster with any of 22 comparative modern populations. They felt the skulls were more closely aligned with South Asian, Pacific, and Australian populations than with North Asian and recent North American Indians. They concluded that "the studied Paleoindians arrived in the Americas prior to the establishment of the crania shape that is distinctive of recent Northern Asians and North American Indians, and that the colonization of the Americas was more complex than has previously been proposed" (Steele and Powell 1997, p. 218). This contrast was also reported by Jantz and Owsley (2001). Again using craniometric data, they concluded Paleo-Indians were more similar to Polynesians, Europeans, and East Asians than to recent American Indians.

Taken altogether, the form of the Paleo-Indian skull relative to most of the comparative samples is a reflection of not only geogenetic linkages but also sedentism and its related nutritional, growth, health, and activity benefits and stresses. Thus, African samples cluster together (geogenetic linkage) despite both nomadism and sedentism being represented. The same can be said for the European, Northeastern Asian, and Oceanic sets. Given that archaeological remains of Paleo-Indians strongly suggest a nomadic hunting life way, then the cranial differences between Paleo-Indians and recent Native Americans should have been interpreted along economic lines as much as geogenetic. Only in the last sentence of their article do Steele and Powell (1992) remark on the possibility of "adaptational" factors contributing to the cranial differences between Paleo-Indians and recent Native Americans. All but one sentence in this article is clearly aimed at identifying possible "genomic" differences between Paleo-Indians and recent Indians.

It should be noted that Steele and Powell (1992, p. 329) speak of Paleo-Indian crania as not being "classically sinodont in craniofacial appearance. Instead, it differed by appearing as much like modern southern Asians [recall they use this term to refer to Chinese, who have traditionally been classified as Mongoloids] as it did recent North American Indians and northern Asians. In this respect our findings resemble the contentions of previous scholars that the earliest recovered samples were proto-Caucasoid or proto-Mongoloid."

There has never been an analysis carried out to show if there is a relationship between craniofacial morphology and Sinodonty or Sundadonty. Steele and Powell have assumed that vaults, faces, and teeth go together like a hand in a glove. In fact, Sinodonty is found in people whose craniofacial variation includes every shape in South and North America, including robust California Indians, heavy and long-skulled Southwest US Basketmakers, and robust long-headed Archaic crania from Mexico, Brazil, and Chile, to round-headed gracile Southwest Puebloans, Chinese, Japanese, Buriats, and a long list of other long- and round-headed Northeast Asians. As for early Native Americans having been proto-Caucasoids, a notion strongly championed by Birdsell (1951), Harris and Turner (1974) showed that dental morphology was in opposition to such typological thinking.

Genetics and the Peopling of the New World

During the first half of the twentieth century, scholars who investigated issues relating to the settlement of the New World came primarily from archaeology and skeletal biology. During the past 50 years, genetic data have played an increasingly important role in debates on Native American population history. Researchers have applied three different kinds of genetic data to the problem. Initially, focus was on nuclear genetic markers, from red blood cell antigens and serum proteins to red cell enzymes, immunoglobulins, and white blood cell antigens (cf. Mourant 1954; Mourant et al. 1976; Roychoudhury and Nei 1988; Cavalli-Sforza et al. 1994). In the 1980s, a new and different type of genetic marker was used, one derived from the single-stranded DNA of the mitochondria (mtDNA) which was transmitted, with but few exceptions, through maternal lineages (for reviews, see Cann 1988; Long 1993). Finally, in the 1990s, the Y chromosome was sequenced and a surprising variety of interesting polymorphisms emerged (cf. Hammer and Zegura 2002; Jobling et al. 2004).

The literature in the field has expanded at an exponential rate during the past two decades. It is beyond the scope of this review to provide a detailed synthesis of genetic studies. The goal is to highlight some of the results from the three different sorts of genetic data to determine the extent to which the analyses of synchronic genetic data correspond with peopling models based on diachronic dental data.

Nuclear Markers

Around 1950, the nascent field of human genetics started to weigh in on the issue of Native American origins. On that date, W.C. Boyd published his seminal work *Genetics and the Races of Man*. Therein, he utilized available data on three red cell antigen systems (ABO, Rh, MN) to set up a classification of modern human groups. He deemed Native Americans to be sufficiently distinct from other groups to warrant their own racial category. In this regard, he noted that Indians lacked the "r" allele of the Rh system and the A^2 and B alleles of the ABO system, although Eskimos did have a low frequency of B. Indians also showed a relatively high frequency of the M allele and a marked dichotomy in frequencies of the A and O alleles of the ABO system. Populations south of the US-Mexico border showed essentially 100 % O alleles, while some North American groups, in particular Algonquians, Athapaskans, and Eskimo-Aleuts, exhibited high frequencies of the A allele. While similarities to Asian populations were noted (lack of r and A^2), Boyd felt that the high frequency of the M allele and the very low frequency of B were sufficient to distinguish Asian and American "races."

Laughlin (1951) used blood group data along with anthropometric and osteometric comparisons to assess the affinities of Aleut populations. He felt the presence of the B allele indicated Aleuts were closer to Eskimos than Indians. Moreover, he noted that the "B present in the Eskimos is an indication of their recent Asiatic heritage" (Laughlin 1951, p. 119). Throughout his career, Laughlin (1963, 1966) adhered to the notion that there were two major groups in the Americas – American Indians and Aleut-Eskimos. After comparing Native Americans to Siberians for allele frequencies on the ABO and MN systems, Laughlin (1966, p. 473) opined that the "essential affinity of the Eskimo-Aleut stock with Asiatic Mongoloids, rather than with American Indians, is well attested."

With the development of starch gel electrophoresis in the early 1950s, there was a dramatic increase in the number of genetic surveys across the Americas and throughout the world and in the number of genetic systems that became standard markers for population profiles. By the 1970s, the original three RBC antigen standards were complemented by the addition of many more antigen systems and serum proteins (e.g., Diego, P, Duffy, Kell, Kidd, Haptoglobin, Transferrin, Albumin, etc.). By the time of their massive worldwide synthesis, Cavalli-Sforza et al. (1994) were able to tabulate data on 120 nuclear alleles.

Beginning in the 1970s, Szathmary (1979, 1981, 1993, and elsewhere) played an important role in making inferences on long-term population history based on the analysis of Native American gene frequency profiles. One of her early efforts, prepared with Nancy Ossenberg, had the eye-catching title "Are the Biological Differences Between Eskimos and North American Indians Truly Profound?" (Szathmary and Ossenberg 1978). This paper developed the position that Indians and Eskimos were not as distinct as many scholars had presumed (cf. Laughlin 1963, 1966), even suggesting that the two groups might have differentiated from a common stock after their arrival in the New World. Until this time, authors had disagreed on the number of possible migrations to the New World, but the consensus was that the ancestors of Aleut-Eskimos constituted not only a separate migration but the last major migration across the Bering Strait. While the arguments and analysis in these works are interesting, Szathmary limited her comparisons between Aleut-Eskimos and northern Indians of the American Subarctic, to wit Athapaskans in the west and Algonquians in the east. It is now well established that these northern groups are more similar to Eskimo-Aleuts than Indian groups from Mesoamerica, Central America, and South America (cf. Schanfield 1992; Cavalli-Sforza et al. 1994).

Authors who focus on GM allotypes have proposed different migration scenarios to account for variation in immunoglobulin genetic variants. Williams et al. (1985) observed that $Gm^{1;21}$ was present in "Paleo-Indians," Na-Dene, and Eskimo-Aleut samples, while $Gm^{1,2;21}$ was absent in Eskimo-Aleuts and $Gm^{1;11,13}$ was absent in Paleo-Indians. Na-Dene speakers had all three allotypes. This observation led the authors to conclude that Gm data supported the three-wave model of Greenberg et al. (1986) for peopling of the New World.

Also focusing on immunoglobulins, Schanfield (1992) pointed out that the work of both Szathmary (1993) and Williams et al. (1985) provided only a limited picture given their emphasis on North American native populations. When Schanfield synthesized Gm data from both North and South American populations, he found South Americans differed consistently from non-Na-Dene North American Indians, Na-Dene speakers, and Eskimo-Aleuts. He feels his data suggest that "in the peopling of the New World, at least four separate migrant groups crossed Beringia at various times" (Schanfield 1992, p. 381). He further suggested that the ancestors of South American Indians arrived before 17,000 BP while North American Indians arrived when the ice-free corridor opened up at the end of the Pleistocene. Both Eskimo-Aleuts and Na-Dene groups are thought to be later Holocene arrivals.

A grand synthesis of patterns of variation in nuclear genetic markers was accomplished by Cavalli-Sforza et al. (1994) in *The History and Geography of Human Genes*. This worldwide analysis of 120 markers in over 40 genetic systems devoted entire chapters to populations in each major geographic region, including a chapter on the Americas. To maximize the availability of genetic data across as many loci as possible, the authors combined data sets and came up with 23 New World groups, defined primarily on linguistic grounds. Importantly, the analysis included several Eskimo, Na-Dene, Siberian, North American, and South American groupings. After conducting a variety of distance analyses and two- and three-dimensional ordinations, Cavalli-Sforza et al. (1994, pp. 340–341) concluded:

> The genetic patterns in the Americas fully confirm the three waves of migration suggested by dental and linguistic evidence: Amerinds, Na-Dene, and Eskimo. Their order in time is strongly suggested by their north-south geographical order. Further refinements may reveal that more than one entry contributed to the first wave, but the archeological information is contradictory and our understanding of the genetic pattern of Amerinds is incomplete, so that further investigations are required to settle this problem.

Going well beyond classic nuclear markers, Reich et al. (2012) addressed the issue of origins through the analysis of 364,470 single-nucleotide polymorphisms in 52 Native American, 17 Siberian, and 57 "other" populations. They found evidence for three migration streams into the New World. The initial stream, which they call "First Americans," is comprised of American Indians from South America, Central America, Mesoamerica, and a few groups near the US-Mexican border. The second stream is "Eskimo-Aleut." Significantly, Greenland Eskimos and Aleuts cluster with Northeast Siberians, in line with earlier results on genetic markers and dental morphology. The third stream is represented by a single Chipewyan (Na-Dene) sample; this group also clusters with Algonquians of the eastern Subarctic, a point also made by Scott and Turner (2006). Reich et al. (2012, p. 373) suggest their results "are consistent with a three-wave model proposed mostly on the basis of dental morphology and a controversial interpretation of the linguistic data." Despite defining three distinct migration streams, they note that the second and third streams (i.e., Eskimo-Aleut, Na-Dene) are strongly admixed with First Americans. Despite this caveat, this meta-analysis supports what has long been contended on the basis of dental morphology; that is, Macro-Indians (or First Americans) from North, Central, and South America show homogeneity supporting a relatively recent common ancestor, with no evidence to suggest a second and separate ancestor for South American Indians. The analysis also revealed that Eskimo-Aleuts and Na-Dene-Algonquian represent two additional movements into the New World, a finding that is not totally obscured by later admixture with First American populations. Just as many are disparaging the three-wave model for the peopling of the Americas (cf. Stojanowski et al. 2013), Reich et al. (2012) step forward with evidence suggesting there is still life in the "dusty proposal" put forward by Greenberg et al. (1986) almost 30 years ago.

Mitochondrial DNA

When geneticists first discovered that mutationally induced variation in mitochondrial DNA (mtDNA) might help unravel human evolutionary history, there were severe sampling limitations. To harvest enough mtDNA for analysis, researchers had to collect human placentas, often a formidable task. The development of PCR (polymerase chain reaction) techniques in the early 1990s allowed researchers to obtain mtDNA samples from many kinds of tissue samples, including bone.

This development revolutionized the study of mtDNA, and research teams quickly pursued historical questions on every continent, among both living and earlier human populations.

Although mtDNA variation has been evaluated in groups throughout the world, the geographic region that has received an inordinate amount of attention is the New World. Because of sampling limitations, the early studies were regional in scope (Ward et al. 1991, 1993; Shields et al. 1992, 1993). With improved methods, expanding sample sizes, and cooperation among research teams, groups eventually addressed bigger issues regarding the internal differentiation of New World populations and dispersal dates from ancestral Asian populations (Wallace and Torroni 1992; Torroni et al. 1993, 1994; Forster et al. 1996; Malhi et al. 2002; Eshleman et al. 2003).

Mitochondrial DNA variation is studied through a combination of restriction fragment length polymorphisms (RFLPs) and direct nucleotide sequencing of the relatively short hypervariable control region (HVR-I and II). Haplogroups are distinguished by a combination of RFLPs and HVR-I and HVR-II polymorphisms (Schurr 2004a).

Jobling et al. (2004, p. 291) show the worldwide distribution of the major mtDNA clades, or haplogroups. Of the 27 major clades shown (lettered A to Z), New World populations exhibit the presence of only five haplogroups – A, B, C, D, and X. Numerous articles have been devoted to the issues of (1) how these haplogroups vary within and among Native American populations, (2) whether or not they were brought by separate founding groups or differentiated after arrival in the New World, and (3) the time depth for the origin of each haplogroup.

Regarding mtDNA haplogroup variation, North, Central, and South American Indians (Amerinds) all exhibit haplogroups A, B, C, and D. Eskimo-Aleuts, by contrast, have essentially no B and very little C (Schurr 2004a). Athapaskans were initially thought to lack the B haplogroup (Lorenz and Smith 1994), but it now appears to be present but infrequent in Na-Dene-speaking groups. Haplogroup X is limited to northern North American Indians from the Northwest Coast and Subarctic culture areas (Brown et al. 1998).

While the pattern of mtDNA haplogroup variation is coming into focus, opinions on the meaning of this variation have yet to reach a consensus. Some early studies favored the notion that the haplogroups indicated four separate migrations into the New World (Schurr et al. 1990; Horai et al. 1993; Lorenz and Smith 1996). Torroni et al. (1994) concluded there were three migrations: two Amerind migrations, with an early dispersal of A, C, and D, and a later migration that involved the B haplogroup. Athapaskans, with an exceptionally high frequency of the A haplogroups, were thought to constitute a third migration. Starikovskaya et al. (1998) also believed there was an early migration that carried the A, C, and D haplogroups with a later migration bringing B. Although there are several proponents of multiple migrations, the majority of researchers contend that the mitochondrial DNA variation evident among all Native Americans is best explained by a single migration event with haplogroup differentiation occurring after arrival in the Americas (Merriwether 1995, 2002; Kolman et al. 1996; Merriwether et al. 1996; Bonatto and Salzano 1997; Malhi et al. 2002; Silva et al. 2002).

From the outset, geneticists have argued that mtDNA is useful not only for describing patterns of variation but also for estimating times of divergence on a branching tree. Using either coalescence or distance methods of estimation in conjunction with several assumed mutation rates, most researchers addressing the issue of the initial New World settlement have arrived at very old dates for this event (Schurr 2004b). Several authors contend the first wave of migrants arrived in the Americas more than 30,000 years ago (Bonatto and Salzano 1997; Starikovskaya et al. 1998). Other workers give dispersal estimates of between 20000 and 30,000 BP (Torroni et al. 1994; Silva et al. 2002). Starikovskaya et al. (1998) dated early Amerinds at 34,000–26,000 BP with a later migration at 16,000–13,000 BP. Torroni et al. (1994) tried to come up with an estimate that agreed with either an early entry date (30,000+ BP) or a late entry date (ca. 13,000 BP) compatible with the Clovis-first model. Instead of coming down on one side or the other of this debate, their estimate fell in the middle with a range of 22,000–29,000 years ago.

Despite differing opinions on the numbers of migrations and times of dispersal, mtDNA geneticists are in fundamental agreement that Native American haplogroups are of Siberian origin. Torroni et al. (1994, p. 1162) reflect the sentiments of many when they say "We accept that all significant human entry into the Americas was by way of Siberia during periods of glaciation, when a land bridge connected Siberia and the extreme northwest of the Americas." When haplogroup X was discovered in American Indians, this was initially thought to represent a possible migration from Europe, or at least some founding Amerinds had Caucasian ancestry (Brown et al. 1998). If so, why is there no haplogroup H in Native Americans, as this is far more common in Europeans (ca. 40 %) than haplogroup X (ca. 2 %) (Schurr 2004a)? An alternative to a direct trans-Atlantic migration of X-bearing Europeans was developed by Reidla et al. (2003) who feel that haplogroup X represents a fifth rare mtDNA clade that came into the Americas across Eurasia, originating as far west as the Near East (Reidla et al. 2003). Finally, there are no haplogroups that link modern or ancient Americans to Southeast Asian or South Pacific populations, a population source for early Americans favored by some osteologists (Neves and Pucciarelli 1991; Steele and Powell 1992, 1997; Powell and Neves 1999).

Taking a somewhat unconventional approach, Perego et al. (2009) addressed the issue of migration routes into the Americas through the analysis of two rare mtDNA haplogroups: D4h3 and X2a. The distribution of D4h3 is primarily along the Pacific coast, with most samples coming from South America but also some from Mexico and California. With but one exception, this haplogroup is limited to the Americas but the exception is interesting. One individual from eastern China had the D4h3 haplogroup and control-region motif of 16301–16343 comparable to that in Native Americans. The senior author has long contended that China was a possible geographic source for Native Americans and this one small puzzle piece supports that position. The other haplogroup, X2a, is found exclusively in the Great Lakes region, Great Plains, and western Canada. It has been found only in the Americas. Perego et al. (2009) feel the divergence times for these two haplogroups was almost coincident at around 16,000 BP. Whether it happened before or after entry into the New World is not clear. The distribution of the two haplogroups suggests that the ancestral groups may have entered the New World along two different paths: D4h3 along the Pacific coast and X2a following an interior route (O'Rourke 2009).

A combination of archaeology and genetic variation has led researchers to develop a Beringian Standstill model (Tamm et al. 2007). Although sites in Alaska do not go back beyond the late Pleistocene, Pitulko and his colleagues (2013) have excavated the Yana Rhinoceros Horn site in northern Siberia that goes back 30,000 BP. The abundant material and zoological remains at this site show that people were well adapted to the rigors of an Arctic environment during the early Upper Paleolithic. In conjunction with genetic diversity that is unique to Native Americans, the Yana site raises the possibility that groups could have entered Beringia at least 30,000 BP but could not move further into the Americas because of major physiographic barriers (i.e., ice sheets, glaciers). During the standstill (also called Beringian incubation model), the Asian progenitors of Native Americans had ample temporal and spatial opportunity to differentiate within the broad confines of Beringia. When environmental conditions improved around 15,000 BP, populations could disperse south along a Pacific coastal route and/or via an interior corridor and carry their genetic differences with them.

Y Chromosome

As a complement to mtDNA, recent genetic studies that focus on the settlement of the Americas are evaluating recently discovered polymorphisms on the Y chromosome. The long neglected Y, whose strict paternal transmission complements the maternal transmission of mitochondrial DNA, exhibits two major types of polymorphisms on the nonrecombining segment (NRY) of the chromosome. First, there are point mutations that result in single-nucleotide polymorphisms (SNPs). The mutation rates for these polymorphisms are slower than for the second type of polymorphism – short tandem repeats (STRs). Taken together, researchers use SNPs and STRs to define a diverse array of haplogroups and haplotypes. As with mtDNA, Y chromosome polymorphisms have been used to estimate the number of migrations, the timing of dispersal of populations to the Americas, and the Old World sources for this peopling event.

Evolving and diverse nomenclatural systems applied to Y polymorphisms make the literature on this system difficult to decode for nonspecialists. To allay confusion, workers convened a consortium in 2001 to develop a common set of standardized terms for Y chromosome binary haplogroups (Y Chromosome Consortium 2002; Hammer and Zegura 2002). Based on this new system, it appears that most Native Americans exhibit haplogroup Q, an observation that led some workers to conclude that a single founding male lineage is sufficient to account for the ancestry of all Native Americans (Tarazona-Santos and Santos 2002; Jobling et al. 2004). Haplogroup Q is, however, defined on the basis of several distinct SNPs and

STRs, which other workers have interpreted as indications of multiple migrations from Asia. Lell et al. (2002) suggest that the Q-M3 and P-M45a Y haplogroups dispersed eastward from central Siberia along with the C and D haplogroups of mtDNA. Moreover, these authors feel that the haplogroups P-M45b and RSP4Y came from south Siberia along with a subgroup of the A haplogroup of mtDNA (control-region sequence variant 16192T and the *Rsa*I polymorphism at np16392). Karafet et al. (1999) and Ruiz-Linares et al. (1999) also conclude there were at least two founding Y haplogroups in the Americas.

Regarding the timing of dispersal, most estimates for arrival in the New World favor the long chronology (cf. Schurr 2004b). For their two migrations, Lell et al. (2002) estimate the first wave arrived in the New World ca. 20,000–30,000 BP with the second wave arriving much later, ca. 7,000–9,500 years ago. In contrast to those who see great time depth for Y haplogroups in the Americas, Seielstad et al. (2003) attempted to set an upper limit for initial entry into the New World based on a mutation (M242) that occurred just before the arrival of populations in the New World. Using a mutation rate of 0.18 % per generation, the authors estimated that M242 arose around 15,000 BP. These workers, who consider 18,000 an upper limit for New World settlement, thus favor an entry into the New World that followed, rather than preceded, the Last Glacial Maximum.

Macro-Indian Dental Variation

Now that contrasting models for the peopling of the New World from skeletal biology and genetics have been briefly reviewed, the case that can be made from tooth crown and root morphology will be presented in more detail. Table 1 lists the archaeologically derived Indian series used in this chapter. Altogether 3,584 individuals are represented in 17 North American groups and 11 South American groups. All the data in Table 1 were collected by the senior author. A key set of 29 largely independent, normal, age- and sex-free crown and root traits were scored for occurrence and expression using the Arizona State University dental anthropology system (Turner et al. 1991). An overwhelming number of individuals are pre-Columbian in age. Hence, there is little chance for European, African, or Oceanic admixture in this Pan-American assemblage, whose chronometric ages range from protohistoric to late Paleo-Indian. Although the exact modes of inheritance are still under investigation for these and other dental traits, it is believed that each has a substantial genetic component for occurrence and expression (Scott 1973; Harris 1977; Berry 1978; Scott and Turner 1988, 1997; Nichol 1990).

Space limitations permit reviewing only a few of the 29 traits, so mainly those that distinguish Northeast Asian Sinodonty from Southeast Asian Sundadonty are presented (Turner 1983, 1987, 1990a). Figures 1 and 2 illustrate five of these traits – incisor shoveling, double shoveling, *tuberculum dentale*, and first and second lower molar root number

Fig. 1 *Arrow 1* indicates right upper central incisor shoveling trait in a female skull from prehistoric Alabama site Lu25–425. *Arrow 2* points to double shoveling. Not discussed in this report, but one of the key traits used in the multivariate analysis, *arrow 3* points to canine *tuberculum dentale* (CGT neg. no. 6-6-80:19)

Fig. 2 *Arrow 1* indicates left lower first molar with two roots in prehistoric Peruvian male from a cemetery in the Chicama Valley. Had there been a supernumerary third root, it would be out of view on the distolingual aspect. Not discussed in this report, but one of the key traits, *arrow 2* points to a one-rooted lower second molar (CGT neg. no.7-3-80:7. Reprinted courtesy of Dental Anthropology Newsletter)

Findings

American Indian dental morphological variation, assessed against the background of archaeological and linguistic information, led to the following generalizations:

1. There are three dental clusters of Macro-Indians: North America, South America, and an interregionally convergent group.
2. Dental variation is relatively low among Macro-Indians.
3. The Macro-Indian dental divisions arose by local evolution.
4. South America was colonized soon after North America.
5. Individual dental trait frequencies show only random variation.
6. Only Northeast Asian Sinodonty is present in the New World.
7. Dental variation supports the Clovis/epi-Clovis prehistory and Greenberg language migration models.

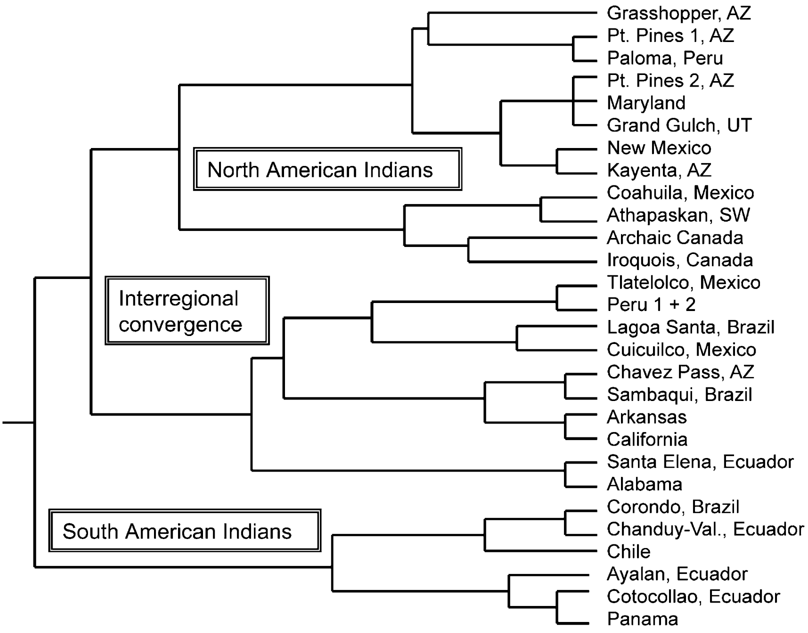

Fig. 3 Dendrogram of North and South American pre-Columbian dental relationships based on mean measures of divergence clustered with Ward's method, 29 dental traits. Computer reference: North and South America

Three dental clusters: Figure 3 is a dendrogram computed with Ward's clustering method for the 106 possible pairwise mean measures of divergence, a multivariate similarity/dissimilarity statistic developed by C.A.B. Smith (Berry and Berry 1967) with widely used adjustments for sample size and determination of statistical significance (references in Turner 1985). There are three primary dental groups: North America (at the top), South America (at the bottom), and a middle group that shows interregional convergence.

The Paloma sample is surely a misclassification attributable to chance. Some interregional convergence is expected given that dental microevolution (in the sense of gene frequency changes) is probably best explained as caused largely because of random changes due to founder's effect, population structure, and local genetic drift. There is no archaeological or other evidence to believe, for example, that the Ecuadorian Santa Elena series is similar to the Alabama sample because of ancestry closer than to each sample's respective regional relationships. Instead, the Santa Elena-Alabama similarity is most likely an example of the occasional convergences that should be expected if Macro-Indian dental evolution was mainly due to chance, not selection or gene flow. As will be discussed below, the relatively low amount of variation, despite the two main North and South American clusters, is not supportive of multiple Paleo-Indian migrations.

Low dental variation: Inspection of Table 1 reveals a low amount of trait frequency variation between the 29 groups relative to that in, say, eastern Asia or even New World Arctic people (Turner 1991). This limited New World Indian dental divergence is probably what causes the rather limited "treeness" of the dendrogram in Fig. 3. This suggests either substantial gene flow throughout the Americas or a relatively recent colonization of the Americas with only minor in situ dental differentiation. Excellent "treeness" has been obtained throughout the New World (Arctic, Subarctic, non-Arctic) with these same dental traits and statistical methods (Turner 1987). Table 1 shows that upper central incisor shoveling and lower first molar root number have very different overall frequencies in the New World. The former is a high frequency trait, and the latter, a low frequency trait. Scott (1973) demonstrated that trait frequency was positively correlated with trait expression in the offspring of specific mating types, providing strong evidence for polygenic inheritance. As can be seen, shoveling is universally high (>70 %) among the groups, whereas three-rooted lower first molars are uniformly at a low frequency, averaging about 6 %. Both traits have little variation within and between North and South America. These two traits, like the other 27, show no sign of clinal variation from north to south, east to west, coastal to interior, or low to high elevation. Trait frequencies have no identifiable gross environmental correlates in the New or Old World that would suggest the effects of short-term natural selection.

Dental divisions arose by local evolution: Table 1 also lists the North and South American means and ranges for eight traits, seven of which distinguish Sinodonty from Sundadonty, plus a trait found almost exclusively in Native Americans – the Uto-Aztecan premolar. The tabulation shows that there are no statistically significant differences in some traits and very little in all others except the enamel extension, between pre-Columbian North and South American Indians. None of these traits has a north-south mean difference greater than 6 % (enamel extensions). There is no tendency to exhibit less "Mongolization" or Sinodonty in South America than in North America, that is, there is no evidence for Sundadonty. The differences between the means appear to be mainly random. What little difference there is between North and South America is better interpreted as due to postcolonization local evolution rather than to pre-differentiated multiple migrations. Moreover, the archaeology, craniology, and odontology the senior author has personally seen and read about in Russian sources for eastern Siberia do not provide any cultural or biological basis for hypothesizing markedly differentiated source populations in Primorye, Chukotka, trans-Baikalia, or Yakutia. However, the fact that these Siberian geographic districts and their pre-Russian cultures are recognizable today and prehistorically could mean that they were also distinctive even earlier in Late Pleistocene times as well and would have served as incubator habitats for some amount of pre-Beringian biocultural and linguistic differentiation.

No genetic bottlenecking at Panama: Because there are few dental differences between North and South American Indians relative to even smaller area of eastern Asia, it would appear that there was no meaningful Paleo-Indian genetic bottlenecking in Panama. The size of the Paleo-Indian population wave that advanced through the isthmus was large enough to contain a representative sample of the North American Indian dental gene pool. A trait-by-trait comparison of presumed North and South American Paleo-Indians (Turner 1992a) turns up no differences greater than the within-continent range of trait occurrence. However, as is well known from various studies of blood group and DNA markers (Spuhler 1979; Szathmary 1979; Shields et al. 1992), the initial Paleo-Indian gene pool probably did not contain a representative sample of Chukotka genes, let alone Pan-Northeast Asian genes. For example, allele B of the ABO system was seemingly not carried across the Bering land bridge by Paleo-Indian colonists, and the three-rooted lower first molar gene(s) was carried by only a small proportion of the first Beringian migrants.

South America colonized soon after North America: In 1976, MacNeish suggested that North America was populated for some 100,000 years, while South America had been inhabited for only 25,000 years. Had this been the actual occupational history of the New World and if continuous occupation and regular postcolonization dental microevolution are assumed (Turner 1986), then the North American samples should have exhibited in Fig. 3, on the basis of time alone, about fourfold more internal dental divergence than do the samples from South America. That is, the secondary branching in North America should be much further to the left compared with South America. The dendrogram provides no support for unequal evolutionary time in North and South America, nor do the individual trait values in Table 1. Admittedly, variation in the rate of dental microevolution, connected as it must be to population structure, size, and demography, does not allow precise estimates of separation between branching populations, in this case North and South America. However, claims for 25,000–30,000 years of South American occupation are certainly pushing the envelope of credibility on the basis of both New World and Old World dental evolutionary considerations and most archaeological evidence (Lynch 1991; Haynes 2002a; Fiedel 2004). In the Old World, it is a question of the antiquity of Sinodonty, which may date to around the age for Upper Cave Zhoukoudian, sometime between 11,000 and 30,000 years BP (Chen et al. 1992).

Individual dental trait frequencies show only random variation: Comparisons of the means for North and South American dental trait frequencies (Table 1) show no identifiable trends that could be attributed to multiple migrations, differential geographic selection, or some other type of localized natural selection directly affecting teeth. While these samples are not ideal for rigorously assessing the likelihood of selection pressure, the more obvious correlates are absent. Hence, the dental samples of the South American Pacific coastal populations of Chanduy-Valdivia, Santa Elena, Paloma, Peru, and Chile are not especially similar according to the analysis in Fig. 3. These groups might be relatively similar due to some form of coastal environmental selection, but if this were so, then they should have also incorporated the coastal Sambaqui of Brazil. Samples from upland environments are not any better correlated than the coastal groups. Mountain-plateau-originating Grasshopper and Point of Pines 1 are linked to coastal Peru. Mountain-located Cotocollao clusters with coastal-lowland Panama. High rainfall and tropical coast Sambaqui folk are linked to low rainfall Arizona plateau Chavez Pass. The two long-lasting deep-winter Archaic Canada and Iroquois samples are joined, but their link with Coahuila from the cool winter high desert of northern Mexico does not suggest cold selection. Only city-state organization versus non-city-state seems to be a source of possible selection. Thus, Tlatelolco, a late and large central Mexican Aztec metropolis, clusters with the similarly developed Peruvian samples. Their clustering together may be the result of oral and other disease selection associated with agricultural economies and highly processed cereal and tuber foods. However, if caries selection had been responsible, then city-state-level Tlatelolco and Peru should have higher frequencies of simpler and potentially more caries-resistant teeth, such as 4-cusped lower second molars, less shoveling, and fewer first molar cusps 6, which is not the case for either sample. Still, disease selection requires further study with respect to dental morphology because caries are rare in hunters and gatherers but are very common among agriculturalists.

Only Sinodonty is present in the New World.

Shoveling: Figure 4 illustrates upper central incisor shoveling. Tables 1 and 2 show crown and root trait frequencies within the Americas, eastern Asia, Melanesia, Australia, and western Europe. Shoveling is very common throughout the Americas and in Northeast Asia. There is no significant difference in the shoveling frequencies of North America (91.7 %) and South America (91.9 %). It is less common in Southeast Asia and Australia, much less so in Melanesia, and very rare in western Europe. This trait alone shows that Paleo-Indians more likely originated in the north China-Mongolia gene pool than in those of the other areas. That gene pool, in turn, had to have had its morphogenetic origin in the Sundadont dental pattern of Southeast Asia and South China – the closest dental pattern in the world

to Sinodonty. Clearly, Paleo-Indians did not originate in Europe, Oceania, or Southeast Asia according to the distribution of the incisor shoveling genes. The African dental pattern is too different from that of Sinodonty to be considered relevant to Native American origins considerations (Turner 1992b).

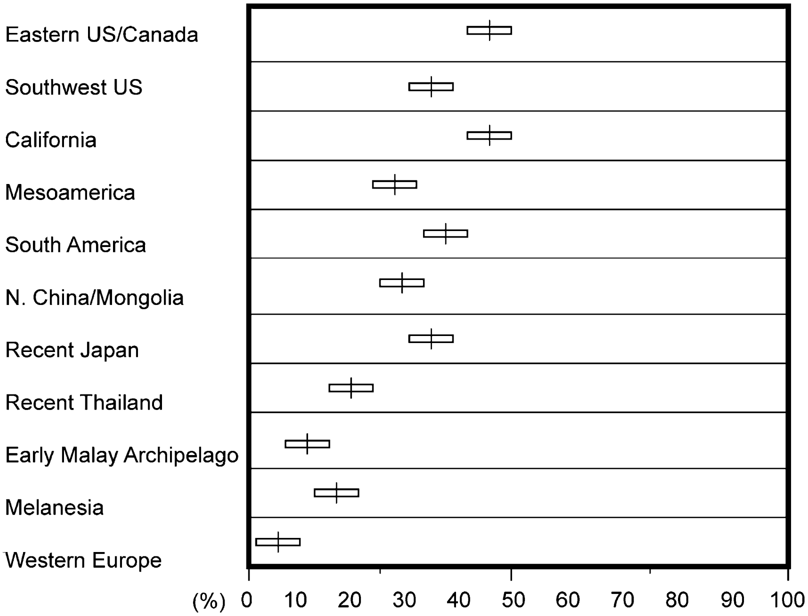

Fig. 5 Circum-Pacific and European frequencies of upper first molar enamel extension

The frequency of shoveling in the earliest North and South American crania is high (ca. 90.1 %) (Turner 1992a, p. 18), nearly identical to that of recent populations (Table 1). This apparent similarity is not what would be expected for the implication that the Kennewick skeleton was not a Sinodont (Powell and Rose 1999), as well as the claim that early South American skeletons were also not Sinodonts (Lahr 1995, p. 163).

Enamel extensions: Figure 5 shows the frequencies for the enamel extension polymorphism, a quasi-continuous trait found on the buccal surface of the upper first permanent molar. While shoveling might conceivably have some minor adaptive value (Mizoguchi 1985), it is difficult to imagine how selection could favor the tiny extension of enamel on the subgingival root surface. In fact, these smooth enamel extensions could have a slightly negative value because they do not provide a porous surface for periodontal tissue attachment, hence favoring the formation of periodontal disease pockets in the adjacent alveolar bone. Enamel extension variation provides essentially the same frequency picture as shoveling; namely, extensions are common in Indians and Northeast Asian Sinodonts, slightly less so in Southeast Asian Sundadonts and very uncommon in Melanesians, Australians, and Europeans.

