Abstract. Motivated by applications to secure multiparty computation, we study the complexity of realizing universally composable (UC) commitments. Several recent works obtain practical UC commitment protocols in the common reference string (CRS) model under the DDH assumption. These protocols have two main disadvantages. First, even when applied to long messages, they can only achieve a small constant rate (namely, the communication complexity is larger than the length of the message by a large constant factor). Second, they require computationally expensive public-key operations for each block of each message being committed.

Our main positive result is a UC commitment protocol that simultaneously avoids both of these limitations. It achieves an optimal rate of 1 (strictly speaking, $1 - o(1)$) by making only few calls to an ideal oblivious transfer (OT) oracle and additionally making a black-box use of a (computationally inexpensive) PRG. By plugging in known efficient protocols for UC-secure OT, we get rate-1, computationally efficient UC commitment protocols under a variety of setup assumptions (including the CRS model) and under a variety of standard cryptographic assumptions (including DDH). We are not aware of any previous UC commitment protocols that achieve an optimal asymptotic rate.

A corollary of our technique is a rate-1 construction for *UC commitment length extension*, that is, a UC commitment protocol for a long message using a single ideal commitment for a short message. The extension protocol additionally requires the use of a semi-honest (stand-alone) OT protocol. This raises a natural question: can we achieve UC commitment length extension while using only inexpensive PRG operations as is the case for stand-alone commitments and UC OT? We answer this question in the negative, showing that the existence of a semi-honest OT protocol is necessary (and sufficient) for UC commitment length extension. This shows, quite surprisingly, that UC commitments are qualitatively different from both stand-alone commitments and UC OT.

Keywords: Universal composability, UC commitments, oblivious transfer.

1 Introduction

A *commitment scheme* is a digital analogue of a locked box. It enables one party, called the *committer*, to transfer a value to another party, called the *receiver*, while keeping it hidden, and later reveal it while guaranteeing to the receiver its originality. Commitment schemes are a fundamental building block for cryptographic protocols withstanding active adversarial attacks. As such, efficient implementations of the latter—particularly in realistic complex environments where they are to execute—crucially hinge on them. Such complex environments are today epitomized by the universal composability (UC) framework [6], which allows for a protocol to run concurrently and asynchronously with arbitrarily many others, while guaranteeing its security.

The first constructions of UC commitments were given by Canetti *et al.* [7,8] as a feasibility result. (It was also shown in [7] that it is impossible to construct UC commitments in the plain model, and that some setup such as a *common reference string* (CRS) is required.) Since then, and motivated by the above, a series of improvements (e.g., [14,13,28,19,33,4,1,25]) culminated in constructions achieving under various cryptographic assumptions *constant* communication rate and practical computational complexity, making it possible to commit to, say, L group elements by sending $O(L)$ group elements and performing $O(L)$ public-key operations (e.g., exponentiations).

Shortcomings—as well as ample room for improvement, however, remain, as the constant rate currently achieved is small and the computational cost per committed bit is high. This is the case even when committing to long messages and even when ignoring the cost of offline interaction that does not depend on the committed message. More concretely, the communication complexity is bigger than the length of the message by a large constant factor, and the online computation includes a large number of computationally expensive public-key operations for each block of the message being committed.¹ This is not satisfactory when considering concrete applications where UC commitments are used, such as UC secure computation and UC zero-knowledge. (See [4,28,1] for additional motivation on these applications.)

Our Results. We obtain both positive and negative results on the complexity of UC commitments. Our main positive result is a UC commitment protocol which simultaneously overcomes both of these limitations. Specifically, it achieves an *optimal rate* of 1 (strictly speaking, $1 - o(1)$) by making only few calls to an ideal oblivious transfer (OT) oracle and additionally making a black-box use

¹ Recent constructions [28,4] that work over standard DDH groups require at least 10 group elements and at least 20 public key operations per commitment instance. A very recent work by [25] (improving over [16]) requires 5 group elements in a bilinear group (assuming SXDH).

of a (computationally inexpensive) PRG. By plugging in known efficient protocols for UC-secure OT (e.g., [34]), we get rate-1, computationally efficient UC commitment protocols under a variety of setup assumptions (including the CRS model) and under a variety of standard cryptographic assumptions (including DDH). We are not aware of any previous UC commitment protocols which achieve an optimal asymptotic rate.

Our main idea is to use a simple code-based generalization of the standard construction of commitment from δ -Rabin-string-OTs [11,26,24,18]. The key observation is that the use of a rate-1 encoding scheme with a judicious choice of parameters yields a rate-1 construction of UC commitments.

Next, we show how to further reduce the computational complexity of the basic construction by using OT extension [2,23,24]. Our improvement ideally suits the setting where we need to perform a large number of commitments in a single parallel commit phase (with potentially several reveal phases), as with applications involving cut-and-choose. In particular, we show that the number of calls to the OT oracle can be made independent of the number of instances of UC commitments required. (Note that such a result does not follow from multiple applications of the basic construction.) We stress that when handling a large number of commitment instances (say, in garbled circuit applications of cut-and-choose), the number of public key operations plays a significant role (perhaps more than the communication) in determining efficiency. While current state-of-the-art UC commitment protocols [28,4] suffer from the need to many computationally expensive public-key operations, our result above enables us to obtain better computational as well as overall efficiency.

Lastly, another corollary of our technique is a rate-1 construction for *UC commitment length extension*, that is, a UC commitment protocol for a long message using a single ideal commitment for a short message. The extension protocol additionally requires the use of a semi-honest (stand-alone) OT protocol. This raises a natural question of whether we can achieve UC commitment length extension while using only inexpensive PRG operations as is the case for stand-alone commitments and UC OT. We answer this question in the negative, showing that the existence of a semi-honest OT protocol is necessary (and sufficient) for UC commitment length extension. This shows that UC commitments are qualitatively different from both stand-alone commitments and UC OT, which can be extended using any PRG [2], and are similar to adaptively-secure OT whose extension requires the existence of (non-adaptively secure) oblivious transfer [29].

We note that our constructions are only secure against a static (non-adaptive) adversary; we leave the extension to adaptive security for future work.

