# Knocking Out $P_k$ -free Graphs

Matthew Johnson, Daniël Paulusma\*, and Anthony Stewart

School of Engineering and Computing Sciences, Durham University, South Road, Durham, DH1 3LE, UK {matthew.johnson2,daniel.paulusma,a.g.stewart}@durham.ac.uk

Abstract. A parallel knock-out scheme for a graph proceeds in rounds in each of which each surviving vertex eliminates one of its surviving neighbours. A graph is KO-reducible if there exists such a scheme that eliminates every vertex in the graph. The PARALLEL KNOCK-OUT problem is to decide whether a graph G is KO-reducible. This problem is known to be NP-complete and has been studied for several graph classes since MFCS 2004. We show that the problem is NP-complete even for split graphs, a subclass of  $P_5$ -free graphs. In contrast, our main result is that it is linear-time solvable for  $P_4$ -free graphs (cographs).

# 1 Introduction

We consider *parallel knock-out schemes* for finite undirected graphs with no selfloops and no multiple edges. These schemes, which were introduced by Lampert and Slater [14], proceed in rounds. In the first round each vertex in the graph selects exactly one of its neighbours, and then all the selected vertices are eliminated simultaneously. In subsequent rounds this procedure is repeated in the subgraph induced by those vertices not yet eliminated. The scheme continues until there are no vertices left, or until an isolated vertex is obtained (since an isolated vertex will never be eliminated). A graph is called *KO-reducible* if there exists a parallel knock-out scheme that eliminates the whole graph. The *parallel knock-out number* of a graph G, denoted by pko(G), is the minimum number of rounds in a parallel knock-out scheme that eliminates every vertex of G. If G is not KO-reducible, then  $pko(G) = \infty$ .

*Examples.* Every graph G with a hamiltonian cycle has pko(G) = 1, as each vertex can select its successor on a hamiltonian cycle C of G after fixing some orientation of C. Also every graph G with a perfect matching has pko(G) = 1, as each vertex can select its matching neighbour in the perfect matching. In fact it is not difficult to see [2] that a graph G has pko(G) = 1 if and only if G contains a [1,2]-factor, that is, a spanning subgraph in which every component is either a cycle or an edge.

We study the computational complexity of the PARALLEL KNOCK-OUT problem, which is the problem of deciding whether a given graph is KO-reducible.

The main motivation for doing so stems from the close relation to cycles and matchings as illustrated by the above examples. We also consider the variant in which the number of rounds permitted is fixed. This problem is known as the k-PARALLEL KNOCK-OUT problem, which has as input a graph G and ask whether  $pko(G) \leq k$  for some fixed integer k (i.e. that is not part of the input).

Known Results. The 1-PARALLEL KNOCK-OUT problem is polynomial-time solvable, because it is equivalent [2] to testing whether a graph has a [1, 2]-factor, which is well-known to be polynomial-time solvable (see e.g. [3] for a proof). However, both the problems PARALLEL KNOCK-OUT and k-PARALLEL KNOCK-OUT with k > 2 are NP-complete even for bipartite graphs [3]. On the other hand, it is known that PARALLEL KNOCK-OUT and k-PARALLEL KNOCK-OUT (for all  $k \ge 1$ ) can be solved in  $O(n^{3.5} \log^2 n)$  time on trees [2]. These results were later extended to graph classes of bounded treewidth [3]. It remains open whether a further generalization is possible to graph classes of bounded clique-width. Broersma et al. in [4] gave an  $O(n^{5.376})$  time algorithm for solving PARALLEL KNOCK-OUT on *n*-vertex claw-free graphs. Afterward this was improved to an  $O(n^2)$  time algorithm for almost claw-free graphs (which generalize the class of claw-free graphs) [13]. The latter paper also gives a full characterization of connected almost claw-free graphs that are KO-reducible. In particular it shows that every KO-reducible almost claw-free graph has parallel knock-out number at most 2. In general, KO-reducible graphs (even KO-reducible trees [2]) may have an arbitrarily large parallel knock-out number. Broersma et al. [4] showed that a KO-reducible *n*-vertex graph G has  $pko(G) \le \min\{-\frac{1}{2} + (2n - \frac{7}{4})^{\frac{1}{2}}, \frac{1}{2} + (2\alpha - \frac{7}{4})^{\frac{1}{2}}\}$ (where  $\alpha$  denotes the size of a largest independent set in G). This bound is asymptotically tight for complete bipartite graphs [2]. Broersma et al. [4] also showed that every KO-reducible graph with no induced (p+1)-vertex star  $K_{1,p}$ has parallel knock-out number at most p-1.

**Our Results.** We address the open problem of whether PARALLEL KNOCK-OUT is polynomial-time solvable on graph classes whose clique-width is bounded by a constant. This seems a very challenging problem, and in this paper we focus on graphs of clique-width at most 2. It is known that a graph has clique-width at most 2 if and only if it is a cograph [7]. Cographs are also known as  $P_4$ -free graphs (a graph is called  $P_k$ -free if it has no induced k-vertex path).