One-rooted upper first premolar: Figure 6 shows the frequencies for the upper first (P3 in paleontological notation) premolar root number polymorphism, which can have one to three roots. As with the shoveling and enamel extensions, one-rooted upper first premolars are common in Northeast Asian Sinodonts and

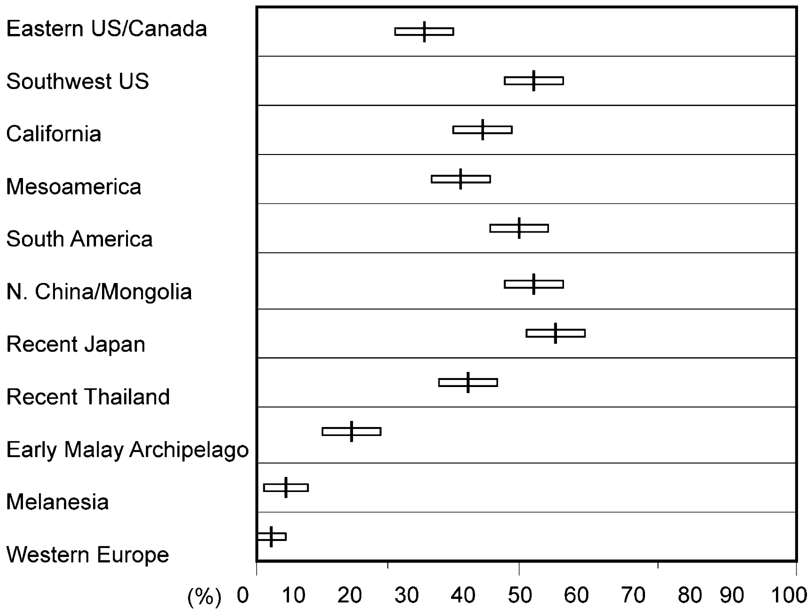

Fig. 6 Circum-Pacific and European frequencies of one-rooted upper first premolars (P3)

all pre-Columbian Indians, less common in Southeast Asian Sundadonts, and slightly less common in Melanesians, Australians, and western Europeans. While there is less continental Old World and South Pacific Islander occurrence of one-rooted upper first premolars, there is nothing in the data to suggest that American Indian ancestry was anything other than from Northeast Asian Sinodonts.

Deflecting wrinkle: Figure 7 shows the frequencies of another tiny secondary trait, the first permanent molar deflecting wrinkle. This polymorphism is the degree of distalward deflection from none to pronounced of the medial ridge of cusp 2 (mesiolingual cusp). This feature has almost no potential for adaptation as it is usually worn off the first molar by the beginning of reproductive age. The deflecting wrinkle is common in pre-Columbian American Indians and Northeast Asian Sinodonts. It is less frequent in Sundadonts and western Europeans. Melanesians and Australians are highly variable for the deflecting wrinkle, and the present Oceanic samples have a substantial frequency, fitting the geographic expectation of an old Southeast Asian origin for the ancestors of Pacific Islanders.

Three-rooted lower first molar: Figure 8 shows the frequencies for the three-rooted lower first permanent molar, another root polymorphism with one to three possible roots. Lower molar and upper premolar root numbers are statistically unrelated morphogenetic features. By far, worldwide, the two-rooted condition is most common for the lower first molar root number. The oldest known example of a three-rooted lower first molar in anatomically modern humans is the 22,000-year-old mandible fragment from the Tabon Caves site on Palawan Island in the western Philippines, excavated by Fox (1970). The fragment has three root sockets at the

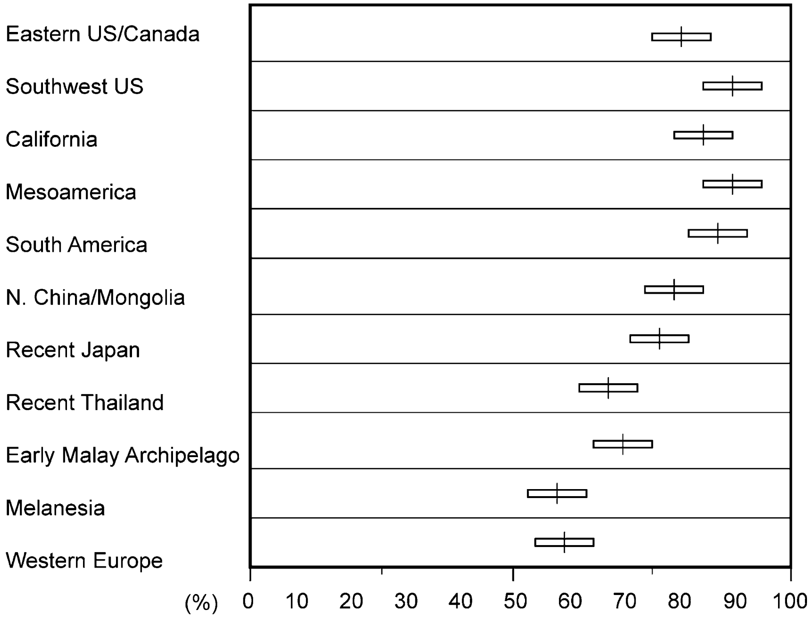

Fig. 7 Circum-Pacific and European frequencies of lower first molar deflecting wrinkle

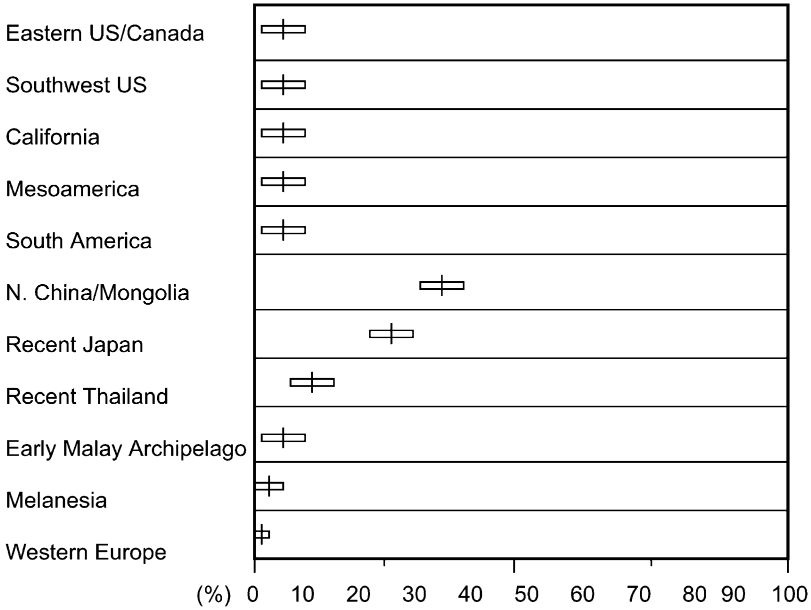

Fig. 8 Circum-Pacific and European frequencies of three-rooted lower first molars

first molar location. Three-rooted lower first molars are a Sinodont characteristic, but, like the missing B allele in living American Indians, Paleo-Indian colonists almost failed to carry to the New World the gene(s) responsible for this accessory root on the lower first molars.

Dentition Supports Ice-Free Corridor, Epi-Clovis/Clovis-First, and Macro-Indian Models

Unlike the other dental traits discussed here, three-rooted lower first molar frequency is less than that of Northeast Asian Sinodonts, and this trait is generally uncommon although uniformly present at about 5 % in pre-Columbian Indians. These characteristics imply two events. First, the initial number of Siberians to reach eastern Beringia was apparently small and not strongly representative for all genetic characters. Second, the trait's Pan-American uniformity suggests (1) that after crossing the ecologically patchy Bering land bridge, group size increased significantly because similar dental gene samples were carried southward to all other parts of the New World and (2) all American Indians discussed here are descended from the founding Siberian epi-Clovis migrants whose archaeological record for colonizing Alaska and Chukotka begins about 12,000 BP (Goebel et al. 2003). The demographic events of rapid population growth and widespread territorial expansion, leading to genetic stabilization in North and South America, could have occurred first in interior Alaska or later after subsequent generations reached and passed through the inhospitable and limiting corridor between the Cordilleran and Laurentide ice sheets of Canada. Unfortunately, there is nothing that can be identified in the dental data that help explain where and how the rapid expansion began, regardless of how one defines migration (i.e., wavelike, pulsed, clonal spread, chaotic drift, niche based, continuous leakage, leapfrogging, etc.), or which migration route one chooses ("ice-free corridor," Pacific coast, ice-crossings and polar desert trek to Atlantic coast, or some combination of these). However, given the rarity of Paleo-Indian sites in Alaska, the recent Fairbanks and Brooks Range finds notwithstanding (West 1981, 1996; Powers et al. 1990; Hoffecker et al. 1993; Kunz and Reanier 1994; Yesner 2001; Yesner and Pearson 2002, others), the model favored here is that of demographic growth, related faunal extinctions (Martin 1990), and genetic drift stabilization as having explosively started at the southern exit of the western Canadian ice sheet corridor. The corridor entry is favored over the coastal route because of the severe boating difficulty of getting past the Late Pleistocene glacial ice mass on and around the Alaska Peninsula (Elias 2002; Turner 2002; Hoffecker and Elias 2003). In contrast to the rarity of Clovis or Clovis-like fluted points along the entire Pacific coast of North America, Carlson (1991) identified at least 40 archaeological sites in the ice-free corridor area of British Columbia and Alberta that had various types of fluted points.

Elsewhere the senior author (Turner 1992a) inventoried a number of dental observations from crania that were "candidates" for Paleo-Indian chronometric status. None of these incomplete individuals deviated from the Sinodont pattern. Since then, he has examined the teeth of four other crania that are dated as Paleo-Indian or Early Archaic. These include Sulphur Springs woman, excavated in southern Arizona by Waters (1986), Horn Rock Shelter double burial near Waco, Texas, and the Wilson-Leonard female, also from Texas (Young et al. 1987; Steele 1989; Steele and Powell 1992). These four also conform to the Sinodont dental pattern as best as can be determined given the considerable amount of tooth wear they and other hunter-gatherers exhibit worldwide.

Finally, some archaeologists (reviewed in Dixon 1999; for opposition, see Carlson 1991; Haynes 2002b) and geneticists (discussed previously) have argued for a Pacific coastal entry route to North and South America from Siberia despite the absence of archaeological evidence for, and Alaska Peninsula glacial evidence against, such a route (Workman 2001; Turner 2003). Moreover, Macro-Indian language family distributions in the Americas, Penutian, for example (Ruhlen 2000), do not suggest Pacific coastal entry. As for dental morphology, the Pacific coast samples presented in Table 1 show no sign of meaningful differences with interior samples as would be expected, had there been an earlier more Sundadont-like migration or a fourth American variant of Sinodonty.

Conclusion

In assaying the different types of biological data brought to bear on the peopling of the Americas, there are disagreements on the numbers of migrations and their timing, but there are many points of agreement as well. The homogeneity among American Indians indicated by dental morphology is paralleled by mtDNA and Y chromosome haplogroup data and single-nucleotide polymorphism (SNP) arrays. The dentition shows a dichotomy between North American and South American Indians, and this is also evident in genetic markers. Several studies critique the three migration model of Greenberg et al. (1986), but these often fail to include data on Eskimo-Aleut populations. If researchers argue that mtDNA and Y chromosome data support a position that Eskimo-Aleuts differentiated from American Indians after the arrival of a common ancestor in the New World, there are serious problems with their data sets (or the interpretation thereof). On the basis of teeth, nuclear markers, and even craniometry, Eskimo-Aleuts are consistently more closely aligned with recent Asian populations than are American Indians.

The placement of other northern groups, especially Na-Dene speakers, is a bit less certain than the Eskimo-Aleut case. Based on similarities in mtDNA, Shields et al. (1993) concluded that Eskimo-Aleuts and Athapaskans were very closely related, diverging from one another in the American Arctic as recently as 7,000 years ago. This same general position has long been advocated by Szathmary (1979, 1981, 1993); Szathmary and Ossenberg 1978) based on the variation in blood group and serum protein polymorphisms. Cavalli-Sforza et al. (1994) found Na-Dene groups fell between Eskimo-Aleuts and Amerinds in general. This intermediary position is also indicated by dental morphological variation (Turner 1985; Scott 1991;

Scott and Turner 1997, 2008). When ancillary fields are taken into account, especially linguistics and archaeology, it is hard to reconcile common origins for Eskimo-Aleuts and Na-Dene speakers in the Holocene. Even rare genetic markers speak against this purported tie. Albumin Algonquin (formerly Albumin Naskapi) is found in polymorphic frequencies in Athapaskans and Algonquians but not in Eskimos (Lampl and Blumberg 1979). Eskimos have the B allele and Subarctic Indians do not (Harper 1980). The Y chromosome haplogroup C-M130 has also been found exclusively in Athapaskan and Algonquian populations (Schurr 2004a).

The level of genetic diversity in the Americas has led some authors to conclude that the New World was peopled long before the Last Glacial Maximum, with many estimates exceeding 30,000 years BP. To a considerable extent, this runs counter to what is known about the archaeology of Siberia and Beringia, let alone Australia whose aborigines' biology, tools, and language have evolved so much that few resemblances remain with their Southeast Asian homeland. The New World founding population had to have been in place in Northeast Asia before any groups could start budding off to colonize the Beringian landscape. In a recent synthesis of mtDNA and Y chromosome analyses, Schurr (2004a) proposes three major peopling events from Asia to the Americas: (1) the initial founding population in the Americas came from south-central Siberia and arrived in the New World between 20,000 and 14,000 cal year BP; given the presence of ice sheets across the breadth of Canada, the route of this migration is presumed to be coastal; (2) a second migration, following an interior route, contributed to many of the populations of North and Central America; and (3) Beringian populations, including the ancestors of Aleuts, Eskimos, and Na-Dene speakers, came into New World following the Last Glacial Maximum.

Although Schurr's reconstruction parallels dental findings in a number of ways, the degree of dental differentiation in the New World still favors a late entry model, a position more in line with current archaeological knowledge (Haynes 2002a; Fiedel 2004) and some genetic studies (cf. Seielstad et al. 2003). In principle, there is no objection to an earlier date for the peopling of the New World. At present, a compelling case has not been made for this position, especially in light of archaeological success in Australia in finding very early sites by a much smaller number of archaeologists and geologists (Jelinek 1992). If a coastal migration did take place, more evidence for this event is required. For example, of all the pre-Clovis archaeological sites listed by Schurr (2004a) to support early entry, none are along the Pacific coast. Scholars will continue to find "pre-Clovis" sites and develop molecular clocks and models of linguistic differentiation that indicate early human entry into the Americas, but the final arbiter of dispersal will come from archaeological sites that have excellent stratigraphy and no dating issues. Granted, a major problem associated with a coastal migration is the presumption that most early sites are now under water and mostly inaccessible.

The dental characteristics of pre-Columbian American Indians easily fit with both the hypothesis of a rapidly expanding Clovis- or epi-Clovis first colonization event, long advocated by Martin (1990) and Haynes (1991), and the Macro-Indian language evolution model developed by Greenberg (1990). Because all prehistoric and unadmixed living Native Americans, including Na-Dene/Greater Northwest Coast and Aleut-Eskimo, only briefly discussed here, have the Sinodont dental pattern, it would seem that when a date for the emergence of full-blown Sinodonty in Asia is established with some certainty, then that will have to be the earliest possible date for the subsequent colonization of the Americas, assuming that early and late similarity actually means genetic continuity. Inasmuch as the Upper Cave crania seem to have a Sinodont dental pattern, then whatever date is finally settled on for that assemblage will provide a reasonable time estimate for the potential colonization of the Americas.

It is necessary to focus on Upper Cave since there are only a few sites in Siberia with Late Pleistocene human remains. One site near Lake Baikal, called Mal'ta, seems to have European- rather than Asian-like teeth (Turner 1990b), an observation supported by aDNA which shows individuals from this site had the European haplogroup U (Willerslev 2013). Two sites west of Lake Baikal have physical anthropological signs of "Mongoloid" or Sinodonty. These are the Late Pleistocene Yenisei River sites in and near Krasnoyarsk. In the city of Afontova Gora, a fragment of a subadult frontal bone found in a river bank section was thought to have been Mongoloid because of the size and form of the adhering nasal bones (Alekseev 1998). Upstream ca. 35 km (21 mi) is Listvenka, from which came a mandible of a child whose unerupted first molar is slightly more Asian than European in overall appearance. Hence, broadly speaking, the pre-Arctic ancestral homeland of Paleo-Indians must have been in north China, Mongolia, and southern Siberia. It is easy to envision how newly evolved Sinodonts quickly expanded into northeastern Siberia, after they succeeded in domesticating the dog for hunting and hauling, perhaps drifting north out of China via the Vitim River system. Although people were in northern Siberia at 30,000 BP (Pitulko et al. 2013), population density above the Arctic Circle was likely circumscribed so the ancestral Paleo-Indian northward drift would have been rapid and with little human resistance in Beringia. Because the dental differences between the north China-Mongolia group and all unadmixed Indians are small compared with the much larger difference between Northeast and Southeast Asians, the relatively small amount of intra-trait dental variation within the New World may reflect the simple evolutionary fact that Sinodonts have been in the Americas for a relatively short period of time, less time than it took for Sinodonty to evolve out of Sundadonty. Moreover, the colonists and their dogs were so reproductively successful that the usual genetic drift cause of short-term dental trait frequency change was reduced or negated by the large population size that quickly grew south of the east Beringian Arctic steppe. This evolutionary scenario, despite years of bioarchaeological research, does not differ much from that first proposed on craniological grounds by Hrdlička (1925). While some readers may find such lack of theoretical and empirical change as unthinkable in the rapidly changing world of science, others, ourselves included, recognize it as a tribute to Hrdlička's empirical orientation and one of the more probable scenarios in the complex world history of Late Pleistocene human microevolution and dispersal. For the present, Macro-Indian dental variation is not supportive of a Pacific coastal entry route to North and South America, leaving the late entry ice-free corridor model as dentally most parsimonious.

Overview of Paleolithic Archaeology

Nicholas Toth and Kathy Schick

Contents

Abstract

The Paleolithic, or Old Stone Age, comprises over 99 % of human technological history and spans a time range from 2.6 Ma (the earliest recognizable stone tools and archaeological record) to 10,000 years ago (the end of the last ice age). There are three major stages of the Paleolithic: (1) The Early Paleolithic which includes the following: (a) the Oldowan, from 2.6 to about 1.0 Ma, characterized by simple core forms on cobbles and chunks (choppers, discoids, polyhedrons), battered percussors (hammerstones and spheroids), flakes and fragments, and retouched forms such as flake scrapers. Cut marks and fracture patterns on animal bones indicate meat and marrow processing, with the use of simple stone knives and hammers. This stage is associated with the later australopithecines and the earliest forms of the larger-brained genus *Homo* and documents the first hominid dispersal out of Africa and into Eurasia, (b) The Acheulean, which lasted from approximately 1.7 Ma to 250,000 years ago and was

characterized by large bifaces such as handaxes, cleavers, and picks. The early Acheulean is associated with *Homo erectus/ergaster*, while the later Acheulean (by ca. 500,000 years ago) is associated with the even larger-brained *Homo heidelbergensis*. (2) The Middle Paleolithic/Middle Stone Age, from about 250,000 to 30,000 years ago, characterized by a focus on retouched flake tools, such as scrapers, points, and backed knives, and prepared core technologies such as the Levallois method. The controlled production and use of fire appears to be widespread for the first time. This stage is especially associated with archaic forms of *Homo sapiens* (having modern-size brains but more robust faces and postcranial skeletons), including the Neanderthals (see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3) and the earliest anatomically modern humans (see chapter "▶ Origin of Modern Humans," Vol. 3). (3) The Late Paleolithic, from 40,000 until 10,000 years ago, characterized by blade tool industries; a proliferation of artifacts in bone, antler, and ivory; and the emergence of rich symbolic art in the form of paintings, engravings, sculpture, and personal body adornment (see chapters "▶ Modeling the Past: Archaeology," Vol. 1, "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," and "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3). Early examples of clear architectural structures, musical instruments, and mechanical devices (spear-throwers and bows and arrows) appear during this time. This stage is especially associated with anatomically modern humans, *Homo sapiens sapiens*.

Introduction

The Paleolithic is the term applied to a very broad, early period of human prehistory beginning with the first archaeological evidence of stone toolmaking approximately 2.6 Ma, through to the end of the Pleistocene epoch about 10,000 years ago, when the last continental glaciation receded. It documents the emergence of a wide range of new technological, behavioral, and adaptive traits through time (Toth and Schick 2010). It is important to appreciate that over 99 % of human technological development took place during the Paleolithic. The Paleolithic thus constitutes the bulk of the time span of human technological development and human prehistory and documents the emergence and evolution of the genus *Homo*. The term is applied primarily to prehistoric developments in the Old World, as the New World's earliest archaeological evidence appears only toward the very end of Paleolithic times, during the last phases of the terminal Pleistocene glaciation. In the New World, however, the period of Late Ice Age hunter-gatherers is often referred to as "Paleo-Indian" and is contemporaneous with the last few thousand years of the Paleolithic in the Old World. For overviews of human evolution and the Paleolithic, see also Boyd and Silk (2012), Burenhult (2003), Clark (1982), Ciochon and Fleagle (2006), Delson et al. (2000), Gamble (1986), Johanson and Edgar (1996), Jones et al. (1992), Klein (2009), Lewin and Foley (2004), Mithen (1996), Noble and Davidson (1996), Renfrew and Bahn (1996), Roberts (2011), Scarre (2013), Schick and Toth (1993), Stringer and Andrews (2005), Tattersall (1999), Tattersall and Schwartz (2000), and Toth and Schick (2010).

"Paleolithic" literally means the "Old Stone" (paleo = old, lithic = stone) Age, as it represents the earliest phases of human technological development when the vast majority of the tools represented in the archaeological record were made of stone. At the end of the Pleistocene, the Paleolithic is followed by the later phases of the Stone Age, the Mesolithic and then the Neolithic. During the Mesolithic (in some regions referred to as the "Epipaleolithic"), stone technologies continued to evolve as stone tool-using hunter-gatherers adapted to changing environments of the current (Holocene) epoch, sometimes characterized by small (microlithic) stone tools. During the last phase of the Stone Age, often referred to as the Neolithic (or "New Stone" Age), a transition occurred from hunting-gathering to a more settled way of life based on food production (agriculture and herding), but stone continued for some time to be used for tools (such as ground axes, projectile points, and sickles).

The Paleolithic is traditionally divided into three major subdivisions: (1) the Early Paleolithic (also sometimes called the Lower Paleolithic) or Early Stone Age (ca. 2.6 Ma to 250,000 years ago); (2) the Middle Paleolithic or Middle Stone Age (ca. 250,000–30,000 years ago); and the Late Paleolithic (also Upper Paleolithic) or Later Stone Age (ca. 40,000–10,000 years ago). The "Lower"/"Middle"/"Upper" designations for the Paleolithic stages were developed in Europe in the late nineteenth and earlier twentieth centuries, based primarily on diagnostic artifact types and technological patterns observed in the stratigraphic and cultural sequences in various regions of Europe. More recently, with the appreciation that other parts of the world did not follow the precise cultural-historical sequence of Europe, many researchers have put less formal emphasis on these designations in favor of the more neutral terms "Early"/"Middle"/"Late" on a worldwide scale. This latter terminology will be used here.

For the first hundred years of Paleolithic research, these Paleolithic subdivisions were used to express a general chronological sequence (a relative chronology) without a firm sense of how many years ago each phase began or ended (an absolute chronology). During the past half-century, however, radiometric dating techniques have allowed the development of a more precise chronological framework for this Paleolithic sequence worldwide (see chapter "▶ Chronometric Methods in Paleoanthropology," Vol. 1), with approximate times for the beginning and end of each phase.

Change from one stage of the Paleolithic to the next, however, does not always entail an immediate or complete turnover in artifact types, though it does generally represent an obvious and perceptible shift in the types of artifacts dominating the archaeological tool assemblages and often a corresponding shift in the dominant methods used in making these tools. For instance, while modified flake tools are present at a number of Lower Paleolithic sites, they become the dominant artifact form, often with consistent or repeated shapes, at many Middle Paleolithic sites. There is also some regional variation in the absolute chronology of the sequence, with evident technological transitions in some regions occurring earlier or later than in other regions. For instance, the transition from the Middle Paleolithic/Middle Stone Age to the Late Paleolithic/Later Stone Age happens somewhat earlier in some regions than in others.

Perspectives on Early Stone Tools

The earliest prehistoric archaeological record is now approximately 2.6 Myr old, based on the recognition of flaked stone artifacts in securely dated deposits in East Africa. The fossil record of bipedal hominids, however, goes back at least 6 Ma, several Myr before the first appearance of stone tools (see chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). On the basis of modern primate analogs, especially from chimpanzees, a range of tools and tool-using behaviors might be postulated for hominid populations prior to 2.6 Ma. Such hypothetical early tool use likely involved highly perishable, organic raw materials that provide no enduring, visible archaeological record.

A handful of nonhuman species have been documented to show some minimal use of tools in the wild, including sea otters, birds (such as crows, finches, and Egyptian vultures), and even mud wasps (Shumaker et al. 2011). Aside from humans, however, the only other animals showing habitual use of a variety of tools for a variety of purposes are our closest living relatives, the chimpanzees (McGrew 1992). What is more, chimpanzee toolmaking and tool-using skills appear to be learned over several years, suggesting a simple culturally transmitted system.

We now know that there is variability among different chimpanzee groups in the sets of tools (see chapters "▶ Great Ape Social Systems", "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition", "▶ The Hunting Behavior and Carnivory of Wild Chimpanzees," Vol. 2, and "▶ Modeling the Past: Archaeology," Vol. 1) they commonly use, showing cultural variation among chimpanzees in their tool kits. Modern chimpanzee tool use includes nut cracking with stone and wood hammers and anvils, termite fishing, ant dipping with sticks or grass stems, and using chewed-up wads of leaves as sponges to obtain water or for self-cleaning. Although some chimpanzee tools consist of unmodified objects used for a particular task, chimpanzees do intentionally modify or shape some of their tools, such as the sticks and grasses used for termite fishing or ant dipping and the chewed leaves used as sponges.

Deliberately manufactured stone artifacts in the early archaeological record represent the earliest evidence of tool production by early hominids. As such, they reveal the development of a reliance on stone tool use in early hominid adaptation by at least 2.6 Ma. Although stone tool use may have been affected by seasonal, environmental, or other opportunities, the archaeological record reveals a consistent manufacture of stone tools that persisted from this time onward until recent times.

Early stone artifacts clearly indicate a number of interesting behavioral characteristics of these early hominids: they selected stone raw materials at specific locations, transported manufactured artifacts and unmodified stone from one place to another on the paleolandscape, and discarded artifacts (and sometimes parts of animal carcasses) in distinct concentrations at many localities some distance from the raw material sources. Moreover, the manufacturing process used to produce early stone artifacts is one that is not observed in any nonhuman animal, even among chimpanzees, highlighting the novelty of behavioral innovation in the early stone toolmakers. Although early stone tools are admittedly simple and do not show elaborate shaping, they represent clear evidence of a new and unusual behavior pattern: the deliberate, controlled fracture of rock through percussive blows.

Technological patterns seen in early stone artifacts indicate they were produced primarily through a technique sometimes called "free hand, hard hammer percussion." This involves hitting one rock (the hammer) against another (the core) to bring about controlled fracture of the core (called conchoidal fracture, as the shock waves can produce radiating, shell-like ripples in finer-grained materials) and produce numbers of sharp pieces called flakes, a process called flaking or knapping. Experiments have shown that the main objective of early stone tool making was likely the production of such sharp flakes to use as cutting tools. Thus, a primary tool in the early hominid tool kit was likely the sharp-edged flake, and many of the cores found at early sites were likely by-products of the toolmaking process (see chapter "▶ Modeling the Past: Archaeology," Vol. 1).

Early stone toolmaking hominids were consistently producing such fractured stones at a number of early site localities. Early Paleolithic sites often involve dozens of flaked cores and thousands of flake products. Analysis of early archaeological materials often reveals extensive, controlled flaking of cores, involving rotation and manipulation to produce a series of flakes from the same piece of stone. Such fine core manipulation and exploitation is observable at even the very earliest Stone Age sites at Gona in Ethiopia, showing consistent, controlled, and skillful flaking of cores by 2.6 Ma.

With such skillful flaking observable among early hominid toolmakers on the one hand and the diverse tool-using and toolmaking cultures observable in chimpanzees (McGrew 1992) on the other, a natural question is whether the production of early stone tools represents skills beyond those seen in other apes. Wild chimpanzees are known to have ca. 40 cultural traits, which can pattern geographically (Whiten et al. 1999). At the subspecies level, chimpanzee groups in closer proximity tend to share more of these cultural traits (Toth and Schick 2009; Whiten et al. 2009). Although chimpanzees are known to use stones as hammers and anvils in nut-cracking activities in West Africa, wild chimpanzee tool manufacture does not involve the intentional percussive flaking of stone, and wild chimpanzees have not developed sharp-edged tools for cutting in their assorted tool kits. It has been possible, however, to explore through experiments how comparable toolmaking skills of early hominids are to those of apes in captivity. An essential question in such experiments is whether the toolmaking skills of early hominids represent a significant departure from an ape "substrate" of toolmaking ability and what insights we might gain regarding early hominid cognitive abilities. Do early hominid toolmakers exhibit special cognitive or biomechanical skills or abilities,

Fig. 1 Kanzi, a bonobo (*Pan paniscus* or "pygmy chimpanzee"), flaking stone. Kanzi learned stone tool manufacture by modeling or imitation followed by years of trial and error, and he uses his tools to cut open a container to obtain food. His stone toolmaking skills have improved since the start of this experiment in 1990. Many of his artifacts resemble those found at Oldowan sites, although overall his flakes and cores still show some important differences from those found at Early Paleolithic sites

or do these emerge only much later in human biological and technological evolution? (see chapter "▶ Theory of Mind: A Primatological Perspective," Vol. 2).

Experiments were begun in 1990 teaching a bonobo (see chapters "▶ Great Ape Social Systems" and "▶ Primate Intelligence," Vol. 2) (pygmy chimpanzee), Kanzi (Savage-Rumbaugh and Lewin 1994), to make and use stone tools (Fig. 1) (Toth et al. 1993; Schick et al. 1999). The experiment involved introducing the use of a stone tool for cutting and retrieving a foodstuff, initial demonstrating (modeling) stone tool manufacture, and a subsequent period of trial-and-error learning on Kanzi's part in both the toolmaking and tool-using operations. This experiment has clearly shown that apes can become adept at some aspects of stone toolmaking. However, after more than 15 years of this experiment, some distinct technological differences have persisted in the bonobos' artifacts compared to artifact assemblages found at early Paleolithic sites (Toth et al. 2006; Toth and Schick 2009). Some of these differences appear to reflect lesser skill in the bonobo toolmaker, perhaps reflecting lesser cognitive appreciation of particular facets of the toolmaking process (such as flaking sharper edges of the core), although others are likely related to biomechanical differences in the hand and arm of the apes.

This experiment highlights how skilled and adept early stone hominids were in their stone toolmaking by the time of the earliest known archaeological occurrences 2.6 Ma. The skillfulness reflected in the earliest stone tools might suggest that even earlier stone technologies existed, yet undiscovered and perhaps rare on the paleolandscape, whose makers were not quite as proficient in flaking stone and who did not produce such a readily recognizable product. Or it may be that hominids were "preadapted" to efficiently flaking stone because of selection for other manipulative skills that were later transferred to stone knapping when the need arose. The ape stone tool making experiments give important clues as to what technological characteristics might be found in such hypothetical "Pre-Oldowan" technologies.

Early Paleolithic

The Early Paleolithic comprises a long time interval, between 2.6 Ma and approximately 250,000 years ago. It not only includes this extremely large span of human prehistory but also encompasses, over time, sites across huge geographical distances, from southern Africa to eastern Asia. During this period of more than 2.25 Myr, profound evolutionary changes occurred among hominids, and some marked changes are observed in the archaeological record in multiple parts of the Old World.

In Africa, where the Early Paleolithic is often referred to as the Early Stone Age, two industries have been recognized: (1) The first to appear, starting 2.6 Ma, the Oldowan industry (named after Olduvai Gorge in Tanzania), consists of stone industries containing simple cores and flaked pieces, along with some battered artifacts such as hammerstones and (2) starting between 1.7 and 1.5 Ma, or approximately 1 Myr after the onset of Oldowan technology, the Acheulean industry (named after the locality of St. Acheul in France) appears, with new distinctive artifact forms in the form of relatively large bifacial tools (handaxes, cleavers, and picks).

Oldowan

The Oldowan is the first recognizable archaeological record, with simple flaked and battered stone artifacts, sometimes found with cut-marked and broken animal bones, emerging around 2.6 Ma. Although similar types of simple lithic industries are found throughout time, archaeologists usually use a cutoff of around 1 Ma when referring to the Oldowan Industrial Complex. The Oldowan coexisted for several hundred thousand years with the Acheulean handaxes industries, starting about 1.76 Ma. Oldowan sites are known first from Africa and subsequently document the spread of hominids outside of Africa into parts of Eurasia, notably producing archaeological sites in the Near East, the Republic of Georgia, and eastern Asia. These sites are found especially in tropical and subtropical climatic regimes, in particular grassland/woodland environments.

At Dikika, Ethiopia, it has been argued that marks on surface bovid bones believed to date to 3.3 Ma were produced by stone tool-wielding hominids, in this case the contemporary *Australopithecus afarensis* (McPherron et al. 2010). Others, however, have argued that these marks could be produced by crocodile teeth (Njau 2012) or by trampling (Domínguez-Rodrigo et al. 2010). No stone tools have been found at this locality. Until new evidence comes to light, the claim of stone cutting tools from this time period should be regarded as unsubstantiated.

In East and North Africa, most Oldowan sites are open-air occurrences that are located along stream courses, in deltaic settings, or on lake margins. These were areas of close proximity to water and were depositional settings where sediments could build up over time. In South Africa, Oldowan artifacts are found in karstic limestone cave deposits and may have been carried there by hominids or brought in by natural forces such as slope wash or gravity. The high incidence of hominid bones in South African cave deposits (especially robust australopithecines) may be the result of predation and/or scavenging by carnivore such as leopards and hyenas.

Oldowan industries are contemporaneous with a number of bipedal hominid forms, including later australopithecines (see chapter "▶ The Species and Diversity of Australopiths," Vol. 3) (*Australopithecus garhi*, *A. aethiopicus*, *A. robustus*, and *A. boisei*), whose cranial capacities ranged from about 400 to 550 cm^3, and early forms of the more encephalized genus *Homo* (see chapter "▶ Evolution of the Primate Brain," Vol. 2) (*H. rudolfensis*, *H. habilis*, *H. ergaster/erectus*), whose cranial capacities ranged from about 600 to 850 cm^3. Although it is possible that all of these hominids used stone technology to a greater or lesser extent, many anthropologists believe that the genus *Homo* was probably the more habitual toolmaker and tool user, as its brain size almost doubles in the first million years of the Oldowan, while its jaws and teeth tend to diminish in robusticity. By 1 Ma, only *Homo ergaster/erectus* was known in the human paleontological record, while the australopithecines became extinct. Interestingly, *Homo ergaster/erectus* appears to have much more modern limb proportions and stature relative to earlier hominids and is the first form clearly identified outside of Africa (see chapters "▶ *Homo ergaster* and Its Contemporaries," "▶ Later Middle Pleistocene *Homo*," and "▶ Defining *Homo erectus*," Vol. 3).

Oldowan industries are characterized by simple technologies (sometimes called Mode 1) consisting of cores made on pebbles or chunks (choppers, discoids, polyhedrons, heavy-duty scrapers, facetted spheroids), battered percussors (hammerstones and battered spheroids), debitage (flakes and fragments), and retouched pieces (scrapers, awls, etc.) (Fig. 2) (Hovers and Braun 2009; Isaac 1989; Leakey 1971; Schick and Toth 2010; Toth and Schick 2006, 2009). Common raw materials include volcanic lavas, quartz, and quartzite. The most common techniques for producing Oldowan artifacts were hard hammer percussion and bipolar technique (in which the core to be flaked is set on a stone anvil and hit with a stone hammer). At Olduvai Gorge, some technological trends have been observed through time, with later Oldowan sites showing higher frequencies of such artifact classes as scrapers and battered spheroids and lower frequencies of choppers. These sites are sometimes assigned to a "Developed Oldowan," but this designation is more difficult to apply elsewhere.