Related Work. We already mentioned above the series of results leading to constant-rate UC-commitments. Here we give a brief overview. Canetti *et al.* [7,8] were the first to construct (inefficient) UC commitments in the CRS model from general assumptions, and also achieve adaptive security. Shortly thereafter, Damgård and Nielsen [14] presented UC commitments with $O(1)$ exponentiations for committing to a single group element. Their construction is based on

N -residuosity and p -subgroup assumptions, and is also adaptively secure (without erasures), but requires a CRS that grows linearly with the number of parties. A construction of Damgård and Groth [13], also adaptively secure without erasures and based on the strong RSA assumption, requires a fixed-length CRS.

An important improvement in concrete efficiency was presented recently by Lindell [28]; this is achieved for static corruptions based on the DDH assumption in the CRS model. Blazy *et al.* [4] build on Lindell’s scheme to achieve adaptive security (assuming erasures); they also obtain improvements in concrete efficiency. Fischlin *et al.* [16] also build on Lindell’s scheme and present a non-interactive scheme using Groth-Sahai proofs [21]. Furthermore, they also provide an adaptively secure variant (with erasures) based on the DLIN assumption on symmetric bilinear groups. As mentioned above, none of these works achieve rate 1. We provide a concrete analysis of our protocol, with a comparison to [28,4] in Section 3.3.

A code-based construction of UC commitments from OT was recently used by Frederiksen *et al.* [18] as part of an efficient protocol for secure two-party computation. While this construction uses a similar high level technique as our basic construction, its suggested instantiation in [18] only achieves a small constant rate.

Our work also considers the extension of UC commitments. We mainly focus on the goal of *length extension*, namely using an ideal commitment to a short string for implementing a UC commitment to a long string. For standalone commitments, such a length extension is easy to implement using any PRG. This is done similarly to the standard use of a PRG for implementing a hybrid encryption scheme. It was previously shown by Kraschewski[27] that this simple extension technique does not apply to UC commitments. We strengthen this negative result to show that *any* extension protocol for UC commitments implies oblivious transfer. Similar negative results for adaptively secure OT extension were obtained by Lindell and Zarusim [29]. and for reductions between finite functionalities by Maji *et al.* [30]. Negative results for statistical UC coin-tossing extension were obtained by Hofheinz *et al.* [22].

In an independent work [12], Damgård *et al.* also construct UC commitments using OT, PRG and secret sharing as the main ingredients. While the basic approach is closely related to ours, the concrete constructions are somewhat different, leading to incomparable results. In particular, a major goal in [12] is to optimize the asymptotic computational complexity as a function of the security parameter, achieving in one variant constant (amortized) computation overhead for the verifier. Moreover, they achieve both additive and multiplicative properties for UC commitments, which are not considered in our work.

Organization of the Paper. The rest of the paper is organized as follows. Model, definitions and basic functionalities are presented in Section 2. Our main construction—rate-1 UC commitment from OT—is presented in Section 3, together with the case of multiple commitment instances and a concrete efficiency analysis. Finally, the treatment of UC commitment extension—rate-1 construction and necessity of OT—is presented in Section 4. Due to space limitations,

only proof sketches are presented in the main body; full proofs as well as complementary material are deferred to the full version.

2 Model and Definitions

In this section we introduce some notation and definitions that will be used throughout the paper. We denote the computational security parameter by κ , and the statistical security parameter by σ . A function μ is negligible if for every polynomial p there exists an integer N such that for every $n > N$ it holds that $\mu(n) < 1/p(n)$.

In this paper we will be concerned with efficient universally composable (UC) [6] realizations of functionalities such as commitments. Assuming already some familiarity with the framework, we note that it is possible to consider variants of the definition of UC security in which the order of quantifiers is “ $\forall \mathcal{A} \exists \mathcal{S} \forall \mathcal{Z}$ ”. Contrast this with our definition (and also the definition in [28]) in which the order of quantifiers is “ $\exists \mathcal{S} \forall \mathcal{Z} \forall \mathcal{A}$ ”. Both definitions are equivalent as long as \mathcal{S} , in the former definition makes only a blackbox use of \mathcal{A} [6]. Indeed, this will be the case in our constructions. Therefore, as in [28], we demonstrate a single simulator \mathcal{S} that works for all adversaries and environments, and makes only a blackbox use of the adversary. (In this case, one may also denote the ideal process by $\text{IDEAL}_{\mathcal{F}, \mathcal{S}^{\mathcal{A}}, \mathcal{Z}}$.)

We will sometimes explicitly describe the functionalities we realize. For instance, if a functionality \mathcal{F} accepts inputs only of a certain length ℓ , then we will use the notation $\mathcal{F}[\ell]$ to denote this functionality. We let $\text{cc}(\mathcal{F})$ denote the communication cost, measured in bits, of realizing \mathcal{F} in the *plain model*.

The multi-commitment ideal functionality $\mathcal{F}_{\text{MCOM}}$, which is the functionality that we UC realize in this work, is given in Figure 1. As mentioned above, $\mathcal{F}_{\text{MCOM}}[\ell]$ will explicitly denote that the functionality accepts inputs of length exactly ℓ . We will be giving our constructions in the OT-hybrid model.

