where 0.8 is the weight between A and C and also between B and C. The activation leaving a node is not simply the activation entering the node. Rather, the raw input activation is passed through a function known as the activation function to determine the output. Rosenblatt (1958) advanced the following activation function:

if input is greater than a threshold
then the activation output is 1
else the activation output is 0.

Learning commences in a *perceptron* by setting weights to any random starting point. One by one, examples are presented to the network and a learning rule

Fig. 6.1.14.2.2 Perceptron

¹⁹¹ At http://en.wikipedia.org/wiki/Types_of_artificial_neural_networks a few of the many kinds of neural networks are surveyed.

determines whether the initial weights will produce the output required. If not, the learning rule modifies the weights. Training stops when a set of weights is found that produce the correct output for all inputs.

The *perceptron* learning rule is simple:

- (a) If the output is correct then do not change any weight.
- (b) If the output is too small then increase the active weight by a constant.
- (c) If the output is too large then decrease the active weight by a constant.

Rosenblatt (1958) demonstrated that starting with any set of initial weights, the *perceptron* learning rule will incrementally modify weights until a set of weights that leads to the desired output is found. The constant, d , is called the learning rate and is generally set between 0 and 1. A large learning rate will modify weights each time by a large amount and lead to faster training. However, as we discuss below, this can also lead to sub-optimal training.

Let us consider the training of the *perceptron* initialised with weights as depicted in Fig. 6.1.14.2.2. The *perceptron* is required to learn from the data in Table 6.1.14.2.1, which contains the *training data*. The training itself is tabulated in Table 6.1.14.2.2.

The *perceptron* can be configured with any number of input and output nodes and the learning rule will still find a set of weights, if one exists, that maps the input into the outputs. A great deal of excitement surrounded the introduction of Rosenblatt's (1958) *perceptron* as a result of the breadth of applications imaginable. However, the excitement waned when Minsky and Papert (1969) illustrated how the *perceptron* fails to find a set of weights if the examples are non-linearly separable. This limits the application of *perceptrons* to little more than trivial problems.

Data is linearly separable if a straight line or plane can be drawn to separate examples into different types of outputs. Please refer again to the figures of Section 6.1.9.3 above, of which the first one illustrates the plot of points that represent X or Y. The shaded points represent the value 1 on (X OR Y). We see clearly that a straight line can be drawn that separates those X and Y data points that have a value 1 on (X OR Y) from those that have a value 0. In contrast, in the second figure of Section 6.1.9.3 we see that a similar straight line cannot be drawn. The exclusive-Or function is said to be non-linearly separable. Minsky and Papert (1969) demonstrated that the Perceptron cannot learn patterns that are non-linearly separable such as the exclusive-Or function.

Table 6.1.14.2.1 Training data for perceptron example

Example	A	B	C
1	1	1	1
2	1	0	0
3	0	1	0
4	0	0	0

Table 6.1.14.2.2 Perceptron training

Example	Input at A	Input at B	Weight A/C	Weight B/C	Raw input at C	Activation at C	Expect activation	Learning rule outcome
1	1	1	0.8	0.8	1.6	1	1	Correct. Leave weights unchanged
2	1	0	0.8	0.8	0.8	1	0	Output is too large so decrease the active weight
3	0	1	0.5	0.8	0.8	1	0	Output is too large so decrease the active weight
4	0	0	0.5	0.5	0.0	0	0	Correct output so leave weights unchanged
1	1	1	0.5	0.5	1.0	1	1	Correct output so leave weights unchanged
2	1	0	0.5	0.5	0.5	0	0	Correct output so leave weights unchanged
3	0	1	0.5	0.5	0.5	0	0	Correct output so leave weights unchanged
4	0	0	0.5	0.5	0.5	0	0	Correct output so leave weights unchanged

Rumelhart, Hinton, and Williams (1986a)¹⁹² and Werbos (1974) demonstrated that non-linearly separable problems can be learnt by a neural network provided that there were at least three layers of neurons as depicted in Fig. 6.1.14.2.1. A network that has a hidden layer cannot be trained with the *perceptron* learning rule.

¹⁹² Also see Rumelhart, Hinton, and Williams (1986b).

This is because the error of the nodes in the hidden (middle) layer cannot be known. The error on the output layer is known because the output desired is available in the data set and the network's output is known. However, the desired output on a hidden layer is unknown. Without knowing the error on hidden layers, the weights between input and hidden nodes cannot be adjusted.

6.1.14.3 Back Propagation of Errors

Rumelhart et al. (1986a) developed a new learning rule called the *Generalised Delta Learning Rule* or *back propagation of errors*. In this learning rule, the error on the hidden nodes, though not known, is estimated from the error at the output layer. The mathematics involved can be difficult but the intuition is straightforward. The error of hidden nodes is related to the error of nodes in the next layer. In fact, the error is a derivative of errors in the next layer. The hidden layer error is estimated as the derivative of the output layer error. Using the derivative of the output layer to estimate the hidden layer error turns out to work quite well.

The approach does however assume that the derivative can be calculated on all output values. In order to ensure this, Rumelhart et al. (1986a) applied an activation function that generated a continuous output. The most commonly used activation function is the *sigmoidal* or *S-curve function*.

Since its introduction, the multi-layer feedforward neural network trained with back propagation of errors has been applied in thousands of applications. Many neural network packages are available commercially and others are available as open source programs.¹⁹³

6.1.14.4 Setting Up a Neural Network

Setting up a neural network involves determining a topology. A network topology is a specification of the number of neurons in the input layer, the output layer and in each of the hidden layers. Decisions regarding the number of nodes in the input and in the output layers depend on the way data is to be encoded for the network.

Data encoding refers to the format of data to be input to the neural network. For example, the percentage split argument in our Split Up system for automated assistance in settling divorces encodes:

- A percentage split outcome awarded to the husband, measured with 14 categories; [0–10%, 11–20%, 21–30%, 31–35%, 36–40%, 41–45%, 46–50%, 51–55%, 56–60%, 61–65%, 66–70%, 71–80%, 81–90%, 91–100%] as output.

¹⁹³ The Usenet news group comp.ai.neural-nets maintains a monthly posting of a Frequently Asked Question (FAQ) that lists packages available. Regardless of the package used, the use of a neural network involves two main steps; defining the network and training it with data. These steps are discussed in the next two sections.

- An input variable that represents the contributions the husband has made relative to the wife with values on a five point scale: [much more, more, same, less, much less].
- An input variable that represents the level of wealth of the marriage. This is also a five point scale: [very high, high, average, low, very little].
- An input variable that represents the future needs the husband has relative to the wife with values on a five point scale: [much more, more, same, less, much less].

Figure 6.1.14.4.1 illustrates the topology with 15 input nodes, 5 hidden nodes and 14 output nodes that implements the percentage split network in the Split Up study. Five of the input nodes encode values for the contribution variable. The next five encode the “needs” variable and the remaining five encode the “wealth” variable. A marriage where the judge considers the husband has contributed *much less* than the wife, has future needs *much more* than the wife and is of *average wealth* is encoded as [0,0,0,0,1,1,0,0,0,0,0,0,0,1,0]. This is quite a sparse encoding as the same values could be encoded in a far more compact way. For example, an encoding scheme illustrated in Table 3 could be used to encode the same case using only three input nodes as [-1,1,-0.5].

Table 6.1.14.4.1 shows a sample encoding in the Split Up system. More compact encoding schemes enable for the development of neural networks with fewer input nodes and connections to be designed. However, the compactness makes training more difficult.

Once the input and output encoding is determined, the next decision involves selecting the number of hidden layers and the number of nodes at each layer.

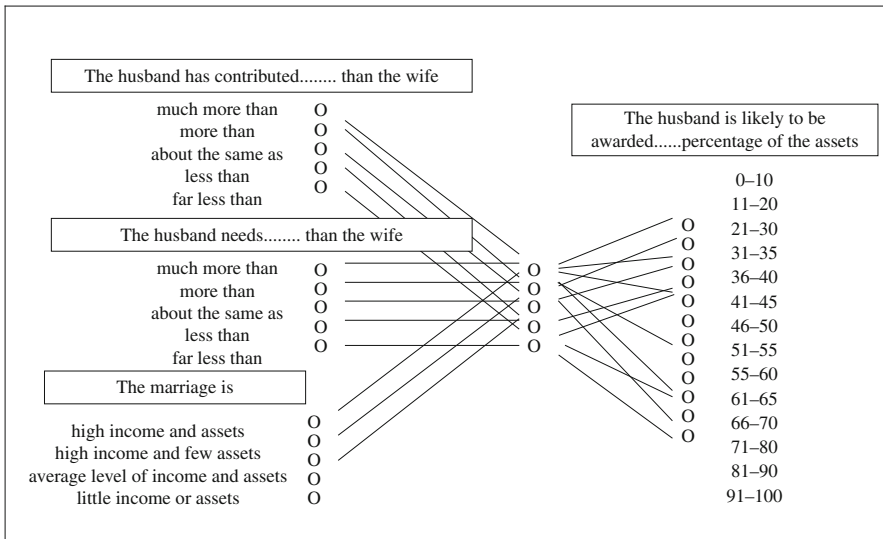

Fig. 6.1.14.4.1 Topology of percentage split network in Split Up

Table 6.1.14.4.1 Sample encoding in Split Up

Data value	Encoding
Much less	-1
Less	-0.5
Same	0
More	0.5
Much more	1
Very high income and assets	1
High income and assets	0.5
Average income and assets	0
Low income and assets	-0.5
Little income or assets	-1

Cybenko (1989) demonstrated that a single hidden layer is sufficient to approximate any (linear or non linear) continuous function. This means that any function between inputs and outputs can be approximated with a neural network that has only one hidden layer. This is not to say that the optimal number of hidden layers is one.

Haykin (1994) reviewed a body of research that has been devoted to the discernment of optimal network architectures. All of the approaches surveyed recognise a relationship between training set size and network size. However, a procedure that can be applied to determine the best topology for any data set has not been found. Lengers (1995) demonstrated a method based on trying many hundreds of different topologies using artificial intelligence search techniques.

Once a neural network topology is defined, training may commence. In the next section, processes are discussed to ensure training occurs effectively.

6.1.14.5 Training a Neural Network

Multi-layer feed-forward networks are commonly trained with the back-propagation of errors learning rule. Training involves exposing a network to a training set that is comprised of data examples, with known outputs. The learning rule adjusts the internal weights of a network in a direction that will minimise the errors made by the network on subsequent exposure to the examples. An *epoch* is completed when all training set examples are presented to the network. Typically, a network with many nodes and examples requires many hundreds, thousands or tens of thousands of epochs before the learning rule discovers a set of weights that will minimise the error made on classifying examples.

Training a neural network is as much art as science and requires the adjustment of many parameters during the training. A plot of the errors at each epoch is useful. This is depicted in Fig. 6.1.14.5.1. The error is often measured as the proportion of the training set examples that are incorrectly predicted by the network. For example, an error rate of 0.75 indicates that for 75% of examples in the training set, the output calculated by the neural network did not match the output that was observed in the training set. We see in Figure 6.1.14.5.1 that the error rate remained quite high for

Fig. 6.1.14.5.1 Plot of error rate vs. epochs

the first 600 or so epochs. By epoch 1000 the rate was quite low. Furthermore, it did not alter terribly much between epoch 1300 and epoch 1700.

Training a neural network involves making decisions regarding the following parameters:

- Learning rate
- Momentum
- Bias term
- Stopping criteria

6.1.14.6 Learning Rate

The learning rate specifies the speed with which learning occurs. If this is too high, the weight matrix¹⁹⁴ may be caught in a local minima and never find the set of weights that corresponds to an optimal solution. Figure 6.1.14.6.1 depicts learning as the search for the set of weights that will realise the smallest error. The initial weights, typically selected at random, lead to large errors. As the learning rule adjusts the weights, the error of the network reduces, until no further reduction seems to occur during epoch after epoch. The weights at this point may be the best set that will be discovered; i.e. they represent global minima. However, this cannot be known with certainty because the weights may represent local minima. They do not change from epoch to epoch because any change leads to an error that is worse, so the learning rule re-adjusts the weights back to the local minima.

Many variants introduce additional parameters to tune. Others, such as *quickProp* Fahlman (1989) dynamically modify many of the parameters, including the learning rate.

¹⁹⁴ A *weight matrix* “is used to list the weight values (strengths) that exist in the network. The position of a weight within the matrix will define which units the weight connects. Sometimes, more than one weight matrix is used to describe the way in which the units are connected in a network. For example, if units are placed in layers then a single matrix might be used to describe the connections between two layers” (Callan, 1999, p. 226).

Fig. 6.1.14.6.1 Weight space for error reduction

6.1.14.7 Momentum and Bias

There is no theoretical way of knowing whether the weights obtained are the best set possible or are an instance of weights stuck in local minima. The generalised delta rule includes a term known as the *momentum*, to add stability to a network and to guard against being caught in local minima. This term represents the extent to which weight values in previous epochs carry over into subsequent epochs. The user sets the momentum of the learning rule.

Momentum values are usually set between 0.3 and 1. A momentum term set too low will result in a network that may not be able to climb out of local minima regardless of the learning rate adjustments. In addition to momentum, terms known as *bias* represent constants that act as additional inputs to each node. The topology of the network, number of examples and the characteristics of the data all impact on these parameters.

A bias term is included in many implementations of neural networks and can be thought of as a fixed, constant input into each neuron. Bias terms are usually set between -1 and $+1$. Bias provides additional stability and restricts erratic learning behaviour. Modifying the bias term during training sometimes helps a network seemingly stuck at one error level to begin to make small gains on each epoch.

6.1.14.8 Training Stopping Criteria

Typically, training ceases when a fixed maximum number of epochs are reached or when the network performance has reached a threshold error level. A stopping criteria based on an error threshold is better than one based on number of epochs, but the error should be measured on examples not seen during training. The extent to which the trained network will generalise and perform correctly on cases not in the training set depends on the size and coverage of the training set, the architecture of the network and the complexity of the problem. Two extremes are to be avoided if adequate generalisation is to ensue: *undertraining* and *overtraining*.

Undertraining of a neural network occurs if the network is not exposed to enough examples. Learning is difficult in this situation simply because the training patterns available are not sufficiently representative of the true population of cases.

Another variation of the same extreme occurs if the network is not exposed to the training set for a sufficient number of epochs. The opposite extreme is known as *over-generalisation*, *overtraining* or *overfitting*. If a sufficiently large network has been exposed to an abundance of examples, far too many times, it can learn each input–output pair so well that it, in effect memorises those cases. The network classifies training set cases well but may not perform so well with cases not in the training set. The network is said to be *overtrained* or *overfitted*.¹⁹⁵

The objective in training any neural network is to avoid either undertraining or overtraining. This can be achieved in various ways. In the Split Up project, this goal was achieved by pursuing the *cross-validation resampling method*.

However, perhaps the most important consideration in avoiding over-training or undertraining involves the discernment of a domain specific appropriate metric for measuring errors. A measure of classifier performance typically used in classifier training in non-legal domains is the number of examples correctly classified. As Weiss and Kulikowski (1992) point out, this measure of network performance may not be adequate for all domains. They suggest a metric that includes the costs of predicting a positive outcome when the actual outcome was negative (called *false positives*) and the risks associated with predicting a negative outcome when the actual outcome was positive (called *false negatives*).

For example, a network, trained to discern the presence or absence of a disease will ideally, err far more times on the side of predicting a disease when there is none present than it will err in missing a disease that is actually present. A False positive/False negative analysis of errors is not warranted in family law, because the direction of the error is not as critical as it is in medical diagnostic problems. A network that predicts the husband is to receive 60% of the property errs if the judge in the case actually awarded 55%. However, another network errs in a similar and in a no more or less damaging manner if it predicts the husband is to receive 50% of the assets. Thus, the direction of the error is not critical for our purposes.

The stopping criteria for neural networks that model legal domains are invariably subjective. It is unreasonable to expect perfect performance from neural networks in discretionary domains of law, because networks are trained on data from many judges, and thus cannot always exactly predict the outcome of any one judge on

¹⁹⁵ A nice exemplification of *overtraining* is found in the Wikipedia entry for “Artificial neural network” (http://en.wikipedia.org/wiki/Artificial_neural_network):

A common criticism of artificial neural networks, particularly in robotics, is that they require a large diversity of training for real-world operation. Dean Pomerleau, in his research presented in the paper “Knowledge-based Training of Artificial Neural Networks for Autonomous Robot Driving”, uses a neural network to train a robotic vehicle to drive on multiple types of roads (single lane, multi-lane, dirt, etc.). A large amount of his research is devoted to (1) extrapolating multiple training scenarios from a single training experience, and (2) preserving past training diversity so that the system does not become overtrained (if, for example, it is presented with a series of right turns — it should not learn to always turn right). These issues are common in neural networks that must decide from amongst a wide variety of responses.

all cases. The measurement of the performance of a neural network, by counting the number of correctly classified examples, leads to a measure of network performance that may be too fine-grained for legal applications and thus increases the risk of overtraining. Given that a perfect performance is unlikely, other acceptable criteria must be adopted. There seems no theoretical basis to underpin such criteria, so acceptable criteria must be selected heuristically.

A good measure of a neural network's performance in a discretionary legal domain includes an indication of the magnitude of the error. An error of 5% either way when estimating a judge's decision about the percentage of marital assets to be awarded to the wife is, in our view, tolerable. On the other hand, a network which outputs a percentage split which deviates by 20% from that given by a judge, is assumed to have erred. Although the cut off point for declaring that an error has occurred is necessarily subjective it is important that a metric be discerned which can be applied consistently to all neural networks in the Split Up system.

The metric adopted in the Split Up study makes use of the following encoding scheme. Consider a network with five binary outputs. A network output of [1,0,0,0,0] for a particular example indicates that the first bit is set. If the actual output has the fifth bit set [0,0,0,0,1], we consider the network to have made an error of magnitude four. If the actual output sets two bits such as it would in [0,1,1,0,0] we take the average of the positions of the set bits. In this case we say the actual bit set is in position 2.5. If the expected output was [0,0,1,0,0] then the error is of magnitude 0.5 (i.e., in the range between 2.5 and 3). The use of an error heuristic based on the position of the set bit has advantages in that it is simple, easy to calculate and has a direct association with the interpretation placed on the bits. Encoding the five values "much more", "more", "about the same as", "less" and "much less" as bit string could be achieved with as few as three bits. However, a five bit number enables the position of the set bit to correspond directly with one of the values.

The error heuristic we use is central to the training of the neural networks used in the Split Up project. Training is halted in Split Up networks once the proportion of errors of magnitude three or more is observed to be 3% or less. An error of magnitude three represents a significant error for most neural networks. However, the cost of totally eliminating these errors is high, in that the additional training required increases the risk of overtraining.

A number of neural networks in legal domains have been trained successfully, although the use of neural networks in law is far from widespread. In the next section we review these attempts in order to argue that many neural networks have not been appropriately trained, and further inappropriate data has been used.

6.1.14.9 Application to Law of Neural Networks

Hunter (1994) notes that neural networks are essentially statistical. By this he means that associations between inferred outcomes and facts are represented as statistical associations captured as inter neuron weights. As such, connectionism derives support from the same jurisprudential theories as does any statistical method.

In the 1960s, Kort (1964) and Nagel (1964) both developed statistical methods for analysing cases. Their goal was to predict decisions. Both authors advanced methods for determining how the courts weighed individual facts to reach a decision. Kort's method was based on the solving of simultaneous equations in order to ascertain the weight of factors, while Nagel used discriminant analysis. These authors validated their statistical approach by drawing on the jurisprudence of legal realists. As stated in chapter one, we claim that connectionism can be useful for resolving situations that involve open texture, yet their effectiveness depends on the type of open textured situation studied.

The classification of situations, characterised as open textured by Prakken (1993a), provides a useful framework for a survey of neural network approaches. We argue that neural networks are best applied to situations that involve the open texture inherent in judicial discretion though some inroads can also be made toward resolving classification difficulties. To recapitulate, Prakken (1993a) identifies situations characterised as open textured as those that involve classification ambiguities, defeasible rules or vague terms. We appended the situation characterised by judicial discretion to that list. In the following, we shall survey notable applications of neural networks to each of these open textured situations.

PROLEXS (Walker et al., 1991) operates in the domain of Dutch landlord-tenant law. It operates with four knowledge groups, each of which have their own knowledge representation language and dedicated inference engine:

- legislation: a rule-based system¹⁹⁶;
- legal knowledge;
- expert knowledge; and
- case law: using case-based retrieval.¹⁹⁷

PROLEXS resorts to neural networks in case selection, case abstraction and credit assignment. The PROLEXS perceptron dealt with apartment suitability and had as its inputs the age of the tenant, the disability of the tenant, the quality of the apartment and the presence of an elevator. Various weights were assigned, and some learning was attempted. Rather than rely on manual specification of weights, the use of a perceptron allowed for automatic weight generation, avoiding the danger of manual specification of weights. The use of hidden layers in a neural network can improve the accuracy of the predictions generated by the network.

Borges, Borges, and Bourcier (2002) use neural networks to model the legal reasoning of judges at the Court of Appeal, Versailles, France. As does Hunter (1994),

¹⁹⁶ Historically within AI & Law, rule-based systems came under criticism because of too rigid interpretation of legislation, leaving no room for interpretation. Bench-Capon (1993a = 1994 [at a conference and a journal, both of them with Indra M. Carr as editor]) argued that rule-based representations of legal knowledge can nevertheless be acceptable, if the use made of the rules is sophisticated.

¹⁹⁷ For retrieving legal cases, see e.g. Zeng, Wang, Zeleznikow, and Kemp's (2005) "Knowledge Representation for the Intelligent Legal Case Retrieval".

they claim that one of the main obstacles to the use of neural networks in legal domains, is the inability of such networks to justify their decision making. They develop a multilevel perceptron justification algorithm. They claim that their models can be used for improving the self-justification process of a decision-maker and for predicting or suggesting new lines of reasoning based on implicit knowledge. Borges, Borges, and Bourcier (2002) use employment contracts cases. Borges et al. (2003) study the topography of a multilayer perceptron with backpropagation algorithm to improve connectionist classification.

Hobson and Slee (1994)¹⁹⁸ study a handful of cases from the U.K. theft act and also use neural networks to predict the outcome of theft cases. They used a series of leading cases in British theft law to train a network to predict a courtroom outcome. Results they obtained were less than impressive which they attributed to flaws in the use of neural networks in legal reasoning. This criticism was too harsh. Neural networks have much to offer knowledge discovery from databases (KDD). However, any application of KDD to data drawn from the legal domain must be carefully performed. Due attention is required so that key assumptions made at each phase of the KDD process are clearly articulated and have some basis in jurisprudence. For example, the cases used in the Hobson and Slee study involved leading cases. We believe that leading cases are not well suited to a KDD exercise involving neural networks.

6.1.14.10 Application to Classification

Bench-Capon (1993b) applied neural networks to a problem that involved open texture in the manifestation of classification difficulties. He identified six variables as inputs into a neural network that modeled the imaginary domain of social security entitlements in the United Kingdom. The output represented whether or not an applicant was entitled to social security benefits. The open texture in this domain manifested itself as difficulties inherent in classifying whether the applicant was entitled to social security benefits.

Presented with cases that were not used for training, the neural network was able to suggest an outcome that reflected the weightings of input variables in prior cases. However, limitations were apparent in that, in some cases the network was clearly in error. For example for every case in the training set that output a social security benefit, it had, as one of the inputs, the fact that the applicant was over a certain age. This was because the applicant's age was a limiting condition for the granting of a benefit. However, when dealing with some unseen cases, the neural network granted a benefit to some applicants under the limiting age.

A neural network cannot be guaranteed to perform correctly on cases that were not present in the training set. If trained appropriately, then we may estimate the proportion of all possible cases that will be classified correctly. However, we will not know with certainty which class of cases will be incorrectly classified. This

¹⁹⁸ We already referred to that study in Sections 6.1.11.1 and 6.1.11.5 above.

is not necessarily a condemnation of neural networks. The limiting condition in the Bench-Capon's study (1993b) is more aptly represented as a rule. Furthermore, the rule seems to be one, which is applied in an all or nothing, way: without any exceptions. In law, very few rules in operate in this way. The Bench-Capon study can thus be seen to apply neural networks to a classification task that is more obviously suited to a series of simple rules.

Warner (1994) does not explicitly claim that neural networks have the potential to resolve situations in law characterised by classification difficulties. Rather, he maintains that neural networks are appropriate to use in modelling law, because they exhibit the capacity to emulate the parallel reasoning process of a lawyer. He argues that legal problem solving behaviour is often described as a serial process that progresses in a step-by step fashion, from the initial problem description, to the goal of the reasoning. Yet, legal reasoning involves a parallel process of assimilating facts to reach partial solutions and assimilating partial solutions to reach a final solution. Warner's rationale for the use of neural networks in law is open to criticism, in that the distinction between problem solving performed in series and in parallel, is by no means clear. For instance, it is not clear why a parallel process should succeed in law where a serial process will fail. Furthermore, according to Hunter (1994), there is little support from jurisprudential theorists for the notion that legal reasoning is, in any sense, parallel.

Despite the shortcoming in the rationale that Warner (1994) uses to justify the use of neural networks, the actual task to which he applies neural network, is one that attempts to deal with classification difficulties in the domain of consideration in contract law. His network attempts to classify a case according to whether the contract involved a consideration. The uses of neural networks for modelling legal reasoning by Bench-Capon and Warner are similar, in that each of these authors applies neural networks to resolve classification difficulties; difficulties that contribute to a perception of law as open textured. The application of neural networks to legal reasoning by Philipps (1991) and by Thagard (1989) differ from these approaches, in that their studies can be seen to apply connectionism in an attempt to resolve defeasible rules.

6.1.14.11 Application to Rule Defeasibility

Philipps (1989) demonstrates how neural networks can assist in dealing with defeasible rules by examining a hypothetical example taken from Roman Law. The will of a hypothetical citizen whose wife was pregnant read:

If a son is born to me let him be heir in respect of two thirds of my estate, let my wife be heir in respect of the remaining part; but if a daughter is born to me, let her be heir to the extent of a third; let my wife be heir to the remaining part.

This hypothetical will can be seen to involve two rules, one governing the distribution of the estate in the event of the birth of a daughter and the other governing the distribution of the estate in the event of the birth of a son. Rather than representing these rules as clauses in a logic program or rules in a rule based reasoner, Philipps trained a feed forward neural network with back-propagation of errors to deliver the

correct output when exposed to scenarios that involved the birth of a boy and the birth of a girl, but not the birth of both. He then put forward a case that necessarily defeats these rules; one in which twins, a boy and a girl are born. In this case, the network that had not been exposed to this scenario during training, produced an outcome that indicated the mother receives two shares, the son receives three and the daughter receives four.

Philipps argues this outcome is reasonable, in that it represents an equilibrium based on past cases. However, Hunter (1994) points out that the notion of equilibrium with past cases is jurisprudentially flawed. There is no notion of moral correctness, nor any appeal to reason, that reflect higher principles. We agree with Hunter on this point, because we believe that, in this Roman Law example, reasoning is best modelled as deductions made from known legal rules. However, this is not the case in discretionary domains. Another instance of the application of connectionism for modelling defeasible rules in law can be seen in the work of Thagard (1989).

He proposed a theory of explanatory coherence that aims to model the way in which competing hypotheses are supported by available evidence. Some nodes in the network he developed represent propositions about each hypothesis. Other nodes represent available evidence. Links exist between evidential nodes and hypothesis nodes. Each has an associated weight that may be excitatory or inhibitory. To determine which hypothesis has more support, the network is activated. Nodes feed activation (or inhibition) to other nodes which provide feedback to each other, until an equilibrium is reached. The network is then settled.

Thagard (1989) trialed his ECHO program (cf. [Section 2.2.1](#) above in this book) on a murder case in which the competing hypotheses were X was innocent and X was guilty. Propositions associated with these hypothesis included C broke his hand punching X and C broke his hand falling on a rock. Thagard's propositions did not include rules from statutes or from legal principles, but could easily have been extended thus. Propositions that reflected statutes or principles would compete for activation with other propositions and those hypotheses that remained most active after the network settled, would be deemed to have, in Thagard's terms, more explanatory coherence.¹⁹⁹

In this way, the Thagard approach can be interpreted as one which attempts to resolve those situations in law that are characterised as open textured, because of the presence of defeasible rules. The Thagard approach is certainly intuitively appealing, but requires much further research. Attempts by Thagard and Philipps to use neural networks to model reasoning with defeasible rules can be seen to be overly ambitious if we relate their attempts to the use of Toulmin argument structures (for which, see [Sections 3.2](#) and [3.11](#) in this book).

Inputs and outputs of their neural networks correspond to datum and claim of the Toulmin Argument Structure. The force, rebuttal, warrant and backing cannot be represented using conventional connectionist systems. So, in the Roman law

¹⁹⁹ *Coherence in finite argument systems* is the subject of Dunne and Bench-Capon (2002).

example, commentators such as Hunter are unlikely to accept the neural network conclusion, because it cannot supply a warrant or supporting evidence. This does not point to a flaw with the use of connectionism in law, but, in our view only highlights that the procedure used to infer a claim is only one component of the structure used to persuade a reader of the feasibility of the claim. This opacity of neural networks calls for an alternative provision of transparency for the advice given by a knowledge-based systems. This is why in our Split Up system, where calculations are by means of neural networks, we have a separate automated generation of explanations for the output obtained by the neural networks.

6.1.14.12 Vagueness

Law is replete with terms that are vague.²⁰⁰ A concept such as “within reasonable limits”, specified in a statute, is labelled a vague term by Brkic (1985). What is “a reasonable period”? This is vague. The presence of vague terms was enough to entice Brkic (1985) to condemn the use of deduction to model legal reasoning. To our knowledge, connectionism has not been applied to tasks that involve vague terms.²⁰¹ Vague terms present difficulties, because there are a number of senses in which a term may be considered vague. A statutory concept such as “within reasonable limits” may signify that a decision-maker has recourse to an element of discretion in much the same way that a Family Court judge has some flexibility in distributing marital property. If all relevant principles, rules and factors were made clear to a decision maker who then had to weight the factors in order to determine whether a current case fell within reasonable limits, we would be inclined to regard the resolution of vague terms in much the same way as we see the allocation of discretion.

However, the above paragraph does not describe not all vague concepts appearing in statutes. A vague concept such as within reasonable limits, may be included in a statute, with no supplementary material that would assist a decision maker in defining the term. Legislative drafters often prefer this flexibility, so that Courts will lay down principles to guide future decision makers. A connectionist system can conceivably be developed that has, as inputs, the facts of a case and outputs one of a permitted number of uses of the vague concept. This use of connectionism is not dissimilar to the use of connectionism to resolve classification difficulties.

Transvaluationism is an account of *vagueness* proposed by philosopher Terry Horgan. Horgan states (2010, p. 67):

The philosophical account of vagueness I call “transvaluationism” makes three fundamental claims. First, vagueness is logically incoherent in a certain way: it essentially involves

²⁰⁰ For example, see George Christie’s (1964) “Vagueness and Legal Language”. It is not merely the terms that are vague. Some concepts as well are confused and confusing, he argued concerning the concept “due process of law”, in an article (Christie, 1984b) which aptly appeared in a book entitled *Les notions à contenu variable en droit*.

²⁰¹ It is not only terms that are vague. See Jonathan Yovel’s discussion of vagueness in Section 4.6.2.2 above, in the context of his treatment of *relevance*.

mutually unsatisfiable requirements that govern vague language, vague thought-content, and putative vague objects and properties. Second, vagueness in language and thought (i.e., semantic vagueness) is a genuine phenomenon despite possessing this form of incoherence — and is viable, legitimate, and indeed indispensable. Third, vagueness as a feature of objects, properties, or relations (i.e., ontological vagueness) is impossible, because of the mutually unsatisfiable conditions that such putative items would have to meet.²⁰²

6.1.14.13 Application to Modelling Discretionary Legal Domains

The application of neural networks to the task of learning the way in which judges weight relevant factors in a *discretionary* domain²⁰³ does not presume more from neural networks than they can deliver. As we have seen, the use of neural networks to resolve classification ambiguities or to mimic reasoning with defeasible rules makes questionable jurisprudential assumptions. We claim that neural networks can be appropriately applied to learn the way in which judges, have combined factors in past cases. To do this, we adopt a legal realist stance that variations displayed by individual judges on similar cases in a discretionary domain, are not the result of the application of different legal principles. However, a number of obstacles must be overcome if this paradigm is to be usefully applied. Hunter (1994) and Aikenhead (1996) identify prominent flaws in the way in which neural networks have been trained for use in past legal applications.

The concerns they raise focus on the explication deficiencies of neural networks, the assembly of appropriate data and methods used for the training of neural networks. We successively survey these concerns in order to describe the steps we have taken to ensure our neural networks are appropriately trained. The lack of explication facility inherent in the connectionist paradigm weighs heavily against their use in law. To overcome this problem we need to return to jurisprudence in order to discover how explanations fit into the scheme of legal reasoning.

The jurisprudence of the legal realism movement²⁰⁴ is central to the application of the connectionist paradigm, in that this movement advocates a separation of

²⁰² More can be found s.v. “Transvaluationism” in the Glossary at the end of this book.

²⁰³ *Discretionary*, as opposed to *mandatory*. In particular, as applied to judicial decision-making: what is up to the judge to decide, unfettered by mandatory rules, is discretionary. See Section 4.2.5. Meikle and Yearwood (2000) are concerned with the provision of support for the exercise of discretion, and how the need to avoid the risk of adversely affecting it when using a computer tool, inspired the structural design of EMBRACE, a decision support system for Australia’s Refugee Review Tribunal. Leith (1998) has warned about the risks, with AI applications to law, that judicial discretion be restricted, if computer tools come to be involved in the judicial decision-making process.

²⁰⁴ “Legal realists are jurispruders for whom the reliance on rules is an anathema. They argue that judges make decisions for a range of reasons which cannot be articulated or at least are not apparent on the face of the judgement given” (Stranieri & Zeleznikow, 2005a, Glossary). See, e.g., Rumble (1965), in the history of ideas. Wilfrid Rumble began his paper by stating (ibid., p. 547, his brackets):

Even now, the nature of American legal realism is the subject of widespread and often intense disagreement. Its significance has, to be sure, seldom been denied. Most jurists would agree with the evaluation of Mr. Justice Cardozo that “the most distinctive product of the last decade [the 1920’s] in the field of jurisprudence is the rise of a group of scholars

the decision making process from the process of justifying that decision. Thus, reasoning to reach a conclusion and explaining that conclusion can be seen as two distinct processes. Drawing this distinction enables us to design a system that uses neural networks to infer conclusions and another system to explain the conclusions. A decision is made on the basis of facts inputted. We assume that rules and principles are not necessarily factors for arriving at a decision. However, rules, principles and the facts of a case, in addition to the decision itself, are necessary in order for a justification to be advanced.

Discretion, defined as the ability of individual judges to assign different relative weights to relevant factors is accommodated in the first phase, the reaching of a conclusion. The second phase, justification of the decision does not necessarily involve a reproduction of the reasoning steps nor does it necessarily require that all factors that were relevant, even if they are highly weighted, are reported as a justification of the decision.

A barrister who suspects that her client will condemn her performance, will be tempted to offer the client a conservative prediction. Yet, that factor cannot be included in an explanation without defeating the purpose. The justification phase necessarily requires a reference to rules or principles. Decisions explained without reference to established statutes or precedents are totally untenable in liberal democracies. Legal concepts are useful tools for justifying a decision and can be applied by an artificial reasoner to justify or explain any decision. A family law expert displays the same capacity. Given the same set of facts an expert is able to justify a property decision of 70% to the husband and yet, is also able to create a justification for an output of 50% to the husband for the same case.

6.1.14.14 Unsupervised Neural Networks

The neural networks we have previously discussed are *supervised neural networks*. This means that during training the network is presented with the example and the output is learnt for that example. For instance, during training of the Split Up percentage split network, input values for contributions, needs and wealth are presented to one network along with a percentage split of assets that the trial judge awarded in that case.

In supervised learning, the system developer tells the system what the correct is, and the system determines weights in such a way that once given the input it would produce the desired output. The system is repeatedly given facts about various cases, along with expected outputs. The system uses the learning method to adjust the weights in order to produce outputs similar to the expected results. The bulk of our discussion on neural networks for data-mining legal data sets involved a consideration of supervised neural networks.

styling themselves realists". Nonetheless, the contours of this "product" are still not universally agreed upon. Even the legal realists were baffled. The confession of one — "I do not know what it [legal realism] means" — has been echoed by others.

In *unsupervised learning* the neural network is not presented with inputs and outputs. Rather, the entire data set is presented to the network. The network is required to cluster examples into groups of similar examples. There are many types of unsupervised networks including Self-Organising Maps, Grossberg nets, In-star, out-star, Bi-directional Associational Maps and Hopfield networks (Hecht-Nielson, 1990). There is a variety of applications (either potential or actual) of unsupervised neural networks in data mining, including for the purposes of crime detection. Unsupervised neural networks known as *self-organising maps* or *Kohonen networks* have been applied in a text mining context by Merkl and Schweighofer (1997), Schweighofer and Merkl (1999) and Merkl et al. (1999). Self-organising maps will be discussed in the next section.

6.1.14.15 Text Clustering with Self-Organising Maps (Kohonen Neural Networks)

Kohonen (1982) first introduced *self-Organising maps (SOM)* or *Kohonen networks*. The basic SOM architecture consists of two layers of nodes as illustrated in Fig. 6.1.14.15.1. Each input is connected to every output node. A randomly assigned weight is associated with each connection. The inputs nodes represent feature values that distinguish one example from another.

The data miner sets the size of the SOM output grid. The SOM in Fig. 6.1.14.15.1 contains 25 nodes in a 5*5 configuration. There is no systematic way to determining the optimal size of an output grid. Trial runs with grids of varying sizes are generally performed until an appropriate configuration is adopted.

During training, feature vectors are presented to the SOM. Figure 6.1.14.15.2 illustrates the presentation of a first example that has values [5,5]. Those values represent activation that flows forward along each connection and are attenuated by the weight associated with each connection. The weights are initially set randomly. Each output node receives slightly different activation because the weights are initially different. One of the output nodes received the greatest activation and is called the *winner*. The weights between the input and the winner are increased so as to ensure the same node is the winner if the same input is presented again. Weights to nodes near the winner are also increased with the use of a *neighbourhood function* illustrated in Fig. 6.1.14.15.3. Figure 6.1.14.15.4 illustrates the presentation of the second example.

Fig. 6.1.14.15.1 Basic self organising map architecture

Fig. 6.1.14.15.2 Presentation of an example to a SOM

Fig. 6.1.14.15.3 Weights strengthened after first example

Fig. 6.1.14.15.4 Presentation of second example

Fig. 6.1.14.15.5 Presentation of a third example to SOM

Figure 6.1.14.15.4 illustrates that a different node emerges upon presentation of quite different inputs. The weights between that winner and the inputs are strengthened. Figure 6.1.14.15.5 illustrates the presentation of an input that is more similar to the first instance than the second instance.

The winning node in Fig. 6.1.14.15.5 is closer to the winning node after presentation of the first example than the second example because the example [5,7] is more similar to [5,5] than it is to [2,1].

After repeated exposure to a sufficiently large number of cases, different areas on the output grid will reflect different clusters of examples. Manual examination is required in order to label regions on the grid to reflect the meaning of each cluster.

The distance between regions on the grid represents the similarity between clusters. For example, the top left region of the output grid in the study by Merkl and Schweighofer (1997) corresponded to cases that involved chemical weapons and was labelled “arms control”. The bottom centre region was labelled “Human rights” and corresponded to documents on treaties and torture.

Merkl and Schweighofer (1997) applied a hierarchical variation to the standard SOM. Miikkulainen (1993) introduced a *hierarchical self organising map* where the output grid is used as an input grid to another SOM and that output is used as input to yet another SOM. This has benefits in that the higher-level grids represent more abstract clusters. More pragmatically, training time is substantially reduced. For example, the top level grid in the study by Merkl and Schweighofer (1997) discovered four key clusters in public international law: humanitarian law, human rights, environment law and other matters.

6.1.15 Using Fuzzy Logic

Andrew Stranieri and John Zeleznikow

Natural language has many terms that are used frequently but are not precisely defined. For example, the term “young man” is not precisely defined yet is useful in many contexts. Fuzzy logic models the way in which imprecise terms in rules can combine with other imprecise terms and imply conclusions which are also often not precisely defined. To appreciate fuzzy logic and its potential application in law, we must first understand its precursor, fuzzy set theory. Zadeh (1965)²⁰⁵ introduced the idea of a fuzzy set as a more general form of classical sets. In classical set theory an element either is, or is not, a member of a set. The boundary that demarcates the set from other sets is crisp.

In fuzzy set theory, an element belongs to a set to a degree that ranges from 0, which is equivalent to not in the set, to 1, which means the element is clearly in the set. Values between 0 and 1 indicate varying degrees of membership. Table 6.1.15.1 illustrates elements that represent age in years of men. Alongside each element is a rating for the degree of membership of each element to the set “young man”.

A person who is 15 years old is clearly a member of the young person set whereas the 25-year-old person is less clearly a member of the same set. Being 25 years old

Table 6.1.15.1 Degree of membership of “young person set”

Age in years	0	5	10	15	20	25	30	35	40	45	50	55	60
Degree of membership	1	1	1	1	0.9	0.7	0.6	0.4	0.3	0.2	0	0	0

²⁰⁵ Also see, e.g., Yager and Zadeh (1994), Ross (1995).

would be very young for being a champion marathon runner, but quite old for being a champion swim sprinter.

We are not implying that there is uncertainty regarding the person's age. We may be quite certain the person is 25 yet express the view that the person is not unequivocally young.

Interpreting the degree of membership figure as an uncertainty about membership of the set is also misleading. We can be quite certain that a man aged 25 belongs to the set with a degree that can be quantified as 0.7.

Chen (2001) states that there are at least five important explanations on the role of fuzzy logic in data mining:

1. *Knowledge Granulation* – Fuzzy sets are conceptual extensions of set theory and are primarily geared towards various aspects of knowledge representation and predetermining most of the activities of data mining, especially knowledge granulation. Fuzzy sets are linguistic information granules capturing concepts with continuous boundaries. They are one of a number of contributing technologies towards data mining.
2. *Better Tolerance* – Fuzzy sets exploit uncertainty in an attempt to make system complexity manageable. Fuzzy logic can deal with incomplete, noisy and imprecise data and is helpful in developing better uncertain models of the data than is possible with traditional methods. Since fuzzy systems can tolerate uncertainty and utilise language-like vagueness to smooth data, they may offer robust, noise-tolerant models or predictions in situations where precise data is unavailable or too expensive.
3. *Data Classification* – Fuzzy logic works at a high level of abstraction and is thus useful for data mining systems performing classification (Han & Kamber, 2001).
4. *“Indirect” Contribution to Data Mining through its relationship with Artificial Neural Networks* – Fuzzy set theory by itself is neither a machine learning nor a data mining technique. However, fuzzy set theory does have a close relationship with the weights used in artificial neural networks.
5. *Increased chance of Knowledge Discovery Due to Vagueness* – Fuzzy set theory can be combined with other data mining and uncertain reasoning approaches. By allowing vagueness, the chance of uncovering hidden knowledge is enhanced.

As Phillips and Sartor (1999) note, a judge must decide on legally relevant situations, which can only be described in indeterminate terms. The decisions must be determinate and can often only be expressed as a numerical quantity. But what is indeterminacy? Indeterminacy is not uncertainty. To quote the Roman maxim — *Mater semper certa est, pater semper incertus* — one can never be certain that a man was the real father of a child, even if he was the mother's husband. But the concept of a father is certainly determinate. Phillips and Sartor (1999) argue that fuzzy logic is an ideal tool for modelling indeterminacy. Legrand (1999) has developed guidelines for the use of Fuzzy Logic to model legal reasoning.

Phillips (1993) has used fuzzy reasoning in modelling traffic accident law. Borgulya (1999) also uses fuzzy logic methods to model decisions made by judges

regarding traffic accidents. He provides information for courts and lawyers about the seriousness of an actual case compared to previously tried cases. Xu, Kaoru, and Yoshino (1999) constructed a case-based reasoner to provide advice about contracts under the United Nations Convention on Contracts for the International Sale of Goods (CISG). Shapira (1999) investigates the attitude of Jewish law sources from the second to fifth centuries to the imprecision of measurement. He argues that the Talmudic sources were guided by primitive insights compatible with fuzzy logic presentation of the inevitable uncertainty involved in measurement.

6.1.16 Using Genetic Algorithms in Data Mining

Andrew Stranieri, John Zeleznikow, and Ephraim Nissan

6.1.16.1 Evolutionary Computing and Genetic Algorithms

Evolutionary computing refers to the task of a collection of algorithms based on the evolution of a population toward a solution of a certain problem. These algorithms can be used in applications requiring the optimisation of a certain multidimensional function. The population of possible solutions evolves from one generation to the next, ultimately arriving at a satisfactory solution to the problem.

The various algorithms differ in the way in which a new population is generated from the present one, and in how the members are represented within the algorithm. The two most significant evolutionary computing techniques are:

- (1) *Genetic Algorithms* – Genetic algorithms are general-purpose search algorithms that use principles derived from genetics to solve problems. A population of evolving knowledge structures that evolve over time – through competition and controlled variation – is maintained. Each structure in the population represents a candidate solution to the concrete problem and has an associated fitness to determine which structures are used to form new ones in the competition. The new structures are created using genetic operators such as crossover and mutation. Genetic algorithms are very useful in search and optimisation problems, because of their ability to exploit the information accumulated about an initially unknown search space in order to bias subsequent searches into useful subspaces, namely their robustness.
- (2) *Evolutionary Algorithms* – Evolutionary algorithms are computer-based problem solving systems that use computational models of evolutionary processes as key elements in their design and implementation. Examples include evolutionary programming, evolution strategies, classifier systems and genetic programming. Evolutionary algorithms share a common conceptual base of simulating the individual structures via processes of selection, mutation and reproduction.

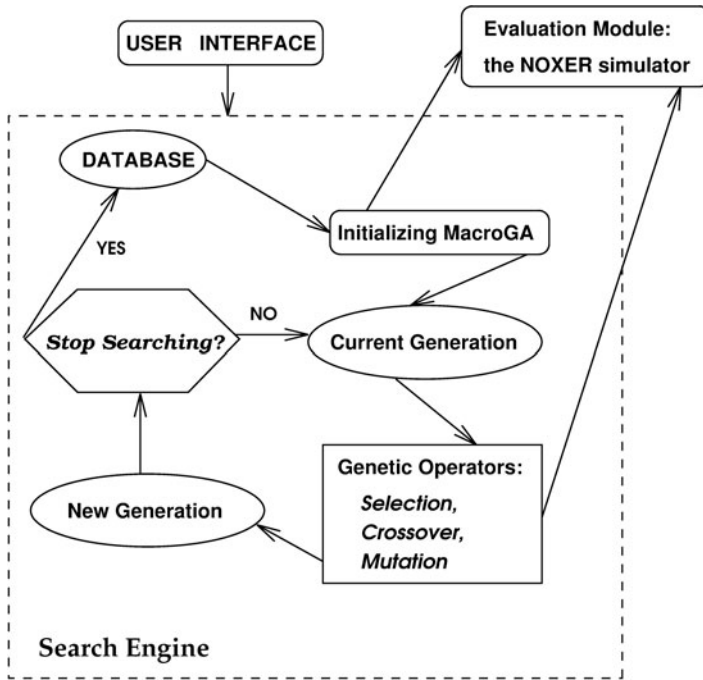

Fig. 6.1.16.1.1 The genetic algorithm in the control flow of FUELCON (Nissan et al., 2001)

For example, Fig. 6.1.16.1.1, which is from Nissan, Galperin, Soper, Knight, and Zhao (2001), shows the control flow of FUELCON, an expert system for designing how to refuel the core of a nuclear reactor. It is based on a genetic algorithm called *MacroGA*. Each individual solution is a configuration of fuel units (themselves assemblies of rods) in the grid which is the cross-section of the core of the reactor (in one-eighth symmetry). Solutions were evaluated by means of NOXER, a software tool in reactor physics. Figure 6.1.16.1.2, which is also from Nissan et al. (2001), shows how FUELCON's population of solutions (the "cloud" of solutions) eventually moves into a better region, and contains the optimal solution. The method was *macroevolution*, because the population of competitors is a population of clouds of solutions, thus a set of sets, a population of populations.

The following is quoted from Zhao, Knight, Nissan, Petridis, and Soper (1998), and explains the genetic algorithm in FUELCON (this was the doctoral project of Jun Zhao, supervised by Nissan and others):

In macroevolution, a number of species co-evolve. In the scheme of macroevolution we have adopted,

- A number of species are used, with no dominant species.
- Migration is controlled by a migration rate (or probability) determining when migration occurs, the number of migrants per migration (normally two), and a migration topology, such as the so-called ring or line topology.

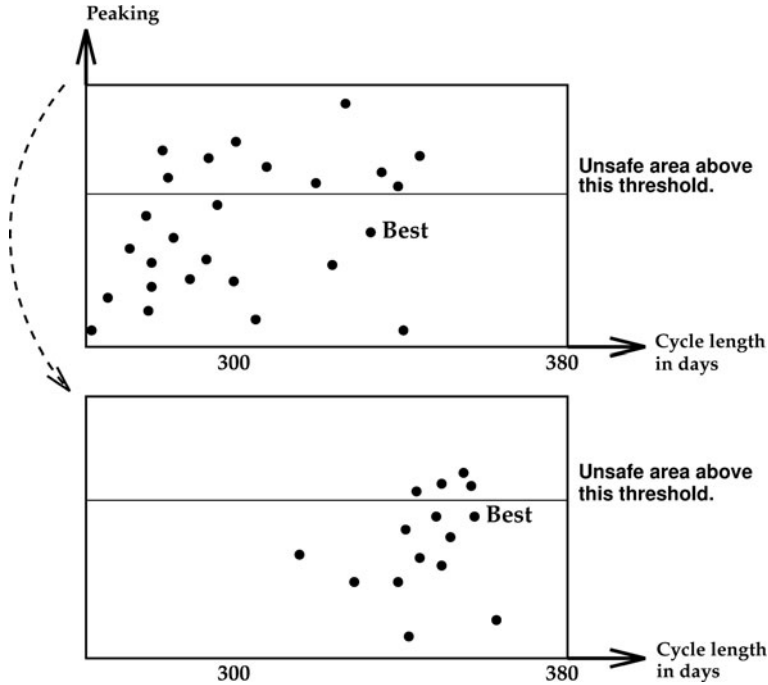

Fig. 6.1.16.1.2 FUELCON’s cloud of solutions moves to a better region, and the optimal solution is found (Nissan et al., 2001). Each individual solution (which is a configuration of fuel in the core of the reactor) is shown as a *dot*

- Migrants are the best individuals in the source species, and they will compete with all the individuals within the destination species for survival; the same number of least fit individuals will then be removed.
- Each species has a different crossover and mutation rate, which are generated from a mutation rate range and a crossover rate range.
- The ranking selection method is applied to all species.
- It is only as a particular case, that all species may happen to use the same crossover and mutation operators.

More generally, such uniformity is not necessary (*ibid.*). The same paper also explained:

In the macro genetic algorithm, the first step is to initialize its parameters, and a set of species. At this stage, the probability of migration is set, each species is initialized in terms of selection operator, crossover operator, mutation operator, population size, and crossover and mutation rates. After initialization, all species evolve in parallel, and migrations take place at each generation. At each generation, the best individual is recorded and checked. If the current best individual is acceptable in terms of fitness, then a termination message, “Stop”, is distributed to all species, and the macroevolution process comes to an end.

Here is an outline of how FUELCON works (ibid.):

1. Initialize the MacroGa with setup parameters, such as the number of species (sub-populations), the number of generations, population size for each species, etc.
2. Create the current generation, and evaluate the fitness for each individual in the population.
3. Apply the genetic operators to create a next generation.
4. Check whether an acceptable loading pattern has been found. If so, go to step 6.
5. Replace the current generation with the next generation, then save the search information (i.e., the best reload pattern), and go to step 3.
6. Save the final search results to the database, and stop.

The advantages of this macroevolution (in which we have a population of populations) were explained (ibid.) as stemming from:

- (1) A set of weakly interacting species, allowing each species to concentrate on a separate area of the search space. The species can search their own regions aggressively (under high selection pressure) and hence quickly, without the risk of a premature loss of diversity.
- (2) The use of different crossover and mutation rates in the various species, avoiding the problem of having to determine effective values for these parameters. The inclusion of rather high mutation rates in some of the species adds a strong hill-climbing element to the search, without generating a random one. Hill-climbing has been shown to be an effective ingredient in genetic algorithms; macro evolution allows its introduction in a natural way while gaining the advantage of point 1.

New parameters to be determined for effective performance appear however as the migration rate between species, and the number of individuals exchanged at each migration. Values for these parameters giving good performance were easy to determine however, confirming that macrogenetic algorithms are robust, requiring little parameter tuning for a new application.

The FUELCON project however involved no data mining. Cios, Pedrycz, and Swiniarski (1998) claimed that evolutionary computing is useful to data mining because it can be used to solve optimisation problems. The optimisation processes are based on a population of potential solutions rather than relying on a population of potential solutions rather than relying on a single search point being moved according to some gradient based or probabilistic search rules.

6.1.16.2 Genetic and Other Methods as Applied to Transforming Pre-processed Data Upstream of the Data Mining Phase

Data that has been selected and pre-processed may not necessarily be ready for exposure to a data-mining algorithm. Some transformation of the data

may dramatically enhance the benefit of the subsequent data mining phase. Transformation can be performed in five ways:

- (a) *Aggregation of data values.* This involves transforming values into categories or groups. Values on an age variable captured in years and months, for example, may be transformed into five pre-defined age groups. Aggregating values is also known as *binning* because it involves transforming values of a feature into a small number of categories.
- (b) *Normalisation of data values.* A variable with large values measured, for instance in the thousands could dominate a variable with very small values measured in the thousandths in the data mining phase. Normalising involves transforming both sets of values so that they fall within the same range. Scaling values so that they fall within a specified range is particularly important if two or more features have vastly different ranges.
- (c) *Feature reduction.* This involves the removal of features that are not relevant or make no sizeable contribution to the data mining exercise.
- (d) *Example reduction.* Example reduction involves eliminating records from the data set. Data-sets in law are typically too small to contemplate example reduction.
- (e) *Restructuring.* Restructuring involves decomposing the data-set into smaller parts for independent data mining exercises.

Restructuring a data set into smaller parts for independent mining exercises is particularly important for mining from data sets in law. This is due to the lack of availability of large data sets that reflect judicial reasoning. For example, 94 variables were identified by specialist family lawyers as relevant for determining property outcomes in Australian family law. A data mining exercise with so many variables requires data from many thousands of cases for meaningful results. However the mining exercise was decomposed into 35 independent, small and manageable data mining exercises. Most of these smaller exercises involved less than five variables, so that mining was possible, though not ideal, with data from around one hundred cases.

Feature reduction involves the removal of features that are irrelevant or will not contribute to the data mining exercise. Irrelevant features may clutter the data mining phase making the discovery of meaningful patterns difficult or at worst, impossible. There are three main ways that feature reduction is performed:

- (a) *Expert heuristics.* Legal specialists well acquainted with the jurisdiction the data-set derives from often have a clear view of the extent to which a feature may be irrelevant and warrant removal. The articulation of a reason for each feature's relevance presents as a simple and effective, yet not foolproof mechanism for the identification of irrelevant features. In law, the relevance of a feature typically derives directly from a statute, precedent case, regulation or commonly accepted practice. However, this is not always the case. Most family law specialists claim the wife's hair color is irrelevant and should not play a role in

mining aimed at predictive property split orders. In contrast, some specialists claim hair color is entirely relevant in property proceedings as judges may, correctly or not, regard that blond women have better prospects for re-marriage and therefore ought to be awarded fewer marital assets.

- (b) *Statistical techniques.* Statistical techniques can be applied to the data-set to identify features that do not contribute to the prediction. *Principal components analysis (PCA)* is the technique most often used to determine such features. PCA involves the analysis of variance between features and the class variable in a prediction exercise. PCA requires specialist statistical software, since the calculations are cumbersome. PCA is applicable only to features that are numeric.²⁰⁶
- (c) *Data mining.* The third approach used in feature reduction involves the application of a data mining technique in order to discover features that do not contribute to the mining. The *rule induction* algorithm is often applied in this way because features that are irrelevant do not appear in rules derived with this algorithm. Alternatively, *genetic algorithms* can be applied: see below.

Within category (c), we mention the application of genetic algorithms in a project related to our *Split Up* system for assisting in negotiations for marital splits. Skabar, Stranieri, and Zeleznikow (1997) applied the following method with excellent results. The search method they resorted to was *genetic algorithms*. These they used in order to look for the best subset of features of the Split Up data-set for neural network training. They found a subset of 17 features predicted percentage split in property proceedings as well as the original 94 featured data-set.

The use of expert heuristics is the best of the three approaches when using a data-set that derives from legal databases. The statistical and data-mining approach may yield counter-intuitive results that while correct, are not readily explained or accepted. For example, many of the features found to be unnecessary by Skabar (1997) in predicting percentage split outcomes such as the contributions made by the husband are central in statutes and common-sense reasoning in family law. Specialist lawyers, judges and other commentators explain virtually every judgement with reference to this feature. The fact that a data-mining method does not need this feature in order to make good predictions cannot be taken to mean that the feature is not taken seriously by judges in reaching decisions. It is more likely that this is an artefact that arises because the interdependence between this feature and other features results in accurate predictions when using a combination of other features.

²⁰⁶ Suppose that we have N tuples from k -dimensional space to compress. Han and Kamber (2001) say PCA searches for c k -dimensional orthogonal vectors that can be best used to represent the data, where $c \leq k$. The original data is projected onto a much smaller space, resulting in data compression. PCA can be used as a form of dimensionality reduction. Unlike attribute subset selection, which reduces the attribute set size by retaining a subset of the initial set of attributes, PCA “combines” the essence of attributes by creating an alternative smaller set of variables. The initial data can then be projected onto this smaller set.

6.1.16.3 Nearest Neighbours Approaches and Their Integration with Genetic Algorithms

Below, we discuss evolutionary computing in order to illustrate an innovative use of genetic algorithms in law by Pannu (1995). However, before doing this we briefly overview the *k-nearest neighbour* algorithm that is required for an understanding of the approach which Pannu (1995) uses. According to Ripley (1996), the *k-nearest neighbour* (*k-NN*) algorithm is attributed to Fix and Hodges (1951). It is a relatively simple algorithm for classifying examples in a sample that uses two basic steps to classify each example:

1. Find the *k* nearest, most similar examples in the training set to the example to be classified
2. Assign the example the same classification as the majority of *k* nearest retrieved neighbours.

A trivial example involves classifying whether a young man is likely to be classified with an even split of marital property given the data in Table 6.1.16.3.1. Say the example to be classified is a young man represented as [1,0,1,0] and that *k* = 3. Assuming each feature is equally important, the three most similar examples are examples 1, 2 and 3. The majority of the *k* neighbours, (i.e examples 1 and 2) are classified. Even so the young man example will also be classified as receiving an even split.

Issues that need to be considered when using the *k-NN* algorithm include:

- *Choice of Similarity metric.* Typically a Euclidean distance metric is deployed such as

$$\sum (x_e - x_t)^2$$

where

$$x_e - x_t$$

is the difference between the example value and the a training set value for each feature. This can be modified by weighting each feature differently

Table 6.1.16.3.1 Sample data for *k*-th nearest neighbour example

Ex.	Age young	Age elderly	Sex male	Sex female	Split
1	1	0	1	0	Even
2	1	0	1	0	Even
3	0	1	1	0	Uneven
4	0	1	0	1	Uneven

$$\sum w(x_e - x_t^2)$$

This metric, which combines the difference between points linearly, is adopted.

- *Optimal choice of k.* The decision about the size of k must be made in advance. A large value of k introduces computational complexity, whereas a small value k is less accurate. Refinements of the algorithms involve dropping examples that are not needed to correctly classify the example.

Michie, Spiegelhalter, and Taylor (1994) illustrate that the k-NN compares favourably with respect to error rates in classification tasks against neural networks, Bayesian belief networks and linear or logistic regression. The k-NN approach is embedded in the genetic algorithm of Pannu (1995) discussed next.

Pannu (1995) applied genetic algorithms to discover a prototype, ‘perfect’ exemplar for cases with a specified outcome. Good exemplars for cases are useful because future cases can be mapped to exemplars with different outcomes to predict likely outcomes and to identify weaknesses in a case. Two elements are required in order to generate a good exemplar; a distance metric to measure the degree of similarity between one case and another, and a search procedure that can explore an very large number of possible exemplars to find the best one.

The approach Pannu (1995) used integrated k-th nearest neighbour distance metric with a genetic algorithm described by Kelly and Davis (1991). The distance metric computes a distance between two vectors. The distance algorithm was based on the k-th nearest neighbour algorithm.

For Pannu (1995), the vector elements were a 1 or a 0 and represented whether or not a factor was present in a case. A fitness function that sought to find a exemplar case did so by minimising the distance between itself and all other cases with the same outcome and by maximising the distance between itself and exemplars for cases that had different outcomes.

Evolutionary computing techniques have not been extensively applied in the legal domain though the work by Pannu (1995) indicates some possibilities. Quite recent data mining techniques broadly categorised as kernel machines are described in the next section, though these algorithms have not yet been applied to law.

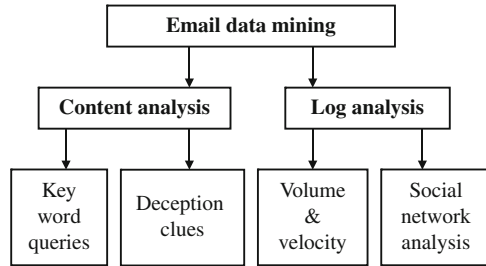

6.2 Case Studies of Link Analysis and Data Mining

6.2.1 *Digital Resources and Uncovering Perpetration: Email Mining, Computer Forensics, and Intrusion Detection*

6.2.1.1 Email Mining

One form of *text mining* is *email mining*. In a section entitled “Email Text Mining”, Gray and Debreceeny (2006) remarked: “The text of the email is essentially unstructured. Minkov and Cohen (2006) notes that these characteristics of emails allow us to view a set of semistructured emails as a graph, with nodes representing

Fig. 6.2.1.1.1 A framework for email data mining, redrawn from Gray and Debreceeny (2006)

actors, temporality, subject matter and meetings. We can exploit these characteristics by employing a variety of techniques as illustrated in Figure [6.2.1.1.1].” Those techniques can be blended, and, e.g., one can analyse content (emails and their file attachments) while also analysing the log: for example, the social network of senders and recipients, possibly in relation to roles known from the structure of an organisation of which these are employees. “Within corporate email systems, it is relatively simple to match email recipients to corporate roles and responsibilities” (Gray & Debreceeny, 2006).

From the *temporal mining of an email log*, volume and velocity are metrics that can be analysed. “Volume measures the number of emails a person sends and/or receives over a period of time. Velocity measures how quickly the volume changes. Gradual change would be low velocity and sudden jumps in volume would be high velocity” (Gray & Debreceeny, 2006). This is potentially useful when trying to detect suspicious activities. “In terms of continuous monitoring of volume and velocity, the key issue is determining the optimum time intervals to sample the data” (ibid.). “Changes in velocity over time for no apparent reason may also indicate suspicious activities. The first task is to create a *baseline normal* profile and then changes in volume and velocity compared to the profile for no apparent reason may indicate suspicious activities” (ibid.).

Rolling histogram is a concept that has arisen in the literature concerning this. “Recognizing that the baseline profile can evolve over time, Stolfo, Creamer, and Hershkop (2006) use the term ‘rolling histogram’ to reflect the dynamic aspects of an employee’s profile changing over time. The concept of the rolling histogram is like other moving averages where the profile is updated based on a moving window of a time interval (e.g., a twelve-week moving average)” (Gray & Debreceeny, 2006). Stolfo et al. (2006) used software called Email Mining Toolkit (EMT). It is freely available.²⁰⁷ It was developed at Columbia University, includes approximately 132,000 lines of Java code, and interfaces with relational databases.

Link and network monitoring is another kind of analysis of the log, in relation to the social network of the senders and the recipients within an organisation.²⁰⁸ Gray and Debreceeny (2006) remarked:

²⁰⁷ <http://www1.cs.columbia.edu/ids/emt/>

²⁰⁸ *Email surveillance* is the subject of, e.g., Browne and Berry (2005).

Once the networks and cliques are identified, continuous monitoring techniques could be used flag emails that fall outside the established patterns. For example, an email from a high-level executive to a warehouse worker, where no similar emails existed before, could be suspicious. Emails from employees to customer domains where the employee does not hold a position that normally communicates with customers would be suspicious. Unlike the monitoring of volume and velocity, link and network monitoring could be performed on a near real-time basis.

Another direction of research in *email mining* is *deception research*. Deception can be of the sender trying to deceive the addressee, of then of both of them in collusion trying to deceive their employer. Moreover, distinguish *sender deception* (lying about the sender's identity) from *content deception*.

6.2.1.2 The Enron Email Database as an Opportunity for Research

The Enron scandal spawned text mining research into the email database of Enron. In the words of Gray and Debreceeny (2006):

A large corpus of emails from Enron was put into the public domain by the Federal Energy Regulatory Commission following its investigation of the corporation in relation to alleged manipulation of "electricity and natural gas markets in California and other Western states in 2000 and 2001." The original corpus contained 0.6m emails from 158 users (Klimt and Yang [2004a, 2004b]). These users included key participants in the events that brought down the corporation in 2001 [...] Elimination of [email] duplicates reduced the corpus to 0.2m messages; an average of 757 messages per user. They also worked to remove quotations of previous emails in subsequent emails in that thread. [...] The Enron email corpus has subsequently been transformed into a relational database format and published in MySQL format (Shetty and Adibi, 2004). [...] Exploring the emails may be undertaken by targeted analysis based upon known patterns, or by automated techniques. [...] Emails also provide a flavor of the relationship between the external auditors and Enron. A total of 466 emails in the corpus were sent from Enron email addresses to Andersen email addresses. A surprising proportion of these emails were comprised of jokes often in poor taste, event announcements and personal mail. There were 33 emails from Andersen email addresses to Enron email addresses. Again, many of these emails were related to matters other than the audit.

Research into the Enron email database has adopted various techniques, with different purposes. Gray and Debreceeny (2006), whose viewpoint is that of auditors, mentioned that even such a rudimentary technique as looking for key words yielded results: "Emails could be searched for key words such as finder's fee, bribe, kick-back, and similar words that could indicate questionable actions or overrides of controls. This would be cherry-picking the naive fraudsters. It is hard to believe that a fraudster would use such words in the company email, but they do as found by researchers who have explored the Enron email corpus" (ibid.). "Probably the most discussed continuous email monitoring is the *Carnivore* system developed by the FBI to scan emails in the United States. The CIA and NSA are assumed to have similar systems to monitor email traffic outside of the U.S. The difference being that the FBI needs a court order before it can monitor a specific person's email traffic in the U.S. By the way, companies do not need a court order to monitor employee emails." (ibid.).

One strand of research was intended to discover structures within the organisation. This is part of the discipline analysing social networks, in order to identify communities and model their evolution. The Enron email dataset was made available to the public,²⁰⁹ and this has enabled research to flourish.²¹⁰ Gray and Debreceeny (2006) pointed out:

Research on automated understanding of the emails within the Enron corpus is still at a relatively early stage. A considerable amount of research has gone into understanding social network relationships within email data sets. Whilst this is an important first step in identifying key relationships that can be used for assurance purposes, social network analysis does not on its own allow identification of emails that may be critical to an assurance issue. As discussed above, there are also a variety of techniques to analyze the text within a corpus including natural language processing and machine learning. The next step is to match content analysis and social networks.

For those who “want to recognize a group of authors communicating in a specific role²¹¹ within an Internet community, the challenge is recognize possibly different roles of an author within different communication communities. Moreover, each individual exchange in electronic communications is typically short, making the standard text mining approaches less efficient than in other applications” (Chaoji et al., 2010).²¹² The textual corpus of Enron emails corpus is a suitable domain of application: “An example of such a problem is recognizing roles in a collection of emails from an organization in which middle level managers communicate both with superiors and subordinates. To validate our approach we use the Enron dataset which is such a collection” (Chaoji et al., 2010).

Wilson and Banzhaf (2009) applied a genetic algorithm to the discovery of social networks within the Enron email database. “Heer [jheer.org] has built a variety of tools that allow visual representations of several types of social networks including Friendster relationships (Vizter) and relationships expressed in Enron emails (Enronic). These tools are based on natural language processing techniques”, and one of the tools, Enron Corpus Viewer, plots a graph being “a visual representation of the social networks embedded in the Enron corpus” (Gray & Debreceeny, 2006).

Chapanond, Krishnamoorthy, and Yener (2005) developed such an analysis of the Enron email data. They constructed an email graph, and studies its properties by using *graph theoretical* and *spectral analysis* techniques. “The graph theoretical analysis includes the computation of several graph metrics such as degree distribution, average distance ratio, clustering coefficient and compactness over the email graph. The spectral analysis shows that the email adjacency matrix has a rank-2

²⁰⁹ Enron Email Dataset, <http://www-2.cs.cmu.edu/enron/> and later on at <http://www.cs.cmu.edu/~enron/> (maintained by W. W. Cohen). Moreover, the following is also available: Enron Employee Status Record, at http://isi.edu/~adibi/Enron/Enron_Employee_Status.xls

²¹⁰ E.g., Klimt and Yang (2004a, 2004b). Keila and Skillicorn (2005), Diesner and Carley (2005), McCallum et al. (2005), and Priebe et al. (2005).

²¹¹ Role identification in a corpus of emails is a special case of automated text categorization.

²¹² Chaoji et al. (2008a, 2008b, 2010) and Goldberg et al. (2008) stem from the same team, led by Boleslaw K. Szymanski at the Rensselaer Polytechnic Institute, in Troy, New York state.

approximation. It is shown that preprocessing of data has significant impact on the results, thus a standard form is needed for establishing a benchmark data”.

Goldberg et al. (2008) are concerned with “Social networks that arise spontaneously and evolve over time”: “Their loose membership and dynamics make them difficult to observe and monitor”. Goldberg et al. (2008) presented “a set of tools for discovery, analysis and monitoring evolution of hidden social groups on the internet and in cyberspace. Two complementary kinds of tools form a core of our approach. One [SIGHTS] is based on statistical analysis of communication network without considering communication content. The other [Recursive Data Mining] focuses on communication content and analyzes recursive patterns arising in it” (ibid.).

6.2.1.3 Discovering Social Coalitions with the SIGHTS Text Mining System

One of the tools presented by Goldberg et al. (2008) is SIGHTS (Statistical Identification of Groups Hidden in Time and Space). SIGHTS was “designed for the discovery, analysis, and knowledge visualization of social coalition in communication networks by analyzing communication patterns”. The algorithms of SIGHTS “extract groups and track their evolution in Enron-email dataset and in Blog data. The goal of SIGHTS is to assist an analyst in identifying relevant information” (Goldberg et al., 2008).

SIGHTS has three main modules: Data Collection/Storage, Data Learning and Analysis, and Knowledge Extraction/Visualisation. The data sources are email data, or blogs, and it was envisaged to also include a link to chatrooms at a later stage. From the data sources, data are collected, and a semantic graph and metadata are stored in a database. “The Data Collection Modules operate on semantic graphs. The graphs are constructed by adding a node for each social network actor and a directed edge from sender’s node to a recipient’s node. The edges are marked with the time of the communication and, possibly, other labels. Some edge labels are only appropriate for specified types of graphs” (from section 2 of Goldberg et al., 2008).²¹³ Blog Collector is a module accessing blogs, one of the data sources.²¹⁴

²¹³ “The user may have communication data existing in a variety of formats. SIGHTS handles the stand-alone input of a reasonable range of these formats in order to facilitate the introduction of new data into the program. Among these is a plain-text XML format which is well-documented. SIGHTS is also able to read from a database that is constructed according to specified guidelines. Blogs data is collected from LiveJournal.com blogs service provider. The semantic graph is constructed by creating a node for each blogger and the edge between any pair of bloggers who participated in the discussion in the comments of a post.” (from section 2 of Goldberg et al., 2008).

²¹⁴ “Blogs collector monitors LiveJournal.com update feed and records the permanent address of the post. Two weeks after the date of the initial post, the blogs collector visits the page of the post and collects the thread of comments using the screen-scraping techniques. Blogs collector allows the establishment of ‘interest filters’ that can narrow the data collection to posts on a certain topic. Blogs collector provides the interface for the analyst to tag posts as interesting and not interesting that will create the training set for the interest learning program. This information is also stored in the database and is accessible to other modules of the application” (from section 2 of Goldberg et al., 2008).

The algorithm modules of SIGHTS interact with the database, retrieving from it the semantic graph and metadata, and storing in it derived data. The algorithm modules include:

- Real Time Clustering,
- Leader Identification,
- Topic Identification,
- Cycle Group Analysis,
- Stream Group Analysis.

Interactive visualisation, through which users access the output of the algorithm, accounts for:

- Size vs Density plot,
- Graph of Clusters plot,
- Group Persistence view,
- Leaders and Group Evolution view,
- interactive Graph of Overlapping Clusters.

Goldberg et al. (2008, section 2) explained:

Temporal group algorithms identify hidden groups in the stream of communications for the user specified time scales [(Baumes et al., 2006; Camptepe et al., 2005).] Noteworthy among them are the cycle model algorithms that identify all groups of users who persistently communicate over a time interval and the stream model algorithm that finds groups based on frequently communicating triples followed by merging correlated triples. Such groups usually communicate over multiple time intervals during the period of interest in a streaming fashion. Our algorithms also give the group structure hierarchy and can be modified to track evolution. An example of the evolution of a group found in the ENRON email data set is shown in

a figure comprising three graphs, which show the evolution of a part of the Enron organisational structure in the periods 2000–2002 (respectively, the graphs showed relations at Enron during September 2000–September 2001, March 2000–March 2001, and September 2001–September 2002). All three graphs represented frequent structures; and the nodes in the graph represent actors of the Enron community. Some of those nodes (*B*, *C*, *D*, *F*) were present in all three time-intervals.

In SIGHTS, there is an Opposition Identification Module. Its task is to identify “the positive and negative sentiments between pairs of bloggers based on the length and average size of the messages in the conversations that took place among them” (from section 2 of Goldberg et al., 2008). From LiveJournal.com, SIGHTS splits threads of comments into conversations between pairs of bloggers. “The module employs the Support Vector Machine classifier²¹⁵ that was trained using a data set that was manually created to determine the oppositions between bloggers using the

²¹⁵ Support vector machines are the subject of Section 6.1.9.3 in this book.

length of the conversation and the average length of the message in the conversation to determine whether bloggers opposed each other in a given conversation” (ibid.).

Bennett and Campbell (2000) provided a good introduction to *support vector machines (SVMs)*. Ingo Steinwart and Andreas Christmann published a book (2008) on support vector machines. So did Campbell and Ying (2011), whose abstract states, among the other things:

Support Vectors Machines have become a well established tool within machine learning. They work well in practice and have now been used across a wide range of applications from recognizing hand-written digits, to face identification, text categorisation, bioinformatics, and database marketing. In this book we give an introductory overview of this subject. We start with a simple Support Vector Machine for performing binary classification before considering multi-class classification and learning in the presence of noise.

An early definition of the concept was as follows: “The *support-vector network* is a new learning machine for two-group classification problems. The machine conceptually implements the following idea: input vectors are non-linearly mapped to a very high-dimension feature space. In this feature space a linear decision surface is constructed. Special properties of the decision surface ensures [*sic*] high generalization ability of the learning machine. [...] High generalization ability of support-vector networks utilizing polynomial input transformations is demonstrated” (Cortes & Vapnik, 1995, p. 173).

The Wikipedia entry²¹⁶ is usefully detailed. Here is its introduction:

Support vector machines (SVMs) are a set of related supervised learning methods that analyze data and recognize patterns, used for classification and regression analysis. The original SVM algorithm was invented by Vladimir Vapnik and the current standard incarnation (soft margin) was proposed by Corinna Cortes and Vladimir Vapnik. The standard SVM takes a set of input data and predicts, for each given input, which of two possible classes the input is a member of, which makes the SVM a non-probabilistic binary linear classifier. Since an SVM is a classifier, then given a set of training examples, each marked as belonging to one of two categories, an SVM training algorithm builds a model that assigns new examples into one category or the other. Intuitively, an SVM model is a representation of the examples as points in space, mapped so that the examples of the separate categories are divided by a clear gap that is as wide as possible. New examples are then mapped into that same space and predicted to belong to a category based on which side of the gap they fall on.

More formally, a support vector machine constructs a hyperplane or set of hyperplanes in a high or infinite dimensional space, which can be used for classification, regression, or other tasks. Intuitively, a good separation is achieved by the hyperplane that has the largest distance to the nearest training data points of any class (so-called functional margin), since in general the larger the margin the lower the generalization error of the classifier.

Whereas the original problem may be stated in a finite dimensional space, it often happens that in that space the sets to be discriminated are not linearly separable. For this reason it was proposed that the original finite dimensional space be mapped into a much higher dimensional space, presumably making the separation easier in that space. SVM schemes use a mapping into a larger space so that cross products may be computed easily in terms of the variables in the original space, making the computational load reasonable. The cross products in the larger space are defined in terms of a kernel function $K(x,y)$ selected to suit the problem. The hyperplanes in the large space are defined as the set of points whose inner

²¹⁶ http://en.wikipedia.org/wiki/Support_vector_machine (accessed in April 2011).

product with a vector in that space is constant. The vectors defining the hyperplanes can be chosen to be linear combinations with parameters α_i of images of feature vectors that occur in the data base.

6.2.1.4 Recursive Data Mining

Recursive Data Mining, is “a text mining approach that discovers patterns at varying degrees of abstraction in a hierarchical fashion. The approach allows for certain degree of approximation in matching patterns, which is necessary to capture non-trivial features in realistic datasets. Due to its nature, we call this approach *Recursive Data Mining* (RDM)” (Chaoji et al., 2010). Goldberg et al. (2008) also described a complementary set of tools, using *Recursive Data Mining* (RDM). Those tools’s task is “to identify frequent patterns in communication content such as email, blog or chat-room sessions”. The approach of Goldberg et al. (2008) “enables discovery of patterns at varying degrees of abstraction, in a hierarchical fashion, and in language independent way”. They “use RDM to distinguish among different roles played by communicators in social networks (e.g., distinguishing between leaders and members). Experiments on the Enron dataset, which categorize members into organizational roles demonstrate that use of the RDM dominant patterns improves role detection” (ibid., from the abstract). Szymanski and Zhang (2004) and Coull and Szymanski (2008) resorted to Recursive Data Mining for *masquerade detection* (within *intrusion detection* affecting computer resources)²¹⁷ and *author identification*. These are subjects investigated using various techniques by other authors (e.g., de Vel et al., 2001; Elsayed & Oard, 2006).

Goldberg et al. (2008) “used *Recursive Data Mining* (RDM) for distinguishing the roles of the communicators in a social group. In general, RDM discovers, in a recursive manner, statistically significant patterns in a stream of data. The key properties of the pattern discovery in RDM include: (i) no restriction of the size of gaps between patterns, (ii) recursive mining in which discovered patterns are replaced by the new token and the mining is repeated on the newly created string, (iii) tolerance to imperfect matching” (from section 1 of Goldberg et al., 2008).

In Recursive Data Mining, “In the first iteration, the algorithm captures statistically significant patterns from the initial sequences. The patterns obtained

²¹⁷ Greg Stocksdales of the National Security Agency Information Systems Security Organization defined *spoofing* as “Pretending to be someone else. The deliberate inducement of a user or a resource to take an incorrect action. Attempt to gain access to an AIS [i.e., Automated Information System] by pretending to be an authorized user. Impersonating, masquerading, and mimicking are forms of spoofing” (Mena, 2003, p. 429). More precisely, Stocksdales defined *mimicking* as “Synonymous with impersonation, masquerading, or spoofing” (in Mena, 2003, p. 424). Moreover, Stocksdales’ glossary also includes an entry for *mockingbird*, defined as “A computer program or process that mimics the legitimate behavior of a normal system feature (or other apparently useful function) but performs malicious activities once invoked by the user” (ibid.). *Spoofing* instead of *masquerading* sometimes occurs indeed in the terminology of the research literature. For example, Gosh et al. (2005) discussed *InFilter*, a tool whose task is “predictive ingress filtering” for the purpose of detecting *spoofed Internet Protocol (IP) traffic*.

are assigned new tokens. The initial sequences are re-written by collapsing each sequence pattern to its newly assigned token, while retaining the rest of the tokens. Next, the algorithm operates on the re-written sequences and continues to iterate through the pattern generation and sequence re-writing steps until either the sequences cannot be re-written further or a predefined number of iterations is reached.” (Chaoji et al., 2010, section 4).

Goldberg et al. (2008, section 4) introduced the algorithm shown in Fig. 6.2.1.4.1, using not just one classifier for the entire process, but a different classifier for each level of RDM abstraction. “The process starts with a sliding window of predefined length passing over the input sequence one token at a time. At each stop, patterns with all possible combinations of tokens and gaps are recorded. When pass is completed, the recorded patterns are checked for frequency of their occurrence”. In fact, not all patterns are of equal importance. “Some patterns could be either too specific to a certain text or insignificant because they contain very commonly occurring words. In either case, they are ineffective in classifying the mined text while adding to the computational cost of the algorithm. The ‘usefulness’ of a pattern is computed via a statistical significance test. A pattern is deemed significant if its frequency of occurrence (based on a unigram model) is larger than the expected number of occurrence in a random string. Patterns that are deemed insignificant are eliminated from further consideration.” (ibid.).

“At each position in the sequence, the tokens in the significant patterns are matched against the tokens in the sequence” (ibid.). A *dominant pattern* at position j in the input sequence is that pattern whose matching score is the highest, starting at location j in the sequence. The matching score is calculated using this formula:

$$\text{score}(\mathcal{P}_i, S_{o,j}) = \begin{cases} 1 & \text{if } \mathcal{P}_i = S_{o,j} \\ \epsilon & \text{if } \mathcal{P}_i = \text{GAP}, \epsilon < 1 \\ 0 & \mathcal{P}_i \neq S_{o,j} \end{cases}$$

Require: Set of sequences \mathcal{S}

Ensure: Sets of patterns (features) \mathcal{L} , one for each level

```

12: return  $\mathcal{L}$ 

```

Fig. 6.2.1.4.1 Recursive Data Mining Algorithm 1 from Goldberg et al. (2008)

“ \mathcal{P}_i is the i th token of the pattern and j is an index over sequence S . ϵ is intended to capture the notion that a match with a gap is not as good as an exact match but much better than a mismatch.” Goldberg et al. (2008) explain:

During the second pass of the sequence at level v , the sequence for level $v+1$ is formed. The sequence corresponding to a dominant pattern is replaced by the new token for this dominant pattern. Unmatched tokens are copied from sequence S_v to the new sequence S_{v+1} .

“Like most supervised learning tools, RDM has two stages of processing — training and testing. The *training phase* starts with *pattern generation*, and follows by pattern selection through the *pattern significance assessment* step.” (Chaoji et al., 2010, section 4). Goldberg et al. (2008, section 4) explain the training phase as follows:

The training phase uses the dominant patterns generated at each level to construct an ensemble of classifiers, one for each level. The classifiers can be created from any machine learning method, such as Naïve Bayes or Support Vector Machine.²¹⁸ Given a set of input sequences, along with the class labels, dominant patterns are generated for each label starting at level 0 to level *max_level*. The union of all dominant patterns at a level v across all input sequences forms the set of feature for classifier at level v . For the ensemble of classifiers, the final posterior class probability is the weighted sum of the class probabilities of individual classifiers. Each classifier is assigned a weight that reflects the confidence of the classifier. The original input sequences are further split into a new training set and a tuning set. Each classifier in the ensemble trains its model based on the new training set. The confidence value of classifier at level v , *conf* (C_v), is defined as the relative accuracy on the tuning set. The testing phase follows the training phase in terms of the level by level operating strategy. [...]

Advantages of recursive data mining include there being no length restriction on the patterns formed: “This allows arbitrary size patterns to be discovered. Most of the other published techniques work on a fixed size window” (Chaoji et al., 2010, section 1); the ability of the method to also discover approximate, (i.e., similar) patterns; and that this method is *hierarchical*, the hierarchy resulting from the *recursive* processing: “This enables us to capture patterns at various levels of abstractions. Moreover, the hierarchical nature allows us to remove noisy symbols from the stream as we move from a lower level to a higher level in the hierarchy. This ultimately leads to discovery of *long range patterns* that are separated by long noisy intermediate segments.” (ibid.).

In the Recursive Data Mining method, as explained in Chaoji et al. (2010), the total score for a pattern, starting at index j in S , is given by

$$\text{score}(\mathcal{P}, S_v[j]) = \sum_{i=1}^{|\mathcal{P}|} \text{score}(\mathcal{P}[i], S_v[j+i])$$

After the training phase, there is the testing phase. This is done level by level. Of the dominant patterns at level 0, the frequency is counted over the level 0 test sequence. This results in a vector of frequencies. It is the feature vector at level 0. Then the

²¹⁸ We have said something about support vector machines at the end of Section 6.1.2.3.

same is done at the next level. Let the level that has just been done be v . Then the next level sequence is generated, by applying the rewriting rules for dominant patterns. “This process continues till all levels of dominant patterns are exhausted. Each classifier in the ensemble classifies the test data and the final probability of class C given a sequence x is assigned based on the following weighing scheme

$$\mathbf{P}(C | x) = \sum_{i=1}^{\max_levels} \text{Conf}(C_i) \times \mathbf{P}_{C_i}(C | x)$$

where x is a test sequence and

$$\mathbf{P}_{C_i}(C | x)$$

is the posterior probability assigned by classifier C_i ” (Goldberg et al., 2008, section 4).

6.2.1.5 The Disciplinary Context: A Brief Introduction to Computer Forensics

The foregoing in the present Section 6.2.1 is concerned with *email mining*, which is a technique within *text mining*, as well as within *computer forensics*. It is not necessarily the case that AI methods are used in the analysis of computer forensic evidence. The most obvious connection would be the discovery process and the data mining techniques used for example on the Enron database of emails indeed.

Dealing with *computer crime* requires expertise in computing, of course; e.g., in *computer security*. Nevertheless, when it comes to forensic investigation once a transgression was committed or is suspected, *computer forensics* (also known as *evidential computing*, or *forensic computing*) is not confined to computer crime alone. For example, evidence from a firm’s computers may be seized so that forensic accountants examine the data.

*Computer forensics*²¹⁹ is the use of techniques that are specialised for the collection, identification, description, provision with security, retrieval, authentication, analysis, interpretation and explanation of digital information, when a case being investigated involves the use of computing or of a data carrier.²²⁰ *Digital evidence*²²¹ is any digital information that could be used as evidence in a legal case. One also speaks of *digital crime*, and *digital forensics*.

²¹⁹ *Computer forensics* = French *investigation informatique*. Throughout this book, I haven’t tried to provide equivalent terminology across languages, but let us exemplify here how terminology differs, in the case of French: unless you are told or were already aware, you could not just guess the French term correctly, based on the English term.

²²⁰ *Data carrier* = French *support d’information*.

²²¹ *Digital evidence* = French *preuve numérique*.

We have already referred previously to digital forensics. This was when we discussed, in [Section 4.3.4](#), the costs/benefits analysis of digital forensic investigations into digital crime.

The *hash value*²²² of some given digital information is generated by an algorithm applied to a file or to some logical or physical memory unit. The algorithm is such that it is impossible to modify the digital information without the hash value also being modified. If the hash value was not modified, then it is assumed that the digital information was not modified. To be on the safe side, the hash value is calculated in two different manners, especially when it comes to hard disks.

*Chain of evidence*²²³ in computer forensics is the recording of the stages of the inquiry (investigation), in order to guarantee that some given digital evidence is indisputably derived from some given digital information. The record describes how that digital information was preserved, gives its hash value, describes software and hardware used for preventing tampering (by rewriting), describes the operations carried out and the software employed, informs about incidents and especially about any modification of the digital information being analysed, lists the items of evidence collected, and provides the series numbers of the data carriers used for recording such evidence. For such a record to be a judicial document (which includes the inquiry documents of an examining magistrate), e.g., in France, it is necessary that the chain of evidence be requested by some judicial authority, and that it be accompanied by a chain of custody.

The *chain of custody*²²⁴ is a report or notes of the proceedings of the seizure or reception of some give digital information and of its support. It contains information about who had detained it previously (an owner, or user, or custodian), about the place and circumstances of this digital information being obtained, retrieved or transmitted, about the data carrier (including a physical description with a photograph, as well as the series number), and possibly a description consisting of metadata, the data structure, and the hash value. The chain of custody also specifies whether the data are accessible or otherwise, and whether there is a seal (with its identification). Also included are information about accompanying documents, the dates when the data carrier was opened and closed, mentions of any modification that has occurred (such as the suppression of a password), a description of how (if such is the case) the data carrier was returned (in terms of accessibility to data, to whether a label was applied, or to any seal). Also a photograph is included.

A *forensic copy*²²⁵ is a whole copy, bit by bit, of digital information present on a data carrier, including blank spaces, precluded areas, and queues. The software used in order to obtain the forensic copy is specified. The forensic copy must have the same hash value as the original of which it is the copy; otherwise, the chain of evidence must specify the reasons for difformity.

²²² *Hash value* = French *empreinte numerique*, or *valeur de hachage*.

²²³ *Chain of evidence* = French *rapport d'investigation*.

²²⁴ *Chain of custody* = French *rapport de garde*.

²²⁵ *Forensic copy* = French *copie-image*.

*Forensic computing*²²⁶ is the subject of a book by Sammes and Jenkinson (2000) which deals with data security, but especially shows how information held in computer systems (that possibly was deliberately hidden, or then, subverted, for criminal purposes) can be recovered in such a way that its integrity cannot be challenged, legal issues associated with computer-generated evidence, and practices required to ensure its admissibility. A more recent book is Carrier's (2005) *File System Forensic Analysis*.²²⁷ London-based Overill (2009) discussed the development of Master's modules in computer forensics and cybercrime for computer science forensic science students.²²⁸

A distinction has been made, in the literature, between *computer* and *digital forensics*. The name *digital anti-forensics* has been given at least as early as Shirani (2002) – and apparently made popular following an article by Harris (2006) of Purdue University²²⁹ (cf. Rogers, 2005, also from Purdue) – to strategies to evade computer forensic investigations, as well as ways to exploit critical failures in computer forensics software or in the reliability of computer security systems. Harris wrote (2006, pp. S44–S45):

Currently there is no unified definition for anti-forensics. This is not surprising however, since it is a relatively unexplored field. Several definitions are available and each has its own relative merits. Some of those definitions look only at specific segments of anti-forensics. Some have seen anti-forensics as simply breaking tools or avoiding detection (Foster and Liu, 2005) while others have only related anti-forensics to system intrusions (Shirani, 2002). [...]“Peron and Legary pinpoint anti-forensics as the attempt to “limit the identification, collection, collation and validation of electronic data” so that the crime investigation is hindered (Peron and Legary, 2005). This definition is not complete however, since it disregards the analysis of the evidence. Evidence analysis is essential to the forensic process; therefore, we must include it if we list each phase in our definition. Another definition by Grugq identifies antiforensics as “attempting to limit the quantity and quality of forensic evidence” (Grugq, 2005). This definition is useful as well, but it only considers the evidence and completely ignores the forensic process. If we combine Grugq's ideas with those of Peron and Legary, we can arrive at a concise yet precise definition of anti-forensics. In this paper, we will consider anti-forensics to *be any attempts to compromise the availability or usefulness of evidence to the forensics process*. Compromising evidence availability includes any attempts to prevent evidence from existing, hiding existing evidence or otherwise manipulating evidence to ensure that it is no longer within reach of the investigator. Usefulness maybe compromised by obliterating the evidence itself or by destroying its integrity.

²²⁶ Kruse and Heiser (2002) is a book on computer forensics. As we couldn't delve, here, in computer forensics any further, we confined ourselves to just providing a few definitions, that were loosely adapted from Lerti (2006). Handling digital evidence in relation to computer crime is the topic of Casey (2000 [new edn., 2004], 2001) and Kanellis et al. (2006). McHugh (2001) provides a historical and methodological overview of intrusion detection in computer security.

²²⁷ Cf. Carrier & Spafford's article (2004) “Event reconstruction of digital crime scenes”.

²²⁸ Of course, the literature about *digital forensics* is vast. For example, Goel et al. (2005) discussed *Forensix*, a reconstruction system. Tang and Daniels (2005) discussed a framework for *distributed forensics*.

²²⁹ I owe Dr. Jeimy Cano the information that the name *digital anti-forensics* has been in use (at least) since 2006, following an article at a conference by Harris (2006). Actually, the conference was at West Lafayette, Indiana, where Ryan Harris was based, pursuing a MS in information security from Purdue University.

Harris (2006, p. S45) enumerated four kinds of anti-forensic activities, namely, *evidence destruction*, *evidence source elimination*, *evidence hiding*, and *evidence counterfeiting*. Harris (ibid., table 1) classified common antiforensic methods as follows. *MACE alterations* involve destroying (“Erasing MACE information or overwriting with useless data”),²³⁰ or counterfeiting (“Overwriting with data which provides misleading information to investigators”). *Removing/wiping files* involves destroying (“Overwriting contents with useless data”), or hiding: “Deleting file (overwriting pointer to content)”. *Data encapsulation* involves hiding: “Hiding by placing files inside other files”. *Account hijacking* involves counterfeiting: “Evidence is created to make it appear as if another person did the ‘bad act’”. *Archive/image bombs* involve counterfeiting: “Evidence is created to attempt to compromise the analysis of an image”. In *disabling logs*, what is involved is source elimination: “Information about activities is never recorded”.

While trying to suggest countermeasures, Harris recognised that the *human element* is likely to be the most difficult to handle. Harris (2006, p. S47, table 2) listed the following exploits of the various anti-forensic actions. For *MACE alteration*, the human element is: “Investigator may assume accuracy of dates and times”. For *removing/wiping files*, the human element is: “Investigator may fail to examine deleted files”. For *account hijacking*, the human element is: “Investigator may fail to consider whether the owner of the account was actually the person at the keyboard”. Harris listed no human element for *archive/image bombs*. For *disabling logs*, he gave this human element: “Investigator may not notice missing log records”.

In the next column in the table, Harris listed the forms that the *tool dependence element* takes in the various anti-forensic activities. For *MACE alteration*, the tool dependence element is: “Tools may not function with invalid or missing dates or times”. For *removing/wiping files*, the tool dependence element is: “Methods of restoring deleted files are specific to the tool — so effectiveness may vary”. For *account hijacking*, the tool dependence element is: “Tool may not be capable of extracting information that would aid investigator in determining who was in control of the account”. For *archive/image bombs*, the tool dependence element is: “Improperly designed software may crash”. For *disabling logs*, he gave this tool dependence element: “Software may not flag events that indicate logging was disabled”.

In the third and last column in the table, Harris listed the forms that the *physical/logical limitations element* takes in the various anti-forensic activities. For *MACE alteration*, the element of physical or logical limitations is: “Invalid dates and times make collating information from multiple evidentiary sources difficult or

²³⁰ The New Technology File System (NTFS) is a file system developed and introduced by Microsoft in 1995 with Windows NT. As a replacement for the FAT file system, it quickly became the standard for Windows 2000, Windows XP and Windows Server 2003. NTFS keeps track of lots of *time stamps*. Each file has a time stamp for “Create”, “Modify”, “Access”, and “Entry Modified”. The latter refers to the time when the MFT entry itself was modified. These four values are commonly abbreviated as the *MACE values*. Other attributes in each NFT record may also contain timestamps that are of forensic value.

impossible”. For *removing/wiping files*, the element of physical or logical limitations is: “Time required to restore wiped file contents may outweigh the evidentiary value of the data it contained”. For *account hijacking*, the element of physical or logical limitations is: “Zombied computer accounts may produce so much indirection that it is almost impossible to actually find the origin of an attack. Lack of detailed information may keep investigator from determining actual account user”. For *archive/image bombs*, the element of physical or logical limitations is: “Useful information might be located in the bomb itself, but outside the logical limitations of the investigator’s system”. For *disabling logs*, he gave this element of physical or logical limitations: “Missing data may be impossible to reconstruct”.

Insecurity governance or *insecurity management* is a branch of information technology concerned with how to respond, on an organisational level, to threats to computer security. *Multimedia forensics* is specifically concerned with uncovering perpetrators of piracy targeting protected digital content or encrypted applications. Typically, perpetration consists of unauthorised music and movie copying, either for private use or for selling pirated copies, thus eating a big bite of the profit of the record industry and the movie studios. Chang-Tsun Li (of the University of Warwick, England), has published a book (Li, 2008) on state-of-the-art *pirate tracking software*. A particular technique, *traitor tracing*, can be applied to multimedia forensics, but the term has previously been used also in the literature about cryptography.

6.2.1.6 Digital Steganography

In Section 8.2.5, we are going to concern ourselves with *digital image forensics*, which consists of computational methods of detection of image tampering. It is worthwhile to also mention another discipline: *digital steganalysis* is a forensic activity within *digital steganography*, which itself also comprises the deeds of perpetrators, not only the attempts by investigators to uncover those deeds. “*Steganography* is the art and science of writing hidden messages in such a way that no one, apart from the sender and intended recipient, suspects the existence of the message”.²³¹ *Steganography* also denotes a particular system of ascribing or claiming to decipher hidden messages.

The history of secret writings is the subject of Kahn (1967, 2nd edn., 1996). Steganographies were associated with mysticism and occult studies in the early modern period, and particularly, with claims in the writings of the German abbot

²³¹ <http://en.wikipedia.org/wiki/Steganography> “Generally, messages will appear to be something else: images, articles, shopping lists, or some other *covert* and, classically, the hidden message may be in invisible ink between the visible lines of a private letter. The advantage of steganography, over cryptography alone, is that messages do not attract attention to themselves. Plainly visible encrypted messages — no matter how unbreakable — will arouse suspicion, and may in themselves be incriminating in countries where encryption is illegal. Therefore, whereas cryptography protects the contents of a message, steganography can be said to protect both messages and communicating parties.” (ibid.).

Johannes Trithemius (1462–1516),²³² discussed by Noel Brann (1981, 1999, 2006), Arnold (1971, 2nd edn. in 1991), David Kahn (1967, 2nd edn. 1996), Umberto Eco (1995, in one of the sections of his chapter 6), and Walker (1958, pp. 86–90). Later early modern steganographers included Giovambattista della Porta (in his *De furtivis litterarum notis*, of 1563), Blaise de Vigenère (in his *Traité des chiffres*, of 1587), and Gustavus Selenus (in his *Cryptometrices et cryptographjiae libri IX*, of 1624).²³³

Regardless of that cultural context, generally speaking:

Steganography has been used throughout history for secret communications. Criminals have always sought ways to conceal their activity in real, or physical space. The same is true in virtual, or cyber space. Digital steganography represents a particularly significant threat today because of the large number of digital steganography applications freely available on the Internet that can be used to hide any digital file inside of another digital file. Use of these applications, which are both easy to obtain and simple to use, allows criminals to conceal their activities in cyber space. In fact, the NIJ Guide for Electronic Crime Scene Investigation for First Responders²³⁴ states that potential digital evidence in child abuse, child exploitation, and terrorism investigations includes information regarding steganography. Thus, steganography presents a significant challenge to those who investigate it because detecting hidden information and then extracting that information is very difficult and may be impossible in some cases.²³⁵

²³² “Until 1499 Trithemius’ reputation rested primarily on his monastic, mystical and humanist writings. Then, in that year, his magical notoriety burst onto the historical stage like a lightning bolt, signaled by a 1499 letter to a Carmelite friend, Arnold Bostius (1445–1499), announcing the birth of the art of steganography, a form of cryptography ostensibly invoking angels for the conveyance of secret messages. Far from having himself invented the art therein described, Trithemius assured Bostius, he had been instructed in its principles through a divine revelation. Inasmuch as the intended recipient had deceased prior to the letter’s arrival, the prior of his cloister gained access to its contents and, aghast at what he therein encountered, instigated the abbot’s necromantic legend. If the unforeseen disclosure of the Bostius epistle can be said to have delivered the first serious blow to Trithemius’s reputation, a second severe blow was inflicted in the following decade by the French scholar Carolus Bovillus (c. 1479–1553), who, following a 1503 Sponheim visit in which he was given access to the partially completed *Steganographia*, condemned its author in a widely circulated letter as a diabolically inspired sorcerer” (Brann, 2006, p. 1136).

²³³ Of Trithemius’ Latin treatise *Steganographia, hoc est, ars per occultam scripturam animi sui voluntatem absentibus aperiendi certa*, published in Frankfurt on the Main “ex officina typographica Matthiae Beckeri, sumptibus Joannis Berneri”, in 1605, 1608, and 1621, there exists a partial English edition: *The Steganographia of Johannes Trithemius*, edited by Adam McLean, and translated by Fiona Tait, Christopher Upton and J. W. H. Walden. It was published in 1982 in Edinburgh, Scotland, in the *Magnum Opus Hermetic Sourceworks*.

²³⁴ Generally speaking, concerning *first responding officers*, also called *first responders* (which strictly speaking is a broader category, as sometimes the earliest responders are members of the public), Miller (2003) writes: “The first responders at a crime scene are usually police officers, fire department personnel or emergency medical personnel. They are the only people who view the crime scene in its original condition. Their actions at the crime scene provide the basis for the successful or unsuccessful resolution of the investigation. They must perform their duties and remember that they begin the process that links victims to suspects to crime scenes and must never destroy the links” (ibid., p. 118).

²³⁵ From <http://www.sarc-wv.com/> This is the address of the site of the Steganography Analysis and Research Center within Backbone Security.

In fact:

Steganography includes the concealment of information within computer files. In digital steganography, electronic communications may include steganographic coding inside of a transport layer, such as a document file, image file, program or protocol. Media files are ideal for steganographic transmission because of their large size. As a simple example, a sender might start with an innocuous image file and adjust the color of every 100th pixel to correspond to a letter in the alphabet, a change so subtle that someone not specifically looking for it is unlikely to notice it.²³⁶

Applications of digital steganography include the following²³⁷:

- Concealing messages within the lowest bits of noisy images or sound files.
- Concealing data within encrypted data or within random data. The data to be concealed is first encrypted before being used to overwrite part of a much larger block of encrypted data or a block of random data (an unbreakable cipher like the one-time pad generates ciphertexts that look perfectly random if you don't have the private key).
- Chaffing and winnowing.²³⁸

²³⁶ <http://en.wikipedia.org/wiki/Steganography>

²³⁷ From <http://www.sarc-wv.com/> This is the address of the site of the Steganography Analysis and Research Center within Backbone Security.

²³⁸ See http://en.wikipedia.org/wiki/Chaffing_and_winnowing “*Chaffing and winnowing* is a cryptographic technique to achieve confidentiality without using encryption when sending data over an insecure channel. The name is derived from agriculture: after grain has been harvested and threshed, it remains mixed together with inedible fibrous chaff. The chaff and grain are then separated by winnowing, and the chaff is discarded. The technique was conceived by Ron Rivest. Although it bears similarities to both traditional encryption and steganography, it cannot be classified under either category. This technique is remarkable compared to ordinary encryption methods because it allows the sender to deny responsibility for encrypting their message. When using chaffing and winnowing, the sender transmits the message unencrypted, in clear text. Although the sender and the receiver share a secret key, they use it only for authentication. However, a third party can make their communication confidential by simultaneously sending specially crafted messages through the same channel.” An explanation of the workings (on which, variations exist) follows hereby (ibid.): “The sender (Alice) wants to send a message to the receiver (Bob). In the simplest setup, Alice enumerates the bits in her message and sends out each bit in a separate packet. Each packet contains the bit’s serial number in the message, the bit itself (both unencrypted), and a message authentication code (MAC) whose secret key Alice shares with Bob. Charles, who transmits Alice’s packets to Bob, interleaves the packets with corresponding bogus packets (called ‘chaff’) with corresponding serial numbers, the bits inverted, and a random number in place of the MAC. Charles does not need to know the key to do that. Bob uses the MAC to find the authentic messages and drops the ‘chaff’ messages. This process is called ‘winnowing’. Eve, an eavesdropper located between Alice and Charles, can easily read Alice’s message. But an eavesdropper between Charles and Bob would have to tell which packets are bogus and which are real (i.e., to *winnow*, or ‘separate the wheat from the chaff’). That is infeasible if the MAC used is secure and Charles does not leak any information on packet authenticity (e.g., via timing). When an adversary requires Alice to disclose her secret key, she can defend with the argument that she used the key merely for authentication and did not intend to make the message confidential. If the adversary cannot force Alice to disclose an authentication key (which knowledge would enable the adversary to forge messages from Alice), then her messages will remain confidential. On the other hand, Charles does not even possess any secret keys that he could be ordered to disclose.”

- Mimic functions convert one file to have the statistical profile of another. This can thwart statistical methods that help brute-force attacks identify the right solution in a ciphertext-only attack.
- Concealed messages in tampered executable files, exploiting redundancy in the i386 instruction set.
- Pictures embedded in video material (optionally played at slower or faster speed).
- Injecting imperceptible delays to packets sent over the network from the keyboard. Delays in keypresses in some applications (telnet or remote desktop software) can mean a delay in packets, and the delays in the packets can be used to encode data.
- Content-Aware Steganography hides information in the semantics a human user assigns to a datagram. These systems offer security against a non-human adversary/warden.
- Blog-Steganography. Messages are fractionalized and the (encrypted) pieces are added as comments of orphaned web-logs (or pin boards on social network platforms). In this case the selection of blogs is the symmetric key that sender and recipient are using; the carrier of the hidden message is the whole blogosphere.

Moreover, one also speaks of *network steganography* (“All information hiding techniques that may be used to exchange steganograms in telecommunication networks can be classified under the general term of network steganography”),²³⁹ and of *printed steganography* (as the output of digital steganography may be in the form of printed documents): when using printed steganography, “A message, the *plaintext*, may be first encrypted by traditional means, producing a *ciphertext*. Then, an innocuous *covertext* is modified in some way so as to contain the ciphertext, resulting in the *stegotext*.”²⁴⁰

The ciphertext produced by most digital steganography methods, however, is not printable. Traditional digital methods rely on perturbing noise in the channel file to hide the message, as such, the channel file must be transmitted to the recipient with no additional noise from the transmission. Printing introduces much noise in the ciphertext, generally rendering the message unrecoverable. There are techniques that address this limitation, one notable example is ASCII Art Steganography.²⁴¹

One sometimes talks about *fingerprints*, and a *fingerprint vault scheme*, in digital steganography: see Li, Niu, Wang, Jiao, and Sun (2005).

6.2.1.7 Digital Forensics and Bayesian Networks

Bayesian networks have been applied to the evaluation of evidence in digital forensic investigations (Kwan, Chow, Law, & Lai, 2008).²⁴² Moreover, Overill et al.

²³⁹ <http://en.wikipedia.org/wiki/Steganography> “Contrary to the typical steganographic methods which utilize digital media (images, audio and video files) as a cover for hidden data, network steganography utilizes communication protocols’ control elements and their basic intrinsic functionality. As a result, such methods are harder to detect and eliminate” (ibid.).

²⁴⁰ <http://en.wikipedia.org/wiki/Steganography>

²⁴¹ <http://en.wikipedia.org/wiki/Steganography>

²⁴² Halliwell et al. (2003) built upon the application of Bayesian networks (BNs) to inferring the probability of defence and prosecution statements based on forensic evidence. Halliwell et al.

(2010b) have developed a *sensitivity analysis* for such an application. “A Bayesian network representing an actual prosecuted case of illegal file sharing over a peer-to-peer network has been subjected to a systematic and rigorous sensitivity analysis. Our results demonstrate that such networks are usefully insensitive both to the occurrence of missing evidential traces and to the choice of conditional evidential probabilities” (ibid., from the abstract). The study concerns a court case tried in Hong Kong, “involving the use of a BitTorrent (BT) peer-to-peer (P2P) network to act as the initial ‘seeder’ for illegally uploading a copyright protected audio-visual file for subsequent distribution was constructed and examined. In Hong Kong only the uploading of copyright protected material is prohibited whereas in the UK any activity infringing copyright is forbidden” (ibid., section 1). In order to carry out the sensitivity analysis, Overill et al. (2010b) proceeded as follows:

We have systematically replaced the aggregated likelihoods from the original survey [(Kwan et al., 2008)] by the minimum and maximum values of the responses provided by the sample of 31 expert digital forensic investigators. We have removed ‘outlier’ values from this sample by discounting any single response lying at either extreme of the range. [...] In addition, we have simultaneously set all the likelihoods to their respective minimum and maximum values in turn.

It was claimed that the Bayesian network in the study for which the sensitivity analysis was carried out “is insensitive to the occurrence of missing evidence and also to the choice of evidential likelihoods to an unexpected degree.” Overill, Silomon, and Chow (2010a) conceded that in extreme cases of missing evidential traces, much lower probabilities for the investigative hypothesis were found.

It must be said however that even with the sensitivity analysis, the Bayesian-skeptic general critique of Bayesian methods in a judicial contexts is not assuaged at all. The sensitivity analysis is to the satisfaction of statisticians, but this by itself does not prove that Bayesianism is safe for evaluating evidence in criminal cases, other than in the relatively harmless application to having the prosecutor assess whether to prosecute.

Potentially, and if taken per se, more interesting also for the Bayesian skeptics is another method from that same team, which tries to calculate *operational complexity* (Overill, Silomon, & Chow, 2010a). The very idea is tantalising, and a proper definition may satisfy perhaps also the Bayesian skeptics.

Nevertheless, the way Overill, Silomon, and Chow (2010a) defined and employed it, operational complexity is applied to the quantification of forensic evidential probabilities: “From the complexity of formation of a set of traces via a

(2003) noted: “This is an important development as it helps to quantify the meaning of forensic expert testimony during court proceedings, for example, that there is ‘strong support’ for the defence or prosecution position. Due to the lack of experimental data, inferred probabilities often rely on subjective probabilities provided by experts. Because these are based on informed guesses, it is very difficult to express them accurately with precise numbers. Yet, conventional BNs can only employ probabilities expressed as real numbers.” (ibid., p. 42). This is oblivious to the critique of Bayesianism in law (see Sections 2.4 and 5.1 in this book). Halliwell et al. (2003) introduced an extension of probability theory, allowing to express *subjective probabilities* as *fuzzy numbers*.

specified route a measure of the probability of that route can be determined. By determining the complexities of alternative routes leading to the formation of the same set of traces, the odds indicating the relative plausibility of the alternative routes can be found” (ibid., from the abstract). Overill, Silomon, and Chow (2010a) exemplified this method of their by applying in the context of a digital forensic examination. The court case taken as a real case study is still the same that was tried in Hong Kong, about BitTorrent and the illegal upload of a copyright protected audio-visual file.

The *operational complexity model* (OCM) is described as follows:

The various *feasible routes* by which the recovered set of digital evidential traces could have been formed are first enumerated. For each feasible route k by which the set of digital evidential traces $\{E_i\}$ could have been formed the operational complexity of that route is given by:

$$C_k = KLM_k + CC_k$$

C_k is the operational complexity of each feasible route k . It is a measure which “comprises a cognitive complexity component specified by the GOMS-KLM model²⁴³ [(Kieras, 2001)] and a suitably defined computational complexity (CC) [(Papadimitriou, 1994)] component.” C_k is inversely related to p_k , i.e., its probability of occurrence:

The constant of proportionality is determined uniquely by the normalization condition on the sum of the probabilities over all feasible routes k :

$$p_k \propto C_k^{-1}$$

The constant of proportionality α reflects the units in which the complexity of each of the feasible routes k is measured, and is given by:

$$\sum p_k = 1$$

It should be noted here that while the OCM model makes use of a complexity metric it is not based on Shannon information theory [(Shannon & Weaver, 1949)], which would lead to an inverse exponential relation:

$$\alpha = (\sum C_k^{-1})^{-1}$$

Let $\{E_i\}$ be a recovered set of digital evidential traces. Let H_k be the hypothesis that feasible route k was taken. Overill, Silomon, and Chow (2010a) combined their definitions as given above, with probabilistic calculations. The *posterior probability* of a feasible route k leading to the formation of $\{E_i\}$ is given by

²⁴³ The GOMS (Goals, Operators, Methods, Selections) family of models of *cognitive complexity* includes the GOMS Keyboard-Level Model (KLM), developed by Kieras (2001), and which provides a tractable means of measuring human involvement in the operational process.

$$\Pr(H_k|\{E_i\})$$

The *posterior odds* for two alternative routes k and k' leading to the formation of the same recovered set of digital evidential traces $\{E_i\}$ is then given by:

$$O(k:k') = \Pr(H_k|\{E_i\}) / \Pr(H_{k'}|\{E_i\})$$

Note that the odds are independent of the constant of proportionality since α appears linearly in both the numerator and the denominator.

In a digital forensics context, if H_k represents the prosecution's contention regarding the formation of $\{E_i\}$ and $H_{k'}$ is the defence's alternative contention, then the odds $O(k:k')$ provide a measure of the relative plausibility of the two competing hypotheses. More generally, if a total of n feasible routes are identified which are each capable of leading to the formation of the set of recovered traces, then the odds that feasible route k was taken are given by:

$$O(k) = \Pr(H_k|\{E_i\}) / \Pr(H_k^c|\{E_i\})$$

where H_k^c is the hypothesis that feasible route k was *not* taken, and involves summing the individual probabilities of the remaining $n-1$ feasible routes.

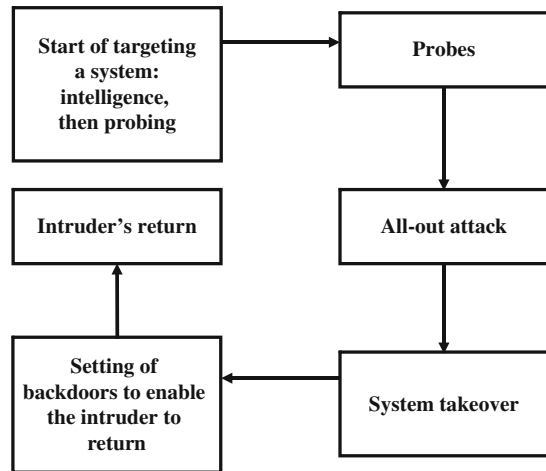

6.2.1.8 Intrusion Detection in Computer Resources A Glimpse of an Intruder's Modus Operandi

One of the areas of *computer forensics* is *intrusion detection*.²⁴⁴ “An intrusion is when a hacker attempts to break into or misuse a computer system, Web site, or network. Yet another way to define an intrusion is any set of actions that attempt to compromise the integrity, confidentiality, or availability of a computer resource” (Mena, 2003, p. 301). “There are two types of potential intruders, the outside hacker and the inside one. Remarkably, FBI studies have revealed that 80% of intrusions and attacks come from within organizations” (Mena, 2003, p. 302). In the rest of Section 6.2.1, we are only going to discuss the subject selectively.

Mena (2003, section 10.2, pp. 302–309) provides an articulate, detailed description of the likely *modus operandi* of a hacker intent on intruding into a target system. See Fig. 6.2.1.8.1. Mena's description of the *intelligence* stage an intruder would carry out, enumerates such Web resources that the hacker may use in order to learn about the structure of a firm or organisation, and in order to detect possible openings for an intrusion. For example, security at the networks and webpages of the new acquisitions of a company are likely to lag behind the security at parent company. A distributed database, the *Domain Name Service (DNS)*, mapping addresses and hostnames to each other, may be configured insecurely, and then an attacker may

²⁴⁴ John McHugh (2001) provides a historical and methodological overview of intrusion detection in computer security.

Fig. 6.2.1.8.1 Stages in the *modus operandi* of an intentional system intrusion (based on text in Mena, 2003, pp. 302–303)

learn addresses, and then the map of the internal network of the firm or organisation that the attacker is targeting.

It is at the next stage, *scanning*, that the intruder may use automated discovery tools in order to carry out *ping sweeps* (sending *ping* requests, i.e., checks whether a system is alive, massively in parallel), and *port scans* (which may be done, e.g., by using a tool called *Nmap*, which determines which type of operating system a target computer is using).

At the next stage, *probing*, “an attacker will attempt to identify user accounts, network resources, users and groups, file-sharing lists, and applications” (Mena, 2003, p. 306). Mena explains which utilities an intruder may use for probing, on different operating systems. The next stage is attack, and Mena (*ibid.*, p. 307) explains which utilities on different operating systems an intruder may use in order in order to eavesdrop for passwords, and would then break in.

At the next stage, the intruder would try to take *control* of the system. Mena (*ibid.*, p. 307) explains which utilities an intruder would use in order to gain *administrator privileges*. And finally, the intruder would set *trapdoors*, “to secure privileged access, and enabling return”, Mena explains (*ibid.*, p. 308), proceeding to enumerate which tools a cybercriminal would be use at this last stage. For example, *netcat*, a tool for network debugging and exploration, “reads and writes data across network connections”, is used “for planting remote-control, services”, and “can create almost any kind of connection a perpetrator needs” (*ibid.*).²⁴⁵

²⁴⁵ The research literature about *intrusion detection* is vast. See, e.g., e volume edited by Kreibich and Jahnke (2010).

6.2.1.9 A Classification of Intrusion Detection Systems

Intrusion detection systems (IDS) try to automatically detect break-ins, but also “a legitimate user misusing system resources” (Mena, 2003, p. 311). Coull, Branch, Szymanski, and Breimer pointed out (2003, p. 24):

Standard security deployments such as firewalls, patched operating systems and password protection are limited in their effectiveness because of the evolving sophistication of intrusion methods and their increasing ability to break through entry points of a guarded infrastructure [...]. An intrusion detection system (IDS) addresses the layer of security following the failure of the prior devices. This layer usually monitors any number of data sources (i.e., audit logs, keystrokes, network traffic) for signs of inappropriate or anomalous behavior. Since attacks occurring at this level are sophisticated enough to bypass entry point protection, advanced algorithms and frameworks for detection are required to prevent total subversion of critical resources. While no computer or network is entirely secure, intrusion detection is essential for any computer-based infrastructure, in which the value of its assets draws the attention of potential attackers.

Patterns of detection include *misuse intrusions*, vs. *anomaly intrusions*. (One also classifies the respective tasks into *penetration identification vs. anomaly detection*.) *Anomaly intrusions* can be detected based on a profile of the system being monitored. As an example,²⁴⁶ consider Zhang, Zhu, Jeffay, Marron, and Smith (2008, p. 1):

In the context of Internet traffic anomaly detection, we will show that some outliers in a time series can be difficult to detect at one scale while they are easy to find at another scale. In this paper, we develop an outlier detection method for a time series with long range dependence, and conclude that testing outliers at multiple time scales helps to reveal them. We present a multi-resolution anomaly detection (MRAD) procedure for detecting network anomalies.

As to *misuse intrusions*, being “well-defined attacks on known weak points of a system” (Mena, 2003, p. 309), they can be detected by data mining audit-trail information, using pattern matching (ibid.). Mena (2003, p. 311) suggests to use a hybrid program, combining both approaches, that “would always be monitoring the system for potential intrusions, but would be able to ignore spurious false alarms if they resulted from legitimate user actions” (ibid.). But false negatives, i.e., ignoring intrusive activities that are not anomalous, “is far more serious than the problem of false positives”, i.e., false alarms (ibid., p. 310).²⁴⁷ *Misuse detection schemes* look for attacks “in the form of a pattern or signature²⁴⁸ so that even variations of

²⁴⁶ Also see, e.g., Perdisci et al. (2009). They described the McPAD system.

²⁴⁷ “It is not uncommon for the number of real attacks to be far below the false-alarm rate. Real attacks are often so far below the false-alarm rate that they are often missed and ignored” (http://en.wikipedia.org/wiki/Intrusion_detection_system).

²⁴⁸ A *signature* is string of information that an intrusion detection sensor looks for in a packet sent through the network, and if the string matches the signature, then it is detected as an event in an intrusion detection context. Packets are small manageable pieces into which the data is broken up, so it could be sent through a network. A *signature-based intrusion-detection system (IDS)* “monitors packets in the Network and compares with preconfigured and predetermined attack patterns known as signatures. The issue is that there will be lag between the new threat discovered and Signature being applied in IDS for detecting the threat. During this lag time your IDS will

the same attack can be detected”, but, “not unlike virus detection systems — they can detect many or all known attack patterns, but are of little use for as yet unknown attack methods” (ibid.). *Anomaly detection* tends to rely on techniques from artificial intelligence²⁴⁹:

An *Anomaly-Based Intrusion Detection System* is a system for detecting computer intrusions and misuse by monitoring system activity and classifying it as either *normal* or *anomalous*. The classification is based on *heuristics* or rules, rather than patterns or *signatures*, and will detect any type of misuse that falls out of normal system operation. This is as opposed to signature based systems which can only detect attacks for which a signature has previously been created.

In order to determine what is attack traffic, the system must be taught to recognize normal system activity. This can be accomplished in several ways, most often with *artificial intelligence* type techniques. Systems using *neural networks* have been used to great effect. Another method is to define what normal usage of the system comprises using a strict mathematical model, and flag any deviation from this as an attack. This is known as strict anomaly detection.

Anomaly-based Intrusion Detection does have some short-comings, namely a high false positive rate and the ability to be fooled by a correctly delivered attack. Attempts have been made to address these issues through techniques used by PAYL and MCPAD.

Apart from *misuse IDSs*²⁵⁰ and *anomaly IDSs*,²⁵¹ there also exist a different criterion of classification: *host-based IDS*,²⁵² also known as *event log viewer*, carrying out monitoring for suspicious activity by checking event logs from multiple

be unable to identify the threat” (http://en.wikipedia.org/wiki/Intrusion_detection_system). “Many attacks are geared for specific versions of software that are usually outdated. A constantly changing library of signatures is needed to mitigate threats. Outdated signature databases can leave the IDS vulnerable to new strategies” (ibid.).

²⁴⁹ http://en.wikipedia.org/wiki/Anomaly-based_intrusion_detection_system

²⁵⁰ *Misuse detection* is the subject of, e.g., Kinder et al. (2005) and Meier et al. (2005).

²⁵¹ *Anomaly detection* within intrusion detection is the subject of, e.g., Valeur et al. (2005); Latendresse (2005); Agbaria and Friedman (2005). The research literature about this subject is vast. Bear in mind however that *anomaly detection* is a broader subject, as the more general topic looms large in *data mining* research. “*Anomaly detection*, also referred to as *outlier detection*, refers to detecting patterns in a given data set that do not conform to an established normal behavior. The patterns thus detected are called anomalies and often translate to critical and actionable information in several application domains. Anomalies are also referred to as *outliers*, surprise, aberrant, deviation, peculiarity, etc. Three broad categories of anomaly detection techniques exist. Supervised anomaly detection techniques learn a classifier using labeled instances belonging to normal and anomaly class, and then assign a normal or anomalous label to a test instance. Semi-supervised anomaly detection techniques construct a model representing normal behavior from a given normal training data set, and then test the likelihood of a test instance to be generated by the learnt model. Unsupervised anomaly detection techniques detect anomalies in an unlabeled test data set under the assumption that majority of the instances in the data set are normal” (http://en.wikipedia.org/wiki/Anomaly_detection). As to computer security: “Anomaly detection for IDS is normally accomplished with thresholds and statistics, but can also be done with *soft computing* [i.e., neural, genetic, or fuzzy techniques], and inductive learning. Types of statistics proposed by 1999 included profiles of users, workstations, networks, remote hosts, groups of users, and programs based on frequencies, means, variances, covariances, and standard deviations” (ibid.). It was Dorothy Denning (1986) who introduced anomaly detection for intrusion detection systems.

²⁵² *Host-based intrusion detection* is the subject of, e.g., Dreger et al. (2005).

sources (Mena, 2003, p. 321). They operate in nearly real time, so “system faults are often detected quickly” (ibid.). “These host-based IDSs are ideal for detecting computer misuse from inside users or outsiders who have already infiltrated a network” (ibid.). Coull et al. explain (2003, p. 25):

Traditionally, there have been two main classes of IDSs: hostbased and network-based systems. A host-based IDS monitors the detailed activity of a particular host. Depending on the specific IDS implementation, any number of data sources can be used to search for malicious activity. Solaris Basic Security Module (BSM) provides system call traces which are typically used as datasets for host-based IDSs [²⁵³]. For instance, when an analysis of the BSM data shows signs of an intrusion, the IDS alerts the system administrator of an attack. In other implementations, hostbased systems also use such identifying information as a user’s keystrokes and command execution patterns.

By contrast, there exist *network-based IDSs*, and these monitor all network traffic. They monitor networks of computers as well as other devices, these being routers and gateways, that intruders tend to attack: “rather than using machine and process-oriented data, such as that from BSM, network-based IDSs primarily use data from network traffic in detecting intrusions.” (Coull et al., 2003, p. 25). “A network-based IDSs view is restricted to what passes over a given line” (Mena, 2003, p. 321). In particular, *tcpdump* is a popular program for capturing network traffic. It can display or store every field belonging to a TCP packet.²⁵⁴ Some IDSs are hybrids, that combine network-based and host-based intrusion-detection in the same package (Mena, 2003, p. 321).

Let us say something about the difference between intrusion detection systems (*IDS*) and *firewalls*. A firewall is a fence, without much discernment. A firewall is placed at the perimeter of a computer system.²⁵⁵ An IDS can be placed outside the firewall, in order to gather information about an attack, as well as inside a firewall, in order to check information that goes out. A firewall, once it is turned on, shuts off all communication from outside (while not blocking outgoing connections from inside the system), and then turns back on some few well-chosen items. A firewall restricts access to designated points, but cannot detect whether by other criteria

²⁵³ A document describing BSM is S.M. Inc.’s Sunshield *Basic Security Module Guide*, Solaris7 (Sun Part No. 8052635-10, October 1998).

²⁵⁴ Available via anonymous FTP from ftp.ee.lbl.gov (by V. Jacobson, C. Leres, and S. McCanne, June 1989). ICP is the Transmission Control Protocol. The Internet is based (among the other things) on this protocol.

²⁵⁵ A firewall is defined by Greg Stocksdale of the U.S. National Security Agency Information Systems security Organization as “A system or combination of systems that enforces a boundary between two or more networks. Gateway that limits access between networks in accordance with local security policy” (Mena, 2003, pp. 422–422). Stocksdale provided an example based on the UNIX operating systems: “The typical firewall is an inexpensive micro-based UNIX box kept clean of critical data, with many modems and public network ports on it, but just one carefully watched connection back to the rest of the cluster” (Mena 2003, p. 423). An *application level gateway* is defined by Stocksdale as “A firewall system in which service is provided by processes that maintain complete TCP [i.e., the Internet’s Transmission Control Protocol] connection state and sequencing. Application level firewalls often re-address traffic so that outgoing traffic appears to have originated from the firewall, rather than the internal host” (Mena 2003, p. 419).

a communication from outside going through the designated points is legitimate. More generally, a firewall cannot by itself recognise attempts to break it. A fence around premises blocks intruders from walking it, but not from climbing on the fence, or digging under the fence. It is an IDS that has the task to recognise attacks. Moreover, a firewall is at the boundary, whereas an IDS may also recognise attacks inside the system.²⁵⁶

Malicious traffic analysis is necessary not only in traditional computer networks, but also in *wireless mobile ad hoc networks (MANET)*. These have a highly dynamic topology, without infrastructure. There may be *malicious intermediate nodes* in a MANET, and these constitute a threat both to security and to anonymity. Mizanur Rahman et al. (2008) proposed RINOMO, an anonymous on-demand routing protocol for MANETs. It is purported to be robust, and to both protect anonymity, and achieve security in MANETs. In order to obtain secure communication, legitimate nodes in the network need be authenticated.²⁵⁷ Once they are authenticated, they

²⁵⁶ “Though they both relate to network security, an intrusion detection system (IDS) differs from a firewall in that a firewall looks outwardly for intrusions in order to stop them from happening. Firewalls limit access between networks to prevent intrusion and do not signal an attack from inside the network. An IDS evaluates a suspected intrusion once it has taken place and signals an alarm. An IDS also watches for attacks that originate from within a system. This is traditionally achieved by examining network communications, identifying heuristics and patterns (often known as signatures) of common computer attacks, and taking action to alert operators. A system that terminates connections is called an *intrusion prevention system*, and is another form of an *application layer firewall*” (http://en.wikipedia.org/wiki/Intrusion_detection_system).

²⁵⁷ Yu et al. (2008) discussed *biometric*-based user authentication in mobile ad hoc networks. “In high security MANETs, continuous authentication is desirable so that a system can be monitored for the duration of the session to reduce the vulnerability. Biometrics provides some possible solutions to the authentication problem in MANETs, since it has direct connection with user identity” (ibid., p. 5). They proposed to use not just one biometric technology, but *multimodal biometrics*, in order “to exploit the benefits of one biometric while mitigating the inaccuracies of another. We propose an optimal multimodal biometric-based continuous authentication scheme in MANETs” (ibid.).

“Biometrics, which refers to identifying an individual based on his or her physiological or behavioral characteristics, has the capability to reliably distinguish between an authorized person and an imposter. A biometric system can be operated in two modes: (1) verification mode and (2) identification mode (Jain et al., 2000). The former is called *person verification*, or *person authentication*. A biometric system operating in the verification mode either accepts or rejects a user’s claimed identity, while a biometric system operating in the identification mode establishes the identity of the user without any claimed identity information” (Khuwaja, 2006, pp. 23–24). Jain et al. (1999) is a book on the subject. Bromby (2010) discussed how biometrics can aid certification of digital signatures. The most mature technique for person verification, or one of the most mature, is fingerprint-based identification. Other approaches are based on “face, hand geometry, iris, retina, signature, voice print, facial thermogram hand vein, gait, ear, odor, keystroke dynamics, etc.” (Khuwaja, 2006, p. 24). For example, *iris recognition* is the subject of Li et al. (2002), Yunhong et al. (2003). *Retina recognition* is discussed by Yoichi Seto (2009).

Biometric fusion (or *information fusion in biometrics*: Ross & Jain, 2003) is “[t]he general method of improving performance via collection of multiple samples” (Rattani, Mehrotra, & Gupta, 2008, p. 485). *Multi-biometrics* is “[t]he ability to utilize multiple biometrics modalities (multimodal), instances within a modality (multi-instance), and/or algorithms (multi-algorithmic) prior to making a sepecific verification / identification or enrollment decision” (ibid.), where *enrollment* is “[t]he initial process of collecting biometric data from a user and then storing it in a template for later use” (ibid., p. 484).

can communicate by using *pseudo IDs*. The generation of pseudo IDs resorts to pairing-based cryptography. Mizanur Rahman et al. claimed (2009, p. 179):

Nodes can generate their pseudo IDs independently and dynamically without consulting with system administrator. As a result, RINOMO reduces pseudo IDs maintenance costs. Only trust-worthy nodes are allowed to take part in routing to discover a route. To ensure trustiness each node has to make authentication to its neighbors through the designed anonymous authentication process. Thus, RINOMO safely communicates between nodes without disclosing node identities. It also provides different desirable anonymous properties such as identity privacy, location privacy, route anonymity, and robustness against several attacks.

6.2.1.10 Intrusion Detection by Means of Various Learning Techniques

Some IDSs resort to neural networks, for profiling (rather than for classification), whereas some other IDSs resort to machine learning algorithms (Mena, 2003, p. 322). Mena (ibid., section 10.7, pp. 313–318) presents a case study from the MITRE corporation, of the use of data mining for intrusion detection (their Data Mining in ID project). Data mining is called for, because of data overload. “Metalearning IDSs have been developed at Columbia University. Metalearning integrates a number of different classifiers. This type of IDS benefits from a multilayered approach in which machine learning and decision procedures detect intrusions locally” (Mena, ibid., p. 323).

Various approaches within machine learning have been applied to intrusion detection.²⁵⁸ Zonghua Zhang and Hong Shen (2004) reported about the online training of *support vector machines*²⁵⁹ for real-time intrusion detection. So did Kim and Park (2003). Hu et al. (2003) applied a variant, called *robust support vector machines*, to anomaly detection in computer security.²⁶⁰ Another method in machine learning is *boosting*.²⁶¹ Webb (2000) introduced *multi-boosting*. The

²⁵⁸ In Canada, the joint editor of the *Computational Intelligence* journal, Ali Ghorbani, and his collaborators (Ren, Stakhanova, & Ghorbani, 2010) have described an online *adaptive* approach to *alert correlation*. Bear in mind that apart from *machine learning* (which is part of *artificial intelligence*), there also exist adaptive control (which is part of *systems & control*, historically a different discipline within the mathematics of engineering, concerned with the modelling of *dynamic systems*).

²⁵⁹ *Support vector machines (SVMs)* are the subject of Section 6.1.9.3 in this book.

²⁶⁰ Hu et al. (2003) presented an application *robust support vector machines (RSVMs)*, to anomaly detection over noisy data. They described as follows the advantage of RSVMs for the purposes of intrusion detection: “RSVMs effectively address the over-fitting problem introduced by the noise in the training data set. With RSVMs, the incorporation of an averaging technique in the standard support vector machines makes the decision surface smoother and controls the amount of regularization automatically [...]. Moreover, the number of support vectors of RSVMs is significantly less compared to those of standard SVMs. Therefore, RSVMs have a faster testing time” (ibid., p. 168). RSVMs were introduced by Song et al. (2002), who applied them to *bullet hole image classification*.

²⁶¹ “Boosting improves the predictive power of classifier learning systems by adjusting the weights of training instances. It manipulates the training data in order to generate different classifiers. Boosting uses all instances at each repetition, but maintains a weight for each instance in the

algorithm appeared *ibid.*, in table 4 on p. 169. “MultiBoosting can be viewed as combining AdaBoost²⁶² with wagging.²⁶³ It is able to harness both AdaBoost’s high bias and variance reduction with wagging’s superior variance reduction” (*ibid.*, p. 159). Bie, Jin, Chen, Xu, and Huang (2007) applied that approach to intrusion detection:

[T]raditional data mining based intrusion detection systems use single classifier in their detection engines. In this paper, we propose a meta learning based method for intrusion detection by MultiBoosting multi classifiers. MultiBoosting can form decision committees by combining AdaBoost with wagging. It is able to harness both AdaBoost’s high bias and variance reduction with wagging’s superior variance reduction.

Bie et al. explained (*ibid.*, p. 811):

MultiBoosting [(Webb, 2000)]²⁶⁴ can be considered as wagging (which is in turn a variant of bagging) committees formed by AdaBoost. A decision is made as to the size of sub-committees, and how many sub-committees should be formed for a single run. In the absence of an a-priori reason for selecting any specific values for those factors, MultiBoost takes a single committee size T and sets the number of subcommittees and the size of those sub-committees to square of T . Note that both these values must be whole numbers, it is necessary to round off the result. Deriving the values is achieved by setting a target final

training set that reflects its importance; adjusting the weights causes the learner to focus on different instances and so leads to different classifiers. The multiple classifiers are then combined by voting to form a composite classifier” (Stranieri & Zeleznikow, 2005b).

²⁶² “AdaBoost, short for Adaptive Boosting, is a machine learning algorithm, formulated by Yoav Freund and Robert Schapire [(1997)]. It is a meta-algorithm, and can be used in conjunction with many other learning algorithms to improve their performance. AdaBoost is adaptive in the sense that subsequent classifiers built are tweaked in favor of those instances misclassified by previous classifiers. AdaBoost is sensitive to noisy data and outliers. However in some problems it can be less susceptible to the overfitting problem than most learning algorithms. AdaBoost calls a weak classifier repeatedly in a series of rounds $t = 1, \dots, T$ from a total T classifiers. For each call a distribution of weights D_t is updated that indicates the importance of examples in the data set for the classification. On each round, the weights of each incorrectly classified example are increased (or alternatively, the weights of each correctly classified example are decreased), so that the new classifier focuses more on those examples” (<http://en.wikipedia.org/wiki/AdaBoost>).

²⁶³ Wagging is the subject of section 7.4.2.2. in Rokach and Maimon (2008). “Wagging is a variant of Bagging [Bauer and Kohavi (1999)] in which each classifier is trained on the entire training set, but each instance is stochastically assigned a weight” (*ibid.*, Rokach & Maimon’s brackets). Webb (2000, p. 161) explained wagging: “Wagging (Bauer & Kohavi, in press [1999]) is variant of bagging, that requires a base learning algorithm that can utilize training cases with differing weights. Rather than using random bootstrap samples to form the successive training sets, wagging assigns random weights to the cases in each training set. Bauer and Kohavi’s (in press [1999]) original formulation of wagging used Gaussian noise to vary the instance weights. However, this can lead to some instance weights being reduced to zero, effectively removing them from the training set. Instead, following a suggestion from J. R. Quinlan (personal communication, May 1998) the new technique uses the continuous Poisson distribution to assign random instance weights. As the assignment of instance weights by bagging can be modeled by the discrete Poisson distribution, use of the continuous Poisson distribution can be viewed as assigning instance weights using an equivalent distribution to bagging, but over a continuous rather than discrete space.”

²⁶⁴ Contrast this to the theory of *multiclass boosting* of Indraneel Mukherjee and Robert Schapire (2011).

sub-committee member index, where each member of the final committee is given an index by starting from one. Due to too great or too low error, that allows the premature termination of boosting one sub-committee to lead to an increase in the size of the next sub-committee. An additional sub-committee is added with a target of completing the full complement of committee members if the last sub-committee is prematurely terminated. When this additional sub-committee also fails to reach this target, this process is repeated, adding further sub-committees until the target total committee size is achieved.

There exist applications of machine learning also to intrusion detection in *wireless sensor networks (WSNs)*. Misra, Abraham, Obaidat, and Krishna (2009) described the LAID scheme. They applied *learning automata* for that purpose. The feedback is an *S-shaped function*: the feedback from the environment to the automaton is not crisp (completely favourable or completely unfavourable), but also any continuous value within those extremes.

6.2.1.11 Masquerading and Its Detection

Anomaly detection systems can detect previously unknown attacks, and therefore “anomaly-based systems are strongly applicable to masquerade detection” (Coull et al., 2003, p. 25). *Masquerading* is a security attack – one of the most damaging kinds of attacks indeed – “in which an intruder assumes the identity of a legitimate user. Many approaches based on Hidden Markov Models and various forms of Finite State Automata were proposed to solve this problem” (ibid., p. 24). Coull et al. explain (ibid.):

Masquerade attacks typically occur when an intruder obtains a legitimate user’s password or when a user leaves their workstation unattended without any sort of locking mechanism in place. It is difficult to detect this type of security breach at its initiation because the attacker appears to be a normal user with valid authority and privileges. This difficulty underlines the importance of equipping computer systems with the ability to distinguish masquerading attacker actions from legitimate user activities.

The detection of a masquerader relies on a user signature, a sequence of commands collected from a legitimate user. This signature is compared to the current user’s session. The underlying assumption is that the user signature captures detectable patterns in a user’s sequence of commands. A sequence of commands produced by the legitimate user should match well with patterns in the user’s signature, whereas a sequence of commands entered by a masquerader should match poorly with the user’s signature. Designing algorithms to distinguish legitimate users and masqueraders based on user signatures has been extensively studied [(Maxion & Townsend, 2002; Schonlau et al., 2001)].

In particular (Coull et al., 2003, p. 25):

A seminal work by Schonlau et al. [(2001)] analyzes the performance of various masquerade detection methods. Results showed that the method yielding the lowest number of false alarms was *uniqueness*, which had a false positive rate of 1.4%. However, it had a false-negative rate of 60.0%. Another good performer was the *Bayes one-step Markov* with a false positive rate of 6.7% and a false negative rate of 30.7%. In another paper [(Maxion & Townsend, 2002)], Maxion and Townsend analyzed the sources of error made by the detection mechanisms covered by Schonlau et al. and proposed several improved methods, among which the *Naïve Bayes with updates* yielded excellent 1.3% of false positive rate with a respectable 38.5% of false negative rate.

Coull et al. (2003) – an article from Boleslaw Szymanski’s team at Rensselaer Polytechnic Institute in Troy, NY – approaches masquerading detection by applying to that task “a new algorithm that uses pair-wise sequence alignment to characterize similarity between sequences of commands” (ibid., p. 24). “Sequence alignment has been extensively applied in the field of bioinformatics as a tool for comparing genetic material [(Gelfand, Mironov, & Pevzner, 1996; Goad & Kanehisa, 1982)]. Our algorithm, which is a unique variation of the classic Smith-Waterman algorithm [(Smith & Waterman, 1981)], uses a novel scoring scheme to construct a semi-global alignment. The algorithm produces an effective metric for distinguishing a legitimate user from a masquerader” (Coull et al., ibid.). “The novelty of our approach results from application of techniques used in bioinformatics for a pair-wise sequence alignment to compare the monitored session with the past user behavior. Our algorithm uses a semi-global alignment and a unique scoring system to measure similarity between a sequence of commands produced by a potential intruder and the user signature, which is a sequence of commands collected from a legitimate user.” (ibid.). After testing, the team found that “that the described algorithm yields a promising combination of intrusion detection rate and false positive rate, when compared to the published intrusion detection algorithms” (ibid.).

Coull et al. (2003, p. 27) explained why they chose to depart from the Smith-Waterman algorithm:

The problem with using a purely local alignment to characterize similarity between command sequences is that both a prefix and suffix can be ignored in both sequences. For intrusion detection, it is critical that we align the majority of the tested block of commands to the user’s signature. If we were to allow a large prefix and large suffix of the tested block of commands to be ignored then the intrusion itself might be ignored.

Also using a purely global alignment algorithm would have been unsuitable (Coull et al., ibid.):

The problem with using a purely global alignment is that there may be large portions of the signature that do not necessarily align with a segment of the user’s commands. Thus, we want to design a scoring system that rewards the alignment of commands in the user segment but does not necessarily penalize the misalignment of large portions of the signature.

Let *UserSig* stand for the *signature sequence*. It represents the user’s typical command behaviour. Let *IntrBlck* stand for the tested block, i.e., the block being tested for intrusion. This is the monitored command sequence, which may contain a possible subsequence of masquerader commands. “Since the *UserSig* is significantly longer than the *IntrBlck*, it is expected that most of the commands in the *UserSig* will not participate in the alignment” (Coull et al., 2003, p. 27). Coull et al. (ibid., p. 28, figure 4) modified the Smith-Waterman *local alignment algorithm*, and proposed the following *semi-global alignment algorithm*:

```
Input: string UserSig of length m,
         string IntrBlck of length n
1. Initialize a matrix, D,
   of type integer
```

```

2. for i=0 to m
3. for j=0 to n
4. if (j=0 or i=0)
5. D[i][j]=0;
6. else
7. if (j=n or i=m)
8. top=D[i][j-1];
9. left=D[i-1][j];
10. else
11. top=D[i][j-1] - gUserSig;
12. left=D[i-1][j] - gIntrBlck;
13. if (top<0) top=D[i][j-1];
14. if (left<0) left=D[i-1][j];
15. diagonal=D[i-1][j-1] +
        matchScore(UserSigi-1,
                    IntrBlckj-1);
16. D[i][j]=maximum(top, left, diagonal);
17. return D[m][n];

```

Coull et al. (2003, p. 27) explained that in the beginning, this algorithm initialises a matrix of float. This matrix is used to store the score throughout the alignment process.