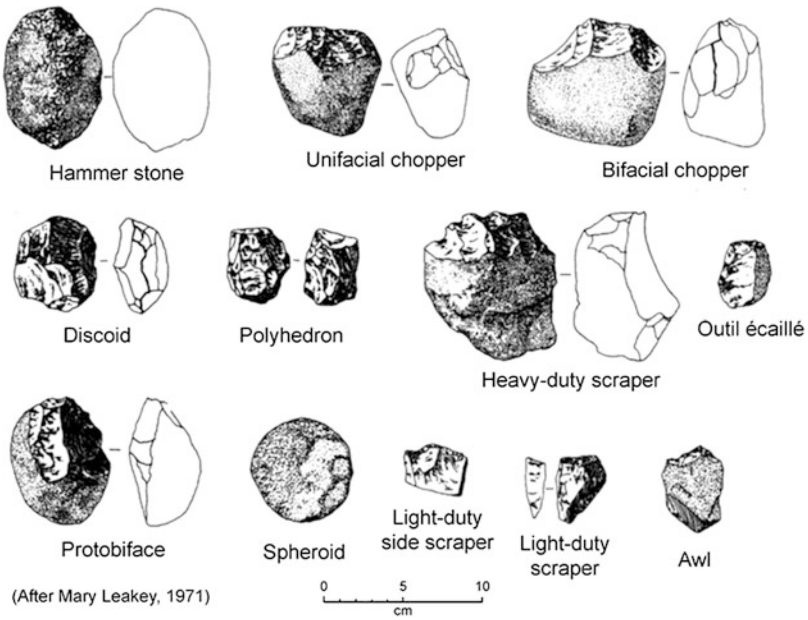

Fig. 2 Typical Oldowan artifacts found at Early Paleolithic sites. These are examples of flaked and battered stone artifacts found at Olduvai Gorge, with their common or conventional designations ("types") noted

Microwear patterns on a small sample of Oldowan tools suggest that flakes were used for animal butchery, woodworking, and cutting soft plant matter. Experiments in using stone tools (Fig. 3) have shown that Oldowan flakes can be used to efficiently process the carcasses of animals from the size of small mammals to elephants (Fig. 4) and stone hammers could easily break bones for access to nutritious marrow and skulls for brain tissue. Choppers could have been used to chop branches to make spears or digging sticks, although many such Oldowan core forms were probably by-products of flake production. It is likely that a rich range of perishable organic material cultures were also used, including containers of shell, horn, skin, or bark; wooden clubs and/or throwing sticks; wooden spears or digging sticks (Fig. 5); and horn or bone fragments as digging tools. In addition, a small sample of bone specimens from South African caves are polished and striated on their pointed end, suggesting that these may have been used as opportunistic digging tools to gain access to underground vegetable resources or insects such as termites.

Although evidence of fire has been found at a few Oldowan sites (in the form of reddened, baked sediments, burnt bones, or fire-cracked stone), it cannot be ruled out that natural agents, such as lightning strikes and brushfires, may have produced these fires. No clear architectural structures have been found at Oldowan sites, and it is possible that Oldowan hominids could have been sleeping in trees at night (perhaps building nests like chimpanzees) rather than on the ground, in order to

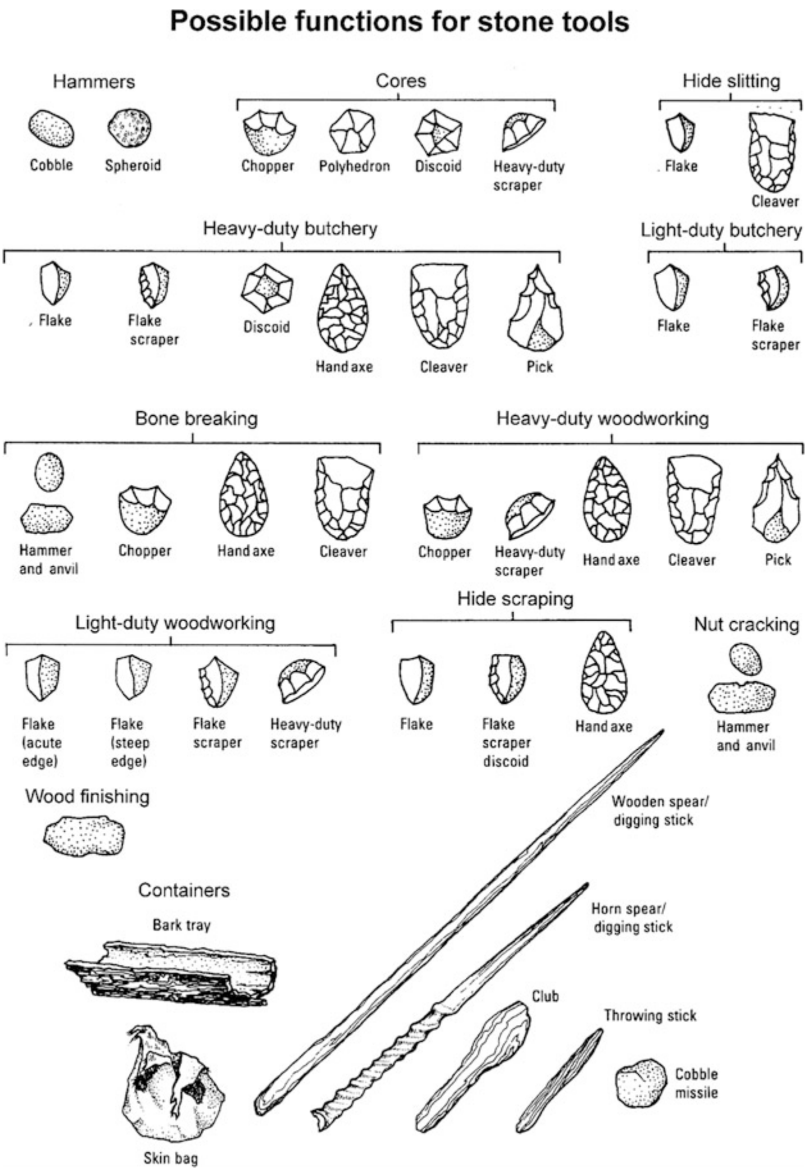

Fig. 3 Potential functions of Early Paleolithic artifacts, both Oldowan and Acheulean forms, based on experiments using tool replicas for various purposes

avoid predation by nocturnal carnivores (see chapters "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition," "▶ Great Ape Social Systems," and "▶ The Hunting Behavior and Carnivory of Wild Chimpanzees," Vol. 2).

It seems clear that these Oldowan hominids were concentrating lithic material and animal bones at favored locations on the landscape (a pattern not seen in

Fig. 4 Butchery of an elephant, the world's largest terrestrial mammal, using simple Oldowan flakes (The elephant had died of natural causes)

Fig. 5 Sharpening a wooden branch with a simple stone flake. Such implements could have been used as spears, digging sticks, or skewers to carry meat resources

nonhuman primates today), but the precise behavioral patterns that formed these concentrations are still debated. Interpretations for these concentrations include home bases or central foraging places; favored places due to proximity to shade, water, or food resources; intentional stone caches; and scavenged carnivore accumulations. It is also possible that Oldowan sites formed through more than one behavioral pattern. Cut marks and percussion marks/fractures on bones show that hominids were accessing meat and marrow resources from animal carcasses obtained through scavenging or hunting. The modified bones at Oldowan sites typically come from animals ranging in size from small mammals to those weighing hundreds of pounds. This is a scale of carnivory that is not seen in the nonhuman primate world and was most likely greatly facilitated through the use of stone tools.

At present, there is debate as to whether hominids accessed larger animals through more marginal scavenging (getting the ravaged leftovers of carnivore kills) or, rather, had access to more complete carcasses through hunting or confrontational scavenging. In any case, the processing of larger animal carcasses could have significantly increased the dietary breadth (and thus survivorship and reproductive success) of Oldowan hominids, although the majority of Oldowan hominid diet was likely derived from plant foods such as fruits, berries, nuts, edible leaves, and underground storage organs (roots, tubers, corms, and rhizomes). Carrying devices may have facilitated the collection and transport of dietary items that could be consumed at a later time.

Important Oldowan localities include Gona, Fejej, and the Omo Valley in Ethiopia; East and West Turkana in Kenya; Olduvai Gorge in Tanzania; Sterkfontein and Swartkrans Caves in South Africa; Ain Hanech and El Kherba in Algeria; the lowest levels at ʻUbeidiya in Israel; and Dmanisi in the Republic of Georgia.

Acheulean

The Acheulean Industrial Complex is characterized by the presence of large bifacial handaxes, cleavers, and picks (sometimes called Mode 2 technologies), which are found from approximately 1.76 Ma to 250,000 years ago. The earliest known Acheulean sites are Kokiselei 4, West Turkana, Kenya, dated to 1.76 million years ago (Lepre et al. 2011), and Konso in Ethiopia, dated to 1.76 million years ago (Beyene et al. 2013). At Kokiselei four large cobbles of phonolite lava were flaked into crude handaxes and picks, while at Konso-Gardula, similar large picks and bifaces and unifaces were manufactured primarily from large flakes. Such handaxe/cleaver industries are contemporaneous and sometimes regionally co-occurring with the simpler Oldowan-like (Mode 1) industries. Acheulean and contemporaneous Mode 1 industries are found throughout Africa and Eurasia, but classic handaxe and cleaver assemblages are especially characteristic of Africa, the Near East, the Indian subcontinent, and Western Europe. Elsewhere, notably Eastern Europe and most of eastern Asia, simpler Mode 1, Oldowan-like technologies are found. This was a period of major climatic change, with numerous cold/warm oscillations that would have especially affected northern latitudes of Eurasia. For most of this period, hominids would have flourished only during the warmer periods in these northern latitudes. Hominids extended their range from grasslands and woodlands of tropical and subtropical regions to cooler, more temperate climates during this period (Fleagle 2010; Gamble 2005; Norton and Braun 2010; Shipton and Petraglia 2010).

Contemporaneous hominid forms (see chapter "▶ *Homo ergaster* and Its Contemporaries," Vol. 3) include *Homo ergaster/erectus* and the later, larger-brained *Homo heidelbergensis* (sometimes referred to as "early archaic *Homo sapiens*"). Cranial capacities range from about 800 to 1,400 cm^3, generally increasing over the time span of this period. In the early Acheulean, robust australopithecines (see chapters "▶ Analyzing Hominin Phylogeny: Cladistic Approach" and

"▶ The Species and Diversity of Australopiths," Vol. 3) (*A. robustus* and *A. boisei*) still existed, but most anthropologists do not regard these forms as plausible Acheulean toolmakers, and in any case they appear to have gone extinct by 1 Ma.

New elements in Acheulean industries (in addition to Mode 1, Oldowan-like artifacts that continue to be found) include handaxes, cleavers, picks, and knives (generically called "bifaces") made either on large flakes struck from boulder cores or on larger cobbles and nodules. A range of well-made retouched tools, such as side scrapers, awls, and backed knives, are also common. Frequently used raw materials include fine-grained lavas, quartzites, and flints. Earlier, cruder bifaces were produced by hard hammer percussion (Fig. 6), while later more refined bifaces

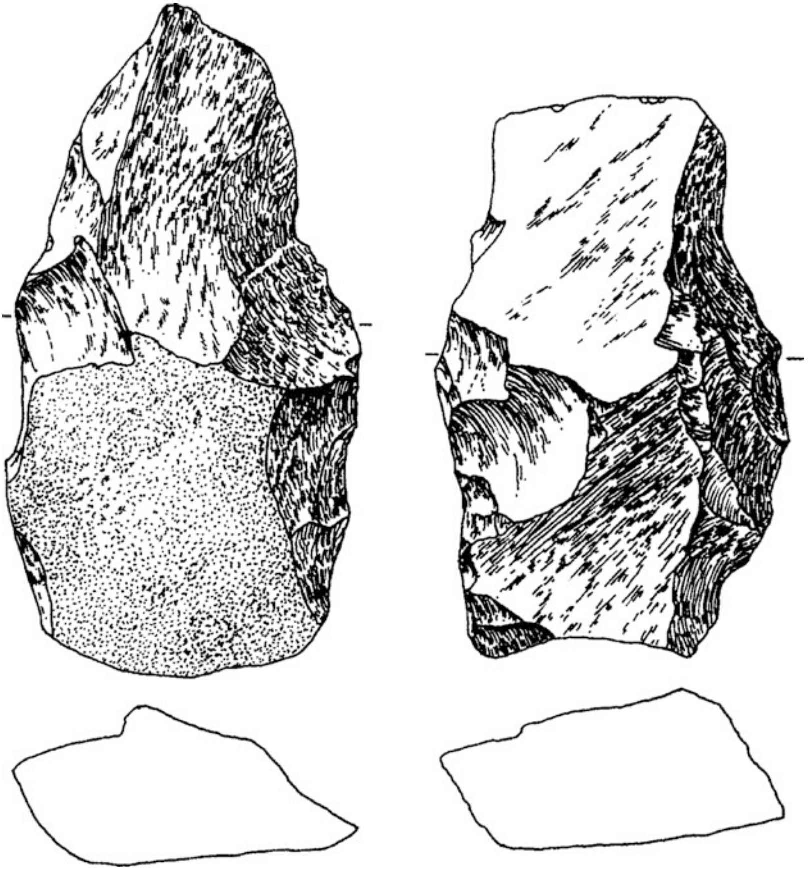

Fig. 6 Early Acheulean tools: relatively crude handaxe (*left*) and cleaver (*right*), approximately 1.4 Myr old. These artifact forms, made on large flakes or cobbles, show definite shaping to leave a sharp working edge, especially toward the tip end of the handaxe and the bit of the cleaver, with the lower part of the tool shaped or left natural to serve as a handle. They usually show some, though relatively low, degree of symmetry in their plan view and their cross-section and were made by hard hammer percussion

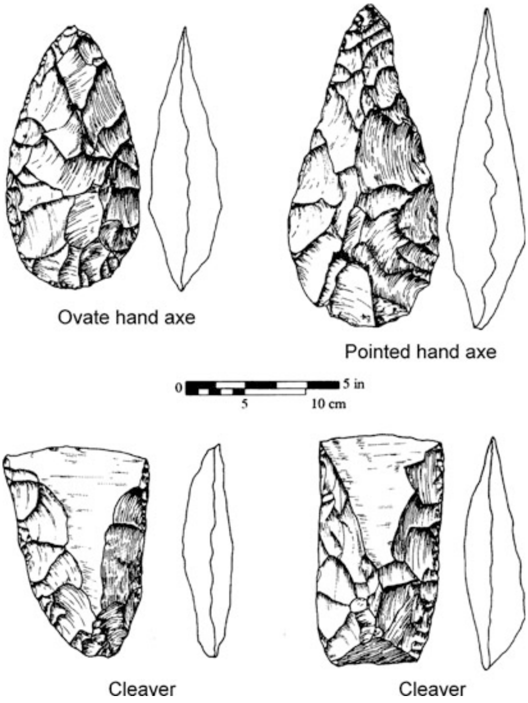
Fig. 7 Late Acheulean tools: beautifully made, highly symmetrical handaxes and cleavers typical of the latter part of the Acheulean, approximately 400,000 years old. These forms clearly show more cognitive complexity, craftsmanship, and probably an aesthetic sense hundreds of thousands of years before the first representational art



were probably finished by the soft hammer technique, in which a softer material, such as wood, bone, ivory, antler, or even soft stone, was used as a percussor, producing thinner, more invasive flakes (Fig. 7). Prepared core techniques, notably the Levallois tortoise core technique (in which a large, predetermined flake is removed from the upper surface of a discoidal core) and, more rarely, early blade production, are found in some later Acheulean industries. Sharpened wooden spears are known from later Acheulean times, as at Schöningen in Germany (see chapter "▶ Modeling the Past: Archaeology," Vol. 1) and Clacton in England, suggesting that more formal hunting weaponry was established as part of a regular subsistence pattern by at least this time if not earlier.

The fact that Acheulean and contemporaneous hominids successfully occupied cooler, more temperate latitudes suggests that they were better adapted to such cooler conditions. Use-wear patterns on side scrapers indicate that many of these tools were used to scrape hides, strongly suggesting that animal skins were being used for simple clothing, blankets, and/or tent or hut coverings. Evidence of fire in the form of charcoal or ash layers is occasionally seen in later Acheulean times but is by no means widespread in the archaeological record during this period. There is no definitive evidence of architectural structures during Acheulean times, although arguments have been made in this regard. Sites are found in numerous caves and rock shelters as well as many open-air sites.

Handaxes and cleavers, in particular, indicate the ability to impose bilateral symmetry on lithic materials. This clearly shows higher cognitive abilities and motor skills than are manifested in the Oldowan. Even modern humans who learn to make stone tools normally require considerable apprenticeship before they can produce well-made handaxes and cleavers. Although there is a wide range of handaxe forms through time and space, it is common that at certain Acheulean sites, there are recurrent shapes and sizes, as if there were stylistic norms of production among their makers. Presence of ocher at some sites and, occasionally, incised bone may indicate the emergence of proto-symbolic behavior as well.

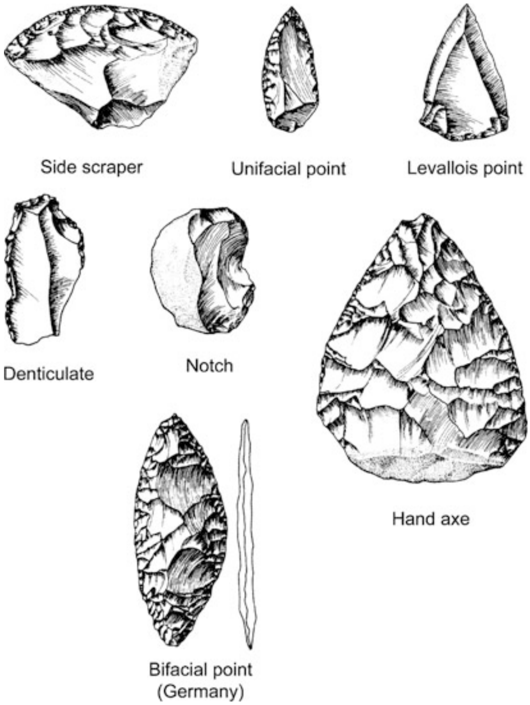
Important Acheulean sites/localities include Konso-Gardula, Middle Awash, Melka Kunture, and Gadeb in Ethiopia; Olduvai Gorge and Peninj in Tanzania; Olorgesailie and Isenya in Kenya; Kalambo Falls in Zambia; Elandsfontein and Montagu Cave in South Africa; Ternifine in Algeria; ‘Ubeidiya and Gesher Benot Ya’aqov in Israel; Swanscombe, Hoxne, and Boxgrove in England; Saint-Acheul and Terra Amata in France; and Torralba and Ambrona in Spain. Important contemporaneous Mode 1 localities include Atapuerca (TD6) in Spain, Arago Cave in France, Clacton in England, Bilzingsleben and Schöningen in Germany, Vértesszölös in Hungary, Isernia in Italy, and the Nihewan Basin and Zhoukoudian (“Peking Man”) cave in China.

It has recently been argued (Wilkins et al. 2012) that stone points from Kathu Pan 1, South Africa, believed to date to ca. 500,000 years ago, could have functioned as hafted spear points, based upon the morphology of the artifacts and edge damage. These artifacts are associated with a stone tool industry, often referred to as the “Fauresmith” that includes handaxes and is considered by some to be transitional between the Acheulean and the Middle Stone Age. If this argument is valid, this would put the origins of hafted technologies several hundred thousand years before the first widely accepted evidence of hafting (see chapters “▶ Modeling the Past: Archaeology,” Vol. 1, and “▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories,” Vol. 3). Kathu Pan 1 also shows evidence of systematic blade production, another trait which tends to appear in the archaeological record in later times (Wilkins and Chazan 2012).

Middle Paleolithic/Middle Stone Age

The Middle Paleolithic industries of Europe, the Near East, and North Africa (sometimes called the “Mousterian” after the site of Le Moustier in France) and Middle Stone Age industries of sub-Saharan Africa are found between approximately 250,000 and 30,000 years ago. They are found in tropical, subtropical, temperate, and even periglacial climatic regimes. During this time, hominids extended their ranges to most environmental zones of Africa and Eurasia except harsh deserts, the densest tropical forests, and extreme northern or arctic tundras.

Fig. 8 Middle Paleolithic tools: numerous retouched flake tools, such as side scrapers, points, and denticulates, were made on flake blanks, some struck from prepared cores. It is possible that some of these points were hafted to wooden shafts as thrusting or throwing spears



It appears that hominids were somehow able to cross the water between Southeast Asia and Australia and then attached to New Guinea and Tasmania, by late in this period. Contemporary hominid forms include those often designated as archaic *Homo sapiens* (including the Neanderthals of Europe and the Near East) and anatomically modern humans.

Handaxes and cleavers tend to be less common (although toward the end of the Middle Paleolithic of Western Europe, smaller, well-made handaxes are found), and the emphasis in these stone industries is on retouched forms made on flakes (such as side scrapers, denticulates, and points) that become numerous in many of these assemblages (Fig. 8). Hard hammer and soft hammer techniques were common during this period. Many of these industries exhibit prepared core methods, notably the Levallois technique for more controlled production of flakes, points, and sometimes blades. Wooden spear technology continues from the Acheulean (as seen at Lehringen, Germany, where a spear with a fire-hardened tip was associated with an elephant carcass), and stone points with tangs or thinned bases suggest that these forms may have been hafted onto spear shafts, suggesting the development of composite tools. Rare bone points are also known from this time.

Fire and hearth structures are much more common during this period, although clear architectural features outlined by stones or bones are rare. Sites are numerous in caves and rock-shelters, as well as open-air sites on plateaus and along river floodplains.

Occasional perforated and grooved shells and teeth at a few sites imply the emergence of some personal adornment and, along with the infrequent presence of ocher as well as a number of well-documented burials, suggest at least some symbolic component to hominid behavior during this period of the Paleolithic (McBrearty and Brooks 2000).

Important Middle Paleolithic/Middle Stone Age sites include Combe Grenal, Pech de L'Azé, Le Moustier, La Quina, and La Ferrassie in France; Krapina in Croatia; Cueva Morin in Spain; Tabun, Skhūl, Kebara, Amud, and Qafzeh in Israel; Shanidar in Iraq; Dar es-Soltan in Morocco; Bir el Ater in Algeria; Haua Fteah in Libya; Kharga Oasis in Egypt; Diré-Dawa, Omo-Kibish, and Middle Awash in Ethiopia; Enkapune Ya Muto, Prospect Farm, and Kapthurin in Kenya; Kalambo Falls and Twin Rivers in Zambia; and Florisbad, Border Cave, Klasies River Mouth Cave, and Die Kelders Cave in South Africa.

Late Paleolithic

The Late Paleolithic (often called Upper Paleolithic in Europe and Later Stone Age in Africa) is found between 40,000 and 10,000 years ago, at which time the last glaciation receded. This period of human prehistory overlaps and is contemporaneous with the end of the Middle Paleolithic/Middle Stone Age in some regions. During this time, humans inhabited tropical, subtropical, temperate, desert, and arctic climates; occupied present-day Australia, New Guinea, and Tasmania after crossing significant bodies of water; and, late in this period, spread to the Americas via the Bering Straits (see chapters "▶ The Dentition of American Indians: Evolutionary Results and Demographic Implications Following Colonization from Siberia" and "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3). Late Paleolithic industries are almost always associated with anatomically modern humans (*Homo sapiens sapiens*), but some early Upper Paleolithic sites in Europe are also contemporaneous with the last populations of Neanderthals (see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3) there.

Late Paleolithic stone industries are often characterized by blade technologies, elongated flakes produced by soft hammer or indirect percussion, in which a punch is placed on the edge of a blade core and struck with a percussor. These blades were then made into a variety of tool forms, including end scrapers, burins, and backed knives (Fig. 9). Some Late Paleolithic technologies emphasized bifacial points, such as the Solutrean of Spain and France and the Paleo-Indian occurrences of the New World (Clovis and Folsom) (see chapter "▶ The Dentition of American Indians: Evolutionary Results and Demographic Implications Following Colonization from Siberia," Vol. 3). Such points may have been produced by soft hammer technique or by pressure flaking, in which small flakes are detached by directed pressure rather than by percussion. Some raw materials appear to have been heat treated to make them easier to work. Other Late Paleolithic technologies emphasized bladelets (small blades) and geometric microliths, which were hafted as composite tools into a range of projectiles and cutting tools. These microlithic

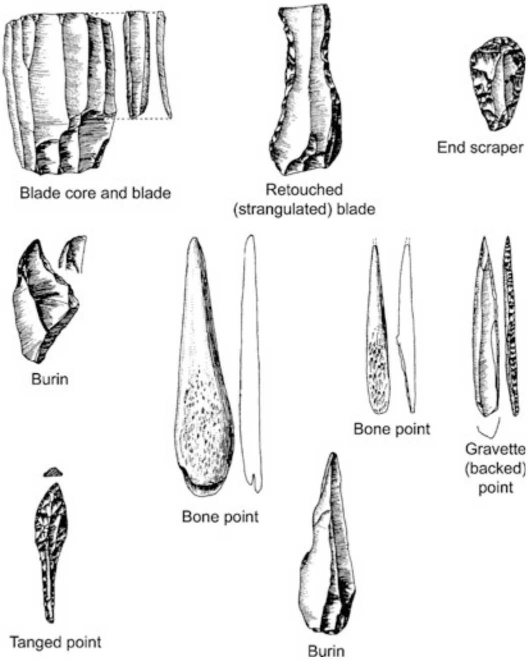


Fig. 9 Late Paleolithic tools: tools made on blades struck from prepared cores were important components of these technologies, made into such forms as end scrapers, burins, and points, as were formal tools shaped from bone, antler, and ivory

technologies are characteristic of the Later Stone Age of Africa as well as some parts of central and eastern Asia.

A diagnostic element of many Late Paleolithic industries is an emphasis on nonlithic materials for tools, including bone, antler, and ivory, made into a range of artifact forms such as points, needles, spear-throwers, shaft straighteners, and harpoons. Hooked spear-throwers are essentially mechanical devices to increase the velocity and/or distance of a projectile, and thus represent a significant advance in hunting technology or weaponry. The small size of some points and microliths toward the end of the Late Paleolithic suggest the development of bow and arrow technology, and arrows are preserved at Stellmoor, Germany.

Several human sculptures from the Late Paleolithic suggest clothing such as hooded parkas, headdresses, and aprons. The development of bone and antler needles also suggests that sewed clothing was common after 20,000 years ago, and recently discovered impressions on fired clay fragments from the Czech Republic indicate woven textiles, presumably of plant material.

Controlled use of fire appears to be a universal trait during this period, with hearths sometimes lined with stones. Architectural features are much more common than in earlier periods, with hut structures delineated by stone or bone patterns, by postholes, and sometimes with hearth structures and other apparent activity areas within (such as toolmaking or tool-using). Sites tend to be more numerous and have denser concentrations of materials, suggesting larger populations and more regular habitation of sites.

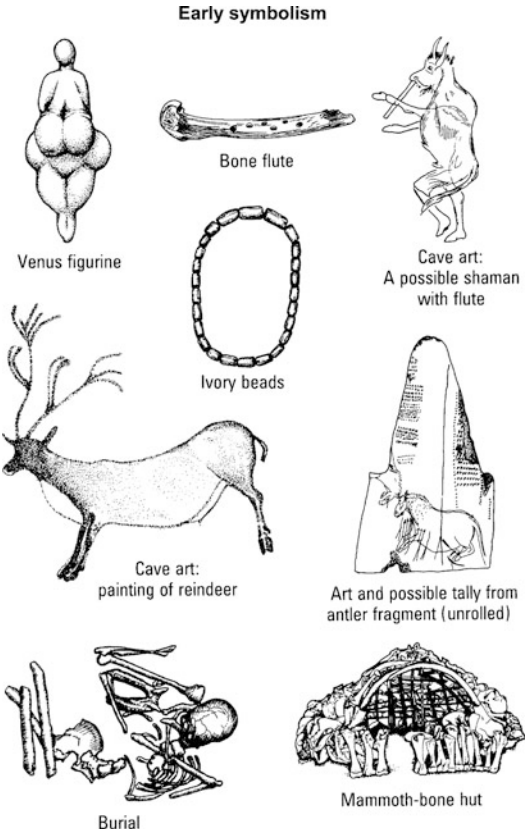

Fig. 10 Examples of probable symbolic behavior in Late Paleolithic times, expressed in art, personal adornment, music, notation, burial, and possibly more formal architecture

Relatively late in the time span of the Late Paleolithic, the first evidence of human occupation of the Americas appears. The most widespread evidence is attributed to the Clovis culture, characterized normally by fluted spear points and often associated with mammoth remains, dating to ca. 13,500–13,000 years ago. Several sites may predate the Clovis in the Americas by several thousand years (Meltzer 2010).

One of the most distinctive characteristics of the Late Paleolithic is the proliferation of symbolic expression in art and personal adornment (Fig. 10). This can be seen in the naturalistic representation of animals and, more rarely, humans in painting and sculpture as well as in the more abstract geometric designs. A variety of media were employed for artistic expression, including use of charcoal, pigment paints, antler, bone and ivory, and clay, as well as a diversity of techniques, including drawing, painting, engraving, carving, and modeling. Personal adornments are sometimes numerous, manifested in beads or pendants of shell, bone, tooth, antler, ivory, and stone. This proliferation of symbolic expression, best seen in the European Upper Paleolithic, has sometimes been referred to as the “Creative Explosion.” Some of these artistic manifestations, particularly paintings, drawings, and engravings, are located in deep, hard-to-access recesses of caves, suggesting a ritualistic and religious aspect to this symbolism. In view of the complexity of the material culture of this period and its well-developed symbolic component, it is likely that modern human language abilities were fully developed by this time, if not before.

Late Paleolithic burials are more common and more elaborate than in the Middle Paleolithic. Men, women, and children were sometimes interred with rich grave goods, including stone tools, jewelry, and bone/antler/ivory artifacts. Again, this suggests an important symbolic component and a probable belief in an afterlife, in other words, something akin to a spiritual belief and a religion.

Important sites include Lascaux, Pincevent, La Madeleine, Abri Pataud, Cro-Magnon, Solutré, Chauvet, and Laugerie Haute in France; El Castillo, Altamira, and Parpalló in Spain; Dolní Věstonice in the Czech Republic; Vogelherd in Germany; Istállóskö in Hungary; Willendorf in Austria; Kebara Cave in Israel; Ksar Akil in Lebanon; Kostienki and Sungir in Russia; Mezin and Mezhirich in Ukraine; Mal'ta in Siberia; Zhoukoudian Upper Cave in China; Lukenya Hill in Kenya; Mumba Cave in Tanzania; Nelson Bay Cave, Die Kelders, Elands Bay Cave, and Wilton, in South Africa; Haua Fteah in Libya; Lake Mungo in Australia; and Blackwater Draw in New Mexico (North America).

Conclusion

The earliest evidence of hominid technology dates to between 2.6 and 2.5 Ma in the Ethiopian Rift Valley. The Oldowan, characterized by simple cobble cores, flakes, retouched flakes, and battered percussors, is associated in time with later australopithecines and early forms of larger-brained hominids assigned to the genus *Homo*. Cut marks on fossil mammalian bones and hammerstone fracture of long bones indicate that one aspect of these early technologies was the processing of animal carcasses.

By 1.8–1.7 Ma, the prehistoric record documents the emergence of *Homo ergaster/erectus* and the early Acheulean, characterized by new artifact forms such as handaxes, cleavers, and picks. The first hominid migrations out of Africa and into Eurasia are documented at the same time. Later Acheulean sites, ca. 500–250 Ka, are often characterized by better-made and more symmetrical handaxes and cleavers and are associated with *Homo heidelbergensis*. Handaxe industries are known for much of Africa, the Near East, Western Europe, and the Indian subcontinent. In much of Eastern Europe and East Asia, contemporary hominid populations were producing simpler cobble cores and a range of retouched flake tools.

The Middle Stone Age/Middle Paleolithic emerges around 250 Ka, usually characterized by prepared core technologies (e.g., Levallois cores, flakes, and points), side scrapers, denticulates, and retouched points. In Africa these industries are associated with larger-brained archaic forms (sometimes assigned to *Homo helmei*) and early anatomically modern humans. In the Near East, such industries are associated with Neanderthals and modern humans. In Europe the Middle Paleolithic appears to be exclusively associated with Neanderthals. In East Asia during this time, the lithic industries are usually simpler core/flake/retouched flake industries, associated with archaic forms of hominids. Evidence of fire becomes very common during this period.

The Late Paleolithic (Upper Paleolithic, Later Stone Age) emerges in the Old World in the last 50,000 years. Industries are often characterized by blade production, blade tools such as backed knives, end scrapers, and burins, and a range of unifacial and bifacial point styles. For the first time, materials such as bone, antler, and ivory (and presumably a very rich wood technology) became major raw materials for tools. Architectural features such as hut structures and well-made hearths became common for the first time. The first representational artwork was produced on cave walls in the forms of paintings and engravings as well as mobiliary sculpture and engraving.

During the last glaciation, modern humans reached Australia by 40 Ka and the Americas by at least 15 Ka. Around the world, stone industries document a greater variability over time and space, suggesting stronger regional cultural rules regarding material culture and more innovation and technological change over time. With more complex technologies and adaptive patterns, humans were able to occupy extreme environments such as dense tropical forests, arid deserts, and frigid tundras. In a number of places in the Near East, Africa, East Asia, Oceania, and North and South America, these Paleolithic foraging societies slowly emerged as sedentary farmers, and then in some of these places, complex societies emerged as "civilizations" with urban centers.

The Paleolithic lasted over two-and-a-half million years and, in terms of duration, covers well over 99 % of human technological history. It is no exaggeration to say that the human lineage is a product of its Paleolithic past and that the modern human condition, characterized by industrialization, farming, urban life, and ever-increasing networks of communication and globalization, is firmly rooted in its Stone Age past.

Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia

Nicholas J. Conard

Contents

Abstract

This chapter examines large-scale patterns of behavioral change that are often viewed as indicators for the advent of cultural modernity and developed symbolic communication. Using examples from Africa and Eurasia, the chapter reviews patterns of lithic and organic technology, subsistence, and settlement as potential indicators of modern behavior. These areas of research produce a mosaic picture of advanced technology and behavioral patterns that come and go

during the late Middle and Late Pleistocene. Based on these data the emergence of modern behavior, as seen in the archaeologically visible material record, appears to be gradual and heterogeneous in space and time. During the early part of the Late Pleistocene, personal ornaments in the form of perforated seashells are documented in southwestern Asia and northern and southern Africa. By about 40,000 years ago (Ka), a diverse array of personal ornaments are documented across the Old World in association with Neanderthals and anatomically modern humans. These include both modified natural objects and fully formed ornaments. The timing and distribution of the appearance of figurative art, mythical imagery, and other classes of artifacts including musical instruments point to a more punctuated development of fully modern behavior during the middle of the Late Pleistocene and certainly no later than 40 Ka. Due perhaps in part to the long and intense history of research, much, but by no means all, of the relevant data come from Europe. Early figurative art from the Aurignacian of southwestern Germany, northern Italy, Austria, and southern France provides undisputed evidence for fully developed symbolic communication and behavioral modernity. This chapter also discusses some of the hypotheses for the development and spread of cultural modernity and rejects a strict monogenetic model in favor of a pattern of mosaic polycentric development. This chapter highlights the need for new refutable, regional and superregional hypotheses for the advent and spread of behavioral modernity.

Introduction

The question of when in the course of human evolution hominids became like ourselves has been at the center of several decades of productive debate in paleoanthropology. Reduced to the most fundamental level, the appearance of anatomical and behavioral modernity is a question of at what time in the course of evolution hominid anatomy and behavior fall within the variability documented in recent societies. The key component of fully modern cultural behavior is communication within a symbolically organized world and the ability to manipulate symbols in diverse social and economic contexts.

This chapter will not address the development of modern human anatomy; here, I consider some of the key evidences for the evolution of complex behavioral systems. While there is no consensus about when modern behavior can first be identified in the archaeological record, by no later than about 40 Ka, various finds documenting the production of diverse ornaments, musical instruments, figurative representations, and mythical imagery provide undisputed evidence for cultural modernity. These and other archaeologically visible indicators of cultural modernity point to a patchy development of complex cultural behavior and symbolic communication across the Old World. While regional patterning is becoming increasingly visible (Delporte 1998; McBrearty and Brooks 2000; Bon 2002; Conard and Bolus 2003; Hovers and Belfer-Cohen 2006; Texier et al. 2010; d'Errico and Stringer 2011; Porraz et al. 2013), the current data on this topic include an uneven distribution of evidence that has been put through a selective taphonomic filter and that reflects diverse regional histories of research. These biases hinder the location of convincing centers of origin and dispersal for many of the key features considered here.

