Preface to the Second Edition

The field of polymer blends is one that continues to grow year by year. More and more blends are now available and can consist of several polymers, all combining to give enhanced properties for a specific application. The preface that was included in the first edition clearly states the state of the field both then and now. Certainly there have been changes, and this new edition reflects those changes.

The biggest changes to this edition occur in the second section on applications where the content has been rearranged in better keeping with current thinking. New to this edition are chapters on degradation, stabilization and flammability of polymer blends, polymer blends with nanoparticles, and polyethylenes and their blends. Also there are three new appendices, on trade names, commercialization dates, and notations and symbols.

The first edition of the *Polymer Blends Handbook* was edited by Leszek A. Utracki who also wrote several of the chapters in that book. It was his idea that the time was ripe for a new edition of the book, and he arranged for all of the chapter authors and had the book well underway. Unfortunately, Leszek left this world on July 11, 2012. Just before, while he was hospitalized, he completed the work on the new chapter on polyethylene and its blends. His last update to the chapter took place on July 7, 2012.

This book is really a tribute to Leszek A. Utracki, the man and the scientist. He was proud of the first edition, and we think that he would be proud of this edition as well.

I would like to express my gratitude to Leszek for inviting me to serve as a coeditor of this book and to all of those, especially the authors of the chapters and the section reviewers, who have made this book possible. Finally, I thank my family, and I am also quite confident that the Utracki family was instrumental in enabling him to do the work.

Preface to the First Edition

Science as a methodical investigation of nature's capacities evolved from the humble craft tradition. Its goal is to provide the most general and the simplest possible description of the observable character of nature. In the past, the singular concept of "science" comprised all aspects of intellectual endeavor: the arts, the sciences, and the crafts. It was Diderot's *Encyclopédie ou Dictionnaire Raisonné des Sciences*, *des Arts et des Métiers* of 1751–1766 that first divided the old "science" into these three parts. The next split – that between the basic and applied sciences – is barely a century old. Basic science has been described as motivated by the desire to discover connections between natural phenomena, while applied science is the application of the discovered laws of nature for the material benefits of mankind. The boundary between the two is not rigid since experimental observation frequently provides a spur to fundamental discoveries.

In the golden times of the scientific institutions in Europe and North America, the most prominent scientists, often the Nobel Prize winners, directed the work. In the USA, during the years 1945–1975, basic scientific research was considered "essential for the national security, economic growth and survival of the basic democratic values" (J. Krige & D. Pestre, *Science in the 20th Century*, 1997). In the 1960s, several major corporations supported research institutes with total freedom of the research topics.

During the last two decades of the twentieth century, there has been an apparent reversal in the appreciation of science. Except for a few domains (e.g., astrophysics or atomic physics, project *genome*), intellectual efforts are being directed toward short-term developmental work of a commercially pertinent nature. This tendency is global, evident in the industrial, academic, as well as state-supported laboratories. The CEOs hired for a contract to manage an institution are focused on the present. Managing has become a profession divorced from technical knowledge – a research institute, finance company, or pig farm may "benefit" from guidance by the same person. These tendencies are reflected in the evolution of polymer science and technology.

The history of synthetic polymers is incredibly short. The term *polymer* was introduced in 1832. The first synthetic polymer (phenol-formaldehyde) was commercialized as *Bakelite*™ in 1909, while the first thermoplastic (polystyrene, *Trolitul*™), 6 years later. The early polymer industry was developed by entrepreneurs that had little if any technical background. The commercial successes (and

less known but more numerous failures) predated even the fundamental idea of what constitutes the polymeric species. As late as 1926, Hermann Staudinger unsuccessfully advocated the concept of a linear, covalently bonded macromolecule. This idea was finally accepted during the Faraday Society meeting in 1935, only after Carothers reported on his polymerization studies and demonstrated the validity of the polycondensation theory, developed by his younger colleague from du Pont de Nemours, Paul Flory. The theory provided the relationships between the molecular weights and the reaction kinetics, thus making it possible to ascertain the validity of the newly formulated polycondensation principles that postulated the sequential addition of bifunctional units to form linear macromolecules.

In 1900, the world production of plastics was 25 kton, doubling during the following 30 years, then redoubling in 5. The most spectacular growth was recorded in the early 1940s when the demand created by the convulsions of World War II engendered a spectacular growth of 25 % per annum. During the first 30 post-war years, the global plastics industry sustained an average growth rate of 15 %/year. By 1992, the world production of plastics had reached 102 million m^3/year, while that of steel was 50 million m^3/year. Furthermore, from 1980 to 1990 plastics production increased by 62 %, while that of steel decreased by 21 %. Only during the past 20 years or so has plastics consumption shown smaller and more erratic advances. It is expected that by the year 2000, the world production of plastics will be 151 million tons/year. Considering the uneven polymer consumption around the world, polymer production has the potential to increase tenfold by the mid-twenty-first century. Polymers are the fastest growing structural materials.

Rubber blending predates that of thermoplastics by nearly a century. In 1846, Parkes introduced the first blends of *trans*- and *cis*-1,4-polyisoprene, i.e., natural rubber (NR) with gutta-percha (GP). By varying the composition and/or adding fillers, the blends were formed into a variety of flexible or rigid articles.

Polymer blends were developed alongside the emerging polymers. Once nitrocellulose (NC) was invented, it was mixed with NR. Blends of NC with NR were patented in 1865 – 3 years before the commercialization of NC. The first compatibilization of polyvinylchloride (PVC) by blending with polyvinylacetate (PVAc) and their copolymers dates from 1928. PVC was commercialized in 1931, while its blends with nitrile rubber (NBR) were patented in 1936 – 2 years after the NBR patent was issued. The modern era of polymer blending began in 1960, after Alan Hay discovered the oxidative polymerization of 2,4-xylenols that led to polyphenylene ether (PPE). Its blends with styrenics, *Noryl*[TM], were commercialized in 1965.

At present, polymer alloys, blends, and composites consume over 80 wt% of all plastics. In addition, the polymer blends segment of the plastics industry increases about three times faster than the whole plastics industry. Blending has been recognized as the most versatile, economic method to produce materials able to satisfy complex demands for performance. By the year 2000, the world market for polymer blends is expected to reach 51 million tons per annum, worth well over US$ 200 billion. The tendency is to offer blends that can be treated as any other

resin on the market; hence, their processibility must closely match that of single-phase polymers but offer a much greater range of performance possibilities.

In the economically advanced countries, plastics have displaced conventional materials for most applications. Today, the market pressure forces the resin manufacturers to provide better, more economic materials with superior combinations of properties, not as a replacement for wood or steel but rather to replace the more traditional polymers. This has resulted in:

- Increased scale of production
- Use of multicomponent and multiphase materials
- New processing methods

For example, twin-screw extruders with 80 t/h throughput and injection (100,000 kN) molding presses with shot size of 100 l of polymer are available. Composites where the matrix is a polymer blend that comprises six different polymers have been introduced. Gas and multiple injection processes, melt-core technology, solid-state forming, and microcellular foams all lead to new products with advanced performance. The polymer industry is becoming increasingly sophisticated.

To support these new tendencies, the research community has been asked to provide better predictive methods for the multicomponent blends as well as improved sensors for the closed-loop process control. In particular, the evolution of morphology during the compounding and processing steps is of paramount importance. Microrheology and coalescence are the keys to describing the structure evolution of polymer blends.

In the early 1990s, the first mathematical models capable of predicting the evolution of morphology during compounding of polymer blends were developed. The fully predictive model provided good agreement with the experimentally determined variation of morphology inside a twin-screw extruder. However, it must be recognized that the morphology developed inside the compounding or the processing unit is dynamic. Upon removal of stress and in the absence of effective compatibilization, the morphology changes with time.

Today, very few unmodified resins are being used. Some polymers require less modification than others. For example, the semicrystalline polymers that already have a two-phase structure may need modification less urgently. By contrast, the amorphous resins, such as PVC, PS, PPE, or polycarbonate of bisphenol A (PC), are brittle and require blending more frequently. The advantages of blending fall into two categories.

(a) Blending may improve resin or product performance by:

1. Producing materials having a full set of the desired properties at lowest cost
2. Extending the engineering resins performance by incorporation of less expensive polymers
3. Improving specific properties:
   - Toughening brittle polymers eliminates the need of using low-molecular-weight additives (e.g., plasticizer in the flexible PVC formulations).
   - Blending with a more rigid and more heat-resistant resin may lead to improved modulus and dimensional stability.

- Incorporation of a semicrystalline polymer into an amorphous resin improves solvent and chemical resistance (e.g., in blends of PC with PEST).
- Incorporation of a nonflammable resin into a flammable one improves flame resistance (e.g., styrenics or acrylics with PVC).
- Blends with polymers having either −OH or −SH functionality result in permanently antistatic blends (e.g., ethylene oxide-co-epichlorohydrin with ABS/PC blend).
- Biodegradable materials can be produced by incorporation of a biodegradable resin.
- Blending makes it possible to produce integrated multilayer structures.
4. Providing means for recycling of industrial and/or municipal plastics waste
5. Rebuilding high molecular weights of partially degraded polymers, thus making it possible to produce high-performance articles from the plastics waste

(b) Blending may lead to improved processibility in the following ways:

1. Incorporation of a miscible resin with a lower glass transition temperature (T_g) makes it possible to process the high-T_g resin at temperatures well below the thermal degradation limit (e.g., PS/PPE blends).
2. Incorporation of an immiscible, low-viscosity resin makes it possible to reduce pressure drop across dies or runners, thereby increasing productivity (e.g., LCP/PEEK blends).
3. Blending with a resin that either by itself shows high strain hardening (SH) (e.g., LDPE in blends with another PO) or when reactively blended forms long-chain branches (e.g., PS in blends with PO) results in blends having a controllable degree of SH. These materials show better processibility in technologies where the extensional flow field is important, namely, film blowing, blow molding, wire coating, and foaming.
4. Incorporation of elastomeric particles improves nucleation of gas bubbles; thus, it stabilizes the foaming process and reduces bubble size and the final foam density.
5. Incorporation of a degradable resin into an engineering or specialty one provides the means for generation of a controllable amount of foaming gas during the ensuing stages of processing, namely, injection molding.
6. Blending different grades of the same resin broadens the molecular weight distribution, which in turn results in easier, more stable processing (as well as better mechanical performance).
7. Blending improves product uniformity (scrap reduction) and plant economy.
8. Blending ascertains quick formulation changes and, thus, plant flexibility and productivity.
9. Blending reduces the number of grades that need to be manufactured and stored.
10. Blending technology offers methods for producing higher-aesthetic-value materials, e.g., films or coatings without gel particles (or "fish eyes") and moldings with streak-free surface finish.

The aim of the *Polymer Blends Handbook* (PBH) is to provide the most comprehensive information on all aspects of polymer blend science and technology. The book will be useful for students entering the field as well as for seasoned professionals. The contributors to PBH are renowned experts from eight countries and four continents, who work in academe, government laboratories, and industry.

In consequence, the book may be considered as comprising two parts: 1. fundamental principles (nine chapters) and 2. technology (eight chapters and four appendices). Each chapter provides an introduction to the pertinent topic, discusses the principal aspects and the typical approaches used by the experts in the area, provides numerical values of pertinent parameters, and gives extensive references that facilitate further topical studies.

PBH comprises 17 chapters with the following topics: 1. Introduction to polymer blends, 2. Thermodynamics, 3. Crystallization, 4. Interphase and compatibilization by addition of a compatibilizer, 5. Reactive compatibilization, 6. Interpenetrating polymer networks, 7. Rheology, 8. Morphology, 9. Compounding, 10. Processing, 11. Use of radiation, 12. Properties and performance, 13. Applications, 14. Degradation and aging, 15. Commercial blends, 16. Role of polymer blends' technology in polymer recycling, and 17. Perspectives. Furthermore, the appendices provide information on 1. International abbreviations for polymers and polymer processing, 2. Miscible polymer blends, 3. Examples of commercial polymer blends, and 4. Dictionary of terms used in polymer science and technology.

Finally, the editor wishes to express thanks and personal appreciation to the contributors. They invested much time outside their regular duties, collecting the material and setting it into uniform text. They showed a high spirit of cooperation and great patience. The *Polymer Blends Handbook* is a testimonial of their efforts.

About the Editors

Leszek A. Utracki, 1931–2012, was Senior Research Officer at the National Research Council of Canada, Industrial Materials Institute, and adjunct professor at McGill University, Department of Chemical Engineering, in Montreal, Quebec. Professor Utracki was the author/editor of 21 books and had written 48 book chapters, hundreds of journal articles, as well as meeting proceedings, which placed him on the ISI list of Highly Cited Researchers. He was the cofounder and President of the Canadian Rheology Group and the Polymer Processing Society (International). He also organized and served as the series editor of the book series "Progress in Polymer Processing" and as a member in the editorial boards of several research journals. He was the recipient of many international awards, but one is specifically worth mentioning: just a few months after he passed away, he was awarded the Queen Elizabeth II Diamond Jubilee Medal of Distinction, which is to honor significant contributions and achievements by Canadians.

Leszek A. Utracki was born and educated in Poland. After completing his postdoctorate at USC in Los Angeles with Robert Simha, he settled in Canada. He was a passionate researcher in the fields of thermodynamics, rheology, and processing of multicomponent/multiphase polymeric systems. Sadly, he passed away a few months after embarking on the work for the second edition of the *Polymer Blends Handbook*, during which he had made important contributions to the work. This edition of the handbook is dedicated to his memory.

Charles A. Wilkie is currently Professor Emeritus of Chemistry at Marquette University. He received his B.S. degree from the University of Detroit and his Ph.D. in Inorganic Chemistry from Wayne State University, following which he joined Marquette University. He has been assistant, associate, and full professor and retired as the Habermann-Pfletschinger Professor in 2009. His main areas of interest for the past several years have been polymer nanocomposites and fire retardancy.

Abstract

While this chapter serves as an introduction to all the subsequent chapters, it is quite comprehensive. A brief history as well as information on polymer synthesis, nomenclature, and properties is provided. The need to formulate polymer alloys and blends and the resulting benefits are explained. Since the vast majority of polymer pairs are thermodynamically immiscible, compatibilization and reactive extrusion are necessary to improve interfacial adhesion and to optimize blend performance. How polymer morphology is influenced both by blend

composition and the imposed process conditions is discussed first. This provides the theoretical basis for understanding the concept of polymer blending.

The raison d'etre of polymer blending is developing materials having enhanced performance. Performance itself depends on the polymer pair types employed, their relative amounts, extent of miscibility, nature and amount of compatibilizer used, and the method of blending. A key issue is the process of mixing polymers during which blends undergo a complex combination of shear and elongation and the evolution of blend microstructure becomes crucial and requires close attention. Each category of polymer pairs, from commodity resins and their blends, to engineering resins and their blends, and to specialty polymers and their blends is discussed in detail. Pertinent theoretical as well as experimental results are presented and reviewed.

The concern over environmental issues and sustainability has opened up another vibrant research field, namely, biobased and biodegradable polymer blends. An overview of major developments and recent trends in biodegradable blends with an emphasis on PLA blends are also discussed. This chapter closes with an outlook for the future of this important subject.

1.1   Introduction

The world production of plastics in 1900 was about 30,000 t – in the year 2010 it had reached 265 Mt, with thermoplastics contributing about 90 % of this amount, while the rest was thermosets. For the last 20 years, plastic production has increased at the rate of about 5 % per year, with no saturation in sight. In 2010, China accounted for 23.5 % of plastic production, whereas Europe and the North American (NAFTA) region contributed 21.5 % and 20.5 %, respectively (Plastics-the facts 2011, PlasticsEurope, 20th ed). According to a report by Global Industry Analysts Inc., global plastic consumption is set to reach 297.5 Mt by 2015.

Polymers are classified as either *natural*, those that resulted from natural biosynthesis, or *synthetic*. The *natural* (polysaccharides, proteins, nucleic acids, natural rubbers, cellulose, lignin, etc.) has been used for tens of thousands of years. In Egypt the musical string instruments, papyrus for writing, and styrene (in a tree balsam) for embalming were used 3,000 BC. For millennia shellac has been used in Indian turnery (Chattopadhyaya 1986). The natural rubber was used by *Olmecs* at least 3,000 years ago (Stuart 1993).

The term *synthetic* polymer refers equally well to linear, saturated macromolecules (i.e., *thermoplastics*), to unsaturated polymers (i.e., *rubbers*), or to any substance based on cross-linkable monomers, macromers, or prepolymers (i.e., *thermosets*). The focus of this handbook is on blends of thermoplastics made of predominantly saturated, linear macromolecules.

In the last quarter century, there have been two major developments, one technical and one economic, which have given a new direction to the polymer industry. There has been a revolution in polyolefin technology that started during the last decade of the

twentieth century, and this is related to the development of metallocene and single-site catalysts. The use of these catalysts allows for the synthesis of improved polymers with well-defined structures and closely controlled molecular architectures. Separately, there has been a shift toward green chemistry, promoted by concerns about sustainability and raw material availability. The need to provide alternatives to petroleum-based products has led to the development and commercialization of biobased plastics. Simultaneously, there has been increasing emphasis on the recycling of postconsumer plastics (Yeh et al. 2009). Additionally, there has been consolidation in the industry and an overall shift in production of commodity resins to countries in Asia.

There are many sources of information about polymer history (Martuscelli et al. 1987; Seymour and Cheng 1987; Vogl and Immergut 1987; Alper and Nelson 1989; Morris 1989; Seymour 1989; Sperling 1992; Mark 1993; Sparke 1993; Utracki 1994, 1998a; Freinkel 2011; Strom and Rasmussen 2011).

The abbreviations used in this text are listed at the end of this chapter.

1.2   Early Polymer Industry

1.2.1   The Beginnings

The polymer industry traces its beginning to the early modifications of shellac, natural rubber (NR, an amorphous *cis*-1,4-polyisoprene), gutta-percha (GP, a semicrystalline *trans*-1,4-polyisoprene), and cellulose. In 1846, Parkes patented the first polymer blend: NR with GP partially co-dissolved in carbon disulfide. Blending these two polyisoprene isomers resulted in partially cross-linked (co-vulcanized) materials whose rigidity was controllable by composition. The blends had many applications ranging from picture frames, tableware, ear trumpets, to sheathing the first submarine cables.

1.2.2   Modified Natural Polymers

The first man-made polymer was nitrocellulose (NC). The main use of the NC resins was a replacement of the natural and expensive materials, viz., ivory, tortoise shell products, amber, ebony, onyx, or alabaster. The use of cellulose acetate (CA), as a thermoplastic, began in 1926. Cellulose ethers and esters became commercially available in 1927. Casein cross-linked by formaldehyde gave hornlike materials – *Galalith*™ has been used to manufacture shirt buttons or as imitation of ivory and porcelain (Pontio 1919).

1.2.3   Synthetic Rubbers

The first polymerization of isoprene in sealed bottles was reported in 1884 by Tilden. *Methyl rubber* was thermally polymerized at 70 °C – the reaction

required 3–6 months, giving poor quality products. In 1926 BASF developed sodium-initiated polymerization of butadiene known as *Buna*™ for butadiene + natrium. The first successful, general-purpose rubbers were copolymers of butadiene with either styrene, *Buna-S*, or acrylonitrile, *Buna-N* (Tschunkur and Bock 1933; Konrad and Tschunkur 1934). Poly(2-chlorobutadiene), *chloroprene* (Carothers et al. 1931), was introduced in 1931 by du Pont. Elastomeric polysulfides (Patrick 1932), were commercialized in 1930 as *Thiokol*™. In 1937 butyl rubber (copolymer of isobutylene with isoprene) was invented. The synthetic rubber production took a big leap during the Second World War (WW2) (Morton 1982).

1.2.4   Synthetic Thermosetting Polymers

The first commercially successful *synthetic* polymer was phenol-formaldehyde (PF) resin (Smith 1899). The resin was introduced in 1909 by Baekeland as *Bakelite*™. The urea-formaldehyde (UF) resins were discovered in 1884, but production of *Beetle*™ moldable resin commenced in 1928. Three years later, *Formica*™, phenolic paper covered with decorative layer protected by UF, was introduced. The thiourea-formaldehyde molding powders were commercialized in 1920, while in 1935, Ciba introduced *Cibanite*™, aniline-formaldehyde (AF) resins, molding materials, and then, 2 years later, the melamine formaldehyde (MF).

Epoxy compounds were discovered by Prileschaiev in 1909, but its importance was realized only during WW2. In 1956, glass fiber reinforcements were introduced. The thermoset polyesters (TS) were developed by Ellis in 1933–1934. The first use of glass-reinforced TS dates from 1938.

1.2.5   Synthetic Thermoplastic Polymers

The synthetic polymers are divided into three categories:
1. Commodity
2. Engineering
3. Specialty

The five large-volume polymeric families that belong to the commodity resins are polyethylenes (PE), polypropylenes (PP), styrenics (PS), acrylics (PMMA), and vinyls (PVC). According to the web site, www.icis.com, the market share of these plastics in 2011 was 178 Mt – in other words, they represent about 70 % of all plastics.

The five engineering polymer families are polyamides (PA), thermoplastic polyesters (PEST), polycarbonates (PC), polyoxymethylenes (POM), and polyphenylene ethers (PPE). According to a March 2013 Industry Experts report entitled "Engineering Plastics – A Global Market," 19.6 Mt of engineering plastics were produced in 2012. In other words, these polymers constitute only about 10 % by volume of all polymers produced. However, due to superior properties, they command a much larger percentage by value of the plastic consumption.

Table 1.1 High-performance materials: a comparison

No.	Material	Strength (GPa)		Modulus (GPa)	
		Theoretical	Observed	Theoretical	Observed
1.	Polyethylene (standard)	21	≤ 0.03	316	0.2
2.	Polyethylene gel-spun	21	6.0	316	220
3.	Polyester (standard)	24	0.07	124	2.2
4.	Polyester oriented	24	1.2	124	21
5.	Aromatic polyamide	21	3.6	190	125
6.	Aromatic polyester (EFK)	–	4.1	–	139
7.	Poly(phenylene benzothiazole)	–	4.2	371	365
8.	Polyazomethin	–	4.7	–	125
9.	Carbon fiber	–	3.1	–	235
10.	Steel	29	2.1–3.5	–	210

The engineering and specialty polymers show high mechanical performance, and the continuous use temperature $150 \leq \text{CUT}(°\text{C}) \leq 500$.

The polymer industry increasingly favors high technology and high value-added materials. These are obtained either by means of new polymerization methods, by new processing technologies, or by alloying and reinforcing. For example, new syndiotactic PP or PS (sPP or sPS, respectively) surpasses the performance of their predecessors. The gel-spun PE fibers have 200 times higher tensile strength than standard PE. Aromatic polyester (EKF from Sumitomo) has tensile strength of 4.1 GPa, to be compared with 70 MPa of a standard polyester resin (see Table 1.1).

New types of polymers are also being introduced, e.g., dendritic-structure polymers (Fréchet et al. 1992; Schluter and Rabe 2000), carbosilane dendritic macromolecules (Roovers et al. 1993), the "hairy rod" molecular structures where rigid-rod chain macromolecules are provided with short and flexible side branches (Wegner 1992), etc. However, the polymer technology invariably moves away from the single-phase materials to diverse combinations of polymers, additives, and reinforcements. While synergistic effects are often cited, the main reason is a need for widening the range of properties, for development of materials that would have the desired combination of properties – tailor-made polymeric systems. With single-phase polymers, one can only change the molecular weight or form copolymers. This can require significant effort. By contrast, blending is easy and inexpensive, and it is especially useful when only small volumes are required. Also, scale-up is straightforward. At present, about a third of the synthetic resins are used in blends and another third in composites.

1.2.6   Compounding and Processing

The first mixer was an annular container with a spiked rotor for rubber compounding (Hancock 1823). The calendar/two-roll mill was patented by Chaffe in 1836 and manufactured by Farrel Co. A counterrotating twin-shaft internal mixer

with elliptical rotating disks or sigma blades was developed by the end of the 1800s (Freyburger 1876; Pfleiderer 1880). The first hand-operated extruder was a ram press, used for forming NR or GP and then later NC.

The first belt-driven extruders with Archimedean screw were patented much later (Gray 1879). In 1939, Paul Leistritz Maschinenfabrik built electrically heated, air-cooled extruder, with nitrided barrel, having $L/D = 10$, an automatic temperature control, variable screw speed. The machine is considered a precursor of the modern single-screw extruders, SSE. During the WW2 breaker plates, screen packs, crosshead dies, coextrusion, monofilament extrusion, film blowing, and biaxial sheet orientation were introduced. In the 1950s, a coextrusion process, venting, and two-stage screws were developed. In the 1980s the microprocessor control evolved into computer-integrated manufacturing, and the helical grooved feed barrels, high-pressure gear pumps, air lubricated die flow, and biaxial film orientation were introduced (Utracki 1991a, c).

Pfleiderer patented the first modular counterrotating twin-screw extruder (TSE) in 1882. An intermeshing, corotating TSE, the predecessor of the modern machines, was designed for extrusion of CA. The TSE was used by I. G. Farbenindustrie for the production of PA-6 (Colombo 1939). In 1959, Werner and Pfleiderer introduced ZSK machines (vented, intermeshing, corotating, with segmented screw and barrel, twin-screw extruders). These provided good balance between the dispersive and distributive mixing at relatively high output rates. In 1979 Japan Steel Works (JSW) developed TEX-series TSEs for reactive compounding, permitting an easy change of the screw direction from co- to counterrotation. In collaboration with Sumitomo Chem., barrel elements with sampling ports were designed, providing ready access to the processed material for determining the reaction progress and morphology (Nishio et al. 1990). American Leistritz has been active in designing TSE kneading elements that improved mixing capability by maximizing the extensional flow field. More information on the evolution of the extrusion technology can be found in ▶ Chap. 9, "Compounding Polymer Blends".

Injection molding of NC dates from 1872. The early machines were hand operated. They used an axially movable screw or plunger and were equipped for devolatilization. The commercial-scale injection molding of PS has begun in 1931. In 1932 Gastrow developed the first automatic unit, *Isoma-Automat* (30 g capacity per shot), with torpedo-type heating chamber. In 1951, Willert invented an in-line reciprocating screw plasticization that revolutionized the injection molding industry. The first automated injection molding plant was developed by Eastman Kodak in 1950.

Hayatt used blow molding in 1880 to produce baby rattles out of CA tubes or sheets. In 1942, Plax Corp. started manufacturing *squeezable* LDPE bottles. By the end of the 1950s, blow molding was the most rapidly developing processing method. In 1965 Wyeth, using the stretch blow molding, produced polyethylene terephthalate (PET) bottles. In 1972, Toyo Seikan started to produce multilayered blow molded bottles from PP and EVAl. In 1976 Ishikawajima-Harima introduced intermittent coextrusion blow-molding system for large parts.

1.2.7 Development of Polymer Science

1.2.7.1 Polymerization

Cellulose modification dates from 1833 (Braconnot). In 1838 Regnault photopolymerized vinylidene chloride. A year later, Simon observed that heating styrene in the presence of air generated a tough gelatinous material – a low molecular weight PS. Polyoxymethylene (acetal) was discovered in 1859. In 1872 several new polymers were announced, viz., PVC, polyvinyl bromide (PVB), and phenol-formaldehyde (PF). Polymethacrylates were discovered by Kahlbaum in 1880, polymethylene in 1897, 1 year later polycarbonate by Einhorn, polyamide-6 (PA-6) in 1907, etc. In the 1920s, the list of polymers rapidly started to increase, viz., polysulfide (PSF), polyvinyl alcohol (PVAl), poly(styrene-co-maleic anhydride) (SMA), polyvinyl formal (PVFO), etc. During the next decade, polyacetylene (PACE), styrene-acrylonitrile copolymer (SAN), low-density polyethylene (LDPE), polyvinylidene chloride (PVDC), epoxy resins (EP), polyamides (e.g., PA-66, PA-610, PA-106), polysiloxanes (PDMS), polychlorotrifluoroethylene (PCTF), polytetrafluoroethylene (PTFE), and many others were discovered (Utracki 1989a).

Most early thermoplastics, e.g., PVC or PS, were obtained in the free radical polymerization, initiated either by heat or by sunlight. The first systematic studies of the free radical chemistry commenced 80 years later (Ostromislensky 1911, 1915, 1916). Fikentscher empirically determined which one of the 30-or-so monomers *liked* or *disliked* to copolymerize with each other. The advantage of latex blending was also established. The theory of the free radical copolymerization was only developed in the 1940s (Alfrey et al. 1952).

The polycondensation reactions have been known since the mid-1800 (Lourenço 1859; Wurtz 1859, 1860). In 1927, Carothers and his colleagues provided the basis for understanding the nature of these reactions (Carothers, 1931). Good agreement between Flory's theoretical predictions and the experimental observations of the average molecular weight (MW) provided convincing arguments for the acceptance of the linear macromolecule model.

The alkyl-lithium-initiated, *living* anionic polymerization of elastomers was described in 1928 by Ziegler. To polymerize styrene-isoprene block copolymers, Szwarc et al. (1956) used sodium naphthalene as an anion-radical di-initiator, while Shell used an organolithium initiator. The polymerization mechanism was described by Bywater (1965).

In the early 1950s, Ziegler found that in the presence of $ZrCl_4 + AlR_3$ ethylene can be polymerized at low temperature and pressure into linear, high-density polyethylene (HDPE). The catalysts developed by Ziegler, and later by Natta, become known as *Ziegler-Natta*, *Z-N* catalysts. These can be defined as polymerization initiators created from a catalyst (1) and cocatalyst (2), where (1) is halide or oxyhalide of transition metals from groups IV to VII and (2) is an organometallic compound of metal from groups I to III. The *Z-N* catalyst is prepared by mixing ingredients (1) and (2) in a dry, oxygen-free solvent (Natta and Danusso 1967). A more recent Z-N catalyst development is

$MgCl_2$-supported catalysts that have a 100-fold more active sites per mole of Ti and about ten times higher propagation rate (Rieger et al. 1990).

The newest, single-site metallocene catalyst makes it possible to control MW, molecular weight distribution (MWD), comonomer placement, stereoregularity, and lifetime of the reactive chain end (Kaminsky et al. 1985, 1992; Kaminsky 1998; Swogger 1998; Choi and Soares 2012). The use of either $(Cp)_pR'_s(Cp)MeQ_{3-p}$ or $R''_s(Cp)_2MeQ'$ (where Cp is cyclopentadienyl (substituted or not) radical; Me is metal from group 4b, 5b, or 6b; and R', R'', Q, and Q' are radicals (viz., aryl, alkyl, alkenyl, alkylaryl, or arylalkyl), s = 0–1, p = 0–2), for the polymerization of ethylene copolymers, provides independent control of MW and density. The catalyst is used in combination with a large amount of alumoxanes.

In 1975 Mitsui Petrochemicals introduced metallocene-made LLDPE *Tafmer*™, with controlled comonomer placement, but rather low MW. In 1991, Dow Plastics produced developmental quantities of ethylene copolymers with up to 25 mol% of butene, hexene, or octene, *Affinity*™ resins. The use of a metallocene catalyst with a single cyclopentadiene ring resulted in a certain degree of randomization of the polymerization process. The catalyst produced PP with narrow molecular weight distribution, *and a long-chain branching*, similar to LDPE. In the early 1990s, Exxon Chemical Company (now ExxonMobil) worked to develop metallocene catalysts for use in Union Carbide's (now Dow Chemical) gas-phase UNIPOL™ PE process. Later, in 1997, the two companies formed a joint venture called Univation Technologies which introduced XCAT™ metallocene catalysts. The resulting linear low-density polyethylene finds application in flexible packaging, pallet stretch wrap, and food packaging and agricultural films. The most recent development is PRODIGY™ bimodal catalyst that allows for the synthesis of bimodal film resins in a single reactor, resulting in a PE with improved performance and processability.

The metallocene catalysts are also used to produce high melting point polymers out of *commodity* monomers, e.g., sPS, with $T_g = 100\ °C$, and $T_m = 266\ °C$, or syndiotactic poly(*p*-phenyl styrene), (sPhPS), with $T_g = 196\ °C$, $T_m = 352\ °C$, and the decomposition temperature, $T_{decomp} = 380\ °C$. Since sPhPS is miscible with sPS in the whole range of concentration, blends of these two syndiotactic polymers can be processed at any temperature above $266\ °C$ (Watanabe et al. 1992). Polycyclohexylethylene (PCHE) is a metallocene resin, developed by Dow as a replacement for PC in the production of optical disks. PCHE has low shrinkage (0.02 % after 24 h), higher light transmission than PC (91.9 % vs. 89.8 %, respectively) and high flex modulus of 71 GPa.

1.2.7.2 Polymer Physics
Molecular Weight (MW)
Osmotic pressure measurements for the determination of MW were used in 1900 to characterize starch. Twenty years later, the solution viscosity measurements were introduced by Staudinger for this purpose. However, it was Mark and his collaborators who developed the concept of the intrinsic viscosity ([η]) and demonstrated that it provides information on the volume of individual colloidal particles, thus on MW.