Each position (i, j) in the matrix corresponds to the optimal score of an alignment ending at $UserSig_i$ and $IntrBlck_j$. This optimal score is computed by starting at the upper left corner of the matrix (i.e., at the point $(0,0)$) and then recursively making a step yielding the maximum from the three following options:

- Option 1 (diagonal step): The alignment score ending at position $(i-1, j-1)$ plus $matchScore(UserSig_i, IntrBlck_j)$, which is a penalty or reward for aligning the $UserSig$'s i th command with the $IntrBlck$'s j th command.
- Option 2 (top-down step): The alignment score ending at position $(i, j-1)$ plus $gUserSig$, which is the penalty for introducing a gap into the $UserSig$, or
- Option 3 (left-right step): The optimal score ending at position $(i-1, j)$ plus $gIntrBlck$, which is the penalty for introducing a gap into the $IntrBlck$.

If Option 1 yields the largest value, then the optimal alignment matches $UserSig_i$ with $IntrBlck_j$. If Option 2 or Option 3 yields the largest score, then the optimal alignment associates either $UserSig_i$ or $IntrBlck_j$ with a gap.

There are three essential parameters used in the scoring system. The $matchScore(UserSig_i, IntrBlck_j)$ function returns a negative value if the two commands do not match well and a positive value if they do. The $gUserSig$ and $gIntrBlck$ are negative gap penalties associated with inserting gaps into the $UserSig$ and $IntrBlck$, respectively.

This approach heavily penalises “any gaps that may be inserted into the user signature, as we do not want commands in the tested block to be aligned with gaps in the user’s signature” (Coull et al., 2003, p. 29). Eventually, a paper by Coull and Szymanski (2008) in the journal *Computational Statistics and Data*

Analysis described further progress concerning sequence alignment for masquerade detection. Their method included the algorithm for alignment, enriched with “several scoring systems, methods for accommodating variations in user behavior, and heuristics for decreasing the computational requirements of the algorithm” (ibid., p. 4116). Another paper from Szymanski’s team (Bivens, Palagiri, Smith, Szymanski, & Embrechts, 2002) applied *neural networks* to network-based intrusion detection. Another approach to intrusion detection was described by Branch, Bivens, Chan, Lee, and Szymanski (2002), from the same team: it resorted to *time dependent deterministic finite automata*.

6.2.1.12 Honeypots for Trapping Intruders

The goal of HoneyNet Project²⁶⁵ – reported about by Spitzner (2003a) – is trapping hackers, by providing them with so-called *honeypots*. Information on hackers is gathered “by deploying networks (called honeynets) around the world to be compromised” (ibid.). HoneyNet is just one out of several projects resorting to networks of honeypots. The HoneyNet Research Alliance coordinates honeynet research around the world. The seminal paper on honeypots was by Cheswick (1992),²⁶⁶ of AT&T Bell Laboratories.²⁶⁷ Cheswick’s paper began as follows:

On 7 January 1991 a cracker, believing he had discovered the famous sendmail DEBUG hole in our Internet gateway machine, attempted to obtain a copy of our password file. I sent him one. For several months we led this cracker on a merry chase in order to trace his location and learn his techniques. This paper is a chronicle of the cracker’s “successes” and disappointments, the bait and traps used to lure and detect him, and the chroot [sic] “Jail” we built to watch his activities.

Basically, *honeypots* could be any out of various computer resources, such as a computer on a network, or a password file, or an entry in a database, or an Excel spreadsheet. Typically, research into honeypots has been concerned computers in a network which are used as an information system resource, the value of that resource lying in its unauthorised or illicit use. It is a computer unused by the legitimate users of the network: they don’t know about it, so it is not involved in legitimate network traffic. The assumption is that any traffic it gets is malicious by definition, i.e., attacks. An attacker would think this is a normal computer. A log is maintained on a remote machine, of any interactions the honeypot gets. There are *low-interaction honeypots*, and *high-interaction honeypots*.²⁶⁸

²⁶⁵ Papers about the project are posted at the website of the HoneyNet Project, under the rubric “Know Your Enemy” Whitepapers (<http://www.honeynet.org/papers/>).

²⁶⁶ Honeypots are the subject of, e.g., Provos and Holz (2007), Göbel et al. (2006), Spitzner, 2002, (2003b, 2004); Oudot (2003); Oudot and Holz (2004); Dulaunoy (2010), Crandall, Wu, and Chong (2005); Pouget and Holz (2005).

²⁶⁷ By the late 2000s, Bill Cheswick was affiliated with the Department of Computer Science of Columbia University, in New York City.

²⁶⁸ The presentation in the present Section 6.2.1.12 is partly based on a nicely organised slideshow by Claire O’Shea (2005), available on the Web.

Low-interaction honeypots are simple, low-cost, and low-risk (because an attacker never enters a real system). The information obtained by this kind of honeypots is limited however, there are new types of attacks such honeypots may miss, and moreover attackers may easily detect that this is a honeypot. In a low-interaction honeypot, what an attacker interacts with is a simulated computer, and one real machine may simulate various things, such as an entire network of *virtual honeypots*.

High-interaction honeypots are real systems running real services, and these services will be compromised. Interactions will be monitored and logged in detail, so detailed information would be obtained about what an attacker did. Moreover²⁶⁹:

Honeypots can be classified based on their deployment and based on their level of involvement. Based on the deployment, honeypots may be classified as

1. Production Honeypots
2. Research Honeypots²⁷⁰

What is used is the *fishbowl* analogy. In real life, a fish swims inside a fishbowl at home, and never gets out of a fishbowl, inside which it finds various props, such as rocks and plants. In a honeypot organised like a fishbowl, a framework has been set up, that provides data logging and also security for the host, because the attacker

²⁶⁹ [http://en.wikipedia.org/wiki/Honeypot_\(computing\)](http://en.wikipedia.org/wiki/Honeypot_(computing)) At that webpage, a few types of honeypots are briefly described. For example, some honeypots are specialised as *anti-spam tools*. Moreover: “An e-mail address that is not used for any other purpose than to receive spam can also be considered a spam honeypot. Compared with the term *spamtrap*, the term ‘honeypot’ might better be reserved for systems and techniques used to detect or counter attacks and probes. Spam arrives at its destination ‘legitimately’ — exactly as non-spam e-mail would arrive” (ibid.). The Honeypot Project, which is open-source, “uses honeypot pages installed on websites around the world. These honeypot pages hand out uniquely tagged spamtrap e-mail addresses. *E-mail address harvesting* and *spammers* can then be tracked as they gather and subsequently send to these spamtrap e-mail addresses” (ibid.). Moreover, there also exist *database honeypots*: “Databases often get attacked by intruders using *SQL Injection*. Because such activities are not recognized by basic firewalls, companies often use database firewalls. Some of the available SQL database firewalls provide/support honeypot architectures to let the intruder run against a trap database while the web application still runs as usual” (ibid.).

²⁷⁰ “*Production honeypots* are easy to use, capture only limited information, and are used primarily by companies or corporations; Production honeypots are placed inside the production network with other production servers by an organization to improve their overall state of security. Normally, production honeypots are low-interaction honeypots, which are easier to deploy. They give less information about the attacks or attackers than research honeypots do. The purpose of a production honeypot is to help mitigate risk in an organization. The honeypot adds value to the security measures of an organization. *Research honeypots* are run by a volunteer, non-profit research organization or an educational institution to gather information about the motives and tactics of the *Blackhat* community [see http://en.wikipedia.org/wiki/Black_hat] targeting different networks. These honeypots do not add direct value to a specific organization. Instead they are used to research the threats organizations face, and to learn how to better protect against those threats. This information is then used to protect against those threats. Research honeypots are complex to deploy and maintain, capture extensive information, and are used primarily by research, military, or government organizations” (ibid.).

could not get out of the fishbowl into other parts of the host system. Appropriate *data control*, invisible to the attacker, should be in place to prevent harm done from inside the fishbowl to machines outside it. There is still a risk that such data control would not be successful, and that other machines in the host network would be at risk. This is a disadvantage. Inside the fishbowls, there are machines that we want the attacker to attack (setting this up effectively is difficult), so the attacker's interaction with them could be watched. This is done by *data capture*, also invisible to the attacker, and recording all of the attacker's activities while in the fishbowl. (Anything that implements data control and data capture is called a *honeynet*.) Such monitoring is time-intensive, which is a disadvantage, but a detailed profile of attack can be captured, and new types of attack can also be captured, and these are advantages. Another problem with honeypots, is that the attacker may use the honeypot for carrying out criminal activities, and the host would be blamed.

Usually, high-interaction honeypots are used for research purposes, and not for intrusion detection in operational systems, because setting up and maintaining high-interaction honeypots inside operational systems would be too expensive. Symantec's Decoy Server, as well as Honeynets, are examples of high-interaction honeypots. Most *honeypot research* is on the several ways to use a honeypot as part of a security system for the purposes of *intrusion detection and prevention*. Another use of honeypots is for *attack analysis*: by observing how attackers behave, hopefully better tools to guard against them could be developed.

Moreover, honeypots can be used as *decoys*. The host populates all unused addresses on one's network with honeypots, so the attacker would have to waste time to attack such honeypots. Automated attacks by *malware* (malicious software, especially *worms*)²⁷¹ is slowed down by decoys. As to human attackers, they are both slowed down, and annoyed, and therefore hopefully discouraged.

Another use of honeypots is as *tar pits*, also intended to slow down an attacker. A tarpit allows an attacker to open a connection, but then reduced the window size to zero. The attacker cannot get any data through, and cannot close the connection, and this uses up resources on the attacker's system. For example, a tarpit may consist of an *open email relay*, that would entice spammers because they would expect to be able to send out spam through that anonymous mail relay. The tarpit however would respond very slowly, wasting the time of spammers. Moreover, such a honeypot may pretend it forwards the mail, but actually drop it, and human spammers would be duped into thinking they had been successful, whereas automated spammers would assume success and move on.

²⁷¹ A *worm* is defined by Greg Stocksdale of the U.S. National Security Agency Information Systems security Organization as an "Independent program that replicates from machine to machine across network connections often clogging networks and information systems as it spreads" (Mena, 2003, p. 430). In contrast, a virus is "a program that can infect other programs by modifying them to include a possibly evolved copy of itself" (Stocksdale, in Mena, *ibid.*).

A major use of honeypots is as *burglar alarms*, because once the honeypots are compromised, system administrators know that an attack is going on. There has been speculation with some evidence, that based on abnormal activity on the honeypots, attacks can be detected a few days in advance.

Yet another use of honeypots is as a so-called *honeycomb*, in *automatic signature generation*. It detects patterns, and created *intrusion detection signatures* faster than with *manual signature generation*. *Honeyd* is a low-interaction honeypots, and uses the honeycomb as a plug-in.²⁷² A single machine simulates the network stack of each machine in a group of virtual machines, and also simulates the physical network between them.

The *Honeyd* machine²⁷³ has been used as a network decoy, for detecting worms, for capturing spam, and for providing a front end that selectively forwards packets²⁷⁴ to high-interaction honeypots. What *Honeyd* tries to do, is to fool so-called *fingerprinting tools* (such as *Xprobe* and *Nmap*). What is meant by *fingerprinting* in intrusion detection, is testing a network behaviour.²⁷⁵ Tools like *Nmap* generate a *fingerprint*, which looks like abstruse code, but typifies the behaviour of the network being tested.

²⁷² The concept of a *honeycomb* was introduced by Christian Kreibich and Jon Crowcroft (2004). Kreibich has also been working on *botnets* (Caballero, Poosankam, Kreibich, & Song, 2009). Juan, Kreibich, Lin, and Paxson (2008), whose team also included Kreibich, discussed a tool for offline and live testing of *evasion resilience* in network intrusion detection systems. Cf. Dreger, Kreibich, Paxson, and Sommer (2005), on *host-based intrusion detection*.

²⁷³ *Honeyd* is available as an open source, at <http://www.honeyd.org>

²⁷⁴ When data is sent through a network, the data is broken up in to small manageable pieces called *packets*.

²⁷⁵ Moreover (http://en.wikipedia.org/wiki/Application_protocol-based_intrusion_detection_system): “An *application protocol-based intrusion detection system (APIDS)* is an *intrusion detection system* that focuses its monitoring and analysis on a specific application *protocol* or protocols in use by the computing system. [...] An APIDS will monitor the dynamic behavior and *state* of the protocol and will typically consist of a system or agent that would typically sit between a *process*, or group of *servers*, *monitoring* and analyzing the application protocol between two connected devices. A typical place for an APIDS would be between a *web server* and the *database management system*, monitoring the *SQL* protocol specific to the *middleware/business logic* as it interacts with the *database*.” Monitoring dynamic behaviour on the part of an APIDS involves the following. “At a basic level an APIDS would look for, and enforce, the correct (legal) use of the protocol. However at a more advanced level the APIDS can learn, be taught or even reduce what is often an infinite protocol set, to an acceptable understanding of the *subset* of that application protocol that is used by the application being monitored/protected. Thus, an APIDS, correctly configured, will allow an application to be ‘*fingerprinted*’, thus should that application be subverted or changed, so will the fingerprint change” (ibid.). In general, regardless of their being protocol-based or otherwise, there is a class of intrusion detection systems that are known as *middleware-level IDSs*. For example, Naess, Frincke, McKinnon, and Bakken (2005) discussed configurable middleware-level intrusion detection for embedded systems.

Honeypots and honeynets²⁷⁶ can be used in combination with *automated monitoring tools*. These can look for suspicious activity and send out alerts. One such tool is *Swart*. It monitors log files for predefined patterns. It is at such tasks that *data mining* has a role to play. The honeypots gather data about network attacks, and any interaction with them is assumed to be an attack. It is in order to detect this or that attack, that *pattern matching* is resorted to. Still, the more sophisticated attacks are, the harder it is to catch them with honeypots. It has also been argued that making it possible to detect the presence of honeypots may prove to be a deterrent:

Just as honeypots are weapons against spammers, honeypot detection systems are spammer-employed counter-weapons. As detection systems would likely use unique characteristics of specific honeypots to identify them, a great deal of honeypots in use makes the set of unique characteristics larger and more daunting to those seeking to detect and thereby identify them. This is an unusual circumstance in software: a situation in which “*versionitis*” (a large number of versions of the same software, all differing slightly from each other) can be beneficial. There’s also an advantage in having some easy-to-detect honeypots deployed. Fred Cohen, the inventor of the *Deception Toolkit*, even argues that every system running his honeypot should have a deception port that adversaries can use to detect the honeypot. Cohen believes that this might deter adversaries.²⁷⁷

Some honeypot systems only target automated attacks by propagating malware, rather than attacks by human attackers. This is the case of the *Nepenthes* system.²⁷⁸ Göbel, Hektor, and Holz (2006) discussed the collection of malware that spread automatically (such as network *worms* or *bots*) by using the *Nepenthes* low-interaction honeypot. The purpose is obtaining the malware itself, its binary code is downloaded and stored for further in-depth analysis. *Nepenthes* only simulates the vulnerable parts of a service, not the full service for an attacker to interact with. Human attackers would easily detect *Nepenthes*, whereas this tool is useful for interacting with propagating malware instead. The modules of *Nepenthes* include:

- *vulnerability modules* (which simulate the vulnerable parts of network services);
- *shellcode parsing modules* (these analyse the code received by a vulnerability module, which is in a low-level, machine-executable, assembly language, and extract information about the malware)²⁷⁹;

²⁷⁶ “Two or more honeypots on a network form a *honeynet*. Typically, a honeynet is used for monitoring a larger and/or more diverse network in which one honeypot may not be sufficient. Honeynets and honeypots are usually implemented as parts of larger *network intrusion detection systems*. A *honeypot* is a centralized collection of honeypots and analysis tools.” Quoted from [http://en.wikipedia.org/wiki/Honeypot_\(computing\)](http://en.wikipedia.org/wiki/Honeypot_(computing))

²⁷⁷ [http://en.wikipedia.org/wiki/Honeypot_\(computing\)](http://en.wikipedia.org/wiki/Honeypot_(computing)) citing Fred Cohen’s *Deception Toolkit* (in turn, accessed in 2006 at <http://all.net/dtk/index.html>).

²⁷⁸ The source code of the *nepenthes* system is available from <http://nepenthes.mwcollect.org>

²⁷⁹ “Shellcode parsing modules analyze the received payload and automatically extract relevant information about the exploitation attempt. Currently, only one shellcode parsing module is capable of analyzing all shellcodes received in the wild. The module works in the following way: First, it tries to decode the shellcode. Most shellcode is obfuscated with an XOR encoder. An XOR decoder is a common way to ‘encrypt’ the native shellcode in order to evade intrusion detection systems

- *fetch modules* (the information which is the output of the shellcode parsing modules is used by the fetch modules in order to download the malware from some remote location);
- *submission modules* (these handle the malware once it has been downloaded: they save its code to hard disk, or store it in a database, or send it to developers of antivirus software); and
- *logging modules* (information about the simulation is logged by these, so that patterns in the collected data could be detected and an overview provided).

There also is an *event-driven notification mechanism* in Nepenthes, so that the events triggered by each step of an attack be registered and reacted to.

Traditional honeypots are servers (or devices that expose server services) that wait passively to be attacked. *Client Honeypots* are active security devices in search of malicious servers that attack clients. The client honeypot poses as a client and interacts with the server to examine whether an attack has occurred. Often the focus of client honeypots is on web browsers, but any client that interacts with servers can be part of a client honeypot (for example ftp, ssh, email, etc.).²⁸⁰

In particular, there again is the distinction between *high-interaction client honeypots* and *low-interaction client honeypots*, just as there is such a distinction concerning just traditional honeypots:

High interaction client honeypots are fully functional systems comparable to real systems with real clients. As such, no functional limitations (besides the containment strategy) exist on high interaction client honeypots. Attacks on high interaction client honeypots are detected via inspection of the state of the system after a server has been interacted with. The detection of changes to the client honeypot may indicate the occurrence of an attack against that has exploited a vulnerability of the client. An example of such a change is the presence of a new or altered file.

High interaction client honeypots are very effective at detecting unknown attacks on clients. However, the tradeoff for this accuracy is a performance hit from the amount of system state that has to be monitored to make an attack assessment. Also, this detection mechanism is prone to various forms of evasion by the exploit. For example, an attack could delay the exploit from immediately triggering (time bombs) or could trigger upon a particular set of conditions or actions (logic bombs). Since no immediate, detectable state change occurred, the client honeypot is likely to incorrectly classify the server as safe even though it did successfully perform its attack on the client. Finally, if the client honeypots are running in virtual machines, then an exploit may try to detect the presence of the virtual environment and cease from triggering or behave differently.²⁸¹

and string-processing functions. After decoding the code itself according to the computed key, this module then extracts more information from the shellcode (e.g., credentials). If enough information can be reconstructed to download the malware from a remote location, this information is passed to the next type of module” (Göbel et al., 2006, p. 20).

²⁸⁰ http://en.wikipedia.org/wiki/Client_honeypot

²⁸¹ Ibid. Several such systems are briefly described at that webpage. So are several *low-interaction client honeypots*. “Low interaction client honeypots differ from high interaction client honeypots in that they do not utilize an entire real system, but rather use lightweight or simulated clients to interact with the server. (in the browser world, they are similar to web crawlers). Responses from servers are examined directly to assess whether an attack has taken place. This could be done, for

6.2.2 *The United States' Anti-Drug Network (ADNET)*

Law enforcement agencies in the United States resort to ADNET (Anti-Drug Network), with data-mining assistance from the MITRE Corporation. This is briefly described by Mena (2003, section 7.5, pp. 210–212). The bodies that share data within ADNET include the U.S. Department of Defence, the U.S. Coast Guard, the Department of Justice, the Department of State, the Department of Treasury, the Federal Communications Commission, and the U.S. intelligence community.

A U.S. governmental source explains²⁸²:

The ADNET program's mission is the implementation of information systems, technologies, and services at the secret and sensitive-but-unclassified level for Department of Defense, federal, state, local, and tribal law enforcement and partnering nations.

ADNET supports the Deputy Assistant Secretary of Defense for counternarcotics and its mission of counter-narcoterrorism, including:

- Statutory detection and monitoring
- Demand reduction activities
- Support to domestic and host nation law enforcement
- Other missions that support the war on terrorism, readiness, national security, and security cooperation goals
- ADNET provides application and customer enclave services to the counter-narcoterrorism communities of interest.

Another source, being a resource for the press, provides further detail:

ADNET is a community of interest that provides command, control, communication, computer, and intelligence (C4I) capabilities to help the Department of Defense (DoD) and other federal, state, and local governments detect, monitor, and interdict activities related to narcotics trafficking and narco-terrorism (CNT). These efforts are directed by the Office of the Deputy Assistant Secretary of Defense for Counternarcotics and Global Threats.²⁸³

The same press resource from the U.S. government explains the capabilities and services of ADNET as follows:

ADNET is the primary secure link among DoD, the Office of National Drug Control Policy, Federal Communications Commission, Homeland Security, National Guard (high intensity drug trafficking areas), intelligence community, Justice, and Treasury. Interagency groups leverage ADNET's secure and accredited operational infrastructures at the Secret and Sensitive But Unclassified (SBU) levels to complete CNT tactical and strategic missions. ADNET develops and operates critical information systems such as the Counterdrug Consolidated Database (CCDB), Webshare collaboration system, FORUM (request for

example, by examining the response for the presence of malicious strings. Low interaction client honeypots are easier to deploy and operate than high interaction client honeypots and also perform better. However, they are likely to have a lower detection rate since attacks have to be known to the client honeypot in order for it to detect them; new attacks are likely to go unnoticed. They also suffer from the problem of evasion by exploits, which may be exacerbated due to their simplicity, thus making it easier for an exploit to detect the presence of the client honeypot" (ibid.).

²⁸² See <http://www.disa.mil/services/adnet.html>

²⁸³ See <http://www.disa.mil/news/pressresources/factsheets/adnet.html>

information), counter drug (CD) common operational picture (COP), and electronic mail to support these interagency groups.

These systems utilize ADNET's enterprise products and services which includes

- maintenance of six (6) separate architectures (development, test, user acceptance, continuity of operations (COOP), ADNET-Secret, and ADNET-SBU) for full life-cycle development;
- extensive security engineering to include design and implementation of security configurations and firewall and intrusion detection system monitoring and maintenance;
- certification and accreditation documentation to ensure compliance with DoD and customer policies for operating on Secret and SBU;
- full service network operations center and service desk to provide customer and technical support from the network to the customer's edge device;
- engineering and fielding of complete information systems to include telecommunications, hardware, software development, installation, security engineering, accreditation, training, network operations, and service desk.

ADNET manages a number of devices at customer locations consisting of workstations, routers, switches, firewalls, storage area networks, and servers in the Secret and Unclassified environments.

ADNET operates an unclassified information sharing portal technology system supporting the combatant commanders, federal, state, local, and foreign governments doing intelligence preparation of the battlefield, joint operations, operational evaluations, and interdiction. The El Paso Intelligence Center leverages the ADNET Unclassified portal to allow vetted users to access the National Seizure System.

Additionally, DoD's general counsel has authorized the ADNET program to host U.S. person data on their systems.

MITRE, Mena (2003) reported, was "working on a now-fielded prototype targeting system that analyzes passenger vehicle crossing data and develops data mining rules and tools that help operators perform real-time analysis to identify potential counter-narcotics targets" (ibid., p. 211). In particular, MITRE was applying techniques from *machine learning*. "The objective is to provide end users with a system that will quickly indicate if an individual coming into the United States is worthy of further inspection" (ibid.). For an incoming car at the border, this is done via the licence plate. Based on this input, ADNET informs the customs system operator about the travel patterns of that car, and whether this trip is different – and suspicious (ibid., p. 210).

The following is quoted from MITRE (2001)²⁸⁴:

Anti Drug Network (ADNET): A middle-aged man in a light blue Mustang is on the way to enter the United States from Mexico through one of the numerous customs checkpoints along the southwest border. He is confident no one will suspect that he is transporting more than 10 pounds of heroin in secret compartments inside his vehicle; he has done it before and he plans to do it again and again.

²⁸⁴ This text from MITRE (2001) was quoted by both Jesus Mena (2003), and Hakikur Rahman (2009, pp. 176–177).

But, a customs system operator at a site near El Paso, Texas, uses the Anti-Drug Network (ADNET) system to access data on the driver and his car via his license plate. It's just routine check and takes a few moments.

The agent quickly learns through a system that accesses a large data warehouse of information on crossings, seizures, and motor vehicles that the driver makes this trip on a regular basis, at a regular time, but this trip is different. She decides it is worth her time and trouble to continue the inspection. Ten minutes later, she finds more than a dozen small packages of white powder inside the vehicle. The drugs were seized and the driver was arrested.

Situations like this occur almost daily across the many ports of entry along the Mexican/U.S. border and other entry points into the United States. It may happen to many other countries and continents. Sophisticated data-sharing systems developed by the ADNET community (i.e., Department of Defense, U.S. Coast Guard, Department of Justice, Department of State, Department of Treasury, Federal Communications Commission, and the intelligence community) give U.S. drug and law enforcement officials a cache of information needed to track the flow of illegal narcotics and other dangerous substances into the country.

6.2.3 Investigating Internet Auction Fraud

6.2.3.1 What the Problem Is

Wikipedia has an informative entry for “Internet fraud”,²⁸⁵ with a usefully detailed classification.²⁸⁶ Choo (2008) proposed a typology of organised crime groups on the Internet. Dawn Gregg and Judy Scott (2008) described a typology of complaints about eBay sellers: eBay is the world largest online auction website.²⁸⁷ “In an *online*

²⁸⁵ Fraud, regardless of the Internet, has been approached within AI & Law in respect of *ontologies*: Vandenberghe, Leary, and Zeleznikow (2003) discussed the goal of developing a *financial fraud ontology*.

²⁸⁶ http://en.wikipedia.org/wiki/Internet_fraud

²⁸⁷ <http://www.ebay.com> This is a generalised auction site, in the sense that customers are allowed to put up many different kinds of items for sale on the auction site. But in respect of the mode of bidding, eBay has a *forward auction* facility. What distinguishes an auction from other forms of selling is that the seller puts up the items for sale, without giving a fixed price. Moreover, an *auctioneer* manages the process. “There are several different types of auctions, the most common ones being an increasing bid auction (English auction), a decreasing bid auction (Dutch auction), and a price quantity pair auction. Auctions found their way onto the internet as early as 1995” (Chan et al., 2001b, p. 384). On the Internet, *increasing bid auctions* are known as *forward auctions*, whereas *decreasing bid auctions* are known as *reverse auctions*. In a forward auction, “the seller puts up an item for sale and specifies an acceptable minimum price or reserve price that he is willing to accept. The item is then posted on the auction site together with the minimum price and the bidding is kept open for a specified period. During this period, potential buyers bid for the item and the latest high bid is displayed (but not the identity of the bidder). When the specified period lapses, the highest bidder is required to purchase the item at the bid price. There are clearly defined rules for the auction site that the bidder and the seller of the item are required to adhere to” (ibid., pp. 384–385).

By contrast, at a reverse auction “the seller puts up an item for sale at a high price. The price of this item is progressively reduced until a potential buyer accepts the bid and the items are then deemed to have been sold to the buyer” (ibid., p. 385). “An example of a decreasing bid auction

auction scheme, a fraudster starts an auction on a site such as eBay or TradeMe with very low prices and no reserve price, especially for typically high priced items like watches, computers, or high value collectibles. The fraudster accepts payment from the auction winner, but either never delivers the promised goods, or delivers an item that is less valuable than the one offered – for example, a counterfeit, refurbished, or used item.²⁸⁸

Gregg and Scott's (2008) categories include the sellers delivering goods not as requested by the buyer, or delivering goods of low quality, or goods without ancillary item or parts, or then goods being defective or damaged; moreover the goods supplied may be or black market items. In a so-called *accumulation* fraud, a seller builds up his or her reputation by making the initial investment of selling much low-value merchandise over a long period of time. Next, the seller presents an offer of expensive goods, but once buyers make their payment, they never get the expensive

site is Klik klok, which auctions gold and jewellery" (ibid., p. 386). The third kind of auction is a *price quantity pair auction*: it "has potential buyers making a bid for a certain quantity of an item at a certain price and sellers offering to sell a given quantity at a specified price. The buyer's bids are progressively increased and seller's 'asking' price progressively decreased until matching bids are obtained and the requisite quantity is then deemed to have been sold to the buyer at the right bid price" (ibid., p. 385). Sites like eBay are *C2C auction sites*, i.e., customer-to-customer sites, as opposed to *B2B auctions*, i.e., broker-to-broker auctions. One of the models of B2B auctions is "Use of a liquidation broker to sell excess items. In this case, the liquidation broker is essentially a third party auction site that does the auctioning for you" (ibid., p. 386). Otherwise, one may auction items at one's own website, or one may resort to "the auction facility on a virtual market site that one is a participant in to auction excess inventory" (ibid.). These, too, are B2B models, according to Chan et al. (2001b). As to C2C auction sites, they are any of three types: generalised auction sites (such as eBay), specialised auction sites, or *agent-based auction supporting sites*, i.e. "agent based services or search engines that will allow a buyer to specify an item, and the mobile agent or search engine would then visit relevant new sites returning information on where the item can be found. An example of this is www.usaweb.com" (ibid., p. 386).

²⁸⁸ From section "Online auction and retail schemes" at http://en.wikipedia.org/wiki/Internet_fraud Online auction fraud is akin to online retail fraud. "*Online retail schemes* involve complete online stores that appear to be legitimate. As with the auction scheme, when a victim places an order through such a site, their funds are taken but no goods are sent, or inferior goods are sent. In some cases, the stores or auctioneers were once legitimate, but eventually stopped shipping goods after accepting customer payments. Sometimes fraudsters will use phishing techniques to hijack a legitimate member accounts on an online auction site — typically an account with a strongly positive online reputation — and use it to set up a phony online store. In this case, the fraudster collects the money, while ruining the reputation of the conned eBay member. When victims complain that they have not received their goods, the legitimate account holder receives the blame. A more subtle variation of online auction fraud occurs when a seller ships an item to an incorrect address that is within the buyer's ZIP code using the United States Postal Service's Delivery Confirmation service. This service does not require the recipient to sign for the package, but offers confirmation that the Postal Service delivered the package within the specified ZIP code. The item shipped is usually an empty envelope with no return address and no recipient name, just a street address different from that of the victim. The delivery of the envelope with the Delivery Confirmation barcode attached suffices for the Postal Service to record the delivery as confirmed. The fraudster can then claim the package has been delivered, and offer the Delivery Confirmation receipt as proof to support the claim." (ibid.).

goods they purchased. In his own discussion of frauds at eBay auctions, Wahab (2004) stated:

With respect to forms of online auction fraud, there are several activities which constitute fraudulent behaviour including:

Non-delivery: involves the seller placing an item up for bid when, in fact, there is either no item at all or the seller has no intention to sell. As a result, the item is never delivered to the buyer after he/she purchases the item.

Misrepresentation: Occurs when the seller's purpose is to deceive the buyer as to the true value of an item by listing false information or using fake pictures of the item.

Non-payment: Involves a buyer placing the highest bid and winning the auction, and as the merchandise is delivered no money is paid. The victim in this case is actually the seller.

Triangulation: Involves three parties: the perpetrator, a consumer, and an online merchant. The perpetrator buys merchandise from an online merchant using stolen identities and credit card numbers. Then, the perpetrator sells the merchandise at online auction sites to unsuspecting buyers. Later, the police seize the stolen merchandise to keep for evidence, and the buyer and merchant end up the victims.

Fee stacking: Involves adding hidden charges to the item after the auction is over to obtain more money. Instead of a flat rate for postage and handling, the seller adds separate charges for postage, handling, and shipping. As a result, the buyer has to pay more than anticipated.

Black-market goods: These goods include copied software, music CD's, videos, etc. The goods are delivered without a box, warranty, or instructions. Auction sites such as eBay try to stamp out selling such items by prohibiting the selling of unauthorised copies of software, games, music, or video. Multiple violations of eBay's unauthorised copy policy could result in the suspension of your account.

Wahab (2004) also listed fraudulent kinds of bidding on online auctions:

Multiple bidding: This occurs when a buyer places multiple bids (some high and some low) using different aliases. The multiple high bids cause the price to escalate, and scares off other potential buyers from bidding. Then, in the last few minutes of the auction the same buyer withdraws their high bids, only to purchase the item with their lowest bid. On eBay, it is not permitted to use secondary User IDs or other eBay members to artificially raise the level of bidding and/or price of an item. Equally, retracting bids is not allowed as a rule on eBay, as all bids are binding, except: sales of real estate or businesses, sales of items that are prohibited by law or by eBay's User Agreement, and other exceptional circumstances (typographical errors, significant change in the description of the item, inability to reach the seller, and unauthorised use of the buyers ID and password)

Shill bidding: is the intentional sham bidding by the seller to drive up the price of his/her own item that is up for bid. This is accomplished by the sellers themselves and/or someone that is associated with the seller making bids to purposely drive up the price of the seller's item.

Shield bidding: occurs when the buyer uses another email address or a friend (the shield) to drive up prices and discourage bids on an item she wants. At the last minute, the shield withdraws the high bid, allowing the buyer to win the item at a lower price. Most auction sites forbid retracting a bid once it's made, and on eBay shill and shield bidding is clearly prohibited.

Summing up the foregoing kinds of fraudulent behaviour, Wahab (2004) remarked: "Although one or more forms may be prevented under the auction site policies, the main concerns for online auction fraud lies in the non-delivery, delivery of defective goods or late delivery, failure to disclose all relevant information, and non-payment". Wahab (2004) listed the following factors in buyers' behaviour that make them vulnerable to fraud at online auctions:

- (a) *Lack of knowledge*: where the buyer is not fully aware of the site policies or safe harbour principles. Many buyers act on the assumption that standard policies exist in all auction sites.
- (b) *Payment Methods*: money orders or personal cheques were listed as methods of payment by 80% of the victims that reported Internet auction fraud. The National Consumers League found that most of the consumers who lost money in Internet auctions paid with a money order (48%), personal cheques (32%), or cashier's cheques (7%).
- (c) *Negligence*: engaging in online auction activities has its stakes as well as its advantages. Thus, the lack of cautious conduct may very well result in becoming a victim of fraud. Buyers and sellers who do not act carefully by checking retail prices and information about each other, reading their feedback ratings, or using common sense in assessing the price of the item up for a bid, could become the perfect victims of fraud.

FADE (Fraud and Abuse Detection Engine) is a data mining system developed by the online auction site eBay in order to detect fraud perpetrator at its site (Mena, 2003, p. 254). Some unscrupulous sellers never supply the merchandise they sold, or then they misstate its features. Internet auction fraud has been ranked the highest amongst the reported fraud cases in electronic commerce (Ochaeta, 2008). Often fraudsters try to build up a reputation for themselves, by initially selling to or buying from traders with a good reputation, for a while, a lot of low priced or cheap products; or then they may sell to or buy from accomplices moderate value or expensive items. Morzy (2008) proposed algorithms for mining the reputation of participants of online auctions. Morzy identified further fraudulent practices, beside the ones described by Gregg and Scott (2008). Those practices considered by Morzy include *bid shilling*, that is to say, as seen earlier, the use of a false bidder identity to drive up the price of an item on behalf of the seller; and *bid shielding*: the perpetrators comprise a role called the *shielder*, and a role of the one who is going to fraudulently win the auction. The shielder offers an artificially high bid for an item, so that other bidders be discouraged from competing for an item; then, at the last moment, the shielder withdraws the bid, and his or her accomplice, who is the second highest bidder, wins the auction. Chua and Wareham (2002, cf. 2004), concerned with self-regulation for online auctions, proposed a taxonomy, quoted by Kwan et al. (2010) and presented in two tables (Tables 6.2.3.1.1 and 6.2.3.1.2).

Kobayashi and Ito (2008) proposed a transactional relationship visualisation system in Internet auctions. Credit card phantom transactions in online auctions was discussed, from a fraud detection perspective, in Chae, Shim, Cho, and Lee (2007). Anonymacy and information asymmetry were identified by Sakurai and Yokoo (2003) and Chae et al. (2007) as being important factors in online auction fraud. A seller or a buyer might submit a false-name bid by pretending to be a potential buyer or seller, thus enabling the perpetrator to manipulate the supply-and-demand chain. Ku, Chen, and Chiu (2007a) proposed a data mining approach for internet auction fraud detection – “a simple method which is detected potential fraudster by social network analysis (SNA) and decision tree to provide a feasible mechanism of playing capable guardians in buyers’ auction activities” – whereas Ku, Chen, Wu, and Chiu (2007b) were concerned with online gaming crime.

Table 6.2.3.1.1 Kinds of fraud perpetrated by sellers at online auctions

Seller as fraudster	
Bid shilling	Seller bids on own auctions to drive up the price
Misrepresentation	Seller intentionally misdescribes the item
Fee stacking	Seller adds hidden costs such as handling charges to the item after the auction ends
Failure to ship	Seller never sends the goods
Reproductions and counterfeits	Seller advertises counterfeit goods as the real thing
Triangulation fencing	Stolen goods are sold
Shell auction	Seller sets up an auction solely to obtain names and credit cards

Table 6.2.3.1.2 Kinds of fraud perpetrated by buyers at online auctions²⁸⁹

Buyer as fraudster	
Bid shielding	Two buyers collude on an auction. One bidder makes a low bid, while the second makes an inflated bid. Before the auction ends, the higher bidder withdraws
Failure to pay	Buyer never sends the money
Buy and switch	Buyer receives merchandise and refuses it. However, buyer switches original merchandise with inferior merchandise
Loss or damage claims	Buyer claims item was damaged and buyer disposed of it. Buyer wants money back

Jun Gu from the University of Edinburgh presented a case study of eBay, the online auction site (Gu, 2007), and included a table comparing eBay to Sotheby’s, a traditional auction company. See Table 6.2.3.1.3. “The potential shopping risks for a consumer who purchases at Sotheby’s and EBay could be inferred from [. . .] major differences as revealed in the [. . .] table” (Gu, 2007, p. 3).

Internet auction fraud is also a domain researched, e.g., by Kwan et al. (2010). That study, carried out by computer scientists at King’s College London and the University of Hong Kong, is concerned with Internet auction fraud involving the

²⁸⁹ Also consider *PayPal fraud* perpetrated by purchasers at eBay auctions. The following quotation is from section “PayPal fraud” at http://en.wikipedia.org/wiki/Internet_fraud “In a *collection in person PayPal scheme*, the scammer targets eBay auctions that allow the purchaser to personally collect the item from the seller, rather than having the item shipped, and where the seller accepts PayPal as a means of payment. The fraudster uses a fake address with a post office box when making their bids, as PayPal will allow such an unconfirmed address. Such transactions are not covered by PayPal’s seller protection policy. The fraudster buys the item, pays for it via PayPal, and then collects the item from the victim. The fraudster then challenges the sale, claiming a refund from PayPal and stating that they did not receive the item. PayPal’s policy is that it will reverse a purchase transaction unless the seller can provide a shipment tracking number as proof of delivery; PayPal will not accept video evidence, a signed document, or any form of proof other than a tracking number as valid proof of delivery. This form of fraud can be avoided by only accepting cash from buyers who wish to collect goods in person.”

Table 6.2.3.1.3 Sotheby's vs. eBay (based on Gu, 2007)

	Sotheby's	eBay
Registration procedure for the buyer	Proof of identity (passport, driving license, etc.)	Providing a valid email address.
Registration procedure for the seller	1. Evaluating the item for a decision of acceptance. 2. Contracting with the seller if that item has been accepted.	1. Verifying the identity of Seller by phone or credit card. 2. Offering PayPal or a merchant account credit card as a payment method.
Liability distribution	The Sotheby's, the seller, and the buyer.	The seller and the buyer
Criteria for a decision of purchase	Descriptions and examinations of the specific item.	Descriptions only.

selling of faked goods in Hong Kong, and goods bearing false trade descriptions or forged trademarks.

Kwan et al. (2010) quoted from Ochaeta (2008) six steps in a safe Internet auction: (a) Initial buyers and sellers registration; (b) Setting up a particular auction event; (c) Scheduling and advertising; (d) Bidding (which handles the collection of bids from buyers); (e) Evaluation of bids and closing the auction; (f) Trade settlement. This last step involves payment, and the transfer of goods. At sites such as eBay, typically the seller is not the auctioneer, so the trade settlement step this final step involves the payment of fees to the auctioneer and other agents.

At the initial step, namely, the registration of the initial buyers and sellers, the authentication takes place of the trading parties. They exchange cryptography keys, and a profile is created for each trader. The profile states in which kinds of products the trader is interested, and possibly his or her authorized spending limits.

The second step, which is the setting up a particular auction event, consists of setting up of the protocol and rules of the auction. "Such rules include the descriptions of the items being sold or acquired, the type of auction being conducted (e.g. open cry, sealed bid, or Dutch), parameters negotiated (e.g. price, delivery dates, terms of payment), starting date and time of the auction, and the auction closing rules, etc." (Kwan et al., 2010).

At step (c), i.e., scheduling and advertising, typically involves items of the same category (such as art, or jewelry) being auctioned together on a regular schedule. This is done in order to draw the attention of potential buyers. "Popular auctions are sometimes mixed with less popular auctions. Items to be auctioned in upcoming auctions are also advertised. Potential buyers are notified of these upcoming events" (Kwan et al., 2010).

During the bidding step (i.e., step c), bids made by potential buyers are collected, the bid control rules of the auction are applied (involving minimum bid, bid increment, and deposits required with bids), and participants are notified when new higher bids are submitted. Next, step (d) consists of the evaluation of bids and the

closing of the auction. Closing rules are implemented, and a notification is given to the winners and losers of the auction.

Whereas law enforcement agencies, the auction sites themselves, as well as newspaper articles advise users to be careful, to “be cautious at their end and perform background checks of sellers that they wish to transact with. Such suggestions however, require users to maintain constant vigilance and spend a considerable amount of time and effort in investigating potential dealers before carrying out a transaction” (Pandit, Chau, Wang, & Faloutsos, 2007, p. 202), this is not really helpful, and merely shifts the burden of responsibility to the users: “Such suggestions however, require users to maintain constant vigilance and spend a considerable amount of time and effort in investigating potential dealers before carrying out a transaction. To overcome this difficulty, self-organized vigilante organizations are formed, usually by auction fraud victims themselves, to expose fraudsters and report them to law enforcement agencies” (ibid.), but such grassroots efforts are not sufficient. Hence the usefulness of the advice a data mining tool, *NetProbe* (see in Sections 6.2.3.2 and 6.2.3.3), can give users by actually checking the stream of transactions of all users in order to identify likely fraudsters. “Specifically, NetProbe [...] is able to spot sellers that are prone to commit the ‘non-delivery’ type of fraud. idea is that such sellers usually have ‘accomplices’, that is, nodes with good reputation, who have never committed any fraud, but are willing to give good feedback scores to the fraudsters-to-be.”²⁹⁰

There exist *reputation systems* (Resnick, Zeckhauser, Friedman, & Kuwabara, 2000; Resnick, Zeckhauser, Swanson, & Lockwood, 2003; Melnik & Alm, 2002), and these are used by the online auction sites. “But they are usually very simple and can be easily foiled” (Pandit et al., 2007, p. 202). Nevertheless, reputation systems are applied extensively, and they do have an impact on patterns of behaviour: “In an overview, Resnick et al. [(2000)] summarized that modern reputation systems face many challenges which include the difficulty to elicit honest feedback and to show faithful representations of users’ reputation. Despite their limitations, reputation systems have had a significant effect on how people buy and sell” (Pandit et al., 2007, p. 202). The following is quoted from a Wikipedia entry²⁹¹:

A *reputation system* computes and publishes reputation scores for a set of objects (e.g. service providers, services, goods or entities) within a community or domain, based on a collection of opinions that other entities hold about the objects. The opinions are typically passed as ratings to a reputation center which uses a specific reputation algorithm to dynamically compute the reputation scores based on the received ratings.

Entities in a community use reputation scores for decision making, e.g. whether or not to buy a specific service or good. An object with a high reputation score will normally attract more business than an object with a low reputation score. It is therefore in the interest of objects to have a high reputation score.

Since the collective opinion in a community determines an object’s reputation score, reputation systems represent a form of collaborative sanctioning and praising. A low score represents a collaborative sanctioning of an object that the community perceives as having

²⁹⁰ From a project report by C. Faloutsos, at <http://www.cs.cmu.edu/~christos>

²⁹¹ http://en.wikipedia.org/wiki/Reputation_system

or providing low quality. Similarly, a high score represents a collaborative praising of an object that the community perceives as having or providing high quality. Reputation scores change dynamically as a function of incoming ratings. A high score can quickly be lost if rating entities start providing negative ratings. Similarly, it is possible for an object with a low score to recover and regain a high score.

Reputation systems are related to *recommender systems*²⁹² and *collaborative filtering*,²⁹³ but with the difference that reputation systems produce scores based on explicit ratings from the community, whereas recommender systems use some external set of entities and events (such as the purchase of books, movies, or music) to generate marketing recommendations to users. The role of reputation systems is to facilitate trust (Resnick et al., 2000) (Jøsang, Ismail, & Boyd, 2007), and often functions by making the reputation more visible.

Reputation systems are often useful in large online communities in which users may frequently have the opportunity to interact with users with whom they have no prior experience or in communities where user generated content is posted like YouTube or Flickr. In such a situation, it is often helpful to base the decision whether or not to interact with that user on the prior experiences of other users.

Reputation systems may also be coupled with an incentive system to reward good behavior and punish bad behavior. For instance, users with high reputation may be granted special privileges, whereas users with low or unestablished reputation may have limited privileges.

Concerning types of reputation systems, the same entry explains concisely:

A simple reputation system, employed by eBay, is to record a rating (either positive, negative, or neutral) after each pair of users conducts a transaction. A user's reputation comprises the count of positive and negative transactions in that user's history.

More sophisticated algorithms scale an individual entity's contribution to other node's reputation by that entity's own reputation. PageRank is such a system, used for ranking web pages based on the link structure of the web. In PageRank, each web page's contribution to another page is proportional to its own pagerank, and inversely proportional to its number of outlinks.²⁹⁴

Reputation systems are also emerging which provide a unified, and in many cases objective, appraisal of the impact to reputation of a particular news item, story, blog or online posting. The systems also utilize complex algorithms to firstly capture the data in question but then rank and score the item as to whether it improves or degrades the reputation of the individual, company or brand in question.

6.2.3.2 Data Mining and Online Auction Fraud: Techniques in the Background of NetProbe

Jung, Han, and Suh (1999) applied case-based reasoning to the categorisation of the risk involved in electronic commerce transactions. A team from Carnegie Mellon

²⁹² See at http://en.wikipedia.org/wiki/Recommendation_system concerning *recommender systems*, also called *recommendation systems*. Cf. Leskovec, Singh, and Kleinberg (2006), "Patterns of Influence in a Recommendation Network".

²⁹³ For *collaborative filtering*, see at http://en.wikipedia.org/wiki/Collaborative_filtering

²⁹⁴ The algorithm of PageRank (Brin & Page, 1998) was already outlined, it was eventually realised, in the notion of Katz centrality in a social network (Katz, 1953). See Section 6.1.2.1 in this book. a team in Seoul (Phuoc et al., 2009), interested in a good ranking system for World Wide Web search engines, compared the Katz status index, an old model, to *PageRank*.

University – comprising Shashank Pandit, Duen Horng Chau, Samuel Wang, and Christos Faloutsos – described *NetProbe*, a fast and scalable data mining system which they designed and implemented, for fraud detection in online auction networks (Pandit et al., 2007).²⁹⁵ Experiments with NetProbe as reported in Pandit et al. (2007) were conducted on a synthetic dataset of very large graphs with as many as 7,000 nodes and 30,000 edges. Experiments were also conducted on a real dataset crawled from the eBay online auction website. This real dataset was “with nearly 700,000 transactions between more than 66,000 users, where NetProbe was highly effective at unearthing hidden networks of fraudsters, within a realistic response time of about 6 minutes” (Pandit et al., 2007, p. 201). It is a recognised fact among scholars that the social networks, let alone the networks of transactions, of criminal organisations are dynamic. Pandit et al. (ibid.) came up with a solution: “For scenarios where the underlying data is dynamic in nature, we propose *Incremental NetProbe*, which is an approximate, but fast, variant of NetProbe. Our experiments prove that Incremental NetProbe executes nearly doubly fast as compared to NetProbe, while retaining over 99% of its accuracy”.

Figure 6.2.3.2.1 shows an overview of the NetProbe system. NetProbe systematically analyses the transactions of users of online auction sites, and offers users the advantage that they can query the trustworthiness of any other user, and the query results are visually explained to the user through an interface. The general problem is that fraudsters build for themselves a reputation at the online auction site, by behaving correctly for a while. Once they hit, they are burnt out, but they can still trade through accomplices who still have a good reputation at the same auction site.

In NetProbe, users and transactions were modelled as a *Markov random field (MRF)* which is tuned for the detection of suspicious patterns generated by fraudsters. MRFs are suitable for such problem-solving about inference, that there is uncertainty in observed data.²⁹⁶ A *Markov random field (MRF)* is a probabilistic

²⁹⁵ A different team, Yungchang Ku, Yuchi Chen and Chaochang Chiu, also proposed a data mining approach for detecting potential fraudsters at online auction sites (Ku et al., 2007a). Their approach is based on social network analysis and on a decision tree. The intended users are prospective buyers.

²⁹⁶ A now old book about Markov random fields is the one by Ross Kindermann and J. Laurie Snell (1980). MRFs have been discussed in the artificial intelligence literature about *belief propagation* (e.g., Yedidia, Freeman, & Weiss, 2003). Moreover, MRFs can be used for a wide variety of machine vision or image processing problems, e.g. Mitchell (2010), Li (2009), Jin, Fieguth, and Winger (2005, cf. 2006), Kato and Pong (2001), Feng and Chen (2004). Yuri Boykov, Olga Veksler and Ramin Zabih (1998) combined MRFs with *graph cuts*: they reduced stereo vision to a *multiway cut problem* on a certain graph. Boykov et al. (1998) “focus on MRFs with two-valued clique potentials, which form a generalized Potts model. We show that the maximum a posteriori estimate of such an MRF can be obtained by solving a multiway minimum cut problem on a graph. We develop efficient algorithms for computing good approximations to the minimum multiway, cut. The visual correspondence problem can be formulated as an MRF in our framework” (ibid., from the abstract). They also applied their “techniques to MRFs with linear clique potentials” (ibid.).

Also see Wu and Chung (2005a, 2005b): they “introduce[d] a novel energy minimization method, namely iterated cross entropy with partition strategy (ICEPS), into the Markov random field theory. The solver, which is based on the theory of cross entropy, is general and stochastic. Unlike some popular optimization methods such as belief propagation (BP) and graph cuts (GC),

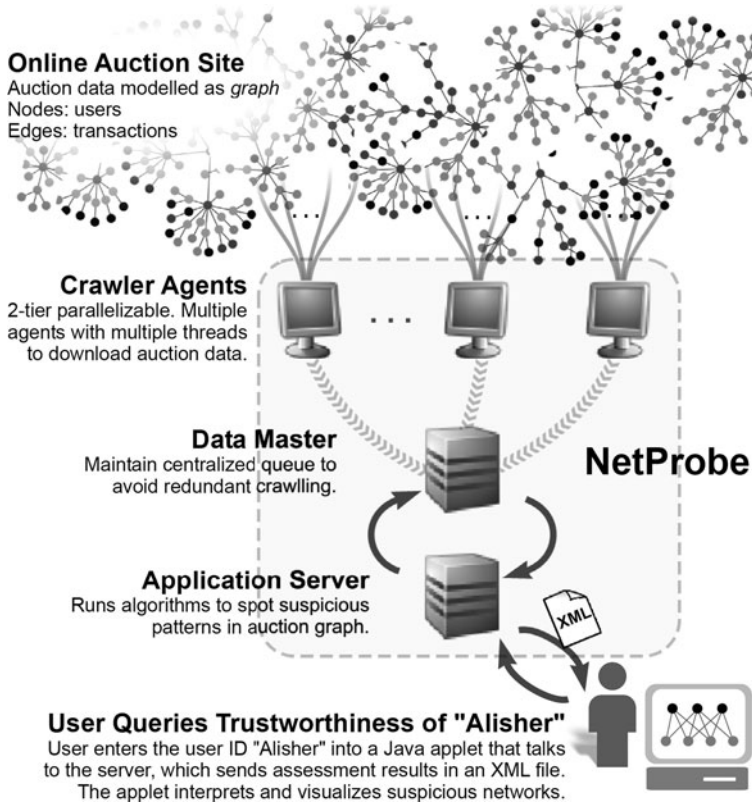

Fig. 6.2.3.2.1 An overview of the NetProbe system. By kind permission of “Polo” Chau of Carnegie Mellon University, and by kind permission of the Secretariat of IW3C2 for the WWW conferences. From Pandit et al. (2007)

ICEPS makes no assumption on the form of objective functions and thus can be applied to any type of Markov random field (MRF) models. Furthermore, compared with deterministic MRF solvers, it achieves higher performance of finding lower energies because of its stochastic property. We speed up the original cross entropy algorithm by partitioning the MRF site set and assure the effectiveness by iterating the algorithm. In the experiments, we apply ICEPS to two MRF models for medical image segmentation and show the aforementioned advantages of ICEPS over other popular solvers [...]” (Wu & Chung, 2005a, from the abstract).

Hiroshi Ishikawa (2003) proposed a method to solve exactly a first order Markov random field optimization problem, more generally than available before. “The MRF shall have a prior term that is convex in terms of a linearly ordered label set. The method maps the problem into a minimum-cut problem for a directed graph, for which a globally optimal solution can be found in polynomial time. The convexity of the prior function in the energy is shown to be necessary and sufficient for the applicability of the method” (ibid., from the abstract).

Du, Li, Chen, Zhang, and Yao (2006) combined MRFs with the well-known *simulated annealing* optimisation technique (itself inspired by annealing in metallurgy, which involves heating and

model defined by local conditional probabilities. The concept is useful for devising contextual models with prior information: Markov random field theory is typically resorted to in order modeling context dependent entities (such as, in image processing within computer science, image pixels). Basically, an MRF is an undirected graph, that is to say, the edges between pairs of nodes are not arrows. Each node in a MRF can be in any of a finite number of states. The state of a node statistically depends upon each of its neighbours (i.e., those nodes to which the given node is connected by an edge), and upon no other node in the graph. A *propagation matrix*, symbolised as ψ , represents the dependency between a node and its neighbours in the given MRF. Each case $\psi(i, j)$ in the matrix has a value which is equal to the probability of a node i being in state j given that it has a neighbour in state i . If an assignment of states to the nodes in a MRF is given, then by using the propagation matrix it is possible to compute a likelihood of observing that assignment. The problem of inferring the maximum likelihood assignment of states to nodes, where the correct states for some of the nodes are possibly known before hand, is solved by those using MRFs by resorting to heuristic techniques,²⁹⁷ and

controlled cooling) as well as with optimisation by means of a *genetic algorithm*, for the purposes of image segmentation. In annealing from metallurgy, the heat causes the atoms to become unstuck from their initial positions and wander randomly through states of higher energy. Their being cooled slowly gives them more chances of finding configurations with lower internal energy than the initial one. In simulated annealing, each step of the algorithm replaces the current solution by a nearby solution, chosen randomly with a probability that depends both on the difference between the corresponding function values and also on a global parameter called the *temperature*. The temperature is gradually decreased during the process. The dependency is such that the current solution changes almost randomly when the temperature is large, but increasingly *downhill* as the temperature goes to zero. Allowing *uphill* moves potentially saves the method from becoming stuck at *local optima*. (For convenience, this explanation is partly reworded from http://en.wikipedia.org/wiki/Simulated_annealing) *Uphill* and *downhill* belong to the standard terminology of *operations research* (i.e., *optimisation techniques*), as moving towards a minimum or a maximum is metaphorised as moving through rough terrain. The *Boltzmann machine* is a neural network that uses the idea of simulated annealing for updating the network's state (Ackley, Hinton, & Sejnowski, 1985).²⁹⁷ This is so because enumerating all states would be exponential in time, and because of the lack of any known theoretic method that would solve this problem for a general MRF. Wu & Chung explained (2005a, p. 230), concerning various methods (including *belief propagation*, or alternatively *simulated annealing*, or *iterated conditional modes*, or *graph cuts*, or *mean field approximation*, or *relaxation labelling*, or *graduated nonconvexity*), as well as their own application of *cross entropy*:

One of the earliest efforts to optimize MRF objective functions was made by Kirkpatrick, Gellatt, and Vecchi [(1983)] who proposed the solver, simulated annealing (SA). SA can guarantee to converge to a global minimum as long as the temperature is decreasing slowly enough which makes SA too slow for practical use especially for clinical data. Another pioneering work was done by Besag [(Besag, 1986)], where the iterated conditional modes (ICM) was presented. This is a fast solver at the cost that it finds local optima in a neighborhood where only one site label is allowed to change. After those two methods, quite a few solvers were introduced [(Li, 2009, 3rd edn., this citation is to the previous edn. 2001)], such as mean field approximation (MFa), relaxation labeling (RL), graduated non-convexity (GNC), etc. Recently two efficient and fairly accurate solvers, belief propagation (BP) [(Yedidia et al., 2003)] and graph cuts (GC) [(Boykov, Veksler, & Zabini, 2001)], were

an especially powerful heuristic method to do that is the *iterative message passing scheme* of the *belief propagation* algorithm.

In order to detect likely fraudsters, a *belief propagation* mechanism was resorted to in NetProbe, that algorithm being generally used in order to infer the maximum likelihood state probabilities of nodes in the MRF, given a propagation matrix and possibly a prior state assignment for some of the nodes. The standard notions about belief propagation are as follows:

- Let vectors be indicated in a bold font, as opposed to scalars. The k th element in a vector \mathbf{v} is indicated as $\mathbf{v}(k)$.
- Let S be the set of possible states in which a node can be.
- Let $\mathbf{b}_n(\sigma)$ stand for the probability that node n is in state σ . That probability is called the *belief* that n is in state σ .
- Nodes pass *messages* to each other. Iterative message passing is how belief propagation works. “Let \mathbf{m}_{ij} denote the message that node i passes to node j . \mathbf{m}_{ij} represents i ’s opinion about the belief of j . At every iteration, each node i computes its belief based on messages received from its neighbors, and uses the propagation matrix to transform its belief into messages for its neighbors” (Pandit et al., 2007, p. 203). \mathbf{m}_{ij} is a message vector. $\mathbf{m}_{ij}(\sigma)$ is the σ th element of that vector.
- Let $N(i)$ be the set of nodes that are the neighbours of node i .
- Let k be a normalisation constant.

proposed. These two solvers are now often used for MRF models because they give good accuracy in an efficient way, which means they can find “global” optima within a rather large neighborhood while maintaining acceptable time complexity. [...] BP and GC are not applicable to all types of objective functions. They obtain their accuracy at the cost of function form restrictions. For example, standard BP is only proper for pairwise MRFs and generalized BP is either not for all functions [(Yedidia et al., 2003)]. So we cannot solve by BP such MRF models as FRAME [(Zhu, Wu, & Mumford, 1996, cf. 1998)] or multi-level logistic (MLL) with more than two sites in a clique [(Li, 2001)]. The same situation occurs for graph cuts because GC will work only when the energy function is regular [(Kolmogorov & Zabih, 2004)]. These may considerably limit the usage of the two popular solvers. In this paper, we proposed a new simple stochastic solver for MRF modeling, called cross entropy (CE). This idea is originated from the field of operations research to simulate rare events [(Rubinstein, 1997)]. This paper combines the idea of CE with MRF theory for the first time and applies the whole model to medical image segmentation. The CE solver is a general and stochastic optimization method that can be applied to any kind of MRF formulation. Unlike BP and GC, CE makes no assumption on the form of the objective function so it is able to solve more complicated MRF models. The efficient CE solver is completely insensitive to initialization and more importantly, as a stochastic method, CE tends to find more global optimum than deterministic solvers like BP.

Then this pair of value assignment formulae holds, in belief propagation:

$$\mathbf{m}_{ij}(\sigma) \leftarrow \sum_{\sigma'} \psi(\sigma', \sigma) \prod_{n \in N(i) \setminus j} \mathbf{m}_{ni}(\sigma')$$

$$\mathbf{b}_i(\sigma) \leftarrow k \prod_{j \in N(i)} \mathbf{m}_{ji}(\sigma)$$

The first formula states that the messages that node i passes to node j (that is to say, i 's opinion about the belief of j in state σ) is assigned the value obtained by multiplying the sums of all the propagation matrix cells which are the likelihoods that a node is in state σ given that it has a neighbour in state σ' , for the products (done for all such nodes n other than j that are i 's neighbours) of node n 's opinion about the belief of i in state σ' .

The second formula states that the belief of i in state σ (that is to say, the probability that node i is in state σ) is assigned as value a normalisation constant multiplied for the products of the messages that node j passes to node i (that is to say, j 's opinion about the belief of i in state σ), for all such j that j is a neighbour of node i .

The standard algorithm is as follows: “Starting with a suitable prior on the beliefs of the nodes, belief propagation proceeds by iteratively passing messages between nodes based on previous beliefs, and updating beliefs based on the passed messages. The iteration is stopped when the beliefs converge (within some threshold), or a maximum limit for the number of iterations is exceeded” (Pandit et al., 2007, p. 203). “In case there is no prior knowledge available, each node is initialized to an unbiased state (i.e., it is equally likely to be in any of the possible states), and the initial messages are computed by multiplying the propagation matrix with these initial, unbiased beliefs” (ibid., fn 4).

Fraud detection as a domain of application of link analysis is related to two other application domains: *trust propagation*, and *authority propagation*. The latter's goal is to rank webpages by importance: a webpage is considered to be important, if webpages that are themselves considered important point to it. This kind of computation is carried out by *PageRank* (Brin & Page, 1998)²⁹⁸ and by *HITS* (Kleinberg,

²⁹⁸ Brin and Page were affiliated with Stanford University when they published that paper, in which they explained how Google crawls and indexes the Web. They explained: “Google is designed to crawl and index the Web efficiently and produce much more satisfying search results than existing systems. The prototype with a full text and hyperlink database of at least 24 million pages is available at <http://google.stanford.edu/> To engineer a search engine is a challenging task. Search engines index tens to hundreds of millions of web pages involving a comparable number of distinct terms. They answer tens of millions of queries every day. Despite the importance of large-scale search engines on the web, very little academic research has been done on them. Furthermore, due to rapid advance in technology and web proliferation, creating a web search engine today is very different from three years ago. This paper provides an in-depth description of our large-scale web search engine — the first such detailed public description we know of to date. Apart from the problems of scaling traditional search techniques to data of this magnitude, there are new technical challenges involved with using the additional information present in hypertext to produce better search results” (from the abstract of Brin & Page, 1998).

1998).²⁹⁹ By contrast, the goal of trust propagation is to distinguish good from bad websites, bad ones being those of scams (phishing), or ones with pornography. An example of a trust propagation system is *TrustRank* (Gyongyi, Molina, & Pedersen, 2004).³⁰⁰ Pandit et al. (2007, p. 203) also stated affinity between their own project and that of Neville and Jensen (2003), Neville, Jensen, and Friedland (2003), and Neville et al. (2005), who respectively carried out automated classification of movies³⁰¹ and stock databases by aggregating features across

²⁹⁹ In the conclusions section, Kleinberg (1998) stated, among the other things: “We began with the goal of discovering *authoritative pages*, but our approach in fact identifies a more complex pattern of social organization on the WWW [i.e., the World Wide Web], in which hub pages link densely to a set of thematically related authorities. This equilibrium between hubs and authorities is a phenomenon that recurs in the context of a wide variety of topics on the WWW. Measures of impact and influence in bibliometrics have typically lacked, and arguably not required, an analogous formulation of the role that hubs play; the www is very different from the scientific literature, and our framework seems appropriate as a model of the way in which authority is conferred in an environment such as the Web.”

³⁰⁰ Zoltan Gyongyi, Hector Garcia-Molina, and Jan Pedersen has published that article while at Stanford University. They explained: “Web spam pages use various techniques to achieve higher-than-deserved rankings in a search engine’s results. While human experts can identify spam, it is too expensive to manually evaluate a large number of pages” (from the abstract of Gyongyi et al., 2004). As an alternative, the paper “propose[d] techniques to semi-automatically separate reputable, good pages from spam. We first select a small set of seed pages to be evaluated by an expert. Once we manually identify the reputable seed pages, we use the link structure of the web to discover other pages that are likely to be good. In this paper we discuss possible ways to implement the seed selection and the discovery of good pages” (ibid.). Experiments whose results were presented in the paper had been “run on the World Wide Web indexed by AltaVista and evaluate the performance of our techniques. Our results show that we can effectively filter out spam from a significant fraction of the web, based on a good seed set of less than 200 sites” (ibid.).

³⁰¹ Neville and Jensen (2003, p. 78): “In this paper, we introduce relational dependency networks (RDNs), an undirected graphical model for relational data. We show how RDNs can be learned and how RDNs and Gibbs sampling can be used for collective classification. Because they are undirected graphical models, RDNs can represent the cyclic dependencies required to express autocorrelation, and they can express a joint probability distribution, rather than only a single conditional distribution. In addition, they are relatively simple to learn and easy to understand. We show preliminary results indicating that collective inference with RDNs offers improved performance over non-collective inference that we term ‘individual inference’. We also show that RDNs applied collectively can perform near the theoretical ceiling achieved if all labels of neighbors are known with perfect accuracy. These results are very promising, indicating the potential utility of additional exploration of collective inference with RDNs.” In the example dataset from the movie domain, there are three types of objects: movies, studios, and actors (ibid., p. 83).

nodes in a graph.³⁰² Neville et al. (2005)³⁰³ explained (ibid., from the abstract):

We describe an application of relational knowledge discovery to a key regulatory mission of the National Association of Securities Dealers (NASD). NASD is the world's largest private-sector securities regulator,³⁰⁴ with responsibility for preventing and discovering misconduct among securities brokers. Our goal was to help focus NASD's limited regulatory resources on the brokers who are most likely to engage in securities violations. Using statistical relational learning algorithms, we developed models that rank brokers with respect to the probability that they would commit a serious violation of securities regulations in the near future. Our models incorporate organizational relationships among brokers (e.g., past coworker), which domain experts consider important but have not been easily used before now.

³⁰² Besides, Pandit et al. (2007, p. 203) considered *graph mining* to be more remotely related to their own research on NetProbe. In particular, whereas NetProbe carries out systematic, large-scale checks on auction site user transactions, in graph mining either topologies are uncovered on the Web, or then fast algorithms are devised with the task of searching and mining for specific, or frequent graph patterns. Examples of such graph mining algorithms are embodied in tools such as *gSpan* (Yan & Han, 2002) for mining frequent subgraph patterns (cf. Yan, Zhu, Yu, & Jan, 2006) – a task which falls within *frequent pattern mining* (of which Han et al., 2007 is a survey) – and the *GraphMiner* system (Wang et al., 2005). Related algorithms were described in Pei, Jiang, and Zhang (2005), Yan, Zhou, and Han (2005), and Zeng, Wang, Zhou, and Karypis (2006). The latter proposed a graph mining algorithm called *Cocain*.

Temporal data mining was surveyed by Laxman and Sastry (2006). Discovering frequent patterns in an *event sequence* fits in that area, whereas *episode mining* fits in both that area, and graph mining. “Discovering patterns in a sequence is an important aspect of data mining. One popular choice of such patterns are episodes, patterns in sequential data describing events that often occur in the vicinity of each other. Episodes also enforce in which order events are allowed to occur” (Tatti & Cule, 2010, from the abstract). “A pattern in a sequence is usually considered to be a set of events that reoccurs in the sequence within a window of a specified length. Gaps are allowed between the events and the order in which the events occur is often also considered important. Frequency, the number of sliding windows in which the episode occurs, is monotonically decreasing” (ibid., section 1). “The order restrictions of an episode are described by a directed acyclic graph (DAG): the set of events in a sequence covers the episode if and only if each event occurs only after all its parent events (with respect to the DAG) have occurred [...] Usually, only two extreme cases are considered. A parallel episode poses no restrictions on the order of events, and a window covers the episode if the events occur in the window, in any order. In such a case, the DAG associated with the episode contains no edges. The other extreme case is a serial episode. Such an episode requires that the events occur in one, and only one, specific order in the sequence. Clearly, serial episodes are more restrictive than parallel episodes. If a serial episode is frequent, then its parallel version is also frequent.” (ibid.). Also see Tatti (2009), Zhou et al. (2010), Gwadera et al. (2005a, 2005b), Casas-Garriga (2003), and Mannila, Toivonen, and Verkamo (1997).

³⁰³ Neville et al. (2005) was jointly authored by a computer scientists team from the University of Massachusetts at Amherst (Jennifer Neville, Özgür Şimşek, and David Jensen), and a team from NASD, the National Association of Securities Dealers (John Komoroske, Kelly Palmer, and Henry Goldberg). In 2011, Jennifer Neville was affiliated with Purdue University in West Lafayette, Indiana.

³⁰⁴ NASD is in Washington, D.C. It was established in 1939. “NASD has a nationwide staff of more than 2,000, and its regulatory responsibility now includes 5,200 securities firms that operate more than 100,000 branch offices and employ 660,000 individual securities brokers” (Neville et al., 2005, section 2.1).

There may be an ethical and perhaps even legal problem with this, because a person may find him- or herself considered guilty by association. But what is being evaluated is not guilt, but reputation. Association with disreputable players tarnishes one's own reputation as well. NASD already had a database of brokers, called *CRD* (*Central Registration Depository*), in operation since 1981.³⁰⁵

Neville et al. (2005, p. 449) indicated the limitations of handcrafted rules in use at NASD before machine learning was applied:

NASD currently identifies higher-risk brokers using a set of handcrafted rules. These rules are based on information intrinsic to the brokers such as the number and type of past violations. They do not exploit social, professional, and organizational relationships among brokers even though NASD experts believe this information is central to the task. Indeed, fraud and malfeasance are usually social phenomena, communicated and encouraged by the presence of other individuals who also wish to commit fraud [(Cortes et al., 2001)]. It is, however, difficult to accurately specify these patterns manually. As such, relational learning methods have the potential to improve current techniques.

Neville et al. (2005, p. 457) claimed that the findings of their own project supported the general beliefs at NASD, while reaching predictions differently:

NASD staff began this project contending that information about the professional and organizational networks that connect brokers would provide useful information for determining their risk for serious violations of securities regulations. The results of this research have borne out those beliefs. Our relational models provide predictions that are competitive with, but significantly different from, the predictions provided by NASD's hand-tuned rules, which only examined brokers and their disclosures, ignoring additional relational information such as coworkers at present and past firms. These models show important potential for NASD's screening process. They identified higher-risk brokers not previously identified by the NASD rules, and thus provided additional targets for NASD examinations. Furthermore, being identified as higher-risk by both our models and the HRB model³⁰⁶ model was found

³⁰⁵ As stated by Neville et al. (2005, section 2.2): "CRD was established to aid in the licensing and registration of its broker-dealers and the brokers who work for them. CRD maintains information on all federally registered broker-dealers and brokers for the SEC [i.e., the U.S. Securities and Exchange Commission], NASD, the states, and other federally authorized private sector regulators, such as the New York Stock Exchange. Originally implemented in June 1981, CRD has grown to include data on approximately 3.4 million brokers, 360,000 branches, and 25,000 firms. For firms, CRD information includes data such as ownership and business locations. For individual brokers, CRD includes qualification and employment information. Information in CRD is self-reported by the registered firms and brokers, although incorrect or missing reports can trigger regulatory action by NASD."

³⁰⁶ The HRB model is NASD's identification of *high-risk brokers* by handcrafted rules. Neville et al. explained (2005, section 3): "Currently, NASD generates a list of higher-risk brokers (HRB) using a set of handcrafted rules they have formed using their domain knowledge and experience. This approach has two weaknesses we aim to address. First, the handcrafted rules simply categorize the brokers as 'higher-risk' and 'lower-risk' rather than providing a risk-ordered ranking. A ranking would be more useful to examiners as it would allow them to focus their attention on brokers considered to have the highest risk. Second, NASD's handcrafted rules use only information intrinsic to the brokers. In other words, they do not utilize relational context information such as the conduct of past and current coworkers. NASD experts believe that organizational relationships can play an important role in predicting serious violations. For example, brokers that have had serious violations in the past may influence their coworkers to participate in future schemes. Furthermore,

to be more predictive of future problems than being identified by either model alone, thus permitting NASD to focus examinations on those most likely to have a serious violation in the near future. And finally, the probability estimates assigned to brokers by our models in general agreed with the subjective ratings of NASD examiners, thus the ranking provided by our models can be used to prioritize examiners' attention.³⁰⁷

We now go back to NetProbe. In NetProbe, the “key idea is to infer properties for a user based on properties of other related users. In particular, given a graph representing interactions between auction users, the likelihood of a user being a fraudster is inferred by looking at the behaviour of its immediate neighbors” (Pandit et al., 2007, p. 203). This is why trust propagation and authority propagation research are akin to the method of NetProbe. Some “non-trivial design and implementation decisions” were made by the Carnegie Mellon team “while developing NetProbe. In particular, we discuss the following contributions: (a) a parallelizable crawler that can efficiently crawl data from auction sites, (b) a centralized queuing mechanism that avoids redundant crawling, (c) fast, efficient data structures to speed up our fraud detection algorithm, and (d) a user interface that visually demonstrates the suspicious behavior of potential fraudsters to the end user” (Pandit et al., 2007, p. 202).

6.2.3.3 How NetProbe Works

In NetProbe, it was the transactions between users that were modelled as a graph, a *Markov random field (MRF)* indeed (we provided a definition for this in the previous subsection; see Section 6.2.3.2). Each node stands for a user. Each edge stands for one or more transactions between pairs of users. If there is an edge between two

some firms tend to be associated with continuous misconduct (i.e., they do not regulate their own employees and may even encourage violations). Lastly, higher-risk brokers sometimes move from one firm to another collectively, operating in clusters, which heightens the chance of regulatory problems. A model that is able to use relational context information has the potential to capture these types of behavior and provide more accurate predictions.”

³⁰⁷ Neville et al. (2005, p. 457) also indicated some limitations: “That said, the available data provide only relatively weak abilities to exploit the relational aspects of the domain. In CRD, individual brokers are directly related only through firms. Even branch relationships have to be inferred from address information, although this limitation will be obviated beginning this October [2005] when each broker will be systematically linked to a branch. More importantly, we do not know which individual brokers work together directly, nor what other social or organizational relationships they may share. To enhance their knowledge of potential links among individuals, NASD is investigating other recent technologies, most notably the NORA (Non-Obvious Relationship Awareness) system produced by Systems Research and Development, a Nevada-based company recently acquired by IBM. Such relationships could add substantially to the data analyzed in the work reported here, which could only use branch and firm relations present in CRD. The work reported here also exemplifies a framework that may be useful to projects that seek to develop screening tools to aid field examiners working in other domains such as health care, insurance, banking, and environmental health and safety. In such cases, development of a labeled training set may be impractical in the initial stages of a project. While the most accurate class labels would be the judgments of examiners, examiners' time is typically limited and organizations may be understandably skeptical about devoting large amount of examiners' time to labelling data sets.”

nodes, this indicates that the two users for whom the two nodes stand, have transacted at least once. Each node can be in one out of three states, namely, fraud, accomplice, or honest, or then its state may be undetermined, in the sense that NetProbe does not assign a state to that node. Pandit et al. (2007, p. 204) pointed out the similarity to authority propagation as used in order to rank the importance of webpages (see in the Section 6.2.3.2):

As is the case with hyper-links on the Web (where PageRank [(Brin & Page, 1998)] posits that a hyper-link confers authority from the source page to the target page), an edge between two nodes in an auction network can be assigned a definite semantics, and can be used to propagate properties from one node to its neighbors. For instance, an edge can be interpreted as an indication of similarity in behavior — honest users will interact more often with other honest users, while fraudsters will interact in small cliques of their own (to mutually boost their credibility). This semantics is very similar in spirit to that used by TrustRank [(Gyongyi et al., 2004)], a variant of PageRank used to combat Web spam. Under this semantics, honesty/fraudulence can be propagated across edges and consequently, fraudsters can be detected by identifying relatively small and densely connected subgraphs (near cliques). However, our previous work [(Chau et al., 2006)] suggests that fraudsters do not form such cliques. [...] Instead, we uncovered a different *modus operandi* for fraudsters in auction networks, which leads to the formation of *near bipartite cores*.³⁰⁸ Fraudsters create two types of identities and arbitrarily split them into two categories — *fraud* and *accomplice*. The fraud identities are the ones used eventually to carry out the actual fraud, while the accomplices exist only to help the fraudsters carry out their job by boosting their feedback rating. Accomplices themselves behave like perfectly legitimate users and interact with other honest users to achieve high feedback ratings. On the other hand, they also interact with the fraud identities to form near bipartite cores, which helps the fraud identities gain a high feedback rating. Once the fraud is carried out, the fraud identities get voided by the auction site, but the accomplice identities linger around and can be reused to facilitate the next fraud.

NetProbe uses the propagation matrix in order to detect *bipartite* cores in the graph. In NetProbe, a particular propagation matrix was devised, so that the belief propagation mechanism would suite the behaviour of fraudsters and their accomplices. The intuition (Pandit et al., 2007, pp. 204–205) was that a fraudster would avoid linking to another fraudster. Rather, a fraudster would link heavily to accomplices.

³⁰⁸ What is meant is that inside the graph which represents the online auction site, one expects to find such subsets of the nodes (i.e., such subsets of the users), that the given subset is a *complete bipartite graph*. That is to say, the given subset could be divided into two subsubsets, and each node in either subsubset has edges linking it to all nodes in the other subsubset. If we replace “all” with “one or more of the”, then we would have a *bipartite graph* that is not a *complete bipartite graph*. This is also a possibility that is relevant for detecting fraudsters and their accomplices at sites like eBay. In the application at hand, which is to fraudsters at an online auction site, a fraudster is linked to all of his or her accomplices, but two or more fraudsters may share accomplices. If a particular fraudster is the only fraudster using his or her accomplices, that is to say, if the fraudster has exclusive use of his or her accomplices, then one of the subsubsets in the (complete) bipartite core is a singleton set, i.e., such a set that it only contains one element. It may also be that if the subsubset comprising the fraudsters comprises more than one fraudster, then the bipartite core is *not* a complete bipartite graph, because it may be that one of the fraudsters in the fraudsters’ subsubset is only using some of the accomplices of another fraudster in that subsubset, and the former fraudster may be using as well some accomplices that the latter fraudster is not using.

Table 6.2.3.3.1 NetProbe’s propagation matrix

Neighbour state	Node state		
	Fraud	Accomplice	Honest
Fraud	ϵ	$1 - 2\epsilon$	ϵ
Accomplice	0.5	2ϵ	$0.5 - 2\epsilon$
Honest		$(1 - \epsilon)/2$	$(1 - \epsilon)/2$

An accomplice, instead, would link to both honest nodes, and fraudsters, but the accomplice has a higher affinity for fraudsters. As to honest nodes (i.e., innocent users), they link to honest nodes as well as to accomplices, because the honest user believes that the accomplice to be honest.

Pandit et al. (2007, p. 205) gave the table shown here as Table 6.2.3.3.1, and in particular, in their experiments they found it useful to set the value of ϵ to 0.05. Each case in the table denotes the probability that the given node is in the state identified by the column, given that this node itself has a neighbour in the state identified by the row.

In the running example shown in Figs. 6.2.3.3.1, 6.2.3.3.2, 6.2.3.3.3, 6.2.3.3.4, 6.2.3.3.5, and 6.2.3.3.6, the graph consists of users numbered from 0 to 14, and of these, nodes 7–14 are a bipartite core. All nodes are initially given the value “unbiased”, in the sense that they are equally likely to be honest, or a fraudster, or

an accomplice. Pandit et al. (2007, p. 204, figure 2) resorted to the convention of depicting as red triangles the fraudsters, as yellow diamonds the accomplices, as white ellipses the honest nodes, and as gray rounded rectangles the unbiased nodes. By iteratively passing messages, the nodes affect each other’s beliefs. Pandit et al. (2007, p. 205) explained:

Notice that the particular form of the propagation matrix we use assigns a higher chance of being an accomplice to every node in the graph at the end of the first iteration. These

accomplices then force their neighbors to be fraudsters or honest depending on the structure of the graph. In case of bipartite cores, one half of the core is pushed towards the fraud state, leading to a stable equilibrium. In the remaining graph, a more favorable equilibrium is achieved by labelling some of the nodes as honest. At the end of execution, the nodes in the bipartite core are neatly labeled as fraudsters and accomplices. The key idea is the manner in which accomplices force their partners to be fraudsters in bipartite cores, thus providing a good mechanism for their detection.

Goldberg et al. (2008), who were concerned with evolving social networks, remarked: “Their loose membership and dynamics make them difficult to observe

Fig. 6.2.3.3.6 Stage 6 in a sample execution of NetProbe. By kind permission of “Polo” Chau of Carnegie Mellon University, and by kind permission of the Secretariat of IW3C2 for the WWW conferences. Detail from a figure in Pandit et al. (2007)

and monitor”. Sparrow (1991) among others recognised that criminal networks are dynamic, not static. All the more so, online auction sites burst with activity.³⁰⁹ Pandit et al. (2007, p. 205) remark that in practice, given the very large size of the graph, it would be too strong a requirement if NetProbe had to propagate beliefs over the entire graph each and every time that a node (i.e., a user) or an edge (i.e., a transaction) is added to the network. In order for the users to get answers to their queries in real time when using NetProbe, the Carnegie Mellon team which developed NetProbe, also developed Incremental NetProbe, a version which allows approximation. This avoids wasteful recomputation from scratch of node beliefs. Incremental NetProbe incrementally³¹⁰ updates node beliefs as small changes occur in the graph. Figure 6.2.3.3.7 shows an example of Incremental NetProbe. The assumption, when using Incremental NetProbe, is that the addition of a new edge would only have a local effect. Incremental NetProbe works as follows (ibid.):

Whenever a new edge gets added to the graph, the algorithm proceeds by performing a breadth-first search of the graph from one of the end points (call it n) of the new edge, up to a fixed number of hops h , so as to retrieve a small subgraph, which we refer to as the

³⁰⁹ In fact, Prof. Christos Faloutsos (<http://www.cs.cmu.edu/~christos>), who supervised the development of NetProbe at Carnegie Mellon University, is also quite active in *graph mining*, and, in particular, in researching evolving graphs. See Section 6.2.4 below.

³¹⁰ In computer science, an *incremental* system is such that additions do not intrude into what was already there. This prevents having to do extensive changes to what one already had, once a new version is installed.

Fig. 6.2.3.3.7 An example of Incremental NetProbe. By kind permission of “Polo” Chau of Carnegie Mellon University, and by kind permission of the Secretariat of IW3C2 for the WWW conferences. From Pandit et al. (2007). *Red triangles* represent fraudsters, *yellow diamonds* represent accomplices, *white ellipses* represent honest nodes, while *gray rounded rectangles* represent unbiased nodes. An edge (shown as a *dotted blue line*) is added between nodes 9 and 10 of the graph on the left hand side. Normal propagation of beliefs in the 3-vicinity of node 10 (shown on the right hand side) leads to incorrect inference, and so nodes on the boundary of the 3-vicinity (i.e. node 6) should retain their beliefs

h-vicinity of *n*. It is assumed that only the beliefs of nodes within the *h*-vicinity are affected by addition of the new edge. Then, “normal” belief propagation is performed only over the *h*-vicinity, with one key difference. While passing messages between nodes, beliefs of the nodes on the boundary of the *h*-vicinity are kept fixed to their original values. This ensures that the belief propagation takes into account the *global* properties of the graph, in addition to the local properties of the *h*-vicinity.

6.2.3.4 A Non-Mining Model for Reasoning on the Evidence of Online Auction Fraud

At the end of Section 6.2.3.1, we mentioned a study about online auction fraud by Kwan et al. (2010). That study, carried out by computer scientists at King’s College London and the University of Hong Kong, is concerned with Internet auction fraud

involving the selling of faked goods in Hong Kong, and goods bearing false trade descriptions or forged trademarks. Let us elaborate about the original proposal in Kwan et al. (2010). Its approach is not from data mining. It is in probabilistic analysis, and strictly speaking, could be performed in theory on paper, maybe with a good calculator as help. We nevertheless dwell on this here, for the sake of representativeness, because it is often the case that AI systems for legal evidence include probabilistic analysis (notwithstanding the controversial status of Bayesianism for judicial purposes).

Kwan et al. (2010) proposed (basing themselves on several prosecuted cases) an investigation model for online auction fraud in selling of counterfeit goods using a Bayesian network approach. They made three ancillary hypotheses, substantiating the overall prosecution hypothesis that an online auction fraud crime has been committed. Namely, they hypothesised that perpetrators uploaded auction-related material, such as images or descriptions of the items. They hypothesised that manipulation (editing) of the corresponding auction item had taken place, such as adjusting the price. And they hypothesised that communication (e.g., by email or by instant messaging) had occurred between the seller and the buyer, concerning the auctioned fake item.

Those three sub-hypotheses are supported by 13 distinct evidential traces, again obtained from the responsible digital forensic examiners. Kwan et al. (2010) represented this in a Bayesian network model for the prosecution's main hypothesis and three ancillary hypotheses, with the related evidential traces; it is redrawn in Fig. 6.2.3.4.1. "This does not of itself substantiate the whole prosecution case. The auctioned item also has to be procured physically by the investigator and to be examined by the trademark owner in order to ascertain whether or not the item is counterfeit in nature" (ibid.).

Fig. 6.2.3.4.1 A Bayesian network model, redrawn from Kwan et al. (2010), for prosecution hypotheses and evidential traces related to cases of online auction fraud

Note however that the approach in Kwan et al. (2010) is *not* from data mining. They intended it to be applied once suspects had already been identified, and were being prosecuted. In practice, they provided an interpretation of a typical case, being an abstraction of twenty cases that had actually been prosecuted in Hong Kong.

In Fig. 6.2.3.4.1, the prosecution hypotheses are as shown in Table 6.2.3.4.1. The evidential traces in Fig. 6.2.3.4.1 are as shown in Table 6.2.3.4.2.

Kwan et al. (2010) also developed a Bayesian network model for evaluating the relevance of the digital evidential trace, representing the defence’s scenarios; it is redrawn in Fig. 6.2.3.4.2.

In Fig. 6.2.3.4.2, the prosecution hypotheses are as shown in Table 6.2.3.4.3.

The evidential traces in Fig. 6.2.3.4.2 are the same as in Fig. 6.2.3.4.2:

E_{d1} has the same definition as E_{p1} .
 E_{d2} has the same definition as E_{p2} ,
 and so forth.

Table 6.2.3.4.1 The prosecution hypotheses in Fig. 6.2.3.4.1

H_p	The seized computer has been used as transaction tool for the fake item.
H_{p1}	Uploading of auction material related to the fake item has been performed.
H_{p2}	Manipulation of the corresponding auction item has been performed.
H_{p3}	Communication between the seller and the buyer on the fake auction item has occurred.

Table 6.2.3.4.2 The evidential traces in Fig. 6.2.3.4.1

E_{p1}	Material of the auctioned fake item (e.g., image file, text files, etc.) was found on the seized computer.
E_{p2}	Seller’s account login record was retrieved from the auction site.
E_{p3}	Meta-data of a file found on the seized computer matched with that found on the auction site.
E_{p4}	IP address assigned to the seized computer matched with that which performed the data transfer.
E_{p5}	Internet history / cached contents for transferring the auctioned fake item material was found on the seized computer.
E_{p6}	Seller’s account login record was retrieved from the auction site.
E_{p7}	IP address assigned to the seized computer matched with that logged into the auction site.
E_{p8}	Editing of an auction item has occurred (e.g., price adjustment) on the auction site.
E_{p9}	Enhanced material of an auction item (e.g., image file, text file, etc.) was found on the seized computer.
E_{p10}	Messages from auction site related to an auction item were found on the seized computer.
E_{p11}	Messages to/from the buyer related to an auction item were found on the seized computer.
E_{p12}	Address book containing covert investigator’s email account was found on the seized computer.
E_{p13}	IP address assigned to the seized computer matched with that which performed the email communication.

Fig. 6.2.3.4.2 A Bayesian network model, redrawn from Kwan et al. (2010), for the defence’s scenario, explaining out the same evidential traces which the prosecution interprets in terms of online auction fraud

Table 6.2.3.4.3 The prosecution hypotheses are as shown in Table 6.2.3.4.3

H_d	The seized computer has been used as transaction tool for the fake item.
H_{d1}	Auction material related to the fake item was downloaded from the auction site.
H_{d2}	Manipulation of a non-fake item has taken place.
H_{d3}	Communication between the seller and the buyer on a non-fake auction item has occurred.

Kwan et al. (2010) – who did not acknowledge the misgivings that several important law scholars have concerning the application of Bayesianism to criminal cases – used a *likelihood rate* (*LR* for short), in the version devised by Evett (1993) in order to represent the situation where it is uncertain whether or not the evidence is a result of the suspect’s activity:

$$LR = \frac{\Pr(E|H_p)}{\Pr(E|H_d)}$$

where *E* is the total digital evidence related to the crime. Kwan et al. (2010) claimed:

In our simple Bayesian network models, the existence of each individual trace of digital evidence does not imply the existence of any other such traces. Since the evidential traces are mutually independent, their individual probabilities can be multiplied together to determine the probability of *E* given a root hypothesis. The prior probability values of the individual evidential traces for the online auction fraud models (both prosecution and defense) were obtained from a survey of the digital forensic examiners of the Hong Kong Customs & Excise Department, and are generally accepted values within this community of experts.

As calculated by Kwan et al. (2010), the LR of evidence for hypothesis *H_{p1}* against the evidence for hypothesis *H_{d1}* is:

$$\frac{\Pr(E|H_{p1})}{\Pr(E|H_{d1})} = \pi_{p1}/\pi_{d1} \quad \text{where}$$

$$\pi_{p1} = \Pr(E_{p1} | H_{p1}) \times \Pr(E_{p2} | H_{p1}) \times \Pr(E_{p3} | H_{p1}) \times$$

$$\times \Pr(E_{p4} | H_{p1}) \times \Pr(E_{p5} | H_{p1})$$

$$\pi_{d1} = \Pr(E_{d1} | H_{d1}) \times \Pr(E_{d2} | H_{d1}) \times \Pr(E_{d3} | H_{d1}) \times$$

$$\times \Pr(E_{d4} | H_{d1}) \times \Pr(E_{d5} | H_{d1})$$

which they calculated as:

$$\approx \frac{0.9 \times 0.75 \times 0.6 \times 0.75 \times 0.85}{0.9 \times 0.05 \times 0.6 \times 0.01 \times 0.01} \approx \frac{0.258}{0.0000027} \approx 95,600$$

Similarly, Kwan et al. (2010) calculated the LR values for H_{p2} against H_{d2} and H_{p3} against H_{d3} . It was especially for the prosecution's first sub-hypothesis that they found strong support. It cannot be however overemphasised that the concerns of scholars who are skeptical about Bayesianism in a judiciary context are important, and must be addressed. In Kwan et al. (2010) there is no mention of how controversial this topic is. There is one context however in which applying this kind of model would be unproblematic, and this is if the prosecution carries out such calculations when evaluating whether it has evidence strong enough for prosecuting. That is to say, this would just fit in a costs/benefits model.

6.2.4 Graph Mining for Malware Detection, Using Polonium

6.2.4.1 Preliminaries About Graph Mining

The leader of the team from Carnegie Mellon University that developed NetProbe, the tool for detecting fraudsters and their accomplices at online auction sites which we described in Sections 6.2.3.2 and 6.2.3.3 above, Prof. Christos Faloutsos,³¹¹ is also quite active in *graph mining*. This is the area within data mining that is concerned with very large graphs.³¹² Finding the mastermind of some activity within a graph is just one of the problems for which graph mining can be put to use. Another such use is modelling virus propagation, or how news propagates through blogs on the Web (this allows to understand the impact of blogs): the Blogosphere consists of blogs and posts (postings on a blog); there is a blog network, linking blogs, and (at a more detailed level) a post network, linking posts. Posts may be popular, but they tend to decay: post popularity drops off as days elapse since when the posting took place. Another task is finding patterns: rules, and outliers. Another problem is to understand how do real graphs look like, in social contexts involving very large

³¹¹ See <http://www.cs.cmu.edu/~christos>

³¹² See a long slide presentation, graphMining.ppt, at the same website.

graphs (such as the Internet map, or friendship networks, or protein interactions, of the food web in ecological systems, such as the smallmouth bass, which is a cannibalistic fish, along with leeches, phytoplankton, and zooplankton in Little Rock Lake).

A major side to Faloutsos' research on graph mining is the study of the temporal evolution of graphs. One application is tracking communities over time. In social network analysis, a static task is finding community structures. a dynamic task is monitoring community structure evolution, spotting abnormal individuals, or abnormal time-stamps. *Network forensics* is yet another application, the task being the identification of abnormal traffic pattern and finding out the cause.

One aspect of the temporal evolution of graphs is the study of *densification*, such as in affiliation networks (authors linked to their publications), or in patents being cited, or in physics papers citations. Another problem is, given a growing graph with such and such count of nodes, *generate* a realistic sequence of graphs that will obey all the static and dynamic patterns, such as power laws, or patterns about the diameter (a small diameter is a static pattern, whereas diameters shrinking or stabilizing is a dynamic pattern). Faloutsos has been developing a generator in which such properties can be proven. For time evolving graphs, Faloutsos has applied tensors; these are multi-dimensional extensions of arrays, and there exist various decomposition methods for them, just as there exist decomposition methods for arrays.³¹³ Faloutsos and colleagues used tensor-based methods in order to spot patterns and anomalies on time evolving graphs, as well as for monitoring purposes, by application to streams.³¹⁴ *PeGaSus* is an open source Peta Graph Mining library, developed by Faloutsos and others, which performs typical graph mining tasks such as computing the diameter of the graph, computing the radius of each node, finding the connected components, and computing the importance score of nodes.

³¹³ In an overview of the application of tensor factorisations and decompositions in data mining, Morten Mørup explains (2011, p. 24): "Tensors, or multiway arrays, are generalizations of vectors (first-order tensors) and matrices (second-order tensors) to arrays of higher orders ($N > 2$). Hence, a third-order tensor is an array with elements $x_{i,j,k}$. Tensor decompositions are in frequent use today in a variety of fields ranging from psychology, chemometrics, signal processing, bioinformatics, neuroscience, web mining, and computer vision to mention but a few. Factorizing tensors have several advantages over two-way matrix factorization such as uniqueness of the optimal solution (without imposing constraints such as orthogonality and independence) and component identification even when only a relatively small fraction of all the data is observed (i.e., due to missing values). Furthermore, multiway decomposition techniques can explicitly take into account the multiway structure of the data that would otherwise be lost when analyzing the data by matrix factorization approaches by collapsing some of the modes. Tensor decompositions are in frequent use in psychometrics in order to address questions such as 'which group of subjects behave differently on which variables under which conditions?'" Arguably, this may also be useful for data mining for investigative purposes or for criminal intelligence purposes.

³¹⁴ The projects of Faloutsos' team mentioned in Section 6.2.4.1 were described in See Tong, Faloutsos, and Jia-Yu Pan (2006); Tong and Faloutsos (2006); Leskovec, Kleinberg, and Faloutsos (2005); Leskovec, Chakrabarti, Kleinberg, and Faloutsos (2005); Leskovec and Faloutsos (2007); Sun, Tao, and Faloutsos (2006); Sun, Xie, Zhang, and Faloutsos, (2007).

6.2.4.2 The *Polonium* System

Esmaili, Safavi-Naini, Balachandran, and Pieprzyk (1996) applied case-based reasoning to the differentiation between hostile intrusions of computer systems and other anomalous transactions.³¹⁵ Duen Horng “Polo” Chau, of the Carnegie Mellon University team that developed NetProbe, also developed (in collaboration with Symantec, the world’s leading security software provider) *Polonium*,³¹⁶ a tool for detecting malware.³¹⁷ A *malware instance* is defined as a program that has malicious intent. Computer viruses are just one kind of malware. Other kinds include worms, Trojan horses, rootkits, spyware, adware, and so forth.³¹⁸ Infected files are also considered malware. Chau, Nachenberg, Wilhelm, Wright, and Faloutsos (2010) claimed: “We evaluated it with the largest anonymized file submissions dataset ever published, which spans over 60 *terabytes* of disk space”,³¹⁹ with over 900 million files described in the raw data, from a total of 47,840,574 machines. *Polonium* resorts to graph mining. Like NetProbe, it also resorts to the belief propagation algorithm. “We adapted the algorithm for our problem. This adaptation was non-trivial, as various components used in the algorithm had to be fine tuned; more importantly, [...] modification to the algorithm was needed to induce iterative improvement in file classification.” (Chau et al., 2010). A reputation-based approach was adopted. In a nutshell, “the key idea of the *Polonium* algorithm is that it infers a file’s goodness by looking at its associated machines’ reputations iteratively. It uses all files’ current goodness to adjust the reputation of machines associated with those files; this adjusted machine reputation, in turn, is used for re-inferring the files’ goodness.” (ibid.).

The reputation-based approach adopted is a Symantec protection model that, for ever application that users may encounter computes a *reputation* score, and protects them from files whose score is poor. Various attributes contribute to reputation: whether an application comes from known publishers, whether it already has many users, and so forth. “Symantec has computed a reputation score for each machine based on a proprietary formula that takes into account multiple anonymous aspects of the machine’s usage and behavior. The score is a value between 0 and 1” (Chau et al., 2010). Intuitions include: “Good files typically appear on many machines and bad files appear on few machines.” (ibid.). Another intuition is what was called *homophilic machine–file relationships*: “We expect that good files are more likely to appear on machines with good reputation and bad files more likely to appear on

³¹⁵ Data mining has been applied to malware detection also by Muazzam Ahmed Siddiqui in his doctoral thesis discussed in Orlando, Florida (Siddiqui, 2008).

³¹⁶ The tool was probably named *Polonium* because of its association with the doctoral student “Polo” Chau, or at any rate the coincidence is apt, but the official explanation is that *Polonium* is an acronym for *Propagation Of Leverage Of Network Influence Unearths Malware*.

³¹⁷ See Chau et al. (2010), and an informal discussion in Chau (2011).

³¹⁸ At www.symantec.com/norton/security_response/malware.jsp Symantec provides definitions for kinds of malware.

³¹⁹ Emphasis in the original.

machines with low reputation. In other words, the machine-file relationships can be assumed to follow homophily.” (ibid.).³²⁰

Computing *reputation* credibly was made possibly by the worldwide Norton Community Watch program, with millions of users contributing data anonymously. This is a huge file submissions dataset. The raw data undergo processing at Symantec, and then are fed into Polonium, which mines the data statistically, and machine learning is applied. “Each contributing machine is identified by an anonymized machine ID, and each file by a file ID which is generated based on a cryptographically-secure hashing function” (Chau et al., 2010). An undirected, unweighted bipartite graph of files and machines was generated “from the raw data, with almost 1 billion nodes and 37 billion edges (37,378,365,220). 48 million of the nodes are machine nodes, and 903 million are file nodes. An (undirected) edge connects a file to a machine that has the file. All edges are unweighted; at most one edge connects a file and a machine. The graph is stored on disk as a binary file using the *adjacency list* format” (ibid.); “we want to label a file node as good or bad, along with a measure of the confidence in that disposition” (ibid.).

Polonium computes the reputation for a given application, and is used in concert with other Symantec malware detection technologies. In the belief propagation algorithm as used in Polonium, belief corresponds to reputation. The Polonium team treated each file as a random variable X , whose value is

- either x_g (this being the “good” label)
- or x_b (this being the “bad” label).
- The probability $P(x_g)$ is the file goodness,
- whereas $P(x_b)$ is the file badness,

and the sum of the two probabilities is 1. Therefore, by knowing the value of one also knows the other. For each file i , the goal is to find the marginal probability

$$P(X_i = x_g),$$

that is the goodness of that file. Domain knowledge helps infer label assignments.

³²⁰ Social influence is the subject of the papers in Forgas and Williams (2001). LaFond and Neville (2010) carried out *randomisation tests* for distinguishing *social influence* and *homophily effects*. A clear case where social influence is posited, is in the NASD beliefs that for determining the reputation of sock brokers, association with disreputable brokers is tarnishing, because one may be influenced into behaving irregularly like them (Neville et al., 2005). See fn 189 sqq. above. In artificial intelligence, Charlotte Gerritsen, Michel Klein and Tibor Bosse applied *agent-based simulation* to criminology: “A large group of offenders only shows criminal behaviour during adolescence. This kind of behaviour is largely influenced by the interaction with others, through social learning” (ibid., from the abstract). Their own study set to “to simulate social learning of adolescence-limited criminal behaviour, illustrated for a small school class. The model is designed in such a way that it can be compared with data resulting from a large scale empirical study” (ibid., from the abstract).

Terminology with the respective definitions include: *file ground truth* for “file label, good or bad, assigned by human security experts” (here, by file an executable file is meant); *known-good file* for “file with good ground truth”; *known-bad file* for “file with bad ground truth”; and *unknown file* for “file with unknown ground truth”. “Symantec maintains a *ground truth database* that contains large number of *known-good* and *known-bad* files, some of which exist in our graph. We can leverage the labels of these files to infer those of the unknowns. The ground truth files influence their associated machines which indirectly transfer that influence to the unknown files” (Chau et al., 2010).

Moreover, the possibility of errors is recognised: in the case of Polonium, *True Positive (TP)* stands for “malware instance correctly identified as bad”, as opposed to *False Positive (FP)* for “a good file incorrectly identified as bad”. False positives are a price to pay that comes with some successful malware detection tools: Tesauro, Kephart, and Sorkin (1996), who applied neural networks, were able to detect “boot sector viruses” with over 90% true positive rate in identifying those viruses, but on the other hand this came at a 15–20% false positive rate. In Polonium, there is a tradeoff concerning false positives, that is expressed in how the belief propagation algorithm is made to stop.³²¹

Virus signatures are virus profiles, or virus definitions. Malware detection comes in two major categories: *anomaly-based detection*, based on some presumed “normal” behaviour from which malware deviates; and *signature-based detection*, in which malware instances are detected because they fit some profiles (Idika & Mathur, 2007; Chau et al., 2010). It was Kephart and Arnold (1994) who first used data mining techniques to automatically extract virus signatures. Schultz, Eskin, Zadok, and Stolfo (2001) were among those who pioneered the application of machine learning algorithms (in their case, Naive Bayes and Multi-Naive Bayes) to classify malware.

In Naive Bayes, for a given sample we search for a class c_i that maximises the posterior probability

$$P(c_i | x; \theta')$$

by applying Bayes rule. Then x can be classified by computing

$$c_l = \arg \max_{c_i \in C} P(c_i | \theta') P(x | c_i; \theta')$$

Concerning how belief propagation was applied in Polonium, Chau et al. (2010) explain:

At a high level, the algorithm infers the label of a node from some prior knowledge about the node, and from the node’s neighbors. This is done through iterative message passing between all pairs of nodes v_i and v_j . Let $m_{ij}(x_j)$ denote the message sent from i to j . Intuitively, this message represents i ’s opinion about j ’s likelihood of being in class x_j . The prior knowledge about a node i , or the prior probabilities of the node being in each possible class are expressed through the *node potential function* $\phi(x_i)$

³²¹ See an explanation in fn 207 below.

This prior probability is called a *prior*. Once the procedure execution is completed, the goodness of each file is determined: “This goodness is an estimated marginal probability, and is also called *belief*, or formally $b_i(x_i) (\approx P(x_i))$, which we can threshold into one of the binary classes. For example, using a threshold of 0.5, if the file belief falls below 0.5, the file is considered bad” (ibid.). The messages are obtained as follows (ibid.):

Each edge e_{ij} is associated with messages $m_{ij}(x_j)$ and $m_{ji}(x_i)$ for each possible class. Provided that all messages are passed in every iteration, the order of passing can be arbitrary. Each message vector m_{ij} is normalized over j (node j is the message’s recipient), so that it sums to one. Normalization also prevents numerical underflow (or zeroing-out values). Each outgoing message from a node i to a neighbor j is generated based on the incoming messages from the node’s other neighbors.

Let $N(i)$ be the set of nodes that are the neighbours of node i . Let k be a normalizing constant. Let the *edge potential* be notated as $\psi_{ij}(x_i, x_j)$; “intuitively, it is a function that transforms a node’s incoming messages collected into the node’s outgoing ones. Formally, $\psi_{ij}(x_i, x_j)$ equals the probability of a node i being in class x_i given that its neighbor j is in class x_j .” (ibid.). The message-update equation is:

$$m_{ij}(x_j) \leftarrow \sum_{x_i \in X} \phi(x_i) \psi_{ij}(x_i, x_j) \prod_{k \in N(i) \setminus j} m_{ki}(x_i)$$

When the execution of the belief propagation algorithm ends,³²² the node beliefs are determined according to this formula:

$$b_i(x_i) = k \phi(x_i) \prod_{x_j \in N(i)} m_{ji}(x_i)$$

In Polonium, the intuition that good files are (slightly) more likely to appear on machines with good reputation and bad files (slightly) more likely to appear on machines with low reputation (that is to say, the *homophilic machine–file*

³²² “The algorithm stops when the beliefs converge (within some threshold. 10^{-5} is commonly used), or a maximum number of iterations has finished. Although convergence is not guaranteed theoretically for generally graphs, except for those that are trees, the algorithm often converges in practice, where convergence is quick and the beliefs are reasonably accurate.” (Chau et al., 2010). In particular, in Polonium, there is a departure from how usually a belief propagation is made to terminate, and this involves how *true positive rates (TPR)* rather than *false positive rates (FPR)* are treated: “the Polonium algorithm’s termination criterion is goal-oriented, meaning the algorithm stops when the TPR does not increase any more (at the preset 1% FPR). This is in contrast to Belief Propagation’s convergence-oriented termination criterion. In our premise of detecting malware, the goal-oriented approach is more desirable, because our goal is to classify software into good or bad, at as high of a TPR as possible while maintaining low FPR — the convergence-oriented approach does not promise this; in fact, node beliefs can converge, but to undesirable values that incur poor classification accuracy. We note that in each iteration, we are trading FPR for TPR. That is, boosting TPR comes with a cost of slightly increasing FPR. When the FPR is higher than desirable, the algorithm stops” (ibid.).

Table 6.2.4.2.1 Edge potentials in polonium

$\Psi_{ij}(x_i, x_j)$	$x_i = \text{good}$	$x_i = \text{bad}$
$x_j = \text{good}$	$0.5 + \varepsilon$	$0.5 - \varepsilon$
$x_j = \text{bad}$	$0.5 - \varepsilon$	$0.5 + \varepsilon$

relationships assumption) was converted into an edge potential defined according to Table 6.2.4.2.1, where the value of ε was set to 0.001.

Moreover, for machine nodes, the *node potential function* maps the reputation score computed by Symantec, into the machine’s prior. That exponential mapping obeys the following formula (where k is a constant whose value is based on domain knowledge):

$$\text{machine_prior} = e^{-k \times \text{reputation}}$$

This translates the intuition about what machine reputation contributes to the file reputation, into the machine prior. “Similarly, we use another *node potential function* to set the file prior by mapping the intuition that files that appear on many machines are typically good” (ibid.). This maps file prevalence into file prior. That is to say, the intuition about file goodness is translated into an unknown-file prior. And finally, the intuition about file ground truth is mapped into known-file prior: “For known-good files, we set their priors to 0.99. For known-bad, we use 0.01” (ibid.). “Note that no probability is ever 0, because it can ‘zero-out’ other values multiplied with them. A lower bound of 0.01 has been imposed on all probabilities. Upper bound is, therefore, 0.99, since probabilities of the two classes add up to 1” (ibid.).

When developing Polonium, the team modified the file-to-machine propagation between nodes of the graph: the edge potential based on the homophilic intuition is used in order “to propagate machine reputations to a file from its associated machines. Theoretically, we could also use the same edge potential function for propagating file reputation to machines. However, as we tried through numerous experiments — varying the ε parameter, or even ‘breaking’ the homophily assumption — we found that machines’ intermediate beliefs were often forced to changed too significantly” (ibid.): what was happening, was that such change “led to an undesirable chain reaction that changes the file beliefs dramatically as well, when these machine beliefs were propagated back to the files. We hypothesized that this happens because for a machine’s reputation (used in computing the machine node’s prior) is a reliable indicator of machine’s beliefs, while the reputations of the files that the machine is associated with are weaker indicators”. Based on this hypothesis, the team found this solution: “instead of propagating file reputation directly to a machine”, the had Polonium “pass it to the proprietary formula that Symantec uses to generate machine reputation, which re-compute a new reputation score for the machine”. Experiments showed “that this modification leads to iterative improvement of file classification accuracy” (ibid.). Figure 6.2.4.2.1 shows an overview of the Polonium technology. Figure 6.2.4.2.2 shows the scalability of Polonium: the run time per iteration is linear to the number of edges.

6.2.5 Link Analysis with Coplink

We have referred to the Coplink project in Section 6.1.2.4. *Coplink* is a tool for criminal intelligence analysis which finds links in databases among such entities. Coplink, developed by a team at the University of Arizona in collaboration with the Tucson police, performs data integration, pooling together the various information sources available (Hauck et al., 2002; Chen, Zheng, et al., 2003; Chen et al., 2003). It “evolved into a real-time system being used in everyday police work” (Hauck et al., 2002, p. 30). Drawing on experience gained with the Coplink project,³²³ Chen et al. (2004) presented a general framework for crime data mining. Next, Xiang et al. (2005) described a prototype system called the COPLINK Criminal Relationship Visualizer.³²⁴

At the Tucson Police Department (TPD), records at the time consisted of about 1.5 million criminal case reports, containing details from criminal events spanning the period from 1986 to 1999 (Hauck et al., 2002, p. 31). Notwithstanding investigators being able, before Coplink became available, to access the Records management System (RMS) to tie together information, when it came to finding relationships inside the records they had to manually search the RMS data (ibid.).

In Coplink, a concept space is applied (ibid.):

Coplink’s underlying structure is the *concept space*, or automatic thesaurus, a statistics-based, algorithmic technique used to identify relationships between objects of interest. A concept space consists of a network of terms and weighted associations that assist in concept-based information retrieval within an underlying information space.

In addition, co-occurrence analysis³²⁵ uses similarity and clustering functions to weight relationships between all possible concept pairs. The resulting network-like concept space

³²³ Coplink is accessible at <http://ai.bpa.arizona.edu/coplink>

³²⁴ Also see Schroeder, Xu, Chen, and Chau (2007).

³²⁵ Consider, within data mining, the task of *frequent pattern mining*, of which Han, Cheng, Xin, and Yan (2007) is a survey. They explained (ibid., p. 56): “Frequent patterns are itemsets, subsequences, or substructures that appear in a data set with frequency no less than a user-specified threshold. For example, a set of items, such as milk and bread, that appear frequently together in a transaction data set, is a *frequent itemset*. A subsequence, such as buying first a PC, then a digital camera, and then a memory card, if it occurs frequently in a shopping history database, is a (*frequent*) *sequential pattern*. A *substructure* can refer to different structural forms, such as subgraphs, subtrees, or sublattices, which may be combined with itemsets or subsequences. If a substructure occurs frequently in a graph database, it is called a (*frequent*) *structural pattern*. Finding frequent patterns plays an essential role in mining associations, correlations, and many other interesting relationships among data. Moreover, it helps in data indexing, classification, clustering, and other data mining tasks as well. Thus, frequent pattern mining has become an important data mining task and a focused theme in data mining research. Frequent pattern mining was first proposed by Agrawal et al. (1993) for market basket analysis in the form of association rule mining. It analyses customer buying habits by finding associations between the different items that customers place in their ‘shopping baskets’. For instance, if customers are buying milk, how likely are they going to also buy cereal (and what kind of cereal) on the same trip to the supermarket? Such information can lead to increased sales by helping retailers do selective marketing and arrange their shelf space. Since the first proposal of this new data mining task and its associated efficient mining algorithms, there have been hundreds of follow-up research publications, on various kinds of extensions and

holds all possible associations between objects, which means that the system retains and ranks every existing link between every pair of concepts. Analysts frequently use this technique to develop domain-specific knowledge structures for digital-library applications.

In Coplink, detailed case reports serve as the underlying space, while concept derive from the meaningful terms that occur in each case. Concept space analysis easily identifies relevant terms and their degree of relationship to the search term. The system output includes relevant terms ranked in the order of their degree of association, thereby distinguishing the most relevant terms from inconsequential terms. From a crime investigation standpoint, concept space analysis can help investigators link known objects to other related objects that might contain useful information for further investigation — such as people and vehicles related to a given suspect.

Hauck et al. (2002, p. 31) listed three main steps involved in building a domain-specific concept space (CS). The first step consists of identifying document collections in the specific subject domain, and for the Tucson police, the collection was the case reports in the existing database. Each piece of information in the case reports database was categorised and stored in well-organised structures. At the second step, the terms were filtered and indexed (ibid., pp. 31–32):

A co-occurrence analysis captures the relationships among indexed terms. Developers then insert the resulting concept space into a database for easy manipulation with an appropriate algorithm. These last two steps were customized for the Coplink CS. After optimizing the code and tuning the database, building a Coplink CS takes approximately five hours, an acceptable period considering the TPD's requirements. [...] Term types in the CS concept space were divided into five main categories: Person, Organization, Location, Crime, and Vehicle. For the first four categories, only one piece of information such as a person's full name, street address, or crime type can function as a search term. For a vehicle, on the other hand, a single piece of information — such as color, make, or type — results in so many matches that using it as a search term would generate a flood of relevant terms. To avoid this problem, the Coplink CS combines two or more nonspecific vehicle terms into one composite term.

Hauck et al. (2002, p. 32) described how they applied co-occurrence analysis, by first identifying terms, and then computing the term frequency and document frequency for each term in a document, using a method proposed by Chen and Lynch (1992) for the automatic construction of networks of concepts characterising document databases.

The number of occurrences of term j in document i is the term frequency, tf_{ij} . By contrast, the document frequency df_j is the number of documents in a collection of N documents in which term j occurs. N is the total number of documents in a collection, whereas w_j is the weight of words in descriptor j . By d_{ij} one represents the combined weight of term j in document i . This is calculated as follows:

$$d_{ij} = tf_{ij} \cdot \log (N \cdot w_j / df_j)$$

applications, ranging from scalable data mining methodologies, to handling a wide diversity of data types, various extended mining tasks, and a variety of new applications.”

Higher weights are assigned to such term types that are more descriptive and more important than others. Such higher weights are intended to ensure that relationships associated with these term types be always ranked reasonably. In particular, in the concept space of Coplink it was crime types that were assigned higher weights.

Term co-occurrence analysis was performed, according to Hauck et al. (2002, p. 32), based on the asymmetric cluster function, where W_{jk} are the similarity weights from term j to term k , whereas W_{kj} are the similarity weights from term k to term j , and where d_{ij} and d_{ik} are the combined weight of both descriptors j and k in document i :

$$W_{jk} = \text{WeightingFactor}(k) \cdot \left(\sum_{i=1}^n d_{ijk} \right) / \left(\sum_{i=1}^n d_{ij} \right)$$

$$W_{kj} = \text{WeightingFactor}(j) \cdot \left(\sum_{i=1}^n d_{ikj} \right) / \left(\sum_{i=1}^n d_{ik} \right)$$

Where *WeightingFactor* is used in order to penalise general terms, so that general terms be pushed down in the co-occurrence table, and is calculated according to the formulae:

$$\text{WeightingFactor}(k) = \log(N/df_k) / \log N$$

$$\text{WeightingFactor}(j) = \log(N/df_j) / \log N$$

The combined weights of descriptors were calculated according to the formulae:

$$d_{ijk} = tf_{ijk} \cdot \log(N \cdot w_j / df_{jk})$$

$$d_{ikj} = tf_{ijk} \cdot \log(N \cdot w_k / df_{jk})$$

“where tf_{ijk} represents the number of occurrences of both term j and term k in document i — we chose the smaller number of occurrences between the terms; df_{jk} represents the number of documents in a collection of N documents in which terms j and k occur together” (Hauck et al., 2002, p. 32).

Chen et al. (2004) described how three kinds of data mining are done in the Coplink project: *named-entity extraction*, *deceptive-identity detection*, and *criminal-network analysis*. Let us consider the first one first: “Our first data mining task involved extracting named entities from police narrative reports, which are difficult to analyze using automated techniques” (ibid., p. 53). The team deliberately chose challenging data: “We randomly selected 36 narcotics-related reports from the Phoenix Police Department that were relatively *noisy* — all were written in uppercase letters and contained many typos, spelling errors, and grammatical mistakes” (ibid.).

In order to carry out named-entity extraction, Hsinchun Chen’s team used a modified version of the AI Entity Extractor system. In order to identify the names of persons, locations, and organisations in a document, that tool performs a three-step

process. The first step consists of identifying noun phrases according to linguistic rules. At the second step, “the system calculates a set of feature scores for each phrase based on pattern matching and lexical lookup. Third, it uses a feed-forward/backpropagation neural network to predict the most likely entity type for each phrase” (ibid.).

The second data mining task for Coplink reported about in Chen et al. (2004) “involved automatically detecting deceptive criminal identities from the Tucson Police Department’s database, which contains information such as name, gender, address, ID number, and physical description. Our detective consultant manually identified 120 deceptive criminal records involving 44 suspects from the database” (ibid.). In a case study, the team had developed a taxonomy for criminal identity deception. Based on that taxonomy, the team (ibid., pp. 53–54)

selected name, birth date, address, and Social Security number to represent a criminal’s identity and ignored other less reliable fields. Our method employed string comparators to compare values in the corresponding fields of each record pair. Comparators measure the similarity between two strings. We normalized the similarity values between 0 and 1, and calculated an overall similarity measure between two records as a Euclidean vector norm over the four chosen fields. A Euclidean vector norm is the square root of the sum of squared similarity measures and is also normalized between 0 and 1.

We employed a holdout a holdout validation method using two-thirds of the data for training and the rest for testing. In the training stage, we tried threshold values ranging from 0.00 to 1.00 that differentiated between deceptive and non-deceptive records. We first determined the optimal threshold to be reached when the association decisions best matched our expert judgments, 0.48, then used this value to assess our algorithm’s predicted association accuracy in the testing stage. [...] With this technique, law-enforcement officers can retrieve existing identity records relating to a suspect in their databases that traditional exact-match techniques often fail to locate.

As to the criminal-network analysis, Chen et al. (2004) used a concept-space approach of the kind described earlier in this section. With that technique, they extracted criminal relations from the incident summaries. The goal was to create a likely network of suspects. “Our data came from 272 Tucson Police Department incident summaries involving 164 crimes committed from 1985 through May 2002” (ibid., p. 54). In particular (ibid., pp. 54–55):

Co-occurrence weight measured the relational strength between two criminals by computing how frequently they were identified in the same incident. We used hierarchical clustering to partition the network between these subgroups. We also calculated centrality measures — degree, betweenness, and closeness³²⁶ — to detect key members in each group, such as leaders and gatekeepers. [...] Data mining uncovered 16 target gang members from the resulting network. In [a visualisation], the circles represent subgroups the system found, and they bear the labels of their leaders’ names. A circle’s size is proportional to the number of members in that subgroup. The thickness of straight lines connecting circles indicates the strength of relationships between subgroups.

We conducted a two-hour field study with three Tucson Police Department domain experts who evaluated the analysis’s validity by comparing the results against their knowledge of gang organization. They confirmed that the system-found subgroups correctly

³²⁶ For these concepts, see in Section 6.1.2.1 above; cf. in fn 14.

represented the real groups' organization. [...] Studying criminal networks requires additional data mining capabilities: entity extraction and co-occurrence analysis to identify criminal entities and associations, clustering and block modelling for discovering subgroups and interaction patterns, and visualization for presenting analysis results. One drawback of our current approach is that it generates mostly static networks. Given that criminal networks are dynamic, future research will focus on the evolution and precision of criminal networks.

The point that criminal networks are dynamic, and that techniques need be capable of dealing with that, was already made by Sparrow (1991). Efficient algorithms for searching graphs, and using Coplink's concept space, were discussed by Xu and Chen (2004), based in Tucson, Arizona, who used as a data set one year's worth of crime reports from the Phoenix Police Department. Their algorithms compute the shortest paths between two nodes in a graph, based on weighted links. They found that the efficiency of their algorithms differed, and whereas one algorithm was suitable for small and dense networks (such as kidnappers), another algorithm was efficient when the network is large and sparse, which is the case of narcotics networks.

At the University of Arizona in Tucson, Yang Xiang, Michael Chau, Homa Atabakhsha, and Hsinchun Chen described (Xiang et al., 2005) a project in the visualisation of criminal relationships: the Coplink Criminal Relationship Visualizer. They contrasted the use of two views, namely, a *hyperbolic tree* view, and a *hierarchical list* view. They explained (ibid., p. 76):

The COPLINK Visualizer includes a hyperbolic tree view and a hierarchical list view implemented in Java. The hyperbolic tree was developed based on a freely available program written in Java (<http://www soi.city.ac.uk/~livantes/Research.html>). Users can submit search terms to the system and the search terms have to be one of the five chosen entities, namely person, vehicle, organization, location, and incident/crime type.

They found the hyperbolic tree view to be more efficient for an "associate" task. Nevertheless, participants in the experiment generally found the hierarchical list view easier to use, apparently because they were more familiar with it. Opinions among the participants were divided as to which of the two views is more useful. The team proposed that both views are helpful, even though at some tasks the hyperbolic tree performs better. A hyperbolic tree view shows a hierarchy fanning out around the node which is the root of the tree. Viewers have the option to focus on one part of the tree, which is enlarged, whereas the rest of the tree is shown smaller and further away from the centre.

6.2.6 The EDS Project for the U.S. Federal Defense Financial Accounting Service

Mena (2003, section 7.7, pp. 213–219) describes a data mining project previously reported about in Vafaie, Abbott, Hutchins, and Matkovskly (2000), developed for the United States' Federal Defense Financial Accounting Service by prime contractor EDS Corporation and various subcontractors. An important aspect of that project

was the application of machine learning techniques. The task was to develop a tool for detecting suspicious government financial transactions, because of the known occurrence of fraud in the vendor payment system. There was the problem of what to learn from, as the number of known cases from which to learn was not large, and moreover, data about these were incomplete. “Then, there is the problem that fraud is often hidden in large sets of legitimate transactions” (Mena, 2003, p. 213).

In establishing investigation goals, there was a concern with containing the costs. Whereas identifying suspicious payments was the primary goal, there was the constraint of maintaining a low false-alarm rate. “This cost concern is due to a limited number of examiners to investigate suspicious payments” (ibid.). Whereas the detection of suspicious financial transactions was the primary goal, other goals were also set, namely, that the data mining process to be developed could be generalised for use in other applications within the agency, and that knowledge transfer would be in place, so that the agency’s existing staff could carry out the data mining process.

Having set the goals, the developers of the project took a step of knowledge discovery, i.e., they tried to understand the business methods involved, as well as the data, and the data were prepared. Initial exploratory analyses were performed, to enhance data preparation.

Next, the step was taken of assessing the modelling challenges (Mena, 2003, p. 214). Challenges included: “the data set is a very large payment database with incomplete information in the vendor payment data file” (ibid.); “payments are unlabeled and cannot be verified” (ibid.); and besides “there is a very small number of known fraud payments with instances of multiple payments from the same case” (ibid.). It was decided to use a cross-validation methodology, with several models (actually several modellers developed hundreds of models) using different data mining strategies. Then, a set of the best eleven models would be retained.

“The main strategy was to create multiple structured and random samples for training and testing of fraud detection models” (ibid.) Of the structured samples (called *splits*), eleven were for known fraud data. Each split had “training, testing, and validation data subsets of 33 overlapping samples of fraud cases. In addition, 11 corresponding random splits were used with training, testing, and validation data subsets for non-fraud data of 33 non-overlapping samples of non-fraud” (Mena, 2003, p. 215). *Data balancing* required that the non-fraud set of samples be small enough, so that *false positives* be avoided (i.e., non-fraud transactions being taken to be fraud). “In addition to being split, the data was also rotated to ensure the validity of the models” (ibid.).

Classification algorithms generally differ, by their error rate, according to the data sets used, and how the data are structured has an impact on those error rates. In particular, in the project at hand, that much resulted from the step of evaluating the investigation algorithms. There was no clear winner, out of five algorithms (neural networks, logistic regression, linear vector, projection pursuit, and decision tree) on six datasets, because, for example, all five algorithms turned out to be first or second at least once, and of these, three algorithms were winners at least once, but four algorithms were worst at least once (ibid., pp. 215–216).

The next step was to select the investigation ensembles of models, because using just one model has shortcomings, depending on the non-exhaustive search by different algorithms for the best model, and because “iterative algorithms converge to local minima, such as neural networks” (ibid., p. 216). “Model ensembles make decisions by committee of algorithms” (ibid.).

Next, data were prepared for data mining: “some input and output data specifications are controlled via automated scripting” (ibid., p. 217). Next, the models were created and tested. The criteria for both their generation and their testing were multiple. The more fraud sensitive a model is, the better, but if the model is prone to false positives, this is a shortcoming. To make predictions more robust, the best models were combined.

The final step of the project as reported was to test the model on validation data. Which transactions were used for training, testing, and validation did much matter for the results obtained. But all in all, the ensemble tended to be a better classifier than any of its individual components (but not always) – it was found that “model ensembles mitigate risk compared to single-model solutions and that the ensemble, although not necessarily the best model, was always among the best, and rarely among the worst” (ibid., p. 219) – and “97% of known fraud cases were accurately detected in the validation data set sample” (ibid., p. 218). The models selected 1,217 suspicious transactions, so that the agency would carry out investigations to find out whether these were fraudulent payments.

6.2.7 Information Extraction Tools for Integration with a Link Analysis Tool, Developed in the Late 1990s by Sterling Software

Already by the late 1990s, text mining had results to show. During the 1990s, in the United States, several Message Understanding Conferences (MUC),³²⁷ sponsored by DARPA,³²⁸ were held. It built upon research in natural language automated understanding, an active and successful field in the 1970s and 1980s (See [Section 5.2](#) above). The challenge was how to handle effectively masses of data. Traditionally, computer tools for understanding natural-language multi-sentence text had been successful, based on knowledge stored in long-term memory about narrow domains.

Douglas Lenat embarked upon the implementation of an enormous knowledge-base, CYC, of computational representations of items of common sense (Lenat & Guha, 1990), but that enterprise had its critics within the artificial intelligence scholarly community, at a time when the 1990s “AI Winter” was setting in, as leading AI scholars, and a multitude of teams worldwide, had become disenchanted with AI’s near-term perspectives of taking on open-textured problems. Whereas the CYC

³²⁷ By *messages*, what is intended is incoming documents whose text is *unformatted*; that is to say, they are *free-text*. The arrival of such textual records is referred to as *unformatted message traffick*.

³²⁸ DARPA is the United States’ Defense Advanced Research Projects Agency.

database is available online, had been historically important, and still has potential, arguable in practice the real breakthrough came with the proliferation of projects developing *ontologies*, for a multitude of application domains. One application is *financial fraud ontology* (Kingston, Schafer, & Vandenberghe, 2004). See Section 6.1.7.7 in this book.

Richard Lee of Sterling Software in McLean, Virginia, reported (Lee, 1998) about several tools for *information extraction (IE)* being developed by his firm. He claimed he had “demonstrated that the state of the art in Artificial Intelligence — specifically, Natural Language Understanding — is advanced enough that we can implement a practical Information Extraction tool which populates relational data bases with detailed information from free-text messages” (ibid., p. 67). Sterling Software’s first system with an IE capability was the *Counter-Drug Intelligence System (CDIS)*, “which was developed to support analysts tracking the entire spectrum of narcotics-related activities from crop cultivation and precursor chemical production to delivery of the drugs into the United States” (ibid., p. 66). At the core, there was a Sybase relational database. All the entity types involved were stored in that database, along with “a dozen narcotics-related event types” as well as “the full assortment of relations and roles” (ibid.). A second tool with an IE capability was specifically developed by Sterling Software for DARPA’s MUC-6 (within the conference series mentioned earlier). “It extracted and templated information on Individuals, Organizations, Locations, Money, Dates, and Times, from Wall Street Journal articles” (ibid.). That tool was reported about in Lee (1995).

Sterling Software then developed a third tool with an IE capability, the *Migration Defense Intelligence Threat Data System (MDITDS)*. At its core, there was a Memex database: “not, strictly speaking, a relational data base engine, but the design has separate tables for the primary entity types, a table for events, and the crucial Association table” (Lee, 1998, p. 66). MDITDS was to be combined with a link analysis tool, which was being developed by Orion Scientific (ibid.). A continuation tool was also been developed, around an Oracle relational database (ibid.), and with additional event types. A knowledge base was being developed for intelligence messages (ibid., p. 67).

Lee admitted (ibid., p. 66) that cross-sentence reasoning was still beyond the capability of his extraction tool: the tool had no problem, when handling a message about the arrival of an airplane carrying drugs, with realising that the drugs were seized, but the tool could not realise that the Movement event reported about was a transshipment involving both the aircraft and the drugs.

The handling of *coreference* (different instances within the text of referring to the same object or person) was to be improved (ibid., p. 67). “One limitation of the IE tool is that it makes no effort to decide whether an item it has found in a message is the ‘same’ as another item already in the data base; it errs on the side of assuming it is not” (ibid.). Nevertheless, Lee claimed that the generation of excess records could be handled once the IE tool was integrated with a link analysis tool: “It is up to the analyst to use various tools — including link analysis — to decide that the two records refer to the same item. This leads to a useful synergy between the two tools and the analyst” (ibid.).

Sterling Software was also developing the *Information Extraction Component (IEC)*, with all the types of entities involved in the previous projects developed by the firm and mentioned here. In particular IEC, was endowed with “the various event types relevant to Counter-Terrorism analysts”,³²⁹ and it was to be delivered “with the knowledge bases needed for extracting from newswire articles” (ibid., p. 66).

All Sterling Software’s tools with an IE capability except the project for MUC-6 were developed on contracts of the United States Department of Defense. All versions of Sterling Software’s IE tool were reportedly developed using a natural-language processing tool, the *NLToolset*, produced by Lockheed-Martin (ibid., p. 67). Lee explained (ibid., p. 64):

The IE operates by first looking for phrases containing all the references to the entities of interest, plus any date and time references. It then analyzes the phrases and clauses containing those references to find all the entity-to-entity associations (relations). It then analyzes the clauses for events of interest, assigning each entity reference, date and time in the clause to the appropriate role in the event. For each item found, it constructs a *frame* — a representation which categorizes each piece of pertinent information by putting it into the appropriate *slot*.

Once frames had been generated, to the extent that the extraction tool was able to identify coreference it merged those frames that refer to the same item. Next, those frames were converted into database records. “Typically, each frame is mapped to a single data base record, with each slot mapped to a data base field, but it is often more complicated” (ibid., p. 64).

Lee (1998, p. 65) provided an example whose input was this message:

PILOT PABLO GARCIA, COLOMBIAN, PPT 2324224, ARRIVED AT MIAMI INTERNATIONAL AIRPORT ON 27 JUN 97. HE WAS ARRESTED BY U.S. CUSTOM AGENTS WHEN 300 KGS OF COCAINE WAS FOUND IN THE SPARE FUEL TANK OF HIS CESSNA FIREBAT.

³²⁹ Lee (1998, p. 63) pointed out that event types had to be more specific per area of application, than the entities to be stored in the relational database. Entities of interest as listed, included: Individuals, Organisations (government, commercial, military, extralegal, and so forth), Places (of various grainsizes, ranging from street addresses to entire continents), Facilities (such as factories, airports, hotels, or warehouses), Documents (such as passports, driver’s licenses, or bank book), Money, Vehicles (air, land, or sea), Drugs, and Weapons. By contrast (ibid.):

For Counter-Drug analysts, the events include:

- Processing, purchasing, transporting, etc of drugs
- Planning, meeting, or communicating about any of the above
- Arrest of traffickers or seizure of drugs, money, weapons, etc.

For Counter-Terrorism analysts, on the other hand, the events include:

- Killing, kidnapping, hostage-taking, etc of people
- Bombing, hijacking, etc of buildings and vehicles
- Buying, stealing, etc of weapons and money
- Training in weapons and tactics
- Arrest, conviction, punishment etc of terrorists

Lee claimed that “the frames would look something like this” (ibid.):

INDIVIDUAL:

This reflects an application of data structures (namely, frames with slots) which were already used in artificial intelligence in the 1970s and 1980s. What was not very developed as yet, was ontologies technology. Still, there is a continuity: we find in Lee's example both types (in event frames and relation frames), and instances of types (in the frames for individual, document, place, facility, date, organisation, drugs, and vehicle).

6.2.8 The Poznan Ontology Model for the Link Analysis of Fuel Fraud

A team at the Poznan University of Technology, in Poland, comprising Czeslaw Jędrzejek, Maciej Falkowski, and Maciej Smolenski, reported (Jędrzejek, Falkowski, & Smolenski, 2009) about an application of ontologies technology to link analysis for investigating scams involving chains of transactions made by a

multitude of straw companies, and whose goal is fuel fraud.³³⁰ In particular, what is involved is a kind of crime known as a fuel laundering scam. “This crime mechanism is to buy rebated oil (in Poland heating oil) from a licensed distributor and then mix it (i.e. add components) and sell to the retail market as duty paid diesel” (ibid., p. 83).

In order to avoid the considerably higher excise tax or duty on Diesel fuel, fraudsters process heating oil or agricultural oil by *fuel laundering* – i.e., by removing the dye identifying these, and adding components – into Diesel fuel that is suitable for engines. The lower-quality fuel thus obtained is then illicitly sold to drivers as Diesel fuel at a pump at gas stations. The cost of transforming the fuel is negligible, and as tax is avoided, the operators pocket the difference. This is a big sector on the black market, both in Poland and, e.g., in the United Kingdom.

The crime mechanism involves a flow of fuel, fuel components, and money, and this is masked by issuing fictitious invoices, either with or without payment. Whereas “the methods to hide the proceeds (i.e. executing the crime scheme) are very similar” (Jedrzejek et al., 2009, p. 81) – notwithstanding its also being true that “fraudsters may use many types of schemes, techniques and transactions to achieve their goals” so that “we need a conceptual model of fuel laundering crime of significant generality” (ibid.) – in the three major cases from Poland that the team studied “prosecutors had an enormous problem to uncover money flows from the source of money (profit centre) to sinks (where the money leaves companies and goes as cash to organizers of the scheme) and in retrospect, some of them did not even attempt to do this” (ibid.).

The purpose of the Poznan team’s project was to develop adequate analytic tools to help with investigations and prosecutions. The tool developed is *FuelFlowVis*. The unwieldy difficulties with which the prosecutors were faced are explained in the paper: “This occurs because the use of traditional analysis tools (spreadsheets or non-semantic visualization tools) cannot provide information about chains of transactions — a separate binary relations’ view does not give complete insight into the crime mechanism. The consequence of this fact is incomplete understanding of a crime mechanism” (ibid.).

The team was faced with the general problem of its being very difficult to model economic crime (cf. e.g. Chau, Schroeder, Xu, & Chen, 2007) for the purpose of developing a knowledge-based system. The team was also provided with an opportunity, as whereas data mining tools for investigating money laundering have become available, fuel laundering was still virgin territory for AI & Law as catering to the needs of national financial intelligence units.

The team mainly studied three large fuel laundering cases from the 2001–2003 period, that went to court in Poland in 2008. Data sources were incomplete, especially when it came to electronic data (these are often lost in the time lapsed since the crime being perpetrated, and the case going to court). Only for one of the three cases, a rather complete set of money transfers was available, along with the most

³³⁰ Incidentally, e.g. Anne Alvesalo (2003) discusses the investigation of economic crime.

important invoice information. The lack of data for the other two cases — “we did not have the original wire transfer data; only the aggregated ones” (Jedrzejek et al., 2009, p. 81) — made it impossible to apply to them a particular data mining technique, namely: triggering rule-based red flags. Most defendants were charged with money laundering, or signing false documents, or fraudulently reclaiming VAT from the tax office, as well as with conspiracy, of tax evasion in the form of simple non-declaration of income, of false data in a tax statement, or of directing illegal activity performed by another person (ibid.).

The Poznan team developed a formal model of fuel laundering and money laundering, the model being based on a *minimal ontology* (coded in OWL). It is minimal, in the sense that the team deliberately only included there necessary concepts that follow in the logical order of uncovering facts about a crime (ibid., p. 82). That minimal ontology – which is itself structured as eight layers in fact-uncovering order (only five layers were shown in a table ibid.) — constitutes an application layer, which in turn is “embedded in an upper level ontology of criminal processes and investigation procedures” (ibid.).

Modules in the ontology include one (Person.owl) “describing persons as social entities and groups of persons” (ibid.); another module (Document.owl) “specifying legal meaning of documents and their content” (ibid.); a module LegalProvision.owl about legal acts and sanctions; the module intent.owl about a person’s intentions; the module Action.owl about activities; the module Object.owl describing goods, and in particular, fuels and the added components involved in fuel laundering; and moreover general concepts and relations were defined in the module MinimalModel.owl.

The taxonomy of concepts of the module Object.owl states that both DieselComponent and GasComponent are kinds of FuelComponent; that Diesel, Gas; and IllegalDiesel are kinds of Fuel; and that Fuel, FuelComponent, and HeatingOil are kinds of goods (ibid., p. 83).

The taxonomy of concepts of the module Person.owl states (ibid.):

- that MajorOwner, MinorOwner, and StrawOwner are kinds of Owner;
- that ManagementBoard is a kind of GroupOfPersonsCinectedToCompany;
- that GroupOfPersonsCinectedToCompany is a kind of GroupOfPersons;
- that GroupOfPersons, Fraudster, and PersonWhoFalsifiedDocument are a kind of PhysicalSubject;
- that IndirectManager is a kind of PersonNotConnectedToCompany;
- that Owner, DecisivePerson [sic], MiddleLevfelDecisivePerson, and OtherPersonRealatedToCompany are a kind of PersonConnectedToCompany;
- that Physical Subject, PersonConnectedToCompany, and PersonNotConnectedToCompany are a kind of Person;
- that HeadOfSingleUnit, HeadOfMultipleUnits, ChiefAdministrativePerson, ChiefAccountant, and DeputyHeadOfMultipleUnits are a kind of MiddleLevelDecisivePerson;

- thaty ChairmanOfTheBoard, MemberOfTheBoard, and DeputyPerson are a kind of DecisivePerson;
- and that Procurtent [sic] and OtherDeputy are a kind of DeputyPerson.

As can be seen, the concepts defined were such that were found to be useful on an ad hoc basis. For convenience in the exposition, Jedrzejek et al. (2009, p. 82) stated in *database relational notation* the most important concepts that at the time of their writing were functional in their FuelFlowVis tool.³³¹ This notation consists of the name of a relation, followed by a parenthesis containing a list of attributes. In turn, an attribute (such as Money-Transfer) may itself be a relation. That is to say, Jedrzejek et al. (ibid.) implicitly conceptualised their relational schema by allowing what in database research is known as *nested relations*³³²:

```
Flow (Money_Transfer,
      Invoice,
      Goods/Service)
Money_Transfer (From_Entity,
                To_Entity,
                Method_of_Transfer,
                Data,
                Value,
                Title-of-Transfer)
Method_of_Tranfer (Electronic_Transfer,
                  Cash)
Fuel (Component_of_Gas,
      Gas,
      Component_of_Gas,
      Diesel)
```

Title_of_Transfer states what is the money transferred for, which is in order to obtain some given kind of goods in exchange. In link analysis as performed while investigating fuel laundering, that attribute is both important and problematic. “The crucial step is the unification of money transfer and invoice data, because perpetrators usually enter meaningless information in a ‘title of payment field’” (ibid., p. 85).

The Poznan team’s project resulted in a tool called *FuelFlowVis*. It is a “visual intelligent analytic tool” (ibid., p. 83). Its purpose is to support prosecutors in the management and building of evidence when handling a fuel laundering scam. “The tool serves to give an investigator an insight into size, timing and topology of transactions. This is controlled by various filters” (ibid., p. 84). Moreover, users are enabled to “inspect invoices or money transfers separately, or in a combined view,

³³¹ They actually store the data in a relational database, and queries are in SQL (ibid., p. 85).

³³² Concerning nested relations, see in fn 47 above, and in the text citing that footnote.

at various cales. Usually, one manipulates [the] left local panel and has a small size shaded overview in the right panel” one the screen, when in main application view (ibid.).

Link analysis is visualised in graphs, which are shown either in detail, or in a simplified view with just selected objects, or by showing aggregated relations (ibid.). In the link analysis diagrams, some graphs are *transfer diagrams*, and whereas the nodes represent persons, companies, or other entities, the connections between nodes are of the following types: fuel component invoices (shown in green), gas invoices (shown in blue), Diesel oil invoices (shown in red), or money transfers (shown in black).

Some other graphs are *roles of person’s diagrams*, and the connections between nodes in these graphs are of the following types (ibid.): “Approve of electronic money transfer” (shown as a solid red line); “Cash transfer (Drawing cash on authorization or passing cash)” (shown as a dashed red line); “Real or informal ownership of a company (directing activities of a straw company owner)” (shown as a solid black line); “Informal management of a company” (shown as a dashed black line); and “Other activities” (shown as a blue line).

For a given node, *input neighbors* are such companies that transferred money or goods to the company represented by that given node, whereas by contrast *output neighbors* are such companies to which money or goods were transferred from the node considered (ibid., p. 85). The data mining capabilities of FuelFlowVis include also the search of paths, by means of a path algorithm (ibid.). The criminal organisation “consists of many straw companies, whose only rationale is to obscure patterns of transactions and move suspicion away of a mixing shop” (ibid., p. 86), where rebated fuel is fraudulently upgraded. In fact (ibid.):

It has to be understood that although flow of money is real, operations are mostly fictitious — no change of material goods takes place. Similarly, for most operations, invoices were properly drawn pretending a legal operation, but actually the[y] were false. Phony companies have no real infrastructure, and most of the time invoices are produced by a scheme mastermind.

6.2.9 Fiscal Fraud Detection with the Pisa SNIPER Project

A team based in Pisa, Italy, and whose members are Stefano Basta, Fosca Giannotti, Giuseppe Manco, Dino Pedreschi and Laura Spisanti reported about the SNIPER project (Basta, Giannotti, Manco, Pedreschi, & Spisanti, 2009). SNIPER is an auditing methodology, applied to an area in fiscal fraud detection,³³³ namely, the

³³³ A comprehensive survey of research into the application of data mining to fraud detection was provided by Phua, Lee, Smith-Miles, and Gayler (2005). Cf. Kou, Lu, Sirwongwattana, and Huang (2004), Weatherford (2002).

detection of Value Added Tax (VAT) fraud. Such fraud can take various forms, such as underdeclaring sales, or overdeclaring purchases. Moreover, fraudulent claims are possible for credits and refunds, because “tax charged by a seller is available to the buyer as a credit against his liability on his own sales and, if in excess of the output tax due, refunded to him” (ibid., p. 27).