At present, we see diverse points of view regarding the origins of behavioral modernity, and current interpretations include but are not limited to the following models: (1) gradual African origin (McBrearty and Brooks 2000), (2) coastal origin in connection with new dietary patterns during the early Late Pleistocene (Parkington 2001), (3) punctuated late African origin (Klein 2009; Klein and Edgar 2002), (4) gradual origins across multiple human taxa and multiple continents (d'Errico et al. 2003), and (5) relatively late origins among multiple human taxa, including Neanderthals' own Upper Palaeolithic revolution (Zilhão 2001, p. 54). Here, I argue for a mosaic polycentric advent of behavioral modernity (Conard 2008). The evolution toward behavioral modernity accelerated in the middle of the Late Pleistocene, and culturally modern behavior with diverse regional signals and local innovations can be seen in many parts of Africa, Europe, Asia, and Australia between 30 and 45 Ka. While archaic and modern humans must have interacted in many regions in the context of diverse social and ecological settings, ultimately modern humans were at a demographic advantage in all regions and replaced archaic humans with relatively little interbreeding (Prüfer et al. 2013; Sankararaman et al. 2014).

This chapter reviews some of the evidence for advanced cultural behavior and argues for a highly variable pattern of development depending on specific historical and evolutionary contingencies. The development of modern behavior does not in my view represent a one-time-only quantum leap, but a complex pattern of innovation, spread, and local extinction of new traits through cultural selection and social reproduction. Social, technological, and linguistic reproductions through learning are fostered by the biological success of the members of societies, but are not only driven by demographic growth. Demographic trends and complex patterns of intra- and intersocietal contacts led to mosaic patterns of cultural development that result from specific historical and ecological events and processes during the Pleistocene. The current archaeological record provides glimpses of these evolutionary processes, but it would be naive to think that our current data on the fleeting material remains of the development and spread of behavioral modernity provide a one-to-one indication of where and when advanced technology, highly developed patterns of settlement and subsistence, ornaments, music, and abstract and figurative representation evolved. The question of why fully modern cultural behavior evolved is still more difficult to answer, but recent years have begun to see attempts to address the thorny questions of causality (Klein 2009; Parkington 2001; Shennan 2001; Lewis-Williams 2002; Conard and Bolus 2003; Jerardino and Marean 2010; Kuhn and Hovers 2013). Much more work is needed that addresses the potential causes of cultural evolution and develops testable hypotheses. In this context, monocentric and polycentric models need to be formulated and tested explicitly.

Turning to the more mundane aspects of archaeology, it is necessary to stress the ambiguities and problems with dating sites in excess of 40,000 years. Radiocarbon dating, the strongest tool for dating Later Stone Age (LSA) and Upper Paleolithic assemblages, begins to reach its limits in the period before 40 Ka. Here, several factors come into play. In this period, in excess of seven radiocarbon half-lives, contamination becomes a serious problem. The isolation of preserved collagen in bones and similar problems related to sample preparation become more problematic than in younger periods (Higham 2011). Also, the physics of the AMS and beta counting become more challenging as minimal contamination begins to affect the results more strongly and the uncertainties related to the chemistry and instrument background become significant. Equally important is the wealth of evidence that there are major fluctuations in radiocarbon levels, probably in connection with variations in production due to magnetic excursions (Voelker et al. 2000; Beck et al. 2001; Conard and Bolus 2003; Hughen et al. 2004). These factors tend to make radiocarbon ages underestimate the calendar age of archaeological materials in excess of 30,000 years (Higham 2011; Higham et al. 2012).

Other methods, including luminescence dating, have great potential for sorting out the chronology of the emergence of modern human anatomy and behavior, and the prospects for gaining improved chronological control for the later stages of human evolution are excellent (Richter et al. 2000; Jacobs et al. 2003a, b, 2008; Tribolo et al. 2013).

This presentation will of necessity be brief and in no way attempts to be encyclopedic. Instead, I consider examples to illustrate the overall pattern of behavioral evolution. These examples are often drawn from regions where I have worked and know the data best. The subject matter is divided into two main sections. The first deals with the nuts and bolts of Paleolithic archaeology and focuses on lithic and organic artifacts and patterns of subsistence and settlement. The second section deals more with data that provide more direct access to the Paleolithic world of symbols, beliefs, and communication and reviews evidence for burials, ornaments, figurative and nonfigurative representation, and music as a means of defining modern cultural patterns. In general, the results from a review of the latter kinds of evidence give a better indication of the origins of behavioral modernity. My concern here is not in developing trait lists or single signatures for modernity, but rather to look at the evolutionary contexts of diverse classes of data that may help us to identify patterns of behavioral evolution. Other similar reviews of this evidence at different geographic scales can be found in a number of publications and should be consulted along with the primary references for further details (Deacon and Deacon 1999; McBrearty and Brooks 2000; d'Errico 2003; d'Errico et al. 2003; Conard 2004a; Hovers and Belfer-Cohen 2006; Klein 2009; d'Errico and Stringer 2011). Finally, many of the chapters in this volume present up-to-date information that is of central importance for defining the evolution of modern behavior.

Technology, Settlement, and Subsistence as Measures of Modernity

Lithic Technology

Stone artifacts are a physically robust class of artifacts and often survive the numerous potential forms of taphonomic destruction. In this regard, they are a major source of data on early human behavior. In many Paleolithic settings, stone artifacts are the most abundant class of anthropogenically altered material. These attributes of lithic artifacts make them the most important means of defining Paleolithic cultural groups. Thus, if specific lithic artifacts can be shown to provide an indication of modern cultural behavior, scholars could use such finds as indicators of modernity.

Despite attempts to define linear and cladistic systems for the evolution of stone tools (Foley 1987; Foley and Lahr 2003), lithic technology is based on learned behavior and is not directly transmitted biologically. Thus, it comes as little surprise that new forms of lithic technology come and go over the more than two-million-year-old Paleolithic record. Oldowan technology is the most common form of flint knapping at the pyramids of Giza (Conard 2000), and this simplest of knapping approaches comes and goes throughout the Stone Age. Many other knapping technologies also come and go over the last several hundred thousands of years that are the backdrop for the development of anatomical and cultural modernity. Hand axes, Levallois technology, blade technology, and other elements of stone knapping come and go and do not provide certain indicators of behavioral modernity.

Additionally, the ethnographic record points to the problems associated with viewing lithic technology as a clear indicator of levels of cultural evolution. Subrecent ethnographic sources document cases of hunter-gatherers in regions including, for example, parts of Australia and Tierra del Fuego, who used Stone Age technologies that would leave no traces of behavioral modernity. These groups were undeniably modern humans and highly developed in respect to their linguistic skills and their ability to manipulate symbols, yet the lithic technology and the archaeologically visible material culture would leave no traces of this modernity.

Lithic technology provides no simple solution to the problems related to identifying modernity. Even blades, which were once seen as clear indicators for behaviorally modern Upper Paleolithic and Later Stone Age cultures, have been demonstrated in diverse contexts in Africa, the Near East, and Europe (Rust 1950; McBurney 1967; Besançon et al. 1981; Singer and Wymer 1982; Conard 1990, 2012; Révillion 1994; McBrearty and Brooks 2000; Locht 2002; Meignen 2011; Wojtczak 2011; Fig. 1). These blade-based assemblages date to the second half of the Middle Pleistocene and the Late Pleistocene and include technologies based on Upper Paleolithic platform cores and non-Levallois and Levallois blade production.

Lithic assemblages document a heterogeneous pattern of development, with forms coming and going across the Old World. While in Europe there is doubtless a difference between Middle and Upper Paleolithic assemblages, many forms typically associated with the Upper Paleolithic appear in earlier periods, and it is becoming increasingly clear that the variability documented by Bordes (1961) in the Middle Paleolithic of southwestern France reflects only a small portion of the overall lithic variability. Many regions of Europe (Bosinski 1967, 1982; Conard and Fischer 2000) show a diverse pattern of cultural development that is analogous to that documented in Africa (Clark 1982, 1988; McBrearty and Brooks 2000). Also in the Near East, the early Middle Paleolithic includes lithic assemblages such as Yabrudian and Humalian, and the later Middle Paleolithic is characterized by

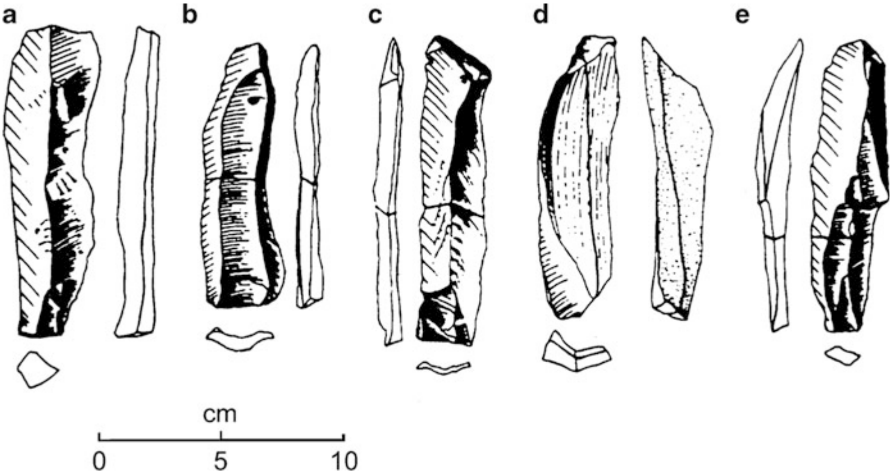

Fig. 1 Kapthurin Formation, Kenya. Late Middle Pleistocene blades ca. 250,000 years old (After McBrearty and Brooks 2000)

Levalloisian assemblages that were made by both Neanderthals and anatomically modern humans (Shea 2003). The latter observation demonstrates how tenuous the link is between anatomical and cultural evolution.

As Bosinski (1982), Clark (1982, 1988), and others have long pointed out, the Middle Stone Age (MSA) and Middle Paleolithic are marked by the growth and increased visibility of local traditions. The frequently made suggestion that lithic technology from these periods is static or even boring strikes me as incorrect. In many areas where high-quality data are available, MSA and Middle Paleolithic assemblages show considerable diversity. The development of local traditions appears to increase with time in some areas of Africa and Eurasia (Bosinski 1967; Conard and Fischer 2000; Wadley 2001; Jöris 2002; Conard et al. 2012; Porraz et al. 2013), but these trends are, to a certain extent, a reflection of the improved quality of data that results from both better chronological control and more numerous assemblages per unit time. Researchers who try to define variability must consider the quality and density of the available data. In general, early periods of the MSA and Middle Paleolithic have provided less data suitable for addressing these questions than the later phases of these periods or the LSA or Upper Paleolithic. Thus, it is not surprising that, in general, assemblages from more recent periods document more technological and typological variation than samples from earlier periods.

The complexity of Middle Paleolithic and MSA lithic technology is highly variable, but at times advanced. Hafting and composite tools have been documented directly and indirectly in many regions. In Africa, we can consider the standardized-backed forms from Howiesons Poort assemblages to be strong candidates for hafting, as well as numerous point assemblages of the Late Pleistocene and perhaps the Middle Pleistocene (Singer and Wymer 1982; McBrearty and Brooks 2000; Lombard and Phillipson 2010; Fig. 2). In southwestern Asia, Shea (1988, 1993, 1998) has

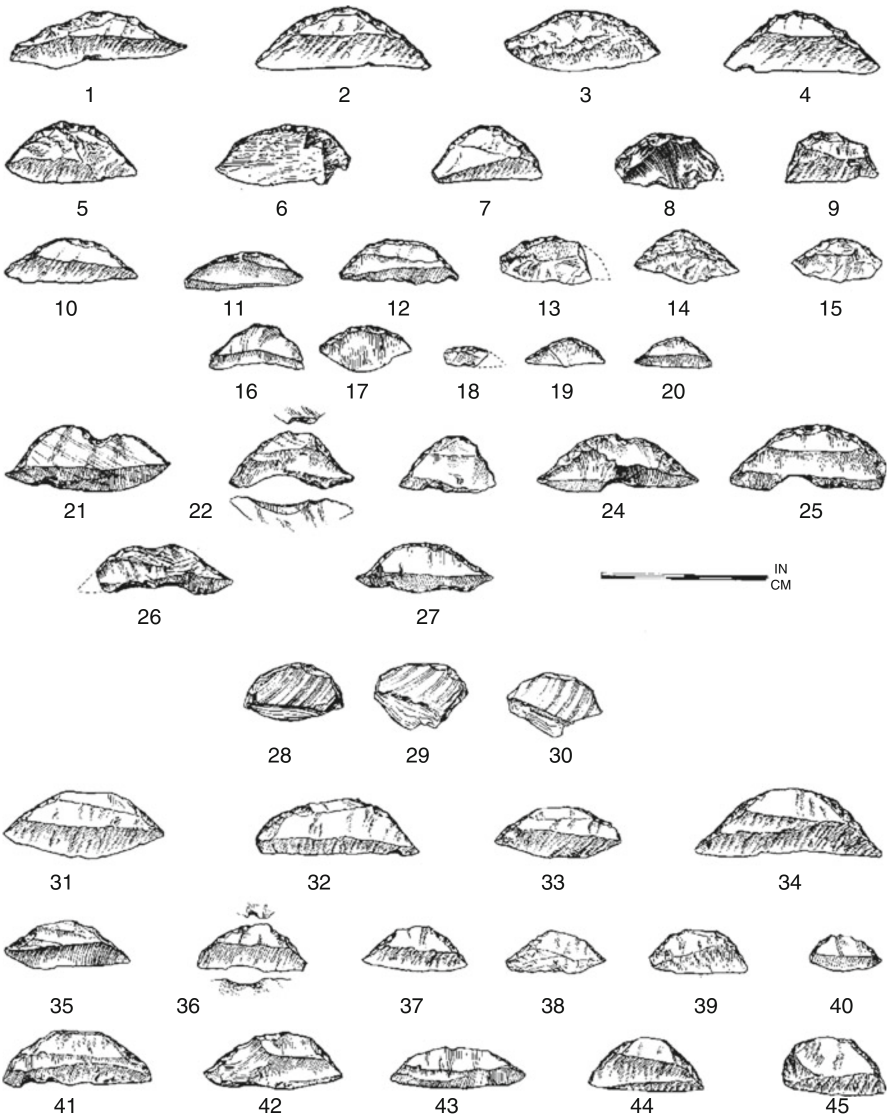

Fig. 2 Klasies River Mouth, South Africa. Highly standardized lithic artifacts from the Howiesons Poort assemblage ca. 75,000 years old (After Singer and Wymer 1982)

long argued for hafting based on patterns of damage to artifacts and use wear. Mastic attached to Middle Paleolithic artifacts at Umm el Tlel in central Syria also demonstrates the use of hafting and provides evidence for composite tools (Boëda et al. 1998). In Europe, a similar pattern is present with small-backed artifacts that almost certainly required hafting being recovered at (Conard 1992) Fig. 3 (Tönchesberg). European chipped stone points would have required hafting

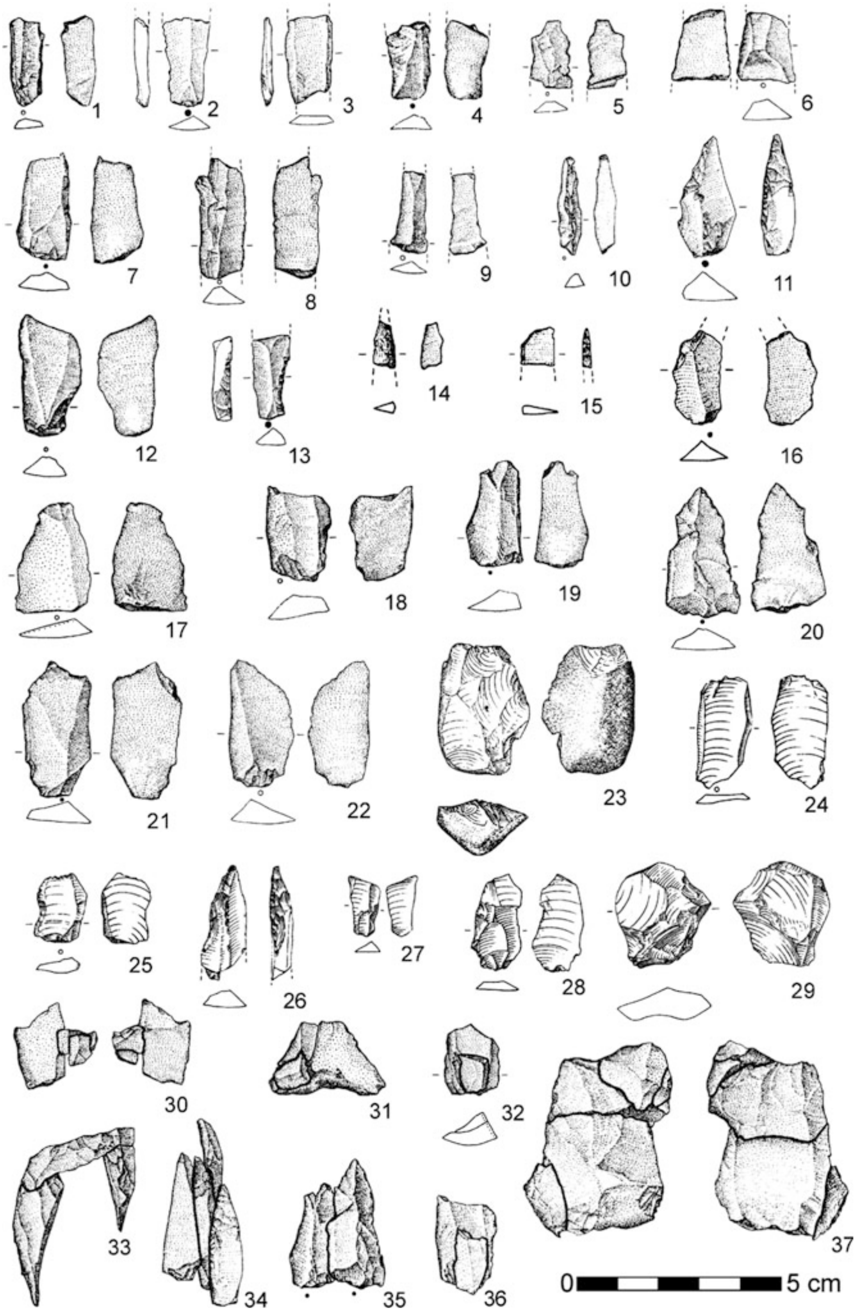

Fig. 3 Tönchesberg 2B, Germany. Middle Paleolithic assemblage with blades, bladelets, backed points, and backed bladelets and imported lithic materials ca. 100,000 years old (After Conard 1992)

as on other continents, and mastic has been recovered, for example, at the Middle Paleolithic sites of Königsaue (Mania and Toepfer 1973), Neumark-Nord (Mania et al. 1990; Meller 2003), Bocksteinschmiede (Wetzel and Bosinski 1969), and Inden-Altdorf (Pawlik and Thissen 2011) in Germany and Campitello Quarry in Italy (Mazza et al. 2006). The production of mastics such as birch pitch requires advanced knowledge of pyrotechnology and material sciences and provides good evidence for advanced cultural behavior (Wadley et al. 2009; Roebroeks and Villa 2010; Pawlik and Thissen 2011). Through experimental and use-wear studies, Rots has also demonstrated the hafting in multiple contexts during the Middle Paleolithic and MSA (Rots 2010, 2013; Rots et al. 2011).

Lithic assemblages of the MSA and Middle Paleolithic do not provide the evidence needed to define precisely when modern patterns of human behavior developed. They do, however, clearly show a heterogeneous pattern of technological development and transmission indicating that the beginnings of the LSA and Upper Paleolithic did not see fundamental revolutionary changes in technology across the Old World. This transition saw the further development of both new and older technologies. While more advanced forms of lithic technology came into broader use in the LSA and Upper Paleolithic, most of these technologies have well-documented precursors in earlier periods.

Organic Technology

The development of organic technology shows a pattern analogous to that of lithic technology. While the LSA and Upper Paleolithic are defined on the basis of new artifact forms that occur in easily detectable numbers, organic artifacts have antecedents extending into the ESA and Lower Paleolithic. Thus, the beginnings of the LSA and Upper Paleolithic reflect legitimate archaeological divisions, but the changes represent a further elaboration and intensification of technologies that in some cases existed earlier.

In regard to this question, the most important information comes from the finds from Schöningen in northern Germany, where Thieme's excavations have yielded eight wooden spears with multiple designs and other wooden tools dating to the late Lower Paleolithic about 300 Ka BP (Thieme 1997, 1999, 2007; Fig. 4). These tools are of the highest workmanship and lend support to the importance of wooden tools from Clacton-on-Sea (Oakley et al. 1977) and Lehringen (Thieme and Veil 1985). Middle Pleistocene hominins manufactured the spears and other wooden artifacts from Schöningen with great care, and their context demonstrates a high degree of planning depth, social organization, and sophisticated communication. Unless we postulate that this part of Northern Europe enjoyed a privileged position in human cultural evolution, we must conclude that organic technology and diverse well-made wooden tool assemblages were a part of the daily life of the Lower and presumably Middle Paleolithic inhabitants of Europe. These waterlogged sites provide a highly favorable setting for preservation that cannot be matched in other sedimentary settings, but occasional finds of preserved wood in Africa and

Fig. 4 Schöningen, Germany. Lower Paleolithic wooden spear and horse bones ca. 300,000 years old (Photo N.J. Conard)

the Near East leave room for optimism that future work may uncover comparable wooden artifacts.

Much has been made of the development and elaboration of bone, ivory, and antler tools in recent years (Gaudzinski 1999; d'Errico 2003; d'Errico et al. 2003; Soressi et al. 2013). MSA assemblages from sites including Apollo 11 (Vogelsang 1998), Klasies River (Singer and Wymer 1982) (see Fig. 5), Sibudu (Backwell et al. 2008), and Blombos (Henshilwood et al. 2001) have produced a wealth of bone artifacts (Fig. 4). Many examples are sharpened bones and bone splinters. Other bone tools show a series of notches or more enigmatic forms. An exceptional case is the elaborately made harpoons from Katanda in D. R. Congo (Brooks et al. 1995); these finds would be remarkable if they were indeed of early Late Pleistocene age. Certainly, by the middle of the Late Pleistocene, bone tools were widespread in the MSA.

The European Lower Paleolithic also documents early examples of bone tools including carefully manufactured hand axes (Segre and Ascenzi 1984; Gatti 1993).

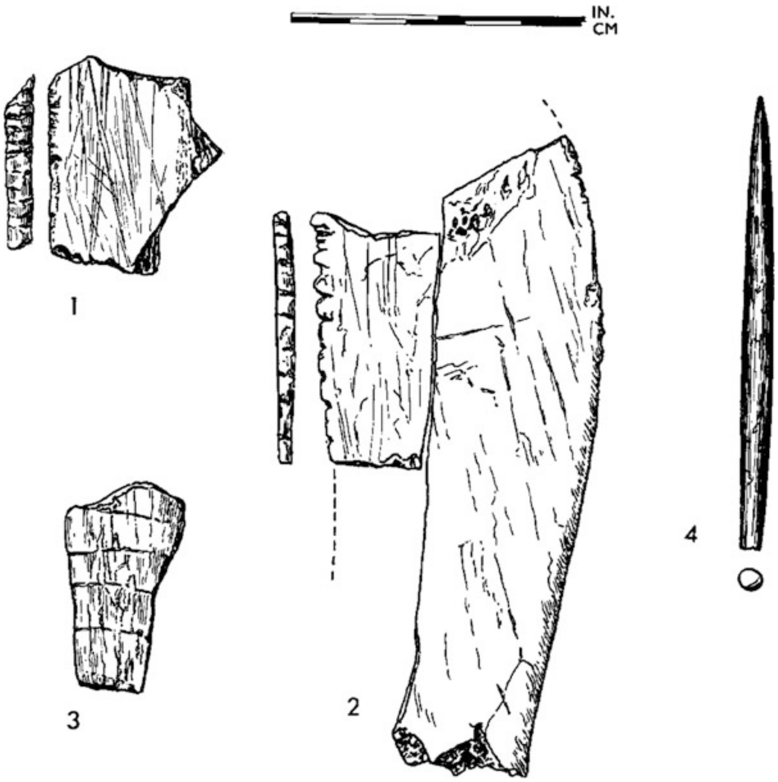

Fig. 5 Klasies River Mouth, South Africa. Bone artifacts from Middle Stone Age deposits ca. 75,000 years old (After Singer and Wymer 1982)

Similarly, bone tools are well documented at Middle Paleolithic sites, including Salzgitter-Lebenstedt (Gaudzinski 1999), Große Grotte (Wagner 1983), and Vogelherd (Riek 1934). Bone tools are by no means as common or complex as those of the Upper Paleolithic, but they no doubt existed in Middle Paleolithic assemblages. Bone tools were clearly used by late Neanderthals in many settings, and they have occasionally been documented in large numbers (d'Errico et al. 2003). While research continues to document more diverse and more specialized osseous tools associated with archaic hominins, such as those from Abri Peyrony and Pech de l'Azé I (Soressi et al. 2013), tools from the Middle Paleolithic are often less elaborate than the organic tools of the Upper Paleolithic. Split base points, for example, serve as diagnostic artifacts for the early Aurignacian over much of Europe and occur in significant numbers starting around 40 Ka (Albrecht et al. 1972; Hahn 1977).

Finally, the Late Pleistocene sees further evidence for cultural innovations that should be mentioned here. These innovations include the widespread use of grinding technology during the MSA and Middle Paleolithic of northern Africa (Wendorf et al. 1993; Van Peer et al. 2004), evidence for fire-making technology in the Swabian Aurignacian (Riek 1934, p. 161; Weiner and Floss 2004), and water transport technology in the form of perforated ostrich eggshells (Vogelsang 1998; Parkington et al. 2005; Texier et al. 2010; but see Kandel 2004). As these and other less well-studied categories of finds and behavioral innovations become topics of more systematic research, they will play a more prominent role in the discussions about the evolution of cultural modernity.

Subsistence

Patterns of subsistence vary in time and space due to changing environmental conditions and changes in technology combined with changing social and settlement strategies. Although most sites do not contain preserved botanical remains, there is every reason to assume that plants played an important part in the diet of all hominids, just as they do for all ethnographically documented societies (Owen 2005). The diet of Neanderthals as reflected in stable isotope data indicates a relatively high component of animal resources (Bocherens et al. 1999, 2001; Bocherens 2011), but these results do not preclude the use of plants in the diet, and even in the harshest arctic and desert environments, plants are seasonally available and nutritionally important.

This is not the place to summarize the history of research on this question, but recent decades have seen a shift from assuming that archaic and early modern humans practiced fully developed systems of hunting and food sharing, to a critical assessment and rejection of earlier interpretations by many Anglophone colleagues. More recently, many case studies have provided convincing evidence that both later archaic and anatomically modern humans practiced systematic hunting of large, medium, and small game. These data by no means suggest that patterns of subsistence are homogenous over whole continents or subcontinents, but the advocates of subsistence forms based on scavenging or ineffective forms of hunting (Binford 1989; Stiner 1990, 1994) seem to have overstated the case against the existence of reliable hunting economies within MSA and Middle Paleolithic societies (Marean and Kim 1998; Marean and Assefa 1999). In recent years faunal studies have increasingly shown a diverse array of adaptations among late archaic and early modern humans (Clark and Speth 2013), with increasing evidence for intensification and the exploitation of a broader range of taxa as hominin population densities increase and highly ranked faunal resources become less available (Stiner 2005, 2013; Speth 2010, 2013).

Again in this context, the finds from Schöningen are of central importance and have redefined the discourse on Lower Paleolithic subsistence. Thieme's (1997, 1999, 2007) team recovered eight spears from Schöningen in direct association with the bones of several dozen horses in deposits dating to ca. 300 Ka (Voormolen 2008; van Kolfschoten 2014). These discoveries from the mid-1990s brought the more extreme assessment of Lower and Middle Paleolithic subsistence based on obligate scavenging to an end, and as far as I am aware, the implications of these remarkable finds for documenting hunting of large game by archaic hominids and the implications of the recovery of a yew wood spear with the skeleton of an Eemian age forest elephant at Lehringen have not been questioned in recent years. These finds do not demonstrate that hunting large game was a universal phenomenon in the late Middle and Late Pleistocene, but they do document the existence of well-planned and successfully executed hunting of large and fast game using refined and deadly technology.

More mundane sources of information tend to support this view. Numerous faunal assemblages indicate that late archaic and early modern humans had frequent early access to game. In most settings, the possibility of scavenging cannot be completely excluded, but active hunting is the most parsimonious explanation for the faunal assemblages at sites including, for example, Salzgitter-Lebenstedt (Gaudzinski and Roebroeks 2000), Tönchesberg (Conard 1992), and Wallertheim (Schmidtgen and Wagner 1929; Gaudzinski 1995; Conard and Prindiville 2000). In other contexts, in many parts of Eurasia and Africa, similar evidence for the role of mammals in the diet of Middle Paleolithic and MSA people is available (Gaudzinski 1996; Marean and Kim 1998; Marean and Assefa 1999; Burke 2000; Bocherens et al. 1991, 2001; Costamagno et al. 2006; Rendu et al. 2011, 2012; Clark and Speth 2013). Finally, it must be stressed that scavenging fresh carcasses is an attractive economic option in contemporary hunting and gathering societies (O'Connell et al. 1988). Thus, there is no reason to stigmatize Paleolithic scavenging as a premodern adaptation.

In southern Africa, Klein and Parkington have developed new approaches and hypotheses for the development of subsistence practices during the MSA. Parkington (2001) stresses the key role of the exploitation of coastal resources for brain development and the origin of cultural modernity in coastal settings. He has also suggested that similar processes may have driven human evolution in other coastal environments, including the circum-Mediterranean region. Jeraldino and Marean (2010) have also emphasized the role of coastal adaptations in the later phases of human evolution in southern Africa. Klein (2009) has looked at small game such as tortoises and marine resources as playing an important role in MSA and LSA subsistence. He argues that until ca. 50 Ka, hunting was limited to comparatively easily hunted game and that people only started systematically hunting dangerous animals, including suids and buffalo in the late MSA and LSA. Klein sees this shift in subsistence as an indication of the rise of cultural modernity in connection with genetic mutations and the appearance of fully developed language. Both Parkington's and Klein's hypotheses have been received with considerable skepticism, but both hypotheses present entirely welcome, refutable models for the rise of cultural modernity. Given the general lack of clearly formulated models that provide causal explanations for the rise of behavioral modernity, these hypotheses, even if they are later demonstrated to be incorrect, have fostered considerable new research. This is certainly the case of the critical assessment of the early evidence for hunting by Binford and colleagues in the 1980s and 1990s.

Like the other data we have considered thus far, the evidence on subsistence during the Middle and Upper Pleistocene shows a pattern of advanced adaptations at an early date. With the possible exception of Parkington's model for increased use of marine resources in the Late Pleistocene, the data on subsistence tend to argue against a revolutionary change in economic and social behavior that defines the appearance of cultural modernity. The archaeological record of Mediterranean Europe demonstrates that Neanderthals also exploited marine resources as far back as during the late Middle Pleistocene and indicates that the early use of shellfish was not limited to modern humans living in Africa (Cortés-Sánchez et al. 2011). This being said, Stiner, Speth, and other scholars have documented how intensification led to the exploitation of lower ranked and more diverse resources as over the course of the Middle and Late Pleistocene (Stiner et al. 1999; Stiner 2005; Speth 2010, 2013; Steele and Klein 2009; Steele and Alverez-Fernandez. 2011; Conard et al. 2013). In general, hominins tend to exploit highly ranked resources when they are available, and thus, under similar conditions both archaic and modern hominins often exploited large- and medium-sized bovids, cervids, and equids when they were available (Münzel and Conard 2004).

Settlement

Reconstructing patterns of settlement and the organization of space is one of the more elusive ways of trying to define modern patterns of behavior. This relates to the general difficulty of reconstructing settlement dynamics in any period and particular problems associated with Paleolithic periods, where the amount and quality of data are generally poorer than in later periods. The analysis of Paleolithic settlement in the contexts of defining modern behavioral forms has two major approaches, one intrasite and the other regional.

Binford (1998), Wadley (2001), and others have argued that spatial organization within a find horizon can be used to define cultural modernity. Binford, for example, sees repetitive modular units of hearths and bedding areas in rock shelters as a hallmark of modern spatial organization. In his view, this pattern of spatial organization is not present before the LSA or Upper Paleolithic. Wadley sees a marked increase in spatial organization during the late MSA of Rose Cottage Cave in the Free State of South Africa as a further indication that the final stages of the MSA may reflect the period in which cultural modernity developed.

In Europe, Kolen (1999) has pointed to the lack of clear evidence for architecture as an indication that neither Lower nor Middle Paleolithic groups regularly built shelters as centers of social and economic interaction, as are known in many later archaeological periods. Instead, archaic humans used what Kolen refers to as "nests" to provide shelter. If correct, this would indicate that settlement dynamics of archaic humans, including Neanderthals, fell outside the range of culturally modern people. Several researchers have questioned this model and suggest that even if clear architectural features other than hearths are generally lacking before the Upper Paleolithic, late Middle Paleolithic sites document spatially structured activity areas similar to those one would expect in sites of modern hunters and gatherers (Vaquero et al. 2001, 2004; Conard 2001b; Chacón Navarro et al. 2012).

As with many of the criteria considered here, it is unclear to what extent taphonomic factors and the quality of data affect our interpretations. Kolen, however, is certainly correct to note that clear evidence for anthropogenic shelters and dwellings is extremely rare prior to the Upper Paleolithic. Although less effort has been invested in studying the spatial structure of MSA sites, recent work at Sibudu has demonstrated the use of bedding and regular site maintenance in multiple find horizons (Goldberg et al. 2009, 2013a; Wadley et al. 2011). This kind of research promises to provide insights into the organization of space by early modern humans in southern Africa.

At a larger scale of analysis, we see more tantalizing, yet largely inconclusive, evidence for the use of space and distant resources as indicators of behavioral modernity. Important works by Geneste (1988), Roebroeks et al. (1988), Floss (1994), and others examine the use of distant raw materials as a source of information on Paleolithic economic and spatial organization. Especially in the context of the continental European approaches to the study of patterns of lithic reduction and technology (Geneste 1988; Hahn 1988; Boëda et al. 1990), much research has been aimed at linking patterns of lithic technology to systems of mobility and settlement. These and other studies show the nearly universal pattern that more distant raw materials are present at sites in more reduced form than local raw materials. This applies for all Paleolithic periods. In later periods more raw materials from distant sources are transported to sites, but there is no specific moment that reflects a quantum shift from non-modern to modern patterns of behavior. Also, the “provisioning of place” (Kuhn 1995) – that is, the movement of quantities of raw material to sites for future use – is documented on sites of both modern and archaic hominins (Conard and Adler 1997).

Examination of the abundance of distant raw materials as a reflection of the size of territories and long-distance economic and social relationships has also provided ambiguous results. Middle Paleolithic assemblages document the use of raw materials from 100 or more km away (Floss 1994; Féblot-Augustins 1997). Nonetheless, such long-distance transport of tools and raw materials is still more common in the Upper Paleolithic, and the difference is more one of degree than of kind. So far these kinds of data have not led researchers to devise a reliable means of distinguishing between archaic and modern behavioral forms. These lithic data also suggest mosaic, context-dependent systems of adaptations with considerable variability, rather than a black-and-white world of unilinear evolution, in which quantum leaps between archaic and modern behavior can be readily identified.

Finally, an analysis of site types and links between sites within settlement systems shows considerable diversity in MSA and Middle Paleolithic systems of settlement, but no easily recognizable criterion for defining behavior modernity (Conard 2001c, 2004b). Here, as in other areas, I doubt whether the search for a holy grail of cultural modernity is a productive way of defining a research program. Scholars continue to struggle to identify the origins of a settlement system that reflects a symbolically mediated landscape inhabited by culturally modern people. Furthermore, if our definition of behavioral modernity includes all ethnographically documented patterns of settlement, we must concede that a nearly endless diversity of adaptations among subrecent hunters and gatherers are by definition modern and by no means easy to distinguish from hypothetical non-modern settlement dynamics as indicated by the distribution of archaeologically visible material cultural remains.

Beyond Technology, Subsistence, and Settlement

As the discussion above suggests, identifying clear criteria for behavioral modernity is probably more likely in the realms of ideology and symbolic communication than in the nuts and bolts archaeology of chipped stone and faunal remains. Here, I consider several lines of argument and sets of data that lie outside the pragmatic economic concerns of day-to-day subsistence.