For the freely rotating chains, the dependence (today known as *Mark-Houwink-Sakurada* equation) was obtained (Guth and Mark 1934):

$$[\eta] \equiv \lim_{c \to 0}[(\eta/\eta_o) - 1]/c = KM_v^a \tag{1.1}$$

where η and η_o are viscosities of the solution and solvent, M_v is the viscosity-average molecular weight, and K and a 0.5–0.7, are equation parameters. In 1933 the ultracentrifugation was developed (Kraemer and Lansing 1933). Utility of light scattering for the determination of MW was demonstrated 11 years later (Debye 1944, 1946).

Free-Volume Concept

The free-volume theory of liquids dates from the beginning of the twentieth century. Two expressions for *the free-volume fraction*, f, have been proposed, either $f = (V - V_{occ})/V$ or less frequently used $f = (V - V_{occ})/V_{occ}$ (V_{occ} is the occupied volume). The theory was used to interpret the temperature (T) and pressure (P) dependencies of liquid viscosity (Batschinski 1913). The V_{occ} was defined as the specific volume at which the liquid viscosity is immeasurably high, $\eta \to \infty$. Good correlation was found between V_{occ} and either the critical volume or the van der Waals constant b, viz.

$V_{occ}/(V_{crit}/3) = V_{occ}/b = 0.921 \pm 0.018$. Batschinski wrote:

$$\eta = a_o + a_1/f = a_o + a_1 V/(V - V_{occ}) \tag{1.2}$$

where a_i are equation parameters. Forty years later, more accurate data of viscosity (spanning several orders of magnitude) and specific volume for a series of paraffin's with molecular weight MW = 72–1,000 g/mol led to the logarithmic dependence (Doolittle 1951):

$$\ln \eta = a_o + a_1 V/(V - V_{occ}) \tag{1.3}$$

where v_o is the value of v at a characteristic solidification temperature, T_o, at which the fluid viscosity increases to infinity. Equation 1.3 provided a basis for the derivation of well-known WLF time-temperature shift factor a_T (Williams et al. 1955).

The free-volume model has been also incorporated into thermodynamic theories of liquids and solutions (Prigogine et al. 1957), and it is an integral part of theories used for the interpretation of thermodynamic properties of polymer blends (Utracki 1989a). In particular, it is a part of the most successful equation of state (EoS) derived for liquids and glasses (Simha and Somcynsky 1969), critically examined using data for 56 principal polymers (Rodgers 1993). Since the mid-1960s, the lifetime of ortho-positronium has been used to measure the free-volume fraction f. Accordingly, f increases linearly with the temperature:

$$f = -0.13556 + 6.2878(T/T^*) \quad \text{for} \quad 0.0165 \leq T/T^* \leq 0.0703$$

where T* is the temperature reducing parameter in Simha-Somcynsky theory (Utracki 1998b). More detailed analysis indicated that the free volume should be discussed in terms of distribution of the holes. For example, the measurements showed that above T_g the number of holes does not increase, but their volume does (Kobayashi et al. 1989). In PS/PPE blends, the size of the free-volume spaces in PS was found smaller than that in PPE (Li et al. 1999b).

Viscoelasticity

In 1874, Boltzmann formulated the theory of viscoelasticity, giving the foundation to the modern rheology. The concept of the relaxation spectrum was introduced by Thompson in 1888. The spring-and-dashpot analogy of the viscoelastic behavior (Maxwell and Voigt models) appeared in 1906. The statistical approach to polymer problems was introduced by Kuhn (1930).

Busse (1932) observed that "green" rubber under stress shows a dual behavior, suggesting the presence of two types of interactions: few widely separated strong ones, acting as physical cross-links, and many weak ones of the van der Waals type, which make it possible for one macromolecule to slip by the others. This postulate was the first connotation of the chain entanglement. Bueche (1952, 1956, 1962) adopted the entanglements' concept for the interpretation of polymer flow. He calculated the molecular friction constant per statistical segment as the unit force needed to pull the undeformed macromolecule through the surrounding medium at unit speed, $f_o = F/N$ (with N being the number of statistical segments per macromolecule), deriving the relations (see Eq. 1.4) between the diffusion constant, D, or zero-shear viscosity, η_o, and such molecular parameters as density, ρ, molecular weight, M, and radius of gyration, R_g:

$$
\begin{aligned}
&D\eta_o = (\rho N_A/36)\left(R_g^2/M\right)k_B T; \quad \text{and} \quad \eta_o = (\rho N_A/36)\left(R_g^2/M\right)N^* f_o \\
&\text{for:} \quad M \le 2M_e \quad N^* = M/M_o \\
&\text{for:} \quad M > 2M_e \quad N^* = \beta(M/M_o)(\rho N_A/48)(M/M_e)^2\sqrt{M}\left(R_g^2/M\right)^{3/2}
\end{aligned}
\tag{1.4}
$$

where numerical constant $\beta \cong 0.6$. The dependence predicts that for low molecular weight liquids (M below the value of the critical molecular weight for entanglement, $M_c = 2M_e$, where M_e is the molecular weight between entanglements), η_o should be proportional to M, while for high molecular weight macromolecules (above M_c), to $M^{3.5}$. Thus, predictions of the entanglement-based theory are in good agreement with the observations: $\eta_o \propto M^{3.4}$ (Gupta 2000). The correlation between the plateau modulus and entanglement concentration soon followed (Ferry et al. 1955). The long disputes on the nature of entanglement led to defining it as "a special type of interactions, affecting mainly the large-scale motions of the chains, and through them, the long time end of the viscoelastic relaxation time spectrum" (Graessley 1974).

Entanglement-based theories have now been largely superseded by reptation theories that owe their origins to the work of de Gennes (1979) and of Doi and Edwards (1986) and Doi (1995). The essential idea here is that entangled polymer molecules can be considered to be contained within a tube; the orientation of the tubes and the motion of the chains within the tubes relax over different timescales. This concept has been developed by a large number of authors over the years, and a simple and readable model that accounts for the main mechanisms has been published by Marrucci and Ianniruberto (2003). A major success of the reptation theory has been in establishing the molecular weight dependence of polymer diffusion.

Work to further expand the reptation-tube model has been explored. Pokrovskii (2008), for example, has shown that the underlying stochastic motion of a macromolecule leads to two modes of motion, namely, reptative and isotropically diffusive. There is a length of a macromolecule $M^* = 10M_e$ where M_e is "the macromolecule length between adjacent entanglements" above which macromolecules of a melt can be regarded as obstacles to motions of each other and the macromolecules reptate. The transition to the reptation mode of motion is determined by both topological restriction and the local anisotropy of the motion.

1.3 Polymer Structure and Nomenclature

1.3.1 Basic Considerations

A *polymer* is a substance composed of *macromolecules*, built by covalently joining at least 50 molecular mers, or the *constitutional repeating units or CRU*. The longest sequence of CRU defines the *main chain* of a macromolecule. The main chain may be composed of a series of *subchains*, identified by some chemical of physical characteristic (e.g., tactic placement). The main chain may also contain long or short *side chains* or *branches*, attached to it at the *branch points*. A small region in a macromolecule from which at least four chains emanate constitutes a *cross-linking point*. A macromolecule that has only one cross-link is the *star macromolecule*.

A macromolecule consisting of several cross-linked chains, but having a finite molecular weight, is a *micronetwork*. A highly ramified macromolecule in which each CRU is connected to every other CRU is a *polymer network*. When the main chain of a macromolecule has numerous branch points from which linear side chains emanate, it is *comb macromolecule*. The CRU is defined as a bivalent organic group, not necessarily identical to the source from which the macromolecule was prepared – it is the largest identifiable group in the polymer dictated by the macromolecular structure. To discuss the structure of polymer molecules, one may consider the chemical nature of CRU, type of the linkages, the global macromolecular arrangement, and the topochemical character of the macromolecule, tacticity, etc. These are summarized in Table 1.2.

Table 1.2 Macromolecular structures

No.	Characteristic	Examples
1	*Recurring constitutional repeating units, CRU*	
1.1	*Structure*	Aliphatic, aromatic, heterocyclic, metallo-organic
1.2	*Joining similar CRU*	Homopolymers (linear, branched, dendritic, cross-linked, etc.)
1.3	*Joining different CRUs*	Copolymers, multipolymers, polyadducts, polycondensates…
1.4	*Joining polymer segments*	Block copolymers, graft copolymers, ladder polymers
2	*The nature of bond between CRU*	For example, ether, ester, amide, urethane, sulfite
3	*Macromolecular structure*	Linear, branched, cross-linked, dendritic
4	*Topochemical characteristics of macromolecule*	
4.1	*Geometrical isomers*	For example, rubber and gutta-percha are poly(1,4-isoprene), *cis-* and *trans-*, respectively
4.2	*Optical isomers*	Having optically active C*; e.g., polypeptides, polysaccharides
4.3	*Tacticity*	Isotactic, syndiotactic, and atactic
4.4	*Helical structures*	Polypeptides, tactic polymers
4.5	*Head-to-tail, head-to-head*	For example: PIB or PS

1.3.2 Polymer Nomenclature

Macromolecular compounds can be classified according to (Kumar and Gupta 2003):

1. The chemical structure of the repeating unit (viz., polyamides, polyesters, polyolefins)
2. The structure (viz., linear, branched, ladder, or cross-linked)
3. The phenomenological behavior or technological use
4. The source of the compounds (viz., synthetic, natural, and derived products)

The Commission on Macromolecular Nomenclature defined 52 terms related to polymer structure, including *polymer*, *constitutional units*, *monomer*, *polymerization*, *regular polymer*, *tactic polymer*, *block polymer*, *graft polymer*, *monomeric unit*, *degree of polymerization*, *addition polymerization*, *condensation polymerization*, *homopolymer*, *copolymer*, *bipolymer*, *terpolymer*, *and copolymerization* (IUPAC 1974). The Commission remains the leading nomenclature body in the polymer field. Table 1.3 lists the pertinent sources for information on the nomenclature of polymeric materials.

Since there are difficulties in assigning systematic and unique abbreviations to polymers, only a short list has the IUPAC's official sanction. The IUPAC Macromolecular Nomenclature Commission has published three sets of rules for naming polymers:

1. Traditional, *trivial names* are sanctioned by the historical use and approved by IUPAC as an alternative (examples are listed in Table 1.4)
2. *Structure-based* nomenclature
3. *Source-based* nomenclature proposed by the Commission

Table 1.4 Traditional and systematic names of polymers

No.	Traditional name	Systematic name
1.	Polyethylene	Poly(methylene)
2.	Polypropylene	Poly(propylene)
3.	Polyisobutylene	Poly(1,1-dimethyl ethylene)
4.	Polybutadiene	Poly(1-butenylene)
5.	Polyisoprene	Poly(1-methyl- 1-butenylene)
6.	Polystyrene	Poly(1-phenyl ethylene)
7.	Polyacrylonitrile	Poly(1-cyano ethylene)
8.	Polyvinyl alcohol	Poly(1-hydroxy ethylene)
9.	Polyvinylacetate	Poly(1-acetoxy ethylene)
10.	Polyvinylchloride	Poly(1-chloro ethylene)
11.	Polyvinylidenefluoride	Poly(1,1-difluoro ethylene)
12.	Polytetrafluoroethylene	Poly(difluoro methylene)
13.	Polyvinylbutyral	Poly[(2-propyl-1,3-dioxane-4,6-diyl) methylene]
14.	Polymethylacrylate	Poly[1-(methoxycarbonyl) ethylene]
15.	Polymethylmethacrylate	Poly[1-(methoxycarbonyl)-1-methyl ethylene]
16.	Polyformaldehyde	Poly(oxy methylene)
17.	Polyethylene oxide	Poly(oxy ethylene)
18.	Polyphenylene ether	Poly(oxy-1,4-phenylene)
19.	Polyethylene terephthalate	Poly(oxyethylene-oxyterephthaloyl]
20.	Poly-ε-caprolactam	Poly[imino(1-oxohexamethylene)]
21.	Polyamide-6,6 or polyhexamethyleneadipamide	Poly[imino(1,6-dioxohexa methylene) iminohexa methylene]; or poly(iminoadipoyliminohexa methylene)

1.3.2.1 Structure-Based Nomenclature

For organic, regular, single-strand polymers, the structure-based system of naming polymers should be used. This nomenclature describes chemical structures rather than substances. Three steps are to be followed in a sequence:

1. Identify the constitutional repeating unit, CRU.
2. Orient the CRU.
3. Name the CRU.

The name of the polymer is *poly(CRU)*. The preferred CRU is one beginning with the subunit of highest seniority. The order of seniority is heterocyclic rings, chains containing heteroatoms (in the descending order O, S, Se, Te, N, P), carbocyclic rings, and chains containing only carbon. The seniority is expressed by brackets and internal parentheses (see examples in Table 1.4).

After the CRU and its orientation, reading left to right, have been established, the CRU or its constituent subunits are named. The name (the largest identifiable unit) includes description of the main chain and the substituents. The subunits are named according to the rules for nomenclature of organic chemistry. The name of the CRU is formed by citing, in order, the names of the largest subunits within the CRU. More complicated, regular single-strand polymers can be represented as multiples of repeating units, such as [ABC]$_n$. The name of the polymer is *poly(ABC)*, where (ABC) stands for the names of A, B, and C, taken in the order of seniority. An extension of the structure-based method to linear inorganic and/or coordination polymers is limited by the general lack of a system for naming bivalent radicals. Few polymers with inorganic, covalently bonded backbones have trivial names (viz., poly(dimethylsiloxane) or poly(dichlorophosphazene)), some can be named by (as organic polymers) using bivalent radicals, e.g., poly[oxy(dimethyl silylene)] or poly[nitrilo (dichlorophosphoranylidyne)].

Structure-based nomenclature is also applicable to copolymers having a regular structure, regardless of the starting materials used (viz., poly(oxyethylene-oxyterephthaloyl)). In principle, it should be possible to extend the existing structure-based nomenclature beyond regular, single-strand polymers to polymers that have reacted, cross-linked polymers, ladder polymers, and other more complicated systems.

1.3.2.2 *Source-Based* Nomenclature

Traditionally, polymers have been named by attaching the prefix *poly* to the name of the CRU, real or assumed monomer, the source from which it is derived. Thus, PS is the polymer made from styrene. When the name of the monomer consists of two or more words, parentheses should be used, but for common polymers such as polyvinylchloride, polyvinylacetate, etc., it is customary to omit them. Different types of polymerization can take place with many monomers, and there are different ways for obtaining a polymer. For example, name such as polyvinyl alcohol refers to a hypothetical source, since this polymer is obtained by hydrolysis of polyvinylacetate. In spite of deficiencies, the source-based nomenclature is still entrenched in the literature. It is also the basis for naming and classifying copolymers (see Table 1.5).

Table 1.5 Nomenclature of copolymers

No.	Type	Connective	Example
1.	Short sequences		
1.1.	Unknown or unspecified	-co-	Poly(A-co-B)
1.2.	Statistical	-stat-	Poly(A-stat-B)
1.3.	Random	-ran-	Poly(A-ran-B)
1.4.	Alternating	-alt-	Poly(A-alt-B); (AB)n
1.5.	Periodic with at least three monomeric units	-per-	Poly(A-per-B-per-C); (ABC)$_n$; (ABAC)$_n$; (AABB)$_n$
2.	Long sequences		
2.1.	Block	-block-, or -b-	Poly A-block-poly B; poly(A-b-B)
2.2.	Graft (polymeric side chain different)	-graft-or -g-	Poly A-graft-poly B; poly(A-g-B); AAAAA (g-BBB)AAAAAAA
2.3.	Star	-star-	Star-poly A
2.4.	Star block	-star-...-block-	Star-poly A-block-poly B
3.	Networks		
3.1.	Cross-linked	-cross-	Cross-poly A
3.2.	Interpenetrating	-inter-	Cross-poly A-inter-cross-poly B
3.3.	Conterminous	-cross-	Poly A-cross-poly B

1.3.3 Copolymers

When mers are not identical, the polymerization leads to a *copolymer*. For divalent mers, a *linear copolymer* is obtained, but when at least some mers are able to join more than two units, the polymerization leads to *branched* or *cross-linked copolymer*. When the polymerization starts on a polymer chain of different chemical character than the one that is subsequently forming, the resulting structure is known as *grafted copolymer*. Thus, the arrangement of the different types of monomeric units must be specified. Several types of arrangements are shown in Table 1.5, where A, B, and C represent different CRUs. The systematic source-based nomenclature for copolymers involves identification of the constituent monomers and description of their arrangement. This is achieved by citing the names of the constituent monomers after the prefix "poly" and by placing between the names of each pair of monomers an italicized connective to denote the kind of arrangement by which those two types of monomeric units are related in the structure.

The structures listed in Table 1.5 are divided into three categories: *short sequences, long sequences, and networks.* Within the first category, a sequence of placement of individual CRU is considered, within the second the placement of long sequences of CRU defines the copolymer type, while to the third belong cross-linked networks, cross-linked polymers, and chemical-type interpenetrating polymer networks. The network is a cross-linked system in which macromolecules of polymer A are cross-linked by macromolecules of polymer B (Sperling 1992). The composition can be expressed as, e.g., *block*-co-poly(butadiene/styrene) (75:25 wt%) or *graft*-co-poly[isoprene/(isoprene; acrylonitrile)] (85:15 mol%).

Table 1.6 Descriptors for nonlinear macromolecules and macromolecular assemblies

Polymer structure	Descriptor
Cyclic	*cyclo*
Branched (unspecified)	*branch*
Short-chain	*sh-branch*
Long-chain	*l-branch*
With f (give numerical value) branch points	*f-branch*
Comb	*comb*
Star (unspecified)	*star*
With f (give numerical value) arms	*f-star*
Network	*net*
Micronetwork	*m-net*
Polymer blend	*blend*
Interpenetrating polymer network	*ipn*
Semi-interpenetrating polymer network	*sipn*
Macromolecule-macromolecule complex	*compl*

1.3.4   Macromolecular Assemblies

To describe polymers or polymer blends with greater precision, the qualifiers listed in Table 1.6 have been suggested (Jenkins et al. 1993). In a series of four papers, Wilks (1997a–d) has compared the polymer nomenclature styles and structure representation systems used by Chemical Abstracts Service (CAS), the IUPAC, and MDL Information Systems, Inc. (MDL).

1.3.5   Polymer Blend Terminology

The terminology used in polymer blends' science and technology is summarized in Table 1.7 (Utracki 1989a, b). Universal adoption of a consensus nomenclature is vital to the description of chemical structures in online searching and in publishing works. For instance, different kinds of surfaces, interfaces, and interphases provide challenges to develop consistent nomenclature. This is a continuous process as polymers, its variations, and their blends are studied. The definition and nomenclature relating to polymer liquid crystals are recommended in IUPAC (2001), regular single-stranded polymers in IUPAC (2002), terms related to polymers containing ionizable or ionic groups and of polymers containing ions in Jones (2009), and so is the graphical representation of single-strand (copolymers) and irregular polymers in IUPAC (2012).

1.4   Introduction to Polymer Blends

Polymer blends constitute almost one third of the total polymer consumption, and their pertinence continues to increase. According to bcc Research, the global

Table 1.7 Terminology of polymer blends

Term	Definition
Polymer	A substance composed of large molecules, the *macromolecules*, built by covalently joining at least 50 molecular mers, segments, or recurring *constitutional repeating units*, *CRU*. Commercial polymers may contain up to 2 wt% of another polymeric modifier
Copolymer	Polymeric material synthesized from more than a single monomer
Engineering polymer (EP)	Processable polymeric material, capable of being formed to precise and stable dimensions, exhibiting high performance at the continuous use temperature CTU > 100 °C and having tensile strength in excess of 40 MPa
Polymer blend (PB)	Mixture of at least two macromolecular substances, polymers or copolymers, in which the ingredient contents is above 2 wt%.
Homologous polymer blend	Mixture of two homologous polymers (usually a mixture of narrow molecular weight distribution fractions of the same polymer)
Miscible polymer blend	Polymer blend, homogenous down to the molecular level, associated with the negative value of the free energy of mixing: $\Delta G_m \approx \Delta H_m \leq 0$ and a positive value of the second derivative $\partial^2 \Delta G_m \partial \phi^2 > 0$. Operationally, it is a blend whose domain size is comparable to the dimension of the macromolecular statistical segment
Immiscible polymer blend	Polymer blend whose free energy of mixing $\Delta G_m \approx \Delta H_m > 0$
Compatible polymer blend	Term to be avoided! At best a utilitarian, nonspecific term indicating a marketable, visibly homogeneous polymer mixture, with enhanced performance over the constituent polymers
Polymer alloy	Immiscible, compatibilized polymer blend with modified interface and morphology
Compatibilization	Process of modification of the interfacial properties in immiscible polymer blend, resulting in reduction of the interfacial tension coefficient and stabilization of the desired morphology, thus leading to the creation of a polymer alloy
Interphase	Third phase in binary polymer alloys, enhanced by interdiffusion or compatibilization. Thickness of this layer varies with the blend components and compatibilization method from 2 to 60 nm
Compatibilizer	Polymer or copolymer that either added to a polymer blend or generated there during reactive processing modifies its interfacial character and stabilizes the morphology
Chemical compatibilization	Compatibilization by incorporation of a compatibilizer, usually either a copolymer or multipolymer
Physical compatibilization	Compatibilization by physical means: high stress field, thermal treatment, irradiation, etc.
Reactive compatibilization	Compatibilization during reactive processing, extrusion, or injection molding
Engineering polymer blend	Polymer blend or polymer alloy that either contains or has properties of an engineering polymer
Interpenetrating polymer network (IPN)	Polymer alloy, containing two or more polymers in the network form, each chemically cross-linked. Sequential, simultaneous (SIN), and latex type IPNs are known
Thermoplastic IPN	Polymer alloy, containing two or more polymers in a co-continuous network form, each physically cross-linked. The cross-linking originates in crystallinity, ion cluster formation, presence of hard blocks in copolymers, etc.

market in volume for engineering resins and their blends was more than 22 billion pounds in 2012; polycarbonates and polyamides are the most prominent, and these account for about 60 % of the total market.

1.4.1 Benefits and Problems of Blending

The following material-related benefits can be cited:
  (i) Providing materials with a full set of desired properties at the lowest price
 (ii) Extending the engineering resins' performance
(iii) Improving specific properties, viz., impact strength or solvent resistance
(iv) Offering the means for industrial and/or municipal plastic waste recycling
    Blending also benefits the manufacturer by offering:
  (i) Improved processability, product uniformity, and scrap reduction
 (ii) Quick formulation changes
(iii) Plant flexibility and high productivity
(iv) Reduction of the number of grades that need to be manufactured and stored
 (v) Inherent recyclability, etc.

1.4.2 Compatibilization

The topic is extensively treated in ▶ Chap. 4, "Interphase and Compatibilization by Addition of a Compatibilizer" and ▶ Chap. 5, "Reactive Compatibilization", and thus only the key features are mentioned below. Several books and reviews also provide extensive information on the topic (Newman and Paul 1978; Kotliar 1981; Porter et al. 1989; Porter and Wang 1992; Brown 1992; Ajji and Utracki 1996; Datta and Lohse 1996; Utracki 1998a; Bucknall and Paul 2000; Robeson 2007).

It is noteworthy that in the absence of the configurational entropy effects (see ▶ Chap. 2, "Thermodynamics of Polymer Blends"), the miscibility of polymer blends depends on the balance of small enthalpic and/or non-configurational entropic effects. Sensitivity of this balance to small variation of the macromolecular structure is illustrated in the series of papers on miscibility of model polyolefins – e.g., see (Rabeony et al. 1998). Another example is provided by the photoisomerization initiated, reversible phase separation of PVME blends with stilbene-substituted PS (Ohta et al. 1998).

While miscibility is limited to a specific set of conditions, the immiscibility dominates – most polymers form immiscible blends that require compatibilization. Alloys' performance depends on the ingredients, their concentration, and morphology. The alloying process must result in *stable* and *reproducible* properties of polymer blends. Thus, the morphology must either be stable, unchanged during the forming steps, or the changes must be well predicted. The alloying makes use of an appropriate dispersing method (viz., mechanical mixing, solution, or latex blending) and compatibilization.

The latter process must accomplish three tasks:

1. Reduce the interfacial tension, thus giving a finer dispersion.
2. Stabilize the morphology against thermal or shear effects during the processing steps.
3. Provide interfacial adhesion in the solid state.

The compatibilization strategies comprise (i) addition of a small quantity of cosolvent – a third component, miscible with both phases, (ii) addition of a copolymer whose one part is miscible with one phase and another with another phase, (iii) addition of a large amount of a core-shell copolymer – a compatibilizer-cum-impact modifier, (iv) reactive compounding that leads to modification of at least one macromolecular species that result in the development of local miscibility regions, and (v) addition of a small quantity of nanoparticles which influence blend structure similarly to particle-stabilized water/oil emulsions.

Commercial alloys may comprise six or more polymeric ingredients. The increased number of components, n, increases the number of interfaces between them: $N = n(n-1)/2$. For such complex systems, it may be necessary to use an ingredient with highly reactive groups, capable of interacting with several polymeric components, e.g., such multicomponent copolymer as ethylene-glycidyl methacrylate, triglycidylisocyanurate, etc. Alternatively, one may carry a sequential blending, incorporating one polymer within another and then combining the preblends into the final alloy, hence reducing the number of interfaces that must be simultaneously controlled.

While the reduction of the interfacial tension, ν, is relatively easy by introduction of a macromolecular "surfactant," the stabilization of morphology and improvement of the interfacial adhesion in the solid state may not be so. One may use either a single compatibilizer that can perform all three compatibilization tasks, or a combination of agents, each playing one or two different roles. For example, stabilization of the desired dispersion (accomplished by addition of "surfactant" to mechanically mixed compound) may be accomplished by partial cross-linking of one of the three phases: matrix, dispersed, and the interphase. In the latter case, the interfacial adhesion in the solid state is also improved.

The density profile across the interface follows an exponential decay (see Fig. 1.1). The intercepts of the steepest tangential line with the horizontal lines defining the volume fraction of either one of the two polymeric ingredients, $\phi = 0$ and 1, define the thickness of the interphase, Δl (Helfand and Tagami 1971, 1972). Experimentally Δl varies from 2 to 60 nm (Kressler et al. 1993; Yukioka and Inoue 1993, 1994). Measurements of Δl have been used to map the miscibility region of PC/SAN blends when varying the AN content and temperature (Li et al. 1999a).

For high molecular weight polymer blends (M $\rightarrow \infty$), the Helfand and Tagami theory predicts that in binary blends (i) the interfacial thickness, Δl_∞, is inversely proportional to the interfacial tension coefficient, v_∞, the product, $\Delta l_\infty v_\infty$, being independent of the thermodynamic interaction parameter, χ; (ii) the surface free energy is proportional to $\chi^{1/2}$; (iii) the chain ends of both polymers concentrate at the interface; (iv) any low molecular weight third component is repulsed to the interface; and (v) the interfacial tension coefficient increases with molecular weight

Fig. 1.1 Density profile
across the interface, defining
thickness of the interphase
to an asymptotic value: $v = v_{\infty} - a_o M^{-2/3}$. The value of v can be measured or calculated from the molecular structure of two polymers, e.g., by means of the Hoy's group contribution method. The computed and experimental values of v for 46 polymer pair showed good correlation with an average error of $\pm$ 36 % (Luciani et al. 1996, 1997).

The concentration dependence of v_{∞} may be expressed as (Tang and Huang 1994; Ajji and Utracki 1996)

$$v = v_{CMC} + (v_o - v_{CMC})\exp\{-a\chi Z_c\phi\};$$
$$d = d_{CMC} + (d_o - d_{CMC})\exp\{-a\chi Z_c\phi\} \tag{1.5}$$

where a and a_1 are adjustable parameters, Z_C is the copolymer's degree of polymerization, and subscript CMC indicates the "critical micelles concentration." It is important to note that v and the diameter of the dispersed phase follows the same mathematical dependence.

The amount of compatibilizer required to saturate the interface, w_{cr}, can be expressed by the two limiting equations:

$$w_{cr} = 3\phi M/aRN_A; \qquad w_{cr} = 27\phi M/[\langle r^2\rangle RN_A] \tag{1.6}$$

where ϕ is the volume fraction of the dispersed phase, R is the radius of the dispersed drop, N_{Av} is the Avogadro number, M is the copolymer molecular weight, $a \geq 5$ nm^2 is the specific cross-sectional area of the copolymer macromolecule, $\langle r^2\rangle = KM$ is square end-to-end distance of the copolymer, and K is the characteristic parameter of the polymeric chain. The first equation in Eq. 1.6 was derived assuming that *all* compatibilizer's molecules cross the interface once, while the second assuming that di-block copolymer macromolecular coils are randomly

deposited on the interface (Mathos 1993; Ajji and Utracki 1996). The reality is somewhere in between these two ideal cases. Both relations predict that the amount of copolymer required to saturate the interface is proportional to the total interfacial area expressed as ϕ/R.

Measurements of ν for the commercial resins' blends depended on the contact time of the two polymers. Helfand et al. theory predicts that owing to diffusion of low molecular weight ingredients to the interphase, ν should decrease with time. This indeed was observed for most blends, but an opposite effect was also seen for some PA/PO blends. The effect depended on the nature and amount of antioxidants and stabilizers in each resin. POs frequently contain acidic stabilizers, viz., sterically hindered phenols, (hydro)-peroxide decomposers (e.g., tris(2,4-di-tert-butyl phenyl)-phosphite), radical scavengers such as thio-derivatives (Herbst et al. 1995, 1998). When blending thus stabilized PO with PA, chemical reactions between the acidic stabilizers and $-NH_2$ of the PA chain ends result in formation of a rigid membrane. Measuring the interfacial tension coefficient as a function of the contact time shows increasing values of the interfacial tension coefficient. These time effects should be incorporated when predicting the blends' morphology (Luciani et al. 1996, 1997).

Initially, the most common method of compatibilization was an addition of a third polymeric component, either a block or a graft copolymer. It was assumed that the compatibilizer would migrate to the interface, broadening of the segmental concentration profile, Δl. There are several reports indicating that addition of a block or graft copolymer reduces ν and alters the molecular structure at the interface, but it rarely increases the interphase thickness. Another disadvantage of the addition method is the tendency for a copolymer to migrate to at least five different locations, forming saturated solutions and micelles in both phases, as well as the interphasial layer (block copolymers may also form mesophases). Hence, the copolymeric compatibilizer that is to be added to a blend should have:

(i) Maximum miscibility with the respective polymeric components.
(ii) Molecular weight of each block only slightly higher than the entanglement M_e.
(iii) Concentration just above CMC. In industry the time effects are important – the higher is the viscosity of the blend's components, the longer is the diffusion time, thus the slower the processing.

The morphology of commercial blends usually is far from equilibrium. Preparation of the alloys must take thermodynamic and kinetic parameters into account if the desired effects are to be achieved. The effects of copolymer addition on the dispersion size and blend performance have been studied (Hobbs et al. 1983; Fayt et al. 1986a; Armat and Moet 1993; Alsewailem and Gupta 2002). The interface/morphology relationship in polymer blends with thermoplastic starch has also been studied (Taguet et al 2009).

From the economic as well as the performance points of view, the reactive compatibilization is most interesting (see ▶ Chap. 5, "Reactive Compatibilization"). The process involves (i) sufficient dispersive and distributive mixing to ascertain required renewal of the interface; (ii) presence of a reactive functionality, suitable to react across the interphase; (iii) sufficient reaction rate making it

possible to produce sufficient quantity of the compatibilizing copolymer within the residence time of the processing unit. The method leads to particularly thick interphase, thus good stability of morphology.

The reactive blending has been used since the beginning of the plastic industry. For example, two polyisoprene isomers, NR and GP, were softened by addition of $SCl_2 + CS_2$ and milled in a hot rubber mill. During milling, the solvent partially decomposed co-vulcanizing NR with GP (Parkes 1846). A patent from 1939 describes reactive blending of PVAl with multicomponent acrylic copolymers containing maleic anhydride (I. G. Farbenindustrie 1939). In the early 1940s, BASF used a corotating TSE for reactive extrusion of PA-6. Since the mid-1960, the reactive extrusion has been used for toughening and general modification of the engineering resins, viz., PA, PET, PC, or PBT. In 1971, Exxon patented styrene grafting of PE in reactive extrusion followed by blending with PPE for improved processability and excellent performance. Oxazoline-grafted polymers were used as compatibilizers in reactive blending of PC with PA. In 1975 du Pont started to manufacture the *super tough PA*, *Zytel-ST™*, by reactive blending of PA-66 with maleated ethylene-propylene-diene elastomer (EPDM-MA). The reactive compatibilization of the PPE/PA was developed in 1977 (Ueno and Maruyama 1979). More details on reactive compatibilization can be found in ▶ Chap. 5, "Reactive Compatibilization" as well as in a monograph published by Utracki (1998a).

It has been known for a long time that emulsions of low viscosity liquids can be stabilized not just by the use of surfactants but also by means of added nanoparticles (Pickering 1908). This behavior is found to carry over to polymer blends as well (Vermant et al. 2008; Fenouillot et al. 2009; Yoo et al. 2010). It is found that the morphology that results with the use of nanoparticles is finer than that in the case of pure blends since the interfacial tension is lowered. The morphology is also more stable against annealing. This effect is the result of the nanoparticles locating themselves at the blend interface and forming a solid barrier that inhibits drop coalescence. For this result to be observed, though, the size, shape, surface chemistry, and loadings of the nanoparticles must be tailored such that the Gibb's free energy of the interface is minimized when nanoparticles are located there. Else, there can even be transfer of nanoparticles from one phase to another (Goldel et al. 2012). A benefit of using nanofillers like carbon nanotubes in immiscible polymer blends is that the electrical percolation threshold can be significantly lowered (Goldel and Potschke 2011). This topic is explored in ▶ Chap. 17, "Polymer Blends Containing "Nanoparticles"".