The team developing SNIPER aims at having a rule-based computer tool that by means of data mining, would “identify the taxpayers with the highest probability of being VAT defrauders, in order to support the activity of planning and performing effective fiscal audits” (ibid.). A major constraint is the limited auditing capability of the competent revenue agency: “In Italy for example, audits are performed on only 0.4% of the overall population of taxpayers who file a VAT refund request” (ibid.). The resulting *sample selection bias*, by which auditors focus on suspicious subjects, has the consequence that “the proportion of positive subjects (individuals who are actually defrauders in the training set is vast compared with that in the overall population” (ibid.). The same constraint on auditing capability also “poses severe constraints in the design of the scoring system” (ibid.), and “the scoring system should concentrate on a user-defined fixed number of individuals (representing the auditing capability of the agency), with high fraudulent likelihood and with a minimum false positive rate” (ibid.).

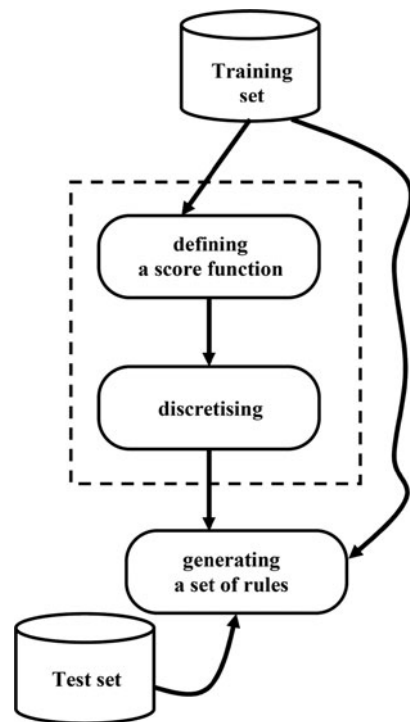

Fig. 6.2.9.1 The initial, preprocessing part of SNIPER’s flowchart

The fraud detection scenario has several objective functions (i.e., criteria) to be optimised, “and a traditional classification system may fail in accomplishing such a multi-purpose task” (ibid.). These typical criteria were enumerated (ibid.):

- *Proficiency*: scoring and detection should not rely only on a binary decision boundary separating defrauders from non-defrauders. Rather, higher fraud amounts make defrauders more significant. For example, it is better to detect a defrauder whose fraud amounts to \$1000 than one whose fraud amounts to \$100.
- *Equity*: a weighting mechanism should highlight those cases where the fraud represents a significant proportion of the business volume. For example, an individual whose fraud amounts to \$1000 and whose business volume is \$100,000 is less interesting than an individual whose fraud amounts to \$1000 but whose business volume is only \$10,000.

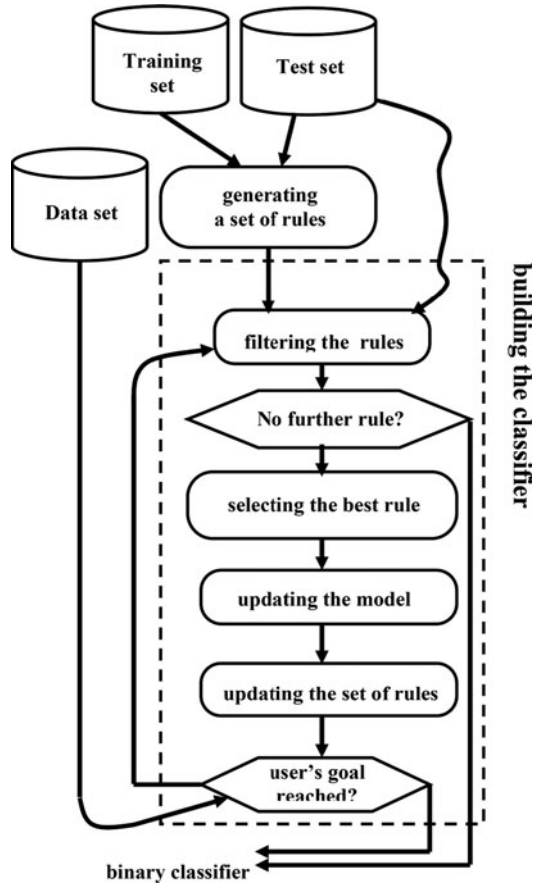

Fig. 6.2.9.2 The classifier-building part of SNIPER's flowchart

- *Efficiency*: since the focus is on refunds, scoring and detection should be sensitive to total/partial frauds. For example, a subject claiming a VAT refund equal to \$2000 and entitled to \$1800 is less significant than a different subject claiming \$200 who is entitled to nothing.

Basta et al. (2009, p. 29) pointed out that

In general, supervised techniques (using a training set of known fraudulent cases) based on hybrid or cost-sensitive classification suffer from low interpretability, which makes them inadequate for the problem at hand. In addition, the aforementioned problem of sample selection bias makes it difficult to devise a proper training set. Recently, semi-supervised and unsupervised methods have been proposed to partially overcome these drawbacks. Unfortunately, these techniques fail to provide interpretable explanations for the ‘outlierness’ of a fraudster.

Rather, the team opted for adopting a rule-based classification approach. This is because intelligible explanations made available to the auditors are more important than the scores themselves. By receiving explanations, auditors can get an idea of which behavioural mechanism behind the fraud to investigate. A drawback of rule-based classification techniques is that as, in the problem at hand, the underlying data distribution is such that occurrences of positive cases of fraud are rarely observed, the classifier would be poor at predicting accurately. In SNIPER, the approach is flexible, being “an ensemble method that combines the best of several rule-based baseline classification tools” (ibid.), each handling specific subproblems. The system should gradually learn a set of rules, and devise a scoring function. “Tuning the function allows different aspects of VAT fraud to be emphasized, from which baseline classification tools can then be trained in order to associate class labels to individuals according to their relevance to the aspect of interests” (ibid.). Bad rules, i.e., such rules that would degrade overall accuracy, are to be filtered out iteratively, until a final binary classifier is obtained, which advises whom to audit or not audit. Experiments were claimed to have shown SNIPER to be effective, outperforming traditional techniques (ibid.). In Figs. 6.2.9.1 and 6.2.9.2, I redrew the flowchart from Basta et al. (2009, p. 27, figure 1).

Chapter 7

FLINTS, a Tool for Police Investigation and Intelligence Analysis: A project by Richard Leary explained by its author

7.1 Introduction: Motivations and History of the Project

This chapter is the result of research conducted by myself into the benefits that can be gained by the application of a general theory and methodology for the process of obtaining, managing and using evidence in police investigation and intelligence analysis. Central to this thesis are methods and processes that help investigators and intelligence analysts to ask better questions. This introductory section presents a brief chronology of the development of those ideas and research. My standpoint was informed by having been a Detective Police Officer for a number of years in the United Kingdom.

My original ideas about improving police investigation and intelligence analysis came from ideas that involved the combination of different types of evidence. Furthermore, I had experimented with ideas about how we could improve police investigation and intelligence analysis by developing a better understanding about techniques for the reduction of “uncertainty” as presented in a paper at the First World Conference on Criminal Investigation and Evidence at the Hague in 1995. Uncertainty reduction (*entropy*) for me is at the heart of all good science and is the bedrock of rational systems of discovery. Something I remain convinced upon to this day.

In 1996, two additional papers were published in the Police Research Group’s publication, *Focus*. The first was entitled *A Revolution in Criminal Investigation*, and concerned extending the application of forensic principles and genetic evidence within policing. The second was entitled *DNA: The Promise*; it challenged the traditional use of evidence, and proposed new ways for the systematic management and use of evidence in the investigation of multiple cases rather than solely of single cases. These three papers provided the ideas behind the systematic use of large collections of evidence, and helped I to formulate the original ideas underpinning a prototype system of software (called the “Forensic-Led Intelligence System”, FLINTS) that became adopted by West Midlands Police. Prior to this, forensic

evidence was almost exclusively used in the investigation of single, isolated events such as a burglary, a murder, or a rape, rather than in the routine investigation of linked series of crimes.

In 1996, I developed an interest in the methods of analysis and synthesis of evidence developed by John Henry Wigmore.¹ Although this approach was exclusively concerned with single, isolated cases, and was intended primarily for use by advocates preparing for court, it provided a foundational methodology for the charting of logical relations between evidence as an aid to developing powerful arguments. I also developed an interest in the science of complexity, which provided valuable ideas about how complex systems function and the way in which information in such systems behaves and can be used. That same year, I won the Forensic Science Society Scholarship and used that funding to continue this research into new ways of using and managing forensic evidence. Systemizing the combination of different evidence types and developing intelligence from forensic evidence were the focus of this work.

At this time, I was seeking to operationalise my research findings in the form of a system so as to accomplish two goals: to overcome five weaknesses identified in police investigation and practice, and to draw on the lessons learned from Wigmore, molecular biology, and complexity theory.

In 1998, I was appointed Scientific Officer to West Midlands Police and tasked to implement new methods of managing and using forensic evidence. In 1999, for the first time in the world, I and scientists from the Forensic Science service experimented with the use of highly sensitive technology for recovering DNA from surfaces that had merely been touched by humans. Although it was usual to recover DNA from visible samples, the experiment focused on material that was invisible to the human eye. The intelligence gained from this evidence was used to identify groups of criminals operating in networks. At this time, there was a national crime problem involving the defrauding of elderly citizens. Confidence tricksters were gaining access to the homes of elderly people on the pretext of being public officials, and using the opportunity to steal cheque books and other valuables. Using “supersensitive” recovery techniques, DNA was successfully recovered from door knockers, handles and other objects that had merely been touched by offenders. Applying new policy, procedures and techniques in accordance with the general theory and methodology described in this thesis, evidence was recovered that resulted in the detection of networks of criminals and crimes. This was later responsible for the prosecution of key people involved in organizing and committing these offences. The technique subsequently became a forensic service offered to investigators.

As a result of this work over a number of years I decided to implement some the main themes of the work into a software system. The resulting software was FLINTS. Mark Compton programmed the computer code under my guidance; I provided domain expertise that shaped how the programmer embodied the conceptual foundations behind my new approach to evidence management and implement it into the software.

¹ See [Section 3.2](#) in this book.

In 1999, Nick Tofiluk, Chief Superintendent (later, Assistant Chief Constable) of the West Midlands Police, developed an interest in FLINTS and offered strategic assistance in overcoming organisational barriers to implementation of the system in the West Midlands Region. This resistance was an interesting reaction which I learnt greatly from. In essence, the resistance emanated from protectionist attitudes amongst some Detectives, Managers and the IT Department because adopting FLINTS meant (A) admitting that we could do things faster, cheaper and more effectively and (B) it involved the use of modern computing power and threatened job security. Whilst the former was true the latter was not. FLINTS merely ensured that humans could achieve more and be employed in the things they do best; reasoning, deciding, evaluating and decision making whilst the computer could access, count, sift, sort and process information at breath-taking speed. I and Nick agreed to work together and I was given great assistance in overcoming these organizational barriers. Responsibility for the development of the methodology and conceptual underpinnings continued to remain my own.

In 2002, I began work on a case study intended to develop a new approach to managing the problem of shifting contexts and standpoints in evidence management. In 2003, the first iteration of a new case study was programmed and used to simultaneously manage and analyse evidence in hundreds of cases of fraud. Lawyers involved in the original litigation had been unable to manage these cases without the application of the approach because the body of evidence was too vast for manual methods to succeed. Although the system, called MAVERICK, is outside the scope of this chapter, it uses a unique methodology to manage the way in which evidence is perceived and managed.

In 2004, using MAVERICK, I responded to requests in the provision of two important areas of assistance to law enforcement and financial organizations: First, I provided assistance in meeting the compliance obligations laid down by the Proceeds of Crime Act and Terrorism Act of 2000. This assistance was in terms of “disclosures” of material to the National Criminal Intelligence Service about suspected terrorist funding and financial crimes committed during organised crime involving fraud and deception. These disclosures were made on behalf of U.K. lawyers representing large corporate organisations who had been targeted with fraud. Second, I provided assistance in the management of a mixed mass of evidence concerning 2 million financial transactions suspected to contain material subject to the above legislation. My methodology and the MAVERICK software were used throughout.

7.2 Early Beginnings

The traditional approach to the management of evidence in policing has involved narrow conceptions of the way evidence is managed, analysed and used. My experience demonstrated that practitioners² adopted narrow views as well as uninspired

² This includes police officers, Crime Scene Investigators and lawyers.

approaches³ towards the study and use of evidence as a science. This included the way that evidence should be collected and the many uses to which it could be put. A common experience was that whilst cases may appear to be overwhelming proven “on paper”, by simply adopting another standpoint or considering an alternative explanation about some aspect of the case, an alternative view could be deemed not only plausible, but often persuasive. Often, this was the result of investigators treating and interpreting evidence only in the light of the hypothesis they were pursuing. Evidence is too often seen in light of the support it can give to a narrow or single hypothesis. Alternatives are not considered, or, if they are, they are dismissed too readily. Narrow or single hypotheses often appear in the form of a case theory. For example, the theory may propose that a particular act had been perpetrated by a particular individual, or that an event took place “in the following way”, thereby favouring a particular explanation. This narrow view has implications not only for single cases, such as the investigation of historical events or crimes, but also for intelligence analysis and predictive enquiry. In terms of single cases, it creates barriers to the consideration of alternative explanations.

Evidence that may support an alternative theory may be ignored, resulting in the wrong conclusion being drawn. In terms of intelligence analysis, the narrow focus can prevent users of evidence from considering fruitful lines of enquiry that would potentially prevent a threat from becoming a reality. Simple explanations or those that appear obvious are considered at the expense of those more difficult to uncover. Collections of evidence often contain many layers of information in which indirect links and associations may not be immediately obvious. Accessing and testing these areas of our collections of evidence present many opportunities for the discovery of new knowledge.

This insight provided valuable lessons about the way evidence is sought, collected and used, and seemed crucial to developing a better approach. What seemed

³ Following my appointment as a Detective in 1981 in the inner City of Birmingham, England, I found the lack of determination that some investigators adopted in the search for evidence in their investigations was surprising. In particular, the search for evidence in pursuit of one side of the story struck me. I cannot claim that this bias was borne of some high-grounded moral attitude, but rather, quite simply, of the futility of learning all sides of the story. It became apparent fairly early on that evidence is always available, in some form, somewhere, and it is only our determination and ingenuity in finding it that is in question. Furthermore, any collection of evidence eventually has to be tested by others. These may be Crown Lawyers, Defence Lawyers, a Jury or a Judge, and any suspect; therefore, I had a responsibility not only to satisfy my own view of the evidence, but also to demonstrate that I had tested arguments in favour of my hypothesis as well as those counter to it. This paid off many times, particularly in generating new sources of covert information from within the criminal fraternity. Balance and fairness demonstrates reliability, which was something that informants sought from an investigator when seeking to impart information, especially in cases involving violent or serious crime. Anticipating the opposing view, seeing evidence from different perspectives and demonstrating that evidence had been collected in support as well as negation of a hypothesis was crucial. Whilst it is never possible to overturn every possible stone, it is possible to demonstrate that one has overturned every *reasonable* stone, bearing in mind the available evidence and the issues under investigation.

to be missing was the development of a truly systematic forensic⁴ attitude towards the management and use of evidence.

7.3 FLINTS 1

FLINTS is a modernised neo-Wigmorean approach to the management, analysis and use of evidence in pre-trial criminal fact investigations. It was designed on the basis of the methodology in this thesis to model the relationships between people, crime, locations, times and evidence in ways useful to analysts, investigators and policy makers. This kind of Wigmorean evidence modelling serves a number of purposes in the generation and discovery of knowledge. However, there are two principal purposes it is concerned with: first, the provision of understanding of the attributes of evidence we already possess about events that have already take place, and second, the provision of insights into evidence we do not yet possess, but need, and into events that may yet take place. At the end of this chapter, a case study in “linked burglary crime” is described, and the methodology and use of FLINTS are demonstrated.

Policing has suffered⁵ from a lack of knowledge about the structural and intellectual questions surrounding the collection and use of evidence as a discipline and has therefore been unable to construct a conceptual framework and a set of operating principles that would allow police organisations to gain maximum knowledge from their collection of evidence.

The mechanisms I put forward in my doctoral dissertation to aid the modelling of relationships within networks of evidence are achieved by organising the systems and structures under which evidence is discovered, collected, considered and stored so that links and connections inherent in the evidence can be speedily established. This in turn aids the formation of new hypotheses and the elimination of old hypotheses. Questions can be asked of the system to draw on the complex combinations of evidence that already exist, but that are perhaps not readily known, as well as those combinations and connections not known to exist but that are strongly suspected to exist.

This demonstrates that although we may be in possession of information, we are often unaware of the evidence’s existence, or, if we are aware of its existence, we are sometimes oblivious to its meaning and the links that exist within the information. The contribution that approaches like this can make to developing our understanding of the environment in which we operate is underestimated. What we “possess” and what we “know” are often very different. Establishing the difference between what

⁴ To this end, *forensic* is meant to portray an interrogative, questioning approach. The *Shorter Oxford English Dictionary* defines the term as “pertaining to, connected with, or used in courts of law; suitable or analogous to pleadings in court, or a speech or written thesis maintaining one side or the other of a given question.”

⁵ I argued that much in chapter 1 of my doctoral dissertation.

we possess and what we know provides the ability to establish what we “do not possess” and “do not know”. Optimising systems to undertake this function is crucial in getting the most benefit from the evidence collections we have. Applications for use of this approach are many.

Identifying links and connections between crimes and events that we know⁶ have taken place and people that we believe are connected to these occurrences helps us to identify links and connections with other crimes, events and people that *may* be linked, but for which evidence is currently not available to justify, negate or sustain that belief.⁷ Investigators can set out to establish whether sufficient evidence, even if not presently available, does exist in some form, somewhere, to justify or negate the hypothesis. This helps us to investigate crime not only on the basis of single events in time, but also on the basis of chains of events in time and space, and thus represents a whole new way of thinking about crime investigation and intelligence analysis. Let us imagine a series of ten crimes of burglary linked on the basis of DNA evidence.

Let us consider an example: a series of 10 crimes linked by a single DNA profile. Figure 7.3.1 illustrates that at each of the 10 crimes, DNA evidence in the form of a crime stain⁸ was recovered. The hypothesis is formulated that these 10 events are linked because DNA recovered at each crime scene has produced the same genetic profile, namely that of suspect “A”.

We can formulate a hypothesis that the donor of the DNA at each of the scenes of crime is the same person, even though we do not yet know their name.⁹ In an effort

⁶ Here, the term “know” does not mean a fact that has been established beyond challenge. It means instead “that which we are prepared to accept on the basis of reliable evidence currently in our possession”.

⁷ Challenge may come in the form of counter-arguments put forward by our adversaries or, just as importantly, counter-arguments we construct ourselves to test some argument that we are naturally persuaded by. The former is simple; adversaries or colleagues may favour another argument or explanation that they put to us in the form of a challenge, and we can deal with it on that basis. The latter is sometimes difficult because it involves constructing counter-assertions ourselves, often in the knowledge that we are already satisfied with the current explanation. The approach may go something like this: “Is this explanation or argument sustainable if new evidence were to be made available?” Alternatively, it may go like this: “Is my explanation or argument sustainable in the light of the following alternative hypothesis?” This thought process may involve considering a range of possible explanations or arguments ranging from that which is highly probable to that which is highly improbable. It may also involve considering that which is impossible. The reason for this is simple: that which is impossible on the basis of evidence currently available may become possible in the light of new evidence or some other explanation. The process may instead be as simple as viewing the evidence we currently have in a different light or from a different standpoint.

⁸ *Crime stain* means DNA recovered in some form from a crime scene and that awaits matching against reference samples stored in a database. A match with one of these samples would enable the investigator or analyst to formulate a hypothesis that the individual may have had the “opportunity” to commit the crime. It does not necessarily mean that they *did* commit the crime.

⁹ In addition to the problem of false positives and adventitious matches, investigators and analysts should also keep in mind that identical twins share the same DNA code. Identical twins (monozygotes) originate from a single embryonic cell and therefore share the same genomic DNA. Therefore, wherever monozygotic twins are suspected of involvement in a crime, both must be

Fig. 7.3.1 A hypothetical series of 10 crimes linked by a single DNA profile

to identify the donor of the DNA, we might search for any matching DNA profiles from former suspects and convicted persons stored in the National DNA Database. However, it is possible that after the search, despite our establishing that the crimes appear to be linked, no profiles from suspects and convicted persons matched Profile A. We would then be left with the task of identifying the offender by other means.

7.4 Identifying “Unknown” Offenders

How can we set about identifying “unknown” offenders? We could sit around and hope that we “get lucky” or we could appeal for witnesses to the events in the hope that someone, somewhere, might have the evidence we need. One effective approach is to explore methods that reduce the level of uncertainty associated with the number of people in the database that could account for the DNA profile.¹⁰

We can create a “virtual offender” to account for the presence of DNA Profile A at the scene of each of the crimes and await other evidence that might indicate a legal identity. This can be done by systematically exploring the information we already possess to ascertain whether there are any indications anywhere in our systems as to the possible identity of the individual who possesses DNA Profile A. Not only might this produce a suggestion of their identity, it might also lead us to search for additional information in areas where we are likely to find useful indicators of the offender’s true identity.

So far we have only considered DNA evidence recovered from each of the 10 crimes. There may be other evidence available that we have not considered. Fingerprints, footwear, tool marks, handwriting, hairs, fibres, witness evidence and

considered “suspects” and therefore both must be treated for the purposes of an investigation as requiring us to eliminate them from suspicion. The hypothesis that the virtual suspect or offender may be one of two identical twins must always be considered.

¹⁰ The ideal position is to be able to eliminate all persons except one. Once we have reduced the uncertainty to a single individual, we can then use other evidential tests to challenge the reliability of the analysis and conclusion.

other clues may provide a suggestion about the likely identity of the suspect if we consider this evidence alongside the DNA.

Imagine that a fingerprint found at burglary 4 is identified as the index finger on the right hand of a known former burglar called Mr. George Smith. The question then arises: “Does George Smith have DNA profile A?” If he does, fingerprint evidence has suggested a method to establish the identity of the original donor of DNA profile A – possibly Mr. George Smith. If the answer affirms this, then Mr. George Smith may be asked to provide a DNA sample for comparison and, if matched to DNA recovered from one or more burglary scenes, asked to account for the presence of his DNA at each of the 10 scenes. Other evidence types can also be used in this way.

Many types of evidence can help us to identify people that we know exist in the population but for whom we have no means of distinguishing them as individuals. Used in combination, these sources of evidence present us with a range of possibilities to identify individuals uniquely. Some involve direct and some involve indirect chains of reasoning.

7.5 Systemising the Identification of Unknown Offenders

Policing and intelligence work has for too long approached the identification and elimination of suspects in a conceptually narrow way. The focus of attention has been on the use of names rather than a wider concept involving the use of *indicators of identity*.¹¹ Intelligence systems employed in law enforcement use names as the key identifier. The same is true of evidence systems used in fingerprint and other forensic databases.

The ability to systematically (and routinely) identify *persistent offenders* has great potential for decision-making and for optimising investigative effectiveness. Identifying those persons who commit most of the crimes in our systems offers greater returns on the investments we make in the deployment of staff and financial resources.

The use of a wide range of indicators of identity can be used rather than narrow, single indicators (typically only a name) to provide a more inquisitive methodology for identification. Rather than simply referring to offenders by either their name or as simply “unknown”, they can be referred to as “virtual unknowns”. They can be classified and catalogued in a database alongside indicators of the characteristics we do know. As the investigation of crime continues over time, we can explore different combinations and different inferential chains of links by using these indicators in combination to help us set about filling in the gaps in our knowledge. Researching

¹¹ This concentration on the use of a name as a means to identify people is surprising bearing in mind the large proportion of the population that share the same name. Some with the same name even share the same date of birth.

direct and indirect chains of links may eventually produce or suggest a possible indicator as a means of identification.

Let us consider this approach in detail. If we are satisfied from the available evidence that a crime has been committed, we can infer that someone who may (as yet) be unknown committed the crime. Unknown persons can be classified as “virtual suspects” simply by giving them a unique number to act as an identifier until their true identity is discovered. Once we have allocated a unique number to the “unknown”, we can then think about them as a “virtual unknown” person. This provides us with a whole new way of thinking about the problem of identification. We can use a range of indicators about their characteristics, their identity or their personal circumstances to do so. Taken together, these indicators can provide the means to link different aspects of identity until one or more of those indicators provide a suggestion of a name.¹²

It is the ability to develop and navigate direct and indirect chains of inference between indicators that presents the opportunity to identify individuals. This is an example of a broader use of the concept of evidence and the wider uses to which it can be put to.

Table 7.5.1 is a *multidimensional identification index* designed to present a systematic approach to the use of a range of indicators to identify people.

Referring to Table 7.5.1, let us imagine that Event 2 was a burglary in which the offender shed hair. Subsequent DNA analysis of the hair produced a DNA profile. However, no reference sample of the offender existed in the National DNA Database, therefore the offender cannot be immediately identified by name. Genetic information gained from DNA profiling of the hair provided further information about the person’s physical characteristics: their hair colour, eye colour, ethnic ancestry and height. These additional indicators are used to begin to fill gaps in the *virtual persons record* that may become useful to us.

The same DNA profile is found at Event 4, the theft of a motor vehicle. A witness to Event 4 states that the offender was seen to have a distinctive tattoo on his right forearm: an eagle and sword. He was aged between thirty and forty years, was a white European and had brown to red hair.

Because Event 4 revealed the same DNA profile as Event 2, we can begin to cross-reference specific details of *indicators* from Event 4 to Event 2.¹³ The index demonstrates how we can use a method of cross-referencing evidence from one event to another so as to provide us with a system to navigate inferential links, gaining clues to the identification of individuals and even groups of individuals as we progress. In this example, it can be seen that the DNA recovered in Events 2 and

¹² A *virtual suspect or offender* is a person who is known to exist because evidence of their presence at a scene of crime has been discovered, but whose identity is yet to be established.

¹³ For example, the original Indicators (DNA, tattoo, age and hair colour) that we discovered from Event 4 are marked with a red # sign. Because the same DNA profile was found at Events 2 and 4, we can infer that all details for Event 4 should also apply to Event 2. These inferred indicators are marked with a blue # sign.

4 provided us with genetic information about the offender's physical characteristics and ancestral ethnicity, and these become a part of the index.

A search of the tattoo file in the multidimensional index reveals that two people are known to have a tattoo of this description: a male aged sixty-five years, of West Indian appearance and with a recorded name of Charles, and a thirty-two-year-old male of White European appearance called Finney. Neither had previously provided DNA profiles. The system could be automated to check for those persons within the population with indicators that match a tattoo as well as any other indicators available. This narrows down those in the system that could potentially match with the available information.

Computers can be used to manage and track the chains of connections produced by this kind of cross-referencing. Although the methodology is simple, the potential links involved soon become complex and require an efficient means of tracking and cross-referencing. This process helps us to eventually establish an identity using the conventional method of a legal name, ultimately reducing the uncertainty about the legal identity of the person of interest to us. Another useful attribute of this method is that the indicators of identity can be searched in predetermined ways involving one indicator or a combination of indicators to "cleave out" of the system configurations of information of interest to us. We may need to identify a white male, aged fifty to fifty-five years, with brown hair and blue eyes, and who drives a white BMW car. This may produce a range of potential suspects, some with known legal names and others still classified as "virtual unknowns". Again, the process of cross-referencing indicators, combining indicators and exploring inferential routes between records may produce an indicator of interest in determining a true identity.

Let us consider another aspect to this process. The evidence we have does not mean that the *virtual suspect or offender* was alone when the crimes were committed; they may have committed any one or any combination of these crimes with any number of other individuals. The index may provide evidence of links between individuals and hence their potential identity. Even the notion of virtual criminal networks can be used in this way. For example, we may have evidence in our system to suggest that a number of crimes have been committed, and by means of a range of indirectly linked indicators, a complex network of links between a group of people may be suggested. These groups can be used as sources of suggested names for elimination purposes. As with the fingerprint evidence at burglary 4 in Table 7.5.1, if we can establish an accomplice of our "virtual offender" acting in concert at (say) burglary 6, that evidence (whatever it may be)¹⁴ may suggest a potential name for the donor of the DNA found at each of the 10 crimes.

¹⁴ Evidence should always be subjected to questions about its reliability, relevance and probative force.

7.6 Link Detection

Modelling networks of offenders can assist in the identification of suspects and groups of suspects for crimes that may already have occurred and for crimes that are yet to occur if action is not taken. Let us consider how this can be done and how FLINTS can assist in this. Searching each of the 10 crimes for additional evidence types such as a fingerprint or tool mark or footwear impressions may give rise to suspicion about a group of suspects or even an additional single suspect who may also have been involved.

Figure 7.6.1 demonstrates how a multidimensional approach to evidence management and analysis can aid in the detection of links between series of crime evidence and people. The same approach can be used to detect links between groups of people, geographic locations and chronologies using different *mixtures* of evidence. Figure 7.6.1 is an illustration of a database of crimes that can be examined for linkages on the basis of different evidence types. Each square in the illustration represents one crime. Each blue square is a crime scene from which DNA of type A has been recovered. As already stated, these 10 crimes are potentially linked.

A useful question might concern which of the remaining crimes in the database are linked based on an analysis of a variety of evidence types and, importantly, which are linked on the basis of combined evidence types. If any other evidence type (for example, those listed in the illustration) can provide a suggestion of a linked suspect, then we can set out to implicate or eliminate that suspect based on the DNA evidence.

Fig. 7.6.1 A multidimensional approach to evidence management and analysis¹⁵

¹⁵ A finger mark at linked crime 6 suggests the name “George Smith” as a suspect. Smith may possess DNA profile type A. If so, we can connect him with the series of 10 linked crimes. If he does not, one of his associates may. Other evidence types may indicate additional links between other crimes and Smith as well as other series of crimes and other suspects. Some of the new suspects may be connected to Smith as associates.

Inferential links may be discovered on the basis of high frequencies of offending in particular geographic areas or where a crime bears a particular *modus operandi*. These observations may reveal interesting patterns to consider as hypothetical links within the original linked series. This may reveal evidence that suggests suspects for consideration in the original series linked by means of DNA.¹⁶ Using this idea, a search of the FLINTS system may reveal potential suspects on the basis of the frequency of crimes bearing striking similarities to the series of 10 that are believed to be linked.

Investigators and analysts can begin to discover and understand complex networks and connections between people, events, locations, times and evidence in ways not previously possible. FLINTS not only allows this to be done – it allows it to be done speedily, efficiently and with reliable and actionable results. In *Foucault's Pendulum*, Umberto Eco (1988, p. 225) describes an innate characteristic that exists in databases of information. This description by Eco could well have been a description of FLINTS:

No piece of information is superior to any other. Power lies in having them all on file and then finding connections. There are always connections you have only to want to find them.

FLINTS is designed to act as an evidence integrator that brings together collections of evidence and arranges them in such a way that users can formulate questions. The principal objectives are to enable the marshalling of substance-blind sources of evidence that enable links between people, events, locations, times and evidence to be discovered by the process of analysis and questioning.

Figure 7.6.1 demonstrates the fundamental principle of integration, management and analysis of evidence around the key attractors of people, events, locations, times and evidence. If we begin from the left-hand side and work through the chart, we see that evidence is put into the system from various sources. These may be sources such as fingerprints and DNA, but in fact can be any class of information that we determine as reliable. *Accepted fact*, a concept well understood in law, has great potential in intelligence analysis. There are many facts about the way we live, work, behave and communicate that are generally available. These characteristics can be used as evidence in the form of *accepted fact* and treated in much the same way as DNA, fingerprints and other forensic evidence types.

Evidence of many kinds is integrated in the FLINTS database around the key attractors of people, events, locations, times and evidence so that links, associations and connectivity within the data can be detected. The system allows questions to be formulated in a structured way by investigators and analysts using a conventional computer that runs Microsoft Windows. Figure 7.6.2 is an illustration of the flow of evidence through FLINTS.

¹⁶ One of those crimes may have been detected or there may be an item of evidence at any one of the crime scenes that may provide an insight into the identity of the “virtual suspect or offender”.

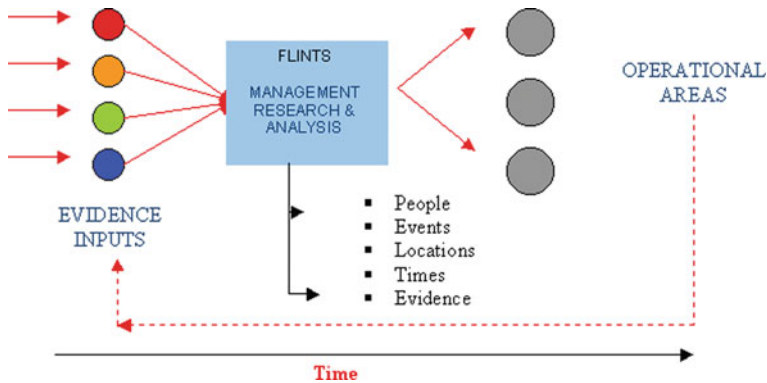

Fig. 7.6.2 The flow of evidence through FLINTS

7.7 The First Generation of FLINTS

The prototype FLINTS system began managing forensic evidence matches in the West Midlands Police department in April 1999 following a request from the force to use the system.¹⁷ The system had been designed to demonstrate the benefits of its underlying concept¹⁸ and used fingerprint and DNA evidence to do so. Evidence based on footwear, handwriting, tool marks and drugs were soon to follow. The system provided for the integration, management, analysis and performance measurement assessments as well as for the systematic allocation and management of enquiry work.¹⁹ Protocols designed for key managers and key analytical tasks became part of the West Midlands Police strategic policy.

Forensic matches reported by departments for specific evidence types are input into FLINTS by means of a standard formula. For example, DNA matches reported by the National DNA Database, fingerprint matches reported by the West Midlands Fingerprint Bureau²⁰ and physical evidence matches such as footwear and tool marks reported by forensic laboratories are brought together in the FLINTS Bureau for entry into the underlying databases.

¹⁷ This system was the prototype version of FLINTS.

¹⁸ FLINTS was designed on the basis of *Intellogic* as an executable computer programme for use in forensic investigation. Other applications were not pursued as computer programmes at this stage.

¹⁹ The enquiry work referred to is often called an *action package*. This package is a file of evidence produced by FLINTS that contains all the necessary evidence, photographs, plans and ancillary intelligence necessary to carry out an enquiry and usually leads to the arrest of a suspect. The suspect is normally the target in the action package.

²⁰ Fingerprint matches are input automatically, but their quality must be checked by the intelligence system's manager.

Strategic and analytical management tasks can be undertaken for a wide variety of purposes. Some of the tasks undertaken: maintaining a “tracking system” for the enquiry work allocated, assessing the performance of operational police areas by individual evidence types as well as by individual scene examiners, comparing evidence yields by operational areas and individuals, managing information about suspects identified, and comparing operational areas for trends.

7.8 Integration, Linking and Analysis Tools

From the initial implementation, it became apparent that FLINTS gives the user access to ranges and classifications of intelligence data about people, events, locations, times and evidence. The system enables the user to “visualise” the evidence in a number of ways that provides a range of perspectives on the data. Geographical visualisation, network visualisation and spreadsheets of varying kinds can be requested and presented in user-friendly ways. Wigmore recognised the power of visualising evidence for temporal analysis and the synthesis of arguments. FLINTS thus uses a Wigmorean approach in the development of scenarios of interest to the analyst and investigator.

Arthur Conan Doyle gave Sherlock Holmes a number of attributes important to his task that are rarely *all* seen at once in analysts and investigators in real life: keen curiosity, high native intelligence, a fertile imagination, powers of perception, a superb stock of knowledge and extreme ingenuity. In Arthur Conan Doyle’s 1887 novel *A Study in Scarlet*, the first story to feature the character of Sherlock Holmes,²¹ Holmes explains to Watson the difference between some of these attributes:

I have already explained to you that what is out of the common is usually a guide rather than a hindrance. In solving a problem of this sort, the grand thing is to be able to reason backwards. That is a very useful accomplishment, and a very easy one, but people do not practice it much. In the every-day affairs of life it is more useful to reason forwards, and so the other becomes to be neglected. There are fifty who can reason synthetically for one who can reason analytically.

In *The Five Orange Pips*, Arthur Conan Doyle has Holmes explain to Dr. Watson the importance of understanding how chains of events can be studied and reasoned about. He says:

²¹ “Although Conan Doyle wrote 56 short stories featuring Holmes, *A Study in Scarlet* is one of only four full-length novels in the original canon. The novel was followed by *The Sign of Four*, published in 1890. *A Study in Scarlet* was the first work of fiction to incorporate the magnifying glass as an investigative tool” (http://en.wikipedia.org/wiki/A_Study_in_Scarlet). The novel’s quite negative portrayal of Mormons was heavily prejudiced and even libellous, as Conan Doyle allegedly eventually came to acknowledge (*ibid.*).

The ideal reasoner would, when he has once been shown a single fact in all its bearings, deduce from it not only all the chain of events which led up to it, but also all the results which would follow from it.

There are no formal rules in existence for *reasoning* and, if they did exist, they would represent a *logic of discovery*. Schum (1994, p. 479) believes that this illustrates what he calls *bottom up* and *top down* reasoning.²² These are useful metaphors because they can aid investigators and analysts in understanding the frame of thinking in which they are operating.

FLINTS goes some of the way towards helping analysts and investigators develop their curiosity; because they are provided with high-quality data, and the system operates on the basis of questions, the user's imagination and perception of events, people, locations and times are important. This mass of knowledge and data is stocked, awaiting enquiry by users. Although FLINTS can never replace human powers of reasoning, it does provide a foundation and system from which users can access evidence, analyse it, synthesise questions and hypotheses, and visualise results in ways that are easily understood. In addition, the system then allows the results of those queries to be entered into the system as new inputs in the form of new questions in a circular and almost endless quest for new knowledge. The analyst and investigator can access substance-blind evidence about series of crimes, series and networks of active criminals, crime patterns, and areas where the frequency of crime is high. It can also identify travelling criminals. The system concentrates the mind of the user on using the weight of the evidence to link nodes rather than on the type of evidence involved.

Although by 2001 the Home Office was considering the potential of FLINTS and the approach underpinning the software to enhance the use and management of forensic evidence and intelligence nationally), a report from that year acknowledged that much more could be done to train users to get the best from the system.²³

The FLINTS system has the potential to support substantial improvements in police efficiency and effectiveness in West Midlands. However, the force is far from using the system to its full capability. This includes the as yet untapped potential for FLINTS [to be used] as a senior strategic management information tool. West Midlands should therefore refine its

²² Schum (1994) provides a diagram illustrating these processes. Their uses are in the generation and testing of hypotheses.

²³ FLINTS was adopted by the West Midlands Police, the Warwickshire Constabulary, the West Mercia Constabulary, the Staffordshire Police and the Hampshire Constabulary. The Tayside Police in Scotland and the Dorset Police are also considering adopting the system. The national body responsible for police technology – the Police Information Technology Organisation (PITO, a part of the Home Office) – are considering adopting the forensic module of FLINTS as a national system accessible to every police officer in England, Wales and Scotland. The system was recommended as a “best practice” by two of Her Majesty’s Inspectors of Constabulary. The first, Keith Povey, afterward became Her Majesty’s Chief Inspector of Constabulary; the second is Sir David Blakey. See also Management Summary, Home Office Policing and Reducing Crime Unit (2001) Evaluation of the Impact of the FLINTS Software System in West Midlands and Elsewhere (Home Office, United Kingdom).

FLINTS Project Plan so as to maximise its beneficial impact [...] This national potential includes the opportunity for forces to improve detection of crimes²⁴ committed by offenders across policing boundaries.²⁵

7.9 Expanding FLINTS to Other Police Areas

In April 2001, following a recommendation from the Regional Forensic Science Group,²⁶ FLINTS began to manage forensic matches for West Mercia, Warwickshire and Staffordshire by means of a wide-area computer network linking the forces together. FLINTS gave the forces access to all West Midlands databases dealing with crime, incident handling²⁷ and custody data via FLINTS computer terminals of the type described towards the end of this chapter. In the future, it is predicted that each of these forces will also integrate all their current non-forensic databases of police information into FLINTS so as to realise the benefits that the West Midlands region is seeing. At present, the Midland Region communicates using high-bandwidth networking technology and shares all forensic intelligence data. It is the first Region to have adopted this approach. In Fig. 7.9.1, the current FLINTS communication channels are indicated by red lines; these represent the flow of data as in the original installation of FLINTS, at the West Midlands Police. However, note that these lines do not yet make for a complex system whereby each force can communicate with any other force or combination of forces as needs

²⁴ It should be noted that the reference is plural. This is an important feature of the rationale and design behind the FLINTS approach. FLINTS manages evidence and information about *volumes of crime* as well as single crimes. The traditional approach is based on managing evidence and information as single cases.

²⁵ There are 43 police forces in England and Wales. These are distributed and resourced on the basis of political boundaries, with separate Chief Officers and Police Authorities. Each force decides its own policy for crime investigation, detection and reduction as well as the structural arrangements for the delivery of the policing service to the community. There is a natural tendency to concentrate on crime committed within the force's boundaries, and crimes committed elsewhere attract less attention. This provides the strategic opportunity for criminals who are prepared to travel to commit crime with very little likelihood of being detected based on repetition of their offences. Criminals who reside in one police area and who travel to commit crime in other police areas are difficult to track and detect, and pose a serious threat to the community at large. Amongst other things, the National Criminal Intelligence Service (NCIS) was set up in 1996 to provide support to forces nationally in dealing with travelling criminals, yet no national system or ability to both monitor nominals (suspected persons), crimes they have links to, their associate networks and forensic evidence matches is capable of linking them with crimes and other persons. FLINTS could fill that gap.

²⁶ Forensic science and best practice is monitored jointly by a number of police and Forensic Science Service Regional User Boards. These operate across regional areas and serve a number of police forces. The Midland Region is served by boards for West Midlands, West Mercia, Staffordshire, and Warwickshire. It was chaired at the time by Mr. Peter Hampson, Chief constable of the West Mercia Police.

²⁷ The system is called *Command and Control Data*. This includes access to the emergency (999) system.

Fig. 7.9.1 Original (*red*) and envisaged (*blue*) communication channels

arise.²⁸ The next stage was to envisage an expanded capacity whereby each force would effectively input its data into one system, communicate in complex ways and make thorough use of feedback looping (the blue lines in Fig. 7.9.1).

In addition to these police services, a number of others expressed an interest in inputting their forensic match data into the system so that it can be shared in exchange for the improved analytical capability they would obtain.²⁹ This will enlarge the network and database, and will extend the system's analytical capability. The benefits of extending the system to other police forces will be the wide-scale integration of evidence managed in those force areas. As of April 2002, with the exception of the Midland Region and Hampshire, each evidence type was managed within isolated systems. The benefits of a substance-blind integration and treatment of evidence has yet to be realised in those areas. For example, police forces outside the Midland Region cannot manage matches from their diverse evidence types within one system, they cannot access management information about matches with other evidence collections and they have yet to automate the preparation of Evidence and Intelligence "action packages". In short, Wigmorean approaches have yet to be adopted, but the tide is beginning to turn and FLINTS, with its ancestral foundations in Wigmorean analysis, is proving to be the catalyst for this change.

Access to accurate intelligence is central to being able to exercise good decision-making in policing. FLINTS provides this access through the integrated management of evidence as well as through a structured approach to the asking of questions of and about the evidence itself. Wigmore knew even in 1913, when he published his first edition of the *Principles of Judicial Proof* (Wigmore, 1913, 3rd edn. 1937) that

²⁸ Feedback loops involving an iterative process of hypothesis generation, testing and re-generation are limited. This type of process is important in the search for new knowledge in systems.

²⁹ Hampshire began using FLINTS in 2002, and as of April 2002, negotiations were underway to include Kent, Metropolitan Police, Tayside, South Wales, Dyfed Powys and Strathclyde. Two national Home Office projects, CRISP and VALLIANT, are studying the potential to link the databases of every police force. On 10 April 2002, the CRISP Project Team met with the West Midlands Police FLINTS Project Team, and subsequently reported that CRISP was considering using FLINTS as the central analytical tool for managing and interpreting the information.

the visualisation of evidence is crucial to gaining an understanding of the complex relationships and dependencies that exist in evidence. The ability to visualise links and networks is central to the ability to generate new knowledge about the evidence we possess and the hypotheses we are constructing by asking questions.

7.10 Volume Crimes and Volume Suspects: Not *Single* Events and *Single* Suspects

Police forces in the United Kingdom are based on geographical and political boundaries. Though there are benefits to the geographic organisation of the 43 police services in England and Wales, one drawback is the fragmentation of intelligence. Criminals can travel from one force area to another to commit crime, often frustrating intelligence strategies thereby. By identifying series of crimes linked on the basis of their rationale, the gathering and linking of provable evidence across wide geographical areas by means of intelligence networks enables the police service to operate in a target-rich environment and circumvent the problems brought on by geographical boundaries. Instead of second-guessing where crime is emerging, FLINTS can give up-to-date and reliable indications of areas where activity is likely to be most prolific and of those persons who are likely to be most active. FLINTS can also give its users specific as well as linked cases in which evidence exists to arrest offenders and often charge them with crimes. It can also be used to analyse, disrupt, fragment and control organised networks of criminals. FLINTS is proving to be a useful tool not only for crime detection in the Midlands but also nationally, serving as a targeting tool for the identification and disruption of criminal networks. Her Majesty's Inspector of Constabulary reported in 2000 that nationally:

FLINTS has the capacity to link suspects with crimes that would not otherwise have been linked, for example, linking chequebook evidence from frauds with that from stolen vehicle crime [...] there is real potential for this system to be developed nationwide in the future. . . As FLINTS is developed it should be possible to utilise it to help identify series of offences which can then help to inform the tasking process. Potentially this database provides an exciting tool for crime investigation [...]

7.11 Performance Monitoring and System Identification

Identifying the outcomes of those processes by which evidence is managed and generated provides insights into new methods of generating and using evidence. As well as identifying outcomes of evidence generation processes such as fingerprint collection and DNA swabbing at scenes and classifying these outcomes by evidence type, FLINTS enables more complex configurations to be identified.

In 1999, as part of developing the treatment of evidence as a complex substance-blind commodity,³⁰ it became apparent that if DNA could be extracted from objects

³⁰ The term *substance-blind evidence* is borrowed from Schum (1994).

merely touched by humans,³¹ it could also be extracted from objects merely touched by persons committing crimes. This minute trace evidence had traditionally been thought to be beyond the ability of forensic science, but possible application areas now include crimes such as thefts of motor vehicles, deception, and fraud against elderly victims, in which offenders produce false identification papers and pose as government or public utility officials to gain access to the victim's home³² to steal.

If DNA could be extracted from minute sources,³³ in this case faint and smudged fingerprints, it was proposed to the Forensic Science Service that in partnership with the West Midlands Police, an experiment should be run to recover minute traces by swabbing objects at crime scenes for DNA. These swabs would include DNA from objects merely touched by humans. For example, vehicle crimes would provide sources such as gear levers and steering wheels touched by the thieves. Thirty cases of burglary were targeted for the use of the Low Copy Number DNA technique and each involved elements of distraction tactics exercised against elderly victims.³⁴ National covert intelligence sources indicated³⁵ that a number of active individuals

³¹ DNA profiling has developed rapidly in recent years to become more and more sensitive and discriminating. The Forensic Science Service (FSS) can now offer a specialist service that has major implications for police investigating not just the most serious current crimes, but also those that happened decades ago. DNA Low Copy Number (DNA LCN) is an extension of the routine FSS SGM Plus™ profiling technique that enables scientists to produce DNA profiles from samples that contain very few cells, such as a single flake of dandruff or the residue left in a fingerprint. These profiles are fully compatible with those in the National DNA Database. DNA LCN profiles have been successfully generated from items such as discarded tools, matchsticks, nose and ear prints, weapon handles and ammunition casings in support of the FSS Major Crime Service. Given its high sensitivity, DNA LCN can be a particularly useful tool for investigating serious crimes when other profiling techniques have been exhausted or when options for forensic evidence appear to be limited. It can provide extremely valuable intelligence for Investigating Officers, but its context and interpretation need to be considered carefully. The relevance of a profile obtained through DNA LCN needs to be carefully considered, as it can offer valuable intelligence to police – but only within the framework of each individual case. DNA evidence, whether obtained through DNA LCN or another DNA SGM Plus™ technique, is always corroborative and its significance will always depend on what else is known about the suspect.

³² Elderly people are chosen as victims on the premise that they may experience difficulties in the recollection of identity. More disturbing is the premise that they will not be able to survive cross-examination. In one extreme case, a criminal admitted to me that elderly witnesses, especially the very elderly, may not survive long enough to give evidence in court.

³³ This method is known as *Low Copy Number DNA* because it recovers small traces and then amplifies the trace material into sufficiently large samples for profiling. Another term for the procedure is *supersensitive DNA*.

³⁴ A typical technique is to visit the victim with false identification and claim to be a member of one of the public utilities. Once inside the premises, the offender has expertise in locating the victim's cash savings. Many elderly victims do not use bank accounts. It is not unusual for several thousands of pounds to be stolen in cases of this sort. Many victims later die, but "proximity" in terms of causation of death is almost impossible to prove.

³⁵ Classified source.

were involved. As a result of using the Low Copy Number technique, DNA profiles were recovered from objects merely touched by the offenders that had committed the crimes. These were places such as door handles, door knockers, bells and so forth. As a result, 80% of the identified suspects were matched against DNA traces and later convicted and given prison sentences.³⁶

7.12 Using FLINTS: A Tour of the System as the User Sees It

Here are three simple examples of the questions we might ask the system to deal with at the start of an exploration of the evidence. The precise nature of the question is a matter for the user to define, and will be determined by the type of problem and enquiry they face. This problem or enquiry might be very focussed and might search for particular items of information about specific people, events or locations. However, it might also be quite broad and search for strategic masses of data that could be used to formulate more focussed questions:

1. “Show me any links between suspect Mark Smith and any crimes.”
2. “Show me robbery events over three months in Wolverhampton along with any links between those events and people.”
3. “Show me a list of prolific offenders³⁷ and list them alphabetically.”

The first two questions allow us to simply link people with crimes on the basis of evidence that we can prove to high standards of reliability, and the latter question enables the identification of those persons who repeatedly offend. Faced with answers to questions like these, we can set about deciding the most appropriate response to take in a rational and reliable way. The options may be to arrest the suspect, use covert surveillance, investigate the crimes or the people involved in detail, or engage in ampliative discovery by asking further questions to expand our field of knowledge around the people, events, locations, times and evidence itself. Let us look at the results of the questions we have posed above by accessing the FLINTS system. The illustrations below (Figs. 7.12.1 and 7.12.2) are taken from real questions asked of the database.

³⁶ The idea to use Low Copy Number DNA to find small traces of DNA left at scenes was raised at a meeting of Crime Scene Examiners in 1999 in the West Midlands Region. The hypothesis was that use could be made of the technique providing that a location could be identified where the offender was known to have touched some part of the scene. This would greatly assist the swabbing process and enhance the likelihood of recovery of trace material for DNA profiling. A national operation called “Operation Liberal” employs similar forensic techniques to target and identify burglary offenders where elderly victims are involved.

³⁷ That is, a list of people who have been linked by evidence to crimes on more than one occasion.

QUESTION 1

“Show me any links between suspect Mark Smith and any crimes.”

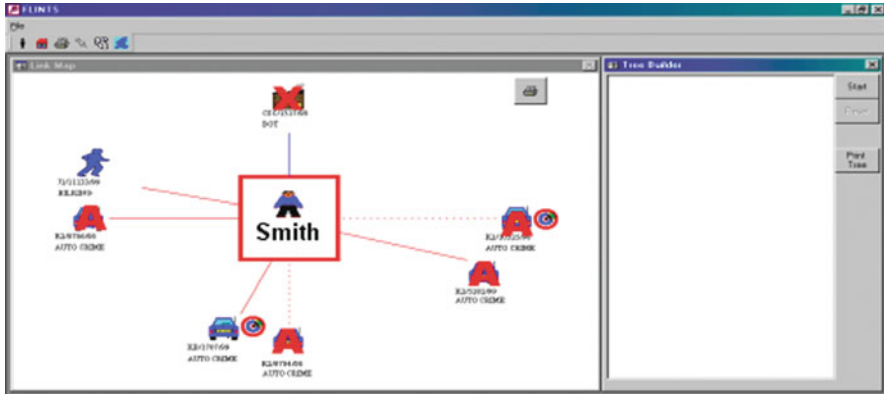

Fig. 7.12.1 An example of framing a question in FLINTS

QUESTION 2

“Show me all the robbery events in the last three months in Wolverhampton, along with any links between those events and people.”

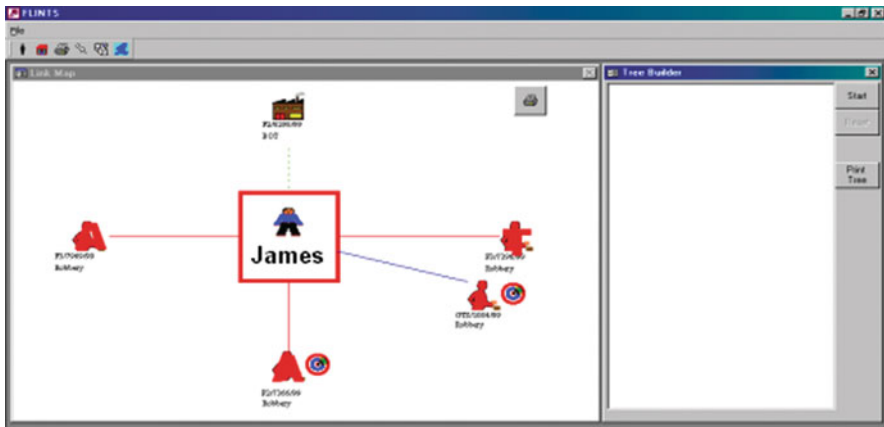

Fig. 7.12.2 A second example of framing a question in FLINTS

FLINTS has answered the question by presenting us with a modified Wigmorean chart illustrating the inferential dependencies by means of simple nodes and lines (arcs). We can see a node (“Smith”) in the centre of the chart surrounded by seven other nodes around the outside of the chart that depict links to events (crimes) and other people (suspects). The arcs depict the inferential evidence – in this case, fingerprints and DNA. The dotted line depicts a partial fingerprint match.

Two charts result from this question. In the first (Fig. 7.12.2) we see that an individual called “James” has been selected by the database as the centre of an interesting network of four robbery offences and one burglary at a factory. Furthermore, one of the links is between the node for James, currently the centre of the network, and another individual node with a target sign adjacent to it. This indicates that there is a second network of links to be investigated in addition to those in the first chart. By asking the database for further information, we see in the second chart (Fig. 7.12.3) a set of links between the James node and another node bearing the name Massey. This tells us that James and Massey are implicated in yet another robbery.

The detection of volume offending is greater than expected. In another chart (Fig. 7.12.4), we can see that the node “Ford” has been identified by the system as a volume offender on the basis of forensic fingerprint evidence and DNA. He has been linked to twelve burglary offences at houses based on fingerprint evidence, to one offence of theft of a car based on fingerprint evidence, to three offences of burglary at houses based on DNA evidence, and to one offence of burglary at a dwelling house based on fingerprint and DNA evidence. If other evidence types such as footwear, tool marks, drugs, handwriting and so forth were added to the list, the volume and frequency might be even higher. Without FLINTS, it would not be possible to detect such complex linkages over time and geography by different evidence types.

The information contained in the charts presented thus far has been detailed at a micro level, with illustrations of links between certain sets of nodes. However, it is useful to be able to switch between a macro and micro view in the same way

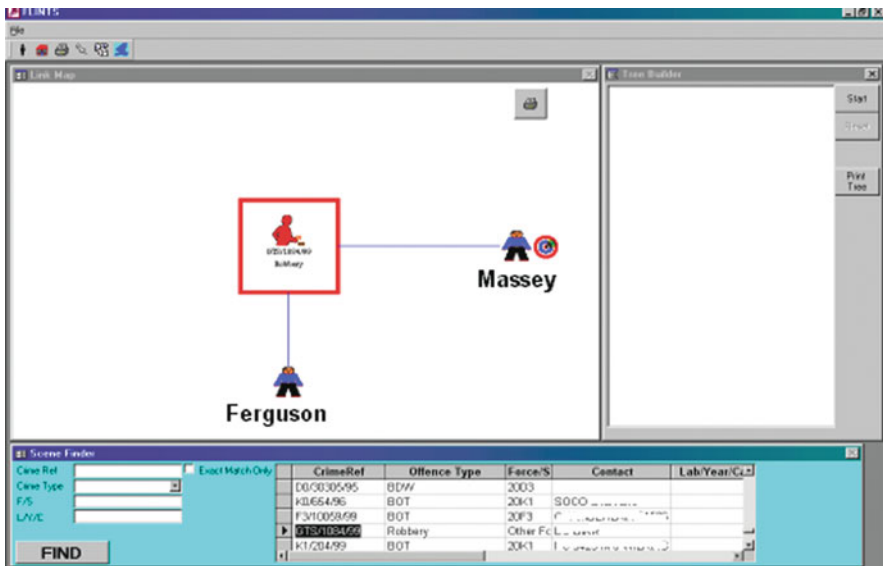

Fig. 7.12.3 Links being formed in FLINTS

Fig. 7.12.4 The network of links around Ford

that we read a text – sometimes quickly, by scanning the text looking for key areas of interest, then slowly, reading the same text carefully, noting detailed meanings, relationships, connotations and implications. In the chart below (Fig. 7.12.5), we see a depiction of a “syllogistic tree” of *all* links in the database involving the node “Smith”. This chart can help the analyst and investigator to understand networks of links that we should know already exist and networks of links that may exist but that have not yet been discovered. It can act as a prompt for asking further and better questions. For example, we can now ask ourselves a question such as:

Faced with the following tree of links, and based on my knowledge of the prevalence and geography of crime elsewhere in the system [Fig. 7.12.6], what other links may exist between these nodes for which we do not yet have evidence?

Searching our database may begin with a simple question such as the one depicted for the node “Smith”. The scenarios around Smith and other nodes of interest may begin to develop as we begin to ask further questions and receive answers to them that we can in turn use to formulate further questions. From this process, we begin to see emerging items and combinations of evidence.

The locations of events and crimes, as well as the locations that suspects and victims habitually go to or reside at (Fig. 7.12.6) should be regarded as prime material for intelligence generation. In this chart, the yellow dots refer to scenes of crimes and the red dot refers to the location or last known residence of the suspect for those crimes. Adding the dimensions of space and time to the range of tools provided by FLINTS has enabled analysts to examine crimes from the standpoint of the geographer. Clustering events by their locations begins to give us insights into the movements and activities of suspects and thus lets us synthesise potential as well as real links, raise propositions about events that suspects may have been involved in

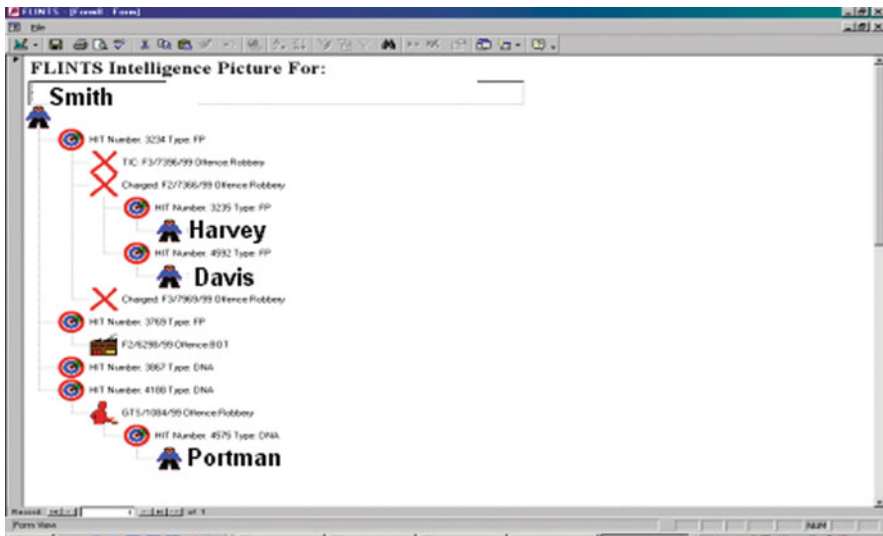

Fig. 7.12.5 Confirmed and rejected links in FLINTS

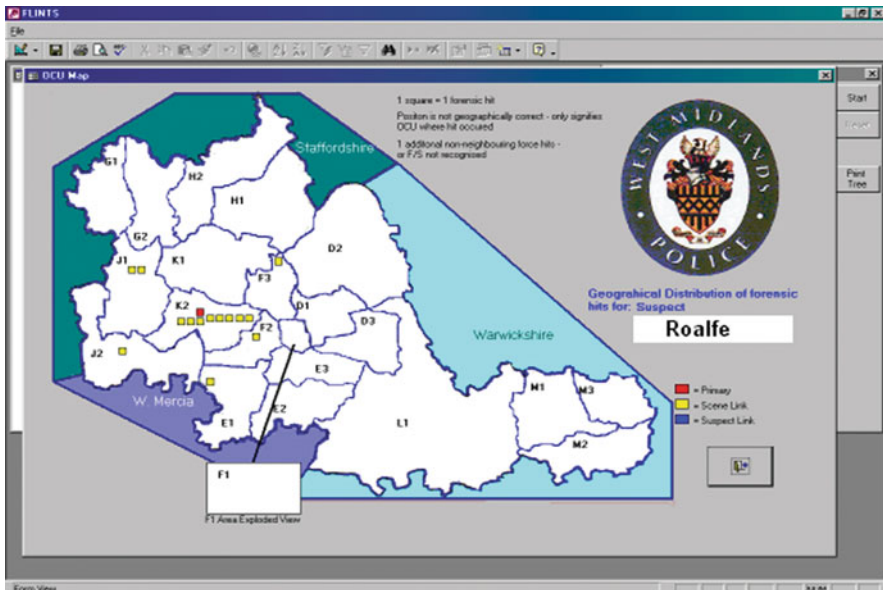

Fig. 7.12.6 A regional pattern of incidents and potential links

as well as events that are still emerging, look for crimes where there are elements of outstanding forensic evidence which we may use to either implicate or eliminate our sets of currently interesting suspects, and even identify vulnerable areas where victims are at greater risk. The chart containing the map (Fig. 7.12.6) illustrates these points.

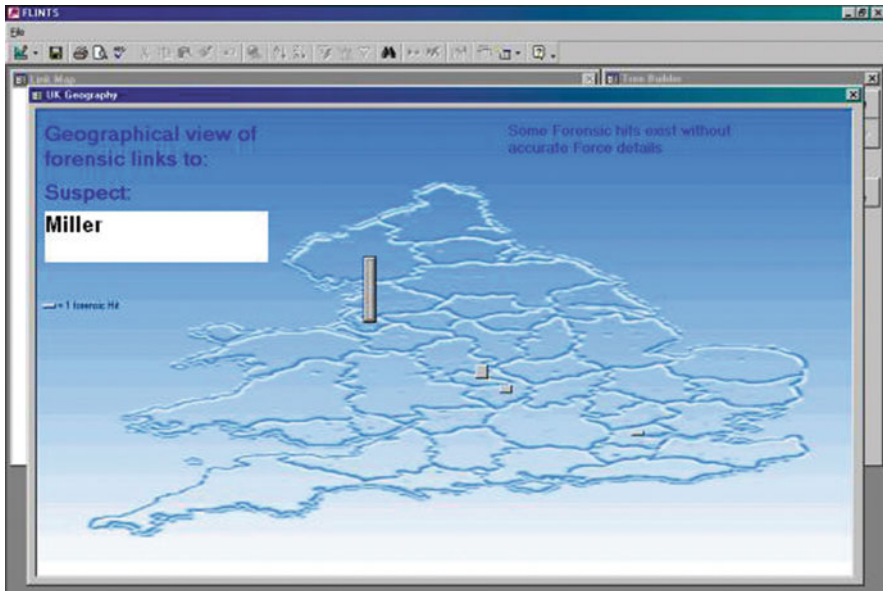

Fig. 7.12.7 A georeferenced view of forensic links to a suspect

In the illustrations in Figs. 7.12.6 and 7.12.7, and 7.12.8, we can see how we can adopt macro and micro views of geography to help us gain a better understanding of the characteristics and prevalence of the events and suspects we are currently interested in, or perhaps that we *should be* interested in given the emergence of new and interesting networks. Here, in our quest to gain insights into the activities of a node called “Miller”, we learn that the suspect’s links to crime span almost the length of the United Kingdom, notwithstanding the fact that his residence is in Liverpool. In this case, the events are burglary offences at factory premises from Liverpool in the northwest to the Midlands and on to London in the southeast. From this we may infer that the suspect has been using either the motorway network or the rail system to travel between events and crimes. Interestingly, one of the events in the series involves the theft of a car, so we may also infer that Miller has been stealing vehicles to undertake the journeys. Our next enquiry may be about vehicles stolen at or near the crimes in and around Liverpool, the Midlands and London.

One specific function the system undertakes is performance management by using various measures and indicators. In the following illustration (Fig. 7.12.8) we can see the way in which a variety of categories of data can be drawn together to allow managers to assess the relative performance of police departments. On the left-hand side can be seen a series of preformatted questions from “Unresolved

Fig. 7.12.8 Sample performance reports that can be generated by FLINTS

Actions by OCU”³⁸ to “Crime Type Distribution by OCU”. The dates between the times of interest can be selected for the analysis and the resulting chart will reflect these dates.

The chart shown in Fig. 7.12.9 is the result of asking the system to measure and present the number of crime scenes, by operational area, in which matches³⁹ have been successfully achieved. Differences between areas can be evaluated, the way that scenes of crime examiners are used between different areas can be assessed, and the relative efficiency of staff in recovering evidence between different areas can also be assessed. If one area is achieving a high success rate, the others can examine the practices being adopted and try to emulate those achievements.

Other questions can be formulated to identify repeat offenders, and these questions can be used for strategic analysis and offender targeting. Offender targeting can be the concentration of both overt and covert means of monitoring the activities of key suspects within a population strongly suspected of involvement in series crime. One of the benefits of this function in FLINTS is the auditing and tracking capability that results from the analysis. This can help to justify decisions to third parties in later debates. In Table 7.12.1 we can see the answer to a question (where ‘hits’ means ‘matches’):

Show me the evidential hits in FLINTS for 1.6.1999 for suspects with more than one hit.

³⁸ OCU is a police area called an *Operational Command Unit*.

³⁹ Police Forces use the term *hit* instead of *match*.

Fig. 7.12.9 A histogram of hit OCUs, by evidence type

Kelly	Bart	18.4.58	Burglary	11010001	Fingerprint
Kelly	Bart	18.4.58	Burglary	10110001	Footwear
Kelly	Bart	18.4.58	Burglary	11000001	DNA

In reality, the list in Table 7.12.1 would run to many pages. Lists can be prepared for different police areas and over different time spans, thereby giving different perspectives on the evidence. Note the squares filled in blue: for these squares, the crime reference numbers are the same, therefore Kelly and Jones may have committed this crime as accomplices. Fig. 7.12.10 illustrates how this correlation can be identified and brought to the attention of investigators.

In Table 7.12.2, we can see the result of asking the system to prepare a list of those scenes of crime that have been matched against suspects and list them by

Fig. 7.12.10 A conclusion generated by FLINTS that calls a key finding (correlation) to the investigator's attention

operational area. In this case, we can see a list of persons identified as being suspects for single crimes as well series-linked crimes, along with the evidence type involved for the Sutton Coldfield area. The list has been abbreviated for illustration purposes.

Analysts, investigators and scene examiners can access their own reports as well as those of other areas to help formulate hypotheses about active offenders, crime types and the prevalence of particular suspects by area, crime type and density of offending.

The integrated approach to the management, analysis and synthesis of evidence now seen in the FLINTS system is enabling the police service to take a more sophisticated yet still pragmatic approach to the management and use of the evidence contained in police data systems. This approach permits analysts to solve problems that were known to exist yet that were too complex to tackle in the past.

A good example is the relationship between the incidence of crime and the illegal use of drugs, which has until now been *assumed rather than proven*. No reliable evidence has been produced to date to demonstrate this relationship, although intuitively many governments and police sources have claimed it to exist. Whilst there is evidence that many persons arriving in police custody are under the influence of drugs, the evidence to explain the networks of people and crimes involved has been too complex to even bring together let alone analyse. FLINTS treats evidence and crimes in a substance-blind way. It is thus as applicable to the investigation of drug offences as it is to the investigation of burglary, rape, theft or homicide. Likewise, the evidence types it draws on are treated as “fuzzy” categories rather than “strictly deterministic” categories, and are equally applicable to DNA, fingerprints, footwear and a whole range of other forensic evidence types. Persuading the

police service to treat evidence generically, in a substance-blind way, would pave the way to accessing a rich matrix of linked networks of people, events, times, locations and evidence.

A joint Government and Police Committee⁴⁰ chaired by a Minister asked early in 2001 that FLINTS be used to assist in identifying markets for the distribution of illegal drugs in the United Kingdom. Identifying those who travel across boundaries to commit a crime and who deal in drugs will aid the identification of travelling networks of criminals involved in drug trafficking or related offences. For example, at present there is no evidence available about those persons who engage in the illegal trafficking of drugs between the coastal towns of Sussex and the middle counties of England and Wales, yet there are data available that drug importation does take place

⁴⁰ The approach was made by Mr. Peter Hampson, QPM, Chief Constable, West Mercia Police, in February 2001.

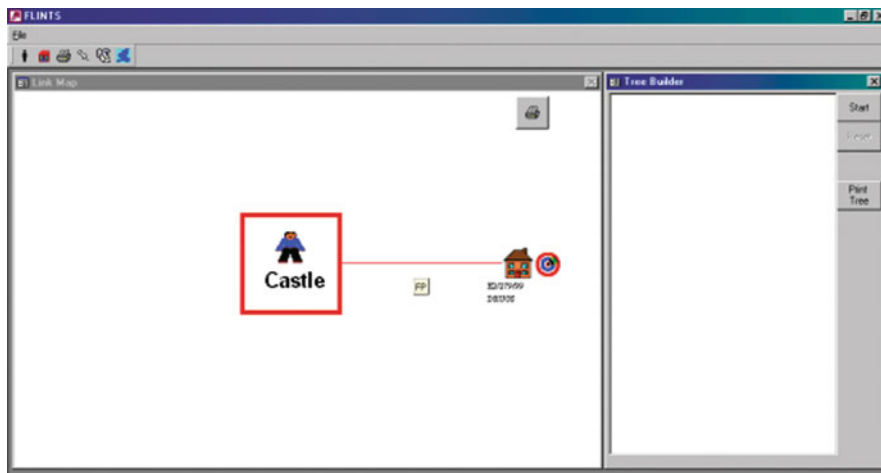

Fig. 7.12.11 Link between one suspect and evidence

on the southern coast and that the drugs arrive in the Midlands Region in smaller consignments. One way to tackle the problem of gaining a better understanding and real knowledge about this would be to apply the methods embodied in FLINTS.⁴¹

We can see how FLINTS, using a substance-blind approach to evidence, enables the system to be used for the analysis of drug networks. In this example (Fig. 7.12.11) we can see that the node “Castle” is linked to one offence of illegal possession of drugs on the basis of *fingerprint* evidence rather than a chemical drug analysis. Using fingerprint evidence in this way is an example of the substance-blind approach, and serves to illustrate how the use of one evidence type can inform the use of another. The fingerprint evidence involved came from the examination of paper wraps used to store the individual packs of drugs. The imaginative decision to use fingerprint analysis in this way was central to the ability to create a link to the networks.

However, we should also note from the chart that another network is operating behind the one visualised here. It is depicted by the “target” appearing against the crime node on the right of the screen. The system is telling us to look further because there are additional interesting links. In Fig. 7.12.12, the result of asking the system to present us with those additional links is illustrated. What we then see is that the node “Castle” is also linked to a node called “Kosko” and another node called “Castle”. This latter node is in fact a brother of the first Castle. Probably the most interesting aspect of this analysis is not that we have fingerprint evidence presenting us with a scenario linking three formerly unknown associates but rather proving that none of the people involved in the network reside in the West Midlands Police area, where the drugs offence was committed.

⁴¹ A substantial data set was being compiled to enter into FLINTS to establish the extent and weight of illegal drugs that reach markets and the magnitude of their people networks. A presentation of the findings to the Government was planned for Autumn 2001.

Fig. 7.12.12 Additional links suggested by FLINTS

An overview of the links between these nodes quickly demonstrates the extent of the network based solely on fingerprint evidence. Chemical analysis of the drug may reveal evidence of its source and original consignment. The use of evidence about telephone traffic among Castle, Kosko and Castle may reveal evidence of linked communications before, during and immediately after the events involving the handling of illegal drugs.

Figure 7.12.13 demonstrates how complex links between different people and different crimes can be identified using different but integrated evidence types and by using FLINTS in this way. These links would take very long periods of time to identify using conventional investigations. In this illustration, Williams has been linked to two offences of burglary at factory premises, three burglary crimes at domestic dwellings, one robbery and one theft of a car. It can also be seen that Kennedy and Tennison have been linked to the node marked with a "X". This is, in fact, the same crime as the node marked with a "Y". This visual approach is thus a method to indicate quickly that Williams, Kennedy and Tennison may have committed at least one crime together whilst Williams has been implicated in another six crimes. The hypothesis suggests to the analyst that all three may have been operating together. Further links can then be explored by pressing the target icons depicted next to certain nodes. These indicate further lines of immediate enquiry available to the analyst. In this way, FLINTS allows the user to "surf" the connections and links inherent in the evidence. Figure 7.12.14 shows the police intelligence picture generated by FLINTS.

Fig. 7.12.13 Identification of complex links by FLINTS

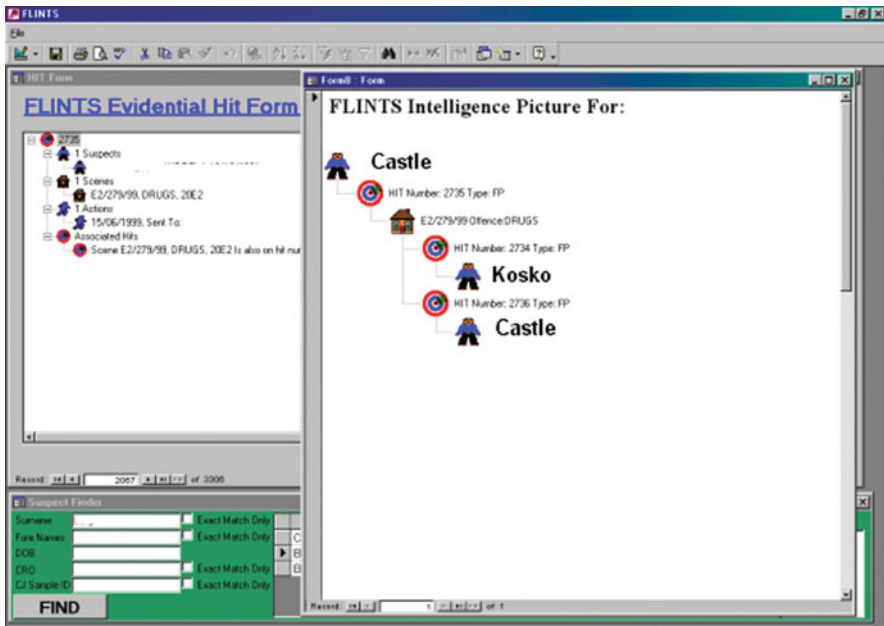

Fig. 7.12.14 The intelligence picture generated by FLINTS

7.13 The Intellectual Foundations of FLINTS

Large corporate bodies such as police forces have become far better at generating, transmitting, storing, and retrieving information than they have at making use of it to expose useful configurations and scenarios that can withstand repeated challenges and tests about the data’s credibility and legality. Storing masses of data is *in itself* an unproductive pursuit because this does not automatically translate into masses of knowledge. Strategies and tools are needed to help the investigator and analyst make use of the evidence known to exist in order to discover evidence that may exist but that has not yet been discovered. One useful tool that will be described in detail later in this chapter is the ability to formulate useful questions. Good questions aid in the discovery of interesting configurations of evidence and chains of inferential reasoning from which useful conclusions can be drawn. Another useful tool that I will deal with later in this chapter is the formulation of stories to act as a mechanism for providing a structure in which configurations of evidence can be presented in a useful way. No matter how far-ranging and how thorough our search for evidence is, there will always be gaps and there will always be a degree of doubt. That doubt may be small and unpersuasive, but it will always be there to some degree.

In addition, strategies and tools are needed to aid us in the identification of known or suspected gaps in our knowledge as well as areas of weakness in our chains of reasoning. Circumstances often exist in which it is useful to be able to corroborate or negate an inference that we have drawn or are preparing to draw based upon evidence we currently possess. In this regard, we may see the following simple chains of reasoning (Figs. 7.13.1 and 7.13.2) depicted with black nodes and arcs that need to be tested by the search for evidence that will either corroborate or negate the node or arc. Corroborative evidence is depicted by red nodes and arcs, an approach borrowed from Schum (1994).

A number of the problems that policing faces in terms of the analysis and synthesis of evidence involve the manner in which evidence is managed and organised. Twining, Anderson and Schum are committed to the view that how well an organisation manages its existing thoughts and evidence will ultimately influence how well the organisation is placed to generate or discover new thoughts and new

Fig. 7.13.1 Simple chain of evidence generated by FLINTS

Fig. 7.13.2 Corroborated chain of evidence generated by FLINTS

evidence that will prove useful to the problems they face. The strategies an organisation adopts in evidence management play a key role in its ability to discover new evidence, new scenarios and new explanations. In addition, drawing defensible conclusions from databases will depend upon the quality of the information, its inherent credibility and the probative force it delivers. Dealing with evidence in systems for multiple-case analysis, as depicted so far, is subject to the same tests as dealing with evidence handled in single cases in a traditional way. Successful investigation and discovery depends not only upon strategies and methods designed to marshal our information in ways useful and meaningful to solving our problems (as stated here), but also upon the ability of the user of the evidence to keep in mind and continually test for the evidence's credibility, relevance and reliability. Inference chains are only as strong as their weakest link.

FLINTS symbolises a novel approach for marshalling evidence in pre-trial criminal investigations. The opportunity to exploit complex relationships and networks of links between people suspected of involvement in criminal activity allows the investigator at a tactical level and the police manager at a strategic level to identify threats and marshal finite resources more effectively and in direct response to identified problems. Identifying the problems we face is the first step in solving them. The deployment of resources and time is evidence-led and directed to specific needs. Events can be connected or associated by virtue of their characteristics and typology, which allow investigators to link events into chronological series. This is not simply a matter of macro-level linking of high volumes of events over extended time periods – it also enables investigators to undertake the micro-level analysis of single events in the search for evidence. An item of evidence in one case may fill a gap or even a series of gaps or part of a chronology in another case.

7.14 What Is It About FLINTS That Makes It Different?

FLINTS uses a modified form of Wigmore's method for the analysis and synthesis of evidence in pre-trial investigations. The aim of the FLINTS approach and software is to introduce and develop a systematic method for the management of facts

founded upon the rational traditions of Francis Bacon, John Locke, John Stuart Mill and Stanley Jevons.

A frequent observation by practitioners using FLINTS for the first time is that it makes great use of “hard” evidence as opposed to the traditional approach in intelligence work, which relies more on the use of “soft” evidence. Though this description is useful, it can be misleading and problematic. The FLINTS approach and software was designed to make a distinction between tangible evidence such as fingerprints, blood samples, DNA profiles, footprints, drugs, firearms, and so on, and testimonial evidence from human witnesses. Examples here would be witnesses observing events and intelligence reports from informant agents.

This distinction is an important feature of the FLINTS approach. It draws on the differences between the attributes of the credibility of tangible evidence that differ from the attributes of the credibility of testimonial evidence in a number of ways important to this thesis. In the case of tangible evidence, we can draw on its authenticity and chain of custody as well as on the accuracy and reliability of the collection and sensing devices we use. Examples here might be DNA swabbing kits, electronic sensors, cameras, electrostatic lifting devices and sound recordings. In addition, we have the competence of those persons who operate and interpret these devices to draw upon. For testimonial assertions, we have to keep in mind the difficulties that surround the veracity, objectivity and observational sensitivity of human sources of evidence. Although this distinction is important, it does not mean that one form of evidence is naturally superior to another.

In its present form, FLINTS overcomes many of the investigative difficulties associated with attempts to link together different criminal activities, different people and different sources of evidence. One way of describing the utility of FLINTS is to say that it provides an elegant means for forming audit trails of related criminal activities.

7.15 A Case Study in Linked Burglary

One cannot overstate the importance of developing the *capacity* to ask good questions and how this differs from a *protocol* for asking good questions. Checklists for questions in the form of a protocol provide a good method of checking that certain things have been done, but investigators and analysts cannot operate effectively without basic training in good thinking. Evidence arrives in our hands from diverse sources, in diverse conditions and with varying levels of reliability. A modernised neo-Wigmorean approach has been incorporated in the form of computer software called FLINTS. Now let us explore a real-world scenario and the investigation of a series of burglary crimes using the methodology and software developed in this thesis.

This example is a real case of burglary, but with some fictional and additional hypotheses and evidential scenarios used to illustrate the potential of the methodology and of the use of FLINTS. The burglary scene depicted in the photograph (Fig. 7.15.1) presents many opportunities to recover physical, forensic and trace

Fig. 7.15.1 Annotated photograph of a burglary scene

evidence. The scene examination reveals that the door is open, having previously been left locked and secured by the victim earlier that day. There is also clear physical evidence of damage on the inside of the door, where some kind of tool appears to have been used. The lock has been forced open, which would allow an intruder to exit the premises. This evidence raises a hypothesis that the door could have been used as a point of exit and is therefore an ideal location for seeking contact trace material, but the question arises early on as to where the alleged offender entered the premises.

This question is central to our ability to detect the crime, because when people enter and leave premises, especially by the use of force, they may leave contact trace material behind as a result of their physical contact and proximity with objects that make up the fabric of the building. Windows, doors, furniture and objects that the intruder has touched provide excellent opportunities to recover evidence. Opportunities are presented to target searches for contact trace material that could provide evidence of the identity of the intruder, the clothes they were wearing and the kind of contact they had with the premises.

In the real case (the subject of the photograph), a search of the premises and grounds was made and the lower ground-floor casement window in the foreground of the photograph was found open and damaged. This raised a hypothesis that entry was gained by means of the open casement window. The hypothesis was supported by evidence that the owner of the property had left the premises locked and secured

when she left for work earlier that day. There was no damage to the window locks when she had left home earlier that day and her jewellery and cash was now missing from a bedroom. Damage had been caused to furniture inside and a message in lipstick had been left on the dresser mirror that read “It is not over yet – we’ll be back.” Footwear marks were apparent in the soil below the window. On the kitchen work surface near the window that was believed to be the point of entry, there was a small smudge of red fluid that appeared to be blood. The fluid was located on the glass close to the forced lock. Another red fluid that may be blood was apparent on the kitchen work surface. A red fibre was snagged on the window ledge alongside some scuff marks, and was thought by the Scene of Crime Examiner to have been made by gravel embedded in the sole of a shoe when the intruder(s) entered.

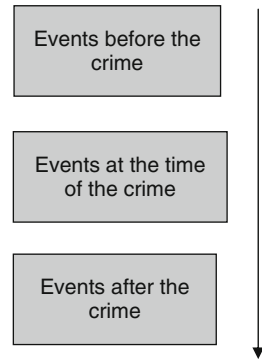

Initially, the geography and extent of the scene of crime were thought to be the boundary of the premises. However, there was circumstantial evidence that the intruder(s) must have left the garden area by some means. On the pathway in the garden, a metal pole was found that the victim said was foreign to the scene. A hypothesis was raised that this might have been delivered into the scene by the intruder(s) as a tool to assist their entry into the building; as a result, the pole was recovered for examination at a laboratory.

The intruder(s) were not within the boundary of the property at the time the search was undertaken, and the gate remained locked and secure. It was hypothesised that they left by climbing the fence. A damaged shrub pointed out by the victim revealed a damaged fence panel. Directly above the panel, a fibre was found snagged on the top of the fence, but this time it was blue in colour. This gave rise to a series of new hypotheses: were there one, two or more offenders? If a single offender, were they wearing a red and a blue garment? Where did they go after climbing the fence?

Our observations of the scene should not be restricted to the house and garden. We can infer from the evidence available that the intruders probably left by climbing the fence. The scene now needs to be extended to encompass further pathways outside the perimeter of the garden. A “scene” can incorporate any place, any person or any “thing” that has been party to the events *prior to, at the time of* and even *after* the event under investigation.⁴² The combination of events and times serves a number of purposes. One of them is the construction of stories to help us glue together the events we know about in a meaningful way that helps us to explain the events we do not know about but need to understand. The construction of stories such as

⁴² Wigmore (1913, p. 149) dealt with “time and place” as a means of proof. “Proximity, on the part of the accused, as thus presented for consideration, may be, in itself, of various degrees, from mere vicinity, up to actual juxtaposition or contact. It may also be of various kinds, such as proximity to the person of the deceased, or to the scene of the crime, or both; and it may exist at different stages; as before the commission of the crime, or afterwards, or both before and after. The strongest form in which this circumstance can be presented, and the one which requires the least reasoning to give it effect, is undoubtedly that of the juxtaposition of the persons of the accused and deceased, proved, by actual observation to have existed both immediately before and immediately after the crime is perpetrated. These show presence at the moment of actual perpetration, with the greatest effect possible, short of direct evidence.”

Fig. 7.15.2 A chronological sequence of events

these helps us to search for evidence to either confirm or negate the evidence we will produce to fill in our knowledge gaps. In addition to helping us tell stories and discover new evidence, the stories provide an ideal form of classifying our search for and interpretation of evidence. Figure 7.15.2 shows a Chronological sequence of events.

A whole series of events can go into making up a “scene”. People suspected of involvement in the crime can and should be treated as potential crime scenes in themselves, especially if they’re a suspect or a victim, because they may have played star roles as “actors” in the theatre of the crime. Victims in particular can provide good evidence from their direct knowledge for two reasons: First, they have knowledge of events either before the crime was committed, at the time the crime was committed, or some time after the crime was committed. Second, they often have domain knowledge of the place, the time, the prevailing circumstances and even the people who may have been involved and those who may not have been involved. Victims often have a stock of ancillary knowledge useful to the provision of contextual evidence about the commission of the crime. Sometimes this knowledge will be small, but often it will be more extensive than one might expect.

In the case we are investigating in the present example, the victim provided important evidence about the condition of the premises before the crime was committed, and about how an intrusion and entry had changed the physical condition of the building. She had also pointed out that the metal pole was foreign to the premises and thought to have possibly been used as a tool to effect entry and discarded when the intruders left. It is crucial that investigators and Scene of Crime Examiners fully understand that the relevance, credibility and weight of any physical, forensic and contact trace material will be directly conditioned by this type of evidence from a victim or a witness. If a suspect is arrested as a result of fingerprints being identified on the tool, that suspect might find it difficult to persuade us that the tool did not belong to them but rather belonged to the owner of the premises or the victim.

It was decided that residents in houses opposite the “scene” may have witnessed activity before, during or after the crime was committed. Perhaps they saw strangers to the area loitering or climbing the fence, or heard the sounds of the window

and door being forced. We formed a hypothesis that the offender(s) had at some point climbed the fence, and that asking questions of residents near the scene could provide additional evidence. Who could have seen the offender(s) leaving or even entering the premises?

As a result of asking residents opposite the scene about the events of that day, we discovered an elderly lady who claimed to have seen two men climbing the fence and leaving the garden during the afternoon. She had been suspicious, so had watched them run, walk, then run again along the street towards a car parked nearby. One of them was carrying a black bag and she saw one of the men drop something. When he returned to pick it up, the other man forced him to carry on and leave the object. He threw it over the fence into the garden he had climbed out of, and that object appeared to be the pole found in the garden. The witness pointed out in the garden the direction in which the “pole” had been thrown and identified the metal tool in the garden on the pathway as being similar to the object she had seen thrown.

The object was recovered for forensic analysis, with emphasis placed on DNA and fingerprints in an attempt to identify the persons in possession of it earlier that day. Evidence was sought about the credibility of the witness. She said she had never experienced serious difficulties with her sight other than short-sightedness, but felt she could be sure of what she had seen. She did wear glasses for short-sightedness and had been wearing them at the time of the incident. The investigator might have chosen to question and confirm the credibility of the witness’s evidence by asking her to repeat a car registration plate or some other unique object in the street under similar conditions to those under which the events were seen to unfold.

Control and elimination samples of DNA and of fingerprints were taken from the elderly witness and the victim to distinguish them from any foreign DNA and finger marks found on any of the exhibits recovered from the scene. During this exercise, the witness said that she had subsequently thought about the incident and now thought that she recognised the car the men had got into as one very similar to the car owned by the previous owner of the house. Also, one of the men appeared familiar in appearance, as if she had seen him before in the area. On being asked why she had not said so earlier, she replied that she had been concerned that she might have been wrong. This provides us with a good example of Schum’s equivocation testimony.⁴³

⁴³ Schum (1994, p. 107) provides a detailed methodology for assessing the relative strengths and weaknesses inherent in testimonial evidence provided by an eyewitness. The methodology serves to illustrate how important it is for investigators to bear in mind the attributes of evidence and the way in which reliability has to be *assessed* and not merely accepted. Schum’s method is based on a non-statistical approach and involves asking a variety of questions about the behaviour of the witness relevant to assessing their credibility as well as other factors that might influence a person’s credibility. Schum believes that most credibility-related questions fall into three main classifications or, as he calls them, “major attributes”: veracity, objectivity and observational sensitivity. Let us assume that a witness “W” provides us with evidence that event “E” occurred. Let us further assume that the event did in fact take place and that “W” obtained evidence from his own senses causing “W” to *believe* that the event occurred – therefore, “W” *knows* that “E” occurred. We did not observe the event “E”, so how are we to verify the account given by “W”? Because “W”

This gives rise to another hypothesis: that one of the offenders may have been the previous owner returning to the house to commit the crime. An enquiry with the victim reveals that she was involved in a dispute with the former owner about an outstanding sale of some of the contents that she had refused to pay for because they were substandard and faulty. She said that the dispute had become acrimonious, but did not believe that the former owner would burgle her home, even though she had been threatened on a previous occasion when she refused to withdraw her legal action. Instead, she had put this down to frustration about the legal action. However, as a precaution, she had reported it to her lawyer and he had written a letter to the former owner warning him about the consequences of any further actions involving threats and intimidation. This might provide important evidence about “motive”.

Enquiries revealed that the former owner of the premises had a number of convictions for burglary of dwelling houses, two of which were offences similar in nature to the present crime – lower ground-floor windows had been forced open, escape was by means of a door to the rear, and there had been episodes of climbing on both occasions. He also had other convictions for violence and damage to property.

claims to have witnessed the event with his own senses, are we also to say we *know* that event “E” occurred? What we have really discovered is that “W” *claims to know* that event “E” occurred, not that event “E” actually did occur. In considering the testimony of “W” we are faced with a chain of inferences about what “W” believes, what “W” sensed and whether event “E” did occur. Schum demonstrates the decomposition of evidence when he tells us that we can also consider our own credibility in receiving the evidence from “W” because we are not passive in the receipt of evidence. If we question our own credibility, all we can really say is that we believe witness “W” told us that event “E” occurred. Let us examine this in detail to see what he means. In a diagram, one can see that “W” believes that “E” occurred based on the evidence of his senses, and this is depicted in the form of a chain of inferences. Each node in the chain indicates a point of uncertainty about what “W” tells us. If we include an assessment of our own ability to receive and convey the evidence of “W”, then the inferential chain becomes much longer. Not only must we consider veracity, objectivity and observational sensitivity in respect of witness “W”, we must also consider our own major attributes in the receipt and management of that evidence. This becomes increasingly important when dealing with evidence from questionable sources or when there are competing accounts of events from witnesses. Take, for example, intelligence sources where information is offered in return for favour or reward. The recruitment of intelligence sources from the criminal fraternity or from foreign countries for the receipt of intelligence should not be based simply on the ability of the source to provide information. A well-placed source in a criminal network of offenders or a foreign diplomat working as a defence attaché in a host country may well be in a position to provide timely, high-quality information. However, they may also be in a position to provide false or misleading information to undermine operations they have been recruited to oppose. Take, for example, a drug dealer providing the police with information. Though he may indeed have valuable information, he may also have a motive for “informing” on competing drug dealers who pose a threat to his own trade in illegal drugs. He may also provide the information to arrest many smaller drug dealers as a means of providing himself with a more open and exploitable market. In intelligence scenarios, a foreign source may provide valuable information about international negotiations concerning a new military capability. However, what is really being practised is a deception designed to distract attention away from new technology being developed in another area and that is of greater importance to that power. Schum (1994, p. 115) also provides a schematic diagram for depicting his classification of recurrent forms of evidence. He provides fifteen classifications.

The items of physical, forensic and contact trace material recovered included photographs of the suspected point of entry (the lower ground-floor window), the work surfaces in the kitchen (with suspected blood stains present), the footwear scuff mark to the window sill, damage inside the premises and the writing on the dresser mirror, the damage to the door suspected to be the point of exit, the garden area (including the metal pole on the pathway) and the fence suspected to have been climbed as an escape route. A photograph was also taken of the place at which the elderly witness said she saw the people climbing out of the garden. This provided evidence that she could indeed have seen what she claimed to have seen. Other items recovered included the suspected blood stains, the debris from the scuff marks, the metal tool, the fibre snagged on the window and the fibre snagged on top of the fence. A single footmark was found in the soil outside the casement window, and this was identified by the victim as a foreign mark. It was photographed and cast to reveal the size and weight of the shoe that created it to serve as evidence for comparison with any shoes later recovered from suspects. All the victim's shoes were examined for the presence of similar patterns to those in the flower bed in an attempt to eliminate extraneous evidence and reduce the potential number of sources of the mark.

Control samples were taken from all surfaces from which items had been recovered. For example, a control sample of soil from near the footmark, a sample of debris from the path, a control sample swab from the kitchen surface and glass (where the suspected blood was recovered) and a sample of wood from the window and fence for comparison with any clothing taken from suspects.

7.16 Forensic Decision-Making

The objective of the investigation was to discover the identity of the person(s) who committed the crime as well as the identity of the people seen climbing out of the garden. This was done to try to reduce the suspect population to as small a number as possible. From the available items of evidence the following hypotheses were constructed:

1. The premises had been entered by force, possibly via the casement window and by use of the metal tool recovered on the garden path.
2. One or both of the intruders had cut themselves in forcing the casement window, had bled onto the work surface inside the premises, and had scuffed the window sill with a shoe and grit from outside.
3. The premises had been searched and the mirror had been written on by the intruders with a message bearing relevance to an ongoing dispute.
4. The intruders had left by the open but now damaged door and climbed the fence to escape.
5. One of the intruders had thrown the metal tool away; it landed in the garden on the path.

Of prime interest was the identity of the former owner of the premises and whether he had both a motive⁴⁴ and the opportunity to commit the crime. In addition, it was important to determine whether there was any physical, forensic or contact trace material available to connect him to the enquiry or eliminate him. He was identified by the victim and her lawyer, and from this information his convictions were found, including the fact that he was already registered in the National DNA Database following a conviction three years previously for violence. This meant that simply submitting the suspected blood from the scene to the National DNA Database for profiling and comparison would provide valuable evidence about whether he had had an opportunity to commit the crime. Also, the elimination sample of the victim, who lived alone, would also have to be submitted to ensure that the suspected blood did not originate from her, however unlikely that might seem. Also of concern was the fact that a false positive might result in linking the former owner of the premises to the crime solely because he had lived there previously.

The DNA profiling process is very sensitive, and it could potentially pick up old genetic material from when the suspect was resident there. In an attempt to clear up this point, the victim reported that she had cleaned the surfaces almost daily with a surface cleaner and that the previous owner had not been present for eighteen months.

Whilst DNA profiling was being undertaken, including a comparison of the scene stains and the control samples from the witness and victim, enquiries were conducted into the background of the former owner of the burgled premises. Intelligence was received and later confirmed that at the time when the crime had been committed, the previous owner of the premises had been in police custody and then remanded to prison to await trial for a theft that was not connected with the burglary. This effectively provided an alibi for him and challenged the basis of the enquiry. There was no reason to question the honesty and credibility of the victim and the elderly witness, so the police were left with the task of identifying (from the population) who else might have committed the crime.

It was decided not to interview the former owner in prison on the following grounds. A hypothesis was considered that although he could not have committed the crime personally, he might know who had and might have been involved as a conspirator in arranging the crime. If questioned, then, he might forewarn the intruders so they could dispose of valuable forensic and trace evidence. No evidence was available to indicate who might have committed the crime, but blood recovered from the scene might link to someone already in the DNA database.

Five days after the submission of the suspected blood to the National DNA Database, the initial results were received by the police. The suspected blood from the kitchen work surface was confirmed to be blood, and wholly different from the victim's and witness's control samples, but it did not match with any person in the

⁴⁴ Evidence of *motive* is distinctly different from evidence of *opportunity* . One may have a motive to commit a crime, but that does not mean that the opportunity will present itself. Detectives sometimes mistake the two because motive and opportunity may on occasions converge, providing some additional probative force.

Database, including the former owner of the premises (the prime suspect). However, the FLINTS Co-Coordinator contacted the officer and informed him that one of the blood stains, although not matched to any person in the National DNA Database, did match with seven other DNA samples submitted from seven other crimes of burglary in the last two years as well as with samples from an offence of car crime.

Whilst no person had been matched, FLINTS now gave grounds for believing that the offender was a serial burglar responsible not only for this crime but for seven others. The problem now was to identify the offender. The National DNA Database was contacted and asked to confirm the gender⁴⁵ of the donor of the scene's blood samples and whether the two stains emanated from different donors. The Database confirmed that the donors were both male and were different people.

FLINTS was consulted in an effort to assist in identifying potential suspects for the series of nine crimes (eight burglary crimes and a car crime). In the mind of the investigator, the previous owner still had reason to be involved in the main burglary, so it was decided to begin the enquiry by identifying his network of associates. The investigator asked the system to follow five lines of enquiry and constructed the following questions:

1. Show me the links between the former suspect and any other known criminals in the system: what is the extent of his criminal network and who is in it?
2. Show me the geography of the nine crimes: where were they committed?
3. Show me a time line of the crimes: what is their chronology?
4. Show me all the burglary crimes committed in the area of the main crime: is any physical, forensic and contact trace evidence available in any of them?
5. Show me the current keeper of the car formerly owned by the former suspect: who has it now?
6. Show me the most prolific offender for burglary [in cases bearing the following features] in the area of. . . and over the time period of. . .

The answers to the questions provided the investigator with new evidence and emergent lines of enquiry. In answer to Question 1, it was revealed that the former suspect had a primary network of ten links to other criminals, all of whom he had been arrested with on previous occasions. In answer to Question 2, FLINTS told the investigator that the nine crimes fell within a radius of a spate of burglary crimes extending to 35 offences, all of which bore distinctive signatures in terms of the *modus operandi*. The answer to Question 3 was that all 35 offences had a regular pattern in that each was committed between 3.15 and 5 pm on a Tuesday or Thursday afternoon. The answer to Question 4 was that eleven of the crimes had various items of outstanding physical, forensic and trace evidence that could be submitted for

⁴⁵ The presence of X and Y chromosomes reveals that the genomic material comes from a man; the absence of a Y chromosome reveals that the donor was a woman. DNA markers used for criminal investigation routinely test for sex, but in my experience this eliminative test is not widely used despite its enormous value. For example, if a DNA profile is gained from material left at the scene of the crime, the gender test eliminates 50% of the suspect population from suspicion.

analysis and comparison with reference databases of people. Blood and finger marks were also available.

The answer to Question 5 gave the hoped-for breakthrough: the car was now registered to one of the associates in the primary network of the former suspect. He had incurred a Fixed Penalty Ticket for a parking violation on the day the main crime had been committed, and only three streets away near a shopping precinct. The payment of the Fixed Penalty Ticket had been made in the name of the current keeper of the car and via a bank account in the shopping precinct three streets away from the scene of the burglary. His DNA profile was not present in the National DNA Database. Two days before the burglary crime being investigated, he had visited the former suspect in prison.

Tangible grounds now existed to formulate a hypothesis that the current keeper of the car had committed the crime. This conclusion was reached on the basis of his former convictions for burglary in houses, his presence in the vicinity at the time the crime had been committed, the fact that he was the keeper of the vehicle seen by the witness in the same street the crime had been committed, and that he had no legitimate reasons for being inside the premises. The vehicle was now parked regularly outside his home address and used by him in the area. The decision was made to arrest the suspect (the current keeper of the car) in an attempt to recover evidence that would either eliminate or incriminate him. On arrest, his wardrobe was searched and a pair of blue denim trousers was found. These were bloodstained (Fig. 7.16.1); moreover, he had a cut to his right hand, and a red jumper was found along with a pair of shoes similar in pattern to that in the foot mark found in the soil outside the window.

At interview, he denied being involved in any burglary crimes at any time other than those of the crimes for which he had been convicted. He agreed to supply a DNA sample in the form of a mouth swab to eliminate him from the enquiry. The

Fig. 7.16.1 Bloodstained denim trousers. Are these consistent with having bled after climbing through a casement window?

DNA process would take five days, so it was important whilst he was in custody to use other evidence available to either eliminate him or implicate him.

The blue denim jeans were sent to the laboratory, and under microscopic analysis the fibres appeared similar to the fibre recovered from the fence, but because denim is a common fabric in clothing, a definitive conclusion of identity would be unlikely. The red fibre also resembled that recovered from the scene, but was a rare fibre and thus more discriminating than the denim. However, one pair of shoes was examined by a forensic scientist and compared with the shoe mark recovered from the soil bed (Fig. 7.16.2). The scientist reported that it was very similar (a close match), that there appeared to be blood on the shoes and that there were traces of debris in the sole. The scientist made a detailed examination and produced a statement identifying points of similarity in the pattern and distinguishing damaged sections that she said made the shoes unique.

Figure 7.16.2 shows footwear mark in blood, suitable for DNA swabbing and profiling. This may reveal the identity of a victim or the attacker who bled during the crime. The question arises whether the shoe was placed into the blood already present or blood was delivered to the floor from traces already on the shoe. Figure 7.16.3 shows the footwear used as evidence.

Those same damage marks on the sole were present in the soil cast taken at the scene. The suspect was later charged with the burglary on the basis of his presence in the area at the time the crime was committed as well as the fact that his shoes matched the foot mark outside the casement window at the point of entry.

Fig. 7.16.2 Footwear mark in blood suitable for DNA swabbing and profiling

Fig. 7.16.3 Footwear used as evidence

He continued to deny involvement, although he admitted that he had knowledge of the dispute between his associate (as former owner of the property) and the victim. Faced with this evidence, he still declined to state who he had been with the day the crime had been committed and had no alibi evidence to offer.

His car was examined by a Scene of Crime Examiner, who revealed a number of finger marks in the front passenger area. These were sent for fingerprint examination with a suggestion that they be searched against the marks of the ten associates identified by FLINTS. One set of marks was identified as those of a third male. These in turn matched some outstanding finger marks at one of the linked burglary crimes. The third man was also arrested, and admitted his involvement in the original crime, saying that he had been recruited to settle a dispute between the former owner and the current owners of the premises.

Five days later, the National DNA Database reported that the DNA taken from the first man arrested and in custody matched that in all nine linked burglary crimes,

including (based on the blood found on the kitchen work surface) the main crime and an additional theft of a motor vehicle. Furthermore, FLINTS now reported an additional link by means of fingerprint and handwriting evidence to a deception practised in a department store, where a cheque from a stolen book of 25 cheques had been used and presented fraudulently. The cheque book had been stolen during a car theft. The damage to the door in the main crime that was believed to have been the point of exit matched the edge of the metal pipe recovered from the garden path (Fig. 7.16.4).

The chart shown in Fig. 7.16.5 illustrates the crimes linked by forensic evidence to the suspect. The burglary and theft of the motor vehicle are linked by DNA evidence and the deception is linked by handwriting and fingerprint evidence. This chart demonstrates the links to those crimes that were the subject of a forensic link as well as links to an additional 35 potential offences of burglary that may have been linked to the suspect, depending upon the available evidence. Each of these crimes may have outstanding forensic material available for comparison with reference evidence against the main suspect as well as his associates. These could be

Fig. 7.16.4 Tool mark from the point of entry at the burglary scene. Microscopic comparison used to compare the tool mark in the paint with the tool recovered from the garden at the scene

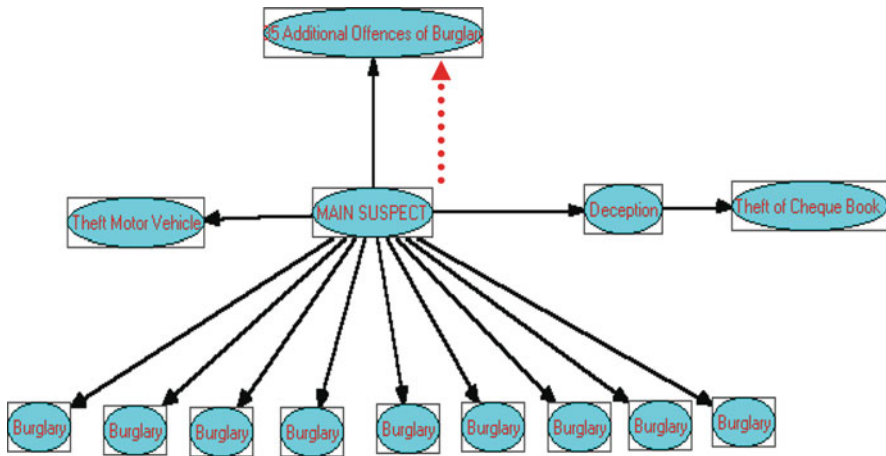

Fig. 7.16.5 Chart of links for the linked crimes and offender. This graph shows the topology of what can be interpreted as a Bayesian belief network

DNA, fingerprints, footwear, tool marks, firearms, handwriting, drugs, or, indeed, any forensic or physical contact trace material.

Analysis of the damage to the casement window and the door used to escape the premises revealed that the damage matched with the tip of the metal tool recovered from the path. A similar length of pipe was found in the boot of the car belonging to the suspect, and a comparison of the cut end sections of the two pieces revealed that they had once been a single pipe.

7.17 Second-Generation FLINTS

The discussion so far has centred on the conceptual ideas underpinning FLINTS and the prototype version built to prove those concepts in practice. The remainder of the chapter will be devoted to developments since testing of the prototype and a description of the newer version, now called FLINTS 2.

FLINTS 2 utilised the conceptual foundations of FLINTS 1, namely the systematic integration, analysis and use of information to inform the investigation and intelligence process. FLINTS 2 is an enhanced version of FLINTS 1 that allows access to information from a wider range of sources and allows this information to be manipulated in different ways. For example, new data sources include tables of information about arrested persons, about persons stopped and searched, and about vehicles. The new version also allows access to Command and Control⁴⁶ logs, and

⁴⁶ The Command and Control System is simply the computer that manages information about incidents and crimes reported to or attended by police. It contains details of each incident and the officers attending, as well as brief report details and times.

this enables information about incidents and crimes to be directly viewed and read on the screen.

FLINTS 2 was also built to incorporate advanced mapping software so that geographical analysis could be undertaken at a more atomistic level. Geographical analysis provides useful insights into the way in which information about events, people and time can be marshalled.

Two specific features of FLINTS 1 were enhanced because they have great potential for the future. The first, a “prolific (volume) offender search”, offers the ability to analyse the activity of persistent offenders. The second, a crime “hot spot search”, allows us to monitor the frequency with which crime occurs in different geographic areas. These functions allow the investigator or analyst to generate hypotheses about who in the known criminal population may be offending repeatedly and about the locations where crime seems to happen most. By combining these functions, the investigator or analyst can contemplate both detection and prevention strategies. Interventions can then be targeted more acutely and the results measured over time.

Two new search and analysis functions were added. The first allows a search to be made for addresses of interest, and the second allows searches to be conducted for vehicle license numbers and partial numbers. These searches can be used to answer obvious questions about people, addresses and vehicles, but they can also be used to answer less-obvious questions. For example, if we want to know the name of a man but all we have is a partial registration number of what is believed to be his brother’s car, we can set about identifying the car, then the owner, then the owner’s family members. We could use the address search to provide lines of enquiry to establish which family members live where and whether any of those addresses are of interest to us. Using these search functions together or in chains of questions, we are able to navigate around the data warehouse in search of information to substantiate or negate hypotheses or to open up and test new hypotheses. It is the interplay of good questions and thoughtful analysis that allows the system to be used to best effect.

Figure 7.17.1 is an illustration of the main functions of FLINTS 2. The key list in Table 7.17.1 identifies the functions which in Fig. 7.17.1 correspond to numbers. Another new feature is the ability to use electronic mail (e-mail) to communicate intelligence findings to other personnel. Actioning forensic matches between people and crimes can be done instantaneously, thereby informing staff of a developing hot spot or the identify of a prolific offender in real time. Just as importantly, the results of this communication can be received in real time.

FLINTS 2 is a “tailor made” system designed to support the West Midlands Police in undertaking their investigations and intelligence work. It is built on the

Fig. 7.17.1 The main functions offered by the FLINTS 2 toolbar

13 = Setup options.

same conceptual foundations as FLINTS 1, but uses wider sources of information. Links between people, crimes, locations and times are primarily based on forensic evidence, but incorporated into FLINTS 2 is the ability to use “accepted fact”. Here, the term “accepted fact” refers to information that is collected in the course of routine work and that would not normally be challenged. For example, the following are examples of accepted facts: that Frederick James owns a Ford Fiesta with license number X123 GHF, and that Hugh Flannery was arrested with Frederick Prosser on 15 November 1999. Another accepted fact might be the details about a “stop and search” conducted by a police officer under the Police and Criminal Evidence Act. The fact that these events happened at a particular place, at a particular time, and involved particular people is not normally challenged. These sorts of facts therefore provide important links in chains of reasoning and seemed ideal for inclusion in the system. Introducing the term “accepted fact”, which has been borrowed from the terminology of law, into intelligence work is an important step forward for law enforcement. It allows us to explain to intelligence personnel that the collection, analysis and use of everyday information can be extremely effective if the information is systemised and managed carefully; this is especially true where there is a mixed mass of information. However, the terminology also allows us to but remind personnel that information of any kind is always subject to tests of credibility, relevancy and probative force.

7.18 Access to the System: Searching or Surfing?

The traditional approach taken by intelligence organisations in Europe and North America has been based on a policy of a “need to know”. This means that only those persons who “need to know” are allowed access to intelligence information. This has been an openly accepted policy, but one might ask “how do you know if you need to know before you have access to the information?” Evidence is only as good as the uses found for it, so giving wider and more open information access to staff offers a greater potential for the evidence contained in a database to be put to

good use. That is, staff accessing the system will potentially discover new scenarios and combinations of evidence that in turn can be fed back into the system as new inputs. Wide-ranging and open access offers high-quality feedback benefits, but has to be balanced against the risks of misuse.

FLINTS may thus create a measure of tension because the very opportunity and ability to access the complexity inherent in combinations of evidence will nearly always justify the user in claiming that they have a “need to know”. The nature of the policy currently operating in the West Midlands Region is currently classified as “sensitive”, so it is not possible to publish it in this thesis. However, what can be said is that success was gained by applying for a policy of very wide-ranging access for users in order to ensure sufficient access to the complexity of linkages in the system. FLINTS now presents so many opportunities for linking that it is feasible to literally “surf” the system to discover links between crimes and suspects based on evidence that can be immediately acted upon. This is compatible with what Peirce ([1901] 1955, pp. 150–155) termed *abductive reasoning* and equates to acting on the basis of hypotheses that are mere hunches or insights, then recognising evidential opportunities presented as tests of their justification. The ability to formulate and ask questions speedily, then bring together the answers equally speedily while bearing in mind both what we have learnt and what we may want to learn if the opportunity presents itself is an example of Peirce’s reasoning. The process is similar to the asking of questions followed by seeking evidence to either refute or confirm the hypothesis embedded in the questions.

Sir Edward Crew, the Chief Constable of the West Midlands region, commented about FLINTS that “the system is beginning to produce so many cases that a wholesale re-evaluation needs to be taken about deployment of staff across the West Midlands. In some areas so many evidence leads and cases are being produced that there are insufficient staff in current structures to manage the arrests.”⁴⁷

Inappropriate access could present opportunities for corrupt practices and illegitimate use of the evidence. This problem has to be balanced against the need for wide-ranging and (as far as possible) open access to the system by investigators and analysts. The philosophy of this thesis and the design of the access system is therefore intended to support broad access but with security levels and passwords incorporated to prevent misuse.

Access to the FLINTS system cannot be gained until the user completes a log-in procedure, as shown in Fig. 7.18.1. Having negotiated the log-in procedure, users enter the system and gain access by negotiating a unique (individualised) password screen (Fig. 7.18.2). Passwords can be changed at regular intervals by the user or by system administrators to protect against security breaches. All changes are logged and tracked by means of audit trails. The toolbar at the top left corner of Fig. 7.18.2 is used to navigate through the system and to select the relevant options.

⁴⁷ Sir Edward Crew, addressing a meeting of the Jill Dando Institute of Crime Science and the West Midlands senior management team.

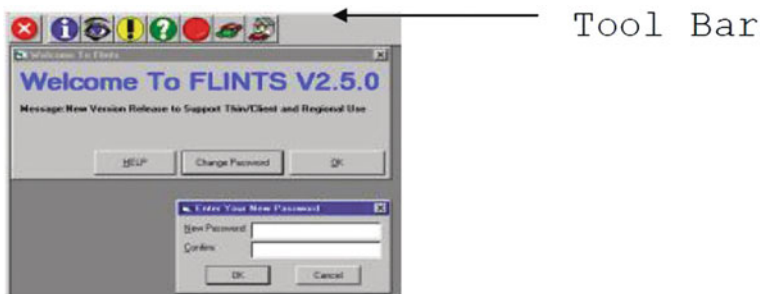

Fig. 7.18.2 The Toolbar in FLINTS 2

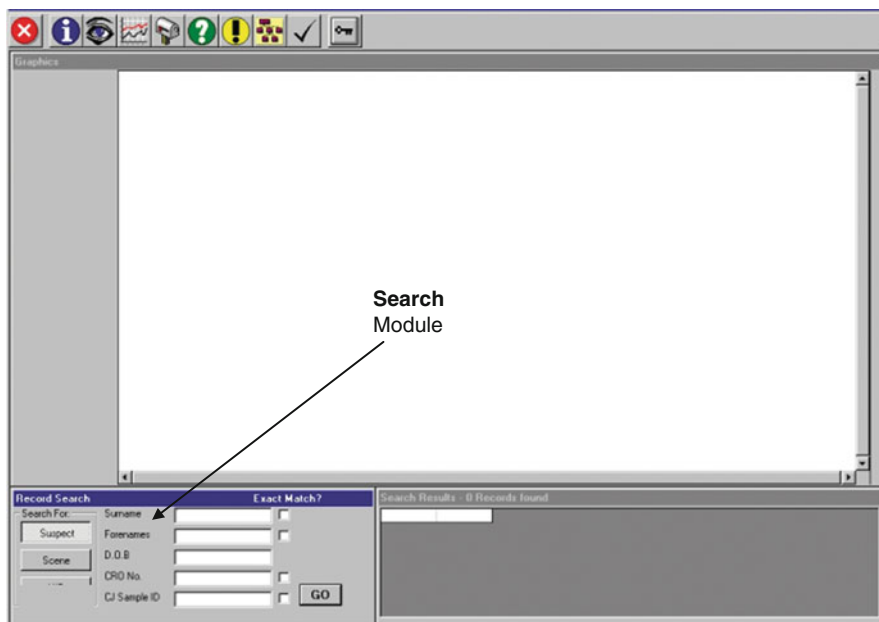

Fig. 7.18.3 The FLINTS 2 desktop environment

Once the user has negotiated the password and security system, they see the basic operating desktop (Fig. 7.18.3). This desktop gives the user the tools to undertake searches, analyse results and navigate the system.

7.19 Asking Questions About People and Suspects

Figure 7.19.1 illustrates the results of entering a suspect’s name (here, “Tyler”) into the system. Tyler may be of interest as part of an enquiry or in response to a request for intelligence information as part of someone else’s enquiry.

In terms of suspects, any single field or combination of fields can be used to construct a search. Searches can be made by reference to surname, forenames, date of birth, criminal record number and DNA sample reference number. Names or identifying features (in any of the fields) can be selected and analysed further as the user’s interest is raised.

Fig. 7.19.1 The results of searching on a suspect name

7.20 Asking Questions About Crimes and Events

Crime types are coded into the system for ease of retrieval. Figure 7.20.1 illustrates the result of a search for *burglary dwelling crimes*. (These are coded as crime type BDW.) Once found, crimes on the list can be selected, viewed, cross-referenced and searched again to provide more details about each crime as progress is made. This search could result from trying to locate a crime of particular interest based on its *modus operandi* or other discriminating features.

Searches can also be done by geographic police area, such as a town, village, city or the whole of a police area. Geographic criteria entered into a search can change

Fig. 7.20.1 The results for searching by code (here, for Burglary Dwelling Crimes)

Fig. 7.20.2 The results of searching based on a police area

the results enormously. Figure 7.20.2 illustrates a search of a police area called 20L2.⁴⁸ Again, crimes can be selected and analysed further as the user's interest is raised.

In terms of crimes, any single field or combination of fields can be used to construct a search. Searches can be made by reference to crime reference numbers, crime types, geographic locations and even laboratory references for forensic samples.

7.21 Displaying Modified Wigmorean Charts: Graphical Results in FLINTS

One of the most powerful intellectual tools that FLINTS 1 possessed was the ability to visually display links within the evidence stored in the system. This feature has been retained and enhanced in FLINTS 2. Having obtained a list of search results, the user can select the required entry, and the links within the evidence in the system will be illustrated. Figure 7.21.1 demonstrates this feature.

Prior to FLINTS, the task of bringing together the evidence to construct such a chart would have been very time-consuming. It would involve accessing many systems, as well as the arduous task of drawing a chart encompassing all the nodes and all the arcs. Apart from being time-consuming, the many actions required of the user to obtain the information and then construct the chart would involve the risk of error. The automated system in FLINTS 1 and 2 speeds this process up and reduces the risk of error. In addition, the process can be repeated time and time again as new and interesting scenarios or links are discovered. This means that immense amounts of information can be marshalled and tested in different ways as the process of discovery unfolds. Users can combine different strategies and different functions⁴⁹ to analyse, synthesise and hypothesise about relationships, links and networks of people and crimes of interest to the investigator's particular tasks. This process is unique to FLINTS 1 and 2.

Figure 7.21.1 provides an example of a search of the system and a graphical display of the result. Let us imagine that we have decided that a suspect called "Tyler" is of interest to us. In the top portion of the chart, we can see links between Tyler

⁴⁸ This area is a suburb of the West Midlands.

⁴⁹ Here, *function* simply means *questions*.

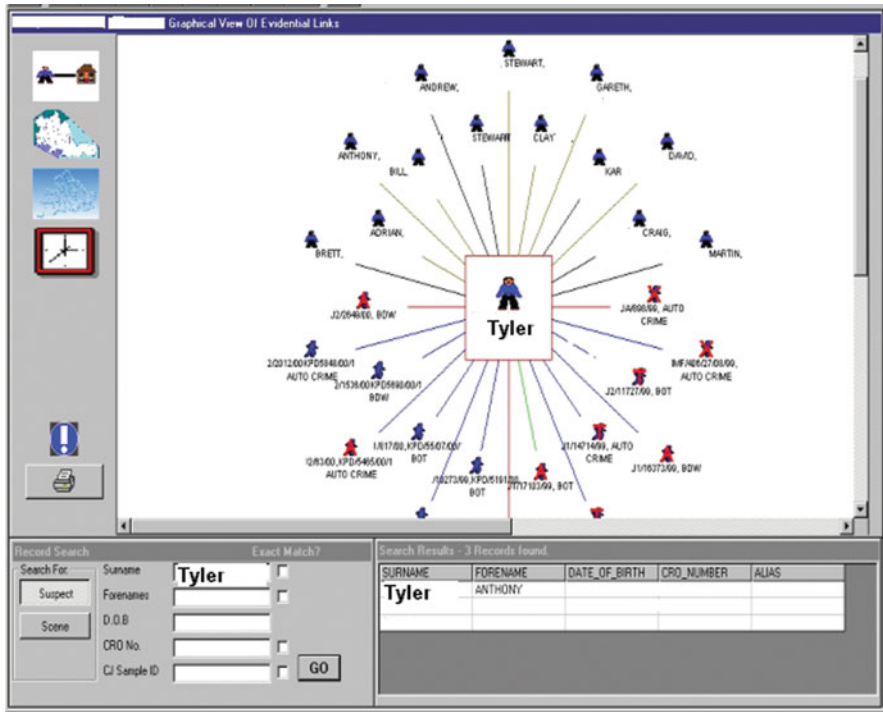

Fig. 7.21.1 Graphical display of the results of a search

and his former associates. These are people he has previously been arrested with or prosecuted with as a co-accused person. In the lower portion of the screen, we can see links to crimes based on inferences from forensic evidence. These present us with hypotheses about opportunity and will need to be tested alongside additional evidence. The different coloured lines refer to different evidence types or links.

I would like to stress my claim that the ability to manage, juxtapose and ask questions of evidence in a variety of ways provides valuable insights into interesting scenarios and possibilities. In Fig. 7.21.1, each forensic link is colour-coded and can be identified by placing the cursor on top of a line linking two objects or nodes together. Further information about each crime scene or person may be obtained by placing the cursor on top of the relevant icon. Additional information will appear that can then be presented in another graphical view.

On the left side of Fig. 7.21.1, the user can make use of a series of functions on a toolbar. This has been designed to display the evidence in a number of ways and to reveal interesting combinations of the evidence. Figure 7.21.2 is an expanded illustration of the toolbar itself. A key list is provided in Table 7.21.1.

The presence of evidence is not always the same as evidence of the validity of the inference one can draw from it. Checking evidence for authenticity is as important in FLINTS as it is in the management of evidence in single cases. Figure 7.21.3 is

Fig. 7.21.2 Enlarged view of the results toolbar of FLINTS 2

Fig. 7.21.3 A sample warning to confirm the validity of links

an illustration of the warning system that instructs the user to check the validity of the evidence before acting upon it.

This approach helps to eliminate errors in recording and in evidence interpretation, as well as false positives. Imagine the presence of a DNA match demonstrated visually to an investigator on a chart. Before the investigator decides to take action, they are prompted to check on the validity of the match by checking secondary

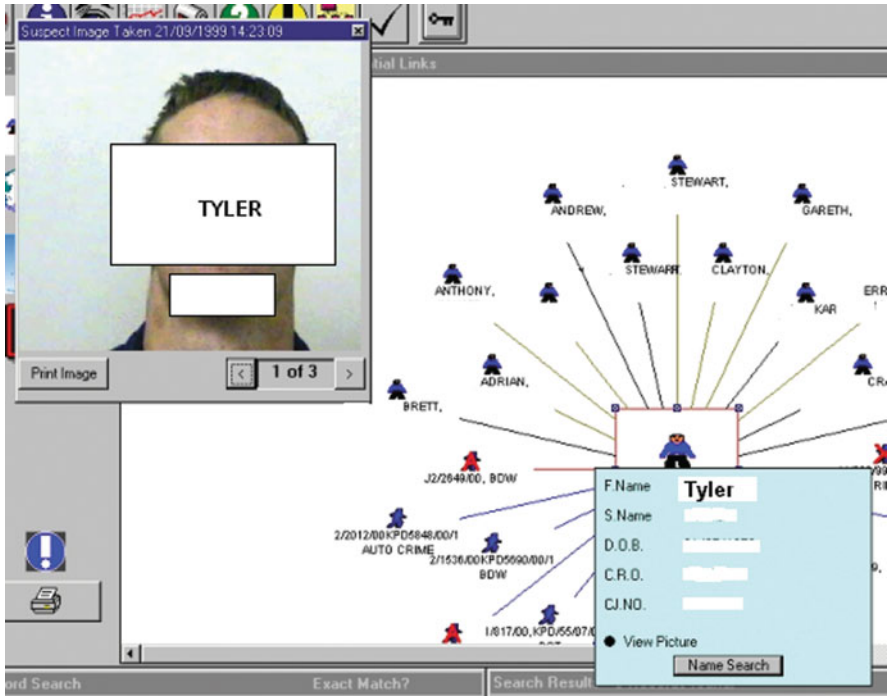

Fig. 7.21.4 FLINTS provides immediate access to photographs of suspects in its database

systems such as the National DNA Database or the Custody Records System in an attempt to uncover corroborative evidence.

As in Fig. 7.21.4, any available photographs of a suspect who appears in the chart can be viewed instantaneously. If there are a number of photographs available, they can be viewed chronologically. This has many uses, but one important one is the identification of unknown suspects.

7.22 Geographical Analysis

Figure 7.22.1 provides an enlarged view of the toolbar icons in Fig. 7.21.2, plus explanations of the features. Figure 7.22.2 provides an example of the map that can be generated by clicking the second map icon in Fig. 7.22.1.

Figure 7.22.2 is a map of the West Midlands Region and surrounding county police forces of Staffordshire, West Mercia and Warwickshire. Crimes committed by a network of linked offenders are plotted on the map to give an impression of the distribution of the crimes. This display can give analysts insights into the places where suspects and their associates habitually offend, and compare these locations with each person's place of residence. This chart could then be compared with and indeed overlaid by another chart dealing with undetected crimes. There may be some

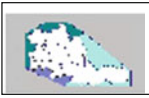

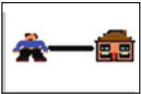

-  (1) This icon can be selected to view a network of suspects geographically. In addition, links between suspects and crimes across England and Wales can be identified. The links are then presented in the graphics screen.

-  (3) This icon can be selected to view the graphics screen.

Fig. 7.22.1 Icons for geographic analysis. (1) Icon for selecting geographic overview. (2) Icon for selecting a subset Area. (3) Icon for displaying the results for a selected view

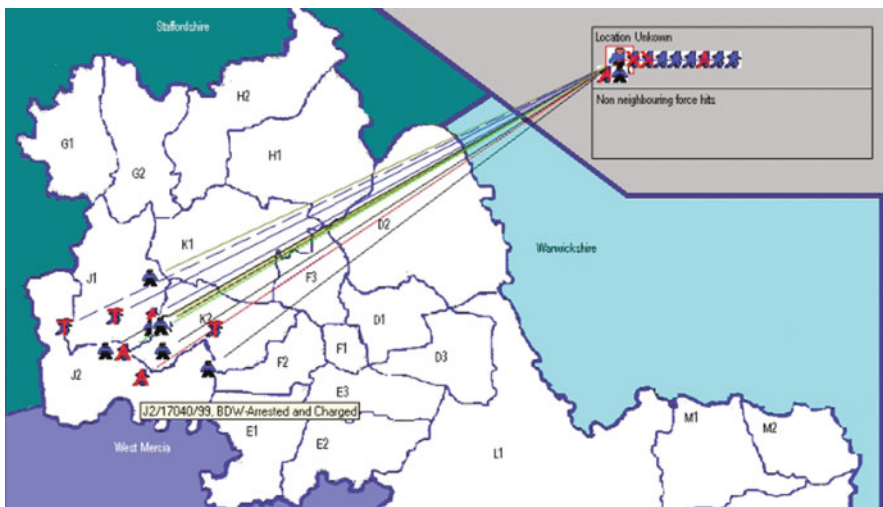

Fig. 7.22.2 Map of locations within the West Midlands region

correlation between those crimes known to have been committed by the identified network of persons and those crimes as yet undetected.

Figure 7.22.3 illustrates crimes that have been recorded across two police areas. This map display presents an opportunity to identify travelling criminals. Cylinders of various heights are used to give an impression of the number of crimes in each area. In this illustration, we have a hypothesis that a known offender, identified by means of DNA evidence, has been linked by forensic evidence to one crime in the West Midlands Region and another crime on the southern coast of England. Without FLINTS technology, these links could not be speedily identified during routine analytical work.

It illustrates crimes that have been recorded across two police areas.

Fig. 7.22.3 Map of the West Midlands region and of crimes within the region

7.23 Temporal Analysis

FLINTS results can also be subjected to temporal analysis using the toolbar icon in Fig. 7.23.1.

The use of temporal analysis in intelligence work can provide useful evidence to infer “opportunity” and assess how groups of crimes may be connected with each other. This assists in the provision of hypotheses and ranges of questions that can be explored elsewhere in the system.

Linking these types of hypotheses with those connected with “virtual offenders and suspects” provides additional insights into the identification of those in the population who ought to be considered as more likely offenders and those who perhaps should not be so considered. Reducing the certainty attached to some suspects in

This icon can be selected to display a chronology of events, which can then be presented on the graphics screen.

the database is a useful method of indicating those who should be considered for further inductive eliminative exercises.

Figure 7.23.2 illustrates a chronology of crime for the suspect Tyler identified earlier in this chapter.

7.24 Prolific (Volume) Offenders Search

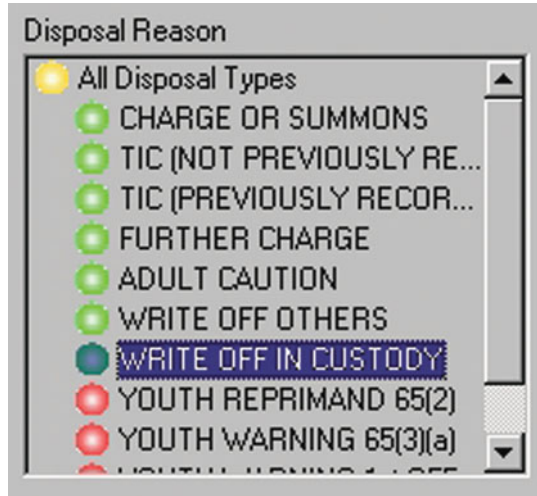

The prolific offender search function (Fig. 7.24.1) allows the user to ask the system questions designed to elicit information about persons who repeatedly commit crimes – that is, persons identified by evidence as doing so. The police, acting under Home Office instructions, classify these as “detections” and refer to them in a number of ways. Figure 7.24.2 illustrates the various ways in which these classifications are listed. These ways are called *disposal types*.

Prolific offenders can be identified by crime type, geography, and disposal type, as well as by reference to time. The results of searching under these criteria can be presented graphically in the form of a chart. This view has many uses in the construction and testing of hypotheses about crime and offenders.

Fig. 7.24.1 Searching for prolific (volume) offenders

Fig. 7.24.2 Disposal Types Used by FLINTS

7.25 Using Geography to Identify Prolific Offenders

In the West Midlands Region, operational areas are known as Operational Command Units (OCUs). These OCUs are listed in groups or clusters called Divisions, and coded from A to M. Any one or a number of these areas can be selected to provide the basis for a geographic query. Figure 7.25.1 illustrates this.

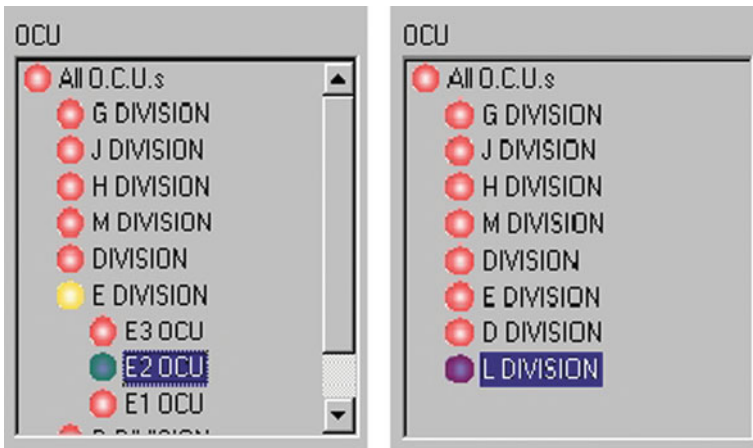

Fig. 7.25.1 List of available Operational Command Units (OCUs)

Fig. 7.25.2 List of available offence types

In addition, a single description or group of descriptions of crime can be selected to provide the offence type, as shown in Fig. 7.25.2.

For example, looking at Figs. 7.25.1 and 7.25.2 shows that we can select the E Division, the E2 OCU, and burglary crime during the last ninety days, by reference to where the crime was committed. This query (Fig. 7.25.3) would give us information about burglary crimes committed in E Division’s E2 OCU during the last ninety days and let us view the information graphically. We could also select any one of the crimes to view the original report on screen directly to access additional information.

Figure 7.25.3 demonstrates the way in which the user is presented with a textual version of the question. This approach reminds the analyst at regular intervals about the question they are asking.

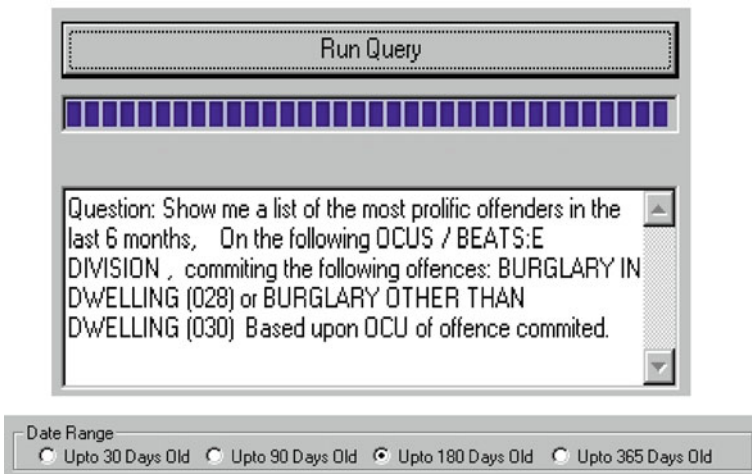

Fig. 7.25.3 The query definition dialog box

Fig. 7.25.4 The results of specifying a date range in a query

Figure 7.25.4 shows the results of a search. This screen allows the user to select items of interest from the results of the search for further searching or viewing in the graphical viewer.

Figure 7.25.5 is an example of the type of report that can be accessed using FLINTS 2 technology. The first illustration is a report concerning a crime included in the Crimes System and the second is a report concerning a Command and Control entry.

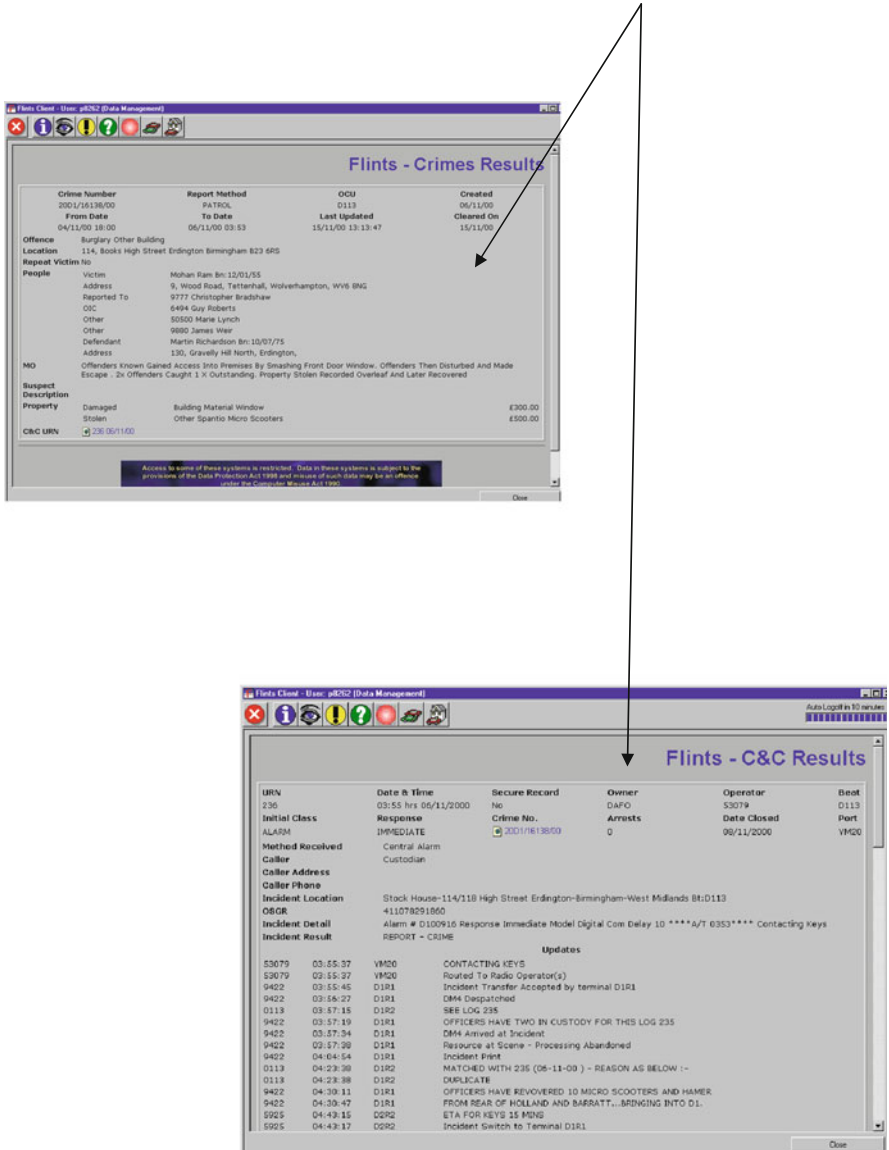

Fig. 7.25.5 The results of a query

Fig. 7.25.6 Graphical depiction (map)

A map can be presented to display the relationships between crimes committed and events (indicated by black crosses) and the offender's address (indicated as a red cross). See Fig. 7.25.6 for an example.

By integrating searches between functions, detailed information about individuals and crimes can be accessed speedily. This feature can again include photographic details, as shown in Fig. 7.25.7.

All the links to this individual can displayed using the graphical viewer along with information on their geography, chronology and associates.

Fig. 7.25.7 Summary of crime results plus photograph of suspect

7.26 Hot Spot Searches

As illustrated in Fig. 7.26.1, the hot spot search function allows users to identify geographic areas where the frequency of crime is high. This can be done by reference to times, locations, and crime types, and can be compared with address details for prolific offenders. This provides a powerful analytical tool for strategic analysis of crime frequencies as well as a briefing tool for patrolling officers and investigators.

Figure 7.26.2 illustrates an example of using the hot spot feature to search for incidents rather than crimes. The address, the day, the date, the time, the reference number of the incident, the type of incident and any notes made by the reporting office can be accessed remotely by the analyst.

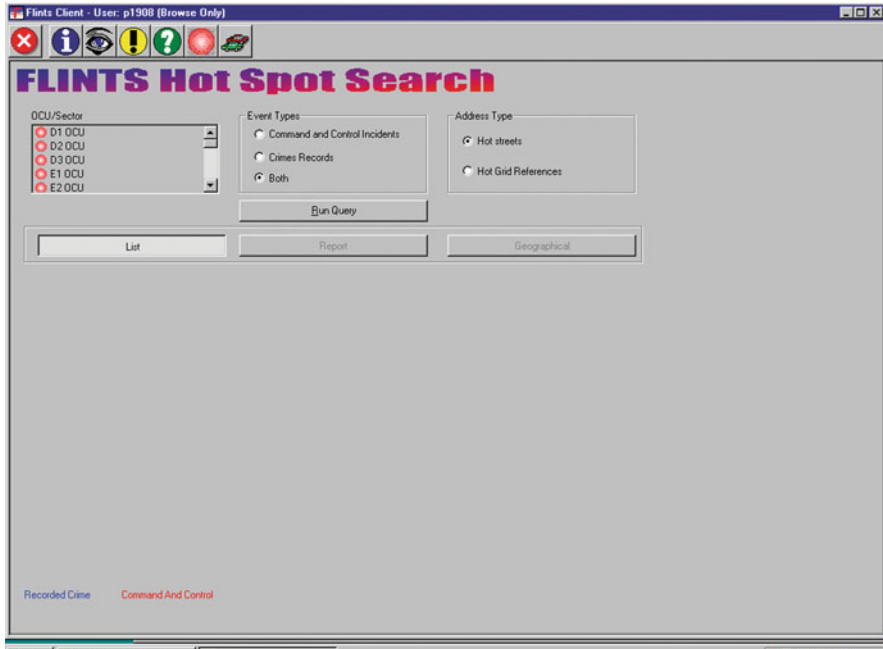

Fig. 7.26.1 The FLINTS search function for identifying hot spots

7.27 Vehicle Searching

FLINTS also offers a powerful tool for searching for vehicles (Fig. 7.27.1). The tool offers a range of options (Fig. 7.27.2). The results of vehicle searches appear in the form of lists from which the analyst can select those vehicles that appear to be of interest (Fig. 7.27.3).

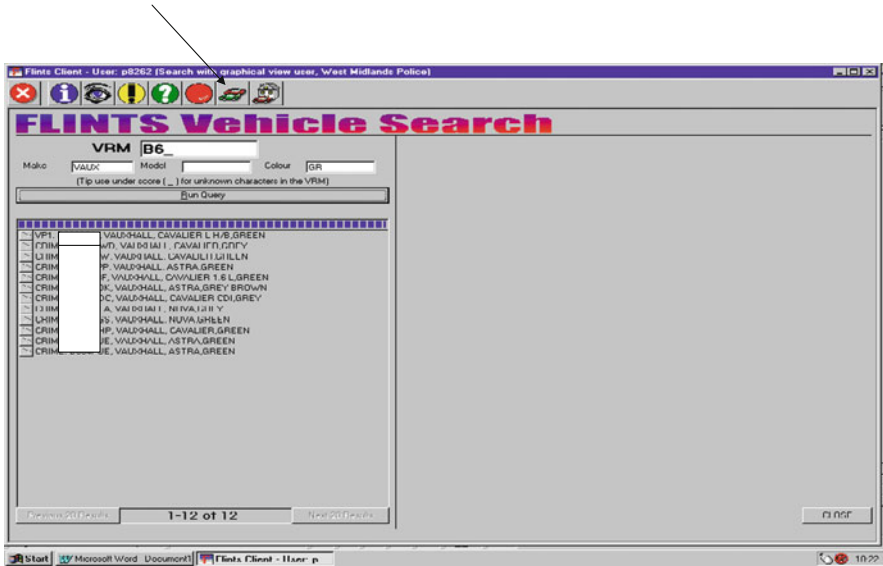

Fig. 7.27.1 The FLINTS vehicle search dialog box

Searches can be conducted on the basis of partial information, such as partial vehicle numbers, makes, models and colours.