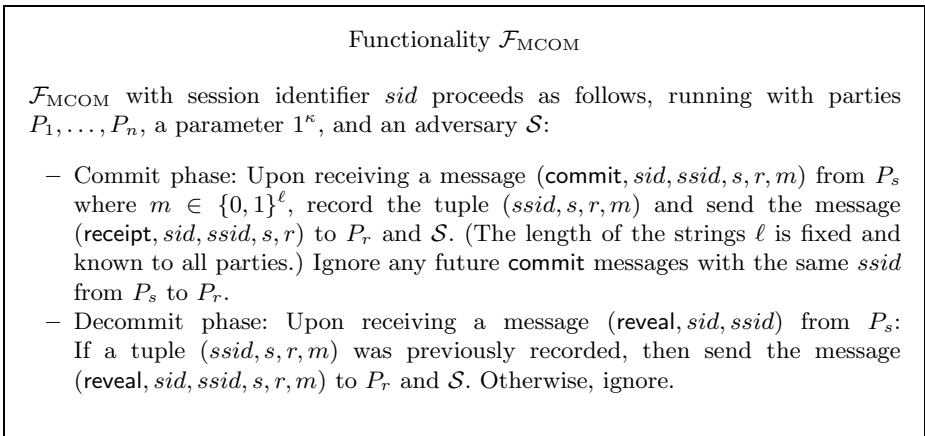

Fig. 1. Functionality $\mathcal{F}_{\text{MCOM}}$ for multiple commitments

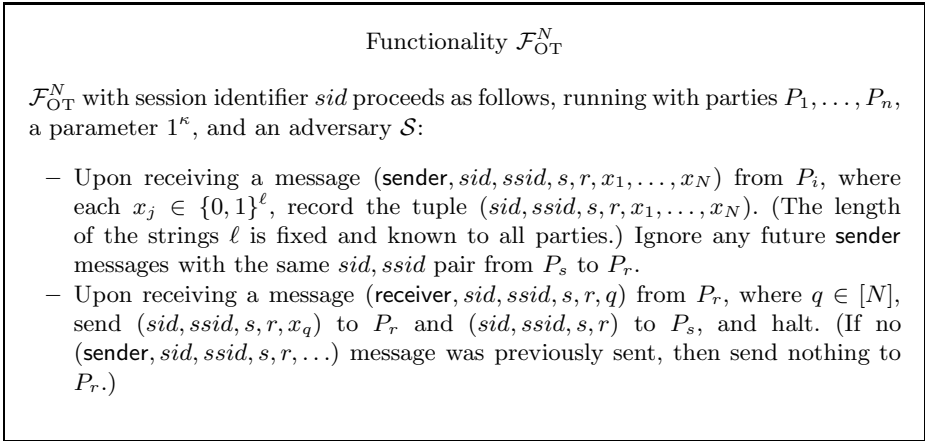

Fig. 2. Functionality $\mathcal{F}_{\text{OT}}^N$ for 1-out-of- N oblivious transfer. We omit superscript N when $N = 2$.

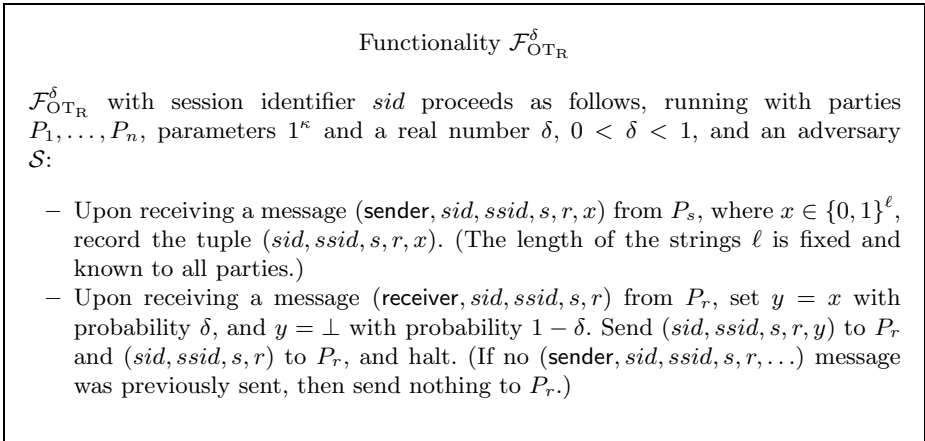

Fig. 3. Functionality $\mathcal{F}_{\text{OTR}}^\delta$ for Rabin-OT with noise rate δ

The oblivious transfer functionality $\mathcal{F}_{\text{OT}}^N$, capturing 1-out-of- N OT for $N \in \mathbb{Z}$, is described in Figure 2. When $N = 2$, this is the standard 1-out-of-2 string-OT functionality, denoted by \mathcal{F}_{OT} . The δ -Rabin-string-OT functionality, denoted $\mathcal{F}_{\text{OTR}}^\delta$, is described in Figure 3.

3 Rate-1 UC Commitments from OT

A recent line of work has focused on the practical efficiency of UC commitment in the CRS model [28,4,1,19,33]. In these works, a κ -bit string commitment is

implemented by sending $O(1)$ group elements and computing $O(1)$ exponentiations in a DDH group of size $2^{O(\kappa)}$. We start this section by presenting a κ -bit UC-secure string commitment protocol in the \mathcal{F}_{OT} -hybrid model where the total communication complexity of each phase (including communication with the OT oracle) is $\kappa(1 + o(1))$. The above implies that if OT exists (in the plain model), then there is a UC-secure protocol for an N -bit string commitment in the CRS model which uses only $N + o(N)$ bits of communication.

Thus, our construction improves over previous protocols which achieve constant rate, but not rate 1. Using, for example, the DDH-based OT protocol of [34], we can get a rate-1 UC-commitment protocol in the CRS model which is quite efficient in practice; alternatively, if we wish to obtain a construction in the single global CRS model, we may instead start with the OT protocols given in [10,1]. We then address the setting where multiple UC commitments need to be realized, showing again a rate-1 construction where, in particular, the number of calls to the OT oracle is independent of the number of UC commitments required. We conclude the section with concrete efficiency analysis of our constructions.

On the “Optimality” of Our Construction. We note that our construction achieves essentially “optimal” rate. In any statistically binding commitment scheme as with our construction, the commit phase communication must be at least the message size. Moreover, any static UC secure commitment scheme must be equivocable, since the simulator for an honest sender does not know the message during the commit phase, and yet must be able to provide openings to any message. Therefore the communication in the decommit phase must be at least the message size, via an argument similar to the lower bound on secret key size in non-committing encryption [32].

3.1 Main Construction

Our idea is to use a simple code-based generalization of the standard construction of commitment from δ -Rabin-string-OTs [11,26,24,18]. Our key observation is that the use of a rate-1 encoding scheme with a judicious choice of parameters yields a rate-1 construction of UC commitments. We start off with the following reduction.

Rate-1 Rabin-OT from OT. We first show an efficient realization of Rabin-OT for a given $\delta \in (0, 1)$, denoted $\mathcal{F}_{\text{OT}_R}^\delta$, in the \mathcal{F}_{OT} -hybrid model, making black-box use of a PRG.