It is imperative to mention that component polymer surfaces and interfaces play a major role in the properties and applications of blends such as in biocompatibility, switching, or adaptive properties. Whether it is an everyday plastic part or parts in automotives or in an airplane, not only the development of interfacial morphology but also the analyses of blends interfaces are equally important. The compatibilizing effect is primarily due to the interfacial activity of the constituent partners. This in turn raises the question of what are the effects of the molecular weight, concentration, temperature, and molecular architecture of the

compatibilizer. Anastasiadis (2011) has reviewed interfacial tension in binary polymeric blends and the effects of copolymers as emulsifying agents. The diffused interface widths in binary blends such as PVC/EVA and PS/PMMA have been studied (Ramya 2013). When there is a large difference in compressibility between constituent polymers, Cho (2013) interpreted pressure coefficient of interfacial tension and argued that there exist a region that $\delta_\gamma/\delta P < 0$. Polymer surface and interface characterization techniques differ based on the environments (such as air, vacuum, liquid, etc.). Stamm (2008) has lucidly described several aspects of surface and interface characterization and provided a list of different techniques in which those could be applied. The other technique known as grazing incidence small-angle neutron scattering is also gaining attention due to its surface sensitivity in the investigation of nanostructures in thin films and at surfaces (Buschbaum 2013).

1.4.3 Morphology

The morphology depends on the blend concentration. At low concentration of either component, the dispersed phase forms nearly spherical drops, and then, at higher loading, cylinders, fibers, and sheets are formed. Thus, one may classify the morphology into dispersed at both ends of the concentration scale and co-continuous in the middle range. The maximum co-continuity occurs at the phase inversion concentration, ϕ_I, where the distinction between the dispersed and matrix phase vanishes. The phase inversion concentration and stability of the co-continuous phase structure depend on the strain and thermal history (Song et al. 2009, 2011). For a three-dimensional (3D) totally immiscible case, the percolation theory predicts that $\phi_{perc} = 0.156$. In accord with the theory, the transition from dispersed to co-continuous structure occurs at an average volume fraction, $\phi_{onset} = 0.19 \pm 0.09$ (Lyngaae-Jørgensen and Utracki 1991; Lyngaae-Jørgensen et al. 1999). The co-continuity contributes to synergism of properties, e.g., advantageous combination of high modulus and high impact strength in commercial blends. Detailed discussion of the phase co-continuity and its effect on morphology and rheology is given in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends".

When discussing the morphology, it is useful to use the *microrheology* as a guide. At low stresses in a steady uniform shear flow, the deformation can be expressed by means of three dimensionless parameters – the viscosity ratio, the capillarity number, and the reduced time, respectively:

$$\lambda \equiv \eta_d/\eta_m; \quad \kappa = \sigma d/v; \quad t^* = t\dot{\gamma}/\kappa = \gamma/\kappa \quad (1.7)$$

where σ is the local stress, η_d and η_m is the dispersed phase and matrix viscosity, respectively, $\dot{\gamma}$ is the deformation rate, and d is the droplet diameter. The capillarity number may be used in its reduced form $\kappa^* \equiv \kappa/\kappa_{cr}$, where the critical capillarity number κ_{cr} is defined as the minimum capillarity number sufficient to cause breakup of the deformed drop. The drop can break when $1 < \kappa^* < 2$.

For $\kappa^* > 2$ the drops deform into stable filaments, which only upon reduction of κ^* disintegrate by the capillarity forces into mini-droplets. The deformation and breakup processes require time – in shear flows the reduced time to break is $t_b^* \geq 100$. When values of the capillarity number and the reduced time are within the region of drop breakup, the mechanism of breakup depends on the viscosity ratio, λ – in shear flow, when $\lambda > 3.8$, the drops may deform, but they cannot break. Dispersing in extensional flow field is not subjected to this limitation. Furthermore, for this deformation mode κ_{cr} (being proportional to drop diameter) is significantly smaller than that in shear (Grace 1982).

The use of microrheology for the description of drop deformation and break was found to provide a surprisingly good agreement with experimental observations for the morphology evolution during compounding in a TSE (Utracki and Shi 1992; Shi and Utracki 1992; 1993). The predictive model (without adjustable parameters) was further improved by incorporation of the coalescence (Huneault et al. 1995a). A similar model has also been proposed (Moon and Park 1998).

The flow affects the blend morphology, but the structure variations also engender changes to the rheological response. The flow affects morphology in two ways – it changes the degree and type of dispersion on a local level and imposes global changes of morphology in formed parts. The latter effects originate from the flow-imposed migration of the dispersed phase that, for example, may cause formation of skin-core structures, weld lines, etc. The flow-imposed morphologies can be classified as (i) dispersion (mechanical compatibilization), (ii) fibrillation, (iii) flow coalescence, (iv) interlayer slip, (v) encapsulation, and others (Utracki 1995).

Flow may also cause mechanochemical degradation that generates reactive components, viz., radicals, peroxides, acids, etc. Transesterification, *trans*-amidation, and ester-amide exchange reactions during processing are well documented (their rate depends on the total interfacial area that in turn depends on flow) (Walia et al. 1999). These reactions may be responsible for the formation of compatibilizers that increase the interfacial area, affect the phase equilibria and the regularity of the main chain, and thus modify the degree of dispersion, blend's crystallinity, and, hence, performance. Use of cross-linked PE (XLPE) and different elastomers (EPDM, EVAc, butyls) as insulation materials is well known in the power distribution cable industries. Flow behavior and morphology of melt mixed blends of XLPE and silicone elastomers with and without compatibilizer (vinyl silane) have been studied (Mukhopadhyay et al. 1990). Surface morphology of the blends revealed the presence of a cross-linked microgelled silicone elastomer that seemed to disperse as a filler in the continuous XLPE matrix.

Miscibility of the blend components has an obvious effect on morphology (for detailed discussions, see ▶ Chap. 8, "Morphology of Polymer Blends"). During processing, the hydrostatic and shear stresses can change the lower critical solubility temperature (LCST) by at least 60 °C. This may result in formation (inside the processing unit) of a miscible blend. The blend emerging from the extruder may phase separate by the spinodal decomposition mechanism into a co-continuous structure, whose degree of dispersion can be controlled, for example, PBT/PC blends.

Stress-induced fibrillation occurs in a steady-state shearing or extension, when the capillarity ratio $\kappa > 2$. Under these conditions, flow is co-deformational. Since, $\kappa \propto d$, it is easier to fibrillate coarser dispersions where $\phi > a\lambda^b$ (the numerical value of the a and b parameters depends on the composition of the blend) (Krasnikova et al. 1984). Flow through a capillary of POM dispersed in a copolyamide (CPA) at $T = T_m(POM) + 6\ °C$ resulted in fibrils with diameters of about 20 μm and length 3.2 mm. Fibrillation of POM in EVAc strongly varied with λ. For $\lambda \approx 1$, the finest morphology was found (Tsebrenko et al. 1976, 1982). At temperatures slightly above the melting point, $T > T_m$, coalescence combined with stress-induced crystallization resulted in the formation of long fibers. The effect has been explored for performance improvement of blends comprising liquid-crystal polymers (LCP) (La Mantia 1993; Champagne et al. 1996).

The shear-induced interlayer slip was theoretically predicted – it creates a tree-ring structure in the extrudates (Utracki et al. 1986; Utracki 1991b; Bousmina et al. 1999). The relation may be used to describe the steady-state viscosity of antagonistically immiscible polymer blends, such as PP/LCP (Ye et al. 1991; Utracki 1986, 1991b).

The shear-induced segregation takes place in any system comprising flow elements with different friction coefficient, either miscible or immiscible (Doi and Onuki 1992). Migration of the low viscosity component toward the high stress regions may result in a flow-induced encapsulation. The effect has been well documented and successfully explored in polymer processing (Utracki 1987, 1988, 1989a, 1991a, 1995). For example, the high viscosity engineering resins with poor resistance to solvents, e.g., PC, PEST, or PEEK, can be blended with a low melt viscosity LCP. Extrusion through a die with sufficiently long land causes LCP to migrate toward the high stress zone near the die land, thus lubricating the die flow, improving the throughput, and enveloping the resin in a protective layer of LCP (Cogswell et al. 1981, 1983, 1984).

From an industrial viewpoint, polymer morphology can change due to physical aging even after a part has been extruded or injection molded, and this has implications on the performance of a polymer during service. Amorphous polymer melts when rapidly cooled to below their T_g form nonequilibrium structures which can relax over time by losing free volume (Struik 1978). As a consequence, mechanical properties can change, often for the worse. The use of polymer blends can retard this process since specific interactions such as hydrogen bonding and dipole-dipole interactions can restrict molecular mobility and increase long-term stability (Cowie and Arrighi 2010). Cowie and Ferguson (1989) have studied the physical aging of blends of PS and PVME using enthalpy relaxation and determined that the blend aged at a slower rate as compared to PVME alone.

In closing this section, we note that research interest in polymer blend miscibility is quite active as it affects final blend morphology. Recently, using a lattice-based equation of state, White and Lipson (2012) provided new correlations between the microscopic character of blend components and their bulk miscibility. These authors studied twenty-five polymer blend systems divided into two categories UCST and LCST and have found that the averaged difference between pure component energy parameters is significantly greater for LCST blends than for UCST blends.

1.4.4 Rheology

The rheology of polymer blends is discussed in detail in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends". Here only an outline will be given. Since the flow of blends is complex, it is useful to refer to a simpler system, e.g., for miscible blends to solutions or a mixture of polymer fractions, for immiscible blends to suspensions or emulsions, and to compatibilized blends to block copolymers (Utracki 1995; Utracki 2011). It is important to remember that *the flow behavior of a multiphase system should be determined at a constant stress*, *not at a constant deformation rate*.

For miscible blends, the free-volume theory predicts a positive deviation from the log-additivity rule, PDB. However, depending on the system and method of preparation, these blends can show either a positive deviation, negative deviation, or additivity (Utracki 1989a). Upon mixing, the presence of specific interactions may change the free volume and degree of entanglement, which in turn affect the flow behavior (Steller and Żuchowska 1990; Couchman 1996). For immiscible blends, the flow is similarly affected, but in addition there are at least *three* contributing phases: those of polymeric components and the interphase in between. Flow of suspensions provides good model for blends with high viscosity ratio, $\lambda > 4$, while for blends with $\lambda \approx 1$, the emulsion model is preferred. The block copolymer is a good model for well-compatibilized polymer alloys.

The fundamental assumption of the classical rheological theories is that the liquid structure is either stable (Newtonian behavior) or its changes are well defined (non-Newtonian behavior). This is rarely the case for flow of multiphase systems. For example, orientation of sheared layers may be responsible for either dilatant or pseudoplastic behavior, while strong interparticle interactions may lead to yield stress or transient behaviors. Liquids with yield stress show a *plug flow*. As a result, these liquids have drastically reduced extrudate swell, $B \equiv \equiv d/d_o$ (d is diameter of the extrudate, d_o that of the die) (Utracki et al. 1984). Since there is no deformation within the plug volume, the molecular theories of elasticity and the relations they provide to correlate, for example, either the entrance pressure drop or the extrudate swell, are not applicable.

The concentration dependence of the constant-stress viscosity provides information on the inherent flow mechanism. The experimental data should be evaluated considering the log-additivity rule, $\ln \eta_b = \sum \phi_i \ln \eta_i$. There are five possible types of behavior, described as (1) positively deviating blend (PDB), (2) negatively deviating blends (NDB), (3) log-additive blends, (4) PNDB, and (5) NPDB. These can be described combining the emulsion model of polymer blends with the interlayer slip (Utracki 1991b; Bousmina et al. 1999). Owing to the variability of the blend structure with flow, the rheological responses are sensitive to the way they are measured. Since the structure depends on strain, the responses measured at high and low values of strain are different. For this reason, the selected test procedure should reflect the final use of the data. When simulation of flow through a die is attempted, the large strain capillary flow is useful. However, when the material characterization is important, the dynamic tests are recommended. The dynamic

measurements of polymer blends at small strains are simple and reliable. The storage and loss shear moduli (G' and G'', respectively) should be first corrected for the yield stress and then analyzed for the relaxation spectrum (Utracki and Schlund 1987; Riemann et al. 1995; Friedrich et al. 1995).

Two types of rheological phenomena can be used for the detection of blend's miscibility: (1) influence of polydispersity on the rheological functions and (2) the inherent nature of the two-phase flow. The first type draws conclusions about miscibility from, e.g., coordinates of the relaxation spectrum maximum; cross-point coordinates (G_x, ω_x) (Zeichner and Patel 1981); free-volume gradient of viscosity, $\alpha = d(\ln\eta)/df$; the initial slope of the stress growth function, $S = d(\ln\eta_E^+)/d\ln t$; the power-law exponent $n = d(\ln\sigma_{12})/d\ln\dot{\gamma} \cong S$, etc. The second type involves evaluation of the extrudate swell parameter, $B \equiv \equiv D/D_o$, strain (or form) recovery, apparent yield stress, etc.

Compatibilization enhances dispersion, increases the total apparent volume of the dispersed phase, rigidifies the interface, and increases interactions not only between the two phases but also between the dispersed drops. These changes usually increase the blend's viscosity, elasticity, and the yield stress. The compatibilizer effects are especially evident at low frequencies. There are two mechanisms that may further affect these behaviors: (i) the copolymer may form micelles inside one or both polymeric phases instead of migrating to the interphase and (ii) an addition of compatibilizer may increase the free volume resulting in decreased viscosity.

The time-temperature, t-T, superposition principle is not valid even in miscible blends well above the glass transition temperature, T_g (Cavaille et al. 1987; Ngai and Plazek 1990; Chung et al. 1994). In miscible blends, as either the concentration or temperature changes, the chain mobility changes and relaxation spectra of polymeric components in the blends show different temperature dependence, thus the t-T principle cannot be obeyed. Furthermore, at the test temperatures, the polymeric components are at different distance from their respective glass transition temperatures, $T - T_{g1} \neq T - T_{g2}$, which affects not only the t-T superposition but also the physical aging time (Maurer et al. 1985). In immiscible PO blends, such as PE/PP, at best, the superposition is limited to the melt within narrow temperature ranges (Dumoulin 1988).

For most blends, the morphology changes with the imposed strain. Thus, it is expected that the dynamic low strain data will not follow the pattern observed for the steady-state flow. One may formulate it more strongly: *in polymer blends the material morphology and the flow behavior depend on the deformation field*, *thus under different flow conditions*, *different materials are being tested*. Even if low strain dynamic data could be generalized using the t-T principle, those determined in the steady state will not follow the pattern. Chuang and Han (1984) reported that for blends at constant composition, the plots of N_1 versus σ_{12} and G' versus G'' are independent of T. However, for immiscible blends, the steady-state relation may be quite different from the dynamic one. The agreement can be improved by means of the Sprigg's theory (Utracki 1989a).

Four measures of melt elasticity have been used: the first normal stress difference, N_1; the storage modulus, G'; and the two indirect ones, the entrance-exit

pressure drop, P_e (*Bagley correction*), and the extrudate swell, B. In homogeneous melts, the four measures are in a qualitative agreement. In the blends where the dispersed phase is rigid, B and P_e is small. By contrast, for the readily deformable dispersed phase, the deformation-and-recovery provides a potent mechanism for energy storage, leading to a large elastic response. In short, neither Bagley's entrance-exit pressure drop correction, P_e, nor the extrudate swell, B, should be used as a measure of blends' elasticity. In both cases, not the molecular deformation but the *form recovery* dominates the observed dependence.

Two contributions to the tensile stress growth function, η_E^+, should be distinguished: one due to the linear viscoelastic response, η_{EL}^+, and the other originating in the structural change of the specimen during deformation, η_{ES}^+. The first can be calculated from any linear viscoelastic function, while the second depends on the intermolecular interactions or entanglements, and its value depends on the total strain, $\varepsilon = t\dot{\varepsilon}$, and either strain rate $\dot{\varepsilon}$ or straining time, t (Utracki 1988, 1989, 1995; Takahashi 1996). Owing to the industrial importance of strain hardening, $SH \equiv \log(\eta_{ES}^+/\eta_{EL}^+)$, a large body of literature focuses on the optimization of blend composition to maximize SH. Since SH depends on the entanglement, either interchain reactions that lead to branched macromolecules, blending linear polymers with branched ones, synthesizing bimodal resins, or widening the molecular weight distribution may result in improved SH. Extensive work on SH has been done for PE blends, especially the ones comprising LDPE (Utracki and Schlund 1987). Several other resins with long-chain branching (viz., bPC, bPP, or a biodegradable polybutylenesuccinate, etc.) have been introduced as special grades for, e.g., film blowing, blow molding, wire coating, or foaming (Imaizumi et al. 1998).

The convergent flow at the die entrance provides strong elongational flow. In 1989 Laun and Schuch derived for Newtonian liquids that $P_e \approx 1.64\sigma_{12}$. The relation is satisfactory for homopolymers, but for the blend, the prediction is about one decade too low. On the other hand, this type of flow provides excellent means for mixing highly viscous dispersed phase. An extensional flow mixer (EFM) was developed. The device provides good mixing for multicomponent polymer systems, e.g., for blends with components having widely different viscosities, viz., PE with UHMWPE, PP with high elasticity EPR, and PC with PTFE (Nguyen and Utracki 1995; Utracki and Luciani 1996a; Luciani and Utracki 1996; Tokohisa et al. 2006).

1.4.5 Developing Commercial Blends

There are several methods of blending, viz., mechanical (dominant), solution, latex, fine powder, as well as several techniques adopted from the IPN technology. Not always the finest dispersion is desirable – the size and shape of the dispersed phase must be optimized considering the final performance of the blend.

The polymer blends' performance depends on the properties of the ingredients, their content, and morphology. Since the cost is virtually fixed by the material and

the compounding method, the economy depends on blend's morphology, tailored for a specific application. Blends have been developed for economic reasons, viz., improvement of either a specific property (e.g., impact strength) or engendering a full set of required properties, extending engineering resin performance, improving processability, recycling, etc.

There are several approaches to evaluation of the blend economy. For example, the cost of a blend equals the weight average of material cost, plus the compounding cost per unit mass, e.g., $C_b = \Sigma w_i C_i + K$. Another approach is to calculate the cost-to-performance ratios for diverse materials and/or compositions. For example, one may ask *how much a unit of the tensile modulus or the strength at yield will cost* and optimize the composition accordingly. However, with growing frequency, the blend economy is based on the replacement calculations, comprising the total cost, that of material, compounding, forming, assembling, customer satisfaction, esthetics, service life-spans, and then the ease of disposal or recycling.

For a major resin manufacturer, blending provides means to improve and broaden the resin performance, and therefore, it enhances the demands and sale. By contrast, the resin user starts with a set of performance parameters that the material must possess. In both cases, the basic preposition is the same: *to have a blend with desired characteristics*, one must use a component that already shows this characteristic, or simply, *one cannot create something out of nothing*.

While extension of the engineering resin performance constitutes the largest part of the high-performance blends' production, the most difficult and interesting task is the development of blends with a full set of desired properties. To achieve this goal, a systematic approach has been developed (Utracki 1994). The procedure starts with the selection of blend components, each possessing at least one of the desired properties. For example, to improve impact strength, an elastomer should be used; to induce flame retardancy, a nonflammable polymer; to improve modulus, a stiffer resin should be incorporated; etc. Since for each property there are several candidates to select from, the selection is guided by the principle of the compensation of properties – advantages of one component should compensate for deficiencies of the other, e.g., the disadvantages of PPE (processability and impact strength) can be compensated for by those of HIPS. Next, the method of compatibilization, compounding, and processing must be selected. Since polymer blends' performance depends on morphology, the goal is to ascertain the desired structure by selecting an appropriate resin grade (rheology) as well as the methods of compatibilization, compounding, and processing.

Interesting studies on the morphology development during dispersive mixing were published by Kozlowski (1994, 1995). In this fundamental work, a rotating disk mixer was used. The disk had a milled grove in which stationary spreader was inserted. The gap clearance, speed of rotation, temperature, shape of the spreader, and pressure were controlled. The device simulated the dispersive processes that take place in internal mixers or extruders. A model of stepwise generation of morphology was proposed, where the original pellet (of the dispersed phase) undergoes deformation into elongated plates, which under stress break into fibers and finally into drops. The final morphology is a result of dispersion and

coalescence processes that depend on the viscoelastic character of the component, the interfacial tension properties, and the stress history (see ▶ Chap. 9, "Compounding Polymer Blends").

The ideal compounding unit should have (i) uniform elongational and shear stress field; (ii) flexible control of temperature, pressure, and residence time; (iii) capability for homogenization of liquids having widely different rheological properties; (iv) efficient homogenization before onset of degradation; and (v) flexibility for the controllable change of mixing parameters.

Most blends described in the patent literature have been prepared using either an internal mixer or a single-screw extruder (SSE). In standard configuration, SSE is inadequate for the preparation of blends with controlled morphology. Furthermore, due to the presence of "dead spaces," the run-to-run reproducibility of the SSE-extruded blends may be poor. SSE should not be used for reactive blending. However, there are several designs of mixing screws, profiled barrel elements, and add-on mixing devices that ameliorate SSE mixing capability. From between the latter devices, RAPRA's cavity transfer mixer (CTM) or the patented extensional flow mixer (EFM) should be mentioned. The first of these is a sort of "dynamic motionless mixer," where material is transferred from the cavities in the barrel to those on the screw, enhancing the distributive mixing (Gale 1980). The EFM is a motionless device in which the extensional forces provide dispersive mixing for blends with components having widely different viscosities, viz., PE with UHMWPE, PP with high elasticity EPR, PC with PTFE, gel particles in reactor powders, etc. (Utracki and Luciani 1996a).

More expensive but easier to control is a twin-screw extruder, TSE. Owing to the modular design with many types of elements fulfilling different functions, TSE can be optimized for specific tasks. The ratio of the dispersive-to-distributive mixing can be adjusted, and the width of the residence time can be controlled. TSE is excellent chemical reactor for polymerization, modification of polymers, and reactive compatibilization (Rauwendaal 2001). As a result, the blend quality and run-to-run reproducibility are improved. Computer models have been developed to predict variation of blend's morphology along the screw length in these machines (Shi and Utracki 1992, 1993; Huneault et al. 1993, 1995b).

1.4.6 Blends' Performance

The quality of compounded blend affects the processing and performance. Layering, poor weld lines in injection molded parts, and skin-core extrudate structure with low notched Izod impact strength all indicate poor blend quality – either not adequate dispersion or poor stabilization of morphology. Compounding demands precise control of process variables. At the present, most alloys are prepared by reactive processing. It has been reported that pellet blending of two blend lots may lead to apparent immiscibility and bad weld-line strength. Evidently, even a small variation in the extent of reaction may make them immiscible. The mixed lots may pass standard tests, but still yield unacceptable products.

Historically, blending was used to improve the impact strength of the early resins, i.e., toughening of PS, PVC, PMMA, PET, PA, etc. With time, blends evolved into multipolymer systems that not only have to be impact modified but also compatibilized. Many blends have been formulated with a multicomponent modifier that simultaneously compatibilizes and impact-modifies the mixtures.

The following observations can be made: (1) The maximum toughening of brittle polymers has been obtained dispersing ca. 10 vol.% of a ductile resin with domain diameter of d ≈ 0.1–1.0 μm –the lower limit is for resins that fracture by the shear banding, whereas the higher for those that fracture by the crazing and cracking (Bucknall 1977; Bucknall et al. 1984). (2) The phase co-continuity provides the best balance of properties, e.g., high rigidity in the presence of large deformability (or elongation). The properties depend on the thickness of the interpenetrating strands, thus also on compatibilization. (3) For the best barrier properties, the lamellar structure is desirable. To create it, the blend should comprise large but stable drops with diameter d ≈ 5–50 μm. During biaxial stretching (e.g., in blow molding or film-blowing processes), the large drops easily deform into lamellae.

Two types of mechanical tests are recognized: low speed (tensile, compressive, or bending) and high speed (impact). Poor compatibilization affects both. For example, in tensile tests the maximum strain at break and the yield stress can be dramatically reduced by poor inter-domain adhesion. Similarly, the lack of adhesion is responsible for low-impact strength – the specimens are brittle. Several toughening mechanisms have been proposed, viz., crazing, shear-banding, cavitation, particle debonding, elastic deformation of the toughening particles, etc. (Arends 1996).

Polymeric systems are roughly classified as either brittle or pseudo-ductile. The first type has low crack initiation as well as propagation energy and it fails by the crazing-and-cracking mechanism. Typical examples are PS, PMMA, and SAN. The second type has high crack initiation energy, but low crack propagation energy, and it tends to fail by yielding and shear banding. Typical examples are PA, PEST, and PC. As usual, there are some polymers, e.g., POM and PVC, which show intermediate behaviors – in many systems the fracture takes place by a mixed mode. The transition from brittle to ductile mode of fracture depends on the intrinsic properties of the material as well as on the external variables such as geometry, temperature, loading mode, test rate, etc. To detect the mechanism of fracture, the stress-strain, and the volume-strain dependencies should be known. "Toughness" is defined as the total area under the stress-strain curve, thus abruptly ending curves without the yield point are characteristic of brittle materials. The volume-strain dependence provides means for quantitative identification of the fracture mode – pure shear banding shows no volume expansion, whereas pure crazing and cracking show the maximum volume expansion.

Wu (1985, 1987, 1988, 1990) postulated that the brittle/ductile behavior of a neat amorphous polymer is controlled by two intrinsic molecular parameters: the entanglement density, ν_e, and the chain stiffness (given by the characteristic chain constant, C_∞). Assuming that crazing involves chain scission, the stress, σ_z,

Fig. 1.2 Izod impact
strength at room temperature
as a function of diameter of
elastomeric particles in
methylmethacrylate-
butadiene-styrene copolymer
used for toughening
polyvinylchloride resin
(After Bartelo and Mori 1994)
should be proportional to $\nu_e^{1/2}$ and the yield stress, σ_y, proportional to C_∞. In consequence, $\sigma_z/\sigma_y \propto \nu_e\sqrt{3M_v/\rho_a}$, where M_v is the average molecular weight of a statistical segment and ρ_a is the polymer density. For brittle polymers, $\nu_e < 7.5$.

Effectiveness of the toughening process depends on the diameter of the elastomeric particles and their concentration. At constant concentration, the toughness versus particle diameter dependence goes through a maximum – abscissa of its location, d_{opt}, does not depend on concentration, whereas the ordinate does (see Figure 1.2). The optimum particle size, d_{opt}, depends on the entanglement density of the matrix resin, as well as on the fracturing and toughening mechanisms. In general, small particles, having weight-average diameters in the range of 0.2–0.4 μm, work well in the presence of shear yielding, while larger particles in the range of 2 and 3 μm are more effective in the presence of crazing (Bucknall and Paul 2009). Another important characteristic is interparticle spacing (Bucknall and Paul 2009, 2013).

However, the determination of the d_{opt} may be ambiguous, owing to the polydispersity of sizes as well as to inclusion of the matrix polymer inside the elastomeric particle. For example, it has been accepted that to toughen PS into HIPS, the optimum diameter is defined as a diameter of the elastomeric particles expanded by inclusion of the PS mini-drops. In PVC, the diameter of the elastomer was defined as the diameter of the original butadiene latex particle before grafting it with styrene and methylmethacrylate. In PC, the "optimum" diameter was defined by availability of the core-shell toughening agent – it is difficult to find toughness with elastomeric particles having diameter $d < 100$ nm. The strategy for the preparation of polymer blends with stable morphology demands that blends have thick interphase, $\Delta l \leq 60$ nm. Frequently it is impossible to decide how far the toughening by rubber core extends into the interphase. Many impact-resistant engineering resin blends have been formulated using a core-shell multicomponent copolymer with a *rigid* core and elastomeric shell whose thickness and affinity with the matrix resin was adjusted.

In many cases, toughening of a brittle polymer can be achieved by introduction of stiffness heterogeneity, viz., incorporation of an elastomer, immiscible polymer, solid particles, gas bubbles (i.e., foaming or microfoaming), etc. However, the size and concentration of these heterogeneities should be optimized. For most thermoplastics, the optimum diameter of the dispersed elastomeric particle is d < 3 μm and its volume fraction $0.05 < \phi < 0.10$. The accepted mechanism of toughening considers the heterogeneity to be a stress concentrator, generating excessive crazing and/or shear banding of the matrix, thus requiring higher amount of energy to cause fracture. The stress concentration factor was defined as $\gamma \propto 1/(1 - a\phi^{2/3})$ where the parameter a depends on the matrix (Bucknall 1977; Partridge 1992). For blends with pseudo-ductile matrix, d_{opt} depends on concentration, as it is important to keep the distance between the elastomeric particles approximately constant.

During the early works on compatibilization of PE/PS blends in Prof. Heikens laboratories, it was noted that addition of a small amount of one polymer to another improved impact properties. Since these two polymers are antagonistically immiscible and upon solidification void formed around the dispersed particles, it was concluded that it is the presence of the voids that accounts for the toughening effect (D. Heikens, 1982, private communication). About 15 odd years later, the microcellular blends have been introduced. For example, microfoamed blends of HDPE with PP (using CO_2 in an autoclave) showed significantly improved impact strength (Dorudiani et al. 1998). Similar enhancement of mechanical performance was reported earlier for N_2-microfoamed PS, SAN, or PC (Collias and Baird 1995). Now, microfoaming is being used to reduce the material consumption, part weight (by 30–50 %) (Kumar and Suh 1990), but it can also help to improve the mechanical performance, especially of the injection molded parts.

Under the triaxial stresses in the region ahead of the sharp crack, a particle may cavitate at a certain strain, changing the stress field of the matrix from the dilatation to the distortion dominated. Thus, the matrix may deform plastically, what consumes energy. The mechanism depends on the size of the dispersed toughening particles and the inherent plastic deformation capability of the matrix (Borggreve and Gaymans 1989; Lazzeri and Bucknall 1993; Yee and Shi 1995; Groeninckx et al. 1995). In PC cavitation occurred well before shear yielding (Parker et al. 1992). Blends comprising relatively high concentration of two engineering resins may require toughening of both phases by sequential reactive blending.

Formation of co-continuous structures in blends of either a brittle or pseudo-ductile resin with an elastomer may result in a quantum jump of toughness, without greatly affecting the key engineering properties of the high-performance resin. Commercial blends of this type, e.g., POM, PA, PC, or PET with an elastomer, are available (viz., *Triax*™ series).

1.4.7 Evolution of Polymer Alloys and Blends

The historical evolution of the polymer blend technology is presented in the following order:

1. Commodity resins (styrenics, PVC, acrylics, PE's, PP)
2. Engineering resins (PA, PEST, PC, POM, PPE)
3. Specialty resins (PSF, PAE, PARA, PAr, PPS, LCP, PEI, PEA, etc.)

Blends of polymer A with polymer B will be discussed following the adopted rules: (i) symbol A/B is used to identify any mixture of polymer A with B, independently of the concentration range or morphology, and (ii) the A/B blends are discussed under the name of the lower category polymer, i.e., blends of engineering or specialty polymers with a commodity resin are discussed in the category of commodity resin blends, blends of specialty polymers with engineering resins are discussed in the category of engineering resins, hence "specialty resin blends" consider only mixtures of two (or more) specialty resins.

1.5 Commodity Resins and Their Blends

Five large-volume polymeric groups belong to this category: polyethylenes, polypropylene, styrenics, acrylics, and vinyls. Their world market share remains relatively stable – the commodity resins represent 71 % of all consumed plastics.

1.5.1 Polystyrene (PS)

Simon in 1839 named the distillate of *Styrax officinalis* a *styrol*. By 1845, the thermal polymerization of styrene as well as the thermal depolymerization of PS was known. In 1915, I. G. Farbenindustrie started commercial production of PS, *Trolitul™*. Until the 1950s, PS was produced in small quantities – the resin was brittle, thermally unstable, with poor solvent and scratch resistance. The main use of styrene was in the manufacture of styrenics, viz., *Buna-S*, SBR, or ABS.

Common PS is atactic and amorphous. It has good optical clarity, low dielectric loss factor, modulus E = 3.2 GPa, strength σ = 45–65 MPa, density ρ = 1,050 kg/m^3, and CUT = 50–70 °C. Because of brittleness and low chemical resistance, the demand for neat PS has decreased, and except for foaming, PS is rarely used. PS can also be polymerized into crystalline forms: isotactic (iPS) or syndiotactic (sPS) with T_m = 230 °C or 272 °C, respectively. The former was polymerized using Ziegler-Natta catalyst (Ishihara et al. 1986), while the latter using a single-site metallocene titanium-based catalyst (Imabayashi et al. 1994).