In Section 3 we give a linear-time algorithm for solving the PARALLEL KNOCK-OUT problem on cographs. The first step of the algorithm is to compute the cotree of a cograph. It then traverses the cotree twice. The first time to compute to what extent "large" subgraphs can be reduced by themselves and how many free "firings" from outside are available. The second time to check whether the number of free external firings is sufficient to knock them out. In this way it will be verified whether the whole graph is KO-reducible. In Section 4 we prove that both the PARALLEL KNOCK-OUT problem and the k-PARALLEL KNOCK-OUT problem ( $k \ge 2$ ) are NP-complete even for split graphs. Because split graphs are  $P_5$ -free, our results imply a dichotomy result for the computational complexity of the PARALLEL KNOCK-OUT problem restricted to  $P_k$ -free graphs, as shown in Section 5, where we also give some (other) open problems.

### 2 Preliminaries

We denote a graph by G = (V(G), E(G)) and write |G| = |V(G)| to denote the order of G. An edge joining vertices u and v is denoted by uv. If not stated otherwise a graph is assumed to be finite, undirected and simple.

Let G = (V, E) be a graph. The *neighbourhood* of  $u \in V$ , that is, the set of vertices adjacent to u is denoted by  $N_G(u) = \{v \mid uv \in E\}$ . For a subset  $S \subseteq V$ , we let G[S] denote the *induced* subgraph of G, which has vertex set S and edge set  $\{uv \in E \mid u, v \in S\}$ . A set  $I \subseteq V$  is called an *independent set* of G if no two vertices in I are adjacent to each other. A subset  $C \subseteq V$  is called a *clique* of G if any two vertices in C are adjacent to each other. A subset  $D \subseteq V$  is a *dominating set* of a graph G = (V, E) if every vertex of G is in D or adjacent to a vertex in D.

The union of two graphs G and H is the graph with vertex set  $V(G) \cup V(H)$ and edge set  $E(G) \cup E(H)$ . If  $V(G) \cap V(H) = \emptyset$ , then we say that the union of G and H is *disjoint* and write G + H. We denote the disjoint union of r copies of G by rG.

For  $n \geq 1$ , the graph  $P_n$  denotes the *path* on *n* vertices, that is,  $V(P_n) = \{u_1, \ldots, u_n\}$  and  $E(P_n) = \{u_i u_{i+1} \mid 1 \leq i \leq n-1\}$ . For  $n \geq 3$ , the graph  $C_n$  denotes the *cycle* on *n* vertices, that is,  $V(C_n) = \{u_1, \ldots, u_n\}$  and  $E(C_n) = \{u_i u_{i+1} \mid 1 \leq i \leq n-1\} \cup \{u_n u_1\}$ . The graph  $K_n$  denotes the *complete graph* on *n* vertices, that is, the *n*-vertex graph whose vertex set is a clique. A graph is *complete bipartite* if its vertex set can be partitioned into two classes such that two vertices *u* and *v* are adjacent if and only if *u* and *v* belong to different classes. The graph  $K_{p,q}$  is the *complete bipartite graph* with partition classes of sizes *p* and *q*, respectively.

Let G be a graph and let  $\{H_1, \ldots, H_p\}$  be a set of graphs. We say that G is  $(H_1, \ldots, H_p)$ -free if G has no induced subgraph isomorphic to a graph in  $\{H_1, \ldots, H_p\}$ . If p = 1 we may write  $H_1$ -free instead of  $(H_1)$ -free. A  $P_4$ -free graph is also called a *cograph*. A graph G is a *split graph* if its vertex set can be partitioned into a clique and an independent set. Split graphs coincide with  $(2K_2, C_4, C_5)$ -free graphs [9].

We also need some formal terminology for parallel knock-out schemes. For a graph G = (V, E), a KO-selection is a function  $f : V \to V$  with  $f(v) \in N(v)$  for all  $v \in V$ . If f(v) = u, we say that vertex v fires at vertex u, or that u is knocked out by a firing of v. If  $u \in U$  for some  $U \subseteq V$  then the firing is said to be internal with respect to U if  $v \in U$ ; otherwise it is said to be external (with respect to U).

For a KO-selection f, we define the corresponding KO-successor of G as the subgraph of G that is induced by the vertices in  $V \setminus f(V)$ ; if G' is the KO-successor of G we write  $G \sim G'$ . Note that every graph without isolated vertices has at least one KO-successor. A sequence

$$G \rightsquigarrow G^1 \rightsquigarrow G^2 \rightsquigarrow \cdots \rightsquigarrow G^s$$
,

is called a *parallel knock-out scheme* or *KO-scheme*. A KO-scheme in which  $G^s$  is the null graph  $(\emptyset, \emptyset)$  is called a *KO-reduction scheme*; in that case G is also

called KO-reducible. A single step in a KO-scheme is called a *(firing) round*. Recall that the parallel knock-out number of G, pko(G), is the smallest number of rounds of any KO-reduction scheme, and that if G is not KO-reducible then  $pko(G) = \infty$ .