Lemma 1 (Rabin-OT from OT [5,11,26,24]). *Let $G : \{0, 1\}^{\kappa_{\text{prg}}} \rightarrow \{0, 1\}^\ell$ be a secure PRG, and let $\delta \in (0, 1)$ such that $1/\delta$ is an integer. Then, there exists a protocol which UC-realizes a single instance of $\mathcal{F}_{\text{OT}_R}^\delta[\ell]$ in the $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$ -hybrid model such that:*

- *The protocol has total communication complexity at most $\ell + (1/\delta) + 3\kappa_{\text{prg}} \cdot 1/\delta$ bits, including communication with $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$.*

- The protocol makes at most $1/\delta$ calls to the $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$ functionality and requires each party to make a single invocation of G .

The protocol works by implementing $\mathcal{F}_{\text{OT}_R}^\delta[\ell]$ in the $\mathcal{F}_{\text{OT}}^N[\ell]$ -hybrid model for $N = 1/\delta$. Then $\mathcal{F}_{\text{OT}}^N[\ell]$ is realized in the $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$ -hybrid model.

Rate-1 UC-Commitments from Rabin-OT. The construction is presented in the following lemma. Further construction and proof details can be found in the full version.

Encoding scheme Enc

Parameters: n', d, n such that $n' > d > n$.
Input: $m \in \{0, 1\}^\ell$ for any $\ell > n \log(n + n')$.

- Parse $m \in \{0, 1\}^\ell$ as $(m_1, \dots, m_n) \in \mathbb{F}^n$ where \mathbb{F} is such that $\log |\mathbb{F}| = \ell/n$.
- Let e_1, \dots, e_n and $\alpha_1, \dots, \alpha_{n'}$ be $(n + n')$ distinct elements in \mathbb{F} .
- Pick random polynomial p of degree d such that $m_i = p(e_i)$ for all $i \in [n]$.
- Output encoding $m' = (p(\alpha_1), \dots, p(\alpha_{n'})) \in \mathbb{F}^{n'}$.

Fig. 4. A rate-1 encoding scheme based on the multi-secret sharing scheme of [17]

Lemma 2. *Let σ be a statistical security parameter, and let n be such that there exists $\epsilon \in (0, 1/2)$ satisfying $n^{1-2\epsilon} = \sigma^{\Omega(1)}$. Then, for $\delta = (2n^\epsilon + 4)^{-1}$, and any $\ell > n \log(2n + 2n^{1-\epsilon})$, there exists a protocol that statistically UC realizes a single instance of $\mathcal{F}_{\text{MCOM}}[\ell]$ in the $\mathcal{F}_{\text{OT}_R}^\delta[\ell/n]$ -hybrid model in the presence of static adversaries such that:*

- The protocol has communication complexity $\ell(1 + 2n^{-\epsilon})$ bits in each phase, including communication with $\mathcal{F}_{\text{OT}_R}^\delta[\ell/n]$.
- The protocol makes $n(1 + 2n^{-\epsilon})$ calls to the $\mathcal{F}_{\text{OT}_R}^\delta[\ell/n]$ functionality.

Proof. The protocol uses the randomized encoding scheme Enc described in Figure 4 with parameters n as in the Lemma, and $n' = n + 2n^{1-\epsilon}$ and $d = n + n^{1-\epsilon} - 1$. Note that $\delta = (d + 1 - n)/2n'$. Scheme Enc takes as input $m \in \{0, 1\}^\ell$ and parses them as n elements from a field \mathbb{F} and satisfies the following properties:

- it has rate $1 + 2n^{-\epsilon}$;
- any $(d + 1 - n)/n' = 2\delta$ fraction of the symbols reveal no information about the encoded message²;
- any encodings of two distinct messages differ in $\Delta \stackrel{\text{def}}{=} n' - d$ positions (and we can efficiently correct $\Delta/2$ errors);

² We actually require a slightly stronger property to achieve equivocation, namely, that we can efficiently extend a random partial assignment to less than 2δ fraction of the symbols to an encoding of any message.

The construction realizing $\mathcal{F}_{\text{MCOM}}[\ell]$ in the $\mathcal{F}_{\text{OTR}}^\delta[\ell/n]$ -hybrid model is described in Figure 5. We first analyze the protocol’s complexity:

Communication. In the commit phase, the sender transmits the encoding, i.e., $n(1 + 2n^{-\epsilon})$ symbols of \mathbb{F} via $\mathcal{F}_{\text{OTR}}^\delta[\ell/n]$. Since $\log |\mathbb{F}| = \ell/n$, the communication complexity is $(n + 2n^{1-\epsilon}) \cdot \ell/n = \ell(1 + 2n^{-\epsilon})$ bits. In the reveal phase, the sender sends the encoding in the clear. It follows from the calculations above that the communication complexity of this phase is also $\ell(1 + 2n^{-\epsilon})$ bits.

Computation. In the commit phase, the sender makes $n(1 + 2n^{-\epsilon})$ calls to $\mathcal{F}_{\text{OTR}}^\delta[\ell/n]$.

We now turn to the proof of security. Note that $\delta = O(n^{-\epsilon})$ while $\Delta = O(n^{1-\epsilon})$. Simulating when no party is corrupted or both parties are corrupted is straightforward. We briefly sketch how we simulate a corrupted sender and a corrupted receiver:

Corrupt Sender. Here the simulator extracts the committed value by looking at the corrupted codeword \mathbf{c} that P_s sends to the ideal OT functionality and compute the unique codeword \mathbf{c}^* that differs from \mathbf{c} in at most $\Delta/2$ positions. In addition, the simulator reveals each symbol of \mathbf{c} to the honest receiver with probability δ . If \mathbf{c} and \mathbf{c}^* agree on all the positions that are revealed, then the committed value is the message corresponding to \mathbf{c}^* ; else the committed value is \perp .

Next, suppose P_s sends a codeword \mathbf{c}' in the reveal phase. We consider two cases:

- if \mathbf{c}' and \mathbf{c} differ in at most $\Delta/2$ positions, then $\mathbf{c} = \mathbf{c}^*$ and the simulator extracted the correct value;
- otherwise, the honest receiver accepts with probability at most $(1 - \delta)^{\Delta/2}$, which is negligible in σ .