The high-impact PS, HIPS, has been known since 1911 (Matthews 1911, 1913). In the USA, Ostromislensky (1924, 1926–1928) patented copolymerization of styrene with *rubber*, *balata*, *or other elastic and plastic gum*. Production of HIPS, *Victron™*, by the Naugatuck Chemical started in 1925, but soon it was discontinued.

PS is miscible with several polymers, viz., polyphenylene ether (PPE), polyvinylmethylether (PVME), poly-2-chlorostyrene (PCS), polymethylstyrene (PMS), polycarbonate of tetramethyl bisphenol-A (TMPC), co-polycarbonate of bisphenol-A and tetramethyl bisphenol-A, polycyclohexyl acrylate (PCHA),

polyethylmethacrylate (PEMA), poly-*n*-propyl methacrylate (PPMA), polycyclohexyl methacrylate (PCHMA), copolymers of cyclohexyl methacrylate and methylmethacrylate, bromobenzylated or sulfonated PPE, etc. Information on other miscible blends may be found in ▶ Chap. 21, "Miscible Polymer Blends".

Similarly, poly-α-methylstyrene is miscible with PMMA, PEMA, PBMA, and PCHMA. Poly-*p*-methylstyrene and poly-*p*-t-butylstyrene show miscibility with polyalkyl(meth)acrylates. However, PS is immiscible with PMMA, PMA, polyethylacrylate (PEA), polybutylacrylate (PBA), or PBMA (Somani and Shaw 1981).

In miscible blends, it is important that both components are in the entangled state. In particular, during processing in the extensional flow field (e.g., blow molding, film blowing, wire coating, calendering, or foaming), an enhancement of strain hardening (SH) can only be obtained when the concentration of the high molecular weight component is at least comparable to the critical concentration of entanglement, $c \geq c^*$. Under these circumstances, large increases of SH were observed, e.g., for PS blended with ultra-high molecular weight PS (UHMW-PS) or SAN blended with ultra-high molecular weight PMMA (UHMW-PMMA). By contrast, addition of immiscible UHMW-PS to SAN did not show any improvement of SH (Takashi 1996; Takahashi et al. 1996; Koyama et al. 1997; Minegishi et al. 1997, 1998). Examples of blends that were evaluated for SH are listed in Table 1.8.

1.5.1.1 PS/Commodity Resin Blends

The most common immiscible PS blends are those prepared to improve the impact strength of PS or its copolymers, viz., HIPS or SBR (Table 1.9).

It was reported that incorporation of 0.1–18 vol.% of either acrylic or olefinic elastomer particles (e.g., in HIPS) into a thermoplastic (viz., PE, PP, PS, SAN, PEST, PPE/HIPS, PC, PEI, PA, fluoropolymers, etc.) resulted in excellent control of the foaming process (Campbell and Rasmussen 1994). The bubble diameter could be calculated from the concentration of rubber particles. When these were lightly cross-linked, the stretched membrane provided an excellent barrier against coalescence of gas bubbles. Thus, reliable nucleation and absence of coalescence lead to foaming stability. For example, in autoclave foaming of PS with N_2, the cell size was less than 40 μm, independently of the saturation pressure and only slightly increasing with the foaming temperature.

Postulating that the rubber particles are stretched to membranes all having the same thickness, the foam cell size can be expressed as

$$D_{cell} = D_o + \left(d_{rubber}^3 / nt\right)^{1/2}; \quad n = 3 \text{ to } 6 \tag{1.8}$$

where D_{cell} is the cell size, d_{rubber} is the initial diameter of rubber particle, D_o is the diameter of foam cell in the absence of rubber particles, and t is thickness of the rubber shell after foaming. Depending on the initial assumption of

Table 1.8 Strain hardening in molten polymer blends

Polymers	Type	SH behavior (references)
PMMA/ UHMW-PMMA	Miscible	General rule: large enhancement of SH only for c(UHMW) > c* = 1.2 wt%; SH ≤ 10 (Minegishi et al. 1997)
PS/UHMW-PS	Miscible	Large enhancement of SH increasing with T; SH ≤ 10 (Minegishi et al.1998)
SAN/UHMW-PS	Immiscible	At 145 °C no effect on SH; SH ≤ 2 (Koyama et al. 1997)
SAN/UHMW-PMMA	Miscible	Large enhancement of SH; SH ≤ 10 (Koyama et al. 1997)
PE/UHMWPE	Miscible	Large enhancement of SH; SH ≤ 10 (Okamoto et al. 1998a, b; Kotaka 1998)
Bimodal POs	Miscible	Large enhancement of SH; SH ≤ 10 (Münstedt and Kurzbeck 1998)
LLDPE/LLDPE	Miscible	Average SH for the narrow and broad MWD LLDPEs (Schlund and Utracki 1987)
LLDPE/LDPE	Immiscible	Presence of LDPE increased linearly SH of LLDPE (Schlund and Utracki 1987)
		Enhancement of SH for c ≥ 10 wt% LDPE
LDPE/PS	With 0–5 wt% of SEBS	SEBS (micelles in LDPE phase) reduced the strain at break; additive SH; yield stress (Utracki and Sammut 1987, 1990)
LDPE/PS	Compatibilized	Better SH; the blends are suitable for foaming (Y. Horiuchi, 1998, personal communication)
PMMA/PVDF	Miscible	30 wt% of PVDF reduced SH of PMMA at 160 °C (Kotaka 1998)

PE and CSR	Herbing and Salyer 1963
PE and styrene-ethylene bulk copolymer	Gorham and Farnham 1964
PO and EVAc	Yamamoto et al. 1971
Either PP or PE	Ogawa et al. 1973
5–95 wt% PS with 95–5 wt% PO and 0.5–10 wt% SEBS (foaming)	Zeitler and Mueller-Tamm 1977
PP and SEBS	Holden and Gouw 1979
1–99 wt% of either LDPE, LLDPE, HDPE, EVAc, PP, or EPR (chemical foaming to open-cell structures)	Tashiro et al. 1983
LLDPE	Canterino and Freudemann 1985; Canterino et al. 1986
Reprocessed PE/PS, compatibilized with 0.5–40 wt% of EVAc	McCullough and Stevens 1985
$\geq$ 60 wt% of partially neutralized ionic PS (e.g., a copolymer of styrene and acrylic acid) with $\geq$ 1 wt% PE ionomers, foamed with 3–20 wt% of $NaHCO_3$	Park 1986a, 1986b, 1988
PE or PP compatibilized with a nonsymmetrical 3-block copolymer, S1-D-S2	Hoenl et al. 1993
HDPE and either SBS or SIS	Swartzmiller et al. 1993, 1994

the cell geometry, the geometrical factor can be calculated as n = 3 to 6. Adequacy of Eq. 1.8 is shown in Fig. 1.3.

The second large group of styrenic blends comprises these with polyolefins – they are summarized in Tables 1.10 and 1.11. These blends are mainly used in packaging. Formulated for extrusion, injection, and blow molding, they show excellent processability, improved impact strength, low moisture absorption, and shrinkage. The performance characteristics (e.g., modulus, toughness, ductility, transparency, or gloss) can be controlled by composition and morphology.

Table 1.11 Addition of styrenics to PO

Additive to PE	Reason	References
1. Addition of styrenics to PE		
SAN	Improved crack resistance	Jankens 1963
5–20 wt% SBR	Impact strength	Dow Chem. 1963
SB, SBS, or a *p*-methylstyrene-b-isoprene copolymer	Improved crack resistance	Minekawa et al. 1971
Styrene-grafted HDPE	Higher modulus	Yui et al. 1978
ABS with CPE or low molecular weight PS	Impact strength	Kamosaki et al. 1978
SEBS	Mechanical properties	Davison and Gergen 1977, 1980
SBS or SEBS as compatibilizers for PS/PE	Recyclability	Lindsey et al. 1981
HIPS with HDPE and SEBS	Impact strength	Castelein 1982
PS/LDPE; MI ratio $R = MI_{PS}/MI_{PE} = 790$, weight ratio $Y = 10$ to $Y = [394.7 + 1.18R - 295.1 \log D]$; density: $D = \rho = 15$–$30 kg/m^3$. R and Y control the co-continuous blends morphology	Flexibility, dumping small vibrations, stiffness, heat insulation, low water permeability	Hoki and Miura 1987
5–50 wt% PS with LDPE a chemical blowing agent and a peroxide (0.05–0.1 pph DCP)	Dimensionally stable, $\rho = 20$–$30 kg/m^3$, cells 1.5 mm	Park 1986c, 1987, 1995
LDPE/PS = 80/20 blends compatibilized in a twin-screw extruder with supercritical CO_2	Studies of the rheology during closed-cell foaming	Lee et al. 1998
2. Addition of styrenics to PP		
PS or HIPS	For nacreous soda-straw tubes	Ogawa et al. 1973
ABS with either CPE or low molecular weight PS	Impact strength	Kamosaki et al. 1978
PS with HIPS and SEBS	Mechanical performance	Holden and Gouw 1979
PS was compatibilized by adding either SBS or (SB)$_n$	Higher modulus	Grancio et al. 1981, 1983
PS or HIPS and a nonsymmetrical, linear 3-block copolymer of styrene and butadiene, S1-D-S2, where the polystyrene blocks $S1 \geq S$	Processability, impact and stress-cracking resistance, impermeability to H_2O	Hoenl et al. 1993
PS with recycled PP – co-continuous morphology	Performance, recyclability	Morrow et al. 1994
sPP-co-sPS from single-site metallocene catalyst	Compatibilization of sPP/sPS	Razavi 1994
PP, EPR, EVAc, and PS blended with 1–50 wt% of the silane-modified-based resin, cross-linking catalyst and 1–20 wt% of a foaming agent	Resilient foams with superior, compression strength, and heat-insulating properties	Kobayashi et al. 1997

Other patents described similar blends prepared either by different methods or comprising different compatibilizer. For example, PO was mixed with styrene in the presence of an initiator that caused polymerization at temperatures below melting point of PO (Vestberg and Lehtiniemi 1994).

Interesting blends, having a broad range of properties, were prepared in two steps: (1) BR was grafted and cross-linked with either styrene or methylmethacrylate to produce a core-shell copolymer. (2) Next, it was blended with PO for improved processability, impact resistance, rigidity, etc. (Aoyama et al. 1993, 1994). Structural blends of styrene-grafted PP with either SBR, SBS, or an acrylic elastomer were developed (DeNicola and Conboy 1994).

Since the early 1990s, the constrained geometry metallocene catalysts have been used by Dow to produce either alternating or pseudo-random ethylene-co-styrene interpolymers (ESI) (Stevens et al. 1991). ESI with up to 50 wt% styrene is semicrystalline; it is known to compatibilized PE/PS blends since it forms domain structures into which the homopolymers can dissolve. ESI also has good melt strength, mechanical, impact, and damping characteristics (Ellebrach and Chum 1998). Flow and processing information on ESI were published (Karjala et al. 1998).

Himont (now Lyondell Basell) introduced a family of PP-based blends under the trade name of *Hivalloy*™. Some grades seem to be mechanical alloys of PP/PS, compatibilized and impact modified by incorporation of SEBS and EPR. Others are reactor made – here porous grains of PP serve as reaction beds for the polymerization and grafting of PS, SMA, acrylics, etc.

PS is one of the most frequently foamable thermoplastic resin. Blends that belong to this category are presented in Table 1.12. Blends containing ≥ 50 wt% PS (MW = 200 kg/mol) and acrylic copolymers were described as particularly useful for the manufacture of low-density foams. The acrylic copolymer contained methylmethacrylate and, e.g., 5 wt% of ethylacrylate. The presence of the copolymer facilitated foaming, but it reduced the foam compressive strength. The best balance was obtained using about 22 wt% of the copolymer. The foam had closed cells with cell diameter varying from 0.1 to 1 mm (Smith and Cross 1996).

1.5.1.2 PS/Engineering Resin Blends

The majority of PS blends that belong to this category are mixtures with PPE. Discovery of PPE miscibility with PS led to a family of *Noryl*™ blends, commercialized in 1965. Since that time, the PPE/PS blends were modified by the incorporation of a variety of additives. The PPE/PS blends show the glass transition temperature, $T_g = 100$–210 °C, continuously increasing with PPE content. The most often used compositions contain less than 30 wt% of PPE (PPE is about three times more expensive than PS).

PPE is the most "natural" additive that upgrades performance of PS to the required level. PS/PPE blends have been used as a replacement for PS in applications where higher HDT and/or impact strength is required. These alloys are easy to foam for the manufacture of, e.g., hot water piping insulation, in automotive applications, etc. Examples of PPE/PS blends are listed in Table 1.13.

Table 1.12 Foamable PS blends

Blend	Comment	References
PS with low concentration of siloxane-oxyalkylene copolymers	Reduced interface tension, easier bubble nucleation and growth, smaller cells	Granda et al. 1977
PS with radial teleblock SBS, PMS, naphthenic extender oil, formed at P = 1.4 MPa and then foamed using microwaves at 10–100 MHz	Molded articles had thin skin and uniformly foamed interior	Siedenstrang and Thorsrud 1984
PS with SAN, ABS, and 15–50 wt% of SMA	Chemical foaming ($NaHCO_3$) during injection molding	Sprenkle 1980
75–98 wt% of PS, 2–25 wt% of a BR (MW = 200–300 kg/mol)	Easy to foam due to fine dispersion of BR spheres	Henn et al. 1996
Mixtures of emulsion copolymers comprising acrylonitrile, butadiene, styrene, and acrylic or methacrylic acid	Low-density foams for non-wovens, carpets, fleece, or cardboard	Matner et al. 1977
SBR blends with 10–50 wt% of plastisol PVC	For foamed, flame-resistant carpet backing	Morgan and Ribaudo 1980
SBR, ABS, MABS, and/or SBS, with either PS, PO, PVC, PPE, PA, POM, PC, PSF, or PEST	For high impact strength moldings	Aoki et al. 1981
Polymer alloys of SMA and cellulose esters at a ratio varying from 1:100 to 100:1	Reaction between anhydride and cellulosic – OH facilitated foaming and gave good product performance	Heslinga and Greidanus 1982
5–35 wt% of SEBS, 65–90 wt% of PB-1, 5–30 wt% of EPR or EPDM, 2–15 wt% of LDPE	Foams had excellent bending capability, tear strength, stiffness, and HDT	Hwo 1996
Two SBR copolymers, (1) with of 53–75 wt% of styrene and (2) with 42–75 wt% of styrene	Cured foams for shoe soles with high shock absorption	Hashimoto and Ohashi 1985
ABS compositions	Foamed with supercritical CO_2 at P ≤ 5 MPa	Kumar et al. 1995
45–90 wt% of PS or styrene-acrylic acid copolymer with 10–55 wt% of PVDC or vinylidenechloride-methyl acrylate copolymer	Physically foamed products had improved O_2 and H_2O permeability, toughness, and flame resistance	Romesberg 1991
PS, SMA, SAN, PMS, or HIPS blended with SBS and an extending oil and then incorporated into PA, PEST, PPS, SAN, ABS, ASA, PC, PPE, PO, their copolymers, or blends	A general method for the production of a variety of foamable injection moldings	Burnell 1993
75–97 wt% of either PS or HIPS and 3–25 wt% of an elastomeric (co)polymer having a T_g < −20 °C	Foamable materials with good performance characteristics	Blumenstein et al. 1994
Latex copolymers were blended, cross-linked, and foamed: (1) 20 wt% styrene, 20 wt% divinylbenzene, 60 wt% 2-ethylhexyl acrylate with (2) 80 wt% styrene, 20 wt% divinylbenzene	Pen-cell foams with great absorbency were prepared for baby dippers, for paint rollers, filters, etc.	Brownscombe et al. 1997

PPE/SAN with cross-linking and C3–C6 hydrocarbon blowing agents	Hahn et al. 1992
PPE with, e.g., PS, PMS, PES, PEI, PC, PA, PEST, PP, or PE and the blowing and nucleating agents	Bland and Conte 1993

Five *Caril*™ grades of expandable PPE/PS beads (diameter 0.3–0.5 mm) offer HDT up to 120 °C, thus are suitable for the production of microwavable and steam-cleanable packaging with the wall thickness $\geq$ 1 mm. The recommended density of molded product is $\rho = 60$ kg/m^3. Other foamable, flame-retardant PPE/PS blends, with good acoustic and thermal insulation properties, have been produced in suspension polymerization of a PPE solution in styrene and pentane. Resulting beads had diameter d = 0.5–1.0 mm and could be steam pre-foamed and compression molded in a standard equipment. The cited advantages are high HDT, non-flammability, dimensional stability, strength, stiffness, low molding cost, low density, easy lamination with decorative and weather-resistant ASA, and recyclability (Koetzing and Diebold 1995).

Table 1.14 Compatibilization of PS/PC blends by SAN

Additive to PC	Reason	References
Either SAN or styrene-allyl methacrylate-butyl acrylate-methyl methacrylate copolymer or with a *multilayered copolymer* from styrene, allyl methacrylate, benzyl acrylate, divinylbenzene	Toughening, high mechanical performance, solvent resistance	Kishida et al. 1978a, b
SAN and a styrene-grafted acrylic rubber	Improved mechanical properties	Kamata et al. 1979
PS and MBS	Higher modulus	Lee 1980

PS is antagonistically immiscible with all other engineering resins, viz., PA, PC, POM, and PEST. PS has been added to these polymers to improve processability and reduce cost without unduly affecting the performance (the so-called extension of the engineering performance).

Non-compatibilized blends of PS with either PEST or PEST and PMMA have been used for decorative applications or as the so-called plastic paper (Kamata et al. 1980). Similarly, PAr blends with either SAN (Brandstetter et al. 1983a, b, c) or high-performance blends of LCP with thermoplastic polymers (e.g., PP, PS, PC, PI) (Haghighat et al. 1992) showed adequate performance for the envisaged applications. However, most PS blends with engineering resins require compatibilization. Thus, for example, PS with PA-6 was compatibilized by addition of either methylmethacrylate-styrene copolymer (SMM) (Fayt et al. 1986b) or SMA (e.g., used in PARA/PS blends) (Lee and Char 1994). POM was blended with a small amount of either PS poly(α-methyl styrene) (MPS) or SAN and with particulate fillers (Tajima et al. 1991). PAr/PS blends were compatibilized with PAr-PS segmented copolymer (Unitika Ltd. 1983).

Several blends comprising PC and diverse styrenics, viz., ABS, SAN, SB, SBS, MBS, etc., are known (see Table 1.14). Similarly as for PVC blends (see Table 1.15), the strong interactions between AN and carbonyl groups of PC (in PVC it is the tertiary carbon) are responsible for the good performance. An interesting variation of the compatibilization procedure involved dispersing PC in water with vinyl monomer(s) that subsequently were polymerized. The in situ formed graft copolymers acted as a compatibilizer (Kanai et al. 1978; Kakizaki et al. 1979a). In 1974, polyphenylenesulfide, PPS, was blended with either PS or a styrene copolymer (Miyanishi 1976). Acid-base forces are responsible for strong molecular interactions. An understanding of specific forces is required if polymer blend systems are to be formulated, so as to satisfy steadily increasing demands on their performance and durability (Mukhopadhyay and Schreiber 1995).

Later, to provide a complete set of the required performance characteristics, multicomponent blends were promoted, for example, PC, PPE, ASA, SAN, PS, phosphate esters, PTFE, and SEBS (Niessner et al. 1993) or PC, PEST, ABS modified by incorporation of alkyl (meth)acrylates and glycidyl methacrylate, and PPE with either PS, HIPS, or SEBS and a polyalkyl(meth)acrylate (Laughner 1993).

Table 1.15 PVC/ABS-type blends

Additive to PVC	Reason	References
ABS	For either phonographic records or artificial leathers	Parker 1951; Schule 1952
5–30 wt% of either methylmethacrylate-acrylonitrile-butadiene-styrene(MABS)	High impact strength, mechanical properties	Himei et al. 1967
1–50 wt% ABS and post-chlorinated PVC	Improved processability, impact strength, and thermal stability	Kojima et al. 1970
ABS grafted with acrylonitrile-ethyl acrylate-styrene	Improved toughness	Tanaka et al. 1971a, b, c
ABS and SBS	Improved impact strength	Minekawa et al. 1971
MBS or MABS	Impact strength	Kumabe et al. 1973
Multilayer butadiene-styrene-divinylbenzene-butylacrylate-methyl methacrylate	Processability and high impact resistance	Usami and Ochiai 1976
Poly(2-cyano-5-norbornene) and ABS	Impact strength	Matsuura et al. 1978
PB grafted with styrene, methylmethacrylate, and maleic anhydride (ABSM-MA) or a mixture of ABS and SMM-MA	Processability, high impact strength, mechanical properties	Dufour 1982
Methylstyrene-styrene-acrylonitrile-grafted polybutadiene or with maleated styrene-methylmethacrylate-butadiene (ABS-MA)	Processability, high impact strength, mechanical properties	Dufour 1988
ABS and vinylchloride-ethylhexyl acrylate	Abrasion resistance	Greenlee et al. 1992
Core-shell copolymer: EPDM grafted with styrene-butadiene methacrylate or allyl cyanurate	Processability, high notched impact strength	Siol et al. 1993a, 1995
CPVC and PMMA, methylstyrene-acrylonitrile-methyl methacrylate, methylstyrene-acrylonitrile-styrene, imidized-PMMA, imidized-SMA, and SAN	Economy, high HDT and impact strength	Soby et al. 1994

1.5.2 Acrylonitrile-Butadiene-Styrene (ABS)

The first mechanical blends of NBR with SAN, known as "type-A ABS," date from 1936. In the mid-1940s, Dow started emulsion polymerization of "ABS-type G." By the late 1950s, the *high heat ABS* were invented, viz., interpolymers of α-methylstyrene and acrylonitrile (Irving 1961), a mixture of methylmethacrylate-α-methylstyrene either with styrene-grafted polybutadiene (SBR) or with an ABS (Kanegafuchi 1967, 1984), a mixture of SMA and ABS (Stafford and Adams 1972), a mixture of SMA with ABS and MBS (Tatuhiko and Akira 1982), a mixture of SMA-MMA with ABS, etc.

Acrylonitrile-styrene-acrylate terpolymers, known as either ASA or AAS, constitute another class of ABS resins, viz., *Centrex™*, *Luran™* S, *Richform™*, *etc*. These materials may also contain reactive groups, viz., maleic anhydride or glycidyl methacrylate.

Weather-resistant ABS can be obtained either by the incorporation of EVAc (Fukushima and Mitarai 1971) or by replacing PB with EPDM to obtain AES (Wefer 1984, 1985, 1988). Alternatively, blends of SAN with maleated EPDM and CPE may be used (Kim et al. 1992). However, the non-weatherable styrenics are frequently prepared by dissolving an elastomer in methylmethacrylate and either styrene or α-methylstyrene, and then polymerizing them into methyl methacrylate-butadiene-styrene graft copolymers (MBS) (Ruffing et al. 1964; Schmitt et al. 1967). There is a great diversity of the MBS copolymers, viz., graft, core-shell, or multilayer type – lately also with acidic or epoxy groups (Lee and Trementozzi 1979, 1980, 1981, 1982; McKee et al. 1982; Keskkula et al. 1984).

1.5.2.1 ABS/SMA Blends

The ABS/SMA blends show excellent processability, high heat deflection temperature (HDT) low warpage, stiffness at high temperature, good impact strength, as well as solvent and chemical resistance. They successfully compete with PPE or PC alloys for the automotive applications (trim, instrument panels, roof linings, hubcaps, headlight housings), electronics, and electrical industry, houseware, appliances, power tools, industrial machinery, plumbing products, parts for washing machines and vacuum cleaners, etc. An example of commercial blends is *Cadon™*.

1.5.2.2 ABS/PVC Blends

There are several reasons for blending PVC with ABS-type copolymers, viz., to improve processability, mechanical properties, and low-temperature toughness. Good properties of these blends originate from the miscibility between PVC and SAN part of ABS. In some commercial blends, viz., *Geloy™*, ABS may be replaced by ASA to obtain improved miscibility and weatherability. For enhancement of HDT, SMA may also be added. The blends with more than 30 wt% PVC are self-extinguishing but are more difficult to process.

1.5.2.3 ABS/PC Blends

Blends of PC with 5–70 wt% ABS were developed in the early 1960s. The basic technology has been used to produce such alloys as *Bayblend™*, *Cycoloy™*, *Idemitsu™ PC/ABS*, *Iupilon™*, or *Triax™ 2000*. The consumption of ABS/PC blends is increasing as the cost-to-performance ratio is low and properties are predictable (Khan et al. 2005). The alloys combine good processability of ABS with excellent mechanical properties, impact, and heat resistance of PC. The opaque blends show dimensional stability, low shrinkage and moisture absorption, high stiffness and hardness, good impact resistance at temperatures (T ≥ −50 °C), excellent UV stability, processability, mechanical properties, heat resistance, flame retardancy, good chemical resistance, but poor to gasoline, aromatic hydrocarbons, esters, ketones, and some chlorinated hydrocarbon. The ABS/PC blends are being manufactured with either a dispersed or co-continuous morphology.

There are many similarities between ABS/PVC and ABS/PC blends. Both are immiscible, having three distinct phases of PVC or PC, SAN, and an elastomer

Table 1.16 PC/ABS-type blends

Reason	Additive to PC/ABS	References
Toughness	10–70 wt% ABS	Grabowski 1964a
HDT and stiffness	Styrene-α-methylstyrene-acrylonitrile, PSF	Grabowski 1970, 1971, 1972
HDT an impact resistance	MBS and PAES	Yamauchi et al. 1974
Processability, HDT, impact resistance	Polyethersulfone, PES	Weaver 1972
Flow, weatherability, thermal, and mechanical performance	EVAc	Hasegawa et al. 1974
Pearl-like iridescence, dyeability	PMMA	Ikura et al. 1974
Heat resistance, dimensional stability	PVC	Hardt et al. 1975
Mechanical performance	CPE grafted with SAN	Kabuki et al. 1973
Processability, impact strength	Skin-core graft copolymers of styrene and acrylonitrile on elastomeric latex particles	Sakano et al. 1978
Solvent and impact resistance	MBS and acrylic elastomer	Kitamura 1986

(Suarez and Barlow 1984). The blends are compatibilized by the dipole-dipole interactions between PC and SAN, particularly evident in SAN with ≥ 25 wt% AN (Kim and Burns 1988, 1990). ABS/PC blends can also be compatibilized by incorporation of either acrylic, acidic, or epoxy groups (see Table 1.16).

In the late 1970s, the reactive blending of PC/ABS began to dominate the technology. Initially, the PC blends with ABS modified by incorporation of the maleic anhydride moieties (ABS-MA), later ABS with acrylic acid groups (ABS-AA) were developed. The third generation blends comprise ABS modified by copolymerization with glycidyl methacrylate (ABS-GMA). Examples are listed in Table 1.17.

In 1983, Monsanto developed blends with co-continuous morphology, *Triax™ 2000*. These alloys comprised PC, ABS, and styrene-methylmethacrylate-maleic anhydride (SMMA-MA) (Jones and Mendelson 1985). One year later, PC was reactively blended with either ABS, SAN-GMA, or NBR or with graft copolymers of acrylonitrile-butadiene-α-methyl styrene-methyl-methacrylate (MeABS) and acrylonitrile-α-methyl styrene-methyl methacrylate copolymer (MeSAN) (Kress et al. 1986). The blends were commercialized by Bayer as *Bayblend™*.

In 1992, low gloss and moldable blends, with electrostatic discharge properties, were developed. They comprised PC, ABS, and either a graft copolymer of styrene, hydroxyethyl methacrylate, and acrylonitrile bonded onto a 1,3-butadiene rubber (ABS-HEMA), styrene-acrylonitrile-methacrylic acid copolymer (SAN-MAc), styrene-acrylonitrile-hydroxyethyl methacrylate (SAN-HEMA) or an acrylonitrile polymer containing gels (Vilasagar and Rawlings 1994). *Cycoloy™* is the PC/ABS blend from General Electric Co (now SABIC).

Table 1.17 PC/ABS reactive blends

Composition	Reason	References
PC with ABS and rubber-modified SMA	Processability, impact strength, heat resistance	Henton 1980, 1982
PC with SAA and EMMA	Impact strength, mechanical properties	Thomas 1982
PC with ACM and SAA	Impact strength and HDT	Henton 1984
PC/ABS with EAA acidic compatibilizer	Processability and impact strength	Grigo et al. 1984
PC/ABS with SMA-AA	High HDT and impact strength	Brandstetter et al. 1982a, b, c; 1983a, b, c
PC/ABS with SMM-GMA	Processability, impact strength, and heat resistance	Daicel 1982, 1983, 1984
PC/MBS with SAN and PEST	Impact strength and thermal stability	Teijin Chem. 1980
PBT, PC, ABS, and PB grafted with acrylate esters and AN, ACM	Rigidity, flowability, solvent resistance, impact strength, dimensional stability	Bier and Indner 1982; Neuray et al. 1982
PC, PEST, polyester carbonate, etc., with 30–90 wt% of SMA + ABS and 2.5–20 wt% of a chemical blowing agent	Foamable engineering blends having excellent physical performance	White and Krishnan 1989
PC, PEST, or PEI with 1–50 wt% of ABS and a chemical foaming agent	Moldable blends for chemical foaming	Allen and Avakian 1987

1.5.2.4 ABS/PA Blends

ABS/PA mixtures are immiscible; hence, the standard three strategies are applicable: (i) addition of a small amount of ABS to improve PA toughness without a compatibilizer, (ii) generation of non-compatibilized blends with co-continuous morphology, and (iii) compatibilized blends in the full range of composition. ABS is an amorphous resin, while PAs are semicrystalline; hence, it is advantageous to incorporate ABS as either a dispersed or a co-continuous phase – the latter being preferred. However, addition of semicrystalline PA to ABS increases mold shrinkage, and thus, addition of filler is advised. Owing to high processing temperatures of PA, it is essential to use high heat ABS. For the adequate impact performance, at least 10 wt% of ABS should be added, but at this level, the compatibilization is required. The reactive compatibilization involves the use of ABS that has been modified by incorporation of either acrylic acid, maleic anhydride, or polyvinylphenol (PVPh).

The reason for blending ABS with PA is to reduce moisture sensitivity, improve toughness, and reduce shrinkage and warpage of the latter resin. The alloys show good processability; surface finish; high heat stability; a chemical, oil, wear, and abrasion resistance; dimensional stability; low-temperature impact strength; reduced moisture sensitivity; and economy. Synergistic properties have been reported. Examples of commercial alloys are *Stapron™ N*, *Novalloy™-A*, *Techniace™ TA*, *Triax™ 1000*, *Ultramid™*, and *Macslloy™* (Utracki 1994). Also, in a series of papers, Kitayama et al. (2000a, b, 2001) have described the blending of PA6 with SAN.

The first ABS/PA blends were announced in 1961 (Grabowski 1964b, 1966) and much later introduced as *Elemid™*. *Triax™-1000* is an alloy of PA-66 with ABS-MA, having the phase co-continuity (Lavengood et al. 1986, 1988). PA-6 was also blended with BR grafted with styrene and MA (SBMA) (Asahi-Dow Ltd. 1981). Later, transparent blends of copolyamide(s), PA, and ABS were developed (Fox et al. 1989). Blending either ABS-MA or EPR-MA, with amine-terminated PA or PEST, resulted in alloys with excellent performance (Akkapeddi et al. 1990, 1992a, 1993; Okada et al. 2004). Similarly, either ABS-MA or ABS-GMA copolymer was used to compatibilize and to toughen PA blends with other resins, viz., PC, PEST, or PAr (Yuichi and Suehiro 1989). Later the role of elastomer, its type, and location in the PA-66/SAN/Elastomer system was studied (Nair et al. 1997, 1998).

1.5.2.5 ABS/PEST Blends

The thermoplastic polyesters (PEST) are dominated by two resins: polyethylene terephthalate (PET) and polybutylene terephthalate (PBT). There are similarities between ABS/PA and ABS/PEST blends.

In blends with ABS, a part of PEST may be replaced by PC, and 10–20 wt% of an impact modifier may also be added, e.g., MBS, poly(methylmethacrylate-g-butadiene-co-styrene), poly(MMA-g-n-BuA), high rubber ABS ($\geq$ 50 wt% PB), or ASA with $\geq$ 50 wt% acrylate rubber, etc. Examples of commercial blends are *Alphaloy™ MPB*, *Cycolin™*, *Diaaloy™ B*, *Malecca™ B*, *Maxloy™*, *Lumax™*, *Triax™ 4000*, and *Ultrablend™ S*. The alloys show excellent moldability, low post-molding shrinkage and warpage, stress-crack resistance, high gloss, high temperature stiffness, toughness and mechanical strength, high heat resistance at temperatures T $\leq$ 140 °C, low shrinkage, good dimensional stability, impact strength, good wear and abrasion resistance, good thermal and weathering resistance, as well as solvent (e.g., to gasoline and motor oils) and chemical resistance. An abbreviated evolution of the PEST/ABS technology is summarized in Table 1.18.