We will use the following result of Broersma et al. [2].

**Lemma 1 ([2]).** Let p and q be two integers with  $0 . Then <math>K_{p,q}$  is KO-reducible if and only if  $pko(K_{p,q}) \leq p$  if and only if  $q \leq \frac{1}{2}p(p+1)$ .

# 3 Cographs

In this section we show that PARALLEL KNOCK-OUT can be solved in linear time for cographs. For doing so we need to introduce some extra notation and terminology.

Let  $G_1$  and  $G_2$  be two disjoint graphs. The *join* operation  $\otimes$  adds an edge between every vertex of  $G_1$  and every vertex of  $G_2$ . The *union* operation  $\oplus$  creates the disjoint union of  $G_1$  and  $G_2$  (note that we may also write  $G_1 + G_2$  instead of  $G_1 \oplus G_2$ ).

It is well known (see, for example, [1]) that a graph G is a cograph if and only if G can be generated from  $K_1$  by a sequence of operations, where each operation is either a join or a union. Such a sequence corresponds to a decomposition tree, which has the following properties:

- 1. its root r corresponds to the graph  $G_r = G$ ;
- 2. every leaf x of it corresponds to exactly one vertex of G, and vice versa, implying that x corresponds to a unique single-vertex graph  $G_x$ ;
- 3. every internal node x has at least two children, is either labeled  $\oplus$  or  $\otimes$ , and corresponds to an induced subgraph  $G_x$  of G defined as follows:
  - if x is a  $\oplus$ -node, then  $G_x$  is the disjoint union of all graphs  $G_y$  where y is a child of x;
  - if x is a  $\otimes$ -node, then  $G_x$  is the join of all graphs  $G_y$  where y is a child of x.

A cograph G may have more than one such tree but has exactly one unique tree [5], called a *cotree*, if the following additional property is required:

4. Labels of internal nodes on the (unique) path from any leaf to r alternate between  $\oplus$  and  $\otimes$ .

We denote the cotree of a cograph G by  $T_G$  and use the following result of Corneil, Perl and Stewart [6] as a lemma.

**Lemma 2** ([6]). Let G be a graph with n vertices and m edges. Deciding if G is a cograph and constructing  $T_G$  (if it exists) can be done in time O(n + m).

We now present our algorithm, which we call Cograph-PKO, for solving PARALLEL KNOCK-OUT on cographs.

**Sketch.** We start by giving some intuition. Let G be a cograph. We may assume without loss of generality that G is connected, as otherwise we could consider each connected component of G separately. We first construct the cotree  $T_G$ . Because G is connected, the root r of  $T_G$  is a  $\otimes$ -node. Recall that  $G_r = G$  by definition. Consider a partition (X, Y) of the set of children of r such that

$$p = \sum_{x \in X} |G_x| \le \sum_{y \in Y} |G_y| = q.$$

Note that G has a spanning complete bipartite graph with partition classes  $\bigcup_{x \in X} V(G_x)$  and  $\bigcup_{y \in Y} V(G_y)$ . Hence, if  $q \leq \frac{1}{2}p(p+1)$  then G is KO-reducible by Lemma 1. However, such a partition (X, Y) need not exist, but G might still be KO-reducible. In order to find out, we must analyze the cotree of G at lower levels.

The main idea behind our algorithm is as follows. As mentioned above, the graph  $G_x$  corresponding to a join node x has at least one spanning complete bipartite subgraph. We will show that it is sufficient to consider only bipartitions, in which one bipartition class corresponds to a single child z of x. We chose z in such a way that if the corresponding complete bipartite subgraph is unbalanced (with respect to the ratio prescribed in Lemma 1) then the vertices of  $G_z$  correspond to a "large" bipartition class. We will then try to reduce  $G_z$  as much as possible by internal firings only. If  $G_z$  cannot be reduced to the empty graph, then external firings for supergraphs of  $G_z$ . Hence, we first traverse  $T_G$  from top to bottom, starting with the root r, to determine the number of external firings for each graph  $G_z$ . Afterward we can then use a bottom-up approach, starting with the leaves of  $T_G$ , to determine the number of vertices a graph  $G_z$  can be reduced to by internal firings only. If this number is zero for r then G is KO-reducible; otherwise it is not.

**Full Description.** Let G be a connected cograph, and let  $x \in V(T_G)$ . We say that  $|G_x|$  is the *size* of x. We fix a *largest* child of x, that is, a child of x with largest size over all children of x. We denote this child by z(x) (if there is more than one largest child we pick an arbitrary largest one). Let C(x) consist of all other children of x in  $T_G$  (so excluding z). We write  $F(x) = \sum_{y \in C(x)} G_y$ .