Corrupt Receiver. In the commit phase, the simulator acts as the ideal OT functionality and for each symbol of the encoding, decides with probability δ whether to send (and, thereby fix) a random element of \mathbb{F} as that symbol to the receiver.

Next, the simulator receives the actual message m in the reveal phase. We consider two cases:

- As long as less than a 2δ fraction of the symbols are transmitted in the simulated commit phase above, the simulator can efficiently extend a random partial assignment implied by the transmitted symbols to the encoding of m ;
- otherwise, the simulation of the reveal phase fails with probability at most $e^{-n'\delta/3}$, which is negligible in σ .

Putting things together:

Theorem 1 (Rate-1 UC commitments from OT). *Let κ be a computational security parameter, and let $\alpha \in (0, 1/2)$. Then, there is a protocol which UC-realizes a single instance of $\mathcal{F}_{\text{MCOM}}[\kappa]$ using κ^α calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ and a black-box use of a PRG, where the total communication complexity of each phase (including communication with \mathcal{F}_{OT}) is $\kappa(1 + o(1))$.*

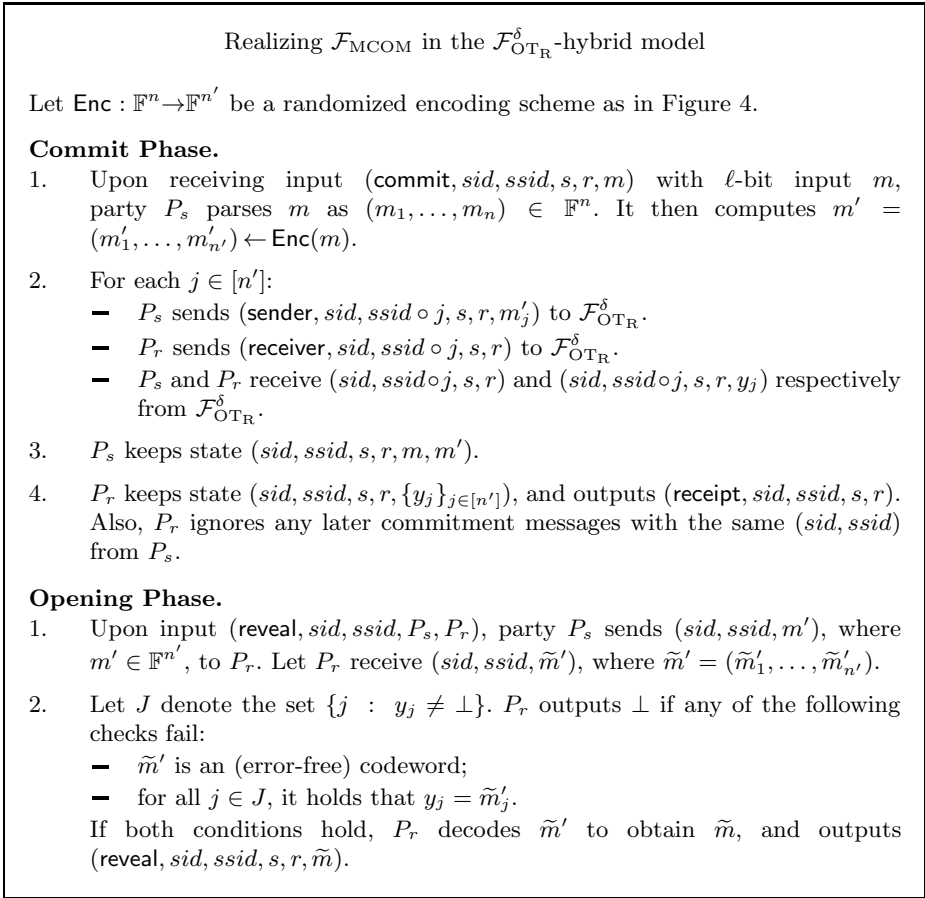

Fig. 5. A statistically UC-secure protocol for $\mathcal{F}_{\text{MCOM}}$ in the $\mathcal{F}_{\text{OTR}}^\delta$ -hybrid model

Proof. We set $\ell = \kappa$ and $\sigma = \kappa$. Then we pick $n, \epsilon \in (0, 1/2)$ such that $n^{1+\epsilon} = \kappa^\alpha/10$. Note that $\sigma, n, \epsilon, \ell$ satisfy conditions of Lemma 2. Further, setting $\kappa_{\text{prg}} = \kappa^\alpha$, also ensures that $O(\kappa_{\text{prg}} n^{1+\epsilon}) = o(\kappa)$. The security proof readily follows from composing the protocols given in the Lemmas 1 and 2. We just need to analyze the complexity of the resulting protocol.

Communication. By Lemma 1, to implement $n + 2n^{1-\epsilon}$ calls to $\mathcal{F}_{\text{OTR}}^\delta[\kappa/n]$, we need to communicate $(n + 2n^{1-\epsilon})((\kappa/n) + O(\kappa_{\text{prg}} n^\epsilon)) = \kappa + 2\kappa n^{1-\epsilon} + O(\kappa_{\text{prg}} n^{1+\epsilon})$ bits in the $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$ -hybrid model. For $n, \epsilon, \kappa_{\text{prg}}$ as set above, it follows that the communication cost of this phase is $\kappa(1 + o(1))$ bits in each phase. *Computation.*

By Lemma 1, to implement the required $n + 2n^{1-\epsilon}$ calls to $\mathcal{F}_{\text{OTR}}^\delta[\kappa/n]$, we need to make blackbox use of PRG, and additionally $(n + 2n^{1-\epsilon}) \cdot (1/\delta) = 2n^{1+\epsilon} + 8n$, i.e., at most κ^α calls to the $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ functionality.

3.2 Multiple Commitment Instances

Next, we show how to further reduce the computational complexity of the previous construction by using OT extension [2,23,24]. Our improvement here extends to the setting where we need to perform a large number of commitments in a single parallel commit phase (with potentially many reveal phases), as with applications involving cut-and-choose. In particular, we show that the number of calls to $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$ can be made independent of the number of instances of UC commitments required. (Note that such a result does not follow from multiple applications of the protocol implied by Theorem 1.)