Table 1.18 PEST/ABS blends

Composition	Reason	References
PET with MBS	Notched impact strength and embrittlement resistance	Sauers and Barth 1970
PAr with ABS	Processability and impact strength	Koshimo 1973
PBT/ABS/SEBS	Stable morphology	Gergen and Davison 1978
PBT with carboxyl-modified ABS	Chemical, solvent, and impact resistance	Tanaka et al. 1979
PBT + PET or PC, with ABS or ACM (rubber particle diameters $d \cong 0.4$ μm)	Impact strength and balance of other properties	Bier and Indner 1982; Binsack et al. 1982
PBT with either ABS-MA or ABS-GMA	Heat, chemical, and impact resistance	Orikasa et al. 1989
PET or PBT with an AES-GMA (*Techniace™*)	Flowability and good balance of properties	Hirai et al. 1988, 1989, 1992

1.5.2.6 ABS/TPU Blends

Developed in the early 1960s, ABS/TPU blends combine TPU's toughness and paintability with ABS's low-temperature impact strength and adequate HDT. The main advantage is the excellent impact behavior at $T \geq -40\,^{\circ}C$. Furthermore, TPU improves antifriction properties, abrasion, and chemical resistance. Stiffness is also increased and the flowability of injection molding compounds is good. ABS is usually dispersed in the TPU matrix. TPU was also successfully blended with SBR grafted with acrylonitrile, acrylate, or methacrylate esters (MABS) (Abe et al. 1977), with SMM-MA copolymer (Gomez 1992), and with bulk-polymerized ABS (Henton et al. 1992). Depending on the type of TPU, compatibilization may be necessary. Examples of commercial alloys are *Prevail*™ and *Techniace*™ *TU*.

1.5.2.7 ABS/PSF Blends

In these blends, ABS's role is to improve flowability and reduce cost, while that of PSF is to improve the shape retention at high temperatures. ABS/PSF blends are compatibilized either by *phenoxy*, EVAc-GMA, or SMA copolymers. They have good processability, high notched Izod impact strength, plateability, hydrolytic stability, and economy. However, they may show poor surface and weld-line strength. *Arylon*™ and *Mindel*™ *A* are examples of the commercial ABS/PSF alloys, while *Ucardel*™ is an example of PSF blends with SAN. Evolution of ABS/PSF blends' technology is summarized in Table 1.19.

Table 1.19 PSF/ABS blends

Composition	Reason	References
PSF with 40–52 wt% ABS and poly (α-methyl styrene-co-AN)	Excellent flow, good impact resistance, non-flammability	Ingulli and Alter 1969, 1970
Polyarylethersulfone (PAES) with AES	Toughness and impact strength	Barth 1970
ABS with equal amount of PSF and PC	Processability, rigidity, and impact strength	Grabowski 1971, 1972
PAES with EVAc and/or MBS	Tensile, flexural, and impact strength	Lauchlan 1971
PAES with PC and either MBS or ABS	High HDT and impact resistance	Yamauchi et al. 1974
PSF with 10 wt% anhydride-terminated PSF and MABS	Excellent HDT and impact resistance	Aya et al. 1979
PSF with AES	Thermal stability and impact strength	Sumitomo 1982
PSF with cross-linked acrylate copolymer, cross-linked SAN, and uncross-linked SAN	Good tensile modulus, yield strength, impact resistance, and respectable HDT $= 106\,^{\circ}C$	Robeson 1985
PSF/ABS with EVAc-GMA	Processability, HDT, and impact strength	Orikasa and Sakazume 1990, 1992
PSF with 25–45 wt% semicrystalline PPS and 0–10 wt% MBS	resistance to impact, high temperatures, and adverse environmental conditions	Golovoy and Cheung 1994

1.5.3   SBS Block Copolymers

In 1961, using lithium catalyst, a series of styrene-isoprene (SI) and styrene-butadiene (SB) block copolymers were synthesized (Bull and Holden 1977). The resins had $T_g \approx -90$ to $+90$ °C. Full-scale production started in 1965. Since then, numerous two- and three-block copolymers have been developed, with hydrogenated and maleated block copolymers also being offered. With the world consumption of 330 kt/year, the block copolymers constitute the largest part of the commercial TPE market. Large quantity of SBS resin is used in blends. Commercial resins include *Elexar™*, *Collimate™*, *Finaclear™*, *Kraton™*, *Thermolastic™*, and *Tufprene™*.

1.5.3.1 SBS/SEBS Blends with Commodity Resins

SBS copolymers are used in blends as compatibilizers, impact modifiers, or stabilizers of morphology and performance. As shown in Table 1.20, they have been

Table 1.20 SBS blends with other styrenics

Composition	Reason	References
PVC with ABS and SBS	Toughness and performance	Minekawa et al. 1971
SBS with PS, EVAc, and other ingredients	For elastic films	Hinselmann et al. 1973

SBS with 20–30 wt% PO	Processability, mechanical properties	Tabana and Maki 1976
PS with HIPS, PP, and SEBS	Performance, co-continuous morphology	Holden and Gouw 1979
SEBS with diverse polymers, including PE	Dispersed drops of d = 200 nm	Davison and Gergen 1980
PP/PS with either SBS or (SB)$_n$	Moldability and mechanical properties	Grancio et al. 1981, 1983
HDPE with PS and SEBS	Superior performance over HDPE/PS	Lindsey et al. 1981
HIPS with HDPE SEBS	Impact strength	Castelein 1982
LLDPE with SEBS	Transparent, impact resistant	Holden and Hansen 1989
PS, LLDPE, and SEBS	Impact strength, lack of yellowing	Seelert et al. 1993
PP and PET reactively blended with maleated SEBS	Rigid blends with good impact strength and adhesion to solids	Tekkanat et al. 1993, 1994
PA/PO/SEBS compatibilized by SMA	Moldable, good impact strength	Chundury 1993, 1994
PO with PA, PET and styrenics	Recycled commingled scrap	Weber et al. 1994
SBS, EVAc, PS, and LLDPE or ULDPE	Elastomeric films	Djiauw 1994
PO with SEBS, SEPS, SEB grafted with maleic anhydride acrylic or sulfonic acid	Moldable resin with good impact strength, scratch, and abrasion resistance	O'Leary and Musgrave 1993
PP with either SBR, SBS, or an acrylic elastomer, and PP grafted with styrene	Stand-alone structural materials	DeNicola and Conboy 1994

frequently incorporated along other styrenics. There are many patents for mixtures of PO with SBS-type copolymers. Their history is outlined in Table 1.21.

1.5.3.2 SBS Blends with Engineering Resins

Since the anionically polymerized block copolymers are relatively expensive, they have been more frequently used in blends with engineering than commodity resins. Owing to miscibility of styrene blocks with PPE, the SBS and SEBS are "natural" tougheners for this polymer. However, for blending with PEST, PC, POM, or PA, the copolymer should be modified by incorporation of acidic, acid anhydride, or epoxy moieties.

SBS with Polyphenylene Ether (PPE)

Evolution of PPE blends with SBS-type block copolymers is summarized in Table 1.22. SBS or its derivatives have been frequently used to stabilize the morphology in more complex blends. In Table 1.23 examples of this type of system are presented.

Table 1.22 SBS Blends with polyphenylene ether

PPE modifiers	Reason	References
PPE with 10–90 wt% SBS	Processability and toughness	Kambour 1970

HIPS, SBS, SBR, EPR, and hydrogenated poly(bisphenol-A-phosphite)	Impact strength, processability, and flame retardancy	Sugio et al. 1984
ABS and SEBS	Moldability, toughness, strength	Ueda and Sasame 1986
PS, SBR, and SBS	Plateability and mechanical properties	Mitsubishi Gas Co. 1985
HIPS, SEBS, and LLDPE	High impact strength	Hambrecht et al. 1986
HIPS and either SB, SBS, or $(SB)_n$	Cracking and impact resistance	DeMunck and Lohmeijer 1986

SBS with Polyamides (PA)

SBS or SEBS has been used as an impact modifier in PPE/PA blends, with PA usually being the matrix and PPE an organic, low-density filler. The blends were developed in the early 1970s by the Asahi Chemical. By the end of the decade, the first reactive blends were announced by the Sumitomo Chemical (Ueno and Maruyama 1981) and General Electric (Van der Meer et al. 1989).

The simple, SBS/PA blends were in parallel development with the PPE/SBS/PA ones. Addition of SBS to PA improved the tensile and impact strength of the latter resin. The blends comprise either 1–25 wt% SBS as a dispersed or at higher concentration as co-continuous phase (see Table 1.24).

SBS with Thermoplastic Polyesters (PEST)

The development of PEST/SBS blends parallels that of the PA/SBS ones. First, blends of PBT, ABS, and SEBS were disclosed (Gergen and Davison 1978). Four years later, the reactive compatibilization was discovered – PBT was blended with SEBS and SMA (Durbin et al. 1983). By the end of 1970s, multicomponent blends comprising PBT, PET, PC, and either SEBS, $(SB)_n$, butadiene-caprolactone-styrene,

PPE with HIPS, PE, and SEBS	Ting 1990
PPE with PP and SEBS	Lee 1990
PPE/PET or PPE/PA reactively compatibilized with SEBS-GMA	Mayumi and Omori 1988
PPE/PET or PPE/PA reactively compatibilized with SEBS-MA	Modic and Gelles 1988
PPE/PBT, toughened by addition of urea-butylated resin and SEBS	Mizuno and Maruyama 1990
PPE with PC, PBT, and either SBS, SEBS, or a core-shell copolymer	Brown and Fewkes 1992, 1994
Epoxy- or phosphate-functionalized PPE, with PBT or PET, palmitamide, SEBS, and PC	Yates 1993
PPE with PA-66, SEBS, SB; a styrene-butadiene radial copolymer; citric acid; and either citric acid or chloro-epoxy triazine	Gianchandai et al. 1993
PPE with PA-6 or PA-66, MA and toughened with SB	Lee 1994
PPE-MA or PPE-GMA, with sPS, SEBS, and fillers	Okada and Masuyama 1994

or butadiene-caprolactone block copolymer were developed (Wambach and Dieck 1980). Reactive compatibilization of PEST/SEBS by addition of MA was disclosed in 1984. The method was general, applicable to polyamides as well as to polyesters (Shiraishi and Goto 1986).

SBS with Polycarbonates (PC)

Similarly to blends of SBS with PA or PEST, these with PC were first described in 1976. However, owing to the weak interactions between SBS and PC, these systems require compatibilization. Thus, either SBS must be acidified (e.g., with SEBS-MA) or acidified acrylate added, viz., MABS, MBS, SMA, etc. Selected examples are listed in Table 1.25.

Table 1.24 Evolution of the SBS/PA blends

Composition	Reason	References
PA-66, SEBS, *phenoxy*, and bisphenol-A-epichlorohydrin	Tensile and impact strength of PA	Freed 1975

PC, modified SEBS, and hydroxyethyl acrylate-terminated ε-caprolactone	Wilkey 1994

1.5.3.3 SBS Blends with Specialty Resins

SEBS must be processed below 280 °C; thus, its use with specialty resins has been limited to polyphenylenesulfide (PPS) (Garcia and Martinovich 1984). Sometimes SBS and a specialty resin are parts of a multicomponent blend, viz., PPS, PPE, either PA- 6 or PA-12, SEBS (*Kraton™ G*), an acidified polyolefin (e.g., EPR-MA, PE-GMA, or EVAc-GMA), and reactive compatibilizer

(citric, maleic, or agaric acid). Here, PPS was a matrix, and PA was the dispersed phase that contained PPE/SEBS and a filler (Ishida and Kabaya 1994).

1.5.4 Polyvinylchloride (PVC)

PVC was first synthesized by Regnault in 1835. The first patent on vinyl chloride monomer (VCM) polymerization was granted in 1912 to Ostromislensky. However, to make commercially viable articles, PVC must be stabilized and either plasticized or blended. In 1927, B. F. Goodrich started production of plasticized PVC, *Vinylite™* (Semon 1933).

The first patented PVC alloys were prepared by latex blending with PVAc and poly(vinylchloride-co-vinylacetate) (PVCAc) (Voss, and Dickhäuser 1930, 1933, 1935, 1936). I. G. Farbenindustrie commercialized PVC extruder blended with polyacrylic ester – the so-called rigid formulation (Fikentscher and Heuce 1930; Fikentscher and Wolff 1931). *Troluloid™* and *Astralon™* were the first commercial thermoplastic polymer blends.

PVC blended with *Buna-N* produced excellent thermoplastic materials (Badum 1942). These blends were prepared either in a rubber mill, by latex blending, or powder blending and then extruding. The rigid PVC not only had higher heat HDT than the flexible one, but it was *permanently* plasticized. In 1940 also B. F. Goodrich patented the NBR/PVC blends. Many forms of PVC and its copolymers have been developed over the years to fit specific uses, viz., latex, plastisol, organosol, flexible, and mostly the rigid formulation. In 1991 world production of PVC was 22.0 Mt or 21.6 wt% of the thermoplastic resin market.

1.5.4.1 PVC/NBR Blends

The PVC/NBR blends were commercialized in 1936 by Bergisch-Gladbach. Nearly identical alloys, *Geon™ Polyblends*, were introduced by B.F. Goodrich 1947. To ascertain adequate interaction between PVC and NBR, the AN content in NBR should be at least 25 wt%. Most commercial blends contain 50–90 wt% NBR that acts as a solid plasticizer and processing aid. PVC blends with cross-linked NBR have been foamed since the 1940s, initially for the production of buoyancy vests, shock absorption and insulation (McCracken 1984), and later for shoe soles. Still later, acidification of NBR made it possible to incorporate the NBR/PVC blends into PA, PC, or PEST (Iwanaga et al. 1990). It was also found that NBR provides good compatibilization and toughening in blends of PVC with carbon monoxide-ethylene-vinylacetate copolymer (COPO-VAc) (Lund and Agren 1993). There are several commercial PVC/NBR blends, viz., *Geon™*, *JSR NV*, *Krynac™ NV*, *Nipol™*, *Paracril™ OZO*, or *Vynite™*.

1.5.4.2 PVC/Acrylics Blends

The most common acrylic, PMMA, shows limited miscibility with chlorinated hydrocarbons (e.g., PVDC, PVC, CPVC, or CPE). The miscibility depends on the type of chlorinated polymer, tacticity of PMMA, and molecular weights

PMMA with dehydrochlorinated PVC were found miscible and easy to foam for the cryogenic insulation in space vehicles	Jayabalan 1982; Jayabalan and Balakrishnan 1985
Copolymer of ethylene, 1–60 % acrylic ester and 1–30 % CO_2 or SO_2	Rys-Sikora 1983, 1984
Core, cross-linked silicone rubber; inner shell, cross-linked acrylate elastomer; outer shell, styrene-AN copolymers	Lindner et al. 1990

of the two polymers. The origin of miscibility is the interaction between the -CHCl- group of PVC and the carboxyl group of the acrylic (Jager et al. 1983). Acrylics have been incorporated into PVC blends quite early (Small and Small 1951). In spite of PVC miscibility with PMMA, blends of these two polymers are not commercially important. To be useful, the blends must be toughened, preferably by acrylic elastomers. Some of the toughening agents are listed in Table 1.26.

Examples of commercial PVC/acrylics blends are *Acrylivin*™, *Decoloy*™, *Enplex*™, *Hostalit*™, *Kane-ace*™, *Kydene* ™, *Metabulen*™, or *Vinidur*™. The blends have been used for industrial, commercial, and consumer goods; in medical, electrical, and chemical engineering equipment; for food or beverage; as aircraft or mass transit interior components; for power tool housings; etc.

1.5.4.3 PVC/Elastomer Blends

These blends, usually with 30–60 wt% PVC, are represented by *Carloy*™, *OxyBlend*™, or *Vynaprene*™. They have been formulated for extrusion, calendering, injection, or blow molding, e.g., into bottles, sheets for exterior signs, window accessories, cables and hoses, printing plates and rollers, shoe soles, profiles, military coax jacketing, etc. PVC blends with ABS and modified ABS were already discussed. In Table 1.27 an abbreviated list of PVC blends comprising non-acrylic elastomer(s) is provided.

1.5.4.4 PVC/Polyolefin Blends

PVC is antagonistically immiscible with PO. Thus, the standard strategies are applicable: (i) addition of a small amount of PO to improve processing and impact strength, (ii) co-continuous morphology, (iii) incorporation of PO as part of a copolymer comprising miscible with PVC segments, and (iv) compatibilized blends. Owing to difficulties in compatibilization, the PVC/PO blends are not commercial (Liang et al. 1999). Evolution of these systems is outlined in Table 1.28.

1.5.4.5 PVC/CPE and PVC/CSR Blends

PVC blends with CPE were patented and commercialized in 1956 as *Hostalit*™. Blends with CSR soon followed. By the mid-1970s, the emphasis shifted toward blends with acrylic elastomers. Ternary alloys were developed, viz., of PVC with CPE and poly(methyl methacrylate-co-butyl acrylate) (MMBA) (Maruyama et al. 1977) or PVC, CPVC, and either MABS or a mixture of PMMA with imidized-PMMA or imidized-SMA (Soby et al. 1994). These blends have been used for outdoor applications, flame-retardant wall coverings, and automobile interiors. Injection molded components include gullies in sewage systems, caps for road reflector posts and bench slats, etc. Evolution of these blends is traced in Table 1.29.

1.5.4.6 PVC/TPU (Mainly Polyester-Type) Blends

Initially, two-component, PVC/TPU blends were proposed (B. F. Goodrich Co. 1960), but soon, PVC/TPU blends with a modifier, e.g., ABS (Waugaman et al. 1963); NBR or PA (Képes 1959) were disclosed. Blending was also carried out by mixing PVC with polyols and isocyanates and then polymerizing these two (Dainichiseika Color & Chemicals 1982, 1983). Commercial PVC/TPU blends (with NBR) are represented by *Duralex™*. The materials are usually formulated for extrusion, e.g., for wire and cable insulation, hoses, and packaging.

Later, foamable, recyclable PVC blends were disclosed. They comprise PVC plasticized with DOP and/or epoxidized soybean oil, blended with either TPU and/or EVAc. The formulation could be foamed either during extrusion or injection molding. The material is used to produce anti-slip shoe soles with good abrasion resistance (Shin et al. 1998).

1.5.4.7 PVC/EVAc and PVC/EVAc-VC Blends

The miscibility of PVC with EVAc depends on the VAc content. Blends of PVC with PVAc were patented in 1938. PVC, or poly(vinylchloride-co-acetate) (PVCAc), was also blended with polyvinylacetal (PVA) (Lonza Elektrizitätswerke & Chem. 1948). In later patents, PVC instead of being mechanically blended with PVAc was copolymerized with vinyl acetate. The copolymer still required toughening; thus, it was emulsion polymerized in the presence of styrene-butadiene-vinylacetate latex (Farbwerke Hoechst 1970). Latex blending (followed by spray drying) was a simple and efficient mixing method (Hammer 1971). Similarly, PVC and/or PVCAc was blended with a variety of butadiene-butyl acrylate-styrene copolymers (Ide and Deguchi 1971). PVC blends with ethylene-vinyl acetate-carbon monoxide copolymer (EVAc-CO) and a methylmethacrylate graft copolymer, *Kane-Ace™*, are also commercially interesting (Mitsui Petrochemicals 1983).

Commercial PVC blends with either EVAc or PVC-VAc have been offered for outdoor applications since the 1970s as high impact strength, rigid formulations (e.g., *Denkovinyl™*, *Hostalit™*, *Vinidur™*, *Solvic™*, or *Trosiplast™*). The resins show good hardness, rigidity, adequate heat, chemical, and flame resistance.

1.5.4.8 PVC Blends with COPO

The first PVC/COPO blends were developed in 1960 (Mullins 1964). It was reported that PVC melt viscosity decreased by addition of COPO (Hammer 1973). Later, the compositions were modified – PVC was blended with ethylene-carbon monoxide-vinylacetate copolymer (COPO-VAc) and BMMM (Reardon 1982).

1.5.4.9 PVC Blends with Engineering Resins

Owing to poor thermal stability of PVC, the high temperature blending must be avoided. Thus, only few PVC/engineering resin blends are known. These are summarized in Table 1.30.

The first commercial blend of this type is *Cylon™*. Here PVC is the matrix, and PA (that melts below 215 °C!) the dispersed phase. The two resins were compatibilized using the well-known PVC plasticizer – *Elvaloy™* (a terpolymer

of ethylene, carbon monoxide, and acrylics). These soft to semirigid alloys were commercialized for wire coating, automotive applications, and blow molding (Grande 1997; Hofmann 1998). They are flame, abrasion, and chemicals resistant, easy to process, and tough.

1.5.5 Polyvinylidenechloride (PVDC)

Polyvinylidenechloride, PVDC, was discovered in 1838 by Regnault but commercialized 100 years later as *Saran™*. The commercial PVDC is modified by the incorporation of either 15–20 wt% vinyl chloride or 13 wt% vinyl chloride and 2 wt% acrylonitrile. PVDC blends are summarized in Table 1.31.

1.5.6 Polyvinylidenefluoride (PVDF)

PVDF was patented in 1948 and commercialized by Pennsalt in 1962. It is a semicrystalline polymer with $T_g = -56$ to $-35\ °C$, 50 % crystallinity, and $T_m = 160–180\ °C$. PVDF has been blended mainly with PMMA (Lin and Burks 1993). The blends are suitable for the use as stable electrets or weather-resistant architectural coatings. Nearly 25 wt% of PVDF consumption is in weather-resistant architectural spray finishing or coating to metals, roofing, curtain walls, wall panels,

window frames, doors, hand rails, fascias, awnings, louvers, and canopies. PMMA/ PVDF blends are commercially available, e.g., *Polycast*™ from Royalite. PVDF blends are summarized in Table 1.32.

1.5.7 Acrylic Blends

Polymethylacrylate (PMA) and polymethylmethacrylate (PMMA) were discovered, respectively, in 1880 and 1930. The resins have been used for the production of transparent plastic sheets, viz., *Plexiglas*™ or *Perspex*™, and used for the military aircraft cockpit canopies, gunner's turrets, and the like (Riddle 1954). Acrylic elastomers (ACM or ANM) were developed by Röhm in 1901 and commercialized in 1948 as *Hycar*™ vulcanizable copolymers of ethyl acrylate, allyl maleated lactones, chloroethyl vinyl ether, butadiene, isoprene, acrylonitrile, etc. (Mast et al. 1944). Since the 1950s, a wide variety of acrylic compatibilizers and impact modifiers have been developed.

1.5.7.1 Co-poly(meth)acrylates (MBA and MBS)

In the 1950s, the core-shell, emulsion-type methylmethacrylate-butadiene-styrene terpolymer (MBS) was developed to toughen PVC or PC. These blends could also contain other polymers, viz., SAA (Murdock et al. 1960), SMM and PS (Murdock et al. 1962), SMM-AN (Schmitt et al. 1967), *high heat* ABS (Kanegafuchi Chemical Industry 1967), HIPS (Ward 1970), MMVAc-AA (Holland et al. 1970), SMMA (Blasius 1992), etc. Table 1.33 traces the evolution of these systems. Later, these multipolymers were modified by incorporation of MA, AA, or GMA units to serve as reactive compatibilizers and toughening agents for PA, PEST, or PC blends.

1.5.7.2 Impact modification of PMMA

PMMA, like PS, is brittle and requires toughening. These efforts are summarized in Table 1.34.

1.5.7.3 PO Blends with Acrylic Polymers

PMMA is antagonistically immiscible with polyolefins – blends of this type have been used in non-critical applications, viz., PP/PMMA blends with EVAc were used as plastic paper (Yamamoto et al. 1971), while those with PVC (or CA) as wood-like materials (Yahata et al. 1971). For more demanding applications, either PO should be blended with an acrylic copolymer comprising a PO block, or PO should be grafted with acrylic moieties. Examples of the PO/Acrylics blends are listed in Table 1.35.

Blends of a PO (PE, PP, PB, P4MP, their blends, and copolymers, e.g., with 1-alkenes, vinyl esters, vinyl chloride, methacrylic esters, and methacrylic acid) with 0.2–50 wt% of a graft copolymer showed high tensile modulus and high sag resistance without increased melt viscosity. The blends could be shaped into foamed profiles at T = 200–230 °C.

To prepare the graft copolymer, a PO (MW = 50–1,000 kg/mol) was either dissolved or swollen in an inert hydrocarbon, monomers (≥80 wt% of a methacrylic ester, $CH_2 = C(CH_3)COOR$), and an initiator was added to the heated mixture while stirring. As a result, acrylic branches of a relatively high molecular weight (MW = 20–200 kg/mol) were grafted onto the PO macromolecules. The graft copolymer could be used as a compatibilizer-cum-impact modifier in a variety

1.5.7.4 PC Blends with Acrylic Polymers

PMMA has been blended with PC since 1971. Two types of PMMA/PC systems are of interest: (i) impact-modified alloys and (ii) miscible blends. To the first category belong *Meta-marble*™ blends of PMMA/PC with ABS (Ikura et al. 1974) or with ASA (Giles and Sasserath 1986). Blends of PC with two acrylic copolymers showed good processability, notched impact strength, and HDT (Eckel et al. 1993).

Acrylic polymers are recognized for their miscibility with a variety of polymers, viz., miscibility of PMA with PVAc (Kern 1957). PMMA is miscible with standard PC at T < LCST ≈ 140 °C. The miscibility range can be greatly increased by modifying the PC chain ends (LCST ≤ 300 °C) (Kambour 1988). Demixing PMMA/PC blends by the spinodal decomposition mechanism generated alloys with excellent mechanical properties (Kyu 1990).

PMMA is also miscible with fluorinated PC (Drzewinski 1993, 1994).

1.5.7.5 PEST Blends with Acrylic Polymers

Blends of PEST with acrylic polymers are limited to systems with acrylic elastomers. Examples are listed in Table 1.36. PBT and PET were reported to form miscible blends with either a poly-*p*-methoxyphenyl methacrylate or poly(phenyl methacrylate) (Siol et al. 1993b, 1994).

1.5.7.6 PPE Blends with Acrylic Polymers

Poly(2,6-dimethyl-*p*-phenylene ether) (PPE) was rarely blended with acrylics, viz., with styrene-methylmethacrylate-co-*cis*-polyisoprene (Abolins and Reinhardt 1976) and PMMA (Izawa and Nakanishi 1973; Matsunaga et al. 1974).

1.5.7.7 PA Blends with Acrylic Polymers

Polyamides, PA, can be impact modified by addition of acrylic multipolymers, e.g., methylmethacrylate-co-methacrylic acid-co-ethylacrylate (Halliwell 1965, 1966), ethylene-2-hydroxy ethyl methacrylate-methylmethacrylate (Hepworth et al. 1970), or ethylene-ethylacrylate-acrylic acid ionomer (Meyer and Tacke 1978).

1.5.7.8 POM Blends with Acrylic Polymers

These systems are not of industrial importance. However, addition of an acrylic was reported to improve processability, abrasion resistance, and weatherability of POM. For example, to improve weatherability, POM was blended with polythioisocyanate, TPU, PMMA, and benzotriazole (Endo et al. 1990). POM/TPU with EMMA and benzotriazole show enhanced performance (Okuda 1990). POM was also blended with EGMA (Takahashi and Kobayashi 1992), EGMA/AS, EGMA/PMMA, or their mixture (Kobayashi and Shinohara 1993).

1.5.8 Polyethylenes (PE)

1.5.8.1 Homopolymers

Properties of PE depend on molecular weight (MW), molecular weight distribution (MWD), as well as on the degree and type of branching (Peacock 2000). The density and modulus of PEs increase with crystallinity. As shown in Table 1.37, seven principal categories of PE are recognized. Commercial polyethylenes are generally copolymers of ethylene with varying amounts of α-olefins, and the comonomer has the effect of reducing crystallinity and density.

The first polymethylene was obtained in 1897 by the thermal decomposition of diazomethane. In 1931, about half a gram of PE was obtained in a free radical polymerization at high T and P. In 1937, *Telcothene*™, a blend of PE and polyisobutylene (PIB) was produced for submarine cables, and in 1939, the first LDPE, *Alketh*™, plant with 100 t/year capacity went into operation (Kennedy 1986). In 1951, HDPE was polymerized using the Z-N catalyst (Zletz 1954).

Table 1.37 Polyethylenes

No.	Type	Code	Density (kg/m^3)	Characteristics
1.	Ultra-high MW	UHMWPE	$\rho \approx 969$	MW > 3,000 kg/mol
2.	High density	HDPE	941–969	High MW and crystallinity
3.	Medium density	MDPE	926–940	
4.	Low density	LDPE	910–925	Long-chain branching, $T_m = 115\ °C$
5.	Linear low density	LLDPE	910–925	Ziegler Natta type with short branching, $T_m = 120–135\ °C$
6.	Very low density	VLDPE	900–910	
7.	Ultra low density	ULDPE	855–900	$T_m = 40–85\ °C$

In 1957, Du Pont Canada developed LLDPE, *Sclairtech*™ (Lank and Williams 1982). In the 1980s, new catalysts made it possible to polymerize VLDPE and ULDPE, commercialized in 1986. The newest PEs (*Tafmer*™ was introduced by Mitsui Petrochemicals in 1975) are prepared using the single-site metallocene catalysts (Choi and Soares 2012). These new resins have controlled MW, MWD, comonomer placement, and density. Their melting point, T_m = 70–120 °C, increases linearly with density, ρ = 880–930 kg/m^3. Details of the different catalysts used for olefin polymerization and the resulting molecular structures and attendant properties may be found in the recent review by Posch (2011). We note that Exxon Mobil has developed a grade for tough, high clarity films called Enable™ mPE 35-05HH resin that can extend downgauging opportunities on LLDPE and LDPE film equipment. This resin and its blends are useful for making compression packaging film, lamination film, stand-up pouch film, and medium- and heavy-duty bag film.

1.5.8.2 PE Blends

As much as 30% of all polyolefin products involve blends (Robeson 2007). It has been found, for example, that blending metallocene-catalyzed linear low-density polyethylenes (mLDPEs) with HDPE improves the Izod impact strength and some tensile properties of HDPE. Adding mLLDPE to LDPE increases the ductility of LDPE (Cran and Bigger 2009). In general, PE blends can be divided into three categories: (1) PE lots blended to meet standard specifications for density and melt flow, (2) PE modified with ≤ 15 wt% of other polymer(s), and (3) PE bends with other thermoplastics or thermoplastic elastomers.

PEs are immiscible with nearly all polymers; thus the standard strategies are applicable: (i) non-compatibilized blends with low concentration of the dispersed phase, e.g., blends of either PP or PE with 2 wt% PVAl; (ii) non-compatibilized blends for the use in noncritical applications; (iii) non-compatibilized blends having co-continuous morphology, e.g., PE, blended with neoprene rubber at a ratio 1:1 and then irradiated by electron beam; and (iv) compatibilized blends.

PE/Elastomer Blends

Polyolefins have been modified by the incorporation of elastomers to improve low-temperature impact strength and elongation. Table 1.38 provides examples of these systems.

PE/EPR or EPDM Blends

The first patent on PE/EPR blends was deposited before commercialization of EPR (Corbellini 1962). Several similar inventions were disclosed, viz., HDPE blends with EPR (Crawford and Oakes 1963, 1966), PE with EPDM (Prillieux et al. 1962), PE/EPDM blends with either PP or PB (Schreiber 1966), PE with EPR and ethylene-acetoxybicycloheptene copolymer (Shirayama and Iketa 1971), or VLDPE with EPR, EPDM, or their mixtures (Nishio et al. 1992). To improve PE/EPDM adhesion to polar materials, PE was first grafted with MA and then blended with EPDM (Honkanen et al. 1983).

The first reactor-type thermoplastic polyolefin (R-TPO) was LLDPE/PP (Yamazaki and Fujimaki 1970, 1972). The three-component R-TPOs (PE with PP and EPR) soon followed (Strametz et al. 1975). PE was also polymerized in the presence of active catalyst and an olefinic copolymer (Morita and Kashiwa 1981). Blending amorphous co-polyolefins with crystalline POs (HDPE, LLDPE, PP) and a filler resulted in moldable blends, characterized by excellent sets of properties (Davis and Valaitis 1993, 1994). Blends of polycycloolefin (PCO) with a block copolymer (both polymerized in metallocene-catalyzed process) and PE were reported to show outstanding properties, viz., strength, modulus, heat resistance, and toughness (Epple and Brekner 1994).

Later, blends of a partially cross-linked thermoplastic elastomer with 5–40 parts of a PO (viz., LLDPE, PP, EPR, or PB-1) were developed for low-density, foamable alloys (Okada et al. 1998a). The density was reduced at least by a factor of two. In the following patent, 1–17 wt% of a long-chain branched PP was also added (Okada et al. 1998b). The extruded foam was free of surface roughness caused by defoaming, was soft to the touch, and showed excellent heat and weathering resistance.

For the power distribution cable industries, insulation compounds are selected primarily to obtain required electrical properties for their intended service and anticipated conditions of use. PE insulation is very sensitive to partial discharges,

while XLPE insulation is better where temperature stability is concerned. PE can be cross-linked either by chemical reaction (such as peroxides) or by γ-ray or by high-energy electron beam irradiation. However, in cable fabrication, chemical cross-linking of PE is used almost exclusively. Cross-linking of PE decreases modulus and elongation but increases ultimate tensile strength. However, enhanced thermal characteristics and excellent electrical properties coupled with mechanical toughness and good resistance to chemicals make XLPE an ideal insulant for applications in many types of electrical cables. Blends of various synthetic elastomers (EPM, EPDM, EVAc, Butyls, Silicones) with XLPE have been studied (Blodgett 1979; Mukhopadhyay and Das 1989, 1991). The effects of ethylene to propylene ratio (E/P) on the flow behavior, structure, mechanical properties, and failure mechanisms of XLPE and EPDM blends have also been studied (Mukhopadhyay et al. 1989; Mukhopadhyay and Das 1990).