Fig. 7.27.2 Options available in the FLINTS vehicle search

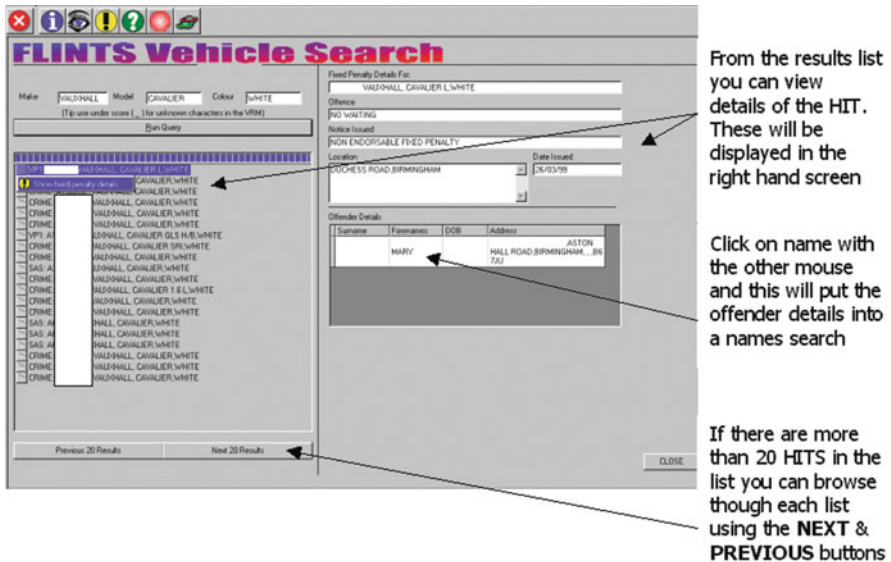

Fig. 7.27.3 The results of a vehicle search

7.28 Analytical Audit Trails

Using FLINTS 1 and 2 can involve navigating many inferential links between people, crimes, events, places and times. For example, a user may begin by searching for a suspect for a series of crimes but soon find themselves navigating links that change their priorities or produce unexpected opportunities to discover new issues of interest. The speed with which the system searches, retrieves information and then presents graphical charts can result in users “losing their way”. Users can navigate so many links and find so many opportunities within charts that it can be difficult to know where the evidence trail started and how they arrived at a particular conclusion.

An audit trail has been built into the system to help users manage this potential confusion. This function can be activated by the user and will record as well as present audit trails. Figure 7.28.1 is an illustration of a *simple* audit trail. Audit trails can become long lists of links, depending on the analysis.

The function serves two purposes: First, it helps the analyst to maintain a log of analytical activity that allows the user to “backtrack” through the analysis. The analysis can also be repeated by following the audit trail if the occasion arises. Second, the function can help others to check how a particular conclusion was arrived at. For ease of interpretation, the example presented here is a simple one – but is nonetheless a real audit trail from FLINTS. In Fig. 7.28.2 we can see an example of a complex network of links between 37 suspects. The suspect at the

Fig. 7.28.1 The hierarchy of links in a network of associates

centre of the chart is called “Barker”. The chart represents a series of links beginning with Hudson, then Smythe, Arnold, Chance and finally Barker. The original search began with Hudson, but by navigating only three more steps the analysis ended with an extensive network of linked criminals and crimes.

A valid question at this point might be: “What benefit has been gained by this approach?” The answer is that at each level of search, a different chart was viewed (similar to the one in Fig. 7.28.2). This approach can give many different perspectives and insights into many networks involving suspects, crimes, locations and chronologies. Each of the five suspects from Hudson to Barker was viewed as a separate step in an analytical chain of reasoning. Each suspect, from Hudson through to Barker, became a central node at each stage in the process. That is, they became a central focus of the analysis, and all links known to exist between crimes and suspects were displayed in a chart.

Those charts also appear similar to the one illustrated in Fig. 7.28.2. At each stage, therefore, the analyst can decide where the analysis will journey next, and by which route. Different routes will provide different results and different links. Many unknown features and characteristics of networks between suspects and crimes could be discovered in this manner.

Another answer to the question would be that Fig. 7.28.2 has four links between suspects and burglary crimes (indicated by arrows). The suspects linked to these crimes have been linked by means of forensic evidence and are thus liable to be arrested on suspicion of committing those crimes. The hypothesis is that they had the “opportunity” to commit those crimes. However, there are indirect links between

Fig. 7.28.2 List of links and hypothesis summary

other suspects and these crimes that may indicate different hypotheses. We could, for example, draw inferences about which suspects might be acting together in crime and which are not. These hypotheses can then be tested by performing other analytical work. This is an example of the way in which the system acts as a generator and tester of hypotheses. Some may be substantiated and some may not, but the

important thing is the ability to ask the question. In this example (Fig. 7.28.2), we could formulate a hypothesis that Barker, Chance and Arnold have been acting together as burglars. There is direct evidence of a link between Chance and Arnold and one burglary. Other hypotheses of equal validity could also be formulated, but from even this brief analysis, Barker has already become a suspect of great interest to us.

There are seven links to crimes of burglary in this chart, of which three are linked directly to Barker and four are linked indirectly via another suspect. The chart presents many hypotheses for testing the possible involvement of Barker and others in crime as well as many opportunities for intelligence generation. Recording the way in which the chart was navigated might prove important to those we seek to persuade subsequently of the validity of our logic.

The potential to develop evidence marshalling can be appreciated if Fig. 7.28.2 is considered in the light of potential developments. In FLINTS 1 it was already possible to have a snapshot of all the links in FLINTS 1 at a given point in time using a set of predetermined *attractors*. For example, it was already possible to ask FLINTS 1 a complex question using several objects as attractors in a truncated chain.

The ability to navigate very complex layers of information and follow direct and indirect links like these using the powerful visualisation techniques demonstrated by FLINTS 1 and 2 provides great potential for the development of future systems.

Chapter 8

The Forensic Disciplines: Some Areas of Actual or Potential Application

8.1 Crime Scenario Modelling: The Dead Bodies Project, and a Scenario Space Generated Using an ATMS

8.1.1 *Generating Crime Scenarios Automatically*

Jamieson (2004) discussed the methodology of *crime scene investigation (CSI)*, involving human scenarios.¹ Ross Gardner and Tom Bevel's (2009) *Practical Crime Scene Analysis and Reconstruction* addresses² every aspect of the analysis and reconstruction of the events surrounding a crime, and comprises an introduction and history of *crime scene analysis*, followed by theoretical and practical considerations, and then *event analysis*, this being a practical methodology for *crime scene reconstruction (CSR)*. Event analysis in the form introduced and presented by Gardner and Bevel uses specially designed worksheets that cover internal, external, and terminal ballistics as they apply to understanding trajectories. Next, significant investigative questions of CSR are discussed in Gardner and Bevel (2009), before turning to *crime scene protocols* and their effect on reconstruction. This is followed by a chapter on *bloodstain pattern analysis*,³ and then by a chapter by Matthew Noedel about shooting scene processing and reconstruction, a chapter by Scott Wagner on *forensic pathology* about *dead bodies*, in relation to CSR, and finally by chapters by Gardner and Bevel about writing crime scene reconstruction reports, about arguments and ethics, and about developing and using demonstrative exhibits in support of the crime scene analysis. The latter is about crime scene analysts testifying in court cases.

¹ Concerning fact investigation in general, see Binder and Bergman's book (1984), as well as, e.g., Zander (1979). In a British context, Cook and Tattersall (2008) is a pocket-sized handbook about the processes and actions involved in the role of Senior Investigating Officer. The issues covered comprise, among the other things, crime scene examination and investigative strategies.

² In the shorter compass of a book chapter, crime scene investigation is the subject of an introductory article by Marilyn Miller (2003, 3rd edn. 2009).

³ For which, Section 8.8 below; it is also the subject of a book by those same authors (Bevel & Gardner, 2008, 3rd edn.).

Studies of crime scene investigation conducted in a cognitivist vein include Schraagen and Leijenhorst (2001) and Ormerod, Barrett, and Taylor, (2008). In an article entitled “Distributed Cognition at the Crime Scene”, Chris Baber (2010) from the University of Birmingham discussed in the journal *AI & Society* a conceptualisation of *crime scene examination*, in terms of *distributed cognition*.⁴ “In this paper, Distribution is defined by the number of agents involved in the criminal justice process, and in terms of the relationship between a Crime Scene Examiner and the environment being searched” (ibid., from the abstract). Baber’s approach combines cognition and ergonomics. Baber pointed out (2010, p. 423):

Crime Scene Examination presents an interesting and challenging domain in which to consider the notion of Distributed Cognition for the simple reason that it is not always apparent where the act of ‘cognition’ is situated. The ultimate aim of the criminal justice process, of course, is to acquire evidence which can be combined with information from other sources in order to produce a case that can be tried in Court. Contrary to its representation in popular fiction, the examination of a crime scene is unlikely to yield evidence that immediately links a suspect to a crime. Rather, the collection of evidence is part of a complex web of investigation that involves many individuals, each considering different forms of information in different ways.

Baber situates the role of *crime scene examiner (CSE)* within the criminal justice process (ibid.):

The CSE is part of a much larger investigative system, each member of which has their own skills and roles (Smith et al., 2008). In a sense, Crime Scene Investigation involves sets of ad-hoc teams pursuing independent goals with quite limited overlap (Smith et al., 2008). Thus, there is typically a demarcation between roles. Having said this, the nature of this demarcation has been subject to significant shifting over the years, with the ongoing digitisation of Crime Scene Examination leading to further changes. For example, there used to be a specific role of Crime Scene Photographer whose function was to capture and process images of the crime scene (either prior to evidence recovery or at stages during the recovery process, depending on the nature of the crime). However, with the growing use of digital cameras by CSEs, this role has (in some Police Forces) changed. This has the interesting implication that the function of a photograph taken by the Crime Scene Photographer was to capture the scene as clearly as possible in order to aid discussion of the scene in Court (or during subsequent investigation), but the function of a photograph taken by the CSE could be to illustrate the evidence recovery process; [. . .]

⁴ For this concept, see Dror and Hamard (2009). Baber remarks (2010, p. 424): “While I suggest that Crime Scene Examination necessarily involves several agents performing cognitive activity, this is not to argue that this results in an ‘extended mind’ across these agents; as Dror and Hamard (2009) point out, to argue for an extended mind is analogous to arguing for extended migraine – just because an event occurs in one brain does not inevitably mean that other brains will share this event. Dror and Hamard’s (2009) argument is that one should not separate cognitive states from mental states. This criticism raises a core problem for the notion of ‘Distributed Cognition’, because it implies that cognition cannot be ‘distributed’ across agents because one cannot share mental states. A primary assumption of ‘Distributed Cognition’ is that it is not ‘cognition’ which is distributed so much as objects-in-the-world, which plays a role in supporting, structuring and aiding the activities of cognition.”

Baber explains (2010, p. 426):

What is happening in Crime Scene Examination is the mediation of cognition through the collection, manipulation and dissemination of a variety of artifacts; each artifact is interpreted in particular ways by the agents who come into contact with it. My argument will be that, for the various agents involved in this evidence chain, each artifact can ‘afford’ a particular set of responses, that is, the artifacts are resources for action, and the actions will be recognised by different agents according to their training and experience. I am using the notion of ‘afford’ in the sense introduced by Gibson (1977, 1979), as a form of perception–action coupling in which the physical appearance of an object in the world supports particular physical responses (e.g., a pebble ‘affords’ grasping in the hand).

Once recovered, evidence is shared (Baber, 2010, p. 429):

The preceding discussion implies that the search of a scene is guided by experience, expectation and the ability to recognise items of evidential value. In this respect, the notion of Distributed Cognition can be interpreted in terms of the use of objects in the world as resources-for-action. The Crime Scene Examiner recognises objects as resources-for-action which may well differ from untrained observers. For example, while the untrained observer might assume that a pane of glass in a window could yield fingermarks, they might be less inclined to immediately assume that it could also yield footwear marks, and still less inclined to recognise its potential for yielding DNA (the latter two could arise from someone climbing in through the window, or from pressing their forehead against the window to see if anyone is at home).

So far, this description looks very much like a process that involves the mental states of an individual; the CSE interprets the scene, recognising objects as resources-for-action, and then recovers the evidence. However, what makes the Crime Scene Examination process different from a Sherlock Holmes story is that the CSE submits the evidence for interpretation by other people. Indeed, it is unlikely for the CSE’s notes and reports from the scene to include any deduction. Rather the report will be as descriptive as possible.⁵ This representation, of the scene and its evidence, is passed along the recovery train. So we have a set of processes that could ostensibly represent the stimulus (or input) to a cognitive processing system. This processing is (formally) undertaken by people other than the CSE.

Prakken et al. (2003) discussed appropriate argument structures for reasoning about evidence in relation to hypothesising crime scenarios. It was a paper on using argumentation schemes for reasoning on legal evidence, mainly by way of an exploration of applying *Araucaria*, the argument visualisation system from the University of Dundee in Scotland,⁶ to an analysis in the style of Wigmore Charts. Case-based

⁵ Baber (2010, p. 430) concedes that there may be problems with striving to be objective by only providing descriptions, in that some useful information may be missed: “One could make a strong argument that this lack of information helps an analysis to be as objective as possible, by focussing only on the item at hand (and avoiding the potential for bias that Dror et al. (2005) demonstrated). On the other hand, it might be useful to have some knowledge of the item in situ, so as to decide how best to conduct analysis. If the Forensic Scientist had recovered the item herself then such information would be recalled by her, but when it is delivered in a batch of bags then such information is not obviously available. As an example of why this could be problematic, consider a finger-mark left on a window. This mark might not be detailed enough to form a print, but could indicate whether the window has been forced up or whether someone climbed down the window, knowing the orientation of the mark on the window can help decide how best to analyse it, but this might not have been provided in the evidence log.”

⁶ *Araucaria* is available for free at <http://www.computing.dundee.ac.uk/staff/creed/araucaria>

reasoning was applied by Toland and Rees (2005) to the task of recalling similar instances of volume crime, when confronted with a crime being investigated: the task was the identification of crimes with similar *modus operandi*, and the reasoning involved potential repeat offenders. Ribaux and Margot (1999) applied case-based reasoning to the categorisation of cases of burglary, with the retrieval of cases with similar profiles. The work reported about in Oatley et al. (2004) is concerned with assisting the police in detecting the perpetrators of burglary from homes, which is a high-volume crime with low detection rates; that project made use of a variety of data mining techniques, including: classification and association rules,⁷ neural network clustering, survival analysis and Bayesian belief nets, case-based reasoning, as well as ontologies and logic programming.

A team that was initially led in Edinburgh by John Zeleznikow, in the early 2000s, worked on projects whose aim was to produce software tools assisting in the assessment of evidence in given limited, specialist domains. Jeroen Keppens and Burkhard Schafer were members of that team. Eventually, as various persons moved around to other affiliations, sequel projects emerged at different locations. The present section is concerned with one of those lines of research.

Keppens and Zeleznikow (2002, 2003) and Keppens and Schafer (2003a, 2003b, 2004) have reported about a project whose application is in post-mortem inquests, with the goal of determining whether death occurred through natural causes, homicide or suicide. In their Dead Bodies Project,⁸ a so-called “truth maintenance system”, or ATMS (a well-known AI approach to consistency)⁹ is resorted to, in order to maintain a space of “possible worlds” which correspond to hypothetical scenarios. The architecture is shown in Fig. 8.1.1.1.

The project resorts to neither conventional expert systems, nor case-based reasoning. Any case is potentially unique. Crime investigation is very difficult to proceduralise. The design solution adopted for this project was to develop a model-based reasoning system, i.e., such a system that given a problem instance, a model of the problem is constructed, and a problem-independent technique is applied. In the same project, dynamic preference orderings are assigned to uncertain events. Default orderings may be overruled by inferred orderings.

An article by Keppens and Schafer (2005) “characterises an important class of scenarios, containing ‘alternative suspects’ or ‘hidden objects’, which cannot be

⁷ A definition of *association rules* as a form of data mining is found in fn. 36 in Chapter 3.

⁸ Ronald Wright (2005, 2nd edn.; 2009, 3rd death) provides an overview of the *investigation of traumatic deaths*.

⁹ In Section 2.1.2 above (see in particular some historical information in fn. 1 in Chapter 1) we have already come across the approach known in artificial intelligence as *Assumption-based Truth Maintenance System (ATMS)*. An ATMS is a mechanism that enables a problem solver to make inferences under different hypothetical conditions, by maintaining the assumptions on which each piece of information and each inference depends (de Kleer, 1986, 1988). The goal of computation with an ATMS is to find minimal sets of premises sufficient for the support of each node. One has to find all minimally inconsistent subsets (NOGOODSs), and to find all maximally consistent subsets (GOODSs).

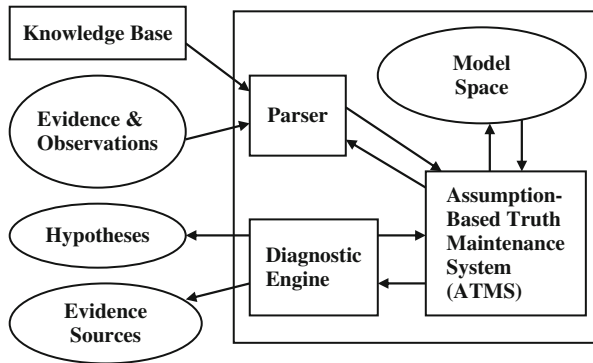

Fig. 8.1.1.1 The early architecture of the Dead Bodies Project of Keppens and Zeleznikow (2002, 2003)

synthesised robustly using conventional abductive inference mechanisms. The work is then extended further by proposing a novel inference mechanism that enables the generation of such scenarios.”

Keppens and Schafer (2006) reported about a more advanced state of the same project applying artificial intelligence to crime scenario modelling. The prototype of a decision-support system was presented, for crime scenario construction. It is component events, rather than entire scenarios, that are stored. (By *scenario*, a description of a combination of events and situations is meant.) The component events are composed into useful scenarios by an algorithm. The input is a description of the available evidence. A network of plausible scenarios is then generated. Those scenarios in turn can be analysed, with the goal of devising effective evidence collection strategies. The algorithm was allegedly highly adaptable to unanticipated cases, by allowing a major crime being investigated to be matched by component events in several different ways. One advantage hoped for was the avoidance of such pitfalls of human reasoning as *premature case theories*, or rather *premature convergence*, such that police investigators tend to focus on the more likely suspects they had identified early on.¹⁰

¹⁰ Keppens and Schafer (2006, section 2.1), citing McConville, Saunders, and Leng (1991) and Greer (1994). Once investigators think they already have the culprits, they tend to apply *confirmationism*, also known as *cognitive dissonance*, by which they privilege such information that confirm their preconceptions, and tend to disregard contrary evidence. “While the police service might pay lip service to a falsificationist model of rationality (‘asking witnesses to come forward to eliminate them from the inquiry’) existing reward structures make it difficult to implement this in practice. Our proposed system accounts for this by combining a ‘backchaining’ abductivist model of reasoning with a ‘forward chaining’ model that is based on the idea of indirect proof, sidestepping the issue of falsification and induction in a universe with only finitely many alternatives” (Keppens & Schafer, 2006, section 2.2). *Forward chaining* and its opposite, *backchaining*, are standard concepts from rule-based knowledge-based systems in artificial intelligence.

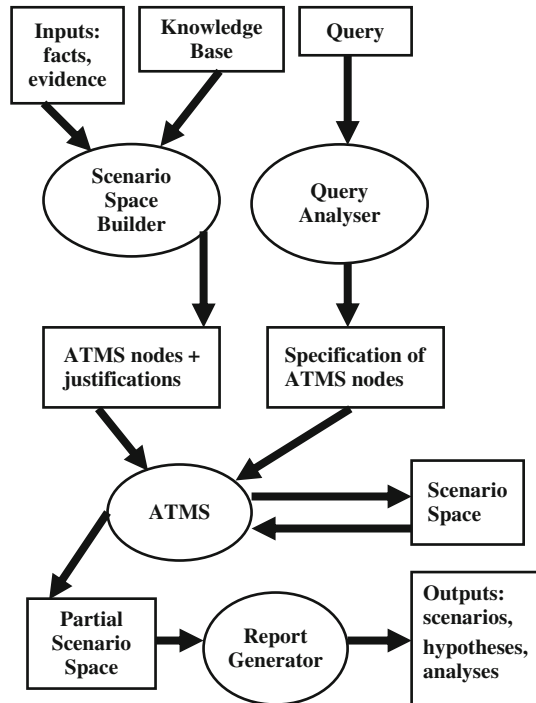

Therefore, that project belongs to a category of software tools known as *compositional modellers*, and introduced by Falkenhainer and Forbus (1991) in their paper ‘Compositional modeling: finding the right model for the job’. Compositional modelling was also discussed by Keppens and Shen (2001). In compositional modellers, small, generic and reusable rules called *model fragments* capture a domain’s first principles. These are “fundamental theories describing the behaviours and mechanisms that occur in the domain of interest [. . .]. The compositional modelling paradigm is adapted to the crime investigation domain by employing causal rules describing how combinations of assumed states and events lead to new states and events in plausible crime scenarios” (Keppens & Schafer, 2006).

Another category in which the system described by Keppens and Schafer (2006) is *abductive diagnosers*. In abductive diagnosis (Console & Torasso, 1991), what the conditions are of a physical system under investigation are determined by comparing observations as predicted by models, to such observations that are extracted from the real world. The generation of models, in an abductive diagnoser, is done by resorting to a knowledge base of *first principles* about the given domain. First principles are general rules, independent from the decision procedure, and in this they differ from the *heuristic rules* (i.e., *rules of thumb*) found in rule-based expert systems. In the project of Keppens and Schafer (2006),

the first principles are expressed by means of causal rules describing how some states and events are triggered by other known or assumed states and events. The possible causes of a given set of available evidence are inferred by means of an abductive inference procedure. These causes form the hypothetical scenarios describing plausible crimes. Potential additional evidence that may confirm or contradict these scenarios is then deduced using the same causal rules. This abductive, first-principles based approach recognises that while the individual scenarios encountered in a major crime investigation may be virtually unique and vary widely, the underlying domain knowledge on evidence and the types of events that create it are not. It also encourages a principled hypothetico-deductive investigative methodology because it hypothesises all (known) possible causes of the available evidence, composes these causes into plausible scenarios and deduces additional evidence from the plausible scenario. This promotes consideration of many scenarios, instead of individual ones, in deciding on future investigative actions. Finally, the approach also allows making expert domain knowledge available to less experienced investigators.

The architecture of the decision-support system described by Keppens and Schafer (2006) is shown in Fig. 8.1.1.2. An *assumption-based truth maintenance system* (ATMS) is the central inference mechanism in this architecture. A *scenario space* is maintained by means of the ATMS. “All” possible scenarios that explain the available evidence are stored in the scenario space. The scenarios are represented as logic predicates; these predicates denote events and states, or causal relations between events and states. Causal relations between assumptions, states, and events are represented as *scenario fragments*, each of these being a tuple comprising a set of variables, a set of relations called *preconditions*, a set of relations called *postconditions*, and a set of relations called *assumptions*. There also is a representation of inconsistencies, e.g., “a person can not kill himself both with such an intention (i.e. in a suicide) and without this intention (i.e. in an accidental self-killing)”

Fig. 8.1.1.2 The architecture of the decision-support system described by Keppens and Schafer (2006), redrawn and rearranged from their figure 2. Data structures are shown in this figure as rectangles, whereas ellipses correspond to the inference mechanism

(Keppens & Schafer, 2006, section 4.4). The knowledge base comprises property definitions, a set of scenario fragments, and a set of inconsistencies. “Property definitions describe which types of predicate correspond to a symptom, fact, hypothesis or investigative action” (ibid., section 4.5). An example of scenario fragment is this one (Keppens & Schafer, 2006, section 4.3):

if a person P suffers from ailment or injury C, C is the cause of death of P, and there is a medical examiner E, and assuming that E determines the cause of death of P and makes the correct diagnosis, then there will be a piece of evidence in the form of a cause of death report indicating that according to E, the cause of death of P is C.

Keppens and Schafer explained (2006, section 3.2):

Once constructed, the scenario space is analysed through a series of *queries*. Queries are questions about the scenario space. Their answers are computed by extracting relevant parts from the scenario space and reported back in an understandable format. To interface between the human and scenario space, a *query analyser* translates standard types of user queries into a specification of ATMS nodes of interest, and a *report generator* provides the means to represent a partial scenario space back to the user.

What the scenario space is made to initially contain, is based on the initial set of given *facts* and *evidence*, and is constructed by means of a *knowledge base*.

For example, these five pieces of evidence appear in an example from Keppens and Schafer (2006): n_1 : “A hanging corpse of a person identified as johndoe has

been found”; n_{11} : “A report by a psychologist identified as *frasier* (n_{15}) stating that *johndoe* may have been suicidal prior to his death”; n_{14} : “The observation of suicide trial marks on the body of *johndoe*”; n_{16} : “The body of *johndoe* exhibits signs of petechiae” (i.e., small red to purple spots on the eyes or skin, caused by either disease or asphyxiation); n_{20} : “A report by a medical examiner identified as *quincy* (n_7) stating that the cause of death of *johndoe* was asphyxiation”.

One possible scenario based on this evidence is suicide by hanging. For example, “The hanging corpse (n_1) and the summed cause of death (n_{20}) are the consequents of *johndoe*’s hanging (n_5), which he was unable (unwilling) to end (n_4). The petechiae is caused by asphyxiation (n_{15}) resulting from the hanging. *john-doe*’s suicide by hanging requires that *johndoe* is suicidal (n_7) and the last two pieces of evidence are a consequence of his suicidal state” (Keppens & Schafer, 2006, section 4.1).

Each scenario was represented as a *causal hypergraph*. A hypergraph is a generalisation of a graph, such that an edge may appear not just between two nodes, but between a set of nodes including two or more nodes. But scenarios were represented as directed acyclic hypergraph, whose nodes are events or states, whereas the edges are directed hyperarcs, each one from a set of at least one event or state, towards one and only one event or state. The scenario of suicide by hanging was shown in Keppens and Schafer (2006, figure 3), but we find it more convenient to translate here that hypergraph into a ruleset and a list of propositions. The ruleset is shown here in Table 8.1.1.1 (where \wedge stands for *and*); each rule corresponds to one of the hyperarcs of the causal hypergraph of the scenario of suicide by hanging. The correspondence between node identifiers and particular propositions is listed in Table 8.1.1.2. In Table 8.1.1.1, each row stands for a directed hyperarc of the causal hypergraph, and here in the order we chose to reflect the arrangement in Keppens and Schafer’s (2006) original diagram of their figure 3, from top to bottom. The meaning of the nodes is defined in Table 8.1.1.2.

Keppens and Schafer (2006, section 4.2) classify information by distinguishing *facts* (“pieces of inexplicable, certain information”) from *evidence* (“information that is certain and explicable”), by distinguishing three kinds of “uncertain and

<i>n</i> ₂₁ :	suicidal-death(johndoe)

explicable” information (*uncertain states*,¹¹ *uncertain events*,¹² and *hypotheses*¹³), and by distinguishing three types of *assumptions*, i.e., of “uncertain and inexplicable information”:

- *Default assumptions* describe information that is normally presumed to be true. In theory, the number of plausible scenarios that explain a set of available evidence is virtually infinite, but many of these scenarios are based on very unlikely presumptions. Default assumptions aid in the differentiation between such scenarios by expressing the most likely features of events and states in a scenario. A typical example of a default assumption is the presumption that a doctor’s diagnosis of the cause of death of person is correct (e.g. *n*₁₈).
- *Conjectures* are the unknown causes of certain feasible scenarios (e.g. *n*₇). Unlike default assumptions, conjectures are not employed to differentiate between the relative likelihood of scenarios.
- Uncommitted *investigative actions*, i.e. possible but not yet performed activities aimed at collecting additional evidence, are also treated as assumptions. At any given stage in the investigation, it is *uncertain* which of the remaining uncommitted investigative actions will be performed. The reasoning required to perform such an action involves looking at its consequences instead of its causes, and therefore they are *not* (causally) *explicable*. As such, investigative actions assume a similar role as default assumptions and conjectures: i.e. they are employed to speculate about the plausible (observable) consequences of a hypothetical scenario.

¹¹ An example of *uncertain state* is node *n*₄, “johndoe was unable to end his hanging”.

¹² An example of *uncertain event* is node *n*₁₅, “johndoe asphyxiated”.

¹³ An example of *hypothesis* is node *n*₂₁, “johndoe’s death was suicidal”.

8.1.2 *The Structure of ATMS Inference in the Scenario Space Builder*

The scenario-space builder instantiates scenario fragments as well as inconsistencies, into an ATMS. In the *initialisation phase*, an ATMS is generated that contains one node per piece of available evidence. Next, a *backward chaining phase* is executed. All plausible *causes* of the available evidence are added to the ATMS. A process is repeated, until exhausting all possible unifications¹⁴ of individual consequents of a scenario fragment with a node already in the ATMS. That process does the following for each possible unification: it instantiates the antecedents and assumptions of that scenario fragment; the process adds a node to the ATMS for antecedent instance that does not already have a node; it adds an assumption node to the ATMS for each assumption instance that does not already have a node; and the process adds to the ATMS a *justification* (i.e. a rule like the rows in Table 8.1.1.1, but also added nodes such as assumption nodes can be included) “from the nodes corresponding to the antecedent and the assumption nodes corresponding to the assumptions, to the node corresponding to the consequent” (Keppens & Shafer, 2006, section 5.2.1).

Once the backward chaining phase is exhausted because action as described was taken for each possible unifications, execution enters the *forward chaining phase*.

¹⁴ Take for example the syllogism “All men are mortal, and Socrates is a man; therefore Socrates is mortal”. In predicate calculus, the three expressions

$$\begin{aligned} &\forall X(\text{man}(X) \Rightarrow \text{mortal}(X)). \\ &\text{man}(\text{socrates}). \\ &\text{man}(\text{socrates}) \Rightarrow \text{mortal}(\text{socrates}). \end{aligned}$$

respectively stand for “All men are mortal”, “Socrates is a man”, and “Socrates is a man, therefore Socrates is mortal”. *Unification* is an algorithm that an automated problem solver can use in order to determine that *socrates* may be substituted for *X*. For it to apply inference rules, “an inference system must be able to determine when two expressions are the same or *match*. In propositional calculus, this is trivial: two expressions match if and only if they are syntactically identical. In predicate calculus, the process of matching two sentences is complicated by the existence of variables in the expressions. Universal instantiation allows universally quantified variables [that is: for all *X*] to be replaced by terms from the domain. This requires a decision process for determining the variable substitutions under which two or more expressions can be made identical (usually for the purpose of applying inference rules). Unification is an algorithm for determining the substitutions needed to make two predicate calculus expressions match” (Luger & Stubblefield, 1998, section 2.3.2., p. 68). “Generally, a problem-solving process will require multiple inferences and, consequently, multiple successive unifications. Logic problem solvers must maintain consistency of variable substitutions. It is important that any unifying substitution be made consistently across all occurrences of the variable in both expressions being matched” (ibid., p. 69). “Once a variable has been bound, future unifications and inferences must take the value of this binding into account. If a variable is bound to a constant, that variable may not be given a new binding in a future unification. If a variable X_1 is substituted for another variable X_2 and at a later time X_1 is replaced with a constant, then X_2 must also reflect this binding” (ibid.). Unification substitutions are combined and returned thanks to the composition of unification substitutions.

What this phase does, is adding to the ATMS all possible *consequences* of the plausible scenarios. Whereas the *backward chaining* phase repeated its process until exhausting all possible unifications of individual *consequents* of a scenario fragment with a node already in the ATMS, by contrast the *forward chaining* phase carries out the following process for each possible unification of the set of *antecedents* of a scenario fragment with a set of nodes already in the ATMS. That process instantiates the assumptions and consequents of that scenario fragment; the process adds an assumption node to the ATMS for each assumption instance that does not already have a node; the process adds to the ATMS a node for each consequent instance that does not already have a node; and the process adds to the ATMS a justification for each consequent instance, “from the nodes corresponding to the antecedent and the assumption nodes corresponding to the assumptions, to the node corresponding to the consequent instance” (Keppens & Shafer, 2006, section 5.2.1).¹⁵

The forward chaining process is repeated until exhausting all unifications of scenario fragment antecedents with sets of nodes in the ATMS. And finally, the *consistency phase* is carried out: “inconsistent combination of states and events are denoted as nogoods. This involves instantiating the inconsistencies from the knowledge base based on information in the ATMS and marking them as justifications for the nogood node.” (ibid.). In the terminology of ATMS, a *nogood* is such a justification that has led to an inconsistency, that is to say, from its node there is an arc $\rightarrow \perp$ and this implies that one of the propositions conjoined by *and* in the nogood must be false. With an ATMS, one has to find all minimally inconsistent subsets (NOGOODSs), and to find all maximally consistent subsets (GOODSs).

Keppens and Schafer (2004, section 3) pointed out similarities between what the ATMS does in their Dead Bodies project, and what a defence solicitor would do:

In developing alternative scenarios consistent with the evidence, the ATMS performs some of the scrutiny a good defence solicitor would subject the prosecution case to. A defence solicitor has broadly speaking two strategies available to him. First, he can question the factual correctness or the legal admissibility of evidence presented by the prosecution. Second, he can accept the evidence at face value and argue that alternative explanations for their presence are possible that do not incriminate his client. We are concerned here primarily with this second strategy. However, it is here that we encounter a certain ambiguity, an ambiguity explicitly recognised by the Scots law of evidence. The defence has in fact again two strategies available to it. The first can be dubbed the “Perry Mason Stratagem”. Like the fictitious advocate, the defence can pursue its own investigation and “point to the real culprit”. In Scots law, this is known as the special defence of incrimination [Field & Raitt, 1996], recently used (unsuccessfully) in the Lockerbie trial

for an atrocity ascribed to an act of terror: an PanAm passenger aircraft exploded while flying over Scotland in 1988 because of a bomb on board.

¹⁵ In the section 5.2.2 in their article, Keppens and Shafer (2006) supplied the formal algorithm for generating the scenario space.

This strategy has a number of psychological and legal advantages. The same reason that makes it the solution of choice for crime writers also works well with juries: no loose ends are left and the crime is avenged. Procedurally, it allows the defence to submit also other pieces of evidence. This corresponds to the “forward chaining” aspect of our ATMS: The party named by the defence will have interacted causally with the crime scene. This will have created evidence which can strengthen the defence case. This allows introduction of additional “suspect specific” evidence (such as alibi) evidence about other people, which otherwise might be ruled out as irrelevant. The defence of course need not prove the guilt of the other party; it only needs to establish it as a plausible alternative. [...]

8.1.3 An Extension with Bayesian Networks, Entropy, and Returned Evidence Collection Strategies

Keppens, Shen, and Lee (2005a) described an extension of the scenario space generation, resorting to Bayesian modelling: “this paper shows a compositional modelling approach to synthesise and efficiently store a space of plausible scenarios within a Bayesian Network (BN) [...]. Furthermore, it presents an application of the maximum entropy reduction technique to determine which investigative actions are most likely to reduce doubt” (ibid., section 1). In this extension of the work already described earlier in the present Section 8.1, scenario fragments also incorporate a set of probability distributions, one for each combination of the antecedent and assumption variables.

Thus, the following scenario states that if a victim V has petechiae on his eyes and the investigators examine V’s eyes, then evidence of petechiae is discovered with a certain probability:

```
if {petechiae(eyes(V))}
assuming {examination(eyes(V))}
then {evidence(petechiae(V))}
distribution evidence(petechiae(V)) {
true, true -> true:0.99, false:0.01}
```

Keppens et al. (2005a, section 2.1) explained that, by adopting the notation shown in Table 8.1.3.1, the general representation for a scenario fragment, incorporating probability distributions, is as follows:

Table 8.1.3.1 A notation for the predicates and values involved

$\{p_1, \dots, p_k\}$	the set of antecedent predicates
$\{p_1, \dots, p_m\}$	the set of assumption predicates
p_n	the consequent predicate
v_i	any of the values that variable p_i can take
q_j	a real value in the range $[0,1]$

```

if { $p_1, \dots, p_k$ }
  assuming { $p_l, \dots, p_m$ }
  then { $p_n$ }
  distribution  $p_n$  {
    :
     $v_1, \dots, v_k, v_l, \dots, v_m \rightarrow v_{n1} : q_1, \dots, v_{nj_n} : q_{j_n}$ 
    :
  }

```

By contrast, the general representation of an inconsistency is as a special kind of scenario fragment, as follows:

```

if { $p_1, \dots, p_k$ }
  then {nogood}
  distribution nogood {
     $v_1, \dots, v_k \rightarrow \top : 1, \dots, \perp : 0$ 
  }

```

where \top stands for the value *true*, and the reversed \top stands for the value *false*. Moreover, in the knowledge base there also are prior distributions for assumed states and events. In order to enable the compositional modelling of Bayesian networks, presumptions concerning the scenario fragments include the presumption that the causal hypergraph is acyclic (“There are no cycles in the knowledge base”: Bayesian networks are inherently acyclic), and the presumption that “*Any two probability distributions taken from two scenario fragments involving the same consequent variable are independent*”. Intuitively, this assumption indicates that the outcome of an influence implied by one scenario fragment is not affected by that of another” (ibid.).

Entropy was adopted as a measurement of doubt, this being a concept from information theory. It is also adopted in machine learning (Mitchell, 1997) and in model-based diagnosis (Hamscher, Console, & de Kleer, 1992). Keppens et al. (2005a, section 3.2) explained that the entropy over an exhaustive set of mutually exclusive hypotheses

$$H = \{h_1, \dots, h_m\}$$

is given by:

$$\epsilon(H) = - \sum_{h \in H} P(h) \log P(h)$$

By resorting to conventional techniques from Bayesian networks, it is possible to compute the values $P(h)$. As in crime investigation, additional information is

generated through evidence collection, Keppens et al. (ibid.) proposed that given e set of pieces of evidence

$$E = \{e_1 : v_1, \dots, e_n : v_n\},$$

“the entropy metric of interest for the purpose of generating evidence collection strategies is the entropy over a set of hypotheses H ”, as per the formula:

$$\epsilon(H | E) = - \sum_{h \in H} P(h | E) \log P(h | E)$$

Conventional Bayesian network techniques allows computing the conditional probability values $P(h | E)$. Keppens et al. (ibid.) also proposed that selecting investigative

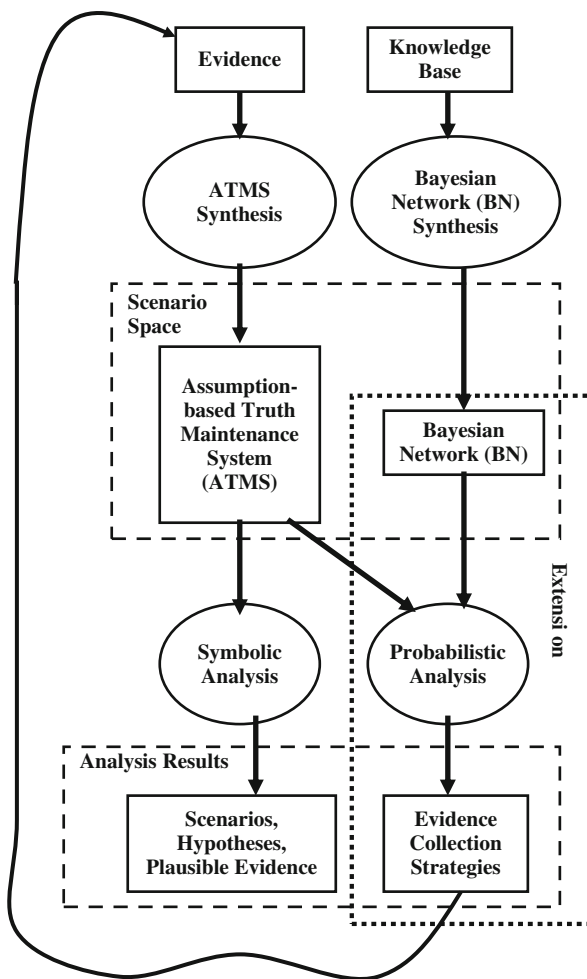

Fig. 8.1.3.1 The extended architecture, redrawn from Keppens et al. (2005b, section 3, figure 2): Bayesian networks appear in the knowledge representation, and evidence collection strategies appear in the output

actions from a given set A according to the following criterion is a useful evidence collection strategy:

$$\min_{a \in A} E(\epsilon(H | E), a)$$

They discussed minimal entropy-based evidence (EPE) collection in their section 3.3. They conceded however (Keppens et al., 2005a, in their section 3.4) that whereas that “technique guarantees to return an effective investigative action, it does not ensure globally optimal evidence collection”. They proposed a remedy, in order to reduce the “likelihood of obtaining poor quality locally optimal evidence collection strategies”. This is done by only “considering the EPEs after performing a sequence of actions”, although this incurs computation overheads. They then proposed a simplified equation for that remedy. Next, they turned to discussing how to allow multiple evidence sets, or multiple hypothesis sets instead of just one.

In Fig. 8.1.3.1, we redraw from Keppens, Shen, and Schafer (2005b, section 3, figure 2) the architecture of their system, as extended with Bayesian networks in the knowledge representation, and with evidence collection strategies in the output.

8.1.4 Further Research

Jeroen Keppens

As argued by Schum (1994), a key aspect of evidential reasoning concerns the development of hypotheses. Indeed, as demonstrated by Aitken and Taroni (2004), probabilistic approaches to evidential reasoning tend to favour the statistics paradigm of hypothesis testing. This idea is not only useful when assessing evidence in court, it has been embraced by a part of the forensic science community, such as Cook, Evett, Jackson, Jones, and Lambert (1998), as a means to assess the probative force of evidence during the investigation of a (alleged) crime. But while hypotheses are readily available for testing once a case reaches court, the formulation of hypotheses during the investigative stage is not straightforward.

As argued by Keppens and Zeleznikow (2003), this requires what Peirce (1903) termed abduction or abductive reasoning. Keppens and Schafer (2006) have developed an abductive reasoning approach to produce the hypotheses required for evidential reasoning during a crime investigation. Being a knowledge based approach, it employs a knowledge base and a corresponding inference mechanism. The knowledge base consists primarily of generalised and reusable fragments of plausible scenario, such as one predicting the medical symptoms generated by a blow to the head and another indicating those resulting hitting one’s head against the ground in a fall. Generally speaking, these scenario fragments express cause-effect relationships. The inference mechanism instantiates these scenario fragments to specific circumstances and combines them to compose plausible scenarios, which can then be analysed further.

The overall approach is inspired by earlier work on compositional modelling by Keppens and Shen (2004), an family of methods designed to generate formal models of real-world or hypothetical scenarios. Compositional modelling works on the idea that while the specific combination of circumstances contained within an individual scenario are relatively rare, and therefore difficult to generalise, the constituent elements appear rather more frequently. For example, while the circumstances of the murder of one of the victims of the serial killer Dr Harold Shipman might be relatively rare, the component elements such as injection with an overdose of diamorphine and the resulting evidence reoccur more frequently. Therefore, the use of compositional modelling helps to tackle, to some extent, significant knowledge acquisition problem involved with a system of this kind.

More recent developments in this strand of research have sought to further address the knowledge acquisition bottleneck and to allow more useful modes of inquire with the resulting scenario models. One extension concerns the modelling problem that arises when there are an unknown number of plausible instantiations. For example, an unknown number of unknown persons can be involved in a plausible crime scenario, such as the person a fingerprint belongs, the person who has been seen fleeing the scene of the alleged crime and the suspicious person observed in CCTV footage near the scene prior to the alleged crime. During the investigation it is not known whether this concerns three distinct individuals, two individuals (with two pieces of evidence referring to the same person) or just a single individual (to whom all evidence relates). Keppens and Shafer (2004, 2005) have proposed a *peg-unification* technique that involves representing all unknown instantiations as so-called pegs and employs an algorithm to explore all possible assumptions of equivalences between pegs simultaneously.¹⁶

¹⁶ *Peg unification* is useful for *coreference resolution*. Keppens and Schafer explained (2003b, section 4):

The task of identifying different references to the same entity is known as *coreference resolution* in computational linguistics. In the analysis of a discourse, it is important that references to the same entity are correctly associated with one another because each of the expressions that contains one of these references may add some information about the entity in question. For example, in the sentence “Every farmer who owns a *donkey*, beats *it*.” “a donkey” and “it” refer to the same entity. The first half of the sentence conveys that the entities of interest are all donkeys owned by farmers. The second half of the sentence communicates that the entities of interest are beaten. Thus, the sentence as a whole imparts the knowledge that all donkeys owned by farmers are beaten.

A wide range of techniques has been devised to perform coreference resolution tasks, such as the one illustrated in the example. The vast majority of these techniques specialise in examining texts for discourse analysis or information extraction. An important property of the existing approaches is that they tend to consider only a single possible solution at any one time, while the present problem domain requires a method that can represent and reason with multiple possible worlds simultaneously.

As to *pegs* (Keppens & Schafer, 2003b, section 4.1):

The objective of this work is to identify possible references to the same unknown or partially specified entities in the scenario space. In order to correctly distinguish such entities, the notion of *pegs* is adopted from the literature on coreference resolution [(Karttunen,

Another extension of the work has augmented the original purely symbolic representation of scenarios with probabilities. More specifically, Keppens, Shen, and Price (2010) have devised a method to compose conventional conditional probability distributions from partial specifications thereof and incorporated the partial ones into the scenario fragments. This allows the original abductive reasoning approach

1976; Landman, 1986]). Pegs refer to a specific entity whose exact identity remains unknown (or partially specified). In this paper, each peg is identified by an expression of the form $_n$, where n is a non-negative natural number. At the start of the scenario space generation algorithm $n = 0$, and n is incremented by 1 after each generation of a new peg. As such, each new peg is identified uniquely.

New pegs may be introduced into the scenario space during the instantiation of causal rules of the form $\text{if } \{A_n\} \text{ assuming } \{A_s\} \text{ then } \{c\}$, where A_n is a set of antecedent predicates, A_s is a set of assumption predicates and c is a consequent predicate. Whenever a rule, whose antecedent or assumption predicates contain variables that do not occur in the consequent sentence, is applied during the inverse modus ponens phase of the scenario space generation algorithm (i.e. step 2), then those variables are instantiated by pegs. Consider, for instance, applying inverse modus ponens on rule

$$\begin{array}{l} \text{if } \{\text{scene}(S)\} \text{ assuming } \{\text{person}(P), \text{took}(P, G)\} \\ \text{then } \{\neg \text{evidence}(\text{recover}(G, S))\} \end{array}$$

given the piece of evidence: $\neg \text{evidence}(\text{recover}(\text{handgun}, \text{home}(\text{victim})))$. The required substitution $\{G/\text{handgun}, S/\text{home}(\text{victim})\}$ does not provide an instance for P . Here, P refers to an unknown entity and it is therefore substituted by a peg, say, $_0$. Therefore, the assumptions $\text{person}(_0)$ and $\text{took}(_0, \text{handgun})$ are added to the scenario space. Similarly, pegs may also be introduced during the modus ponens phase of the scenario generation algorithm (i.e. step 3). In this case pegs are introduced when a rule whose consequent predicates contain variables that do not occur in the antecedent or assumption sentences, is applied.

Keppens and Schafer (2003b, section 4.2) explained *peg unification* as follows:

Because a peg refers to an unknown entity, it can be treated as a constant that uniquely identifies that entity, or it can be unified with a ground term, including another peg or terms containing other pegs. In the latter case, the unification is possible if it is hypothesised that the entity represented by the peg and the entity represented by the term unified to the peg are the same one. This hypothesis must therefore be made explicit by means of an assumption whenever an inference is made that depends on the unification of a peg and a ground term. In the remainder of this paper, such assumptions are referred to as *peg unification assumptions*.

In this paper, each peg unification assumption takes the form $\text{bind}(_n, t)$, where $_n\psi$ is a peg and t is a ground term (which may include a peg). A peg unification assumption $\text{bind}(_n, \psi t)$ is added to the scenario space for each pair of predicates that can be matched using a substitution that contains a mapping of the form $_n/t$.

The binding relation implied by these assumptions is transitive. Therefore, peg unification can not only be assumed, but also be entailed by other peg unification assumptions. This knowledge is represented explicitly in the scenario space: for each pair of peg unification assumptions

$$\text{bind}(_i, t_1(\dots, _j, \dots)) \quad \text{and} \quad \text{bind}(_j, t_2(\dots, _k, \dots)),$$

the following new justification is added to the emerging scenario space:

$$\begin{array}{l} \text{bind}(_i, t_1(\dots, _j, \dots)) \wedge \text{bind}(_j, t_2(\dots, _k, \dots)) \\ \rightarrow \text{bind}(_i, t_1(\dots, t_2(\dots, _k, \dots), \dots)) \end{array}$$

to be used to produce Bayesian networks describing sets of plausible scenarios. Such a Bayesian network can, in turn, be employed to assess the usefulness of investigative actions based on the informativeness of the evidence they might produce. This extension also enables the knowledge engineer to express his/her lack of certainty regarding cause-effect relationships expressed by the scenario fragments.

However, the integration of probabilities with the approach potentially introduces a further knowledge acquisition challenge: the elicitation of suitable probabilities. Keppens (2007, 2009) has sought address this concern by employing qualitative and semi-quantitative abstractions of conditional probability tables. Fu, Boongoen, and Shen (2010) have independently developed another approach based on a similar idea, exploiting fuzzy sets¹⁷ as a means of qualitative abstraction instead.

8.2 Processing Human Faces: A Panoply of Contexts

8.2.1 Computer Tools for Face Processing: Preliminary Considerations

Mike Redmayne of the London School of Economics in London, writing (Redmayne, 2002) in *The Modern Law Review*, describes a problematic case of face recognition on the part of a forensic expert: “Stephen Hookway was convicted of the robbery of a bank in Salford.” (Salford is in the Greater Manchester area.) The following is quoted from Redmayne (*ibid.*, pp. 23–24):

The only evidence against him was the testimony of a “facial mapping” expert. The expert carried out a detailed examination of photographs of Hookway, and compared them to photographs of the robbery. He found a number of similarities between them. His findings were, he said, “very powerful support for the assertion that the offender was the appellant”. He could not, however, say for sure that Hookway was the robber. “He conceded that, if a trawl were made through Manchester, it may be possible to find one or two people of similar appearance”. The Court of Appeal acknowledged that, in the absence of a database, “it is impossible to know how many others may look the same as a particular accused”. As in *Smith* [a case in which recognition depended on DNA evidence], relatives complicated the case: the defendant’s brother was produced in court, at which the expert admitted that “he could not exclude the possibility that there was somebody else who closely resembled the

Scenario space generation first *unifies* the relevant sentences (i.e. the consequent of the causal rule during inverse modus ponens, the antecedents of the causal rule during modus ponens, or the inconsistent sentences of the constraint) with nodes in the emerging scenario space, and return the substitution σ required to achieve the unification. Next, scenario space generation *records* each binding that unifies a peg with a term in the scenario space and a newly created set A_p . Then, the process *instantiates* the remaining sentences (i.e. the antecedents and assumptions during inverse modus ponens or the assumptions and consequent during modus ponens) by applying the substitution σ and the process adds those that do not already exist in the scenario space as new nodes. And finally, scenario space generation *generates* a justification if applying a causal rule, or a nogood if applying a constraint.

¹⁷ Fuzzy approaches are the subject of [Section 6.1.15](#) in this book.

defendant”. A similar point about the parity of evidence against Hookway and his brother can be made. Despite all this, the Court of Appeal refused to quash the conviction.

Victor S. Johnston and Craig Caldwell, of the Department of Psychology of New Mexico State University, Las Cruces, pointed out (Johnston & Caldwell, 1997):

Humans are experts in facial recognition. They can recognize and discriminate between a very large number of faces seen over a lifetime, often following a single short exposure.¹⁸ In contrast, humans have poor recall ability; they may not be able to recall the features of a close associate, or even a family member, in sufficient detail to construct a facial composite (Ellis, Davies, and Shepherd, 1986; Goldstein and Chance, 1981; Rakover and Cahlon, 1989). As a consequence, current facial composite procedures, which depend heavily on recall rather than recognition, may not be using the best approach for generating an accurate composite of a target face.

“Face processing touches upon a variety of contexts, and is investigated in different disciplines (Young & Ellis, 1989). Rakover and Cahlon (2001) is on face recognition in cognition and computation, and, while offering an overview of theories and models, it proceeds to present an original approach (the Schema Theory and the Catch Model) with criminological applications. It proposes a cognitive law of Face Recognition by Similarity (FRBS). Davies, Ellis, and Shepherd (1981), *Perceiving and Remembering Faces*, introduces issues in face recognition and its associated mental processes. Raymond Bruyer’s edited volume (1986) provided an overview of the neuropsychology of face perception.

A forensic context is only one of the many facets of face recognition. The neuropsychology of face perception and face recognition is treated in Ellis et al. (1986). To psychologists, face recognition is a major challenge for human cognition. Apart from varying facial expressions, let alone disguises, even the views of a face when a head is rotated by different angles do not lend themselves to straightforward recognition on the part of humans exposed to such sights from real life, or by watching a video clip, or at a glance from photographs shot on the fly.

To human cognition, the challenge of recognising a given person in a photograph is not the same as recognising the face of a person who is standing in front of the cognitive agent. Face processing belongs in cognitive science as well as, in a different perspective, in computer science. Techniques from automated image recognition are involved in automated recognition or identity validation systems for security or other identification purposes (Nissan, 2003b, pp. 360–361).

8.2.2 Face Recognition Tools for Identification

8.2.2.1 Facial Recognition Classification, from a Database of Mug Shots

Face recognition is a major area within image processing, in computer science. To say it with Mena (2003, p. 167):

¹⁸ There are studies in the psychology of eyewitness testimony that researched the effects of exposure duration on eyewitness accuracy and confidence (e.g., Memon, Hope, & Bull, 2003).

Facial recognition software works by measuring a face according to its peaks and valleys – such as the tip of the nose, the depth of the eye sockets – which are known as *nodal points*. A human face has 80 nodal points; however, facial recognition software may require only 14 to 22 to make a match, concentrating on the inner region of the face, which runs from temple to temple and just over the lip, called the “golden triangle”. This is the most stable area because if an individual grows a beard, puts on glasses, gains weight or ages, this region tends not to be affected. The relative positions of these points are converted into a long string of numbers, known as a face print.

Databases of photographic images of suspects or convicted perpetrators are available to the police. Such photographs are usually *mug shots*: the face of the person is shown frontally. Suppose the police have a facial photograph of a suspect they are searching for. They want to identify that suspect, among the individuals whose mug shots are in the database.

For such a task of classification, the facial recognition tool of Attrasoftware is useful (Mena, 2003, section 6.7, pp. 165–167). The firm, Attrasoftware,¹⁹ applies neural networks to tasks in facial recognition and, more generally, image processing. “Its facial recognition product is highly accurate, versatile, and capable of searching millions of images, easily handling over a terabyte of data” (ibid., p. 196).

The technique resorts to neural networks with supervised learning (i.e., the network is trained to recognise a predefined correct output). The tool is first *trained* to recognise the face of the suspect whose photograph is the input. This step is carried out by using the ImageFinder interface. The window of ImageFinder shows the image, a toolbar (whose keys include: Train, Search, Classify, Batch, Example, Biometrics, and help), and an array of keys for various functions (for image processing, or for training or retraining, or for saving, sorting, classifying, undoing, and so forth).

In an example given by Mena (ibid., section 6.7), the given photograph is matched to a photograph of (apparently) the same man, smiling and wearing a hat. It also retrieved a photograph of the same man with a beard. What the user did, was to click on the *Train* button and wait a little bit until the message “Training End!” appears. Mena explains (ibid., p. 166):

The user can modify the setting parameters, like blurring, sensitivity, external weight cut, image type, segment size, etc. Once training is complete, the system can be directed to go out and look for images that match the training sample, with the output having an integer, representing a similarity value. The higher the score between the training image(s) and the retrieved images, the better the match.

Another kind of situation is when the person is physically present, and a decision needs to be taken as to whether to let that individual in. In the United States, facial recognition systems are used by casinos, but it is potentially valuable for other kinds of situations when prescreening is necessary or advisable.

Similarity search for images can be specialised for human faces, which is the case of face recognition software. Bear in mind however that there is thriving research

¹⁹ <http://attrasoftware.com>

into general image similarity search. For example (*ERCIM News*, October 2010, p. 11), Andrea Esuli from ISTI-CNR in Pisa has been researching

highly efficient similarity search, for which he has developed a novel algorithms based on prefix-permutation indexing. [...] He] has turned this algorithm into a working search engine for images (<http://mipai.esuli.it>) that currently allows image similarity search on CoPhIR, the largest image dataset availbale for research purposes. Esuli’s algorithm allows similarity searches to be conducted on CoPhIR in sub-second response times, a feat currently neither attained nor approached by competing systems.

In fact, MiPai is based on the PP-Index data structure for approximated similarity search (Esuli, 2009a, 2009b, 2010; Bolettieri et al., 2009). In the demo provided at Esuli’s website, one can perform similarity search on the about 106 million images currently available in the CoPhIR collection.²⁰ Esuli explains²¹:

The similarity measure used in this demo is based on a linear combination of the five MPEG-7 visual descriptors provided by the CoPhIR collection. The resulting concept of similarity is rather general, which is in line with the generalized nature of the images in the collection.

This means that this may be considered a “general purpose” search system, where one may retrieve images globally similar to the one given as the query, for many aspects: color palette, distribution of colors in the image, presence of similar edges or textures.

This does not means that this is an “all purpose” search system, i.e. you can’t change the general similarity criterium with a more specific/specialized one. For example, you can’t find shots of your cat climbing a wall given a shot of him sleeping on the sofa. You’ll likely find shots of cats/dogs/teddy bears similar to your cat placed on a sofa similar to your sofa.

Efficiency comes at a cost, and a trade-off is made with accuracy²²:

One thing to be noted is that MiPai is an approximated method, thus the efficiency is paid with accuracy, i.e., the 100 selected images may not identify the exact (with respect to the MPEG-7 similarity measures) 100 most similar images. The MiPai algorithm offers multiple possibilities, both at index and search time, to trade efficiency for accuracy of results.

8.2.2.2 Reconstructing a Face from Verbal Descriptions: Mug Shots, vs. Sketches and Composites

Let us consider to faces in forensics in particular. Facial portraits, or *mugs*, may just be a photograph (a *mug* shot) of a suspect or convict; otherwise, if the portrait was made based on the verbal description of a victim or eyewitness, it used to be drawn by a sketch artist manually (such a portrait is sometimes called an *Identikit*). See Laughery and Fowler (1980) on the sketch artist and Identikit procedures for recalling faces, in a psychological perspective. An early example of a sketch produced manually in order to identify a perpetrator is from the Renaissance: a man and his child (who was to become a famous painter) were robbed, and on reaching

²⁰ <http://cophir.isti.cnr.it/>

²¹ <http://mipai.esuli.it>

²² <http://mipai.esuli.it>

the town of Bologna, the boy skilfully drew a sketch, based on which the authorities promptly identified the robbers.

An alternative to the sketch of a sketch artist is a *composite*, by which initially a photographic *photofit* was intended. The term *photofit* is still in use in the U.S., whereas in the U.K. the more general term *composite* is preferred. Research was conducted on the photofit method during the 1970s (Penry, 1974; Ellis, Shepherd, & Davies, 1975; Davies, Ellis, & Shepherd, 1978). Its shortcoming is that a face is composed of different photographic segments, for the eyes and for the mouth, and the separation lines are visible and interfere with recognisability. See Wogalter and Marwitz (1991), on the construction of face composites.

Photofit evidence is not without problems. It is “a method to obtain details of the appearance of a suspect, which when first introduced was expected to be more useful than it has proved” (Osborne, 1997, p. 308). “It was widely assumed that such photofit pictures were merely for incidental use in establishing a suspect that could then be put on an identification parade. A very strange result however occurred in the [English] case of *R v Cook* [1987] QB 417” (ibid.), and Osborne describes it as follows:

In *Cook* the accused was convicted on the basis of a photofit prepared by the victim. After the photofit had been prepared the police arrested the suspect and put him in an identification parade. The victim identified him. In the course of the trial the photofit was put in evidence, the judge ruled it admissible as ‘part of the circumstances of the identification’. This was upheld on appeal. It was considered that neither the hearsay rule [for excluding evidence] nor the rule against admission of a previous consistent statement applied to this situation because in preparing the photofit the officer was merely doing what a camera would have done. This result has been much criticised and it is suggested that it is wrong. A photofit is nothing like a camera because there is the interposition of human intelligence. It is suggested that a photofit is hearsay, just as a verbal description of the accused would have been and should have been ruled inadmissible. The decision however, has been upheld in another case, *R v Constantinou* (1989) 91 Cr App R 74, on somewhat similar facts.

In France, face composites (in French: *portrait robot*) were developed by a police chief in Lyons during the 1950s, and only consisted of three sliding parts (*bandes coulissantes*), respectively for the hair and forehead, the eyes and eyebrows, and the mouth and chin. A sketch artist used to complete the composites with scars or moles. Eventually the police in Paris adopted the American *identity kit*. From 1993, the French police resorts to computerised face composites, which in French are called *portrait robot informatisé* (Tribondeau, accessed 2006, s.v. *portrait robot*).

Internationally, there exist various computerised systems, including E-FIT, PROfit (CD-FIT), and Mac-A-Mug Pro.²³ These old computerised systems appear to be less satisfactory than the manual method, with faces drawn by a sketch artist. Apparently E-FIT is good at recognising the faces of famous persons, whereas PROfit is good for recognising faces of persons with low distinctiveness. In the CRIME-VUs project (see below), an attempt has been made to improve on those

²³ The E-FIT website is interesting; Amina Memon recommends it in her course handouts: http://www.visionmetric.com/index.php?option=com_content&task=view&id=17&Itemid=25

older systems. Bear in mind that composites are an *indicative tool* rather than an *implicative tool* (DNA evidence is an implicative tool, instead); nevertheless, composites are used in courtroom situations as evidence, even though it is not a weighty one.²⁴

Johnston and Caldwell claimed (1997):

One of the most widely used systems for generating composite faces was developed by Penry (1974), in Britain, between 1968 and 1974. Termed “Photofit”, this technique uses over 600 interchangeable photographs, picturing five basic features: forehead and hair, eyes and eyebrows, mouth and lips, nose, and chin and cheeks. With additional accessories, such as beards and eyeglasses, combinations can produce approximately fifteen billion different faces. Alternatives to Photofit include the Multiple Image-Maker and Identification Compositor (MIMIC), which uses film strip projections, Identikit, which uses plastic overlays of drawn features, and several computerized versions of the Photofit process, such as Mac-A-Mug Pro and Compusketch. Using Compusketch, a trained operator with no artistic ability can assemble a composite in less than an hour. Because of such advantages, computer aided sketching is becoming the method of choice for law enforcement agencies.

Nevertheless, there is a shortcoming (Johnston & Caldwell, 1997):

Systems such as Photofit and Compusketch depend on the ability of a witness to accurately recall the features of a suspect and to be aware of which features and feature positions of the generated composite require modification. Such systems may actually inhibit identification by forcing a witness to employ a specific cognitive strategy; namely, the recall of isolated features. Davies and Christie (1982) have shown that this single feature approach is a serious source of distortion, and Baddeley [(1979)] has concluded that any exclusively feature-based approach is misconceived.

Frowd et al. (2010a) explain:

Face recognition essentially emerges from the parallel processing of individual facial features and their spatial relations on the face (see Bruce & Young, 1986, for a review). In contrast, face production is traditionally based more on the recall of information: the description and selection of individual features. While we are excellent at recognising a familiar face, and quite good at recognising an unfamiliar one, we are generally poor at describing individual features and selecting facial parts (for arecent review, see Frowd, Bruce, & Hancock, [2008]).

²⁴ Frowd et al. (2005) presented what they referred to as being a forensically valid comparison of facial composite systems. Brace [sic], Pike, Kemp, Tyrner, and Bennet (2006) discussed whether the presentation of multiple facial composites improves suspect identification. Bruce [sic], Hancock, Newman, and Rarity (2002) had claimed that combining face composites yields improvements in face likeness. McQuiston-Surret, Topp, and Malpass (2006) discussed the use of facila composite systems in the United States. Frowd, McQuiston-Surret, Anandaciva, Ireland, and Hancock (2007) provided an evaluations of some systems for making facial composites, from the United States. Frowd, McQuiston-Surret, et al. (2007) tried to apply caricature in the attempt to improve the recognition of facial composites. Hasel and Wells (2006) claimed that applying morphing to facial composites helps with identifications, but Wells and Charman (2005) had claimed that building composites can harm lineup identification performance.

8.2.2.3 *FacePrints* for Generating Facial Composites

Caldwell and Johnston (1991) describe how a tool, *FacePrints*, based on an interactive genetic algorithm (GA) has been useful in assisting a witness to build a facial composite of a criminal suspect. That genetic algorithm²⁵ “can rapidly search a ‘face-space’ containing over 34 billion possible facial composites” (ibid., p. 416). An important feature of *FacePrints* is that it “relies on recognition rather than recall” (Johnston & Caldwell, 1997). *FacePrints* “begins by generating a set of thirty random binary number strings (genotypes) and developing these into composite faces (phenotypes)” (ibid.), where the binary string expresses a sequential set of coordinates in six position axes, corresponding to the shape and position of facial features. The witness views, one at a time, the thirty composites of the “first generation” of the algorithm, “and rates each face on a ten point scale according to its resemblance to the culprit” (ibid.); “the witness may not be aware of why any perceived resemblance exists” (ibid.). Then “the genotype of the fittest face and a second genotype, chosen in proportion to fitness from the remaining twenty-nine faces, are paired for breeding” (ibid.). In personal communication with the present author (13 December 1996), Victor S. Johnston remarked about the advantages of his approach: “The advantages of the GA are: 1. based on recognition rather than recall, 2. no interview required that could bias witness, 3. no exposure to mug shots. It is difficult to see how any bias could be introduced into a procedure that is driven only by the witness’ recognition ability”.²⁶

8.2.2.4 The CRIME-VUs and EvoFIT Projects

Innovative tools for suspect recognition from facial composites include EvoFit (Frowd, Hancock, & Carson, 2004, 2010a)²⁷ and EFIT-V (Gibson, Solomon, Maylin, & Clark, 2009). In the United States, the leading tool is FACES. In South Africa, the ID software was developed (Tredoux, Nunez, Oxtoby, & Prag, 2006). “The basic operation of these ‘recognition-based’ systems is similar. They present users with a range of complete faces to select. The selected faces are then ‘bred’ together, to combine characteristics, and produce more faces for selection. When repeated a few times, the systems converge on a specific identity and a composite is ‘evolved’ using a procedure that is fairly easy to do: the selection of complete faces” (Frowd et al., 2010a). But (ibid.):

One problem with the evolutionary systems is the complexity of the search space. They contain a set of face models, each capable of generating plausible but different looking faces. The models, which are described in detail in Frowd et al. (2004), capture two aspects of

²⁵ Genetic algorithms are the subject of Section 6.1.16.1 in this book.

²⁶ For the application of genetic algorithms to evolving facial images, also see Hancock (2000), Hancock and Frowd (2001).

²⁷ The EvoFIT website is at <http://www.evofit.co.uk/> Charlie Frowd’s website is at this other address: <http://www.uclan.ac.uk/psychology/research/people/Frowd.html>

human faces: *shape* information, the outline of features and head shape, and pixel intensity or *texture*, the greyscale colouring of the individual features and overall skin tone. The number of faces that can be generated from these models is huge, as is the search space. The goal then is to converge on an appropriate region of space before a user is fatigued by being presented with too many faces.

At the Face Perception Group (Faces Lab) at the Department of Psychology of the University of Stirling, in Scotland, the combination of facial composites, as well as sketches, and the effects of morphing between facial composites of the same depicted person, are studied in relation to effectiveness for recognition, in the framework of the CRIME-VUs project (Combined Recall Images from Multiple Experts and Viewpoints). The project, which was a predecessor of the EvoFIT project and produced an early version of the tool EvoFIT, had the aim of “examin[ining] the effectiveness of developing methods to construct and view composite images in 3D, and explor[ing] whether combining judgements from different witnesses could result in better composites” (Bruce & Hancock, 2002).

In CRIME-VUs, multiple techniques were resorted to, in forensically friendly format, and combining information from witnesses in different ways. One image processing technique used is morphing, for blending images into each other or to various degrees. Apparently the morph (of four composites) performs better than the best (and the worst) composite.

Hancock, Bruce, and Burton (1998) compared computer systems for face recognition with human perceptions of faces. Different image formats are compared, as to their impact on human and automatic face recognition, in Burton, Miller, Bruce, Hancock, and Henderson (2001). Bruce et al. (1999) were concerned with recognising persons from images captured on video. Importantly, in face recognition by humans, the recognition of unfamiliar faces (Hancock, Bruce, & Burton, 2000) is distinct from familiar face recognition (Burton, Bruce, & Hancock, 1999).

At the University of Central Lancashire (in Preston, northwest England) and the University of Stirling (in Scotland), Charlie Frowd and collaborators (Vicki Bruce, Peter Hancock, and Leslie Bowie, and others) has developed a novel “facial composite system”, called *EvoFIT*. “Face construction by selecting individual facial features rarely produces recognisable images”, whereas EvoFIT works by the repeated selection and breeding of complete faces” (Frowd et al., 2010a). EvoFIT is based on a holistic face coding scheme and an evolutionary interface²⁸:

Using this system, witness choose from a selection of faces that bear a resemblance to an assailant (a composite is ‘evolved’ over time by breeding together the selected faces). In recent experiments, EvoFIT has outperformed other current composite systems (in the most recent realistic study, EvoFIT reached a level of naming roughly twice that of another UK composite system [...]). [...] EvoFIT has also been used in a criminal investigation, Operation Mallard (Northants). [...] (note that this system has the additional advantage that a verbal description is NOT required).

²⁸ The quotation is from <http://www.psychology.stir.ac.uk/staff/cfrowd/index.php> ABM is the industrial partner for EvoFIT; they also produce PRO-fit, one of the two facial composite systems used in the UK (the other one is E-FIT).

EvoFIT is now available for police and research use. It also has a construction ‘wizard’, rather like a wizard use to install software on a computer, and allows a composite to be constructed by a novice user. Please see www.evofit.co.uk

When a witness (or in general, a user) has to use EvoFIT, EvoFIT “presents users with screens of 18 such faces. Users select from screens of face shape, facial textures and then combinations thereof before the selected faces are bred together using a Genetic Algorithm,²⁹ to produce more faces for selection. This process is normally repeated twice more to allow a composite to be ‘evolved’” (Frowd et al., 2010a).

Concerning a field trial of EvoFIT in 2007 with the Lancashire constabulary, developers claim³⁰:

Given that it is not essential for a witness or victim to describe a face in detail to use EvoFIT, which was a limitation with previous composite systems, the number of potential crimes that can benefit from this technology is very large. To date, about 20 police personnel have been trained, and there has been great success in a range of crimes in Lancashire from theft to burglary to indecent assault [. . .]. Lancashire police are delighted with the effectiveness of the system. They are also using the new caricature animation format to present their EvoFITs of wanted persons to the public, a procedure that has been shown to substantially improve recognition rates.

Frowd et al. (2010a) “explored two techniques. The first blurred the external parts of the face, to help users focus on the important central facial region. The second, manipulated an evolved face using psychologically-useful ‘holistic’ scales: age, masculinity, honesty, etc. [. . .] Performance was best using both techniques”. Frowd et al. (2010a) shows that the latest techniques, *external feature blurring* and *holistic tools*, enable a composite to be created from a two day-old memory of a face with fairly-good correct naming rates, 25%. This is compared to 5% from a traditional feature system under the same conditions. Charlie Frowd kindly provided for publication in this book, in August 2010, a screenshot of the first generation of faces from which the genetic algorithm of EvoFIT starts, as well as a screenshot showing the blur. Refer to Figs. 8.2.2.4.1 and 8.2.2.4.2.

Also, by the summer of 2010, Frowd’s team had just finished developing a new interview for EvoFIT. It is called the *Holistic-CI*, and promotes an even better quality composite – a correct naming rate of 40%, which is clearly quite remarkable. The experiment for this is described in Frowd et al. (2010b). Frowd et al. (2010b) explain:

Facial composites are normally recovered from a witness’s memory after a cognitive interview (CI). Here, we investigated the effect of different types of interview on composites produced from a newer evolving system, EvoFIT, which is based on the selection and breeding from arrays of complete faces. The holistic-cognitive interview (H-CI) promoted better likenesses and much more identifiable images than composites produced after the CI. Composites from both the hair-recall interview (HairI) and the holistic interview (HI) were identified similarly, and worse than composites from the CI.

²⁹ Genetic algorithms are the subject of Section 6.1.16.1 in this book.

³⁰ At <http://www.evofit.co.uk/> (accessed in 2010).

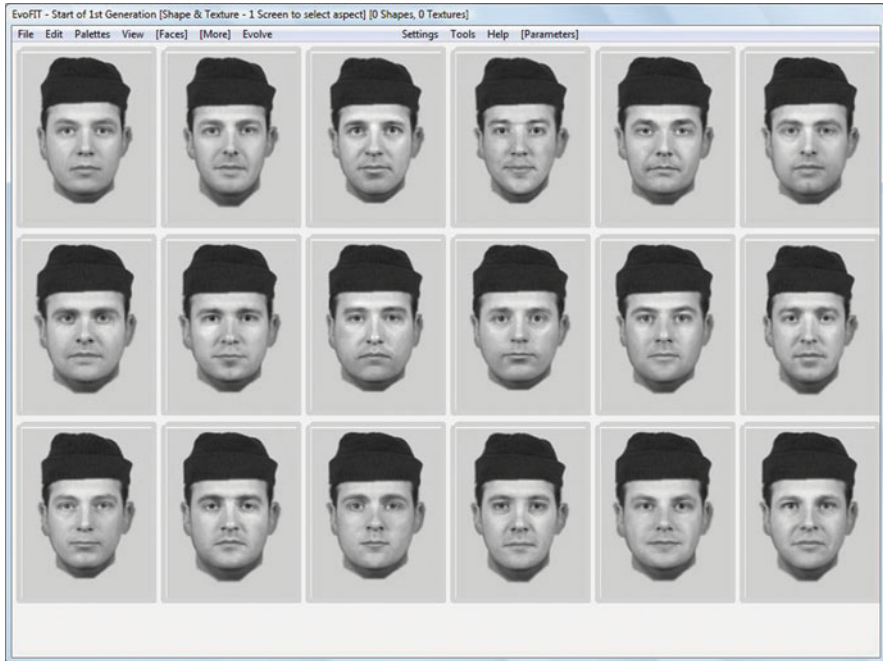

Fig. 8.2.2.4.1 A screenshot from EvoFIT. Courtesy of Charlie Frowd

Fig. 8.2.2.4.2 A screenshot from EvoFIT, showing the blur. Courtesy of Charlie Frowd

Frowd explained (pers. comm., 19 August 2010) the relation between the CRIME-VUs and EvoFIT projects: “The CRIME-VUs project developed EvoFIT to a level where people could name the images at about 12% under the long delay. This gave us the evidence to take to the EPSRC government funding body to develop the blurring and the holistic tools, to essentially make it work as well as it does today”.

8.2.3 Age-Progression Software and Post-Surgery Face Recognition

There is a different kind of application of computer graphics for face processing, that is in use in various contexts as explained below. It is *age-progression software*. Based on a facial image, this kind of software predicts how the particular person would age, or would have aged, for some parameter of assumed wear. To the police, age-progression software is potentially useful for the purposes of getting a better idea of how a given person would look, when trying to locate missing persons.

Aprilage Development Inc.³¹ in Toronto produces the APRIL Age Progression Software is the only statistically based age progression software. This software generates a stream of aged images of faces from a standard digital photograph. The wrinkling/aging algorithms are based upon two sources: (a) published data regarding facial changes associated with aging; (b) research of several thousand people of all ages, ethnicities and lifestyle habits, even though the widening of the range of racial backgrounds was gradual, by segmenting additional populations: Version 2.4 (released in 2007) also included South Asian facial aging, and a Hispanic/Latino component was scheduled to be released soon afterwards. That same version also includes a 3D Component, which allows the user to work with an image of a face in various positions, in three dimensions. Version 2.4 reportedly enabled more flexibility with starting age: that version can age a child as young as 6, or an adult as old as seventy-two years of age. The same version also included a new flipbook feature, intended to improve the workflow for repetitive tasks.

Moreover, adjustment of the output images is possible, in order to take into account whether a person will age as a smoker versus a non-smoker (Smoking Simulation Software), if he or she adds excessive weight or experiences a high degree of unprotected sun exposure. APRIL ages an individual’s face from adolescent to adulthood both as a non-smoker and as a pack-a-day consumer. It graphically predicts the premature wrinkling and unhealthy skin tone caused by cigarettes. The APRIL software was originally developed for use in science exhibits at Science Museums. Another context of use is as a health education tool, warning against smoking, obesity, and sun exposure (the latter possibly resulting in skin cancer: the

³¹ <http://www.aprilage.com> “Founded in 1998, Aprilage Development Inc. has developed APRIL® Age Progression Software in association with the Ontario Science Centre and with the support of the National Research Council of Canada. The software is used in more than a dozen countries for health and science education, entertainment and product marketing.”

software graphically predicts the premature wrinkling in the face by the effects of UV exposure). And indeed, the Roswell Park Cancer Institute in Buffalo, NY, was instrumental in helping develop the first version of APRIL.

Additional applications were envisaged, to assist in finding lost and missing children, and to help to identify criminals. In fact, APRIL can be used to help predict what an individual would look like after many years. For example, the tool could show how a pre-teen child who went missing may look as a teenager. APRIL was reportedly being used alongside a facial recognition software, for such applications to law enforcement and security. An application in a medical setting is that the software can be used in hospitals or in doctors' offices to illustrate how aging affects various medical, cosmetic, or surgical procedures. Reportedly, the tool was also being used at academic courses in gerontology.

Figures 8.2.3.1, 8.2.3.2, 8.2.3.3 and 8.2.3.4 were kindly supplied by Deirdre Hogan, Director of Sales at Aprilage, with permission to reproduce them here. These are pairs of images, the one on the left side in each pair being the photograph of a child or young adult, and the one on the right side in the same pair being a prediction of how that same individual would look as an adult or in old age. Respectively,

1. Figure 8.2.3.1 is file “gray_hair_example_Aprilage.jpg” from Aprilage, and shows normal aging of a white male young adult, the image on the right side showing him with grey hair, at age 72. The grey hair was obtained by applying the grey hair function.
2. Figure 8.2.3.2 is Aprilage's file “smoker-1-hi-res 45.JPG” and shows a girl, and how she would look aged 45, by assuming she smokes. The smoking factor was applied.

Fig. 8.2.3.1 Normal aging of a white male young adult (*left*), to age 72 (*right*). The grey hair was obtained by applying the grey hair function. Compliments of Aprilage Progression software (www.aprilage.com/www.age-me.com)

Fig. 8.2.3.2 A girl (*left*), and how she would look aged 45, by assuming she smokes. The smoking factor was applied. Compliments of Aprilage Progression software (www.aprilage.com/www.age-me.com)

Fig. 8.2.3.3 A boy (*left*) of South Asian background, with a projection reflecting normal aging of the same person (*right*), the way he would look aged 60. The image of this person as an old man did not have the grey hair function applied. Compliments of Aprilage Progression software (www.aprilage.com/www.age-me.com)

3. Figure 8.2.3.3 is Aprilage’s file “male SA org 2.5_3.jpg” and shows a boy of South Asian background, with a projection reflecting normal aging of the same person, the way he would look aged 60. The image of this person as an old man did not have the grey hair function applied.
4. Figure 8.2.3.4 is Aprilage’s file “male Lat org 2.5_2.jpg” and shows a young male of Latino background, and how he would look with normal aging at age 70. The image as an old man did not have the grey hair function applied.

Fig. 8.2.3.4 A young male (*left*), and how he would look with normal aging at age 70 (*right*). The image as an old man did not have the grey hair function applied. Compliments of Aprilage Progression software (www.aprilage.com/www.age-me.com)

8.2.4 Facial Expression Recognition

Lisetti and Schiano (2000) reported about an automated facial expression recognizer they were developing. Moreover, they

present some of the relevant findings on facial expressions from cognitive science and psychology that can be understood by and be useful to researchers in Human-Computer Interaction and Artificial Intelligence. We then give an overview of HCI applications involving automated facial expression recognition, we survey some of the latest progresses in this area reached by various approaches in computer vision (*ibid.*, from the abstract).

They went on to “propose an architecture for a multimodal intelligent interface capable of recognizing and adapting to computer users’ affective states” (*ibid.*). Their article is part of a multidisciplinary special issue of *Pragmatics & Cognition* on facial information processing in human cognition (Dror & Stevenage, 2000); see there, e.g., Anna Wierzbicka’s (2000) “The semantics of human facial expressions”.

8.2.5 Digital Image Forensics

Digital image forensics consists of computational methods of detection of image tampering. Such tampering is also done by computer (*digital forgeries*). Images typically portray people, and tools from image forensics work on models in three dimensions of the bodies that appear in the picture. Distinguish between computer models of the reasoning of and about deception, and computer techniques intended to enable the detection of forgeries, within forensic science. This is the case of a

technique that maps inconsistencies in lighting in doctored, composite photographs, by associating a sphere with its own index of lighting with different regions of the photograph (Johnson & Farid, 2007a).³²

The need for such technology was made acute by the spread and level of sophistication of digital imaging technology that can be used for manipulating digital images, including the production of photo hoaxes³³ or maliciously doctored photographs. Johnson & Farid remarked (2007a, p. 250):

The field of digital forensics has emerged over the past few years to combat this growing problem. Several techniques have been developed to detect various forms of digital tampering. Statistical techniques have been developed for detecting cloning [(Fridrich et al., 2003; Popescu & Farid, 2004)]; splicing [(Ng & Chang, 2004)]; re-sampling artifacts [(Popescu & Farid, 2005a; Avcıbaşı et al., 2004)]; color filter array aberration [(Popescu & Farid, 2005a)]; and disturbances of a camera's sensor noise pattern [(Lukáš et al., 2006)]. Optical techniques have been developed to detect chromatic aberrations [(Johnson & Farid, 2006a)], and geometric techniques for rectifying perspective distorted planar surfaces [(Johnson & Farid, 2006b)]. More recently two related approaches have been developed for detecting inconsistencies in lighting [(Johnson & Farid, 2005, 2007b)]. Building specifically on this work, and more broadly on all of these forensic tools, we describe a new lighting-based digital forensic technique.

Johnson's dissertation (2007, p. 54) explains:

Lighting environments can be captured by a variety of methods, such as photographing a mirror sphere [(Debevec, 1998)], or through panoramic photography techniques. These methods produce high dynamic range images, known as light probe images, that represent the lighting environment function $L(V)$. The spherical harmonic coefficients are computed by integrating the lighting environment function $L(V)$ against the corresponding spherical harmonic basis function [(Ramamoorthi & Hanrahan, 2001)]:

$$l_{n,m} = \int_{\Omega} L(\vec{V}) Y_{n,m}(\vec{V}) d\Omega$$

³² A popularistic introduction to this branch of image processing was provided by Hany Farid (2008), whereas Popescu and Farid (2005b) is a technical journal article, and Micah Kimo Johnson's dissertation (2007) is available online. Farid's team is at Dartmouth College.

³³ Johnson and Farid (2007a, figure 1) gave a poignant example, by showing a fake cover of a celebrity magazine. The original *Star* magazine cover showed actress Katie Holmes on the right side, with her left hand on the left shoulder of actor Tom Cruise. The cover headline claimed: "TOM & KATIE Are They Faking It?". The fake cover, instead, showed the paper's first author, Kimo Johnson, in place of Tom Cruise, and the pre-headline read "KIMO & KATIE". One could tell it was fake, however, because there was a shadow on the right side of Kimo's face, whereas there was much light in the environment (as could be seen from Holmes' own face, and also from Cruise's face in the original). In Johnson (2007, p. 26), figure 3.1 shows a "photograph of the *American Idol* host and judges" which "is a digital composite of multiple photographs. The inconsistencies in the shape and location of the specular highlight on the eyes suggest that these people were originally photographed under different lighting conditions." Enlarged details show the eyes of the various persons in that photograph.

Johnson's dissertation (2007, pp. 54–55) shows several light probe images,³⁴ each on a sphere, and captured at places like inside Grace Cathedral in San Francisco, Galileo's Tomb and the Uffizi Gallery in Florence, and so forth. From each such light probe image, lighting environment coefficients were computed. Next, these lighting environment coefficients were each used to render a Lambertian sphere, characterising the respective lighting environment. Being *Lambertian* means that it reflects light isotropically (ibid., p. 7).³⁵ Johnson (ibid., p. 47, figure 4.4) showed how lighting environments could be rendered on spheres, by displaying the first three orders of spherical harmonics as functions on the sphere: from top to bottom, that figure showed the order zero spherical harmonic, $Y_{0,0}(\cdot)$; the three order one spherical harmonics, $Y_{1,m}(\cdot)$; and the five order two spherical harmonics, $Y_{2,m}(\cdot)$. "Irradiance describes the total amount of light reaching a point on a surface. For a Lambertian surface, the reflected light, or radiosity, is proportional to the irradiance by a reflectance term ρ . In addition, Lambertian surfaces emit light uniformly in all directions, so the amount of light received by a viewer (i.e., camera) is independent of the view direction. A camera maps its received light to intensity through a camera response function" (ibid., p. 48). Moreover, "the change in the intensity profile due to an increased exposure time t_2 can be modeled by a linear change to the profile of exposure time t_1 " (ibid., p. 49). The relationship between image irradiance and intensity is expressed by a formula that can itself be rewritten in terms of spherical harmonics. Lighting environments can be estimated (ibid., section 4.1.3) and compared (ibid., section 4.1.4).

By introducing results, Johnson explained (2007, p. 54, section 4.2):

We tested our technique for estimating lighting environment coefficients on synthetically generated images and real images of natural lighting environments. The synthetic images were rendered using the *pbrrt* environment [(Pharr & Humphreys, 2004)] with data from a gallery of light probe images maintained by Paul Debevec [(1998)]. The natural images were obtained in two different ways. For the first set, we photographed a known target in a variety of lighting conditions. For the second set, we downloaded twenty images from Flickr, a popular image sharing website [³⁶]. Results from four visually plausible forgeries are also presented. For all images, the lighting environment coefficients were estimated from the green channel of the image. Although all three color channels could be analyzed, we find that this is often unnecessary since the estimation is invariant to both multiplicative and additive terms.

³⁴ Light probe images by Paul Debevec, available at <http://www.debevec.org/Probes>.

³⁵ "The standard approaches for estimating light direction begin by making some simplifying assumptions about the surface of interest: (1) it is Lambertian (i.e., it reflects light isotropically); (2) it has a constant reflectance value; (3) it is illuminated by a point light source infinitely far away; and (4) the angle between the surface normal and the light direction is in the range 0° – 90° " (Johnson, 2007, p. 7).

³⁶ Flickr home page, at <http://www.flickr.com>.

In the discussion section in Johnson and Farid (2007a, section IV),³⁷ they pointed out the following, which is relevant to doctored images that show side by side persons who were originally not photographed together:

When creating a composite of two of more people, it is often difficult to exactly match the lighting, even if the lighting seems perceptually consistent. The reason for this is that complex lighting environments (multiple light sources, diffuse lighting, directional lighting) give rise to complex and subtle lighting gradients and shading effects in the image. Under certain simplifying assumptions (distant light sources and diffuse surfaces), arbitrary lighting environments can be modeled with a 9-dimensional model. The model approximates the lighting with a linear combination of spherical harmonics. We have shown how to approximate a simplified 5-dimensional version of this model from a single image, and how to stabilize the model estimation in the presence of noise. Inconsistencies in the lighting model across an image are then used as evidence of tampering.

We showed the efficacy of this approach on a broad range of simulated images, photographic images, and visually plausible forgeries. In each case, the model parameters can be well approximated, from which differences in lighting can typically be detected. There are, however, instances when different lighting environments give rise to similar model coefficient – in these cases the lighting differences are indistinguishable.

In conclusion: “While any forensic tool is vulnerable to counter-measures, the precise matching of lighting in an image can be difficult, although certainly not impossible” (ibid.). The analysis of three forgeries (ibid., figure 12) associate differently shaded spheres characterising different lighting environments to different elements in the composite. For example, in one doctored photograph, ducks standing on the ground were added very close to players at a match. The shading effect on the spheres associated with two of the ducks are identical, but different from the shading effect on the spheres associated with two of the players. In another photograph, three men are standing side by side. The first one to the left is a football coach wearing sunglasses, a red shirt and white trousers. The other two men are soldiers holding rifles and wearing camouflage. The two spheres associated with the two soldiers have an identical shading effect, but the latter is different from that of the sphere associated with the football coach. Another photograph (ibid., figure 12) “is a forgery where the head of rapper Snoop Dogg has been placed on the body of an orchestra conductor” (with crossed arms, besuited, and with a white papillon; but the skin of a hand is that of a black person, like the face). Spheres rendered from the estimated lighting coefficients are associated with the head and the trunk, and the shading effect on the two spheres is different.

8.2.6 Facial Reconstruction from Skeletal Remains

Forensic *facial reconstruction* is the reproduction of an individual human’s face from skeletal remains. To say it with Aulsebrook, Iscan, Slabbert, and Becker (1995): “Forensic facial reconstruction is the reproduction of the lost or unknown

³⁷ Understandably, Johnson and Farid’s article (2007a) shares very much with the doctoral dissertation (Johnson, 2007).

facial features of an individual, for the purposes of recognition and identification. It is generally accepted that facial reconstruction can be divided into four categories: (1) replacing and repositioning damaged or distorted soft tissues onto a skull; (2) the use of photographic transparencies and drawings in an identikit-type system; (3) the technique of graphic, photographic or video superimposition; (4) plastic or three-dimensional reconstruction of a face over a skull, using modelling display”.

Whereas Aulsebrook et al. (1995) is a review of “work done on both superimposition and plastic reconstruction”, nevertheless “the authors believe that only the latter category can correctly be termed facial reconstruction”. Computer-graphic techniques fit in categories (2), (3), and (4).

Caroline Wilkinson (2004) presents the Manchester method of forensic facial reconstruction. She also discusses how to reconstruct the faces of children. Her book collates all published facial tissue data, and describes tissue variations with reference to age, sex, stature and ethnic origin, for use by practitioners. Wilkinson also evaluates the accuracy of current methods.

There are factors which militate in favour of one candidate reconstruction rather than another one. In one case from England, in which a man’s body was found at a stage of decomposition in which it looked like a lump of fat, two facial reconstructions were developed, one with a European likeness, and the other one with a Near Eastern likeness, whose appropriateness was suggested by the fact that on the teeth of the skull there were traces of *kat*, a recreational drug in common use in Yemen (and by some in Saudi Arabia). Eventually it was discovered that the man was a Yemeni-born grandfather who had been murdered by his own son.

In another case, a large set had been developed of possible face reconstructions for the body of a young woman, and when she was eventually identified, and it was possible to verify the accuracy of the reconstructions from photographs, it turned out that none of those reconstructions looked anywhere close to how she actually looked like when alive.

Not always facial reconstruction is for forensic purposes. A professor in Sheffield who reconstructed the face of ancient Egypt’s Queen Nefertiti, related, at a workshop in Edinburgh in the summer of 2004, how after a television broadcast on that project of his, a lady phoned to inform him that he got it wrong. He conceded to her that there may be errors, but then she claimed: “I am Nefertiti”. She promised she would send him evidence in support. John Prag and Richard Neave (1997) are concerned with reconstructing the facial appearance of ancient people; one of these is the famous King Midas, and another one is Philip II, the powerful father of Alexander the Great. The portrait of Philip II from coins provided cues for reconstruction. Another category also treated in the same book is ancient human remains retrieved from bogs. Prag and Neave’s book caters to a broad audience, yet includes moderately technical detail. An early example is a sculpture of the head of Tamerlane (see Fig. 8.2.6.1): a “[p]ortrait head of Timur [was] made by the Soviet scholar M. M. Gerasimov. This sculpture is very accurate as it is based upon the skull found in Timur’s grave. By closely studying such skulls and then working out the exact position of muscles, eyes, skin, hair and so on, Gerasimov pioneered the

Fig. 8.2.6.1 The portrait head of Timur (i.e., Tamerlane), as reconstructed by Mikhail Gerasimov

reconstruction of the portrait heads of long dead people” (Nicolle, 1990, p. 144, in a caption to a photograph).

Archaeologist and anthropologist Mikhail Mikhailovich Gerasimov (1907–1970) “developed the first technique of forensic sculpture based on findings of anthropology, archaeology, paleontology, and forensic science. He studied the skulls and meticulously reconstructed the faces of more than 200 people, including Yaroslav the Wise, Ivan the Terrible, Friedrich Schiller and, most famously, Tamerlane” ([Gerasimov] 2007). Gerasimov’s early work, from 1927 on, was on skulls of prehistoric or exotic humans. “It took a decade of studies and experiments to come close to individual portrait resolution quality of historical persons”, yet “his first public work of this type is dated 1930”, this being the “face of Maria Dostoyevskaya, mother of Fyodor Dostoyevsky” (ibid.). He worked on the skulls of Yaroslav the Wise in 1938, and of Tamerlane in 1941. “In 1953 the Soviet Ministry of culture decided to open the tomb of Ivan the Terrible and Gerasimov reconstructed his face” (ibid.). See Eve Conant’s article (2003), and Mikhail Gerasimov’s

own *The Face Finder* (Gerasimov, 1971), originally of 1968. The earliest version of his memoirs appeared in Russian in 1949.

Facial reconstruction, as mainly developed for forensic purposes, when applied in an archaeological context has enabled even glaring departure with respect to ancient portraits (conditioned by cultural conventions) to be ascertained. Olga Wojtas (1996) reported that “[f]orensic techniques used by the police to establish the identity of unknown bodies have revealed what sixteenth-century Scottish humanist, classicist, historian and poet George Buchanan looked like. [...] Most of the portraits of the time pay tribute to his brain power by depicting a man with an enormous forehead, a literal “highbrow”. But Buchanan’s skull [...] is relatively small, with an average-sized forehead”. Anatomist Matthew Kaufman “decided to find out whether any of the portraits were accurate”, and then, having had the face reconstructed from a plaster cast, “was staggered” as “it turned out to be almost identical to a portrait of Buchanan now hanging in the Royal Society in London” and which, significantly, “avoids the convention of linking exceptional intellect to a large forehead”. The newspaper report concludes with the interviewee remarking that head size as an indicator of intellect is a widespread belief. Nevertheless, a distinction is to be made between beliefs and pictorial or other culture-bound representational conventions.

It must be noted that whereas, when discussing forensic archaeology, we mentioned that there is a perception that this discipline is ahead in the application of scientific techniques to forensics for some applications, this is not the case of face reconstruction. An expert in forensic face reconstruction was skeptical, during her lecture at a workshop in Edinburgh, of forensic archaeology precisely inasmuch face reconstruction is involved. In fact, in forensic face reconstruction, once human remains are identified and photographs of the dead person are obtained, it happens sometimes that face reconstructions that had been developed are found to be wide of the mark, and in some real case it can be seen that alternative reconstructions that had been proposed, could be seen to be quite different even before the identification was made. (It basically depends on the methods, and on assumptions.)

By contrast, no such validation is possible, when the face of a person from antiquity is reconstructed. In turn, this is different from peat bodies, which may be well conserved even after a millennium, and what one sees is a blackened face that is not a reconstruction; such is the case of the body of a garrotted man who was found in Denmark. His face, short facial hair, and hat are well preserved, but the mangling of his neck is an effect of his execution, before his body was thrown into the bog.

8.2.7 Considerations about Socio-Cultural Factors in Portraiture That Have Been Analysed with Episodic Formulae

In [Section 5.3](#), we have been concerned with the representation of narratives by means of *episodic formulae*. One of the models that adopt that approach is TIMUR

(Nissan, 2008b). In [Section 5.3.1](#), among the other things I explained that the analysis in TIMUR is of

a perhaps apocryphal anecdote about the emperor Tamerlane. He invited three painters in turn, and commissioned from each, his own portrait. The first painter painted the king as a very handsome man, and Tamerlane had him beheaded, to punish him for his excessive flattery. The second painter represented the king realistically, if one means by that: warts and all. Tamerlane had him beheaded, as he found it intolerably offensive to see himself represented with hideous features. The third painter portrayed the king in the act of shooting an arrow, and did so “realistically”, yet without revealing the physical defects, because the posture was such that these would not be apparent. How did the third painter portray Tamerlane? In fact, in order to shoot the arrow from his bow, Tamerlane was kneeling down, so one would not notice that one leg was shorter. To aim, Tamerlane shut an eye, so one could not tell out the squint which affected his eyes (because you need to see both of them open, to tell out). This way, the life of the third painter was saved.

I also pointed out that this story of Tamerlane and the three painters involves fairly complex epistemic structures of belief and intentionality, and these are involved in the characters’ reasoning about the human body of one of them, and about the depiction of that body in a portrait (i.e., in a given kind of representation). There are factors involving *ontologies*: Tamerlane shares with the three painters their all’s being instances of kind ‘human being’, but, Tamerlane doesn’t possess the specific skills associated with kind ‘painter’. At any rate, he contracts out to painters the task of painting his portrait. The painters are utterly at his mercy, because his authority is absolute. Tamerlane, being an instance of kind ‘absolute ruler’, of which there only is (at most) one in a given polity, possesses a very high degree of authority on all other agents within the polity, and they in turn not only do not possess authority on him (except his doctor, if he considers him authoritative and follows his advice), but also hardly can resist his orders. Therefore, it is extremely dangerous for them to provoke his susceptibility, which is both affected by emotion, and is rational at the same time. He does not need to be concerned about the same in the reverse relation (unless he does so to so many and to such a degree, that the polity would rebel as well as his own otherwise obedient army).

Now refer to [Fig. 8.2.7.1](#). This is figure 4 from Nissan (2008b, p. 574). The diagram shows an agent’s mind, action, and structure, in relation to norms and to the portrait which in turn represents one of the agents, namely, Tamerlane. In section 3.6 of Nissan (2008b), ‘Intentions and Effects of Portraying the Ruler’ (ibid., pp. 546–555), I discussed eight examples from different cultures and historical periods, of cultural factors and effects associated with the portrait of a person in power. In section 3.15 in Nissan (2008b), ‘Tamerlane Reading the Mind of Painter1’ (ibid., pp. 564–565), episodic formulae express how Tamerlane may have reasoned about the first painter’s own reasoning when choosing to paint him in the manner he did. The value of this kind of analysis is that it provides a formal means for representing reasoning about an individual’s portrait, and also the fact that there is a difference between a portrait and an image unaffected by cultural factors. Even a photograph, for example a mug shot, carries an important luggage of cultural traditional conventions.

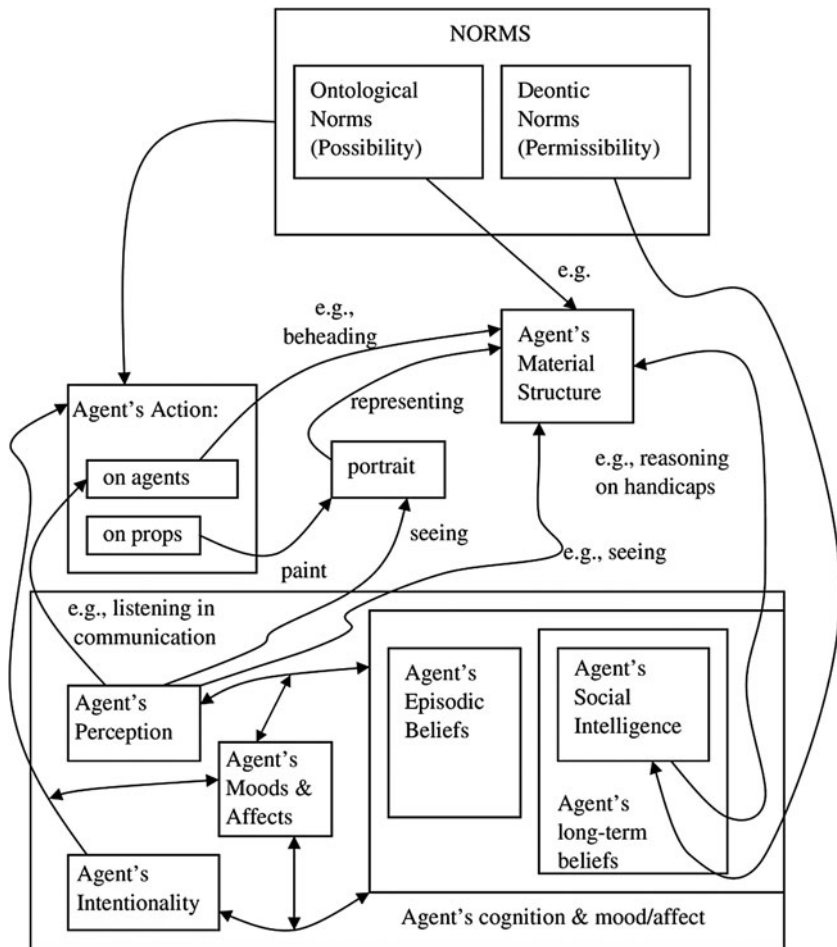

Fig. 8.2.7.1 An agent's mind, action, and structure, in relation to norms and to the portrait which in turn represents one of the agents. This is relevant for making sense of the story of Tamerlane and the three painters who, in turn, endanger themselves by painting his portrait

8.3 The Burgeoning Forensic Disciplines of Expert Opinion

8.3.1 General Considerations, and Some of the Specialties

Franke and Srihari (2008) provided an overview of *computational forensics*, at the very beginning of the proceedings of an international workshop about that domain. By *computational forensics*, what is meant is computer techniques for any discipline

within forensic science.³⁸ Concerning the booming of forensic specialties, Hans Nijboer remarked³⁹ (2000, p. 3):

[W]e can observe the fast development of forensic techniques and forensic specialties in the broader sense. Between archaeology or accountancy in its forensic form and the forensic zoology we indeed see over [one] hundred different forensic disciplines, of which some are well-established (like forensic psychiatry) and some have just started in developing 'objective' standards (shoe-print comparison)

– a development among whose critics he is.

It has become clear that DNA based techniques are in fact not perfect but they are not too weak. But at the same time it was discovered that many techniques and methods lack a sound basis in a broader scientific sense. Very often objective standards and information about the validity and reliability of specific forensic techniques are simply unknown (ibid., p. 7).

Student enrolment is affected by the blooming of the forensic sciences.⁴⁰ An exception to the generally declining enrolment in chemistry at U.K. university departments, is the number of students who want to study forensic chemistry. In the present Section 8.3, we are going to raise some points concerning an array of forensic disciplines, combining forensic science, engineering-related issues, and forensic psychology. In the remaining sections of this chapter, we are going to deal with sample areas, each in turn. These areas in which computing or electronics, or sometimes more specifically knowledge-based systems of pattern-matching software, have actually been applied. Or then, they are areas in which there may be some potential for application.

Reliance on expert testimony may be problematic,⁴¹ from the viewpoint of legal evidence theory, in that (in an Anglo-American perspective) there is a risk of tacitly

³⁸ *Computational forensics* is about what computing can do for forensic science. It should not be mistaken for *computer forensics* (itself part of *digital forensics*), i.e., the forensic discipline concerned with illegal actions involving a computer. In a sense, we find here a distinction similar to the one between *computational science* – i.e., *scientific computing*: what computing can do for science – and *computer science*, the science of computing.

³⁹ Nijboer's (2000) was an overview of current issues in legal evidence. In the tenth anniversary issue of the e-journal *International Commentary on Evidence*, published at Berkeley in California, Nijboer (2008) provided comparative comments on current issues in evidence and procedure from a Continental perspective, as have emerged during the 2000s. He "discusses three dimensions of generality in evidence and procedure: (1) generality of fundamental issues in evidence and fact-finding and insights about them across national borders, (2) generality of issues of criminal evidence across various relevant disciplines (and professions), and (3) generality with respect to specific issues of criminal evidence and its principles and rules addressing the various probanda of specific crimes (murder, theft, rape, arson, negligence causing a serious traffic accident, et cetera)." Nijboer (2008) made frequent references to case law of the European Court of Human Rights (ECHR).

⁴⁰ Brenner (2000) is a glossary of forensic science. James and Nordby (2003, 3rd edn. 2009) is an edited volume with overview chapters on various forensic disciplines. In that volume, Zeno Gerads (2005, 2nd edn.; 2009, 3rd edn.) provides an overview of the *use of computers in forensic science*.

⁴¹ There is a literature about expert evidence. For example, Carol Jones (1994) is concerned with expert evidence in Britain.

shifting paradigm from fact-finding by courts because the court has freely formed an opinion (*free proof*), to some form of binding reliance on expert testimony. In itself, reliance on expert witnesses may be problematic, perhaps because they may be misunderstood, but also because, in all frankness, trained judges tend to have a better reputation than both lawyers (whose reviled variant is the “shyster”), and expert witnesses (whose reviled variant is reputed to be the “hired gun”, or to no lesser degree the more benign, if unfortunately rather benighted, astrologer-type; at any rate, lawyers during cross-examination typically try to discredit the expert witness of the other side).

If the perspective we are to adopt is historical, it will be important to point out that *free proof* (that has its detractors, among legal theorists in Anglo-American jurisdictions) was an achievement, especially as meant, or in the form it took, in Continental Europe. It replaced the so-called *legal proof* (in Latin *probatio legalis*, in French *preuve legale*, in German *gesetzliche Beweistheorie*), and emancipated the judicial evaluation of the evidence from the older law of proof. This also involved the demise of torture as means for obtaining evidence; torture was deemed necessary for obtaining proof as necessary, in turn, to secure conviction, according to the system of legal proof, as opposed to the system of free proof that replaced it. In Continental Europe, free proof replaced rules of *quantum and weight*; these did not use to be part of the English and American judiciary systems.

Another kind of problem is that some important areas of expert testimony, such as forensic psychology or psychiatry, are treated variably, according to the country in which the court is, apart from the diffidence that lawyers are claimed to have of psychologists (see, e.g., Nissan, 2001f). Whatever negative may happen without expert testimony? In a section entitled “Evidence sans Expert”, barrister and consultant psychiatrist Mahendra (2007, p. 1490), writing in England, commented on a recent court case:

That expert evidence plays a crucial role in modern litigation is well accepted. It is required by a court which acknowledges its lack of expertise on the relevant issues on which it requires the assistance of experts. But this does not mean that evidence which would normally be within the province of the expert is not present in the course of a trial even while no expert is present. This evidence may influence the judge and, where present, a jury.

One such area concerns mental disorder which, being commonly found, may then play some part in these deliberations and, yet, may not be subject to expert opinion in these circumstances. As lay individuals are known to hold all manner of views, not all reliable or valid, on psychiatric matters there may be scope for misunderstanding and even injustice. The issue came up in *R v Osbourne* [2007] EWCA Crim 481, [2007] All ER (D) 206 (Mar).

Forensic psychology⁴² is not necessarily about the state of mind of a perpetrator, or of a victim. It has important things to say about the reliability of identification from memory. Uncertainty about an identity turns out in a broad array of forms, when

⁴² See for example a volume, *Forensic Psychology*, edited by Joanna Adler (2010, 2nd edn. [originally of 2004]). In that book, section 1, entitled ‘Forensic Psychology in Context’, comprises chapter 1, ‘Forensic psychology: concepts, debates and practice’, by Joanna R. Adler; and chapter 2, ‘Public perceptions of crime and punishment’, by Jane Wood and G. Tendayi Viki.

it comes to legal matters. Oftentimes, it is about personal identity: the identity of a human individual, possibly a culprit (not just in real life, but in whodunit fiction as well) or one otherwise liable, or, then, a victim. Identification is oftentimes required of witnesses.

The literature on the assessment of witness reliability is very extensive; writing about eyewitness identification would be a book in its own right.⁴³ In her 2008 course handouts in *Psychology, Law and Eyewitness Testimony* at her website at the University of Aberdeen in Scotland, psychologist Amina Memon has provided useful entry points into the scholarly literature: “Gary Wells (USA) has an excellent website containing numerous articles on eyewitness memory”⁴⁴; “Maryanne Garry (New Zealand) provides access to all her publications on false memories”⁴⁵ “Loftus also provides access to her articles on misinformation and false memory as well as some good links”⁴⁶ “Paul Ekman makes his papers on deception available on his website”⁴⁷ “Gary Well’s website [has] lots of good links”⁴⁸; and so forth. Other

Section 2, ‘Investigation and Prosecution’, comprises chapter 3, ‘USA and UK responses to miscarriages of justice’, by Tom Williamson; chapter 4, ‘The interpretation and utilisation of offender profiles: a critical review of ‘traditional’ approaches to profiling’, by Laurence Alison and Emma Barrett. Section 3, ‘Testimony and Evidence’, comprises chapter 5, ‘Eliciting evidence from eye-witnesses in court’, by Mark R. Kebbell and Elizabeth L. Gilchrist; and chapter 6, ‘The ageing eyewitness’, by Amina Memon, Fiona Gabbert and Lorraine Hope. Section 4, ‘Correlates of Criminality – sensations and substances’, comprises chapter 7, ‘The status of sensational interests as indicators of possible risk’, by Vincent Egan; chapter 8, ‘Drug use and criminal behaviour: indirect, direct or causal relationship?’, by Ian P. Albery, Tim McSweeney and Mike Hough; and chapter 9, ‘Drug arrest referral schemes and forensic perspectives on the treatment of addiction’, by Andrew Guppy, Paul Johnson and Mark Wallace-Bell. Section 5, ‘Persistent Offending’, comprises chapter 10, ‘Life-course persistent offending’, by Alex R. Piquero and Terrie E. Moffitt; and chapter 11, ‘Stalking, Lorraine Sheridan and Graham Davies’. Section 6, ‘Intervention and Prevention’, comprises chapter 12, ‘Domestic violence: current issues in definitions and interventions with perpetrators in the UK’, by Elizabeth L. Gilchrist and Mark Kebbell, chapter 13, ‘Effective programmes to prevent delinquency’, by Brandon C. Welsh and David P. Farrington; and chapter 14, ‘Parenting projects, justice and welfare’, by Anthony H. Goodman and Joanna R. Adler. Section 7, ‘Punishment and Corrections’, comprises chapter 15, ‘Women in prison’, by Nancy Loucks; and chapter 16, ‘Applied psychological services in prisons and probation’, by Graham Towl.

⁴³ For a treatment of the psychology of person identification, see Clifford and Bull (1978). In Bull and Carson (1995), the chapter ‘Assessing the Accuracy of Eye-witness Identifications’ (Cutler & Penrod, 1995) has long been a useful entry point to the subject. Eyewitness psychology (e.g., Loftus, 1974 sqq, Ross et al., 1994) is but one area of forensic psychology. The *American Journal of Forensic Psychology* was established in the early 1980s; the *British Journal of Forensic Psychiatry & Psychology*, at the end of that same decade.

⁴⁴ <http://www.psychology.iastate.edu/faculty/gwells/homepage.htm> (cf fn. 19 in Chapter 4).

⁴⁵ <http://www.vuw.ac.nz/psyc/staff/maryanne-garry/index.aspx>

⁴⁷ <http://www.paulekman.com/downloadablearticles.html>

⁴⁸ <http://www.psychology.iastate.edu/~glwells/>

than concerning witnesses, forensic psychology may, e.g., concern the custody of children of divorced parents.⁴⁹ And then there is forensic psychiatry.⁵⁰

Cutler and Penrod (1995) are concerned with eyewitness identification of criminals in the United States, and Ross, Read, and Toglia (1994) are likewise concerned with criminal investigations with adult witnesses. In Bull and Carson (1995), Daniel Yarmey's chapter (Yarmey 1995) 'Earwitness and evidence obtained by other senses' is also about the identification of a person, such as a perpetrator. Hammersley and Read (1993), which appeared in a volume on the identification of suspects and its psychology, deals with voice identification by humans and computers.⁵¹

Henry Lee's Crime Scene Handbook (Lee, Palmbach, & Miller, 2001) is devoted to how to conduct an investigation,⁵² starting by protecting and managing a crime scene; the *Handbook* includes a chapter, "Logic Trees", that could justifiably be of interest to such computer scientists who are interested in formalising general reasoning for the purposes of assisting crime analysis. One of the case studies in that volume is on shooting scene reconstructions. For a treatment of science in the criminal investigations, see, e.g., Kaye (1995) and Saferstein (1995); the latter considers forensic ballistics,⁵³ chemistry, and medicine. Cook et al. (1998)

⁴⁹ For a U.S. perspective, see Ackerman (1995).

⁵⁰ See, e.g., Lonsdorf (1995), Belfrage (1995), Chiswick and Cope (1995), Faulk (1994), Lloyd (1995), Gunn and Taylor (1993). Eigen (1995) considers forensic psychiatry in the context of British history.

⁵¹ Also see Hollien (1990), about voice in forensic contexts.

⁵² Kaye's (1995) *Science and the Detective: Selected Reading in Forensic Science* is a useful introduction. Lane, Tingey, and Tingey (1993) is a specialised encyclopaedia, but in a rather popularistic perspective. As to the *Encyclopedia of Forensic Sciences* (Siegel, Knupfer, & Saukko, 2000), its 1440 pages contain more than 200 articles.

⁵³ Concerning forensic ballistics, <http://en.wikipedia.org/wiki/Ballistics> states the following: "In the field of forensic science, forensic ballistics is the science of analyzing firearm usage in crimes. It involves analysis of bullets and bullet impacts to determine the type. Rifling, which first made an appearance in the fifteenth century, is the process of making grooves in gun barrels that imparts a spin to the projectile for increased accuracy and range. Bullets fired from rifled weapons acquire a distinct signature of grooves, scratches, and indentations which are somewhat unique to the weapon used. The first firearms evidence identification can be traced back to England in 1835 when the unique markings on a bullet taken from a victim were matched with a bullet mold belonging to the suspect. When confronted with the damning evidence, the suspect confessed to the crime. The first court case involving firearms evidence took place in 1902 when a specific gun was proven to be the murder weapon. The expert in the case, Oliver Wendell Holmes, had read about firearm identification, and had a gunsmith test-fire the alleged murder weapon into a wad of cotton wool. A magnifying glass was used to match the bullet from the victim with the test bullet. Calvin Goddard, physician and ex-army officer, acquired data from all known gun manufacturers in order to develop a comprehensive database. With his partner, Charles Waite, he catalogued the results of test-firings from every type of handgun made by 12 manufacturers. Waite also invented the comparison microscope. With this instrument, two bullets could be laid adjacent to one another for comparative examination. In 1925 Goddard wrote an article for the Army Ordnance titled 'Forensic Ballistics' in which he described the use of the comparison microscope regarding firearms investigations. He is generally credited with the conception of the term 'forensic ballistics', though he later admitted

and Jamieson (2004) are important articles, proposing rational approaches to crime scene investigation. Dixon (1999) discusses police investigative procedures.

In situations which involve forensic scientists, sometimes human remains⁵⁴ are only an incomplete skeleton. Consider the problem of determining whether the person was a man or a woman. “The estimation of sex from skeletal remains is often difficult because of the great overlap of the ranges of the measurements between both sexes in general”, in the words of Riepert, Drechsler, Schild, Nafe, and Mattern (1996, p. 140), a study whose “data from a large sample [being radiographs of the ankle] provide an objective basis for sex identification. The single measurement of the calcaneus length allows an estimation of sex with nearly 80% accuracy” (ibid.).

Sometimes, it is the identity of an object or other asset that is of interest; this, in turn, is amenable to the detection of the values of some attributes of the object, such as the owner, or geographic origin. To clarify the difference between (i) personal identification, (ii) the identification of attributes of a human individual other than one’s unique identity as partly captured by one’s full name, and (iii) the identification of attributes of an object other than ownership, consider such differences within the scope of the practice of one of the forensic disciplines: forensic entomology.⁵⁵

Identifying a corpse is an example of (i), whereas identifying its whereabouts at death or shortly afterwards is an example of (ii). The latter is exemplified in the following quoted passage (Turner, 1987, p. 134), which, next, also illustrates (iii), concerning the geographic area of origin of a consignment of marijuana:

Human corpses, whether they have been produced naturally or as the result of foul play, are processed by [...] insect decomposers in the same way as any other piece of carrion. Forensic entomology is concerned with interpreting the insect evidence. This involves providing information about the time of death, and possibly changes in the location of the body based on a study of the insects present in the corpse when it is found. A good illustration of this is provided by a Russian case history (Arutyunov, 1963, in Keh, 1984). Living fly larvae found on a partially skeletonized body in a seawater tank were identified as species that are intolerant of salt-water. It was therefore deduced that the body had been dumped in the tank only a short time before it was discovered. The age of the larvae suggested death occurred about 2 weeks prior to the finding of the corpse. These observations were confirmed by the murderer’s confession. The victim had been shot 2 weeks previously and then the body had been moved by car and put into the tank the day before it was discovered.

A detailed knowledge of insects, their habits, life histories and delectations have also been useful in solving less macabre forensic problems. In an interesting and well-publicized recent case [(Joyce, 1984)] the New Zealand police intercepted a large consignment of marijuana. When the usual chemical analyses failed to identify the source of the marijuana the consignment was examined for insects. The bodies of sixty insects were recovered and

it to be an inadequate name for the science. In 1929 the St. Valentine’s Day Massacre led to the opening of the first independent scientific crime detection laboratory in the United States.”

⁵⁴ Boddington, Garland, and Janaway (1987) and Cox and Mays (2000) are at the interface with forensic osteology within forensic pathology. In Krogman and İşcan (1986), the topic is the human skeleton in forensic medicine.

⁵⁵ Forensic entomology is the subject of Catts and Goff (1992), Catts and Haskell (1990), Keh (1984), Stærkeby (2002). An overview of forensic entomology is provided by Gail Anderson (2005, 2nd edn.; 2009, 3rd edn.).

from these entomologists were able to precisely pinpoint the origins of the marijuana to a region 200 km SW of Bangkok, near a stream or lake where fig trees and termites are found. As in the previous case the detailed entomological evidence was of paramount importance in convicting the suspects.

As seen, one of the areas of application of forensic entomology is in the service of *post mortem* analysis. Also related to the latter (within forensic pathology) – though not necessarily so, as there are other applications as well in criminal investigation – are techniques from the forensic analysis of soils and geological evidence: Junger (1996) set “to determine the discriminative qualities of the various procedures to discern at what point soils become indistinguishable from one another” (from the abstract).

One hundred samples were collected from three different sites; a beach, an island isolated by a river, and a bus parking lot. The samples were analysed using color determination, particle size distribution analysis and mineralogical profiles of the twenty-five most common soil minerals. Of the three hundred samples examined, over one-half could be discriminated by color alone, the remainder needing only particle size distributions analysis for differentiation, negating the need for lengthy mineralogical examinations (*ibid.*).

Moreover – cost being a factor in decision-making about how to analyse the evidence – these tests required only “very inexpensive equipment”, and the calculations were not demanding in terms of either training or cost (*ibid.*). Cole and Ackland (1994) provide case studies in homicide investigation, in respect of forensic pathology, and in a British context.

In general on legal medicine, see, e.g., Schneider, Nagano, and Geserick (1994). Legal medicine’s aims (not confined to perpetrator identification) include, e.g., problems hospitals are faced with, in care for the critically ill newborn. Clements (1994) is on forensic obstetrics, in respect of safety and liability for malpractice in British law. Clark and Crawford (1994) is on the history of legal medicine and of medical jurisprudence. Sometimes, veterinary surgeons act as witnesses (BVA, 1979).

And then, there is (human) forensic odontology, or forensic dentistry (Bowers, 2002; Glass, 2005, 3rd edn. 2009). Whereas the dentist who used to have a person in care may help in identification by means of stored X-ray items, there is, as well, a different kind of application: “Bite marks left on human tissue and bitten material have become an important aspect of scientific evidence used for the conviction or acquittal of a suspect”, to say it with the abstract of Nambiar, Bridges, and Brown (1995), where use of a computer program for shape analysis is described.

Forensic chemistry and toxicology,⁵⁶ while sometimes resorted to in relation to forensic medicine, have a wider range of applications. In general, note that particular classes of techniques find disparate applications in the forensic sciences. Bob Ardrey (1994) is concerned with mass spectrometry, for such purposes. Or, then, consider chromatographic analysis; Ian Tebbett (1992) is concerned with gas chromatography in forensic science.

⁵⁶ See Molina’s (2009) *Handbook of Forensic Toxicology for Medical Examiners*; as well as, e.g., Pardue (1994), Cone and Deyl (1992).

Ukpabi and Peltron (1995) provide a review of the use of the scanning electron microscope is made in order to identify the cause of fibre damage, for application within “forensic textiles” (*sic*) as being an area of textile studies.⁵⁷ Trace evidence analysis is discussed in Deedrick (2001) concerning fabric processing, and in Ballou (2001) on fibre from wigs. Biermann and Grieve (1996) reported about a database of mail order garments and its statistical evaluation, for the forensic purpose of estimating the frequency of fibre types found in clothing. But see in Section 8.3.2.

8.3.2 *Statistics Comes into the Picture*

At the end of Section 8.3.1, we mentioned textile fibre types and their frequency as found in clothing. Allen and Pardo (2007a, pp. 116–119) offered a critique, in terms of the *reference-class problem* (see Section 2.4 above) of how probability theory was applied to juridical proof concerning carpet fibres in Finkelstein and Levin (2003). The problem, Allen and Pardo claim (2007a, pp. 117–118),

arises from an ambiguity in the sentence, “Based on manufacturing records, an expert testifies the frequency of such fibers in carpets is less than 1 in 500.” What does this mean? Whose records? Which records? Does the statistic refer to those who make a particular kind of carpet, or all U.S. manufacturers, or all manufacturers in the world? Or all carpets ever made in the history of the world to date? And once we know the class to which it applies, why is this the appropriate class in which to place Jones [a suspect, a neighbour of where a crime was perpetrated] and his carpet sample [i.e., carpet fibres taken from Jones’s house, and matching an unusual carpet fibre found at the scene]? Is the fiber more or less prevalent in his part of the world, country, state, region, age group, gender, profession, socioeconomic class, and so on? Each of the different classes suggested by these questions would reveal different probabilities and likelihood ratios, but the evidence under consideration has not changed. Indeed, the evidence would likely have widely varying likelihood ratios. The probative value of the evidence cannot be simply the ratio derived from any arbitrarily chosen reference class. [. . .] A second problem with their conclusions concerns how the fiber evidence connects with other evidence.

In fact, had there been the case that there is (*ibid.*, p. 119)

conclusive evidence that the crime scene fiber had been planted after the fact to frame Jones would reduce the value of the fiber evidence to zero. Even if we have no evidence about this possibility, how do we know that it was brought from the suspect’s home? Even if it was, how do we know that it was from carpeting in his home rather than, say, from having been picked up on the shoes of the actual perpetrator when he was at a party at the home of the person wrongly accused of the crime? These possibilities further show the disjunct between the value of evidence, on one hand, and the likelihood ratio calculated on the basis of a specified reference class, on the other. [. . . T]here may be no data for other plausible reference classes, which means that the mathematics can be done only by picking these or some variant. [. . .] Using the data one has does not make the proffered analysis correct or true in some sense; instead, it is reminiscent of relying on the lamppost more for support than illumination.

⁵⁷ Those authors themselves were affiliated with the Department of Clothing and Textiles, at the Faculty of Human Ecology of the University of Manitoba in Winnipeg, Canada.

Statistics turns up in a multitude of contexts from forensic science. Actually, application in legal contexts dates back from the early modern period.⁵⁸ “Legal applications of probabilistic and statistical reasoning have a long history, having exercised such pioneers as Nicolas Bernoulli, Condorcet, Laplace, Poisson and Cournot (Zabell, 1988). After a period of neglect interest has resurfaced in recent years, and the topic has given rise to many challenging problems” (Mortera & Dawid, 2006).

Many pioneers of probability and statistics, including the Bernoullis, Condorcet, Laplace, Poisson and Cournot, were motivated by problems of quantification and combination of legal evidence and judgement. But the trail they blazed became disused and overgrown as statisticians lost interest in such questions while legal evidence scholars confined themselves to issues of admissibility, precedent and other such formal rules, paying remarkably little attention to problems of interpretation. Very occasionally some aspect of statistical evidence or argument would break surface – significant legal cases include the 1865 Howland will case and the 1894 Dreyfus case – but it was not until the 1968 Californian case of *People v. Collins*, in which the prosecution presented a fallacious statistical argument in an attempt to magnify the impact of eye-witness identification evidence, that the issues became subject to serious discussion and argument. This stimulated what became known in the academic legal community as “the new evidence scholarship” [...] The probabilities debate remained academic until 1985 when, with the advent of DNA profiling and its numerical “random match probabilities”, presentation of, and argument about, statistical evidence of various kinds started to become much more common in the courts (Dawid, 2004b).

Dawid and Mortera (1994) suggest a reason for the delay in the actual emergence of statistics in court: “The infamous trial *People v. Collins* (1975) was one of the first cases where statistical analysis of evidence was made. Unfortunately the analysis was so poor that it set back the introduction of statistical evidence in court for many years” (ibid., p. 2).⁵⁹

A critic of Bayesianism in judiciary contexts, Ron Allen remarked about probability levels (Allen, 2008a, p. 320):

The equally obvious probabilistic interpretation to give to these numbers is that they are relative frequencies, as propensity and classical accounts are plainly inapposite. That raises an immediate difficulty because virtually never is the data presented at trial in relative frequency formats, and even when it is (DNA evidence, good statistical evidence of disparate treatment), it must be combined with evidence that is not (“The defendant raped me”, “I was treated in a way that people with different skin color were not”).

Allen (2008a, pp. 320–321) proceeded to claim:

The solution to this problem appears equally obvious: subjective Bayesianism. One can translate impressions about evidence into subjective beliefs and then compute posterior probabilities in the light of new evidence. This not only maintains consistency among belief states, but has the added advantage of seeming to approximate what trials seem to be about, which is updating beliefs in the light of new evidence. Yet another advantage of

⁵⁸ See on this Nissan (2001b), reviewing Rosoni (1995).

⁵⁹ In the context of forensic science, see the book on Bayesian networks by Taroni et al. (2006), Aitken (1995), Aitken and Taroni (2004), Robertson and Vignaux (1995). An introduction to statistics for forensic scientists was authored by David Lucy (2005).

this approach is that it provides an answer to other important questions such as the meaning of relevance, prejudice, and probative value. “Relevance” means a likelihood ratio of anything other than 1:1; “prejudice” means that the evidence is likely to affect the rationality of appraising the likelihood ratio, and “probative value” means how far from a 1:1 ratio the likelihood ratio is.

And yet: “I believe it is wrong all the way down, from the most general questions of the basic structure of proof at trial to the most detailed question of the probative value of discrete pieces of evidence” (ibid., p. 321). In the rest of that paper, and in much of his published *oeuvre*, Allen shows why. His arguments are cogent, and cannot be safely ignored. We have given more space to them in other places throughout this book. At any rate, there is a raging controversy between those endorsing probabilistic accounts of judicial proof, and those opposing that kind of approach. Computing scientists turning to modelling legal evidence can only ignore the controversy at their risk and peril.

Gastwirth and Miao (2009), concerned with race discrimination in employment practices, provided a statistical analysis of the data in disparate impact cases from the United States. They took issue with the specific rationale behind a court ruling, petitioners’ brief, and respondent’s brief. The petitioners were claiming reverse discrimination at a Fire Department after an examination was cancelled. Baldus and Cole (1980) is a book on statistical proof of discrimination.

David Kaye (1982) was concerned with statistical evidence of unlawful discrimination of various kinds: discrimination in *ad hoc* decision making, discrimination in the application of a rule, discrimination in the formulation of a rule, and discrimination in the operation of a rule. Michael Finkelstein (1980) discussed the judicial reception of multiple regression studies in race and sex discrimination cases. Kaye (1982, pp. 775–776) was especially concerned with

how statistical proof fits into discrimination litigation in two areas in which such evidence commonly is employed. The courts have relied heavily on statistical evidence in cases in which a criminal defendant alleges that he was indicted by an unconstitutionally selected grand jury or an unconstitutionally empanelled petit jury (Finkelstein, 1978, pp. 18–58). In essence, a claim of disparate treatment is presented, and statistical analysis of the pattern of selection is therefore appropriate. There is no constitutionally permissible basis for systematically excluding, say, members of defendant’s race from the population of citizens who are eligible for jury duty. Where direct evidence of discrimination is unavailable, statistical methods have been pressed into service.

Writing in 1980, Kaye concluded that, among the other things (1982, p. 782–783):

The courts tend to adopt a fairly realistic attitude toward such matters as defining the relevant population, and recent opinions reveal increasing awareness of classical hypothesis testing in evaluating measured differences. However, the process of drawing a conclusion for legal purposes entails an integration of statistical and non-quantitative information, making classical hypothesis testing inapposite to factfinding in litigation. A full-fledged Bayesian analysis of the probability of discrimination is theoretically more satisfying but is too controversial and, in a sense, too powerful to have much chance of becoming judicially accepted and of contributing to accurate decision making by judges or juries. Presentation of the likelihood function avoids the objections to Bayesian inference, but a more mundane calculation of the probability that an observed difference would arise in the absence of discrimination might be more easily comprehended by a court. Such a calculation should be

the starting point for any formal analysis, and consideration should be given to supplementing this calculation with fuller presentations, such as displays of prediction intervals and likelihood functions.

Houck (1999) discussed statistics in relation to trace evidence. “The inability to place a specific probability estimate on chance association has led to a widespread view that trace evidence is much weaker than DNA evidence, a problem which has been referred to as “the tyranny of numbers” [(Houck, 1999)].

However, as noted by Houck (1999, p. 3), “the tyranny of numbers is a consequence of an over-reliance on deduction and mathematics, and these ultimately limit a discipline by requiring it to fit in a preordained model. [. . .]” Bayesian statistical approaches have become popular in many branches of forensic science in recent years” (Pye, 2006, pp. 24–25). Pye further remarks (*ibid.*, p. 25):

Quantitative methods, including formal hypothesis testing, clearly have an important role to play in the assessment of all forms of trace evidence, but they can rarely provide a complete answer. Issues of “uniqueness”, “rarity”, “randomness” and “representativeness” in relation to trace evidence are usually difficult to quantify in an exact mathematical or meaningful statistical way. Statistical estimates of frequency of occurrence are usually context-dependent, based on the extent and timing of any sampling carried out, and on the methods used for sample collection and data analysis.

As pointed out by Houck (1999), “context, is in fact, the crucial component to a proper grasp of the significance of trace evidence. Without context, we are communicating mere facts with no foundation of meaning, much in the way Poincar[é]’s pile of stones is not a house”. The existence of a suitable context for the evaluation of the significance of trace evidence depends partly on the experience/knowledge of the trace evidence examiner, the availability of database information relating to the materials under examination, and the willingness of those instructing the forensic examiner to provide relevant information relating to the circumstances of the case. The examiner is not always provided with information which may have an important bearing on the assessment of the *evidential value* of the scientific findings. Partly for this reason, the examiner should, normally restrict his/her assessment to the likely *scientific significance* of any apparent similarity. The wider issue of evidential significance is more properly a matter for the court. Over the past fifteen years there have been great improvements.

Richard Overill and Jantje Silomon devoted a paper (2010) to what they term *digital metaforensics*, i.e., “quantifying the investigation” into digital crime cases (cf. Section 4.3.4 above). Their article, in line with those authors’ record of research, resorts to statistics, and concerns (*ibid.*, from the abstract):

two related areas of digital forensics. The first involves quantifying the extent to which the recovered digital evidential traces support the prosecution’s contention that a particular digital crime has been committed. The second addresses the issue of quantifying the cost-effectiveness of the digital forensic investigative process, in order to optimise the deployment of valuable and scarce resources for maximum efficacy.

Their thrust is to provide metrics that would appear to be more precise than such qualitative statements as “very likely”.

Not surprisingly, defence lawyers assigned to digital crime cases have become aware of this discrepancy and have attempted to exploit it to persuade the court that the prosecution does not possess evidence of sufficient probative value. However, the development of potentially

suitable methodologies and techniques for the quantitative interpretation of digital forensic investigations is underway [...] and offers the prospect of bringing a degree of numerical certitude to the recovered evidence in such cases.

It remains to be seen whether this is not merely an illusion. The skeptics concerning Bayesianism in a judicial context may point out that merely quantifying does not ensure that the quantification, apart from sounding grand, is also credible for good reason.

8.3.3 *Some More Forensic Disciplines*

Apart from subserving legal medicine, forensic toxicology is also involved in environmental poisoning (Sigmund, 1995). Other forensic disciplines are concerned with the environment; such is the case of forensic engineering for environmental cases (Shuirman & Slosson, 1992), or, then, of forensic economics as applied to the liability for environmental damages, caused by hazardous substances pollution.⁶⁰ When it comes to engineering, there are fields of application (other than assessment of environmental damage) which correspond to subareas of expertise within forensic engineering. Forensic engineering may be in the realm of civil engineering (in cases of structure collapse), or, for example, automotive engineering.⁶¹ There is a role, in court, for computer-aided accident reconstruction (Bohan, 1991). Johnson (1985) was concerned with the (mis)interpretation of the causes of motorcycles collision vis-à-vis driver behaviour.⁶² A car crash involves impact. Another kind of impact is involved in forensic ballistics.⁶³

William Bodziak published (2000) the book *Footwear Impression Evidence*. He also provided an overview of forensic footwear evidence in the form of a book chapter (2005b), preceded by a chapter (Bodziak, 2005a) concerning vehicles, namely, about forensic tire impression and tire track evidence. Let us consider the Wikipedia entry⁶⁴ for “Forensic footwear evidence”. The incentive to resort to such expertise is

⁶⁰ Ward and Duffield (1992) is in a U.S. perspective.

⁶¹ Within automotive engineering, Peters and Peters (1994) is relevant for U.S. law.

⁶² Also see José Almirall’s paper (2001), “Manslaughter Caused by a Hit-and-Run: Glass as Evidence of Association”.

⁶³ Sellier and Kneubuehl (1994) is in forensic ballistics, in a medical context.

⁶⁴ It is remarkable that there are concise, yet valuable introductions to various forensic science disciplines, posted as entries on Wikipedia. These include a general entry “Forensic science”; various entries from the physiological sciences (“Forensic pathology”, “Forensic dentistry”, “Forensic anthropology”, “Forensic entomology”); entries with affinity to the social sciences (“Forensic psychology”, “Forensic psychiatry”); entries in other specialisations (“Fingerprint analysis”, “Forensic accounting”, “Ballistics”, “Bloodstain pattern analysis”, “DNA analysis”, “Forensic toxicology”, “Forensic footwear evidence”, “Questioned document examination”, “Explosion analysis”); entries on cybertechnology in forensics (“Information forensics”, “Computer forensics”); entries related to engineering (“Forensic engineering”, “Fire investigation”, “Vehicular accident reconstruction”); entries on people in forensics (“Edmond Locard”, “Bill Bass”); and related articles (“Crime scene”, “CSI effect”, “Trace evidence”). For all of these, see

because of the availability of footprints. The problem is that how strong the evidence is is questionable. The same entry admits: “The Unabomber, Theodore Kaczynski, was known to keep shoes with smaller soles attached to the base in order to confuse investigators about the size of the suspects.”⁶⁵ The introduction to a Wikipedia entry for “Forensic footwear evidence”⁶⁶ reads as follows:

Forensic footwear examination is the study of footwear impressions evidence created. Such evidence is used in legal proceedings to determine the identities of persons at the crime scene. Footwear evidence is often the most abundant form of evidence at a crime scene and in some cases can prove to be as specific as a fingerprint. Initially investigators will look to identify the make and model of the shoe or trainer which made an impression. This can be done visually or by comparison with evidence in a database both methods focus heavily on pattern recognition and brand or logo marks. Information about the owner of any footwear can be gained from the analysis of wear patterns which are dependant on angle of footfall and weight distribution. Detailed examination of footwear impressions can help to link a specific piece of footwear to a footwear imprint as each shoe will have unique wear characteristics.

Perhaps the value of such evidence is especially for excluding suspects. Many people can be expected to wear shoes of the same model and size. Nevertheless, the shoe itself may be available, and more solid evidence can be obtained from it, for identifying the person who was wearing it: “*Footwear insole imprints* are imprints left in the inside of footwear caused by contact from the person’s foot. Analysis of the insole imprints can be used to link a person(s) to a piece of footwear.” Moreover:

Footwear trace evidence is trace evidence that is recovered from footwear. Types of trace evidence that could be recovered include skin, glass fragments, body hair, fibres from clothing or carpets, soil particles, dust and bodily fluids. The study of this trace evidence could be used to link a piece of footwear to a location or owner.

For our present purposes, it is interesting that information technology is helpful in the form of *footwear databases*:

Forensic investigators can use computerized footwear databases to quickly compare the class characteristics between footwear impression and outsole profile of footwear outsoles stored in the database. This greatly reduced the time required to match shoeprint to. Examples include the Footwear Intelligence Technology (FIT) launched by the Forensic Science Service (FSS) in February 2007. Such systems contains information on thousands of footwear patterns with daily updates from both manufacturers and police forces.

A team at the University of Buffalo led by Sargur Srihari reported (Ramakrishnan, Malgireddy, & Srihari, 2008; Ramakrishnan & Srihari, 2008) about shoe-print extraction from latent images, by resorting to *conditional random fields*.

<http://en.wikipedia.org/wiki/> followed with the name of the entries, with each blank space replaced with an underscore.

⁶⁵ Don Foster’s stylometric analysis (see Foster, 2001, chapter 3) was important for identifying the Unabomber. Also the latter’s sister-in-law, a professor of philosophy came to believe she knew he was the Unabomber because of what he wrote and the way he wrote. See in Section 6.1.10, and in fn. 94 in Chapter 6 in particular.

⁶⁶ http://en.wikipedia.org/wiki/Forensic_footwear_evidence.

Let us turn to a few other specialties. If real estate is involved in a case, this may concern situations where a structure did or may collapse, or where there was a fire and structural engineering and fire simulation experts need investigate (either concerning negligence, or arson).⁶⁷ Their models in fire simulation within a building are in *computational fluid dynamics*. In less dramatic circumstances involving real estate, surveyors may testify as expert witnesses in court (Clarke, 1985; Watson, 1975).

Forensic accounting (e.g., for *fraud investigation*) is specialised per countries: see Lemar and Chilvers (1995) for Britain; Frank, Wagner, and Weil (1994) and Bologna and Lindquist (1995) for the U.S.A.; and Zier (1993) for Canada. The Wikipedia entry⁶⁸ remarks in the introduction:

Forensic Accounting is the specialty practice area of accounting that describes engagements that result from actual or anticipated disputes or litigation. “Forensic” means “suitable for use in a court of law”, and it is to that standard and potential outcome that Forensic Accountants generally have to work. *Forensic Accountants*, also referred to as *Forensic Auditors* or *Investigative Auditors*, often have to give expert evidence at the eventual trial. All of the larger accounting firms, as well as many medium-sized and boutique firms, have specialist Forensic Accounting departments. Within these groups, there may be further sub-specializations: some Forensic Accountants may, for example, just specialize in insurance claims, personal injury claims, fraud, construction, or royalty audits.

We have already seen how link analysis and data mining have been put to good use in order to uncover frauds: by mining email databases in the Enron case

⁶⁷ As http://en.wikipedia.org/wiki/Fire_investigation points out: “Fire investigation is one of the most difficult of the forensic sciences to practice. In most forensic disciplines, even the basic question of whether a crime has been committed is normally obvious. During a fire investigation, an entire process must be undertaken just to determine if the case involves arson or not. The difficulty of determining whether an arson fire has occurred or not arises because fires destroy evidence. A fire investigator looks at what is left behind after a fire and obtains information to piece together the events that occurred in the moments leading up to the fire. One of the challenging aspects of fire investigation is the multi-disciplinary base of the investigator’s job. Fires can be caused by or involve most things people see or use. For this reason, fire investigators need to know not only basic science of fire behavior, but knowledge of many different areas of study (including construction, electricity, human behaviour, vehicles etc.) is helpful. If the fire origin has, for example, a gas appliance, an investigator should know enough about appliances to either include or exclude it as a possible cause of the fire. Fire investigators must also know their own limitations and call upon experts to assist when needed. Accordingly, fire investigators sometimes work with forensic electrical engineers (when examining electrical appliances, household wiring, etc.) or others skilled in forensic engineering (gas-powered appliances, air handling equipment, gas delivery systems, etc.)” Concerning certification of the experts, the same entry explains: “In the USA, some states require that fire investigators obtain certification as a Certified Fire Investigator (CFI). The International Association of Arson Investigators, a professional group of fire investigators, grants CFI certification. The National Association of Fire Investigators (NAFI), a professional association of fire and explosion investigators, offer several National Board Certified fire investigation certifications, including Certified Fire and Explosion Investigator (CFEI), Certified Vehicle Fire Investigator (CVFI), and Certified Fire Investigation Instructor (CFII). For more information, please visit their website at <http://www.nafi.org>.”

⁶⁸ http://en.wikipedia.org/wiki/Forensic_Accounting.

(Section 6.2.1), by trying to identify fraudsters and accomplices at online auction sites (Section 6.2.3), the U.S. Federal Defense Financial Accounting Service's EDS project (Section 6.2.6), and the tool for detecting fuel frauds developed in Poland (Section 6.2.8). The latter project is a case in point for how conventional forensic accounting is in practice powerless when faced with very complex flows of transactions, unless use is made of link analysis or data mining technology.

8.4 The Contribution to Forensic Science of Anthropology and Archaeology

8.4.1 *Forensic Archaeology and Anthropology*

Some interdisciplinary interfacing of forensics sometimes occurs with kinds of reconstruction other than forensic; for example, forensic archaeology applies techniques from archaeology to criminal investigation.⁶⁹ Forensic archaeology applies techniques from archaeology to criminal investigation: see Hunter et al. (1997). The following is quoted from a call for participation in a workshop on Archaeology and Forensic Science, held at the British Academy in London on 27 February 2007, in concomitance with the Council for British Archaeology's 2007 Winter General Meeting.

Forensic archaeology is a relatively new concept in Britain and these presentations explore how archaeology in its many facets has developed from its traditional roots into the arena of criminal investigation. As these talks show, this is mostly, but not exclusively, concerned with searching for and excavating clandestine graves, including mass graves. Search involves systematic sequencing of various techniques including the use of aerial imaging, geophysical survey, as well as cadaver dogs but, unlike more traditional archaeology, is affected by the decay dynamic of buried human remains. Recovering modern buried human remains also poses problems in that the type of evidence needed can be very different from the evidence archaeologists and anthropologists normally identify. It also needs to be obtained within the constraints of a novel legal framework and presented in court. These issues are pursued and, using case studies, a number of different scenarios are outlined which detail the different methodologies used in excavation and the different types of evidence – archaeological, anthropological and environmental – that could be used to obtain a successful conviction.

The titles of the talks are indicative of how disciplines meet within forensic archaeology: "Archaeology and the crime scene", "Physical anthropology: forensic identification, trauma and case studies", "Geophysics: divergence, human decay dynamics and case studies", "Applications of ecology, botany, and palynology to criminal investigation". *Palynology* (see Section 8.5.5 below) is the study of pollen, in respect of morphology, biochemistry, and biogeography. The public consisted of archaeologists: active, retired, or students.