Theorem 2. *Let κ be a computational security parameter, and let $\alpha \in (0, 1/2)$. For all $c > 0$, there exists a protocol which UC-realizes κ^c instances of $\mathcal{F}_{\text{MCOM}}[\kappa]$ with rate $1+o(1)$ that makes κ^α calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ and a blackbox use of correlation robust hash functions (alternatively, random oracle, or non-blackbox use of one-way functions).*

Proof. We repeat the protocol of Theorem 1 κ^c times to construct κ^c instances of $\mathcal{F}_{\text{MCOM}}[\kappa]$ using $\kappa^{c+\alpha}$ calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$. By Theorem 1, the communication cost of this construction is $\kappa^c(1 + o(1))$. We note that for each instance of this protocol, the commit phase has $o(\kappa)$ communication in addition to the cost involved in communicating with $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$.

We then implement the required $\kappa^{c+\alpha}$ calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ using the constant rate UC-secure OT extension protocol of [24] which makes blackbox use of correlation robust hash functions (alternatively, random oracle, or non-blackbox use of one-way functions). This implementation requires κ^α calls to the $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ functionality, and has communication complexity $O(\kappa^{c+2\alpha}) = o(\kappa^{c+1})$ bits for $\alpha \in (0, 1/2)$. Therefore, the total communication complexity of this protocol in each phase (including communication with the $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ functionality) is $\kappa^c(1 + o(1))$ for $c > 1$.

3.3 Concrete Efficiency Analysis

In this section, we provide an analysis of the concrete efficiency of our protocol, specifically requiring that the statistical security loss be $< 2^{-\sigma}$ for statistical security parameter σ , and the seedlength for PRG be 128. This reflects the state-of-the-art choices for similar parameters in implementations of secure computation protocols. In addition to the communication complexity, we will also be interested in the number of public key operations. (In practice, public-key operations (e.g., modular exponentiation) are (at least) 3-4 orders of magnitude slower than symmetric-key operations (e.g., AES).)

In the concrete instantiation of our UC commitment protocol in the CRS model, we will use (1) the protocol of Nielsen *et al.* [31] for OT extension in the RO model since it has better concrete security (cost $\approx 6 \cdot 128$ bits for each instance of 128-bit OT excluding the “seed” OTs) than the protocol of [24]), and (2) the protocol of Peikert *et al.* [34] to realize “seed” OTs in the CRS model (with concrete cost per OT instance equal to 5 modular exponentiations and 6 elements

in a DDH group of size 256). Note that for realizing 128 instances of $\mathcal{F}_{\text{OT}}[128]$, the cost is $6 \cdot 128 \cdot 256 = 196608$ bits and the number of modular exponentiations is $5 \cdot 128 = 640$.³ We stress that this cost is independent of parameters ℓ, σ , and number of commitment instances. In the following we summarize the cost of our construction for some parameters. Our costs are calculated by choosing concrete parameters for the encoding scheme **Enc** used in Lemma 2, and then apply the transformation of Lemma 1, and finally realizing \mathcal{F}_{OT} using state-of-the-art protocols as discussed above.

For long strings, say of length $\ell = 2^{30}$, and for $\sigma = 30$, we can get concrete rate as low as 1.046^{-1} in each phase. However, the choice of parameters necessitate working over a field \mathbb{F} with $\log |\mathbb{F}| = 2^{19}$. If we work over relatively smaller fields \mathbb{F} with say $\log |\mathbb{F}| = 512$, then the rate of the encoding can be made 1.19^{-1} (resp. 2.01^{-1}), but the cost of realizing OTs (including OT extension) makes the total rate of the commit phase $\approx 9.58^{-1}$ (resp. 5.55^{-1}). Note, however, that there are standard techniques to reduce the communication cost of realizing OTs in our setting. For instance, by replacing Rabin-OT with d -out-of- n' OT (for d, n' as in Figure 4), we may then use standard OT length extension techniques. This however has the drawback that RS encodings need to be performed over large fields, and further the number of public-key operations increases with the number of commitment instances.

Consider the following alternative approach that ports our construction to work with smaller fields, and yet get concrete rate close to 1. First, the sender parse the message m as a matrix where each element of the matrix is now from the field of desired size. Next, the sender performs a row-wise encoding (using **Enc**) of this matrix, and sends each column of the encoded matrix via $\mathcal{F}_{\text{OTR}}^\delta$. Later in the reveal phase, the sender simply transmits the encoded matrix. As noted earlier, the above approach lets us work over small fields, and the concrete rate would be as good as the concrete rate for encoding each row.

Next, we discuss the cost of our basic construction when committing to short strings. For short strings, say of length $\ell = 512$ (resp. 256) and $\sigma = 20$, while the rate of our reveal phase can be as low as 4.6^{-1} (resp. 8.12^{-1}), the rate of our commit phase can be very high ($\approx 1000^{-1}$). While we concede that this is not very impressive in terms of communication cost, we wish to stress that our constructions do offer a significant computational advantage over the protocols of [28,4] since we perform only a fixed number of public key operations independent of the number of commitment instances. In Appendix A, we propose efficient constructions to handle commitments over short strings in settings where a large number of such short commitments are used, e.g., in cut-and-choose techniques.

Efficiency in the preprocessing model. Our protocols can be efficiently adapted to the preprocessing model [3,31], and further, the online phase of our protocol can

³ The protocol of [34] requires CRS of size m for m parties (cf. [10]). However, since CRS is a one-time setup, this does not affect our (amortized) communication cost. Alternatively, we could use the DDH based construction of [10] which uses a constant sized (6 group elements) global CRS for all parties and will only mildly increase (by a multiplicative factor ≈ 6) the cost of realizing the “seed” OTs).

be made free of cryptographic operations. First, note that any UC commitment protocol can be preprocessed, for example by committing to a random string in the offline model, and sending the real input masked with this random string in the online commit phase. Therefore, the online rate of the *commit* phase of the protocol in the preprocessing model can always be made 1. Next, the online rate in the *reveal* phase of our protocol is exactly the rate of the underlying encoding. Note that in the online reveal phase, we only need the receiver to check the validity of the encoding.