Burials

Most of the more complete human skeletons from before the Middle Paleolithic and Middle Stone Age appear to be the result of extraordinarily favorable taphonomic contexts. Despite arguments to the contrary by Gargett (1989, 1999) and other colleagues, there are a wealth of Middle Paleolithic human skeletons that seem to have been buried deliberately (Solecki 1971; Trinkaus 1983; Defleur 1993). Such burials could be motivated by purely practical factors like the need to dispose of undesirable cadavers, but I think it is more likely that the numerous burials of Neanderthals and anatomically modern humans of the Middle Paleolithic reflect the deliberate burial of kin and are linked to personal and emotional ties between the living and the dead. Defleur (1993) has summarized much of the evidence for Middle Paleolithic burials and points to a number of convincing cases in Europe and the Levant. Debate on the presence of Middle Paleolithic burials continues with Rendu and colleagues (2013) favoring the existence of burials and Goldberg and colleagues (2013b) insisting on very high standards of data to document the presence of burials in the Paleolithic record. The question of the deliberate inclusion of grave goods and the identification of specific ritual practices is perhaps still more contentious and difficult to demonstrate beyond doubt.

In the Upper Paleolithic the data are unambiguous, and many burials preserve opulent grave goods that reflect the status of the individuals and the needs of the dead in the afterlife. Examples of burials from Sungir', Dolní Věstonice, the Grimaldi Caves, and other sites suggest that the system of beliefs in association with death and the afterlife were much more elaborate in Upper Paleolithic than Middle Paleolithic societies. These Upper Paleolithic burials are universally accepted as indicators of cultural modernity. As far as I am aware, aside from somewhat enigmatic cases like the highly fragmented and partially burnt assemblage from Klasies River Mouth in South Africa, the MSA and early LSA have not produced sufficient data for burials to allow conclusions to be drawn about practices and beliefs in sub-Saharan Africa. Human skeletal material, for example, in the Upper Cave of Zhoukoudian in China is suggestive of early Upper Paleolithic burials in the Far East (Pei 1939; Wang 2005), and the burials at Lake Mungo in Australia point to the cultural sophistication of the earliest inhabitants of that continent over 40 Ka BP (Thorne et al. 1999).

Pigments and Ground Ochre

In recent years, there have been a number of reports of early occurrences of pigments and discussions of the importance and meaning of the use of pigments (Barham 1998; McBrearty and Brooks 2000; d'Errico and Soressi 2002; Hovers et al. 2003; Dayet et al. 2013). On the basis of this work, it has become clear that pigments were used in some MSA contexts during the later Middle Pleistocene and in numerous MSA and Middle Paleolithic settings of the Late Pleistocene (Watts 1998). Southern Africa has yielded particularly abundant evidence for the use of ground ochre during the MSA. Barham's (1998) work at Twin Rivers in Zambia is a noteworthy example of the presence of many pieces of modified ochre in Middle Pleistocene contexts, and numerous MSA sites dating to the Late Pleistocene including Klasies River (Singer and Wymer 1982; d'Errico et al. 2012), Diepkloof (Dayet et al. 2013), Peers Cave, Hollow Rock Shelter (Watts 2002), Hoejiespunt (Will et al. 2013), Klipdrift (Henshilwood et al. 2014), Apollo 11 (Vogelsang 1998), and Blombos (Henshilwood et al. 2001) have produced much evidence for grinding of pigments. Recent work at Blombos has documented tool kits for making and storing pigments (d'Errico and Stringer 2011). Parkington has argued that the use of pigments provides additional indications of the advent of behavioral modernity in the MSA, particularly in more coastal settings, where Howiesons Poort and Still Bay assemblages are concentrated. Watts (1998, 2002) has reviewed the evidence for the use of pigments in the MSA and concludes that they are extremely common at many MSA sites and reflect a widespread ability to structure the world into a symbolically organized whole. Watts rejects the hypothesis that ground ochre was primarily used for strictly utilitarian purposes, including tanning hides, while Wadley (2005; Wadley et al. 2009) emphasizes the practical uses of ground ochre. Through a program of experimental and archaeological observations, Wadley has shown that worked ochre from Sibudu, and likely elsewhere, often served as a component of mastic.

In the Levant and Europe, Hovers et al. (2003) see strong evidence for the use of ochre at Middle Paleolithic sites including Qafzeh (Vandermeersch 1969). Sites including Maastricht-Belvédère (Roebroeks et al. 2012), Pech de l'Azé (Bordes 1972; d'Errico and Soressi 2002), Cueva de los Aviones, and Cueva Antón (Zilhão et al. 2010) document the use of red, yellow, and black pigments in Middle Paleolithic contexts and suggest that Neanderthals regularly used pigments. Zilhão and d'Errico emphasize that the use of symbols and complex technology evolved independently among Neanderthals and was not the product of acculturation after contact with fully modern humans as has been argued by White (2000), Hublin et al. (2013), and Mellars (2005). The potential uses of ground ochre include body painting, rock painting, drawing, ritual, medicinal, as well as more mundane purposes. Although we rarely have reliable information on the specific use of these early occurrences of ochre, they are presumably, at least in some settings, such as in Middle Paleolithic burials, connected with religious beliefs that speak for a high level of cultural development and a significant degree of symbolic communication (Hovers et al. 2003). As with other potential indicators of advanced cultural attributes discussed above, the use of ochre does not appear to reflect a quantum leap signifying the shift from archaic to modern patterns of behavior. Both anatomically modern and archaic humans used pigments and presumably attached symbolic meaning to red, black, and perhaps other ground mineral pigments. Here, however, Wadley's caveats against assuming that ground ochre served as primarily as pigment should be reiterated. Given the likely use of mineral pigments in the MSA and Middle Paleolithic, the use of organic pigments is likely, even if difficult to demonstrate with direct archaeological observations.

Decorated Objects and Nonfigurative Representation

There is a long history of claims for deliberate nonutilitarian modification of objects in Paleolithic contexts. These include finds from the Lower Paleolithic, such as incised bones from Bilzingsleben (Mania 1990; Steguweit 2003), and many finds from later periods. These objects are often controversial and are usually not accepted as demonstrating complex symbolic communication. Following other lines of argument, colleagues have suggested that the perfect symmetry of some hand axes indicates an advanced aesthetic development, but Wynn (1995) and Haidle (2004) argue that hand axes do not necessarily reflect symbolically based communication or language. Over the course of the Middle Paleolithic and MSA, larger numbers of enigmatic objects have been published, including the cross-incised stone and modified fragment of a mammoth tooth from Tata, Hungary (Vértes 1964), and the so-called mask from La Roche-Cotard (Lorblanchet 1999). Some researchers have included evidence for collected fossils or curated natural products as indicators of advanced aesthetic and behavioral patterns (Schäfer 1996).

Particularly in recent years, the MSA has produced a number of incised objects that have been taken as evidence for symbolic communication and a high degree of cultural development. Important examples of these finds include engraved linear and crosshatched patterns on pieces of ochre from Still Bay deposits at Blombos dating to ca. 75 Ka (Henshilwood et al. 2002) and incised pieces of ochre from, for example, Peers Cave, Klein Kliphuis (Mackay and Welz. 2008), and Klasies River Cave 1 d'Errico et al. (2012). Current excavations at Diepkloof have produced hundreds of fragments of decorated ostrich eggshells from Howiesons Poort contexts including pieces that are interpreted as originating from decorated ostrich eggshell flasks (Parkington et al. 2005; Texier et al. 2010). Similar finds have also been recovered from MSA contexts at sites including Klipdrift (Henshilwood et al. 2014) and Apollo 11 (Vogelsang 1998). These finds are unquestionably the result of deliberate manufacture and probably reflect the desire of the craftsperson to convey symbolic content and aesthetically meaningful as well as practical information to members of his or her social group. There can be little doubt that such carefully produced decorated objects and the nonfigurative representations they carry communicated specific information from the maker to people who used or saw these objects. Deciphering the specific meaning broadcast through these finds is not easy, and few specific explanations for their meaning have been presented. With increasing amounts of carefully executed fieldwork during the MSA, there is reason for optimism that contextual information will help archaeologists to develop hypotheses to explain the meaning of these finds. The concentration of these finds in southern Africa may be simply a reflection of the intensity of high-quality research in this region, or perhaps an indication that this form of storing and using symbolic information was more common in this part of the world than in other geographic areas. Some colleagues accept these finds as definitive evidence of cultural modernity with fully developed symbolic communication, modern cognitive abilities including language (Henshilwood et al. 2002; d'Errico et al. 2003; Texier et al. 2010). The wealth of finds of engraved objects in the southern African MSA demonstrate that symbolic artifacts of this kind are not as exceptional as initially thought and that marked and decorated objects have a prominent role in the symbolic repertoire of MSA material culture.

Personal Ornaments and Jewelry

The manufacture and use of personal ornaments convey social information about individual identity and group affiliation. This means of projecting assertive individual style or emblematic style reflecting social affiliation within a larger demographic group (Wiessner 1983) is an important characteristic of modern behavioral patterns and has been the focus of much recent research (Vanhaeren 2002; Kölbl and Conard 2003; Vanhaeren and d'Errico 2006). The archaeological distribution of ornaments provides a clearer signal than many of the classes of information considered above.

Early evidence for the use of marine shells as ornaments comes from burial contexts from Qafzeh Cave in Israel and dates to about 100 Ka (Bar-Yosef and Vandermeersch 1993). Perforated marine shells of similar age are also documented at Skhūl Cave in Israel (Vanhaeran et al. 2006) and Grotte des Pigeons in Morocco (Bouzouggara et al. 2007). Slightly younger examples of perforated marine shell ornaments come from Still Bay deposits at Blombos Cave dating to about 75 Ka (Henshilwood et al. 2004, 2011) and MSA contexts at Sibudu (d'Errico et al. 2008). Starting roughly 40 Ka, personal ornaments have been documented in many parts of the Old World from multiple regions of Africa, Eurasia, and Australia. Early ornaments include ostrich eggshell beads from early LSA contexts in Enkapune Ya Muto rock shelter, Kenya, with associated radiocarbon measurements between 30 and 40 Ka (Ambrose 1998). AMS radiocarbon dates directly on ostrich eggshell beads from deposits representing the transition from the MSA to LSA at Mumba Cave in Tanzania (Fig. 6; Weiß 2000; Conard 2004a) have yielded multiple dates

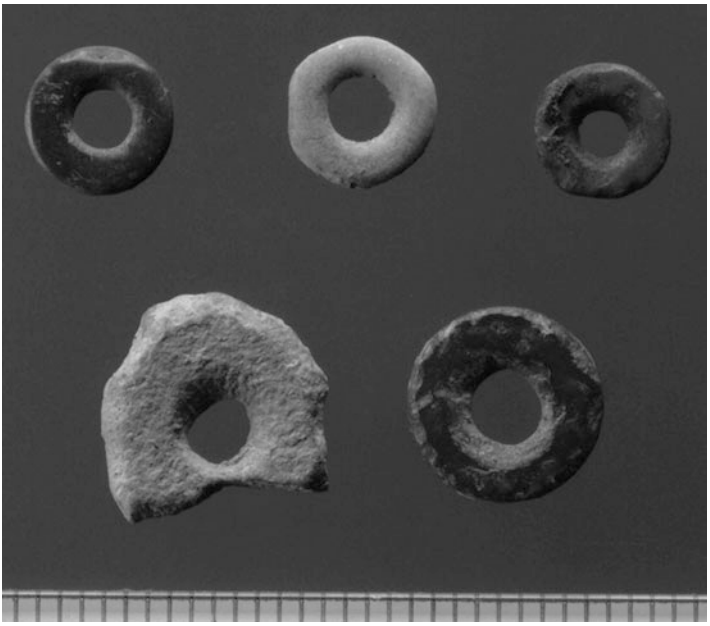

Fig. 6 Mumba Cave, Tanzania. Ostrich eggshell beads radiocarbon dated between 29,000 and 33,000 radiocarbon years ago scale in millimeters (Photo H. Jensen)

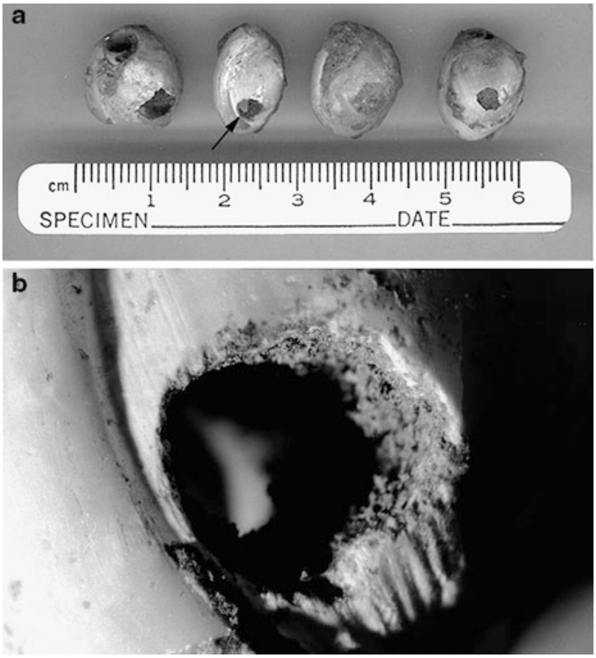
between 29 and 33 Ka uncalibrated radiocarbon years, or starting roughly 36 Ka cal BP, and lend support to the early dates from Enkapune Ya Muto. There is every reason to assume that these East African ornaments were made by anatomically and presumably culturally modern people.

Excavations at Ksar Akil in Lebanon (Azoury 1986) and at Üçagizli in the Hatay Province of Turkey (Kuhn et al. 1999, 2001) have produced rich assemblages of perforated marine shells from Initial Upper Paleolithic contexts dating to about 40 Ka (Fig. 7). Similar finds have been recovered from other Mediterranean early Upper Paleolithic contexts, including Riparo Mochi on the Ligurian Coast of Italy (Kuhn and Stiner 1998; Stiner 1999). Douka (2013) has recently developed new methods for dating marine shells and has repeatedly demonstrated the finds date to roughly 40 Ka BP. With the exceptions of late Middle Paleolithic sites of Cueva de los Aviones and Cueva Antón in Spain (Zilhão et al. 2010), the perforated shells have normally been interpreted as having been produced and used by anatomically modern humans.

In Europe there is considerable evidence for a rapid spread in the use of ornaments with the beginning of the Upper Paleolithic. In addition to the Spanish examples, Neanderthals apparently created a wide range of perforated and incised ornaments in Châtelperronian contexts such as at Grotte du Renne at Arcy-sur-Cure (Leroi-Gourhan and Leroi-Gourhan 1964; d'Errico et al. 1998; Baffier 1999). These finds remain at the center of considerable debate about whether or not Neanderthals developed advanced symbolic communication. At more or less the same time,

Fig. 7 Üçagizli Cave, Turkey. Perforated marine shell ornaments dating to ca. 40,000 radiocarbon years ago (After Kuhn et al. 2001)



numerous examples of early Aurignacian ornaments have been recovered from several regions including the Swabian sites such as Vogelherd, Geißenklösterle, and Hohle Fels (Conard 2003a; Higham et al. 2012; Wolf et al. 2013; Fig. 7). In addition to incised and perforated natural forms such as teeth, these artifacts include diverse ornaments made of mammoth ivory. It is noteworthy that many of the oldest forms of ornaments in Europe are not only perforated natural objects but also completely carved, three-dimensional ivory beads, pendants, and figurines in which the maker completely dictated the form of the artifact (Conard 2008, 2010).

Although earlier examples of personal ornament are known, by around 40 Ka ornaments are well documented across much of the Old World. These data are consistent with the hypothesis that modern cultural behavior spread rapidly between roughly 30 and 50 Ka. Personal ornaments from the Upper Cave of Zhoukoudian, Shuidonggou Locality 2 (Gao et al. 2002), and Xiaogushan Cave (Archaeological Institute of Liaoning Province 2009) document the presence of this class of artifacts in association with flake-based lithic assemblages in northeastern China by 30 Ka (Pei 1939; Conard 2013). Shell beads from Mandu Mandu Creek Rock Shelter in Western Australia dating to more than 30 Ka (Morse 1993) suggest that the use of personal ornaments was indeed widespread at an early date. Although Australia lies outside the scope of this review, the colonization of Sahul was an event in prehistory that required crossing the vast open water of Wallacea with rafts or other forms of boats. The best available dates for the colonization lie in the range of ca. 42–45 Ka and fit with the pattern suggesting the rapid spread of advanced behavioral patterns at about this time (O'Connell and Allen 1998, 2004).

Figurative Representations

The presence of figurative art is universally accepted as an indication of behavioral modernity. As far as I am aware, no one has disputed that figurative representations are a hallmark of modern cultural behavior. Mann (2003) has gone so far as to argue that representational art is the "gold standard" by which behavioral modernity can be identified and measured. This being said, figurative representations can be viewed as documenting fully developed symbolic communication, but the lack of such artifacts in the archaeological record tells us little since many recent archaeological cultures lack figurative art. Clearly many forms of symbolic communication, including speech, stories, and song, are archaeologically nearly invisible.

In Africa, the earliest figurative art is from the late MSA of Apollo 11 (Fig. 8), dating between 25,500 and 27,500 radiocarbon years ago (Vogelsang 1998). These examples of painted mobile art depict a number of animals, geometric forms, and a therianthrope. The Middle Pleistocene-aged, anthropomorphic-shaped stone from Tan-Tan, Morocco (Bednarik 2003), much like a similar object from Berekhat Ram, Israel (Goren-Inbar 1986; Goren-Inbar and Peltz 1995; d'Errico and Nowell 2000), appears to be a modified natural form rather than deliberately carved figurine. In the Levant there is little or no evidence of figurative art before 30 Ka.

The situation in Europe is very different, in that several sites have provided evidence of figurative representation between 30 and 40 Ka. The earliest figurative art includes the mammoth ivory figurines from four caves in Swabia in southwestern Germany (Hahn 1986; Schmid 1989; Conard and Bolus 2003; Conard 2003b; Conard 2009; Conard et al. 2009a) and several red monochrome paintings from Fumane in northern Italy (Broglio 2002; Broglio and Dalmeri 2005). The Swabian caves of Vogelherd, Hohlenstein-Stadel, Geißenklösterle, and Hohle Fels (Fig. 9a, b)

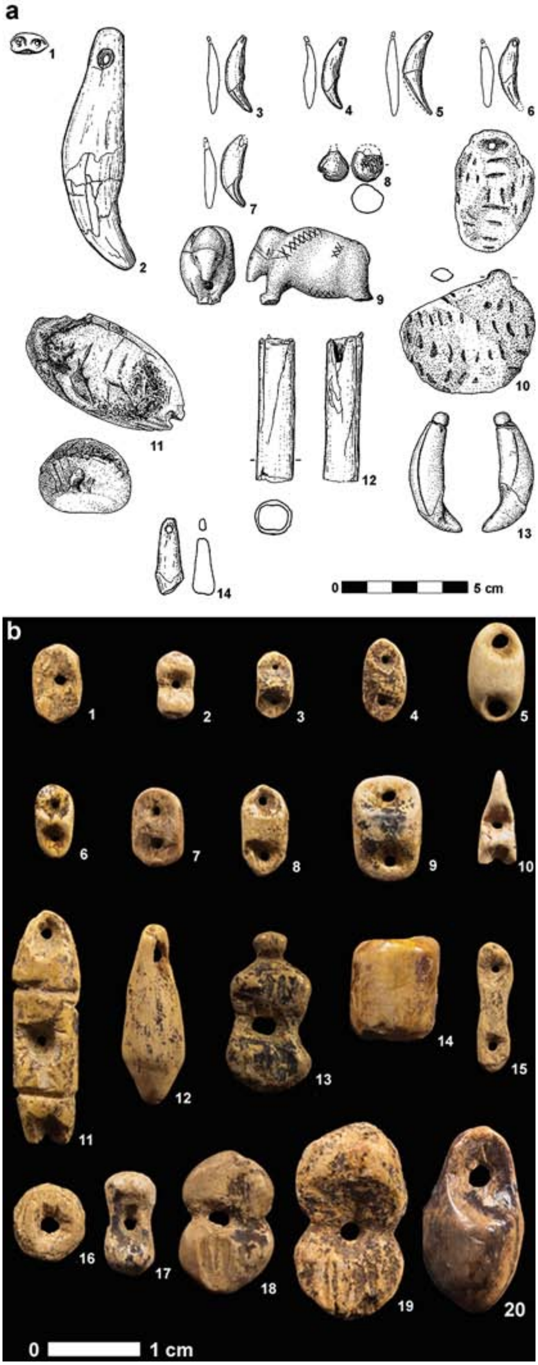

Fig. 9 (**a**) Sirgenstein, Bockstein Cave, Hohlenstein-Stadel, Vogelherd, Bockstein-Törle, Germany. Personal ornaments from the Aurignacian dating to ca. 36,000–30,000 radiocarbon years ago (After Conard 2003a) (**b**) Ivory ornaments from the Swabian Aurignacian, ca. 34 Ka radiocarbon years BP. *1–5* and *11–16* Hohle Fels; *6–10* and *17–20* Vogelherd (Photo: W. Binczik; Eberhard Karls Universität Tübingen)

Fig. 10 Mammoth from Vogelherd, ca. 34 Ka radiocarbon years BP (Photo: H. Jensen; Eberhard Karls Universität Tübingen)

have produced about 50 mostly fragmentary, small, ivory figurines and isolated representations in bone and stone dating well in excess of 30,000 radiocarbon years, which corresponds to closer to 40 Ka in calendar years. Due to the noisy radiocarbon signal in this period and above-average ^{14}C production, the radiocarbon ages at the Swabian caves and the similarly aged deposits from Fumane significantly underestimate the age of these artworks (Conard and Bolus 2003). The most recent calibrated radiocarbon dates place the beginning of the Swabian Aurignacian at about 42.5 Ka and at the very beginning of this cultural tradition (Higham et al. 2012). The Swabian ivory figurines include depictions of lions, mammoths (see Fig. 10), horses, bisons, bears, a water bird, a fish, numerous unidentified fragments, and three therianthropes that combine features of lions and humans (Hahn 1986; Conard 2003b; Wehrberger 2013; see Fig. 11). The depictions of mythical imagery, in the form of therianthropic representations, appear simultaneously with other more naturalistic depictions of animals and humans and provide unique insight into the system of beliefs of Paleolithic peoples (Conard 2010). These artworks from the Swabian caves are usually small and beautifully carved. The oldest of the figurines is likely a remarkable female figurine, the "Venus of Hohle Fels" (Fig. 12) that excavators found in the basal Aurignacian deposit of Hohle Fels Cave in the Ach Valley (Conard 2009). This find, and abundant ivory working debris from the basal Aurignacian at Hohle Fels and the lower Aurignacian at Geißenklösterle, demonstrates that this rich tradition of ivory carving in the region dates back to the start of the Aurignacian, the period in which modern humans initially migrated up the Danube corridor. The early figurative depictions from Swabia suggest that figurative representations evolved very quickly and reached a high level of refinement almost immediately. These finds stand in sharp stylistic contrast to the highly schematic paintings of animals, unknown forms, and a possible therianthrope from Fumane (Broglio 2002).

Fig. 11 *1* Geißenklösterle, *2* Hohle Fels, *3* Hohlenstein-Stadel, Germany. Three lionmen carved from mammoth ivory, ca. 34,000 radiocarbon years BP (Photo: *1* P. Frankenstein, H. Zwietasch; Landesmuseum Württemberg, Stuttgart. *2* H. Jensen; Eberhard Karls Universität Tübingen. *3* Y. Mühleis; Landesamt für Denkmalpflege im RP Stuttgart)

Geißenklösterle has also produced a painted rock from this period that preserves traces of red, yellow, and black pigments (Hahn 1986).

Most of the spectacular paintings from Grotte Chauvet in the Ardèche region of southern France (Fig. 13) appear to postdate the examples of figurative art from Swabia and Fumane (Clottes 2001). Here, numerous depictions of animals date back as far as 32,000 radiocarbon years ago, which corresponds to roughly 36 Ka cal. The selection of animals depicted in Chauvet, with an emphasis on dangerous, strong, and large animals, shows remarkable similarities to the Aurignacian figurines from Swabia and no stylistic similarities to the schematic depictions from Fumane. Therianthropic representations are present at these sites and, as in Swabia and at Apollo 11, suggest that depictions of mythical images have been part of the cultural repertoire of many groups of people from the beginning of artistic representation. Other important sites in this context include Stratzing in Lower Austria,

Fig. 12 Hohle Fels, Germany. Female figurine carved from mammoth ivory, age ca. 36 Ka radiocarbon years BP (Photo: H. Jensen; Eberhard Karls Universität Tübingen)

Fig. 13 Grotte Chauvet, France. Early Upper Paleolithic parietal art radiocarbon dated to ca. 30,000 years ago (After Clottes 2001)

where a human figurine of stone has been dated to between 30 and 32 Ka (Neugebauer-Maresch 1989). Abri Cellier, La Ferrassie, Abri Blanchard, and Abri Castanet in southwestern France have produced an impressive group of engraved representations in stone of animals and vulvas dating between ca. 30 and 34 Ka radiocarbon years ago (Leroi-Gourhan 1995; White et al. 2012). Recently paintings in Peștera Coliboaia, Romania, have been discovered dating to ca. 32 Ka that show stylistic similarities to the paintings in Grotte Chauvet and suggest that Chauvet may not stand entirely alone with respect to early parietal art (Besesek et al. 2010; Clottes et al. 2011).

These figurative depictions from European contexts are the oldest known worldwide. They all date to the early Upper Paleolithic and were presumably made by modern humans; however, as far as we can tell, Neanderthals still occupied parts of Europe at this time, roughly 40 Ka. At present, there is no concrete evidence for a direct association between modern humans and early figurative art in Swabia. Thus, the hypothesis that Neanderthals created the figurative art and other remarkable finds of the early Aurignacian, although highly improbable, had not been entirely refuted (Conard et al. 2004a).

The specific context in which figurative art developed has been the subject of considerable discussion of late and will not be elaborated on here (Lewis-Williams 2002; Conard and Bolus 2003). Regardless of the specific social-cultural conditions that led to the development and spread of figurative art, there is a broad consensus among archaeologists and paleoanthropologists that the makers of these early artistic traditions were culturally modern people (Churchill and Smith 2001; Klein 2009). While many other advanced behavioral forms have precursors in earlier periods, there is no convincing evidence for figurative depictions prior to the beginnings of the European Upper Paleolithic.

Music

Perhaps because of the long research tradition and favorable taphonomic conditions, the earliest examples of musical instruments have been recovered from early Aurignacian contexts in Swabia (Hahn and Münzel 1995; d'Errico et al. 2003; Conard et al. 2004b, 2009b). As with figurative representations, evidence for music and musical instruments can be seen as an indication of fully developed cultural forms based on symbolic communication. The assumption in this context is that where there is figurative art and music, there must have been fully developed language, by which Paleolithic people assigned specific concrete and abstract meaning to words and could efficiently communicate information about the past, present, and future. Thus, where there is figurative art and music, there must have been behaviorally modern people.

While speech, song, music, and dance presumably existed still earlier, the oldest musical instruments known are two bone flutes from swan radii and one mammoth ivory flute from the Aurignacian archaeological horizon II at Geißenklösterle (Hahn and Münzel 1995; Conard et al. 2004b), fragments of a bone and ivory flute from Vogelherd (Conard and Malina 2006), and fragments of two ivory flutes and one nearly complete flute carved from the radius of a griffon vulture from the basal Aurignacian of Hohle Fels (Conard et al. 2009b; Fig. 14). These deposits have been dated by thermoluminescence and radiocarbon to about 40–37 Ka. Reconstructions

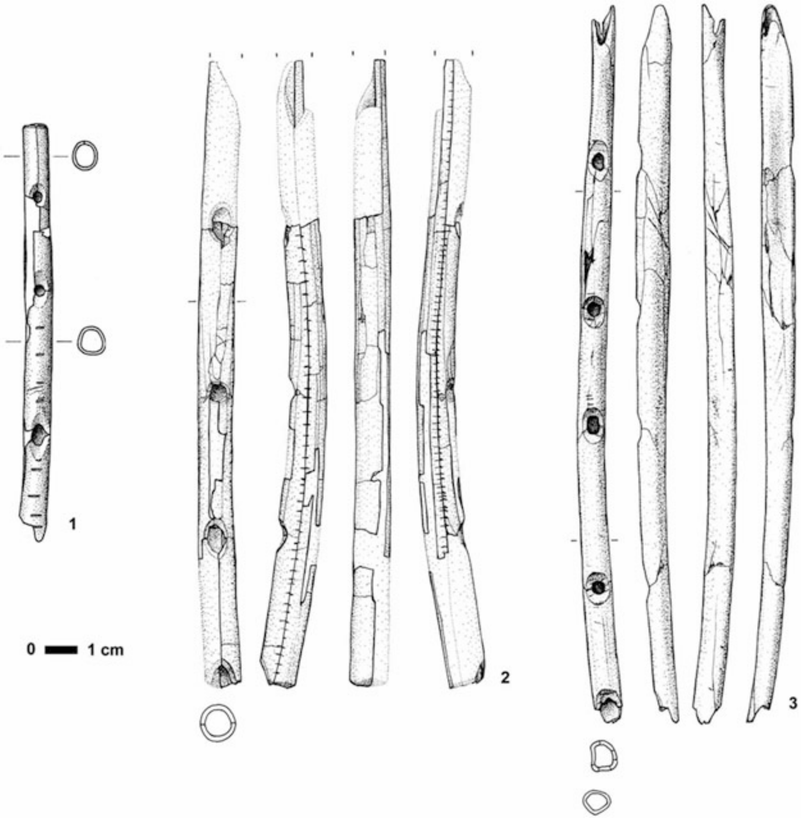

Fig. 14 *1* Geißenklösterle Flute 1 from a swan radius, *2* Geißenklösterle Flute 3 from mammoth ivory, and *3* Hohle Fels Flute 1 from a radius of a griffon vulture (Drawing: *1* A. Frey. *2–3* R. Ehmann. Eberhard Karls Universität Tübingen)

of the swan bone flutes produce a high-pitched but pleasing music. Friedrich Seeberger (2002, 2004) has recorded a CD of Ice Age music played on a reconstructed bone flute of the kind known from Geißenklösterle. This flute can be played without a reed and is clearly a flute rather than a trumpet-voiced instrument as suggested by d'Errico and colleagues (2003). The ivory flutes and the griffon vulture flutes can be played in similar manners and produce attractive tones and musical possibilities but have a lower register of tones due to their larger diameters. While Aurignacian musicians may have played very different-sounding music, Seeberger's playing provides a striking impression of what this early Upper Paleolithic music may have sounded like. Interestingly, all of the flutes and fragments of flutes recovered thus far are from horizons containing a wide range of rich settlement debris from day-to-day life, suggesting that bone and ivory flutes and the music played on them formed part of the daily lives of the Aurignacian inhabitants of the Swabian Jura. Finally, it is no coincidence that all of these early flutes have been found in caves. The Aurignacian musicians of the region certainly chose to use the outstanding acoustic characteristics of the caves to accentuate the impact of their music.

Other sites, most notably Isturitz in the French Pyrenees, have produced additional flutes and indicate that wind instruments were in fairly wide use during the early Upper Paleolithic (Buisson 1990; d'Errico et al. 2003). Of course, there are countless other less conspicuous forms of percussion and wind instruments that could have existed during the early Upper Paleolithic or still earlier, yet they remain to be identified. Claims for earlier examples of Middle Paleolithic flutes have generally been met with skepticism in archaeological circles, as was the case with recent claims for a Middle Paleolithic flute made from a cave bear bone from Divje Babe in Slovenia (Turk 1997; Albrecht et al. 1998).

Conclusions

This overview has touched on some, but by no means all, of the evidence for the development of behavioral modernity. I have mentioned some of the main data sets and lines of reasoning that play a role in the discussions and debates about the origins of modern behavior. This leads to the question of by what means, where, and under what circumstances behavioral modernity arose and which of the hypotheses for its origins lies closest to the mark?

The answers to these questions depend on how the evidence is weighed and interpreted. From my point of view, there can be no doubt that European Aurignacian societies by roughly 40 Ka had all of the hallmarks of modern behavior including Mann's "gold standard" of figurative art as well as musical instruments. The best evidence for early figurative art and music comes from the caves of the Swabian Jura. While one could argue that some important Upper Paleolithic artifact forms developed in the Upper Danube drainage in the period around the time of the arrival of modern humans, naming this region as the single global center for the origin of cultural modernity would be a radical and naive interpretation. The broadly contemporary finds of figurative art from Fumane, and slightly later finds from southern France and the Wachau of Austria, indicate that the beginnings of the Upper Paleolithic reflect a time in which earlier behavioral forms were replaced by behavioral forms that lie within the range of modern variability. This transition appears to have begun across much of Europe about 45 Ka when modern humans entered a continent inhabited by Neanderthals. Based on the presence of late Neanderthals in several regions of Europe (Hublin et al. 1995; Smith et al. 1999), it appears that there must have been a period in which both archaic and modern humans coexisted in Europe, and contact between the two forms of people must have occurred (Conard 2006). Given the poor chronostratigraphic resolution and scarcity of human fossil material during this key period between roughly 30 and 45 Ka, it is difficult to specify exactly how long both hominins coexisted in specific regions, but progress is being made on clarifying the regional sequences and the most recent estimates suggest a coexistence of several thousand years (Higham et al. 2011, 2012, 2014).

Early anatomically modern humans at Skhūl and Qafzeh in the Levant predate many remains of Neanderthals in southwestern Asia and point to an initially successful colonization of the region. The reappearance of Neanderthals in the Levant by roughly 60 Ka suggests that Neanderthals had more successful adaptations and demographic advantages over anatomically modern humans in interactions dating to the middle part of the Late Pleistocene. While evidence for strict contemporaneity is still lacking, this observation indicates that in some settings in which both hominins produced Middle Paleolithic artifact assemblages, Neanderthals had the upper hand (Conard 2008). However, in later encounters the situation was different. At about 45 Ka, modern humans arrived in western Eurasia with more developed cognitive skills (Lewis-Williams 2002) or behavioral advantages (Marean 2005) that led to demographic success relative to the indigenous Neanderthals. In western Eurasia, a period of dynamic equilibrium between Neanderthals and anatomically modern populations existed, in which moderns presumably profited from the knowledge and cultural practices of the "archaics" and vice versa.

There is little reason to postulate a violent rapid advance of Neanderthals into the Levant replacing indigenous anatomically modern humans in the middle of the Late Pleistocene, and similarly there is little reason to assume that the arrival and spread of modern humans into Europe was either universally rapid or brutal. On the contrary, the transition from the Middle to the Upper Paleolithic and the infiltration and eventual complete dominance of *Homo sapiens sapiens* in Eurasia probably took on countless local ecologically and historically dictated variants in which there was give and take between archaic and modern humans. This pattern is reflected in the diverse regional signatures of the archaeological records from nearly every region that has produced relevant data for this transition. These data show very different archaeological signatures depending on the environmental and social-cultural setting encountered by incoming populations (Conard 1998; Conard and Bolus 2003). Evidence from the sites occupied by late Neanderthals indicates that they too manufactured and used ornaments (Baffier 1999), and as we have seen above, there is little that separated the patterns of technology, subsistence, and settlement reflected in Middle Paleolithic artifact assemblages from those of the MSA or early Upper Paleolithic. Still, some time presumably in the early and middle parts of the Late Pleistocene and certainly no later than 40 Ka, people began producing material cultural remains that allow us to identify behavioral modernity. This pattern of behavior was carried primarily, but perhaps not exclusively, by anatomically modern humans (Zilhão et al. 2010; d'Errico 2003).

Many characteristics of modern behavior can be found across much of the Old World, and the distribution of advanced cultural traits is significantly determined by the intensity of research in different regions. The recent trend of important discoveries being made in MSA contexts in southern Africa will no doubt continue as more work is done. The data from Klasies River, Apollo 11, Rose Cottage Cave, Blombos, Sibudu, Diepkloof, the Pinnacle Point sites, and Klipdrift clearly show the enormous potential of the subcontinent. Elsewhere, a similar intensification of research would perhaps produce a similar increase in data relevant to the definition of cultural modernity. Although this chapter has not addressed these regions in detail, research in China and East Asia is improving the database and documenting new patterns of cultural evolution during the Late Pleistocene (Wang 2005; Conard 2013; Ono 2013). Western Eurasia also has considerable potential, but there is less reason to assume that the archaeological record will be so radically transformed by further work. Instead, important gaps will be filled and gradually a more complete picture of the highly variable behavioral patterns during the Lower, Middle, and Upper Paleolithic will emerge. With time we will be better able to develop and test new hypotheses for the evolution and spread of cultural modernity, and this problematic concept will continue to undergo debate (Henshilwood and Marean 2003; d'Errico and Stringer 2011). For example, colleagues including Shea (2011) have long argued that we should jettison the simplistic and controversial concept of behavioral modernity and instead work to gain a better understanding of behavioral variability. Researchers in Tübingen are developing a model for behavioral plasticity and the evolution of "hyperplasticity" to help explain how cultural complexity developed over the course of human evolution (Kandel et al. 2014). This model arises in part from the observation that, over the course of human evolution, behavioral patterns become increasingly detached from direct environmental causality, and ever more behavioral patterns and solutions to problems appear in the archaeological record. Hominins increasingly have created their own environment until they could occupy even the most inhospitable parts of the planet. This pattern continues today, and the concept of hyperplasticity offers the advantage of not reducing human evolution to a dichotomy between archaic or modern behavior.