⁶⁹ See Hunter et al. (1997).

Even though the quotation given earlier states that forensic archaeology is rather new in Britain, it must be said that whereas in the United States, forensic science is strong in physical anthropology, apparently Britain is ahead in other disciplines for forensic identification (including of human remains), that are grounded in forensic archaeology. Various scientific disciplines contribute techniques to archaeology, and experts conversant with both archaeology and forensics find more rigour within the former disciplinary tradition, which has much to contribute to forensics.

In the rest of this chapter, as well as in Sections 8.4.2, 8.5.2, and 8.5.5, I am going to provide information from notes I took at the 2007 London workshop referred to. John Hunter of the University of Birmingham is an archaeologist who moved into forensic archaeology, and (like the other speakers from the workshop) assists the police and appears in court as an expert witness. He started his talk by dispelling the misconception that forensic archaeology (i.e., archaeology used in forensic environments) is forensic science used in archaeology.

Around a serious crime event, the incident is attended to by an array of professionals: the scene of crime officer, the senior investigating officer, the coroner, the Home Office pathologist, the Forensic Science Service, the scientific support manager, the Crown Prosecution Service, and others.

A common ground for archaeology and forensic science is the search and recovery of human remains, skeletal analysis, and analytical science. Key divergences include: the timeframe of operation (archaeologists choose when going out, whereas a police investigation cannot be deferred, e.g., because of bad weather), hierarchies (Hunter referred to himself as being quite powerful within his archaeological team, whereas when he is called to assist the police, or is called to testify in court, the mutual positioning is different), a two-way knowledge base (which is not the case of archaeological practice), legal constraints (on disclosure), the role of the expert witness (as opposed to an archaeologist addressing scholars), and “publication” to a jury (as opposed to a peer-reviewed journal).

Concerning appearing in court as an expert witness, Hunter (like another speaker on the same day) pointed out that whereas one usually thinks about trials in terms of justice being done, actually trials are games, and the barrister who has been most persuasive, wins. It is the task of the barrister of the other side to try to ruin your professional reputation as an expert witness.

Moreover, unlike archaeology, forensic archaeology deals with the recent dead and the living. When dealing with graves, in archaeology it is necessary to distinguish between context and non-context. In contrast, in forensic archaeology it is necessary to distinguish between context and contamination. Preserving the integrity of the grave can facilitate finding out about identity, cause and manner of death, and the interval since death. Have the remains *been* buried (by somebody), or have they *become* buried? A buried body may cause different types of vegetation change: the vegetation is different from the surroundings, for example, either higher, or lower. It is lower on the grave than surrounding vegetation, is the grave was originally covered with stones. Apart from the vegetation change, there also is a topographic change. There can be expected to be a disturbance caused by body

remains. There may be linkage between sites. The cues on (or in) the terrain may be artefactual, ecological, or ecofactual (e.g., intrusive vegetation).

There is a window of opportunity that should not be lost, when the police is looking for a body after a death presumed to be recent. After three weeks from death, the body is decaying, and this continues for other three weeks, during which the body is emitting temperature. Thermal imaging in order to find out a burial, when there has been a crime, needs to exploit that window of opportunity. Non-invasive imaging techniques are available, and recommended. The more invasive a forensic technique, the greater the risk of losing forensic evidence, because of various reasons. A non-invasive imaging technique can reconstruct the volume and shape (inside the ground) of a mass grave: how deep it is, how long, and so forth. This can be visualised by computer in three dimensions, as a volumetric model, and animated (by having the system of reference with the three axes rotate). The same example was made during the same workshop by Cheetam, in a talk about the forensic and archaeological application of survey methods from geophysics; the given volumetric model was developed by applying a technique that measures earth resistivity (see in Section 8.5.2 below).

Hunter pointed out that the search for a grave may have a positive outcome, i.e., recovery, or a negative outcome, i.e., elimination. It may be a search concerning a recent incident, with a named victim, with a suspect being identified, and with an unknown disposal site, yet with the body remains being recovered. Or then it may be an old incident, with no name to the victim, with no suspect, but with a specific location. An example of the latter kind of situation is the case of a witness who reports seeing (or that a relative had seen), thirty years before, a child being buried at a specific location. This is a more usual kind of intelligence.

When searching for a grave, there are distinctions to be made concerning spatial scope. It may be a search in the backgarden of a given urban house, using imaging techniques from geophysics. Or then, the scope may be broader, and aerophotography may be resorted to. It is only if and once the remains *are* found, that one can look into the matter and say whether there was a murder or not. Questions proper to ask include: How was the grave dug? Was it dug in a hurry, or carefully prepared? Is there foreign material in the grave? Did the perpetrator leave any traces in or around the grave? The grave is a very rich source of material. There is a pattern to how people tend to dispose of bodies. They tend to dispose of bodies in places they know. The expert in court only gives information. It is the barrister's task to interpret. For example, the expert may say whether the material taken out of the grave was taken off site, or whether the material found in the grave was put there from on-site or off-site.

Taphonomics studies decay. Analysis in taphonomics interacts with other disciplines. The expert is likely to ask the entomologist, the climatologist, and so forth. One of the examples illustrated by Hunter was a mass grave excavation, showing depositional events and taphonomic variables. One may find commingled, saponified remains. An important notion is joints: fifteen main points on the body. As mentioned earlier, a computer-generated section of the mass grave can be visualised

in three dimensions and rotated (actually, such imaging matters because it delimits the outer contour of the mass grave).

8.4.2 *Factors Involved in Forensic Anthropology*

8.4.2.1 Preliminaries

The second lecture at the workshop on Archaeology and Forensic Science, held at the British Academy in London on 27 February 2007, was given by forensic archaeologist and anthropologist Corinne Duhig, affiliated with Anglia Ruskin University and with Wolfson College of the University of Cambridge, and a consultant for “Gone to Earth”, a small firm (with three consultants in all, operating individually in the whole of Britain). The logo of “Gone to Earth is the profile of a fox excavating a bone. Actually, scavengers such as foxes (and crows) disturb burials and sometimes cause remains to be uncovered. It must be said that in Britain there is a policy different from policies from the Continent concerning foxes: as there is no rabies in the country, foxes are not systematically culled. Foxes are frequent in urban backgardens. (What they do to your garden may prompt unprinted expletives.)

By the late 2000s, body remains (even ancient) are more likely to be reported in the United Kingdom that it used to be a few decades ago. The forensic anthropologist’s⁷⁰ (and apparently Duhig’s own) breakdown of casework by type is: ca. 75% non-forensic (non human, or archaeological), the rest being forensic (homicide, suicide, misadventure, or open), or “other”. Physical anthropology as applied to forensic identification, trauma and case studies, is different from physical anthropology as done in mainstream archaeology. The role of the forensic anthropologist is search and excavation, assistance to the Home Office Pathologist (who by the late 2000s has been more receptive to the anthropologists than, say, twenty years earlier), defleshing and reconstruction (a body still with soft tissue is reduced by the anthropologist to a skeleton, and then rebuilding is carried out; in archaeology, too, there is cleaning and rebuilding, but of course there is no recent soft tissue).

Then the anthropologist develops an anthropological profile for identification. A lot of it is exclusion; for example, the pathologist is notified by the anthropologist that the body does not match the profile. Other tasks of the anthropologist include skeletal trauma mapping, sequencing and interpretation, and taphonomic interpretation.⁷¹ The remains may be fresh, or decomposing, or fully skeletonised, or burnt, or cremated (usually perpetrators don’t know how to cremate well), or disrupted (e.g., because of a road accident, or an airplane crash), or dismembered (which was deliberately done by a perpetrator), or processed (by a perpetrator, to make the remains less identifiable).

⁷⁰ Marcella Sorg (2005; 3rd edn. 2009) provides an overview of *forensic anthropology*.

⁷¹ William Haglund (2005; 3rd edn. 2009) provides an overview of *forensic taphonomy*, which is about burial.

The Big Four of identification are: ethnology, sex, age, and stature. Ethnology for the forensic anthropologist at present in the United Kingdom involves a greater range than archaeologically (as, e.g., now there are people from South Asia, the Far East, and sub-Saharan Africa in the country, and that wasn't the case in antiquity or the early Middle Ages). It is concerning the identification of sex and age, that anthropologists are most useful to the police. Homicide demographics involve mainly young adult males. This is very different from archaeological remains. As to stature, one ought to bear in mind two things:

- (a) informant error, as people quite frequently overestimate the height of others, and moreover (especially males) their own stature;
- (b) size for postulated activity, e.g., a required limb length to do something: the forensic anthropologist has to work out from length and angulation of limbs, whether it is possible for the given person to have done a given activity, e.g., movement. Could that child have extended an arm and picked up that given thing?

8.4.2.2 Ante-mortem Skeletal Pathology, and Para-, Peri-, and Post-mortem Traumas

As explained by Corinne Duhig in the same lecture, the identification of a person from body remains involves various factors. It depends on reliable record or recollection of informants, as well as preservation in remains. For *ante-mortem skeletal pathology*, the range of values includes: life-history trauma (battery, torture); evidential trauma; and non-trauma. Identification as based on preservation in remains also depends on epigenetic/non-metric traits (e.g., dental variables can be extremely variable); on body build (degree of muscularity: it depends on how much tissue you have, in the available remains); on handedness (was that person left-handed?); and on shoe size (the latter is something that is not asked in archaeology).

Let us turn to "*para-mortem*" trauma. This is a term invented by Duhig herself. Identifying para-mortem trauma properly has important implications at a criminal trial. Violence may have been directed at a person alive or perceived to be alive, or, in contrast, at or close to the time of death. Violence may have been for the purpose of homicide or suicide, or of causing pain, or of mutilation. Injuries may have been produced by blunt weapons, or by sharp weapons, or by projectiles. The latter, in turn, may include, e.g., bomb fragments. Moreover, para-mortem trauma may have resulted from accidental injury and death (e.g., in an air crash). Forensic anthropologists do not have the responsibility for determining the type of death.

Types of para-mortem trauma include: blunt trauma, sharp-weapon trauma, and projectile wounds. In particular, blunt trauma (which is involved, e.g., in crimes of passion) may be: simple depressed fracture of skull; various crushed features of skull; or fracture of the post-cranial skeleton (i.e., of the skeleton other than the skull). Kinds of post-cranial fracture importantly include defence injury to a forearm (as a person under physical attack usually rises the forearms to protect him- or herself).

Sharp-weapon trauma consists of incisions. These may be stab wounds (which tend to be on the edge of ribs), or cut/slash wounds. The latter often are superficial; they are common in accidents. As to projectile wounds, they may be entry wounds (more regular; if in the skull); or exit wounds (less regular, larger; if in the skull). Small calibre projectiles often stay in, and have no exit, so there would be an entry wound, but no corresponding exit wound. Holes in the skull, which in a forensic context are identified as projectile wounds, if found in archaeological remains instead, at first sight may be believed to be due to the skull being damaged because of defective preservation. For the forensic anthropologist analysing *para-mortem* trauma, it is important to determine *wound sequencing*, i.e., the direction and sequencing of wounds. May I add that this is interesting in view of *models of time* from artificial intelligence or, more broadly speaking, from computer science (see Section 8.4.2.3). Constraints preclude some candidate sequencing. This could be a promising direction for computer application to forensic anthropology.

Having dealt, with *para-mortem trauma*, let us turn to *peri-mortem trauma*. This concerns early decomposition stages. It also concerns violence directed at a body: dismemberment, defleshing, and so forth, as having been carried out by a perpetrator. It is also of interest to determine for which purpose, such violence directed at a dead body was carried out. And finally, there is *post-mortem trauma*. It concerns later decomposition stages. Post-mortem trauma may be due to human activity (accidental disturbance, or second burial), or to animal activity (damage, scattering), and so forth. Peri-mortem and post-mortem processing wounds include, e.g., cutting by blades or by saws, for the purpose of dismemberment.

8.4.2.3 A Digression on Formal Models of Time

An important class of temporal representations from artificial intelligence is such methods that are based on variants of *temporal logic*. We are not referring to formal representations of tense in natural language. Temporal logics are independent of natural language, and therefore are not directly concerned with tense. Temporal logics as used in artificial intelligence⁷² were introduced by Allen (1983b, 1984, 1991),⁷³ and originally were only concerned with intervals (by means of an *interval calculus*, rather than with time points. Temporal logics have been used, for example,

⁷² Within artificial intelligence, see e.g. Shoham and McDermott (1988) about temporal reasoning.

⁷³ A useful online survey of temporal logic is Galton (2008). van Benthem (1995) is more detailed and more technical; whereas van Benthem (1983, 2nd edn. 1991) is a book on temporal logic. Fisher, Gabbay, and Vila (2005) is a handbook. Cf. Antony Galton's book (1987) and critique (1990) of James Allen's *theory of action and time*. Also consider Alur, Henzinger, Kupferman (2002) *alternating-time temporal logic*, which eventually gave rise to Wooldridge and van der Hoek's (2005) *Action-based Alternating Transition Systems (AATS)*, used by Bex et al. (2009) in order to represent reasoning about the narrative of an alleged crime (see Section 3.4.4.4 in this book).

Surveying the broader context of kinds of temporal representations, Fabio Alberto Schreiber explains (1994, section 3): "In the logicians' community there is a strong debate on the need of creating a non standard *Temporal Logic*. Scholars having mathematical and physical background and interests claim that times can be designated by terms in a first order theory, which is more

for tasks in engineering (e.g., Knight, Ma, & Nissan, 1999). In James Allen's interval calculus, there is a composition table of basic interval-to-interval relations, e.g., if they contain each other, or partly overlap. That approach to qualitative reasoning about time inspired Tony Cohn's approach to qualitative reasoning about space. It is based on Clarke's *calculus of individuals* and uses a set of eight basic relations on spatial regions, i.e., how one region connects to another. Cohn, Gooday, and Bennett (1995) compare structures in spatial and temporal logics. Cui, Cohn, and Randell (1992) show how space and time are both taken care of in their formalism. Cohn et al. (1994) show how temporal continuity is exploited in their qualitative spatial calculi. The papers Nissan (2001g, 1997b) are about formalisms of space, more broadly meant.

In Section 5.3.3.2 we considered *time granularity*, different *grainsizes* being, for example, a year or a day. Bettini et al. (2000), a book on time granularities and how they are processed in representations from computer science, in particular from the viewpoints of database design, of constraint reasoning, and of automated knowledge discovery. Also see Bettini, Wang, and Jajodia (2002); cf. Schreiber (1991, 1994).

By contrast to temporal logics, different kinds of representation were developed for linguistics by semanticists, in order to represent the semantics of *tense*, as intended by linguists: Alice ter Meulen's book (1995) was reviewed by Nissan (1998b), a review reworked into appendix B of Nissan (2011a). In her book, "temporal reasoning is considered a form of logical reasoning, in which quantificational force, binding, and context change are core concepts" (ter Meulen, 1995, p. 3). Her structured semantic objects are *Dynamic Aspect Trees (DATs)*.

Computer science also has temporal representations for concurrency. One which is considerably complex, and is used to modelling concurrent computation, is Tony Hoare's notation (and respective theoretical framework) known as *Communicating Sequential Processes (CSP)*, which he published in a book by the same title (Hoare, 1985). It is a powerful technique, and requires a good understanding of the theory behind it. A current textbook on the subject is Roscoe's *The Theory and Practice of Concurrency* (Roscoe, 1998). The latter book is about the untimed version of CSP, with modelling without measuring the passage of time. By contrast, for modelling also such measurements (in either real numbers, or as discrete time points), there exists a version of Hoare's approach that has been named *Times CSP*:

than adequate for time modeling. Besides [Bertrand] Russel and [Willard] Quine, these authors – referred often to as *detensers* – comprise [James] Allen, [Drew] McDermott, [Robert] Kowalski and others. People interested in linguistic aspect of logic, on the other hand, feel that time is tightly woven into languages, under the form of different tenses of the verb, and they relate modal to temporal notions [...] [Arthur] Prior and [Georg Hendrik] Von Wright belong to this *tensers* school. Just to show how things become complicate, we only mention that, in his theory of tense, [Hans] Reichenbach defines three different times for each tense: an *utterance* time, at which the sentence is expressed, a *reference* time, which we refer to in the sentence, and an *event* time, which is the object of the sentence".

it reinterprets CSP over time, records the exact time at which each event occurs, it associates with events non-negative real numbers.⁷⁴

A simpler representation for concurrent processes and temporal constraints is *Petri nets*. Think of such a variant of a flipper game, that little balls (we are going to call them *tokens*) are scuttling along routes between obstacles, that can be figured out as being small doors, or closed valves (these we call *transitions*). There are one or more such conduits that each reaches such a valve (i.e., incoming arcs upstream of the transition), and one or more conduits that proceed forth from it (outgoing arcs downstream of the transition). In each conduit, there will be at most one ball at a time. One or more balls will stop at the transition, and this valve will not open, unless from each and every incoming arc, a ball has arrived. If all such balls are there, then the valve would open (i.e., the transition *fires*), and the balls would move further. There is a major departure with respect to the real physical world. In the latter, you would expect that if you had, say, three marbles right before the valve, and the valve opens, then beyond that valve those marbles will still be three balls. Not so with the kind of directed graphs that are known as *Petri nets*. If beyond the valve there only is one outgoing arc, then those three marbles would turn into just one marble, whereas if two arcs leave the open valve, then those three balls will become two: one for each outgoing arc. Petri nets are such directed graphs, that along every route (itself made up of arcs), there is an alternation of *places* (drawn as hollow circles), and *transitions* (drawn as a barrage: a short line drawn across). Moreover, *tokens* move through the graph according to rule we have described. See Fig. 8.4.2.3.1.

As I wrote in Nissan (2011a, appendix A):

Petri nets have proved to be a major paradigm for other computer application domains, e.g., for scheduling in manufacturing, or for logic validation when modelling digital systems. This has not been the case in legal computing. Petri nets were applied to legal systems

Fig. 8.4.2.3.1 Three successive states in the execution of a sample Petri net

⁷⁴ It is covered in a textbook by Steve Schneider (1999). Also see Schneider (2001). He has also co-authored a book on security protocols (Ryan, Schneider, Goldsmith, Lowe, & Roscoe, 2000).

in Holt and Meldman (1971).⁷⁵ In the literature of the discipline of artificial intelligence and law, a few papers are concerned with temporal structure (Bauer-Bernet, 1986; Poulin et al., 1992; Vila and Yoshino, 1995, 1998;⁷⁶ Knight, Ma, and Nissan, 1998), and Petri nets have been applied quite sporadically, less frequently than temporal logic, the latter being an approach in artificial intelligence which was introduced by Allen ([1983a, 1983b], 1984). Farook and Nissan (1998) have applied Petri nets to the representation of mutual wills. Valette and Pradin-Chézalviel (1998), in the same journal special issue as the former, applied time Petri nets to the modelling of civil litigation. Rossiter et al. (1993) described an application of Petri nets (within a formal model for quality assurance) to legal documentation organized as hypertext. Raskin et al. (1996) modelled by means of Petri nets, *deontic* states, i.e., states of obligation or permissibility.

For most purposes, the representation of *asynchronous, concurrent processes* is best suited by Petri nets indeed. The representation of concurrency among processes is not well suited by *finite state automata*, because for a large number of tasks, the number of states becomes unwieldy. Petri nets were originally defined by Petri in 1962 (Petri, 1966), and then refined and named after him by Holt (e.g., Holt, 1971; cf. Miller, 1973). Research into this paradigm developed during the 1970s and boomed in the 1980s. The literature is vast, with a choice of general works and a variety of proceedings. Among the books, see, e.g., Proth and Xie (1996), Peterson (1981), David and Alla (1992), Reutenauer (1990), Fernandez and Best (1988). Over the years, several different classes of Petri net formalisms were introduced, but we confined ourselves, in this article, to a simple application of the standard kind. As to fancy kinds of Petri nets, it may be that some amongst the present readership may find it useful to find about *predicate/transition nets* and then apply it in their own research (Genrich & Lautenbach, 1979). Reutenauer (1990) was concerned with the mathematics of Petri nets. Brown (1989a, 1989b) provides a treatment of Petri nets in terms of formal logic. In algebraic logic, the *box calculus* is a causal algebra with multilabel communication, within the Petri nets paradigm (Best & Hall, 1992; Esparza & Bruns, 1994). Olderog (1991) draws a comparison of three formalisms for representing concurrent processes; these include Petri nets.

8.4.2.4 Software Tools for Human Anatomy

There exists software for anatomy. For example, a workshop on the Mathematical Foundations of Computational Anatomy (MFCA'06) was held in September 2006

⁷⁵ Also by Anatol Holt, cf. Holt (1971, 1988). In Holt (1988), *diplans* were introduced, for the purposes of studying coordination in the workplace and of automation. “Diplans are the expressions of a new graphical language used to describe plans of operation in human organizations. With diplans, systems of constraint, which may or may not take the form of procedure definitions, can be specified. Among the special strengths of diplans is their ability to render explicit the interactive aspects of complex work distributed over many people and places – in other words, coordination. Diplans are central to coordination technology, a new approach to developing support for cooperative work on heterogeneous computer networks.” (ibid., from the abstract).

⁷⁶ Cf. Vila and Yoshino (2005), and cf. Fisher et al. (2005) on temporal logics in AI.

in conjunction with the MICCAI'06 conference. Works in computational anatomy are also presented, for example, at the Annual International Conferences of the IEEE Engineering in Medicine and Biology Society (EMBS), and at the Annual Meetings of the International Society for Computer Assisted Orthopaedic Surgery (CAOS).

Arbabi, Boulic, and Thalmann (2007a, 2007b) described a fast method for finding the range of motion in the human joints, and in the hip joint in particular. The context is the diagnosis of hip disease: "Finding the range of motion for the human joints is a popular method for diagnosing", and the claim was made that it is both more trustworthy "and easier to find the range of motion by employing computer based models of the human tissues. In this paper we propose a novel method for finding range of motion for human joints without using any collision detection algorithm. This method is based on mesh classifying in a cylindrically segmented space" (Arbabi et al., 2007b, from the abstract). The method illustration was the determination of the range of motion in the human hip joint, but actually the method could be applied more generally to the joints in the human body.

From that same Swiss team in Lausanne, also see Abaci et al. (2007a), on object manipulation and grasping "in an object manipulation context. Our proposal is a novel method that combines a tubular feature classification algorithm, a hand grasp posture generation algorithm and an animation framework for human-object interactions. This method works on objects with tubular or elongated parts, and accepts a number of parameter inputs to control the grasp posture" (ibid., from the abstract).

Being able to model grasping by computer, as well as being able to determine by computer the range of motion in the human joints (even though this is for the purposes of diagnosis in vivo), is arguably relevant for questions akin to the one asked at the end of Section 8.4.2.1 above: "Could that child have extended an arm and picked up that given thing?"

The history of the project of modelling hip joints is related in the following, which is quoted from Magnenat-Thalmann and Gilles (2007, p. 25)⁷⁷:

Since 2002, Prof. Nadia Magnenat-Thalmann of the Swiss National Center of Competence in Research Co-Me has been leading a project on interactive clinical visualization for hip joint examination. The goals of this research are to build a 3D patient-specific functional model of the hip joint, of the hip joint, and to develop interactive tools allowing clinicians to examine hip behaviour. Such tools will be invaluable aids in diagnosis and treatment planning, particularly for osteoarthritis and impingement syndrome pathologies.

Also consider, e.g., *MuscleBuilder*, a computer-graphic modelling tool for human anatomy (Aubel & Thalmann, 2007; cf. 2000, 2001, and Gutiérrez et al., 2005, 2007). In cultural terms, this is an extension of the genre of anatomy handbooks, which itself is grounded in the history of the ideas, as well as of the arts. Jonathan Sawday's (1996) is a book in cultural history, concerned with the dissection of the human body in the culture of the English Renaissance, in relation to conceptualisations of the body in several domains, including the arts.

⁷⁷ Nadia Magnenat-Thalmann leads a team in Geneva, whereas Daniel Thalmann leads a team in Lausanne. Cf. in Section 5.2.15 above.

Take illustrations in anatomy handbooks, through history, as made by illustrators by observing dissected bodies. Bernez (1994) discussed the aesthetics of seventeenth-century Dutch painter Gérard de Lairesse's illustrations for Bidloo's *Anatomia Humani Corporis*. Bernez shows how anatomic drawings within the history of art actually reflected moralising intents, about life and death, on the part of the artists, and, paradoxically, aesthetic ideal as well. Bernez shows that de Lairesse's anatomic drawings are somehow amenable to a seventeenth-century Dutch genre he practised, the *Vanitas*: "Anatomy as Vanitas: the allegorical representations of life's brevity [. . .]" (ibid., p. 213). "The Vanitas was a genre of still-life painting in which certain objects representing the fruitfulness of nature or the value of human activities were contrasted with elements which evoked the triumph of death" (ibid.).

EnVision (2002) relates about a project led by Michael I. Miller, director of the Center for Imaging Science at Johns Hopkins University, concerning the application to neuroscience of computational anatomy:

"Computational anatomy could be described as a digital textbook of anatomy, with all its variability in healthy humans, adjusted for things like gender, age, and ethnicity, and also in pathological situations that affect anatomy", said Grenander. "The main difficulty is that anatomical substructures form highly complex systems, with variation being the rule", Miller said. As he said in an interview published earlier this year [(Taubes, 2002)], "If machines can compute structures that are equivalent to the structures we see in the world, then we can begin to understand them. In computational anatomy, we now have equations that describe how tissues can grow and bend and morph and change. These equations seem to generate very realistic structures".

Miller's application is to the brain, a soft tissue, "to learn how tissues grow, assume new shapes, and 'morph' into mature structures" (ibid.). Miller is quoted as saying: "Our mathematical formulation deforms structures in a coordinate space, and thus the original structures are entirely recoverable computationally. That is the difference between morphing and morphometrics" (ibid.). In morphing, just a photometric transformation is carried out, without any coordinate system allowing recovery of the previous shape. "For the past decade, Miller's group has been developing computational methods to analyse gross anatomical structures in the human brain, with the objective of creating tools to help neuroscientists and diagnosticians learn from changes in brain substructures. The underlying mathematics are supplied by metric pattern theory, a formalism developed by Ulf Grenander in the Division of Applied Mathematics at Brown University" (ibid.).

Several of the short papers in the special issue on "The Digital Patient" of *ERCIM News* (April 2007) describe such projects that revolve around computational models of human anatomy, and being carried out in various European countries. For example, Xavier Pennec (2007) introduces a project applied to the brain (one of Pennec's partners in France is also a partner of Miller).⁷⁸

⁷⁸ At <http://www-sop.inria.fr/asclepios/projects/ARCBrianVar/> a description is found of Pennec's project.

Among the applications, two that are generally relevant for our present concerns include “the spatial normalization of subjects in neuroscience (ie mapping all the anatomies into a common reference system) and atlas-to-patient registration in order to map generic knowledge to patient-specific data” (Pennec, 2007). Arguably, atlas-to-patient mapping is relevant for computational anatomy to be of any use to forensic anthropology.

González Ballester, Büchler, and Reimers (2007) “are constructing advanced statistical digital models of bone shape and biomechanical properties. These models will lead to the design of a new breed of orthopaedic implants that will guarantee an optimal fit for the whole range of patients” (ibid., p. 27). “During this project, we have extended our ability to analyse the surface shape of anatomies to also include internal structures and bone density information. This results in a compact statistical description of the variability in bone shape and density, and the correlation between them” (ibid.). This suggests, I would say, that conceivably, some similar model could be of use to forensic anthropology and perhaps to forensic ballistics, in order to simulate what may have brought about the conditions observed in a dead human body in a forensic setting.

Computational models of human anatomy find expression also other than through the 3D visualisation of the anatomy. The simulation of pain in robotics has been reported about. Reportedly in the late 2000s, the University of Gifu was expecting to make use of a patient-robot for medical training, in particular in the palpation of patients, before having the trainees exercise in palpation directly on humans. The patient-robot was developed by Yuzo Takahashi. The robot has 24 internal sensors, and if touched in a body part (corresponding to a human body part), it speaks up and conveys the physical distress being simulated. Eight kinds of symptomatology are recognised in the prototype, and the inclusion of more is envisaged. Its skin produces the sensation, when touched, of human skin.

Victor Ng-Thow-Hing is active both in robotics (e.g. Hauser & Ng-Thow-Hing, 2010), and in biomechanical anatomical models of human and animal bodies, a field in which he was supervised by Eugene Fiume in Toronto (Ng-Thow-Hing, 1994, 2001; Agur, Ng-Thow-Hing, Ball, Fiume, & McKee, 2003; Teran et al., 2005; Wu, Ng-Thow-Hing, Singh, Agur, & McKee, 2007). Musculotendon units were built by sketching interactively profile curves directly onto the bones; the curves can be subsequently adjusted to interactively edit the shape of the resulting muscle. As an alternative for producing an initial shape of the muscle, it is also possible to load into the system pre-built muscles from an anatomical library. The muscle models generated were used as *force actuators*, in a robotic simulation sense. The simulation framework allows muscles to be visualised, and the simulation combines the muscles with articulated skeletons. These are made up of rigid bones and of joints; there are various joint constraints.

Hutchinson, Ng-Thow-Hing, and Anderson (2007) applied an anatomical model to reconstruct the turning and running performance of the dinosaur *Tyrannosaurus rex*. This is an example of *computational palaeontology*. That model combined *mass models* as those used by Ng-Thow-Hing in *digital human modelling* at Honda, the *B-spline model* he was using for muscle, and generated a versatile shape primitive

for estimating mass properties of body tissue. Just as he could do that for extant animal species or for humans, he was able to do that for the fossil species, and the model was validated with an ostrich carcass.

8.5 Aspects of the Contribution to Forensic Science of Geology, Geophysics, and Botany

8.5.1 Forensic Geology

Forensic geology (also called *geoforensics*, or *forensic geoscience*) is an important discipline, for criminal investigation as well as for the purposes of litigation, e.g. concerning environmental damages.⁷⁹ Laurance Donnelly (2003, p. 8) pointed out: “Over the past one hundred years or so, several crimes have been solved due to the expertise provided by geologists. However, due to the sensitive and confidential nature of police investigations, only occasionally are these reported in the scientific literature”. In a 1893 German-language handbook for examining magistrates, “Hans Gross, a criminal investigator and professor of criminology [. . .] was one of the first to advocate the use of microscopes in mineralogical studies analysing ‘dust’ and ‘dirt’ on shoes and ‘spots’ on cloth” (Donnelly, 2003, pp. 8–9). This approach was “subsequently used by George Popp in 1904, during a murder investigation (the Eva Disch case), in Frankfurt, Germany” (ibid., p. 9). In France, Edmond Locard (1877–1966), a star of criminalistics who used inventively a variety of techniques (see Section 8.7.1 below), concerned himself with the analysis of dust traces, too, and described them at length (Locard, 1930). “The Federal Bureau of Investigation (FBI) have been using forensic geology since 1935, initially to help solve the Matson kidnapping case” (Donnelly, 2003, p. 9).

Turning to the 2000s, Bergslien et al. (2006) have been trying to apply field portable X-ray fluorescence (FPXRF) spectrometry to both forensic and environmental geology. “There are many environmental applications that may also intersect the forensic arena, such as tracking pollutants in the environment to their source” (ibid., p. 19). A forensic application they reported about “involves analysis of mineral and rock deposits on automobile tires, shoes, carpets etc. and direct comparison with materials found at the crime scene. Knowledge of compositional changes in geological formations may aid in tracing movements of a crime suspect or victim” (ibid.).

At the inaugural meeting of the Forensic geoscience Group of the Geological Society of London, on 20 December 2006 (Ruffell, 2006), Donnelly pointed out (Donnelly, 2006, pp. 3–4):

⁷⁹ Books on forensic geology, or geoforensics, as it is also called, include Pye and Croft (2004), Pye (2007), and Murray and Tedrow (1975).

There are a number of geologists in the UK, and internationally, who currently work with, or have recently worked with the police, other law-enforcers, environmental agencies and humanitarian organisations to help bring some types of crimes to successful conclusions. Some geoscientists have also been involved in forensic investigations in the mining, engineering, minerals and water sectors of industry, or during the investigations of geohazards (also known as natural disasters). The common ground for all these sub-disciplines is that geoscience practice and results may end up as part of a public, international or legal enquiry by government or in courts of law.

Forensic Geoscientists may be broadly divided into two principal fields, depending on their skills, expertise and capabilities. Firstly, there are the laboratory-based geologists who may include for example; geochemists, mineralogists, petrologists, micro-palaeontologists and isotope specialists. These may be involved with forensic investigations to; provide physical evidence for use in court, assist in an investigation, provide intelligence or identify the location of a crime scene. In short, geoscientists may link an offender (or object) to the scene or link the victim to an offender. Secondly, there are field-based geologists, who use their skills in exploration (including for example: geophysics, geochemistry, geomorphology, hydrogeology, environmental geology, remote sensing and geotechnics) to search the ground (to locate murder victim's graves, weapons and other objects).

As opposed to “[t]raditional police methods of finding graves [which] often involve large-scale ‘finger-tip searches’ and ‘trial-and-error’ excavations”, which apart from inefficiency, “may even destroy evidence and ignore subtle ground disturbances”, geologists “are trained to ‘read the ground’” (Donnelly, 2003, p. 9).

Donnelly proceeds to enumerate the main geologists’ techniques for crime scene investigations: the *mineralogical*, *petrological*, and *geochemical analysis* of rock and soil, or even *fossils* (resorting to palaeontology), for evidence in both criminal and civil cases.

Another method is the use of *geological maps* (and conceivably, *geographical information systems* produced by information technology, indeed a category within *geoinformatics* or *geomatics*, could be somewhat customised to reflect, e.g., ease to excavate).

In the UK, maps published by the British Geological Survey (BGS) have been used in police investigations to identify potential burial sites and topographic features mentioned in witness or suspect statements. Since search investigations were usually undertaken under a limited budget, geological maps can be used to eliminate areas of ground which are less likely to conceal buried objects [... E.g., in Kent, where the cretaceous bedrock was exposed, the use of a spade was considered unlikely. (Donnelly, *ibid.*).

McCann, Culshaw, and Fenning (1997) proposed that (in the words of Fenning & Donnelly, 2004, p. 11) “an initial desk or background study of the survey area” – as distinct from a visit to the site “in order to obtain what can only be described a ‘feel’ of the site (i.e. putting the desk study into context)” – should collect all available relevant information about the site, including, among the other things, “Present and historical topographical maps, usually from the Ordnance Survey”, “Geomorphological research studies and reports”, “Present and historical geological survey maps and associated descriptive memoirs from the British Geological Survey”, “Aerial and satellite photography, both current and historical”, “Present and historical soil survey maps with surface vegetation detail”, “Web search of the English Heritage database of geophysical survey results related to archaeological

investigations (Linford, 2002)”, “Library/web search for relevant scientific and press publications and photographs, including university research papers”, “Information on the nature and physical properties of the survey target (e.g. buried metallic weapon, victim’s discarded clothing, or buried human remains)” – in the words of Fenning and Donnelly (2004, *ibid.*), where the method of McCann et al. (1997) is adapted to forensic investigations.

Geomorphological observations enable to interpret “subtle natural ground disturbances arising from the particular crime. These might include vegetation changes, undulations, spring lines, breaks in slope, convex and concave slopes, disturbed ground, periglacial deposits, the occurrence of loose soil, drag marks, and the compaction of ground” (Donnelly, *ibid.*). The interpretation needs to discern whether these exhibit the effects of natural physical processes, or result from human activity, “for example mining subsidence, waste disposal, tipping and digging” (*ibid.*). Besides, *remote sensing* is another category of forensic techniques from geology.

Several other techniques of forensic geology belong in *geophysics*, and are treated in Section 8.5.2 below; as we are going to see, geophysical techniques for forensic investigations involve information technology, and there appears to be an important potential for more applications of computing. Donnelly (2003) explains the basics of geophysics in a forensic context as follows: “Geophysical surveys provide an alternative, more cost-effective method for locating disturbed ground and buried objects. Geophysical surveys measure the vertical and lateral variation of physical properties of the ground. These include electrical conductivity, magnetic, electromagnetic and gravity, etc. If a buried object provides a property contrast this can be used to detect its presence” (*ibid.*, p. 9).

It is to be remembered that specialists from different disciplines are involved in the forensic science side of criminal investigations, whether on the crime scene, or afterwards (or before the scene of the crime is identified). “Search teams are inter-disciplinary and involve the integration of specialists such as ground search personnel, dog handlers, helicopter pilots, forensic scientists, pathologists, mountain rescue, photographers, divers, forensic anthropologists, forensic archaeologists and scene of crime examiners” (Donnelly, 2003, p. 11).

Donnelly (2003, pp. 10–11) provides a case study: the Moor Murders from the 1960s. Several young children were abducted and murdered, and the perpetrators buried them in unmarked graves on Saddleworth Moor, a remote region in the Pennines, Northern England, on the Lancashire and West Yorkshire border. In the mid 1980s the case was reopened, as not all children had been found. During the 1990s, Donnelly himself had been involved in the search for the last remaining body (Donnelly, 2002b, 2004). In personal communication (26 June 2007, reproduced by kind permission) he explained the background and latest developments:

I have been working with the Police for 13 years now. Originally, most of my work was undertaken covertly and without the knowledge of others outside the police. However, since my 2002 presentation at Westminster Palace (see *Geoscientist* [Donnelly] 2002[c]), on forensic geology, there has been a steady increase in UK geologists’ involvement in forensic geology, including both research and case work. There are now several universities, research organisations and consultancies. This is of course, fantastic news. Before this

event there were a few geologists in the UK working with the Police, mainly involved with the identification of rock and soil for helping to solve some crimes.

My primary objective has, and continues to be, to find the grave of a young boy, I believe to be buried in a remote location in part of northern England. In December 2006 I set up the Geological Society of London Forensic Geoscience Group. The first inaugural meeting was held in London, in December 2006 (see attached). Working with the police has presented unique opportunities and enabled me to explain the skills, capabilities, expertise and role of geologists, in police and forensic investigations. As a result, there is now little doubt in the police the valuable role geology may bring to help solve/investigate a crime, but only if geologists' are incorporated properly, with both the police understanding the role of the geologists, and the geologists understanding the role of other investigators (and also his/her limit of expertise).

The setting up of the FGG, in the Geological Society of London [...] is aimed at advance the study and understanding of forensic geology. Our inaugural meeting, held at Burlington House in December 2006, was successful [...]. In October 2007, FGG are supporting the 'Soil Forensic Conference' in Edinburgh [...]. This event will give UK geologists the opportunity to discuss and debate the role of geologists with the police and to identify the ways forward for our profession.

In geology, there exist *soil fingerprinting techniques*, and these can be used for forensic applications. Consider the *SoilFit* project: "The UK SoilFit project (<http://www.macaulay.ac.uk/soilfit/>) [...] aims to integrate data from state-of-the-art soil fingerprinting methods with data currently held in spatially referenced soils databases. This approach could potentially improve both matching of evidential soil samples and prediction of probable geographical origin" (Dawson et al., 2006).

A decision support tool is being developed to assist the forensic scientist in selecting the most appropriate analytical strategy depending on sample size, type and condition. A software prototype has been written to process the data and identify, with probabilities, the soil type. This information is then fed into a prototype rulesbased GIS model to identify areas with appropriate soils, which can be narrowed down by layering intelligence of other spatial data (e.g. distance from roads, broad vegetation types). These prototypes have been built to demonstrate and evaluate the approach for crime investigation. (ibid.)

8.5.2 Techniques from Geophysics in Forensic Archaeology vs. in Archaeology

One branch of forensic geology is forensic geophysics. Geophysical survey consists of surveying the subsurface of the earth by the measurement of its physical properties. "An individual survey may take hours, days or months to complete. Geophysical surveys provide an alternative, more cost-effective method for locating disturbed ground and buried objects, but the choice of instrument, methodology and interpretation need to take several inter-related factors into account.

These include the physical properties of the target (human remains, buried ransom money, jewellery, weapons), the geological profile, depth of burial, topography, ground conditions, age of the burial and the experience and – of course – skills of the operators" (Donnelly, 2002a). Fenning and Donnelly (2004) remarked: "[I]n the last twenty years, the application of geophysical methods in archaeological surveying, plus advances in geophysical instrumentation and computing technology, has

allowed geophysicists to conduct high-resolution surveys of the top 1–2 m below ground surface” (ibid., p. 11).⁸⁰

The third lecture at the workshop on Archaeology and Forensic Science, held at the British Academy in London on 27 February 2007, was given by Paul Cheetham, on “Geophysics: Application to Forensic Science”. Cheetham’s affiliation is with the School of Conservation Science at Bournemouth University. His early formation was in statistics and computing, before he turned to geophysics. He is the foremost authority, in Britain, on geophysics application to forensic science. He started his lecture by pointing out that forensic science being fashionable sometimes causes journalists to describe as “forensic” excavations, such excavations which have nothing forensic about them and are archaeological (or possibly carried out for historical purposes, e.g., excavating remains of Napoleonic troops for the purposes of studying their body parasites). Nevertheless, he stressed, oftentimes archaeologists employ better techniques than forensic science.⁸¹ He stated that he sometimes gasps at articles published in forensic science journals, because of how they lag behind things well established from scientific methods as applied to archaeology.

Moreover, in pursuing some directions of research, one may notice discontinuity in the forensic literature, e.g., three isolated papers (whose respective authors did not continue in the given direction) may not cite each other, and no referee apparently pointed that out, and moreover that technique is considerably more advanced as used in archaeology. Such a picture with sporadic papers in forensic science about techniques from geophysics that don’t even cite each other, and of research projects being discontinued, was contrasted to the situation in archaeological science, that has a tradition of steady work building upon previous work, when it comes to applying techniques from geophysics.

What are the chances, for a given technique, to be applied again and again in crime scene investigation (or, for that matter, while assisting the scientific police)? “If you do it quicker and cheaper, the police will call you back”. During his talk, Cheetham also specifically considered different techniques from geophysics, and the likely reasons why their ranking according to prominence for forensic science vs. archaeology is different.

The big growth area in geophysics has been in smaller scale higher-resolution near-surface survey in what is loosely termed applied engineering, environmental geophysics, or industrial geophysics. This rise has run coincident with a decline in mineral prospecting. In a sense, this was an incentive for geophysics to change the direction of its main thrust for application.

Types of geophysics required for forensic science include: near-surface survey; delineation of discrete small features of the terrain (this requires good lateral resolution); and part of the recovery process. It is archaeological geophysics, which is leading. Forensic geophysics may learn from it. When surveying the subsurface of

⁸⁰ Also Bevan (1991) is concerned with the search for graves resorting to geophysics. By contrast, the approach to the detection of clandestine graves in Davenport et al. (1992) is multidisciplinary.

⁸¹ See Gaffney and Gater (2003), Mellett (1996).

the earth by geophysical techniques, normally measurements are taken above the surface, and are non-intrusive. When the application is forensic, one looks for specific kinds of evidence (e.g., graves), not for anything (just defined by scale) as in archaeological geophysics. When what has to be found is bodies and neonates, such bodies are too small for most techniques from geophysics.

Methods from geophysics that are frequently used in archaeology include: magnetometry; earth resistivity; topsoil magnetic susceptibility; ground penetrating radar (not as good as the previous methods); and electromagnetics. The latter technique for archaeology was developed by the French; according to Cheetham, it is the Cinderella among those techniques. In contrast, forensically, the ranking of the techniques is different. Ground penetrating radar is a good technique, Cheetham stated, for forensic purposes. (Fenning and Donnelly (2004) describe it as enjoying popularity and acclaim in the forensic domain: see below).

Cheetham went on, remarking that earth resistivity can be used for looking for graves or for metal, but is not often used in forensic contexts (see below). Electromagnetics is often recommended, but is almost not used. Magnetometry is applied in metal detectors. Topsoil magnetic susceptibility is only employed for specific uses, within a forensic context, and ranks lower with respect to its rank among techniques for archaeology. We are going to be more precise further down in this chapter, thanks to an invaluable survey by Fenning and Donnelly (2004).

Forensic graves are very different from archaeological graves, in respect of the effectiveness of detecting graves and cremations with the most frequently used geophysical survey techniques. Ground penetrating radar works especially well in sand, rather than in other kinds of terrain. (Cheetham brought as an example a commercial ad for the technique, with a picture showing a demonstration on the sand in front of the Sphinx in Egypt. He pointed out that for an advert, it made sense, because this technique works very well in sand.) Ground penetrating radar is not good for finding small objects.⁸² In archaeometry, ground penetrating radar is put to good use for intensively recording an area, slicing the data into images, possibly animating the images by *time-slice* (e.g., to show ancient cultivations or archaeological features). Our Section 8.5.3 is devoted to the concept of *time slicing*. Time-slicing from geophysics is applied, then, to archaeometry, using computational methods.

Earth resistivity, Cheetham claimed during his lecture, is the Cinderella of forensic techniques from geophysics. Nevertheless, Cheetham pointed out, it is a superbly reliable technique in archaeology, with variants: resistivity electrode arrays are applied to archaeology, even though they are cumbersome. Earth resistivity is good for finding graves. Nevertheless, it is almost never used in forensics, because it is regarded as a low technique by geologists: two hours were reported, for surveying a 7×6 m area. But in archaeology, better is done. Apparently there is no good reason for not applying the method in forensics: it is a matter of lack of investment.

⁸² Also Fenning and Donnelly (2004) point out that, e.g., coins could be located at depths up to 0.5 m using a sophisticated instrument, but only larger objects would be detected if buried deeper (ibid., p. 15).

Reluctance to employ this method for forensic purposes has been its perceived slowness; nevertheless, in applications in archaeology this problem has been overcome. An important application of earth resistivity is in volumetric models, rotated by computer animation, of graves or mass grave. Cheetham brought as an example of application to mass graves the same computer graphic model we had already mentioned by reporting about Hunter's talk (see at the end of Section 8.4.1).

Table 1 in Fenning and Donnelly (2004, p. 12)⁸³ summarises features of various geophysical survey methods.

- The *seismic* method's measured parameter is the travel times of reflected/refracted seismic waves, and the 'operative' physical parameters are the density and elastic moduli that determine the propagation velocity of seismic waves. The seismic method "is either applied to layered geological structures or used to determine depth of bedrock beneath superficial deposits. As such, it is rarely applied in forensic geophysics where a distinct target, such as a buried human body, is the survey objective" (Fenning & Donnelly, *ibid.*, p. 13).
- In the *gravity method*, the measured parameter is the spatial variations in the strength of the gravitational field of the Earth, whereas the operative physical parameter is "the density difference between local rocks and an air-filled cavity" (*ibid.*), and in fact it is "usually employed to detect subsurface cavities, such as caves, graves and disused mine shafts" (*ibid.*). Fenning & Donnelly (*ibid.*) describe the gravity method as costly, time-consuming, and rarely applied in forensic geophysics.
- In the *magnetic* method, the measured parameter is spatial variations in the strength of geomagnetic field, whereas the operative physical parameter is magnetic susceptibility and remanence. This method would not be forensically useful if a corpse was buried naked. "The naked human body has virtually no associated magnetic anomaly and, when buried, is very unlikely to be detected by a magnetic survey. However, a fully clothed body is a different matter. Clothing may include metal buttons, zip-fasteners, shoe eyelets and belt buckles, while pockets may contain spectacles, keys, pens and other ferrous metallic objects" (Fenning & Donnelly, *ibid.*).
- The [*electrical*] *resistivity* method comes in a range of techniques, which "[a]ll involve inserting four steel electrodes into the ground and measuring vertical and horizontal variation in resistivity" (*ibid.*). Or, then, a *multi-electrode* array is sometimes used. In the resistivity method, the operative physical parameter is electrical conductivity, whereas the measured parameters are earth resistance, polarisation voltages or frequency-dependent ground resistance.
- The *induced polarisation* method has the same measured parameters as the resistivity method, but the operative physical parameter is electrical capacitance in

⁸³ It is based on Kearey and Brooks (1984). Incidentally, a current edition of that book is Kearey, Brooks, and Hill (2002).

stead of conductivity. Reportedly, it is less effective and slower a method than resistivity surveys (ibid., p. 14).

- In the *self-potential* method, which is reportedly inexpensive (ibid.), the measured parameter is “naturally occurring ground [electrical] potential due to electrochemical reactions between different rock and groundwater levels and flow” (ibid.), and the operative physical parameter is electrical conductivity. Fenning & Donnelly (ibid.) suggest that, notwithstanding the lack of publications about using this method for forensic purposes of discovering dead bodies, the self-potential method has potential (our pun intended) in that domain.
- In the *electromagnetic* methods, the measured parameter is the response to electromagnetic radiation, whereas the operative physical parameters are electrical conductivity and inductance. “An effective and rapid surveying alternative to resistivity profiling is the electromagnetic inductive conductivity (IC) profiling method, which allows continuous recording of the subsurface conductivity at a walking pace. Electrical conductivity is the reciprocal of electrical resistivity” (ibid.). “No case histories relating to direct detection of buried human remains are known”, but in the literature applications of the method were described, “in defining archaeological features such as graves and tombs” (ibid.).
- In the *ground-penetrating radar (GPR)* method (e.g., Hammon, McMechan, & Zeng, 2000; Mellett, 1996), the measured parameter is the response to high-frequency electromagnetic radiation, and the operative physical parameters are electrical conductivity and the dielectric constant. Whereas in the electromagnetic inductive conductivity method, “instruments are one-man, portable and operat[ing] in the frequency range of 10–15 kHz”, “[t]he much higher frequency range of 25 MHz to 2 GHz is the realm of GPR which has received substantial publicity for its ability to produce high-resolution cross-sections of the surface” (Fenning & Donnelly, 2004, p. 14). Reportedly, Hildebrand, Wiggins, Henkart, and Conyers (2002), who “compared seismic reflection and GPR imaging over a dead pig buried in a wooden coffin at a test site in Illinois” (Fenning & Donnelly, 2004, p. 13), found that “the GPR survey was many times faster than the seismic reflection survey” (ibid.).
- Moreover, *metal detector* methods involve a “one-man, portable hand-held scanning devic[e] with an audible signal or meter output” (Fenning & Donnelly, 2004, pp. 14–15). The smaller the metal object, the shallower the underground range of the instruments. A large object would be detected even if buried somewhat deeper (ibid.).
- And finally, “[t]he advantages of using mobile multi-sensor systems in forensic studies are clearly apparent where there are large tracts of survey and copious detailed data points are required” (ibid.); such mutisensor systems consist of arrays of sensors “which can be man-carried or vehicle-mounted and walked/towed across site” (ibid.), sometimes making use of *differential global-positioning systems (DGPS)*.

The general rule for all those methods is that “[t]he physical property contrast between a target and the surrounding host material of soil and rocks is essential

if geophysical methods are to be effective” (Fenning & Donnelly, 2004, p. 12). “In addition to an understanding of the capabilities of geophysical methods, it is essential that the limitations of these methods be clearly understood.

MacDougall et al. (2002) point out various limitations which can make areas unattractive for geophysical surveys” (Fenning & Donnelly, *ibid.*). For example, “gates, buildings, fences, overhead power cables, parked or moving vehicles and machinery”, being “man-made metallic features at ground surface”, are detrimental for a survey to be conducted, and so it the “[p]resence of man-made metallic and non-metallic features below ground surface e.g. cables, pipes, sewers, reinforced concrete” (*ibid.*). This is also the case of “[e]lectrical interference e.g. mobile phones, electrical machinery, power cables”, of “[c]urrent construction or farming activities”, of “[s]evere ground topography”, of access problems such as bushes and vegetation, of the “[p]resence of farm animals”, and of “[s]easonal factors e.g. tourists, weather” (*ibid.*).

Fenning and Donnelly’s article (2004) has been invaluable for writing part of this section. That article also analyses three case histories. The interested reader is urged to refer to that paper. Whatever we have quoted from it here, can only be an appetiser, not the main course.

8.5.3 A Clarification About Time Slicing

Time-slicing (mentioned in the Section 8.5.2, with data from ground-penetrating radar) is a concept that occurs in a number of different disciplines. Time-slicing can be found in computer operating system design; in cinematography; in synchrotron radiation from physics; in power engineering; and so forth. In a computer’s operating system which, on a serial machine, has to simulate the parallel execution of a large number of programs, this is achieved by means of time slicing: at each time slice, a small number of instructions are executed for each program, one at a time. If the strategy is that a fixed number of instructions is to be executed for each program at each time slice, longer programs will take more time slices. Other strategies are possible.

In contrast, in telecommunications, time slices (i.e., burst, or time slots when the data are transmitted) enable a reduction in power consumption, e.g., of mobile receivers, because when the relevant data are not available, the front end (i.e., the receiver) is switched off, and later on it is informed when to wake up, when the next burst (intended for it) is expected.

As to special effects in cinematography and computer animation, the Wikipedia entry for “Bullet time”⁸⁴ remarks that “Technical and historical variations of this effect have been referred to as time slicing, view morphing, flo mo, mort temps and virtual cinematography”:

⁸⁴ http://en.wikipedia.org/wiki/Bullet_time (accessed in March 2007).

a computer-enhanced variation of slow-motion special effects used in some recent films and computer games. It is characterized both by its extreme permutation of time (slow enough to show normally imperceptible and un-filmable events, such as flying bullets) and by the ability of the camera angle – the audience’s point-of-view – to move around the scene at a normal speed while events are slowed. This is almost impossible with conventional slow-motion, as the physical camera would have to move impossibly fast; the concept implies that only a ‘virtual camera’, often illustrated within the confines of a computer-generated environment such as a game or virtual reality, would be capable of ‘filming’ bullet-time types of moments.

In beam physics, a report in the *Advanced Light Source (ALS) News* (ALS News, 2000) stated that

[i]n early 1996, Alexander Zholents and Max Zolotarev of Berkeley Lab’s Center for Beam Physics proposed the laser time-slicing technique as a way to achieve effective bunch lengths in the femtosecond range. At the heart of the proposal was the use of a high-power, femtosecond laser synchronized with the electron bunches so that a pulse of laser light passed collinearly with an electron bunch through an undulator or wiggler. The high electric field of the shorter laser pulse modulated a portion of the longer electron bunch, with some electrons gaining energy and some losing energy. Subsequently, when the energy-modulated electron bunch reached a bend magnet (or other section of the storage ring with a nonzero dispersion), a transverse separation occurred. A collimator or aperture selected the synchrotron radiation from the displaced bunch slices.

Later on, according to the results of Schoenlein et al. (2000), a Berkeley team – in the words of ALS News (2000) –

generated 300-femtosecond pulses of bend-magnet synchrotron radiation at the Advanced Light Source (ALS) with the aid of a laser ‘time-slicing’ technique. Their proof-of-principle experiment demonstrates that this technique is a viable one for producing ultrashort pulses of x rays. An ALS bend-magnet beamline will soon be commissioned that will be dedicated to time-resolved x-ray diffraction, EXAFS, and other techniques capable of probing the long-range and local structure of matter on a femtosecond time scale.

Readers conversant with artificial intelligence are likely to know about *slice* from the terminology of *naive physics*: that notion of *slice* was introduced in Patrick Hayes’ (1985) so-called *ontology for liquids*, a naive physics model that can handle phenomena in fluid dynamics, and involves spatio-temporal histories of objects. On p. 90, Hayes wrote the following concerning the difference between the formal concepts of *history* and *situation*:

A history differs from a situation in being restricted spatially and extended temporally: it is a connected piece of space-time in which ‘something happens’, more or less separate from other such pieces. Histories, unlike situations, have a *shape*: much of [Hayes’ treatment is] devoted to ways of describing their shape.

Examples of histories include the inside of a room during the afternoon, a horserace and the pouring of water from one cup into another. The idea is that a history shall contain an event, isolating it temporally and spatially from other events. We include the special case in which nothing happens at all. A *state* [...] is an instantaneous ‘slice’ of a history at a certain time-instant. [...] If *h* is a history and *t* a time-instant (we assume a global timescale of some sort with an inequality defined on it), the *h@t* (read *h* at *t*) is the ‘slice’ of *h* at *t*. This is a state, that is, a spatial entity at a particular time.

8.5.4 *From Soil to Scent: Between Current Practice and Imagining the Digital Potential*

8.5.4.1 Scent-Detection, Odorology, Cadaver Dogs, and Gas Soil Surveying: The Detection of the Scent of an Individual, vs. the Detection of a Kind (Graves)

Tribondeau (accessed 2006) credits a country in Eastern Europe with the origination of a particular technique for identification, *odorology* (s.v. *odorologie*, quoted here in my own translation):

Developed since recently by the French police, this practice, which appeared about thirty years ago in Hungary (where it enables solving over 4000 cases per year), enables the identification of perpetrators through their olfactive print (*empreinte olfactive*). Concretely, investigators places cotton ribbons on the scene of the crime; then these conserved inside hermetically closed phials. It just takes, for especially trained dogs, to sniff a piece of cloth imbued with the scent of a suspect who eventually turns up, and subsequently the various phials who are opened in front of these dogs. Like with explosives and narcotics, the dog will stop in front of the phial with the same scent as the suspect. In Hungary, over 18,000 olfactive prints are collected every year. A phial may last during at least ten years.

This is a further development of the widespread employment of dogs for *scent-detection*. The latter method is “Relatively nondestructive. Proven effective even 170 years after burial. Effective over water” (Davenport et al., 1992). These are advantages, whereas disadvantages are as follows: “Most effective when air, ground moist. Dog may be trained for other uses and not properly trained for this type of work; handler may overstate qualifications” (ibid.). Davenport et al. (1992) were concerned with the detection of clandestine graves, and the dogs used were *cadaver dogs*. Using dogs or pigs is also widespread for finding truffles underground, or the method is also in use for detecting landmines, typically for the purpose of demining an area. Davenport et al. (ibid.) had carried out experiments with the detection of pig carcasses, and adopted a multidisciplinary approach to their detection:

Excessive heat causes some discomfort to the dog and this may affect the dog’s ability to locate a scent. When the temperature is extremely high the dog will still locate the scent; however in most cases, it will need to be within approximately a meter of the source. Even if the temperature is high, the results will improve if the ground is moist. Extremely low temperatures also limit the dog’s ability to detect the scent from a distance, especially if the source is buried. If the source is buried in snow with temperatures allowing only minimal melting, the dog must be directly over the source to locate it. If the temperature is warm enough to allow for significant melting the dog can locate the source from a greater distance.

Apart from scent-detection by cadaver dogs, also *soil gas* surveying was carried out (ibid.):

The soil gas surveying performed at the research site holds promise of providing a useful, albeit labor intensive, technique to locate graves. Organic gases were detected within three meters of two of the grave sites; however, the investigators had the privilege of knowing in advance the locations of these sites. Soil gas surveying is best in soils with a low clay content (so as not to clog the probes) and over unfrozen ground.

What can possibly be the use of computing for the techniques mentioned in this chapter? Arguably, even unsophisticated computing methods can be used for the purposes of organisation and classification, e.g., of the dogs and their records. In odorology, such relatively unsophisticated methods from information technology may be nevertheless useful. On the other hand, it may be that chemical sensors as in *electronic noses* are not sophisticated enough; they would only pick up the sort of scent components they were devised to detect. Dogs are much more sensitive. Nevertheless, pattern matching methods, and perhaps data mining methods, from computing could perhaps complement the use of dogs. At any rate:

Despite the importance of the olfactory sense to mankind, the sense of smell in man is often considered the least refined of the human senses, far less sensitive than that of other animals. For example, the human nose possesses only about one million aroma receptors that work in tandem to process olfactory stimuli whereas dogs have about 100 million receptors that distinguish scents at least 100 times more effectively than the average human [(Ouellette, 1999)]. Furthermore, the ability to detect chemicals in the environment is critical to the survival of most prokaryotic and eukaryotic organisms. A clear indication of the importance of olfactory systems in higher eukaryotes is the significant proportion (up to 4%) of the genome that is devoted to encoding products used in building olfactory sensory tissues [(Firestein, 2001)]. The relatively low sensitivity and discrimination capabilities of the human nose, coupled with the common occurrence of olfactory fatigue, has led to the need for electronic instruments with sensors capable of performing repeated discriminations with high precision to eliminate human fatigue.⁸⁵

There are smells that humans could not identify accurately, and electronic noses can, either more accurately or more safely. Electronic noses may not be as good as dog noses (but some are claimed to be as good instead, as we are going to see), but when the task is to smell such substances that would be dangerous even to such police dogs that regularly detect narcotics, electronic noses may be the solution. We devote the next section to electronic noses indeed.

8.5.4.2 Electronic Noses

Odour assessment in industry resorts to any of the following:

- human sensory analysis,
- chemosensors, or
- gas chromatography.

With *gas chromatography*, information is obtained about volatile organic compounds, “but the correlation between analytical results and actual odor perception is not direct due to potential interactions between several odorous components”.⁸⁶ Moreover, the police resorts to police dogs; individuals searching for truffles resorts

⁸⁵ Wilson and Baietto (2009, p. 5101).

⁸⁶ http://en.wikipedia.org/wiki/Electronic_nose (when accessed in April 2011, it had been last modified in March of the same year).

to truffle dogs or pigs; and personnel searching for landmines may resort, among the other things, to dogs or even pigs, but in that case this is not only because the olfaction of such animals is superior to human olfaction, but also because casualties among such animals in case landmines detonate are more acceptable than human casualties. There also is a technique that resorts to wasps: “In the Wasp Hound odor-detector, the mechanical element is a video camera and the biological element is five parasitic wasps who have been conditioned to swarm in response to the presence of a specific chemical”.⁸⁷

Electronic sensing (or *e-sensing*) technologies aim at endowing devices with the capability of reproducing human senses using *sensor arrays* and *pattern recognition* systems. In e-sensing, an *electronic nose* is such a device that is intended to detect odours or flavours. One also speaks of *machine olfaction* in order to denote the automated simulation of the sense of smell. Electronic-nose technology⁸⁸ is the subject of a fifty-page survey by Alphus Wilson and Manuela Baietto (2009).

Since 1982, research has been conducted to develop technologies, commonly referred to as electronic noses, that could detect and recognize odors and flavors. The stages of the recognition process are similar to human olfaction and are performed for identification, comparison, quantification and other applications. However, hedonic evaluation is a specificity of the human nose given that it is related to subjective opinions. These devices have undergone much development and are now used to fulfill industrial needs.⁸⁹

Wilson and Baietto explain (2009, p. 5100):

The sensor technology of artificial olfaction had its beginnings with the invention of the first gas multisensor array in 1982 [(Persaud & Dodd, 1982)]. Advances in aroma-sensor technology, electronics, biochemistry and artificial intelligence made it possible to develop devices capable of measuring and characterizing volatile aromas released from a multitude of sources for numerous applications. These devices, known as electronic noses, were engineered to mimic the mammalian olfactory system within an instrument designed to obtain repeatable measurements, allowing identifications and classifications of aroma mixtures while eliminating operator fatigue [90]. Unlike other analytical instruments, these devices allow the identification of mixtures of organic samples as a whole (identifiable to a source that released the mixture) without having to identify individual chemical species within the sample mixture [91]. Hundreds of different prototypes of artificial-nose devices have been developed to discriminate complex vapor mixtures containing many different types of volatile organic compounds (VOCs) [92]. These prototypes collectively represent various

⁹⁸ On pp. 221–245 in Gardner and Bartlett's (1999) *Electronic Noses: Principles and Applications*.

⁹⁹ But nevertheless, *olfactometers* (when used in one of the senses of that terms) are used to both qualify and quantify. The following is quoted from <http://en.wikipedia.org/wiki/Olfactometer>

An *olfactometer* is an instrument typically used to detect and measure ambient odor dilution. Olfactometers are utilized in conjunction with human subjects in laboratory settings, most often in market research, to quantify and qualify human olfaction. Olfactometers are used to gauge the odor detection threshold of substances. To measure intensity, olfactometers introduce an odorous gas as a baseline against which other odors are compared. Many scientists use the term “olfactometer” to refer to a device used to study insect behavior in presence of an olfactory stimulus. It consists of a tube with a bifurcation (with “T” or “Y” shape) where an insect walks and decides between to choices, usually clean air versus air carrying an odor. This is why this device is also called dual choice olfactometer. Alternatively, an *olfactometer* is a device used for producing aromas in a precise and controlled manner.

The following sense (as defined *ibid.*) is unrelated to electronic noses: “A flow-olfactometer is a complex instrument for creation of well defined, reproducible smell or pain stimuli in the nose without tactile or thermal stimulation. Stimulus rise time is fast enough to allow for recording of Olfactory Evoked Potentials (OEPs).” This device “produces a constant heated and humidified flow of pure air. This air flow runs continuously to the subjects nose. For the length of the stimulus pulse the continuous air flow is replaced by a bloc of odorized air” (*ibid.*). Contrast this to *dynamic dilution olfactometers* (*ibid.*):

The new generations of dynamic dilution olfactometers quantify odors using a panel and can allow different complementary techniques:

- odor concentration and odor threshold determination
- odor suprathreshold determination with comparison to a reference gas
- hedonic scale assessment to determine the degree of appreciation
- evaluation of the relative intensity of odors
- allow training and automatic evaluation of expert panels

These analyses are often used in site diagnostics (multiple odor sources) performed with the goal of establishing odor management plans.

A concept related to the latter is *electrogustometry*, i.e., the measurement of *taste threshold*, i.e., the minimum amount of electrical current required to excite the sensation of taste. When using an *electrogustometer*, current is made to pass through the tongue, and a metallic taste is perceived.

Conventional electronic noses are not analytical instruments in the classical sense and very few claim to be able to quantify an odour. These instruments are first ‘trained’ with the target odour and then used to ‘recognise’ smells so that future samples can be identified as ‘good’ or ‘bad’ smells. Electronic noses have been demonstrated to discriminate between odours and volatiles from a wide range of sources.¹⁰⁰

Electronic noses have a range of applications including *at-line quality control*,¹⁰¹ various tasks in research and development (R&D),¹⁰² and in process and production departments.¹⁰³ A possible application is to olfactive nuisance monitoring, but typical applications have been in the food & beverage sector (e.g., in order to detect spoiled produce), or to flavour & fragrance, or to cosmetics & perfume, as well as to packaging, and in the pharmaceutical and chemical industries.

The working principle of an electronic nose is that it should mimic human (or at any rate, natural) olfaction (it is said sometimes: “the mammalian sense of smell”), and that it should do so as a *non-separative mechanism*. That is to say, an odour (if this is what the device is intended to detect) or a flavour (if this is the device’s target instead) should be perceived as a *global fingerprint*. An electronic nose is an instrument that consists of the following:

- head space sampling,
- sensor array,
- pattern recognition modules.

The latter generate signal patterns which in turn are used for characterising odours. “As a first step, an electronic nose need to be trained with qualified samples so as to build a database of reference. Then the instrument can recognize new samples by comparing volatile compounds fingerprint to those contained in its database. Thus they can perform qualitative or quantitative analysis”.¹⁰⁴ The architecture of the system is as follows¹⁰⁵: “Electronic Noses include three major parts: a sample delivery

“Electrogustometric taste threshold depends on the duration of current pulse and area of contact of electrode and tongue” (<http://en.wikipedia.org/wiki/Electrogustometry>).

¹⁰⁰ http://en.wikipedia.org/wiki/Machine_olfaction (when accessed in April 2011, it had been last modified in February of the same year).

¹⁰¹ As listed at http://en.wikipedia.org/wiki/Electronic_nose tasks of electronic noses within quality control include: conformity of raw materials, as well as of intermediate and final products; batch to batch consistency; detection of contamination, spoilage, or adulteration; origin or vendor selection; and monitoring of storage conditions.

¹⁰² Tasks of electronic noses at R&D laboratories include: formulation or reformulation of products; benchmarking with competitive products; shelf life and stability studies; selection of raw materials; packaging interaction effects; simplification of consumer preference test (ibid).

¹⁰³ Tasks of electronic noses in process and production departments include: managing raw material variability; comparison with a reference product; measurement and comparison of the effects of manufacturing process on products; following-up cleaning in place process efficiency; scale-up monitoring; and the monitoring of cleaning in place (ibid.).

¹⁰⁴ http://en.wikipedia.org/wiki/Electronic_nose

¹⁰⁵ Ibid.

system, a detection system, a computing system”. Electronic noses “generally comprise: an array of sensors of some type; the electronics to interrogate those sensors and produce the digital signals, and finally; the data processing and user interface software”.¹⁰⁶ In particular¹⁰⁷:

The **sample delivery system** enables the generation of the headspace (volatile compounds) of a sample, which is the fraction analyzed. The system then injects this headspace into the detection system of the electronic nose. The sample delivery system is essential to guarantee constant operating conditions.

Let us turn to detection¹⁰⁸:

The **detection system**, which consists of a sensor set, is the “reactive” part of the instrument. When in contact with volatile compounds, the sensors react, which means they experience a change of electrical properties. Each sensor is sensitive to all volatile molecules but each in their specific way. Most electronic noses use sensor arrays that react to volatile compounds on contact: the adsorption of volatile compounds on the sensor surface causes a physical change of the sensor. A specific response is recorded by the electronic interface transforming the signal into a digital value. Recorded data are then computed based on statistical models.

The more commonly used sensors include metal oxide semiconductors (MOS), conducting polymers (CP), quartz crystal microbalance, surface acoustic wave (SAW), and Metal Oxide Semiconductors- Field Effect Transistors (MOSFET), Based on Ion Mobility Spectrometry (IMS), Based on Optical Florescence.

In recent years, other types of electronic noses have been developed that utilize mass spectrometry or ultra fast gas chromatography as a detection system.

The one remaining component of the architecture is the computing system:

The **computing system** works to combine the responses of all of the sensors, which represents the input for the data treatment. This part of the instrument performs global fingerprint analysis and provides results and representations that can be easily interpreted. Moreover, the electronic nose results can be correlated to those obtained from other techniques (sensory panel, GC, GC/MS). Many of the data interpretation systems are used for the analysis of results. These include artificial neural network (ANN),¹⁰⁹ Fuzzy logic,¹¹⁰ pattern recognition modules, etc.¹¹¹

The entire system being a means of converting complex sensor responses into an output that is a qualitative profile of the odour, volatile or complex mixture of chemical volatiles that make up a smell.¹¹²

¹¹¹ http://en.wikipedia.org/wiki/Electronic_nose

¹¹² http://en.wikipedia.org/wiki/Machine_olfaction

A particular application of machine olfaction is to the discovery of explosives.¹¹³ This is the case of the *Fido Explosives Detector*.¹¹⁴ This is a tool of ICx Technologies, Inc.,¹¹⁵ and is based on a proprietary technology invented in 2007 by Timothy Swager of the Massachusetts Institute of Technology. Fido detects trace levels of explosive materials. The name *Fido* reflects the claim that the device's performance at detecting explosives is comparable to that of highly trained explosives detection dogs. There are several configurations of the device: handheld, desktop, or robot-mounted. It has been integrated into both *Packbot* (of the firm iRobot) and *Talon* (of Foster-Miller), and put to use by the U.S. Army in both Iraq and Afghanistan.

The vapour pressure of the chemicals in explosives is low, and this makes the task of discovering explosives by means of an electronic nose more difficult (Jha & Yadava, 2010, p. 364):

An electronic nose consists of chemical sensor array with pattern recognition system to detect and identify vapour prints of target chemical compounds in gaseous phase. Its applications range from monitoring of hazardous chemicals in the environment, detection of disease through body odour or breathe, smell sensing and monitoring of food degradation through bacterial metabolites emission, to detection of explosives and narcotics through sniffing of the suspects. The detection of trace vapours emanating from hidden explosives is of paramount importance to homeland security and forensics. The security applications include sniffing hidden bombs, landmines, and suspected baggages or persons. The forensic uses involve early identification of devices and contraband activities for prevention of difficult countermeasures later. However, developing a portable electronic nose technology for these purposes is a difficult task due to extremely low vapour pressure of most of the chemical compounds comprising modern explosives.

Moreover, there are environmental differences which complicate the challenge (ibid.):

¹¹³ Electronic noses for the detection of explosives are the subject of Pamula (2003); Yinon (2003); Gardner and Yinon (2004); Jha and Yadava (2010). Of course, there are venues of research into the detection of explosives, other than resorting to electronic noses. For example, David Moore (2007) provided a survey of advances in trace explosives detection instrumentation. In particular, section 4.2 in Morre (2007) is concerned with *vapour concentration methods*, and also section 5 is on *trace vapour detection*. Wang (2004) discussed microchip devices for detecting terrorist weapons. Brenda Klock's project plan (2001) concerns aviation in the United States: her plan outlined "the field evaluation for threat detection in X-ray images of bags containing explosives at full and sub-certification weights" (ibid., from the abstract). "X-ray systems in airports are designed to display images of baggage and its contents, including guns, knives, other weapons, and explosives. X-ray systems include a function designed to maintain on-the-job vigilance. Threat Image Projection (TIP) was developed to increase the proficiency of the primary skills required of a screener to interdict threats at the checkpoint. TIP exposes screeners to images of threats (e.g., weapons or explosives) by randomly projecting these threat images onto passenger bags as the bags move through the X-ray system. Alternately, TIP can also project the image of an entire bag containing a threat when there is a suitable gap between passenger bags" (ibid., p. iv).

¹¹⁴ http://en.wikipedia.org/wiki/Fido_Explosives_Detector Also see: <http://www.icxt.com/products/detection/explosive/fido/>

¹¹⁵ <http://www.icxt.com/>

The reliable detection of explosives vapour signature or vapour prints at such low concentrations is a challenging task even for some most advanced detection techniques today. The difficulty is further compounded as the trace explosive vapours are usually camouflaged in complex background of several interfering volatile organic compounds. The compositions of latter vary wildly over various kinds of sites of interest. For example, ambient air over landmines will be drastically different from that near the body of a person boarding an aircraft hiding a bomb or a busy market place threatened with a hidden bomb.

It is far from being the case that only one class of methodologies is employed in electronic noses for detecting explosives. Jha and Yadava (2010) resort to a surface acoustic wave (SAW) platform (*ibid.*, pp. 364–365):

The reliable detection of explosives vapour signature or vapour prints at such low concentrations is a challenging task even for some most advanced detection techniques today. The difficulty is further compounded as the trace explosive vapours are usually camouflaged in complex background of several interfering volatile organic compounds. The compositions of latter vary wildly over various kinds of sites of interest. For example, ambient air over landmines will be drastically different from that near the body of a person boarding an aircraft hiding a bomb or a busy market place threatened with a hidden bomb. them all. Most interesting aspects of SAW sensors are their continuous upgradability in performance through increase in operation frequency, modification in device design, improvement in polymer interface¹⁸, and planar technology.

In the model reported about by Jha and Yadava (2010), pattern recognition is performed by means of a neural network¹¹⁶ with error backpropagation. Actually their article “proposes simulated SAW sensor array model as a validation tool for pattern recognition algorithms” (*ibid.*, p. 369). Data preparation was by dividing the output of each sensor by the respective vapour concentrations and frequency shifts due to polymer coatings. Let

$$\Delta f_{ij}^f \quad C^i \quad \Delta f_p^j$$

respectively stand for the output of each sensor, the respective vapour concentrations, and frequency shifts. Their logarithms are taken to define a new matrix as

$$\Delta f_{ij}^f \leftarrow \log(\Delta f_{ij}^f / C^i \Delta f_p^j)$$

This is followed by the step of this data matrix being mean-centred and variance-normalised with respect to the vapour samples for each sensor in the array. This is called *dimensional autoscaling* (Osuna & Nagle, 1999). It is implemented as

$$\Delta f_{ij}^f \leftarrow (\Delta f_{ij}^f - \overline{\Delta f_j^f}) / \sigma_j$$

¹¹⁶ Neural networks are the subject of [Section 6.1.14](#) in this book.

where

$$\overline{\Delta f}_{ij} = (1/N) \sum_{i=1}^N \Delta f_{ij}$$

and

$$\sigma_j = \sqrt{(1/N) \sum_{i=1}^N (\Delta f_{ij} - \overline{\Delta f}_{ij})^2}$$

“represents the column mean and standard deviation, respectively. Then, the denoising was done by truncating the full rank SVD [i.e., singular value decomposition] expansion of the redefined data matrix by a matrix of lower rank. The procedure implicitly assumes that the rank of the data matrix is lower than the number of sensors in the array. The details of SVD denoising are presented. The data matrix regenerated on the basis of truncated SVD approximates the original data with reduced noise. The preprocessed data matrix as explained above is then PCA [i.e., principal component analysis] processed, and the first few principal components are taken to define the set of features to represent vapour identities. The classification is done by artificial neural network based on the training by error backpropagation algorithm” (Jha & Yadava, 2010, p. 369).

There even exist an application of electronic noses to medical pathology. Dogs can smell some human diseases: “The connection between differences in the aroma of diseased vs. healthy human tissues and diagnostic detection of human pathogenesis is supported by studies using the extraordinarily keen olfactory abilities of well trained dogs whose sense of smell is one million times greater than human’s in the ability to detect melanoma tissues [(Pickel, Manucy, Walker, Hall, & Walker, 2004)], bladder cancer [(Willis et al., 2004)], as well as lung and breast cancers [(McCulloch et al., 2006)].” (Wilson & Baietto, 2009, p. 5125). But electronic noses can also be used for the purposes of detecting diseases: “Many medical researchers have published experimental data in the last ten years to demonstrate the feasibility of using the electronic nose to diagnose human diseases and to identify many different pathogenic microorganisms through the detection of the VOCs [i.e. volatile organic compounds] they emit both in vitro and in vivo [(Casalinuovo, Di Pierro, Coletta, & Di Francesco, 2006)]” (Wilson & Baietto, 2009, p. 5125).¹¹⁷

One also talks about electronic tongues (Wilson & Baietto, 2009, p. 5134):

New emerging technologies are continually providing means of improving e-noses and EAD capabilities through interfaces and combinations with classical analytical systems for rapid discrimination of individual chemical species within aroma mixtures. E-nose instruments are being developed that combine EAD sensors in tandem with analytical detectors such as with fast gas chromatography (FGC) [¹¹⁸]. More complicated technologies such as

¹¹⁷ Also see Persaud’s (2005) ‘Medical applications of odor-sensing devices’.

¹¹⁸ Staples (2000).

optical gas sensor systems also may improve on traditional e-nose sensor arrays by providing analytical data of mixture constituents [¹¹⁹]. These technologies will have the capability of producing recognizable high resolution visual images of specific vapor mixtures containing many different chemical species, but also quantifying concentrations and identifying all compounds present in the gas mixture. Similar capabilities for identifying components of solid and liquid mixtures may be possible with devices called electronic tongues [¹²⁰]. Several recent reviews provide summaries of electronic tongue technologies and discuss potential applications for food analyses [¹²¹].

Whereas Wilson and Baietto (2009) did not mention forensic science specifically, it stands to reason that electronic noses and electronic tongues could find there application as well.

8.5.5 *Forensic Palynology*

Patricia E. J. Wiltshire gave the fourth and last lecture, at the workshop on Archaeology and Forensic Science, held at the British Academy in London on 27 February 2007. The talk had the title “From Archaeology to CSI” (i.e., crime scene investigation), but the analysis of pollen or other plant remains (a field in which Europe is ahead of the United States, in forensic contexts) played an important part in it. The speaker (who was also introduced to the audience by a nickname, “Pollen Pat”, by which colleague in the Forensic Science Service sometimes refer to her), is affiliated with the Forensic Science Service as well as with the University of Aberdeen. She has worked on about 200 crime cases, and often appears in court as an expert witness. Originally she was an environmentalist. From palynology (i.e., the analysis of pollen), she spread into all of forensic science, and in fact, that was the talk in which more, and the most shocking, photographs of decaying human bodies were shown. Nevertheless, it was a lucid, well-argued talk extolling the role of palynology in solving forensic cases.

As exemplified during the talk, these typically were cases of murder. For example, a girl of 15 had been beaten to death. Her boyfriend was suspected, but he denied the charge, and denied he had been in a schoolyard where the girl was believed to have been beaten by a gang of youngsters. Nevertheless, Wiltshire found the pollen of a tree from his garden all over the body of the girl, as well as on the knees of the young man’s trousers. He eventually got a life sentence, and his mother was convicted for covering up for him.

In some other cases brought as examples, no murder was involved; e.g., the speaker had advised the police whether some marks visible on a package had been

¹¹⁹ White, Kauer, Dickinson, and Walt (1996).

¹²⁰ Winquist, Holmin, Krantz-Rülcker, Wide, and Lundström (2000); Söderström, Borén, Winquist, and Krantz-Rülcker (2003).

¹²¹ Gutiérrez, Céspedes, and del Valle (2007); Winquist (2008); Scampicchio, Ballabio, Arcchi, Cosio, and Mannino (2008).

made in Europe or in Mombasa, Kenya. In another case, she belied a rape accusation: a girl claimed she had been pushed on a garden wall, but none of the pollen from the wall appeared on her garments. In the case that concluded the talk, namely, the case of a man wounded in the bottom, the speaker enabled the police to recategorise what at first the police had been believed to be a vicious sex crime, with the criminal still at large. She advised them to wait, before taking that direction of inquiry. Pollen analysis enabled her to reconstruct how the critically wounded man, with two very long stabs entering his body from his anus, got those wounds. Apparently he had been drunk, and tried to climb on a wall at a park, but in so doing, he had impaled himself.

Wiltshire began her talk by pointing out that where microorganisms are inhibited, plant remains (seeds, leaves, stems, pollen, spores) can be preserved for thousands of years. In such cases, the taxonomical identification of the plant to which the well-preserved pollen belongs can be straightforward. Analysis of assemblages of these plant remains has allowed the reconstruction (or at least this is what some think) of ecological environments. Such ideal preservation does not obtain, in most cases, for pollen from archaeological or even recent, forensic contexts. Poor preservation makes it difficult to determine the taxonomical identification of pollen remains.

Botany has been used extensively in archaeology over the last thirty years, through macrofossil analysis and palynology. It can be applied to analysing the function of artefacts (food or medicine remains), or the function of features: retting (soaking), water and food storage, textiles. To be precise, palynology is the study of palynomorphs, i.e., any microscopic objects from the reproduction of plants, such as pollen grains, plant spores, fungal or fossil spores, and so forth. (Actually, palynology studies morphological, biochemical, and biogeographical aspects of these.) When palynology is forensic, it is interfaced to other forensic disciplines, some of them also from ecology, e.g., pedology, i.e., soil analysis. Clearly pedology is important for forensic purposes (e.g., for analysing soil in or around graves, or as traces found on shoes).

Palaeoecological pollen (e.g., as found in blank peat) is easy to identify, whereas, as mentioned, archaeological or forensic pollen is not, as it is in phases of decomposition. This is a problem, for the forensic application of palynology, because what is “forensic” must be defensible in court, and an expert witness is under attack by the barrister of the other side (whereas ethically, the duties of the prosecution expert witness are to the court, rather than to the police). Wiltshire mentioned an authority who once said that palynology is rubbish, because it cannot be proven. Forensic analysis has shown that palynology is very crude (whether palaeoecological, or forensic). Still, the discipline is not alone in that situation. Take medicine. Ecology is not an absolute science; it is like medicine, in that you cannot test hypotheses. What you do have, is symptoms. The discipline not being exact hasn’t prevented Wiltshire from working on about 200 crime cases. Some of her work is clandestine, and involves dressing up, e.g., as a shop assistant.

A forensic expert has to recognise anomalies, and one must know what *is* right, to know what is *not* right. An ecosystem can be recognised by proxy indicators of the place: wood, leaves, seeds, pollens, spores, diatoms, and so forth. Like in medicine,

these are symptoms. From the state of the flora on which a human body fell, it was understood it (a dead girl) was dumped in early August.

Any proxy indicator picked up by an offender might be traced back to the source: this is *Locard's Principle*.¹²² Petrol cans, because of static electricity, have palynological indicators stick to them. Parasitic worm eggs of such worms that parasitise frogs are yet another proxy indicator, and they indicate that there must be a stream or pond. The worm eggs are secondary proxy indicators of frogs, and frogs are secondary proxy indicators of a stream or pond. Worm eggs do not belong in palynology, but by their very nature, they are relevant to the work of a forensic expert who is a palynologist. Palynology can be useful at all stages of decomposition of a corpse. Nevertheless, it is important to avoid contamination of the evidence while dissecting (like the crime scene or the perpetrator of a crime, also staff handling the evidence could leave traces, and it is paramount to be able to tell which is what.)

Let us broaden the discourse about palynology, before turning to software for that discipline. *Palynology* is the study of palynomorphs, both living and fossil. The term was introduced by Hyde and Williams (1944). *Actuopalynology* (as opposed to *palaeopalynology*) is “the study of palynomorphs which are either living, still retain their cell contents, or whose cell contents have been removed by maceration”; one of its branches is *forensic palynology* (used to “to determine the past location of items or persons based on the pollen and spores on or in them”). Note that whereas the antonym of *palaeopalynology* is *actuopalynology*, the antonym of *palaeontology* is *neontology* (i.e., the study of still extant or recent animal or vegetal taxa).

As to applications of *archaeological palynology* (“the analysis of pollen, spores, and other palynomorphs from archaeological sites”), they “include the reconstruction of prehistoric diet, funary practices, artifact function and source, archaeological feature use, cultivation and domestication of plants, and human impact on vegetation”, according to definitions at a webpage by Owen Davis (1999). Archaeological palynology and quaternary palynology are part of *environmental palynology*, i.e., “The use of palynomorphs, their identification, distribution, and abundance to determine past changes in the biota, climate, or surficial geology of an area” (ibid.). A distinct area is *stratigraphic palynology*, i.e., “The use of palynomorphs, their identification, distribution, and abundance to correlate among sedimentary sequences of any age, or to provide chronological control for these sedimentary sequences” (ibid.); “the study of sedimentary sequences often includes both stratigraphic and environmental palynology” (ibid.). One of the areas of palynology is *mellisopalynology*, i.e., the study of pollen in honey or other bee products. Another area is *aeropalynology*. Another subdiscipline is *pollen analysis*.

According to a somewhat circular definition provided by Peter Hoen (1999), *palynomorph* are “A general term for all entities found in palynological preparations”; with the useful addition that: “In addition to pollen grains and spores, the

¹²² On Edmond Locard, a star in the history of French and world criminalistics, see in Section 8.7.1 below.

term encompasses acritarchs, dinoflagellates and scolecodonts, but not other microfossils, such as diatoms, that are dissolved by hydrofluoric acid". Therefore, the delimitation is according to a technique of analysis. According to a broad definition, provided by Owen Davis (1999), *palynomorphs* "include pollen, embryophyte spores, algae, fungal spores, dinoflagellates [which are unicellular aquatic organisms], microforaminifera, chitinozoans [marine fossils, shaped like flasks, occurring individually or in chains, usually assumed to be animal remains], acritarchs [consisting of a central cavity enclosed by a wall of single or multiple layers and a chiefly organic composition], and amoebas. Thus, they "include both plant and animal structures that are microscopic in size (from about 5 μm to about 500 μm), and are composed of compounds that are highly resistant to most forms of decay other than oxidation, being composed of sporopollenin, chitin, or related compounds. In the strict sense, palynomorphs are recognized as microscopic structures that are abundant in most sediments and sedimentary rocks, and are resistant to the routine pollen-extraction procedures including strong acids, bases, acetolysis, and density separation. In a broader sense, other microfossils sometimes are given 'courtesy appointments' as 'palynomorphs' even they do not survive routine pollen-extraction procedures" (Davis, 1999). The term *palynomorph* was introduced in Tschudy (1961).

References in forensic palynology include Bryant and Mildenhall (1996), Bryant, Jones, and Mildenhall (1996), and Faegri and Iversen (1989, p. 174 ff). Also refer to the webpage on forensic palynology of the California Criminalistic Institute,¹²³ to Terry Hutter's forensic palynology website,¹²⁴ to the website of Dallas Mildenhall's Forensic Services in New Zealand,¹²⁵ and to a website of Lynne Milne,¹²⁶ at the University of Western Australia.

There exist software resources for palynology. For example, the European Pollen Database (EPD) can be queried through its website.¹²⁷ It also publishes a newsletter. "The EPD is a relational database handled by Borland's (now Corel) PARADOX software. It contains raw data of pollen counts, C14 dates, geographical location and description of sites, lithological description of the records, chronologies, and bibliographic references. [. . .] The EPD tables can be downloaded and read directly either by PARADOX or by other software such as Microsoft Access. Single files are available in other formats (ASCII and Tilia)" (from the EPD main page), Tilia being "a free software program written by Eric Grimm", and on which, information is provided at the Tilia website.¹²⁸

The EPD website refers to "Web tools provided by the World Data Center for Paleoclimatology [and used in order] to retrieve basic information about a site, as

well as summary pollen diagrams: the Pollen Data Search Engine allows you search by P.I., place, or time; Webmapper is a visual map tool for locating data”. The Pollen Data Search Engine is accessible online,¹²⁹ whereas at another address one can access Webmapper.¹³⁰ The EPD e-list is hosted at the University of Colorado.

Pierre A. Zippi’s PAZ Software¹³¹ develops Mac-supported (but allegedly cross-platform) specialty scientific software solutions, applications having been developed for geological, biostratigraphic and earth science. Biostratigraphic services, such as data analysis, paleo data digitisation, and charting, are available¹³²; whereas Paleontology sample preparation services are available at another website of the same firm.¹³³ One of the products of PAZ software is Palynodata Table Maker 1.0, which (as advertised) “Converts unwieldy Palynodata references and taxa list to tab-delimited ASCII text files. The resulting tab-delimited text files may be imported into spreadsheets, databases or mail merge applications. Greatly increases the usefulness of this large stratigraphic database”. TILIA.12 To Spread (for MacOS) is used to “convert older Tilia 1.12 ASCII data files to tab-delimited spreadsheet files. NAPDToSpread will convert Tilia 2.0 files to spreadsheets. Free with WellPlot”; and so forth. Stephen Juggins’ webpage¹³⁴ provides information on more software for palynology.

8.5.6 Computing in Environmental Forensics

There exist applications of computing to environmental law (McBurney & Parsons, 2001; de Vey Mestdagh, 1999), and there exist computer tools for environmental forensics. The latter field is the subject of Murphy and Morrison (2002), which I reviewed (Nissan, 2003g). Practitioners of environmental forensics are concerned with chemistry, materials science, fluid dynamics, statistics, possibly biology, and they are required to know what the law is, how it works, and how they can construct and present their case effectively, which is typically but not exclusively when they are heard during litigation as expert witnesses. “Environmental forensic investigations frequently deal with the release of contaminants” (ibid., p. xiii). Site history (Bookspan, Gravel, & Corley, 2002, i.e., chapter 2 in Murphy & Morrison, 2002), e.g., at a landfill, requires acquiring documents, from archives or verbal depositions. I see a potential for dedicated software tools for assisting in this: not so much for retrieval (the paper trail is, after all, on paper, and archive material may well date back from before the computer era), as for organizing the development of the investigation report (Nissan, 2003g, p. 572).

Computing is explicitly covered in the next chapter in Murphy and Morrison (2002), as the need for aerial photos (current or historical) of a site lends the subject to that book's chapter 3 (i.e., Ebert, 2002),¹³⁵ on photogrammetry, photointerpretation, and digital imaging and mapping. Electronics is on occasion linked to chemical spillages: a case study (section 3.5.2 in that same book) involves circuit board fabrication plants.

Chapter 5 in Murphy and Morrison's book, namely, Philp (2002), is on isotope measurements. "Bulk isotopic values have been readily available for many years but one of the most significant analytical advances in geochemistry in the past few years has undoubtedly been the development of combined gas chromatography – isotope ratio mass spectrometry (GCIRMS)" (ibid., p. 111). Computing and plotters are conspicuous in such analyses.

When it comes to environmental forensics rather than just environmental science, there is a factor that need be considered, considering computer-assisted modelling as pertaining to various areas of environmental science. "There are currently in excess of 400 groundwater flow (advective) and contaminant transport models" (ibid., p. 338, which is in chapter 8: Morrison, 2002). "In the United States, it is estimated that computer-based predictions of contaminant transport influence legal and policy decisions involving the allocation of at least 1 billion dollars each year" (ibid., p. 339). Several sources of uncertainty affect models.

The calculation-intensive subsurface models (Morrison, 2002) include, e.g., vapour, liquid, colloidal, or cosolvent transport through pavement or soil. "Preferential flows" of infiltrating liquid exploit preferential pathways, either artificial (dry wells, cisterns, utility line backfill, etc.), or natural: "worm channels, decayed root channels [...], soil fractures, slickensides, swelling and shrinking clays, highly permeable soil layers, and insect burrows" (ibid., p. 335). This is fertile ground for computational science (\neq computer science).

"The origin of inverse modeling for contaminant transport in groundwater is predated by research in the heat transfer literature" (ibid., p. 339). Inverse (or reverse) models are also called "backward extrapolation models", "hindcasting" (patterned after "forecasting"), and "backward random walk" (339). "In its simplest application, inverse modeling relies upon measured properties or contaminant concentrations to extrapolate to some point in the past, the age and the location of a contaminant release, most frequently by using geostatistical and optimization approaches" (ibid., p. 339). "In cases where light non-aqueous phase liquids (LNAPLs) are of interest, numerical models are available to predict LNAPL plume migration over time [...] and to age date the release using a direct estimate and nonlinear parameter estimation approach" (ibid., p. 342).

Potential sources of uncertainty affecting inverse models include: "The reasonableness of the selected porosity and hydraulic conductivity value(s)" (ibid., p. 343),

¹³⁵ James I. Ebert is an environmental and forensic scientist who is also a certified photogrammetrist, and a trained archaeologist and anthropologist who has taken part in a project in palaeoanthropology and environmental research at Olduvai Gorge in Tanzania.

“The consistency of the groundwater flow direction and velocity over time”, “The validity of the selected hydraulic gradient(s) values over time and distance from the release”, “The number of data points and time interval during which the data were collected”, “The nature of the release (steady versus non-steady)”, “The loading rate” (possibly based on production records), “The value(s) selected for aquifer(s) thickness (model specific)”, “The horizontal and transverse dispersivity values” (ibid., p. 343), “Contaminant retardation and/or degradation rates” (ibid., p. 344), “Identification of the leading edge of the contaminant plume (model specific)”, “The effect of recharge/discharge rates (if applicable) of water into the system and its impact on plume geometry and contaminant velocity” (ibid., p. 344). Bear in mind that a court may have to decide on whether some aspect of the model was reasonable, e.g., rejecting the defendant’s model. Robert D. Morrison, the author of Ch. 8 in the same book, actually provides legal illustrations for a few of the items listed above. This way, for the “effect of recharge/discharge rates”, he states (ibid., p. 344):

In the *Velsicol* case, for example, the court wrote, ‘the district court rejected the defendant’s water model as inaccurately under representing the extent of chemical contamination in the groundwater supply. In refuting the defendant’s model, the court reasoned that Velsicol had failed to factor in the massive dumping of liquid waste, the ponding of water in the trenches, and the draw down on the aquifer caused by new homes.’

Chapter 9 in Murphy and Morrison (2002), “Forensic Air Dispersion Modeling and Analysis”, features techniques such as the Gaussian plume model analysis. A “case study is a toxic tort in which the plaintiffs claimed dioxin and furan exposure” (ibid., p. 385). “Chapters 10 through 12 [in Murphy & Morrison (2002)] introduce statistical aspects associated with an environmental forensic investigation. Chapter 10 summarizes statistical tests for comparing data sets and evaluating temporal or spatial relationships. Chapters 11 and 12 present advanced pattern recognition techniques, of increasing utility within today’s greater computing power. Chapter 11 discusses particulate pattern recognition techniques used for source identification” (ibid., p. xiv).

Thomas D. Gauthier’s “Statistical Methods” (chapter 10 in Murphy & Morrison, 2002) points out that of the “variety of statistical analysis techniques[,] most examples in the literature involve rather sophisticated applications including principal components analysis and chemical mass balance receptor modeling (discussed elsewhere in [Murphy & Morrison, 2002]). These techniques are powerful analytical tools and provide useful insights for data interpretation but the results can be difficult to explain to a judge or jury” (ibid., pp. 391–392). “Relatively simple statistical analysis techniques can be used in environmental forensic investigations to compare data sets, characterize associations between variables, evaluate trends, and make predictions. Moreover, it is often possible to assign a degree of confidence to the results. This advantage is particularly useful in litigation scenarios where experts are often asked to assign a probability to the correctness of their opinion” (ibid., p. 425).

For the identification of air pollution sources, dispersion or receptor modeling (Watson & Chow, 2002, i.e., chapter 11 in Murphy & Morrison, 2002) is a relevant

tool. Modeling small particles suspended in the air goes by the name “particulate pattern recognition”. “Receptor models use the variability of chemical composition, particle size, and concentration in space and time to identify source types and to quantify source contributions that affect particle mass concentrations, light extinction, or deposition” (ibid., p. 430). Such models include, e.g., *multiple linear regression on chemical markers* (ibid., p. 432), *temporal and spatial correlation eigenvectors* (ibid., p. 433),¹³⁶ and (which is of particular interest in our present book) *neural networks* (ibid., section 11.2.6, pp. 433–434): “Training sets that have known source–receptor relationships are used to establish the linkages in the neural net that are then used to estimate source contributions for data sets with unknown relationships. The network assigns weights to the inputs that reproduce the outputs. Neural networks can provide functional relationships that are solutions to the MLR and CMB equations” (ibid., p. 433), i.e., respectively, to the multiple linear regression and to the chemical mass balance equations. Moreover (ibid., p. 434):

Spectral analysis [. . .], intervention analysis [. . .], lagged regression analysis [. . .], and trend analysis [. . .] models separate temporal patterns for a single variable and establish temporal relationships between different variables. These models have been used to identify sources, to forecast future pollutant concentrations, and to infer relationships between causes and effects. It is especially important to include meteorological indicators in time series models [. . .] and to use data sets with comparable measurement methods and sampling frequencies.

Glenn Johnson, Robert Ehrlich, and William Full (2002, i.e., chapter 12 in Murphy & Morrison, 2002) provide an in-depth tutorial into the use of principal components analysis and receptor models in environmental forensics. Such numerical methods are used in order to determine the three parameters enumerated at the end of the following quotation (ibid., p. 462):

The identification of chemical contaminant sources is a common problem in environmental forensic investigations. Successful inference of sources depends on sampling plan design, sample collection procedures, chemical analysis methods, and knowledge of historical industrial processes in the study area. However, in complex situations where multiple sources contribute similar types of contaminants, even careful project training and design may not be enough. If sources cannot be linked to a unique chemical species (i.e., a tracer chemical), then mapping the distributions of individual contaminant concentrations is insufficient to infer source. If, however, a source exhibits a characteristic ‘chemical fingerprint’ defined by diagnostic proportions of a large number of analytes, source inference may be accomplished through analysis of multiple variables; that is, through use of multivariate statistical methods. The objective of a multivariate approach to chemical fingerprinting is to determine (1) the number of fingerprints present in the system, (2) the multivariate chemical composition of each fingerprint, and (3) the relative contribution of each fingerprint in each collected sample.

Out of the spectrum of numerical methods from the past twenty years, more recently developed “procedures are designed to solve more general problems, which take

¹³⁶ For *eigenvectors*, see in fn. 24 in [Chapter 6](#).

into account complications such as bad data, commingled plumes (i.e., mixing of source fingerprints), and the presence of sources not assumed or anticipated at the start of an investigation” (ibid., p. 462). “In terms of experimental design, the source apportionment problem in environmental forensic investigations falls between two extremes.

At one extreme, all potential sources are known in terms of their chemical composition, location, history, and duration of activity. At the other extreme, none of these are known with certainty. Chemicals at the receptor (e.g., estuary sediments, groundwater at a supply well) may be the result of activities long absent from the vicinity of the site” (ibid., p. 462). Moreover (ibid., p. 463):

In the first case (a priori knowledge of all sources) the problem is a relatively simple one. Appropriate sampling locations can be determined using a conventional experimental design, which is part of conventional experimental statistics. Determination of contribution of each source can be extracted using a variety of linear methods, such as chemical mass balance receptor models (see chapter 11 of [Murphy & Morrison, 2002]). However, even when the contributing sources are known, environmental forensic investigations often proven to be more complex than initially anticipated. Chemicals in the environment may not retain their original composition. [...] The result of degradation will be resolution of one or more fingerprints, not originally anticipated.

When knowledge is uncertain, or unavailable, *exploratory data analysis* is to be used. indeed (ibid., p. 463):

At the other extreme, where nothing is known with certainty, potential sources may be suspected, but samples of the sources (i.e., fingerprint reference standards) may not have been collected, and may not exist in the literature. The industrial history of a region may be imperfectly known. Often, a small, low profile operation may be a major but completely overlooked source of contamination. For cases towards this end of the spectrum, we must take leave of the elegance of conventional experimental statistics, and move into the realm of exploratory data analysis (EDA). The fundamental difference between these two approaches (experimental statistics and EDA) is the former is associated with creation of explicit hypotheses, and evaluation of data in terms of well-defined tests and strong probabilistic arguments. In contrast, the objective of EDA is to find patterns, correlations and relationships in the data itself, with few assumptions or hypotheses [...]. If the fruits of an EDA result in a map where the concentrations of a multivariate fingerprint increase monotonically towards an effluent pipe, and the fingerprint composition is consistent with the process associated with that source, the obvious inference is that the potential source is the actual source. We recognize that we are not working in the realm of classical statistics or formal hypothesis testing, and that EDA is based on less rigorous probabilistic statement. However, such an approach should not be construed as ‘second best’. In environmental forensic, an EDA approach may be the only valid option.

Besides, it is important to consider that there may be bad or questionable data: “Unfortunately such errors rarely manifest themselves as random noise. More often, they contribute strong systematic variability. If unrecognized, the result may be derivation of ‘fingerprints’ which have little to do with the true sources. Therefore, a necessary adjunct to any data analysis in environmental forensics is identification of outliers” (ibid., p. 464). Nevertheless, even “inclusion of vigilant outlier identification and data cleaning procedures” may “resul[t] in deletion or modification of

data”, and then “the data must be clearly identified, and justification for the action must be provided in the narrative that accompanies the analyses” (ibid.).

To infer the sources of contaminants and their contribution, receptor modeling as described in chapter 12 ofd Murphy and Morrison (2002) is used. The *receptor modeling problem* is formally introduced in section 12.1.2 (ibid., p. 464):

The objectives are to determine (1) the number of chemical fingerprints in the system; (2) the chemical composition of each fingerprints; and (3) the contribution of each fingerprints in each sample. The starting point is a data-table of chemical measurements in samples collected from the receptor (e.g., estuarine sediments, ambient air in a residential area). These data are usually provided in spreadsheet form where rows represent samples and columns represent chemical analytes. To the multivariate data analyst this table is a matrix. We will refer to the original data table as the m row by n column matrix \mathbf{X} , where m is the number of samples and n is the number of analytes. We wish to know the number of fingerprints present (k) and chemical composition of each (objectives 1 and 2 above). This can be expressed as a matrix \mathbf{F} , which has k rows and n columns. We also wish to know a third matrix \mathbf{A} , which has m rows and k columns, and represents the contribution of each fingerprint in each sample (objective 3 above). Thus the following linear algebraic equation formally expresses the receptor modeling problem.

$$\text{Matrix dimensions} \quad \begin{matrix} \mathbf{X} \\ (m \times n) \end{matrix} = \begin{matrix} \mathbf{A} \\ (m \times k) \end{matrix} \begin{matrix} \mathbf{F} \\ (k \times n) \end{matrix}$$

Subsequent sections in chapter 12 are devoted to methodological categories and are themselves further subdivided rather densely. They include “Principal Components Analysis” (section 12.2) – the acronym is PCA – as applied to environmental chemometrics, and “Self-Training Receptor Modeling Methods” (section 12.3), which in turn includes

- polytopic vector analysis (PVA): this is an algorithm that evolved over forty years, and whose roots are “in principal components analysis, pattern recognition, linear algebra, and mathematical geology” (ibid., p. 498),
- the unique vector rotation method, and
- the so-called SAFER method (the acronym stands for Source Appointment by Factors with Explicit Restrictions), which “is used in extended self-modeling curve resolution” (ibid., p. 508).

“These three [of section 12.3 in Murphy & Morrison (2002)] are analogous in that (1) they do not require a training data set; (2) they are PCA based methods; (3) they involve solution of quantitative source appointment equations by development of oblique solutions in PCA space; and (4) each involves the use of non-negative constraints” (ibid., p. 498). In fact, this is a particular class of algorithms, in Johnson et al. (2002), that deserves special attention in the book your are reading now, which is specifically concerned with the uses of artificial intelligence for legal evidence. Machine learning, as well as self-training algorithms (such as in artificial neural networks) are well-known to artificial intelligence practitioners. But self-training methods are also known from multivariate statistical analysis. Section

12.3 in Johnson et al. (2002), “Self-training receptor modeling methods”, is about “models designed to resolve three parameters of concern in a multivariate, mixed chemical system: (1) the number of components in the mixture, (2) the identity (i.e., chemical composition or fingerprints) of each component, and (3) the relative proportions of each component in each sample” (ibid., p. 497). Before Johnson et al. (2002), the full polytopic vector analysis (PVA) algorithm had not been set in any single paper (ibid., p. 498).

“PVA was developed for analysis of mixtures in the geological sciences, but it has evolved over a period of forty years, with different aspects of the algorithm presented in a series of publications, by a number of different authors” (ibid.). The originator was a palaeontologist, John Imbrie (1963), and this initially resulted in a series of Fortran programs. This eventually became CABFAC (*Calgary and Brown FACTor Analysis*), which “quickly became the most commonly used multivariate analysis algorithm in the geosciences” (ibid., p. 499). Later on, “William Full, as a PhD candidate at the University of South Carolina in the early 1980s, developed the DENEG algorithm, which allows end-members (sources) to be resolved without a priori knowledge of their composition, and without use of a training data set (Full et al., 1981, 1982)” (Johnson et al., 2002, p. 499). PVA involves resolution of oblique vectors as source compositions. This vector analysis is polytopic, because “PVA involves resolution of a $k - 1$ dimensional solid, a “simplex” or “polytope”, within k dimensional principal component space” (ibid.). So if $k = 4$, the polytope is a tetrahedron. The algorithms at the core of PVA are implemented under default options in the commercial versions of the SAWVECA software of Residium Energy, Inc., Dickinson, Texas. Johnson et al. explained (2002, pp. 506–507):

PVA is one ‘self-training’ method that allows source profiles to be derived in absence of *a priori* knowledge of their chemical composition, but other such methods have seen considerable application in environmental chemical data. One of these is target transformation factor analysis (TTFA), which developed within analytical chemistry/chemometrics rather than mathematical geology/geochemistry (Roscoe and Hopke, 1981; Gemperline, 1984; Hopke, 1989; Malinowski, 1991).

In TTFA, the subroutine that allows estimates of source composition in the absence of known sources is the unique vector rotation method [. . .]. This method begins by establishing a $n \times n$ matrix where each row vector is 100% of a single analyte (i.e. ‘unique vectors’). In turn, each of these vectors is iteratively rotated within principal component space.

Moreover (Johnson et al., 2002, pp. 508–509):

Another receptor modeling method, SAFER (Source Apportionment by Factors with Explicit Restrictions) is used in extended self-modeling curve resolution (ESMCR: Henry and Kim, 1990; Kim and Henry, 1999). Unlike PVA and TTFA, ESMCR does not typically involve transformation to unit length. [. . .] The SAFER method begins by defining the ‘feasible region’ where the simplex vertices and edges may reside. The inner boundary of the feasible region is defined by the convex hull of the data cloud [. . .]. The non-negativity constraints on the analytes define the outer boundary of the ‘feasible region’. [. . .] For a three-component system [. . .], a feasible mixing model may be defined by direct inspection of the data plotted in the principal component space, and manually located within the fea-

sible region (this method is termed SAFER3D). A method of resolving higher dimensional mixing models has recently been described (Kim and Henry, 1999). That method calls on the use of additional explicit physical constraints. Examples of additional constraints may include (1) total mass of samples, (2) *a priori* knowledge of a subset of contributing sources, (3) upper and lower limits on ranges or ratios of analyte compositions, or (4) constraints based on laws of chemistry (Kim and Henry, 1999). As was the case for the unique vector iteration method, SADER has been applied primarily in source apportionment studies in air (Henry et al., 1997).

8.6 Forensic Engineering

Forensic engineering is a discipline¹³⁷ practised by such engineers who appear in court as expert witnesses, or at any rate are involved in dispute resolution and have to develop hypotheses and argue for them in a legal setting, including in front of arbitration panels, or in mediation and conciliation; for the difference between trial, arbitration, and mediation, see Hohns (1987), from the perspective of the forensic engineer in construction related disputes. Specter (1987) provides the following definition: “Forensic engineering may be generalized as the art and science of practitioners who are qualified to serve as engineering experts in matters before courts of law and in arbitration proceedings” (ibid., p. 61). The definition on Wikipedia¹³⁸ is as follows:

Forensic engineering is the investigation of materials, products, structures or components that fail or do not operate/function as intended, causing personal injury for example. The consequences of failure are dealt by the law of product liability. The subject is applied most commonly in civil law cases, although may be of use in criminal law cases. Generally the purpose of a forensic engineering investigation is to locate cause or causes of failure with a view to improve performance or life of a component, or to assist a court in determining the facts of an accident. It can also involve investigation of intellectual property claims, especially patents.

Forensic engineering typically concerns failure: the failure of structures, foundations, materials, or machinery, or of construction as a process. See, e.g., Lewis and Hainsworth (2006). The journal in the field is *Engineering Failure Analysis*. Construction related disputes are just one of the areas within forensic engineering, and involve civil engineers. A special area is automotive engineering, for investigating car crashes. “Forensic engineering involves more than engineers. We have on our roster chemists, architects, contract administrators, fire cause investigators, and experts in packaging, radiology and computer technology” (Garrett, 1987, p. 17).

¹³⁷ In James and Nordby (2005, 2nd edn.; 2009, 3rd edn.), a volume on forensic science, the chapters about forensic engineering comprise one about structural failures, by Randall Noon (2005a; 2009a, 3rd edn.), then a chapter about basic fire and explosion investigation, by David Redsicker (2005, 2009, 3rd edn.), and a chapter on vehicular accident reconstruction, by Randall Noon (2005b; 2009b, 3rd edn.).

¹³⁸ http://en.wikipedia.org/wiki/Forensic_engineering.

Typically, scholarship in the field concerns failure theories, hypothesis testing, and failure investigations. It also concerns legal problems, practices, and policy connected with the testimony of forensic engineers. Not only engineers, but also trial lawyers and insurance adjusters are involved. In 1987, Pergamon Press (now Elsevier) started to publish a journal in the domain, entitled *Forensic Engineering*. In the United States, there is the *Journal of the National Academy of Forensic Engineers*. *Expert* (1985) is a guide for forensic engineers, published by the Association of Soil and Foundation Engineers. Suprenant (1988) is a textbook. Other books in forensic engineering include Noon (1992, 2000), and Lewis, Gagg, and Reynolds (2004). The latter was authored at the Open University in Britain, and it is interesting to see how the website of that institution promotes both its forensic service to external clients, and its curriculum in forensic engineering;¹³⁹ as can be seen, the academic disciplinary compartment is Materials Engineering, home the focus there is on product failure, and individual researchers are specialised in a rather narrow category of materials:

Product failure has been studied in the Materials Engineering Department since its inception, and forms the basis of several courses presented by the department (T839 Forensic Engineering). The loose grouping of individuals study a very wide range of cases, from metal fatigue of crankshafts ([. . .]), stress corrosion or ozone cracking of fuel lines ([. . .]), breakage of glass bottle causing personal injury ([. . .]), failure of power hand tools ([. . .]) to infringement actions in medical devices and garden products ([. . .]). Cases are studied within a framework set by litigation, enquires by insurers, or companies and institutions. Work has also been funded by the Consumer Research Laboratories in order to improve the design of handpumps and rising mains for use in developing countries. Independent research by the group has revealed new and unsuspected failure modes in both traditional and entirely new materials. All members have had recent experience of court procedure and giving expert advice before tribunals. This group has links with the *Fracture and Fatigue* and *Residual Stress* groups in the department. [. . .]

“[T]he insurance industry and the legal profession [are] the primary users of forensic engineering services” (Garrett, 1987, p. 17). Clients typically require “quality technical people to help them solve the puzzle of ‘What happened?’” (ibid., p. 17). “[Y]ou are hired by an insurance company, a lawyer, a builder, a manufacturer, or an irate or injured citizen” (Knott, 1987, p. 11). “We ask clients to refrain from deciding in advance what kind of an expert they need. They may ask for a metallurgist when what they really need is a traffic engineer. And they may need several experts, not just one” (Garrett, 1987, p. 18). “If your client is an insurance company, it is usually interested in proof that it should or should not pay a claim” (Knott, 1987, p. 11) “The work is done to determine the probable cause of a failure or an accident. The lawyer will have to prove the case in court, and a proof in law is not the same as a proof in engineering” (ibid.). There are different categories of what is to be proven, in such cases in which a forensic engineer may be called to testify. “The law has evolved into distinct arenas. For example, strict liability, negligence,

¹³⁹ http://materials.open.ac.uk/research/res_forensic.htm.

and warranty. You may be able to show that the manufacturer had a first-rate quality control program. This is an excellent defense in negligence but has absolutely no application in strict liability” (ibid.).

Software for engineering, especially simulations for *failure analysis*, or then software for *structural risk evaluation*, or software modelling the plasticity and fracture of solid materials, will be of use to the forensic engineer in some categories of cases. Importantly, the entry for “Forensic engineering” in Wikipedia makes a distinction between forensic science and forensic engineering:

There is some common ground between forensic science and forensic engineering, such as scene of crime and scene of accident analysis, integrity of the evidence and court appearances. Both disciplines make extensive use of optical and scanning electron microscopes, for example. They also share common use of spectroscopy (infra-red, ultra-violet and nuclear magnetic resonance) to examine critical evidence. Radiography using X-rays or neutrons is also very useful in examining thick products for their internal defects before destructive examination is attempted. Often, however, a simple hand lens suffices to reveal the cause of a particular problem. Trace evidence is often an important factor in reconstructing the sequence of events in an accident. For example, tyre burn marks on a road surface can enable vehicle speeds to be estimated, when the brakes were applied and so on. Ladder feet often leave a trace of movement of the ladder during a slipaway, and may show how the accident occurred.

Section “methods” (ibid.) remarks:

Methods used in forensic investigations include reverse engineering, inspection of witness statements, a working knowledge of current standards, as well as examination of the failed component itself. The fracture surface of a failed product can reveal much information on how the item failed and the loading pattern prior to failure. The study of fracture surfaces is known as fractography. Fatigue often produces a characteristic fracture surface for example, enabling diagnosis to be made of the cause of the failure. The key task in many such investigations is to identify the failure mechanism by examining the failed part using physical and chemical techniques. This activity is sometimes called root cause analysis. Corrosion is another common failure mode needing careful analysis to determine the active agents. Accidents caused by fire are especially challenging owing to the frequent loss of critical evidence, although when halted early enough can usually lead to the cause. Fire investigation is a specialist skill where arson is suspected, but is also important in vehicular accident reconstruction where faulty fuel lines, for example, may be the cause of an accident.

8.7 Individual Identification

8.7.1 *The Cultural Context: The History of Identification Methods*

It is important to understand the history of the use of fingerprints for identification purposes, in order to realise how the mutual expectations of law enforcers and of perpetrators have evolved. This in turn is potentially useful for the purposes of future AI tools that would reason about the evidence. Understanding the dynamics of how both law enforcers and perpetrators had to become more and more clever, makes one realise that one cannot come up as well with the ultimate technique of detection.

Hardware and software you may produce may prove useful for a while, or even for a long time, but requirements will change, and older techniques will either have to change, or have to be supplemented with something else. Within AI, the area concerned with how to reason with an agent's beliefs about the beliefs of another agent is known as *agents' beliefs* (e.g., Ballim, By, Wilks, & Liske, 2001; Barnden, 2001).

The following example shows how a course of action taken by perpetrators with the intention of suppressing the evidence, actually backfired. During the Troubles in Northern Ireland in the 1970s and 1980s, bombs prepared by terrorists sometimes contained the gloves they had been using. Their assumption was that the blast would destroy the gloves, but it was not so. Law enforcers hoped to find, inside the remains of such gloves, the fingerprints of perpetrators – that is to say, evidence that the terrorists had placed inside the bombs by believing that by so doing, they would destroy the evidence.

Those fingerprints were detected, because of their coating of lipids (traces of the fat on the skin of fingertips). Radioactivity was used, in order to make that coating of lipids (fat from the fingertips) apparent, using a photographic technique or based on luminescence, and the former appeared to be better than the latter.¹⁴⁰ Let us recapitulate, with more technical details:

- The people making bombs would wear gloves.
- When they finished they would place the gloves with the device.
- The fingerprints (contrary to what the bombers had assumed) could then be recovered from the inside of the gloves.
- The radioactive SO₂ (sulfur dioxide) absorbed could then be detected¹⁴¹ by luminescence or by photographic techniques (using silver halides).¹⁴² The graphite

¹⁴⁰ Around 1980s, such circumstances were still secret, but by 2010, when I was informed verbally, they were in the public domain.

¹⁴¹ E.g., in Goode, Morris, and Wells (1979), a team from the Atomic Weapons Research Establishment of the British Ministry of Defence, based at Aldermaston, Berkshire, described the application of radioactive bromine isotopes for the visualisation of latent fingerprints. A vapour phase bromination procedure was investigated for reaction with unsaturated lipids present in a fingerprint deposit.

¹⁴² The light-sensitive chemicals used in photographic film and paper are silver halides. A *silver halide* is one of the compounds formed between silver and one of the halogens, namely: silver bromide (AgBr), silver chloride (AgCl), silver iodide (AgI), and three forms of silver fluorides. As a group, they are often given the pseudo-chemical notation AgX. Silver halides, except for silver fluoride, are extremely insoluble in water.

“Silver halides are used in photographic film and photographic paper, as well as graphic art film and paper, where silver halide crystals in gelatin are coated on to a film base, glass or paper substrate. The gelatin is a vital part of the emulsion as the protective colloid of appropriate physical and chemical properties. Gelatin may also contain trace elements (such as sulfur) which increase the light sensitivity of the emulsion, although modern practice uses gelatin without such components. When absorbed by an AgX crystal, photons cause electrons to be promoted to a conduction band (de-localized electron orbital with higher energy than a valence band) which can be attracted by a sensitivity speck, which is a shallow electron trap, which may be a crystalline defect or a cluster of

fine powder for conventional fingerprint recording could not be used. The photographic techniques proved to be the most efficient.

A medal dated 1969, designed by Jiri Hrcuba, was struck in Czechoslovakia, in bronze, silver, and for the first time, with a golden proof, for the centenary of the death of Jan Evangelista Purkyně, a physician considered the discoverer and founder of *dactyloscopy*, i.e., the identification of persons based on their fingerprints. (Defying the Soviet invasion, the Czech mint also struck Hrcuba's medal, also dated 1969, commemorating Jan Palach, the student who set himself ablaze in protest.) Purkyně (1787–1869) is actually much better known as the father of histology: the middle cortex of the cerebellum were named *Purkinje cells*, after him. Outside the Czech Republic or Slovakia, his family name is usually spelled *Purkinje*.

No mention of Purkyně is made in the entry for “dactyloscopie” in Nathanaël Tribondeau's glossary of criminalistics (Tribondeau, accessed 2006). About the origination of the technique, it just states: “Utilisée pour la première fois en 1880 par l'Anglais William J. Herschel” (“Used for the first time by an Englishman, William J. Herschel”). He got an entry in his name: “Born in 1738 and deceased in 1922, he is the inventor, along with Francis Galton [Darwin's cousin], of dactyloscopy (the collection and analysis of fingerprints). It was looking for some surer means than just a signature, for the authentication of commercial documents, that this English official seconded to Bengal conceived of the idea, from 1880, of having his suppliers mark contracts with their fingerprints, to avoid future disputes. It was only later on, that this procedure was used by the scientific police, with the success we all know about” (my translation).

What Tribondeau does not say about the adoption by fingerprints in France, is related in an article by Jean-Marc Berlière (2005) about the Scheffer Affair, about the first conviction of a suspect, in France, revolving around on identification by fingerprints. Berlière explains that with the emergence, in the positivist era, of the realisation, turned into an obsession in France, that recidivists are responsible for most crimes (this actually came along with now discredited theory of Cesare Lombroso about the born criminal), perpetrators smarted up to the challenge, and

silver sulfide, gold, other trace elements (dopant), or combination thereof, and then combined with an interstitial silver ion to form silver metal speck” (http://en.wikipedia.org/wiki/Silver_halide).

Apart from applications to photography, experiments have been conducted for medical purposes: silver halide optical fibres for transmitting mid-infrared light from carbon dioxide lasers, allow laser welding of human tissue, as an alternative to traditional sutures. Another use is in the making of lenses, exploiting photochromism: Silver halides are also used to make corrective lenses darken when exposed to ultraviolet light. “When a silver halide crystal is exposed to light, a sensitivity speck on the surface of the crystal is turned into a small speck of metallic silver (these comprise the invisible or latent image). If the speck of silver contains approximately four or more atoms, it is rendered developable – meaning that it can undergo development which turns the entire crystal into metallic silver. Areas of the emulsion receiving larger amounts of light (reflected from a subject being photographed, for example) undergo the greatest development and therefore results in the highest optical density” (ibid.).

law enforcement was faced with the problem of how to identify a person who has been using several false names.

Alphonse Bertillon proposed for identification to consider the *identité anthropométrique*, based on measurements of the bones of adults. The French police adopted this technique in 1883. There is a sense in which it was of little help, as perpetrators were unlikely to leave their bones around, yet it was rather useful for identifying recidivists who were using a false name, provided they had been *bertillonnés*, i.e., had their anthropometric measurements taken before. On 16 February 1883, a recidivist was recognised for the first time, based on anthropometric measurements.

By the end of 1883, 49 ex-cons had been identified that way; 241 during the next year (*ibid.*, p. 350, fn. 3). The technique featured, arousing much interest, at the international exposition of Paris of 1889. “Its zenith was when, in the spring of 1892, it enabled Bertillon to identify ‘Ravachol’, who at the time was terrifying Paris, with a Koenigstein who had been *bertillonné* at Saint-Étienne prison two years earlier” (*ibid.*, p. 350, my translation). The technique could tell apart two dissimilar persons, but similar anthropometric data could not be ascribed with certainty to the similar person. This was a major flaw.

Fingerprints were to prove a better technique. Fingerprints were observed by Italian anatomist Marcello Malpighi (1628–1694). That Purkyně described fingerprints in 1823 is mentioned by Berlière (who wrongly Hispanicises his first name as *Juan*). So is empirical use in British-ruled India, as well as the role of the physician Henry Faulds, or the classifications developed by Francis Galton, Edward Henry, and Juan Vucetich during the 1890s.

Berlière relates the role which Bertillon had, in the first conviction in France based on fingerprints.¹⁴³ On 16 October 1902, the body of a male servant was discovered inside the Parisian apartment of a dentist. The motive appeared to be theft. On a broken glasscase, many fingerprints were found. On one side of the glass, there was the print of a thumb, the prints of three other fingers being on the other side: these were the fingerprints of a person who has held the glass after it was broken.

One difficulty was that the fingerprints were overlapping, because of the transparency of the glass. An advantage for Bertillon was that he got the fingerprints of four adjacent fingers of the right hand, i.e., the only hand for which fingerprints had been stored. Bertillon searched the archives, card by card, without classification criteria to guide the search, and identified Henri-Léon Scheffer, born in 1876, who had been arrested and had had his fingerprints taken on 9 March 1902.

Bertillon’s report to the examining magistrate, stating this identification, is dated 24 October 1902. Berlière points out (p. 351, fn. 7) that this case is usually misrepresented as though it was the first time that a perpetrator was identified based only

¹⁴³ The historical origins of identification by fingerprints have been discussed, e.g., by Simon Cole (1999), a criminologist who is prominent among those who question the accuracy, sufficiency, and individuality of fingerprint identification.

on fingerprints. That was not the case, as an intimate relation had been discovered between the victim and Scheffer, and the latter had been among the suspects.

For Berlière, Bertillon's role in identification by fingerprints becoming an established technique is paradoxical, as Bertillon was aware of publications about fingerprints from other countries, yet had been quite reluctant to adopt this method, mainly because of the difficulty to classify fingerprints, but also because he considered them not to be distinctive enough (a laughable claim, vis-à-vis the weakness of his own anthropometric method). Locard was sarcastic about Bertillon in that respect. Edmond Locard (1877–1966) was a younger star of French criminalistics, who established France's first scientific police laboratory (*Laboratoire de Police scientifique*) in Lyons in January 1910, and published during the 1930s a *Traité de criminalistique* in seven volumes of lasting value to forensic laboratories worldwide. Locard's thesis on legal medicine is dated 1902.

Berlière remarks that stubbornness was a trait of Bertillon's personality, and that this played a role in his determined attitude against Dreyfus, when, an expert witness in court, he insisted on interpreting the graphological evidence unreasonably. Berlière points out that this was one reason Locard disliked Bertillon quite intensely. Berlière mentions a major error made by Locard himself: in 1945, a woman was sentenced to forced labour for life, having been identified by him as the anonymous Nazi collaborator who had denounced a partisan in the French Resistance; she was only freed after the error was recognised as such in 1956.

Locard himself developed (among the other things) *graphometrics*, and solved some cases based on graphological evidence; e.g., he solved a case in which a husband guided the hand of his dying wife in writing a will in his favour (in 1923, Locard published a paper about 'L'Écriture à la main guidée' in the *Revue de droit pénal et de criminologie et Archives internationales de médecine légale* in Bruxelles). Vols. 5 and 6 of Locard's *Traité de criminalistique* were published in 1935, and in fact they are entitled *L'Expertise des documents écrits*, being devoted to the analysis of written documents. Vol. 1 appeared in 1931, and was devoted to fingerprints and to other traces (*Les Empreintes et les traces dans l'enquête criminelle*). Vols. 3 and 4 appeared in 1932, and were about identification evidence (*Les Preuves de l'identité*).

Apparently Bertillon's endorsement of fingerprints came after the physician Lacassagne (one of the founders of criminalistics) and Galton had extolled to him the method. He remained reluctant to see his own method, based on anthropometric measurement, made obsolete by fingerprint identification. His successor who took over from him at the police, quoted by Berlière (p. 358), testified that in February 1914, upon Bertillon's death, out of the 1,200,000 cards held by the scientific police, only 60,000 had been classified based on the fingerprints. France adopted classification based on fingerprints considerably later than Argentina, the United Kingdom, and other countries (ibid.). Argentina was pioneering in criminalistics, and there actually is an anecdote (it was even related in the *Reader's Digest*) about Locard, in his student days, becoming enthralled with the discipline one day, when he was accompanying his medicine professor, the famous Lacassaigne. They had to wait because of the rain, and Lacassaigne gave him an Argentinean journal,

asking Locard to translate an article for him on the spot. What Locard read on that occasion determined his professional future. Alexandre Lacassagne (1843–1924) became “Professeur de Médecine Légale” in 1880, and established research in the domain in Lyons, where it was carried further by Étienne Martin, Pierre Mazel, Jacques Bourret, as well as by his most famous continuator, Edmond Locard.¹⁴⁴

In his memoirs of the First World War, ‘Aziz Bek, Head of Intelligence of the Fourth Ottoman Army, described an episode, which started when a spy stole documents (being unable to photograph or copy them on the spot) and then returned them. The commander of the 43th Division in Syria had noticed the disappearance of the defence plans, and on their reappearance he would not touch them. He had a laboratory detect fingerprints, then discreetly obtained the fingerprints of all officers, soldiers and clerks at the division headquarters. A circular was distributed, that had to be signed and returned. This way, a signature would identify the fingerprints unwittingly left on the paper. This led to the identification of an officer and of a soldier, and further investigation uncovered their links to a spy ring (‘Aziz Bek [1933–1937] 1991, pp. 116–117).

Twenty years earlier, a course of action such as this one hadn’t been taken, in France, with the *bordereau* ascribed to Alfred Dreyfus, but then such forensic “expertise” that had been sought at the time, had the goal of confirming his alleged guilt, rather than discovering the actual identity of the spy. “Evidence” had included supposed similarities in the handwriting, as well as the fact that when Dreyfus was ordered to write down under dictation a text identical with that of the dossier, he was visibly shaking (who wouldn’t, in his shoes?).

The example of the forensic “expertise” seeking to confirm that Dreyfus had written the given document, illustrates the pitfalls of *confirmationism* (tests seeking to confirm rather than disprove a hypothesis),¹⁴⁵ and more broadly, of tunnel thinking. The forensic experts were so committed to the claim that the suspect was guilty, that it was almost a foregone conclusion that they would find what they were looking for. This suggests that cognitive science and artificial intelligence research producing computational simulations of tunnel thinking could provide some clarification

¹⁴⁴ Berthold Laufer, who was the United States leading Sinologist during the first three decades of the twentieth century, also authored a report on the history of fingerprinting (Laufer, 1913, 1917). Berthold Laufer was born in Cologne, Germany, in 1874. After earning his doctorate at the University of Leipzig in 1874, Berthold Laufer moved on the following year to the United States. He had obtained an invitation to the American Museum of Natural History in New York City, thanks to the famous anthropologist Franz Boas (1858–1942). Laufer eventually became curator of Asiatic Ethnology and Anthropology at the Field Museum of Natural History, Chicago, where he had moved in 1907, leaving a lectureship in Anthropology and East-Asiatic Languages at Columbia University. He died in 1934, upon leaping from the roof of the hotel in which he lived in Chicago, but the mode of his demise goes unmentioned in Latourette’s (1936) biographical memoir of Berthold Laufer for the U.S. National Academy of Sciences.

¹⁴⁵ *Confirmation bias* as occurring in the police interrogation rooms, see e.g. Kassir, Goldstein, and Savitsky (2003), Meissner and Kassir (2002), and Hill, Memon, and McGeorge (2008). Confirmationism is sometimes referred to as *cognitive dissonance*. This name for the concept was spread by a book by Leon Festinger (1919–1989), *A Theory of Cognitive Dissonance* (Festinger, 1957).

at the theoretical level, which would eventually be put to use in the design of tools for assisting with reasoning about the evidence. It would be blue sky research eventually finding (hopefully) practical application in a better design of tools. One possibility would be to develop an AI tool that would test protocols or possibly other software, trying to ensure that they are not marred by pitfalls of the kind mentioned earlier. In a sense, such pitfalls have already been sometimes argued to affect widespread techniques. The adoption of the Dempster-Shafer statistical technique is rather widespread in AI tools, but a major problem stemming from the adoption of Dempster-Shafer is that it is apparently tilted towards *confirmationism* instead of *falsificationism*.

8.7.2 DNA and Fingerprints

8.7.2.1 DNA Evidence: A Brief Introduction

Computational methods for determining individuality (Srihari & Su, 2008) encompass several domains in forensic science, from fingerprint analysis to handwriting recognition. In the 1990s and 2000s, DNA has become the evidence per excellence for personal identification. DNA evidence is usually considered to be hard evidence about a person's identity.¹⁴⁶ Nevertheless, DNA fingerprinting is not uncontroversial.¹⁴⁷ Concerning DNA evidence, consider the application to paternity claims.¹⁴⁸

¹⁴⁶ An overview of techniques of DNA analysis is provided by Duncan, Tacey, and Stauffer (2005, 2nd edn.; 2009, 3rd edn.), whereas in the same volume, Susan Herrero (2005, 2nd edn.; 2009, 3rd edn.) provides an overview of legal issues in forensic DNA. DNA fingerprinting is treated, e.g., in Baldin (2005), Inman and Rudin (2002), National Research Council (1996), Stockmarr (1999), Lauritzen and Mortera (2002), Meester and Sjerps (2004), Easteal, McLeod, and Reed (1991), Krawczak and Schmidtke (1994), and Butler (2001). See a brief, yet important debate (Krane et al., 2008), with useful bibliographies by the various commentators, about *sequential unmasking* in DNA identification. It was republished in www.bioforensics.com under the rubric *forensic bioinformatics*.

¹⁴⁷ Roberts (1991) is about the controversy about DNA fingerprinting. Nielsen and Nespor (1993) is on human rights in relation to genetic data and screening, in various contexts.

¹⁴⁸ Of course, historically there was interest in ascertaining paternity even before medical knowledge and technology would enable such checks credibly. For example, discussing early modern English midwifery books, Mary Fissell remarks (2003, p. 65): "Midwifery books of the 1670s and 1680s were obsessed by the issues of fatherhood. How could you know the father of a child? In certain circumstances, such as illegitimate births, knowing the father had long been important. These texts devoted much more attention to resemblance between parents and their children than did previous midwifery texts. This crisis in paternity had multiple roots. There was no sudden increase in illegitimate births that might have prompted such an interest. Some of the crisis may be due to longer-term intellectual changes that gradually made similitude a happenstance rather than an indicator of profound connection. No longer did resemblance mean something important about relatedness." Fissell further explains (*ibid.*, pp. 65–66): "The crisis can also be understood in political terms. In [the] 1670s and 1680s, the question of monarchical succession – the transmission from one generation to another – became ever more pressing. Charles II did not have any legitimate sons, and his brother James's Catholicism made him a highly problematic successor. The

An article by an Oslo-based team, Egeland, Mostad, and Olaisen (1997), describes PATER, a software system for probabilistic computations for paternity and identification cases, in cases where DNA profiles of some people are known, but their family relationship is in doubt. PATER is claimed to be able to handle complex cases where potential mutations are accounted for.

Another project resulted in, e.g., Dawid, van Boxel, Mortera, and Pascali (1999), Dawid, Mortera, and Pascali (2001), and Dawid, Mortera, and Vicard (2010), Vicard, Dawid, Mortera, and d Lauritzen (2008), and Vicard and Dawid (2006), specifically about the statistics of disputed paternity. A prominent statistician, Philip Dawid, now at the University of Cambridge, at the time when he was affiliated with University College, London was remarking as follows at his research interests webpage¹⁴⁹:

I have been interested in the application of Probability and Statistics to a variety of subject areas, in particular to Medicine (especially medical diagnosis and decision-making), Crystallography, Reliability (especially Software Reliability) and, most recently, *Legal Reasoning*. I have acted as expert advisor or witness in a number of legal cases involving DNA profiling. This has led me to a thorough theoretical examination of the use of Probability and Statistics for *Forensic Identification*. I head an international research team focusing on the analysis of complex forensic DNA identification cases using Probabilistic Expert Systems. These legally inspired investigations have also highlighted the many logical subtleties and pitfalls that beset evidential reasoning more generally. To address these I have established a multidisciplinary research programme on *Evidence, Inference and Enquiry* [¹⁵⁰] at University College London. This is bringing together researchers from a wide diversity of disciplinary backgrounds to seek out common ground, to advance understandings, and to improve the handling of evidence.

duke of Monmouth's rebellion (the duke being the king's illegitimate son), the Rye House Plot, the Popish Plot [i.e., a libel against Catholics leading to executions] – all kept political instability at the forefront of popular awareness. The high politics of legitimate succession moved right into the birthing room in the Warming Pan Baby scandal, which erupted when James II's wife, Mary of Modena, gave birth a male heir – or did she? She had had eight previous pregnancies, all stillbirths or very short-lived infants. This baby was full-term and healthy, and some observers claimed it was a fraud. They suggested that a healthy baby had been smuggled into the birthing room, concealed in a warming pan, and substituted for Mary's sickly or stillborn babe."

From antiquity to the mid eighteenth century, the *theory of maternal imagination* had currency. It claimed that white parents could have a black child (or vice versa) if the mother, at the time of conception, saw or imagined a man with the other skin colour. A pregnant woman seeing an image of St. John the Baptist wearing hairy skins (or himself hairy) was believed to have given birth to a hairy daughter, who was depicted on the frontispiece of several 17th and early eighteenth century midwifery books. Fissell discussed such imagery. And books sometimes even suggested, Fissell points out, that a woman could deceive her husband by imagining her husband while having intercourse with her lover, so her illegitimate child would resemble her husband rather than her lover.

¹⁴⁹ It can be accessed at <http://www.ucl.ac.uk/~ucak06d/research.html> Philip Dawid's work on identification evidence, disputed paternity, and in forensic statistics includes Dawid (1994, 1998, 2001a, 2001b, 2002, 2004a, 2005a, 2005b, 2008), Dawid and Mortera (1996, 1998), Dawid and Evett (1997, 1998), Dawid and Pueschel (1999), Dawid et al. (1999, 2001), Dawid, Mortera, Pascali, and van Boxel (2002), Dawid, Mortera, Dobosz, and Pascali (2003), Dawid, Mortera and Vicard (2006), Mortera, Dawid, and Lauritzen (2003), Vicard and Dawid (2004, 2006).

¹⁵⁰ www.evidencescience.org

The Wikipedia entry for “Genetic fingerprinting” contains much detail.¹⁵¹ Its introduction states:

Genetic fingerprinting, DNA testing, DNA typing, and DNA profiling are techniques used to distinguish between individuals of the same species using only samples of their DNA. Its invention by Dr. Alec Jeffreys at the University of Leicester was announced in 1985. Two humans will have the vast majority of their DNA sequence in common. Genetic fingerprinting exploits highly variable repeating sequences called minisatellites. Two unrelated humans will be unlikely to have the same numbers of minisatellites at a given locus. In STR profiling, which is distinct from DNA fingerprinting, PCR is used to obtain enough DNA to then detect the number of repeats at several loci. It is possible to establish a match that is extremely unlikely to have arisen by coincidence, except in the case of identical twins, who will have identical genetic profiles. Genetic fingerprinting is used in forensic science, to match suspects to samples of blood, hair, saliva or semen. It has also led to several exonerations of formerly convicted suspects. It is also used in such applications as identifying human remains, paternity testing, matching organ donors, studying populations of wild animals, and establishing the province or composition of foods. It has also been used to generate hypotheses on the pattern of the human diaspora in prehistoric times.

Genetic testing is subjected to regulations (ibid.):

Testing is subject to the legal code of the jurisdiction in which it is performed. Usually the testing is voluntary, but it can be made compulsory by such instruments as a search warrant or court order. Several jurisdictions have also begun to assemble databases containing DNA information of convicts. The United States maintains the largest DNA database in the world: The Combined DNA Index System, with over 4.5 million records as of 2007. The United Kingdom, maintains the National DNA Database (NDNAD), which is of similar size. The size of this database, and its rate of growth, is giving concern to civil liberties groups in the UK, where police have wide-ranging powers to take samples and retain them even in the event of acquittal.

There exist computer tools for carrying out statistical analysis concerning DNA evidence. “[U]sing object-oriented Bayesian networks we have constructed a flexible computational toolkit, and used it to analyse complex cases of DNA profile evidence, accounting appropriately for such features as missing individuals, mutation, silent alleles and mixed DNA traces” (Mortera & Dawid, 2006, section 8, p. 26).¹⁵² Aitken, Taroni, and Garbolino (2003) described their own graphical model for the analysis of possible cross-transfer of DNA material, affecting DNA profiles intended for use as evidence. They resorted to Bayesian networks.

¹⁵¹ http://en.wikipedia.org/wiki/Genetic_fingerprinting

¹⁵² The kind of situations across which one may come is illustrated, e.g., by *DNA mixtures*: “A *mixed DNA profile* is typically obtained from an unidentified biological stain or other trace thought to be associated with a crime. This commonly happens in rape cases, in robberies where an object might have been handled by more than one individual, and also in a scuffle or brawl. For a mixed DNA trace there is no constraint on the number of distinct alleles observed for each marker, since the trace might have been formed as a mixture of biological material from more than one person” (Mortera & Dawid, 2006, section 6.3, p. 16).

8.7.2.2 Statisticians' Disagreements About How to Evaluate DNA Samples

Whereas suspect recognition based on facial composites (let alone on an artist's sketch) is an *indicative tool*, DNA evidence and fingerprint evidence are *implicative tools*. Even though one would have thought that DNA evidence is one area in which the use of statistics faces less challenges than other uses of Bayesianism in law, actually statisticians' disagreements about how to evaluate DNA samples shows that here, too, there are severe problems.¹⁵³ Even though controversies about DNA evidence only very rarely reach the public, they received a popular treatment in two issues of Britain's *New Scientist* magazine in August 2010. The second report was introduced as follows (Geddes, 2010, p. 8):

Last week, a *New Scientist* investigation showed how different forensic analysts can reach very different conclusions about whether or not someone's DNA matches a profile from a crime scene. This week we show how, even when analysts agree that someone could be a match for a piece of DNA evidence, the statistical weight assigned to that match can vary enormously.

In an inset, 'When lawyers question DNA' (on p. 9 in Geddes, 2010) in the special report on DNA evidence in the second issue, Scottish forensic scientist Alan Jamieson, who at scholars' conferences is often a wise and sobering voice about expert testimony, pointed out that defence lawyers can obtain the prosecution's statistical data concerning DNA samples, provided they are only permitted to use them in order to dispute them in the case at hand, and not for the purposes of other investigations and trials; and that moreover, if the case does not reach court, the refutations put forth by the defence would never reach to public domain.

The *New Scientist* report by Geddes (2010), 'What are the chances?', was sub-headlined: "In the second part of our investigation, Linda Geddes shows that *the odds attached to a piece of DNA evidence can vary enormously*" (added emphasis). The article began with a case of conviction then still being appealed in California: "Charles Richard Smith has learned the hard way that you can prove almost anything with statistics. In 2009 a disputed statistic provided by a DNA analyst landed him with a twenty-five-year jail sentence". This was for sexual assault at a parking lot in Sacramento, CA, in January 2006, when a woman was forced into oral sex with the perpetrator. A swab of cells from Smith's penis showed his own DNA and that of another person, and indicated that he had been sexually intimate with an unknown person. The DNA analyst as "Smith's trial said the chances of the DNA coming from someone other than [the victim] were 1 in 15,000. But both the prosecution and the analyst's supervisor said the odds were more like 1 in 47", and a later review reduced this to 1 in 13, "while a different statistical method said the chance

¹⁵³ Criticism also comes from critics of the application of probability theory to juridical proof in general, such as Ron Allen: even though one would have thought that DNA evidence would be a "safer" domain for statisticians, it is not quite so. Allen and Pardo (2007a) offered a critique, in terms of the *reference-class problem* (see Section 2.4 above) of how probability theory was applied to juridical proof concerning DNA random-match evidence in Nance and Morris (2002, 2005).

of seeing this evidence if the DNA came from [the victim] is only twice that of the chance of seeing it come from someone else.” Geddes (2010, p. 8) further remarked:

“Usually DNA evidence is pretty strong”, says David Balding, a statistical geneticist at University College London, whose calculation puts the lowest probability on the link between Smith and [the victim]. “My point is that the number juries are provided with often overstates the evidence. It should be a smaller number”.

On 15 May 1997, Odd O. Aalen from Norway posted a question, in an e-list about statistics in legal evidence¹⁵⁴: “Does anybody on this list know about criminal court cases where purely statistical evidence has been the sole or major evidence, and where the defendant has been convicted on this basis? I am thinking here of purely numerical evidence as opposed to substantive proof and statistical calculations related to this”. On that very day, a reply came from Robert Lempert, a well-known scholar from the University of Michigan: “There have by now been a couple of DNA cases like this”. Arguably, this shows how important the debate on statistics is.