4 UC Commitment Extension

As a corollary of our technique above, we start this section by showing a rate-1 construction for *UC commitment length extension*, that is, a UC commitment protocol for a long message using a single ideal commitment for a short message. The extension protocol additionally requires the use of a semi-honest (stand-alone) OT protocol. We then show that the existence of a semi-honest OT protocol is necessary for UC commitment length extension.

4.1 Rate-1 UC Commitment Length Extension

In this setting, we want a secure realization of a single instance of UC commitment on a ℓ -bit string, for $\ell = \text{poly}(\kappa)$, while allowing the parties to access ideal functionality $\mathcal{F}_{\text{MCOM}}[\kappa]$ exactly once. We show that UC commitment length extension can be realized with rate $1 - o(1)$.

Theorem 3 (Rate-1 UC commitment length extension). *Let κ be a computational security parameter, and assume the existence of semi-honest stand-alone oblivious transfer. Then, for all $c > 0$, there exists a protocol which UC-realizes a single instance of $\mathcal{F}_{\text{MCOM}}[\kappa^c]$ with rate $1 - o(1)$ and makes a single call to $\mathcal{F}_{\text{MCOM}}[\kappa]$.*

Proof. The desired protocol is obtained by using the results of [15,9] to implement the necessary calls to the OT functionality in a protocol obtained by composing protocols of Lemma 2 and Lemma 1.

Using a single call to $\mathcal{F}_{\text{MCOM}}[\kappa]$, we can generate a uniformly random string (URS) of length κ . Interpreting this κ -bit string as a $\kappa^{1/2}$ instances of a $\kappa^{1/2}$ -bit URS, and assuming the existence of semi-honest stand-alone OT, one can apply the results of Damgård *et al.* [15], or Choi *et al.* [9] to obtain κ^α instances of $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ with $p(\kappa^\alpha)$ invocations of a semi-honest stand-alone OT and communication cost $p(\kappa^\alpha)$, where $p(\cdot)$ is some polynomial, as long as $\alpha \leq 1/2$. We set $\alpha \in (0, 1/2)$ such that $p(\kappa^\alpha) = o(\kappa^c)$.

Using Lemma 2 with parameters $\sigma = \kappa$, and n, ϵ such that $n^{1+\epsilon} = \kappa^\alpha/10$, and $\ell = \kappa^c$, we can UC-realize $\mathcal{F}_{\text{MCOM}}[\kappa^c]$ by making $n + 2n^{1-\epsilon}$ calls to $\mathcal{F}_{\text{OTR}}^\delta[\kappa^c/n]$ with $\delta = (2n^\epsilon + 4)^{-1}$. Then, setting $\kappa_{\text{prg}} = \kappa^\alpha$, we use Lemma 1 to UC-realize these $n + 2n^{1-\epsilon}$ calls to $\mathcal{F}_{\text{OTR}}^\delta[\kappa^c/n]$ with communication complexity $(n + 2n^{1-\epsilon}) \cdot ((\kappa^c/n) + (1/\delta) + 3\kappa^\alpha \cdot (1/\delta))$ while making $2n^{1+\epsilon} + 8n$ calls to $\mathcal{F}_{\text{OT}}[\kappa_{\text{prg}}]$.

Thus, for parameters $n, \epsilon, \kappa_{\text{prg}}$ as described above, we see that the communication complexity is $\kappa^c(1+o(1))$ while making (at most) κ^α calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$. As described in the previous paragraph, these κ^α calls to $\mathcal{F}_{\text{OT}}[\kappa^\alpha]$ can be implemented with communication cost $o(\kappa^c)$. Therefore, a single instance of $\mathcal{F}_{\text{MCOM}}[\kappa^c]$ can be realized with communication cost $\kappa^c(1+o(1))$ in each phase.

For any setup where it is possible to construct UC-secure commitments on κ -bit strings (i.e., realize $\mathcal{F}_{\text{MCOM}}[\kappa]$), then assuming the existence of semi-honest stand-alone oblivious transfer, Theorem 3 implies that it is possible to realize UC-secure commitments on strings of arbitrary length (in particular, on κ -bit strings) with rate $1 - o(1)$ in that model. We explicitly state this for the CRS model, where it is known that a protocol for UC commitments in the CRS model implies the existence of semi-honest stand-alone oblivious transfer [15].

Corollary 1. *If UC commitments exist in the CRS model, then they exist with rate $1 - o(1)$.*

4.2 UC Commitment Length Extension Implies OT

We now show that the existence of semi-honest stand-alone OT is necessary for the result above.

Theorem 4. *Let κ be a computational security parameter, and suppose there exists a protocol in which at most one party is allowed to make (at most) a single call to $\mathcal{F}_{\text{MCOM}}[\kappa]$ to UC-realize a single instance of $\mathcal{F}_{\text{MCOM}}[3\kappa]$. Then there exists a protocol for semi-honest stand-alone OT.*

Here we present only a proof sketch. The full proof is deferred to the full version.

Proof. We begin with a proof (sketch) for a weaker statement, namely, that UC commitment length extension from κ bits to 3κ bits implies key agreement. Recall that key agreement is implied by OT.

Key Agreement from Length Extension. Let Π denote the commitment protocol assumed to exist. We construct a bit agreement protocol between two parties, A and B , from Π as follows:

- A commits to a random 3κ -bit string m by acting as the honest sender in an execution of Π , and in addition, sends the query $q \in \{0, 1\}^\kappa$ it makes to the short commitment oracle and a random $r \in \{0, 1\}^\kappa$;
- B runs the UC straight-line extractor for Π to obtain m .

Both parties then agree on the Goldreich-Levin hard-core bit [20] $b = \langle m, r \rangle$ of m .

We now want to argue that an eavesdropper does not learn anything about b in two steps:

- First, if we ignore the query q , then the view of the eavesdropper is exactly the commitment-phase transcript for Π , which reveals no information about m , which means m has 3κ bits of *information-theoretic* entropy.

- The query q then reveals at most κ bits of information about m . Therefore, even upon revealing q , the message m still has $\approx 2\kappa$ bits of (min-)entropy. Then, the Goldreich-Levin hard-core bit works as a randomness extractor to derive a random bit from m .