In our algorithm we recursively define two functions f and l that assign a positive integer to the nodes of  $V(T_G)$ . We write  $f(x) = \bot$  or  $l(x) = \bot$  if we have not yet assigned an integer f(x) or l(x) to node x; for some nodes x our algorithm might never do this (as we shall see, l will define an integer to a node xif and only if f has previously done so). The meaning of these two functions will be made more clear later. In particular, we will show that f(x) (if defined) is the the number of vertices in  $V(G) \setminus V_x$  adjacent to each vertex of  $V_x$ . This function will help us in determining how many additional internal firing rounds we have when we expand  $G_x$  to a larger subgraph of G by moving up the tree. The integer l(x) (if defined) is, as we will prove, equal to the smallest number of vertices in  $G_x$  that cannot be knocked out internally (that is, within  $G_x$ ) by any KO-scheme of G. We will show that l(r) is defined, that is,  $l(r) \neq \bot$ . Hence, there exists a KO-scheme that knocks out all vertices of  $V(G_r) = V(G)$ if and only if l(r) = 0.

#### Cograph-PKO

input : a connected cograph Goutput : yes if G is KO-reducible; no otherwise

**Step 1.** Compute the size  $|G_x|$  for all  $x \in V(T_G)$ .

**Step 2.** Recursively define a function f. Initially set  $f(x) := \bot$  for all  $x \in V(T_G)$ . Set f(r) := 0. Now let x be a vertex in  $T_G$  with  $f(x) \neq \bot$ .

**2a.** If x is a  $\oplus$ -node: f(y) := f(x) for all  $y \in C(x) \cup \{z(x)\}$ .

**2b.** If x is a  $\otimes$ -node: f(z(x)) := f(x) + |F(x)|.

**Step 3.** Let  $B = \{\ell \mid \ell \text{ is a leaf of } T_G \text{ with } f(\ell) \neq \bot\}.$ 

**Step 4.** Recursively define a function l. Initially set  $l(x) := \bot$  for all  $x \in V(T_G)$ . Set  $l(\ell) := 1$  for all  $\ell \in B$ . Now let x be a vertex in T that is either a  $\oplus$ -node with  $l(y) \neq \bot$  for all  $y \in C(x) \cup \{z(x)\}$  or a  $\otimes$ -node with  $l(z(x)) \neq \bot$ .

**4a.** If x is a  $\oplus$ -node:  $l(x) := l(z(x)) + \sum_{y \in C(x)} l(y)$ .

**4b.** If x is a  $\otimes$ -node:  $l(x) := \max\{0, l(z(x)) - f(x) \cdot |F(x)| - \frac{1}{2}|F(x)|(|F(x)|+1)\}$ .

**Step 5.** If l(r) = 0 then return yes; otherwise return no.

Note that for some  $x \in V(T_G)$ , it may happen indeed that  $f(x) = \bot$  or  $l(x) = \bot$  holds (for example, if x is a leaf node not in B then  $l(x) = \bot$ ).

We need some new terminology and a number of lemmas. Let x be a node in  $T_G$ . From now on we write  $V_x = V(G_x)$ . We say that a vertex  $v \in V(G)$  is *complete* to a set  $U \subseteq V(G)$  with  $v \notin U$  if v is adjacent to all vertices of U.

**Lemma 3.** Let  $x \in V(T_G)$  with  $f(x) \neq \bot$ . The following two statements hold:

(i) any vertex in  $V(G) \setminus V_x$  adjacent to a vertex of  $V_x$  is complete to  $V_x$ ;

(ii) the number of vertices in  $V(G) \setminus V_x$  complete to  $V_x$  is equal to f(x).

*Proof.* Let  $x \in V(T_G)$  with  $f(x) \neq \bot$ . Statement (i) follows from the definition of  $T_G$ . We prove (ii) as follows. Let  $\operatorname{dist}(x, r)$  denote the distance between x and r in  $T_G$ . We use induction on  $\operatorname{dist}(x, r)$ . The claim is true for  $\operatorname{dist}(x, r) = 0$  because in that case x = r and  $V(G) \setminus V_x = \emptyset$ .

Let  $\operatorname{dist}(x, r) \geq 1$ . Then x has a parent in  $T_G$ . Denote this parent by x'. By the induction hypothesis, f(x') is equal to the number of vertices not in  $G_{v'}$  that are complete to  $V_{x'}$ . Because  $V_x$  is contained in  $V_{x'}$ , these vertices are complete to  $V_x$  as well. Suppose that x is a  $\oplus$ -node. Then x' is a  $\otimes$ -node. This means that all vertices in F(x') are complete to  $V_x$ . Hence, the total number of vertices in  $V(G) \setminus V_x$  that are complete to  $V_x$  is equal to f(x') + |F(x')| = f(x). Suppose that x is a  $\otimes$ -node. Then x' is a  $\oplus$ -node. This means that no vertex in F(x') is adjacent to a vertex in  $V_x$ . Hence, the total number of vertices in  $V(G) \setminus V_x$  that are complete to  $V_x$  is equal to F(x') = f(x).

The following lemma follows directly from the construction of our algorithm.