Based on the data presented above, a strict unilinear and monocentric model for the evolution of behavioral modernity appears less likely than a pattern of *mosaic polycentric modernity* (Conard 2008, 2010). These data suggest that MSA and Middle Paleolithic societies generally existed within regionally specialized social groups with highly variable material culture. Whether anatomically modern or archaic, these people lived at a similar level of technological and cultural development. Perhaps by the early part of the Late Pleistocene or possibly as late as 40–50 Ka, full behavioral modernity developed in Africa and in Eurasia. Most archaic humans appear not to have mastered the repertoire of new behaviors including fully developed symbolic communication. If, however, some late archaic humans, including Neanderthals, were culturally fully modern as d'Errico and Zilhão have long argued, their behavioral patterns still put them at a reproductive and demographic disadvantage in comparison with the anatomically and culturally modern social groups that propagated across the Old World. The extinction of Neanderthals and Denisovans (see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3) following a small amount of interbreeding (Green et al. 2010; Krause et al. 2010; Prüfer et al. 2013; Sankararaman et al. 2014) does not necessarily mean that they were not culturally modern, just as the extinction of local groups of modern *Homo sapiens* in recent times does not mean that they were not culturally modern. The main characteristic of *Homo* is that our cultural development can, and does, vary independently of our biological substrate (Conard 1990). Thus, late anatomically archaic peoples may or may not have been behaviorally modern, just as early anatomically modern humans may well have been behaviorally archaic (Zilhão 2001). Nonetheless, at the end of the day, only modern humans survived and populated all regions of the globe and outcompeted all other hominins.

In the coming years, archaeologists and paleoanthropologists need to establish high-quality regional databases and specific local scenarios and hypotheses for the evolution of modern patterns of behavior (Hublin et al. 1996; Parkington 2001; Lewis-Williams 2002; Conard and Bolus 2003; Longo et al. 2011; Higham et al. 2011, 2012; Douka et al. 2012; Talamo et al. 2012). As work progresses, researchers should be able to test these hypotheses and better define these diverse regional scenarios to create new models that come closer to reflecting the evolutionary reality that a nuanced history of our species warrants. This work should precede using multiple analytical paradigms and shifting scales of analysis (Conard 2001a). There are certainly multiple approaches to this complex problem, and all contextually informed explanatory models for the rise of cultural modernity are welcome, regardless of whether they originate from the natural sciences, social science, or humanities.

Regardless of where one positions oneself in these debates, only Paleolithic archaeologists and paleoanthropologists are able to make direct observations from the past, and thus they are in the best position to explain how our species evolved. If we accept the fundamental unity of all living people, the question of when hominins became like ourselves remains a relevant question that cannot be left to experts in other fields, who have no direct observations and data from the past. Following this line of argument, we should use our privileged position as the producers and curators of knowledge about the past to continue to refine our models of how populations of modern humans with our remarkable cultural capacities evolved.

remains of our ancestors. Theoretical approaches vary from “positive” positions that describe religion as an adaptation to certain human needs and conditions during the evolution of social behavior to “negative” positions that develop nonadaptive stance, side-product theories, or simply talking religion down. In a longer perspective, adaptive features can be described as emergent features of cultural evolution (mysticism, ethics, myth, and ritual as domains of religion). The focus on religious cognition as mental architecture provides tools for the solution of enduring problems in the understanding of (ancestral?) hominids. As paradigmatic presuppositions may change (revalidation of group selection), and novel hypothesis is generated (superorganism, cognitive niche construction), recent theoretical work on the evolution of religion is enlarging our perspective on a tremendously complex topic that has mainly excited discussion of its cognitive aspects (cognitive science of religion). The vast bio-cultural complexity of gene-culture coevolution must be in the focus of any theory of the evolution of religion.

Introduction

When Darwin founded evolutionary biology by publishing *On the Origin of Species* in 1859, biology and even human behavior were already topics for the natural sciences. Dealing with religion, some authors tried to reformulate naturalistic approaches polemically against the clergy (Rádl 1909). Darwin, known for his agnostic attitude (although he studied theology in Cambridge), was fully aware of the tremendous consequences of his theory; widely known is his famous note to his friend Joseph Dalton Hooker that admitting it was like “confessing a murder” in 1844 (see http://www.darwinproject.ac.uk/): To claim that species are not immutable was the first step against a prevailing theological doctrine – the idea of man, so far depending on creation, was free to fall too. From the starting point “crown of creation,” as being on top of all creatures with an ontological foundation in metaphysical dimensions, man fell down to “a gipsy at the edge of the universe” (Jacques Lucien Monod, 1910–1976).

The new option and challenge was to describe mankind in a perspective of development (process) instead of creation (status). As Darwin assumed that “light will be thrown on the origin of man and his history” (Darwin 1859) by applying his theory of natural selection on man, even human behavior came out of the shade. In his 1871 work *The Descent of Man*, the first approach to a naturalistic view on religion, dealing with the question of the origin of faith, can be found. It contains two aspects: (i) it describes religious behavior as a human universal that depends on a natural and cultural development and (ii) the question whether religion – a *belief* in god – can be explained by natural evolution has nothing to do with the “higher question” whether god exists or not. The barking of “Braubach’s dog,” Darwin’s famous example in this case, is the key to understanding or misunderstanding the concern: The sunshade, moved by the wind, is the target of the dogs barking. Darwin estimates him thinking of some unseen agents moving the cloth.

The misunderstanding is the comparison of the dog's attitude to the unseen agent to the human approach to god. The quest is to formulate a theory offering the possibility to deduce the origin of the specific human behavior from a common ancestral behavior, shown in the dog's behavior as well. The third component, the hypothesis about the phylogenetic roots of the behavior formulated within the methodic approach, is open to modification, discussion, and falsification. Darwin's fear about "committing a murder" was already mentioned in his letter to Hooker, showing his awareness about late effects of his theory – a methodological self-reflection. Furthermore, he was sensitive to the fragility of religious belief system. He acknowledged the religious practice of believers, as treating their world outlook with respect he refrained from attacking religion. In a letter to Karl Marx (1818–1883), he confessed in October 1880: "Incidentally, it is possible that the thought has influenced me here over charge to the pain I would cause some members of my family when I would start to support direct attacks on religion one way or another."

As a milestone towards the theoretical and empirical work of the cognitive and evolutionary psychology of religion, William James focused on *The Varieties of Religious Experience* (1902). While nineteenth-century philosophy was dealing with religion in terms of an anthropological need (projection of an idealized being as god, Feuerbach) or social construction (Marx, Durkheim), the focus was on the psychological phenomenon of religiousness. As an individual experience, they are as well part of our biological bias, depending on our social organization. In this view, even the evolution of religious behavior must have a story of a successful evolutionary development, keeping Dobzhansky's formula "nothing in biology makes sense except in the light of evolution" in mind (Dobzhansky 1973). Whether this process is adaptive or was adaptive may for now be an irrelevant one (some biologists tried to develop pantheistic theories of the evolution of religious behavior in man, introducing *Homo sapiens* as the praying animal, putting him on the top of a teleological evolution with a gnosis-enabled species on top (Hardy 1979)), more important was the foundation of a new background theory for discussing religion: the shift from religion (in a theological and institutional/sociological sense) to religious behavior. The belief and practice in orientation to supernatural beings and powers were open to scientific exploration, independently from the ongoing discussion about their existence. The proof of god's existence became irrelevant – no wonder the integration of an evolutionary history of religious experience into epistemological and theological approaches of religion is sometimes misunderstood as a challenging provocation. Nevertheless, the history of natural sciences, especially human biology, reminds of the need for responsibility. Naturalistic approaches have to be clear in their declaration of intention. When Baudy is offering a paleoanthropological theory of religion, talking about a "paleophysical space consciousness" and the developed feature of a "scenic amendment" as adaptation to Pleistocene environments (Baudy 1997) that are still vitalized today, he is offering a theory of *psychological components* as candidates for the theory of the evolution of religion. When Trinkaus is interpreting *archaeological reports* of burials, grave goods, or even early temple sites (Trinkaus 1985), he is reconstructing the visible but highly fragmented path from our ancestors towards nowadays religious routines. Nevertheless, both aspects are under the retention of being a "just so story," meaning paleo-poetry with a highly narrative component. On the one hand, theoretical assumptions tend to develop "easy to tell"-Panglossian arguments, and on the other hand, interpretations are addicted to their theoretical background and the zeitgeist – both are far from being constant. Compared to other topics in naturalistic explanations (evolutionary ethics, evolutionary epistemology, and evolutionary aesthetics), religion as issue holds a human self-understanding that goes far beyond "topics." Is a description of a "religious nature" – irrespective of being an adaption or not, increasing fitness or not – a substitution of a non-scientific self-understanding by just another story?

Aspects of Religion

Behavior and Evolutionary Psychology

Evolutionary psychology seeks for human psychological traits that are evolved adaptations – therefore, it can be seen as a long-term consequence of Darwin's approach to human nature as part of a natural history by means of natural selection. Human psychology is described as a functional product of natural or sexual selection, like in other approaches of adaptation (in mechanistic perspective on body parts like heart, brain, and blood circuit), the body is modularized, some evolutionary psychologists are arguing that the mind has a modular structure as well: modular adaptations are "invented" for different functions, offering the background for the Spandrel Theory: much of human behavior is the outcome of psychological adaptations that evolved to solve problems in human ancestral environments long time ago. The so-called adapted mind (Barkow et al. 1995: The Adapted Mind. Evolutionary Psychology and the Generation of Culture) pairs fragmented brain *functions* with estimated environmental needs and challenges of our ancestors (see Table 1 for an overview).

More astonishing is the observation that religious commitment often leads to a costly behavior: The participation in rituals takes time and is sometimes risky; a lot of religious systems define certain rules for their members and specialists like celibacy, leading to a poor reproductive success. Even practical costs for displaying a commitment come into count, reaching from sitting in silence to suicide bombing. One major task for evolutionary explanations is clear: The benefits of religious behavior must somehow outweigh the harms mentioned above. Even if the candidates seem to be clear (social bonding, explaining our origin, moral systems, etc.), the problem is still related to the cost problem, one component of the explanatory level. The evolution of religion in a perspective of evolutionary biology and psychology therefore deals with several sets of problems, connected to aspects of the religious behavior of human beings, populations, and institutions. They are confronted with a set of theories and theoretical frameworks aiming to provide a scientific background for the explanation of their development and functionality.

Table 1 Problems and explanatory components of religious behavior

Aspects of religious behavior	
Problems	Explanatory level
Cooperation	**TMT** (terror management theory) (Jonas and Fischer 2006)
Free rider	**MCI** (minimal counterintuitivity) (Purzycki and Sosis 2010)
Costly signaling	**PA** (punishment avoidance) and
Punishment	**CE** (cooperation enhancement)
Punishment avoidance	**SP** (supernatural punishment) (Schloss and Murray 2011)
Monitoring	**SM** (supernatural monitoring) (Bering 2011)
Credibility	**CREDs** (credibility enhancing displays) (Henrich 2009)

Empirical and Practical Aspects

Testing theories about religion is nothing new: The effect of prayer to the sick was the concern of Francis Galton, Charles Darwin's first cousin. In 1872, he is – first of all – confronting presumptions about theology and religion with empirical (or rather statistical) facts, offering verifiable theories: "An unscientific reasoner will be guided by a confused recollection of crude experience. A scientific reasoner will scrutinize each separate experience before he admits it as evidence, and will compare all the cases he has selected on a methodical system" (Galton 1872, p. 125). His conclusion is that "It seems to me clear that all belief in the efficacy of prayer, in the sense in which I have been considering it, must be yielded also." Galton issues two caveats to the physical efficacy of prayer: (i) prayer can provide emotional catharsis through the act of self-expression and (ii) his study does not disparage the possibility of communing in one's heart with god. Assertion (ii) is presented with several constraints around the interference of imagination and personality, but Galton concedes that calm contemplation on the ideals of fellowship, responsibility, and the creative heritage of humanity have "much in common with the effort of communing with a God." In recent works, the alliance between religion and healing became a major topic; the ethnological report shows a large variety of techniques to seek for healing: Meditation, ecstasy, hypnosis, and trance stimulate neurophysiological processes with traceable effects on subjective well-being and health. As some techniques require the assistance or good will of higher-order powers, experts are released from other topics in order to focus on their magic business. It is an open question; if shamanism is the origin of medicine or religion, perhaps both are intrinsically tied together. All recent discussions about the placebo effect still show perplexing results about the magic of a cross-scored tablet; the belief in the substance is the key to the success of the therapy – no matter what the pharmacist tells us about the "true" impact of the substance. On a larger scale, some authors describe a positive correlation between the coping and handling of diseases and the creation of a "positive meaning" based on principles of faith. Coping with contingency is an easier task for the believer; the assumptions of their confession protect them from using a "psycho-hygienic function" (Voland 2010). Demographic studies show doubtless the reproductive success of denominations; they provide a shared rationalization and an intriguing motivation to engage in future projects and producing offspring (Blume 2009). On the other side of the coin, religions do not only disengage fear from the believer, but under certain circumstances (and dispositions), they might endow it. Not only in brute communities like Colonia Dignidad but even in psychotherapeutic facilities a rising amount of patients seek release from fear, disillusion, or suffering from long-term consequences of brain wash they had to experience in their communities. The development of a religious psychosis is as well possible without any despot forcing members of a group to perform certain actions declared as god's wish or ecclesiastical need. A rather new phenomenon is the "market of possibilities" of religious expertise and components, leading to a modal system of religion. Therefore, religious practice becomes an eclectical combination – of incompatible constituents? Many western European believers "on the edge" of established confessions seek inspiration and techniques of spiritual self-awareness in "eastern" meditation techniques. A lot of them simply do not come back, as therapists indicate a growing number of candidates lose their self-awareness in certain meditation techniques that plumb the "how far can you go" without a net. What might be an easy task for a Buddhist novice – losing the thought of a certain self in meditation – can destroy a callow self-consciousness orientated on other ideals and figures from an incommensurable cultural background. Psychiatrists discuss the work field between the keywords "god-intoxication" and "religious-medicine"; on the one hand is the Freudian perspective on religious beliefs as pathology outdated (Navratil 1992), while on the other hand is as well much work to do with questioning the options of integrating religious aspects in therapeutic treatment.

Evolutionary Anthropology and Primatology

The nature versus nurture debate may be the major underlying conflict between natural and social sciences. A change in the scientific approach through changing methodological axioms led towards a renewed understanding of anthropological sciences. It was in the 1950s when Sherwood Washburn (1911–2000) and Theodosius Dobzhansky (1900–1975) arranged the Cold Spring Harbor Symposium. It was a switch in the fixation of anthropologist from ideally race standards and characters (ancestors of idealistic morphology and race theory) to the observation of living populations, published in the epochal anthology *Anthropology Today* (Kroeber 1953). In his contribution "The Strategy of Physical Anthropology," Washburn outlines his theory of a new research approach by a theory-based *comparative biology*, including living relatives out of our pedigree: primates. The exploration of phylogenetic traits of human behavior became a major topic ever since the approaches of primatology, evolutionary ecology, and behavioral biology brought innovative impulses to anthropology. Especially recent works in the Max Planck Institute for Evolutionary Anthropology (Leipzig, Germany) contributed remarkable findings regarding the origin of social behavior, speech, social cognition, and, reaching deep in the humanities, the "theory of mind" (Tomasello 1999). The subject matter can be roughly named by referring to the term *human universals*, as from a different viewpoint, ethnologist Donald Brown calls the outcomes of his cultural-comparative screening of populations. Besides all cultural variations, our species can be described by a certain set of universals we all share (Brown 1991). Universals are nontrivial patterns of behavior that can be observed in all known populations; sexuality, for example, is trivial, as a reproductive need and a basic definition of life, but a code of conduct regulating sexual issues is a human universal. In a phylogenetic perspective, research programs trace the roots of these habits in comprehensive studies of our ancestors, living and extinct. This linking can be pursued to basic religious questions in primatology research. In recent works, primatologists observed the handling of deceased members of primate societies, especially newborn, establishing a vague sketch of primate thanatology in the genus *Pan* (Anderson et al. 2010).

In Wilson's Sociobiology, we find that "the enduring paradox of religion is that so much of its substance is demonstrably false, yet it remains a driving force in all societies. Men would rather believe than know, have the void as purpose, as Nietzsche said, than be void of purpose" (Wilson 1975, p. 561). The falsehood of the "substance" religion is an open question, as in the theoretical view of sociobiology, only the outcome counts: Religious behavior is open to empirical questions, estimating the impact on fitness of any observable behavior. In this approach, we can further on investigate whether religion can be seen as an adaptation (increasing fitness) or not (decreasing fitness).

Cognition and Metaphysics

Studies in the developmental and cognitive psychology offer some interesting aspect of childhood. Up to the fifth year, cognitive strategies can be described that offer religious convictions: All things have a function: birds fly, trees grow, and the sun heats. Kids estimate a knowledge of everything in every being simultaneously with their own perception: You cannot see me when I cover my eyes with my hands. This phenomenon of an imaginary shared perception will slightly fade away, partly substituted by the theory of mind (mind reading) in later child development (Tomasello 1999). This can be linked to a main issue of religious metaphysics: the existence of an all-knowing and ubiquitous observer. In this view, kids are intuitive theists, therefore carrying moral dimensions. (This changes the perspective about "learning" a religion, there is no need to adopt this ontological setting, and it is rather to scrutinize as a rationalist.)

Other problems of the cognitive competences are easy to handle by estimating their adaptive value: The "agent detection device" (ADD) leads us to imagine an agent behind natural events – the branch of this bush is moving; there must be a (unmoved) mover, a *prima causa*. It may be an advantage to take precautions than to ignore it (agnostic ignorance); like the threshold of a smoke detector, it has to be calibrated low enough. This may sound like early stages of animism; the relevant news in here is the fact that we talk about a synthesizing performance of an adapted brain, generating a world view based and calibrated to the environment. The discussion of the theomorphism of man or the anthropomorphism of god is the intellectual field of work, introduced by Feuerbach's projection thesis. They can be linked to the relevant aspects in cognitive sciences – like many other aspects represented in the so-called cognitive sciences of religion (CSR). Some authors expand ADD to a "hyperactive agent detection device," when the benefits of agent detection establish over phylogenetic time, leading to theories explaining why we see "faces in the cloud" (Guthrie 1995) and pass the Rorschach test, opening the approach to empirical testing as well.

Approaches to Religion

Defining Religion

There is a dialectical tension between the scientific and humanistic contents of anthropology. The natural scientist is aiming to give it all a mandatory twist, searching for structures, systems, and principles of all living things. It is an ongoing debate in the theory of sciences, whether biology (recently called "a science of specific solutions") is still a natural science. The challenge of evolution lies in a high degree of complexity as the only changeless component is variation itself. Evolution is a fundamental process of life; the theory holds an expansive force of integration to other scientific disciplines outside the channels of natural sciences. In technical, social, and cultural sciences, the theory of evolution has a late effect. "Darwin's dangerous idea" became a "universal acid" (Dennett 1995).

This aspect – working on specific questions and tasks in detail – is rather ignored in the clean environment of a laboratory. As many reductionists develop mandatory thesis, for example, claiming spin-off products of brain functions, the focus leads to an isolation of doubtless functional parts from environmental needs and conditions. This may satisfy the wishful thinking of the *one* reason that must be – but thinking some steps further shows that it cannot hold position against the complexity of the problem on all scales: The humanist aspect of anthropology simply cannot live with an under-complex explanation of our "human nature," starting from our self-understanding as cultural beings to the need for a free will to fulfill ethical issues. The problem of defining religion takes place in this minefield: It is not a physical object we can lean over; it is not only the human "on its own" like in the problem of philosophical anthropology; when the *explanans* is coincidental to the *explanandum*, the subject of explanation is equal to the object of explanation. Religion is unquestionable observable in its behavioral outcome – but this is a tip of the iceberg, still holding a lot under holy water. The horizontal line in this picture is a metaphysical metaphor, a spell that has to be broken (Dennett 2007) to have a closer, a scientific look at the underwater part of religion. Therefore, theories estimate the ways religion is and works, not as a separate entity but as "culture- and time-bound discursive properties" (as Stausberg puts it in Stausberg 2009).

In his 1921 published study *The Psychological Study of Religion: Its Origin, Function, and Future*, James Leuba (1867–1946) offered 48 different definitions of religion – it may be helpful for scientific history to continue collecting and detecting shifts in methodological and epistemological approaches. A brief and more or less classic definition that fits our needs is from William James (*The Varieties of Religious Experience* 1902:31):

> Religion, therefore, as I now ask you arbitrarily to take it, shall mean for us *the feelings, acts, and experiences of individual men in their solitude, so far as they apprehend themselves to stand in relation to whatever they may consider the divine*. Since the relation may be either moral, physical, or ritual, it is evident that out of religion in the sense in which we take it, theologies, philosophies, and ecclesiastical organizations may secondarily grow.

Feelings, acts, and experiences are the candidates to analyze for religious commitment. As religion thereby is bound to a subjective and substantiate expression in cognitive, social, and emotional processes, it is in reach for behavioral studies. It would be heresy to assume that natural sciences aim to "biologize" religion, but it would be obscurantism to deny advancement in natural and social sciences searching for an evolutionary explanation of human behavior. To avert further damage, a theoretically framed and therefore falsifiable description has nothing to do with "explaining religion away." Unquestionable, a lot of authors expanded the framework of naturalism in the realms of reductionisms – a methodological fallacy.

Origin of Religion

The nature of things is often seen as being determined in an ontological and metaphysical sense. This must be understood without any historical index. As mentioned in the essentialist's perspective, this is not the approach of an evolutionary perspective of religion, offering a specific theoretical account. Religion is understood as an emerging quality; the theory aims to provide the components necessary to generate religious behavior under certain conditions. This is provided by the archaeological record, discussing and interpreting early proofs of religious behavior by reconstructing burials, frequent use of cult sites, or other outcomes of human activities that somehow leave traces (Lewis-Williams 2010; Burkert 1996). Therefore, the origin of religion must be seen in its difference to the beginning in terms of evolutionary appearance. This dualism is a variation ever since the option of questioning religion was enriched by opening it to psychological aspects. When William James described the "The Varieties of Religious Experience" (James 1902), he clearly distinguished two questions: "What is the nature of religion?" and "What is the meaning of religion?" The nature of religion became a psychological problem, dealing with a large variety of the possible forms and attributes of higher forces, seen as an intrinsic factor of human psychology. No need to look for the nature of gods and supernatural actors if there is evidence for its origin in the human mind. But interpreting a cromlech as a religious site or cave art as a meaningful painting in terms of a religious fact demands a theoretical presumption, enabling us to name it. Therefore, we take it easy to classify things as religious in a historical perspective, leaving the question of its origin open. In other words, we define the facts widely sporty, but spare their formation condition.

Components of Religion

The idea of components of religion is fully dissolving the long-lasting perspective on religion as a unit sui generis. The religionist argument aims to keep theology prior to anthropology; the dissolution of religion into anthropology is the worst case scenario. Wrecking religion into functional components is wrong in Eliade's view, because "a religious phenomenon will only be recognized as such if it is grasped at its own level, that is to say, if it is studied as something religious. To try to grasp the essence of such a phenomenon by means of physiology, psychology, sociology, economics, linguistics, art or any other is false" (Eliade 1963, p. xiii); the "big picture" would be missing.

On the other end of the scale, the components as such may be accepted as separate units appearing in the human mind, but the existence of the one thing called religion is seen as an illusion. Religion needs construction! Boyer argues for the continuation of the Aufklärung, when Kant showed that religious ideas are creations of the mind. Religious studies need to go further on; with "the use of better science" they have to "show that the very existence of something called 'religion' is largely an illusion [. . .,] the package does not really exist as such. Notions of supernatural agents, of morality, of ethnic identity, of ritual requirements and other experiences, all appears in human mind independently" (Boyer 2010, p. 1). In this case, religion is not subject to methodological fragmentation prior to theoretical needs – it is denied ontologically; it is an "airy nothing." Such programmatic perspectives on continuing the Aufklärung are worthy of discussion; moreover, they lay open the omnipresent caveat that science sometimes carries the intention of dissolving religion. Still they provide new spheres of action: The cognitive sciences of religion offer a set of a cross-culturally recurrent universal cognitive mechanisms, a “cognitive gear” of religiousness (afterlife, beings with special powers, signs and portents, creationism, spirit possession, rituals, ritual exegesis, the sacred, deference, moral obligation, punishment and reward, and revelation) (see Whitehouse 2008).

Domains of Religion

The modular structure of cognitive skills can be described as a network of brain, body, language, and culture (Mithen 2007). They discuss the human instincts as a biological universal feature of human behavior and wit. Their developmental history offers the explanation theory of evolutionary psychology: The environment of evolutionary adaptedness (EEA) leads to Darwinian algorithms, allowing predictions about processes of adaptation, hence to reconstruct past adaptations by formulation hypothesis (an architecture underlying the human capacity for religion). The evolutionary approach to religion supposes that human phylogeny provided a cognitive integration of the four domains: mysticism, ethics, myths, and ritual (see Table 2 for an overview). In this combination, religiosity emerges as an evolutionary adaptation providing reproductive advantages (see Voland and Söling 2004). Religiosity proves to solve the problems underlying the domains in individual and collective perspective: Individually experienced contingency is answered by commonly shared mysticism. Social interaction is regulated and to a certain degree predictable, enabling human societies to invest in long-term and large-scale projects. The myth provides patterns and externalized powers or agents as templates for commitments, enabling the identification of group members and the detection of free riders. The ritual is the hurdle that has to be taken to fulfill expectations regarding a trustworthy confession to a group, paid back in the offered earthly or heavenly benefit. It may be expected that the selection pressure on religiosity potentially played a major role in human evolution when the population count exceeded family sizes and the competition between groups were judged by its efficiency, competences, and – “naturally” – fitness.

Table 2 Domains of religiosity (see Voland and Söling 2004)

Domain	Mysticism	Ethics	Myth	Ritual
Adapted for	Intuitive ontologies	Social systems	Language instinct	Handicap
Function	Categorization	Social competence	Group communication	Trustworthy articulation
New function	*Coping with contingence*	–	–	–
Differentiation	Assuaged decision-making	Allowing cooperation benefits	Social identity, in-group/out-group differentiation	Combating fraud, detection of free riders

Mysticism

The underlying Darwinian algorithm of mysticism is the competition of intuitive ontologies. They evolved as a coping strategy with unknown components of the surrounding environment – the human mind dependently needs “facts” for judging situations and making decisions. We need to know why the branch of that scrub is moving – the ontology that offers the wind as the one and only explanation will not take the predator into account, proving as a bad explanation. As Tomasello showed in comparative studies, it is most likely that intuitive ontologies are based on social experiences and developed for the need of judging and categorizing social interaction partners. Social detection categories, hence social ontologies based on human agents, are transferred into the natural environment. Our *theory of mind* (ToM) is on the one hand a feature of human evolution; in comparative studies with primate infants, specific human features of detecting intentions are shown (Bullinger et al. 2011). Infants do not only recognize intentions of social partners clearly, showing that the anticipation is based on mind reading as part of our evolved features of our mind. They even tend to assist and therefore invest in the action of the social partner, as long as the execution of the action is hampered by anything only the infant can bring in order. Ontogenetically, the ToM will be calibrated to cultural patterns and social conditions – but we are born as dualists, animists, and “intuitive theists” (see Knight et al. 2004) and think teleologically. On the other hand, the ToM proved as a high-capacity mechanism of the human brain that in general can prove as helpful even in nonsocial conditions; treating nonhuman components as actors can offer ontological concepts that may be incorrect from a distant perspective. But the Darwinian algorithm is not selected for truth, it is selected for effectiveness; as long as the intuitive ontology generates a helpful representation of the environment, their outcome will determine our world view.

Ethics

The question concerning the evolution of altruistic behavior and the establishment of morals is probably the eldest topic in evolutionary biology. As Mayr points out in his philosophy of biology (Mayr 1998), it was already clear to Darwin that altruistic behavior cannot be explained by survival of the fittest alone. Studies about the pattern of cooperation in groups, mathematical models, and investment theories concerning grades of blood relationship (Alexander 1987; Hamilton 1964) showed that patterns based on kinship soon become inappropriate. Stepping over a threshold in respect of group sizes blasting family boundaries, new challenges and behavior patterns arise: *Homo confidens* meets *Homo mendax*. As gene altruism will not handle this encounter, socially established rules regulate interaction. The observance of ethical rules and the punishment of deviant behavior are facilitated by assuming a higher power observing even unseen behavior. A hypothesis claims the belief in god as a program of internalizing moral rules. The external judge becomes irrelevant as long as the sanction of deviant behavior, or even thoughts, is happening in the head. Voland assumes that religion donates morals, not understood in a theological sense that refers to metaphysical values shown in revelation. It is rather a social technique, because fear from punishment makes "good behavior" more probable.

Myth

The function of myth as a social-bonding technique is a double-edged sword: The enhancement of group solidarity and identity must pay a price (the dissociation of out-groups). Members of any unknown collective are screened; as long as they do not match with the standards provided by the own myth or mythical tradition, xenophobia will be a relevant variable. Judging whether someone believes in the same god, therefore is a trustworthy social partner, becomes a feature-depending friend- or foe-decision-making system. The decision is not based on features relevant to cooperation or factual investments, like treated in tit-for-tat systems or other models in game theory (Luce and Raiffa 1989). In a new cultural niche – a niche that is not occupied, but constructed (see section "(Cognitive) Niche Construction") – specific displays and commitments are the key to social acceptance in an idealized group of believers.

Many social scientists showed in early critiques that religion can be described as a highly functional social phenomenon – regardless of any theological aspects (see Durkheim 1981 [1912] for a functional approach and Luhmann (2002) for the orientation function of religion in system theory). Basic social patterns of behavior, social order, and "naturally" language depend on speech; thence, the part of the relevant sacral components in the appearance of these features must be evaluated.

Ritual

Rituals improve the cohesiveness in groups. When special occasions in biographic situations (birth, marriage, *rites de passage*, funeral), social events with political functions (coronations, elections, executions), or festivities in the circle of the year happen, certain patterns of behavior are expected. The repeatability of these events, observable in all known cultures, leads to precise expectations for all participants. The more complex the rituals become, the more the staging will lead to a stratification of its members. In case of magic rituals, aiming to quest or pray for support from higher powers, special castes may arise (shamans, priests, etc.). Besides the memorable and frequently repeated pattern with a clear purpose, rituals are creating sense. They are not only a component in utilitarian structures, they generate and play a key role in social communication, providing conventions. The participation in rituals is associated with the handicap principle. Rituals require investment; only who can afford and is willing to pay the price proves to be a member (see Zahavi 1975; Zahavi and Zahavi 1997). Rituals offer solutions for common problems of social interaction like free riders and cheaters (see Table 3 Cooperation Problems and Solutions).

Table 3 Cooperation problems and solutions

Cooperation problem	Solution	Ritual
Free rider, cheater	Profane punishment	Court
Missing criminal prosecution	Supernatural punishment	Worship
Disbelief	Costly signals	Offering, initiation
Hypocrisy	Showing emotion	Ecstasy, fear
Self-deception	Internalization	Soul-searching, confession

Recent Theories of Religion

In a first overview, we can structure the landscape of evolutionary explanations of religion in two groups with explorative subdivisions and exemplary authors/contributions.

Nonadaptive Theories

Nonadaptive theories describe religion as a useless or even dysfunctional product or by-product of specific mental processes. These processes might be adaptive in other circumstance, but they are not used as intended. Praying for rain will not let it rain, but praying in a group for rain will intensify the social cohesion. Nonadaptive theories may see religion as a neutral feature, developing independently from cultural evolution. The worst case scenario argues for a cultural parasitism: Cultural features spread as cultural parasites (*memes*) *without any selective advantages for individuals or groups.* (*See Table 4 for an overview and scientific representatives.*)

Alexander suggested that religion is a legacy of our phylogenetic heritage (Alexander 1987). As our behavioral fixture has been developed in specific needs and circumstance, it is related to Paleolithic group sizes and social structures, incommensurable with nowadays social systems and therefore adapted to the wrong thing. This is supplemented with arguments from population genetics, as the genetic variation in huge social systems leads to genetic distances within groups, undermining altruistic investment in the same lineage – the currency of fitness.

Religion as epiphenomenon describes religious behavior as based on functional criteria different to religious purposes. Like the spandrel in architecture, the “beautiful” ornament has nothing to do with structural analysis. The conception of the spandrel became a hot selling item, depending on the corner it is decorating. This argument is also known as the Panglossian argument, recommitting on the so-called figure in Voltaire’s Candide (1759), and was first brought into discussion by Steven

Table 4 Systematic overview: evolutionary approaches to religion

J. Gould and Richard C. Lewontin (Gould and Lewontin 1979: The spandrels of San Marco and the Panglossian paradigm: a critique of the adaptationist programme).

In Scott Atran's *In Gods We Trust*, many distinctive research programs in social, cognitive, and historical sciences, all linked to their evolutionary character, are woven together and tested on empirical studies as well. In combining cognitive sciences and evolutionary psychology, his focus is on the cost aspect of religious behavior; many seemingly do not pay out. Hardly surprising, his starting point is a denial of religion as a dedicated "religious faculty" in human cognition; therefore, no religiosity can be supposed as disposition: "Religions are not adaptations and they have no evolutionary functions as such" (Atran 2002, p. 12). Our hands did not evolve for holding a computer mouse; they are adaptive to these purposes but are not adaptations for them. Same with religion, "Religion may be adaptive in some contexts without being an adaptation in an evolutionary sense"; his thought experiment introducing religion as a river flowing through a varied landscape is a good attorney in fact for nonadaptive theories: "the class of humanly plausible religions is one set of paths in the landscape's drainage basin" (Atran 2002, p. 11). The topography of the land is made out of calibrated human brain/mind functions as speech, vision, theory of mind, folk biology, folk psychology, and many others representing peaks. The river, a flow of conceptual information, rushes through the human intelligence; the topography (the peaks as mentioned above plus other factors like weather, the place holder for any inputs in this big picture) causes the river to flow certain ways. If it flows long enough, we might even expect a river bed. A main quest concerns development and consolidation of religious concepts. On the one hand, the development of these concepts (like gods, agents, and spirits) has to be explained, and on the other hand, it must be linked to the costs as far as these beliefs lead to certain behavior. From an evolutionary perspective, the genesis of these beliefs is not sufficient; selection's tolerance for the real costs must be brought to the table as well. The minimally counterintuitive concept (MCI) is offering a theory about our abilities to understand and memorize religious concepts. Ordinary concepts receive a slight modification, thereby compel attention; in a perfectly condensed phrase by Bulbulia, "Religion is the *familiar*, made *strange*" (Bulbulia 2009, p. 160), leading to absurd commitments. As soon as these concepts are alive and become a salient feature in a specific group, the evolutionary fate depends on the survivability of the concept. Results of early empirical studies suggest that recall effects may account for the recurrent features found in religious concepts from different cultures (Boyer and Ramble 2001). This links the evolutionary conditions of emerging to the explanation of religious behavior as well as the features of religious beliefs as a human universal. Known ontological categories, imbedded in folk mechanics, folk biology, and folk psychology, have to be violated in order to be counterintuitive. Depending on the class of objects (persons, animals, plants, artifacts, and natural objects), (i) the estimated psychological qualities, (ii) the biological features, or (iii) the physical properties have to be violated. A growing plant will not make a deal, but an all-knowing, flying, and invisible tree will be a better candidate to be memorized.

Adaptive Theories

On the level of individual selection, religious behavior evolved for the benefit of the individual in comparison to competitors. On the level of kin selection, religious behavior gives advantage to genetically related individuals in comparison to genetically more distant group members. On the level of group selection, religion is selected for the evolutionary success of groups, favoring tools to improve willingness and toughness. (*See Table* 4 *for an overview and scientific representatives.*)

In social sciences, Durkheim and his trendsetting functional definition in his work *Les formes élémentaires de la vie religieuse* (Durkheim 1981/1912) became the framework for theories of religion as an adaptation. For Durkheim, a religious group is "a society whose members are united by the fact that they think in the same way in regard to the sacred world and its relations with the profane world, and by the fact that they translate these common ideas into common practices." The "translation" starts with cognitive processes and ends with practices; the collective consciousness is the consciousness of all individuals. This allows common practices and combined powers and affords for higher goals. Following this pattern will easily lead to advantages of groups compared to other less organized groups or even individuals compared to ones with lower involvement in religious practices. Nowadays, we can state that the critique of religion based on a historical coupling of religion and power misses the core of an obviously evolutionary disposition of religiousness.