PE/PE Blends

Molten polyethylenes of different type chain structures usually are immiscible (see ► Chap. 2, "Thermodynamics of Polymer Blends"). Upon crystallization the spherulites of one PE (having higher T_m) are encapsulated by those of the other PEs. Co-crystallization of two PEs into a single-type isomorphic cell is rare (Utracki 1989a). However, due to low interfacial tension coefficient, the phase coarsening is slow.

Alloys of different PEs constitute a large and important part of the PO technology. For example, in some countries, 70 wt% of PE is sold after blending (e.g., LLDPE with LDPE). As the technology evolves, these blends are prepared from resins of widely different rheological character, giving the viscosity ratios $\lambda \geq 10,000$. Usually, they do not require compatibilization, but owing to such a large value of the viscosity ratio, blending in shear flow is inefficient. Mixing in the extensional flow field is the potential solution (Luciani and Utracki 1996; Utracki and Luciani 1996a). Once cooled below the crystallization point of one component, the blend's morphology is fixed by crystalline cross-links. Blending of different grades and types of PE improves processability and mechanical performance. Blending, as it will be evident from the examples in Table 1.39, also may lead to transparency, improved abrasion resistance, stress-crack resistance, etc.

PE/PP Blends

PE has been used to improve the low-temperature impact strength of PP (see Table 1.40). The blends are mostly immiscible, compatibilized either by addition of EPR, EPDM, by reactive blending, or by post-blending co-cross-linking, e.g., by electron beam or γ-radiation (Utracki and Dumoulin 1995). Recently, Sonnier et al. (2008) showed that the use of 5wt% metallocene random copolymers of ethylene-olefin (mPE) as a compatibilizer increased the elongation at break of an 80/20 blend of high impact PP/HDPE from 60 % to 340 %. This was due to better interfacial adhesion. The comonomer content in mPE ranged from 8.3 % to 19.2% and the comonomer was either butene or octene.

High and low molecular weight PE	Processability and physical properties	Coutant 1994
Reactor blends of LLDPE	Improved MD/TD tear balance	Ali et al. 1994
100 parts of LDPE (ρ = 890–925 kg/m^3), 1–110 parts of a HDPE	Expandable compositions for a small diameter electric wire insulation	Sakamoto et al. 1994
LLDPE with EVAc (10–20 % VAc)	Processability, tear strength, transparency	Benham and McDaniel 1994
LDPE with LLDPE	Improved tear strength and haze	Benham et al. 1995
70–98 wt% of LDPE (with $\leq$ 60 wt% LLDPE) and 2–30 wt% HDPE	For physical foaming of recycled HDPE	Lee 1995, 1996
Bimodal PEs (LCB = 0.01–3; $M_{n1}/M_{n2} > 7$) was lightly cross-linked. The PE-1 was prepared in the first reactor, and PE-2 was prepared in the presence of 15–65 wt% of PE-1 in the second reactor. The reaction could be carried out in the slurry, solution, or gas phase	Blends ($\rho \leq$ 885 kg/m^3) were used for wire/cable coating; weather stripping; seals; foamed articles with closed, open, or mixed cells; containers; medical appliances; drapes and coverings; fibers; tapes; tubes; pipes and hoses: bellows: boots; gaiters; footwear; etc.	Cree et al. 1998

PE/Other Commodity Polymer Blends

The PEs are frequently used as impact modifiers for a variety of other thermoplastics. For example, addition of either PE, CPE, or CSR to PVC improved its moldability, stability, impact strength, and chemical resistance (Matsuda et al. 1960). Blends of PO/PVAl were developed to improve the antistatic properties (Minekawa et al. 1969). LDPE was blended with poly(2-ethyl-2-oxazoline) (PEOX) for improved adhesion, e.g., to PET (Hoenig et al. 1984). Blends of PE, PP, PS, or their copolymers with ethylene-fluorinated vinyl ether copolymer were

PO-g-GMA, acrylamide, vinylpyrrolidone, acrylic, and/or methacrylic acid ester and then blended with either PA or PEST	Adhesion to fillers, excellent performance of filled compositions	Teraya et al. 1994

used for the electrical insulation of high-voltage, submarine cables (Barraud et al. 1993). Blends of LLDPE with EVAc or EEA have comparable physical properties and cost to plasticized PVC (Rifi 1994).

PE/PA Blends

The reasons for blending PE with PA are (1) a desire to improve the impact strength and moisture absorption of PA and (2) to improve rigidity and barrier properties (to oxygen and solvents) of PE. Films and containers manufactured from the latter blends show overlapping lamellar structures that cause high tortuosity for molecular diffusion and significant reduction of oxygen or solvent (e.g., gasoline) permeability. The technology became particularly attractive after the reactive grafting of PO with either maleic anhydride, acrylic acid, or glycidyl methacrylate was invented (Steinkamp and Grail 1976). These modified POs could be directly used in blends with either PA or PEST (Davis 1975). In Table 1.41 examples of PE/PA blends are given.

PE/PC Blends

To increase rigidity of PE, the resin has been blended with about 5 wt% of a high-modulus polymer, e.g., PC (Peters and Schuelde 1963). PC also stabilized PO against the thermal degradation (Schutze et al. 1972). Addition of 3–5 wt% PO

toughened PC (Yamada 1963). For good dispersion, the blending should be carried out at T > 290 °C, using PE grades with the viscosity ratio $\eta(PE)/\eta(PC) \leq 0.3$–0.9. Several impact-modified grades of PC (viz., *Lexan™ EM*) comprise PE (Freitag et al. 1991). However, as Table 1.42 illustrates, most PE/PC blends also contain a polymeric compatibilizer-*cum*-impact modifier.

PE/PPE Blends

The PPE/PE blends are not commercial, but a small amount of PE is frequently added to PPE/HIPS or PPE/SBR blends to improve processability and solvent resistance (see Table 1.43).

To enhanced rigidity of PO, 5–35 wt% of modified PPE was added. In this application, PPE can be considered a low-density filler. Similar effects can be obtained adding a small quantity of other polymers, viz., PC, POM, PPS, etc.

POM was first blended with TPU and then with either PA, LLDPE, PP, PBT, or PET	Flexman 1992

PE/PEST Blends

Addition of PE to PEST is known to improve impact strength, processability, solvent resistance, and weatherability. When more than 5 wt% of PE is required, compatibilization is advisable. Examples of these systems are listed in Table 1.44.

PE/POM Blends

POM is difficult to compatibilize, and without compatibilization only ≤ 10 wt% of POM in PE, or vice versa PE in POM, can be used. For example, addition of a small amount of PE to POM improves its processability, impact and abrasion resistance, hardness, surface finish, and rigidity, while addition of POM to PE improved its modulus and abrasion resistance – see Table 1.45.

PE/Specialty Resin Blends

Most specialty resins are processed at temperatures that limit the possibility of blending them with PE. The PE/specialty resin blends usually contain low concentration, ≤ 5 wt%, of either component. Addition of PE improves the processability, surface finish, chemical, solvent, and impact resistance. Addition of specialty polymer to PE may improve rigidity and processability (viz. PE/LCP). Examples are given in Table 1.46.

1.5.9 Polypropylene (PP)

1.5.9.1 Homopolymers

There are three types of polypropylene: amorphous (aPP), isotactic (PP), and syndiotactic (sPP) (Karian 2003). Performance of these resins depends on the tacticity content. PP was commercialized in 1957 by Hoechst. The slurry process in hexane used the Ziegler-Natta (AlEt$_2$Cl + TiAlCl$_6$) catalyst (Sailors and Hogan 1982). The new metallocene catalysis leads to isomer purity in excess of 96 % (see, for example, Posch 2011). It is also possible to produce branched, *high melt strength PP*, with extensional stress hardening, similar to that of LDPE (Phillips et al. 1992). The new PPs show the melting point, T$_m$ = 120–164 °C. To enhance the performance, PP is usually blended (in the reactor or outside the reactor) with much more viscous PP-copolymers. As a consequence, one of the most serious industrial problem is homogenization of these materials (Luciani and Utracki 1996; Utracki and Luciani 1996b).

Most industrial polypropylenes are isotactic, but a few syndiotactic polypropylenes are available (De Rosa and Auriemma 2006). The advantage of sPP over PP is that impact strength and tensile modulus of sPP are significantly higher. While PP has a planar zigzag helical structure, the sPP has a three-dimensional one that leads to lower crystallinity and melting point: T_m(PP) ≈ 165 vs. T_m(sPP) ≈ 133 °C.

1.5.9.2 PP Blends

PP is brittle, especially at T $\leq$ T$_g$ ≈ 0 °C. The resin fractures by the crazing-cracking mechanism (Friedrich 1983). The discovery of PP immediately followed by search for methods of improvement the low-T impact behavior. PP was blended with EPR or EPDM (Hogan and Banks 1953, 1955), PE (Holzer and Mehnert 1963), sPP (Emrick 1966), aPP (Tanahashi and Kojima 1970), etc.

PP/Other Polyolefin Blends

PP is often made using two reactors in series: the first reactor makes isotactic PP, while the second reactor makes a random copolymer of PP and PE. The copolymer is amorphous, and it is blended with the PP homopolymer to enhance impact resistance (Tan et al. 2005). PP blends with elastomers will be discussed in the following parts. In Table 1.47 few examples of PP blends with other POs are given.

Table 1.47 PP/PO blends

Elastomer added to PP	Comment	References
PP/PIB miscible (?) blends	Low-temperature impact properties	Ranalli 1958
PP miscible with aPP or polybutene-1	Reduction of T_g by up to 20 °C	Romankevich and Frenkel 1980
10–60 wt% PP or LLDPE with EPDM and ≤ 95 wt% PIB or butyl rubber	Soft, easy foamable blends (due to strain hardening)	Matsuda et al. 1981, 1988

PP/PB and a poly(*1*-butene-co-ethylene)	Processability, impact strength, and optical properties	Hwo 1994
High MW aPP blended with high MW of either PP or sPP	aPP was immiscible with PP and partially miscible with sPP	Silvestri and Sgarzi 1998
Addition of EPR to PP	To strengthen spherulites boundary	Lustiger et al. 1998

PP/Elastomer Blends

These blends constitute a large, commercially important group. Usually 5–20 wt% of elastomer have been used. Alloying improves processability (e.g., in blow molding) and impact strength at low temperature. Diverse elastomers have been used, e.g., EPR, BP, PIB, BR, uncured PB, and SBR; *dynamically co-vulcanized* CBR; and BR, CSM, and EPDM (Reid and Conrad 1960, 1962; Dow Chem. 1963; Gessler and Haslett 1962; Esso R&E 1962; Coran and Patel 1978). Blends with amorphous CSR showed good mechanical properties (Shikata et al. 1973). Partially vulcanized blends of CSR with PP and/or ULDPE had good processability, hot-weld strength, interplay adhesion, and crack resistance (Ainsworth 1990, 1994). Addition of CPE improved PP's processability and properties (Newe et al. 1984).

Many EPR and EPDM elastomers show a block copolymer behavior. When blended with PP, they form emulsion-like dispersions. For the ease of compounding, a small amount of PE may also be added. Furthermore, if the elastomeric phase is lightly cross-linked, the morphology is more stable. The PP/EPR blends can be processed by all methods used for PP. They are characterized by good processability, dimensional stability, low shrinkage, high stiffness, tear strength and softening temperature, good mechanical properties (at T = −40 °C to 150 °C), ozone resistance, fatigue, and abrasion resistance (see Table 1.48). These materials have been used in more than 200 applications, in automotive industry, appliances, hardware and plumbing, medical, shoe industry, sports equipment, toys, etc. Examples of commercial PP/EPR blends are *Buna*™, *Dutral*™, *Epcar*™, *Epichlomer*™, *Epsin*™ and *Santoprene*™, *Esprene*™, *Ferrocline*™, *Gafply*™, *Intolan*™, *Kelburon*™, *Larflex*™, *Milastomer*™, *Nordel*™, *Royaltherm*™, *Trilene*™, and *Vistalon*™.

Table 1.48 PP/EPR blends

Elastomer(S) added to PP	Reason	References
0.1–60 wt% EPR, containing 2–25 % ethylene – the earliest patents	Increased impact and tensile strength, superior mechanical properties	Schilling 1964, 1966; Short 1967; Shirayama et al. 1971
EPDM (EPR with dicyclopentadiene or ethylidene-norbornene), partially cross-linked with peroxides	Alloys could be shaped into articles with good properties without further vulcanization	Fischer 1972
EPDM	Unexpectedly high tensile strength	Stricharczuk 1977
Dynamic vulcanization of PP with either EPR or EPDM; *Santoprene*™	A range of Shore hardness, toughness, elongation, impact strength	Coran and Patel 1978

Olefinic, partially cross-linked elastomer: EPDM, EPR, BR, NR, IR, CBR, etc.	For manufacturing automotive components	Ellul 1994
Metallocene PP was alloyed with EPR	For low-temperature heat sealability	Shichijo 1994
PP blended with EPR and EPDM and then irradiated in the presence of O_2	Easily foamed blends with high strain hardening	DeNicola et al. 1995, 1997
Long branch containing PP with partially cross-linked EPR and a foaming agent	Reduction of density by ≥ 2, smooth surface, heat and weathering resistance	Okada et al. 1998

PP/EVAc blends are immiscible; thus, in two-component systems, only a small amount of EVAc can be used, e.g., to improve dyeability, flexibility, electrostatic dissipation, or barrier properties. The hydrolyzed EVAc (EVAl) was also used (Minekawa et al. 1969). In most cases, the PP/EVAc blends are part of more a complex, multicomponent system comprising a reactive compatibilizer (see Table 1.49).

1.5.10 Thermoplastic Olefin Elastomers (TPO)

Ziegler-Natta catalyst makes it possible to polymerize α-olefins into elastomers with controlled degree of crystallinity and cross-likability. The first EPR's were manufactured in 1960, 3 years later, the first EPDM. It is advantageous to produce block copolymers with PP being the rigid and PE the soft block. A direct sequential polymerization of propylene and ethylene-propylene mixture leads to the reactor blends (R-TPO) (Cecchin and Guglielmi 1990).

EPR may be cross-linked by peroxides, while EPDM by the standard methods of the rubber industry. By varying the composition and process variables, a wide range of properties can be obtained. The resin with vulcanized, dispersed phase has CUT ≈ 125 °C, higher than standard TPO, and they are known as the *thermoplastic vulcanizates*, *TPV* (Fritz and Anderlik 1993). Diverse TPOs with properties that range from flexible to rigid (but tough) are manufactured by the large resin producers, as well as by the compounding houses (Utracki and Dumoulin 1995).

Polytransoctanamer (PTO) has been used as a high-performance elastomer and in blends with commodity and engineering resins. Polyoctadecene (POD) blends with PP are thermochromic. The most interesting are the metallocene-type polycyclic polyolefins, e.g., polycyclopentene or polynorbornene, either syndiotactic or isotactic with $T_m = 400–600$ °C.

Table 1.49 PP/EVAc blends

Elastomer added To PP	Comment	References
PP with 18–32 wt% EVAc and/or ethylene-ethylacrylate copolymer (EEA)	Impact strength, elongation, and low-T brittleness	Miller and Reddeman 1962

PP/EVAc and POM, PMMA, PS, or SMM	For paperlike films	Yamamoto et al. 1971
70 wt% PP and EVAc, PVCAc, HDPE	Low-temperature impact resistance	Kojima and Tanahashi 1972
PP/EVAc with maleated LDPE	Melt strength and rigidity	Idemitsu Petrochem. 1983
35 wt% PP, 50% PIB, and 15% EVAc	For films, moldings, and extrusions	Shulman 1984
PP/PC with 2–35 wt% EVAc	Excellent solvent resistance	Giles and Hirt 1986
10–90 wt% PP, 5–60 wt% EVAc, and 5–50 wt% PEOX	Miscible (?) alloy for intermediate layer in recyclable barrier films	Sanchez et al. 1991
PP/EVAc with PP-MA	Low permeability by gases or liquids	Kamal et al. 1992
PP/EVAc with EAA and polybutene	Tough, radiation resistant, heat sealable	Wilfong and Rolando 1993

1.5.11 PP/Engineering Resin Blends

1.5.11.1 PP/PA Blends

There are three types of PP/PA blends: (1) with a small percentage of PO, either acidified or not, (2) alloys with high component ratio where PA is a matrix, (3) and blends with a small amount of dispersed PA to increase rigidity. Table 1.50 gives some examples of these systems.

To toughen PA, 2–5 wt% of either PO, elastomer, *ionomer*, acidified, or epoxidized copolymer may be added. PA/PO blends of type (2) were developed to improve dimensional stability and to reduce water absorbency of PA. Alloying PA with PO reduces the *rate* of water migration to and from the blend, but not the inherent water absorption of PA (Utracki and Sammut 1991, 1992). The alloying is either a two- or three-step reactive process: (1°) acidification of PO, (2°) preparation of a compatibilizer, and (3°) compounding PP, PA, and the compatibilizer. Usually, the reactive blending is carried out in a twin-screw extruder (Nishio et al. 1990; Hu and Cartier 1998). Since it may cause reduction of the blend crystallinity (thus performance), the extent must be optimized. The rigid PA/PP blends usually comprise PA:PP = 3:2 with 12 wt% of a compatibilizing copolymer. Finally, in type (3), incorporation of PA improves processability, solvent resistance, CUT, HDT, and surface finish. For enhanced performance, the blends should be compatibilized.

Table 1.50 PP/PA blends

Composition	Comment	References
1. Toughened PA		
PA, PP, and 0.5 wt% of PP-MA	Compatibilized blends	Davis 1975
PA/PO and ionomer	*Surlyn*™ as a compatibilizer	Toyobo 1981
PA/PO and PO grafted with MA or a compound containing two epoxy groups	High impact strength	Subramanian 1980, 1983, 1984
PO grafted with glycidyl methacrylate, acrylamide, vinylpyrrolidone, acrylic acid esters, and/or methacrylic acid esters and then blended with PA or PEST	Two-stage, reactive impact modification: preparation of reactive compatibilizer and then blending	Teraya et al. 1994
2. Rigid PA/PP blends		
Non-compatibilized PP/PA blends	For films, sheets, or bottles with good printability and low liquid permeability	Mesrobian and Ammondson 1962
PP with PA-6 or PA-66 and GF	Rigid, non-compatibilized blends	Asahi Fiber Glass 1981
PP/PA-6 compatibilized by EPR-MA	Impact-resistant blends	Katsura 1986
PP was maleated and then reactively blended with PA to obtain 12 wt% of PP-co-PA	Two-step blending: maleation of PP, incorporation of PA	Glotin et al. 1989
PA was blended with acidified PP and GF	Moldability, water resistance, HDT, low-T impact strength	Iwanami et al. 1989
Reactive blending of PP/PA-6 with either EPR-MA or SEBS-MA	SEBS-MA gave better impact strength, yield stress, toughness, and modulus	Rösch and Mülhaupt 1994
3. PA/Elastomer blends		
PP, PA-6-co-PA-66, PP-MA with NBR and EPDM	Impact strength, high stress at break, high elongation, good ductility, and high gloss	Tokas 1981
PP, EPR, PA, and SMA, SEBS-MA, EPR-MA, MBA, ASA, etc.	For automotive, electrical, electronics, building, furniture, small appliances, etc.	Chundury and Scheibelhoffer 1994
PP, EPR, PA, and 2 compatibilizers from between SEBS, SEBS-MA, and poly(ethylene-co-acrylic ester-co-MA)	Recyclable high impact strength blends	Chundury 1994
PP-MA was blended with PB	Adhesive to metals and polar polymers: PA, PET, or PC	Lee et al. 1994

1.5.11.2 PP/PC Blends

PP and PC are immiscible; thus, excepting the exploratory use as a "plastic paper," only the two ends of the concentration range have been explored, viz., addition of 5 wt% PP to PC (to improve processability of PC) (Dobkowski 1980) or addition of ≤ 10 wt% of PC (to improve PP processability, enhance crystallinity and crystallization temperature, the appearance, modulus, and impact strength) (Liang and Williams 1991). For concentrations ≥ 10 wt%, compatibilization is necessary.

Table 1.51 PP/PEST blends

Composition	Comment	References
PAr with low concentration of PO, elastomer, or EVAc	Uncompatibilized blends	Koshimo et al. 1973
PBT with PP	Improved moldability of PBT	Seydl and Strickle 1976
PET, PO, and either glycidyl methacrylate-modified PO or vinyl-grafted PO	High heat and moisture absorption resistance	Mukohyama 1993
PBT/PC with PE, PP, or EPR modified with 0.05–15 wt% glycidyl methacrylate and/or 0.1–2 wt% MA	Processability, toughness, rigidity, strength, dimensional stability, and flexural modulus	Fujie 1993
PPE, PA, or PEST with EPDM, SBS, SEBS, or EPR, and PP grafted with styrene and a glycidyl moiety	Flexural and tensile strength	Okamoto et al. 1993, 1994
Recycled PET/PP = 2:3–3:2 and SEBS-MA	For molding battery containers	Tekkanat et al. 1993, 1994
PP with PET or PBT and a polyolefin-polyester graft copolymer	Compatibilized	Fujita et al. 1994
PEST, PA, PP-MA, and either PET or PBT with sodium dimethyl 5-sulfoisophthalate	High tensile and impact strength	Tajima et al. 1994

This is accomplished using ethylene-acrylic copolymer, cellulosics, PA, PVAc, or TPU (Goldblum 1963, 1964); an acrylic elastomer, acrylic elastomer with PP-MA, and either butyl rubber or isobutene-isoprene rubber (Teijin Chem. 1982, 1983); SBR and EEA (Liu 1984); MBS (Overton and Liu 1984); or EVAc (Giles and Hirt 1986).

1.5.11.3 PP/PEST Blends

PP is antagonistically immiscible with PEST, and when the concentration of the dispersed phase exceeds 5–10 wt%, compatibilization is necessary. Initially, the uncompatibilized blends were formulated within the low concentration region of the dispersed phase. By the end of 1980s, reactive compatibilization started to dominate the technology. Examples of PP/PEST blends are listed in Table 1.51.

1.5.11.4 PP/PPE Blends

Two-component blends of PP with PPE are unknown. To get a reasonable performance out of a PP/PPE mixture, first PPE must be toughened using a styrenic resin, and then the blend compatibilized. Thus (see Table 1.52), PP is only one ingredient in multicomponent PPE blends.

1.5.11.5 PP/POM Blends

PP/POM blends are antagonistically immiscible, not available on the market. The early blends contained a small amount of one resin in another, viz., either PP or LDPE, with 1–10 wt% POM showed improved processability, good appearance,

Table 1.52 PP/PPE Blends

Composition	Comment	References
PPE-MA with PP-MA, SBR, glycidyl methacrylate copolymer, and/or phenylenediamine binder	Solvent resistance, moldability, impact, and mechanical properties	Togo et al. 1988
PPE dispersed in PP, PE, PA, PEST, POM, PPS, or PEEK, compatibilized by EPR-MA, EVAc-GMA, and either maleic anhydride or bis(4-phenyl isocyanate)	Processability, heat resistance, and mechanical properties	Nishio et al. 1988, 1994
PPE, PP, and SEBS	Modulus, rigidity, tensile strength, and HDT	Lee 1990
PPE with PP grafted with styrene and MA and EVAc-GMA, styrene-grafted EPDM	Rigidity as well as high heat, chemical, and impact resistance	Furuta and Maruyama 1990
PPE, PP, and PPS with hydrogenated styrene-isoprene block copolymers	Heat, impact, and solvent resistance	Maruyama and Mizuno 1990
PPE modified by glycidol or epichlorohydrin with PP-MA or PP-GMA and PA or PEST	Moldability and mechanical strength	Nakano et al. 1992
PPE with PP, compatibilized with styrene-grafted propylene-methyloctadiene (or hexadiene)	Stiffness and impact strength	Tanaka et al. 1992
PPE/PS, styrene-grafted polypropylene (PP-PS), SEBS and PP	Processability, HDT, impact and tensile strength, stiffness solvent resistance, gloss	DeNicola and Giroux 1994
PPE/PP compatibilized with PO grafted with ethylenically unsaturated *t*-alkylcarbamate	Copolymers used as decomposable compatibilizing agents	Campbell and Presley 1995

and improved performance (Rudin and Schreiber 1964a). However, blends containing higher concentration of ingredients must be compatibilized, viz., by addition of muconic acid-grafted PP (Chen et al. 1991) or by TPU and EBA-GMA (Subramanian 1992).

1.5.12 PP/Specialty Polymer Blends

Most specialty resins require high processing temperatures, while PP usually has $T_{proc} < 250\,°C$. Thus, only few blends of this type are known. For example, addition of PP enhanced throughput of PAES (Gowan 1968, 1969), PEI, PC/PEST blends, etc.

Linear, aromatic polyamides (PARA) are either liquid crystalline, semicrystalline, or amorphous. Mainly the latter resins are used in blends with PP, viz., PARA with PP-MA (Iwanami et al. 1990), PARA with PE-MA, or PP and hydrazine (Yoshihara 1990). Blends of copolyphthalamide (PPA) with PP were compatibilized using either PP-MA (Paschke et al. 1993, 1994) or PP grafted with acrylic acid (Brooks et al. 1993, 1994).

Table 1.53 PP/LCP blends

Composition	Comment	References
Low concentration of LCP in a resin	To improve processability	Cogswell et al. 1981
10 wt% of LCP was blended with, e.g., PP, PS, PC, or PI	Molecular orientation imposed by extrusion through a rotating die	Haghighat et al. 1992
LCP and PP, PET, PA, PC, PE, PVC, PVDC, PPS, PVDF, PVF, or PMMA	To produce oriented films with protrusions that resulted in low friction	Wong 1990, 1994
PP was blended with LCP	2 extruders with a static mixer, to stretch LCP into microfibrils	Sukhadia et al. 1991, 1992
PP/LCP compatibilized with PP-MA	(Processing as described above)	Baird and Datta 1992
LCP with either PP, PPE, PPE/PS, PC, or PEI	(1) Prepregs from an extruder, mixer, and rolls; (2) prepregs consolidated at $T < T_m$	Isayev 1991, 1993

PP blends with a small amount of LCP are of industrial interest for two reasons: (i) to improve processability or (ii) to improve the mechanical performance. The second effect depends on the blend's morphology, i.e., on the orientation of LCP domains. The latter depends on the concentration, viscosity and elasticity ratios, interfacial tension coefficient, flow type and intensity, total strain, drawdown ratio, etc. Three stages of orientation are (1) drop deformation, (2) fibrillation of the domains, and (3) stretching of the LCP chains (Champagne et al. 1996). Only the latter provides a reasonable cost-to-performance ratio. Examples of PP/LCP systems are listed in Table 1.53.

1.6 Engineering Resins and Their Blends

The term *engineering polymer* is applied to a processable resin, capable of being formed to precise and stable dimensions, having high performance at CUT $\geq 100\,^{\circ}$C, and the tensile strength of $\sigma \geq 40$ MPa (Utracki 1989a). Five polymer families belong to this category: PA, PEST, PC, POM, and PPE. While the relative size of the engineering resin market varies from country to country, these polymers constitute about 13 % by volume and 34 % by value of the total plastic's consumption. Since the blends of engineering/commodity resins have already been discussed, here only engineering/engineering and engineering/specialty resins will be considered.

Engineering resins and their blends have been foamed using mainly chemical foaming agents, e.g., hydrazodicarboxylates, benzazimides, or 5-phenyltetrazole. However, products of decomposition of these agents (e.g., alcohol, ammonia, water, etc.) were found to hydrolyze PC, PA PC/ABS, or PEST, reducing the performance of foamed products. For this reason, dihydro-oxadiazinones were proposed as the preferred chemical foaming agents for the engineering resins, their compositions, and blends (including PPE/HIPS) (Nizik 1978, 1979). Another method for foaming high temperature polymers profits from thermal

Table 1.54 Comparative properties of PAs

Property	PA-6	PA-66	PA-11	PA-12	PA-46	PA-610	PA-63T
Tensile modulus (MPa)	1,400	2,000	1,000	1,600	1,700	1,500	$\geq 2,000$

Maximum elongation (%)	200	150	500	300	60	500	50–150
Density (kg/m^3)	1,130	1,140	1,040	1,020	1,100	1,080	1,060–1,120
T_g(°C),	57	57	46	37	295	50	145
T_m (°C)	220	255	185	180		215	240
HDT (°C)	80	105	55	140	90	95	150

instability of polypropylene carbonate (PPCO, MW = 1–1,000 kg/mol) (Kuphal et al. 1990). The process involves blending PPCO with a resin or its blend that is to be foamed. The blend is then heated to T > 300 °C, sufficient to melt the principal resin and to decompose PPCO. Talc, wollastonite, clay, $CaCO_3$, or citric acid can be used as a nucleating agent. The densities of the molded articles were reduced by at least 50 %. Today foaming of the engineering resins with supercritical CO_2 is practiced.

1.6.1 Polyamides (PA)

Polyamides are abbreviated as PA, followed by the number of carbons in a diamine and dicarboxylic acid, viz., PA-66 has six carbons in each component, etc. Poly-ε-caprolactam or polyamide-6 (PA-6) was first studied by Von Brown in 1905–1910, and 30 years later commercialized as *Perlon*™. In the year 1936, PA-66 and several other aliphatic and semi-aromatic polyamides were disclosed (Carothers 1937). Two years later, du Pont introduced *Nylon*™. PA-11 was commercialized in 1955, PA-12 in 1966, PA-612 in 1970, and PA-46 in 1987. In 1976 du Pont started production of the *super tough* PA blends (Damm and Matthies 1990). In 1991 consumption of the thermoplastic PAs was estimated at 1.2 Mt. Comparative properties of the better-known PAs are listed in Table 1.54.

Liquid crystal aromatic polyamides (PARA), poly(*meta*-phenylene isophthalamide), *Nomex*™, and poly(*para*-phenylene terephthalamide), *Kevlar*™-49, were commercialized in 1961 and 1965, respectively. Amorphous aromatic polyamide, *Trogamid*™, was introduced in 1969, and polyphthalamide *Amodel*™ in 1991.

PA started to be blended with other engineering resins at the end of the 1960s, viz., PA with POM (Moncure 1969; Asahi Chem. 1969), PA with POM and PET (Fujiwara 1971), PA-6 reactively compatibilized with PET (Reimschussel and Dege 1969), PA-6-co-diisocyanate copolymer with PET (Illing 1970), etc. By the year 1970, the number of PA blends rapidly started to increase. The main efforts were directed toward improvement of toughness and processability of PA. Reactive compatibilization and impact modification became an integral part of the PA-blends technology.

Table 1.55 PA(1)/PA(2) blends

PA(1)	PA(2)	Comment	References
PA-66	PA-6 or PA-610	Reduced residual stresses in moldings	Stott and Hervey 1958
X-linked PA-66	PA-6 or PA-11	Excellent impact resistance	Uniroyal 1968
PARA	PA-6, PA-66, PA-610, PA-11, or PA-12	To improve the impact strength	Dynamit Nobel 1969
PA(1)	PA(2)	Miscibility/immiscibility studies	Zimmerman et al. 1973
PA-6I6T	Another PA at 1:1	Tough and strong fibers or films	Unitika 1982
PA-6	PA-11	Toughened by sulfonated EPDM	Weaver 1983, 1985
PA-66	Either PA-6, PA-612, PA-11, or PA-12	Printability, clarity, barrier, and dimensional stability	Mollison 1984
PA-6	Poly(trimethyl hexamethylene terephthalamide)	Resistant to cracking when exposed to metal halides	Ube Ind., 1984, 1985
PA-66	PA-6	SMM-MA and mineral filler	Asahi Chemical Industry 1985
PA-66	PA-6	With aminosilane-treated GF	Toray Ind., 1985
PA-mXD6	PA-66 and PBT, or PA-6	Tough, high-T, films; good barrier against O_2 permeation	Mitsubishi Gas Chem. 1985
PA-12	PARA	Transparent blends	Maj and Blondel 1993
PA-6I6T	PA-612 or PA-666, with PA-6, PA-11, or PA-12	At least 5 % shrinkage at 90 °C in at least one direction	Vicik 1994
PA-6 or PA-66	Semi-aromatic copolyamide	Compatibilized with either SMA, maleated EPDM, or MBA	Schmid and Thullen 1994
PA-66	PARA	Maleated elastomer and filler; low-T impact strength and HDT	Heger and Oeller 1994

1.6.1.1 PA(1)/PA(2) Blends

These blends are commercially available, e.g., *Zytel 3100*™ and *Grilon*™ *BT*. They show improved processability, solvent resistance, elongation, low-temperature impact and tensile strength, as well as enhanced barrier properties (see Table 1.55). They have been also incorporated into more complex, multicomponent systems, e.g., PA/PARA = 1:1, PPE, PCL, *ionomer*, EPR, a monomeric mixture of oxide and/or carbonate (e.g., ethylene carbonate, ethylene oxide, etc.), and a polyhydric alcohol (e.g., ethylene glycol or trimethylene glycol). The alloys were used to mold parts for the automotive, electrical, or electronic industries (Hamada et al. 1994).