Correctness is straightforward. To establish security against an eavesdropper, we crucially use the fact that a UC commitment scheme is equivocal, which allows us to essentially argue that m has 3κ bits of information-theoretic entropy. (Indeed, revealing κ bits of information about a 3κ -bit pseudorandom string could reveal the entire string, as is the case when we reveal the seed used to generate the output of a pseudorandom generator.)

Remark. For technical reasons, we will require that the equivocal simulator can simulate not only the public transcript of the protocol, but also the query q made to the short commitment oracle. The existence of such a simulator does not follow immediately from UC security, since the query q may not be revealed to the malicious receiver and the environment. To handle this issue, we basically proceed via a case analysis:

- If the honest sender always reveals q to the receiver either in the commit or the reveal phase, then the equivocal simulator must be able to simulate the query q since it is part of the public transcript.
- Otherwise, we show by a simple argument that a cheating receiver can break the hiding property of the commitment scheme. (See full version for details.)

We are now ready to show the OT implication.

OT from Length Extension. In the OT protocol, A holds (b_0, b_1) , B holds σ , and B wants to learn b_σ . The protocol proceeds as follows:

- Alice runs two independent executions Π_0, Π_1 of the key agreement protocol for two random strings $m_0, m_1 \in \{0, 1\}^{3\kappa}$ in parallel. In addition, A sends

$$z_0 = b_0 \oplus \langle m_0, r_0 \rangle, \quad z_1 = b_1 \oplus \langle m_1, r_1 \rangle.$$

- In the execution Π_σ , B behaves as in the key agreement protocol, which allows him to learn $\langle m_\sigma, r_\sigma \rangle$ and thus recover b_σ . In the other execution, B acts as the honest receiver in an execution of commitment scheme Π .

Correctness follows readily from that of key agreement. We argue security as follows:

- First, we claim that a corrupted semi-honest A does not learn σ . This follows from UC security of the commitment scheme against corrupted senders.
- Next, we claim that a corrupted semi-honest B does not learn $b_{1-\sigma}$. This follows essentially from a similar argument to that for the security of the key agreement protocol with two notable differences: (i) in the execution $\Pi_{1-\sigma}$, B acts as the honest receiver in Π (instead of running the extractor as in the key agreement protocol), and (ii) a semi-honest B learns the coin tosses of the receiver in Π , whereas an eavesdropper for the key agreement protocol

does not. Handling (i) is fairly straightforward albeit a bit technical; to handle (ii), we simply use the fact that the commitment phase transcript reveals no information about the committed value, even given the coin tosses of the honest receiver.

A Efficient Commitments for Cut-and-Choose

While our rate 1 construction has good concrete efficiency for large string commitments, the case of short string commitments leaves a lot to be desired. An obvious approach to handle short strings is simply to concatenate these strings together to form one large string, and then use the rate 1 construction with this string as the input message. While this approach does provide a concrete rate close to 1 when the number of instances is large, it has the drawback that all instances of short strings must be opened simultaneously. In this section, we design more efficient commitment scheme for handling multiple instances of κ -bit strings with two opening phases (as required in techniques such as cut-and-choose). The extension to three or more opening phases is straightforward.

For $i \in [n]$, let the i -th κ -bit string be denoted by m_i , and let $m = (m_1, \dots, m_n)$. Let p denote the number of opening phases, and for $j \in [p]$, let u_j denote the characteristic vector of the subset $S_j \subseteq [n]$ of the strings that need to be opened in the j -th opening phase. Note that u_j is not known to the sender during the commit phase.

Our high level idea is as follows. As in our rate 1 construction, we let the sender encode m into m' using the rate 1 encoding scheme. In addition, for each $i \in [p]$, the sender uses the rate 1/2 encoding scheme (naturally derived from Enc) to encode the zero string $(0, \dots, 0) \in \mathbb{F}^n$ twice using independent randomness to obtain codewords $z^{(1)}, z^{(2)}$ (each of length $2n'$). Next the sender prepares to send symbols through the Rabin-OT oracle. For this, it constructs $M_k = (m'_k, z_k^{(1)}, z_k^{(2)})$ for $k \leq n'$, and symbols $M_k = (z_k^{(1)}, z_k^{(2)})$ for $k \in \{n'+1, \dots, 2n'\}$, as the k -th input to the Rabin-OT oracle. Then, it transmits M_k through Rabin-OT oracle with parameter $\delta' = \delta/2$ (where δ is the best parameter for obtaining commitments on strings of length $n\kappa$). Then, in the j -th opening phase, the receiver sends the randomness (alternatively, a seed to a PRG) to encode u_j into u'_j using the rate 1 encoding scheme. Now, denote the underlying polynomials (cf. Figure 4) for (1) the rate 1 encoding of m by q_m , (2) the rate 1/2 encoding of $z^{(j)}$ as $q_z^{(j)}$, and (3) the rate 1 encoding of u_j by q_u^j . In the j -th opening phase, the sender simply reveals the polynomial $q^{(j)} = (q_m \cdot q_u^j) + q_z^{(j)}$. Now, let $\{\tilde{M}_k\}_{k \in J}$ denote the messages received by the receiver. The receiver checks if for all $k \in J \cap [n']$, it holds that $\tilde{M}_k = (\tilde{m}'_k, \tilde{z}_k^{(1)}, \tilde{z}_k^{(2)})$ satisfies $q^{(j)}(k) = (\tilde{m}'_k \cdot q_u^j(k)) + \tilde{z}_k^{(j)}$. If the check succeeds, then the receiver computes $v_i = q^{(j)}(e_i)$, where e_i are the publicly known points as described in Figure 4. If for all $i \notin S_j$, it holds that $v_i = 0$, then receiver outputs $\{v_j\}_{j \in S_j}$ and terminates, else it outputs \perp and terminates. Let c_1, c_2, c_3 represent our concrete cost of realizing commitments on strings of length $n\kappa$ in the offline, the online commit, and the online reveal phases respectively. It can be verified that the cost of the above scheme that implements n instances of κ -bit commitments with two opening phases is $\approx 8c_1, 2c_2, 2c_3$ in the offline, the online commit, and the online reveal phases respectively.