Campbell sees religion as the solution for the "Darwinian paradox": The only way to restrain human selfishness lies within religion, promoting prosocial behavior and defeating egoism (Campbell 1975: On the conflicts between biological and social evolution and between psychology and moral tradition). In this perspective, the welfare of the individual is prior to the welfare of the group. Examples of elite privileges like priests running on the back of the laity show that this is not an endless game. Leaving the rudiment of individual egoism and changing the scale to a comparative analysis of groups – their bonding components, social cohesion techniques, and competition with other groups and their struggle for existence – we come to a major aspect of the functional aspect of religious behavior in an evolutionary outlook. The bottleneck of social evolution, long before sedentism, came along the natural selection among small units of groups in rivalry for ecological benefits. The existential competition between the groups promoted those with the best defensiveness and probably biggest group size. Evolutionary mechanisms to assure these features by restraining human selfishness and establishing investment in collective attitudes and strategies became the ones that paid out. Especially rituals can be observed in their functional role for group bonding; furthermore, this is not only in the field of expertise of anthropologists and ethnologists, as rituals in military actions, sports, and pop culture show the defining on motivational power of these elements. In this moment, groups are alive in their commitment and are defined by the emotionality of the social experience of being a part in something way bigger – as long as you are "in."

The self-understanding of a group therefore needs criteria for who is “in” and who is “out”; different authors place the myth on this place; sharing stories from a common ground explaining your existence and offering the metaphysical background of it makes you a member (see Voland’s four domains of religiosity, myths, mysticism, ethics, and rituals, in Voland and Söling (2004)). The myth is providing the truth as a strategic construction; in Voland’s approach, the aphorism of Karl Jaspers (German philosopher, 1883–1969) “truth is, what we have in common” has to be inverted: “what we have in common, is the truth,” a hypothesis why religions have to be dogmatic in order to conserve their group-defining myths. Others leave the solution of this topic to a more profane aspect, in commitment theories and behavioral strategies, providing cooperation enhancement by the development of credibility displays (Schloss and Murray 2011). Belief in supernatural agents is adaptive because these agents are all-knowing punishers. Belief in supernatural punishment can enhance within group cooperation, called “cooperation enhancement” (CE). Moreover, it can reduce cheating or free riding, called “punishment avoidance” (PA). In this approach, we can show that standard problems of interaction in groups request special methods of resolution, implemented in certain rituals (see Schloss 2008).

Superorganisms and Realism

A controversial contribution to evolutionary theories of religion may be David Sloan Wilson’s Darwin’s Cathedral, bringing back in models of group selection and explaining religion in terms of a “superorganism.” In his valuation, the term “organism” in the group context is synonymous with “adaptive at the group level.” After years of favoring the individual selection as leading paradigm in sociobiology, the “selfish gene” is getting some competition. Starting with George Williams’ “Adaptation and Natural Selection” (Williams 1996/1966) and the epoch-making “Selfish Gene” from Richard Dawkins in 1976 (Dawkins 2006b), phenotypes were seen as vehicles of benefit for DNA; selection’s targets were condensed to the genetic substrate. When “rethinking the foundations of sociobiology” in 2007, David S. Wilson and Edward O. Wilson put the finger on the 1960s, claiming pivotal events leading to a more or less intransigent rejection of group selection. In their view, multilevel selection theory (including group selection) provides an elegant theoretical foundation for sociobiology (Wilson and Wilson 2007). This is a major impulse for David S. Wilson’s attempt to develop an organismic concept of religious groups, bringing life in the new “gold standard” of sociobiology: “Selfishness beats altruism within groups. Altruistic groups beat selfish groups. Everything else is commentary” (Wilson and Wilson 2007, p. 345). His afford as well bears in mind that the functionalist perspective of evolutionary approaches leads to a methodological reductionism, even if evolutionary theories provide testable hypothesis about religion they might not hit the nail on the head. Hence, paraphrasing Kant, religious studies are blind without biological theory, and biological speculation is empty without scholarly data.

The standard perspectives of cognitive models are based on individualism, whether religion is generated by individual brains emerging religion in a group of individuals or even if the brain is infected by a Congo virus, a technique of memes to occupy human brains. In Darwin's cathedral, the first step, recalling the renaissance of group selection theories, is to claim an averaging fallacy, ruling out group selection by definition. But if a considered trait is a social behavior, "the fitness of an individual is determined by its own trait and the traits of the individual with whom it interacts. These individuals constitute the group, which must be identified accurately to calculate the fitness that determine[s] the outcome of evolution" (Wilson 2002, p. 15), showing clearly the concept of the enemy: a theory of evolution restricted to genetic evolution that sticks to the individual and restricted perspective on a pure gene carrier. His approach aims to reactivate the standard patterns of Darwinian evolutionary development and apply them for group-level adaptations by means of differential survival and reproduction of groups. From the perspective of the selfish gene, there was only one possibility for altruism to evolve: when average returns exceed average costs (see Hamilton 1964). The natural selection of groups will not play a role in comparing groups of altruistic and non-altruistic members, but in comparing *altruistic* groups, we can handle special patterns of human behavior and test hypothesis on religion as a group-level adaptation to enhance in-group cooperation (see Wilson 2005). The approach proposes that religious traits evolve to functionally integrate the behavior of all persons within a (we might then call it religious) group who share them. This is the underlying process that makes a "superorganism" out of it, offering another theoretical framework (like organismic biology describing units as systems) to solve problems of cooperation and coordination. Group selection therefore predicts culturally evolved patterns of behavior to prohibit selfish individualism within groups. It is a shift from a perspective of altruism-based social life to a certain mode of social behavior induced by social control: Monitoring, censure, punishment, and exile are the bricks that automatically request corresponding patterns of behavior like signaling (e.g., the theory of credibility enhancement displays in Henrich (2009)), playing a key role in understanding the evolutionary development and function of rituals. Wilson sees religious groups as rapidly evolving entities adapted to their current environments; therefore, religion is a solidarity technology, and therefore, religious variation will be limited by the purposes as targets of selection: the demand of building and ensuring a community. The question is still open whether the restricted diversity of religions (scholar evidence shows that religions are not set in stone, rather entities on a timescale in constant change) is better explained by the specific needs of optimizing human interaction or by mental habits of the *adapted mind*. "If the individual is no longer a privileged unit of selection, it is no longer a privileged unit of cognition. We are free to imagine individuals in a social group connected in a circuitry that gives the group the status of the brain and the individual the status of the neuron" (Wilson 2002, p. 33).

Evolutionary theories of religion offer a heuristic tool: The theory builds on the distinction between ultimate and proximate causes. Religion plays a key role in coping with reality; dealing with the world leads to a certain knowledge that can be called facts – and a certain set of features that derive or build the domains of mysticism and myth. Following this dichotomy set, two kinds of realism are introduced, a *factual realism* that accurately describes the world (irrespective of its functionality) and a *practical realism* showing useful beliefs, regardless of their validity to the "hard facts" they claim. In the perspective of selection, the factual realism is selected for accuracy, while the practical realism is selected as a biological utility for the effect of the belief. It has to be greater than the cost of holding the belief. This theoretical approach leads to a new framework for working with religious issues without explaining religion away. Even if evolutionary sciences have to be selective and therefore offer a reductionistic perspective, proximate behavior can be explained in a way that leads to the idea of being religious as a natural phenomenon. Compared to other critiques of religion that rather look like weapons against religions, this is a new standard in handling religion. Dawkins, for instance, describes the phenomenon as pathology: Infected brains, run by bad memes invoking religious behavior, take over the human being; therefore, religious behavior as well as the outcome of this "illness" (churches as institutions, castes, priests, mythology, and spirituality) must be treated (Dawkins 2006a). Dennett introduces religions as a carrier of "bad spells" and "toxic mutations." Only healthy people (better to be an atheist than an agnostic) do not show the symptoms (Dennett 2007). In the approach based on practical realism as instrument of social group organization, all of a sudden, the concept of an enemy loses ground. The claim of god becomes irrelevant; whatever the container of practical realism carries is selected for its positive effect of the belief. There is no pathology to defame beliefs and automatically favoring the disbeliever, rather the opposite: As the practical realism provides useful beliefs leading to fitness maximizing behavior on the group level, the outside disbeliever is under suspicion. The theory must handle the phenomenon of deviant behavior within a group or offer bypass theories to reach the goal of the intended behavior. Religions do not evolve for their accuracy, but they evolve to secure harmony. In this sense, we have an evolutionary foundation of moral systems and ethics, as well a theory to cope with the Darwinian paradox (the aporia of social behavior in a world of the survival of the fittest):

> We might therefore expect moral systems to be designed to trigger powerful emotional impulses, linking joy with right, fear with wrong, anger with transgression. We might expect stories, music and rituals to be at last as important as logical arguments in orchestration the behaviour of groups. Supernatural agents and events that never happened can provide blueprints for action that far surpass factual accounts of the natural world in clarity and motivation powers. (Wilson 2002, p. 42)

This deals with religion as a part of human culture, as stories and music can be read as representatives of aesthetical articulation and symbolical representation. Cassirer identified mythological thinking and perception as the fundamental symbolical form. The mythical explanation of the world, to continue his valuation, leads to emotions (cf. Wilson) that generate the phenomenon that myths will not come in objects but in physiognomic features. Hence, we can link the phenomenon of practical beliefs as a key feature of religious behavior to the larger frame of symbolical representation that enables the cultural development of man – and not vice versa. "Myth is filled with the most violent emotions and the most frightful visions. But in myth man begins to learn a new and strange art: the art of expressing, and that means of organizing his most deeply rooted instincts, his hopes and fears" (Cassirer 1946, p. 45). Cassirer denies that fear leads to religion as a mere product. There is more than fear as an "outcome" like myth and religion. "But what is most essential in man's religious life is not the fact of *fear*, but the *metamorphosis* of fear. Fear is a universal biological instinct. It can never be completely overcome or suppressed, but it can change its form" (Cassirer 1946, p. 45).

(Cognitive) Niche Construction

The coevolution of nature and culture is a debate about leaving the boundaries of a discussion focused on the gene as the driving force. The approach of Richerson and Boyd, claiming a cultural evolution "not by genes alone" (Richerson and Boyd 2005), brought a fruitful impulse beside other authors on the topic (Sperber 1996) in preparation for an extension of the niche conception. The concept of the niche was introduced to address key adaptation, enabling an organism to occupy ecological niches by applying organismic licenses. The picture of the niche has been extended to cognitive niches, therefore offering a mental construction of cognitive niches as a theoretical entry to handle cultural development in an evolutionary approach.

> Cultures are defensive constructions against chaos, designed to reduce the impact of randomness experience. They are adaptive responses, just as feathers are for birds and fur for mammals. Cultures prescribe norms, evolve goals, and build beliefs that help us tackle the challenges of existence. In so doing they must rule out many alternative goals and beliefs, and thereby limit possibilities; but this channeling of attention to a limited set of goals and means is what allows effortless actions within self-erected boundaries. (Csikszentmihalyi 1990, p. 91)

Proposed is a conceptual model that maps the causal pathways relating biological evolution to cultural change. It builds on evolutionary theory by placing emphasis on the capacity of organisms to modify sources of natural selection in their environment. Niche construction means influences on more than the ecological surrounding, even social and cultural parameters are changed; therefore, a feedback in form of changing selective aspects of selection plays a role in the process of cultural evolution. The evolutionary dynamics are broadened, allowing to incorporate ontogenetic and cultural processes. Individuals or phenotypes have a more active role, as laying hand on relevant elevating screws, compared to the standard assumption of a passive phenotype determined by genetic dispositions and environmental impact (see Laland et al. 2000; Laland and Sterelny 2006; Kendal et al. 2011). In this new level, not only the question concerning the positive effect of belief is formulated, but the question concerning the positive effect *of* the belief *on* the belief has a theoretical ground. Advocates of this approach argue for taking (cognitive) niche construction seriously: "there is both accuracy and utility in treating niche construction as an evolutionary process in its own right, rather than as merely a product of evolution. Niche construction may be influenced by genetic, ontogenetic and cultural information and feeds back to influence selective processes at each of these levels" (Laland 2009, p. 35). For the formulation of hypotheses on adaptive processes in human evolution, the organism-environment match can be addressed as a reciprocal interaction between various levels of natural selection and aspects of (cultural) niche construction. The phenotype, formerly seen as a passive taker of evolutionary processes, shines in a new light: "Now phenotypes play two roles in evolution, they survive and reproduce but they also construct and modify environments, modifying selection pressures" (Laland 2009, p. 37). Note that on the one hand, all arguments referring to an adapted mind – unfortunately to the requirements of our stone age ancestors – experience contrary wind and on the other hand, the phenotype as an environment modifier will play a certain role in telling "just so stories": The unsatisfying situation of judging adaptations as outcomes of adaptive processes ex post facto only, leading to a Panglossian circular argument, may be altered as the niche construction allows to deal with the process in the beginning. "Human evolution may be unique in that our culture and niche construction have become self-reinforcing, with transgenerational culture modifying the environment in a manner that favours ever-more culture, and niche construction informed by cultural knowledge becoming ever-more powerful" (Laland 2009, p. 39). This perspective may explain religious behavior as unique, because the cognitive construction of its components is self-reinforcing, with transcultural domains of religiosity modifying the social environment in a manner that favors religion in the cultural evolution of *Homo sapiens*.

Perspectives: On eReligion and iReligion

"The predisposition to religious belief is the most complex and powerful force in the human mind and in all probability an ineradicable part of human nature" (Wilson 1979, p. 169). Undoubtedly, there is no question: Religiosity can be seen as a human universal (see Brown 1991). But religion as a subject matter to science runs into a variety of approaches, each of them considering certain aspects of religiosity depending on the methodological background. Ever since psychology joined the disciplines working on this issue, the dictum of William James showed that different heuristics aim for different aspects. In his Varieties of Religious Experience from 1902, he made a distinction between two questions: "What is the nature of religion?" and "What is the meaning of religion?" It can be claimed that the search for the nature caused a vivid field of psychological research, following the assumption that the brain is the location and therefore the place religion "happens."

A recent nomenclature (developed by Joseph Bulbulia) addresses eReligion (the external aspects of religion, the behavioral and cultural outcome) and iReligion (innate religion). Rethinking the relationship of these matters shows the twist that the evolutionary perspective brought into the scientific discussion about religion. The long-lasting deduction of iReligion from the "sacred" eReligion justified an almost metaphysical standing of man as a religious-cultural being. The "big picture" was already in place – this is inverted in cognitive theories, when the fragmented inputs of iReligion reconstitute a religious culture. eReligion is the big picture *at last*, not set in stone from the beginning. But even if the twist brought new approaches, ideas of religious dimensions, and therefore new theoretical perspectives, an underlying dualism seems to be alive: the individual versus social realm of religion(s). For future perspectives on evolutionary aspects of religion, there is much work to do in reframing this problem in the challenging entanglement of nature and culture. Focusing on the recent works, introduced as des CSR, the new aspect of the relation between cognition and culture can be described as dialectic, but not as an antagonism. Referring to the prospects of a cognitive niche construction, the brain is no longer a hardware that is genetically determined to generate a culture by running a heritage program; it becomes a cultural and social artifact. There may be – a tribute to some more or less reductionist naturalists – a lot of biological and even cognitive processes out of reach of our consciousness. They provide the theoretical framework to formulate hypothesis regarding the time and ecological aspects of their development in the biological evolution of *Homo sapiens*. These models of hominization are the starting basis for mental options leaving the area of natural sciences. When symbolical representations take the lead, the click of the ratchet becomes a relevant one – not to be understood as a single event but as the progression from *hominitas* to *humanitas*, when upon biological features, the cultural articulation occurs. This leads as well to religious conceptualizations that clearly operate as symbols, and symbolization is a promising starting point to connect cognition and culture.

A question is whether we have to deal with an encapsulation of religious cognition as a methodological narrowness. As Lawson and McCauley already showed in the 1990s, a proclaimed *cognitive turn* in “Rethinking Religion: Connecting Cognition and Culture” introduced the fundament for the so-called cognitive sciences of religion (CSR; see Barrett and Burdett (2011) for an overview). If this leads to the indication of a narrow-angle glaucoma, all depends on the self-conception and level of methodological self-reflection of the participating disciplines. There is no antidote against the atheistically apodictic – but the increasing discussions and projects on theories of evolution, especially considering evolutionary approaches, speak for themselves. A lot of work ahead, there is no metatheory in sight, capable of combining the contemporary approaches. Not only scientific work has to be done, both scientists and believers (not to be misunderstood as dichotomy) have to learn from recent findings. There are new terms in circulation that may be unsettling, talking about sacred things that may sound defaming. Followers of religion must learn to accept that the progress in sciences creates a new vocabulary and theoretical framework. It may sound crude when Boyer calls religion an “airy nothing” – this will be misunderstood when interpreted as an attack on religion but reveals its true meaning when interpreted with the theoretical background of the coevolution of nature and culture. “Airy nothing” is a phrase out of Shakespeare’s *A Midsummer Night’s Dream* (Act 5, Scene1), when Theseus, the Duke of Athens, claims: “And as imagination bodies forth/The forms of things unknown, the poet’s pen/Turns them to shapes and gives to airy nothing/A local habitation and a name.” The unknown obtains a name: In the beginning was the Word (John 1:1). Besides new terms, religious representatives must accept that religious belief and behavior has not fallen from the sky, but is a natural phenomenon with a natural history that offers benefits to users that can be described within biological purposes. The relation between scientific explanations and religious belief changes as well as the foundations for a false peace. Obstacles like the NOMA proposition (the theory of science and religion as Nonoverlapping Magisteria; see Gould 1997; 1999) proved to be incorrect – rather a spell from the inside that has to be broken, there is no need to take evolutionary biology on a leash. Atheists and some other Brights must acknowledge that religiousness as a natural phenomenon shows certain features and abilities in social systems and might be requested from believers, even in modified form from disbelievers, because its functionality is based on the intrinsic motivation of the human mind generating religious life, practice, and perspective. "It is no obligation to belief; but to act as if you belief." [„Es ist nicht Pflicht, zu glauben, [. . .] sondern es ist bloß und allein dies Pflicht, zu handeln, als ob man es glaubte"Friedrich Karl Forberg (1798, p. 38).

Conclusion

The evolutionary perspective on religion combines research findings and theoretical approaches to test the hypothesis that human religiousness may arise from a vast variety of adaptations in the evolutionary history of *Homo sapiens*, observable both in recent cultures and in the cultural products of our ancestors. Theoretical approaches offer 'positive' positions that describe religion as an adaption to certain human needs and conditions during the evolution of social behavior, providing solutions for cooperation problems in complex communities. They include improving the ability to cope with crises and to overcome the attraction of personal gain by exploiting others; avoidance of harming the common good; improving cooperation and moral solidarity within groups; and improving competitiveness with other groups. So-called domains of religiosity (mysticism, ethics, myth and ritual) describe a modular structure of cognitive skills in a network of brain, body, language and culture, providing an architecture underlying the human capacity for religion. 'Negative' positions develop a non-adaptive stance when they give rise to side-product theories, epiphenomenalism or simply to talking religion down. The vastness of bio-cultural complexity must be the key aspect in any theory of the evolution of religion. Concepts like cognitive niche construction offer new perspectives in gene-culture-coevolution for developing further approaches to the study of religion.

Paleoanthropology and the Foundation of Ethics: Methodological Remarks on the Problem of Criteriology

Mathias Gutmann and Michael Weingarten

Contents

Abstract

In scientific contexts, human beings are usually categorized as such based on certain stated or implicit membership criteria, i.e., a criteriological framework. Thus, reference to humans as such always raises the seemingly empirical question of which traits should be considered "typically human." Common approaches to this question reveal certain methodological shortcomings. First, the complex grammar of human activities is reduced to an impoverished system of traits, characteristics, and features of biological constitution, and second, the argumentation of criteriological approaches relies on potentially problematic

animal–human comparisons. A methodologically sound alternative can be provided by developing a more adequate, semantically dense set of concepts in the first step, building on distinctive hallmarks of human existence, namely human work and other activities. From this perspective, the nonhuman-to-human transformation takes place not just within nature (viz. "first nature"), prior to culture (viz. "second nature"); instead it is accepted that we already need to apply our knowledge of human activities in order to explicate "natural transformations" toward a state of being human. Accordingly, nature and culture both constitute inherent aspects of the human life-form itself, and must jointly provide the methodological starting point for the reconstruction of our predecessors. Adoption of this framework has implications for empirical research as well as for ethical judgment: ethical arguments lose their putative foundation in simple physical descriptions of human beings, and paleoanthropology itself has to face up to its often overlooked nondescriptive and normative assumptions.

Introduction

We are used to thinking of entities – irrespective of their nature – as sufficiently characterized by their respective properties, faculties, or capabilities. Thus, hexapods, arachnids, and decapods may be clearly characterized as possessing three, four, or five pairs of legs, respectively. This example illustrates what we might call the epistemological, or "*criteriological*," paradigm: we apply certain criteria, or combinations of criteria, in order to characterize an entity. The limits of this paradigm (which works well in a lot of scientific and, more generally, ontological contexts) become apparent when we refer to something by the *mode of its existence* – as is often the case for living entities. The intuition behind this move away from straightforward physical properties is that living entities "are" in the way they live; to put it with Aristotle, "in living things, to live is to be" (*De anima* II,4,415b13; for discussion see Thompson 2012). The issue is that the predicate "being alive" has a distinctly different structure than, e.g., "being of color x." Particularly when we refer to human beings, we run into problems, well known among philosophers, that arise from the superficial simplicity of certain predicates we use to define humanhood, such as "being social," "having language," or "having culture" – compared with the famous "featherless biped" (with its no less famous counter-example) or the reference to "being anatomically modern." To take the first example, "being social" is not just one characteristic among many of a being called human, but is indeed the very mode of its existence.

Considering the fact that paleoanthropology deals with the reconstruction of life-forms which preceded the human life-form as we know it, one may well wonder whether there are any ethical or even just normative aspects of to the field at all. And indeed, even if any ethical concepts considered relevant to the field were proven to be invalid – whether based on a general decision theory, on a presupposed preference order of values, or on principles of discourse and communicative action – this would not threaten the validity of paleoanthropological statements proper.

When we take a closer look, however, we see that paleoanthropology and ethics share a remarkable premise: both make central reference to human beings as a unique kind of living entity. Even if we were to avoid the identification of "living entities" with "animals," the underlying definitional scheme for human beings would usually be framed in criteriological terms, that is, in terms of membership criteria for certain salient groups. In such definitional scheme, humans can be described as just another kind of animal (however peculiar), with some specific identifying features. In other words, this approach defines humans as "animals plus x," where "x" stands for one or several unique characteristics. The list of such features, whose aim it is to capture the uniqueness of humans, has historically included, e.g., language ability, tool application, sociability, and/or religiousness. Paleoanthropology, then, seems to be in a privileged position insofar as the field provides knowledge on the emergence of those uniquely human characteristics during the prehistoric phase of human evolution. But a closer look at the possibilities of paleoanthropology itself reveals some intriguing methodological problems, which put this privileged status into question:

1. When we attempt to determine the characteristics that define humans, we must refer to a semantic framework which, formally speaking, is significantly denser in the properties it contains than the resulting descriptions. The priority of a semantically dense description would hold even if our descriptions referred to (possibly functionally structured) complex collections of characteristics.
2. Even if we consider paleoanthropology to be our main source of knowledge about what makes a life-form human, the transition from a more or less purely descriptive to a normative argument cannot be justified with reference to this descriptive knowledge alone. This point is of importance when we consider the difference between normative structures that are relevant to scientific descriptions and categorizations, on the one hand, and those of ethical reasoning, on the other.

With respect to the difference between normative structures in science versus ethics brought up in the second point above, it is important to note that we can accept the relevance of several *normative* aspects of descriptions without at the same time accepting their *ethical* relevance. Whereas normativity is assumed to be an inherent aspect of human action, ethical reasoning deals in particular with the (non-inherent) *justification* of human actions. So for example, each speech act will show intrinsic normative aspects that regulate the speaker's and addressee's expectations and (self-)obligations with respect to the utterance. Thus, promising someone to keep a date involves, first, a public self-obligation on the part of the speaker, which in turn results in specific mutual expectations. The violation of this obligation by the speaker, the breaking of the promise, is not necessarily an issue of morality. At least proximately it may be considered to be just some kind of disturbance of the mutuality of expectations that underlie the speech act itself. It is only in a second step, namely when we ask for the *reasons* behind the violation, that we may reach the realm of ethics.

Despite the vast variety of ethical approaches, it is possible to identify certain fundamental argumentative strategies which apply in this arena. Basically, justification of human actions (or of omissions of action) can proceed along one of three different perspectives (following Pfordten 1996):

1. From an *anthropocentric* point of view, the validity of ethical statements necessarily depends on reference to human beings. This necessity can be understood in many ways–depending on the meaning of the term "human." One might take a species-specific approach, or alternatively a discourse-ethical or a utilitarian approach. In all cases the critical fact is that the *authors* of an ethical statement are themselves members of the group of "human beings."
2. Descriptively weaker than anthropocentrism is the *anthroporelational* justification of actions. In this case, only *some* of the steps of the ethical argument must refer to human affairs, whereas elsewhere the justification may integrate nonhuman relationships too.
3. The descriptively weakest approach is *non-anthroporelational* justification. In this case, humans are not at all referred to as the sole or privileged source of moral behavior; nonhuman living entities, and sometimes even nonliving entities, are equally deemed to be bearers of values. These values may be moral, esthetic, or economic. What makes a value relevant within the framework of non-anthroporelational justification is that it is intrinsic, or inherent – a value that exists essentially, without reference to a procedure of evaluation or value ascription. Non-anthroporelational approaches are dominant, e.g., in the field of "eco-ethics" (see the deep-ecology approach of Naess 1989).

In all three types of approaches, the most important methodological problem is the definition of human beings as a (more or less relevant) reference group for ethical ascriptions or descriptions. From a methodological point of view, even an explicitly non-anthroporelational approach has to defend its normative rules, which are supposed to be arrived at by reference to pieces of nature (e.g., "ecosystems"). At least at this point a substantial reference to the process of giving and accepting reasons is unavoidable, which implies that anthroporelational and non-anthroporelational approaches are not as weak (in terms of the validity they claim for normative statements) as they may initially seem to be (for discussion of explicit reasoning see Brandom 1994; for criticism of "nature-centric" approaches see Gutmann and Janich 2002a, b).

Ethics and the Pitfalls of Criteriology

A second taxonomy of ethical approaches is possible that is quite oblique to our first one. Whereas above we dealt with the possible authors and the possible subjects of ascriptions, we will now deal with the procedures that are adopted to reach ethical justification of human actions or omissions. From this perspective, again, a great variety of types of ethical reasoning can be identified, which we summarize here in three well-known categories:

1. The results of human actions – their intended as well as their unintended products and consequences – are the domain of *consequentialist and utilitarian reasoning*. This type of justification brings up at least three systematic problems. First, the profit or benefit–described as a function of the respective action – must be identified. To this end, a relevance ranking or a utilitarian calculus along the lines of Bentham's principle ("Act so as to produce the greatest good for the greatest number"; cf. Bentham 1789; for discussion see e.g., Nida-Rümelin 2005) has to be applied. Second, the authors of the benefits and losses have to be identified; this is often done by assuming that only those entities that show any form of interest in a specific good, or which show a minimal degree of consciousness, need to be taken into consideration. Third, the objects of human actions underlying a specific intervention can be very different in structure. They are assumed to be pure resources and sources of (predominantly) human welfare, and they may even be considered as possible subjects of the ascription of specific rights. These ascriptions may be guided by certain criteria, such as the degree of consciousness or possible interests that the respective targets of the ascriptions are supposed to show or be capable of (this point is of the utmost importance for utilitarian environmental ethics, bioethics, and medical ethics; Habermas 1997; Düwell and Steigleder 2003).

   A prominent example relevant to actual utilitarian reasoning is presented by Singer's (1998 p. 184f) discussion of the fundamentals of practical philosophy. Singer points out that science has helped overcome the "isolation" of humans in nature by leveling the division between "them" and "us." Taking into account the minimal differences between the human species and other life-forms, there seems to remain no sound argument for preferring human life: accordingly, Singer holds, the life of an anencephalic human baby, which might be "used" for organ harvesting, is no more valuable than, e.g., the life of a healthy baboon, just by virtue of the baby being a member of *Homo sapiens*. The "new ethics" represented by Singer's argument, if adopted, would force us to give new answers to old questions – due to the fact that our "position in the universe" has been radically altered. The key, according to Singer, lies in the fact that we no longer have any criterion to unambiguously determine the difference between animals and humans, which previously had provided the foundation of a radically different ethical evaluation of human life versus animal life (for further reading see Singer 1998, p. 184ff.). It follows that humans now are viewed as animals among other animals, with commonly shared features such as sensitivity to pain, consciousness, the ability to take an interest in specific aspects of one's environment, etc. Meanwhile, according to Singer, even within the (biological) species *Homo sapiens* not all members are equipped with these features equally. Thus, some members are equipped with the property of consciousness – to varying degree–while others are not. It is these individual differences that are relevant for the ethical evaluation of the resulting achievements that are potentially available to members of the species *Homo sapiens,* as well as to all nonhuman animals in reference to their respective life-form.

2. From a different point of view, some principles are considered necessary against which human actions may be judged. Those principles can be assumed to be represented by specific inborn characteristics of the human genus *Homo*. Again, human beings appear to be a token of a type, if the type *Homo* is understood as a biological unit. According to Höffe (2002, p. 74) "being wise" (*sapientia*) is the defining criterion, which – as a capability – characterizes all members of the group. By definition then, humans are reasonable animals, equipped by membership in the genus *Homo* with the capability of rational reasoning. From this point of view, the term "life" retains its biological reference. But nevertheless, some differences can be found within the realm of biological entities, considering the specific *form* of life which is represented by the respective natural kind. Accordingly, the term "ethos" has different meanings. In the first place, it defines the life-form, which in the case of animals is mirrored by a natural environment that fits that life-form's biological needs (Höffe 2002, p. 28). At the same time, animals are restricted to a specific form of life, which is essentially defined by their biological equipment – in contrast to human beings. Their individual life is to a certain extent pre-determined by biology, but not entirely: in its first meaning, ethos is something that animals and humans have in common; it refers to their specific place in life, the respective environment of the life-forms. Ethos in the second (tradition) and third meaning (ways of thought, habits, and characters) refers to aspects of life that are specific to humans. The moral attitudes that are represented by the customs of human communities, and the individual characteristics of humans which are thought to be instantiations of the respective customs and habits, are unique human features (Höffe 2002, p. 28f).
3. The central principle of *discursive ethical reasoning* – representing a third major line of argument – is a presupposition of full symmetry and reciprocity in participation and access, on the one hand, and of obligation, on the other hand. Following the concept of an ideal discourse, anybody who might be concerned by a decision should be allowed to participate in the discourse itself. At the same time, full reciprocity and symmetry should hold in accepting the results as well as the consequences of the decision. This is so because the instantiation of any discourse which is at least oriented at the rules of an ideal discourse is based on the *ability* of human beings to participate in rational reasoning – an ability that ultimately rests upon fundamental aspects of human language acquisition. If we trace this acquisition back to its evolutionary origins, the scope of ethical reasoning becomes based on the acquisition of some specific human characteristics, which constitute the crucial difference to any nonhuman, animal constitution. According to Gehlen's program of philosophical anthropology, Niquet (2003, p. 103) conceives humans as "discoursive animals." Thus, even the "most human" characteristic, which is expressed in the biological species name, would be based upon the biological constitution of *Homo sapiens*. Empirical disciplines including cognitive sciences, linguistics, and evolutionary epistemology, "being

> cultural by nature," can provide the knowledge needed in order to finally answer the question why humans are capable of acting discoursively. From this point of view it is only a small step to assume that rationality and language acquisition are real *biological* characteristics, which render possible the unique human abilities for discourse and discoursivity. The human ability to act in accordance with reason would thus be an inborn character of the biological species *Homo sapiens*, culture comes to be seen as a *biological* feature of the genus *Homo,* and humans are understood as animals which inhabit a self-generated environment (Gerhardt 2001, p. 47). Gerhardt explains some of the implications of this view that are relevant for a criteriological definition of human beings. The capability to give and take reasons ultimately is a biologically given criterion; it is supposed to have the same ontic status as the capability to walk upright or to use language. And like the latter, the discoursive capacity belongs to the group – not necessary to the individual. The relation between the individual and its group, then, has a type–token structure, and the basic life-form is characterized criteriologically: discoursivity is framed as a biological characteristic. The orientation of ethical reasoning toward specific characteristics that are assumed to be unique to *Homo sapiens* is one of the central features of this kind of approach; it can also be found in many other types of ethical approaches (for a critical reconstruction of anthropological presuppositions of this type see Wagner and Laubichler 2001).

Although our simple taxonomy above is neither complete nor treats the topic exhaustively, we can already recognize one remarkable similarity in what is presented under each point of view: they all refer (at least in the form of a "weak naturalism," see Habermas 1999) to a criteriological description of human individuals. The transformation from nonhuman to human takes place within the realm of nature: we start with a situation where there are no humans, and we arrive at a situation where there are. And this transformation is accompanied by the acquisition of properties that are explicitly and exclusively human. Accordingly, the difference to animals should be definable in terms of "new" evolutionary characters (*autapomorphies*, in a strict sense of the word). This similarity brings us back to our central assumption: in animal–human comparisons, whenever we use simple labels for properties we run the risk of ambiguity if we do not carefully lay out our theoretical frameworks. The terms "language" or "action" or even "cognition" may come with much richer logical grammars in an evaluative, normative, or ethical framework than in a basic biological context. To show this, we have to examine the issue of characters in a particular paradigm, namely that of evolutionary theory.

The Problem of Characters

Dealing with human beings as animals, we are confronted not so much with normative but with methodological problems concerning the concept of "characters" – in the sense of properties, or features – as applied in evolutionary theory. From a systematic point of view, the situation seems to be clear-cut. Taken as a whole, the universe of living entities, both animals and plants, displays an overwhelmingly large number of characters. Accordingly, the most important task of the systematicist may be seen in the identification of those characters that are useful or necessary for the reconstruction of evolutionary pathways. But classifying characters in this way – that is, by their utility for analytic purposes – entails certain well-known methodological pitfalls, which can be summarized as follows (for an extensive discussion see Sober 1988; Gould 2002; Bock 1988; Wagner and Laubichler 2001):

1. In order to discern "useful" from "less useful" characters, we have to refer to a criterion which has to be established beforehand and permits the specification of individual characters. But to the extent that such criterion is founded on evolutionary knowledge, we either face the risk of making a circular argument, or else the possibility that our criterion turns out to be irrelevant to the classification of characters for the purpose of evolutionary reconstruction (see Peters and Gutmann 1971, 1972; Weingarten 1992). The most promising counter-strategy might be a kind of "hermeneutic" approach, which would at least avoid direct circularity, even though it might not be seen as supporting the phylogenetic validity usually expected of evolutionary reconstructions (for further reading see Reif 2004).
2. Evolutionary reconstructions are guided by certain principles and procedures – such as the principle of "parsimony" – and these principles themselves must be justified in terms of *biological* theory. To do so one could either assume that the principles in question represent the very form of evolution itself, or else treat them as mere methodological choices.

   On the first strategy, parsimony – to use that example – is based on an implicit assumption about the process of evolution, namely that the tree that minimizes change is likely to be the best approximation of the actual phylogeny (for further reading see Rieppel 2007). Evolution is not only modeled *as if it were* some process of optimization, but instead is explicitly defined *to be* a process of optimization. This justification of reconstructive procedures will necessarily fail, however, because it does not address the question of how we can possibly know that evolution *indeed* follows parsimony. Attempts to answer that question will run into a circular argument again, or else we have to concede that it is possible to know the structure of evolution without applying the procedure in question.

   The alternative strategy, as mentioned, is to adopt the principle under discussion – such as the principle of parsimony – simply as a methodological choice for practical convenience. In this case, no justification is given, as the biological interpretation of the principle remains unexamined (for further reading see Gutmann and Janich 2002a, b; Sober 1988).
3. In order to sidestep the issue of the biological naturalness of our reconstructive procedures, as opposed to their being just the result of methodological choices, we might decide to rely on the fact that, all else being equal, probability favors

complex events being unique. In the words of Wägele (2000, p. 41f; translation ours): "The most economical explanation for the interpretation of identical features in organisms rests on an assessment of the probability that the shared feature is due to a shared cause. It is more likely that a complex chain of events (the evolution of an organ with complicated structure) took place only once than that this sequence occurred several times by coincidence."