### **Lemma 4.** Let $x \in V(T_G)$ . Then $l(x) \neq \bot$ if and only if $V(G_x) \cap B \neq \emptyset$ .

Let x be a node in  $T_G$ . An x-pseudo-KO-selection of G is a function  $V_x \to V(G)$ with  $f(v) \in N(v)$  for all  $v \in V$ . We copy some terminology. If f(v) = u, we say that v fires at u, or that u is knocked-out by a firing of v. Note that every KO-selection of  $G_x$  is an x-pseudo-KO-selection of G (but the reverse implication is not necessarily true). For an x-pseudo-KO-selection, we define the x-pseudo-KO-successor of G as the subgraph of G induced by  $V(G) \setminus f(V)$ . We write  $G \rightsquigarrow^x G'$  to denote that G' is an x-pseudo-KO-successor of G. We call a sequence  $G \sim ^x G^1 \sim ^x \cdots \sim ^x G^s$  an x-pseudo-KO-scheme (where each single step is called a round) if in addition there is no vertex of  $V_x$  that fires at a vertex of  $V_x$  in some round and at a vertex  $V(G) \setminus V_x$  in some later round. We say that G is x-pseudo-reducible to  $G^s$ . Define pseudo(x) as the number of vertices in a smallest graph to which G is x-pseudo-reducible and say that a corresponding x-pseudo-KO-scheme is *optimal*.

**Lemma 5.** The cograph G is KO-reducible if and only if pseudo(r) = 0.

*Proof.* Recall that  $V_r = V(G)$ . Then the statement of the lemma holds because every KO-reduction scheme of G (if there exists one) is an r-pseudo-KO-scheme with pseudo(r) = 0, and vice versa.

The following lemma is crucial for the correctness of our algorithm.

**Lemma 6.** Let  $x \in V(T_G)$  be a  $\otimes$ -node with  $l(x) \neq \bot$ . Then l(x) = pseudo(x).

*Proof.* Let  $x \in V(T_G)$  be a  $\otimes$ -node with  $l(x) \neq \bot$ . By Lemma 4,  $V(G_x) \cap B \neq \emptyset$ . We write z = z(x). Let  $|V_z| = q$  and |F(x)| = p. This enables us to write:

$$l(x) = \max\{0, l(z) - f(x) \cdot |F(x)| - \frac{1}{2}|F(x)|(|F(x)| + 1)\}$$
  
= max{0, l(z) - f(x) \cdot p - \frac{1}{2}p(p+1)}.

Note that  $q \ge 1$  and  $p \ge 1$  by the definition of a  $\otimes$ -node. Let d denote the number of  $\otimes$ -nodes on the longest path from x to a leaf in the subtree of  $T_G$  rooted at x. We prove the lemma by induction on d.

Let d = 0. Then every child of x is a leaf or otherwise all children of that child are leaves.

First suppose z is a leaf. Because  $V(G_x) \cap B \neq \emptyset$ , we find that  $z \in B$ . Hence, l(z) = 1. Then, as  $p \ge 1$ , we find that  $l(z) - f(x) \cdot p - \frac{1}{2}p(p+1) \le 0$ . Hence, l(x) = 0. Note that q = 1. Because z is a largest child of x, all children of x are

leaves. Hence,  $G_x$  is a complete graph on p + 1 vertices. This means that  $G_x$  is KO-reducible. We conclude that pseudo(x) = 0 = l(x).

Now suppose z is not a leaf. Then z has at least two children (which are all leaves). Hence,  $q \ge 2$ . Because  $V(G_x) \cap B \ne \emptyset$ , every child of z is in B, that is,  $V_z = B$  is an independent set, in particular, q = |B|. Because  $l(\ell) = 1$  for every  $\ell \in B$ , this means that l(z) = |B| = q. We distinguish three cases.

#### **Case 1.** q < p.

Then  $l(z) - f(x) \cdot p - \frac{1}{2}p(p+1) = q - f(x) \cdot p - \frac{1}{2}p(p+1) \le 0$ . Hence, l(x) = 0. Let  $y_1, \ldots, y_r, z$  be the children of x for some  $r \ge 0$ . In fact, because  $2 \le q < p$ and z is the largest child of x, we find that  $r \geq 2$ . Assume that  $|V_{y_1}| \geq \cdots \geq |V_{y_r}|$ . By definition,  $q = |V_z| \ge |V_{y_1}|$ . Because q < p, we can pick a set D of  $q - |V_{y_1}| \ge 0$ vertices of  $V(F(x)) \setminus V_{y_1}$ . We define  $T_1 = V_{y_1} \cup D$  and  $T_i = V_{y_i} \setminus D$  for  $i = 2, \ldots, r$ . Note that  $|T_1| = q$ . Let  $\{|T_1|, ..., |T_r|\} = \{j_1, ..., j_s\}$  for some  $s \leq r$ , where  $j_1 \geq \cdots \geq j_s$ . Because  $|T_1| = q$ , we find that  $j_1 = q$ . We partition  $V(G_x)$  into s subsets. For the first subset we pick  $j_s$  vertices from  $V_z$  and also  $j_s$  vertices from each non-empty  $T_i$ . The graph induced by the union of all these vertices has a hamilton cycle, as q < p, so besides  $T_1$  at least one other set  $T_i$  is nonempty. We remove all chosen vertices. Then, for the second subset of our partition, we pick  $j_{s-1} - j_s$  vertices from  $V_z$  and also  $j_{s-1} - j_s$  vertices from each  $T_i$  that is not yet empty. The graph induced by the union of all chosen vertices has a hamilton cycle if there are two non-empty sets  $T_i$  and a perfect matching otherwise. We repeat this procedure until all sets  $T_i$  are empty. In this way we have found a [1,2]-factor of  $G_x$ . Consequently,  $pko(G_x) = 0$ . Hence, pseudo(x) = 0 = l(x).