1.6.1.2 PA/PPE Blends

PAs are excellent candidates for blending with PPE – each ingredient compensates for deficiency of the other. Since the resins are immiscible and brittle, they must be compatibilized and toughened. In consequence, PA/PPE blends comprise minimum four polymeric components: PA, PPE, a styrenic modifier, and an acidic compatibilizer. Usually PA is the matrix in which PPE/styrenic resin domains are dispersed. As time progresses, these blends are getting more complex – examples

are shown in Table 1.56. Commercial blends are *Artley*, *Dimension™*, *Luranyl™*, *Lynex™ A* and *Xyron™*, *Noryl™ GT*, *Remarry™*, *Ultranyl™*, *Vestoblend™*, etc.

1.6.1.3 PA Blends with POM, PEST, or PC

The immiscible blends with ≤ 5 wt% of either component were introduced first (e.g., POM with PA or PARA) before adequate methods of compatibilization were developed. Owing to the crystalline nature of these resins, the blends should also be impact modified. It is noteworthy that in blends of semicrystalline resins, the total crystallinity tends to increase (Nadkarni and Jog 1991). The compatibilization and impact modification are often accomplished using a multipolymer. For example, POM/PA-66 blends have been modified by adding either an ethylene-methylacrylate copolymer (EMAC), PEG (Kohan 1982), or a melamine-derivative "dispersant" (Tsukahara and Niino 1992, 1994).

In PA/PEST blends, PA improves the processability, mechanical properties, and solvent resistance of PEST. Examples of the developed PA/PEST blends are listed in Tables 1.57–1.58. PA blends with PC are similar to those with PEST. Since addition of PA to PC may lead to crystallization of the latter resin, also these blends should be compatibilized *and* impact modified (see Table 1.59).

1.6.1.4 PA/Specialty Polymer Blends

Addition of a small amount of PA improves processability of the specialty resin and is beneficial to performance of the GF-reinforced systems. Addition of specialty resin to PA enhances the thermal behavior and rigidity of the latter resin. For higher concentration of these ingredients, compatibilization and impact modification are required. Since PA is sensitive to heat, oxygen, and moisture, the compounding requires a special care. Examples are listed in Table 1.60.

1.6.2 Thermoplastic Polyesters (PEST)

Aromatic polyesters show good performance and have high T_m and HDT (see Table 1.61). Polyethylene terephthalate (PET) was invented in 1941 and commercialized as *Terylene™* fibers. The catalytic transesterification also lead to PPT, PBT, PHMT, PEN, etc. Polybutylene terephthalate (PBT) has better processability than PET and lower T_m. Poly(ethylene-2,6-naphthalene dicarboxylate) (PEN) has high modulus, strength, HDT, and excellent barrier properties. Polypropylene terephthalate (PPT) is a resin from shell. It combines the high crystallization rate of PBT with performance of PET. Polyarylates [-O-ϕ-C(CH$_3$)$_2$-ϕ-CO$_2$-ϕ-CO-]$_n$ (PAr) are linear amorphous polyesters, usually of bisphenol-A with isophthalic and terephthalic acids – they show intermediate performance between that of PC and PEST – high strength, stiffness, excellent impact strength, and HDT. Polyethyleneterephthalateglycol (PETG) is an amorphous copolymer of ethylene glycol and 1,4-cyclohexanedimethanol, with terephthalic and isophthalic acids. The block copolymers, having hard PBT segments and soft polyetherglycol ones, are versatile elastomers (e.g., *Hytrel™* from du Pont).

PPE dissolved in lactam(s) and then compatibilized and polymerized	The compatibilizer was either PPE-MA, SAA, or SMA	Samuels 1994

PESTs and PCs are known to have low melt strength and are difficult to process in operations involving elongational flows, viz., blow molding, stretching, or foaming. During foaming the cell size distribution is broad, the wall thickness variable and the mechanical properties are poor. To improve the melt strength, a diacid anhydride and a metal compound may be added during extrusion (Hirai and Amano 1993). These additives induce branching, increase MW, and strain hardening. Alternatively, linear and branched resins may be blended.

The branched macromolecules can be produced in reactions with polyols having 3–6 hydroxyl groups. This approach has been successful even for recycling post-consumer PET. For example, ≥ 25 wt% of a bPET with recycled PET were extruder blended with ≤ 20 wt% of a chain extender (e.g., partially neutralized ethylene-methacrylic acid ionomers, copolymers of maleic anhydride or glycidyl methacrylate, etc.). Downstream up to 5 wt% of a chemical or physical blowing agent was incorporated. The blends were used to produce rigid insulation, trays, food packaging, microwave cookware, oxygen and moisture barrier films, etc. (Muschiatti and Smillie 1995).

1.6.2.1 Polyester Blends

The largest group comprises the impact-modified PESTs – these were summarized while discussing commodity resin blends. The commercial blends with, e.g., SMA or acrylic rubber show good processability, rigidity, impact and tensile strength, as well as excellent weatherability, viz., *Arloy™* 2000, *Bexloy™*, *Celanex™*, *Pibiter™ HI*, *Rynite™*, and *Ultradur™ KR*.

The second largest group comprises different combinations of PEST, for example, PET/PBT, PBT/PAr, or PET/PEN. These have been mainly developed for improved processability, good surface properties, HDT, impact strength, and dimensional stability, viz., *Celanex™*, *EMC™*, *Valox™*, etc. Examples of their formulations and performances are given in Table 1.62.

1.6.2.2 PEST Blends with PC

The PEST/PC blends are immiscible (T_g of PC is depressed by ca. 20 °C) and brittle, requiring toughening. Usually, PC blends with PEST contain 10–20 wt% of ABS, ASA, or MBS. In most commercial blends, PC is the matrix, but blends

PA blends with PBT or PAr		
Non-compatibilized PA/PBT	To enhance PBT crystallinity	Toray Ind. 1983
Reactive PA/PBT blends	Acidified ethylene copolymer	Sheer 1982
Reactive PA/PBT blends	Maleated PS	Mitsubishi Petrochem. 1985
Reactive PA/PBT blends	Epoxy compounds	Urabe and Ikuhara 1989
Reactive PA/PBT blends	Either SGMA or SMA	Watanabe and Inozuka 1991
Compatibilized PA/PBT	Low molecular weight PBT	Goetz et al. 1993
1:1 PAr with PA, PET, or PBT	Transparent, impact resistant	Asahara et al. 1977a, b
PAr with PA-6 and Si-compounds or PET	Processability, high gloss, chemical, mechanical, electrical properties, and HDT	Unitika 1982, 1983, 1984
PAr with PA or PARA	PA-co-PAr added; single T_g	Dean 1990, 1992

formulated for low-T impact strength (down to $-40\ °C$) have co-continuous morphology and are reinforced by addition of ≤ 30 wt% of GF. It is vital to avoid reduction of PET crystallinity during blending or processing. The main advantage of the PC/PEST alloys is the increased stiffness, reduced susceptibility to stress cracking on contact with fuels, and an improved resistance to chemicals and fuels. The blends show good processability, heat resistance, ductility, HDT, high modulus at high temperature, good electrical properties, thermal stability, impact, tensile and flexural strength over a wide temperature range, low shrinkage,

and good dimensional stability, but they may have poor weatherability, and their solvent resistance (while superior to that of PC) is moderate. The commercial blends include *Alphaloy*™ *MPB*, *Baitaloy*™ *VL*, *Cycolin*™, *Dialoy*™, *Ektar*™, *Hyperlite*™, *Eastalloy*™, *Idemitsu*™ *S*, *Impact*™, *Lumax*™, *Malecca*™ *B*, *Makroblend*™, *Maxloy*™, *Novadol*™, *Novaloy*™ *B*, *Petsar*™, *Pocan*™, *Sabre*™, *Stapron*™, *Techniace*™ *TB*, *Triax*™ *400*, *Ultrablend*™, *Valox*™, and *Xenoy*™. The blends are mainly used for automotive body panels, in outdoor power or recreational equipment, appliance housings, telecommunications, etc.

The PC/PEST blends were first described in 1966. The first, three-component blends were disclosed in 1972 (see Table 1.63). Many multicomponent alloys comprise PC and PEST. From between them, these with PPE are particularly important – see the following part.

1.6.2.3 PEST Blends with PPE

Blending PPE with either PEST or PC poses similar problems – the polymers are immiscible and brittle, hence require compatibilization and toughening. The PEST/PPE blends are multicomponent systems, with ≥ 5 components: PEST, PPE, styrenic copolymer, compatibilizer, and impact modifier. Examples of commercial blends are *Dialoy*™ *X*, *Gemax*™, or *Iupi-ace*™. For improved modulus and dimensional stability, they are usually reinforced with GF. These alloys are known for excellent processability, high solvent resistance, and dimensional stability. Evolution of these systems is outlined in Table 1.64.

1.6.2.4 PEST Blends with Specialty Resins

PESTs are immiscible with polyphenyl sulfides (PPS) or polyphenylenesulphidesulfone (PPSS). The customary three types of uncompatibilized blends are known, with 5–10 wt% of the dispersed (either PPS or PEST) phase and the phase co-continuity. The compatibilized blends (with a copolymer containing either epoxy or acid anhydride groups) show high tensile and impact strength (Nishiyama et al. 1990, 1991a, b) that can further be improved by addition of a TPE (Nishiyama and Nakakita 1991). PPS/PEST blends were also compatibilized by addition of a PPS-PEST copolymer (Suenaga and Ishikuwa 1991). The alloys could be reinforced with GF, talc, mica, wollastonite, or clay (Gary 1993).

Polyarylethersulfone (PAES) (-[O-ϕ-O-ϕ-SO$_2$-ϕ-]$_{0.25n}$-[O-ϕ-SO$_2$-ϕ-]$_{0.75n}$-) blended with either PAr, PEST, PC, or their mixtures showed well-balanced mechanical properties and good environmental stress-cracking resistance (Robeson and Harris 1985, 1986). For improvement HDT, mechanical properties, and flame retardancy, PET was blended with a PAES: (-[-ϕ-SO$_2$-ϕ-O-ϕ-C (CH$_3$)-ϕ-O]$_n$-) (El-Hibiri et al. 1992). Blends of this type PAES with PC, PET, ZnBO$_3$, and PTFE had high flame retardancy (Jack et al. 1993).

Polyetherimide (PEI) was blended with PAr for improved moldability and mechanical properties (Holub and Mellinger 1981). Similarly, polyestercarbonate (PEC) was blended with either PEI, PA, PI, PAI, or their mixtures, to give alloys characterized by high HDT and tensile strength (Quinn 1984). Blends of PEI, PAr, and PC showed good moldability, flexural strength, and modulus (Holub 1990). Also PEI, PET, and PEC blends had good processability and impact strength similar to PEI (Quinn and Holub 1986). Adding ABS to PEI/PEST blends enhanced the impact resistance (Gaafar 1990). PEI was also blended with PBT and a cross-linking triallyl cyanurate and triallyl isocyanurate (Hosoi 1991). To produce soft, flexible, dimensional stable, and water-resistant materials, polyesteramide (PEA) was blended with PET (and/or PA-6) (Toray Industries, Inc. 1982).

PPE, PC, SEBS, and either PBT or PET	Stable morphology, processability, high impact strength, and solvent resistance	Brown et al. 1987
PPE/PET/PC/EGMA	For automotive applications	Yonetani et al. 1987
PPE/PET with SEBS-GMA	Excellent solvent resistance, moldability, impact and mechanical properties	Mayumi and Omori 1988
PPE/PET, EPR-MA, EVAc-GMA, MA or bis(4-phenyl isocyanate)	Processability, heat resistance, and mechanical properties	Nishio et al. 1988, 1994
PPE, PEST, PS, PC, SEBS, and/or acrylic modifier	High impact strength PPE alloys; *Gemax*™	Yates and Lee 1990
PPE/PBT with PC-b-PS-b-PC, PC, and either SEBS or MBS	Processability, tensile elongation and strength, as well as chemical and impact resistance	Brown and Fewkes 1992, 1994
PPE, PEST or TMPC, PS-VPh, HIPS	PEST is miscible with PVPh, thus PS-VPh is an efficient compatibilizer	Colby et al. 1993, 1994
PPE, PEST, PC-PBT, and SEBS	Excellent rigidity and impact strength	Chambers et al. 1995
Blends with modified PPE		
PPE modified with unsaturated dicarboxylate, e.g., fumaric acid	Reactively blended with PBT, PC, and SEBS for improved mechanical performance	Ishihara 1989
PPE modified with dimethylsiloxanes,	Blends with PPE, PEST, and SEBS for enhanced solvent and impact resistance	Brown 1989
PPE modified with an epoxy-compound	Blended with PPE, PEST, and hydrogenated poly-α-olefin for processability and impact resistance	Hasson and Yates 1993
PPE modified with end-capped with salicylic acid ester	Blended with SEBS and then dispersed in either PA, PEST, PEI, or PS; for processability, resistance to loss of impact strength after recycling	Richards and White 1994
PPE modified with either glycidol or epichlorohydrin	Blended with PP-MA, PP-GMA, *ionomers*, EVAl, PA, and PEST; for moldability, solvent and heat resistance, mechanical strength	Arashiro et al. 1994

The low-temperature phosphate glasses (LTG: -[-Zn-O-P(O_2Na)-O-P(O_2Li)-O-Zn-O-P(O_2Na)-O]-) have been blended with PET, PBT, PEK, PEEK, PPS, PEI, LCP, PC, etc. (Bahn et al. 1991). The blends containing up to 65 vol.% of LTG were reported to have good mechanical properties (Frayer 1993, 1994). The technology makes it possible to generate controlled morphology of the dispersed LTG phase as well as to ascertain its good bonding to the organic matrix.

1.6.3 Polyurethanes (TPU)

The polyester-type thermoset polyurethanes were commercialized in 1942, and the linear thermoplastic ones (TPU) 10 years later. Polyester-type TPUs, *Texin*™ resins for extrusion and injection molding, were introduced in 1961, whereas polyether-type, *Roylar*™, in 1971. Owing to great diversity of the ingredients, the TPU performance can be readily modified. For this reason, as well as because of the cost, TPUs are seldom blended. Their use can be divided into three groups: (i) blends with POM, (ii) blends in which TPU is used as a compatibilizer and impact modifier, and (iii) others.

1.6.3.1 POM/TPU Blends

The oldest and most common method of POM toughening is by incorporation of TPU. *Delrin*™ POM/TPU blends were commercialized in 1960. The others followed, e.g., *Celcon*™, *Duraloy*™, *Formaldafil*™, *Fulton*™ *KL*, *Hostaform*™, *RTP 800*, *TC*, or *Ultraform*™. These alloys have high impact strength and elastic recovery that depend on composition, morphology, as well as on the compounding and processing methods. Examples of these blends are listed in Table 1.65.

1.6.3.2 PC/TPU Blends

TPU has been used to toughen PC, to enhance its mechanical behavior and ESCR. The blends have been used in industrial and medical applications (De Boer and Heuschen 1988; Pinchuck 1991). Blends of PC/PET/TPU with EVAc-GMA and optionally MBS or ABS have good flexural modulus, strength, weld-line strength, solvent resistance, and impact behavior (Laughner 1994). PC blends with a polycaprolactone-polyurethane resin, TPU *Pellethane*™, and either MBS or MBA showed similar behavior (Henton et al. 1993).

Texin™ *3000* and *Texin*™ *4000* are the commercial blends. In the first TPU is the matrix, while in the second PC plays this role. The resins are used for the production of gears, tubings, housings, top-lifts, extruded profiles, and for the automotive industry and consumer goods.

1.6.4 Polycarbonate (PC)

Polycarbonates are polyesters of polyhydric phenols and carboxylic acid. Except for the lack of crystallinity, their properties resemble those of PEST. The most

POM/TPU, with SAN, ABS, AES, PC, PA, PAr, PPE, HIPS, acrylics, imidized acrylics, or SMA	For lower mold shrinkage, good stiffness, elongation, toughness, etc.	Flexman 1992
POM/TPU and EBA-GMA, with PA-612, PA-6, PP, or PET	Good modulus, impact strength, and processability	Subramanian 1992
POM/TPU and di-glycerin, pentaerythritol, *phenoxy*, or PVAl	Tensile strength and elongation at break, impact resistance, etc.	Nagai et al. 1993, 1994

common polycarbonate is that of bisphenol-A (PC), which was commercialized in 1956. PC is tough, transparent, self-extinguished, dimensionally stable, resistant to salts and oxidation, but susceptible to abrasion, stress cracking, and attacks by solvent, acids, and alkali. It is $T_g = 149\ °C$, but the ductile-brittle transition is at 0–10 °C. The resin ought to be toughened, for example, by addition of ABS, MBA, or MBS. The annual consumption and its growth rate of PC are, respectively, 700 kt and 5 %. About 40 % of PC is used in blends.

Originally, the commercial PC resins were linear polymers with high shear viscosity and low melt strength, thus difficult to process in operation involving extensional flows, viz., blow-molding stretching and foaming. Several years ago, branched PC (bPC) became available. The resin is usually blended with linear PC at the ratio that on the one hand is economically viable and on another that provides sufficient melt strength for the required process. For example, 60–95 wt% bPC (MW = 32–45 kg/mol) was blended with 5–40 wt% PC (MW = 15–27 kg/mol). The blends with MFR = 2–8 g/10 min were suitable for extrusion, injection molding, blow molding, and/or foaming at $T_{process}$ = 250–310 °C (Van Nuffel et al. 1998).

1.6.4.1 PC Blends with PPE

Blends of PPE with PC are immiscible and brittle; thus, they must to be compatibilized and toughened (see Table 1.66).

Table 1.66 Examples of PPE/PC blends

PS, PEST, SEBS, and/or MBA	High impact strength	Yates and Lee 1990
PBT, PC-PS-PC block copolymer, and impact modifier	Excellent rigidity and impact strength	Brown and Fewkes 1992, 1994
SAN/PS – compatibilized	Poly(butylacrylate-co-styrene-co-acrylonitrile)	Niessner et al. 1993
PEST/ABS with PS, HIPS, SEBS, PA, PC, and/or PEST	Multicomponent blends prepared by reactive processing	Laughner 1993, 1994
PEST, PC-PBT copolymer, and SEBS	Good rigidity and impact strength	Chambers et al. 1995

1.6.4.2 PC/POM Blends

These blends are immiscible, thus should be compatibilized and toughened. Addition of POM to PC improves the solvent and chemical resistance (Miller 1972). PC blends with POM and TPU were easy to mold into articles having high impact strength (Silvis et al. 1990). POM-b-PC was used either as a compatibilizer or as a modifier of performance for such polymers as PES, PEEK, PA, and PAN (Dhein et al. 1993).

1.6.4.3 PC Blends with Specialty Resins

There is a great diversity of polyimides (PI) having $T_g = 180$–$420\,^\circ$C. Several were blended with PC to improve its stiffness, HDT, and strength. PEI/PC blends were commercialized in 1992 as *Ultem™ LTX*, for injection molding or extrusion. They show higher impact resistance than PEI and higher heat resistance than PC, as well as they retain the strength, chemical resistance, and the hydrolytic stability of PEI.

Fluoropolymers are notoriously immiscible with any other polymer. Usually, they are dispersed in blends of engineering and specialty polymers either to improve processability or to induce lubricity and abrasion resistance. Examples of the PC/specialty resin blends are listed in Table 1.67.

1.6.5 Polyoxymethylene (POM)

Polycondensation of formaldehyde was reported by Butlerov in 1859, but only in 1950 du Pont developed end-capping that prevented unzipping. POM is crystalline, thus rigid, brittle, and chemically nonreactive. Production of *Delrin™* and *Celcon™* started in 1959 and 1962, respectively. The world consumption of POM and its annual growth rate are 500 kt and 5 %.

The most common POM blends are homologous mixtures of POMs having different molecular structures (linear, branched, cross-linked) (Matsuzaki 1991), different molecular weights (Ishida and Sato 1970), or with different end groups (Nagasaki et al. 1991; Hanezawa and Ono 1991). On the second place are blends of POM with TPU, preferably polyester type. POMs are also blended with core-shell acrylic elastomers, MBS or MBA. Commercial blends of POM with PEST are available. To improve weatherability of POM, the resin was blended with PMMA and a fluoropolymer (viz. PTFE, PVF, PVDF) (Katsumata 1991).

For the manufacture of sliding parts, POM blends were developed with PTFE (Ishioka 1991); with PVDF (Shibata et al. 1992); with either wax, PTFE, silicone oil, or PEG; and with EBA-GMA (Takahashi and Kobayashi 1993). Later blending technology of POM involved introduction of the reactive end groups – it makes compatibilization with other polymers relatively simple.

Addition of PPE/PS to POM was used to improve processability, HDT, and mechanical properties (Ishida and Masamoto 1974). Then, POM with a Lewis acid was incorporated into PPE/PA blends to improve compatibilization and induce high heat and impact resistance (Takayanagi et al. 1994). POM blends with specialty polymers are formulated either to take advantage of POM (the resistance to abrasion) or of the specialty resin (e.g., to improve stiffness and wear resistance by incorporation of PEEK or PEI) (Suzuki and Nagahama 1987). POM is miscible with polyvinylphenol, PVPh; thus addition of PVPh to blends of POM with COPO compatibilizes the system (Machado 1993).

1.6.6   Polyphenylene Ether (PPE)

In 1956, by oxidative coupling of *2,6*-dimethyl phenol, poly(2,6-dimethylphenyl ether) was obtained (PPE) (Hay 1959, 1964, 1967, 1968). The resin was commercialized in 1964. PPE is amorphous (T_g = 210 °C), but it can crystallize (T_m = 257 °C). It is thermally stable only to T $\leq$ 150 °C (CUT = 125 °C). It has good rigidity, creep resistance, dimensional stability, and high electrical, chemical, moisture, and flame resistance. The main disadvantages are processability, oxidative degradation, low-impact strength, and weatherability. The resin is usually

"plasticized" by blending with styrenics. The annual production and growth rate of PPE are, respectively, 300 kt and 9 %.

1.6.6.1 PPE Blends

The first PPE blends with PS and polydiphenylsiloxane (PDPS) were reported to be transparent, colorless solids that turn into liquid at 85 °C (Boldebuck 1962). Since then PPE has been modified by blending (e.g., with HIPS, ASA, MBA, SBS or SEBS, etc.), by grafting (Brown 1989), or by reacting its end groups (Richards and White 1994).

Modified PPE is mainly blended with other engineering resins – most of these were already discussed. The principal types of PPE blends are with styrenics, with PA, and with PEST. Owing to miscibility of PPE with PS, the compatibilization is relatively simple. However, blending PPE with either PA or PEST is more challenging, since these systems require reactive compatibilization. Development of PPE grafted with acidic functionality was motivated by this need.

PPE has been blended with most specialty resins – the latter usually as a minor component. Exceptions are the PPE/PPS alloys. Their performance depends on the level of PPS crystallinity. The commercial blends, *DIC PPS* (introduced in 1982), were developed for the electrical, electronic, and mechanical industry. These show good processability, reduced flash in injection molding, toughness, high heat, and chemical resistance.

Several blends of PPE with specialty resins are parts of multicomponent systems. For example, PI was blended with PPE and then cured. The alloys were used as rigid and stable matrices for manufacturing fiber-reinforced composites (Camargo et al. 1986). Similarly, end-capped PPE was blended with SEBS and then dispersed in either PEI, PA, PEST, or PS, to give improved resistance to loss of impact strength after thermal recycling (Richards and White 1994). Blends of PAI with PPS and at least one of either PA, PEST, PC, PPE, PSF, PES, PEI, PEK, PEEK, PPS, PEST, PA, PEA, or siloxanes were compatibilized with aromatic polyisocyanates. The systems showed excellent flowability, high heat resistance, and mechanical strength (Kawaki et al. 1995). Examples of PPE/specialty polymer blends are listed in Table 1.68.

1.6.6.2 Miscible PPE Blends

Miscibility of PPE with PS has been known since 1960. Later, two other PPE blends were announced miscible. PPE blends with polytransoctanylene (PTO) can be processed at 260 °C and have HDT ≥ 194 °C. The patents suggested that PTO is miscible with PPE (Jadamus et al. 1986, 1987). The PPE blends with polyphenyl methacrylate, poly(*p*-methoxy phenyl methacrylate), poly(benzyl methacrylate), or poly(3-phenyl propyl methacrylate) were reported to have the lower critical solution temperature, LCST = 105–150 °C (Fischer and Siol 1993, 1995).

Immiscible, but transparent, are blends of PPE with a copolymer of cyclohexanedimethanol, ethylene glycol, and terephthalic acid (PCTG) – the clarity was achieved by closely matching the refractive indices at the use temperature. The alloys also show good processability, thermal dimensional stability, and economy (Stewart and Massa 1993).

1.7   Specialty Polymers and Their Blends

The *specialty* resins are expensive, produced in relatively small volumes either for a specific application or looking for a market niche. Their $T_g > 200$ °C and modulus > 3 GPa. In 1991 the total world consumption of polysulfones (PSF) and polyethersulfones (PES) was 8.5 kt. Blends of the following polymers are known: polyfluorocarbons, polysiloxanes, sulfur-containing polymers (PPS, PPSS, PES, and PSF), polyetherketones (PEK, PEEK, PEKK), polyimides (PI, PEI, and PAI), PAr, COPO, polyphosphazene (PHZ), and LCP.

1.7.1   Fluorocarbon Polymers

Known in Germany since 1933, polytetrafluoroethylene (PTFE) is a semicrystalline resin (92–98 % crystallinity), with $T_m = 342$ °C and melt viscosity of $\eta \approx 10$ GPas. Other more common fluoropolymers are polychlorotrifluoroethylene (PCTFE), *Hostaflon™* commercialized in 1934, fluorinated ethylene-propylene (FEP), *Teflon™-FEP* introduced in 1972, and numerous copolymers with $T_m = 260$–304 °C, processable at $T_{process} = 315$–425 °C and having the degradation temperature $T_{deg} = 425$–440 °C. The fluoropolymers are characterized by stability at high temperatures; toughness and flexibility at low temperatures; low friction, insolubility, and inertness to chemicals; low dielectric losses; and high dielectric strength. The world consumption of fluoropolymers in 1991 was 72 kt.

In blends, fluoropolymers are used in small quantities to enhance throughput, reduce the frictional properties, and increase the wear resistance. Blends comprising 0.3–50 wt% of a low molecular weight PTFE ($T_m \leq 350$ °C) with engineering resin showed improved antifriction properties (Asai et al. 1991). LLDPE generally exhibits sharkskin melt fracture, but the use of fluoropolymer additives, such as the copolymer of vinylidene fluoride and hexafluoropropylene, can help to eliminate the extrusion instability (Hatzikiriakos and Migler 2005).

PPS and PEEK which blended with fluoro(co)polymers and reinforced with either CF or GF were wear resistant with a short break-in period for forming a self-lubricating film (Davies and Hatton 1994). Many commercial blends contain fluoropolymers (primarily PTFE) for the improved weatherability and wear and solvent resistance: *SUPEC™* – "self-lubricating" blend of crystalline PPS with

PTFE and 30 wt% GF, *Lubricomp*™ blends from LNP and similar *RTP*™ blends from RTP Co. (e.g., 15 wt% PTFE, 30 wt% GF, and any of the following resins: ABS, PA, PEST, PC, PE, PEI, POM, PP, PPE, PPS, PS, PSF, PVDF, SAN, TPU, PEEK, PES, etc.), *Sumiploy*™ from Sumitomo Chem. Co., etc. (Utracki 1994).

1.7.2 Siloxane Polymers

Polysiloxanes, [-O-Si(RR′)-], are linear resins that can be branched or cross-linked into elastomers. They have high compressibility, permeability to gases, low T_g and viscosity, exceptional weatherability, low surface tension coefficient, and are relatively expensive. Siloxane polymers or copolymers have been incorporated into engineering or specialty resins to improve processability, toughness, HDT, and solvent and weather resistance.

The main polymers of this type are polydimethylsiloxane (PDMS) and polymethylphenylsiloxane (PMPhS). Their $T_g = -127$ and -86 °C, respectively. They start oxidizing at 290 °C and 375 °C and undergo structural rearrangement at 435 °C and 410 °C. Polysiloxanes have been used as high temperature impact modifiers that improve the flame resistance, processability, and optical properties. Several commercial blends are on the market, viz., *Rimplast*™ (high tensile, flexural, and Izod impact strength PAs), *Dialoy*™ (PC/PET blends with good chemical, weather, and low-T impact resistance), etc. Evolution of polysiloxane blends with engineering and specialty resins is summarized in Table 1.69.

1.7.3 Polyarylene Sulfide (PPS)

Polyarylene sulfides (PPS), (-φ-S-)$_n$, was commercialized in 1971 as *Rayton*™ *R*. The resin is semicrystalline with $T_g = 194$ °C and $T_m = 288$ °C; thus $T_{process} \geq 290$ °C. PPS is difficult to mold – it tends to adhere to the mold surface and to flow into mold crevices. It has also relatively poor impact resistance. Blends have been developed to alleviate these problems, e.g., with 25 wt% of either PSF, PPE, or PC (Bailey 1977). Commercial PPS blends are available with PPE (e.g., *DIC PPS* commercialized in 1982, *Noryl*™ *APS*), PARA (*RTP 1300*), or PTFE (*Lubricomp*™ *PPS*). They show good processability with reduced flash, are tough, excellent wear, as well as high heat, solvent, chemical, and oxidation resistance.

PPS has been frequently blended with PSFs. The latter resins are mainly amorphous, frequently transparent, with $T_g = 196–288$ °C, able to maintain high-performance characteristics over a wide temperature range, but poor weatherability, notched impact strength, and ESCR. The PPS/PSF blends have been developed to improve PPS processability and/or the mechanical performance over a wide range of temperatures, to improve PSF weatherability, impact, and ESCR characteristics. Evolution of these blends is outlined in Table 1.70.

PArs are aromatic amorphous polyesters, viz., *U-polymer*™, *Ardel*™ *D-100*, *Durel*™, *Arylon*™, etc. Their $T_g \approx 188$ °C and HDT = 120–175 °C. Blends with

PHZ or its copolymer with a siloxane polymer and/or elastomer	Bisazoformamide (foaming agent) gave semirigid, highly flame-retardant foams	Dieck and Quinn 1977

PPS have been developed to improve the performance of PAr – processability, rigidity, and hydrolytic stability.

To the category of amorphous, aromatic polyamides (PARA) belong polyphthalamides (PPhA), e.g., *Amodel*™ (T_g = 127 °C, T_m = 310 °C, HDT = 285 °C, CUT = 180 °C). PPS/PARA blends were formulated to increase the reinforcing effects of GF on PPS. They show good processability, mechanical performance, and resistance to thermal degradation.

Polyimides (PI) were introduced in 1962 as thermally non-processable *Kapton*™. To improve processability, the main-chain flexibility was enhanced by incorporating segments with higher mobility, viz., polyamide-imide (PAI), polyetherimide (PEI), polyimide-sulfone (PISO), etc. These polymers are characterized by high T_g = 150–420 °C and thermal resistance. They are blended with PPS to enhance its moldability, thermal stability, and mechanical performance.

Polyaryletherketone (PEEK), [-ϕ-CO-ϕ-O-ϕ-O]$_n$, was commercialized in 1980 as *Victrex*™. It is a tough resin with T_g = 143 °C and T_m = 334 °C. Blends of PEEK with PPS show synergistic effects toward tensile and flexural strength as well as the impact resistance.

The inorganic low-temperature glasses (LTG) with $T_g \leq 300$ °C are durable and water resistant. LTG was blended with either PPS, PET, PBT, PEK, PEEK, PEI, LCP, PC, or fluorinated polymers (Frayer 1993, 1994).

Oxidation of PPS by addition of N_2O_4 in a sulfuric acid solution results in the incorporation of surfoxide groups, leading to either polyphenylenesulfidesulfoxide or polyphenylenesulfoxide. Their blends with high temperature resins (viz., PSF, PES, PPS, PEI, PAr, PEEK, PC, PI, PAI, LCP, fluoropolymers, cycloolefins, and their alloys or composites) produced high temperature-resistant foams by heating for 5–60 min at T = 300–470 °C (Scheckenbach et al. 1998). The process reduced the moldings' density by at least 50 %.

1.7.4   Polysulfone (PSF)

Polyarylsulfones (PSF or PSU), or polyarylethersulfones (PAES), have the chain structure (-ϕ-SO$_2$-)$_n$. The commercial resins include *Udel*™ PSF,

5. PPS with PEEK and LTG		
PPS with 10–90 wt% PEEK	Processability, strength, and impact resistance	Robeson 1982
PPS/PEEK/PMP, GF, organosilane	Mold release and reduced molding flash	Hindi et al. 1994
Low-temperature glasses (LTG) with 35 wt% PPS	Rigidity, dimensional stability, strength	Frayer 1993, 1994

$[-\phi-C(CH_3)_2-\phi-O-\phi-SO_2-\phi-O-]_n$ (T_g = 196 °C and CUT = 160 °C), *Astrel*™ $[-\phi-\phi-SO_2-\phi-O-\phi-SO_2-]_n$ (T_g = 288 °C), *Victrex*™ PES $[-\phi-SO_2-\phi-O-]_n$ (T_g = 228–232 °C), *Radel*™ *R* PPSF $[-\phi-\phi-O-\phi-O-\phi-SO_2-\phi-O-]_n$ (T_g = 220 °C), *Ultrason*™ *E*, *Talpa*™ *1000*, *Sumilite*™, polyimidesulfone, PISO, *Amoron*™ polythioethersulfone, PTES, etc. Then there is the sinterable polyphenylenesulfone, *Ceramer*™ $[-\phi-SO_2-\phi-]_n$ (T_g = 360 °C, $T_{decomp.}$ > 450 °C), used as an "additive" to high-performance polymers used in harsh environment (Ceramer 1996).