Another posting on the same day provided more detail. It was by Bernard Robertson, editor of *The New Zealand Law Journal*, and definitely a “Bayesian enthusiast” in the controversy about Bayesianism in law. He stated: “The case of Adams provides an interesting example as the only prosecution evidence was DNA while the defence produced some more conventional evidence which tended to point the other way and also produced Professor Donnelly to explain how to use Bayes Theorem to reduce the posterior odds below ‘beyond reasonable doubt’.” Robertson pointed out that this generated publications in the legal literature in England.

In an article by mathematicians from Queen Mary and Westfield College, London – Balding and Donnelly (1995) – a contribution was made to clarify the role of the modes of statistical inference, in the controversy over the interpretation of DNA profile evidence in forensic identification. They claimed that this controversy can be attributed in part to confusion over which such mode of inference is appropriate. They also remark that whereas some questions in the debate were ill-posed or inappropriate, some issues were neglected, which can have important consequences. They propose their own framework for assessing DNA evidence,

in which, for example, the roles both of the population genetics issues and of the non-scientific evidence in a case are incorporated. Our analysis highlights several widely held misconceptions in the DNA profiling debate. For example, the profile frequency is not directly relevant to forensic inference. Further, very small match probabilities may in some settings be consistent with acquittal.

Besides, there is also another kind of risk with DNA evidence. “Even in DNA cases, there is always the possibility of lab error or planted evidence” (Allen, 2008a, p. 328, note 1). The presence of DNA or of fingerprints from a given person at the scene of a crime does not necessarily mean that the person they identify was involved at the crime. In England in 2011, a retired teacher was arrested, demonised by the media,

¹⁵⁴ bayesian-evidence@vuw.ac.nz

and then released in connection with the kidnapping murder of a young woman architect, as there was evidence indicating his presence where she lived, but he was the landowner. He may have had other opportunities of losing hair or leaving fingerprints at the place. Besides, DNA evidence may be mislabelled inside a laboratory. Or then, perpetrators may leave on purpose DNA evidence, perhaps hair, but even blood from a person they want to implicate.

There is even the risk of fake DNA. based on a paper by an Israeli team of scientists led by Dan Frumkin that had appeared in the journal *Forensic Science International: Genetics*, an unsigned item the British periodical *Criminal Law & Justice Weekly*, Vol. 173, No. 34 (August 22, 2009) reported on p. 531, under the headline ‘Fake DNA’, that Frumkin’s team had taken DNA from human hair was taken and multiplied many times, and that an enhanced sample of that DNA “was then inserted into blood cells that had been purged of their previous DNA. Dr Frumkin suggested that, in theory, criminals could use the technique to plant samples of blood or saliva at crime scenes to cover their tracks and implicate another party.” One would not expect to find a sample of saliva at a crime scene other than by the victim or the perpetrator if they were alone and in some isolated place, but if DNA from hair could be planted inside saliva, then the very expectations about how saliva could occur at a crime scene means that perpetrators could frame somebody. “The researchers said that the use of DNA is often the key to proving the guilt or innocence of suspects and that by using the technique they had developed, genetic profiles could easily be synthesized” (ibid.), even though this is currently beyond the ability of your usual perpetrator.

8.7.2.3 Human Fingerprints

Let us turn to *human fingerprints*,¹⁵⁵ which as usually found in investigative contexts are of the hand palm, and in particular, of the tips of the fingers.¹⁵⁶ Steps involving identification by fingerprints are as follows:

- A particular person (suspect X) handles an object (an exhibit).
- That exhibit is exposed to the environment.
- The exhibit is eventually recovered and treated, revealing fingerprints.

¹⁵⁵ See, e.g., Jain and Maltoni (2003) and Champod, Lennard, Margot, and Stilovic (2004). Also see the discussion in, e.g., Stoney (1997), Cole (2001, 2004, 2005, 2006a, 2006b), Cole et al. (2008), Balding (2005), Saks and Koehler (2008).

¹⁵⁶ Sometimes, the terms *fingerprint* and *fingerprinting* are used metaphorically. We have already come across *soil fingerprinting techniques* in a project in forensic geology that resorts to a decision support system, at the end of Section 8.5.1. In Section 8.5.6, we considered *chemical fingerprints*, identifying an individual component in a mixture (taken to be a multivariate, mixed chemical system). Another metaphorical use of the term *fingerprint* is found in *digital steganography*, a discipline we dealt with in Section 6.2.1.5 (which itself spans more, thematically). One sometimes talks about fingerprints, and a fingerprint vault scheme, in *digital steganography*: see

- The developed fingerprints are imaged.¹⁵⁷
- The images of the fingerprints are transferred to a database.
- The images of fingerprints are compared, and if this is done automatically, then a pattern matching algorithm is used.
- Suspect X is identified.

The introduction to the Wikipedia entry for “Fingerprint” states¹⁵⁸:

A fingerprint is an impression of the friction ridges of all or any part of the finger. A friction ridge is a raised portion of the epidermis [skin] on the palmar (palm and fingers) or plantar (sole and toes) skin, consisting of one or more connected ridge units of friction ridge skin. These ridges are sometimes known as “dermal ridges” or “dermal papillae”.

Fingerprints may be deposited in natural secretions from the eccrine glands present in friction ridge skin (secretions consisting primarily of water) or they may be made by ink or other contaminants transferred from the peaks of friction skin ridges to a relatively smooth surface such as a fingerprint card. The term fingerprint normally refers to impressions transferred from the pad on the last joint of fingers and thumbs, though fingerprint cards also typically record portions of lower joint areas of the fingers (which are also used to make identifications).

Fingerprint identification, based on traces left by the skin of some persons’ finger tips, is much debated in the literature, and until the end of the twentieth century its accuracy was hardly questioned, once it had come to be accepted by the beginning of that century. As we are going to see, the probative value of fingerprint evidence is no longer as secure as it used to be, and we are going to come back to that. Itiel Dror and colleagues’ paper “When emotions get the better of us: The effect of contextual top-down processing on matching fingerprints” (Dror, Péron, Hind, &

Li et al. (2005). In *forensic ballistics*, one speaks of *ballistic fingerprinting*. Also in intrusion detection within computer security, metaphorically one speaks of *fingerprints* and *fingerprinting* (Section 6.2.1.12), in relation to attempts to identify an intruder.

One sometimes speaks of fingerprinting for the identification of an individual rhinoceros. Amin, Bramer, and Emslie (2003) described experiments with “rhino horn fingerprint identification”, i.e., “the identification of the species and origin of illegally traded or confiscated African rhino horn”, using techniques of intelligent data analysis. Rhino horns are akin to compacted hair and fingernails, and their chemical composition reflects what the animal has been eating throughout its life. In turn, the chemistry of the food is affected by climate and geology. The so-called *fingerprint* of a rhino horn is a combination of variable values. In the project reported about by Amin et al. (ibid.), *Discriminant Function Analysis* was the principal technique of data analysis used, the prediction of the category in which a given case belongs is obtained by deriving mathematical functions that provide the greatest possible discrimination among categories. The same paper discussed a further stage, at which it was intended to use artificial neural nets for classification, or the automatic induction of classification trees (for the latter, cf. Quinlan, 1986; Kothari & Dong, 2002; Siroky, 2009; Chen et al., 2011). Contrast the task in the rhino project, to the task of identifying an individual, which is the case of techniques for the recognition of cattle based on characteristics of the animal’s back skin that are akin to fingerprints.

¹⁵⁷ A discussion of fingerprint development and imaging, with the chemistry involved in the development explained in clear detail, can be found in an excellent PowerPoint presentation posted online, and authored by Steve Bleay of Britain’s Home Office Scientific Development Branch (Bleay, 2009).

¹⁵⁸ <http://en.wikipedia.org/wiki/Fingerprint>.

Charlton, 2005) is a paper in cognitive psychology, applied to how experts perform at matching fingerprints. Dror and Charlton (2006) and Dror et al. (2006) tried to identify the causes of why experts make identification errors. Dror and Rosenthal (2008) tried to meta-analytically quantify the *reliability* and *biasability* of forensic experts.

“On the palmar surface of the hands and feet are raised surfaces called friction ridges. The scientific basis behind friction ridge analysis is the fact that friction ridges are persistent and unique” (from the Wikipedia entry for ‘Fingerprint’). The Wikipedia entry, which as accessed in late 2007, was detailed and engaging (our present readers are encouraged to access it), states:

Fingerprint identification (sometimes referred to as *dactyloscopy*) or palmprint identification is the process of comparing questioned and known friction skin ridge impressions (see *Minutiae*)¹⁵⁹ from fingers or palms to determine if the impressions are from the same finger or palm. The flexibility of friction ridge skin means that no two finger or palm prints are ever exactly alike (never identical in every detail), even two impressions recorded immediately after each other. Fingerprint identification (also referred to as individualization) occurs when an expert (or an *expert computer system* operating under *threshold scoring* rules) determines that two friction ridge impressions originated from the same finger or palm (or toe, sole) to the exclusion of all others.

A *known print* is the intentional recording of the friction ridges, usually with black printer’s ink rolled across a contrasting white background, typically a white card. Friction ridges can also be recorded digitally using a technique called *Live-Scan*. A *latent print* is the chance reproduction of the friction ridges deposited on the surface of an item. Latent prints are often fragmentary and may require chemical methods, powder, or alternative light sources in order to be visualized.

Computerisation brought about major changes in the *modus operandi* of fingerprint identification. The following is quoted from the Wikipedia entry¹⁶⁰:

Before computerization replaced manual filing systems in large fingerprint operations, manual fingerprint classification systems were used to categorize fingerprints based on general ridge formations (such as the presence or absence of circular patterns in various fingers), thus permitting filing and retrieval of paper records in large collections based on friction ridge patterns independent of name, birth date and other biographic data that persons may misrepresent. The most popular ten print classification systems include the Roscher system, the Vucetich system, and the *Henry Classification System* [. . .]

In the Henry system of classification,¹⁶¹ there are three basic fingerprint patterns: Arch, Loop and Whorl. There are also more complex classification systems that further break down patterns to plain arches or tented arches. [. . .]

An explanation of fingerprint appearance is provided by Bistarelli, Santini, and Vaccarelli (2006, pp. 360–361, section 2.1):

The most evident structural characteristic of a fingerprint is the pattern of interleaved ridges and valleys that often run in parallel. Ridges vary in width from 100 to 300 μm and the period of a ridge/valley cycle is typically about 500 μm . If analyzed at global level, almost

¹⁵⁹ <http://en.wikipedia.org/wiki/Minutiae>.

¹⁶⁰ <http://en.wikipedia.org/wiki/Fingerprint>.

¹⁶¹ On which, see http://en.wikipedia.org/wiki/Henry_Classification_System.

all of the patterns exhibit one or more regions characterized by a distinctive shape and called *singular regions*. These regions can be classified into three typologies according to their shape: loop, delta, and whorl are characterized respectively by a \curvearrowright , Δ , and \bigcirc shape. A particular presence of these singular regions defines the whole fingerprint class: the five classes in Henry's scheme [(Jain & Maltoni, 2003)] are *arch*, *tented arch*, *right loop*, *left loop*, and *whorl*.

At local level, other important features called minutiae refer to ridge discontinuities. Minutiae are sometimes called "Galton details",¹⁶² in honor of the first person who categorized them and observed that they remain unchanged over the individual's entire life [(Lee & Gaensslen, 1991, 2nd edn. 2001)].¹⁶³ Most frequently, the minutiae types can be identified by terminations, where a ridge line ends, and bifurcations, where a ridge bifurcates forming a "Y" [...], even if several types have been observed, described by their shape (dot, island, hook, lake, ridge crossing and multiple bifurcations).

Another important point in the image, which can be used also to align the fingerprint images, is the "core point", corresponding to the center of the north most loop type singular region. In fingers without loop or whorl regions, the core is associated with the point of maximum ridge line curvature. The most important minutiae characteristics are the location coordinates inside the image, their form type (e.g. termination, bifurcation, island, etc.) and the orientation of the ridge (in degree) on which the minutia is found.

Advances in research make it possible to avoid having to develop the prints first, in order to examine fingerprints¹⁶⁴:

Within the Materials Research Centre, University of Swansea, UK, University of Swansea, UK, Professor Neil McMurray and Dr Geraint Williams have developed a technique that enables fingerprints to be visualised on metallic and electrically conductive surfaces without the need to develop the prints first. The technique involves the use of an instrument called a scanning Kelvin probe (SKP), which measures the voltage, or electrical potential, at pre-set intervals over the surface of an object on which a fingerprint may have been deposited. These measurements can then be mapped to produce an image of the fingerprint. [...]

Currently, in crime scene investigations, a decision has to be made at an early stage whether to attempt to retrieve fingerprints through the use of developers or whether to swab surfaces in an attempt to salvage material for DNA fingerprinting. The two processes are mutually incompatible, as fingerprint developers destroy material that could potentially be used for DNA analysis, and swabbing is likely to make fingerprint identification impossible.

The application of the new SKP fingerprinting technique, which is non-contact and does not require the use of developers, has the potential to allow fingerprints to be retrieved while still leaving intact any material that could subsequently be subjected to DNA analysis. [...]

In the United States (ibid.):

The FBI manages a fingerprint identification system and database called IAFIS, which currently holds the fingerprints and criminal records of over fifty-one million criminal record subjects, and over 1.5 million civil (non-criminal) fingerprint records. U.S. Visit currently holds a repository of over 50 million persons, primarily in the form of two-finger records (by 2008, U.S. Visit is transforming to a system recording FBI-standard tenprint records).

¹⁶² Psychologist and anthropologist Francis Galton (1821–1911), Charles Darwin's cousin.

¹⁶³ Allegedly, the first edition was a bestseller of Lee and Gaensslen's (1991) *Handbook of Fingerprint Recognition*. The second edition, of 2001, is a major revision. A more recent handbook is *Handbook of Fingerprint Recognition* by Davide Maltoni, Dario Maio, Anil K. Jain, and Salil Prabhakar (2003, 2nd edn. 2009).

¹⁶⁴ <http://en.wikipedia.org/wiki/Fingerprint>.

Most American law enforcement agencies use Wavelet Scalar Quantization (WSQ), a wavelet-based system¹⁶⁵ for efficient storage of compressed fingerprint images at 500 pixels per inch (ppi). [...] For fingerprints recorded at 1000 ppi spatial resolution, law enforcement (including the FBI) uses JPEG 2000 instead of WSQ. [...]

8.7.2.4 Fingerprints from Dead Bodies

Sometimes forensic fingerprinting specialists are faced not with the task of pinpointing a live suspect criminal from the fingerprints he or she left, but rather with trying to achieve identification for a dead body, based on the skin of the finger tips. Take the case of mummified bodies. “The identification of mummified bodies places high demands on the skills of a forensic fingerprinting specialist. From a variety of methods, he must be able to choose the most appropriate one to reproduce the skin ridges from fingers, which are often shrunk and deformed”, as stated in the English abstract of a paper by Ineichen and Neukom (1995), of the Zurich cantonal police: their “article introduces and discusses a method for indirect fingerprinting. In this method, a negative cast of the mummified fingertip is first produced with a silicon mass. This 3-dimensional negative is then filled with several layers of a white glue/talc mixture, until a skin-thick positive is attained. Using this artificial skin it is possible to reproduce, in a relatively short time, a fingerprint which is free of disturbing skin wrinkles and deformities” (ibid.).

The problem with using fingerprints from dead bodies is that deformation can be expected to be much worse than the elastic deformation that normally affects fingerprints from living persons. Bear in mind that fingers are in three dimensions, whereas fingerprints appear on a surface. Computer methods for fingerprint matching (the fingerprints having been left by persons while alive) have to cope with the problem of elastic deformation. In dead bodies, the deformation caused by decay is plastic, not just elastic. That is to say, the shape that the fingertip has taken will not revert to the previous shape the way that the finger tip of a living person, when pressed against a surface, is going to go back to its previous shape when not pressed.

8.7.2.5 The Problem of Assessing Fingerprint Sufficient Similarity

Are fingerprints really reliable? The courts in the United States and elsewhere have usually been rather unresponsive to challenges to identification accuracy. But there is another problem with the use of *latent prints*, i.e., of such fingerprints that were found at a crime scene (Cole, Welling, Dioso-Villa, & Carpenter, 2008, p. 167):

[A]side from being unresponsive to the question of accuracy, the individuality issue is problematic in its own right (Saks & Koehler, 2008). It is commonly said that the ‘individuality’ or ‘uniqueness’ of friction ridge skin is one of the ‘fundamental premises’ of latent print individualization (Moenssens, 1999).¹⁶⁶ Such discussions generally treat this premise as

¹⁶⁵ See http://en.wikipedia.org/wiki/Wavelet_Scalar_Quantization

¹⁶⁶ Cf. Moenssens (2003).

one that has been satisfied – i.e. the ‘individuality’ of friction ridge skin is ‘known’ or ‘proven’. By this, it would appear that fingerprint proponents mean that the exact duplication of any area of friction ridge skin is extremely unlikely. But such an assertion has little meaning without knowing the conditions under which extreme similarity would be considered ‘duplication’, what scale of area of friction ridge skin is being discussed and at what level of resolution friction ridge skin is observed. Assertions of ‘uniqueness’ or ‘individuality’ could, for all we know, mean nothing more than that, when analysed at the level of molecules, no two areas of friction ridge skin will duplicate exactly. Such a statement is undoubtedly true not only of friction ridge skin, as well as many other objects in the world, but also of little value in measuring how accurately source attributions can be made from those objects by human experts using visual analysis.

For practical legal purposes, mere non-duplication is not what really matters. Rather (ibid.):

Obviously, what is wanted is not the mere assertion of non-duplication, but, rather, measurements of the variability of different areas of friction ridge skin and, crucially, multiple images derived from the same areas of friction ridge skin. In short, the issue is not so much the individuality of an area of friction ridge skin itself, but rather the range of variability of legible impressions that can be produced by a given area of friction ridge skin relative to the range of impressions that could be produced by analogous areas of friction ridge skin from different individuals.

Perhaps most importantly, it makes little sense to discuss the ‘individuality’, or even the ‘variability’, of ‘fingerprints’ as if it were a quality that inhered in friction ridge skin. These qualities can only exist in conjunction with some sort of perceptual system, whether human or mechanical.

Let us consider the common task of identifying suspect perpetrators, based on prints left by their fingers, in the British context. In the words of a scholar based in London, Mike Redmayne (2002, p. 25):

Fingerprint experts have no statistics on which to base their conclusions. There is a large degree of consensus that individual fingerprints are unique, and that a certain number of similarities between two prints proves identity beyond almost any doubt. But there are no figures on which to base these judgments: no way of quantifying the cut-off point at which sufficient similarity proves identity. David Stoney has written perceptively about the process of fingerprint identification. He suggests that, on perceiving enough points of identity, the expert makes a ‘leap of faith’ and becomes ‘subjectively certain’ of identity. In many countries there is a convention that a particular number of points is required before a match is announced. In England and Wales, the magic number was long sixteen. Latterly, few people saw much logic in the ‘sixteen points’ rule, and it was abandoned in 2001. But the convention helps to explain why, when the expert in *Charles* went to court on just twelve points, his evidence was vulnerable to a *Doheny*-style challenge.

The *Doheny* case is one in which identification revolved on the DNA evidence. Also from England and Wales, it was judged in 1997 by the Court of Appeal, “which after agonising over” the risks of misconceptions on the part of jurors of what DNA evidence stands for (Redmayne, 2002, p. 20),

hit upon an ingenious solution. Rather than explaining the subtle but important distinction between the probability of guilt given the DNA evidence and the probability of the DNA evidence given guilt in semantic terms, it would provide a simple illustration to convey the key issues [. . .]. Its sample jury instructions for DNA cases proceeds as follows:

Members of the jury, if you accept the scientific evidence called by the Crown, this indicates that there are probably only four or five white males in the United Kingdom from whom that semen could have come. The defendant is one of them. If that is the position, the decision you have to reach, on all the evidence, is whether you are sure that it was the defendant who left that stain or whether it is possible that it was one of the other small number of men who share the same DNA characteristics.

The quotation, previously given, about fingerprints, as taken from Redmayne (2002, p. 25), is about the case of Neil Charles, convicted of robbery and false imprisonment, and the principal evidence about whom was a fingerprint; moreover, “[t]here was circumstantial evidence to link him to the crime scene – he had been seen acting suspiciously nearby earlier in the day, and [closed-circuit TV] cameras caught him in the area later on” (p. 25). “The defence strategy was simple: to get the expert think of his testimony in *Doheny* terms, so as to draw out an admission that Charles was just one of *n* men who might have left the print” (p. 25). “But the Court of Appeal would not allow two experts to explore these issues further because they had not been called at trial. In any case, it did not think the *Doheny* analogy apt because ‘the Crown’s case did not rest on any random occurrence ratio [sc. match probability]’.” (ibid., p. 25, Redmayne’s brackets).

Redmayne remarks that fingerprint identification is such powerful evidence that perhaps “really there is no room for a *Doheny* argument. The expert makes the leap of faith, leaving no quantifiable gap over which the jury must jump [. . .]. But as the match threshold moves down from 16 points, there is less room for complacency” (ibid., p. 26). There has been contention about the admissibility of fingerprint evidence. Yvette Tinsley, from the Victoria University of Wellington, New Zealand, discussed a possible reform of identification procedures (Tinsley, 2001).

Scotland’s Fingerprint Inquiry¹⁶⁷ is likely to have repercussions also outside Scotland, in the long term. The Inquiry Report was expected in 2011. Oral hearings took place in the summer and autumn of 2009. On 14 March 2008, Scotland’s Cabinet Secretary for Justice, Kenny MacAskill, announced a public judicial inquiry (set up by Scottish ministers under the Inquiries Act 2005). Its remit has been to investigate the steps taken to verify the fingerprints associated with the case of *H.M. Advocate v. McKie* in 1999, and related matters.

The background is as follows. Charged for the murder of Marion Ross, David Asbury was convicted in May 1997, and the prosecution case against him included fingerprint evidence. During the investigation into the murder, a fingerprint was found on the doorframe of the bathroom in Marion Ross’s home. That fingerprint (which became known as “Y7”), was identified as belonging to Shirley McKie, a serving police officer involved in the murder investigation. During Asbury’s trial, McKie denied that the fingerprint was hers. After the murder trial, she was prosecuted for perjury: the charge was that she had lied while giving evidence on oath, because of what she had said in her evidence at David Asbury’s trial. The evidence before the jury at McKie’s trial

¹⁶⁷ <http://www.thefingerprintinquiryScotland.org.uk>

included evidence from defence fingerprint experts that Y7 was not her fingerprint. The jury, unanimously, found Shirley McKie not guilty of perjury. The identification of Y7 was made, originally, by officers of the Scottish Criminal Record Office. Various fingerprint experts have expressed differing views as to whether Y7 is the fingerprint of Shirley McKie. In August 2000 David Asbury was granted interim liberation pending an appeal against his conviction for murder. His conviction was quashed in August 2002. The Crown did not oppose his appeal. Shirley McKie raised an action for damages arising from the identification of Y7 as her fingerprint. It was settled out of court by the Scottish Ministers, without admission of liability, in February 2006.¹⁶⁸

The Scottish government set up the Fingerprint Inquiry to fulfil its commitment to hold an independent, public, judicial inquiry into the circumstances surrounding the Shirley McKie case. The Fingerprint Inquiry's¹⁶⁹ terms of reference, as agreed by the Scottish Ministers, are as follows:

- To inquire into the steps that were taken to identify and verify the fingerprints associated with, and leading up to, the case of *HM Advocate v. McKie* in 1999
- to determine, in relation to the fingerprint designated Y7, the consequences of the steps taken, or not taken, and
- to report findings of fact and make recommendations as to what measures might now be introduced, beyond those that have already been introduced since 1999, to ensure that any shortcomings are avoided in the future.

An editorial (Koehler, 2008) in a special issue of the journal *Law, Probability and Risk*, by Jonathan Koehler from Arizona State University in Tempe, began by noting:

Ten years ago, the notion that a top academic journal should publish an exchange on the scientific validation of fingerprint evidence would have been a non-starter. Until then, all but a few self-interested defendants and defence attorneys believed that when a fingerprint examiner matched a crime scene print (a latent print) to a suspect's reference print, the evidence was absolute and irrefutable. A fingerprint match proved identity if not guilt. Today, however, scientists, attorneys and others are taking a hard look at the forensic sciences in general and fingerprint evidence in particular. The oft-repeated claims that fingerprints are unique and that the source of fingerprint fragments can be identified with certainty have received special attention.¹⁷⁰

¹⁶⁸ The quotation is from the webpage "About the Inquiry: Background" at the site of the inquiry itself, at <http://www.thefingerprintinquiryScotland.org.uk/inquiry/23.html>

¹⁶⁹ Set up under the Inquiries Act 2005, it is one of the first inquiries under that Act to use the Inquiries (Scotland) Rules 2007.

¹⁷⁰ The uniqueness claim was rejected by Balding (2005), Cole (2004) and Saks and Koehler (2008). Koehler noted (2008, p. 85): "Kaye (2003) points out the serious flaws in a study that some rely on as proof of fingerprint uniqueness. As for the certainty of fingerprint identifications, the data (not surprisingly) show that fingerprint examiners are fallible. Many commit false-positive and false-negative errors in proficiency tests and in casework (Cole, 2005, 2006a, 2006b). Indeed, some critics argue that there is no scientific reason to believe that fingerprint examiners can make reliable identifications at all (Epstein, 2002)." A bibliography of legal scholarship rejecting the validity of fingerprint identification can be found in the long very last footnote of Cole (2009), and it should be looked up there.

In an article from the United States cautious about the reliability of fingerprint evidence, Cole et al. (2008) began by pointing out: “Efforts to harness computer fingerprint databases to perform studies relevant to fingerprint identification have tended to focus on 10-print, rather than latent print, identification or on the inherent individuality of fingerprint images.” (ibid., p. 165). That is to say (ibid., p. 166):

Latent print individualization is a forensic technique that endeavours to attribute a ‘mark’ (a crime scene or ‘latent’ print) to the ‘friction ridge skin’ (the corrugated skin that covers human fingers, palms and soles) of an individual. Such attributions are currently achieved through a visual comparison of the mark with an exemplar ‘print’ whose origin is known. These attributions are made by human latent print examiners (LPEs). Computer algorithms (Automated Fingerprint Identification Systems or AFIS) are often used to search large databases for ‘candidate’ prints to present to the examiner, but there is neither an agency or a jurisdiction that currently allows a computer system to make *latent* print attributions nor an algorithm that claims an ability to make such attributions. This is not the case for 10-print attributions, in which the source of a set of 10 ‘inked’, or intentionally recorded, prints is attributed. Such attributions are sometimes made by computer algorithms (Cherry & Imwinkelried, 2006).

Professional LPEs are restricted to three conclusions: individualization, inconclusive and exclusion (Scientific Working Group on Friction Ridge Analysis Study and Technology, 2003).¹⁷¹ Thus, the only ‘inclusionary’ conclusion – i.e. the only conclusion that implicates a suspect – is the conclusion of ‘individualization’. ‘Individualization’, in turn, is defined as the claim that a particular area of friction ridge skin is the only possible source of a particular mark (Scientific Working Group on Friction Ridge Analysis Study and Technology, 2003). In other words, all other possible sources have been eliminated as possible sources of the mark.

Cole et al. (2008) questioned *accuracy*, i.e., how often it is that individualisations based on latent prints are correct: “Does the accuracy vary predictably in response to particular variables, such as, say, the amount of information contained in the mark or the skill level of the examiner?” (ibid., p. 166). They also questioned *sufficiency*: “How much consistent friction ridge detail is it necessary to find, in order to support a conclusion of individualization?” (ibid.). Their third question concerned *individuality*: “How rare are the various friction ridge features used in latent print analysis within various populations? How rare are various combinations of friction ridge features? How similar are the most similar areas of friction ridge skin, of some specified size?” (ibid.). Cole et al. (2008, pp. 166–167):

There have been essentially no empirical studies addressing the accuracy questions (Haber & Haber, 2003, 2008), although some preliminary studies are now beginning to be undertaken (Wertheim et al., 2006; Langenburg, 2004; Haber & Haber, 2006). Purported answers to the sufficiency question are known to have been legislated rather than derived from empirical data (Champod, 1995; Evett & Williams, 1996; Cole, 1999). Current professional guidelines developed in the United States mandate an essentially circular definition of ‘sufficiency’: ‘Sufficiency is the examiner’s determination that adequate unique details of the friction skin source area are revealed in the impression’ (Scientific Working Group

¹⁷¹ The Scientific Working Group on Friction Ridge Analysis, Study and Technology (SWGFAST) was established in 1995, and its mission is to establish consensus guidelines and standards for the forensic examination of friction ridges. See <http://www.swgfast.org/> Several reports are posted at that site.

on Friction Ridge Analysis Study and Technology, 2002, section 1.5). The most sustained scholarly attention has been devoted to individuality, but much of it has focused on demonstrating or asserting the mere fact of the absolute non-duplication of complete fingertip-sized areas of friction ridge skin, rather than on measuring the degree of variability. This is true of both of the two major strands of fingerprint research. Statistical research focused on estimating the probability that exact duplicate areas of friction ridge skin (usually complete fingertips) exist (Pankanti et al., 2002; Stoney, 2001). Anatomical research focused on detailing the formation of friction ridge skin, while occasionally commenting that this process was sufficiently complex to support an assumption of non-duplication as a ‘working principle’ (Cummins & Midlo, 1943; Wilder & Wentworth, 1918; Wertheim & Maceo, 2002).

Nonetheless, defenders of latent print individualization have tended to seek to shift the debate to individuality when pressed concerning accuracy, a tendency that one of us has elsewhere called ‘the fingerprint examiner’s fallacy’, the argument that the accuracy of a source attribution technique may be inferred from the uniqueness or variability of the target object (Cole, 2004, 2006b). [...]

What Cole et al. (2008) themselves did, was to carry out experiments measuring how accurate an automated fingerprint matching system was at identifying the source of *simulated latent* print (i.e., fingerprints taken, as though, from a crime scene, while actually having been obtained for the purposes of the experiment). The computer system carried out the task of a human latent print examiner fairly well, except in that it (like presumably the human expert) tended to produce false positives (ibid., p. 165): “there are non-mate images that scored very highly on the AFIS’s¹⁷² similarity measure. These images would be susceptible to erroneous conclusions that would be given with a very high degree of confidence. Not surprisingly, the same was also true of the simulated latents which contained less information.” They claimed that this is useful for assessing human experts, too: “We suggest that measuring the accuracy and potential for erroneous conclusions for AFISs might provide a basis for comparison between human examiners and automated systems at performing various identification tasks” (ibid.).¹⁷³

8.7.3 Computational Techniques for Fingerprint Recognition

8.7.3.1 General Considerations

Research in *biometrics* within computer science has found various applications,¹⁷⁴ and in particular, identification by means of fingerprints is no longer confined to use by the police. In the words of Bistarelli et al. (2006, pp. 359–360):

¹⁷² AFIS stands for “automated fingerprint identification system”.

¹⁷³ Incidentally, note that Srihari, Srinivasan, and Beal (2008) discussed the discriminability of the fingerprints of twins. Sargur Srihari’s team at the University of Buffalo is active in both computer-assisted handwriting recognition, and computer-assisted fingerprint recognition.

¹⁷⁴ For example, see fn. 177 in Chapter 6.

The term “biometrics” is commonly used today to refer to the authentication of a person by analyzing his/her physical characteristics (like fingerprints) or behavioral characteristics (like voice or gait). Since these characteristics are unique to an individual, their measurement provides a more reliable system of authentication than ID cards, keys, passwords, or other traditional systems while accessing restricted areas in office buildings and factories, or controlling the security of computer networks, electronic commerce, and banking transactions. The reason is that all these secret keys can be easily stolen or cloned to steal the personal identity, or they can also be forgotten by the owner preventing the whole identification process. Biometric characteristics are, instead, generally more difficult to duplicate and they naturally always “follow” the owner. Moreover, an advantage of biometrics is that they cannot be lent (like a physical key), and thus, they [guarantee the owner’s] on-site presence.

The most common biometric techniques are signature verification, retinal analysis, facial analysis, fingerprint verification, hand geometry, and voice verification. These technologies are comparable by the aid of several indicators, such as permanence (measurement should be invariant with time), uniqueness (different values for different persons), universality (everyone should have this trait), acceptability (if people are willing to accept this technology), performance (the recognition accuracy and system requirements) and circumvention (how [easy it is] to fool the system). Fingerprint matching is one of the most diffused biometric techniques used in automatic personal identification, because of its strong reliability and its low implementation cost; moreover, it is also the most mature and explored technology of all [biometric techniques].

Computational fingerprint recognition techniques – examining the pattern of ridges and furrows in fingerprints, and their *minutiae points*, that is to say, *ridge ending* and *ridge bifurcation* – are an active area within image processing. Na, Yoon, Kim, and Hwang (2005) discussed the shortcoming of such techniques. Brislawn, Bradley, Onyshczak, & Hopper (1996) described the FBI compression standard for digitised fingerprint images. Criminal investigation is just one of the area in which fingerprints are used for identification. “The fingerprint sensors are becoming smaller and cheaper, and automatic identification based on fingerprints is becoming an attractive alternative/complement to the traditional methods of identification” (Khuwaja, 2006, p. 25), not only in criminal investigation, but, along with other so-called *biometric* methods employed in *personal authentication systems*, and based on an individual person’s body or sometimes behavioural features, also in e-banking, e-commerce, smart cards, and access to sensitive databases, and sometimes for access into premises with security requirements. The procedure is not without problems. Khuwaja remarks (*ibid.*, pp. 24–25):

The quality of the finger image is the most significant factor in a reliable process (Emiroglu and Akhan, 1997; Jiang et al., 2001). One aspect of fingerprint identification systems, which largely has been overlooked, is the need for a determination on a pixel-by-pixel basis of the reliability of the information. In an image, one region might be highly reliable, while another is not. Sets of information must be extracted from an image by the system, a process known as encoding. This process is made difficult by the fact that different prints of the same finger may be substantially different due to effects such as (a) pressure; increased pressure leads to ridge joining and decreased pressure leads to ridge breaking. (b) dirt and moisture; this can cause phantom joints; (c) elasticity of the skin; the whole image can become sheared and distorted; (d) background; the latent may be taken from a complex background, both in relief and pattern; (e) inking; the amount of ink used to take finger impressions significantly affects the images; and (f) smudging; often regions of the print image are smudged.

Moreover, when fingerprints are scanned, there may be imperfections in the images (ibid., p. 25). Such imperfect images “require some preprocessing before the features on them can be extracted. The imperfections in the images manifest themselves in the form of noncontinuous regions and noncontinuous ridges (Costello, Gunawardena, & Nadiadi, 1994). These areas need either to be enhanced or ignored for valid recognition of the fingerprint” (Khuwaja, ibid.)

Automatic fingerprint identification systems are widely used, and there exist several pattern matching techniques applied to matching fingerprints, but the matching is time-consuming. There exists a series of Fingerprint Verification Competitions (FVC), in which the systems entered by competitors are tested on databases, and the performance is in terms of authentication reliability and speed.

Apart from the time it takes to match fingerprints, another problem is deformation. Hao, Tan, and Wang (2002, section 1) explain this as follows:

In most [automatic fingerprint identification systems], the representation of fingerprints is based on minutiae such as ridge ending and ridge bifurcation, with each minutia being characterized by its locations and orientation. With this representation, the matching problem is reduced to a point pattern matching problem. In the ideal case described by Jain et al. (1997), the matching can be accomplished by simply counting the number of spatially overlapping minutiae. But in practice, the sensing system maps the three-dimensional finger on to two-dimensional images. Once the location, pressure and direction of impression change, the mapping will change accordingly, which inevitably leads to nonlinear deformation of fingerprint images. Two fingerprint images may have translation, rotation or even nonlinear deformation between them. If the time span between two impressions is long, the images may also change due to cuts on finger or skin disease.

In most systems, fingerprint is represented with a set of minutiae which is called template. The representation itself may be noisy due to presence of spurious minutiae and absence of genuine minutiae. Also, the properties of minutiae such as the location and orientation may be inaccurately estimated due to image degradation and imperfect preprocessing.

Considering all these situations, a good fingerprint matching algorithm should meet the following two criteria:

- Be robust to all kinds of possible deformation which are commonly observed in fingerprints and are hard to model.
- Be robust to small perturbation on minutiae and minutiae properties.

Terje Kristensen (2010) reported about a computer application to fingerprint identification, intended to reduce the matching time. To carry out classification a Support Vector Machine (SVM) algorithm¹⁷⁵ was resorted to. “The given fingerprint database is decomposed into four different subclasses and a SVM algorithm is used to train the system to do correct classification. The classification rate has been estimated to about 87.0% of unseen fingerprints. The average matching time is decreased with a factor of about 3.5 compared to brute force search applied” (ibid.).

¹⁷⁵ Support vector machines or vector support machines are the subject of Section 6.1.9.3. Moreover, we have said something about support vector machines at the end of Section 6.1.2.3.

A variety of approaches is encountered in the scholarly literature of automated fingerprint matching. For example, Chen and Kuo (1991) applied *tree matching*. Isenor and Zaky (1986) resorted to *graph matching* in order to solve the problem of *elastic deformation*. The matching is based on *euclidean distance* in Jain, Prabhakar, Hong, and Pankanti (2000) as well as Lee and Wang (1999), who represented the fingerprint with texture information extracted by *Gabor filters*.

In image processing, a *Gabor filter*, named after Dennis Gabor, is a linear filter used for edge detection. Frequency and orientation representations of Gabor filters are similar to those of the human visual system, and they have been found to be particularly appropriate for texture representation and discrimination. In the spatial domain, a 2D Gabor filter is a Gaussian kernel function modulated by a sinusoidal plane wave. The Gabor filters are self-similar: all filters can be generated from one mother wavelet by dilation and rotation.¹⁷⁶

¹⁷⁶ From Wikipedia (http://en.wikipedia.org/wiki/Gabor_filter). The impulse response of a Gabor filter “is defined by a harmonic function multiplied by a Gaussian function. Because of the multiplication-convolution property (Convolution theorem), the Fourier transform of a Gabor filter’s impulse response is the convolution of the Fourier transform of the harmonic function and the Fourier transform of the Gaussian function. The filter has a real and an imaginary component representing orthogonal directions. The two components may be formed into a complex number or used individually” (ibid.). With the convention that “ λ represents the wavelength of the sinusoidal factor, θ represents the orientation of the normal to the parallel stripes of a Gabor function, ψ is the phase offset, σ is the sigma of the Gaussian envelope and γ is the spatial aspect ratio, and specifies the ellipticity of the support of the Gabor function” (ibid.), the Gabor filter is given by the following formulae. As a complex number:

$$g(x, y; \lambda, \theta, \psi, \sigma, \gamma) = \exp\left(-\frac{x'^2 + \gamma^2 y'^2}{2\sigma^2}\right) \exp\left(i\left(2\pi\frac{x'}{\lambda} + \psi\right)\right)$$

The real component is:

$$g(x, y; \lambda, \theta, \psi, \sigma, \gamma) = \exp\left(-\frac{x'^2 + \gamma^2 y'^2}{2\sigma^2}\right) \cos\left(2\pi\frac{x'}{\lambda} + \psi\right)$$

The imaginary component is:

$$g(x, y; \lambda, \theta, \psi, \sigma, \gamma) = \exp\left(-\frac{x'^2 + \gamma^2 y'^2}{2\sigma^2}\right) \sin\left(2\pi\frac{x'}{\lambda} + \psi\right)$$

where

$$x' = x \cos \theta + y \sin \theta$$

and

$$y' = -x \sin \theta + y \cos \theta$$

Fasel, Bartlett, and Movellan (2002) compared Gabor filter methods for another problem in pattern-matching that is relevant for biometrics, namely, the *automatic detection of facial landmarks*.¹⁷⁷

Jain, Ross, and Prabhakar (2001) combined texture features and minutiae features, while being specifically interested in solid-state fingerprint sensors: in fact, these only provide a small contact area “for the fingertip, and, therefore, sense only a limited portion of the fingerprint. Thus multiple impressions of the same fingerprint may have only a small region of overlap. Minutiae-based matching algorithms, which consider ridge activity only in the vicinity of minutiae points, are not likely to perform well on these images due to the insufficient number of corresponding points in the input and template images. We present a hybrid matching algorithm that uses both minutiae (point) information and texture (region) information for matching the fingerprints” (ibid., from the abstract).

Kovács-Vajna (2000) combined triangular matching and dynamic time warping to tolerate nonlinear deformation of fingerprints.¹⁷⁸ Tan and Bhanu (2006) applied genetic algorithms¹⁷⁹ to fingerprint matching. The genetic algorithm “tries to find the optimal transformation between two different fingerprints. In order to deal with low-quality fingerprint images, which introduce significant occlusion and clutter of minutiae features, we design a fitness function based on the local properties of each triplet of minutiae” (ibid., from the abstract). They found that their approach compares favourably with an approach based on mean-squared error estimation.

Ito, Nakajima, Kobayashi, Aoki, and Higuchi (2004) proposed an algorithm for fingerprint matching, which resorts to the *Phase-Only Correlation* function. It uses phase spectra of fingerprint images, and we are going to devote to it a special subsection (see Section 8.7.3.3). Kong, Zhang, and Kamel (2006) were concerned with *palmprint identification*, and for that purpose, they resorted to *feature-level fusion*; as they explained in the abstract:

Multiple elliptical Gabor filters with different orientations are employed to extract the phase information on a palmprint image, which is then merged according to a fusion rule to produce a single feature called the Fusion Code. The similarity of two Fusion Codes is measured by their normalized hamming distance. A dynamic threshold is used for the final decisions. A database containing 9599 palmprint images from 488 different palms is used to validate the performance of the proposed method.

¹⁷⁷ The article by Fasel et al. (2002) “presents a systematic analysis of Gabor filter banks for detection of facial landmarks (pupils and philtrum). Sensitivity is assessed using [...] a non-parametric estimate of sensitivity independent of bias commonly used in the psychophysical literature. We find that current Gabor filter bank systems are overly complex. Performance can be greatly improved by reducing the number of frequency and orientation components in these systems. With a single frequency band, we obtained performances significantly better than those achievable with current systems that use multiple frequency bands. [...]” (ibid., from the abstract).

¹⁷⁹ Genetic algorithms are the subject of Section 6.1.16.1 in this book.

Ying Hao, Tieniu Tan, and Yunhong Wang, from the National Lab of Pattern Recognition at the Institute of Automation of the Chinese Academy of Sciences in Beijing, proposed an algorithm for fingerprint matching that is based on error propagation (Hao et al., 2002). They remarked that traditional methods treat fingerprint matching “as point pattern matching, which is essentially an intractable problem due to the various nonlinear deformations commonly observed in fingerprint images” (ibid., from the abstract). According to their own method (ibid.):

Firstly, ridge information and Hough transformation are adopted to find several pairs of matching minutiae, the initial correspondences, which are used to estimate the common region of two fingerprints and the alignment parameters. Then a MatchedSet which includes the correspondence and its surrounding matched minutiae pairs is established. The subsequent matching process is guided by the concept of error propagation: the matching errors of each unmatched minutiae are estimated according to those of its most relevant neighbor minutiae. In order to prevent the process from being misguided by mismatched minutiae pairs, we adopt a flexible propagation scheme.

The matching algorithm they proposed comprises three steps (ibid., section 2). In the first step, each and every minutia “in the reference template is matched with each minutiae in the input template and all resulting potential correspondences are used to find several most reliable one, the initial correspondences, using Hough transformation” (ibid.). In the second step, “all minutiae surrounding the correspondence are matched and those minutiae pairs whose matching error are less than certain thresholds are added to the MatchedSet” (ibid.). In the third step, the algorithm adjusts “the matching error of each unmatched minutia according to the information provided by the MatchedSet recursively until the number of elements in MatchedSet stops increasing. A conformation process which checks the consistency of the matching errors of elements in the MatchedSet is made to label and remove the mismatched minutiae after each iteration” (ibid.). The MatchedSet is initialised after the two templates have been aligned and the common region estimated. Error threshold are chosen with care, so that only reliable pairs are added to the initial MatchedSet (ibid., section 2.3).

Arun Abraham Ross (2003) developed, under Anil Jain’s supervision, a “hybrid fingerprint system that utilizes both minutiae points and ridge feature maps to represent and match fingerprint images” (from the abstract of the thesis). For image filtering, Ross used Gabor filters (Ross, 2003, section 2.3). Filtered images were underwent *tessellation* (i.e., mosaicking), for ridge feature mapping (ibid., section 2.4 and chapter 3). A deformable model was resorted to, in order to account for the elasticity of fingertips. Ross explained (ibid., in the abstract of the thesis):

The hybrid matcher is shown to perform significantly better than a traditional minutiae-based matcher. The ridge feature maps extracted by this technique have also been used to align and register fingerprint image pairs via a correlation process, thereby obviating the need to rely on minutiae points for image registration. To address the problem of partial prints obtained from small-sized sensors, a fingerprint mosaicking scheme has been developed. The proposed technique constructs a composite fingerprint template from two partial fingerprint impressions by using the iterative control point (ICP) algorithm that determines the transformation parameters relating the two impressions. To mitigate the effect of non-linear distortions in fingerprint images on the matching process, an average deformation

model has been proposed. The model is developed by comparing a fingerprint impression with several other impressions of the same finger and observing the common ridge points that occur in them. An index of deformation has been suggested in this context to aid in the selection of an ‘optimal’ fingerprint impression from a set of impressions. Finally, techniques to combine fingerprint information with the other biometric traits of a subject (viz., face and hand geometry) are presented.

The mosaicking is because of the following problem (Ross, 2003, pp. 55–56):

[T]he average number of minutiae points extracted from a Digital Biometrics optical sensor (500 × 500 image at 500 dpi) is 45 compared to 25 minutiae obtained from a Veridicom sensor image (300 × 300 image at 500 dpi). This loss of information affects the matching performance of the verification system – the relatively small overlap between the template and query impressions results in fewer corresponding points and therefore, results in higher false rejects and/or higher false accepts.

The remedy is as follows (Ross, 2003, pp. 56–57):

To deal with this problem, we have developed a fingerprint mosaicking scheme that constructs a composite fingerprint template using evidence accumulated from multiple impressions. A composite template reduces storage, decreases matching time and alleviates the quandary of selecting the “optimal” fingerprint template from a given set of impressions. In the proposed algorithm, two impressions (templates) of a finger are initially aligned using the corresponding minutiae points. This alignment is used by a modified version of the well-known iterative closest point algorithm (ICP) to compute a transformation matrix that defines the spatial relationship between the two impressions. The resulting transformation matrix is used in two ways: (a) the two template images are stitched together to generate a composite image. Minutiae points are then detected in this composite image; (b) the minutia sets obtained from each of the individual impressions are integrated to create a composite minutia set.

8.7.3.2 Bistarelli, Santini, and Vaccarelli’s Algorithm, Suiting the Hardware Constraints of a Smartcard Architecture

A team from Pisa and Pescara, Italy, comprising Stefano Bistarelli et al., proposed (2006) what they called “a light-weight fingerprint matching algorithm that can be executed inside the devices with a limited computational power” (ibid., p. 359). Their implementation is on a smartcard, and is supported by the Java Card™ platform.¹⁸⁰ In devising their algorithm, they based in on “on the minutiae local structures (the “neighborhoods”), that are invariant with respect to global transformations like translation and rotation” (ibid.). Such local structure information

¹⁸⁰ On which, see <http://www.javacardforum.org/> See Chen (2000b) about the architecture of Java Card. “Performing a biometric verification inside a smartcard is notoriously difficult, since the processing capabilities of standard smartcard processors are limited for such a complex task. With *Match-on-Card* (MoC) technology, the fingerprint template is stored inside the card, unavailable to the external applications and the outside world. In addition, the matching decision is securely authenticated by the smartcard itself, in this way, the card has only to trust in itself for eventually unblocking stored sensitive information, such as digital certificates or private keys for digital signature. Our verification MoC algorithm was developed to work in this very strictly bounded environment” (Bistarelli et al., 2006, p. 359).

about the minutiae characteristics, i.e., ridge pattern micro-characteristics, spares the system the need to pre-align the processing fingerprint templates, “which would be a difficult task to implement inside a smartcard” (ibid., p. 360). The CPU (i.e., the central processing unit) of a smartcard pose limitations: “matching on smartcard environment is bounded by the hardware simplicity (CPU limitations first of all), and thus waiting for a complete minutiae match could lead to a waiting time which is too long for the user. In our algorithm we solve this problem by stopping the computation as soon as it is possible to assert, with satisfactory confidence, that the considered templates belong to the same fingerprint” (ibid., p. 367).

“The main characteristic of the algorithm is to have an asymmetric behavior, in respect to the execution time, between correct positive and negative matches” (ibid., p. 359). Correct positive matches are when the same fingerprint is recognised. Correct negative matches are when two different fingers left the prints. The asymmetric execution time “is because the match procedure stops immediately when few minutiae pairs result in a positive match. If this check does not succeed, for example if the two fingers are different, or if the two acquisitions of the same finger are very disturbed, the procedure is fully executed (lasting longer) and the match decision is taken only at its end” (ibid., p. 360). Bistarelli et al. explained (2006, p. 367):

Our proposed matching algorithm computes how much the neighborhood of a minutia in the candidate template is similar to the neighborhood of each minutia in the reference template. At the end of this scan step, the two most similar minutiae (those whose “similarity value” is the lowest) are matched and then discarded from subsequent scan phases concerning other different minutiae of the candidate template. All these similarity measures are summed together during the process and, at the end, the algorithm can decide if the two templates match by applying a threshold on this global score.

The problem with smartcard hardware limitations is solved “by stopping the computation as soon as it is possible to assert, with satisfactory confidence, that the considered templates belong to the same fingerprint” (ibid.). In fact, the “algorithm stops as soon as it finds some minutiae pairs (i.e. a number between 2 and 5) matching with a very good average similarity value, or even immediately when only the last examined minutiae pair has a matching value lower than a very rigorous threshold. Otherwise, if these two conditions are not true, the algorithm explores all the minutiae pairings space” (ibid.).

We translate into text the flowchart in Bistarelli et al. (2006, p. 367, figure 6). The input of the algorithm is the candidate minutia *C* from a candidate template. *C* is taken to be matched. The reference template is also taken as input, and each of its minutiae is called *R* (where “the minutia information exactly corresponds to its neighborhood features: the terms ‘minutia’ and ‘neighborhood’ can be used as synonyms, since to match a minutia we need to match its neighborhood”, ibid.).¹⁸¹

¹⁸¹ “The algorithm scans sequentially the minutiae of the reference template until a good match for the input minutia is found. Both candidate and reference minutiae lists are stored according to the increasing minutia reliability value: in this way we try to stop the procedure more quickly by scanning a reduced portion of the template minutiae lists. In fact, a minutia with a high reliability in a given template, when not cut away by partial overlapping, will probably have a high reliability

- Step 1.** Initially, minutia R in the reference template is taken, and $MinutiaDissimilarity$ is initialised to zero.
- Step 2.** Take neighbour I or R .
- Step 3.** Take neighbour J of C .
- Step 4.** Is J matched? If yes, increment J by one and go to Step 3. If no, go to **Step 5.**
- Step 5.** Find $NeighDissimilarity$ between I and J . This corresponds to these four substeps (Bistarelli et al., 2006, p. 368), where (ibid., p. 366) Ed stands for “euclidean distance” (between the central minutia and its neighbour), Dra stands for “distance relative angle” (this is the angle between a segment which joins two minutiae points,¹⁸² and the central minutia ridge direction), Oda stands for “orientation difference angle” (this is the difference angle between the central minutia orientation angle and the neighbour ridge orientation angle),¹⁸³ and Rc stands for “ridge count” between the central minutia and its neighbour (See Fig. 8.7.3.2.1):

1. To find the difference in absolute value between corresponding features:

$$EdDiff = |Ed_1 - Ed_2|,$$

$$rcDiff = |Rc_1 - Rc_2|,$$

$$draDiff = |Dra_1 - Dra_2|$$

and

$$odaDiff = |Oda_1 - Oda_2|.$$

Fig. 8.7.3.2.1 Features of the minutiae. Redrawn from figure 5 of (Bistarelli et al., 2006)

also in other templates obtained from the same finger. Thus, the stopping conditions can be met earlier than in a casual disposition of the minutiae in the list. Moreover, it is obviously better to prematurely stop the procedure with few but ‘good’ minutiae than with low quality ones. The minutia of the reference template matched in this way, is then marked as ‘already matched’ and is not considered in the successive iterations.” (Bistarelli et al., 2006, p. 368).

¹⁸² Such as the ending of one ridge, and a bifurcation point of two other ridges close by.

¹⁸³ The orientation difference angle is the difference between two angles, which are each an angle between a horizontal straight line, and the straight line that is tangent to the respective ridge (thus being the central minutia ridge direction) at the given minutia point (such as the ending of the ridge, or a bifurcation point). It is the minutia point being one of the two ends of the segment we mentioned concerning the distance relative angle.

2. To check that every feature difference value is below the corresponding acceptance threshold; if only one difference value exceeds the relative threshold, the two neighbors cannot correspond in the two respective neighborhoods ($edDiff$ must not be greater than the limit set by $edDiffThr$, $rcDiff$ than $rcThr$, $edDiff$ than $draThr$ and $odDiff$ than $odThr$). The set of the four feature difference thresholds can be globally defined as the features *bounding box*, which makes the algorithm tolerant to small non-linear distortions.
3. To multiply each feature difference for the corresponding eight value: thus,

$$edWghtDiff = edDiff \times edWght,$$

$$rcWghDiff = rcDiff \times rcWght,$$

$$odWghtDiff = odDiff \times odWght$$

and

$$draWghtDiff = draDiff \times draWght.$$

The different weight values are necessary to attribute more importance to the features that match better such as, in our test experience, the euclidean distance. Before multiplying for the weight value, we have normalized the feature differences with respect to the bounding box thresholds (to have homogenous values).

4. To sum together all the four weighted differences to represent the global dissimilarity between the two neighbors:

$$\begin{aligned} NeighDissimilarity = & edWghtDiff \\ & +rcWghtDiff \\ & +draWghtDiff \\ & +odWghtDiff. \end{aligned}$$

Step 6. Is BBox, i.e. the bounding box, OK? If yes, go to **Step 7**. If no, discard $NeighDissimilarity$, then increment J by one and go to **Step 3**.

Step 7. Is $J=LastNeigh$ verified? If yes, go to Step 8. If no, increment J by one and go to **Step 3**.

Step 8. Match I and J with best $NeighDissimilarity$:

the algorithm finds for the first neighbor of the reference minutia, the most similar neighbor in the input minutia among those satisfying the bounding box checks; the most similar is the one for which the algorithm finds the lowest $NeighDissimilarity$ value" (ibid., p. 368). "The chosen most similar neighbor in the reference minutia is then marked and not considered while matching other neighbors" (ibid.).

“The obtained *NeighDissimilarity* value is then added to the global similarity score between the minutiae, *MinDissimilarity*” (ibid., p. 368)

$$MinutiaeDiss+ = NeighDissimilarity$$

Moreover:

Increment by one the value of *NM*, that is the number of neighbours matched.

Step 9. Is the $NM=N$ verified? That is to say: has the required minimum number *N* of neighbours been matched?

Step 10. Match *R* and *C*. (*MatchCost* is a temporary average.)

$$MatchCost = \frac{MinutiaeDiss}{NM} \\ MinutiaeMatched + +$$

That is to say:

“if the neighborhoods of the two *R* and *C* minutiae have been matched [. . .], the *MinDissimilarity* score between *M* and *N* is finally divided by the number of matched neighbor pairs and then added to the global dissimilarity value between the candidate and reference templates: the *MatchCost*. The number of matched minutiae *MinutiaeMatched* is then incremented” (ibid., p. 368).

Step 11. Are stop conditions verified? If yes, return a successful match. If no, repeat this procedure with the next candidate minutia *C*.

Step 12. Is $I=LastNeigh$ verified? That is to say:

“at the end of the two neighborhoods scanning and if the procedure has found less than *N* matching neighbor pairs between the two minutiae (“Yes” case [to the test $I=LastNeigh$]), these two minutiae can not be considered as matching because their neighborhoods agree on too few points of evidence to be a reliable pair, even if their *MinDissimilarity* value is very low. Thus, the following minutia *R* in reference template has to be checked (“No” case in [the test of **Step 13**]), but if there are no more minutiae *R* to be examined, the entire procedure [. . .] is repeated for the next minutia *C* in the decreasing reliability order of the candidate template.” (ibid., p. 368).

If yes, go to **Step 13**. If no, increment *J* by one and go to **Step 3**. That is to say: if no, the procedure is repeated for all the other neighbours in the minutia of the reference template, excluding the ones already marked.

Step 13. Is $R=LastMin$ verified? If yes, repeat this procedure with the next candidate minutia *C*. If no, increment *R* by one and go to **Step 1**.

8.7.3.3 The Tohoku Algorithm for Fingerprint Matching Based on Band-Limited Phase-Only Correlation

Tatsuo Higuchi’s team at Tohoku University and Tohoku Institute of Technology published (Ito et al., 2004) an algorithm for fingerprint matching, which resorts

to the *phase-only correlation (POC)* function.¹⁸⁴ It uses phase spectra of fingerprint images. The algorithm was claimed to be “highly robust against fingerprint image degradation due to inadequate fingertip conditions” (ibid., p. 682). It was also claimed that it “exhibits efficient identification performance even for difficult fingerprint images that could not be identified by the conventional matching algorithms” (ibid.). They experimented with the technique they developed, and carried out comparisons to other techniques, by using a prototype (from Yamatake Corporation) of a fingerprint verification system with a pressure-sensitive sensor; the fingerprint database was with fingerprints from employees of the 700-strong staff of Yamatake Corporation.

Given two $N_1 \times N_2$ images (such as two fingerprints to be compared), $f(n_1, n_2)$ and $g(n_1, n_2)$, let their index ranges be:

$$n_1 = -M_1 \dots M_1 \quad (\text{where } M_1 > 0)$$

$$n_2 = -M_2 \dots M_2 \quad (\text{where } M_2 > 0)$$

Let us consider those two functions’ respective two-dimensional *discrete Fourier transforms*, $F(k_1, k_2)$ and $G(k_1, k_2)$:

$$\begin{aligned} F(k_1, k_2) &= \sum_{n_1, n_2} f(n_1, n_2) W_{N_1}^{k_1 n_1} W_{N_2}^{k_2 n_2} \\ &= A_F(k_1, k_2) e^{j\theta_F(k_1, k_2)}, \end{aligned}$$

and

$$\begin{aligned} G(k_1, k_2) &= \sum_{n_1, n_2} g(n_1, n_2) W_{N_1}^{k_1 n_1} W_{N_2}^{k_2 n_2} \\ &= A_G(k_1, k_2) e^{j\theta_G(k_1, k_2)}, \end{aligned}$$

where the ranks of k_1 and k_2 are defined as:

$$k_1 = -M_1 \dots M_1 \quad (\text{where } M_1 > 0)$$

$$k_2 = -M_2 \dots M_2 \quad (\text{where } M_2 > 0)$$

and where

$$\begin{aligned} W_{N_1} &= e^{-j \frac{2\pi}{N_1}} \\ W_{N_2} &= e^{-j \frac{2\pi}{N_2}} \end{aligned}$$

¹⁸⁴ The concept was used earlier by e.g. Kuglin and Hines (1975), and Kenji, Aoki, Sasaki, Higuchi, and Kobayashi (2003).

Moreover, the operator

$$\sum_{n_1, n_2}$$

stands for

$$\sum_{n_1=-M_1}^{M_1} \sum_{n_2=-M_2}^{M_2}$$

$A_F(k_1, k_2)$ and $A_G(k_1, k_2)$ are *amplitude components*. By contrast,

$$e^{j\theta_F(k_1, k_2)}$$

and

$$e^{j\theta_G(k_1, k_2)}$$

are *phase components*. The following formula gives the *cross spectrum*, $R_{FG}(k_1, k_2)$, of the two two-dimensional discrete Fourier transforms, $F(k_1, k_2)$ and $G(k_1, k_2)$:

$$\begin{aligned} R_{FG}(k_1, k_2) &= F(k_1, k_2) \overline{G(k_1, k_2)} \\ &= A_F(k_1, k_2) A_G(k_1, k_2) e^{j\theta(k_1, k_2)} \end{aligned}$$

In the latter formula, $\overline{G(k_1, k_2)}$ stands for the complex conjugate of $G(k_1, k_2)$. By definition, we denoted in that same formula the phase difference as follows:

$$\theta(k_1, k_2) = \theta_F(k_1, k_2) - \theta_G(k_1, k_2)$$

Moreover, the operator

$$\sum_{k_1, k_2}$$

stand for

$$\sum_{k_1=-M_1}^{M_1} \sum_{k_2=-M_2}^{M_2}$$

The ordinary $r_{fg}(n_1, n_2)$ is the correlation function

$$r_{fg}(n_1, n_2) = \frac{1}{N_1 N_2} \sum_{k_1, k_2} R_{FG}(n_1, n_2) W_{N_1}^{-k_1 n_1} W_{N_2}^{-k_2 n_2}$$

and is the two-dimensional *inverse discrete Fourier transform*. The *normalised cross-phase spectrum*, also called the *normalised cross-spectrum*, is given by definition by the following formula:

$$\begin{aligned} \hat{R}_{FG}(k_1, k_2) &= \frac{F(k_1, k_2) \overline{G(k_1, k_2)}}{|F(k_1, k_2) \overline{G(k_1, k_2)}|} \\ &= e^{j\theta(k_1, k_2)}. \end{aligned}$$

The phase-only correlation function is given by the formula:

$$\begin{aligned} \hat{r}_{ff}(n_1, n_2) &= \frac{1}{N_1 N_2} \sum_{k_1, k_2} W_{N_1}^{-k_1 n_1} W_{N_2}^{-k_2 n_2} \\ &= \delta(n_1, n_2) \\ &= \begin{cases} 1 & \text{if } n_1 = n_2 = 0 \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

As a particular case, if the two images are identical, it follows from the latter formula that their phase-only correlation function is the *Kronecker delta function*, $\delta(n_1, n_2)$. In the application at hand, it is two fingerprints that are compared. Ito et al. (2004) found it advantageous to resort for that purpose to the phase-only correlation function, as opposed to the ordinary correlation function, because of how accurate the phase-only correlation function is in image matching: it exhibits a much higher discrimination capability. In fact, when it is plotted as a surface in three dimension, the phase-only correlation function gives a distinct sharp peak when the two images being compared are similar to each other, whereas the peak drops significantly if the two images are not similar. Also with ordinary correlation, there is a peak if the two images are similar or identical, and the peak is not there if the two images are not similar, but with the phase-only correlation the difference is much sharper. “Other important properties of the POC function used for fingerprint matching is that it is not influenced by image shift and brightness change, and it is highly robust against noise” (Ito et al., 2004, p. 683).

In section 3 of Ito et al. (2004), the definition of phase-only correlation function was modified into a *band-limited POC function*, one that is dedicated to fingerprint matching tasks. Meaningless high-frequency components in the calculation of the cross-phase spectrum were eliminated from the new definition. Depending on the fingerprint image, if the ranges of the *inherent frequency band* are given by

$$k_1 = -K_1 \dots K_1 \quad (\text{where } 0 \leq K_1 \leq M_1)$$

$$k_2 = -K_2 \dots K_2 \quad (\text{where } 0 \leq K_2 \leq M_2)$$

– where the parameters K_1 and K_2 can be automatically detected by image processing – the effective size of the *frequency spectrum* is given by the formulae

$$L_1 = 2K_1 + 1$$

$$L_2 = 2K_2 + 1.$$

The *band-limited phase-only correlation function* was defined as follows:

$$\begin{aligned} \hat{r}_{fg}^{K_1 K_2}(n_1, n_2) &= \frac{1}{L_1 L_2} \sum_{k_1=-K_1}^{K_1} \sum_{k_2=-K_2}^{K_2} \hat{R}_{FG}(k_1, k_2) \\ &\quad \times W_{L_1}^{-k_1 n_1} W_{L_2}^{-k_2 n_2}, \end{aligned}$$

where

$$n_1 = -K_1 \dots K_1$$

$$n_2 = -K_2 \dots K_2.$$

Ito et al. remarked (2004, p. 684):

Note that the maximum value of the correlation peak of the band-limited POC function is always normalized to 1 and is not depending on the frequency band size L_1 and L_2 . The shape of the band-limited POC function for the two identical images is always the Kronecker’s delta function $\delta(n_1, n_2)$. Also, note that the original POC function can be represented as

$$\hat{r}_{fg}(n_1, n_2) = \hat{r}_{fg}^{M_1 M_2}(n_1, n_2).$$

As an alternative method for defining a frequency-selective POC function, had the Tohoku team adopted instead some adequate *low-pass filter* to the cross-phase spectrum, this would have resulted in the shape and height of the correlation peak depending on the type of the low-pass filter (Ito et al., 2004, pp. 684–685, citing Kenji et al., 2003), and what is more, this would have required fitting a model peak function to the correlation array, in order to evaluate the similarity between images, whereas with the band-limited POC function this is not required (Ito et al., 2004, p. 685).

Ito et al. (2004, p. 685, figure 5) give an example in which the original POC function would give a false negative, that is to say, when a registered fingerprint was matched to an impostor’s fingerprint, the original POC limited gave a peak. By contrast, the band-limited POC function, for the same input pair of fingerprint, gave no peak. Therefore, the band-limited POC function is more reliable – it discriminates much better – than the original POC function, for the purposes of fingerprint matching.

The algorithm for fingerprint matching using the band-limited POC function takes an input $f(n_1, n_2)$, i.e. the registered fingerprint image, and $g(n_1, n_2)$, i.e. the fingerprint image to be verified. The output is a matching score between $f(n_1, n_2)$ and $g(n_1, n_2)$. The steps of the algorithm are as follows (Ito et al., 2004, p. 686):

Step 1. Store in advance a set of rotated images $f_\theta(n_1, n_2)$ of $f(n_1, n_2)$ over the angular range

$$-\theta_{\max} \leq \theta \leq \theta_{\max}.$$

with an angle spacing 1° .

Step 2. Calculate the POC function

$$\hat{r}_{f_\theta g}^{M_1 M_2}(n_1, n_2)$$

between $f_\theta(n_1, n_2)$ and $g(n_1, n_2)$.

Step 3. Calculate the rotation angle

$$\Theta = \arg \max_{\theta} \{S_1^{M_1 M_2} [f_{\theta}, g]\}$$

by evaluating the similarity between $f_{\theta}(n_1, n_2)$ and $g(n_1, n_2)$, in order to select the rotation-normalised image $f_{\Theta}(n_1, n_2)$.

Step 4. Estimate image displacements (τ_1, τ_2) between $f_{\Theta}(n_1, n_2)$ and $g(n_1, n_2)$ from the peak location of

$$\hat{r}_{f_{\Theta}g}^{M_1 M_2}(n_1, n_2)$$

Step 5. Extend the size of $f_{\Theta}(n_1, n_2)$ and $g(n_1, n_2)$ by τ_1 and τ_2 pixels for n_1 and n_2 directions, to obtain $f'(n_1, n_2)$ and $g'(n_1, n_2)$.

Step 6. Extract the effective fingerprint regions $f''(n_1, n_2)$ and $g''(n_1, n_2)$ from $f'(n_1, n_2)$ and $g'(n_1, n_2)$.

Step 7. Detect the inherent frequency band (K_1, K_2) from the two-dimensional discrete Fourier transforms of $f''(n_1, n_2)$.

Step 8. Calculate the band-limited POC function

$$\hat{r}_{f''g''}^{K_1 K_2}(n_1, n_2)$$

Step 9. Compute the *matching score*

$$S_P^{K_1 K_2} [f'', g'']$$

(by summing the highest peaks of the band-limited POC function: there may be several peaks, because elastic deformation causes them to be produced: see below), and then give the matching score as output, and terminate the execution of the algorithm.

In their experiments, Ito et al. explain (2004, p. 686), they used $\theta_{\max} = 20^\circ$. They also explained (ibid.):

In many cases, the band-limited POC function has multiple peaks, which is caused by elastic fingerprint deformation. The fingerprint image can expand or contract when a fingertip contacts with the sensor surface. Each portion of the fingerprint image will be shifted independently, which means several sub-domains in the image are moving individually. In this case, the POC function produces several peaks corresponding to the multiple translated sub-domains. The height of every correlation peak reflects the matched area of each sub-domain. Hence, we decide to employ the sum of these peaks as an evaluation criterion in order to make the proposed matching algorithm robust against elastic deformation.

8.8 Bloodstain Pattern Analysis, and the Use of Software for Determining the Angle of Impact of Blood Drops

8.8.1 *The Basics*

Do not confuse *DNA profiling* and *bloodstain pattern analysis (BPA)*.¹⁸⁵ In order to carry out the latter (which some prefer to call *blood spatter analysis*), the analyst (or examiner) has to consider, for each blood pattern, factors including the number of blood patterns in the environment (e.g., on the floor and the walls inside a room), dispersion, shape, size, volume, orientation, and location. What is reconstructed (if reconstruction is successful, but not always this is feasible) is the events that occurred during the criminal incident. The analyst has to classify the bloodstain pattern, and then to associate that pattern back to a source event, that is conjectured to have unfolded at the crime scene. Concerning BPA, the Wikipedia entry¹⁸⁶ provides this usefully concise information:

Bloodstain pattern analysis (BPA) is one of several specialties in the field of forensic science. The use of bloodstains as evidence is not new, however the application of modern science has brought it to a higher level. New technologies, especially advances in DNA analysis, are available for detectives and criminologists to use in solving crimes and apprehending offenders. The science of bloodstain pattern analysis applies scientific knowledge from other fields to solve practical problems. Bloodstain pattern analysis draws on biology, chemistry, maths, and physics among scientific disciplines. As long as an analyst follows a scientific process, this applied science can produce strong, solid evidence, making it an effective tool for investigators.

¹⁸⁵ Bloodstain pattern analysis is the subject of a valuable short introduction by Louis Akin (2005), of books by Tom Bevel and Ross Gardner (2008), and by Stuart James and William Eckert (1999), whereas the book by James et al. (2005a) is more recent (whereas their James et al., 2005b is an overview article about the recognition of bloodstain patterns). MacDonell (1993) is still cited sometimes, in the 2000s, in such studies that also cite more recent literature. Cf. MacDonell and Bialousz (1979). Stuart James also edited a paper collection on the subject (James, 1999). With respect to the second edition of 2002, the third edition of Bevel and Gardner's book (2008) includes new chapters that "detail a true taxonomic classification system, with a supporting decision map to aid analysts in the field; a specific methodology based on scientific method; conducting experiments in support of bloodstain pattern analysis; anatomical issues associated to bloodstain pattern analysis; issues surrounding the examination of clothing in bloodstain pattern analysis; as well as a chapter detailing the various presumptive testing and enhancement techniques for bloodstains" (ibid., from the summary). The contents of the third edition include: Bloodstain pattern analysis: its function and a historical perspective – Bloodstain pattern terminology – Bloodstain classification – A methodology for bloodstain pattern analysis – The medium of blood – Anatomical considerations in bloodstain pattern analysis – Determining motion and directionality – Determining the point of convergence and the area of origin – Evaluating impact spatter bloodstains – Understanding and applying characteristic patterns of blood – Bloodstained clothing issues – Presumptive testing and enhancement of blood – Documenting bloodstains – An introduction to crime scene reconstruction and analysis [this is also the subject of a book by those same authors: Gardner and Bevel (2009)] – Presenting evidence – Experimentation in bloodstain pattern analysis – Dealing with the risk of bloodborne pathogens – Appendix A weight/measurement conversion table – Appendix B: Trigonometric functions and their application in bloodstain pattern analysis.

¹⁸⁶ http://en.wikipedia.org/wiki/Bloodstain_pattern_analysis.

Bloodstain pattern categories include: *passive bloodstains*, *projected bloodstains*, and *transfer/contact bloodstains*. The same Wikipedia entry explains: “The definitions used below are from the suggested IABPA terminology list”. In particular: “Passive bloodstains are those stains created by the force of gravity”. *Passive drops* are “Bloodstain drop(s) created or formed by the force of gravity acting alone”. *Drip pattern* denotes “A bloodstain pattern which results from blood dripping into blood”. *Flow pattern* is “A change in the shape and direction of a bloodstain due to the influence of gravity or movement of the object”. *Pool pattern* is “A bloodstain pattern formed when a source of blood is stationary for a period of time”.

“A projected stain occurs when some form of energy has been transferred to a blood source”. The respective terminology includes:

Low Velocity Impact Spatter (LVIS) – A bloodstain pattern that is caused by a low velocity impact/force to a blood source.

Medium Velocity Impact Spatter (MVIS) – A bloodstain pattern caused by a medium velocity impact/force to a blood source. A beating typically causes this type of spatter.

High Velocity Impact Spatter (HVIS) – A bloodstain pattern caused by a high velocity impact/force to a blood source such as that produced by gunshot or high-speed machinery.

Cast-Off Pattern – A bloodstain pattern created when blood is released or thrown from a blood-bearing object in motion.

Arterial Spurting (or Gushing) Pattern – Bloodstain pattern(s) resulting from blood exiting the body under pressure from a breached artery.

Back Spatter – Blood directed back towards the source of energy or force that caused the spatter.

Expiratory Blood – Blood that is blown out of the nose, mouth, or a wound as a result of air pressure and/or air flow which is the propelling force.

“A transfer or contact stain is produced when an object with blood comes in contact with an object or surface that does not have blood. It may be possible to discern the object that left the blood impression.” The respective terminology includes: *wipe pattern*, this being “A bloodstain pattern created when an object moves through an existing stain, removing and/or altering its appearance”; and *swipe pattern*, this being “The transfer of blood from a moving source onto an unstained surface. Direction of travel may be determined by the feathered edge.”

As indicated above, there are other terms currently used in BPA and different ways of classifying bloodstain patterns. For example there is a debate over the misnomer of the LVIS, MVIS, and HVIS as it relates to the physical term ‘velocity’. A sub-committee of the SWGSTAIN [i.e., the Scientific Working Group on Bloodstain Pattern Analysis] has been tasked with addressing the terminology issues and develop a taxonomy for bloodstain patterns.

When it comes to *velocity impact stains*, the same entry explains:

Contrary to what the name states, the terms low-, medium-, and high-velocity impact spatter do not describe the velocity of the blood droplets as they fly through the air. The variation in the ‘velocity’ is meant to describe the amount of energy transferred to a blood source in order to create the stains. Velocity is a speed (m/s) with a direction. Often the terms force and energy are quoted in conjunction with the unit ft/s or m/s which is an incorrect. Force is related to velocity and mass (N or 1 kg ·m·s⁻²). Energy (work) is related to the force exerted on an object (J or N·m or kg·m²·s⁻²).

Physical considerations apply: “Once blood has left the body it behaves as a fluid and all physical laws apply”. In particular, *gravity* “is acting on blood (without the body’s influence) as soon as it exits the body. Given the right circumstances blood can act according to ballistic theory.” *Viscosity* “is the amount of internal friction in the fluid. It describes the resistance of a liquid to flow”. *Surface tension* “is the force that gives the ability to blood to maintain its shape”.

Blood spatter flight characteristics do matter: “Experiments with blood have shown that a drop of blood tends to form into a sphere in flight rather than the artistic teardrop shape. This is what one would expect of a fluid in freefall. The formation of the sphere is a result of surface tension that binds the molecules together. This spherical shape of blood in flight is important for the calculation of the angle of impact (incidence) of blood spatter when it hits a surface. That angle will be used to determine the point from which the blood originated which is called the Point of Origin or more appropriately the Area of Origin.¹⁸⁷ A single spatter of blood is not enough to determine the Area of Origin at a crime scene. The determination of the angles of impact and placement of the Area of Origin should be based on the consideration of a number of stains and preferably stains from opposite sides of the pattern to create the means to triangulate.”

It is important to determine *angles of impact*.

As mentioned earlier a blood droplet in freefall has the shape of a sphere. Should the droplet strike a surface and a well-formed stain is produced, an analyst can determine the angle at which this droplet struck the surface. This is based on the relationship between the length of the major axis, minor axis, and the angle of impact. A well-formed stain is in the shape of an ellipse [See Fig. 8.8.1.1]. Dr. Victor Balthazard, and later Dr. Herbert Leon MacDonell,¹⁸⁸ realized the relationship of the length-width ratio of the ellipse was the function of the sine of the impact angle. Accurately measuring the stain will easily result in the calculation the impact angle. [. . .] Because of the three-dimensional aspect of trajectories there are three angles of impact, α , β , and γ . The easiest angle to calculate is *gamma* (γ). Gamma is simply the angle of the bloodstain path measured from the true vertical (plumb)¹⁸⁹ of the surface [. . .] The next angle that can be quite easily calculated is *alpha* (α). Alpha is the impact angle of the bloodstain path moving out from the surface (see [Fig. 8.8.1.2] with alpha at the top by the stain). The third angle to be calculated is *beta* (β). Beta is the angle of the bloodstain path pivoting about the vertical (z) axis [. . .] All three angles are related through the equation quoted below.

Let L be the length of the ellipse, that is to say, its major axis. Let W be the width of the ellipse, that is its minor axis. Let α be the angle of impact. Those variable are related by the equation

$$\sin \alpha = W/L$$

¹⁸⁷ The *point of origin* is also called the *point of hemorrhage*. Louis Akin “prefers to use the term *point of hemorrhage* to distinguish the area from which the blood was disgorged from other *points of origin*, the latter phrase being a widely used term in blood spatter, ballistics, crime, and accident scene investigation and reconstruction. Although most experts use the word *point*, the word *area* is a more conservative one to use” (Akin, 2005, p. 7).

¹⁸⁸ The author of MacDonell (1993).

¹⁸⁹ The plumb line is parallel to the z axis, in a Euclidean space in three dimensions.

Fig. 8.8.1.1 Upward moving bloodstain showing proper ellipse placement¹⁹⁰

Fig. 8.8.1.2 Angles of impact¹⁹¹

Therefore,

$$\alpha = \arcsin (W/L)$$

The three angles α , β , and γ are related by this equation:

$$\tan \beta = (\tan \alpha) / (\tan \gamma)$$

¹⁹⁰ In the public domain; http://en.wikipedia.org/wiki/File:BPA_ellipse_example.png Image made by Kevin Maloney.

¹⁹¹ In the public domain; http://en.wikipedia.org/wiki/File:BPA_AOI.png Image made by Kevin Maloney. http://upload.wikimedia.org/wikipedia/en/9/91/BPA_AOI.png is the full resolution version.

Measurements need be carried out with diligence and accuracy by the bloodstain pattern examiner (analyst). “In the past analysts have used a variety of instruments. Methods currently used include:

- Viewing loop with an embedded scale in 0.2 mm increments or better that is placed over the stain. The analyst then uses a scientific calculator or spreadsheet to complete the angle calculations.
- Bloodstain Pattern Analysis (BPA) software that superimposes an ellipse over a scaled close-up image of an individual bloodstain. The programs then automatically calculates the angles of impact” (from the Wikipedia entry).

8.8.2 Software

There exists *bloodstain analysis software* for calculating the angles of impact, in bloodstain pattern analysis:

Accurately measuring the stain and calculating the angle of impact requires due diligence of the analyst. In the past analysts have used a variety of instruments. Methods currently used include:

Viewing loop with an embedded scale in 0.2 mm increments or better that is placed over the stain. The analyst then uses a scientific calculator or spreadsheet to complete the angle calculations.

Bloodstain Pattern Analysis (BPA) software that superimposes an ellipse over a scaled close-up image of an individual bloodstain. The programs then automatically calculates the angles of impact.

Using software produces a very accurate result that is measurable and reproducible. One software product for bloodstain pattern analysis is the *Crime Scene Command* program,¹⁹² produced by On Scene Forensics in Austin, Texas, and which is claimed to be easy to use. The originator of Crime Scene Command is Louis L. Akin. There is an *On Scene Blood Spatter Calculator*, for use on homicide scenes. A testimonial by a forensic instructor, Thomas Hanratty, from Milwaukee, Wisconsin, found at the producer’s website, for *Crime Scene Command*, claims: “An officer, either a first responder¹⁹³ or a detective, merely plugs in a few measurements and the dreaded math calculations are performed for him/her. Best of all, a record is generated of a

¹⁹² See http://www.onsceneforensics.com/Crime_Scene_Command.htm

¹⁹³ Concerning *first responding officers*, also called *first responders* (which strictly speaking is a broader category, as sometimes the earliest responders are members of the public), Miller (2003) writes: “The first responders at a crime scene are usually police officers, fire department personnel or emergency medical personnel. They are the only people who view the crime scene in its original condition. Their actions at the crime scene provide the basis for the successful or unsuccessful resolution of the investigation. They must perform their duties and remember that they begin the process that links victims to suspects to crime scenes and must never destroy the links” (ibid., p. 118).

wealth of materials, if the entire program is used; including witnesses, suspects, an evidence log, photo log and bloodstains. And it's all in one complete report.”

The key benefits claimed by On Scene Forensics for *Crime Scene Command* are as follows.¹⁹⁴ The software

- Makes a record of the case information as a number one report.
- Serves as a scene personnel log showing the name, agency, badge number, time in and out, of each person who enters the scene.
- Makes a detailed record of the circumstances surrounding the death of the victim:
 - Weather conditions
 - Environmental conditions
 - Position of victim
- Performs all bloodstain computations instantly including:
 - Angle of impact in degrees
 - Point of origin
 - Transfer stain description and location
- Performs all bullet trajectory computations from a bullet hole in a solid surface including:
 - Gives caliber of bullet
 - Angles of impact in degrees
 - Trajectory path
- Suspect page records all information on the suspect.
- Records evidence found at the scene in a printable log.
- Records photographs taken at the scene in a printable log.
- Records witness statements, res gestae statements, and officers' notes on scene.
- Easy to read permanent record can be stored as a word document on hard drive or disk, and printed, faxed, or emailed.
- Can be used as notes when testifying.

8.8.3 Point or Area of Origin

The description at the end of the previous subsection refers, among the other things, to to *point-of-origin calculations*. Apart from the angles of impact, another thing that needs to be calculated is the *area of origin* indeed. The IABPA definition is: “Point (Area) of Origin – The common point (area) in three-dimensional space to which the trajectories of several blood drops can be retraced.” The *area of origin* is shown in Fig. 8.8.3.1. “The area of origin can give a general location [(Bevel & Gardner, 2008, p. 195)] or relative posture [(James et al., 2005a, p. 219)] of a bleeding victim

¹⁹⁴ Also see Sections 8.8.4 and 8.8.5.

who has received a blow. In the literature, there are several limits used for area-of-origin calculations. These include a tennis ball, a grapefruit, a soccer ball, and a basketball” (Maloney, Killeen, & Maloney, 2009, p. 518).

The Wikipedia entry for “Bloodstain Pattern Analysis” explains:

The *area of origin* is the area in three-dimensional space where the blood source was located at the time of the bloodletting incident. The area of origin includes the area of convergence with a third dimension in the z direction. Since the z-axis is perpendicular to the floor, the area of origin has three dimensions and is a volume.

The term *point of origin* has also been accepted to mean the same thing. However it has been argued, there are problems associated to this term. First, a blood source is not a point source. To produce a point source the mechanism would have to be fixed in three-dimensional space and have an aperture where only a single blood droplet is released at a time, with enough energy to create a pattern. This does not seem likely. Second, bodies are dynamic. Aside from the victim physically moving, skin is elastic and bones break.

Fig. 8.8.3.1 Area of origin.¹⁹⁵ The blue area represents a volume in three-dimensional space. The area of origin is the area in that space to which the trajectories of several blood drops can be traced

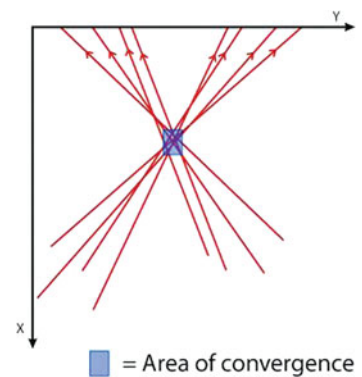

Fig. 8.8.3.2 Point of convergence¹⁹⁶

Fig. 8.8.3.3 Area of convergence¹⁹⁷

¹⁹⁷ In the public domain; http://en.wikipedia.org/wiki/File:BPA_AOC.png Image made by Kevin Maloney.

Once a force is applied to the body there will be an equal and opposite reaction to the force applied by the aggressor (Newton's third law of motion). Part of the force will move the blood source, even a millimetre, and change the origin while it is still producing blood. So the source becomes contained in a three-dimensional volume, or region. As with the area of convergence, the area of origin is easily calculated by using BPA software. There are other longer, mathematical methods of determining the area or origin, one of which is the tangential method.

Other important concepts are the *point of convergence* and the *area of convergence*. "The point of convergence is the intersection of two bloodstain paths, where the stains come from opposite sides of the impact pattern" (from the Wikipedia entry). See Fig. 8.8.3.2. "The area of convergence is the box formed by the intersection of several stains from opposite sides of the impact pattern" (ibid.). See Fig. 8.8.3.3. "To determine the point/area of convergence an analyst has to determine the path the blood droplets travelled. The tangential flight path of individual droplets can be determined by using the angle of impact and the offset angle of the resulting bloodstain. 'Stringing' stains is a method of visualising this. For the purpose of the point of convergence, only the top view of the flight paths is required. Note that this is a two-dimensional (2D) and not a three-dimensional (3D) intersection" (ibid.). "In the past, some analysts have drawn lines along the major axes of the stains and brought them to an area of convergence on the wall. Instead of using a top-down view, they used a front view. This provides a false point/area of convergence" (ibid.).

8.8.4 More Concerning Software

On Scene Forensics provides for *Crime Scene Command*¹⁹⁸ this description of the program at a glance:

This user friendly program installs in seconds and is easy to use without having to attend special classes. The program does all the trigonometric calculations necessary to determine the angle of impact and point of origin for blood spatter, the angle of impact and trajectory for bullet holes, and to estimate the time of death at a homicide scene. There is a crime scene log to enter the name, identification, agency, and purpose for everyone who enters the crime scene. There are separate pages for witnesses, victims, the scene environment, as well as death information for the pathologist. The program will estimate the time of death within four hours for the 18 hours after death.

Photographs of the crime scene, the individual bloodstains, and bullet holes, and items of evidence can be stored with each stain or pattern. The entire program and all the reports it generates can be printed with a single click of a mouse.

The software makes a permanent record of the crime scene that can be stored to hard drive printed as a Word document, faxed, or emailed. The printed reports can be used as bench notes and used on the stand to refresh memory and they satisfy the requirement for a scientific record of crime scene reconstruction.

¹⁹⁸ See Sections 8.8.2 and 8.8.5.

The Crime Scene Command program also includes screens for recording witness statements and making notes at the scene.

Crime Scene Command is meant to be used at the crime scene and is best installed on a laptop computer so that it can be taken to the scene. It is designed to be user friendly to patrol officers and not just to specially trained technicians. The program can be used at any crime scene, not only homicide scenes.

We have referred (in Section 8.8.2) to software products of On Scene Forensics. Another software product for bloodstain pattern analysis is *HemoSpat*, from a Canadian firm, FORident Software Inc.¹⁹⁹ Its owner and lead developer is Andy Maloney. He developed the software, whereas his brother Kevin Maloney is the firm's expert in bloodstain pattern analysis (but neither a co-owner, nor an employee; he is affiliated with the Forensic Identification Section of the Ottawa Police Service). At its website for *HemoSpat*, the firm claims that it is more efficient than the competing *BackTrack* software, because the latter "forces the analyst to follow specific steps which makes it difficult and time consuming to correct mistakes or allow others to review your work. BackTrack does not allow you to use angled surfaces and has problems with current digital image sizes". By contrast, "*HemoSpat* maintains the analytical data from each project making peer review and verification possible." Like *Crime Scene Command*, that tool, too, is claimed to be easy to use. Version 1.3 of *HemoSpat* was released in September 2009, and version 1.4.1. was released in January 2011. The firm's website also states: "The March/April 2011 issue of the *Journal of Forensic Identification* contains an article titled 'One-Sided Impact Spatter and Area-of-Origin Calculations'. This is the result of a combined effort of FORident Software, L'Institut de Recherche Criminelle de la Gendarmerie Nationale in Paris, France, and the Forensic Identification Section of the Ottawa Police Service in Ottawa, Canada." To say it with the abstract of Maloney, Nicloux, Maloney, and Heron (2011):

It is common practice when calculating area of origin from impact spatter to use stains from both "sides" of the pattern – stains to the left and to the right of the blood source. Impact spatter at crime scenes, however, often provides the analyst with bloodstain patterns that are not as pristine as those created in a controlled environment. One situation that may arise is impact spatter consisting of stains from only one side of the pattern because of the removal of an object after the impact, such as a door or a person, or because the stains from one side are not on a planar surface. This study looks at a method of calculating the area of origin using stains from only one side of the pattern and shows that these partial patterns may still provide usable calculations to determine the area of origin.

Maloney et al. (2011, p. 132) explain how the practical need arises:

Bloodstain analysts must work with the data they are presented with at the crime scene, regardless of quantity or quality. Sometimes this means eliminating partial impact patterns because too few stains may be found for a regular analysis. This study demonstrates that at least some incomplete impact patterns – "one-sided" patterns – need not be eliminated from the analysis of the scene because they can still provide an acceptable calculation of the area of origin.

¹⁹⁹ See <http://hemospat.com/index.php> FORident Software Canada, Inc., 132-207 Bank St., Ottawa, Ontario, Canada K2P 2N2. Their email address is inf@hemospat.com

Some articles published by the Maloney brothers in the *Journal of Forensic Identification* can be downloaded from Andy Maloney firm's website. Maloney et al. (2011) is one of these. Another paper is 'The Use of HemoSpat to Include Bloodstains Located on Nonorthogonal Surfaces in Area-of-Origin Calculations' (Maloney et al., 2009), abstracted as follows:

Determining the origin of impact patterns at crime scenes can be a challenge when there is limited or less-than-ideal information. This is made even more difficult if the analyst cannot incorporate data from nonorthogonal and orthogonal surfaces in the same analysis. Using HemoSpat software for impact pattern analysis allows analysts to remove several limitations, maximize the use of this information, and produce precise and reliable results.

By contrast (Maloney et al., 2009, p. 514):

Historically, bloodstain pattern analysts using forensic software for area-of-origin calculations had to exclude nonorthogonal (angled) surfaces from their calculations. Analysts could not incorporate orthogonal and nonorthogonal surfaces at the same time in their analyses [(Eckert & James, 1993, pp. 152–154; Carter, 2001b)].

Maloney et al. pointed out (2009, p. 523):

The task of analyzing bloodstains on nonorthogonal surfaces is made easier by using the HemoSpat software. This allows the analyst to remove objects from the scene, analyse them in a controlled and safe environment, and incorporate the data in an area-of-origin calculation.

From the same website, one can also download a white paper (FORident Software, 2009) about the validation of HemoSpat. The goal was "to validate the accuracy of the HemoSpat bloodstain analysis software against an accepted standard and to examine the reproducibility of the results." This was done in collaboration with the Royal Canadian Mounted Police (RCMP). A comparison was made with the *BackTrack* computer program for bloodstain pattern analysis. Kevin Maloney had earlier participated in the validation of *BackTrack* (Carter et al., 2005). Maloney, Carter, Jory, and Yamashita (2005) is concerned with the representation in three dimensions of bloodstain pattern analysis. Both *BackTrack* and HemoSpat use the *tangent method* outlined by Carter (2001a). Carter (2001b) is an electronic book on the computer-assisted directional analysis of bloodstain patterns, and is provided with the *BackTrack* Suite. "The users have more direct control over the ellipse in HemoSpat using the mouse, whereas *BackTrack* requires the user to enter numbers to adjust the ellipse" (FORident Software, 2009, p. 3).

8.8.5 Effects of Velocity on Blood Drops and Blood Spatter

Louis L. Akin

8.8.5.1 Introduction

The software Crime Scene Command (CSC)²⁰⁰ by On Scene Forensics was created in response to complaints by law enforcement officials that blood pattern software

²⁰⁰ See Sections 8.8.2, 8.8.4, and 8.8.5.

programs were difficult to learn and required classroom instruction. CSC is intended to be user friendly enough for a person with only a basic knowledge of blood patterns to use. It automatically calculates the angle of impact and area of origin and averages the area of origin for several impact stains. The program has additional features such as a scene personnel log, evidence collection log, and separate tabs for information on victims, suspects and witnesses including statements. It also calculates bullet trajectories. Its only drawback is that it does not produce a 3-dimensional diagram like the others do, but that complexity is what requires classroom instruction or a nerd to operate the programs and was left out to produce a fast, reliable, easy to learn and user friendly program.

Through a variety of schools, classes, and seminars, homicide detectives and crime scene technicians or criminalists are garnering a level of expertise that has not previously existed in law enforcement. New technologies, sciences, and applied sciences are available for detectives and criminalists to use in solving crimes and apprehending offenders. Blood pattern analysis may require special schooling and expertise. However, blood pattern evidence collection is an example of an applied science that a homicide detective or first responding police officer can learn to use at a scene without having to become an expert in the field.

Blood spatter interpretation or analysis itself may be compared to tracking. It may take considerable training to reach the level of a tracker who can say that a footprint was made two days before by a pigeon-towed 180 male who has bunions. It does not require that level of training or expertise to be able to look at a footprint and determine which way the person was going. Just pick out the heel and toe.

Likewise, although an expert may be able to see things in the blood pattern that the first responding officer at a crime scene doesn't, a responder can preserve the evidence and take the measurements of the stains in a pattern just as he does at an accident scene. He or she could even learn to determine generally where a victim was positioned by looking at the blood spatter the same way he could tell which way a footprint is going.

A basic understanding of blood spatter analysis will also allow the first responding officer to assist in correctly collecting and preserving blood stain data at the scene. Fortunately, the principles and procedures to learn are not complicated, and while it is easier to use software to make the calculations, the basic principles can be learned from a source as brief as this article and applied by using a hand held calculator. Some critical determinations, such as establishing the point of convergence that shows where the victim was standing can be done without use of a calculator at all.

This basic understanding is important, because the interpretation of blood spatter patterns and other evidence at crime scenes may reveal critically important information such as:

- The positions of the victim, assailant, and objects at the scene during the attack.
- The type of weapon that was used to cause the spatter.
- The number of blows, shots, stabs, etc. that occurred.

- The movement and direction of victim and assailant, after bloodshed began.
- It may support or contradict statements given by witnesses (James & Eckert, 1999, pp. 10–11).

The investigator may use blood spatter interpretation to determine:

- What events occurred.
- When and in what sequence they occurred.
- Who was, or was not, there.
- What did *not* occur.

The lists of precisely what information can be learned by the interpretation of blood stain patterns are similar for Bevel and Gardner (2002), James and Eckert (1999), Hueske (1999), Akin (2004), and Sutton (1998).

8.8.5.2 Photography, and Traditional Determination of Velocities of Blood Spatter

Without a doubt, the most important thing to at a crime scene in regard to blood spatter analysis is to photograph the scene and the blood spatter. The photographs should all be made at a 90 degree angle from the surface on which the blood stains are found and a scale should always be in the photograph so the viewer can tell the size of the drops in the pictures.

The velocity of the blood spatter when it strikes a surface is a reasonably reliable indicator of the speed of the force that set the blood in motion in the first place. The velocity is that of the force causing the blood to move rather than of the speed of the blood itself and it is measured in feet per second (fps); high velocity blood, for instance, *may* be caused by a bullet moving at 900 fps, medium velocity blood spatter may be caused by a spurting artery or by a blunt instrument striking the already bloody head or limb of a victim.

Low velocity stains are produced by normal gravity and the stains are generally 3 mm or larger. It is usually the result of blood dripping from a person who is still, walking, or running, or from a bloody weapon. Dripping blood falls at a 90° angle and forms a 360° circumference stain when it hits a flat surface, depending, of course, on the texture of the surface. See Fig. 8.8.5.2.1 for an example of low velocity spatter.

Medium blood spatter is produced by an external force of greater than 5 fps and less than 25 fps. The stains generally measure 1–3 mm in size. Blood stains this size are often caused by blunt or sharp force trauma, that is, knives, hatchets, clubs, fists, and arterial spurts. They might also result from blood being cast off a weapon or other bloody object.

Most medium velocity blood found at crime scenes will be created by blood flying from a body as a result of blunt or sharp force or the body colliding with blunt or sharp surfaces. It may be the result of a punch, a stab, or a series of blows. A void space may be created by anything that blocks the blood from falling on the

Fig. 8.8.5.2.1 An example of low velocity blood spatter

surface where it would have normally landed. The object creating the void may be either the victim or the attacker's body or a piece of furniture that was moved. See Fig. 8.8.5.2.2 for an example of medium velocity spatter.

High velocity blood spatter is produced by an external force greater than 100 fps and the stains tend to be less than 1 mm. The pattern is sometimes referred to as a mist. High velocity patterns are usually created by gunshots or explosives, but may also be caused by industrial machinery or even expired air, coughing, or sneezing. In any case, the spatter tends to be tiny drops propelled into the air by an explosive force. High velocity droplets travel the least far because of the resistance of the air against their small mass. See Fig. 8.8.5.2.3 as an example of high velocity spatter.

Fig. 8.8.5.2.2 An example of medium velocity blood spatter

Fig. 8.8.5.2.3 An example of high velocity blood spatter

8.8.5.3 Blood Spatter Flight Characteristics

Experiments with blood have shown that a drop of blood tends to form into a sphere rather than a teardrop shape when in flight. The formation of the sphere is a result of surface tension that binds the molecules together.

Fresh blood is slightly more viscous than water, and like water it tends to hold the spherical shape in flight rather than a tear drop shape as seen in cartoons.

This spherical shape of a liquid in flight is important for the calculation of the angle of impact (incidence) of blood spatter when it hits a surface. That angle will

Fig. 8.8.5.3.1 Side view of blood drop in air, and then striking a flat surface

be used to determine the point from which the blood originated which is called the Point of Origin or as this author prefers, the Point of Origin (PO).

Generally, a single spatter of blood is not enough to determine the Point of Origin at a crime scene. The determination of the Angle of Impact and placement of the PO should be based on the consideration of a number of spatters and preferably spatters that will provide an arc of reference points in order to create a triangulation effect.

The process for determining the Angle of Impact is not complicated. When a drop of blood strikes a flat surface the diameter of the drop in flight will be equivalent to the width of the spatter on the surface as seen in Fig. 8.8.5.3.1. The length of the spatter will be longer, depending on the angle at which the drop hit. The following diagram will help the reader to understand this concept.

8.8.5.4 Point of Convergence (POC)

For purposes of instruction, we will consider a case in which a fan shape blood pattern is found on a floor as the result of a gun shot wound to the head. When blood disperses in various directions from a wound the blood drops will tend to fan out. As the drops strike the floor, they will elongate into oval shapes. An imaginary line drawn through the middle of the oval shape lengthwise will run back to the area where the blood came from.

If lines are drawn through several of the blood spatters as in Fig. 8.8.5.4.1 the lines will cross at the point where the person was standing. That point is called the Point of Convergence and will be flat on the floor (if that is where the spatter is located). Somewhere above that point is where the blood originated. If the victim was shot in the head, it may be 4–6 feet (roughly the height of an average person) above that point. Where the blood left the person’s body is called the Point of Origin

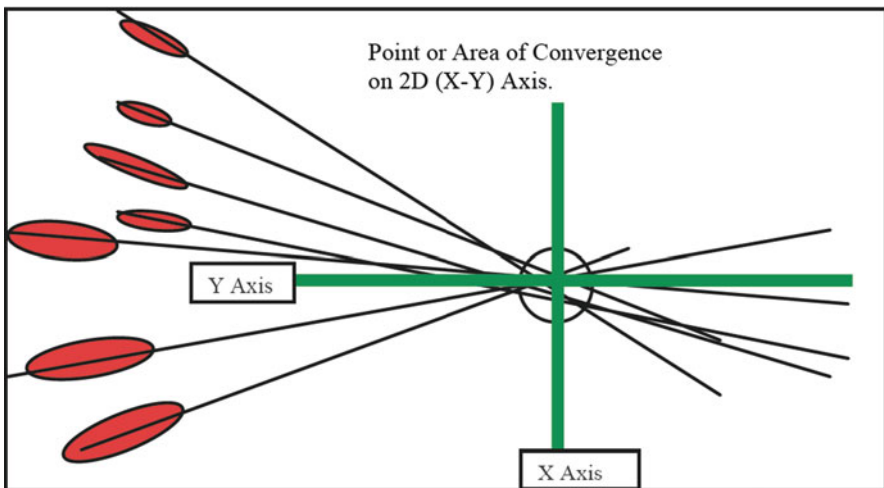

Fig. 8.8.5.4.1 Lines through the central axes of the spatter cross at the Point of Convergence

as previously mentioned. To find the Point of Origin (PO), first determine the two-dimensional Point of Convergence (POC) on the floor as seen in Fig. 8.8.5.4.1.

8.8.5.5 Determining the Angle of Impact (AOI), and the Point of Origin

The next step in the process is to determine the Angle of Impact (AOI) for representative bloodstains. Specialized blood spatter calculator software that performs all the calculations automatically is available from online vendors, but for those who do not mind doing the trigonometry all the calculations can be done on an ordinary hand held scientific calculator or even by the use of printed copies of arc sine tables.

The Angle of Impact is the angle at which the blood drop hit the floor. It can be determined by taking the inverse arc sin of the width divided by the length ratio of an individual blood spatter.

If using software just enter the width and length into the table on the screen and the calculation will be done automatically. If using a hand held calculator, divide the length of the drop into its width, then take the arc sine which is the second function on a hand held calculator (or just look on a trigonometric functions table) to get the degrees of the AOI.

For example, if a drop measures 0.5 mm wide and 1.0 mm long, dividing 1.0 into 0.5 would give a ratio of 0.5. The arc sin of 0.5 is 30 degrees. Find that by using the cosecant function on the calculator, or by looking at an arc sine table. This calculation determines that the blood drop hit the ground at 30 degrees and it is already known that it came from the Point of Convergence.

Measure the distance from the individual drop to the Point of Convergence and multiply that number by the *tangent* (TAN) of the Angle of Impact. This calculation (by the Theorem of Pythagoras) will tell how high up the spatter originated from. The following paragraph explains this more thoroughly.

The *Point of Origin* (PO) is located above the Point of Convergence (POC) on the perpendicular axis. In this case that would be 90 degrees perpendicular to the floor. It is the point from where the blood was disgorged from the body. To determine where that point is located first measure the distance from each blood stain along its central axis to the POC. Then take the TAN of the degrees AOI. Third, multiply the TAN of the AOI by the distance. Measure that distance from the floor up the perpendicular axis and you will arrive at the Point of Origin.

In conclusion, *blood pattern analysis experts* can develop vast amounts of information from the patterns of blood at a crime scene. First responding officers and homicide detectives will be more aware of the value of blood spatter evidence if they understand the fundamentals of pattern analysis. Additionally, *first responding officers* and *detectives* can glean a great deal of information themselves at the scene without becoming experts and they can assist the experts later with the data that they gathered at the scene. If the blood spatter evidence is properly photographed and if accurate measurements are taken of the length and width of the individual spatters and the distance from each spatter to the Point of Convergence, the analyst can later make the necessary calculations based on that data and draw conclusions from them. If the measurements and photographs are not taken, critical information may be lost forever.

Chapter 9

Virtopsy: The Virtual Autopsy*

9.1 Introduction

9.1.1 Preliminary Considerations

In forensic medicine, autopsy remains the gold standard for determining the cause and manner of death. An autopsy consists of two parts. First, an external examination is performed, in which all external findings are documented with photographs and in a written report. Second, the body is opened for the internal examination. All organs are removed, inspected, measured, and sampled for histology, in order to identify pathologies that lie within the organs. All internal findings are added to the written report.

This approach has some disadvantages. Due to its invasiveness, important evidence can be destroyed. In cases of advanced decomposition, liquefied organs lose their structural integrity if their surrounding body cavity is opened. Additionally, some cultural and religious belief systems prohibit the autopsy procedure.

The quality of the final report highly depends on the skills of the investigator to find and appropriately describe the findings. Findings that are overlooked, or conclusions that are poorly formulated, translate into a loss of evidence, that cannot be corrected once the body is buried.

The Virtopsy project began in 2000, at the Institute of Forensic Medicine of the University of Bern, in Switzerland. Its aim is to apply high tech methods from the fields of measurement engineering, automation and medical imaging to create a complete, minimally invasive, reproducible and objective forensic assessment method. The data generated can be digitally stored or quickly sent to experts without a loss of quality. If new questions arise, the data can be revised even decades after the incident.

In the rest of this chapter, the techniques used in the Virtopsy procedure are described, including: post-mortem computed tomography (PMCT) and post-mortem computed tomography angiography (PMCTA), post-mortem magnetic

*This chapter is contributed by Lars C. Ebert, Thomas Ruder, David Zimmermann, Stefan Zuber, Ursula Buck, Antoine Roggo, Michael Thali, and Gary Hatch.

resonance imaging (PMMR) and minimally invasive tissue and liquid sampling as means for documenting internal findings. These results can be combined with and surface scanning and photogrammetry which document the external findings. Following the introduction of the techniques, we explain the different ways of presenting the data, depending on the audience. Finally, the impact and acceptance of Virtopsy within the Swiss justice system is discussed.

9.1.2 Indications for Virtopsy

The Virtopsy approach is applied to a majority of the cases that undergo forensic evaluation at our institute. The additional information acquired through post-mortem imaging prior to autopsy is often used to plan the autopsy, confirm autopsy findings and allow for a second-look if further questions arise in during the forensic investigation.

Fig. 9.1.2.1 Volume reconstructions of a CT scan of a train suicide victim (Osirix, Osirix foundation, Switzerland). (a) Surface reconstruction. (b) Bone reconstruction for quick assessment of the completeness of the body

Fig. 9.1.2.2 Volume rendering of a gunshot victim (Leonardo, Siemens, Germany). Highly x-ray dense materials such as the shotgun pellets and artificial hip joint are automatically color coded to aid with better perception

In all cases of uncertain or unknown identity, the whole corpse of the decedent is scanned for radiologic identification through comparison of ante-mortem data with post-mortem CT. In the case of train-pedestrian incidents, CT data is useful to identify missing organs or skeletal parts (Fig. 9.1.2.1). Additionally, CT is able to detect and, depending on the density of the object, identify foreign bodies such as medical implants (useful for identification) or projectiles and bullet fragments (relevant to the forensic investigation) (Fig. 9.1.2.2). All homicides, deaths under the age of 18 years of age, and complicated cases are also evaluated with the Virtopsy method.

9.2 Technical Aspects of Virtopsy: Imaging Modalities and Techniques

9.2.1 The Virtobot System

Some tasks in forensic imaging are either repetitive or require a high accuracy. Automation could help to increase the quality of examinations and reduce costs. At the Institute of Forensic Medicine in Bern, we developed a robotic system to satisfy these needs. The so-called *Virtobot* (Ebert et al., 2010) is a 6-axes industrial robot, that is mounted onto an external axis along with the computed tomography couch (CT couch), so it can access the entire scannable volume (Fig. 9.2.1.1). It has a changeable end-effector and can therefore mount different tools. We incorporated a surgical navigation system to allow for a closed loop robot control. Currently modules for automated surface scanning and minimally invasive biopsy exist.

Fig. 9.2.1.1 *Right to left:* The Virtobot system with mounted surface scanner, optical tracking system for biopsy, CT scanner and heart-lung machine for post-mortem CT angiography

9.2.2 Photogrammetry and Surface Scanning

The exact three-dimensional recording of the body surface with all injuries as well as the documentation of suspected injurious objects (Thali, Braun, & Dirnhofer, 2003) – including for example vehicles – is carried out with the GOM TRITOP/ATOS III System (Gesellschaft für Optische Messtechnik mbH, Germany). This system delivers a high resolution, three-dimensional scan of the object. It can be employed for true-color 3D digitizing of smallest injuries as well as larger objects such as cars or trucks.

GOM TRITOP is an industrial optical measuring system, based on the principle of digital image-photogrammetry (Luhmann, Robson, Kyle, & Harley, 2006).¹ It is used for full-automatic, highly accurate measurements of 3D coordinates of discrete object points.

The flexible GOM ATOS III optical measuring machine is based on the triangulation principle. Two cameras observe striped patterns projected onto the object.

¹ Luhmann et al. (2006) is a standard reference on close range photogrammetry, “which uses accurate imaging techniques to analyse the three-dimensional shape of a wide range of manufactured and natural objects. Close range photogrammetry, for the most part entirely digital, has become an accepted, powerful and readily available technique for engineers and scientists who wish to utilise images to make accurate 3-D measurements of complex objects” (ibid., from the blurb). The mathematics of close range photogrammetry handles orientation, digital image processing, and the reconstruction of a model in three dimensions. Imaging technology includes both hardware and software. Important topics include targeting and illumination.

Up to four million highly precise 3D coordinates are then calculated from each single measurement. The measurements from different views are transformed into one coordinate system using reference targets to capture the whole objects surface. Next, a high resolution polygon mesh of the object surfaces is generated.

In forensic applications the color information of the measured object is very important for further analyses. The corresponding color value from the photogrammetric recordings is assigned in the TRITOP software to each point of the 3D surface model created in ATOS, resulting in a colored 3D model of the object.

For optimizing work flow, the surface scanner can be mounted to the Virtobot system and from there, it digitalizes the body surfaces of the deceased automatically. This system significantly decreases scanning times and only one operator is required. By using automation, a constant quality of the scans can be maintained, since the process is operator independent. A module for automated photogrammetry is currently in development.

9.2.3 Post-mortem Computer Tomography (PMCT)

9.2.3.1 CT Scanners

A CT scanner makes measurements of the x-ray attenuation through a predefined plane of a cross section of the body. The resulting dataset is a 3D volume consisting of volume pixels (voxels). In helical CT imaging, an x-ray tube rotates around the body, while the body is continuously moved through the gantry (Kalender, Seissler Klotz, & Vock, 1990). Since the resulting data are a set of 2D projections, the x-ray density of each voxel is then calculated by using filtered backprojection. The resulting voxels contain the information about the attenuation of x-ray that is displayed as density, measured in Hounsfield units (HU). 0 HU have been defined to be equivalent to the density of water, -1000 HU (i.e., one thousand below zero) to the density of air. The density of all other organic and inorganic materials vary individually and are used to distinguish between different tissues. On regular CT scanners HU range from -1000 to +3070, but the upper limit may be extended to be +30710 HU. Multislice scanners have a row of several detectors to decrease scanning times and therefore motion artifacts. Dual Source CTs make use of two perpendicular x-ray sources with different energy levels and allow for better differentiation of dense materials.

Typical resolution achieved with standard CT scanners is about 0.5–1.5 line pairs/mm. This means that objects of about 0.5 mm can be discerned. Standard post-mortem full body CT scans with a slice thickness of 1.25 mm and an increment of 0.7 mm consist of around 1500 single images (512*512 pixel in plane resolution).

The fact that CT imaging is based on x-ray attenuation allows for excellent assessment of osseous lesions such as fractures, collections of gas such as vascular gas embolism or detection of foreign bodies. The comparison of individual HU values of different foreign bodies may assist to identify if a given foreign body is metallic or non-metallic. Three dimensional image reconstruction software

applications such as multi planar reformation (MPR) can display gunshot wound trajectories. The assessment of organ injuries with CT falls short of the sensitivity and specificity of MR imaging or autopsy, however, large organ lacerations can be detected. The volume of a fluid or gas collection can be measured (Jackowski et al., 2004) and the weight of organs can be estimated (Jackowski et al., 2006) based on voxel size.

9.2.3.2 Identification by Means of CT Scanning

CT scanning is a common examination performed in clinical radiology, which provides an ample pool of ante-mortem studies for use in cases of unknown identification. With the increased use of medical imaging techniques in clinical medicine, an increasing number of ante-mortem datasets is available. Prominent landmarks in these scans, such as the paranasal sinuses, but also medical implants such as dental implants, bone screws and plates, pacemakers and others can be used for comparison with post-mortem CT datasets for identification. By using maximum intensity projections, post-mortem CT datasets can be compared to ante-mortem 2D x-ray projections, or ante-mortem CT datasets. These techniques are reliable, even if the body has damages due to trauma or putrefaction. The advantages of these techniques are their quickness, reliability and low costs compared to other means of identification such as DNA analysis.

9.2.4 Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging (MRI) is a medical imaging technique. In contrast to CT, MRI is not based on x-rays but uses a strong magnetic field. The strength of the magnetic field is measured in Tesla [T], and current MR units work with 1.5 T or 3 T magnets, creating a magnetic field that is roughly 50,000–100,000 times more powerful than the magnetic field of the earth.

In medical imaging MRI is based on the magnetization of hydrogen atoms in the body. Hydrogen atoms consist of a single proton and a single electron. When placed in a strong magnetic field, the protons of the hydrogen atom align themselves, similar to compass needles, along the axis of the magnetic field (B_0). In order to create an MR image, a short radio frequency (RF) pulse is emitted, altering the alignment of the protons by flipping the axis of the protons out of the magnetic field (B_0).

The time a given proton needs to realign along the axis of the magnetic field after the emission of a RF pulse is called spin-lattice relaxation time (T_1). The RF pulse not only flips all protons out of the axis of the magnetic field, is also synchronizes the phase of each individual proton spin. The desynchronization of the spins after the emission of the RF pulse is called spin-spin relaxation time (T_2). Tissue differentiation on MR images is based on the individual relaxation times T_1 and T_2 of different tissues.

MRI provides greater contrast for soft tissues than CT and is therefore useful for neurological, cardiovascular, and musculoskeletal imaging. In the post-mortem

setting, MRI is a powerful adjunct to CT, its ability to visualize soft tissue organs complements the ability of CT to visualize osseous lesions.

However, there are a few important differences between ante-mortem and post-mortem MRI. The absence of motion artifacts in the post-mortem setting allows for better depiction of anatomical details. The assessment of the cardiovascular system in living patients, involves not only the morphology but also the function of the heart – an aspect that obviously cannot be evaluated in post-mortem MRI. After the cessation of cardiac motion, gravity causes fluids to pool in the dependent parts of the body and the corpuscular elements of fluids, such as blood cells will sediment within the vascular bed. The relaxation times T1 and T2 are both temperature dependent and image contrast may change with decreasing body temperature of a decedent (Fig. 9.2.4.1).

Also note the following shortcomings or limitation:

- With respect to CT, MRI is more time consuming and the time needed for post-mortem MRI may vary significantly, ranging from less than 1 h for focused regional imaging to several hours for whole body MRI.
- MRI scanning is limited to cases that do not involve metallic fragments or MRI incompatible implants. A prior CT scan can help to search for these types of foreign bodies.

Fig. 9.2.4.1 Two different MRI scans showing a case of tuberculosis. (a) T1 weighted scan with bright fat and dark water content. (b) T2 weighted image with bright water content

9.2.5 Post-mortem CT Angiography

The assessment of the vascular bed and lesions of the vascular bed in non-contrast CT studies is very limited. In living patients the visualization of the vessels is achieved by intravascular injection of a contrast medium. The blood circulation distributes the contrast medium to the peripheral vessels and the internal organs, before it is excreted through the kidneys.

For the post-mortem setting, a non-dynamic CT angiography has been developed using the roller pump of a modified heart-lung machine to distribute the contrast medium in the vascular system. Vascular access is gained through a cut-down at the level of the femoral vessels.

- For visualization of the arterial system, a tube is inserted into the femoral artery and contrast medium is injected at a constant pressure. A second tube is inserted in the femoral vein, to drain and collect the overflowing blood from the venous system. Imaging is performed immediately after the instillation of the contrast medium.
- For visualization of the venous system, the injection and drainage tube are simply switched and the procedure and imaging are repeated.

Fig. 9.2.5.1 Volume reconstruction of a CT angiography (Osirix). The surrounding tissue has been virtually removed to expose the arterial system. This image shows a case of aortic dissection

In contrast to ante-mortem angiography, an important portion of the fluid components of blood have leaked out of the vessels and sedimented into the dependent portions of the body. This fluid has to be replaced for the post-mortem angiography and the contrast medium is therefore diluted with a high molecular hydrophilic or lipophilic solution:

- polyethylene glycol (PEG), discussed by Ross et al. (2008),
- or diesel oil, discussed by Grabherr et al. (2006).

Using a high molecular solution rather than a small molecular solution as a volume expander for the contrast medium, prevents leakage out of the vessel wall and subsequent edema.

Post-mortem CT angiography allows for excellent visualization of the entire vascular system of a decedent (Fig. 9.2.5.1). Vascular injuries and extravasation of contrast medium can thereby be diagnosed based solely on imaging. Intraabdominal or thoracic hemorrhages can be traced back to the lacerated vessel/s. Small vascular lesions that can be difficult to visualize during autopsy, may be identified after CT-angiography.

9.2.6 Tissue/Liquid Sampling

In order to define pathologies on a cellular level, a histological examination on tissue samples can be performed. For this technique, the tissue sample is sliced, stained and evaluated under a microscope. During autopsy, a tissue sample is retrieved by cutting a piece from each organ. Apart from the invasiveness of this approach, the quality of the samples is relatively poor, since it can be contaminated with other tissues or body fluids. Several techniques for minimally invasive tissue and liquid sampling have been developed or adapted from clinical medicine by the Virtopsy group.

The standard procedure for minimally invasive sampling involves placing an *introducer needle* to the exact location the tissue sample should be retrieved from. A biopsy gun retrieves the tissue sample through the introducer needle. Three methods to place the introducer needle have been used at our institution: CT guided, navigated and robotic needle placement.²

- In CT guided needle placement, the needle is placed by a radiologist under real-time fluoroscopic guidance inside the x-ray beam. Since CT only displays one slice of the body, accurate needle placement is limited by the possible gantry

² CT guided needle placement is discussed in Aghayev et al. (2007). Navigated needle placement is discussed in Aghayev et al. (2008). Robotic needle placement is discussed in and Ebert et al. (2010).

tilt. Additionally, it comes with radiation exposure for the radiologist. These problems lead to the implementation of a technique based on surgical navigation.

- In surgical navigation, arrays of infrared markers are attached to every tool and anatomic structure that should be navigated. A tracking system then accurately determines the three-dimensional position of each marker. Based on this information and a CT dataset, a computer system tells the user where the needle is in 3D space, relative to a defined target, and guides the user to the target. This method works without radiation exposure to the radiologist, but requires training and skill on the part of the operator.
- In order to completely eliminate the human factor, a biopsy module was developed for the Virtobot system. It can automatically and precisely place introducer needles based on trajectories planned with CT data.

9.2.7 Virtopsy Workflow

The workflow of a Virtopsy is case specific. Depending on the individual case history, the Virtopsy team decides what image modalities are required to answer the forensic questions concerning the cause of death (Fig. 9.2.7.1). In forensic cases where the body displays patterned injuries or if reconstructive questions are opened, a colored 3D documentation of the body surface is recorded.

Using the Virtobot system, the entire body is documented with photogrammetry and surface scanning. Two scalebars and An array of optical and radiopaque markers are applied to the body. For the following photogrammetry, a series of photographs are taken from different positions. The TRITOP software automatically processes the photos and calculated the exact 3D coordinates of the uncoded reference markers as well as the camera positions. This data is exported to the surface scanners ATOS software to subsequently perform the surface scan of the object. Furthermore, the photographs are used for texturing of the surface model. If the Virtobot is used for scanning, the robotic system approaches different predefined positions in space and the attached surface scanner measures the topology automatically. In order to get a complete scan of the body, it has to be turned from supine to prone.

After external documentation, a CT scan is performed. Since the radiopaque markers are visible in the surface scan as well as the CT scan, data from both modalities can be merged into one set of data. In case of suspected vascular injuries or internal hemorrhage, a CT angiography is performed after accessing the femoral arteries and connecting the heart lung machine.

If the body has shown to be free of ferromagnetic foreign bodies such as metal fragments in the CT scans, it is moved to the adjacent MRI suite for an MRI scan. Depending on the suspected pathology, the proper sequences are selected. After finishing the imaging procedures, the body is ready for the standard legal examination. Based on the data gathered during medical imaging, the autopsy approach can be planned.

Fig. 9.2.7.1 Workflow of a standard Virtopsy

9.3 Visualisation: The Main Concepts for Storage, Processing and Visualization of Medical Image Data

9.3.1 Data Storage

Modern radiological scanners generate vast amounts of data. To ensure intra-operability between different manufacturers, the DICOM³ (Digital Imaging and Communication in Medicine) standard was introduced in the early 1990s. The standard not only defines how data is stored, but also the necessary communication protocols. CT and MRI datasets consist of a three-dimensional array of volume pixels (voxels). In CT imaging, each voxel has a size and a Hounsfield value, e.g. an x-ray density. In MRI imaging, the value of a voxel is unitless but otherwise stored in the same format. Surface scanning usually generates three-dimensional polygon meshes. Different standard formats exist for storing polygon meshed, the one most commonly used especially in conjunction with rapid prototyping techniques is STL.

Medical imaging data is stored and analyzed by radiologists using a *Picture Archiving and Communication System (PACS)*. PACSs communicate with medical imaging hardware using the DICOM standard and provide backup services for data integrity. Additionally, dedicated workstations offer different tools for visualization. The configuration as well as the available functions depend on how it is being used and how it can optimally be integrated into the workflow of an institute.

9.3.2 Imaging in Two Dimensions (2D Imaging)

Standard means of looking at medical imaging volume datasets are transversal, cross-sectional cuts. Since current computer screens only can display up to 256 shades of gray, only a selected segment of the 3070 values of the standard Hounsfield scale can be displayed at a time. This is achieved by applying a technique called *windowing*. In windowing, a range of Hounsfield values is defined and transformed to grayscale values. Higher values are depicted as white, lower values as black. By using different windows, different tissues or pathologies can be visualized. They are named to by the tissue that is seen best, i.e. soft tissue, lung, and bone window (Fig. 9.3.2.1).

Modern workstations allow the user to change the plane of the image (the angle of the cutting plane through the volume of data) in realtime. This allows for views that follow local anatomies rather than transversal cuts. If necessary, curved cuts are possible to follow the course of vessels or generate panoramic dental views, so-called *orthopantomograms* (Fig. 9.3.2.2). For diagnostic purposes, PACSs allow the user to measure distances and surface areas on reconstructed planes.

³ <http://medical.nema.org/>

Fig. 9.3.2.1 The same axial cut in a CT dataset with different window levels, giving information about different tissues. (a) Soft tissue window. (b) Lung window. (c) Bone window

9.3.3 Imaging in Three Dimensions (3D Imaging)

Cross sectional imaging is only able to provide two-dimensional views of data that is actually three-dimensional. All PACSs feature a multi planar reformation (MPR) tool, that allows the user to reformat images in the axial, coronal and sagittal image plane. MPR permits localization in three simultaneous planes as well as the exact adjustment of CT exams, for instance to match follow-up exams with a previous study or for the assessment of complex findings (Fig. 9.3.3.1).

(c) Volume reconstruction of the entry wound displaying the bone damage (Leonardo). (d) Volume reconstruction of the exit wound (Leonardo)

An other technique to display a dataset as a whole is the so-called volume rendering. Similar to windowing, a transparency and a color is assigned to each voxel, based on its Hounsfield value. The function defining this mapping is called transfer function. Since the x-ray densities of different tissues are known, predefined transfer functions allow the depiction of bone, soft tissue and skin in colour.

Different shaders allow for a better three-dimensional perception of the generated images. Some special shaders are used for specific task. While standard volume rendering techniques take all transparencies and colors of voxels along a ray into account, Maximum Intensity Projection (MIP) only uses the highest value. This allows for excellent skeletal, angiographic, and metallic detail. A Minimum Intensity Projection on the other hand only uses the lowest Hounsfield value, which best displays gas collections inside the body.

9.3.4 Animation

Unlike medical imaging data, surface scanning produces textured 3D polygon meshes. Since polygon models are easier to manipulate than volume datasets, it allows repositioning of the models and the reconstruction of a sequence of events based on injury patterns and other facts.

For this task, dedicated animation software such as 3D studio MAX (from Autodesk, USA) is used. The polygon models (bones, surface etc.) can be imported directly. A virtual bone system for animation (biped) can be created and adapted to the properties of the polygon model that is to be animated. The biped consists of a set of joints that are linked to each other and have the same range of motion as the corresponding real joint. Bipedes are relatively easy to animate compared to polygon models with thousands or even millions of polygons. The polygon model is now linked to the *biped (rigging)* and every motion on the biped is copied to the polygon model (Fig. 9.3.4.1).

For animation, the biped can be put into different postures at different point in times, the animation is then calculated by interpolating between these postures. This technique is called *keyframing*. It is important to note that animation should be used carefully and should only show motions or positions that are based on facts.

There is in the scholarly literature some discussion of how jurors (in jurisdictions with a jury) may be affected by viewing computer animations: this may be facilitating, but unless special care is taken, there is some risk of prejudicial effects (Kassin & Dunn, 1997).⁴

⁴ Schafer and Keppens (2007), who were discussing computer animation in the context of computer-assisted teaching in evidence courses, have remarked: "In this animation, two competing theories that both claim to account for the evidence are modelled side by side. According to the prosecution, the evidence found was produced by a cold-blooded killing, according to the defence, it was caused by events more consistent with the assumption of self defence. As we can see from the models, only the defence hypothesis produces the type of evidence that was found, in particular it accounts for the bullet trajectory found in the victim. The user can directly change the

Fig. 9.3.4.1 Biped reconstruction of a traffic accident based on surface scans of the motorcycles. The positions during impact have been reconstructed by combining damages on the vehicle with injury patterns documented by photogrammetry, surface scanning and CT

9.3.5 Segmentation

Volume estimations in medical image datasets are possible with a technique called segmentation. In segmentation, each voxel in a dataset is assigned to a material. This way, each organ, pathology, gas collection, fluid collection or tissue can be assigned to a material. Since the volume of a single voxel is known, the volume of all voxels belonging to a material can be calculated. By combining this information with a known density of the tissue, even the weight of organs can be estimated.

Depending on the modality and the pathology or tissue to segment, automatic, semi-automatic and manual techniques exist. In manual segmentation all voxels of a specific material have to be selected by hand. Semi-automatic methods such as region growing and line wire algorithms assist the user to quickly select similar

position of the people involved, the computer calculates how this would have affected the evidence that was created. The scientific knowledge that underlies these models is complex. To calculate the relevant trajectories requires knowledge of geometry and kinetics, to reason about the ability of the accused to shoot from a specific position requires biological, biomechanical and medical knowledge. How much can a hand holding a heavy gun rotate? What would the recoil do to the ligaments? Moreover, it is not contested knowledge, and hence of little interest to the lawyer pleading the case. Nonetheless, the manipulation of the relevant parametric and geometric equations is taken care of by the computer. The user only needs to manipulate the physical objects (victim, gun, accused) to test different theories and explanations. To hide expert knowledge in this way does create problems if these models are used as evidence, in particular if they are used in an adversarial, partisan context. There is also the danger that computing constraints add facts that are either not established, or not established in legally permissible ways (Selbak, 1994; Kassin & Dunn, 1997; Menard, 1993). In our example for instance, the jury may be subconsciously swayed by the facial expressions of the animates, even though they have not been introduced through a witness into the court proceedings. These problems in using computer models in courts are however an advantage when using them for teaching. Without the need for time consuming mathematical preparation, students can be directly exposed to critical scientific thinking and substantive forensic subjects.”

structures. Fully automatic methods are usually organ specific, sensitive to artifacts and contrast changes inside the dataset and fail to deliver data in decomposed bodies or in cases with significant pathologies or extensive damages.

Some software packages such as animation software require polygon meshes and cannot be use with on volume datasets directly. For visualization involving animation, the selected materials can be converted into a 3D polygon mesh by using the marching cubes algorithm. A combination of volume and polygon based rendering can then be used to demonstrate the relevant pathologies.

9.3.6 Image Fusion

Different modalities are used in Virtopsy. Each modality has a specific field of application with respect to different pathologies. In order to get a complete picture and correlate injuries visible in different modalities, it may be necessary to fuse different datasets and combine their information (Thali, Braun, Wirth, Vock, & Dirnhofer, 2003).

Since all datasets have their own independent local coordinate system, a co-registration has to be performed. The standard means of registration is a paired-point registration, where a set of markers is visible in both modalities. The markers are selected in both modalities and the transformation is calculated by minimizing the distance error between the paired point. If the surfaces are similar enough, surface matching can be performed instead.

9.3.7 Rapid Prototyping

Another application of segmentation is rapid prototyping. *Rapid prototyping* is actually a broader concept from *software engineering* – and it is often adopted while developing in a principled manner software systems in general – but in the present context it refers to a group of techniques that quickly generate physical models based on *Computer Aided Design (CAD)* data in small quantities.

State of the art methods for rapid prototyping are *stereolithography* and *3D printing*. Both techniques build up the physical model layer by layer. While stereolithography uses a liquid resin, which is selectively hardened by ultraviolet (UV) light, 3D printing spreads layers of powder onto a table and selectively binds them with colored glue. Unlike milling techniques, these techniques allow for the creation of occluded structures (internal cavities). 3D printing additionally delivers fully colored models.

Rapid prototyping cannot work with volume datasets, requiring polygon meshes and therefore will only work in conjunction with data that is prepared using segmentation techniques. Rapid prototyping techniques can be used for educational purposes or to present medical findings in a way, that is easily understood by medical laypersons, which is a common scenario in forensic investigations (Dolz, Cina, & Smith, 2000).

9.3.8 *Post-mortem vs. Ante-mortem Imaging*

Even though medical imaging techniques used in Virtopsy are the same as methods used in clinical medicine, interpretation of post-mortem image data sets has some differences. Changes common in deceased individuals can be mistaken for pathologies. This includes, but is not limited to: collections of gas due to decomposition, clotted blood and internal lividity. MRI scans change their appearance, if the body temperature is too low. Therefore it is advisable that post-mortem studies be evaluated by radiologists who are experienced in post-mortem imaging.

9.3.9 *Medical Image Data for Radiologists and Pathologists*

Traditionally, radiologists look at volume datasets using transverse cuts either through the body, or through single organs. The possibility to measure distances and surfaces is of additional diagnostic value. The slice stack is browsed through several times with different window levels, in order to view each tissue with the most appropriate contrast.

If necessary, for instance in cases of train suicides, a volume rendering can help to quickly perform an inventory of all body parts. For special purposes such as dental identification, methods such as MIP or VRT are used. Since the use of post-mortem CT angiography alters the liquid levels in vessels, volume measurements performed during autopsy are not reliable after such an intervention. In those cases, segmentation techniques are used instead.

MIP stands for *Maximum Intensity Projection*, whereas *VRT* stands for *Volume Rendering Techniques*. An explanation for both follows.

- *Volume rendering* displays the dataset as a whole, thereby providing a better perception of the three-dimensional structure of a CT dataset. So-called transfer functions are applied to the Hounsfield values⁵ to derive voxel properties,

⁵ Hounsfield units are a measure of density. For example Aamodt et al. stated (1999, p. 143): “Our aim was to assess in Hounsfield units (HU) the CT density of the inner cortical surface of the proximal femur after this bone had been removed. One HU is defined as a number on a density scale in which the X-ray absorption of water has been assigned the value of zero and the air the value of -1000.”

http://en.wikipedia.org/wiki/Hounsfield_scale provides this definition: “The *Hounsfield scale*, named after Sir Godfrey Newbold Hounsfield, is a quantitative scale for describing radiodensity. [...] The Hounsfield unit (HU) scale is a linear transformation of the original linear attenuation coefficient measurement into one in which the radiodensity of distilled water at standard pressure and temperature (STP) is defined as zero Hounsfield units (HU), while the radiodensity of air at STP is defined as -1000 HU. For a material X with linear attenuation coefficient μ_X , the corresponding HU value is therefore given by

$$HU = \frac{\mu_X - \mu_{\text{water}}}{\mu_{\text{water}} - \mu_{\text{air}}} \times 1000$$

such as color and transparency. (A *voxel* is the volume unit, just as a *pixel* is a unit in the plane, in two-dimensional images.)

- *Maximum intensity projection (MIP)* is a way of presenting CT datasets by only displaying the voxel with the highest value along a projection ray. Information about the three-dimensional structure is lost, but it allows comparing CT datasets to orthopantomograms for dental identification.

Orthopantomograms, also called *orthopantograms*, *OPG*, or *panorex*, are not known to the non-specialist by that name, but the thing they name is familiar to dentists’ patients, as they are a panoramic scanning *dental X-ray* of the upper and lower jaws, showing in two dimensions a half-circle from ear to ear. One advantage of such *panoramic* images is their coverage is broad, capturing both facial bones and the teeth, and another advantage is that also patients find the image is easy to understand. Such images can even be made in patients who cannot open their mouth, as the image is shot by introducing in the mouth a flat plastic spatula: dentists ask patients to bite on it, and the process takes about one minute. It is not only on living individuals that such dental X-rays can be taken, and they are useful indeed for identifying bodies. *Dental radiology* uses either *film technology* (which requires a chemical development process, and with the film on either a flat cassette, or a rotating cylinder), or *digital technology*. The first dental panoramic digital systems were designed in 1985–1991. In 1995, Signet, a French firm, introduced DXIS, the first dental digital panoramic X-rays system available on the market. In 1997, Siemens followed, with SIDEXIS. Since then, many manufacturers have been offering their own panoramic digital systems for dental X-rays.⁶

where μ_{water} and μ_{air} are the linear attenuation coefficients of water and air, respectively. Thus, a change of one Hounsfield unit (HU) represents a change of 0.1% of the attenuation coefficient of water since the attenuation coefficient of air is nearly zero. It is the definition for CT scanners that are calibrated with reference to water. *Rationale*[:] The above standards were chosen as they are universally available references and suited to the key application for which computed axial tomography was developed: imaging the internal anatomy of living creatures based on organized water structures and mostly living in air, e.g. humans. [. . .] The Hounsfield scale applies to medical grade CT scans but not to cone beam computed tomography (CBCT) scans.”

The HU of air is -1000; the HU of fat is -120; the HU of water is 0; the HU of blood is +30 to +45; the HU of muscle is +40; the HU for contrast is +130; the Hu of bone is +400 or more (ibid.). “A practical application of this is in evaluation of tumors, where, for example, an adrenal tumor with a radiodensity of less than 10 HU is rather fatty in composition and almost certainly a benign adrenal adenoma” (ibid.). Something about the history of the technology: “CT machines were the first imaging devices for detailed visualization of the internal three-dimensional anatomy of living creatures, initially only as tomographic reconstructions of slice views or sections. Since the early 1990s, with advances in computer technology and scanners using spiral CT technology, internal three-dimensional anatomy is viewable by three-dimensional software reconstructions, from multiple perspectives, on computer monitors. By comparison, conventional X-ray images are two-dimensional projections of the true three-dimensional anatomy, i.e. radiodensity shadows. It was established by Sir Godfrey Newbold Hounsfield, one of the principal engineers and developers of computed axial tomography (CAT, or CT scans).” (ibid.).

⁶ <http://en.wikipedia.org/wiki/Orthopantomogram> states the following concerning the equipment: “Dental panoramic radiography equipment consists of a horizontal rotating arm which holds an

9.3.10 Medical Image Data for Medical Laypersons

If radiological data has to be presented to non-medical professionals, grayscale transverse cuts as used by radiologists are insufficient, since interpretation of these data requires experience and training. This is especially important in forensics, since

X-ray source and a moving film mechanism (carrying a film) arranged at opposed extremities. The patient's skull sits between the X-ray generator and the film. The X-ray source is collimated toward the film, to give a beam shaped as a vertical blade having a width of 4–7 mm when arriving on the film, after crossing the patient's skull. Also the height of that beam covers the mandibles and the maxilla regions. The arm moves and its movement may be described as a rotation around an instant center which shifts on a dedicated trajectory. The manufacturers propose different solutions for moving the arm, trying to maintain constant distance between the teeth to the film and generator. Also those moving solutions try to project the teeth arch as orthogonally as possible. It is impossible to select an ideal movement as the anatomy varies very much from person to person. Finally a compromise is selected by each manufacturer and results in magnification factors which vary strongly along the film (15–30%). The patient positioning is very critical in regard to both sharpness and distortions."

The image is formed as follows (ibid.): "Normally, the person bites on a plastic spatula so that all the teeth, especially the crowns, can be viewed individually. The whole orthopantomogram process takes about one minute. The patient's actual radiation exposure time varies between 8 and 22 seconds for the machine's excursion around the skull. The collimation of the machine means that, while rotating, the X-rays project only a limited portion of the anatomy onto the film at any given instant but, as the rotation progresses around the skull, a composite picture of the maxillo-facial block is created. While the arm rotates, the film moves in a such way that the projected partial skull image (limited by the beam section) scrolls over it and exposes it entirely. Not all of the overlapping individual images projected on the film have the same magnification because the beam is divergent and the images have differing focus points. Also not all the element images move with the same velocity on the target film as some of them are more distant from and others closer to the instant rotation center. The velocity of the film is controlled in such fashion to fit exactly the velocity of projection of the anatomical elements of the dental arch side which is closest to the film. Therefore they are recorded sharply while the elements in different places are recorded blurred as they scroll at different velocity."

There is image distortion (ibid.): "The dental panoramic image suffers from important distortions because a vertical zoom and a horizontal zoom both vary differently along the image. The vertical and horizontal zooms are determined by the relative position of the recorded element versus film and generator. Features closer to the generator receive more vertical zoom. The horizontal zoom is also dependent on the relative position of the element to the focal path. Features inside the focal path arch receive more horizontal zoom and are blurred; features outside receive less horizontal zoom and are blurred. The result is an image showing sharply the section along the mandible arch, and blurred elsewhere. For example, the more radio-opaque anatomical region, the cervical vertebrae (neck), shows as a wide and blurred vertical pillar overlapping the front teeth. The path where the anatomical elements are recorded sharply is called 'focal path'."

Digital dental radiology, using electronic sensors and computers, offers advantages (ibid.): "One of the principal advantages compared to film based systems is the much greater exposure latitude. This means many fewer repeated scans, which reduces costs and also reduces patient exposure to radiation. Lost X-rays can also be reprinted if the digital file is saved. Other significant advantages include instantly viewable images, the ability to enhance images, the ability to email images to practitioners and clients (without needing to digitize them first), easy and reliable document handling, reduced X-ray exposure, that no darkroom is required, and that no chemicals are used."

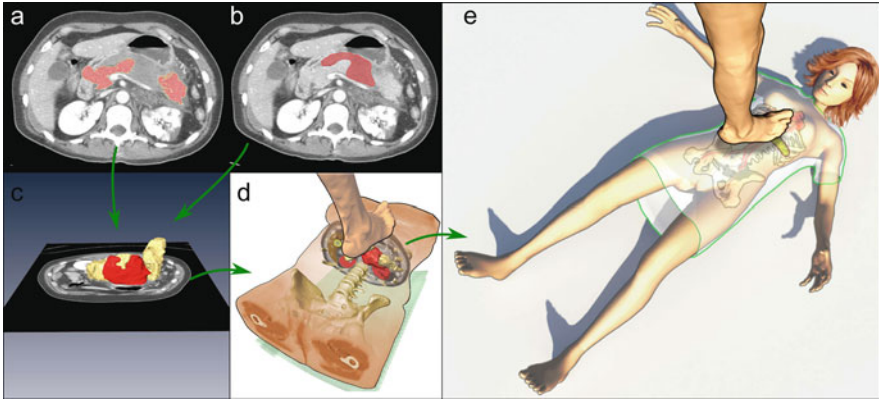

Fig. 9.3.10.1 Visualizing a pancreatic rupture after kick to the chest. **(a)** Segmented pancreas. **(b)** Segmented extravasated blood. **(c)** Polygon model of the segmented pancreas and blood. **(d)** Combination of volume rendering and polygon models. Transparent soft tissue is displayed by volume rendering. Bone, pancreas and blood are displayed as polygon models. **(e)** Final result of the reconstruction that can be put into a virtual crime scene, based on the physical evidence found

lawyers, judges and the jury are not accustomed to this kind of data. A rather simple way of depicting axial cuts is by coloring and labeling different organs. Additionally, a volume rendering showing the plane can help with better orientation.

3D imaging is especially useful for presenting information to an audience of medical laypersons, since it is self-explanatory in most cases. While bone fractures can be displayed directly using volume rendering techniques, some injuries require a combination of segmentation, polygon rendering and volume rendering. Additionally, 3D images can be combined with additional information such as force vectors, position of weapons or attackers during attack, if this is supported by evidence (Fig. 9.3.10.1).

9.4 Virtopsy and the Swiss Justice System

9.4.1 Advantages of Virtopsy in Court

Court members are normally laypersons with respect to forensic medical issues. For them, pictures of conventional autopsy can be distasteful and difficult to interpret. A real autopsy is, honestly, a rather grim process. On the other hand, Virtopsy pictures allow for a more or less abstract look at the inside of a human being. Therefore, Virtopsy pictures are routinely less distasteful and/or disturbing for court members. These types of pictures are more easily understandable, are normally less error prone (e.g. left side / right side confusion), enable three-dimensional color coded reconstructions and provide excellent visualization of given anatomy.

Furthermore, three-dimensional images can easily be shown in court rooms and interactively discussed with court members and other relatives of the deceased. Since Virtopsy data can be stored, with no loss of quality, they can be reused years after they have been made in case additional questions arise, possibly averting the need for exhumation. Virtopsy methods in general are non-destructive, which obviates the possibility of destroying evidence during the procedure.

9.4.2 Virtopsy in the Current Legal System and Practice of Switzerland

Notwithstanding the foregoing, and in particular, notwithstanding these advantages in dealing with criminal cases, Virtopsy is not yet anchored within the present Swiss legal system, meaning the Virtopsy technique is actually not specifically mentioned, in either acts of law or decrees. Moreover, prevailing case law and legal doctrine theory has yet to deal with this forward looking approach in forensic investigation.

The Virtopsy technique is based on research, ongoing for nearly a decade; however it is not yet part of the standard operating procedures of the Swiss Academy of Legal Medicine, which develops the guidelines that define due diligence in the field. On the other hand, the technique is part of the training program for future forensic pathologists at several Swiss universities. These seemingly disparate facts indicate that Virtopsy is not yet an element of what would be considered best practice in Switzerland.

However, the technology is used within certain areas of Switzerland, where the technique is implemented and well established (i.e., the Institute of Forensic Medicine at the University of Bern and its catchment area: the cantons of Bern, Aargau and Solothurn, and in the Canton Wallis, the district Oberwallis). Members of the legal practice in Bern, and in more and more in other cantons such as Lausanne and Zurich, take advantage of the new technique and apply it in conjunction with expert testimony as well evidence that helps to establish the burden of proof in criminal cases.

9.4.3 Criminal Procedure in Switzerland: The Legal Basis for Virtopsy Imaging Methods?

9.4.3.1 Background

Since January 1, 2011 a new, national Swiss Code of Criminal Procedure (SCCP) has been in effect. In Switzerland, the penal authorities include the following: in criminal prosecution the police, the office of the District Attorney, misdemeanor penal authorities, as well as several Courts such as trial court, the appeal board and appeal court at the cantonal level, and the Federal Supreme Court of Switzerland at the national level. Article 14 of the SCCP allows each canton to organize its own trial courts (such as circuit court, district court, and county court, etc.).