#### Case 2. $q \ge p$ and l(x) = 0.

As l(z) = q, the assumption that l(x) = 0 implies that  $q - f(x) \cdot p \leq \frac{1}{2}p(p+1)$ . By Lemma 3, all vertices in  $V(G) \setminus V_x$  that are adjacent to  $V_x$  are complete to  $V_x$ and moreover, the number of such vertices is equal to f(x). This enables us to define the following x-pseudo-KO-scheme. Let all vertices of F(x) fire at different vertices in  $V_z$  for the first f(x) rounds. Let all vertices in  $V_z$  fire at the same vertex of  $V(G) \setminus V_x$  for the first f(x) rounds. Note that q decreases in this way. However, we may not need to perform all these rounds: after each round we check whether  $p \leq q \leq \frac{1}{2}p(p+1)$ . Because  $q - f(x) \cdot p \leq \frac{1}{2}p(p+1)$ , it will eventually happen that  $q \leq \frac{1}{2}p(p+1)$ . If it turns out that q < p, we slightly adjust the previous round by letting a sufficient number of vertices of F(x) fire at the same vertex in  $V_z$  instead of at different vertices, in order to get  $p \leq q \leq \frac{1}{2}p(p+1)$ . We then apply Lemma 1 to knock out the remaining vertices of  $V_x$  in at most p additional rounds. Hence pseudo(x) = 0 = l(x).

#### Case 3. $q \ge p$ and l(x) > 0.

As l(z) = q, the assumption that l(x) > 0 implies that  $q > f(x) \cdot p + \frac{1}{2}p(p+1)$ . Recall that, by Lemma 3, all vertices in  $V(G) \setminus V_x$  that are adjacent to  $V_x$  are complete to  $V_x$ , and moreover, the number of such vertices is equal to f(x). This enables us to define the following x-pseudo-KO-scheme. Let all vertices of F(x)fire at different vertices in  $V_z$  for the first f(x) rounds. Let all vertices in  $V_z$ fire at the same vertex of  $V(G) \setminus V_x$  for the first f(x) rounds. Afterward we can reduce the number of vertices of  $V_x$  by at most  $\frac{1}{2}p(p+1)$  by letting all vertices of F(x) fire at different vertices in  $V_z$ , whereas all vertices in  $V_z$  fire at the same vertex of F(x) until  $F(x) = \emptyset$ . Because  $F(x) = \emptyset$  in the end, and in each round we have reduced the maximum number of vertices of the independent set  $V_z$ , we find that pseudo $(x) = q - f(x) \cdot p - \frac{1}{2}p(p+1) = l(z) - f(x) \cdot p - \frac{1}{2}p(p+1) = l(x)$ .

Let  $d \ge 1$ . Then z is not a leaf as otherwise all children of x are leaves, which contradicts  $d \ge 1$ . Consequently, z is a  $\oplus$ -node. We distinguish two cases.

#### Case 1. q < p.

Observe that  $l(z) \leq q$ . Then  $l(z) - f(x) \cdot p - \frac{1}{2}p(p+1) \leq q - f(x) \cdot p - \frac{1}{2}p(p+1) \leq 0$ . Hence, l(x) = 0. We repeat the same arguments as for the corresponding case for d = 0 to obtain that pseudo(x) = 0 = l(x). So Case 1 is proven.

Before we consider Case 2, we first analyze the subtree of  $T_G$  rooted at x. Let  $s_1, \ldots, s_p$  be the children of z with  $l(s_i) > 0$  for  $i = 1, \ldots, p$  (if such children exist) and let  $t_1, \ldots, t_q$  be the children of z with  $l(t_i) = 0$  for  $i = 1, \ldots, q$  (if such children exist). Note that all children of z are either leaves or  $\otimes$ -nodes. Let z' be a child of z. If z' is a leaf, then pseudo(z') = 1 = l(z'). If z' is a  $\otimes$ -node, we may apply the induction hypothesis to find that pseudo(z') = l(z'). In other words, pseudo $(s_i) = l(s_i)$  for  $i = 1, \ldots, p$  and pseudo $(t_i) = l(t_i)$  for  $i = 1, \ldots, q$ . Then, because  $G_z = G_{s_1} + \cdots + G_{s_p} + G_{t_1} + \cdots + G_{t_q}$ , we find that an optimal z-pseudo-KO-scheme mimics the optimal  $s_i$ -pseudo-KO-schemes and optimal  $t_j$ -pseudo-KO-schemes (we may assume without loss of generality that all external firings outside  $G_z$  in a round are always at a single vertex). Hence, pseudo $(z) = l(s_1) + \cdots + l(s_p) + l(t_1) + \cdots + l(t_q) = l(z)$ .