However, the *improbability* of a transformation taking place more than once does not imply its *impossibility*. And, setting aside this truism, any quantitative probability assessment requires reference to explicit empirical knowledge – which once again brings back the problem of circularity, to the extent that this knowledge is about evolution.

4. Finally, we might be tempted to identify the "likelihood" – or some other kind of immanent criterion – of a given tree as an indication of the tree's correctness, or validity. However, considering that the validity of a tree is always relative to a particular data set, the following objection applies: "It is important to distinguish between the probability of getting the observed data, and the probability of the underlying model being correct. Likelihood says nothing about the probability of the model itself" (Page and Holmes 1998, p. 155). In other words, the consistency of a model must not be confused with its "reality content" – a confusion which is the result of a simple category mistake (for further reading see Sober 1988; Page and Holmes 1998).
5. In addition to this variety of "objective" assumptions on the nature of the organismal features that are supposed to be relevant for evolutionary reconstruction, we can identify a more or less *methodological* line of argument, which refers to the principles of feature recognition itself:
   (a) The strongest approach is taken by a naturalistic interpretation of feature recognition, which implies that living entities "consist" of characters which they simply "have." The identification of characters that are used in the process of structuring nature, e.g. in terms of hierarchies, depends on the "innate" skills of the observer himself (Wägele 2000, p. 13). The resulting type of "evolutionary theory of knowledge" is well established and relies, e.g., on the very fact that the innateness of classificatory abilities does not provide us with valid criteria for the correctness of their application (e.g. Vollmer 1987; Oeser 1987; for a methodological refutation see Janich 1987). However, naturalized epistemologies of this kind face a severe problem of "self-application" by answering the question how we know about the innateness of the respective skills themselves. If an answer is given by reference to the correctness of the classification, a circular argument results (for further reading see Janich 2000).
   (b) A weaker approach would avoid the direct naturalization of feature identification by instead assuming that this process is dependent on the theoretical context at hand. That is to say, it is accepted that if the original taxonomic(!) context of feature description is to be transcended – e.g., in order to establish *systematic* relations between the organisms under investigation – then the specific theoretical context must be taken into consideration, as in the case of

genetic or ecological relations. From this point of view, the conclusion of Wagner and Laubichler is plausible:

> The objects and functional characters that are at the center of every biological theory are not just found objects waiting to be collected in nature, rather they are conceptual abstractions determined by the parameters of a specific theoretical interest (. . .). As such, they can only be identified within the context of the object that is ontologically prior to them. Therefore, a precise formulation of these objects of ontological primacy has to be part of every theory as well. (Wagner and Laubichler 2001, p. 145)

Nevertheless, a methodological alternative to this – however weak – ontological solution of the feature recognition problem is possible, by taking into account the homonymy of one and the same descriptive term serving in different theoretical contexts (such as the term "eye" applied to both *Sepia* and *Pan*). On such approach, the necessity of some theory of the organism can be assumed, which allows the introduction of elementary evolutionary concepts such as the blueprint, or "Bauplan," of a living entity (see Gutmann 2002a; Eckhardt 2000). Wagner and Laubichler express this perspective as follows:

> In other words, we assume the ontological primacy of organisms and derive the objects relevant to the theory, i.e., the biological characters, by means of a conceptual decomposition of the organism. We further argue that if we define biological characters as conceptual abstractions, we also need an appropriately defined organism concept within biological theory. (Wagner and Laubichler 2001, p. 144)

The context dependency of character identification leads to the conclusion that the core problem of biological descriptions is the problem of *comparability*. The truism that only organisms should be compared which are *comparable* then becomes the methodologically most demanding presupposition of character identification. By taking into account that theoretical frameworks are not given per se, but in reference to particular subjects of inquiry ("*Erkenntnisinteressen*") and the respective descriptive and explanatory devices, a methodologically sound alternative even to the weaker types of naturalist concepts can be provided (see Gutmann and Janich 1998).

The above overview on the pitfalls of criteriology has put into focus the challenges of any attempt to define humans contrastively, in comparison with animals. In particular, if we wish to assume that the human-like constitution of an organism is a continuation of animal constitution, the question must be addressed how to deal with those human characters for which we cannot find any antecedents in the animal realm. In order to gain a foothold on this, we must turn to the specific scenarios presented to us by extinct predecessors of human-like organization.

From Remnants to Organisms

Even if we try to apply a character-based description in order to compare humans with nonhuman entities, a distinctive aspect of paleontological research that is relevant when we reconstruct the evolutionary pathways of non-extinct species must be borne in mind. The simple fact is that in the context of organismic descriptions (see below), when we deal with extinct life-forms, we deal with the remnants of formerly living entities. This situation increases the difficulties that we pointed out for criteriological approaches generally:

1. The transformation of the organism as a whole has to be expressed in terms of the transformation of individual characters, or character complexes. Consequently, even functional or reproductive relations must be expressed in terms of characters (Collard and Wood 2000; Wood and Collard 1999; Wagner and Laubichler 2001).
2. We need to assume a representational relation between the organism and those characters used for evolutionary reconstruction. This leads either to the supposition that the character states of current organisms represent evolutionarily older character states (e.g., by maintaining the older character states) or to the conclusion that the current organisms themselves represent an ancestral constitution, as "living fossils."

In both cases, some (valid!) knowledge on the line of evolutionary transformation has to be already available for the identification of relevant characters. Tattersall (1997) underlines the simple fact that it may be impossible to express reproductive continuity in terms of character sequences. The tension between the description of human predecessors and the requirements of a population genetic description of reproductive structure seems to be unresolvable, since it results from what is an empirically insufficient situation:

1. Even if all prehuman fossils found to date are taken into account, the empirical basis of variation analysis seems to be rather speculative. Yet without sound variation analysis, species identification is restricted to a kind of typological differentiation.
2. The reproductive patterns of prehuman populations are assessed in terms of character patterns rooted in typological ordering itself.
3. Fossil remains as well as representatives of genetic traits need to be understood as representatives of specific cultural abilities and technological achievements.

This inconvenient situation is not just the result of a (probably unavoidably insufficient) database; it is a reflex of the nature of paleontology as a scientific project. Because characters need to be integrated into a framework within which they may serve as (biologically) meaningful features of organisms, we have to "interpret" fossil remnants in the light of our biological knowledge. This interpretation leads, in the first instance, not to character sets but to functional designs – to body plans or constructions. These constructions do not represent recent organisms, but rather "possibly viable organisms," which may serve as the predecessors of the known living entities that inevitably constitute our conceptual points of reference. Those functional descriptions of remnants which give rise to the development of a functional plan also refer to functional knowledge borrowed from nonbiological sources (for the procedure, see Gould 1970; Rudwick 1998; Gutmann 2002a; Morris 2003). In describing living entities (belonging to non-extinct species) as if they were functional units, we gain the very starting point of our reconstruction of possible predecessors. One should bear in mind that these constructions are structuralizations of living animals. Thus the transformation next described must be considered as a transformation sequence based on, e.g., biomechanical principles. These principles can be borrowed from engineering practice. When we treat animals as if they were functional units (or "constructions"; see Gutmann 2002a), the transformation of these constructions can be described as either a process of optimization or as a process of differentiation of a given construction in adaptation to different working conditions (for the logic of "*as if*-statements" see Kant 1988 and Lewontin 2000). But because animals are only treated *as if* they were functional constructions, certain fundamental differences to the engineering of machines or engines remain (Gutmann 2005):

1. As in the case of optimizing or developing engines, we start the evolutionary reconstruction with the construction of actual existing forms (biologically described here as functional units). But in contrast to engineering procedures, we *look back* to those constructions that can be regarded as predecessors. This procedure of "retro-engineering" can be formally represented as follows (where K_n stands for the multi-step construction process, with E indicating the terminal construction of actually structuralized animals, and RP are the "reconstruction principles"):

$$K_n\left(A^{\mathrm{RP}}_{K_{n-1}}\right) \Rightarrow \ldots \overset{RP}{\Rightarrow} K_4(A_{K_3}/P_{K_5}) \overset{RP}{\Rightarrow} K_3(A_{K_2}/P_{K_4}) \overset{RP}{\Rightarrow} K_2(A_{K_1}/P_{K_3}) \overset{RP}{\Rightarrow} K_1^E(P_{K_3})$$

2. In the course of optimizing and developing engines, it is often useful and sometimes even necessary to actually shut down and render dysfunctional the artifacts while they are being worked on (though in the case of "Wiener machines" there may be exceptions, insofar as we sometimes need them to be at work in order to optimize them). This marks a fundamental difference to evolutionary transformation lines, because in the latter context each and every "intermediate" reconstruct of a transformation line is required to be "fit for work." In engineering terms, the force-, form-, and material-closure of the intermediates of a biological line of transformation must be maintained during the transformation process itself. Taking into account that we are sometimes confronted with multiple lines of transformation leading back to one and the same starting construction, reconstructed by way of different evolutionary predecessors, it may be more appropriate to speak of differentiation *fields* rather than lines, which are represented as follows (where K again denotes steps of construction, E indicates the terminal construction of actually structuralized animals, RP stands for the "reconstruction principles," DF are the fields of differentiation, and TR the lines of transformation):

$$\begin{tikzcd}
 & & K_{2b} & & \\
 & K_{3_a} \arrow[r, Rightarrow, "RP"] & K_{2_a} \arrow[u] \arrow[d] \arrow[r, Rightarrow, "RP"] & K_1^E & \Bigg\}\mathrm{TR}_1 \\
 & & K_{2_c} & & \\
K_4 \arrow[r, Rightarrow, "RP"] & K_{3_b} \arrow[uu] \arrow[d] \arrow[r, Rightarrow, "RP"] & K_{2_d} \arrow[r, Rightarrow, "RP"] & K_1^E & \Big\}\mathrm{TR}_2 \\
 & K_{3_c} \arrow[r, Rightarrow, "RP"] & K_{2_e} \arrow[r, Rightarrow, "RP"] & K_1^E & \Big\}\mathrm{TR}_3 \\
 & \underbrace{\qquad}_{\mathrm{DF}_3} & \underbrace{\qquad}_{\mathrm{DF}_2} & \underbrace{\qquad}_{\mathrm{DF}_1} &
\end{tikzcd}$$

3. Finally, the antecedent constructions of a given construction are to be "re-interpreted" as the functional "conditions of possibility" of (formerly) living entities (in terms of organismic descriptions). This procedure – which resembles some kind of hermeneutics more than strict scientific deduction – leads to the "envisioning" of possibly viable entities on the basis of the constructional description within a transformation line. This procedure of "reverse engineering" may be represented as follows (abbreviations as above; *Lw* stands for "reinterpretated" animals, for the respective constructions):

$$\begin{tikzcd}
\mathrm{Lw}^{K_n} & \dots & \mathrm{Lw}^{K_4} & \mathrm{Lw}^{K_3} & \mathrm{Lw}^{K_2} & \\
K_n(A_{K_{n-1}}) \arrow[u, Rightarrow] \arrow[r, Rightarrow, "RP"] & \dots \arrow[u, Rightarrow] & K_4\left(A_{K_3}/P_{K_5}\right) \arrow[u, Rightarrow] & K_3\left(A_{K_2}/P_{K_4}\right) \arrow[u, Rightarrow] \arrow[r, Rightarrow, "RP"] & K_2\left(A_{K_1}/P_{K_3}\right) \arrow[u, Rightarrow] \arrow[r, Rightarrow, "RP"] & K_1^E\left(P_{K_3}\right)
\end{tikzcd}$$

For purposes of reconstruction, each construction has to be regarded as a single, coherent functional unit. Consequently, we cannot reduce the reconstruction procedure to the transformation of some individual features or characters. To the contrary: only after the reconstruction is done can we identify the features that may serve as "characters" of evolutionary transformation. The methodology of an "evolutionary hermeneutics" (see Reif 2004; Gutmann 2002a) urges us to anticipate a comprehensive description of those organisms that serve as a source of knowledge on the functional constraints that we are confronted with when dealing with fossil or geological descriptions of ecological settings within which an extinct lifeworld has to be placed. By attempting to characterize human origins in terms of key characters which, once in place, serve to explain the transformation from animal to nonanimal constitution, we are confronted with the same methodological problems explicated above.

Human Characters, Characterizing Humans

When we treat humans as objects of anthropology and replace the term human by "*Homo* sp.," the grammatical structure of our designation implies that humans are animals of a certain kind. Following a common strategy of biological research, we identify the characteristics of those animals that are supposed to be human. By conceptualizing humans as animals we expect to locate their origin within the field of animal organization. We should thus be able to apply the tools which we frequently use to identify the origins of nonhumans. From a methodological point of view, anthropology then becomes a general ontology of being human. Because of human beings' ontological markedness – their exceptional status (in German "*Sonderstellung*"; see Scheler 1947; Plessner 1975) – within the realm of living entities, anthropology is usually accompanied by cosmological considerations. As the philosopher Ernst Cassirer observes, "in the first mythological explanations of the universe, we always find a primitive anthropology side by side with a primitive cosmology. The question of the origin of the world is inextricably interwoven with the question of the origin of man" (Cassirer 1972, p. 3). Both discourses, the anthropological and the cosmological alike, aim at the same question, namely, the problem of *origin*. Human nature is rooted within nature itself, i.e., among the variety of other, nonhuman beings or entities. It furnishes the genus *Homo* with specific and unique properties, abilities, etc. The embedding of human nature into nature as a whole is reflected by the underlying "substance ontology," because it provides the general framework within which all the different entities, constituted as substances, will find their respective places. Relevant aspects of human constitution are usually expressed in terms of defining characteristics such as "l'homme machine, Homo faber, Homo pecans et redivivus, Homo sapiens, Homo mechanicus, Homo sensitivus, Homo negans et patiens, Homo patheticus et divinans, Homo curans, Homo vitalis, Homo oeconomicus, Homo politicus, Homo libidinosus, super-Homo, Homo geometricus" (Scheler 1988, p. 22f; for some methodological criticism of the proposition that humans are cultural entities "by nature," see Weingarten 2001; for further reading see Gutmann 2002b, 2004).

According to this argument, we start with a comparison between animals and humans. A comparison constitutes a three-termed relation between the two things that are being compared and a reference criterion. In order to compare humans with animals, we thus need first to determine the criterion (or criteria) of identity: for example, that (some) animals and humans share, e.g., the same metabolism, or that the DNA sequences of humans may be (more or less) identical with those of (some) animals. However, if these criteria are met we do not then consider humans to be *identical* with animals, but merely deal with them as we deal with animals *in certain respects*. From this point of view we may succeed with the characterization of humans as animals by applying one of two alternative strategies, which we call the homology versus analogy approaches. On the first of these, human characteristics are directly derived from their precursors, and even supposedly defining human properties, such as culture, are understood to have counterparts among animals – a case of homology. Whereas on the second approach, when we assume human characteristics and features as being *like* those of animals, we are dealing with analogy.

Both strategies can be exemplified by empirical studies. We will restrict ourselves here to their respective methodological consequences. When homology is the concept applied, humans are just another type of organisms and, as such, character-bearing systems. Comparing organisms with each other allows us to trace the history of human-specific characters:

> Thus, scientific inquiry based on a homological line of reasoning always has ready justifications. Reconstructions of our phylogenetic past serve the understanding of our morphological design, as well as psychological and behavioral dispositions. Comparative analysis elucidates which features we share with other species and which combinations of traits are different, in particular with respect to ecologically similar species. Information like this can illuminate biological foundations (i.e., constraints and conditions, of human culture). (Weingart et al. 1997, p. 151)

Following this line of thinking, human nature becomes fundamental for culture: the capability to generate culture precedes the actualization of culture, and observed culture becomes a more or less direct expression of human nature's (biological) structures. Accordingly, the ability to create culture is conceptualized in terms of characters again, as we saw above, and thus must – by definition – be acquired due to evolutionary transformation. The same methods are applied as in the reconstruction of evolutionary transformation with respect to more "standard" characters (see section "The Problem of Characters"); culture is to be understood as the result of transformations of characters that constitute human nature itself. Culture then becomes the extended focus of evolutionary theory (with different cultures as tokens of a type expressing the capability for developing culture) and we have to consider the guiding difference between nature and culture as a result of natural transformation processes. In consequence we are urged to search for culture-invariant features which are shared by virtually all members of the species *Homo sapiens,* understood now in terms of natural kinds (for some problems concerning the "correct" determination of the genus, see e.g., Tattersall 1997 or Wolpoff and Caspari 1997; for further discussion see Griffiths 1997). Additionally, culture becomes a kind of evolutionary force or mechanism of a very peculiar kind (for a radical approach of this type see Dawkins 2009).

The inherent problems of such an attempt become apparent when we try to determine, for example, the fitness value of one of Beethoven's symphonies. Setting aside, for the sake of the argument, the empirical problems that accompany the homology approach (discussed by Lewontin 1961; Lewontin et al. 1984; Gould 1988), a wide array of methodological problems remains to be solved. The methodological shortcomings are closely linked to a confusion of different levels of descriptions: The *explanandum* of a homology approach is determined at the language level, without relevant biological implications. Thus we may in fact describe, e.g., the harmonic and structural development of a classical symphony without referring to any biological or evolutionary implications. With reference to evolutionary theory or population genetics, terms like "music" tend to be meaningless.

Alternatively, we might explicitly attempt to explain the *biological* role of music in terms of biological theory. In this case, not the music itself but rather its biological role provides the *explanandum*. However, in taking this track we reproduce the methodological shortcoming of our previous explanatory attempt (see, e.g., Eibl-Eibesfeldt 1997), as we now need to derive music from its biologically described forerunners, which implies the need to determine the fitness value of music per se. The dependence of the *explanandum* on our choice of description will probably undermine our biological analysis right from the start, because there are no biological criteria for, e.g., membership of a given composition in the canon of classical compository art.

A weaker assumption is provided by variants of the analogy approach, which stand in a certain contrast to the homology approach. On the analogy approach, humans are not understood *as* animals but *like* animals. As explicated in Gutmann et al. (2010), analogy approaches claim that the cultural unfolding of humans resembles, in certain limited aspects, the evolutionary process deemed to govern the development of animals. Due to this decisive methodological difference, the central problem of the homology approach is avoided: we do not have to claim that identical *mechanisms* are at work in cultural development, on the one hand, and evolutionary transformation, on the other. In the words of Weingart et al. (1997):

> The basic differences between changing cultures and changing biological populations preclude mere subsumption. It is commonly understood that new cultural practices can be produced in direct response to perceived needs, unlike the randomly generated novelty in evolutionary processes. It is sometimes supposed that this process makes sociocultural theories in terms of the Darwinian model impossible. (Weingart et al. 1997, p. 286)

However, this obvious advance – compared with the shortcomings of homology approaches – comes at a price: to the extent that cultural development can be understood as the result of unique and biologically irreducible processes, the original dualism between nature and culture re-emerges. The most radical exposition of this dualism is presented by Cassirer, who holds that there are indeed unbridgeable differences between nature, on the one hand – which follows a "Darwinian mode" of inheritance – and culture, on the other hand – which follows a "Lamarckian mode" of transformation (Cassirer 1993, p. 126). The key claim here that this difference is not a natural one – that is, not the kind that might be bridged by some version of a "cultural evolution" approach (see Chapter 17yy). It is a methodological difference, originating in two irreducible language games juxtaposed by "analogy" (e.g.: "Tradition is something like evolution"). The resulting "analogy" between the two processes is expressed in terms of a metaphorical description of some central aspects of the human world itself, i.e. without reference to presumed underlying biological concepts. Cassirer's use of a "metaphorical" description of culture – as if it were nature – provides the relevant clues for the solution of the underlying methodological problem (we will pursue these clues in the next section, where we will present a methodologically sound alternative).

The methodological problem consists in the indeterminacy of the concept of analogy, which is assumed to (non-reductively) connect culture to nature. From a formal point of view, an analogy has the structure of a comparison. Let A and B be two entities of different kinds, and let them both have property P. If we additionally know that A displays property Q, we may infer “per analogiam” that B displays the same property. The inference is adequate, however, if Q is implied by P; thus, the syllogism of analogy is either incomplete or non-conclusive. And if it is complete, it becomes just what an analogy was not supposed to be, namely an inference proper. (A good example for analogical reasoning, however misguided, is provided by the s.c. physico-theological proof for the existence of good; for further reading see Gutmann and Warnecke 2006.)

However, despite the indeterminacy problem, “analogies” are often applied as heuristic procedures, in order to structuralize an object in the light of some knowledge – or operational know-how – which was originally gained in a different field of research. Take for example the comparison of a neuron with a piece of electric circuitry, a comparison which leads to the image of an electric grid that is supposed to represent certain electric properties of signal transfer along an axon (s. Hodgkin and Huxley 1952). In this case, we may use the laws of electricity in order to structuralize *biotic* units (neurons) “as if they were” electrical units – that is, artifacts. In doing so we are not stating that neurons *are* artifacts or electric units, but only that some of the *biological* functions of the *biotic* units can be modeled in terms of electric circuitry. However, the explication of the metaphorical phrase “The neuron is some kind of electric circuitry” (which it very obviously is not) allows us to construct some experimental systems that finally lead to a useful *model* based on our approaching neurons as if they were an inanimate object of the relevant kind. The metaphor itself is lost (to a certain extent) and supplanted by the model (for further reading see Gutmann et al. 2010).

The limitation of an analogy then is of a methodological nature, as it remains in the logical grammar of “as if”-relations. This corresponds to the use of the term analogy in contexts where humans are considered to be like animals. If culture is the explanandum, which is to be explained on grounds of analogy, then the explanation will work only if we describe the process of cultural development in terms of reproductive relations. In this case the transformation of species becomes the explanans – *per analogiam* – for the development of culture(s), which might finally lead us to some “phylogeny of culture” (Boyd et al. 1997, p. 364). In order to explore the analogy, it is necessary to cast it in the terminology of species evolution, with reference to properties like “sexually reproducing,” “mutually reproductively isolated,” “highly integrated,” “genetically programmed,” or whatever characters we wished to use (see, e.g., Mayr 1997). But since we are only dealing with phylogeny in these explorations of “as if,” the explanatory power of the analogy remains within the general limits of “as if”-statements – unless we were willing to assume that humans are not just *like* animals but that they literally *are* animals. In the latter case, the analogy argument becomes indistinguishable from the homology approach and the presumed advance concerning the strength of the premises and implications is lost, giving way to the very familiar picture of a classic reductionist line of thinking (for further reading see Gutmann 2004, 2014).

Irrespective of differences in detail, both approaches lead to the same unsatisfactory conclusion, namely, that the treatment of culture on the basis of a character-oriented approach arises from a category mistake, indicated here by the confusion between two different language games. However, as we will now show, we may gain an alternative by defining culture not in terms of characters but as an expression of human activity.

Nature-Culture and Culture-Nature as Aspects of Human Work

As we saw, humans can be defined in terms of culture, which comprises all the differences we may identify in comparing humans with animals. However, we just demonstrated that culture itself cannot be treated as a character without running into logical and methodological difficulties. Mediation-oriented approaches provide an alternative, as both aspects – nature and culture – are there interpreted as the constituents of a relation, not as independently defined concepts. Cassirer's functionalist approach of symbolic forms exemplifies this argument, at least to a certain extent (see Gutmann 2004).

In stark contrast to character-oriented approaches, Cassirer focuses on inter-individual and intersubjective relations that constitute culture, as well as on the relations between culture(s) and (their respective) nature(s). For instance, he has this to say about 'truth':

> Truth is by nature the offspring of dialectic thought. It cannot be gained, therefore, except through a constant cooperation of the subjects in mutual interrogation and reply. It is not therefore like an empirical object; it must be understood as the outgrowth of a social act. Here we have the new, indirect answer to the question "What is man?" Man is declared to be that creature who is constantly in search of himself–a creature who in every moment of his existence must examine and scrutinize the conditions of his existence. In this scrutiny, in this critical attitude toward human life, consists the real value of human life. "A life which is unexamined", says Sokrates in his Apology, "is not worth living." (Cassirer 1972, p. 5f)

The "life worth living" here is understood as the expression of an ongoing process of self-reflection and self-constitution – a process which shapes the specifically human type of world-reference, being derived from the structure of mediated self-reference. The means, media, and patterns *by*, *through,* and *according to which* this mediation takes place, then, are the actual subject matter of reflection; they provide the "symbolic forms" that give shape to human–world relations. These symbolic forms – such as language, myth, art, knowledge – constitute, enable, and structure all human activities; and furthermore, they are the forces of development for these activities themselves. The transformation of human beings is not the result of random external forces but of the transformation of human beings' activities – forced and fuelled by the transformation of their respective (symbolic) forms. Due to the way this immanent process takes place, "external" relations are transformed together with their respective referent. Hence "nature" is not just "non-culture," but a reflection of the transformative effects of human activities, i.e. a reflection of human work. Again in Cassirer's words: "Man's outstanding characteristic, his distinguishing mark, is not his metaphysical or physical nature but his work. It is his work, it is the system of human activities, which defines and determines the circle of "humanity". Language, myth, religion, art, science, history are the constituents, the various sectors of this circle" (Cassirer 1972, p. 68).

Work is understood, on this view, as collective activity mediated by tools, which permanently generates and reproduces the difference between nature and culture. Reproduction in this sense does not refer to genetic reproduction but to the development and transformation of tools and the conditions of their use, *as part of their being used*. And it is work that provides us with the very starting point for "symbolic reconstruction" – that is, a reconstruction of mediated human activities which are not just the result of the organic activities of some specific life-form (namely humans, defined as members of *Homo sapiens*), but rather the result of the entire symbol systems, which gave these activities their respective form. Thus, the relations between the producers and the products, between the aims and purposes identified, the means and tools applied, and finally the relations between the individuals themselves using symbols – and transforming them by using them – are all to be taken into consideration. A markedly comprehensive definition of "humanity" will result from unfolding and exploring the immanent structure of these symbolic forms as well as their ongoing transformation. We are gaining a "generic" definition of "being a human being" *qua* "being human" (cf. Gutmann 2011 on the notion of "human life").

Based on a comprehensive conception of "human being" of this kind, even criteriological characterizations become conceivable, if they refer to conditions that are necessary in order not only to produce but to reproduce symbolic relations:

> Language, art, myth, religion are no isolated, random creations. They are held together by a common bond. But this bond is not a vinculum substantiale, as it was conceived and described in scholastic thought; it is rather a vinculum functionale. It is the basic function of speech, of myth, of art, of religion that we must seek far behind their innumerable shapes and utterances, and that in the last analysis we must attempt to trace back to a common origin. (Cassirer 1972, p. 68)

Setting aside the shortcomings of Cassirer's own concept of this origin (which ultimately leads to some Uexküllian-style functional circuit), the reference to human activities as the expression of the human life-form provides us with a non-reductivist understanding of "being human." The resulting double-barrelled process of analyzing the structure of mediated human activities and tracing back their origins represents a central issue in mediation-oriented approaches (see Gutmann 2004). We are now prepared to use the insights gained within such an approach toward a reconstructive understanding of human beings even in the context of paleoanthropological descriptions (for further reading see Gutmann et al. 2010).

Defining Humans by Their Activities: The Problem of the Methodological Starting Point

Reconstructions of the kind presented above are adequate tools for historical explanation. Such explanations presuppose a semantically rich description as a methodological starting point. The richness of this starting point (applied to human beings) contrasts with the thin semantics of scientific descriptions (applied to organisms generally) because the logical grammar of the human world differs fundamentally from the grammar of its physical or biological descriptions. Based upon the differentiation between the resulting two distinct modes of discourse, namely that of ordinary experience, on the one hand, and that of empirical sciences, on the other, Kambartel (1989) identified a fallacy of category. This fallacy comes into play when we assume a scientific foundation, or "substruction" (Husserl 1963), underlying ordinary experience itself. This substruction ultimately results in the assumption that ordinary language and experience is nothing else than a special case of scientific experiences, characterized by a relative lack of exactness and acuteness (see Gutmann and Rathgeber 2011). The semantic richness and thickness of ordinary language then would appear to be a sign of a conceptual shortcoming rather than an advantage. However, in offering scientific explanations – irrespective of their specifics – we are still explaining *something* in reference to some explicit knowledge, which latter constitutes the *explanans* in the explanatory schema. It is this necessary reference to *something* that is being explained which generates the categorical difficulties, because this *explanandum* (the "something" we are aiming at by applying our explanatory schema) has to be *described*. And it is the adequacy and validity of this description that has to be determinable without direct reference to the *explanans*. Consequently, the direct transition from a scientific context, e.g., a physically or chemically described situation, to a situation of perception or moral judgment – taking place in terms of ordinary experience, dealing with persons and interpersonal relations – is *grammatically* (not empirically) excluded (Kambartel 1989, p. 67). Accordingly, evolutionary reconstructions should be – methodologically – considered as *narratives* that refer a grammatically thinner description (the *explanans*) to a grammatically richer situation (the *explanandum*). The resulting shift from one language of description to another (each with its respective unique grammar) should not be confused with the transition from one state of nature to a second, more complex state of nature. Consequently, the narrative itself becomes methodologically indispensible: according to Kambartel (1989, p. 67) it is only through the creation of a historical narrative that we can relate to the origins of the new grammatical situation.

This grammatical differentiation permits a powerful rejection of reductionist scientific approaches, not only within the confines of evolutionary biology. Moreover, it provides a solution for our problem of scientifically dealing with humans as specimens of *H. sapiens* without reducing them to this description (for the model-theoretical background, see sections "From Remnants to Organisms" and "Human Characters, Characterizing Humans"). In order to do so, we must remind ourselves that we are facing a multitude of different language games and their respective language worlds. The gap between the human world (seen from the perspective of everyday life-world experience) and the world of animals (including humans), plants, physical and chemical objects (in terms of scientific descriptions) can be bridged by means of narrative explanations. Not surprisingly, the complexity of the descriptive language, and the "thickness" of the resulting description, will to some extent resemble the complexity of the described object itself. It makes sense, in light of this fact, that in recent paleoanthropological approaches we are increasingly often confronted with “scenario” techniques (for some methodological reconstructions see Gutmann et al. 2010). The main difference to “classic” approaches, the form of which we explicated above, consists in the – sometimes extreme – complexity of the *explanans*. However, even in the case of scenarios, the fundamental requirement regarding the validity of scientific statements (here, paleoanthropological reconstructions) remains the same as in the more simple case of reconstructive transformation sequences: the connection between the human world and nature must be drawn through narratives. Some intriguing dualisms results from this differentiation between nature and culture; inhabiting the world of persons, having intentions, giving and accepting reasons for one’s own and others’ actions, etc., become irreconcilably separated from the world which the scientific statements themselves refer to. Wilfrid Sellars put it thus:

> To think of a featherless biped as a person is to think of it as a being with which one is bound up in a network of rights and duties. From this point of view, the irreducibility of the personal is the irreducibility of the ‘ought’ to the ‘is’. But even more basic than this (. . .) is the fact that to think of a featherless biped as a person is to construe its behaviour in terms of actual or potential membership in an embracing group each member of which thinks of itself as a member of the group. Let us call such a group a ‘community’. (Sellars 1963, p. 39)

Following Sellars’ argument, a bridging of the gap between science and the everyday life-world seems to be possible, at least to a certain extent, through integration of the scientific image of man into the “manifest” image of ordinary (non-scientific) experience. In Sellar’s words:

> Thus the conceptual framework of person is not something that needs to be reconciled with the scientific image, but rather something to be joined to it. Thus, to complete the scientific image we need to enrich it not with more ways of saying what is the case, but with the language of community and individual intentions, so that by construing the actions we intend to do and the circumstances in which we intend to do them in scientific terms, we directly relate the world as conceived by scientific theory to our purposes, and make it our world and no longer an alien appendage to the world in which we do our living. (Sellars 1963, p. 40)

An alternative strategy, however, would be to cast the sciences themselves as a constitutive part of the human life-form, rendering the scientific perspective a very specific instance of the standardization of perspectives which are provided by ordinary life (e.g. Heidegger 1993; for further reading see Gutmann 2011).

Conclusion I: The Shortcoming of Criteriology in Paleoanthropology

We can avoid a dualism of this kind if we take into account Cassirer’s definition of human beings by referring to their respective mediated activities. This most comprehensive definition provides us with our methodological point of departure. Referring to human activities, we can even provide sound biological descriptions of aspects of these activities. Starting with physical activities, such as the specific human mode of upright walking, the specifics of human phonation and speech, etc., we are able to elaborate scientific descriptions that serve as the methodological points of departure for the reconstruction of possible antecedent human constitutions. As we pointed out before, the resulting reconstructions in terms of “possibly viable organisms” (in the sense of pre-human life-forms) take into account that we need the reference to further language games (and their underlying practices) for life-scientific purposes, namely all the discourse conventions of non-biological, technical, physical, and chemical knowledge and know-how that we used in order to achieve our functional descriptions of living entities (in the *as if*-mode). Accordingly, we can identify three asymmetries, which are often confounded when we do not distinguish between reference to humans *insofar as they are human* and to humans *as biological objects* (organisms):

1. Biological (genetic, physiological, morphological, etc.) descriptions of human beings (as if they were merely living entities) depend necessarily on non-biological knowledge and know-how; in contrast, physics or chemistry can exist without reference to biology.
2. Among other scientific points of reference, paleoanthropology refers to *biological* knowledge (particularly in terms of functional descriptions) of recent life-forms. However, functional biological knowledge can have validity without further reference to paleoanthropology.
3. Scientific descriptions of human beings refer necessarily to (self-)descriptions of human beings *as being human* (images of man-in-the-world, in Sellars’ terms). Their validity and adequacy can be claimed only in the context of non- and prescientific practice and communication. Sciences then are considered to be embedded into human culture–as a (specific and highly relevant) aspect of this culture.

In light of these observations, we can give deeper reasons for the shortcomings of a criteriological foundation of paleoanthropology. When we deal with (nonhuman) living entities as *biological* objects, we describe them in the light of our self-knowledge, thereby applying our technical and scientific knowledge and know-how in terms of organismic descriptions and structuralization. In the specific explanatory framework we have used here, they are described “as if they were” functional units. The relation between the authors (e.g., scientists) and the objects (nonhuman living entities) of description changes fundamentally when the authors themselves become the object of their description, because in the process they refer to themselves as a kind of object that differs from other objects by some specific criteria. In the field of concern to us here, biological or paleoanthropological descriptions of human beings need to be considered as descriptions of humans “as if they were just organisms” – such as animals (viewed as a type of organism). As the philosopher Edmund Husserl, born in 1859, observed on this double-barreled procedure of constitution (of norms, guiding the structuralization), on the one hand, and actual objectivation (via ascription and modeling) of human beings “as animals”, on the other:

> Among the problems of abnormality the problem of nonhuman animality and that of the levels of, higher and lower 'brutes are included. Relative to the brute' man is, constitutionally speaking, the normal case – just as I myself am the primal norm constitutionally for all other men. Brutes are essentially constituted for me as 'abnormal' variants of my humanness, even though *among* them in turn normality and abnormality may be differentiated. (Husserl 1960 (1931), p. 126)

If we overlook the inversion of the "as if"-relation, a (possible and possibly valid) criteriological description gains the methodological status of a statement on the essence of the human constitution. This indispensable asymmetry between a (thinner) scientific description and its (thicker) methodical starting point has implications that are most relevant as the preconditions of a scientific (here: paleoanthropological) foundation of ethics.

Conclusion II: The Criteriological Failure of Ethics

In criticizing criteriological approaches in ethics, we have reached a seemingly curious situation. On the one hand, the pitfalls of ethics can be recognized when we take into consideration the methodological problem, with which paleoanthropological research is confronted. Here, we identified the necessity of starting with a semantically very rich description of human beings, their activities, and the very form of those activities, if only to gain a methodological starting point for a semantically thinner description of humans as biological entities – named *Homo sapiens*. This, however, leads to the difficulties we identified of characterizing the transformation of a nonhuman into a human constitution as a transformation from nature to culture which remains nevertheless embedded into nature. Thus, the anticipation of the semantics of humanity is obscured by its translation into a biological language of characters. On the other hand – and this is the second part of the aforementioned curious situation – the *normative* deficiency of paleoanthropology becomes observable by explicating the semantics of a description of humans *as being human* and their activities in order to provide some basis for ethical reasoning itself. Even by articulating a simple description of human beings as members of *Homo sapiens*, we claim at least its adequacy – and this claim cannot be replaced by an alternative description. So, even if we considered scientific theories to represent states of the world, at least the evaluation of the adequacy of these representations cannot be given in a purely descriptive language again. This dilemma has its very origin in the structure of criteriological characterizations of human beings, in both the field of paleoanthropology as well as that of ethical reasoning.