Article 328 of the SCCP,⁷ which deals with procedure at the lowest court level, contains no specific regulation regarding the conduct of jury trials, which are therefore not yet instituted in Switzerland. Hence, professional judges preside over the courtroom in Switzerland.

9.4.3.2 Legal Basis for Virtopsy in Switzerland

Virtopsy is primarily used for identification of the deceased and for post-mortem investigations of extraordinary deaths (which include offenses, suicides, accidents and unclear deaths). The main Article in SCCP is Article 253, section 3 of which prescribes: “Otherwise, if there is a suspicion of criminal activity, or the identification of a body is in question, the district attorney may take possession of the body and direct further investigations, at times including an autopsy”.⁸ At this point an interpretation of the law is indispensable, according to the relevant rules of interpretation (grammatical, historical, systematical and teleological interpretation element). Under these rules further investigations cover also medical imaging method like a CT or MRI and other Virtopsy methods. This is the legal basis for the application of Virtopsy tools in criminal prosecution in cases of death.

On the other hand, imaging methods can also be used to investigate injuries of living persons (victims of crime or defendants), identification or cases of drug smuggling.. Articles 249 to 252 of the SCCP regulate the search and examination of living people. Articles 249, 250 concern the examination of the surface and therefore includes the use 3D surface scanning. Articles 251, 252 concern examination of the inside of the body, and are therefore relevant to CT and MRI examinations.⁹

These Articles of the SCCP constitute the basis to perform examinations with Virtopsy and imaging methods in Switzerland. We should add that Article 197 Section 1, subparagraph c of the SCCP implies that a compulsory examination like those named for cases of either (extraordinary) death or of living people (victims of a crime or defendants), have to be the “mildest method” possible. The non- or minimally-invasive methods of Virtopsy better satisfy this regulation when compared to full-invasive autopsy.

9.4.3.3 Evidence Law in Switzerland

In general, the key article of law relevant to Virtopsy in Swiss Evidence Law is Article 139 of the SCCP. All means of evidence that science and experience have shown to be valid for discovering the truth are to be utilized in an investigation. Virtopsy and its imaging methods are such means of evidence; especially because of the fact that imaging methods are non- or minimally-invasive and hence better

⁷ See Niklaus Schmid's (2009) *Handbuch des Schweizerischen Strafprozessrechts*, N 380.

⁸ Article 253 Section 3 Swiss Code of Criminal Procedure (SCCP).

⁹ Articles 249–252 Swiss Code of Criminal Procedure (SCCP).

preserve body integrity and human dignity than the classical examinations such as invasive autopsy.

Imaging methods such as CT, MRI or surface scanning are scientifically accepted, in both medicine and surveying. It is the choice of the expert to decide which methods or examinations are necessary to provide an expert opinion.¹⁰ In our opinion, the forensic expert opinion of the 21st century should include all reasonable and available means of evaluation, including medical imaging methods. However, Virtopsy methods do not meet the criteria for exclusion of evidence under Article 140 SCCP.¹¹

According to Article 76 Section 4 SCCP the statements of experts can be recorded using technical aids such as images. Hence the use of images is explicitly approved by legislation for use court.¹²

In Switzerland the prosecuting authorities bear the burden of proof. The party of the proceedings, hence the prosecuting attorney as well as the defense can file requests to present evidence. The defending attorney is only bound to the interests of his client. He has the same rights as the defendant himself. The defense can collect its own evidence. Therefore it would be possible for the defending attorney to ask for expert testimony, which might Virtopsy methods.

Additionally, hospital CT and MRI can be used for forensic purposes. There is no ranking of evidence, but a so-called free consideration of evidence by the judge. All means of evidence are basically considered equal, although some evidence seems to be especially trustworthy like evidence produced by electronic equipment. The conviction of the judge is not based on the external but interior authority of a mean of evidence. Free consideration of evidence by the judge is limited, however and may be dependant on expert testimony.

Experts assist the penal authority by imparting their specialist knowledge, as relevant to the case at hand. Experts must deliver results and opinions based on a contentious and state of the art application of the scientific method.¹³ The expert is the assistant of the penal authority (prosecuting attorney and court) in his field of expertise, rather like *amicus curiae* in Common law Countries. She or he does not make legal judgements or comments about the evidence. The experts have to possess special knowledge and skills in their respective field of expertise.

A legal inspection (a.k.a the external examination) of the body and the autopsy are performed by forensic experts or by an institute of forensic medicine.¹⁴ During a Virtopsy a radiology expert does a reading of the CT or MRI images and surveying engineers perform surface scans. It is possible therefore for several experts to be employed in the same trial.

¹² Article 76 Section 4 Swiss Code of Criminal Procedure (SCCP).

¹³ Schmid Niklaus, N 929 f.

¹⁴ Article 253 Section 3 Swiss Code of Criminal Procedure (SCCP).

In Switzerland there is no standing directory of court experts. However according to Article 183 Section 2 SCCP, the Swiss Federation or the cantons can employ permanent or official experts for some special fields, (e.g. the forensic, radiology, and engineering experts of the Institute of Forensic Medicine of the University of Bern). Furthermore, it is mandatory that experts are completely independent and impartial.¹⁵ Both prosecuting authorities and defendants have the opportunity to comment on the qualifications of the expert and the content of the expert report in advance.¹⁶ Hence, there is the possibility of an objection for both sides according to Article 393 SCCP.¹⁷

The impartial and independent, professional judge has to follow the rule of consideration of evidence and may not give more weight to the visually impressive, intuitive and exact nature of 3D-pictures of the Virtopsy. But in other countries, particularly where juries are involved, the impressive 3D renderings may have considerable sway.

According to Article 189 SCCP¹⁸ if an expert opinion is unconvincing, imprecise, contrary to accepted expectations, or incomplete – in short, if there is any doubt regarding the correctness of the expert opinion – the judge can order a second opinion or an clarification from the first expert opinion. In such cases, Virtopsy has the advantage of the digital nature of the data, which allows for submission anywhere in the world to obtain second expert opinions.

To summarize, the Virtopsy and its imaging methods can be principally used as evidence by either the prosecution or the defense. The professional judge can also request viewing. The images must be annotated by expert commentary by an expert and must be included in the report in an “image folder”. The image folder augments classical examination methods such as autopsy in court.

Chapter 10

Concluding Remarks

In this book, an attempt has been made to capture an array of subjects which all deserve attention, when techniques from computing are applied to the modelling of legal evidence, or then of argumentation, or of both. One chapter covers the treatment of tools for representing and processing narratives as known from natural-language processing. It has become a bulky book, and it originally started as an overlong paper. Looking back on the evolution of what has come to be this book, I doubt I would have had ab initio the courage to undertake such a comprehensive exposition. I owe much to the referees, who encouraged me to abound with the presentation of techniques, as opposed to a more superficial overview. For the very reason that this book tries to cover so much, we had to deal with tools or with discussing problems that have contingently or more fundamentally arisen within different jurisdictions.

This long trip took us from some general and historical considerations (Chapter 1) to an early encounter with models of forming an opinion (Chapter 2), and more specifically with modelling adjudicators' shifts of opinion (belief revision). We then turned (Section 2.2) to models of reasoning about a charge and about a given explanation (in ECHO), or of generating an explanation as exonerating as possible (in ALIBI). In the rest of Chapter 2 we could not avoid the crux of much mathematical and computational modelling of reasoning about legal evidence, namely, we had to come to terms with there being a fierce and well-argued controversy about Bayesianism concerning juridical proof.

We devoted Chapter 3 to the modelling of argumentation. We also discussed there agents' beliefs. Next, in Chapter 4 we discussed various aspects of computer assistance for organisational aspects. We began Chapter 4 with procedural-support systems for organising the evidence, and then proceeded to some criminal justice information systems, next to a discussion of the evaluation of costs and benefits while preparing a case (but also costs and benefits of argumentation itself). In Section 4.4, we discussed factors affecting the suitability or the reliability of eyewitnesses, and in particular we considered a computer tool, ADVOKATE. In Section 4.5, we considered various matters concerning policing. We considered

organisational problems of police intelligence systems. Then we discussed the handling of the suspects. We discussed polygraph tests (a deeply controversial tool). We also discussed lineups, and computerised versions of identity parades. We concluded [Chapter 4](#) with a discussion of relevance. We then devoted [Chapter 5](#) to the formal or computational modelling of narratives, whereas [Chapters 6](#) and [7](#) are about link analysis and data mining techniques.

A panoply of forensic disciplines and their respective tools are the subject of [Chapter 8](#), starting with crime scenario modelling, then continuing with computer processing of human faces, which occurs in various contexts, such as the generation of facial composites. We then discussed various forensic disciplines: forensic anthropology and forensic archaeology, forensic geology, physics, and botany, and then environmental forensics and, more briefly, forensic engineering. We then turned to individual identification by DNA and fingerprint evidence. We discussed problems affecting such evidence. We also presented two different computational models for fingerprint-matching. The Virtopsy team in Bern contributed [Chapter 9](#), about how to conduct a virtual autopsy by means of computer imaging, before carrying out an invasive physical autopsy: planning the latter by means of the virtual autopsy is useful in order to make it less invasive. Also the presentation of evidence in court is facilitated by means of the VIRTOPSY technique.

Let us take an overarching view of the broad set of domains we have been considering. Introducing our present work, relations among disciplinary areas were outlined. It is befitting at this stage to consider again, in increasing degrees of detail, the relations of containment among different disciplinary areas, and how they contribute to each other. Therefore, please refer to [Figs. 10.1](#), [10.2](#), and [10.3](#).

It has been a long journey, throughout this bulky book. The sheer scope of the enterprise makes it very difficult for the end result to always prove satisfactory, and this is why two chapters were entrusted to specialists of a specific domain, and the other chapters, too, are interleaved, here and there, with outer contributions. It is my hope that readers will agree that it has been a worthwhile journey, and that it opened new views, whether the reader is a specialist or a new learner.

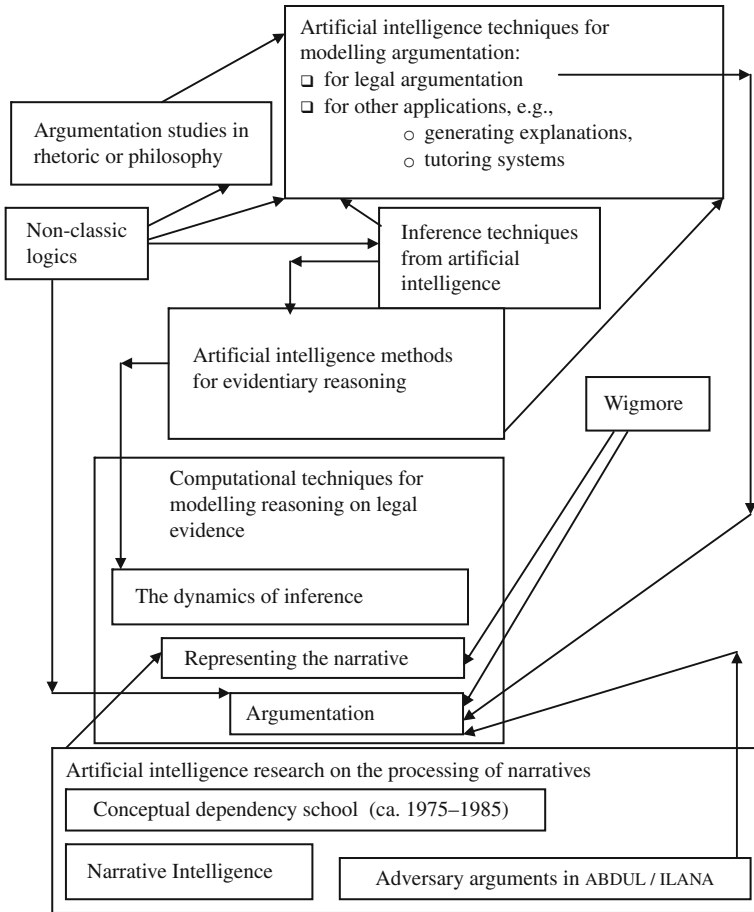

Fig. 10.3 Contributing or containment relations with a focus on computational models of argumentation and their application to law

Appendix: Glossary

This glossary defines such relevant concepts that are drawn from law (whether or not they were treated in the chapters of this book), or from computing (especially artificial intelligence), or argumentation, provided that they were mentioned in some relevant chapter. Tools are defined, if they had been mentioned or discussed in the book. So are abstract concepts, but not names of persons.

Importantly, with a few exceptions (in biometrics and concerning facial composites), this glossary does not cover forensic science or engineering, or forensic psychology or medicine. Much nomenclature had been introduced in the chapters about data mining or the forensic disciplines. Here and there, some passage in the glossary has appeared in sections in Nissan (2008a). This is the case of entries concerning: character evidence, logic and law, the doctrine of chances, *mens rea*, and hearsay.

There was little point to try and replicate, here, definitions for concepts from forensic science that can be found in Brenner's *Forensic Science Glossary* (2000). Even in such areas that were covered, there is no claim of completeness in this glossary. Sometimes a concept was developed more, simply because the present author was so inclined. It is hoped at any rate that this glossary will prove helpful, supplementing or presenting in a different manner such material that was expounded in the chapters of this book. There being a detailed Subject Index is intended to much facilitate access.

Abductive inference A mode of inference, theorised by Charles Peirce. It departs from deductive inference. See [Section 2.2.1.6](#) above. "*Abduction, or inference to the best explanation*, is a form of inference that goes from data describing something to a hypothesis that best explains or accounts for the data. Thus abduction is a kind of theory-forming or interpretive inference" (Josephson & Josephson, 1994, p. 5).

ABDUL/ILANA A tool developed by computational linguists. It was an AI program that used to simulate the generation of adversary arguments on an international conflict (Flowers et al., 1982).

Actus reus The actual performance of a forbidden action, or that action itself, as opposed to the intention (*mens rea*).

Ad hominem argument Such an argument that attacks the person who is claiming the truth of a proposition, in order to attack that proposition. Ad hominem arguments are the subject of Walton (1998b).

Adjudicative fact-finding Judicial decision-making (returning a verdict, as distinct from the later stage, of sentencing). Sometimes different kinds of courts can be alternative venues for adjudication for the same case, apart from the option of turning to arbitration rather than a court of justice. Moreover, sometimes alternative venues are known to have a tendency to adjudicate differently. A U.S. taxpayer disagreeing with the Inland Revenue Service (IRS) has four venues of appeal. Two of these require that before turning to them, the taxpayer pay up front what the IRS demands, whereas the other two venues can be approached without paying in advance the disputed tax bill, but these other venues are known to be more biased against the taxpayer. Without paying in advance, a taxpayer can request a conference with an IRS appeals officer, but such officers are Treasury employees, and clearly favour the IRS. Also without paying in advance, a taxpayer can appeal to the U.S. Tax Court, but in 1989 it issued split decisions 55% of the time (i.e., the finding was a compromise), and that kind of court only decided 4% of cases in favour of taxpayers. But if taxpayers pay up front what the IRS requests and then sue in order to recover, then two venues are open: the U.S. Claims Court (which in 1989 favoured taxpayers in 8% of cases), and the U.S. District Court: in 1989 it found for the taxpayers in 18% of cases, and so appears to be the venue least unfavourable to taxpayers (Topolnicki & MacDonald, 1991, p. 84). In a different domain, contracts are sometimes drawn by specifying which geographic jurisdiction is to adjudicate in case of litigation, and not infrequently (especially when the parties are from different countries), the parties expect that adjudication at one's own place may prove to be more favourable. Thus, sometimes the parties reason as though as the ideal of perfect objectivity of adjudicators was an ideal at variance with actual practice.

Admissionary rules Typically in the U.S. law of evidence: rules about which kinds of evidence can be admitted and heard in court. As opposed to *exclusionary rules*.

ADR See **alternative dispute resolution**.

Adversarial A type of criminal procedure, which is typical of Anglo-American jurisdictions. As opposed to the *inquisitorial* system. During the 1990s, some countries on the European Continent with an inquisitorial system have to some degree shifted towards an adversarial system. In Britain, public inquiries are in theory inquisitorial, rather than adversarial. See **inquisitorial**.

Adversary argument One of two classes of arguments (the other class being *persuasion* arguments), “depending on the goals and expectations of the participants. [...] In [...] *adversary* arguments, neither participant expects to persuade or be persuaded: The participants intend to remain adversaries, and present their arguments for the judgment of an audience (which may or may not actually be present). In these arguments, an arguer's aim is to make his side look good while making the opponent's look bad” (Flowers et al., 1982, p. 275). The ABDUL/ILANA program models such arguers (ibid.).

ADVOKATE A computer system for the evaluation of the credibility of eyewitness evidence (Bromby & Hall, 2002). It is described in [Section 4.4](#) in this book.

Age-progression software A kind of computer graphic software, useful to the police for the purposes of locating missing people, in that it predicts how a given person (based on an old photograph) would have aged meanwhile. See [Section 8.2.3](#).

Agent beliefs Models from AI for treating them were applied to modelling the reasoning about legal evidence, in Ballim et al. (2001) and Barnden (2001). This area is called *attribution* in psychology. See [Section 3.4](#)

AI See [Artificial intelligence](#).

AI & Law Artificial intelligence as applied to law, this being an established discipline both within legal computing and within artificial intelligence.

ALIAS A particular multi-agent architecture, with abductive logic-based agents. It was applied to the modelling of reasoning on the evidence in a criminal case, in Ciampolini and Torroni (2004), using LAILA, a language for abductive logic agents. See [Section 2.2.1.5](#).

Alibi In the proper, legal sense of the term, an alibi states an alternative location. Loosely speaking, one sometimes uses the term more generally, to refer to an alternative, exonerating account provided by a criminal suspect, or by a defendant being tried. It disconfirms a claim which is essential for the accusers for them to prove the charge. “The defence of alibi presupposes that the accused was somewhere else when the offence happened. If he does not remember where he was, then he can give no particulars. If he was alone at the time, he must still give such particulars as he can of where he was and when” (Osborne, 1997, p. 135). See [Section 2.2.2.8](#).

ALIBI A computer system developed by Nissan and his students in various prototypes as early as Kuflik et al. (1989). In an AI perspective, it is a planner which produces alternative explanations, and with respect to an input accusation, it seeks exoneration or a lesser liability. See [Section 2.2.2](#).

Alternative dispute resolution (ADR) In civil cases, *case disposition* (q.v.) includes, among the other options: the court finding for one of the parties, or settlement out of court, or *alternative dispute resolution*. The latter may be either *arbitration*, or *binding* or *nonbinding mediation*.

Ambiguity aversion “Ambiguity aversion is a person’s rational attitude towards probability’s indeterminacy. When a person is averse towards such ambiguities, he increases the probability of the unfavorable outcome to reflect that fear. This observation is particularly true about a criminal defendant who faces a jury trial” (from an extended abstract of Segal & Stein, 2006). “Because most defendants are ambiguity-averse, while the prosecution is not, the criminal process systematically involves and is thoroughly affected by *asymmetric ambiguity-aversion*” (ibid.). Indeed: “The prosecution, as a repeat player, is predominantly interested in the conviction rate that it achieves over a long series of cases. It therefore can depend on [...] general probability as an adequate predictor of this rather. The defendant only cares about his individual case and cannot depend on this general probability”. Because of the ambiguity, from the

defendant's perspective, of his individual probability of conviction, "[t]he defendant consequently increases this probability to reflect his fear of that ambiguity" (ibid.). "Asymmetric ambiguity-aversion foils criminal justice. The prosecution can exploit it by forcing defendants into plea bargains that are both inefficient and unfair. Because plea bargain is a predominant method of case-disposition across the United States, this exploitation opportunity is particularly pernicious" (ibid.).

Amicus curiae In some countries, an expert witness above the parts, appointed by the court.

Anchored narratives (or **AN** for short) The *theory of anchored narratives* was proposed by Wagenaar et al. (1993). The central idea of this approach is that juridical proof is organized around plausible narratives where "plausibility" is determined by the relationship between the story offered at trial and the background knowledge/common sense of the decision maker. A shortcoming of the theory of anchored narratives is that has no operationalization of "not guilty".

In the theory of anchored narratives, narrative (e.g., the prosecution's claim that John murdered his wife) is related to evidence (e.g., John's fingerprints on the murder weapon) by a connection that must be satisfactory for the narrative to hold once the evidence is accepted: "[...] triers of fact [i.e., judges or, in some countries, the jury] reach their decisions on the basis of two judgments; first an assessment is made of the plausibility of the prosecution's account of what happened and why, and next it is considered whether this narrative account can be anchored by way of evidence to common-sense beliefs which are generally accepted as true most of the time" (Jackson, 1996, p. 10). For the story to be comprehensively anchored, each individual piece of evidence need be not merely plausible, but safely assumed to be certain, based on common-sense rules which are probably true (see **generalisations**). Critics point out that this begs the question: generalizations only hold with some degree of probability, if this can be pinpointed. Moreover, Ron Allen pointed out that in the theory of anchored narratives, there is no operationalization of "not guilty" or "not liable". His own related, but earlier work is free from that fault. See [Section 5.1.2](#).

Anti-forensics Strategies to evade computer forensic investigations, in: *digital anti-forensics* (q.v.). See [Section 6.2.1.5](#).

Appeal The right to appeal against a judgment is an ancient Roman principle. It was renewed during the Middle Ages. For example, in Montpellier, a town (now in southwestern France) which obtained privileges of autonomy from the Crown of Aragon, "appeal procedure was used from 1204 [and the town] enacted in 1212 a statute fixing a time limit for first and second appeals exclusively to their [local authorities]. But the kings in France, the counts in Provence swiftly monopolised the competency concerning "final appeals"; and by the end of the XIIIth century, it became impossible for the towns to keep such powers" (Gouron, 1992, pp. 34–35). The reverse of the medal, if the right of some judiciary authorities not to have their judgment appealed against: historically in the United States, one of various meanings that *freedom of proof* – "a slippery term" (Twining, 1997, p. 462) – used to have (unlike the current sense: see **free proof**) was this

one: “freedom from hierarchical controls over fact-finding: for example freedom of triers of fact from appeal or review by a superior authority” (ibid., p. 448). Countries have a hierarchy of courts, and appeal is to a higher court.

Appeal to expert opinion See *Expert opinion*, *Appeal to*.

Applicant In some kinds of trial, this is the plaintiff; then the name for the defendant is *respondent*. The term *applicant* is used in the procedure of employment tribunals in England and Wales. In the *Civil Procedure Rules 1993*, in England and Wales, the term *plaintiff* was replaced with *claimant* (thought to be a more transparent, and more widely understood term: the same reform excised other traditional terms as well).

Araucaria A relatively widespread tool for visualising arguments (Reed & Rowe, 2001, 2004). It was developed at the University of Dundee, in Scotland. The software is freely available. It was also discussed in chapters 11 and 12 in Walton, Reed, and Macagno (2008). See [Section 3.7](#).

Arbitration In civil cases, a form of *case disposition* (q.v.). Like *mediation*, arbitration is a form of *alternative dispute resolution* (that is, alternative to the courts).

AREST A particular expert system, described by Badiru et al. (1988), and whose application was the profiling of suspects of armed robbery. See in the notes of [Section 6.1.3](#).

Argumentation How to put forth propositions in support or against something. An established field in rhetorics, within AI & Law it became a major field during the 1990.

ArguMed Verheij (1999, 2003) described the *ArguMed* computer tool for visualising arguments. It was described by Verheij (1999, 2003). One of its peculiarities is the concept of *entanglement* (q.v.). See [Section 3.7](#).

Argumentation layers Prakken and Sartor (2002) usefully “propose that models of legal argument can be described in terms of four layers. The first, *logical* layer defines what arguments are, i.e., how pieces of information can be combined to provide basic support for a claim. The second, *dialectical* layer focuses on conflicting arguments: it introduces such notions as “counterargument”, “attack”, “rebuttal” and “defeat”, and it defines, given a set of arguments and evaluation criteria, which arguments prevail. The third, *procedural* layer regulates how an actual dispute can be conducted, i.e., how parties can introduce or challenge new information and state new arguments. In other words, this level defines the possible speech acts, and the discourse rules governing them. Thus the procedural layer differs from the first two in one crucial respect. While those layers assume a fixed set of premises, at the procedural layer the set of premises is constructed dynamically, during a debate. This also holds for the final layer, the *strategic* or *heuristic* one, which provides rational ways of conducting a dispute within the procedural bounds of the third layer” (Prakken & Sartor, ibid., section 1.2). See [Section 3.8](#).

Arraignment In criminal cases: “All trials on indictment begin with the ‘arraignment’ which consists of formally putting the counts in the indictment to the accused and inviting him to plead [i.e., to plead guilty or not guilty] to each.

The jury are not empanelled at this stage and in most [English] courts the procedure is that matters are ‘listed to plead’ where nothing else is dealt with but the taking of the plea” (Osborne, 1997, p. 138), Exceptionally (in England) if solicitors write to the Crown Prosecution Service and to the court “that there is categorically to be a not guilty plea, the matter may be listed for trial without this preliminary stage” (ibid.).

Artificial intelligence (AI) Chapter 1 in Patrick Winston’s (1984) popular textbook explained (ibid., pp. 1–2):

There are many ways to define the field of Artificial Intelligence. Here is one:

- Artificial Intelligence is the study of ideas that enable computers to be intelligent.

But what is intelligence? Is it the ability to reason? Is it the ability to acquire and apply knowledge? Is it the ability to perceive and manipulate things in the physical world? Surely all of these abilities are part of what intelligence is, but they are not the whole of what can be said. A definition in the usual sense seems impossible because intelligence appears to be an amalgam of so many information-representation and information-processing talents.

Nevertheless, the goals of Artificial Intelligence can be defined as follows:

- One central goal of Artificial Intelligence is to make computers more useful.
- Another central goal is to understand the principles that make intelligence possible.

Nissan (1991, section 1) introduced the bipolarity of goals of artificial intelligence as follows, in a rather florid style catering to a broad audience:

In the framework of a discussion about the epistemology of computing, Bernard Stiegler (1986) employs a metaphor based on the myth of *Epimetheus and Prometheus*. According to that myth, Epimetheus endowed animals with various qualities, but forgot man. Unfledged and defenceless, to survive, man had to be endowed with reason by Prometheus, who sacrificed himself in the process. Here, this metaphor is going to be transposed onto the following idea, different from Stiegler’s: the Aler [i.e., the practitioner or scholar of artificial intelligence] is an Epimetheus who yearns for becoming Prometheus for the machine. Because of the very nature of the different interests catered to by the two terms in the binomial *science* and *technology*, the technologist relishes his or her Epimethean role. Rational, industrial criteria justify this, and are justified themselves by the social-cultural pattern that produced, e.g., Edison (and for which, see, e.g., Jenkins, 1987, section II). So far, computer technology has endowed the machine with new attributes, just as the myth has Epimetheus endowing the spectrum of animal species with various combinations and dosage of faculties, that – albeit non-ratiocinative – are suitable for inserting them in the natural environment. No *actual* system – scientific prototypes, or industrial applications that computing has produced, escapes Epimetheus’ limits. Not only [that]: nowadays, we [are] witness[ing] a trend in computing that aims at the *mainstreamization*, in computing practice, of AI methods, that are adapted by making them more similar to traditional algorithmic programming. The idea is, that you can describe objects in cohesive clusters, or adopt the AI technique of defining and searching a constraint space of possibilities, with just practical aims, with no cognitive preoccupations (or with just ergonomically [i.e., labour-facilitating] motivated cognitive preoccupations). Aristocrats of AI science may turn up their nose at such down-to-earth interests, when wearing the gown of [fundamental] research, but actually that possible attitude does not exclude taking interest, as a side occupation, in applied projects,

hopefully rentable. Scientific and technological interests each have a specific dignity: admitting the criteria of practice is *not* degradation, it is not tantamount to the guilt of Peer Gynt, who in Ibsen's drama [of 1867] wears a tail to gain [acceptance into] the Trolls' country.

[Whatever] the computer system – implemented or extrapolated as feasible – we were to consider, we are condemned to spot there, at most, Epimetheus' gift – a task-dependent suitability – while being reluctant to consider the system as being *already* intelligent, with no double quotes. This does not necessarily imply a mind/mechanism or soul/matter dualism, even though it may culturally motivate some dependency or counter-dependency (the latter claiming, *because* this runs against dualism, that intelligence *can* be achieved, with a certain technical paradigm, or more in general).

Dissatisfaction with given AI artifacts matches the criteria of Promethean eschatology, practically impossible to please on the ground of all cognitive desiderata. Realistically, such criteria have to be drastically simplified to be coped with step by step, and then they have to be gradually redefined more tightly, while we progress on the alternative trestles of widening the *technical can-do space* and of gaining more *scientific insight*. The arbitrary nature of technical representation shapes, and provisionally delimits, scientific conception, but the latter, in turn, provides feedback for technological development. Awareness that scientific conceptions are a product of *social constructivism*, not just an *objective* product of either occasional serendipity or methodic [perspiration], is helpful to protect the scientist from overly enthusiasm. However, new adepts not always appreciate that, which can explain why in certain domains (e.g., linguistics), AI often becomes an *obtrusive* tool, or even a new theory on its own, instead of being recognized as being a versatile, non-partisan testbed where *representation* subverts *theory*, does not *replace* it.

Different research taxonomies of AI are surveyed by Hall and Kibler (1985); cf. Ringle (1979, 1983). Anyway, AI is most often conceived as fitting in a spectrum between the two ends: simulation of cognition as being the main concern, and the working, but cognitively indifferent tool. The contrast between science and technology – as we witness it in AI, notwithstanding the headway made by the tandem since the Seventies eternalizes distance to be covered; this is easily admitted, once we draw a comparison with the history of science and technology during the positivism era, when distances were thought to be smaller than they later proved to be (and when the [20th] century was figured out by extrapolating into “triumph” current “militant” conceptions of the [19th] century). Nowadays, there is the factor of *impatience*, as Latour (1986) has pointed out: “used to precede, engineers find it uneasy to follow [folk expectations], instead of just stupefy”.

What is most specific in the contrast, inside AI, between technological opulence and scientific eschatology, is tightly bound to a terminological choice, that took sides with only one element of the binomial: by naming the discipline *artificial intelligence* (or, less explicitly and more modestly, *AI*), the distance left to be covered has been seized by the wrong end. A practical, concrete, down-to-earth choice (the nearest end), could have been: defining a *cumulative, open-ended meter, callidiority* (from Latin *callidior*, i.e. “smarter [than]”).

This meter has both the merit and the fault of sparing technology the lashing of cognitive science ambitions, as the callidiority meter measures only past steps, not relativeness with respect to an Omega Point. Yet, such meter could cost ungluing the binomial. For technology, it may mean sinking into marshes – [in] the eyes of AI *scientists* – similar to those that, for up-to-date programmers [since the 1980s], COBOL [programming-language] administrative data processing has become. Production-system based commercial products would be repeated *ad nauseam*, acritically, as a this-worldly relish of a mortal fallen angel, nearly deaf to the *Memento mori*

admonition of newly underfunded basic research. Several AIers fear such an *AI Winter*, that could stem out of premature industrial disillusion, after too feverish a fashion. [And indeed, it took place during the 1990s, with blue-sky research on open-ended problems no longer being funded the way it used to be during the 1980s. The very term *expert system* went out of favour, then being replaced with *intelligent system*.] On the other hand, ungluing the binomial is a scenery that by now cognitive scientists, AI researchers, and the scientific culture of AI cannot afford to accept. Indeed – and this is the fundamental importance of AI – AI as implemented or to be implemented is, nowadays, the testbed that makes theories materialize. Intellect hopes in the advantages of matter. Once we have started considering it feasible to bring the Heavenly Jerusalem down to the Earthly one, not to loose hold has become a cultural imperative.

Association rules “Association rules represent relationships between items in very large databases” (Chan et al., 2001b). Association rules are discovered by means of *data mining* (for which, see [Chapter 6](#)).

An example would be “given a market database, it was found that 80% of customers who bought the book ‘XML for beginners’ and ‘internet programming’ also bought a book on ‘Java programming’.” If X and Y are two sets of disjoint terms, then an association rule can be expressed as conditional implication $X \Rightarrow Y$ i.e. the occurrence of the set of items X in the market basket implies that the set of items Y will occur in this market basket. Two important aspects of an association rule are confidence and support [...]. The confidence of an association rule $r: X \Rightarrow Y$ is the conditional probability that a transaction contains Y given that it contains X, i.e. confidence $(X \Rightarrow Y) = P(X,Y)/P(X)$. The support of an association rule is the percentage of transactions in the database that contains both X and Y, i.e., Support $(X \Rightarrow Y) = P(X,Y)$. The problem of mining association rules can be stated simply as follows: Given predefined values for minimum support and minimum confidence, find all association rules which hold with more than minimum support and minimum confidence.” (Chan et al., 2001b, p. 278, citing Agrawal & Srikant, 1994 for the definition of confidence and support).

ATT-Meta A system for agents’ simulative reasoning by agents on each other, which deals with agents’ beliefs in respect of a formal approach to uncertain reasoning about them. Barnden (2001) applies it to reasoning about legal evidence.

Attribution In psychology: how people (and computational cognitive models) reason about their own beliefs and the ones they ascribe to others. In AI, this area is called *agents’ beliefs*. See [Section 3.4](#).

Auxiliary probative policy (rules of) A category of rules excluding or restricting the use of admitted evidence. As opposed to *rules of extrinsic policy*. In interpretations of the American law of evidence, according to Wigmore’s terminology, *rules of auxiliary probative policy* are such exclusionary rules that are intended to promote rectitude of decision, avoiding unreliability or alleged prejudicial effect.

AVBPA *Audio and Video-Based Biometric Person Authentication*: an acronym for the name of a series of conferences in biometrics.

AVERs The visualisation component of the architecture of a sense-making software tool for crime investigation, as envisaged by Bex et al. (2007). AVERs was “implemented as a web front-end to an SQL database. A case can be represented visually through multiple views; in this paper we will focus on the two graphical views, that is, the evidence view and the story view” (section 6 *ibid.*). Ideally,

they wanted to design a more sophisticated tool than such *investigative analysis software*. Their approach to the story of the prosecution and the defence is qualitative, and does not resort to probabilistic quantification. It fits within logical and computer science research into argumentation, but this is combined with reasoning about stories and evidence. See [Section 5.4](#).

Background generalisations See [generalisations](#).

Backup evidence question In argumentation studies, Walton’s (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008, pp. 381–382). See s.v. [Expert opinion, Appeal to](#) above. The expert source is E ; the subject domain is S ; and A is a proposition about which E claims to be true (or false). The backup evidence question is: “Is E ’s assertion based on evidence?”. It is articulated in three detailed subquestions: “What is the internal evidence the expert herself used to arrive at this opinion as her conclusion?”; “If there is external evidence – for example, physical evidence reported independently of the expert – can the expert deal with this adequately?”; “Can it be shown that the opinion given is not one that is scientifically unverifiable?”.

Bail “Bail is the release of a person subject to a duty to surrender to custody in the future” (Osborne, 1997, p. 95). In English law, the Bail Act 1976 provides that “a defendant who fails without reasonable cause to surrender to custody is guilty of the offence of absconding”, and it lies on the defendant to prove reasonable cause (e.g., sudden serious illness, or an accident on the way to court, for which evidence must be given). The Bail Act 1976 abolished the “common practice to grant an accused bail ‘on his own recognisance’”. This was a fixed sum of money which the accused did not have to provide at the time of granting bail but which, should he fail subsequently to surrender to custody would be forfeited” (Osborne, ibid.).

Bayes, naïve For a given sample we search for a class c_i that maximises the posterior probability

$$P(c_i | x ; \theta')$$

by applying Bayes rule. Then x can be classified by computing

$$c_l = \underset{c_i \in C}{\arg \max} P(c_i | \theta') P(x | c_i; \theta')$$

Also see [naïve Bayesian classifiers](#).

Bayes’ theorem When dealing with a hypothesis H , and some evidence E , Bayes’ theorem states:

$$P(H|E) = P(E|H)P(H)/P(E)$$

this can be read as follows: the *posterior probability* $P(H|E)$, i.e., the probability that H is true given E , is equal to the product of the *likelihood* $P(E|H)$, i.e., the probability that E given the truth of H , and the *prior probability* $P(H)$ of H , divided by the *prior probability* $P(E)$ of E .

Bayesian debate A controversy among legal scholars, concerning legal evidence and the use of statistics, and in particular of Bayes' theorem. See [Sections 2.3](#) and [5.1](#). On statistics in DNA evidence, see [Section 8.7.2.2](#).

Bayesian enthusiasts Such legal scholars of evidence or forensic statisticians who strongly support the use of Bayes' theorem as a foundation for statistical analysis as applied to legal evidence. Opposed by the Bayesio-skeptics. Note that whereas some in both camps accept these labels, there also are objections, and *Bayesians* vs. *skeptics* are more acceptable labels.

Bayesian networks A Bayesian network is a directed acyclic graph (i.e., a graph without loops, and with nodes and arrows rather than direction-less edges), such that the nodes represent propositions or variables, the arcs represent the existence of direct causal influences between the linked propositions, and the strengths of these influences are quantified by conditional probabilities. Whereas in an *inference network* the arrow is from a node standing for evidence to a node standing for a hypothesis, in a Bayesian network instead the arrow is from the hypothesis to the evidence. In an inference network, an arrow represents a relation of support. In a Bayesian network, an arrow represents a causal influence, and the arrow is from a cause to its effect.

Judea "Pearl has always argued for a subjective degree of belief interpretation of the probabilities in Bayesian networks" (ibid.), these being a formalism he introduced and developed in a series of papers in the 1980s, leading to a book (Pearl, 1988). Judea Pearl's "departure from standard Bayesianism arises because he thinks that prior probability distributions are inadequate to express background knowledge, and that also needs to use causal judgments which cannot be expressed in probabilistic terms" (Gillies, 2004, p. 284).¹

Bayesian reasoning or Bayesian updating or Bayesian conditionalisation The use of the formula of Bayes' theorem in order to go from the *prior probability* $P(H)$ of a hypothesis H , to the *posterior probability* $P(H|E)$ of H , i.e., the probability that the hypothesis H is true, given the evidence E .

Bayesianism "*Bayesianism* is, roughly speaking, the view that relating hypotheses to evidence can be solved by bayesian reasoning" (Gillies, 2004, p. 287).

Bayesianism (Imperialistic) A charge made, by supporters of alternative systems of probability, or then by those suspicious of probabilities altogether, not only in a legal scholarship context: Imperialistic Bayesianism consists of the attitude of the Bayesian who dismisses (too quickly, the charge claims) any approach to uncertainty that is not based on Bayes' Theorem.

¹ Dechter, Geffner, and Halpern (2010) is a jubilee volume honouring Judea Pearl.

Bayesio-skeptics Such legal scholars of evidence who have misgivings about the validity or desirability of Bayes' theorem, or even of other probabilistic or statistical formalisms, in the analysis of the evidence of given criminal cases (while not necessarily opposed to such use in civil cases). The term *skeptics* is more widely acceptable, being less charged, albeit less specific.

Bench trial A trial in which the verdict is given by some (trained, professional) judge or judges, instead of by a jury (i.e., popular judges). In some countries there are no jury trials. In countries with jury trials, there are as well bench trials, which apply in different categories of cases.

Beyond a reasonable doubt. The standard for deciding to convict, in a criminal case. The corresponding Latin formula is: *in dubio pro reo* ("If in doubt, find for the defendant"). In contrast, in a civil case the standard for the verdict is less demanding: *more likely than not*. See **utility**. "Proof beyond a reasonable doubt is such proof as precludes every reasonable hypothesis except that which it tends to support and which is wholly consistent with the defendant's guilt and inconsistent with any other rational conclusion" (Stranieri & Zeeleznikow, 2005a, Glossary, s.v. *Proof beyond reasonable doubt*). In contrast, "Proof by a fair preponderance of the evidence is the standard of proof required in civil cases; a decision is made according to that evidence which as a whole is more credible and convincing to the mind and which best accords with reason and probability" (ibid., s.v. *Proof by a fair preponderance of the evidence*).

In the *Carneades* argumentation tool (Gordon & Walton, 2006; Gordon et al., 2007), without sticking to the legal sense of the phrase, the strongest *standard of proof* for an argument was defined to be BRD (*beyond reasonable doubt*): "A statement meets this standard iff it is supported by at least one defensible pro argument, all of its pro arguments are defensible and none of its con arguments are defensible". Cf. **Scintilla of evidence**, and **Preponderance of the evidence**.

A curious effect of the different standards for criminal and civil cases can be seen in the 1995 case of celebrity sportsman O. J. Simpson, that at a criminal trial, a jury on 4 October 1995 found not guilty of the murder of his ex-wife and her friend (a June day in 1994, Nicole Brown Simpson and Ron Goldman had been stabbed to death outside her Brentwood home in California), yet later on, in 1997, was considered "responsible" for their deaths by a civil court that ordered him to pay compensation (not paid because of bankruptcy). This is further complicated by the rule against *double jeopardy*: a defendant in the United States cannot be tried all over again. In late November 2006, Simpson's book entitled *IF I did it, Here's How it Happened* was announced amid an outcry. Publication was decided upon on 1 July 2007, but the family of the male victim acquired the rights to the revenue (e.g., Hunt, 2007). Nevertheless, basically it is quite correct that the justice system cannot afford other than a very demanding standard of proof at criminal trials.²

² In early October 2008, thirteen years to the day after his acquittal from the charge of murder, the former football star was convicted of armed robbery, in the context of an event that he claimed was

Another example is that of actor Robert Blake, who in 2002 was arrested for the murder of his wife Bonnie Lee Bakley, one year after her murder. Retired stuntman Ronald “Duffy” Hambleton testified against Blake, claiming that he had tried to hire him to kill his wife. Blake was acquitted of murder in 2005, but her family filed a civil suit and Blake was found to be liable for her murder. In an appeal, the prosecution suggested that detectives failed to investigate whether associates of Christian Brando (who the woman had been claiming, in a letter to him, had fathered her baby) may have murdered Bakley. Hambleton was one of Brando’s associates, and a witness claimed that Brando (who had an alibi) had said “Somebody should put a bullet in that bitch’s head”. This makes it all the more interesting, that Blake was found liable by a civil court, after being acquitted by a criminal court.

This other example is from the U.K., and concerns the Omagh bombing,³ in Northern Ireland (i.e., Ulster). It killed 29 people in 1998. The police failed to secure a criminal conviction. Only one man, Sean Hoey, faced criminal charges over the Omagh killings, and he was acquitted in December 2007. Another man, Colm Murphy, was found guilty in Dublin’s Special Criminal Court of conspiring to cause the Omagh bombing, but his conviction was later quashed. On 8 June 2009, four men were found to be responsible for the terrorist attack, and the Real IRA was found liable, in a landmark civil case brought by relatives of the victims at Belfast High Court. They had sued five men (one of them was cleared), as well as the Real IRA as an organisation, for up to £14 million.

The case opened in April 2008. Evidence for the case was heard (until March 2009) in both Belfast and Dublin, thus making legal history. It took Mr Justice Morgan three months to sift through the evidence. Those sued were Michael McKevin (the leader of the Real IRA), Liam Campbell, Colm Murphy, and Seamus Daly (these four were found responsible), as well as a man who was cleared, Seamus McKenna (the evidence against him came from his estranged wife, who was eventually considered an unreliable witness).

The judge awarded more than £1.6 million in damages to 12 named relatives who took the action. Much of the evidence was obtained by an undercover FBI agent, David Rupert, who infiltrated the Real IRA. Records and traces on two phones used by the bombers on the day of the attack were important evidence, and the judge deemed it proved that Campbell and Daly were in possession of the phones before and after the attack. Quite importantly, the burden of proof was as required in a civil case, and it is in this context that one has to understand the judge’s statement that he considered the case against Campbell overwhelming.

Big Floyd A ink analysis tool of the FBI (Bayse & Morris, 1987), with inferential capabilities, and applying the notion of template matching for detecting the likelihood that particular types of crimes were committed. See [Section 6.1.2.3](#).

an attempt to recover his own property. One wonders whether the jury could have been insensitive to the highly publicised previous case. See *Trial by the media*.

³ *Omagh* is pronounced *Oma*. The town of Omagh is in County Tyrone.

Biometrics “Biometrics, which refers to identifying an individual based on his or her physiological or behavioral characteristics, has the capability to reliably distinguish between an authorized person and an imposter. A biometric system can be operated in two modes: (1) verification mode and (2) identification mode (Jain et al., 2000). The former is called *person verification*, or *person authentication*. A biometric system operating in the verification mode either accepts or rejects a user’s claimed identity, while a biometric system operating in the identification mode establishes the identity of the user without any claimed identity information” (Khuwaja, 2006, pp. 23–24). Jain, Bolleand, and Pankanti (1999) and Li and Jain (2009) are books on the subject. Bromby (2010) discussed how biometrics can aid certification of digital signatures.

The most mature technique for person verification, or one of the most mature, is fingerprint-based identification (Isobe, Seto, & Kataoka, 2001; Seto, 2002). Other approaches are based on “face, hand geometry, iris, retina, signature, voice print, facial thermogram, hand vein, gait, ear, odor, keystroke dynamics, etc.” (Khuwaja, 2006, p. 24). For example, *iris recognition* is the subject of Li, Yunhong, and Tan (2002), Yunhong, Tan, and Jain (2003). *Retina recognition* is discussed by Yoichi Seto (2009).

Biometric fusion (or *information fusion in biometrics*: Ross & Jain, 2003) is “[t]he general method of improving performance via collection of multiple samples” (Rattani et al., 2008, p. 485). *Multi-biometrics* is “[t]he ability to utilize multiple biometrics modalities (multimodal), instances within a modality (multi-instance), and/or algorithms (multi-algorithmic) prior to making a specific verification/identification or enrollment decision” (ibid.), where *enrollment* is “[t]he initial process of collecting biometric data from a user and then storing it in a template for later use” (ibid., p. 484). See Section 8.7 on *individual identification*.⁴

Blackboard systems “A blackboard system is a group of knowledge modules collaborating with each other by way of a shared database (blackboard), in order to reach a solution to a problem. Its basic components are: the blackboard, knowledge sources (independent modules that collectively contain the knowledge required to solve the problem) and a control mechanism (or scheduler) which directs the problem-solving process by deciding which knowledge source is most appropriately used at each step in the solution process. The knowledge sources have a condition part and an action part. The condition component specifies the situations under which a particular knowledge source could contribute to an activity. The scheduler controls the progress toward a solution in blackboard systems, by determining which knowledge sources to schedule next, or which problem sub domain to focus on” (Stranieri & Zeleznikow, 2005a, Glossary) See Section 6.1.6.1 in this book. Blackboard systems have found application in legal computing: “GBB is an expert system shell based on the blackboard paradigm. It provides the blackboard database infrastructure, knowledge source

⁴ In particular, see Section 8.7.3.1. Also see in the last footnote of Section 6.2.1.9.

languages and control components needed by a blackboard application. It is used in the construction of the CABARET legal knowledge based system” (Stranieri & Zeleznikow, 2005a, Glossary). Ashley’s (1991) HYPO system (which modelled adversarial reasoning with legal precedents) was continued in the CABARET project (Rissland & Skalak, 1991), and the CATO project (Aleven & Ashley, 1997). Besides: “The PROLEXS project at the Computer/Law Institute, Vrije Universiteit, Amsterdam, Netherlands is concerned with the construction of legal expert shells to deal with vague concepts. Its current domain is Dutch landlord-tenant law. It uses several knowledge sources and the inference engines of the independent knowledge groups interact using a blackboard architecture” (Stranieri & Zeleznikow, 2005a, Glossary). Blackboard systems are the subject of Hayes-Roth (1985) and of Engelmores and Morgan (1988).

Blue ribbon jury Specially qualified jury, instead of a jury whose members are ordinary members of the public. This is one of several possible remedies to *trial complexity* (Hewer & Penrod, 1995, p. 533).

Bolding-Ekelöf degrees of evidential strength Introduced in Bolding (1960), Ekelöf (1964). Åqvist (1992) proposed a logical theory of legal evidence, based on the Bolding-Ekelöf degrees. Shimony and Nissan (2001) restated Åqvist’s approach in terms of the probabilistic version of Spohn’s (1988) *kappa calculus* as developed in AI research. (The *kappa value* of a *possible world* is the *degree of surprise* in encountering that possible world, a degree measured in non-negative integer numbers.)

Burden of proof (or **persuasion burden**). Which party in a trial should prove or disprove a given claim. “There is a distinction between the evidential and legal burden of proof” (Jefferson, 1992, p. 19). In criminal cases, the defendant’s “burden is called the evidential burden or onus of proof. The prosecution’s burden is the legal one” (ibid.). See **Evidential burden** (as well as **onus of proof**) and **Legal burden**. The burdens of proof are also important in scientific inquiry; Scientific uncertainty and burdens of proofs in, respectively, scientific practice and environmental law are discussed – from the vantage point of the philosophy of science – in Lemons et al. (1997). Allen and Pardo assert (2007a, p. 108, fn 1), concerning formalisation, that

there are attempts to defend an expected-utility approach to burdens of persuasion with an argument that is valid if, but only if, burdens of persuasion apply to cases as a whole (the defendant is liable or not, guilty or not), but this is false; they apply to individual elements (Allen, 2000).

Burden, evidential One of the two kinds of **burden of proof**, as opposed to **legal burden**. In criminal law in England, “[i]n most offences the Crown does not need to negative [sic] any defence the accused might have. It has to show the *actus reus* and *mens rea*, if any. If the defendant wishes to rely on a defence, he must raise it and show evidence in support, as Lord Diplock said with regard to mistake in *Sweet v Parsley* [1970] AC 132. The same can be said about self-defence, provocation, automatism and duress” (Jefferson, 1992, p. 19).

There is a distinction between the evidential and legal burden of proof. The difference may be illustrated by reference to automatism [. . .]. Before the accused can rely on this defence, he must put forward some evidence that he was acting automatically when he, say, hit his lover over the head with a heavy ashtray. The evidence might consist of a witness's saying that he saw what happened or a psychiatrist's drafting a report. In legal terms he has to adduce or lead evidence. If he does not adduce such evidence, his plea will fail at that stage and the prosecution does not have to lead evidence that his plea should not succeed. If he does, the prosecution has to disprove that he was acting automatically. His burden is called the evidential burden or onus of proof. The prosecution's burden is the legal one. (ibid.).

Burden, legal One of the two kinds of *burden of proof*, as opposed to *evidential burden*. In criminal law in England, "before the accused can rely on [a given] defence, he must put forward some evidence [to that effect]. If he does not adduce such evidence, his plea will fail at that stage and the prosecution does not have to lead evidence that his plea should not succeed. If he does, the prosecution has to disprove [what he claimed in his defence]. His burden is called the evidential burden or onus of proof. The prosecution's burden is the legal one" (Jefferson, 1992, p. 19).

In most area of the criminal law the prosecution must prove both the *actus reus* and the *mens rea* "beyond reasonable doubt". [. . .] The same principle applies to most defences. The prosecution has, for example, to disprove duress and self-defence. Older cases to the contrary are no longer authoritative. To this principle there are three exceptions.

Insanity For the accused to have this defence he must show that he was insane at the time of the offence. The standard of proof is on the "balance of probabilities". That phrase means in effect that if it is more likely than not that the accused was insane, he has the defence. [. . .] The legal reason assigned for this exception is that every person is presumed to be sane; [. . .]. The effect is that if the jurors are not certain either way, the accused does not have this defence.

Parliament expressly placing the burden on the accused [. . .] Parliament can alter the burden by statute and has done so on several occasions [for given kinds of offence and defendant's defence]. [. . .] Where Parliament places the burden of proof on the accused, the standard of proof is on the balance of probabilities, unless Parliament states otherwise.

"*Exception, exemption, proviso, excuse or qualification*" in a statutory offence [. . .] In a case for the possession of morphine, Lord Ackner held that Parliament could place the burden of proof on the accused either expressly or "by necessary implication". When deciding whether the burden was by implication on the accused, the court had to look not just for the language of the enactment but also at its substance and effect. The practical consequences could also be investigated. [. . .] On the facts the prosecution had merely to obtain an analyst's report [which is not a burdensome task for the prosecution]. Therefore, the burden remained on the Crown. [. . .] Where Parliament places the burden of proof on the accused, he bears the legal burden and not just the evidential one. [. . .] The types of argument utilised in *Hunt* will be used in later cases to decide whether an exception in a statute places the burden of proof on the accused. Doing so has to be justified and could not be justified simply on the basis of the grammar of the section containing the offence. In deciding whether Parliament intended to place the burden on the accused one should look at the practicalities. If one side would have serious difficulties in proving something, there was an inference that that party did not bear the burden. It was also a factor whether the crime was serious or not. If it was serious, it was more likely than not that the prosecution bore the onus. The burden was not likely to be placed

on the accused, for it ought not easily to be held that Parliament did not intend to protect the innocent. (Jefferson, *ibid.*, pp. 19–22).

CABARET A computer system for argumentation from AI & Law (Rissland & Skalak, 1991). See [Section 3.9.1. Blackboard systems](#) (q.v.) have found application in legal computing: “GBB is an expert system shell based on the blackboard paradigm. It provides the blackboard database infrastructure, knowledge source languages and control components needed by a blackboard application. It is used in the construction of the CABARET legal knowledge based system” (Stranieri & Zeleznikow, 2005a, Glossary). Ashley’s (1991) HYPO system (which modelled adversarial reasoning with legal precedents) was continued in the CABARET project (Rissland & Skalak, 1991), and the CATO project (Alevén & Ashley, 1997).

CACTUS A piece of software (a simulation system based on a multi-agent architecture) for training police officers in managing public order events, while communicating as they would in a real situation (Hartley & Varley, 2001). See at the end of [Section 6.1.6.2](#).

Carneades A computer tool, implemented using a functional programming language and Semantic Web technology, based on a particular formal model of argumentation (Gordon & Walton, 2006). See [Section 3.7](#).

Case-based learning Learning from case studies, in an educational setting (Williams, 1992). It has provided inspiration for *case-based reasoning* in artificial intelligence. Leake (1996) remarked (citing Williams, 1992): “Although case studies already play a useful role in legal and medical education, students using them generally do not confront the complexity of real episodes and do not have the opportunity to act to execute, evaluate, and revise their solutions”.

Case-based reasoning (CBR) A methodology in artificial intelligence, that instead of matching rules from a ruleset to a situation at hand, tries to match it to some entry from a pool of past cases, by calculating how close they are according to various features (e.g., Leake, 1996; Veloso & Aamodt, 1995). This is similar to, and at least in part overlapping with, *analogical reasoning* (Veloso, 1994). Stranieri and Zeleznikow (2005a) provide this definition:

Case based reasoning is the process of using previous experience to analyse or solve a new problem, explain why previous experiences are or are not similar to the present problem and adapting past solutions to meet the requirements of the present problem.

The contrast between *rule-based* and *case-based* intelligent systems from artificial intelligence should not be mistaken for the contrast between such legal jurisdictions that mainly judge based on precedent (which is the case of Anglo-Saxon countries), and such jurisdictions (such as France) where adjudication is mainly based on rules as stated in law as made by legislators.

Moreover, the two opposite pairs do not overlap even when either rule-based or case-based reasoning is adopted in intelligent software systems applied to the legal domain. Bain’s JUDGE system (Bain, 1986, 1989a, 1989b) is, among the other things, a tool whose AI mechanism is case-based reasoning. It adopts a hybrid approach involving both rule based and case based systems. JUDGE is a

cognitive model of judges' decision-making when sentencing (and indeed it was based on interviews with judges).

Also see **model-based case-based reasoning paradigm**.

CaseMap A commercial software tool for organizing the evidence. It is produced by CaseSoft, an American firm (www.casesoft.com) See *procedural-support systems*, and [Section 4.1.1](#).

Case disposition The manner a case is concluded, i.e., in criminal cases, by conviction, by acquittal, or by plea bargain (a predominant mode in the United States), or by the prosecution's decision not to prosecute, or by the alleged victim withdrawing the charges, or by the defendant dying or becoming incapacitated during the trial. In civil cases, case disposition includes: by the court finding for one of the parties, or by settlement out of court, or by *alternative dispute resolution* (either *arbitration*, or *binding* or *nonbinding mediation*), or by withdrawal of one of the parties (i.e., an employee who cannot afford to pay legal expenses so s/he could have his or her day in court at an employment tribunal), or by forgival and reconciliation.

CATO A computer system for argumentation from AI & Law (Aleven & Ashley, 1997). See [Section 3.9.1](#).

Chances, doctrine of See **doctrine of chances**.

Character In reference to *evidence of disposition and character*: "The word 'disposition' is used to denote a tendency to act think or feel in a particular way. The word 'character' may include disposition, or sometimes mean 'general reputation' or merely the question of whether or not the accused has a criminal record" (Osborne, 1997, p. 313). See **character evidence**, and see **evidence of disposition**.

Character vs. action In argumentation: Walton et al. (2008, p. 330) describe argumentation schemes relating an agent's character to an agent's actions. In particular, §31.3, "Abductive Scheme for Argument from Action to Character", is as follows:

Premise: Agent *a* did something that can be classified as fitting a particular character quality.

Conclusion: Therefore, *a* has this character quality.

Critical Questions

CQ1: What is the character quality in question?

CQ2: How is the character quality defined?

CQ3: Does the description of the action in question actually fit the definition of the quality?

By contrast, §31.4, "Scheme for Argument from Character to Action (Predictive)" is as follows:

Premise: Agent *a* has a character quality of a kind that has been defined.

Conclusion: Therefore, if *a* carries out some action in the future, this action is likely to be classifiable as fitting under that character quality.

Critical Questions

CQ1: What is the character quality in question?

CQ2: How is the character quality defined?

CQ3: Does the description of the action in question actually fit the definition of the quality?

Thus, in both cases the critical questions are the same. Walton et al. (2008, pp. 330–331) added this comment:

Comment: Even though the critical questions are the same for both, the predictive scheme for argument from character to action needs to be distinguished from the retroductive scheme that reasons from character to a particular action, and these two schemes need to be distinguished from the argument from a past action to an agent's character.

Their §31.5, 'Retroductive Scheme for Identifying an Agent from a Past Action' (ibid., p. 331) is as follows:

Factual Premise: An observed event appears to have been brought about by some agent *a*.

Character Premise: The bringing about of this event fits a certain character quality *Q*.

Agent Trait Premise: *a* has *Q*.

Conclusion: *a* brought about the event in question.

Cf. in Walton's *Legal Argumentation and Evidence* (2002, p. 44). Douglas Walton devoted a book to character evidence (Walton, 2006b).

Character evidence Arguments in favour or against a party in a trial, based on flattering or unflattering biographical data. According to the jurisdiction, use of such evidence is not always permitted. *Evidence of prior convictions* is a form of *evidence of disposition and character*. Another form is *uncharged conduct*, by which *uncharged misconduct* is intended: such past misconduct for which no charges were brought. There is much debate about the question of whether evidence of prior convictions has sufficient probative value to be heard by the trier of fact (a jury or a trained judge). At least in some cases (typically, against suspect child-molesters), it may be helpful to point toward what may have been the factual proof, to let it be known that the defendant had already been convicted of the same kind of offence. Nevertheless, in the law of evidence in some countries, exclusionary rules about which evidence can be used apply: *rules of extrinsic policy* give priority to other values (such as the protection of personal rights) over rectitude of decision. It is important to bear in mind that *legal truth* and *factual truth* are not identical. Yet, even withholding from a jury the information that the defendant had prior convictions, such a policy does not extend to a claim that police officers and law enforcement personnel should forego the use of prior convictions, while carrying out criminal investigations. Such a claim has been made, and goes by the name of *jury observation fallacy*.

Osborne (1997, p. 319) remarks about English law: "The general rule was that the character of any party in a civil case, or any witness in any case, is open to attack. The purpose of such attack is of course to show that the party or witness should not be believed". Yet "the fundamental rule [. . .] is that the prosecution may not for the purpose of proving an accused's guilt adduce evidence

of the character of the defendant whether of previous behaviour, previous convictions, or general reputation. The reason is obviously the extreme prejudice to the accused in the eyes of the jury. The main exception to this is the use of the ‘similar fact’ principle” (ibid.). See **similar fact evidence**. Osborne remarks (ibid.):

It has been recognised from the 18th century that an accused could call witnesses to speak to his good character, or cross-examine prosecution witnesses in order to get them to do so. This was exceptional and was intended as an additional protection for an accused, who could not testify before 1898. The important point to note however is that *character is indivisible*. One cannot assert a good character for one type of behaviour without the prosecution having the right to cross-examine or call evidence about other aspects of one’s character. [...] It [is] not open to an accused to put only half of his character in issue.

The defendant loses his shield (his protection from bad character evidence) if he makes *imputations* on the character of the prosecutor or of prosecution witnesses, but determining what is an imputation is not easy. See **shield**, and see **imputation**.

“There were numerous cases in the period 1990–1993 which left unclear what direction the judge [to the jury] the judge should give in respect of a defendant with good character who chooses not to testify” (ibid., p. 320). Should good character only, or primarily instead, affect credibility? If it only affects credibility, then as the defendant didn’t testify, good character evidence is of no use. It is useful, instead, if it is admitted by the court that good character is capable of being relevant to innocence.

Allen and Pardo (2007a) offered a critique, in terms of the *reference-class problem* (q.v.) of how probability theory was applied to juridical proof concerning character impeachment evidence in Friedman (1991).

Within research into argumentation, see Douglas Walton’s (2007) *Character Evidence: An Abductive Theory*.

Claimant In civil cases in England and Wales, the party that turns to the courts for adjudication against another party. In the *Civil Procedure Rules 1993*, the term *plaintiff* was replaced with *claimant* (thought to be a more transparent, and more widely understood term: the same reform excised other traditional terms as well).

Common law In countries like Britain there are both *statutory law*, i.e., laws passed by parliament, and *common law*, i.e., the body of sentences passed by judges, and that serve as precedent. On the European Continent, what really matters is statutory law, and the courts must abide by it when adjudicating.

Complexity (of a trial), or complex litigation Such features that may push a case beyond a jury’s ability, because a difficult challenge is posed to reasoned decision-making. Tidmarsh (1992) and Hewer and Penrod (1995, p. 531) discuss *substantive definitions* of trial complexity, i.e., based on the substance of a case (e.g., antitrust, securities and takeover litigation, or commercial disputes, and products liability torts, or sometimes breach of contract cases); *procedural definitions* of trial complexity (e.g., complexity during the pre-trial phase, complexity during the trial, complexity in the implementation or administration of remedies following the verdict, and complexity arising from the number of

parties); and “*laundry list*” definitions (based on the number of parties, the number of witnesses, the presence of a class action, the existence of a product liability claim, the presence of related cases involving multiple or complex factual or legal issues, the extent of discovery).

Hewer and Penrod (1995, p. 533) recommend the following actions in order to alleviate problems arising from trial complexity according to three dimensions, namely, *complex evidence*, *complex law*, and *voluminous evidence* (for short henceforth: E, L, V): Better organisation of voluminous evidence (E, V); Explain complex legal issues more clearly (L); Limit the volume of evidence (E, V); Limit the time for presentation of evidence (E, V); Stipulate to facts before the trial (E, V); Allow fewer trial interruptions (V); Provide jury with notebooks including pictures and information about witnesses and exhibits (E, V); Allow juror note-taking (E, L, V); Allow jurors to question witnesses (E); Instruct the jurors prior to the evidence (E, L); Provide jurors with written copy of the judge’s instructions (L); More thorough responses to juror questions during deliberations (E, L, V); Specially qualified (blue ribbon) juries (E, L, V); Special masters, i.e., neutral experts to assist jury (E, L, V); Special verdict forms with detailed questions for the jury to answer (L); Judge commenting or summarising of evidence (E, V); Greater reliance on summary judgement (E, L, V); Bifurcation of issues (E, V); Bifurcation of parties (V).

We have dealt with complexity in another sense in [Section 6.2.1.7](#): the *GOMS* (*Goals, Operators, Methods, Selections*) family of models of *cognitive complexity* includes the *GOMS Keyboard-Level Model (KLM)*, developed by Kieras (2001), and which provides a tractable means of measuring human involvement in an operational process.

Composites Composite images of human faces, used for suspect identification. Facial portraits, or *mugs*, typically are not composites, but rather a photograph (*mugshots*), or then portraits of suspects are, drawn by a sketch artist manually, based on a verbal description of a victim or eyewitness (*Identi-kit* procedures). An alternative to mugs and to artist’s sketches is a *composite*, by which initially a photographic *photofit* was intended. The term *photofit* is still in use in the U.S., whereas in the U.K. the more general term *composite* is preferred. Old computerized systems for composites include E-FIT, PROfit (CD-FIT), and Mac-A-Mug Pro. An advanced tool is CRIME-VUs. See [Section 8.2.2](#).

In non technical language, especially in the media, the differences between the various kinds of pictorial or photographic support for suspect identification tend to be blurred, and also the status of the person sought is imprecise. For example, in Italian the media would refer to *fotografie di pregiudicati*, e.g., literally, “photographs of ex-cons”, whereas in Israeli Hebrew mug shots are often referred to informally as *foto-rétsakh*, i.e., literally, “photo-murder”.⁵ Such descriptors are grossly imprecise. (The Hebrew for “composite” is *klasterón*.)

⁵ I received the following (impressionistic) explanation for how the term *foto-rétsakh* came into being – denoting not only mugshots, but also such passport-sized photographs that are perceived to resemble the police’s mugshots. In the 1940s and 1950s, one method of shooting facial photographs

Such images are sometimes made public, not only in order to track down a person wanted on suspicion of a crime, or some youngster or old and forgetful person who has disappeared. Police may release an artist's impression of the face of a dead person they want to identify. That is to say, they already have him or her, but are unaware of that person's identity. The same may apply to a sufferer of amnesia.

Compusketch A system for assisting a witness in approximating his or her description of the facial features of a criminal suspect. It is a computerised version of the Photofit process. See [Section 8.2.2](#).

Computational forensics Computer techniques subserving any discipline within forensic science. See Frank and Srihari (2008). *Computational forensics* should not be mistaken for **computer forensics** (q.v.).

Computer crime Crime that exploits the vulnerability of computer systems, and takes place through breaches of *computer security*. See [Section 6.2.1.5](#).

Computer forensics Another name for *forensic computing*. Also see **digital forensics**. See [Section 6.2.1.5](#). This is quite different from what is meant by **computational forensics** (q.v.).

Computer investigation Actions undertaken, either by the police or by an organisation that experienced computer crime, in order to identify suspect perpetrators as well as in order to find out they managed to evade computer security measures.

Computer security A discipline that provides a preventative response to *computer crime*.

Confabulation A defect of testimony: the witness is also inferring, not merely reporting. *Confabulation* in depositions may occur because witnesses discussed their recollections, and this had an effect on what they later think they remember. In particular, if it was two eyewitnesses who saw the same event and then discussed it, this may influence what they later claim to remember; this is sometimes referred to as *memory conformity*.

Confirmationism An approach to questioning witnesses, which seeks to confirm a given account. It is a flawed approach, and Voltaire lampooned it. *Confirmation bias* as occurring in the police interrogation rooms, see e.g. Kassin et al. (2003), Meissner and Kassin (2002), and Hill et al. (2008).

Confrontation right The right of a defendant to confront his accusers in court.

Consistency question In argumentation studies, Walton's (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008, pp. 381–382). See s.v. [Expert opinion](#), [Appeal to](#) above. The expert source is *E*; the subject domain is *S*;

was to have a man who had to be photographed introduce his head into a hole in a black curtain. The resulting photograph supposedly appeared to portray a murderer. But perhaps this explanation I was given in 2010 is a rationalisation *ex post facto*, which makes it appear as though it was a passport-sized photograph that was initially called *foto-rétsakh*. More plausibly, the term denoted mugshots *ab initio*, and it was only by metaphorical interpretation of the thing denoted (i.e., the *signified*, as opposed to the *signifier*, which is the word itself), that the term was also applied by some to passport-sized photographs with a dark backdrop (especially of an old kind), if that.

and A is a proposition about which E claims to be true (or false). The consistency question is: “Is A consistent with what other experts assert?”. It is articulated in two subquestions: “Does A have general acceptance in S ?”; “If not, can E explain why not, and give reasons why there is good evidence for A ?”.

Contrary-to-duty obligations A norm is violated, yet there are norms about how to deal with such a situation of violation. S.v. **time** in this Glossary, we consider some procedural constraints on temporal sequence at a trial, and how they can be allowed sometimes to be violated. Wishing to model this in terms of AI techniques, it makes sense to resort to techniques concerning contrary-to-duty obligations. Contrary-to-duty obligations are sometimes called *reparational obligations*, when the concept is concerned (as it often has been in the scholarly work of logicians within research into deontic logic) as *remedial obligation* for a state of affairs contravening a previous obligation; see, e.g., Parent (2003).

A related example is that known by philosophers as the one of the *gentle murderer*: one shall not murder, but if he does, let him do it gently; “gentle murder” is also called the *Forrester paradox* (Forrester, 1984). Research on contrary-to-duty obligations is related to *conditional obligations*; on the latter, see Chellas (1974), and on the relation between the two classes of obligations, see Tomberlin (1981). Horty (1993) deals with both classes in terms of nonmonotonic deontic logic.

For a discussion of contrary-to-duty obligations (or *contrary-to-duty imperatives*), see e.g. Carmo and Jones (2002), which is an encyclopedic entry, as well as Chisholm (1963), Åqvist (1967), Hage (2001), Carmo and Jones (1996), Prakken and Sergot (1996, 1997), and Governatori and Rotolo (2002). An approach that resorts to *Petri nets* (a graph representation expressing constraints on temporal precedence) for the representation of deontic states (i.e., states of obligation), including contrary-to-duty obligations, has been proposed in Raskin et al. (1996). By the same team, the paper by van der Torre and Tan (1999) is on contrary-to-duty reasoning. Ursu and Zimmer (2002) are concerned with the representation of duty and contrary-to-duty statements, in computer-aided design tools of the class of critiquing intelligent design assistants. Examples given by Ursu and Zimmer in section 4, of a *secondary* (contrary-to-duty) obligation that comes into effect when the *primary obligation* is violated, include: “Preferred design: uniform wall thickness should be used”, yet: “When unavoidable” – i.e., when walls must have a different thickness – “transition from one wall thickness to another should always be as smooth as possible”. Or then this other example: “There must be an alternative escape route from all parts of the building. However, in the following situations a single route is acceptable”.

Convince Me A computer tool for supporting argumentation (Schank & Ranney, 1995). It is one of the tools reviewed in van den Braak et al. (2006) It is based on Thagard’s Theory of Explanatory Coherence (e.g., Thagard, 2000a). The arguments consist of causal networks of nodes (which can display either evidence or hypotheses), and the conclusion which users draw from them. *Convince Me* predicts the user’s evaluations of the hypotheses based on the arguments produced, and gives a feedback about the plausibility of the inferences which the users draw.

Coplink A tool for criminal intelligence analysis, developed for the Tucson police at the University of Arizona, and performing *network link analysis*. See [Section 6.2.5](#).

Corpus (plural: **corpora**) A collection of documents. For example, corpora are what *information retrieval* tools and *text mining* search automatically. See [Section 6.1.9](#).

Corroborative evidence “Corroborative evidence is that which independently tends to support or confirm other evidence” (Osborne, 1997, p. 303). “The general rule [in England] has always been that evidence does not require corroboration and that the court may act on the uncorroborated evidence of one witness alone, however serious the charge” (ibid.). Still in English law:

Until 1995, however, there were individual classes of cases where the type of evidence, or the type of witness, were deemed inherently “suspect” in some way so as to require extra caution from a court before it considered its verdict. The law on corroboration evolved in a haphazard and piecemeal way and was burdened with difficult technicalities. Classically, three kinds of witness were thought to be sufficiently suspect to require corroboration of their evidence before there could be a conviction, namely children, accomplices, and victims of a sexual offence. There were, in addition, rules which indicated that corroboration should generally be looked for in any case where a witness might have some personal motive for wishing to secure the conviction of the accused, for example someone who had a grudge against the accused, or who might himself have fallen under suspicion of the crime in question. In these cases, a judge would have to remind the jury, in very technical terms, of the risk of convicting on the evidence of the “suspect” witness and then go on to describe what items of evidence could have the technical quality of corroboration on the particular facts of the case. Judges were notoriously prone to get aspects of corroboration wrong, either by directing the jury with insufficient force about the risks of acting without corroboration, or by misidentifying items of evidence in the case which they might say were technically capable of amounting to corroboration but which in fact lacked the necessary quality (ibid.).

Reform abolished the requirement for corroboration of evidence from given categories of witnesses, and also the requirement for the judge to give a warning to the jury ceased to be mandatory and became discretionary (ibid., pp. 304–305).

Criminal trial (as opposed to *civil trial*). In Anglo-American jurisdictions, the sequence is as follows. Initially, there is the *indictment*. Then, the accused is asked to plea *guilty* or *not guilty*. If the defendant pleads guilty (which typically is because of a *plea bargain*), the court hears the facts from the prosecution (with no need to present evidence), then the defence may intervene, and finally the sentence is given. If the defendant pleads not guilty, the case will have to be prosecuted. There is an adjournment to an agreed date. Then the adjourned hearing takes place, following *adversarial* lines (as typical of the *common law* system of Anglo-American jurisdictions). There is the prosecution’s opening speech. Then the prosecution calls witnesses. For each prosecution witness, there is an *examination in chief* of the witness on the part of the prosecution, followed by *cross-examination* of the witness by the defence, and sometimes there is *re-examination* on the part of the prosecution. Then there is the close of the prosecution case. (Now the defence may submit that there is no call to answer. If the court accepts this, then the defendant is discharged. Otherwise:) Defence calls

witnesses. For each one of the defence witnesses, there is an *examination in chief* of the witness by the defence, then *cross-examination* on the part of the prosecution, and sometimes *re-examination* by the defence. Then there is the defence's closing speech to the bench. Now the prosecution may have one more speech, but if this is the case, then the defence must have the last word. Now the factfinders (either lay magistrates, i.e., jurors, or one or more stipendiary magistrates, e.g., trained, professional judges) retire to consider their decision. (if there is a jury, the jury receives instructions from the judges before it retires.) Then the magistrates return and give the verdict (and state no reason). If the verdict is *not guilty*, then the defendant is discharged. If the verdict is *guilty*, then the court hears the facts from the prosecution (with no need to present evidence), and next the defence may intervene. Finally, the sentence is given. See *utility*, and *beyond a reasonable doubt*.

CRIME-VUs A project which produced EvoFIT (under the lead of Charlie Frowd), a computer graphic tool for suspect identification, and validated it with techniques from experimental psychology. The project was conducted at the University of Central Lancashire in Preston, and the Faces Lab of the University of Stirling, Scotland. The approach combines facial composites, sketches, and morphing between facial composites. See [Section 8.2.2.4](#).

Cross-examination Questioning of one of the parties, or of a witness called by one of the parties at a trial, by the other party's lawyer. See [examination](#). During cross-examination, not always questions are direct. Implication and innuendo are often effective. By accumulating details, it is in their *final statement to the court* (also called *final argument*, or more often *closing arguments*) that lawyers propose an account that puts facts in relation to each other, make characterisations, and draw conclusions.

CSI Crime scene investigation.

Daedalus A tool for supporting the activities of the *sostituti procuratori* (examining magistrates and then prosecutors) in the Italian judiciary. Developed by Carmelo Àsaro. A related tool is *Itaca*. See [procedural-support systems](#), and [Section 4.1.3](#).

DART A tool for supporting argumentation (Freeman & Farley, 1996), which was applied to legal situations also by Gulotta and Zappalà (2001). See [Section 3.7](#).

Dead Bodies Project A project (Zelevnikow & Keppens, 2002, 2003; Keppens & Schafer, 2003a, 2004, cf. 2005, 2006) intended to help at *inquests* aiming at ascertain the causes of death, when *prima facie* a crime cannot be ruled out. See [Section 8.1](#).

Decision tree A conditional structure of flow control. Decision trees (as well as IF/THEN rules) are automatically extracted from databases by *machine-learning* tools. Several machine-learning commercial products that primarily produce decision trees were described by Mena (2003, section 7.9, pp. 221–229):

- AC (<http://www.alice-soft.com>)
- Attar XperRule (<http://www.attar.com/>)
- Business Miner (<http://www.businessobjects.com>)

- C5.0 (<http://www.rulequest.com/>), also a rule-extractor; for especially large databases (its algorithm is also used in SPSS's Clementine)
- CART (<http://www.salford-systems.com>), also a rule-extractor; very powerful and accurate, but relatively slow, and for numeric data only
- Cognos Scenario⁶
- Neurosciences aXi Decision Tree⁷
- SPSS Answer Trees⁸
- as well as several free decision tree software tools.⁹

Deafeasibility Carbogim et al. (2000) presented a comprehensive survey of defeasible argumentation. In this book, we have dealt with *defeasibility* in Sections 3.3 and 3.9.1. “Nonmonotonic reasoning [q.v.], because conclusions must sometimes be reconsidered, is called *defeasible*; that is, new information may sometimes invalidate previous results. Representation and search procedures that keep track of the reasoning steps of a logic system are called *truth maintenance systems* or TMS. In defeasible reasoning, the TMS preserves the consistency of the knowledge base, keeping track of conclusions that might later need be questioned” (Luger & Stubblefield, 1998, p. 270).

Defence In court, and previously during the preparations for the trial, the formal standing (and actions taken in that role) of the accused (the defendant) and of his lawyers on his behalf (but he may be representing himself, without resorting to a lawyer).

Defendant The party against whom the *plaintiff* (who in particular may be the *prosecution*) turns to the courts for adjudication. In some kinds of trial, the names are *applicant* for the plaintiff, and *respondent* for the defendant.

Dempster-Shafer theory In statistics and in artificial intelligence: “Dempster-Shafer theory [Shafer, 1976] has been developed to handle partially specified domains. It distinguishes between uncertainty and ignorance by creating belief functions. Belief functions allow the user to bound the assignment of probabilities to certain events, rather than give events specific probabilities. Belief functions satisfy axioms that are weaker than those for probability theory. When the probabilistic values of the beliefs that a certain event occurred are exact, then the belief value is exactly the probability that the event occurred. In this case, Dempster-Shafer theory and probability theory provide the same conclusions” (Stranieri & Zeleznikow, 2005a).

Deontic, deontology Pertaining to duty and permissibility. Deontic logic has operators for duty. Deontological arguments appeal to principles of right or wrong, ultimate (rather than *teleological*) principles about what must, or ought or must not or ought not to be or be done.

⁶ <http://www.cognos.com/products/scenario/index.html>

⁷ <http://www.neurosciences.com>

⁸ <http://www.spss.com/spssbi/answertree/>

⁹ Such free software tools are linked to from the data mining portal www.kdnuggets.com

Deontic logic A modal logic of obligation and permission. Established in the 1940s. It was especially prominent in AI & Law research from the 1970s. See, e.g., Nissan (2008a), Åqvist (1984, 1986), Jones and Sergot (1992). Also see **contrary-to-duty obligations**.

Digital anti-forensics Strategies to evade computer forensic investigations, as well as ways to exploit critical failures in computer forensics software or in the reliability of computer security systems. [Section 6.2.1.5](#).

Digital forensics A discipline that provides techniques and strategies for tackling crime involving digital media.

Digital forgeries Forged items involving digital media, such as images. They are to be detected by *digital forensics*, or in particular *digital image forensics*. See [Section 8.2.5](#).

Digital image forensics See *image forensics*.

Discretion The faculty of making a choice, rather than being compulsively directed. In the legal context, there is e.g., **prosecutorial discretion** (q.v.). But there also is *judicial discretion*. Duke University's George Christie began 'An Essay on Discretion' (Christie, 1986) by stating (ibid., p. 747):

Few terms have as important a place in legal discourse as "discretion". Despite the importance of the term, however, those who use it do not agree on its meaning. It is universally accepted that discretion has something to do with choice; beyond this, the consensus breaks down.

If there is little agreement about the meaning of discretion, there is even less agreement about its desirability. Indeed, participants in the judicial process and observers of that process take a schizophrenic view of discretion. Sometimes they praise it and sometimes they execrate it.

In particular, there is a distinction between *primary discretion* and *secondary discretion* (ibid., pp. 747–748):

In the judicial context, [Maurice] Rosenberg distinguishes between primary discretion and secondary discretion. Primary discretion arises when a decision-maker has "a wide range of choice as to what he decides, free from the constraints which characteristically attach whenever legal rules enter the decision process." Used in this sense, discretion can mean simply that a person has the authority to decide. Courts, judges, and legal scholars often use the term *discretion* in this sense, referring simply to authority to decide, or unconstrained choice.

That is Rosenberg's *primary discretion*. Moreover (Christie, ibid., pp. 748–749); the brackets are Christie's):

Rosenberg contrasts the primary form of discretion with "the secondary form, [which] has to do with hierarchical relations among judges."

The secondary form of discretion enters the picture when the system tries to prescribe the degree of finality and authority a lower court's decision enjoys in the higher courts. Specifically, it comes into full play when the rules of review accord the lower court's decision an unusual amount of insulation from appellate revision. In this sense, discretion is a review-restraining concept. It gives the trial judge a right to be wrong without incurring reversal.

In the limiting case, the choice made by a person exercising primary discretion is by definition the correct choice. The correctness of the choice cannot be attacked because there are no external criteria on which to base such an attack. When secondary discretion is involved, one can attack the correctness of the choice, although the authority of the person to make that choice cannot be attacked. Thus secondary discretion involves the authority to make the wrong decision.

Christie mentions two examples Rosenberg gave, from college football, and notes: “In both cases, everyone agreed that the officials were clearly wrong; but, in both instances, no redress for those errors was possible” (ibid., p. 749). Rosenberg however was “concerned with the effect of secondary discretion on appellate courts’ treatment of certain contested rulings of trial courts, particularly procedural rulings such as denials of motions for new trials” (Christie, ibid.). However, as “in any hierarchically organized bureaucracy, there are limits to the amount of perverseness that superiors are prepared to tolerate in their subordinates” (ibid.), practically “Rosenberg’s secondary discretion – the authority to make wrong decisions – usually boils down to the authority to make decisions to which reviewing authorities will accord a presumption of correctness.” (ibid.) Nevertheless: “The reviewing authority will intervene only if the initial decisionmaker *abused* his discretion” (ibid.). Christie conceded (ibid., fn 12):

Behind this linguistic formula, of course, lie the difficult questions: How perverse must the initial decision be before it will be said to be an abuse of discretion? And are there any objective criteria for deciding degrees of abuse?

Christie then proceeded to remark about when the two kinds of discretion merge, and what the difference is (ibid., 749–750):

A cynic might contend, however, that Rosenberg’s notion of secondary discretion merges with what he calls primary discretion when an inferior is given the authority to make wrong choices that cannot be overturned. There is no practical difference between the authority to make whatever decision one chooses and the authority to make decisions that will be enforced even if they are felt to be wrong. Indeed, primary and secondary discretion do sometimes seem to merge at the edges, but one clear distinction exists – different types of criticism can be leveled at decisions made under different types of discretion.

Also consider *strong discretion*: “According to Dworkin, strong discretion characterises those decisions where the decision-maker is not bound by any standards and is required to create his or her own standards” (Stranieri & Zeleznikow, 2005a, Glossary). Stranieri and Zeleznikow (2005a) also explained:

[Dworkin 1977] presents a systematic account of discretion by proposing two basic types of discretion, that he called strong discretion and weak discretion. Weak discretion describes situations where a decision-maker must interpret standards in her own way, whereas strong discretion characterises those decisions where the decision-maker is not bound by any standards and is required to create his or her own standards. [MacCormick, 1981] does not dispute this conceptualisation but contends that Dworkin’s distinction between typologies is one of degree and not of type.

Discretionary As opposed to *mandatory*. In particular, as applied to judicial decision-making: what is up to the judge to decide, unfettered by mandatory

rules. See [Section 4.2.5](#). However, see the entry for **discretion** above. Kannai, Schild, and Zeleznikow (2007) offer an artificial intelligence perspective on legal discretion. Meikle and Yearwood (2000) are concerned with the provision of support for the exercise of discretion, and how the need to avoid the risk of adversely affecting it when using a computer tool, inspired the structural design of EMBRACE, a decision support system for Australia's Refugee Review Tribunal. Leith (1998) has warned about the risks, with AI applications to law, that judicial discretion be restricted, if computer tools come to be involved in the judicial decision-making process.

Meikle and Yearwood (2000) classify legal decision-making in four quadrants, according to two operational dimensions: "One dimension is the extent to which a system should either be an "outcome predictor" (a highly convergent aim) or should give access to diverse resources about the issues of interest (a highly divergent aim). This is the *predictive-descriptive* dimension. The other is the extent to which a system either needs to support discretion (by permitting complete autonomy, perhaps because the domain has no constraints) or needs to support weak discretion (by permitting only that allowable within prescribed constraints). This is the *strong-weak discretion* dimension" (Meikle & Yearwood, 2000, p. 101).

It was proposed that EMBRACE, as well as Bench-Capon's PLAID (Bench-Capon & Staniford, 1995), may be placed in the quadrant characterised by strong discretion and descriptiveness (instead of predicted outcome, which when there is strong discretion lets the user override the prediction either partly or altogether). We argue that the evolution of *Daedalus* is from weak to strong discretion (provided that validation steps are safeguarded), and that the approach is descriptive, whereas predictiveness is avoided out of a concern to ensure fairness to the suspects.

Also see Lara-Rosano and del Socorro Téllez-Silva's article (2003) on fuzzy¹⁰ support systems for discretionary judicial decision making.

Disposition "The word 'disposition' is used to denote a tendency to act think or feel in a particular way. The word 'character' may include disposition, or sometimes mean 'general reputation' or merely the question of whether or not the accused has a criminal record" (Osborne, 1997, p. 313). See [evidence of disposition](#).

DNA evidence An important use (yet not the only use) of such evidence is for the purposes of identifying perpetrators. See [Section 8.7.2](#).

Dock identification "An old practice, now disapproved [in England], is the so-called 'dock identification' [. . .] where a witness is asked if the man seen at the scene of the crime is present in court. There will clearly be a tendency to look at the man in the dock and pick him just because he is there in that position" (Osborne, 1997, p. 305). "Obviously there is no theoretical objection to a witness testifying that the accused is the man he saw commit the crime. This is direct evidence by a first-hand observer. [Yet], where this happens (i.e. where the witness sees the accused at the trial for the first time after the offence) it is known as a 'dock

¹⁰ Fuzzy logic is the subject of [Section 6.1.15](#) in this book.

identification' and is frowned on except in exceptional circumstances" (ibid.). A remedy is *identification parades*, for which, see [Section 4.5.2.3](#).

Doctrine of chances The odds that a new event is just a coincidence, in view of similar past events. In legal scholarship, it is discussed along with **uncharged conduct** as being a kind of **character evidence**, and in particular with the somewhat different concept of **similar fact evidence** (see s.vv.). Sometimes an expert witness would err clamorously with the statistics: "Forensics and expert witness investigations currently have a high profile in the media, principally in the field related to medical practitioners. The discrediting of evidence provided in the notorious Sally Clark case by Professor Sir Roy Meadows, has made many 'experts', not only medical, but also those operating in different professions, stop and take stock of how we undertake expert witness work, be it within the realm of Civil or Criminal Law" (Smith, 2006). In Britain, Sally Clark, a lawyer by profession, lost her apparently healthy firstborn son, aged 2½ months, to sudden death in December 1996, and then, in January 1998, also her second baby, aged two months, in similar circumstances. She was convicted in November 1999 (by a 10–2 majority) of smothering her two babies; she was sentenced to prison for life, and spent years in prison after her second baby died, in circumstances similar to the death of her firstborn son. Meadows had claimed that there was only one chance in 73 million for this to be a coincidence (no witness qualified in statistics was in court); in so claiming, the Leeds professor was shockingly inaccurate, as the death of siblings is not necessarily statistically independent. Eventually, the mother was released and the expert witness disgraced. After a while, he was reintegrated in the medical profession, and shortly afterwards Mrs. Clark died in her early forties. (In another British case, a young woman was able to refute a similar charge, by bringing evidence that her maternal lineage, traced back to India, had a story of infant death.) A prominent forensic statistician, Philip Dawid, has discussed the Sally Clark case ([2003] EWCA Crim 1020) in Dawid (2004b), which is highly readable even for ones with little mathematical background. A more technical paper is Dawid (2001b). Also see Dawid (2005b, Sec. 4.3 and in particular, Sec. 4.3.1). Already in January 2000, Stephen Watkins' editorial, 'Conviction by Mathematical Error?', was published in the *British Medical Journal*. Dawid finds that both Meadows' and Watkins' calculations were flawed. He was an expert witness in statistics for the defence at the appeal hearing.

Arguably the expert witness's testimony against Sally Clark had been influenced by a case in the United States, in which several babies of the same mother had been believed to have died of cot death, yet she was eventually convicted of having killed them herself.

The following quotations are quoted from Nissan (2001c, section 3: 'The Doctrine of Chances & Uncharged Conduct'); at the time, I was kindly referred to these by Peter Tillers (p.c., 9 Feb. 2000). In the *New York Times*, George Judson (1995) reported from Owego, N.Y., that a defendant, who was a "48-year-old woman accused of smothering her five infant children a quarter of a century ago, was convicted of their deaths today in Tioga County Court. In 1972, a leading medical journal cited the deaths of two infants from rural New York, 'MH' and

'NH', as compelling evidence that Sudden Infant Death Syndrome ran in families. Today, a jury found that the babies [. . .] were murdered by their mother, as were two brothers and a sister before them". The defendant "had confessed to state troopers last year that she had smothered her babies", "a chilling and detailed confession", yet according to her she "had testified that she made the confession only to end hours of questioning by state troopers, saying that her children had simply stopped breathing, sometimes even as she fed them" (ibid.). According to the confession, the babies crying spells were the trigger; in contrast, she "suggested in her confession", the boy she and her husband adopted afterwards is alive as "unlike the five others, he had survived his crying spells because his father was out of work and at home during his infancy, and she had not been left to cope with the child alone". The five murder verdicts are of murder by depraved indifference (i.e., without the conscious intention to kill). The Hoyt case from upstate New York "was striking [. . .] also for the family's place at the center of research" which at the time was prominent in promoting a medical theory on cot deaths (ibid.). "But to a forensic pathologist in Dallas, [. . .] the death of five children in one family from SIDS was statistically impossible, and she believed that [the aforementioned] research was leading pediatricians to disregard danger signs within some families" (ibid.). Benderly (1997) approaches the effect of the Hoyt diagnosis of old and recent multiple murder verdicts from the viewpoint of scientific error and its effects on subsequent research. Williams (1996), referring to the Hoyt case, pointed out: "Criminal defense lawyers know how difficult it is to overcome a confession in a criminal trial, for juries find it hard to fathom why anyone would falsely implicate oneself". "Confessions are usually used as ground truth but are not 100 per cent reliable" (Vrij, 1998a, p. 89); even "people considered as guilty by virtue of a confession may actually be innocent, as some innocent people do confess" (ibid.).

Prof. Tillers also kindly referred me (p.c., 9 Feb. 2000) to the "famous case 'Brides in the Bath'": "Rex v. Smith, 11 Cr. App. R. 229, 84 L.J.K.B.¹¹ 2153 (1915) (husband perhaps drowned a number of wives to recover insurance proceeds; at first sight the drownings were accidental but. . .)". Prof. Tillers also referred me to the news from the *New York Times* of Sunday, March 19, 1995; in the words of the report – from Hot Sulphur Springs, Colorado – "A woman whose 11 marriages earned her the nickname the Black Widow was convicted on Friday of torturing and killing her ninth husband" (NYT, 1995). This particular husband had "hired a private investigator when he began to suspect that she was lying about how many times she had been married", and had intended to sue her for fraud and emotional distress. She was divorced from all previous husbands, except the eighth (her marriage to the ninth was annulled for that very reason), and "except for an elderly man who died of natural causes", and this includes her having divorced (twice) from "the lawyer who helped her avoid questioning in the 1972 shooting death of her third husband". In closing arguments, defense

¹¹ *L.J.K.B.* stands for *Law Journal Reports, Kings Bench.*

lawyers denied there was any physical evidence to dismiss the alibi of the two defendants (the woman and her boyfriend, also convicted, had claimed they had been away, camping). As to the admissibility of character evidence, it is remarkable that the two defendants were convicted even though “[t]estimony about her previous marriages was not allowed during her trial” (ibid.).

Moreover, Prof. Peter Tillers kindly sent me an article by a professor of Law from the University of California at Davis, Edward Imwinkelried (1990), a paper which “has an extensive discussion of the American view of the ‘doctrine of chances’”. Imwinkelried’s paper, “The use of evidence of an accused’s uncharged misconduct to prove *mens rea*: the doctrines that threaten to engulf the character evidence prohibition”, states: “The admissibility of uncharged misconduct evidence is the single most important issue in contemporary criminal evidence law. The issue has figured importantly in several of the most celebrated criminal trials of our time”. The introduction starts by describing a hypothetical case in which: “The accused is charged with homicide. The indictment alleges that the accused committed the murder in early 1990. During the government’s case-in-chief at trial, the prosecutor calls a witness. The witness begins describing a killing that the accused supposedly committed in 1989. The defense strenuously objects that the witness’s testimony is ‘nothing more than blatantly inadmissible evidence of the accused’s general bad character’. However, at sidebar the prosecutor makes an offer of proof that the 1989 killing was perpetrated with ‘exactly the same *modus operandi* as the 1990 murder’. Given this state of the record, how should the trial judge rule on the defense objection?” (Imwinkelried, ibid.).

Federal Rule of Evidence 404(b), “which is virtually identical to Military Rule 404(b)” (the paper was published in the American *Military Law Review*), “forbids the judge from admitting the evidence as circumstantial proof of the accused’s conduct on the alleged occasion in 1990. [. . .] Thus, the prosecutor cannot offer the witness’s testimony about the 1989 incident to prove the accused’s disposition toward murder and, in turn, use the accused’s antisocial disposition as evidence that the accused committed the alleged 1990 murder”. Yet, the judge is permitted “to admit the evidence when it is relevant on a noncharacter theory”, as “uncharged misconduct evidence ‘may, however, be admissible for other purposes, such as proof of motive, opportunity, intent, preparation, plan, knowledge, identity, or absence of mistake or accident’. In our hypothetical case, the trial judge could allow the prosecutor to introduce the 1989 incident to establish the accused’s identity as the perpetrator of the 1990 killing. If the two killings were committed with the identical, unique *modus operandi*, the uncharged incident is logically relevant to prove the accused’s identity as the perpetrator of the charged crime without relying on a forbidden character inference. Hence, the judge could properly admit the testimony with a limiting instruction identifying the permissible and impermissible uses of the evidence” (Imwinkelried, ibid.).

“Unless the judge clearly explains the law governing stipulations, a juror might suspect that any accused who knew enough about the crime to stipulate to the *mens rea* must have been involved personally in the crime. [. . .] When the question is the existence of the *mens rea*, the prosecutor ordinarily has a much

more compelling need to resort to probative uncharged misconduct evidence. [...] The character evidence prohibition is violated when we permit a prosecutor to rely on the theory depicted in [Imwinkelried's] Figure 2 to justify the admissibility for uncharged misconduct evidence. [...] The courts should admit uncharged misconduct evidence under the doctrine to prove *mens rea* only when the prosecutor can make persuasive showings that each uncharged incident is similar to the charged offense and that the accused has been involved in such incidents more frequently than the typical person. [...]" (Imwinkelried, *ibid.*, quoted the way it is excerpted in the the summary).

Imwinkelried's (1990) stated purpose in his paper "is to describe and critique [...] two lines of authority. The first section of the article discusses one line, namely, the case law advancing the proposition that the first sentence in Rule 404(b) [namely: 'Evidence of other crimes, wrongs, or acts is not admissible to prove the character of a person in order to show action in conformity therewith'] is automatically inapplicable whenever the prosecutor offers uncharged misconduct to support an ultimate inference of mental intent rather than physical conduct. The next section of the article analyses the second line of authority. That line includes the decisions urging that under the doctrine of objective chances, the prosecutor routinely can offer uncharged misconduct on a non-character theory to prove intent. Both lines of authority are spurious, and both represent grave threats to the continued viability of the character evidence prohibition".

Double-counting the evidence If the same item of evidence is then used again to make the evidence weightier, this is an example fo double-counting (Robertson & Vignaux, 1995, section 6.2, p. 95):

Each piece of evidence must be considered only once in relation to each issue, otherwise its effect is unjustifiably doubled. However, this does not mean that once an item of evidence has been used by one decision-maker for one purpose it cannot be used by another decision-maker for another purpose. Thus, the fact that the police have used an item of evidence to identify a suspect does not mean that the court cannot use it to determine guilt.

If a defendant is treated as though his or her guilt were likelier, for the very fact that this suspect is being tried, this is an example of the evidence being double-counted (*ibid.*):

Of course, the court must not use the fact that the accused is in the dock as evidence of guilt and then also consider the evidence produced, since to do so would be to double-count the evidence which led to the arrest and which is also used in court. Wigmore cautioned jurors "to put away from their minds all the suspicion that arises from the arrest, the indictment and the arraignment".

This does not mean that the evidence on which the arrest was made, or on which this suspect was identified and retained in the first place, should be given a lesser weight, in order to compensate (*ibid.*):

Fear of double-counting evidence has misled some about the weight of the evidence which caused the suspect to come under suspicion. A man might be stopped in the street because he is wearing a bloodstained shirt and we are now considering the value of the evidence of the shirt. It has been suggested that because this was the reason

for selecting this particular suspect we should change the way the evidence should be thought about, that it is less useful than if the suspect was arrested on the basis of other evidence.

This is not correct. The power of the evidence is still determined by the ratio of the two probabilities of the accused having a bloodstained shirt if guilty and if not guilty. It is just that there happens to be less evidence in one case than the other. When the suspect is stopped because of a bloodstained shirt there may be no other evidence. When the suspect is arrested on the basis of other evidence and then found to have a bloodstained shirt, the likelihood ratio for the bloodstained shirt is to be combined with a prior which has already been raised by the other evidence. Once again the power of an item of evidence is being confused with the strength of the evidence as a whole.

Doxastic Of or pertaining to belief.

Doxastic attitude An attitude of holding some belief.

Doxastic logic A modal logic of belief. In doxastic logic (or *logic of belief*), belief is treated as a modal operator. A doxastic logic uses Bx to mean “It is believed that x is the case.” Raymond Smullyan (1986) defined several types of reasoners.¹² An *accurate reasoner* never believes any false proposition (modal axiom **T**). An *inaccurate reasoner* believes at least one false proposition. A *conceited reasoner* believes his or her beliefs are never inaccurate. A conceited reasoner will necessarily lapse into an inaccuracy. A *consistent reasoner* never simultaneously believes a proposition and its negation (modal axiom **D**). A *normal reasoner* is one who, while believing p , also *believes* he or she believes p (modal axiom **4**). A *peculiar reasoner* believes proposition p while also believing he or she does not believe p . A peculiar reasoner is necessarily inaccurate but not necessarily inconsistent. It can be shown that a conceited reasoner is peculiar. The converse of a normal reasoner is a *stable reasoner*. If a stable reasoner ever believes that that he or she believes p , then he or she really believes p . A *modest reasoner* never believes $Bp \rightarrow p$ (that is, that believing p entails that p is true), unless he or she believes p . A *timid reasoner* does not believe p (being afraid, as though, to believe p) if he or she believes that believing p entails believing something false. A *queer reasoner* is of type **G** and believes he or she is inconsistent, but is wrong in this belief. A *type G reasoner* is a reasoner of type **4** (see below) who believes he or she is modest.

According to Löb’s Theorem, any reflexive reasoner of type **4** is modest. If a consistent reflexive reasoner of type **4** believes that he or she is stable, then he or she will become unstable: she will become inconsistent. A reasoner is of type **4** if he or she is of type **3** and also believes he or she is normal. A reasoner is of type **3** if he or she is a normal reasoner of type **2**. A reasoner is of type **2** if he or she is of type **1**, and if for every p and q he or she (correctly) believes: “If I should ever believe both p and $p \rightarrow q$ (p implies q), then I will believe q .” A type **1** reasoner has a complete knowledge of propositional logic: he or she sooner or later believes every tautology, i.e., any proposition provable by truth

¹² This was summarised in http://en.wikipedia.org/wiki/Doxastic_logic (to which we are indebted for the concepts in this entry).

tables (modal axiom **N**). If a type 1 reasoner ever believes p and believes $p \rightarrow q$ (p implies q) then he or she will eventually believe q (modal axiom **K**).

A type I^* reasoner is somewhat more self-aware than a type 1 reasoner. In fact, a type I^* reasoner believes all tautologies; his or her set of beliefs (past, present and future) is logically closed under *modus ponens*,¹³ and for any propositions p and q , if he or she believes $p \rightarrow q$, then he or she will believe that if he or she believes p then he or she will believe q .

Dynamic uncertain inference Snow and Belis (2002) analysed “a celebrated French murder investigation” (p. 397), namely, the case of which Omar Raddad was convicted in Nice, in 1994, and then pardoned, the conviction being very controversial (the victim’s body was found with, near it, a sentence accusing Raddad written on the floor, scrawled in the victim’s blood). Snow and Belis (2002) “apply ideas about credibility judgments structured by graphs to the problem of dynamic uncertain inference. By *dynamic*, we mean that assessments of credibility change over time without foreknowledge as to the types of evidence that might be seen or the arguments that the [crime] analyst might entertain over time” (ibid., p. 397), in contrast with such “kind of belief change that occurs” when the possible outcomes of experiments “are typically known before one learns the actual outcomes” (ibid., pp. 397–398).

ECHO A computer tool, based on artificial neural networks, for abductive reasoning, developed by Paul Thagard and first applied to the modelling of reasoning on the evidence in a criminal case in Thagard (1989). See [Section 2.2.1](#).

EMBRACE A decision support system for Australia’s Refugee Review Tribunal.

Entanglement A concept expressing an undercutting move in argumentation, in Verheij’s (1999, 2003) *ArguMed* computer tool for visualising arguments (see [Section 3.7](#)). It was described by Verheij (1999, 2003). In the words of Walton et al. (2008, p. 398):

In *ArguMed*, undercutting moves, like asking a critical question, are modelled by a concept called entanglement. The question, or other rebuttal, attacks the inferential link between the premises and conclusion of the original argument, and thereby requires the retraction of the original conclusion. On a diagram, entanglement is represented as a line that meets another line at a junction marked by an X.

Entrapment Such circumstances of obtainment of evidence that the perpetrator was deceived, by being allowed or even enabled or incited to commit an offence, with law enforcement personnel present or even participating.¹⁴ Osborne (1997, p. 298) remarked that in England, some cases

clearly established that, even when policemen acting in plain clothes and participating in a crime go too far and incite criminals to commit offences which would otherwise not have been committed, the law of evidence will not be used to discipline the police.

¹³ In logic, *modus ponens* states that from p being true and $p \rightarrow q$, we can deduce that q is true. As to $p \rightarrow q$, this is a *rule* (also called *clause*) such that “If p is true, then q is true”; q is a *logical consequence* of p .

¹⁴ See in the notes of [Section 4.5.2.1](#) in this book.

There is no defence of “entrapment” known to English law and the law of evidence could not be used to create such a defence by the device of excluding otherwise admissible evidence. Where police had gone too far, the question of their misconduct will be dealt with in police disciplinary proceedings; but insofar the accused was concerned, entrapment would only be relevant to mitigate the sentence imposed, not to the question of admissibility.

Epistemic paternalism According to philosopher of knowledge Alvin Goldman (1991), the attitude by which the rules of evidence prescribe that the jurors will not be provided with some of the evidence. See Section 4.3.2.2.

Evidence-based crime prevention Crime prevention policy and practice as ideally being based on scientific evidence from criminology within the social sciences, rather than the crime policy agenda being driven by political ideology and anecdotal evidence (Farrington, Mackenzie, Sherman, & Welsh, 2006). *Evidence* in the phrase under consideration is not to be understood as *legal evidence*.¹⁵

Evidence discourse Presenting or discussing the evidence, and in particular legal evidence, especially from the viewpoint of discourse analysis. Other disciplinary viewpoints are possible. In an article in a law journal, a scholar from the University of Bristol, Donald Nicolson (1994), discussed epistemology and politics in mainstream evidence discourse, from the viewpoint of critical legal theory, “in relation to three core concepts: truth, reason and justice” (ibid., p. 726). “The main contention of this article is that, given both its intellectual ancestry and political function, mainstream discourse of evidence can best be understood as a form of positivism. This ‘fact positivism’ is to the study and practice of fact-finding what legal positivism is to the study and practice of law. Both encourage the view that the task of lawyers and adjudicators is neutral and value-free. Both focus attention on logic, whether of rules or of proof, and away from the inherently political and partial nature of law and facts” (ibid.).

Evidence, theory of juridical Conventional, vs. the one advocated by Allen (1994), whose “theory of juridical evidence is designed to replace the conventional theory – that the necessary and sufficient conditions of evidence are provided by the rules of evidence – with the thesis that evidence is the result of the interaction of the intelligence and knowledge of the fact finder with the sum of the observations generated during trial. If the conventional theory is true, the rules of evidence should provide a complex and relatively thorough statement of the grounds for the admission of evidence. They do not”, as “The general rules of relevancy provide virtually no comprehensible criteria for admission and exclusion”, whereas Allen’s own theory of juridical evidence provides a set of necessary and sufficient conditions for admissibility (Allen, 1994, p. 630).

Evidence, law of The set of rules that regulate which evidence should be admissible in court. The following is quoted from my own discussion (Nissan, 2001c) of Twining (1997):

¹⁵ Of course, evidence matters for various disciplines. For example, in the paper collection *Evidence*, edited by Bell, Swenson-Wright, and Tybjerg (2008), there are chapters on evidence in law, history, or science.

William L. Twining's 'Freedom of proof and the reform of criminal evidence', relevant for common law, is quite valuable because of the depth vision afforded by the author's charting recent and broader trends of legal theory in Anglophone countries. To Twining, the critics of the common law of evidence, recommending simplification and reduction in scope of its rule, "have won the argument, albeit in a slow and piecemeal fashion. One result is, as I have argued elsewhere, that the common law of evidence is much narrower in scope and of much less practical importance than the discourse of commentators, educators and practitioners has typically suggested" (441). A second trend, "which has proceeded much further in England" than in the U.S. (442), "has been the disaggregation of 'The Law of Evidence' into several bodies of law: Criminal Evidence, Civil Evidence and, increasingly, rules of evidence in tribunals, arbitration and other fora are treated as distinct" (442). "A further result of this trend has been a growing recognition that problems of proof, information handling, and 'evidence' arise at all stages of legal processes" (443). [...] In *Preliminary Treatise of Evidence at Common Law* (1898), "a Harvard scholar, James Bradley Thayer, advanced an interpretation of the law of evidence which has been accepted by most commentators as the classic statement of the modern common law" (Twining: 450), and based on two principles (*ibid.*, from Thayer: 530): "That nothing is to be received which is not logically probative of some matter requiring to be proved" (the exclusionary principle), and: "That everything which is thus probative should come in, unless a clear ground of policy or law excludes it" (the inclusionary principle). In Wigmore's and others' reception, rules excluding or restricting the use of admitted evidence are either intended to promote rectitude of decision (avoiding unreliability or alleged prejudicial effect), these being Wigmore's "rules of auxiliary probative policy"; or, instead – these being exclusionary "rules of extrinsic policy" – they "give priority to other values over rectitude of decision" (Twining: 450). As per Twining's "interpretation, the Thayerite view is that the common law of evidence is a disparate series of exceptions to a principle of free proof" (Twining: 453), it being "broadly true that surviving English law of evidence conforms to the Thayerite model" (463).

Evidence of character See [character evidence](#).

Evidence of disposition A category of evidence that fits into the broader category of *evidence of disposition and character*, and consists of evidence that a particular person has a tendency to act, think, or fell in a particular way. "Evidence of disposition is in general inadmissible for the prosecution both because it is not necessarily logically relevant to the issue of the accused's guilt of the offence with which he is now charged and also because it is clearly highly prejudicial to the accused for the jury to be told of his previous disposition. The risk is that the average jury will lose sight of everything else in the case apart from the striking revelation of the accused's bad character" (Osborne, 1997, p. 313), and if the defendant has convictions for "crimes in the past that are notoriously unpopular with the public", there may "be a tendency in laypersons to wish to punish the accused again for his former crimes whatever his guilt of the present offence" (*ibid.*). Moreover, "drinking and quarrelling are not per se crimes" (*ibid.*), yet they are disposition, and using such traits of the accused in court is not admissible: in England, "evidence of the misconduct of the accused on another occasion *may not be given if its only relevance* is to show a general disposition towards wrongdoing or even a general disposition to commit the type of crime of which he is now accused" (*ibid.*). "The exception to the general rule is the case of so-called 'similar fact' evidence" (*ibid.*). See [similar fact evidence](#). Moreover, an

exception to the inadmissibility of evidence of bad character or disposition of the accused in a criminal case, is that the prosecution has the right to cross-examine in order to obtain such evidence, and the right to adduce such evidence, if the defendant has claimed good character. The prosecution has the right of rebuttal.

Evidence of opinion The kind of evidence provided by an *expert witness*, whereas in contrast: “The general rule is that a witness may only testify as to matters *actually observed* by him and he may not give his *opinion* on those matters. The drawing of inference from observed facts is the whole function of the trier of fact, i.e., in a criminal case the jury” (Osborne, 1997, p. 333) in countries where criminal cases are adjudicated at *jury trials* rather than by trained judges at *bench trials*.

Evidence, requirement of total A principle in the philosophy of science. See Section 4.3.2.2. There exist a weak and a strong version:

(W-RTE) A cognitive agent *X* should always fix his beliefs or subjective probabilities in accordance with the total evidence in his possession at the time.

(S-RTE) A cognitive agent *X* should collect and use all available evidence that can be collected and used (at negligible cost).

There also is a “control” version, formulated but rejected by Alvin Goldman (1991):

(C-RTE) If agent *X* is going to make a doxastic decision concerning question *Q*, and agent *Y* has control over the evidence that is provided to *X*, then, from a purely epistemic point of view, *Y* should make available to *X* all of the evidence relevant to *Q* which is (at negligible cost) within *Y*’s control.

In a social or legal context, the latter principle is improper, because harmful experimentation on human, as well as invasion of privacy, are objectionable. *Exclusionary rules of evidence* are another such example that the *requirement of total evidence* does not apply. Goldman calls such aspects of the philosophical discussion knowledge *social epistemics*. See Section 4.3.2.2.

Evidence, theory of “The distinction between the structure of proof and a theory of evidence is simple. The structure of proof determines what must be proven. In the conventional [probabilistic] theory [which Ron Allen attacks] this is elements to a predetermined probability, and in the relative plausibility theory [which Ron Allen approves of] that one story or set of stories is more plausible than its competitors (and in criminal cases that there is no plausible competitor). A theory of evidence indicates how this is done, what counts as evidence and perhaps how it is processed” (Allen, 1994, p. 606).

Evidential burden See **Burden, evidential**.

Evidential computing Another name for *forensic computing*.

Evidential damage doctrine A doctrine advocated by Ariel Porat and Alex Stein’s *Tort Liability Under Uncertainty* (2001). It proposes to shift the *persuasion burden* (i.e., the *burden of proof*) to the defendant, in such cases that a tort plaintiff cannot adequately prove his or her case (and would currently lose the case) because the defendant’s wrongful actions impair the plaintiff’s ability to prove

the facts underlying the plaintiff's lawsuit for damage (any damage actionable in torts). Such situations that would fall under the evidential damage doctrine, include any action in which the defendant's negligence is established, but causation is indeterminate. For example, toxic exposure, or environmental torts, or such medical malpractice cases in which the doctor was negligent but the patient had a preexisting condition.

Evidentialism In epistemology (the philosophy of knowledge), "a thesis about epistemic justification, it is a thesis about what it takes for one to believe justifiably, or reasonably, in the sense thought to be necessary for knowledge" (Mittag, 2004). Evidentialism is defined by this thesis about *epistemic justification*:

(EVI) Person *S* is justified in believing proposition *p* at time *t* if and only if *S*'s evidence for *p* at *t* supports believing *p*.

Mittag points out (ibid.): "Particular versions of evidentialism can diverge in virtue of their providing different claims about what sorts of things count as evidence, what it is for one to have evidence, and what it is for one's evidence to support believing a proposition". What is evidence, for evidentialism? Mittag explains:

Evidence for or against *p* is, roughly, any information relevant to the truth or falsity of *p*. This is why we think that fingerprints and DNA left at the scene of the crime, eye-witness testimony, and someone's whereabouts at the time the crime was committed all count as evidence for or against the hypothesis that the suspect committed the crime. The sort of evidence that interests the evidentialist, however, is not just anything whatsoever that is relevant to the truth of the proposition in question. The evidentialist denies that such facts about mind-independent reality are evidence in the sense relevant to determining justification. According to (EVI) only facts that one *has* are relevant to determining what one is justified in believing, and in order for one to *have* something in the relevant sense, one has to be aware of, to know about, or to, in some sense, "mentally possess" it. The sort of evidence the evidentialist is interested in, therefore, is restricted to mental entities (or, roughly, to mental "information"). In addition, it is only *one's own* mental information that is relevant to determining whether one is justified in believing that *p*. For example, *my* belief that Jones was in Buffalo at the time the crime was committed is not relevant to determining whether *you* are justified in believing that Jones committed the crime.

There exist objections to evidentialism. For example: even "though one once had good evidence for believing, one has since forgotten it. Nevertheless, one may continue to believe justifiably, even without coming to possess any additional evidence. Evidentialism appears unable to account for this" (Mittag, 2004). Of course, "I forgot what the evidence is" would not make a good impression in a courtroom, but *justifying belief* in the philosophy of knowledge does not necessarily have the same standards of evidence one would expect in civil or criminal courts.

Another objection, which is relevant also for the theory of evidence in law, refuses to identify *probability* with *justification* of belief in a given proposition. One's evidence *supporting* a proposition may be modelled by means of some theory of probability, but this is contentious. Mittag explains (ibid.):

A body of evidence, *e*, supports believing some proposition *p* only if *e* makes *p* probable. If we suppose for simplicity that all of the beliefs that constitute *e* are themselves justified, we can say that *e* supports believing *p* if and only if *e* makes *p* probable. However, one might argue that, even with this assumption, one's evidence *e* can make *p* probable without one being justified in believing that *p*. If this is so, the resulting evidentialist thesis is false.

Alvin Goldman, for example, has argued that the possession of reasons that make *p* probable, all things considered, is not sufficient for *p* to be justified (*Epistemology and Cognition*, 89–93). The crux of the case he considers is as follows. Suppose that while investigating a crime a detective has come to know a set of facts. These facts do establish that it is overwhelmingly likely that Jones has committed the crime, but it is only an extremely complex statistical argument that shows this. Perhaps the detective is utterly unable to understand how the evidence he has gathered supports this proposition. In such a case, it seems wrong to say that the detective is justified in believing the proposition, since he does not even have available to him a way of reasoning from the evidence to the conclusion that Jones did it. He has no idea *how* the evidence makes the proposition that Jones did it likely. Thus, the evidentialist thesis, so understood, is false.

The appeal to probability and statistics here is not essential to this sort of objection, so it would be a mistake to focus solely on this feature of the case in attempting to respond. [...]

Evidential reasoning A major area within artificial intelligence since the 1970s, as well as a prominent area within legal scholarship, in contrast within AI & Law it only emerged as a conspicuous area since around 2000.

Evidential strength There are quantitative approaches for modelling evidential strength. See [Bolding-Ekelöf degrees of evidential strength](#).

EvoFIT A tool for suspect identification, resorting to a genetic algorithm¹⁶ refining a population of facial composites. EvoFIT was developed within the CRIME-VUs project. The team working on EvoFIT is led by Charlie Frowd of the University of Central Lancashire. See [Section 8.2.2.4](#).

Examination or examination in chief Questioning of a witness called by one of the parties at a trial, by the lawyer of the same party. It is followed by cross-examination by the lawyer of the other party, and then possibly by re-examination by the lawyer of the party that called the given witness. Moreover, also a judge can ask questions. More in general, *examination* (as opposed to *examination in chief*) refers to the questioning in court, at any stage, of the parties to a trial, or of their witnesses, by any qualified questioner (a lawyer of the some party or of the other party, or a judge, or the other party if he represents himself without a lawyer).

It is important not to confuse examination in court, with questioning by the police during investigation. Legal proceedings only start once the investigation stage ends: once a suspect is charged, the police can no longer question him or her. *Post-charge questioning* (on the part of police investigators) of terrorism suspects, possibly extended to other categories of criminals, was considered by the British government in November 2007, drawing criticism from civil liberties groups.

¹⁶ Genetic algorithms are the subject of [Section 6.1.16.1](#) in this book.

During investigation, questioning seeks to uncover information. This is not the case in court. Both when a party is examined in court by his own lawyer, and when the other party is cross-examined, in practice the purpose of the questioning is *not* to discover new information (which lawyers dread in court, as it is a risk), but rather to cause the examinee to reply in such a manner that would diminish the prospects of the success of the party against whom the questioning lawyer is pitted. Only when it is a judge who is asking questions, the questioning is genuine, i.e., seeking information not previously known to the questioner. Hickey (1993) discussed presupposition under cross-examination.

The following anecdote was related by American legal scholar Roger Park during a talk he gave in Amsterdam in December 1999. During the 19th century, a lawyer at a trial hoped to expose the bad character of the man he was questioning (see **character evidence**). He asked him whether he had ever been in prison. The man replied that he had. Then the lawyer asked him about the circumstances of this happening. The man explained that he had been made a prisoner by the Indians (Native Americans). The effect was opposite to that intended by the lawyer: given the worldview of both lay and trained judges in the United States in the 19th century, the implication was that the examinee was of good character, a hero. This illustrates the dangers, for a lawyer and the party he or she represents, if the questions are such that information not previously known to the lawyer emerges. Importantly, persons being questioned in court must stick to giving answers without digressing. This is a major constraint, and therefore the lawyer examining the party he represents or that party's witnesses, has the duty to skilfully ask such questions that would enable all those important facts to emerge that would enable the lawyer to construct an effective argumentation. Jackson (1994, p. 70) pointed out:

Consider, for a moment, the very basic process of courtroom examination. Legal theory tells us that the barrister is not giving evidence; he or she is merely asking questions. The evidence is given entirely by the witness. But both linguistic analysis and the philosophy of language (specifically, the theory of speech acts) show that this is an unrealistic account. Grammatically, no doubt, the barristers are asking questions, not making statements. But a question, from the viewpoint of speech act analysis, is an act requesting new information. It is commonly (though not universally) so used at the investigation stage. But the elicitation of new (to him/her) information is precisely what the barrister is *not* seeking to do. It is a commonplace in the training of barristers that they should never ask a question to which they do not already know the answer – more accurately, to which they do not think they know what the witness's answer will be. So questioning by the barrister has a quite different function, the function of presenting an argument, engaging in a battle, sometimes even making claims of fact.

Jackson then discusses “each of these three functions” (ibid.). Take asserting facts: “A barrister who made straightforward factual claims, in the grammatical form of assertions, would readily be pulled up short” [by the judge] (ibid., p. 71). Therefore, assertions are made “[a]ssuredly not up front”, but “e.g. through the presuppositions of questions”. “Of course, the barrister is not on the stand, giving evidence on oath. But it is precisely because his factual statements have *not* thereby been problematised that they become, when uttered, all the

more persuasive” (ibid.). “Not one of these techniques I have briefly described – Socratic questioning (constructing a narrative argument); engagement in battle (destroying the witness rather than the story); stating facts (by presupposition) – is regarded as unprofessional”: quite on the contrary. “[C]riminal investigators should not be inhibited from what they see as the legal constraints on what can be said in court from pursuing a full narrative or holistic account”, as that is what it takes to persuade the court, and that without incurring in “the shyster lawyer syndrome” by which an unscrupulous lawyer is preferable to a respectable one (ibid., p. 71). Characterizations are involved, e.g. as hostile examinations by a barrister “seek to evoke stereotypes of respondents, not simply responses” (ibid., p. 70). It is still Jackson who states (ibid., pp. 70–71):

I wish here to make a distinction between cross-examination which is designed to destroy the story, and cross-examination which is designed to destroy the witness. It is the latter with which I am concerned. It may be illustrated through the “Don’t know” pattern. The barrister may ask the witness a series of questions, to which s/he anticipates that the witness does not know the answer. These questions may relate to matters of quite marginal relevance. But the repetition of “Don’t know” by the witness in respect of even marginal matters will create, and is designed to create, in the minds of the jury an image of a “Don’t know” witness. It is an example of a simple rhetorical technique, *pars pro toto* – which evokes one of the basic narrative assumptions of everyday life: we do not rely upon what is said by people who appear not to know what they are talking about. Trite, maybe. Illogical, certainly. But immensely powerful.

Here is an example of *pars pro toto* negatively affecting a person’s perceived credibility, in the television appearance of that person as being a guest, or “victim” (as guests at broadcasts are called in the slang of the trade). “Believing himself off screen, the victim keeps his head still, but surreptitiously swivels his eyes – perhaps for a glimpse of the audience, or the clock, or for a peep at the monitor. Immediately, by chance or by malicious design, the camera switches to him and he looks shifty, cunning and wicked” (Janner, 1984, p. 147). This is because of a stereotype about swivelling eyes. Viewers are made to see the “victim” swivelling his eyes, that precise moment being highlighted, yet in the stream of events this may have been innocent and unimportant, rather than evidence about his truthfulness when making a specific statement, or about his character in general.

Exchange principle (Locard’s) Anyone or anything entering a crime scene takes something of the scene with them, and leaves something of themselves behind when they depart.

Exclusionary principle In the American law of evidence, according to a formulation originally proposed by James Bradley Thayer, the principle “That nothing is to be received which is not logically probative of some matter requiring to be proved”. See also **inclusionary principle**.

Exclusionary rules Typically in the U.S. law of evidence: rules about which kinds of evidence must be excluded and not heard in court. As opposed to *admissionary rules*. See **(rules of) extrinsic policy** and **(rules of) auxiliary probative policy**, i.e., kinds of exclusionary rules.

Some kinds of evidence are excluded as a matter of policy. Sometimes, for reasons of policy, the law of some given jurisdiction may choose to disregard evidence that by common sense would prove adultery. By the law of England and Wales, until Parliament reformed family law in 1949, this was the case of evidence that could prove adultery because of lack of access of the husband, if a child was nevertheless born. Prior to 1949, such evidence was not admissible.

Sir Douglas Hogg, in his role as barrister in *Russell v. Russell* in 1924 (he had ceased to be Attorney-general earlier that year), had already tried to obtain admissibility for such evidence. “The question for the House of Lords was whether evidence of non-access might be given in divorce proceedings by one spouse with the result of bastardizing a child of the marriage. The answer was of great importance, not only to the parties to the suit, the sole evidence of the wife’s adultery being the testimony of the husband that he did not have access to his wife at any time when the child could have been conceived, but also to all those who were interested in the proceedings in the Divorce Court, either as possible parties or as practitioners” (Heuston, 1964, p. 458).

The House of Lords decided the case ruled such evidence inadmissible: it “held that on grounds of decency and public policy the law prohibited the introduction of such evidence.” (ibid.). Hogg had admitted that the evidence would be inadmissible in a legitimacy case, but “Hogg’s argument was that the rule prohibiting the introduction of such evidence had never been applied to a case in which the object of the suit was to dissolve the bond of marriage on the ground of adultery, it only applied where there was a marriage in existence and the legitimacy of a child born in wedlock was in question” (ibid.). Hogg argued that “Where the issue is adultery the birth of a child is mere accident” (quoted ibid.). “This ingenious argument was rejected by the majority of the House, Lord Finlay saying: ‘To what an extraordinary state would the admission of this evidence in the present case reduce the law of England! The infant may be illegitimate for the purpose of proving adultery; but legitimate for the purpose of succeeding to property or a title!’” (ibid.). Writing in an American journal on legal evidence, Hans Nijboer (2008) provided comparative comments on current issues in evidence and procedure from a Continental perspective, as have emerged during the 2000s. He

finds that while legal scholars are increasingly communicating with legal scholars in other countries and scientists from other fields, there is a simultaneous counter-tendency toward adoption of crime-specific rules of substantive law and evidentiary measures for specific kinds of crime (such as protection of witnesses in rape cases, where the protection complicates the fact-findings process). He concludes from this that there is a tension between greater generality in regard to the first two dimensions and increasing specificity in regard to the third.

Expert evidence Evidence as supplied by an expert witness. The expert’s *expert opinion* is part of the evidence in a case.

Expert opinion, Appeal to In argumentation studies, Walton’s (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008,

pp. 381–382). Its major premise is: “Source *E* is an expert in subject domain *S* containing proposition *A*.” The minor premise is: “*E* asserts that proposition *A* is true (false).” The conclusion is: “*A* is true (false).” Walton accompanied this with critical questions to be asked, and these come in different categories: **expertise question, field questions, opinion questions, trustworthiness questions, consistency questions, and backup evidence questions** (q.v.).

Expert witness A witness called to give testimony in court not because of having been involved in the facts of the case being tried, but because of his or her professional expertise in one of the forensic sciences, bearing on the evaluation of specific elements. Cf. s.v. *Witness vs. expert testimonies*. An expert witness is called to provide *evidence of opinion*.

“[T]he seminal 1993 United States Supreme Court decision *Daubert v. Merrell Dow Pharms.*¹⁷ [is] now widely described as the most important expert evidence decision ever written by the Supreme Court” (Cole 2009, p. 111). “Broadly speaking, *Daubert* [...] might be said to concern ‘the problem of expertise’” (*ibid.*, p. 112) namely (*ibid.*):

Given that courts have long allowed expert witnesses to testify—and given the increasing use of such experts—how are courts to evaluate the testimony of proffered “experts”? Ought anyone who claims the mantle of expertise be permitted to testify in that guise? Or, should courts police claims to the title of “expert” by permitting only those experts deemed legitimate to testify? American courts have long tended toward the latter view; *Daubert* made this commitment (in the federal courts and in the many jurisdictions that subsequently adopted *Daubert* or *Daubert*-like rules) explicit. But, this preference only generates another philosophical dilemma: how are courts supposed to adjudicate claims to expertise when many, if not all, of those claims by their very nature are so technical that legally-trained judges cannot reasonably be expected to be competent to sit in judgment upon them? In other words, the law faces a specific instance of the question asked by the philosophical field known as “epistemology”: how does one certify knowledge as legitimate?

In Britain, not always an expert witness has to appear in court in person, and sometimes it is enough for the expert to provide a report. Nevertheless, typically an expert witness must be ready to be cross-examined and to defend the credibility of his or her opinion on the matter at hand, and his or her professional credibility. An evidently biased expert witness would impress the court unfavourably. Like lawyers, expert witnesses, too, sometimes have a poor image: the lawyer being perceived to be a “shyster”, and the expert witness – a “hired gun”.

A philosopher, Ghita Holmström-Hintikka (2001), applied to legal investigation, and in particular to *expert witnesses* giving testimony and being interrogated in court, the Interrogative Model for Truth-seeking that had been developed by Jaakko Hintikka for use in the philosophy of science. A previous paper of hers (Holmström-Hintikka, 1995), about expert witnesses, appeared in the journal *Argumentation*.

¹⁷ *Daubert v. Merrell Dow Pharms., Inc.*, 509 U.S. 579 (1993).

Bond, Solon, and Harper (1999) is a practical guide for expert witnesses. Carol Jones (1994) is concerned with expert evidence in Britain. Chris Pamplin, the editor of the *UK Register of Expert Witnesses* (<http://www.jspubs.com>), “analyse[d] the results of a major survey of the expert witness marketplace” and among the other things, remarked (Pamplin, 2007a, pp. 1480–1481):

Another change over the years that many experts will find more welcome is the reduction in the number of cases for which they are required to give their evidence in court. It is now altogether exceptional for experts to have to appear in court in “fast-track” cases, and it is becoming less and less likely in those on the “multi-track”. In 1997 we recorded that the average frequency of court appearances was five times a year; some four years later this had dropped to 3.8; it now stands at 3.1.

If this is convenient for the expert witnesses (their worst-case scenario is being cross-examined in court and leaving the court with their reputation in shatters), it must be said that justice may be the loser, in the interest of efficiency, if expert witnesses are not challenged in court every time that they deserve to. The “oracular” expert witness ought to be a nightmare for justice. Yet, case management requires that there will be a limit on how much evidence is to be obtained. In Pamplin’s words (2007b, p. 1488):

Limiting the amount and scope of expert evidence has long been one of the functions of the case management procedures of the civil courts. The time and expense involved in the provision of expert evidence means that the courts must have regard to the proportionality of any request. Indeed, the court should refuse permission where reasons for the request are viewed as frivolous.

However, given that the need for additional evidence is sometimes critical to the court’s ability to make an informed decision, and that the expert evidence itself is often of a highly technical nature, two questions arise:

- How should the courts deal with such requests?
- How much influence should the experts or the parties have upon the court’s decision?

If an expert feels that there is insufficient evidence before the court to prove or disprove a case, does the expert have discretion to request that further tests be carried out? If so, what is the expert’s role in that evidence-gathering process? These were questions considered recently by the Family Court. [In *Re M (a child)* [2007] EWCA Civ 589, [2007] All ER (D) 257 (May), a case that contrasts with *Re W (a child) (non-accidental injury: expert evidence)* [2007] EWHC 136 (Fam), [2007] All ER (D) 159 (Apr). And also at an employment tribunal: *Howard v Hospital of St Mary of Furness* [2007] All ER (D) 305 (May).]

Expert witnesses do not only intervene in courts. Once instructed by a client, they (e.g., forensic engineers advising about product liability) may advise the client about the strength of their case. The client may renounce litigation, or give in to the plaintiff by settling out of court.

“Selecting the right expert may be crucial in court” (Holland, 2007). “An expert who can guarantee availability during the trial, and who can respond to any additional requests promptly will stand out from the other candidates” (ibid.,

p. 1486). “Ideally solicitors would like the expert to be recommended by a colleague, a barrister or client, as this is the best evidence that the expert is up to the job. Many [London] City firms also have internal databases of experts” (ibid.).

With a little application, there is much a prospective expert candidate can do to satisfy these criteria. However, the expert should always bear in mind that the expert’s role is to provide impartial assistance to the court or tribunal. In addition to the criteria above, another paramount factor is the independence of the expert from the appointing party. If the expert is not perceived to be independent, the judge will not give credit to his evidence and opinions and this could be damaging to the client’s case. (ibid., p. 1487).

Moreover, expert testimony may be involved in *alternative dispute resolution*, this being either *arbitration*, or *binding* or *non-binding mediation*. (see **case disposition**.) Baria Ahmed (2007) points out:

A potential expert in alternative dispute resolution (ADR) may adopt a range of roles: an expert consultant may form part of the advocacy team; a party retained expert may provide an opinion on the instructing party’s position; the parties may instruct a neutral expert, appointed through an independent body such as the Royal Institute of British Architects, chosen by the parties jointly or appointed by the mediator or arbitrator; finally, the appointed mediator or arbitrator may themselves be an independent expert in light of their experience in the subject matter of the dispute. In the case of Early Neutral Evaluations and Expert Determinations, the neutral expert is tasked with providing either an “opinion” on the applicable law or a “decision” on the facts. [...] ADR processes, however, permit a non-traditional use of experts. The mediator, for example, may request that the expert makes a presentation of their views with all other participants present, or bring the parties’ retained experts together without their respective clients to review findings, or choose to test their opinions in open/closed meetings.

An American legal scholar, Erica Beecher-Monas (2008), argued that during the 2000s, “courts throughout the common law system have taken an increasingly antithetical approach to expert testimony.” She contrasted civil cases and criminal cases. In the former, but also

in criminal DNA identification cases, courts appear to be actively engaged in scrutinizing the scientific testimony that comes before them. Defense attorneys appear to have little difficulty in challenging questionable scientific testimony. Research scientists are brought into the discourse as experts for the parties or the court. Courts are articulating the bases for their admissibility decisions, and these decisions are being reviewed on appeal.

She pointed out that the situation was different in criminal cases other than involving DNA: “In the criminal cases, however, where criminal identification procedures other than DNA are concerned, each of the participants in the legal process has failed.” She found that prosecutors were not particular about how credible their expert witnesses were:

Prosecutors repeatedly present experts whose testimony they have reason to know is (at best) dubious. Defense attorneys fail to bring challenges to the scientific validity of even patently flawed expert testimony. Courts, when challenges do arise, fail to engage in serious gatekeeping. And reviewing courts refuse to find shoddy gatekeeping to be an abuse of discretion. The consequence of this antithetical approach to admissibility, is

that the rational search for truth, in which the adversary system is supposedly engaged, is taken seriously only in civil cases.

So the problem was not only with the prosecutors. She conceded that “the civil courts are busy minutely scrutinising scientific studies proffered as the basis for expert testimony” but in criminal cases other than DNA, in stark contrast, “the criminal courts are admitting into evidence testimony (again, with the exception of DNA) for which those studies have never been done.” The critique expressed by Beecher-Monas (2008) is not isolated. The American legal scholar Michael Risinger¹⁸ (2007a) sarcastically gave his paper,¹⁹ concerning the courts admitting expert testimony of dubious value,²⁰ a title reminding of the atom bomb’s fictional enthusiast Dr. Strangelove: D. Michael Risinger, ‘Goodbye to All That, Or a Fool’s Errand, By One of the Fools: How I Stopped Worrying About Court Responses to Handwriting Identification (And ‘Forensic Science’ in General) and Learned to Love Misinterpretations of *Kumho Tire v. Carmichael*’.²¹ Itiel

¹⁸ From the Seton Hall University School of Law, in Newark, New Jersey.

¹⁹ It is followed by an Appendix which is an article in its own right (Risinger, 2007b). Cf., e.g., Risinger et al. (2002). Both of these are concerned with expert testimony in handwriting identification.

²⁰ Risinger’s paper (2007a) is described in its abstract as (among the other things) “a picaresque romp through the author’s career, much of which has been spent coming to grips with the realities of forensic science, and the courts’ abdication of their role as gatekeepers in judging the reliability of prosecution-proffered expertise.” Moreover, “the article illustrates how the lower federal courts have managed to ignore or misinterpret *Kumho Tire v. Carmichael* in such a way as to create a jurisprudence of expertise wholly at odds with the clear mandate of the Supreme Court, often by converting decisions with no precedential status into precedents of breathtaking breadth.” Michael Risinger has criticised dubious forensic expertise (especially in handwriting identification) in his articles as early as the 1980s.

²¹ Cole (2009), responding to Risinger (2007a), remarked in a footnote: “On a completely irrelevant note: the first part of Professor Risinger’s title refers to Robert Graves’s memoir *Goodbye to All That*, whose discussion of the experience of being gassed in the First World War indirectly inspired my undergraduate thesis on German preparations for chemical warfare between the two world wars.” Let me add that the intertextual reference in the second part title of Risinger’s article is to the title of a black comedy film from 1964, on the nuclear scare, in which Peter Sellers played three major roles. It is the film *Dr. Strangelove or: How I Learned to Stop Worrying and Love the Bomb*, commonly known as *Dr. Strangelove*, directed, produced by Stanley Kubrick; the screenplay was jointly written by him with Peter George and Terry Southern. It was based on *Red Alert* by Peter George. Eventually in the plot, on board of an airplane with a damaged radio (so it cannot be recalled), “Aircraft commander Major T. J. ‘King’ Kong (Slim Pickens) goes to the bomb bay to open the damaged doors manually, straddling a nuclear bomb as he repairs arcing wires overhead. When he effects his electrical patches, the bomb bay doors suddenly open, the bomb releases and Kong rides it to detonation like a rodeo cowboy, whooping and waving his cowboy hat. The H-bomb explodes and [in automated retaliation, the Soviet Union’s] Doomsday Device’s detonation is inevitable” (quoted from http://en.wikipedia.org/wiki/Dr._Strangelove Also see <http://www.filmsite.org/drst.html> about the same film). The motif of the man riding a shot bomb like a cowboy apparently was after a real-life episode. The protagonist was Harry DeWolf, a future vice admiral and Chief of Staff of the Royal Canadian Navy. After retiring, he published a memoir under the title ‘My Ride on a Torpedo’ (DeWolf 1966), which he began by mentioning that when he retired, “a newspaperman commenting on my service career wrote that I had once ridden a torpedo

Dror and colleagues' paper "When emotions get the better of us: The effect of contextual top-down processing on matching fingerprints" (Dror et al., 2005) is a paper in cognitive psychology, applied to how experts perform at matching fingerprints. Dror and Charlton (2006) and Dror, Charlton, and Péron (2006) tried to identify the causes of why experts make identification errors. Dror and Rosenthal (2008) tried to meta-analytically quantify the *reliability* and *biasability* of forensic experts.

Some jurisdictions encourage conferences of experts sitting side by side and giving testimony together: this is the case of Australia's Federal Court (see **hot-tubbing**) sometimes at a **public inquiry** (q.v.) in Britain, which are inquisitorial (see **inquisitorial**, towards the end of that entry).

ExpertCop A piece of software (a geosimulator, combining simulation and a geographic information system) for training police officers in allocating police presence in given urban environments, for the purpose of preventing crime (Furtado & Vasconcelos, 2007). See **Section 6.1.6.2**.

Expertise question In argumentation studies, Walton's (1997) *Appeal to Expert Opinion* offered (*ibid.*, pp. 211–225) an argumentation scheme for "Argument for Expert Opinion", then reproduced in Walton et al. (2008, pp. 381–382). See s.v. **Expert opinion, Appeal to** above. The expert source is *E*; the subject domain is *S*; and *A* is a proposition about which *E* claims to be true (or false). The expertise question is: "How credible is *E* as an expert source?". It is articulated in five detailed subquestions: "What is *E*'s name, job or official capacity, location and employer?"; "What degrees, professional qualifications, or certification by licensing agencies does *E* hold?"; "Can testimony of peer experts in the same field be given to support *E*'s competence?"; "What is *E*'s record of experience, or other indications of practiced skill in *S*?"; "What is *E*'s record of peer-reviewed publications or contributions to knowledge in *S*?".

Extrinsic policy (rules of) A category of rules excluding or restricting the use of admitted evidence. As opposed to *rules of auxiliary probative policy*. In interpretations of the American law of evidence, according to Wigmore's terminology,

like a cowboy around the deck of a destroyer" (*ibid.*, p. 167). This was on 2 July 1940, aboard the Canadian destroyer *St. Laurent*. DeWolf was skipper, with the rank of lieutenant commander. A young torpedoman who was painting a torpedo lifted the safety catch and pulled back the firing lever. The torpedo leaped free toward the stern, and in frenzy butted causing damage, and at any moment its safety device could be unwound to arm the dormant warhead, which would then explode on contact. The torpedo "would lurch forward with each motion of the ship. It would lurch forward with each motion of the deck; then, as the deck became level, the torpedo would stop, like a bull in the ring, undecided in which direction to make its next charge" (*ibid.*, p. 170). The torpedo rolled against the guardrails, and DeWolf and another officer tried to hold it there, and his colleague "ran to get a key to turn off the compressed air that was driving the propellers", but the ship rolled, the torpedo rolled away, and DeWolf "straddled it, and grabbed hold of the guardrail" (*ibid.*). "As the torpedo advanced, I resisted as much as I could, while going forward hand over hand along the guardrail with my legs locked on the maverick" (*ibid.*, pp. 170, 172). "These antics, no doubt, led to the story of 'riding the torpedo'" (*ibid.*, p. 172). Two colleagues arrived at the scene, wrestled the torpedo steady, and the air was turned off (*ibid.*).

rules of extrinsic policy are such exclusionary rules that give priority to other values over rectitude of decision. These are rules which are not so much directed at ascertaining the truth, but rather which serve the protection of personal rights and secrets.

Eyewitness testimony Historically, the preferred kind of evidence (e.g., by biblical law it is the only admissible kind of testimony). Othello states this request to Iago: “Give me the ocular proof” (*Othello*, III.iii.365). James Ogden (1992) remarks that this request was echoed (comically, for that matter) in late seventeenth-century plays. Ogden states: “*Othello* was one of the most popular plays after the Restoration; some twenty revivals are recorded. Thomas Rymer [(1692)] noted that ‘from all the Tragedies acted on our English Stage, *Othello* is said to bear the Bell away’. To Rymer himself it was ‘a Bloody Farce’ which ‘may be a lesson to Husbands, that before their Jealousie be Tragical, the proofs may be Mathematical’”.

One of the major areas in eyewitness testimony is *identification evidence*. Psychological research has shown that eyewitness testimony is fraught with problems, and that it is precisely the most confident witnesses that may be prone to errors.

FacePrints A project and tool of Johnston & Caldwell at New Mexico State University, for assisting a witness to build a facial composite of a criminal suspect. See [Section 8.2.2](#).

Facial reconstruction The forensic reproduction of an individual human’s face from skeletal remains. Computer-graphic tools exist which support this task. See [Section 8.2.6](#).

Facticity Law’s commitment to relate as validly as possible to occurrences and events outside itself (and which took place in the past), normally requiring various mechanisms of representation based on some sort of truth by correspondence.

Fact positivism As defined by Donald Nicolson (1994), it “is to the study and practice of fact-finding what legal positivism is to the study and practice of law. Both encourage the view that the task of lawyers and adjudicators is neutral and value-free. Both focus attention on logic, whether of rules or of proof, and away from the inherently political and partial nature of law and facts” (ibid., p. 726).

Factfinders Also called *triers of fact*. In a judicial context: the judicial decision-makers who are empowered to give the verdict; i.e., the *jury* (jurors are also called *lay triers of fact*, or *lay factfinders*, or *lay magistrates*, or then *popular judges*, the latter, e.g., at the Assizes in Italy) in a *jury trial*, or the professional judge or judges (also called a *stipendiary magistrate*), in a *bench trial* (a trial with no jury). In a jury trial, before the juror retire to consider their decision, the judge instructs the jury about how to go about the decision-making process. In the United States, instructions to the jury tend to be a standard formula, whereas in England, judges tend to produce an elaborate speech to the jury, highly customized for the case at hand. Also see [Jury](#).

Factual truth The past cannot be reproduced or relived. It can only be reconstructed. Moreover, there are factors – such as *rules of extrinsic policy* to exclude use of some kinds of evidence, such rules being intended to privilege some values (e.g., the protection of personal rights) over the *rectitude of decision* as aiming at

the factual truth, or even considerations in terms of cost/benefits – that militate for there consciously there being an increased likelihood of a gap between the factual truth, and the *legal truth* that will result from the verdict.

Factum probandum (plural: *facta probanda*) That which is to be demonstrated by means of the *factum probans* (or of several *facta probantes*).

Factum probans (plural: *facta probantes*) Evidence in support of a *factum probandum*.

FADE (Fraud and Abuse Detection Engine) A data mining system developed by the online auction site eBay in order to detect fraud perpetrator at its site (Mena, 2003, p. 254).