### Case 2. $q \ge p$ .

We define the following x-pseudo-KO-selection scheme. The firing rounds for the vertices in  $G_z$  are according to an optimal z-pseudo-KO-scheme under the following conditions. For the first f(x) rounds any external firings outside  $G_z$ are at a single vertex, which is not in  $G_x$ . Note that this is possible by Lemma 3. Afterward any external firing outside  $G_z$  must be in F(x) and also for such firings we require that they are at a single vertex in every round. The vertices in F(x) fire in each round at different vertices of  $G_x$  that are in  $G_{s_1} + \cdots + G_{s_p}$  and that are not being fired at by vertices in  $G_x$ . They stop firing in a graph  $G_{s_i}$  as soon as they have knocked out  $l(s_i)$  of its vertices. Note that we are guaranteed a budget of exactly  $f(x) \cdot p + \frac{1}{2}p(p+1)$  firings from vertices outside  $G_z$  into  $G_z$ .

First suppose that  $l(z) - f(x) \cdot p \leq \frac{1}{2}p(p+1)$ , so l(x) = 0. Then we can knock out all l(z) vertices of  $G_z$  that cannot be knocked out by internal firings inside  $G_z$ . As we still need to knock out the vertices of F(x), we check after each round whether q has decreased such that  $p \leq q \leq \frac{1}{2}p(p+1)$  holds. Because  $q - f(x) \cdot p \leq \frac{1}{2}p(p+1)$ , it will eventually happen that  $q \leq \frac{1}{2}p(p+1)$ . If it turns out that q < p, we slightly adjust the previous round as we did in Case 2 for d = 0, in order to get  $p \leq q \leq \frac{1}{2}p(p+1)$ . We then apply Lemma 1 to knock out the remaining vertices of  $V_x$  in at most p additional rounds. We conclude that pseudo(x) = 0 = l(x). Now suppose that  $l(z) - f(x) \cdot p > \frac{1}{2}p(p+1)$ , so l(x) > 0. Then, by the definition of our x-pseudo-KO-reduction scheme, all vertices in F(x) have fired at different vertices in every round for  $f(x) \cdot p + \frac{1}{2}p(p+1)$  rounds. Moreover, all vertices in F(x) are knocked out afterward. Because pseudo(z) = l(z) and we mimicked an optimal z-pseudo-KO-scheme as regards the firings of the vertices of  $G_z$  in each round, we cannot improve. We conclude that  $pseudo(x) = l(z) - f(x) \cdot p - \frac{1}{2}p(p+1) = l(x)$ . This completes the proof of Lemma 6.

**Theorem 1.** The PARALLEL KNOCK-OUT problem can be solved in O(n+m) time on cographs with n vertices and m edges.

Proof. Let G be a cograph with n vertices and m edges. If G is disconnected we consider each connected component of G separately. Hence, assume that G is connected. We construct  $T_G$ . Run Cograph-PKO with input G. By Lemma 4, we find that  $l(r) \neq \bot$ . Hence, we may apply Lemma 6 to find that l(r) = pseudo(r). By Lemma 5, we find that G is KO-reducible if and only if pseudo(r) = 0. As Cograph-PKO outputs a yes-answer if and only if l(r) = 0, we find it is correct. It remains to show that it runs in linear time. We can perform Step 1 in a bottom-up approach starting from the leaves of  $T_G$ . So, Steps 1-3 each visit each node at most once. This means that every node of x is visited at most three times in total. Because every co-tree has at most n+n-1=2n-1 vertices, we find that the running time of Cograph-PKO is O(n). Because constructing  $T_G$  costs time O(n+m) by Lemma 2, the total running time is O(n+m).

# 4 Split Graphs

We show the following result, the proof of which is (partially) based on the NP-hardness proof of 2-PARALLEL KNOCK-OUT for bipartite graphs from [3].

**Theorem 2.** The PARALLEL KNOCK-OUT problem and, for any  $k \ge 2$ , the k-PARALLEL KNOCK-OUT problem are NP-complete for split graphs.

**Proof.** First consider the PARALLEL KNOCK-OUT problem. We reduce from the DOMINATING SET problem, which is well known to be NP-complete (see [10]). This problem takes as input a graph G = (V, E) and a positive integer p. We may assume without loss of generality that  $p \leq |V|$ . The question is whether G has a dominating set of cardinality at most p.

From an instance (G, p) of DOMINATING SET we construct a split graph G'as follows. Let  $V(G) = \{v_1, \ldots, v_n\}$ . We let V(G') consist of three mutually disjoint sets: the set  $V = \{v_1, \ldots, v_n\}$ , a set  $V' = \{v'_1, \ldots, v'_n\}$  and a set W = $\{w_1, \ldots, w_r\}$  where  $r = \frac{1}{2}(n-p)(n-p+1)$ . We define E(G') as follows. First we add the edges  $v_i v'_i$  for  $i = 1, \ldots, n$ . For all  $i \neq j$ , we add the edges  $v_i v'_j$  and  $v_j v'_i$ if and only if  $v_i v_j$  is an edge in E(G). We also add an edge between every  $v_i$ and every  $w_j$ . Finally, we add an edge between any two vertices in V. Observe that G' is indeed a split graph in which V is a clique of size n and  $V' \cup W$  is an independent set of size n + r. We claim that G has a dominating set of size at most p if and only if G' is KO-reducible. First suppose G has a dominating set D of size at most p. Because  $p \leq |V|$ , we may assume without loss of generality that  $D = \{v_1, \ldots, v_p\}$ . We construct a KO-reduction scheme of G' as follows. In the first round let every vertex  $v_i \in V$ fire at  $v'_i \in V'$ . For  $i = 1, \ldots, p$ , let  $v'_i$  fire at  $v_i$ . For  $i = p + 1, \ldots, n$  let  $v'_i$  fire at an arbitrary vertex in D, which is possible because D is a dominating set of G. Finally, let every vertex in W fire at an arbitrary vertex in D as well; this is possible by the construction of G'. The resulting (split) graph G'' consists of a clique  $V \setminus D$  of size n - p and the independent set W of size  $\frac{1}{2}(n - p)(n - p)$ . Because there is an edge between every vertex in V and every vertex in W, we find that G'' is KO-reducible by Lemma 1.

Now suppose G' is KO-reducible. Consider a KO-reduction scheme of G'. Let D be the subset of vertices that are knocked out in the first round. Because each vertex must fire at a neighbour, D is a dominating set of G. We claim that  $|D| \leq p$ . For contradiction, suppose that  $|D| \geq p + 1$ . Let  $V_1 = V \setminus D$  be the subset of V consisting of vertices not knocked out in the first round. Because  $|D| \geq p + 1$ , we obtain  $|V_1| = |V| - |D| \leq n - p - 1$ . Let  $V^*$  and  $W^*$  be the subsets of V' and W, respectively, that consist of vertices not knocked out in the first round. Vertices in  $V' \cup W$  can only be knocked out by vertices of V. Moreover, the total number of vertices that V can knock out in the first round is at most |V| = n. This means that  $V^* \cup W^*$  is an independent set of size

$$|V^* \cup W^*| = |V^*| + |W^*| \ge |V'| + |W| - n = \frac{1}{2}(n-p)(n-p+1).$$

However, as in every round the size of  $V_1$  is reduced by at least 1, the maximum number of vertices in  $V^* \cup W^*$  that  $V_1$  can knock out is at most  $(n - p - 1) + (n - p - 2) + \cdots + 1 < \frac{1}{2}(n - p)(n - p + 1)$ . Hence, the scheme is not a KO-reduction scheme of G'. This is a contradiction, and we have completed the proof for PARALLEL KNOCK-OUT.

Now let  $k \ge 2$  and consider the k-PARALLEL KNOCK-OUT problem. We use the same reduction and the same arguments as for PARALLEL KNOCK-OUT after changing the size of W into  $r := (n-p) + (n-p-1) + \cdots + (n-p-k+2)$ .

### 5 Conclusions

We have shown in Theorem 1 that PARALLEL KNOCK-OUT is linear-time solvable for  $P_4$ -free graphs (whether it is possible to compute pko(G) in polynomial time for cographs is still open). We have also shown in Theorem 2 that PARALLEL KNOCK-OUT and, for any  $k \geq 2$ , k-PARALLEL KNOCK-OUT are NP-complete for split graphs. Because split graphs are  $(2K_2, C_4, C_5)$ -free [9], they are  $P_5$ -free. Hence, Theorems 1 and 2 have the following consequence.

**Corollary 1.** The PARALLEL KNOCK-OUT problem restricted to  $P_r$ -free graphs is linear-time solvable if  $r \leq 4$  and NP-complete if  $r \geq 5$ .

We recall that our long standing goal is to determine the complexity of PAR-ALLEL KNOCK-OUT on graph classes of bounded clique-width and that cographs are exactly those graphs that have clique-width at most 2 [7]. Can we solve PAR-ALLEL KNOCK-OUT in polynomial time for graphs of clique-width at most 3? For this we could start by considering the class of distance-hereditary graphs, which have clique-width at most 3 [11]. We also do not know whether there is a constant c such that PARALLEL KNOCK-OUT is NP-complete for graphs of clique-width at most c. However, it is known that the related NP-complete problem HAMILTON CYCLE, which tests whether a graph has a hamiltonian cycle, is polynomial-time solvable on any graph class whose clique-width is bounded by a constant (this follows from combining results of [12,15], also see [8]).

A different direction from above for extending our results would be to classify the complexity of PARALLEL KNOCK-OUT restricted to *H*-free graphs. The complexity status is open even for small graphs  $H \in \{4P_1, 2P_1 + 2P_2, P_1 + P_3, K_{1,4}\}$ .