False positive At a criminal trial, a false positive is a wrong conviction,²² whereas a *false negative* is a wrong acquittal. In data mining software tools for the detection of suspicious transactions, a false positive is a false alarm, whereas

²² Already Borchard's book (1932) was concerned with wrongful convictions; it is significant that it was published by Yale University Press. Cf. Leo (2005). <http://www.innocenceproject.org/> is a website that documents real life cases of miscarriages of justice. Clive Walker and Keir Starmer's edited book (1999) *Miscarriage of Justice: A Review of Justice in Error* examines the various steps within the criminal justice system which have resulted in the conviction of the innocent, and suggests remedies to avoid such situations in the future. The perspective is especially that of England and Wales. There are two initial chapters in Part I, "The nature of miscarriages of justice", and these are chapter 1, "The Agenda of Miscarriages of Justice", and chapter 2, "Miscarriages of Justice in Principle and Practice", both of them by Clive Walker. Part II, "The Criminal Justice Process in England and Wales and Miscarriages of Justice", comprises chapter 3, "Police Investigative Procedures", by David Dixon; chapter 4, "The Right to Legal Advice", by Andrew Sanders and Lee Bridges; chapter 5, "The Right to Silence", by Keir Starmer and Mitchell Woolf; chapter 6, "Forensic Evidence", by Clive Walker and Russell Stockdale; chapter 7, "Disclosure: Principles, Processes and Politics", by Ben Fitzpatrick; chapter 8, "Public Interest Immunity and Criminal Justice", by Clive Walker with Geoffrey Robertson; chapter 9, "Trial Procedures" by John Jackson; chapter 10, "The Judiciary", by Clive Walker with James Wood; chapter 11, "Post-conviction Procedures", by Nicholas Taylor with Michael Mansfield; chapter 12, "Victims of Miscarriages of Justice", by Nicholas Taylor with James Wood; and chapter 13, "The Role and Impact of Journalism", by Mark Stephens and Peter Hill. This is followed by Part III, "Miscarriages of Justice in Other Jurisdictions", which comprises chapter 14, "Miscarriages of Justice in Northern Ireland", by Brice Dickson; chapter 15, "Miscarriages of Justice in the Republic of Ireland", by Dermot Walsh; chapter 16, "Miscarriages of Justice in Scotland", by Clive Walker; and chapter 17, "The French Pre-trial System" by John Bell. Part IV, "Miscarriages of Justice in Summary", comprises chapter 18, "An Overview", by Helena Kennedy and Keir Starmer. An earlier edition, entitled *Justice in Error*, appeared in 1993. Between the two editions, there had been intervening reforms in England and Wales. The 1999 book, *Miscarriages of Justice*, considers these reforms, and considers whether the concerns expressed earlier have been adequately addressed. The chapters in the 1993 version were: "The criminal justice process in England and Wales and miscarriages of justice", which comprises chapters 3 to 13: "Police Investigative Procedures: Researching the Impact of PACE" by Clive Coleman, David Dixon, and Keith Bottomley; "The Right to Legal Advice" by Andrew Sanders and Lee Bridges; "The Right to Silence" by Fiona McElree and Keir Starmer; "Forensic Evidence" by Russell Stockdale and Clive Walker; "Prosecution Disclosure – Principle, Practice and Justice" by Patrick O'Connor; "Trial Procedures" by John Jackson; "Post-conviction Procedures" by Michael Mansfield and Nicholas Taylor; "The Prevention of Terrorism Acts" by Brice Dickson. Next, Part III, "Miscarriages of Justice in Other Jurisdictions", comprises chapters 14 to 17: "Miscarriages of Justice in the Republic of Ireland" by Dermot Walsh; and "The French Pre-trial System" by John Bell.

a false negative is an undiscovered case. With data mining, Mena remarks (2003, p. 221):

Often an alert of a suspected crime needs verification by human personnel and may require special processing, such as putting a transaction in a special queue or status. A false positive needs special attention and time, while a false negative may cause further losses. In other words, the costs of both are different. However, in both instances, consideration must be given that doing nothing is the worst possible action and option facing a business, government agency, or law enforcement unit. The cost of doing nothing may, in time, be the most expensive option of all, especially in situations involving the destruction of trust, data, systems, property, and human life.

Field question In argumentation studies, Walton's (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008, pp. 381–382). See s.v. *Expert opinion*, *Appeal to* above. The field source is *E*; the subject domain is *S*; and *A* is a proposition about which *E* claims to be true (or false). The expertise question is: “Is *E* an expert in the field that *A* is in?”. It is articulated in four detailed subquestions: “Is the field of expertise cited in the appeal [to expert opinion] a genuine area of knowledge, or an area of technical skill that supports a claim to knowledge?”; “If *E* is an expert in a field closely related to the field cited in the appeal, how close is the relationship between the expertise in the two fields?”; “is the issue one where expert knowledge in *any* field is directly relevant to deciding the issue?”; “Is the field of expertise cited an area in which there are changes in techniques or rapid developments in new knowledge, and, if so, is the expert up to date in these developments?”.

Final submissions The final speeches to the bench of the lawyers for both parties, before the court decides about the case.

FinCEN (Financial Crimes Enforcement Network) The U.S. Treasury agency set up to detect money laundering. A project for FinCEN, whose goal is to identify money laundering networks, by carrying out network link analysis, was reported about by Goldberg and Wong (1998). Links are created in databases of financial transactions.²³

Fingerprints The fingerprints of human hands are, relatively to other *biometric* features, more reliable characteristics of an individual person, “because of their immutability and individuality [. . .]. Immutability refers to the permanent and unchanging character of the pattern on each finger from before birth until decomposition after death. Individuality refers to the uniqueness of ridge details across individuals; even our two hands are never quite alike. Fingerprint techniques have the benefit of being a passive, nonintrusive identification system and have the additional advantage to use low-cost standard capturing devices (Espinosa-Duró, 2002)” (Khuwaja, 2006, p. 25). In biometrics, also *palmprints* are used, of the entire palm of a hand (Kumar, Wong, Shen, & Jain, 2003). In the 2000s, a trend

²³ See Section 6.1.2.2 and fn. 36 in Chapter 6.

became felt, in scholarship, to question the reliability of fingerprint evidence. See [Sections 8.7.2](#) and [8.7.3](#).

Fingerprint identification The identification, by specialized forensic experts (*fingerprint experts*), or the identity of an individual whose fingerprints are available. There is a debate as to how many similarities between two prints proves identity beyond almost any doubt. See [Sections 8.7.2](#) and [8.7.3](#). *Fingerprint identification* is not the same as *fingerprint verification*. Both kinds require *fingerprint recognition*. By analogy with fingerprints of a person's hand being unique identifiers, DNA identification techniques have been called *DNA fingerprinting*. Also in intrusion detection within computer security, metaphorically one speaks of *fingerprints* and *fingerprinting* ([Section 6.2.1.12](#)), in relation to attempts to identify an intruder.

Fingerprint compression Digitised fingerprint cards are held, e.g., by the FBI, in massive quantities, so when digitized, image compression is required. Compression, however, should not be such that features necessary for matching would be lost. "Because fingerprint ridges are not necessarily continuous across the impression due to minutiae, ridges endings, or bifurcations, the information needed to determine that one fingerprint matches another resides in the fine details of the minutiae and their relationships. Consequently, these details have to be retained for matching algorithms" (Khuwaja, 2006, p. 25). Compression techniques use, e.g., wavelet packets (Khuwaja, 2004).

Fingerprint matching algorithms Computational algorithms from image processing, that match a given input fingerprints card against either a single stored fingerprints card (in *fingerprint verification*), or a fingerprints database (in *fingerprint identification*). Some fingerprint matching algorithms use neural networks (e.g., Leung, Leung, Lau, & Luk, 1991; Khuwaja, 2006). "One advantage of any neural network, which performs a fingerprint recognition task, is that it will learn its own coarse-grained features; thus, precise locations do not form any part of an input set (Hughes & Green, 1991)" (Khuwaja, 2006, p. 26). See [Section 8.7.3](#).

Fingerprint recognition Such image processing, possibly computational, that fingerprints are analysed, and matched against a pool of fingerprint cards. If the process is computational on digitised images, fingerprint matching algorithms are applied. The purpose may be either *fingerprint identification*, or just *fingerprint verification*. The finer level is *minutiae detection*, as opposed to coarse-grained features such as ridges in a fingerprint image.

Fingerprint scanning An input technique for digitized fingerprint databases, that transforms extant *fingerprint cards* (as used in manual processing and recognition) into digitized images.

Fingerprint sensors Equipment for an input technique for taking a person's fingerprints, by obtaining a digitized fingerprint image directly from that person. Igaki, Eguchi, and Shinzaki (1990) described a *holographic fingerprint sensor*.

Fingerprint verification A person who claims a given identity has his or her fingerprints checked. The outcome is binary: either acceptance, or rejection. This

is less processing-intensive than the *fingerprint identification* of suspects, and is more typical of situations when security measures are taken, in order to prevent undue access, i.e., in *fingerprinting for security*, an application for which a *personal authentication system* is used.

FLINTS A software tool for criminal intelligence analysis. It performs *network link analysis*, and developed by Richard Leary, who originally applied it in the West Midlands Police. See [Chapter 7](#).

Foil At an *identity parade* (i.e., a *lineup*), or then in a *photoarray*, any out of several look-alikes, known to be innocent, and who appear alongside the suspect. The eyewitness is made to identify the suspect, but without a bias (such as suggesting that the perpetrator is actually one of those persons). Wells (1993) suggested criteria for minimising *foil bias*. See [Section 4.5.2.3](#).

Forensic computing A discipline that provides techniques and strategies for *computer investigations*, in response to *computer crime*. Also known as *evidential computing*, or *computer forensics*. The latter is distinguished from *digital forensics*. See [Section 6.2.1.5](#).

Forensic sciences Various scientific specialties (such as chemistry, areas within medicine, psychology, handwriting analysis, fingerprint analysis, and so forth) when applied for the purposes of crime analysis and fact investigation, or for evaluations for the use of the court. There is a multitude of such specialties, with an increasing role in court. Sometimes globally referred to as in the singular: *forensic science*.

Forensic test A test applying any of the forensic sciences.

Free proof Historically in Continental Europe (in the Romanist tradition), *free proof* – in German *frie Beweiswürdigung*, in French *l'intime conviction* – pertains to the evaluation of the evidence, according to a system which replaced the so-called *legal proof* (in Latin *probatio legalis*, in French *preuve legale*, in German *gesetzliche Beweistheorie*), and emancipated the judicial evaluation of the evidence from the older law of proof (this also involved the demise of torture as means for obtaining evidence). In Continental Europe, free proof replaced rules of *quantum and weight*; these did not use to be part of the English and American judiciary systems.

In the United States, in the context of Common Law systems from Anglo-Saxon countries), *free proof* or *freedom of proof* (not a term of art in England) historically lent itself to several different usages, but in current discussions in legal scholarship in the U.S.: freedom of triers of facts (i.e., factfinders, judicial decision-makers) from *exclusionary rules* affecting the evidence. See Twining (1997), Stein (1996).

Generalisations Or *background generalisations*, or *background knowledge*, or *empirical generalisations*: common sense heuristic rules, which apply to a given instance a belief held concerning a pattern, and are resorted to when interpreting the evidence and reconstructing a legal narrative for argumentation in court.

Geoinformatics or geomatics The science and technology of gathering, analysing, interpreting, distributing and using geographic information. It encompasses surveying and mapping, remote sensing, geographic information systems (GIS), and the Global Positioning Systems (GPS).

Guilty plea Typically, in criminal procedure in Anglo-American jurisdictions, the option a defendant is offered, to admit guilt on the part of the defendant at the beginning of a trial, and this typically in connection with a *plea bargain* being offered, with an explicit grant of sentencing concessions (a lighter sentence) for such a plea. In countries in Continental Europe, typically there was no possibility of a guilty pleas, prosecution was obligatory instead of discretionary, and plea bargaining was not envisaged, and was frowned upon.

Handwriting identification A discipline (Morris, 2000) which in the context of the forensic sciences, is part of the domain of *questioned documents evidence* (Levinson, 2000). See [Section 6.1.10](#).

Hearsay Stated imprecisely: verbal statements attributed to others, or rumours. It is not admitted as evidence in court, if the person to whom the statement is ascribed could be called as a witness²⁴ (See [Sections 4.6.1](#) and [2.5.1](#)). More precisely, the *hearsay rule* (in English and American law) “requires a court to exclude any written or oral statement not made in the course of the proceedings which is offered *as evidence of the correctness of the matter asserted*. A statement which is relevant independently of the real intention of the speaker or the truth of what is stated is not adduced for a testimonial purpose and is therefore outside the scope of the rule” (Pattenden, 1993, p. 138). In fn. 2 *ibid.*, Rosemary Pattenden clarifies “independently of the real of the speaker”: “For example, in a contract case a person is contractually bound if he makes an oral statement which a reasonable man would regard as an acceptance of a proffered offer, even though he did not intend by his words to accept the offer”. In fn. 3, she explains “or the truth of what is stated”: “For example, a statement offered to prove that the declarant could speak or a statement which it is alleged is libellous. The distinction between ‘original’ and ‘testimonial’ use of an out-of-court statement is not, however, absolute. The statement ‘I am alive’ asserts and demonstrates the same thing”.

As to the rationale behind the hearsay rule (which she challenges), Pattenden states:

The basis of the hearsay rule is supposedly the dangers which attach to the use of statements not made by witnesses within the confines of the courtroom where the declarant can be subjected to immediate cross-examination. However, when the question of admitting an out-of-court assertion arises in a criminal trial, no attempt is ever made to measure the real danger which the statement presents to the fact-finding process. Instead the court concentrates on conceptual issues – is the statement being used testimonially? If the answer is yes, does it fall within one of the narrow and inflexible common law

²⁴ Also consider that a broader category is *out-of-court witness statements* (Heaton-Armstrong et al., 2006), which also include statements made to the police by a witness or defendant who also has to give testimony in court.

exceptions to the rule (all of which were created before the end of the nineteenth century) or one of the more recent, but equally limited, statutory exceptions to the rule. If the answer to the second question is no, the evidence is automatically rejected. There is never any question of weighing the probative value of the evidence against the risk of unreliability (Pattenden, *ibid.*, p. 138).

Craig Osborne (1997) remarked: “It is apparent when reading reports of decided cases that courts not always appreciate the existence of a hearsay problem”, as “there are also instances of the very existence of any problem at all being overlooked” (*ibid.*, p. 254). “It is by no means the case that words said outside court and repeated in it will amount to hearsay. What matters is whether the statement from the speaker outside court is *tendered to prove the truth of its contents*” (*ibid.*, p. 255). *Express assertions* are excluded by the hearsay rule (*ibid.*):

With express assertions there must be an intention to communicate, thus non-verbal behaviour such as nods, gestures, pointing or signs may well amount to an express assertion when what the person making the sign did is recounted to the court by another witness. As there must however, be some intention to communicate nobody has ever suggested that, say, a footprint, or yawning is subject to the hearsay rule.

Implied assertions are problematic. “This is where the maker of the statement did not intend to assert any particular fact” (*ibid.*, p. 256). “The reason why it has often been suggested that these kind [sic] of statements ought to be admissible as exceptions to the hearsay rule is that there is a smaller risk of untruthfulness with implied assertions. [. . .] The authorities in England are not entirely conclusive” (*ibid.*).

For the United States, Ron Allen has claimed (2008a, p. 326):

1. The rules of evidence favour admissibility even in the face of legitimate claims of irrelevancy. The standard bearer here is of course the Supreme Court’s decision in *Old Chief v. U.S.* [519 U.S. 171 (1997)], but that simply acknowledged the obvious truth of the narrative structure of proof at trial.
2. This narrative structure is enhanced by liberal admission of evidence, and even the rule once claimed as the embodiment of the exclusionary practices of Anglo-American law – the hearsay rule – has morphed into a rule of admission (Allen, 1992). All statements by parties are admissible, for example, no matter when or under what conditions made, as are all present sense impressions and statements of states of mind or physical conditions. Business records and government reports all come in readily, along with 35 or so other categories of admission. If none of the formal exceptions work, the courts may make up ad hoc exceptions to facilitate admission (Federal Rule of Evidence 807). Although there are some technical exclusionary rules, in reality, like hearsay, they often make promises that they do not keep. Another wide ranging example is the character evidence rules which promise exclusion but permit generous admissibility due to provisions such as FRE 404(b).

An expert system dealing with the hearsay rule is the *Hearsay Rule Advisor (HRA)*. It was developed as an LL.M. project by Susan Blackman (1988), under the supervision of Marilyn MacCrimmon (1989). That expert system “provides advice on whether a statement comes within the definition of hearsay and if so,

whether the statement comes within an exception to the general rule excluding hearsay statements” (MacCrimmon, *ibid.*, p. 468). The initial questions the user is asked by this expert system – MacCrimmon explains (*ibid.*, pp. 467–468) –

classify exceptions based on the context of the trial (whether the declarant is available to testify and the type of trial, civil or criminal). This part of the program eliminates some exceptions as more facts become known. At this time the exceptions included in the program are: dying declarations, declarations against interest, declarations in the course of duty, and business documents (British Columbia only). Hearsay exceptions in the HRA are classified on the basis of four dimensions: EVENT, PERCEIVE, BELIEVE [and] INTEND. First the system searches for an approximate match between the user’s facts and the events in the system. Once a match is found, the user is asked questions designed to assess whether the three dimensions of PERCEIVE, BELIEVE and INTEND for a particular exception are satisfied by the user’s facts. These questions are tailored to fit the EVENT identified so that the system does not waste time with irrelevant or inapplicable questions. These dimensions fit the story model of Pennington and Hastie with the proviso that I assume that belief states are encompassed by the definition of psychological states as is implicit in [their examples]. Legal liability often turns on whether a person knows, thinks, believes certain things and not simply on whether they are in a particular emotional state.

We begin with the declarant as the principal actor. The action is the making of the statement. The EVENT is defined as the events which initiate the required belief states which initiate the goal of telling the truth. Thus for dying declaration the initiating events are the declarant is wounded, and the declarant is dying. It is assumed that these events initiate the belief that the declarant is saying that initiates the goal of telling the truth. For the exception, declarations in the course of duty, the initiating events are the declarant is performing a duty and others are relying on his or her actions which initiate the belief state that the declarant expects to be discovered if he or she makes an error which in turn initiates the goal of avoiding censure by his or her employer.

The dimensions of PERCEIVE [and] BELIEVE may be related to states of the world which enable the declarant to make a true statement. Circumstances which facilitate accurate perceptions are often required. [...] INTEND focuses on the facts of the specific case being considered in order to establish the requisite belief state. [...]

It is quite important to understand that different jurisdictions can be expected, generally speaking, to treat hearsay, too, differently. Take the Italian context (Ferrua, 2010, section 19):

Suppose *P* gave witness in court concerning what (being crucial for convicting defendant *Q*) he was told by *N*, and that the latter, called as witness, is taking advantage of the right to avoid this being a next of kin, or at any rate, that *N* refuses to reply or does not appear at the hearing, and therefore deliberately avoids being cross-examined. There is no doubt that the guilt of the defendant cannot be proven based on statements that *N* may have made during the inquiry. But what are we to say concerning what *N* related to *P*, who provided indirect testimony?

True, *P* is not avoiding being cross-examined, but should we allow conviction based on *P*’s testimony, which reproduces verbatim what *N*’s related, arguably amounts to admit it based on *N*’s statements, who always deliberately avoided being cross-examined. The only conceivable way to deny this would be to claim that the “statements” referred to by the criterion of evaluation²⁵ are only the ones made during the trial, by

²⁵ This is merely a criterion of evaluation (“criterio di valutazione”), not an exclusionary rule (“regola di esclusione probatoria”).

strict analogy with what is in force concerning the cross-examination rule [under the Italian jurisdiction].²⁶

At any rate, the Court of Cassation in Italy ruled on 4 October 2004 that indirect testimony is only inadmissible (“l’inutilizzabilità della testimonianza indiretta”),²⁷ as per “articolo 195 commi 3 e 7 c.p.p.”, if the primary source is not indicated, or if it was requested by one of the parties that primary source be called as witness, and it was not (except because of death, infirmity, or because the person cannot be found). In particular, the Court of Cassation ruled that indirect testimony is admissible, and has to be considered, in such a case that the primary source resorted to the right not to reply, while being a defendant tried for a related crime.²⁸

Hot-tubbing A particular approach to expert witnesses, known by that name especially with reference to a practice at Australia’s Federal Court, but also known (although not by that name) from public inquiries in Britain (see *s.v. Inquisitorial*, towards the end of that entry). In a comparative review, Erica Beecher-Monas (2008) explained:

In Australia, [. . .], the Federal Court has encouraged (through its court rules) both “hot-tubbing” and joint conferences of experts. In the joint conference court rules, judges attempt to control expert witness partisanship by directing expert witnesses to confer, or to produce a document identifying the matters on which the experts agree and those on which they disagree. Under the “hot-tubbing” rules, experts testify together in court, responding to questions from attorneys and each other, as well as the judge. Judges may also appoint their own witnesses, although they rarely do so in criminal trials.

There is a difference between hot-tubbing and joint conferences of experts, in respect of lawyers’ interventions (*ibid.*):

“Hot-tubbing” is also known as taking concurrent evidence. In this procedure, the experts for both sides simultaneously take the stand in court and question each other about their opinions on the record. They are also subject to questioning by the court

²⁶ The original text from Ferrua (2010) is concerned with the second part of “art. 111 comma 4 Cost.”, and it is as follows: “Supponiamo che *P* abbia testimoniato in giudizio su quanto, decisivo per la colpevolezza dell’imputato *Q*, gli ha confidato *N* e che quest’ultimo, chiamato a deporre, si avvalga della facoltà di astensione come prossimo congiunto o, comunque, rifiuti di rispondere o disertare il dibattimento, sottraendosi così per libera scelta al contraddittorio. Nessun dubbio che la colpevolezza dell’imputato non possa essere provata in base alle dichiarazioni eventualmente rilasciate da *N* nell’indagine preliminare. Ma che dire per quanto raccontato a *P*, che ha deposto come teste indiretto? È vero che *P* non si sottrae al controesame, ma consentire la condanna sulla base della sua testimonianza, dove è testualmente riprodotto il racconto di *N*, non equivale forse a consentirla sulla base delle dichiarazioni di *N* che si è sempre sottratto per libera scelta al contraddittorio? La sola via per rispondere negativamente sarebbe, per l’appunto, di sostenere che le ‘dichiarazioni’ a cui si richiama il criterio di valutazione siano solo quelle costituite nel processo, in stretta analogia con quanto vale per la regola del contraddittorio.”

²⁷ The notion of *inutilizzabilità*, i.e., *inadmissibility* of criminal evidence, was discussed in an Italian context in Gambini (1997) and in Grifantini (1993, 1999).

²⁸ An attempt at formalisation of the reasoning about hearsay was made by Tillers & Schum in “Hearsay Logic” (1992).

and the lawyers. Hot-tubbing, in contrast to joint conferences of experts, permits the participation of legal counsel in exchanges among the experts.

Moreover, with *hot-tubbing* the parties have a say concerning procedure (ibid.):

In joint conferences, experts are supposed to work together (with only the experts present) to prepare a document probing areas of agreement and disagreement, to be submitted to the court. In its pristine form, a joint conference will exclude lawyers. In practice, however, there appears to be some flexibility – and the parties may have some ability to modify the joint conference procedure. For example, in one antitrust case, the parties refused to participate in a “hot tub” procedure and agreed to a joint conference only if they could treat the joint conference as mere negotiations, so that any communication or joint report could only be admissible with consent of the parties. If the parties can play such a significant role, it is questionable how far a joint conference can go toward solving the problem of partisan experts.

HUGIN A piece of Belief Net software, using which Neil and Fenton (2000) carried out calculations in order to present probabilistic legal arguments, concerning the **Jury Observation Fallacy** (q.v.).

HYP0 A computer system for argumentation, fairly well-known in the discipline of AI & Law (Ashley, 1991). See [Section 3.9.1](#). HYP0 “is a case based reasoner developed by Ashley and Rissland at University of Massachusetts at Amherst. It analyses problem situations dealing with trade secrets disputes, retrieves relevant legal cases from its database, and fashions them into reasonable legal arguments. It has turned out to be the benchmark on which other legal case based reasoners have been constructed” (Stranieri & Zeleznikow, 2005a, Glossary).

IBIS An Issue-Based Information System that supports decomposing problems into issues. *QuestMap* (Carr, 2003) is a computer tool for supporting argumentation. It is based on IBIS, mediates discussions, supports collaborative argumentation, and creates information maps, in the context of legal education.

Identikit A system for generating composite faces, for the purposes of assisting a witness to describe the features of a criminal suspect. *Identikit* uses plastic overlays of drawn features. See [Section 8.2.2](#).

Identity parade Also called *line-up*, or *identification parade*. A suspect stands in a line alongside *foils*, i.e., persons known to be innocent and who look alike, and the victim or witness has to identify the suspect. A computerised version is *ID parade discs*, on which video clips from a database appear, along with a video clip showing the suspect. See [Section 4.5.2.8](#). In contrast, it is usually undesirable to have a *dock identification*, when the witness sees at the trial the accused for the first time after the offence. Even for such a case in which there was a parade, being an “identification procedure between crime and trial at which the witness has picked out the accused to assist the police”, Osborne (1997, p. 305) raises a problem with *hearsay* (evidence admissibility rules include exclusionary rules which include the hearsay rule, as well as the rule against admission of a previous consistent statement):

If the witness confirms at the trial that he has previously picked out the accused, is he not, in effect, testifying as to a prior consistent statement? Moreover the hearsay implications are compounded if some other person is called to confirm that the witness picked out

the accused at the identification parade. The point is inadequately analysed and it is far from clear as to whether the courts have acknowledged the hearsay problem at all. See, e.g., *R v Osborne and Virtue* [1973] 1 QB 678 where the witnesses in court could not remember whom they had picked out at an identification parade. A police inspector who had been present was allowed to testify about what had happened at the parade without the court acknowledging the hearsay point (Osborne, *ibid.*).

It may be that computer tools for use at identity parades may incorporate some function for recording the outcome with a given witness in such a way that would be useful in court, but it may depend on the jurisdiction (e.g., it would be in agreement with the “philosophy” of validating steps in Asaro’s *Daedalus* in Italy, as opposed to Anglo-American procedural law). It would be interesting to see whether how the software caters to validation may in turn result in something objectionable. Therefore, it would be useful to have a legal professional involved in discussions, during the software requirement analysis and design phase.

IFS (Internet Fraud Screen) A data mining tool giving credit-card fraud alerts, developed by CyberSource for Visa U.S.A. for matching fraud transactions. IFS “uses a combination of rule-based modeling and neural-network modeling techniques” (Mena, 2003, p. 271). IFS’s “profile scores look at more than a dozen different information items, including the customer’s local time and the risk associated with the customer’s e-mail host. CyberSource also provides e-retailers with an IFS report that includes risk profile codes, address verification systems (AVS) codes, and other relevant information to help e-merchants calibrate their risk thresholds and score settings. This helps the e-business subscribers to control the level of risk they want to operate under” (*ibid.*).

Image forensics A branch of forensic science whose goal is the detection of *image tampering*. The tampering is typically done by computer (*digital forgeries*), and the computational methods for detection (*digital image forensics*) belong to image processing within signal processing. See Farid (2008), Popescu and Farid (2007), Johnson (2007). We have discussed such techniques in [Section 8.2.5](#).

Imputation A charge, including a charge possibly implied by a defendant while attacking the credibility of others, and affecting their *character*. (See [character evidence](#)). In a section entitled “Imputations on the character of the prosecutor or his witnesses or on the deceased victim of the alleged crime”, Osborne (1997, p. 323) explains that before *Selvey v DPP* [1970] AC 304, in English law “there was a problem as to whether the accused lost his shield [i.e., its being inadmissible for the prosecution to adduce bad character evidence about him, or to ask such questions during cross-examination that would aim at proving his bad character] by making imputations on prosecution witnesses which were necessary to *develop his defence*, or whether he only lost it if the imputations were *merely to attack* their credibility”. For example, it may be that a defendant would need to claim that it actually was “a prosecution witness who actually committed the offence” (*ibid.*). In *Selvey v DPP*, the House of Lords held that prosecution is allowed to cross-examine “the accused as to character where he casts imputations on prosecution witnesses either in order to show their unreliability or where he

does so in order to establish his defence” (Osborne, *ibid.*, p. 324), yet with exceptions: “In a rape case the accused can allege consent without losing his shield”, “If what is said amounts in reality to no more than a denial of the charge then an accused does not lose his shield”, and “There is an unfettered judicial discretion to exclude cross-examination as to character even if strictly permissible but there is no general rule that this discretion should be exercised in favour of the accused even where the nature of his defence necessarily involves his attacking prosecution witnesses” (*ibid.*). “The difficult question which is for the judge to decide is: ‘What is an imputation?’ The courts have tried, not always with great success, to draw a distinction between what is merely a *denial* of the charge by the accused in forceful language and what amounts to an imputation” (*ibid.*). For example, if a defendant claiming that a witness is “a liar”, should this be merely treated as a denial of the charge, or is it to be treated as an imputation, because “this may in effect be an allegation of perjury”? (*ibid.*).

Inclusionary principle In the American law of evidence, according to a formulation originally proposed by James Bradley Thayer, the principle “That everything which is thus probative should come in, unless a clear ground of policy or law excludes it”. See also **exclusionary principle**.

Independent Choice Logic (ICL) Poole (2002) applied this formalism to legal argumentation about evidence. The formalism can be viewed as a “first-grade representation of Bayesian belief networks with conditional probability tables represented as first-order rules, or as a [sic] abductive/argument-based logic with probabilities over assumables” (p. 385).

Inductive reasoning “Inductive reasoning is the process of moving from specific cases to general rules. A rule induction system is given examples of a problem where the outcome is known. When it has been given several examples, the rule induction system can create rules that are true from the example cases. The rules can then be used to assess other cases where the outcome is not known” (Stranieri & Zeleznikow, 2005a, Glossary).

Inference The process of deriving conclusions from premises.

Inference engine “An inference engine is that part of an expert or knowledge based system that contains the general (as opposed to specific) problem solving knowledge. The inference engine contains an interpreter that decides how to apply the rules to infer new knowledge and a scheduler that decides the order in which the rules should be applied” (Stranieri & Zeleznikow, 2005a, Glossary).

Inference network “The inference net model is a probabilistic retrieval model; since it uses a probability ranking principle. It computes $\Pr(I|document)$, which is the probability that a user’s information need is satisfied given a particular document” (Stranieri & Zeleznikow, 2005a, Glossary).

Inquest In Britain: a judicial or official inquiry, usually before a jury, typically in order to identify the causes of a death, in case this is not certified by a physician, or where the possibility of a crime cannot be ruled out a priori. The *Dead Bodies Project* (developed by Jeroen Keppens and others during the 2000s) has been described in Section 8.1.

Inquiry See **investigation**.

Inquisitorial A type of criminal procedure, which is typical of many European countries on the Continent. As opposed to the *adversarial* system, typical of Anglo-American jurisdictions. The adversarial system features a symmetry between the parties, whereas in the inquisitorial system the court is rather structurally aligned with the prosecution *vis-à-vis* the defendant, yet the court is to be convinced and adjudicates. It is of interest to consider how professionals used to the adversarial system perform, when they have to abide by the inquisitorial system. In England and Wales, as well as in Scotland, whereas the adversarial system characterises court proceedings, *public inquiries* are in theory inquisitorial (see [public inquiry](#)). This is also the case of the *Coroner's court*. Professor Sir Ian Kennedy, who chaired the public inquiry (which lasted two years and nine months, from 1998 until 2001) into the conduct of children's heart surgery at the Bristol Royal Infirmary between 1984 and 1995, and he described in a paper (Kennedy, 2007) his experience in that capacity. In 2005, Parliament passed the Inquiries Act, but the paper is general enough to retain interest even under the new regime of public inquiries (*ibid.*, p. 15). In the interest of openness, information technology (IT) was resorted to (*ibid.*, p. 14):

The Inquiry needed to be completely open so that everyone could see and hear the same evidence. This was achieved by the use of IT with scanning of all the documents: this came to over 900,000 pages. A "Core Bundle" of relevant documents was prepared as a CD available to all legal representatives.²⁹ The daily proceedings could be seen at three separate locations as well as Bristol. It was also vital to create a website (this received over 1 million hits during the Inquiry and won a prestigious NHS³⁰ prize).

The approach was inquisitorial, and therefore (*ibid.*, p. 38):

In keeping with its inquisitorial approach, the Inquiry made it clear that there were no "parties", no "sides", to advance their particular view of events. Witnesses were called by the Inquiry and were the Inquiry's witnesses. They were there to assist the Inquiry. They were not there to score points in their own favour or against others. Legal representatives initially found these challenging propositions. They were used to taking sides on behalf of a client. But, gradually, they understood.

²⁹ In a section about the use of information technology, Kennedy explained (2007, pp. 41–44): "By scanning all relevant documents into the Inquiry's data-base, it was possible to ensure that the Inquiry, and particularly its legal team, could have access to all the relevant evidence collected at the earliest possible stage, and in a manageable form on computers. The creation of a CD containing the 'Core Bundle' achieved the same effect for both the Panel and the legal representatives of all those involved in the Inquiry. Witnesses' statements, and comments on them, were equally added to the database and were thus accessible to those involved. Once they began, the hearings were effectively 'paper free'. Counsel to the Inquiry, and other legal representatives on the occasions on which they addressed the Inquiry, were simply able to identify the unique code given to each document for it to be transmitted onto the computer screens of the panel, other lawyers and onto the screens available to the public. It was estimated that, by not having to search through shelves of box files to find the relevant document and the[n] pass it around to all, the Inquiry was able to accomplish anything from a quarter to a third more work on an average day of hearings."

³⁰ National Health Service.

Its being inquisitorial in a country used to the adversarial system, it is challenging for those conducting the inquiry, as well as to the lawyers (*ibid.*, pp. 37–38):

It is often said that Public Inquiries are inquisitorial by nature. But the reality often is otherwise. One explanation is that those chairing Inquiries are usually unfamiliar with how to translate the idea into practice. Moreover, since they are very commonly judges, their first instinct is to revert to what is familiar and convert the Inquiry's proceedings into a courtroom. And courtrooms, in England, are not characterized by an inquisitorial approach (with the exception of the Coroner's court). Rather they are characterized by what can be described, perhaps a little provocatively, as a gladiatorial approach. The gladiators are the lawyers, usually counsel. The judge watches and gives the thumbs up, or down, at the end. Lawyers provide a further explanation to why the proceedings, though theoretically inquisitorial, soon take on an inquisitorial quality. This is because lawyers also are familiar with courts and the procedure of courts. It comes as no surprise that they will seek to treat the Inquiry as if it were just another court.

This has also to do with how the process of arriving at the legal truth is conceived of (*ibid.*, p. 38), as the lawyers' attitude during the Inquiry

also rests on a fundamental premise, particularly of counsel, that there only is one way to discover the truth and that it is through the cut and thrust of examination and cross-examination. Leave aside the fact that we have already seen that the concept of a single "truth" may be self-delusionary, the approach misses the point of what the Inquiry is seeking to do. It is not seeking to paint a picture just in black and white; that something happened and something else did not, that someone did wrong. It does not occupy a binary world of right and wrong, good and bad. What it is trying to do is understand, and understanding rarely comes in black and white. Furthermore, whatever else may emerge from gladiatorial contest, understanding rarely does.

Some lawyers are counsel to the inquiry, whereas some other persons are the legal representatives of groups and organisations involved in the inquiry (*ibid.*, p. 39). The most prominent duty of counsel to the inquiry is "to take witnesses appearing before the Inquiry through their evidence", ensuring that "the Inquiry heard both the witness' account, any challenges to it and their responses to these challenges" (*ibid.*). Counsel to the Inquiry also organise the material collected by the inquiry. As to legal representatives, what they do during the hearings of an inquiry different from what they would be doing in court. This is because the procedure of the inquiry as defined by Kennedy for the Bristol Public Inquiry does not envisage that it would be the legal representatives who would examine and cross-examine the witnesses: it was up to the counsel to the inquiry to do so (*ibid.*, pp. 39–40). In fact, "there is no *right*, as such, to cross-examination of witness (usually by lawyers) at a Public Inquiry. The Inquiry must, of course, behave fairly at all times" (*ibid.*, p. 40). "The position of the Inquiry was simple. It wanted to hear witnesses telling their stories, rather than have the story filtered through the interventions of their legal representatives, who might seek to gloss over this, or over-emphasise that, out of their perception of what it was good for the Inquiry to hear" (*ibid.*, p. 41).

Also the status of expert witnesses was that of an *amicus curiae*, called to assist the Inquiry (at a bench trial, especially under the inquisitorial system, it would be to assist the court): "Just like other witnesses, experts also were the

Inquiry's experts. They gave evidence to assist the Inquiry in its task", rather than representing one of the two sides in the adversarial system (*ibid.*, p. 38). "They were advised as to the assistance that the Inquiry needed and gave their evidence accordingly, whether in the hearings, or in the conduct of several analytical studies carried out by the Inquiry" (*ibid.*). Nevertheless, this being Britain (*ibid.*, pp. 38–39):

Again, this was unfamiliar territory to legal representatives. They were used to experts appearing for one "side" or another. They urged that the expert should brief them and then they would question a particular witness, or advise the Inquiry, in the light of what they gleaned from the expert's briefing. I indicated that the Inquiry wished to hear from the experts and did not wish to hear their views "second hand", through counsel. I went further, and said that the Inquiry would benefit from experts taking part in the hearings at the same time as other witnesses, so that the Inquiry could test arguments as they were put, and witnesses could refer to experts as peers, sitting alongside them, in discussing areas of technical expertise.

(This is like **hot-tubbing**, *q.v.*, at Australian courts.) Bear in mind that the public inquiry was about a hospital, and whereas some physicians were regular witnesses or were being investigated, some other physicians were called as expert witnesses. Therefore (*ibid.*, p. 39):

This they did, and the Inquiry would sometimes listen spellbound as expert and witness discussed matters of significant complexity, whether it was the correct response to a particular anatomical anomaly in the heart, or why paediatric intensive care was different from the care of adults, or how a particular statistical conclusion could be arrived at. [...] They made it plain that honest professionals could legitimately differ. [...]

Insecurity governance or insecurity management A branch of information technology concerned with how to respond, on an organisational level, to threats to *computer security*.

Instructing party The client of either a lawyer or an expert consultant (an expert witness). The lawyer or the consultant is *instructed* by the client.

Interesting case In law: "For a first instance decision to be interesting it must: 1) be appealed, or 2) includes a new principle, rule or factor in its ratio decidendi, or 3) exhibits an outcome vastly at odds with other similar cases" (Stranieri & Zeleznikow, 2005a, Glossary). Not the same as **landmark case** (*q.v.*).

Interesting pattern In knowledge discovery from databases (KDD) and in data mining: "A pattern is interesting if it is a) easily understood by humans, b) valid (with some degree of certainty) on new or test data, c) potentially useful and d) novel. A pattern is also interesting if it validates a hypothesis that the user sought to confirm" (Stranieri & Zeleznikow, 2005a, Glossary).

InvestigAide B&E An expert system (Valcour, 1997) for the Canadian Police, whose purpose was to support the processing and investigation of breaking and entering cases, by assisting in gathering and recording case data, and providing such information as suspect characteristics.

Investigation Actions undertaken, typically by the police, in order to identify criminal suspects, or the extent of criminal activities. In the United States, the term *investigation* is used. In Britain, it is *inquiry*.

Itaca A tool, modelled after **Daedalus** (q.v.), for the Court of Cassation in Rome, under contract to Siemens, as per the design of Mr. Justice Carmelo Àsaro (who when a prosecutor in Lucca, developed *Daedalus* single-handedly). See **procedural-support systems**, and **Section 4.1.3**.

Jury or lay factfinders In some countries, a group of citizens, not trained judges, who adjudicate trials of some categories of crime. In Anglo-Saxon countries, the judge can instruct the jury, but does not participate in the determination of the verdict. In Italy, some cases are heard by a mixed court (first introduced in colonial Libya), of trained judges and jurors, and after the verdict is given, the justification of the verdict must also be given: it is written by a trained judge, who – if outvoted by the jurors – may write a so-called *sentenza suicida*, i.e., a deliberately flawed justification in order to bring about an appeal. In Anglo-Saxon jurisdictions, a *retrial* may be ordered if some stringent conditions are met. Also see **factfinders**.

Jury observation fallacy A claim, so named, against the use of knowledge of prior convictions of a criminal suspect. See **character evidence**. Fenton and Neil (2000) tried to support this claim by making use of Bayesian networks to present probabilistic legal arguments. Adrian Bowyer summarised this stance in a letter published in the latest issue of June 2001 of the *London Review of Books (LRB)*, a letter immediately signalled in an e-list posting by Mike Redmayne:

Writing about Labour’s proposal in its Criminal Justice White Paper that defendants’ past convictions should be revealed to juries, John Upton (LRB, 21 June) fails to mention the Jury Observation Fallacy. According to this, if a jury finds someone not guilty on the evidence presented in court – in other words, without taking previous convictions into account – the fact that this defendant has previous convictions for similar crimes usually makes it more, not less, probable that he or she is indeed innocent of this particular crime. This is because, when a crime is committed, the police quite reasonably go out and feel the collars of those with previous convictions for similar crimes. They therefore tend to fish in a highly non-representative pool, rather than picking suspects from the general population. This tips the probabilities in the defendant’s favour to an extent that is not outweighed by the likelihood of a certain fraction of past offenders becoming recidivists. If the defendant is considered innocent on the facts of the case, then his past convictions should be seen as evidence not so much of guilt as of the failures of police procedure.

Mike Redmayne (a legal scholar of the London School of Economics, quite at home with probabilistic modelling) was unconvinced by some of the assumptions made. In a posting discussing Fenton and Neil (2000) at an e-list,³¹ he claimed:

Your conclusion is sensitive to the probability that a defendant will be charged given a previous conviction and no hard evidence. If the probability is less than 1 in 200, the fallacy disappears. One point about this is that there are further screening stages between charge and trial, and even between trial and acquittal (the judge can be asked to certify that there is “a case to answer”). It would be very difficult for a case to get to the jury when (more or less) the only evidence against a defendant is that he has previous convictions for crimes similar to the one with which he’s now charged. If there is other

³¹ bayesian-evidence@vuw.ac.nz

evidence against the defendant, surely that affects your conclusion, because it increases the probability of guilt?

There is also likely to be evidence against a defendant other than a previous conviction because most suspects come to police attention independently of their having previous convictions. They may have been caught in the act, or, very often, reported by a member of the public – e.g. the victim.

A few cases will get to court when there is very little evidence other than the defendant's similar previous convictions. At this point, I wasn't sure quite what you meant by "similar" in your model. Similarity can include more than a crime being of the same legal category. It can include similarities in modus operandi, geographical proximity, and so forth. It is where previous convictions have this sort of similarity (sometimes called "striking similarity") that a case may get to the jury on previous convictions alone. (I also suspect that the police rely on such similarities when deciding which suspects to arrest.) If "similar previous conviction" is expanded in this manner, mightn't previous convictions have more probative value than you allow? These are obviously points about the operational reality of the criminal justice system, and you can't be blamed for not mentioning them. [. . .]

Jury research Thriving among psychologists in North America. It has produced various models of jurors' decision-making, as well as empirical results. See [Section 2.1.7](#).

Kappa calculus In AI: a formalism introduced by Spohn (1988). The *kappa value* of a *possible world* is the *degree of surprise* in encountering that possible world, a degree measured in non-negative integer numbers. The probabilistic version of the kappa calculus was applied in Shimony and Nissan (2001) in order to restate Åqvist's (1992) logical theory of legal evidence, which Åqvist based on the *Bolding-Ekelöf degrees of evidential strength* (Bolding, 1960; Ekelöf, 1964). See [Section 2.6](#).

Knowledge acquisition "Knowledge acquisition is the transfer and transformation of potential problem-solving expertise from some knowledge source to a program" (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge based system "A knowledge based system is a computer program in which domain knowledge is explicit and contained separately from the system's other knowledge" (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge discovery "Knowledge discovery is the non trivial extraction of implicit, previously unknown and potentially useful information from data" (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge engineering "Knowledge engineering involves the cooperation of domain experts who work with the knowledge engineer to codify and make explicit the rules or other reasoning processes that a human expert uses to solve real world problems" (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge engineering paradox "The knowledge engineering paradox is that the more competent domain experts become, the less able they are to describe the knowledge they use to solve problems" (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge engineering process "The knowledge engineering process is the process of transferring knowledge from the domain experts to the computer system.

It includes the following phases: knowledge representation, knowledge acquisition, inference, explanation and justification” (Stranieri & Zeleznikow, 2005a, Glossary).

Knowledge representation “Knowledge representation involves structuring and encoding the knowledge in the knowledge base, so that inferences can be made by the system from the stored knowledge” (Stranieri & Zeleznikow, 2005a, Glossary).

Legal burden See **Burden, legal**.

LAILA A language for abductive logic agents, used in ALIAS, a multi-agent architecture. It was applied to the modelling of reasoning on the evidence in a criminal case, in Ciampolini and Torroni (2004). See [Section 2.2.1.5](#).

Landmark case In law (and by extension, in case-based reasoning within artificial intelligence): “A landmark case is one which alters our perception about knowledge in the domain – landmark cases are comparable to rules. Landmark cases are the basis of analogical reasoning” (Stranieri & Zeleznikow, 2005a, Glossary). Not the same as **interesting case** (q.v.).

Learning “Learning is any change in a system that allows it to perform better the second time on repetition of the same task drawn from the same population” (Stranieri & Zeleznikow, 2005a, Glossary).

Legal positivism “Legal positivists believe that a legal system is a *closed logical system* in which correct decisions may be deduced from predetermined rules by logical means alone” (Stranieri & Zeleznikow, 2005a, Glossary).

Legal realism “Legal realists are jurists for whom the reliance on rules is an anathema. They argue that judges make decisions for a range of reasons which cannot be articulated or at least are not apparent on the face of the judgement given” (Stranieri & Zeleznikow, 2005a, Glossary). See, e.g., Rumble (1965).³²

³² Wilfrid Rumble began the first footnote in his paper by pointing out: “There is no infallible method to determine who is a legal realist. The most authoritative list is probably that compiled by Karl Llewellyn in 1931, with the assistance of Jerome Frank and Felix S. Cohen. See Llewellyn, *Jurisprudence: Realism in Theory and Practice* (Chicago, 1962), 74–76” (Rumble, 1965, p. 547, fn. 1). Karl N[ickerson] Llewellyn (1893–1962) was professor at the University of Chicago Law School. His work focused mostly on the topic of legal realism. Llewellyn (1962, repr. 2008) is a compilation of his writings from the 1930s through the 1950s. “Oliver Wendell Holmes, Jr., book, *The Common Law*, is regarded as the founder of legal realism. Holmes stated that in order to truly understand the workings of law, one must go beyond technical (or logical) elements entailing rules and procedures. The life of the law is not only that which is embodied in statutes and court decisions guided by procedural law. Law is just as much about experience: about flesh-and-blood human beings doing things together and making decisions. Llewellyn’s version of legal realism was heavily influenced by [Roscoe] Pound and [Oliver Wendell] Holmes [Jr.]. The distinction between ‘law in books’ and ‘law in action’ is an acknowledgement of the gap that exists between law as embodied in criminal, civil, and administrative code books, and law. A fully formed legal realism insists on studying the behavior of legal practitioners, including their practices, habits, and techniques of action as well as decision-making about others. This classic study is a foremost historical work on legal theory, and is essential for understanding the roots of this influential perspective” (Llewellyn, *ibid.*, from the 2008 publisher’s blurb).

Lex posterior “Lex posterior is the legal principle that states the later rule has precedence over the earlier rule” (Stranieri & Zeleznikow, 2005a, Glossary).

Lex specialis “Lex specialis is the legal principle that states the priority is given to the argument that uses the most specific information” (Stranieri & Zeleznikow, 2005a, Glossary).

Lex superior “Lex superior is the legal principle that states that a ruling of a higher court takes precedence over one made by a lower court” (Stranieri & Zeleznikow, 2005a, Glossary).

Liability Being legally bound or responsible. One category of liability is a defendant’s criminal liability. Another category is tort liability, which, e.g., includes products liability torts and claims. Liability issues arising from the use of expert systems in the field of law were discussed by Karin Alheit (1989), as a particular case of liability in relation to the use of expert systems, for which, see Zeide and Liebowitz (1987). Alheit pointed out, in general concerning knowledge-processing software, that “[t]here exists a tremendous litig[ation] potential over their use, misuse, and even non-use” (Alheit, *ibid.*, p. 43, referring to Zeide and Liebowitz 1987).

Linear regression “In linear regression, data is modelled using a straight line of the form $y = \alpha x + \beta$. α and β are determined using the method of least squares. Polynomial regression models can be transformed to a linear regression model” (Stranieri & Zeleznikow, 2005a, Glossary).

Lineup Also called *identity parade*. A suspect stands in a line alongside *foils*, i.e., persons who look alike, and the victim or witness has to identify the suspect. A computerised version is *ID parade discs*, on which video clips from a database appear, along with a video clip showing the suspect. See Section 4.5.2.3.

Lineup instructions Instructions given to eyewitness before an identification lineup. It is essential that such instructions must not be suggestive. For example, witnesses must not be given the impression that the perpetrator is believed to be one of the persons lines up; in fact, it may be that all of them are innocent. See Section 4.5.2.3.

Link Analysis Network link analysis arose in human factors research, originally in order to determine the layout of machine shops in American industry during the First World War (Gilbreth & Gilbreth, 1917). Link analysis is currently supported by computer tools. One of its applications is to crime investigation, and it is conducted by intelligence analysts. Its aim is to discover crime networks, to identify the associates of a suspect, to track financial transactions (possibly by data mining), to detect geographical patterns (possibly by kind of crime), and so forth. In Coady’s words (1985),

Link Analysis is the graphic portrayal of investigative data, done in a manner to facilitate the understanding of large amounts of data, and particularly to allow investigators to develop possible relationships between individuals that otherwise would be hidden by the mass of data obtained.

See Chapters 6 and 7.

Litigation Risk Analysis A proprietary method of Marc B. Victor, for quantifying legal and factual uncertainties by assuming probabilities, for constructing a decision tree, and for using it in order to evaluate the risks of litigation. See Section 4.3.2.3.

Local stare decisis “Local stare decisis is the tendency of judges to be consistent with the decisions of other members of their own region (or registry)” (Stranieri & Zeelznikow, 2005a, Glossary).

Logic In *How to Do Things with Rules*, William Twining and David Miers (1976, pp. 140–142) made the following remarks about the relation between logic and law; these remarks are of lasting value:

The place of formal logic in legal reasoning is one of the most problematic topics in Jurisprudence. [. . .] First, it is important to realize that the term “logic” is used, even by philosophers, in a number of different senses. [. . .] Secondly, even where “logic” is confined to reasoning leading to necessary conclusions, very general questions of the kind “what is the role of logic in legal reasoning?” are ambiguous and misleadingly simple. For example, this question has been variously interpreted to mean: “To what extent do judges and advocates *explicitly* resort to deduction in justifying their decisions?”; “To what extent can judgments and other examples of argument towards conclusions of law be *reconstructed* in terms of formal logic?”; “To what extent is it feasible to resort to deductive-type arguments in legal reasoning?”; or “To what extent is it *desirable* to do so?”, or even: “What illumination can be gained by applying the techniques of formal logic to examples of legal reasoning?” All these questions are different, although they are related to each other. They are complex questions; beware of glib answers to them.

Thirdly, there is an unfortunate tendency in juristic controversy to present answers to some of these questions as disagreements between extremists. For instance, it is not uncommon to contrast a view that a legal system is a closed and complete system of rules from which all conclusions on points of law in particular cases can be deduced as a matter of logical necessity (sometimes referred to as “the slot-machine model”) with the dictum of Mr Justice Holmes [(Holmes, 1881, p. 1)] that “(t)he life of the law has not been logic, it has been experience”, which can be interpreted to mean that deductive logic plays no role at all in legal reasoning. Stated in this extreme form, both views are patently absurd. It is encouraging to find that few jurists who have been accused of adopting the slot-machine model have been guilty of any such crudity and that even a cursory reading of Holmes reveals that he was concerned to show that logic is only one of a number of factors in “determining the rules by which men should be governed” rather than to deny that it had, or should have, any influence in this respect.

The reference to Holmes is to Oliver Wendell Holmes, the Younger (1841–1935), who was a progressive judge in the U.S. Supreme Court. Twining & Miers go on to quote from an essay by Anthony Gordon Guest [(1961, pp. 195–196)]: “arguments need not be cast in a strictly syllogistic form, provided that they exhibit a logical structure. In the dialectic of the law, logic has an important part to play at a stage when a suggested rule has to be tested in order to discover whether or not its adoption will involve the contradiction of already established legal principles. [. . .]”. Then, Twining & Miers (*ibid.*, p. 142) offer a caveat concerning *arguments about inconsistency*: “Such arguments need to be treated with caution for a number of reasons: First, it is quite common for some kind of rules to ‘hunt in pairs’. [. . .] Secondly, arguments about ‘inconsistency’ and ‘contradiction’ may often be more appropriately expressed as arguments about what

constitutes an appropriate level of generality for a rule or a concept in a particular context". Maxims that point in contradictory directions exist in the common law; they 'hunt in pairs' indeed, and the phenomenon is termed *normative ambiguity* (ibid., p. 210). Twining & Miers illustrate this phenomenon with pairs of proverbs (e.g., "Too many cooks spoil the broth", but "Many hands make light work": ibid.). They go on to list legal examples (ibid., pp. 210–211), then they remark (ibid., p. 212):

First, one must be wary of exaggerating the extent and the importance of normative ambiguity. Often the canons of interpretation may give clear and explicit guidance in a given case, especially where several canons cumulatively support the same conclusion. The difficulties tend to arise where several factors have to be weighed against each other as they favour different results. Secondly, it is important to distinguish between rule-statements which are logical contradictories and those which merely have different tendencies. [...] Moreover there are typically no rules dictating which of two canons is to prevail in such situations. Thus, just as they have carefully avoided laying down strict rules for determining the *ratio decidendi* of a case, so the common law judges have left themselves a fairly wide leeway of discretion in legislative interpretation. The canons indicate factors to be taken into account in deciding a particular case, but do not indicate precisely what weight should be given to such factors.

Loose talk An important concept for the evaluation of the truthfulness of a proposition. Cf. philosopher Terry Horgan account of vagueness he called **transvaluationism** (q.v.) Whereas in court, it is recognised that sometimes people speak other than literally, or with various degrees of precision, and yet are not lying, arguably also advanced natural-language processing capabilities, with which some legal software may be eventually endowed, ought to recognise that much.

Let us consider Dan Sperber and Deirdre Wilson's notion of *loose talk* (Sperber & Wilson, 1986), by means of an example they provide (Sperber & Wilson, 1990). "At a party in San Francisco, Marie meets Peter. He asks her where she lives, and she answers: 'I live in Paris'." Contrast this to a situation in which the location of the event when the occurrence takes place is different: "Suppose Marie is asked where she lives, not at a party in San Francisco, but at an electoral meeting for a Paris local election". There is a difference, concerning the truth value of Marie's utterance, in terms of *relevance* (relevance for discourse, not the relevance of evidence). "It so happens that Marie lives in Issy-les-Moulineaux, a block away from the city limits of Paris. Her answer is literally false, but not blatantly so. If Peter presumed literalness, he will be misled". Yet, assumptions are warranted, that in terms of artificial intelligence could be represented in terms of a nesting of beliefs that agents ascribe to each other. It is not precise that Marie lives in Paris, in the sense that this is inside the city limits.

In ordinary circumstances, however, Marie's answer is quite appropriate, and not misleading. How come? This is easily explained in terms of relevance theory. A speaker wants, by means of her utterance, to make her hearer see as true or probable a certain set of propositions. Suppose these propositions are all quite easily derivable as implications of a proposition Q. Q however has also other implications whose truth the speaker does not believe and does not want to guarantee. Nevertheless, the best way of achieving her

aim may be for her to express the single proposition Q, as long as the hearer has some way of selecting those of its logical and contextual implications that the speaker intends to convey and of ignoring the others.

This example, Sperber and Wilson claim, reflects quite a general phenomenon:

Our claim is that such a selection process is *always* at work, is part, that is, of the understanding of *every* utterance. Whenever a proposition is expressed, the hearer takes for granted that some subset of its implications are also implications of the thought being communicated, and aims at identifying this subset. He assumes (or at least assumes that the speaker assumed) that this subset determines sufficient cognitive effects to make the utterance worth his attention. He assumes further (or at least assumes that the speaker assumed) that there was no obvious way in which achieving these effects might have required less effort. He aims at an interpretation consistent with these assumptions, i.e. consistent with the principle of relevance. When this criterion determines a single interpretation (or closely similar interpretations with no important differences between them) communication succeeds.

For Peter to interpret the answer Marie gave him while in San Francisco, various things are relevant, and the city limits of Paris are not among them. Marie can predict how Peter will understand her answer.

In our example, Peter will be able to infer from Mary's answer quite an amount of true or plausible information: that Marie spends most of her time in the Paris area, that Paris is familiar to her, that she lives an urban life, that he might try to meet her on his next trip to Paris, and so on. It is such cognitive effects which make Marie's utterance sufficiently relevant to be worth his processing effort, in a way Marie manifestly may have anticipated. So, Peter is entitled to assume that Marie intended him to interpret her utterance in this way. Peter would be misled by Marie's answer only if he were to conclude from it that she lives within the city limits of Paris. However it is clear that Marie had no reason to assume that Peter would have to derive such a conclusion in order to establish the relevance of her utterance. Therefore her utterance does not warrant it.

Marie's answer can be expected to be loosely understood. "This loose understanding does not follow from a strictly literal interpretation having been first considered and then discarded in favor of looseness [. . .]. In fact, at no point is literalness presumed". When does it become relevant to understand literally? Suppose that it was in Paris, and for the purposes of a Paris local election, that Marie had stated that she lives in Paris. "If she answers that she lives in Paris, the proposition expressed will itself be crucially relevant, hence the utterance will be understood literally, and Marie will have lied". In fact: "An utterance may be literally understood, but only at the end rather than at the beginning of the comprehension process, and only when relevance requires it". The procedure is actually the same: "The same procedure – derive enough cognitive effects to make up an interpretation consistent with the principle of relevance – yields in some cases a literal interpretation, in others a loose one. In other cases still, it yields a figurative interpretation".

Mac-a-Mug Pro A system for assisting a witness in approximating his or her description of the facial features of a criminal suspect. It is a computerized version of the Photofit process. See [Section 8.2.2](#).

Machine learning A branch of artificial intelligence and of data mining. Basically, machine learning enables AI systems to improve their performance, by augmenting their knowledge. “Most machine-learning based software products are capable of generating decision trees or IF/THEN rules. Some are capable of producing both” (Mena, 2003, p. 221). Mena describes:

- Several products that primarily produce *decision trees* (ibid., section 7.9, pp. 221–229);
- Several *rule-extracting tools* (ibid., section 7.10, pp. 229–232);
- Several *machine-learning software suites* (Mena, 2003, section 7.11, pp. 233–248):
 - ANGOSS (<http://www.angoss.com>)
 - Megaputer (<http://www.megaputer.com>)
 - Prudsys (<http://www.prudsys.de/discoverer>)
 - Oracle data mining suite³³
 - Quadstone (<http://www.quadstone.com>)
 - SAS (<http://www.sas.com>); cf. de Ville (2006).
 - SPSS (<http://www.spss.com/spssbi/clementine>)
 - Teradata Warehouse Miner (<http://www.teradata.com>)
 - thinkAnalytics (<http://www.thinkanalytics.com>)

MarshalPlan A computer tool prototype of David Schum and Peter Tillers, supporting the organization of the evidence, and combining Wigmore Charts, an algebraic approach, and hypertext. Entering its fully operational phase around 2005, yet the project started in the early 1990s. See **procedural-support systems**, and see **Section 4.1.1**.

Mechanical Jurisprudence An article by For Roscoe Pound³⁴ (1908) was entitled “Mechanical Jurisprudence”. For the concept this title expresses, cf. Christie (1984a). Pound opposed the ossification of legal concepts into self-evident truths. By *mechanical jurisprudence*, which he called that way and he condemned, Pound referred to the wooden application of previous precedents to the facts of cases without regard to the consequences. For Pound, the logic of previous precedents alone would not solve jurisprudential problems. In opposition to mechanical jurisprudence, Pound offered his theory of *sociological jurisprudence*. Pound (1908) declared:

Herein is the task of the sociological jurist. Professor Small defines the sociological movement as “a frank endeavor to secure for the human factor in experience the central place which belongs to it in our whole scheme of thought and action.” The sociological movement in jurisprudence is a movement for pragmatism as a philosophy of law; for

³³ <http://www.oracle.com/ip/analyze/warehouse/datamining>

³⁴ The much cited American legal scholar Nathan Roscoe Pound (1870–1964) was Dean of Harvard Law School from 1916 to 1936. He also was the first one to receive a Ph.D. in botany from the University of Nebraska, which was in 1898.

the adjustment of principles and doctrines to the human conditions they are to govern rather than to assumed first principles; for putting the human factor in the central place and relegating logic to its true position as an instrument.

One sentence in Pound (1908) resonates with current endeavours to treat law by means of artificial intelligence:

Undoubtedly one cause of the tendency of scientific law to become mechanical is to be found in the average man's admiration for the ingenious in any direction, his love of technicality as a manifestation of cleverness, his feeling that law, as a developed institution, ought to have a certain ballast of mysterious technicality.

Note however that it is not the purpose of AI to change legal conceptions. It is AI that has to adapt itself, when applied to law, to what legal scholars advocate. Pound (1908) claimed: "Jurisprudence is last in the march of the sciences away from the method of deduction from predetermined conceptions."

Mediation In civil cases, a form of **case disposition** (q.v.). Like *arbitration*, mediation is a form of *alternative dispute resolution* (that is, alternative to the courts). Mediation can be either *binding* or *non-binding*.

Memory conformity If two eyewitnesses who saw the same event then discussed it, this may influence what they later claim to remember. More in general, one has *confabulation* (which is undesirable) when the witness is also inferring, not merely reporting. Concerning the latter, see, e.g., Memon and Wright (1999); Gabbert et al. (2003, 2004); Luus and Wells (1994); Meade and Roediger (2002); Meudell et al. (1995); Principe and Ceci (2002); Skagerberg (2007).

Mens rea The intention to transgress on the part of the defendant, and how specifically it is (if at all) intended to transgress. As opposed to *actus reus*, which is the performance of a forbidden action. Sometimes the intention does not match the action performed. A cardinal doctrine of English criminal law is expressed by the maxim: *Actus non facit reum nisi mens sit rea*, i.e., "An act does not itself constitute guilt unless the mind is guilty". "The maxim draws attention to the two essential elements of a crime" (Curzon, 1997, p. 21): "the physical element (the *actus reus*), i.e. the prohibited *conduct* [. . .] (the so-called 'condition of illegality')", and "the mental element (the *mens rea*), i.e. the *condition of mind* [. . .] (the so-called 'condition of culpable intentionality')" (ibid.). "Some writers suggest a third element – absence of a valid defence, i.e. a defence which might reduce or negate defendant's criminal liability" (ibid.).

Models of time as known from artificial intelligence are potentially relevant for modelling such situations, because of the requirement of a temporal coincidence of *actus reus* and *mens rea*, and this can hold over an interval; the following casenote is quoted from Curzon (ibid.):

In *Fagan v. MPC* (1969), X accidentally drove his car on to Y's foot; he then deliberately left it there for a few minutes. X was charged with assault [. . .] and claimed that there was no coincidence of act and intent. It was held that X's conduct in driving the car on to Y's foot and allowing it to remain there constituted a continuing act; the assault was committed when X decided to leave the car on Y's foot. James J[justice] stated: "It is not necessary that *mens rea* should be present at the inception of the *actus reus*; it can be imposed on an existing act. On the other hand, the subsequent inception of *mens*

rea cannot convert an act which has been completed without *means rea* into an assault” (Curzon, *ibid.*).

“Before 1935, [in English law] it was said that where the accused had caused the victim’s death, he had to show that he did not have the *mens rea* for murder. This burden was placed on the prosecution in *Woolmington v DPP* [1935] AC 462” (Jefferson, 1992, p. 23). “Under the influence of *DPP v Smith* [1961] AC 290 (HL) it was thought that a person intended to do what the natural consequences of his behaviour were. In legal terms a man was presumed to intend the natural consequences of his behaviour. If this presumption was ever irrefutable, s. 8 of the Criminal Justice Act 1967 abolishes it” (*ibid.*).

Take involuntary manslaughter. “If death has occurred but the defendant did not possess an intent to kill or cause grievous bodily harm, then providing the action or omission was not totally accidental and therefore blameless, any ensuing prosecution will be for manslaughter” (Bloy, 1996, p. 159). The following categories are enumerated by Bloy (*ibid.*): *unlawful act manslaughter*, *reckless (subjective) manslaughter*, and *gross negligence*. For the former:

The modern definition was expressed by the House of Lords in *Newbury and Jones* (1976). Lord Salmon said an accused was guilty of manslaughter if it was proved that he intentionally did an act which was unlawful and dangerous and that the act inadvertently caused death. In deciding whether or not the act was dangerous the test is would “all sober and reasonable people” recognise that it was dangerous, *not* whether the *accused* recognised it as such. (Bloy, *ibid.*).

The test [for the dangerous character of the act] is clearly based upon an objective assessment of the circumstances. For example, what conclusions might a reasonable person be expected to reach about the impact of a burglary, late at night, where the occupant of the property is not far short of his 90th birthday? If it is to be reasonably expected that he has a weak heart, or [is] in poor health, then the act of burglary immediately becomes a dangerous act. If however, the reasonable person would not suspect that the victim might in some way be vulnerable to the type of enterprise which is undertaken then a manslaughter conviction is unlikely to be secured on the basis that the act is not a dangerous act. (Bloy, pp. 162–163).

For manslaughter as being the outcome of *gross negligence*, in English law: “The decision of the House of Lords in *Adomako* (1994) is of great significance in helping to clarify the ambit of gross negligence manslaughter and whether or not recklessness is a relevant concept within this species of manslaughter” (Bloy, *ibid.*, p. 166). A patient undergoing surgery suffered a cardiac arrest and subsequently died, because the anaesthetist “failed to notice that an endotracheal tube had become disconnected from the ventilator supplying oxygen to the patient” (*ibid.*, p. 167). “The time period between the disconnection occurring and the [anaesthetist] noticing that this was the cause of the problem was six minutes. [The anaesthetist] was charged with manslaughter and convicted. It was not denied by the appellant that he had been negligent but it was his contention that his conduct was not criminal” (*ibid.*). Bloy (*ibid.*) explains the attitude of the Court of Appeal and then of the House of Lords, which both dismissed Adomako’s appeal:

The Court of Appeal treated the issue as one of breach of duty and stated the ingredients of involuntary manslaughter by breach of duty to be:

- the existence of a duty;
- the breach of the duty causing death; and
- gross negligence on the part of the accused which the jury considered justified a criminal conviction;

In respect of the *mens rea* the Court of Appeal was of the opinion that proof of any of the following states of mind might convince a jury that a defendant had been grossly negligent:

- indifference to an obvious risk of injury to health;
- actual foresight of the risk coupled with the determination to run it;
- an appreciation of the risk coupled with an intention to avoid it but also coupled with such a high degree of negligence in the attempted avoidance as the jury considered justified the conviction; and
- inattention or failure to advert a serious risk which went beyond “mere inadvertence” in respect of an obvious and important matter which the defendant’s duty demanded he should address.

Twining and Miers (1976), while discussing *normative ambiguity* (see our entry for **logic**) provide examples of pairs of maxims pointing in different directions. The following pair is about *mens rea* (*ibid.*, p. 211): “All statutory criminal offences are presumed, irrespective of their wording to include a *mens rea* requirement” (*Sweet v. Parsley* [1970] A.C. 132), but: “The presumption that all statutory offences include a *mens rea* requirement may be rebutted by the seriousness of the conduct to be prohibited” (*R. v. St Margaret’s Trust* [1958] 1 W.L.R.³⁵ 522). Also see Fitzgerald (1961) “Voluntary and involuntary acts”, and Hart’s (1961b) “Negligence, mens rea and criminal responsibility”. Throughout the history of law, there has been variation in how intention has been treated *vis-à-vis* liability (e.g., Jackson, 1971). Jackson (2010) points out:

Legal doctrine does not require proof that the *mens rea* “caused” the *actus reus*; what it requires (normally) is (merely) that the *mens rea* exists “contemporaneously” with the *actus reus* – in order that we may attribute to the latter the appropriate moral opprobrium, i.e. to show from the offender’s intention the required immorality of his act.

Meter-models Quantitative models of the jurors’ decision-making process. In such models, the verdict decision is based on the comparison of a meter reading of the final belief, to a threshold to convict. Different classes of such models include probabilistic models, algebraic models, stochastic models, and such modelling that is based on AI formalisms for belief revision. In the algebraic approach, belief updating is additive, whereas in probabilistic models is multiplicative. See [Sections 2.1.1](#) and [2.1.6](#).

³⁵ *W.L.R.* stands for the *Washington Law Review*.

MIMIC Short for the name *Multiple Image-Maker and Identification Composer*.

A system for generating composite faces, for the purposes of assisting a witness to describe the features of a criminal suspect. MIMIC uses film strip projections. See [Section 8.2.2.2](#).

Minutiae detection Part of *fingerprint recognition*, and a prerequisite for *fingerprint matching algorithms*. This is a finer level than coarse-grained features such as ridges in a fingerprint image. See, e.g., Jiang et al. (2001), Espinosa-Duró (2002). See [Section 8.7](#).

Model-based case-based reasoning paradigm Within case-based reasoning, in artificial intelligence: “The model based approach assumes that there is a strong causal model of the domain task. It generally involves selecting among partially matched cases, in which symbolic reasoning is used to determine the difference between the given problem and the retrieved cases” (Stranieri & Zeleznikow, 2005a, Glossary).

Modus ponens In logic, a form of inference by which if $P \rightarrow Q$ holds and P holds, then Q holds.

Multi-agent system In artificial intelligence, an approach such that intelligent behaviour is coordinated among a number of separate intelligent agents, these being autonomous software modules (sometimes embodied in robots). They are called *autonomous agents*. A precursor was the *blackboard* paradigm (for which, see [blackboard systems](#)). See [Section 6.1.6](#).

Multimedia forensics A branch of forensics concerned with uncovering perpetrators of piracy targeting protected digital content or encrypted applications. Typically, perpetration consists of unauthorised music and movie copying, either for private use or for selling pirated copies, thus eating a big bite of the profit of the record industry and the movie studios. Chang-Tsun Li (of the University of Warwick, England), has published a book (Li, 2008) on state-of-the-art *pirate tracking software*. A particular technique, *traitor tracing*, can be applied to multimedia forensics, but the term has previously been used also in the literature about cryptography. See [Sections 8.2.5](#) and [6.1.2.5](#).

Naïve Bayesian classifiers “Naïve Bayesian classifiers assume the effect of an attribute value on a given class is independent of the other attributes. Studies comparing classification algorithms have found that the naïve Bayesian classifier to be comparable in performance with decision tree and neural network classifiers” (Stranieri & Zeleznikow, 2005a, Glossary). For a given sample we search for a class c_i that maximises the posterior probability

$$P(c_i | x ; \theta')$$

by applying Bayes rule. Then x can be classified by computing

$$c_l = \underset{c_i \in C}{\arg \max} P(c_i | \theta') P(x | c_i; \theta')$$

Nearest neighbour algorithm “The nearest neighbour algorithm is used in information retrieval where data that is closest to the search is retrieved. To perform this search, we need a ‘metric’ (distance function) between the occurrence of each piece of data. The k th nearest neighbour algorithm classifies examples in a sample by using two basic steps to classify each example: (a) Find the k nearest, most similar examples in the training set to the example to be classified; (b) Assign the example the same classification as the majority of k nearest retrieved neighbours” (Stranieri & Zeleznikow, 2005a, Glossary).

Negotiation “Negotiation is the process by which two or more parties conduct communications or conferences with the view to resolving differences between two parties. This process might be formal or mandated as in legal and industrial disputes, semi-formal, as in international disputes or totally informal as in the case of two prospective partners negotiating as to how they will conduct their married life” (Stranieri & Zeleznikow, 2005a, Glossary).

Network representation schemes “A network representation scheme is a knowledge representation scheme using graphs, in which nodes represent objects or concepts in the problem domain and the arcs represent relations or associations between them. Semantic networks are an example of a network representation scheme” (Stranieri & Zeleznikow, 2005a, Glossary).

Neural networks “A neural network receives its name from the fact that it resembles a nervous system in the brain. It consists of many self-adjusting processing elements cooperating in a densely interconnected network. Each processing element generates a single output signal which is transmitted to the other processing elements. The output signal of a processing element depends on the inputs to the processing element: each input is gated by a weighting factor that determines the amount of influence that the input will have on the output. The strength of the weighting factors is adjusted autonomously by the processing element as data is processed” (Stranieri & Zeleznikow, 2005a, Glossary). “Neural networks are particularly useful in law because they can deal with a) classification difficulties, b) vague terms, c) defeasible rules and d) discretionary domains” (ibid.). See [Section 6.1.14](#).

Network topology “A neural network topology is a specification of the number of neurons in the input layer, the output layer and in each of the hidden layers” (Stranieri & Zeleznikow, 2005a, Glossary).

Nonmonotonic reasoning Such reasoning that it is not true that adding new information would never make the set of true statements to decrease. This is a standard concept in artificial intelligence. As a textbook explains ” (Luger & Stubblefield, 1998, p. 269):

Traditional mathematical logic is *monotonic*: It begins with a set of axioms, assumed to be true, and infers their consequences. If we add new information to this system, it may cause the set of true statements to increase. Adding knowledge will never make the set of true statements decrease. This monotonic property leads to problems when we attempt to model reasoning based on beliefs and assumptions. In reasoning with uncertainty, humans draw conclusions based on their current set of beliefs and assumptions. In reasoning with uncertainty, humans draw conclusions based on their current set of beliefs;

however, unlike mathematical axioms, these beliefs, along with their consequences, may change as more information becomes available. *Nonmonotonic reasoning* addresses the problem of changing belief. A nonmonotonic reasoning system handles uncertainty by making the most reasonable assumptions in light of uncertain information. It then proceeds with its reasoning as if these assumptions were true. At a later time, a belief may change, necessitating a reexamination of any conclusions derived from that belief.

Obligation See **deontic logic**, and **contrary-to-duty obligations**.

Ontology “An ontology as an explicit conceptualisation of a domain” (Stranieri & Zeleznikow, 2005a, Glossary). See Sections 6.1.7.3 and 6.1.7.4. “Legal ontologies are generalised conceptual models of specific parts of the legal domain. They provide stable foundations for knowledge representation” (Mommers, 2003, p. 70). For example, Mommers (2003) presented an ontology “based on an analysis of the relation between the legal domain and knowledge about that domain. It is explained how knowledge in the legal domain can be analysed in terms of three dimensions (acquisition, object and justification), and how these dimensions can be employed in alternative designs for collaborative workspaces” (ibid.). Boer, van Engers, and Winkels (2003) discussed using ontologies in order to compare and harmonise legislation.³⁶

Onus of proof The same as **evidential burden**. See **Burden, evidential**. “In any given scenario the onus of proof indicates the degree of certainty for a given outcome to occur. In a criminal case in Common Law countries such proof must be beyond reasonable doubt, whereas in most civil cases in such countries, the proof required is by a fair preponderance of the evidence (i.e. more than 50% likely to occur)” (Stranieri & Zeleznikow, 2005a, Glossary). Jefferson explains (1992, p. 19):

There is a distinction between the evidential and legal burden of proof. The difference may be illustrated by reference to automatism [. . .]. Before the accused can rely on this defence, he must put forward some evidence that he was acting automatically when he, say, hit his lover over the head with a heavy ashtray. The evidence might consist of a witness’s saying that he saw what happened or a psychiatrist’s drafting a report. In legal terms he has to adduce or lead evidence. If he does not adduce such evidence, his plea will fail at that stage and the prosecution does not have to lead evidence that his plea should not succeed. If he does, the prosecution has to disprove that he was acting automatically. His burden is called the evidential burden or onus of proof. The prosecution’s burden is the legal one.

³⁶ “In the E-POWER project relevant tax legislation and business processes are modeled in UML to improve the speed and efficiency with which the Dutch Tax and Customs Administration can implement decision support systems for internal use and for its clients. These conceptual models have also proven their usefulness for efficient and effective analysis of draft legislation. We are currently researching whether conceptual modeling can also be used to compare ‘similar’ legislation from different jurisdictions to improve the capacity of the Dutch Tax and Customs Administration to react to future consequences of increased movement of people, products, and money between EU member states and increased harmonization between tax authorities in Europe. In addition, addressing the problem of comparing models is also expected to improve our methodology for modeling legislation.” (Boer et al. 2003, p. 60).

- Open-textured legal predicate** “Open textured legal predicates contain questions that cannot be structured in the form of production rules or logical propositions and which require some legal knowledge on the part of the user in order to answer” (Stranieri & Zeleznikow, 2005a, Glossary).
- Opinion question** In argumentation studies, Walton’s (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008, pp. 381–382). See s.v. *Expert opinion, Appeal to* above. The expert source is *E*; the subject domain is *S*; and *A* is a proposition about which *E* claims to be true (or false). The opinion question is: “What did *E* assert that implies *A*?”. It is articulated in four detailed subquestions: “Was *E* quoted as asserting *A*? Was a reference to the source of the quote given, and can it be verified that *E* actually said *A*?”; “If *E* did not say *A* exactly, then what did *E* assert, and how was *A* inferred?”; “If the inference to *A* was based on more than one premise, could one premise have come from *E* and the other from a different expert? If so, is there evidence of disagreement between what the two experts (separately) asserted?”; “Is what *E* asserted clear? If not, was the process of interpretation of what *E* said by the respondent who used *E*’s opinion justified? Are other interpretations plausible? Could important qualifications have been left out?”.
- Outlier** A major anomaly, a notable departure from a pattern. Outliers may be a useful indicator for the purposes of crime detection. See [Chapter 6](#). “Data objects that are grossly different from or inconsistent with the remaining set of data are called outliers” (Stranieri & Zeleznikow, 2005a, Glossary).
- Overfitting** “Overfitting occurs when the data mining method performs very well with data it has been exposed to but performs poorly with other data” (Stranieri & Zeleznikow, 2005a, Glossary).
- Overtraining of neural networks** “A neural network over-trains if it has been exposed to an abundance of examples, far too many times. In this case it can learn each input-output pair so well that it, in effect memorises those cases. The network classifies training set cases well, but may not perform so well with cases not in the training set” (Stranieri & Zeleznikow, 2005a, Glossary).
- Palmprints** In biometrics, the print of the entire palm of a hand (Kumar et al., 2003), instead of just *fingerprints*. This is used in personal authentication systems, but is not practical in criminal investigation, as it is only seldom that a suspect would leave an entire palmprint, rather than fingerprints. See [Section 8.7](#).
- PATER** A software system for probabilistic computations for testing paternity claims (Egeland, Mostad, & Olaisen, 1997). See [Section 8.7.2.1](#).
- Pattern recognition** “The creation of categories from input data using implicit or explicit data relationships. Similarities among some data exemplars are contrasted with dissimilarities across the data ensemble, and the concept of data class emerges. Due to the imprecise nature of the process, it is no surprise that statistics has played a major role in the basic principles of pattern recognition” (Principe et al., 2000, p. 643).

PEIRCE-IGTT A piece of software: an abductive inference engine from artificial intelligence, developed by a team led by John Josephson. One of its applications was to the modelling of reasoning on the evidence in a criminal case. See [Section 2.2.1.5](#).

Pentitismo In the Italian criminal justice system, an arrangement on the part of the prosecution, by which some political terrorist or member of the Mafia who was himself highly liable, were permitted to turn into a **state witness** (q.v.) against other defendants. There is some similarity to the *supergrass* system of Britain.

In Italy, a somewhat equivalent system is the *pentitismo*: in the late 1970s, as well as during the 1980s and still during trials held during the 1990s, on occasion a “repentant” terrorist would act as state witness against one or more defendants. Such a witness used to be called a *pentito*, or a *superpentito*. Sometimes the deal drew strong criticism, and in all fairness, defeated justice, such as when the murderer of a journalist obtained, by turning state witness, his own liberty, as well as that of the woman who had been his girlfriend before they were separately arrested in different circumstances. Once released, he immediately proceeded to wed another woman. One photograph that was highly visible in the mass media showed him talking, and, inside the same frame, the grim face of the father of the journalist whose murder justice had renounced punishing. It has also happened that the sincerity of a *superpentito*, securing convictions, was quite dubious. This was the case of the state witness during the Sofri case (for the 1972 terrorism-related killing of a police inspector), as well as of a witness from the Mafia against former prime minister Andreotti, who was convicted for the violent death of a journalist. Also the testimony of a state witness who had raped and murdered in the Circeo case, securing the convictions of other far rightists for a bombing with massive casualties in Bologna (it took place on 2 August 1980), appears to be discredited.

Personal authentication systems Systems for verifying the personal identity of a person, using biometric characteristics; e.g. using fingerprints with *digital signature technologies* (Isobe et al., 2001; Seto 2002).

Personal stare decisis “Personal stare decisis is the tendency of judges to be consistent with themselves” (Stranieri & Zeleznikow, 2005a, Glossary).

Persuasion argument One of two classes of arguments (the other one being *adversary* arguments), “depending on the goals and expectations of the participants. [It] consists of arguments in which the participants are motivated to reach a common agreement, for example in order to solve some problem”: “the participants are both willing to be persuaded as well as trying to persuade” (Flowers et al., 1982, p. 275). This is relevant for computer tools for supporting negotiation.

Persuasion burden See [burden of proof](#).

Photoarray An alternative to a *lineup* at which a suspect and foils are physically present and standing alongside each other. In a photoarray, the eyewitness is made to see a set of photographs instead. Also called *photospread*. An alternative is such an identity parade that there is no physical presence, but the eyewitness is made to see video clips of the suspect and foils. See [Section 4.5.2.3](#).

Photofit A system for assisting a witness in approximating his or her description of the facial features of a criminal suspect. See [Section 8.2.2](#).

Pirate tracing software A kind of software subserving *Multimedia forensics*, for uncovering perpetrators of piracy targeting protected digital content or encrypted applications. See [Sections 8.2.5](#) and [6.1.2.5](#).

Plaintiff The party that turns to the courts for adjudication against another party (the defendant). In some kinds of trial (at employment tribunals in England and Wales), the names are: *applicant* for the plaintiff; *respondent* for the defendant. In the *Civil Procedure Rules 1993*, in England and Wales, the term *plaintiff* was replaced with *claimant* (thought to be a more transparent, and more widely understood term: the same reform excised other traditional terms as well).

Plausibility, relative “The distinction between the structure of proof and a theory of evidence is simple. The structure of proof determines what must be proven. In the conventional [probabilistic] theory [which Allen attacks] this is elements to a predetermined probability, and in the relative plausibility theory [which Ron Allen approves of] that one story or set of stories is more plausible than its competitors (and in criminal cases that there is no plausible competitor). A theory of evidence indicates how this is done, what counts as evidence and perhaps how it is processed” (Allen, 1994, p. 606). See Allen (1991, 2008a, 2008b).

Plausible inference “Polya developed a formal characterisation of qualitative human reasoning as an alternative to probabilistic methods for performing commonsense reasoning. He identified four patterns of plausible inference: inductive patterns, successive verification of several consequences, verification of improbable consequences and inference from analogy” (Stranieri & Zeleznikow, 2005a, Glossary).

Plea A statement made in court by other party in argument of the case. In particular, in Anglo-American criminal procedure,³⁷ the answer given by the defendant at the start of the trial, after the indictment. The answer is either *guilty*, or *not guilty*.

Plea bargain In Anglo-American criminal procedure, and in countries influenced by that system: an offer which the prosecution has a discretion to make, so that in return for a *guilty plea* at the start of the trial (before evidence is submitted to the court), the defendant is offered sentencing concessions (a lighter sentence). Bargaining about the sentence also takes place if one of the defendants is offered the option to become a prosecution witness against other defendants. In countries on the European Continent, it used to be the case that there could be no plea bargaining. *Plea bargaining* applies in criminal cases, and should not be mistaken for a *settlement out of court*, stopping the proceedings in the trial of a civil case.

Police science A field encompassing all aspects of law enforcement, focusing on the factors that affect crime and the police response to crime (Greene, 2006). One aspect of this discipline is the generation or refinement of methods of investigation, enabled by technological advances.

³⁷ Kamisar, LaFave, Israel, and King (2003) covers criminal procedure in the United States of America.

Polygraph testing Testing by means of hardware equipment, recording levels of arousal while the person tested is being questioned. Various methods exist. Polygraph testing and polygraph evidence are admitted in some countries (such as the United States), while being frowned upon for good reason in some other countries (including the United Kingdom). See [Section 4.5.2.1](#). In the U.S., the Polygraph Protection Act of 1888 banned most polygraph tests for personnel selection purposes; the police in the U.S. resorts to such tests extensively during investigation. In some other countries (e.g., in the U.K.), the police is not allowed to use polygraph tests.

Post-charge questioning Questioning of a suspect on the part of the police, after legal proceedings have started. This is not supposed to happen. Legal proceedings only start once the investigation stage ends: once a suspect is charged, the police can no longer question him or her. *Post-charge questioning* (on the part of police investigators) of terrorism suspects, possibly extended to other categories of criminals, was considered by the British government in November 2007, drawing criticism from civil liberties groups.

Preponderance of the evidence On balance, the evidence seems to favour adjudication one way rather than in the other. This standard of proof is weaker than *beyond reasonable doubt*. Without sticking to the legal sense of these phrases, in the *Carneades* argumentation tool (Gordon & Walton, 2006), a standard of evidence stronger than *scintilla of evidence* and weaker than *beyond reasonable doubt* is The second weakest is PE (preponderance of the evidence): “A statement meets this standard iff its strongest defensible pro argument outweighs its strongest defensible con argument”. A stronger standard (yet weaker than BRD, *beyond reasonable doubt*) is DV, which is defined as follows: “A statement meets this standard iff it is supported by at least one defensible pro argument and none of its con arguments is defensible”.

Principal component analysis In statistical data analysis: “Principal components analysis (PCA) is the technique most often used to identify features that do not contribute to the prediction from a data-set. PCA involves the analysis of variance between features and the class variable in a prediction exercise. PCA requires specialist statistical software, since the calculations are cumbersome. PCA is applicable only to features that are numeric” (Stranieri & Zeleznikow, 2005a, Glossary).

Principled negotiation “Principled negotiation promotes deciding issues on their merits rather than through a haggling process focussed on what each side says it will and will not do” (Stranieri & Zeleznikow, 2005a, Glossary).

Prior convictions (evidence of) See [character evidence](#) (of which this is a kind); **jury observation fallacy**.

Private privilege The rule by which some categories of witnesses cannot be compelled to disclose certain kinds of information or documents. This includes protection from *self-incrimination*, either for the accused – who under English law “may not be asked questions which tend to show that he may be guilty of any other offence than that with which he is presently charged” (Osborne, 1997,

p. 338) – and for other witness: “In a criminal case no witness can be compelled to answer any question which would, in the opinion of the judge, have a tendency to expose the witness to any criminal charge” (ibid.). Another kind of private privilege is *legal professional privilege*, by which lawyer–client communications, as well as communications with third parties for the purpose of actual or pending litigation, are protected from disclosure. Yet, the client may waive this privilege, and direct his or her lawyer accordingly. Moreover, communications to facilitate crime or fraud are not privileged.

Privilege A rule that protects some kinds of communication or material documents from disclosure at trial or during a police investigation. There is *private privilege*, and there is *public interest privilege*.

Probabilistic information retrieval models “Probabilistic information retrieval models are based on the probability ranking principle which ranks legal documents according to their probability of relevance to the query given every available source of information. The model estimates the probability of relevance of a text to the query, on the basis of the statistical distribution of terms in relevant and irrelevant text, given an uncertainty associated with the representation of both the source text and the information need, as well as the relevance relationship between them” (Stranieri & Zeleznikow, 2005a, Glossary).

Probability Donald Gillies (2004, p. 286) provides this usefully concise explanation:

Probability theory originated from the study of games of chance, and these still afford a good illustration of some of the basic concepts of the theory. If we roll a fair dice, the probability of getting 5 is 1/6. This is written $P(5)=1/6$. A *conditional probability* is the probabilities of a result given that something else has happened. For example, the probability of 5 given that the result was odd, is no longer 1/6, but 1/3; while the probability of 5 given that the result was even, is no longer 1/6, but 0. A conditional probability is written $P(A|B)$. So we have $P(5|\text{odd})=1/3$, and $P(5|\text{even})=0$. A related concept is *independence*. Two events A and B are said to be *independent* if the conditional probability of A given B is the same as the probability of A , or, in symbols, if $P(A|B)=P(A)$. Successive rolls of a die are normally assumed to be independent, that is to say, the probability of getting a 5 is always the same, namely 1/6, regardless of what results have appeared so far. An important concept for probability in AI is *conditional independence*. A and B are said to be *conditionally independent* given C , if $P(A|B\&C) = P(A|C)$.

Also see **Probability, prior and posterior**.

Probability, objective “An *objective probability* is one which is supposed to be a feature of the objective world, such as mass or electrical charge. A well-known objective interpretation of probability is the frequency interpretation. For example, to say that the probability of 5 is 1/6 on this interpretation is taken to mean that, in a long series of rolls of the die, the result 5 will appear with a frequency of approximately 1/6. Those who adopt this interpretation estimate their probabilities from frequency data” (Gillies, 2004, p. 287).

Probability, prior and posterior With reference to Bayes’ theorem, which when dealing with a hypothesis H , and some evidence E , states:

$$P(H|E) = P(E|H)P(H)/P(E)$$

this can be read as follows: the *posterior probability* $P(H|E)$, i.e., the probability that H is true given E , is equal to the product of the *likelihood* $P(E|H)$, i.e., the probability that E given the truth of H , and the *prior probability* $P(H)$ of H , divided by the *prior probability* $P(E)$ of E . A synonym of *prior probability* is a *priori probability*. A synonym of *posterior probability* is a *posteriori probability*.

Probability, subjective It “is taken to be the measure of the degree of belief of a particular individual that some event will occur. For example, if I say that my subjective probability that it will rain in London tomorrow is $2/3$, this means that I believe to degree $2/3$ that it will rain in London tomorrow. A woman’s degree of belief can be measured by the rate at which she is prepared to bet, or her betting quotient. It can be shown that, starting from this way of measuring belief, the standard axioms of probability can be derived. An application of the subjective theory of probability to Bayesianism produces what is known as *subjective Bayesianism*. Here $P(H)$ is taken to represent the prior degree of belief of Mr. R , say, that H is true, while $P(H|E)$ represents his posterior degree of belief in H after he has come to know evidence E . A rational man on this approach changes his degree of belief in the light of new evidence E from $P(H)$ to $P(H|E)$, where the value of $P(H|E)$ is calculated using Bayes Theorem” (Gillies, 2004, p. 287).

Probative value “Probative value is a relational concept that expresses the strength with which evidence supports an inference to a given conclusion. It is a crucial concept for determining admissibility (see Fed[eral] R[ules of] Evid[ence] 403, which instructs judges to exclude evidence when its probative value is substantially outweighed by its prejudicial, confusing, or duplicative effect) and for determining whether parties have satisfied their burdens of proof” (Allen & Pardo, 2007a, p. 108, fn. 2).

Procedural *Procedural*, as opposed to *substantive*, as opposed to *procedural*, pertains to how to administer the judiciary process. For example, the order in which the parties and their witnesses testify belongs in procedure.

Procedural representation scheme In artificial intelligence: “A procedural representation scheme is a knowledge representation scheme in which knowledge is represented as a set of instructions for solving a problem. Examples of procedural representation schemes include production rules”, i.e., IF-THEN rules (Stranieri & Zeleznikow, 2005a, Glossary).

Procedural-support systems A category of computer tools for assisting humans in handling court cases. “Procedural-support systems are AI & Law programs that lack domain knowledge and thus cannot solve problems, but that instead help the participants in a dispute to structure their reasoning and discussion, thereby promoting orderly and effective disputes” (Prakken & Renooij, 2001). “When procedural-support systems are to be useful in practice, they should provide support for causal reasoning about evidence” (ibid.). Available operational tools include *CaseMap*, *MarshalPlan*, and (in Italy) *Daedalus*. See Section 4.1.

Production rule In artificial intelligence: a rule consisting of a *condition part* (or *left-hand part*) and an *action part* (or *right-hand part*). It is also called an *IF-THEN rule*.

Production rule system In artificial intelligence: “Production rule systems are expert systems which consist of a set of production rules, working memory and the recognise-act cycle (also known as the rule interpreter)” (Stranieri & Zeleznikow, 2005a, Glossary).

PROLEXS “The PROLEXS project at the Computer/Law Institute, Vrije Universiteit, Amsterdam, Netherlands is concerned with the construction of legal expert shells to deal with vague concepts. Its current domain is Dutch landlord-tenant law. It uses several knowledge sources and the inference engines of the independent knowledge groups interact using a blackboard architecture” (Stranieri & Zeleznikow, 2005a, Glossary). See Section 6.1.14.9 in this book, and s.v. **blackboard systems**. PROLEXS is the subject of Walker, Oskamp, Schrickx, Opdorp, and van den Berg (1991) and of Oskamp et al. (1989).

Prosecutorial discretion The choice being left to the prosecutor (in some jurisdictions, especially in the Anglo-American adversarial system), whether to prosecute or not, and if not, to propose a *plea bargain*. As opposed to *obligatory prosecution*, which until recently used to be common in Continental Europe. Prosecution, as being the decision to charge a suspect with a crime, is the subject, e.g., of books by Miller (1969) and by Jacoby, Mellon, Ratledge, and Turner (1982). Cf. Kingsnorth, MacIntosh, and Sutherland (2002).³⁸ **Discretion** (q.v.) is a broader concept.

Public inquiry As public inquiries in Britain are inquisitorial, as opposed to the adversarial system that characterises the courts, the impact of this contrast is explained at the entry for **inquisitorial**. As early as the Bristol Public Inquiry in the late 1990 (it was chaired by Sir Ian Kennedy: see **inquisitorial**), “the Inquiry established a process whereby the statements of witnesses who were not to be called were made available on the Inquiry’s website, together with the comment, if any, of someone identified by the Inquiry’s lawyers as having been the object of criticism in the statement” (Kennedy, 2007, p. 37). That was also the case of witnesses that were called to give oral evidence before the Inquiry, but then their statements with the comments were not posted at the website until the

³⁸ Flowe et al. (2010) pointed out: “Prosecutors have the discretion to determine whether a suspect will be charged and what charges the suspect should face (Bordenkircher v. Hayes, 1978). Prosecutors also have a legal and ethical obligation to protect felony suspects who are not just innocent-in-fact, but who are also innocent-in-law (California District Attorneys Association, 1996). Charges should not be filed even if the prosecutor has a personal belief in the suspect’s guilt. Rather, issuing decisions should be guided by whether the evidence in the case is legally sufficient and admissible. Previous archival research has found that felony charges are more likely to be issued if there is physical evidence to support the allegations (Albonetti, 1987; Feeney, Dill, & Weir, 1983; Jacoby et al., 1982; Miller, 1969; Nagel, & Hagan, 1983) and if the crime is serious, such as when a victim has been injured (Kingsnorth et al., 2002). Factors that may lead prosecutors to not file charges include: A primary aggressor has not been identified (e.g., the California Primary Aggressor Law requires a primary aggressor be identified), the suspect is thought to be innocent, or there are ‘interests of justice’ concerns, such as the suspect will provide testimony in a more serious case (Silberman, 1978). Despite the fact that much research has been carried out examining the relationship between evidentiary factors and felony issuing decisions, little is known about the role that eyewitness identification evidence may play in prosecution.”

witness had given oral evidence. That way, the contributions of the various witnesses were known in advance. This made it possible to schedule the witness' appearance accordingly. Resorting to a website did away with *Salmon letters* (ibid.):

Not only was this [web-supported procedure] fair to all, but it allowed the Inquiry to take account of and explore differences of view when questioning witnesses. Moreover, it meant that the Inquiry could avoid a procedure known as the issuing of "Salmon letters", named after Lord Justice Salmon who chaired the Royal Commission on Tribunals in 1966. The purpose of "Salmon letters" was to put individuals on notice should they have been criticised in evidence. It was a procedural response to the evidence heard, designed to ensure fairness. I took the view that it reflected an approach which equated Public Inquiries with judicial proceedings. It was, therefore, inappropriate and, moreover, unnecessary. Fairness could be maintained in a far more coherent and sensible way. In effect, the "Salmon letters" procedure introduced an unnecessary formal step into the proceedings, which commonly provoked legal to-ing and fro-ing. By getting witnessed to reveal and confront their various accounts well in advance, everyone knew where they stood. There was no need to have resort to some additional, and time-consuming, and, frankly, out-dated procedural mechanism.

Public interest privilege Also called *public interest immunity*. A category of *privilege*, by which "evidence is excluded because of some public interest in withholding it which outweighs the usual public interest in open litigation" (Osborne, 1997, p. 340). A lesser legal concept than *privilege* is *confidentiality*, and it, too, is such that communications in professional–client relationships are sometimes protected (which is, instead, a right, and is considered *private privilege*, for the client of a lawyer). "[O]ne originally separate basis of public privilege which has merged somewhat into the mainstream is the rule that no question may be asked in proceedings which would tend to lead to the identification of any person who has given information leading to the institution of a prosecution" (ibid., p. 342).

Questioned documents evidence Evidence from forensic tests (Levinson, 2000), concerning the authenticity of documents or parts thereof, of their authorship ascription, of their date, or of the hand in which they are written. There exist techniques for determining authenticity, age, ink and paper sources, equipment used, forgeries, alterations, and erasures, as well as *handwriting identification*, the latter being the subject of Morris (2000). See Section 6.1.10. The following is quoted from the introduction to the useful entry for 'Questioned document examination' in Wikipedia³⁹:

Questioned document examination (QDE) is known by many names including *forensic document examination*, *document examination*, *diplomats*, *handwriting examination*, and sometimes *handwriting analysis*, although the latter name is not often used as it may be confused with graphology. Likewise a forensic document examiner is not to be confused with a graphologist, and vice versa. The questioned document division of a crime lab is sometimes referred to as "QD" in popular media.

The task of forensic document examination is to answer questions about a disputed document using a variety of scientific processes and methods. Many examinations involve a comparison of the questioned document, or components of the document, to a

³⁹ http://en.wikipedia.org/wiki/Questioned_document_examination

set of known standards. The most common type of examination involves handwriting wherein the examiner tries to address concerns about potential authorship.

One task of a forensic document examiner is to determine if a questioned item originated from the same source as the known item(s), then present their opinion in court as an expert witness. Other tasks include determining what has happened to a document, determining when a document was produced, or deciphering information on the document that has been obscured, obliterated or erased.

Professional organisations include the American Society of Questioned Document Examiners (ASQDE), the American Academy of Forensic Science (AAFS), the Southwestern Association of Forensic Document Examiners (SWAFDE), and the Southeastern Association of Forensic Document Examiners (SAFDE) in the U.S.A.; the Canadian Society of Forensic Science (CSFS); the Australasian Society of Forensic Document Examiners (ASFDE) in Australia and Asia; the Gesellschaft für Forensische Schriftuntersuchung (GFS) in Frankfurt (Germany); the Asociación Profesional de Peritos Calígrafos de Cataluña (in Spain); the National Association of Document Examiners (NADE); the Association of Forensic Document Examiners (AFDE); and so forth.

Questioning During police investigations, the process of asking suspects, or actual or potential witnesses, such questions that seek to uncover information. This is quite different from *examination* in court. It is important not to confuse examination in court, with questioning by the police during investigation. Legal proceedings only start once the investigation stage ends: once a suspect is charged, the police can no longer question him or her. *Post-charge questioning* (on the part of police investigators) of terrorism suspects, possibly extended to other categories of criminals, was considered by the British government in November 2007, drawing criticism from civil liberties groups.

Questmap A computer tool for supporting argumentation (Carr, 2003). *QuestMap* is based on IBIS, mediates discussions, supports collaborative argumentation, and creates information maps, in the context of legal education. Collaborative problem identification and solving is the purpose of IBIS, an Issue-Based Information System. Problems are decomposed into issues. See [Section 3.7](#).

Ratio decidendi The rationale of a decision made by an adjudicator in a court case. The ground or reason for the decision. The point in a case that determines the judgement. “*Ratio decidendi* is Latin for the “reasons for decision”, that is the legal reasons why the judge came to the conclusion that he or she did. It is the fundamental basis for the rule of law in common law systems. Stare decisis says that the ratio decidendi will apply to subsequent cases decided by courts lower in the hierarchy” (Stranieri & Zeleznikow, 2005a, Glossary).

Reason!Able A computer tool for supporting argumentation (van Gelder, 2002). Some tools envisage collaboration among users, yet *Reason!Able* only has one user per session. It guides the user step-by-step through the process of constructing an argument tree, containing claims, reasons, and objections, the latter two kinds being complex objects which can be unfolded to see the premises. See [Section 3.7](#).

Rebutter A defendant's answer in matter of fact (about the accusation and the evidence) to a plaintiff's (or, in particular, prosecution's) *surrejoinder*. (See [replication](#).)

Reference-class problem Allen and Pardo (2007a, p. 109) find that scholarship which applies probability theory to juridical proof

suffers from a deep conceptual problem that makes ambiguous the lessons that can be drawn from it – the problem of reference classes. The implications of this problem are considerable. To illustrate the problem, consider the famous blue bus hypothetical. Suppose a witness saw a bus strike a car but cannot recall the color of the bus; assume further that the Blue Company owns 75 percent of the buses in the town and the Red Company owns the remaining 25 percent. The most prevalent view in the legal literature of the probative value of the witness's report is that it would be determined by the ratio of the Blue Company buses to Red Company buses, whether this is thought of as or plays the role of a likelihood ratio or determines information gain (including an assessment of a prior probability) [...] But suppose the Red Company owns 75 percent (and Blue the other 25 percent) of the buses in the county. Now the ratio reverses. And it would do so again if Blue owned 75 percent in the state. Or in the opposite direction: it would reverse if Red owned 75 percent running in the street where the accident occurred (or on that side of the street) and so on. Or maybe the proper reference class has to do with safety standards and protocols for reporting accidents. Each of the reference classes leads to a different inference about which company is more likely liable, and nothing determines the correct class, save one: the very event under discussion, which has a likelihood of one and which we are trying to discover.

“The blue bus hypothetical [...] exemplifies the general implications of reference classes, and those implications would hold for practically any attempt to quantify a priori the probative value of evidence” (ibid., p. 113).

Regression In statistics: “In linear regression, data is modelled using a straight line of the form $y = \alpha x + \beta$. α and β are determined using the method of least squares. Polynomial regression models can be transformed to a linear regression model.” (Stranieri & Zeleznikow, 2005a, Glossary).

Rejoinder The defendant's answer to the plaintiff's *replication*. (See [replication](#).)

Relevance Pertinence of a piece of evidence, for the purposes of proving that which is to be proven in court, as a criterion for such evidence to be heard or excluded instead. Yovel (2003) provided a mildly formalised treatment, with a notation in *MicroProlog* style, of what in legal scholarship about evidence is known as *relevance*. See [Section 4.6](#) in this book. Here is a definition from a legal textbook on evidence: “The purpose of calling evidence in court is to try to prove certain facts to be true. Evidence which assists in this process is relevant and that which does not assist is irrelevant. It is the first rule of evidence, and one to which there are no exceptions, that irrelevant evidence is never admissible in court. This does not mean that relevant evidence is always allowed, because sometimes the court disallows it despite its relevance. The greater proportion of this book is about rules which limit the extent to which relevant evidence can be used” (Templeman & Reay, 1999, p. 1). Modern theories of relevance are the subject of Tillers (1983). Also see Richard Lempert's (1977) ‘Modeling Relevance’.

There also exist other senses of *relevance*: in *sensitivity analysis* from statistics, including when it is applied to legal evidence, “An item of evidence is called ‘relevant’ to a hypothesis if observing the evidence changes the probability

that the hypothesis is true” (Levitt & Laskey, 2002, p. 375). Moreover, for the *relevance of an utterance*, see in the entry for **loose talk** in this Glossary.

Teun van Dijk (1989) describes the concept of relevance as it applies to a class of modal logics broadly called “relevance logics” as a concept grounded firmly in the pragmatics, and not the semantics or syntax of language. Within a discursive community, the data items in a generic argument must be relevant to the claim to the satisfaction of members of the community. The purpose of van Dijk’s article was stated as follows (ibid., p. 25):

In this paper an attempt will be made to provide a general and informal discussion of “relevance” and related notions from this linguistic point of view. More particularly, it will be argued that the relevance requirement must be satisfied by any compound sentence, viz. by all connectives, and by any coherent discourse, i.e. not only deductive or argumentative, in natural language. Although such a claim might have feed-back in the philosophy of logic, we will be concerned with the applications of some recent ideas from relevance logics in the explicit characterization of these properties of natural language.

Reparational obligations See **contrary-to-duty obligations**.

Replication In American law: the plaintiff’s (or the prosecution’s) reply to the “defence”, intended as the original statement of the defendant or his defence lawyer (or team of lawyers). The plaintiff’s *replication* may prompt an answer in matters of fact, called the defendant’s *rejoinder*, which may prompt the plaintiff’s *surrejoinder*, which may prompt the defendant’s *rebutter*, which may prompt that plaintiff’s *surrebutter*.

Resolution “Resolution is a semi-decidable proof technique for first order predicate calculus, which given an unsatisfiable well formed formula, proves it to be unsatisfiable. If the well formed formula is not unsatisfiable, there is a possibility that the algorithm may not terminate” (Stranieri & Zeleznikow, 2005a, Glossary).

Respondent In some kinds of trial, the defendant; then the name for the plaintiff is *applicant*.

Rule base (or ruleset). “The rule base of a legal (or indeed any) rule based expert system is that part of the system in which the rules are stored. It is kept separate from the other part of the expert system, the inference engine” (Stranieri & Zeleznikow, 2005a, Glossary).

Rule-based expert system “A rule based expert system is a collection of rules of the form : IF condition(s) THEN action. Rule based systems include production rule systems, and some would argue, logic based systems as well” (Stranieri & Zeleznikow, 2005a, Glossary).

Rule-extracting tools A category of *machine learning* tools. Several commercial rule-extracting tools were described by Mena (2003, section 7.10, pp. 229–232):

- AIRA (<http://www.godigital.com.br>), and Excel add-on
- DataMite,⁴⁰ for relational databases
- SuperQuery (<http://www.azmy.com>)
- WizWhy (<http://www.wizsoft.com>)

⁴⁰ http://www.lpa.co.uk/ind_top.htm

Salmon letters See **public inquiry**.

Scheme *Argumentation schemes* are “predefined patterns of reasoning. A single scheme describes an inference, the necessary prerequisites for that inference, and possible critical questions that might undercut the inference” (van den Braak & Vreeswijk, 2006).

Scintilla of evidence A tenuously probative piece of evidence, enough to motivate probing further, searching for more evidence. Without sticking to this sense of the phrase, in the *Carneades* argumentation tool the weakest standard of evidence is SE (*scintilla of evidence*): “A statement meets this standard iff it is supported by at least one defensible pro argument”.

Secondary obligation See **contrary-to-duty obligations**.

Sensitivity analysis An analysis of how given pieces of evidence being available, would affect the demonstrability of given claims. It can be used when evaluating litigation risk: see [Section 4.3.1](#). It can be useful for a costs/benefits analysis of whether to obtain some piece of evidence: see [Section 4.3.2](#). Levitt and Laskey (2002, Sections 1.4.4 and 1.5.4) discussed and exemplified such a sensitivity analysis, in the context of their analysis of the evidence in a murder case by means of Bayesian networks (BNs). Their example concerns the French case in which Omar Raddad was convicted in 1994 of murdering his employer, but then pardoned because of how controversial the case was. Levitt & Laskey (*ibid.*, p. 375) wrote:

The BN knowledge representation can capture useful quantitative behaviour regarding alternative explanations for the same items of evidence. For example, the relevance of items of evidence regarding Raddad depends on their relationship in the evidential argument implied by the BN, and [...] they can change as evidence accrues. In particular, the evidence of Raddad’s location at the time of the murder is co-dependent with the evidence from the examiner’s testimony about the time of death. The relevance of one depends dynamically on the other, and they co-vary as evidence is accrued to the global evidential argument about Raddad’s guilt or innocence that is modelled by [a given] BN [...]. This introduction of the examiner’s testimony [...] does not change the probability of Raddad’s guilt. That is, the evidence is not relevant to Raddad’s guilt given the evidence accrued up to that point. The examiner’s report becomes relevant when we accrue the evidence that Raddad was with his relatives on Monday. In the presence of the examiner’s report, the evidence provides an alibi and greatly reduces the probability of guilt. Subsequently, the evidence regarding a possible typographical error of the recording of the day of the death changes the relevance of Raddad’s alibi for his whereabouts on Monday from very strongly relevant to very weakly relevant.

The process of exploring complex models to identify subtleties such as this can be facilitated by computational tools, which are in turn enabled by the sophisticated representational and inferential capabilities of the modular BN_{Frag} [i.e., Bayesian network fragments] architecture described in this Article. For example, sensitivity analysis can be used to examine the impact of changes in modeling assumptions of the strength of relevance of evidence to hypothesized conclusions. [...] The term sensitivity analysis has multiple, related, but different definitions in the literature on statistics and scientific experimentation. [...] We illustrate the use of a particular sensitivity analysis, sometimes called an “importance measure,” specifically to compute a measure of the weight or relevance of evidence items to a BN query. An item of evidence is called “relevant” to a hypothesis if observing the evidence changes the probability that the hypothesis is true. [...]

Sentenza suicida In Italy: a justification of a verdict written by a trained judge in a deliberately flawed manner, so that an appeal trial would necessarily take place, thus overturning a verdict given by jurors who outvoted that judge at a *mixed court* (nonexistent in Anglo-Saxon countries): see [jury](#).

Settlement out of court In a civil case, an agreement among the parties not to continue in the case being litigated. It involves a compromise as to compensation. A settlement out of court should not be mistaken for *plea bargaining*, which applies in criminal cases.

Shield For a defendant in a criminal case: such protection that makes it inadmissible for prosecution to cross-examine in order to obtain bad character evidence, or to adduce such evidence. See [character evidence](#), and see [imputation](#). Situations in which the defendant loses his shield include such that come into being if he claims good character for himself, or bad character for prosecution witnesses (or for the prosecutor).

Shield bidding A form of malpractice related to *online auction fraud*. It is also known as *bid shielding*. It “occurs when the buyer uses another email address or a friend (the shield) to drive up prices and discourage bids on an item she wants. At the last minute, the shield withdraws the high bid, allowing the buyer to win the item at a lower price. Most auction sites forbid retracting a bid once it’s made, and on eBay shill and shield bidding is clearly prohibited” (Wahab, 2004). See [Section 6.2.3](#).

Shilling A form of malpractice related to *online auction fraud*. It is known as *bid shilling*, or *shill bidding*. “The ability to disguise identity, revoke bids, and maintain multiple on-line identities may facilitate undesirable practices like *shilling*. Shilling is where sellers arrange for false bids to be placed on the items they are selling. Sellers place the bid themselves by using multiple identities or by using confederates. The idea is to force up the cost of a winning bid and encourage interest in the auction” (Mena, 2003, p. 256). “*Shill bidding*: is the intentional sham bidding by the seller to drive up the price of his/her own item that is up for bid. This is accomplished by the sellers themselves and/or someone that is associated with the seller making bids to purposely drive up the price of the seller’s item.” (Wahab, 2004). Cf. [shield bidding](#). See [Section 6.2.3](#).

Similar fact evidence An exception to the rule which in criminal law prevents the disclosure of evidence of disposition and character (see [evidence of disposition](#)). In England, “the law will permit the prosecution to adduce evidence of previous misconduct where its nature, *modus operandi* or some other circumstance, shows an unmistakable similarity to the offence charged. This must be strong enough to go beyond any question of coincidence so as to lead the jury to conclude ‘this is the work of the same man’” (Osborne, 1997, pp. 313–314). For a somewhat different concept, see [doctrine of chances](#).

Situation theory A formal theory that considers actors within the situation in which they are.

Situation Theory grew out of attempts by Jon Barwise in the late 1970s to provide a semantics for “naked-infinite” perceptual reports such as “Claire saw Jon run”. Barwise’s intuition was that Claire didn’t just see Jon, an individual, but Jon doing

something, a situation. Situations are individuals having properties and standing in relations. A theory of situations would allow us to study and compare various types of situations or situation-like entities, such as facts, events, and scenes. One of the central themes of situation theory of meaning and reference should be set within a general theory of information, one moreover that is rich enough to do justice to perception, communication, and thought. By now many people have contributed by the need to give a rigorous mathematical account of the principles of information that underwrite the theory.⁴¹

Slate A particular computer tool; it supports human users' reasoning by argumentation (Brigsjord, Shilliday, Taylor, Clark, & Khemlani, 2006).

Slot-machine model An extreme logicist view of a legal system. See **logic**.

Smurfing "the breaking up of large sums of money into smaller units, and subsequent passing of each segment through multiple accounts. Used by money launderers, the practice is designed to make the money trail extremely difficult to follow" (Sparrow, 1991, p. 252, fn. 1). See **Chapter 6**.

Social epistemics Social aspects of the philosophy of knowledge, according to Alvin Goldman (1987a, 1987b). Because of such social aspects, the *requirement of total evidence* is an invalid principle, and an example of contravening on it is *exclusionary laws of evidence* in court: jurors are not given all the evidence, and Goldman (1991), who approves of this, calls this *epistemic paternalism*.

SPLIT-UP "SPLIT-UP is a hybrid rule based/ neural network system developed at La Trobe University that uses textbooks, heuristics, expert advice and cases to model that part of the Family Law Act 1975 (Australia) which deals with property division. Explanation is provided through the use of Toulmin argument structures" (Stranieri & Zeleznikow, 2005a, Glossary. It was they who developed SPLIT-UP).

Stare decisis Stare decisis is a fundamental principle in common law legal systems. The principle dictates that the reasoning, loosely, *ratio decidendi*,⁴² used in new cases must follow the reasoning used by decision-makers in courts at the same or higher level in the hierarchy. Stare decisis is unknown to civil law, where judgments rendered by judges only enjoy the *authority of reason*.

Traditional stare decisis is when the same decision has to be taken as a higher court judging about the same facts.

Local stare decisis is when the same decision has to be taken as the same court judging about the same facts.

⁴¹ From the summary of Aczel, Israel, Katagiri, and Peters (1993). "Situation theory is the result of an interdisciplinary effort to create a full-fledged theory of information. Created by scholars and scientists from cognitive science, computer science and AI, linguistics, logic, philosophy, and mathematics, it aims to provide a common set of tools for the analysis of phenomena from all these fields. Unlike Shannon-Weaver type theories of information, which are purely quantitative theories, situation theory aims at providing tools for the analysis of the specific content of a situation (signal, message, data base, statement, or other information-carrying situation). The question addressed is not how much information is carried, but what information is carried" (from the publisher's blurb of Aczel et al. 1993).

⁴² The ground or reason for the decision. The point in a case that determines the judgement.

Personal stare decisis is when the same decision has to be taken as the same judge judging about the same facts.

State witness One of the intended defendants in a criminal case, who having been offered a deal by the prosecution, turns into a witness, allied with the prosecution, against at least one defendant. This is not only the case of minor offenders. Sometimes offenders with a heavy liability are offered to become state witnesses, or at any rate to inform investigators in such a manner that would secure convictions. In Britain, a state witness is said to be giving *Queen's evidence*.

In Britain, a *supergrass* may be a very important informer, not necessarily a state witness. The supergrass system in Britain emerged in 1972, and in its heyday years it was used against armed robbers in London. It also was used to combat terrorism in Northern Ireland. The first police informer within the supergrass system was Bertie Smalls, who shopped hundreds of associates in 1976; the operation was masterminded by Scotland Yard detective Tony Lundy.

In Italy, a somewhat equivalent system is the *pentitismo*: in the late 1970s, as well as during the 1980s and still during trials held during the 1990s, on occasion a “repentant” terrorist would act as state witness against one or more defendants. Such a witness used to be called a *pentito*, or a *superpentito*. Sometimes the deal drew strong criticism, and in all fairness, defeated justice, such as when the murderer of the journalist Walter Tobagi obtained, by turning state witness, his own freedom, as well as that of the woman who had been his girlfriend before they were separately arrested in different circumstances. Once released, he immediately proceeded to wed another woman. One photograph that was highly visible in the mass media showed him talking, and, inside the same frame, the grim face of the father of the journalist whose murder justice had renounced punishing. It has also happened that the sincerity of a *superpentito*, securing convictions, was quite dubious. This was the case of the state witness during the Sofri case (for the 1972 terrorism-related killing of a police inspector), as well as of a witness from the Mafia against Italy's former prime minister Giulio Andreotti, who was convicted for the violent death of a journalist. Also the testimony of a state witness who had raped and murdered in the Circeo case, securing the convictions of other far rightists for a bombing with massive casualties in Bologna, appears to be discredited.

Statistically oriented case-based reasoning paradigms In artificial intelligence: “In statistically oriented case based reasoning paradigms, cases are used as data points for statistical generalisation. The case based reasoner computes conditional probabilities that a problem should be treated similarly to previously given cases” (Stranieri & Zeleznikow, 2005a, Glossary). See **case-based reasoning**.

Statistical reasoning “In contrast to symbolic reasoning, statistical reasoning derives its results by checking whether or not there is a statistical correlation between two events. Examples of statistical reasoning include neural networks and rule induction systems. Whilst rule based systems are considered to be examples of symbolic reasoning; the rules are often derived using statistical tests” (Stranieri & Zeleznikow, 2005a, Glossary).

Statutory law In countries like Britain there are both *statutory law*, i.e., laws passed by Parliament, and *common law*, i.e., the body of sentences passed by judges, and

that serve as precedent. “Statutory law is that body of law created by acts of the legislature – in contrast to constitutional law and law generated by decisions of courts and administrative bodies” (Stranieri & Zeleznimkow, 2005a, Glossary).

Stevie An argumentation-based computer tool intended for supporting criminal investigation. Stevie enables analysts to view evidence and inferences, The program is described as distilling out of that information coherent *stories* which are “hypothetical reconstructions of what might have happened”, and which are defined as “a conflict-free and self-defending collection of claims” which moreover is temporally consistent (van den Braak & Vreeswijk, 2006). See [Section 3.10.2](#).

Story A narrative: see [Chapter 5](#). In *Stevie*, a *story* is “a conflict-free and self-defending collection of claims” which moreover is temporally consistent (van den Braak & Vreeswijk, 2006). See [Section 3.10.2](#).

Story model Of Nancy Pennington and Reid Hastie (1986, 1988, 1992, 1993), for modelling jurors’ decision making. It is based on the information processing paradigm from cognitive psychology.

Striking similarity A strong similarity between a crime to previous convictions of a criminal suspect or defendant, such that the crime under trial and the ones from previous convictions are in the same legal category, and shared similarities such as the *modus operandi*, geographic proximity, and so forth. It is where there is such “striking similarity”, that a case may get to the jury on previous convictions alone. See [jury observation fallacy](#).

Substantive *Substantive*, as opposed to *procedural*, pertains to the rules of right administered by a court, rather than to how to administer it.

Supergrass In Britain, an informer whose collaboration is extremely fruitful for police investigators. Such an informer may or not be a **state witness** (q.v.). The latter is always the case, instead, of Italy’s **pentitismo** (q.v.). The supergrass system in Britain emerged in 1972, and in its heyday years it was used against armed robbers in London. It also was used to combat terrorism in Northern Ireland. The first police informer within the supergrass system was Bertie Smalls, who shopped hundreds of associates in 1976; the operation was masterminded by Scotland Yard detective Tony Lundy.

Surrebutter or surrebuttal A plaintiff reply to a defendant’s *rebutter*. (See [replication](#).)

Surrejoinder A plaintiff reply to a defendant’s **rejoinder**. (See [replication](#).)

Teleological Of an argument (as opposed to *deontological* reasoning): of a “[reason given for acting or not acting in a certain way may be on account of what so acting or not acting will bring about. [. . .] All teleological reasoning presupposes some evaluation” (MacCormick, 1995, p. 468).

Text mining “sometimes alternately referred to as *text data mining*, roughly equivalent to *text analytics*, refers to the process of deriving high-quality information from text. High-quality information is typically derived through the divining of patterns and trends through means such as statistical pattern learning. Text mining usually involves the process of structuring the input text (usually parsing, along with the addition of some derived linguistic features and the removal of

others, and subsequent insertion into a database), deriving patterns within the structured data, and finally evaluation and interpretation of the output. ‘High quality’ in text mining usually refers to some combination of relevance, novelty, and interestingness. Typical text mining tasks include text categorisation, text clustering, concept/entity extraction, production of granular taxonomies, sentiment analysis, document summarisation, and entity/relation modelling (i.e., learning relations between named entities)⁴³. See Chapter 6. Commercial tools include:

- AeroText – provides a suite of text mining applications for content analysis. Content used can be in multiple languages.
- Attensity – hosted, integrated and stand-alone text mining (analytics) software that uses natural language processing technology to address collective intelligence in social media and forums; the voice of the customer in surveys and emails; customer relationship management; e-services; research and e-discovery; risk and compliance; and intelligence analysis.
- Autonomy – suite of text mining, clustering and categorisation solutions for a variety of industries.
- Basis Technology – provides a suite of text analysis modules to identify language, enable search in more than 20 languages, extract entities, and efficiently search for and translate entities.
- Endeca Technologies – provides software to analyse and cluster unstructured text.
- Expert System S.p.A. – suite of semantic technologies and products for developers and knowledge managers.
- Fair Isaac – leading provider of decision management solutions powered by advanced analytics (includes text analytics).
- Inxight – provider of text analytics, search, and unstructured visualisation technologies. (Inxight was bought by Business Objects that was bought by SAP AG in 2008).
- LanguageWare – text analysis libraries and customisation tooling from IBM.
- LexisNexis – provider of business intelligence solutions based on an extensive news and company information content set. Through the recent acquisition of Datops LexisNexis is leveraging its search and retrieval expertise to become a player in the text and data mining field.
- Nstein Technologies – text mining solution that creates rich metadata to allow publishers to increase page views, increase site stickiness, optimise SEO, automate tagging, improve search experience, increase editorial productivity, decrease operational publishing costs, increase online revenues. In combination with search engines it is used to create semantic search applications.

⁴³ Based upon the Wikipedia entry http://en.wikipedia.org/wiki/Text_mining (the way it was in late July 2010).

- SAS – solutions including SAS Text Miner and Teragram – commercial text analytics, natural language processing, and taxonomy software leveraged for Information Management.
- Silobreaker – provides text analytics, clustering, search and visualisation technologies.
- SPSS – provider of SPSS Text Analysis for Surveys, Text Mining for Clementine, LexiQuest Mine and LexiQuest Categorize, commercial text analytics software that can be used in conjunction with SPSS Predictive Analytics Solutions.
- StatSoft – provides STATISTICA Text Miner as an optional extension to STATISTICA Data Miner, for Predictive Analytics Solutions.
- Thomson Data Analyzer – enables complex analysis on patent information, scientific publications and news.

Open source resources include⁴⁴:

- GATE – natural language processing and language engineering tool.
- UIMA – UIMA (Unstructured Information Management Architecture) is a component framework for analysing unstructured content such as text, audio and video, originally developed by IBM.
- YALE/RapidMiner with its Word Vector Tool plug-in – data and text mining software.
- Carrot2 – text and search results clustering framework.

Time *Legal time* is a debated issue in legal theory (e.g., Jackson, 1998b), as well as in AI & Law.⁴⁵ For the latter, see a thematic journal issue (Martino & Nissan, 1998) devoted to temporal representation for legal applications. In our present context, it is worth mentioning especially the treatment of a crime narrative in section 5 (pp. 233–238) in Gian Piero Zarri’s article (Zarri, 1998) in that journal issue. Zarri described and applied his NKRL system of representation of time, causality and intentionality. Poulin, Mackaay [sic], Bratley, and Frémont (1989) described a “time specialist” software – using “intervals as the basic temporal element” (ibid., p. 747) – as well as a language, EXPERT/T, based on a temporal logic for legal rules. Temporal logics are popular in AI (Fisher et al., 2005; Knight et al., 1999). Also see “Time in automated legal reasoning” by Vila and Yoshino (2005). For another formalism that is oriented, instead, to the semantic representation of verbal tense, Alice ter Meulen’s trees for temporal representation, stemming from theoretical semantics, refer to a book review by Nissan

⁴⁴ http://en.wikipedia.org/wiki/Text_mining

⁴⁵ Moreover, the *recency effect* is debated in psychology, in relation to legal evidence (Furnam, 1986).

(1998b). One of the products of CaseSoft,⁴⁶ an American firm producing software for legal professionals, is the *TimeMap* chronology-graphing software. Let us consider constraints on *temporal sequence* in a criminal trial in Anglo-American jurisdictions. The phases of such a trial are as follows:

Indictment;

The accused is asked to plea guilty or not guilty;

- If the defendant pleads guilty – plea-bargain:
 1. The court hears the facts from the prosecution (with no need to present evidence);
 2. Defence may intervene;
 3. Sentence.
- If the defendant pleads not guilty, the case will have to be prosecuted;
 1. Adjournment to an agreed date;
 2. Adjournment hearing (following adversarial lines);
 3. Prosecution opening speech;
 4. Prosecution calls witnesses;
 - 4.1. Examination in chief;
 - 4.2. Cross-examination;
 - 4.3. (sometimes) re-examination;
 5. Close of the prosecution case;
 6. (The defence may submit that there is no case to answer. If the court accepts this, the defendant is discharged. Otherwise:)
 7. Defence calls witnesses:
 - 7.1. Examination in chief;
 - 7.2. Cross-examination;
 - 7.3. (sometimes) re-examination;
 8. Defence’s closing speech to the bench (= closing arguments = final submissions);
 9. (Prosecution may have one more speech, but then defence must have the last word.)
 10. The magistrates retire to consider their decision (the decision is taken either by a bench of lay magistrates, i.e., a jury, or a stipendiary magistrate, i.e., a trained judge);
 - if the fact-finders are a jury, before they retire they are given final instructions by the judge;
 11. The magistrates return and give a verdict (and state no reason);
 - 11a. If the verdict is “not guilty”, then the defendant is discharged;
 - 11b. If the verdict is “guilty”, then:
 - 11b.1. The court hears the facts from the prosecution (with no need to present evidence);
 - 11b.2. Defence may intervene;
 - 11b.3. Sentence.

⁴⁶ <http://www.casesoft.com>

How is the delivery of the evidence affected, by the constraints on the temporal sequence of the phases of a trial? There are important implications for the possibility to introduce evidence. Consider for example employment tribunals in England and Wales (thus, we are not dealing now with criminal cases). The Applicant (i.e., the plaintiff) gives his statement, which is read aloud by himself, or silently by the Court. He is then examined by his barrister (he has one, unless he is representing himself), and then cross-examined by the Respondent's barrister. (If the Applicant is an employee, then the Respondent will typically be his employer.)

Some new evidence, not found in the written statement and in the bundle of documentary evidence, may emerge when the Applicant is asked questions as a witness. Cross-examination of the Applicant is followed sometimes by his being subjected to re-examination by his own side's barrister, and then (also optionally) the Court may ask him questions. Then, all witnesses for the Applicant undergo (each in turn) the same cycle of giving their respective statement, being examined, cross-examined, possibly re-examined, and asked questions by the Court. Next, the same happens for the Respondent.

A major problem for the Applicant arises, if witnesses for the defence present new evidence when examined and cross-examined, as the Applicant's barrister may be unaware on the spur of the moment of what to ask next to such an item of evidence emerging, whereas the (former) employee being the Applicant would be quite able, cognitively but not procedurally in the trial, to ask such questions that would expose untruthful evidence when it is submitted by the defence's witnesses when examined or cross-examined. Procedural constraints prevent the Applicant himself from intervening (unless he has no barrister and is representing himself, which in other respects would be a big disadvantage), let alone making a further statement giving evidence in response to the defence's witnesses. (This is not formally forbidden, but in practice this is strongly and tacitly discouraged, because of how complicate the trial would become.)

A further disadvantage for the Applicant is if after he and his witnesses have finished giving evidence, the barrister for the defence submits some further item of documentary evidence (this may be very important, and deliberately withheld for the purposes of an "ambush"): the Court may criticise such a move, yet accept that the new evidence be added to the bundle. The Applicant's barrister may protest, or refrain from doing so if he or she deems that protesting would be impolitic. Even when summing up in the end, the barrister for the Applicant will be unable to introduce new information as evidence, even though the Applicant may have such information that is relevant or even crucial.

It happens sometimes that by agreement between the parties, a witness for the Applicant will be able to give evidence after one or more witnesses of the Respondent, because the witness being late is cogently unable to come before (e.g., if he has to fly from abroad). Nevertheless, it is up to the parties and to the Court to agree about this. It may be of advantage to the Applicant, if the late witness for the Applicant will be asked questions (possibly, even by the Court)

that would enable to assess some evidence that had previously been introduced by a witness for the Respondent. This way, such evidence may be refuted, that would not have been otherwise, because of procedural constraints.

The situation with a late witness for the Applicant is such that procedural constraints on the temporal sequence are overridden because of the agreement between the parties, which enables that witness give evidence after one or more of the witnesses for the Respondent. Out of courtesy, the Court may then instruct the defence that if the defence would like to call back its witnesses that had given evidence before, *after* the late witness of the Applicant, this request would be granted. The defence may then renounce this (perhaps in order not to be perceived as having been put at a disadvantage).

Another way for time constraints to be involved, is that the hearing at the tribunal is booked several months in advance, and one's barrister will have to be paid according to the expected length of the hearing. One tactic of the Respondent may be to cause their witnesses (including ones who do not really introduce important evidence) use more time than expected, so that a new additional hearing, months away, will have to be booked, at which some more witnesses of the Respondent will give evidence, then the Applicant's barrister will sum up, and the Respondent's barrister will sum up. At this additional hearing, the Applicant will have to be silent, not being able to introduce more evidence. Booking another hearing may be beyond what is affordable to the more impecunious party, which oftentimes is an employee of a big corporation. This may in practice compel the Applicant to accept a settlement.

Yet another problem is that sometimes employment tribunals (a president and two further members) are double-booked by the administration of the tribunals, and they themselves only learn about this early during the hearing. For the more impecunious party, this is a major burden, making it more likely that one more hearing will have to be booked. This, too, militates towards the more impecunious party being more likely to accept a settlement.

All of this is interesting both legally, and for AI modelling. The temporal sequence conditions how the evidence can be introduced, and whether evidence can be given in reply. Techniques from AI can represent this. Yet, AI practitioners need know about such procedural constraints. Importantly, there are less exclusionary rules on evidence at employment tribunals in England and Wales, than there are on criminal evidence.

In employment cases, a first deadline applies to the submission of which documentary evidence will go into the bundle. The solicitors of the two parties reach an agreement. Exceptionally (as seen earlier) some new document may be submitted during the hearing, subject to the discretion of the Court. Some time after the bundle of documentary evidence is finalised, the two parties exchange witness statements. This must be simultaneous, in order to avoid that a last-minute change is done in the statement that comes late, so that it would respond to some "surprise" in store in the statement of the other party that arrived early. Exceptionally, on the day after the exchange of statements it may happen that the solicitors for the defence claim to the solicitor of the Applicant that they forgot to email or

to fax one of the witnesses statements. The Applicant may renounce to protest, considering that the Court may override the protest.

All of this is fertile ground for AI modelling. Temporal constraints are so important, at a hearing, that they may make or break a case.

We have explained such situations, that a constraint is not satisfied, but then a standard arrangement is adopted. This can be modelled in terms of **contrary-to-duty obligations** (q.v.).

Toulmin’s model A widespread model of argument structure (Toulmin, 1958). It consists of the following parts: Data (the premises), Claim (the conclusion), Qualifier (the modality of how the argument holds), Warrant (support for the argument), Backing (support for the Warrant), and Rebuttal (an exception). See [Section 3.2](#).

Traitor tracing A technique applied to *pirate tracking software*, within *multimedia forensics*. The term *traitor tracing* has previously been used also in the literature about cryptography. See [Section 6.2.1.5](#).

Transvaluationism An account of *vagueness* proposed by philosopher Terry Horgan. Cf. **loose talk** (q.v.). Vagueness in statements given in court is usually recognised not to amount to untruthfulness. Horgan (2010, p. 67) states:

The philosophical account of vagueness I call “transvaluationism” makes three fundamental claims. First, vagueness is logically incoherent in a certain way: it essentially involves mutually unsatisfiable requirements that govern vague language, vague thought-content, and putative vague objects and properties. Second, vagueness in language and thought (i.e., semantic vagueness) is a genuine phenomenon despite possessing this form of incoherence – and is viable, legitimate, and indeed indispensable. Third, vagueness as a feature of objects, properties, or relations (i.e., ontological vagueness) is impossible, because of the mutually unsatisfiable conditions that such putative items would have to meet.

An important concept in Horgan’s treatment is that of sorites sequence, an example of which is “a sequence of men each of whom has a tiny bit more hair on his head than his predecessor” (when applying vagueness to the descriptor *bald*). Horgan explains (2010, pp. 70–71):

A second essential feature of vagueness is what I call “boundarylessness” – a term I adopt from Sainsbury (1990). This feature, which obtains with respect to a sorites sequence, involves the simultaneous satisfaction by the sequence of the following two conditions:

The Difference Condition: Initially in the sorites sequence there are items with a specific status and every predecessor of an item with this status has the same status. Eventually in the sequence there are items with the polar-opposite status, and every successor of an item with this status has the same status. No item in the sequence has both the initial status and the polar-opposite status.

The Transition Condition: There is no determinate fact of the matter about status-transitions in the sorites sequence.

Examples of polar-opposite statuses are baldness vs. nonbaldness, heaphood vs. non-heaphood, satisfying the predicate “is bald” vs. satisfying the expression “is not bald”, truth vs. falsity.

The Transition Condition needs further conceptual unpacking. It involves, essentially, two conceptual aspects or dimensions, one individualistic and the other collectivistic.

The Individualistic Same-Status Principle (ISS Principle): Each item in the sorites sequence has the same status as its immediate neighbors.

The Collectivistic Status-Indeterminacy Principle (CSI Principle): There is no correct overall distribution of statuses to the items in the sequence.

The ISS Principle is so called because it involves items in the sequence considered individually – each considered in relation to its immediate neighbors. The CSS Principle is so called because it involves the items in the sequence considered collectively. Both principles are essentially involved in the idea of boundarylessness – the idea of an absence of sharp boundaries.

TreeAge Pro Decision tree software, for performing a Litigation Risk Analysis. See [Section 4.3.1](#).

Trial by mathematics Originally, the title of Tribe (1971), about the Bayesian approach to modelling judicial decision-making in criminal cases. Nevertheless, the phrase is likelier to occur in polemical contexts.

Triangulation A form of *online auction fraud* (see [Section 6.2.3](#)). “Involves three parties: the perpetrator, a consumer, and an online merchant. The perpetrator buys merchandise from an online merchant using stolen identities and credit card numbers. Then, the perpetrator sells the merchandise at online auction sites to unsuspecting buyers. Later, the police seize the stolen merchandise to keep for evidence, and the buyer and merchant end up the victims” (Wahab, 2004).

Triers of fact See *factfinders*. Jurors are *lay triers of fact*.

Trustworthiness question In argumentation studies, Walton’s (1997) *Appeal to Expert Opinion* offered (ibid., pp. 211–225) an argumentation scheme for “Argument for Expert Opinion”, then reproduced in Walton et al. (2008, pp. 381–382). See s.v. *Expert opinion, Appeal to* above. The expert source is *E*; the subject domain is *S*; and *A* is a proposition about which *E* claims to be true (or false). The trustworthiness question is: “Is *E* personally reliable as a source?”. It is articulated in three more detailed subquestions: “Is *E* biased?”; “Is *E* honest?”; “Is *E* conscientious?”.

Truth maintenance system (TMS for short) Within artificial intelligence, such representation and search procedures that keep track of the reasoning steps of a logic system. “Nonmonotonic reasoning [q.v.], because conclusions must sometimes be reconsidered, is called *defeasible*; that is, new information may sometimes invalidate previous results. [. . .] In defeasible reasoning, the TMS preserves the consistency of the knowledge base, keeping track of conclusions that might later need be questioned” (Luger & Stubblefield, 1998, p. 270).

Uncharged conduct or uncharged misconduct A kind of bad character evidence: such past behaviour for which no charges were brought. See [character evidence](#).

Utility One theoretical approach to adjudication is in terms of utility: see Friedman (1997, pp. 277–278); Lempert (1977, pp. 1021, 1032–1041). Let there be two options: plaintiff (**p**) wins, i.e., the court finding for the plaintiff, or defendant (**d**) wins, i.e., the finding is for **d**.

It would seem wisest to select the option with the greater expected utility. The formulae are:

$$EU(p) = P(\Pi) \times U(p, \Pi) + P(\Delta) \times U(p, \Delta)$$

and

$$EU(d) = P(\Pi) \times U(d, \Pi) + P(\Delta) \times U(d, \Delta),$$

“where $EU(p)$ and $EU(d)$ represent the expected utilities of judgments for the plaintiff and the defendant, respectively; $P(\Pi)$ represents the probability that the facts are such that the plaintiff is entitled to judgment, and $P(\Delta)$ represents the comparable probability with respect to the defendant” (Friedman, p. 277). Of the two arguments of the (social) utility function U , the first one represents the winner (“the party who receives the judgment”), and the second one stands for the party that in truth deserves to win (“the party who is in fact entitled to judgment”). “Thus, for example, $U(p, \Delta)$ equals the social utility of a judgment for the plaintiff when the truth, if it were known, is such that the defendant should receive judgment. $U(p, \Pi)$ and $U(d, \Delta)$ must each have greater utility than $U(p, \Delta)$ and $U(d, \Pi)$; it is helpful to assume that the first pair has positive utility and the second pair has negative utility” (ibid., pp. 277–278). The *standard of persuasion* $O(\Pi)$ is the degree of confidence when $EU(p) = EU(d)$. The *plaintiff wins* is optimal “only if the fact-finder’s degree of confidence in the plaintiff’s case is at least as great as this level” (ibid., p. 278), if it is a civil case.

$$O(\Pi) = P(\Pi)/(1 - P(\Pi)) = \\ (U(d, \Delta) - U(p, \Delta))/(U(p, \Pi) - U(d, \Pi))$$

In contrast, in a criminal case the standard is *beyond a reasonable doubt*. The negative utility of wrongly convicting an innocent, $U(p, \Delta)$, “far exceeds any of the other utilities in magnitude” (ibid., p. 278). In civil cases, the usual conception is that $U(p, \Pi) = U(d, \Delta)$ and that $U(p, \Delta) = U(d, \Pi)$. “This means that the standard of persuasion, expressed in odds, equals 1, or 0.5 expressed as a probability. This, of course, is the familiar ‘more likely than not’, or ‘balance of probabilities’, standard” (ibid., p. 278).

Virtopsy A computational technique developed by a team in Bern, Switzerland, for carrying out “a virtual autopsy”: information acquired through post mortem imaging prior to autopsy is often used to plan the autopsy, confirm autopsy findings and allow for a second look if further questions arise in during the forensic investigation. See [Chapter 9](#).

Voir dire The jury selection process, with safeguards: the parties can have prospective jurors rejected, as a safeguard intended to weed out such jurors that are perceived to be prone to be biased. “Courts in the USA permit attorneys much more latitude in jury selection (voir dire) than do criminal court procedures world-wide” (Cutler & Penron, p. 208). Nevertheless, “US federal courts and

many state courts (e.g. Massachusetts, California) perform the most perfunctory voir dire and do not permit attorneys to ask questions about jurors' attitudes. Indeed, judges in these courts are not obligated to permit attorneys to ask any questions during voir dire" (ibid.). This is a severe limitation on voir dire as a safeguard, and attorneys are in a sense forced to rely on stereotypes about categories of prospective jurors, rather than on informed evaluations. Moreover, *voir dire* also applies to the acceptance of an *expert witness* being opposed by the opposing attorney. In the words of Knott (1987, p. 14):

The opposing attorney will ask questions that will show that you have limited expertise in the specific field at hand, and therefore your testimony should be limited or disallowed. The attorney is really trying to prevent certain opinions from being introduced and is doing it on the grounds that your expertise does not extend into that area. He or she will ask you questions and, on the basis of your answers, will move to reject you as an expert.

Note: You will not be allowed to say anything more in your defense. The judge will assume the answers you gave during voir dire were complete. Your attorney may ask you additional questions to clear up the confusion, but don't count on it. Note that if the opposing attorney is successful, he or she may have destroyed you and your client's case.

Weight (evidential) The probative value of the evidence.

Wigmore Charts A graphic method of structuring legal arguments, currently conspicuous in some more formal approached within legal evidence scholarship; first introduced by American jurist John Henry Wigmore in the *Illinois Law Review*, 8 (1913), 77. See [Section 3.2](#).

Witness: two-witness rule Mandated by Biblical law for capital cases: two eye-witnesses are necessary, and circumstantial evidence or other evidence is not valid. This rule has been influential. Bernard Jackson, who discussed the matter at length in Jackson (1977), explains (Jackson, 1990, p. 18):

[T]he two-witness rule of the Bible has been widely adopted in countries influenced by Canon law, as indeed have some of the necessary means of avoiding its rigours. When the medieval Canon lawyers sought to construct an institution of corroboration by similar fact evidence (*testes singulares*), they justified their argument by analysis of the facts of the story of Susannah, found in the Apocrypha to the Hebrew Bible. True enough, they said, Susannah could not be rightly convicted when one elder said that she committed adultery under an oak while the other said it was under a holm tree. But that was only because the two elders had claimed to have observed the event *together*. Had they not made this claim, their evidence would not have been regarded as logically contradictory: for though adultery may not be committed simultaneously under two different trees, it may be so committed successively. Moreover, we all know (so the Canon law doctors argued) that adultery with the some lover is an act which is prone to be repeated – *factum iterabile* – unlike some other crimes against Canon law, such as the murder of a Bishop (especially the same Bishop). I have traced the use of this argument for corroboration by similar fact evidence from a Canonist *Summa* of the mid-12th century, written in Bologna, to English treason trials of the 17th century, and a famous divorce case of the same period, which then became one of the principal foundations for the so-called *Moorov* doctrine which Lord Hailsham so fully read into his speech in the House of Lords in the modern leading case of *Kilbourne*.

In Jewish law, this argument would not have been valid for conviction in a criminal case, and two eyewitnesses would have still been necessary, who witnessed the same event and reported about it with no contradiction.

Witness vs. expert testimonies Evidence as given by individuals who have knowledge of specific details in a legal narrative at hand, as opposed to evidence given by professionals (expert witnesses) based on their professional expertise.