PSFs are transparent; flame resistant; have high strength, modulus, and hardness; and HDT > 200 °C. They show excellent resistance to thermal and irradiation degradation, but are difficult to process (high melt viscosity) and have low ESCR and poor weatherability. The latter properties can be improved by blending and/or reinforcing. PSF blends comprise high-performance resins, viz., PPE, PPS, PTFE, etc., with such compatibilizers/impact modifiers as *phenoxy*, EVAc-GMA (Gaafar 1990), SMA copolymers (Golovoy and Cheung 1994), siloxane-polyarylene polyether copolymers, or high temperature MBS. *Mindel*™ *A* and *Arylon*™ are examples of the commercial ASA/PSF blends. They show good processability, toughness, plateability, and heat and water resistance.

Addition of a small amount of PSF to a variety of resins improves hardness, the notched Izod impact strength, plateability, hydrolytic stability, and shape retention at high temperatures. Many PSF blends of or with engineering resins have been developed, viz., with PA, PEST, PC, PPE, or POM. They have high HDT, heat resistance, strength, stiffness, mechanical properties, and ESCR. Polysulfone blends have been foamed using water and either N_2 or CO_2 (Bland and Conte 1991). The blend comprised at least two sulfone polymers, e.g., PES and PSF, and at least one non-sulfone polymer (e.g., PS, PPE, PEI, PC, PA, PEST, PP, or PE). The nucleating agent was either talc, mica, silica, Zn-stearate, Al-stearate, TiO_2, or ZnO. The foams were used as insulation for high temperature structural applications. Since in the preceding part PPS blends with PSF were described, in Table 1.71 examples of PSF blends with other specialty resins are listed.

1.7.5 Polyetheretherketone (PEEK)

Polyaryletherketones (PAEK) are aromatic polymers with ether and ketone linkages in the chain, viz., PEK, PEEK, PEEKK, etc. Polyetheretherketone (*Victrex*™ PEEK), $[-\phi-CO-\phi-O-\phi-O-]_n$, was commercialized in 1980 (T_g = 143 °C, T_m = 334 °C). Commercial blends of PEEK include *Sumiploy*™ PEEK/PES/ PTFE, PEEK/LCP, *Cortem*™ PEEK/LTG, etc. Evolution of PEEK blends' technology is outlined in Table 1.72.

1.7.6 Polyimides (PI, PEI, or PAI)

Polyimides (PI) have imide group, $-R-N = (CO)_2 = R'-$, in the main chain. Owing to a variety of possible R and R' groups, their T_g = 180–420 °C. To improve

Table 1.71 PSF/PI blends

Composition	Comments	References
1. PSF/PI		
PAI with 0.1–50 wt% of either PSF, PA, or PARA	Improved melt flow and good mechanical properties	Toray Industries, Inc. 1979, 1980, 1981
PES/PPBA (T_g = 200–300 °C)	For lacquers and homogenous, clear films	Patton and LaMarre 1983
PEI with PSF, PP, PEC, or PAr; with PC and PEST, PAr or PA, etc.	For good processability, improved flexural and impact strength	Giles, 1983, 1984
PI with 0.01–10 phr PSF solution cast	For films with good blocking resistance	Mitsubishi Chem., 1984
PI with PEI, PES, PAr, PC, PEEK, or PPE, e.g., PI: PEEK: PEI = 1:1:1	T_g = 175 °C, used as crack-resistant coatings with good adhesion to metal	Camargo et al. 1986
PI with PSF, PPS, PPE, or PEI	Moldability, heat and chemical resistance	Ohta et al. 1988
PES with PEI	Improved HDT	Melquist 1993
PES/sulfonyl *bis*(phthalic anhydride)-co-*bis*(*p*-amino cumyl) benzene	Processability, solubility, mechanical, and thermal properties	El-Hibri and Melquist, 1993
LCP-type PI with PES, PI, PEI, PAI, PEK, or PEEK	Remarkably good processability and excellent thermal stability	Okawa et al. 1994
PES/PI (e.g., *XU*-218 or *PI*-2080) miscible blends (single T_g, UCST)	High moduli, tensile strengths, and impact strengths	Karasz and MacKnight 1994
2. PSF blends with fluoropolymers		
PSF/PPS/5–40 wt% PTFE fibrils	Processability, lubricity, anticorrosive	Bailleux et al. 1984
PES/0.3–50 wt% low MW PTFE	Self-lubricity	Asai et al. 1991
PSF/PC or PET, ZnBO$_3$, and PTFE	Flame-retardant, synergistic properties	Jack et al. 1993
Fluorine-containing polycyanurates with PSF, PP, or PEEK	Flame-retardant, low thermal expansion, T_g = 180–320 °C, stable to 430–500 °C	Ardakani et al. 1994
3. PSF blends with other specialty resins		
PES, with poly(*p*-phenylene ether-co-*p*-phenylenesulfonyl)	Miscible, transparent solvent-cast films, with good water and chemical resistance	Newton 1981
PSF with 70 wt% polyether-amide (PEA)	Moldability, high HDT and mechanical properties	Hitachi Chemical Co., Ltd., 1983
PSF/acrylic elastomer/ polyphosphates	Thermal stability, flame retardancy, toughness	Schmidt, 1983
PEEK/PAES with HDT = 157 °C	Low warpage and shrinkage, rigidity, stress-cracking, solvent, and impact resistance	Harris and Robeson 1986, 1987
PES, PEEK, and 20 wt% PEI	Mechanical properties and heat resistance	Rostami 1987
PES/95-75 wt% PEEK	Chemical and hot-water resistance	Tsumato et al. 1987

<div align="right">(<i>continued</i>)</div>

Table 1.71 (continued)

Composition	Comments	References
PAEK, PAE, or PPE, blended with LCP, PI, PAES, or PEST	Processability (warp-free moldings), mechanical properties, and high HDT	Harris and Michno 1988
PES with phenoxy	Chemical resistance and tensile strength	Kraus et al. 1991
PSF with PVP or PEG, radiation cross-linked	For selectively permeable membranes or hollow fibers	Kobayashi and Tanaka 1992
Biodegradable PLA with either PSF, PC, PI, PPE, etc.	To improve the thermal properties	Nemphos and Kharas 1993
PES dissolved in oligooxybenzoyl acid and then polymerized to POBA	Molecular composites, polymerizing while shearing	Tochioka 1993

Table 1.72 PEEK blends with specialty resins

Composition	Comments	References
PEEK/PAI and optionally with PPS	Solvent resistance, hydrolytic stability	Harris and Gavula 1986
95–75 wt% PEEK with PES	Chemical and hot-water resistance	Tsumato et al. 1987
POM/10 phr of PEEK and/or PEI	Wear resistance without loss of slipperiness	Suzuki and Nagahama 1987
PEK/PAI and zinc sulfate hydrate	Good moldability and high impact strength	Smyser and Brooks 1990
LTG with either PEK, PEEK, PPS, PEI, LCP, PC, PET, PBT, or fluorinated polymers	Processability, mechanical properties, stiffness – *Cortem™ Alloys* with either LCP or with PEEK	Bahn et al. 1991
Crystalline and amorphous PEK with PAr	Good flowability and processability	Falk and Herrmann-Schoenherr 1992
POM-b-PC with PES, PEEK, PA, or PAN	Film-forming thermoplastic polymeric alloys	Dhein et al. 1993
ASA, PC, PEST, PEC, PPE, PPS, PEEK, PES, PSF, and/or PPE	Toughened by 30–80 wt% elastomer, e.g., SEBS and core-shell graft copolymers	Niessner et al. 1994
PPS blends with PEEK	Improved mold release and reduced flash	Hindi et al. 1994
PI, PAI, PSF, PEI, PES, PEEK, PPS, or PPE and a polyether-b-polyamide or polyether-b-polyester	Easy to mold blends, flexible and elastic, with excellent chemical and thermal resistance	Movak et al. 1994
PEKK/PEI = 70/30 w/w co-reacted through the terminal amine group of PEI and ketone one of PEKK	Resulted compound with strain hardening was water foamable at T = 335–350 °C, whereas neither PEKK nor PEI can be foamed	Brandom et al. 1997

Table 1.73 PI blends

Composition	Comments	References
PEI with PAr	Moldability and mechanical properties	Holub and Mellinger 1981
PEI/PAI = 1:1	Mechanical properties and ESCR	Maresca et al. 1981
Polyarylethers with PEI	Good ESCR	Robeson et al. 1981
PEI, poly(carbonate-b-siloxane), and EPDM, ABS, MBS or MMBA	Processability and impact strength	Giles and White 1983
PEI, PA-6, and PEI-b-PA	Moldability and impact strength	Robeson and Matzner 1984
PEI with polyestercarbonate (PEC)	High HDT and tensile strength	Quinn 1984
PEI/0.5–20 wt% of a fluoropolymer	Mold release, heat resistance, and shrinkage	Sumitomo Chem. 1985
PI with PAI in the full range of composition	Foamed during the final stage of the condensation reaction at T = 120–320 °C	Long and Gagliani 1986
PI, with PPS, PPE, PEI, and PSF	Moldability, heat stability, chemical resistance, and mechanical strength	Ohta et al. 1988
PEI with PPE-MA	Mechanical performance	White and van der Meer 1989
PEK with either PES, PEI, PEEK, PEST, PAr or PPS, and filler	Processability, mechanical strength, as well as heat and flame resistance	Murakami et al. 1991
PEI, PBT, and triallyl cyanurate and triallyl isocyanurate	High thermal deformation resistance and HDT	Hosoi 1991
Low-temperature glasses with PEI	High modulus, mechanical performance	Bahn et al. 1991
Polyether-b-polyimide-b-siloxane copolymer with low MW PEI	Impact-resistant materials with excellent processability and HDT	Durfee and Rock 1993
PPS/PEI with 30 wt% GF	High flow and no flash	*Supec™ CTX530*
Fluoro-elastomers dispersed in a resin, e.g., PI, PAI, PSF, PEI, PES, PEEK, PPS, PPE, etc.	Moldings: flexible, elastic, self-lubricating, having excellent chemical and thermal resistance	Movak et al. 1994
LCP-PI with either PI, PEI, PAI, PES, PEK or PEEK	Remarkably good processability and excellent thermal stability	Okawa et al. 1994
PBI with 0–95 wt% of PEI	Thermo-oxidative stability	Haider and Chenevey 1994
PI blended with PMS and then foamed by the thermal decomposition of PMS	Nano-foams showed increased craze zone size and higher crack stability than the not-foamed PI films	Plummer et al. 1995; Charlier et al. 1995

processability, flexible groups were incorporated into the main chain. Examples of blends of these resins are listed in Table 1.73.

Polyamideimides (PAI) were obtained by polycondensation of imides with aromatic diamines, $[-N=(CO)_2=\phi-CO-NH-R-NH-CO-\phi=(CO)_2=N-]_n$ ($T_g = 275$ °C, HDT = 265–280 °C). The resin has high tensile and impact strength from T = −190 to T = 260 °C, dimensional stability, good dielectric properties, solvent and chemical

resistance, flame retardancy, good UV stability, and low outgassing in high vacuum. To improve processability, PAI was blended with PA, PSF, or PEST (Toray Industries, Inc. 1979).

Polyetherimide (PEI), [-N(CO)$_2$-ϕ-O-ϕ-C(CH$_3$)$_2$-ϕ-O-ϕ(CO)$_2$CN-ϕ-]$_n$ (T$_g$ = 215–220 °C, HDT = 217 °C, CUT = 170 °C, no weight loss at T $\leq$ 400 °C), was commercialized as *Ultem™*. The resin has high tensile modulus (even at elevated temperatures), approaching that of many glass-reinforced resins. Commercial PEI blends include these with PC (*Ultem™ LTX* introduced in 1990), with PPS (*Supec™ CTX530*) (Utracki 1994), or with polyphenylsulfone (Sanner and Gallucci 2011).

Polyimidesulfone (PISO) was introduced in 1986 *Celazole™* (T$_g$ = 249–349 °C). This transparent resin with flexural modulus of 4.8 GPa and tensile strength of 63 MPa has shown excellent solvent and creep resistance.

1.7.7 Aromatic Amorphous Polyamides (PARA)

There is a great diversity of amorphous aromatic or semi-aromatic polyamides (PARA). The commercial resins include *Trogamid™*, *Quiana™*, *Amodel™*, etc. They have been blended to improve the mechanical properties and impact strength, as well as to enhance the barrier properties of the matrix resin to permeation by gases or liquids. Examples of blends with PARA are listed in Table 1.74. Blends of PARA were also discussed along other blends of polyamides.

Table 1.74 Blends with aromatic amorphous polyamides (PARA)

Composition	Composition	References
PARA with POM	Toughness and impact strength	Asahi Chem. Ind. 1969
PARA with semicrystalline PA	Improved oxygen barrier properties	Dynamit Nobel 1969
PAI with PA-66 or PARA	Processability and mechanical properties	Toray Ind. 1979, 1981
PARA with PC	Nacreous, resistant to oils and boiling water	Mitsubishi Chem. 1980
PARA with 5–95 wt% PPS	Improved moldability, HDT, and impact strength	Shue and Scoggins 1981
PARA with PA-6I6T	For strong fibers or films	Unitika Co., Ltd. 1982
PARA with PES	Increased HDT and mechanical performance	Hub et al. 1986
PPS with PPhA and GF	Stiff, high-performance reinforced alloys	Davies 1990
PARA with maleated PP or PE	Sliding electrical parts, resistance to thermal degradation in contact with Cu	Iwanami et al. 1990
PARA with rubber-modified PS	Transparent, having near-zero birefringence	Angeli and Maresca 1990
PARA with PAr are miscible	Processability, mechanical properties, solvent, weather, HDT, impact and stress-crack resistance	Bapat et al. 1992

Table 1.75 Blends with linear, aromatic polyesters (PAr)

Composition	Comments	References
PAr with PC and PET	Improved impact resistance	Koshimo 1973
PAr blends with PET	Transparent and impact resistant commercial blends	*U 8000* from Unitika or *Ardel™ D-240* from Amoco
PAr/PET = 1:1 with PA-6 or PPS	Enhanced mechanical properties	Asahara et al. 1977a, b
PAr with 1–99 wt% PPS	Processability, impact strength, fire and abrasion resistance	Matsunaga et al. 1978
PAr/PPS and dodecachloro-dodeca-hydro-dimethano-di-benzocyclooctene	Good hydrolytic stability, moldability, and flame retardancy	Salee 1980, 1981
PAr/PET/PPS with ABS or MBS	Improved hydrolytic stability	Salee 1982
PAr with PA-6, *U-polymer™* X-9	Processability, mechanical properties	Unitika, Ltd. 1982, 1983
PAr with polybenzimidazole (PBI)	Miscible blends	Chen et al. 1990

1.7.8 Polyarylates (PAr)

These polyesters, $[\text{-O-}\phi\text{-C(CH}_3)_2\text{-}\phi\text{-CO}_2\text{-}\phi\text{-CO-}]_n$ ($T_g \approx 188$ °C and HDT = 120–175 °C), were introduced in 1974. The commercial resins include *U-polymer™*, *Ardel™*, *Durel™*, and *Arylon™*. Their advantages include transparency, good weatherability, and high HDT. PAr has been blended with nearly all resins, including ABS, EPDM, *ionomers*, LCP, PA, PB, PBI, PBT, PC, PEI, PEK, PET, *phenoxy*, PMB, PS, PPE, PPS, etc. Three types of PAr blends are of particular importance – those with polyesters, PEST, polyamides, PA, and polyphenylenesulfide, PPS. A summary of PAr blends is provided in Table 1.75.

1.7.9 Aliphatic Polyketone (COPO)

This copolymer of carbon monoxide with ethylene and propylene is semicrystalline, with $T_g = 15\text{–}20$ °C, $T_m = 110\text{–}242$ °C (Ballauf et al. 1941). *Carilon™* resin (introduced in 1995) is a strictly alternating copolymer, $[\text{-CO-C}_2\text{H}_4\text{-}]_n$, obtained using metallocene catalyst. It has $T_m \approx 220$ °C, tensile strength $\sigma = 80$ MPa, and elongation at break $\varepsilon = 25\%$. The moldings have outstanding wear and friction resistance, high resilience over a wide temperature range, low sensitivity to water and organic solvents, and good barrier properties, but they are sensitive to UV. Several blends of COPO have been patented, e.g., with SAN (miscible blends), PA-6, and SEBS-MA (Machado 1992), with TPU (George 1992), and with POM and PVPh (Machado 1993).

1.7.10 Blends with Rigid-Rod Polymers

Three types of blends belong to this group: (1) molecular composites, i.e., the molecular LCP solutions, (2) immiscible blends of LCP, and (3) blends of electroconductive polymers.

1.7.10.1 Molecular Composites

In fiber-reinforced composites, the absolute size of the reinforcing fibers is not important, but good adhesion to matrix and the length-to-diameter ratio of the fiber, L/D ≥ 500, are (Piggott 1986). Accordingly, reduction of the reinforcing particle size from, e.g., GF or CF, to rigid-rod molecules seems desirable. If the reinforcement is to be provided by individual macromolecules, the rigid-rod polymer must form molecular solution in selected thermoplastic resin. Such systems are known as *molecular composites*, MC, first generated in the late 1970s (see Table 1.76).

MC can be prepared by dissolution of either the rigid-rod polymer in a monomer that subsequently can be polymerized or by dissolving monomer of the rigid-rod polymer in a thermoplastic resin and then polymerizing it. The selections of the soluble monomer/polymer pair as well as control of the polymerization and phase

Table 1.76 Molecular composites

Composition	Comments	References
Poly(*p*-phenylenebenzobisthiazole) with poly(2,5,(6′)-benzimidazole)	MC of oriented macromolecules; films and fibers had high modulus and strength	Hwang et al. 1983
Poly(*p*-phenylene terephthalamide) (PPTA) with PA-6 or PA-66 in methanesulfonic acid	Coagulation resulted in MC that upon thermal treatment phase separated	Chuah et al. 1989a, b
Poly(2,5,(6′)-benzimidazole) with PAr	MC miscible system	Chen et al. 1990
Rigid-rod [-CO-ϕ(CF₃)-ϕ(CF₃)-CONH-ϕ(CF₃)-ϕ(CF₃)-NH-] in vinylpyridine or pyrrolidone	Polymerization of the monomeric solvent resulted in MC	Stein et al. 1992
Polybenzimidazoles, 5–95 wt% with PARA blended in DMF	Miscible by film transparency, single T_g, FTIR, and X-ray diffraction	Calundann et al. 1992; 1994
PES dissolved in polyoxybenzoyl or *p*-aceto-aminobenzoic acid, polymerizing the latter at the shear rate of 2.0–13 1/s	Solvent-free MC, high modulus and strength, for the manufacture of fibers or rod-shaped extrudates	Tochioka 1993
70–99 wt% PGI, and either PBI or LCP, with PET or PC	Good balance of toughness, tensile modulus, and HDT	Hallden-Abberton et al. 1994
Dissolution of PA or PO in lactams and then polymerizing it into a rigid-rod, e.g., poly(*p*-aminoethyl benzoate) (PAEB)	MC: N-(*p*-amino benzoyl) caprolactam in molten maleated PP, PA-6, PA-66, or PARA and then polymerized; PA modulus x2	Mülhaupt et al. 1994
Poly[2,2′-(*m*-phenylene)-5,5′-bis benzimidazole] (PBI) with 0–65 wt% PEEK	Mechanical, thermal, and chemical properties; for gaskets, seals, valve seats, and O-rings	Andres et al. 1995

separation rates are critical. The IPN approach may "lock" the dispersed structure into a metastable system with sufficient stability for processing (Utracki 1994).

1.7.10.2 Liquid-Crystal Polymers (LCP)

There are several commercial LCPs, viz., *Ekkcel*™ (degrades at $T_{process}$ 400 °C), *Xydar*™, *Vectra*™, *E-konol*™, *X-7G*, *Ultrax*™, *KU 1-90*, *Granlar*™, *Novoaccurate*™, *Rodron*™, *Victrex*™, etc. LCPs are mainly used for injection molding of parts that require exact dimensions and high performance.

Large quantity of LCP is used in blends. These are immiscible, highly oriented systems, where LCP domains provide reinforcement. Since LCPs are expensive, either the desired performance must be achieved using a small amount of melt processable LCP, or the other component of the blend is similarly priced. In blends LCP can (i) improve processability of engineering and specialty polymer (Froix et al. 1981; Cogswell et al. 1981, 1983, 1984), (ii) enhance crystallization of semicrystalline polymers (Hong et al. 1992), (iii) improve stiffness and other mechanical properties in applications where fatigue strength is important (Yamauchi et al. 1991), (iv) provide external protective layer for solvent and/or abrasion sensitive resins, etc. Excepting those with PP, the LCP blends with commodity resins are scarce (see Table 1.77).

1.7.10.3 Electro-Dissipative and Electroconductive Blends

Most organic polymers are insulators. However, there are applications requiring dissipation of the electrostatic charge (ESD) or even electrical conductivity (ECP) that would be comparable to that of metals. The ESD materials should have the surface resistivity $10^{12} \geq R \geq 10^5$ Ω cm. The resistivity of ECP should be $10^5 \geq R \geq 10^{-2}$ Ω cm.

The ESD behavior can be provided by blending in a flexible-chain polymer with an active -OH or -SH group, viz., polyvinyl alcohol (PVAl), ethylene-vinylacetate (EVAc), polyvinylphenol (PVPh), a copolymer of ethylene oxide and epichlorohydrin (EO-CHR), maleated copolymer, aliphatic polysulfides, etc. These low performance resins have been incorporated into a variety of alloys and blends (see Table 1.78).

By contrast, the ECP must have conjugated rigid-rod macromolecules. Several such polymers show high electrical conductivity (usually after doping), viz., polyacetylene (PAc), polyaniline (PANI), polypyrrole (PPy), polyparaphenylenes (PPP), or poly-3-octyl thiophene (POT). The resins are expensive, difficult to process, brittle, and affected by ambient moisture, thus blending is desirable. For uniaxially stretched fibers, the percolation threshold is 1.8 vol.%; hence, low concentration of ECP (usually 5–6 vol.%) provides sufficient phase co-continuity to ascertain conductivity similar to that of copper wires (see Table 1.78).

As a synthetic strategy, simple and versatile reactive blending will continue to play a pivotal role in the development of newer materials. For example, the blending technique is being used to produce bulk heterojunction polymer solar cells (polymer/fullerene) and to develop electrically conductive polymer blends using electrically conductive fillers and additives (Huang and Kipouras 2012).

Table 1.77 Liquid-crystal polymer blends

Composition	Comments	References
1. LCP blends with commodity resins		
PP/LCP with PP-MW as a compatibilizer	LCP macromolecules stretched by simultaneous flow and crystallization in a static mixer	Baird and Datta 1992
PP/LCP	LCP macromolecules stretched in a counterrotating pipe die	Haghighat et al. 1992
PP/LCP	LCP macromolecules stretched under high injection molding stresses	Heino et al. 1993
LCP/PE	Viscosity reduction	Alder et al. 1993
LCP/cycloolefins (COP)	Processability	Epple et al. 1992
LCP and radiation cross-linkable resins	For articles that strain recover upon heating	Toy et al. 1994
2. LCP blends with engineering resins		
Poly(1,4-benzamide) or terephthalamide dispersed in PA	Rigid microfibrils enhanced modulus and improved the thermal behavior	Takayanagi et al. 1980
PET with 2 phr of poly[bis (4-methoxy phenyl)terephthalate]	Processability and excellent mechanical properties	Toray Industries, Inc. 1980
30 wt% PET with LCP	Processability, mechanical properties, HDT = 167 °C	Celanese Corp. 1981, 1984
PC with a wholly aromatic polyester, LCP	Mechanical, tensile and flexural, properties	Froix et al. 1981
PPE or PAEK with LCP, PI, PAES, or PEST	Processability, mechanical properties, and HDT	Harris and Michno 1988
PS/PPE/2–98 wt% of a LCP, stretched into submicroscopic fibers	Tensile strength, high modulus, satisfactory elongation, good impact strength, and high HDT	Isayev 1991, 1993, 1994
PBT with p-hydroxybenzoic acid-ethyleneterephthalate ($T_m \leq 300$ °C)	Co-reaction to increase η, thus orientability and mechanical performance	Dekkers et al. 1992
PC with PAr and LCP	Low anisotropy, high HDT, heat, and impact resistance	Izumi et al. 1992
LCP with PP, PS, PC, PI, etc.	Multiaxial molecular orientation of LCP	Haghighat et al. 1992
LCP with PC and PET or PBT	Ductility, toughness, strength, HDT modulus	Cottis et al. 1993
PBT with segmented block copolymer, LCP-b-PBT	For fibers having high modulus and strength	Farris and Jo 1993
PEI-LCP with PC, PBT, or PA	Processability and mechanical behavior	Bonfanti et al. 1993
LCP block copolymer of the type [rod]$_x$-[coil]$_y$ with PET, PBT, PA	For spinning fibers with high mechanical properties and low shrinkage	Dashevsky et al. 1993, 1994
LCP dispersed in either PEST, PC, PA, or modified PPE	Replacements for fiber-reinforced plastics – recyclable blends	Tomita et al. 1993, 1994

2. Electroconductive blends: ECP systems		
PAc was polymerized into PE	PE with catalyst exposed to acetylene	Galvin and Wnek 1982
Polypyrrole electrochemically polymerized within a matrix resin	Electrically conducting material with improved mechanical properties over those of PPy	Lindsey and Street 1985
PVC with "doped" PANI and an additive	Intrinsically electrically conductive films or fibers	Kulkarni and Wessling 1992, 1993, 1994
Amine-terminated PANI melt-blended with SMA	Materials were suitable for the use as electric conductors	Jongeling 1993
Polyaniline tosylate (PANI) and PETG	For films, inks, fibers, and coatings, in shielding, antistatic, and adhesives	Shacklette et al. 1993
Poly-3-octyl thiophene with PP, PVC, PS, PE, EVAc, PVC/ABS, etc., and dopant, e.g., I_2	Blends were formed into desired shapes and used either as EMI or ESD materials	Kokkonen et al. 1994
PANI with dodecylbenzene sulfonic acid heat treated and then mixed with either PS, PE, PS, ABS, or PP	Soluble thermoplastic ECPBs could be modified by mixing with protonic acid and metallic salts	Karna et al. 1994
Fluorine-containing polycyanurates and a thermoplastic polymer, e.g., PSF, PPE, PEEK	Heat or electrically conducting materials, for electronic packaging, adhesives, in the fabrication of electronic parts	Ardakani et al. 1994
PANI or PPy with polymeric dopant – sulfonated: -PE, -SEBS, -PS, etc.	Electrically conductive polymeric systems with good mechanical properties	Cross and Lines 1995
Matrix polymer and an electrically conducting thermotropic liquid-crystal polymer, LCP	Matrix: PO, EPR, CPE, CSR, PS; dispersed: PANI, PAc, PPy, poly (3-undecylthiophene), poly (3-dodecylthiophene), or polyparaphenylene	Ho and Levon 1995
SBR matrix and PANI filler	Conductivity, swelling, thermal and mechanical properties found to depend on PANI concentration and ratio between PANI-DBSA and PSS	Martins et al. 2006

The material developed by these authors consists of two polyolefin copolymers with different melt flow rates and filled with electrically conductive fillers and other additives. Two of the resins used are propylene/ethylene copolymers with different flow rates and flow ratios ranging from 2:3 to 1:90. The conductive filler particles include copper, silver, iron, or carbon black. These conductive resins can be molded or extruded, and applications range from circuit boards to shielding to implants.

Clearly, blending is an important technique to obtain conducting materials based on intrinsically conductive polymers and conventional as well as rubbery plastics. In a recent study, Martins et al. (2006) prepared an electrically conductive thermoplastic elastomer by blending butadiene-styrene copolymer (SBR) and

polyaniline (PANI) doped with dodecylbenzene sulfonic acid (DBSA) and poly (styrene sulfonic acid) (PSS). PSS also acted as a compatibilizer between PANI and SBR. PANI was doped by reactive processing with DBSA and PSS to produce the conductive complex PANI-DBSA-PSS. This complex was mixed with 90, 70, and 50% (w/w) SBR in an internal mixer with counterrotating blades. A similar strategy can be utilized to formulate thermally conducting plastics (Agarwal et al. 2008).

1.8   Biobased and Biodegradable Blends

In the recent past, there have been intense efforts aimed at developing alternatives to oil-based chemicals and polymers to reduce reliance on petroleum and natural gas (Stewart 2007). Biomass is the feedstock of the biobased economy, and, in practice, this means the use of corn and soybeans (for polyurethanes), although the hope is to eventually utilize agricultural and forest residues. Enzymes or microbial action are employed to convert biomass into useful chemicals and plastics. All the major plastic companies have initiated research programs in this area (Reisch 2002).

Only a few biobased polymers are commercially available (Mohanty et al. 2005). Polymers known as polyhydroxyalcanoates (PHA) are polyesters that are synthesized using bacteria, starting from either sucrose or starch. Varying the nutrient composition changes the chemical makeup of the polymer obtained (Hodzic 2005). This polymer has been commercialized by the Metabolix company under the trade name Mirel, and there are other similar products as well. Alternatively, one may obtain monomers from biomass and then carry out the polymerization using standard techniques. The most important polymer produced in this manner is polylactic acid (PLA) which is a linear polyester; here lactic acid is obtained from the fermentation of corn stover. In the past, the major application of PLA was in resorbable surgical sutures and in implantable drug-delivery devices. Although implantable medical devices are still being made from PLA and its blends (Wang et al. 2012), the material is increasingly being used in packaging where mechanical and thermal properties are not especially important. PLA production has increased significantly in the last 20 years since Cargill Inc. was able to produce high molecular weight PLA using ring-opening polymerization of lactide (Auras et al. 2010). The biodegradability property of PLA is due to the fact that the ester linkages are susceptible to hydrolysis, especially at high temperatures and in the presence of water; once the molecular weight is reduced, bacteria can degrade the material easily.

Biodegradable polymers are attractive since they are less likely to end up in landfills or contribute to the buildup of plastic trash that persists in the environment for a very long time. Biodegradability has also been explored in agriculture to prevent excessive moisture loss and weeds growth and to alleviate the recyclability problems – an agricultural film should last as long as it is needed and then disintegrate under the influence of either microorganisms and/or UV irradiation.

A biodegradable polymer is one that can decompose to small molecules, such as carbon dioxide, under the action of microorganisms is a specified amount of time (Mohanty et al. 2005). Most biopolymers are biodegradable, e.g., a large family of polysaccharides. They have been used in biodegradable blends with synthetic polymers. Some synthetic polymers, viz., PET, are susceptible to biodegradation when copolymerized with polylactones. Polymers with controlled, reversed misci-bility, viz., polyglycoles, are also biodegradable. Polymers with carbon backbones, viz., PE or PP, may be susceptible to biodegradation after incorporation of ketone side groups, -C(R)(COR′)- (Guillet 1973). Biodegradable polybutylene succinate or adipate, *Bionolle™*, has been commercially introduced in 1996 by Showa Denko. Similarly, Novamont introduced fully biodegradable *Mater-Bi™*. The latter mate-rials are blends of starch and other polymers, viz., poly-ε-caprolactone, ethylene-vinyl alcohol, etc.

1.8.1   PLA Blends

Lactic acid produced from the fermentation route is 99.5 % L-lactic acid and condensation polymerization leads to low molecular weight PLLA or poly (L-lactide) (Nampoothiri et al. 2010; Rasal et al. 2010). High molecular weight polymer can be produced by ring-opening polymerization, and one can also adjust the ratio of L- to D-lactic acid units (Auras et al. 2010). Even so, it is not considered to be an engineering polymer since it has poor thermal and hydrolytic stability. Although it has stiffness and strength comparable to commercial polymers like polystyrene and PET (Imre and Pukanszky 2013), it suffers from low values of ductility, HDT, and toughness. Some of these properties can be improved by blending PLA with plasticizers or with other plastics.

The elongation to break of PLA is less than 10 %, but it can be significantly enhanced by the incorporation of low molecular weight plasticizers which are also biocompatible; these include oligomeric lactic acid and low molecular weight polyethylene glycol (PEG) (Martin and Averous 2001). As is normal with the use of plasticizers, however, there is a concomitant reduction in both the elastic modulus and the glass transition temperature. A variation of this procedure has been reported by Rasal and Hirt (2010) who blended PLA with polyacrylic acid followed by physical blending with PEG in solution. Films made from the mixture showed a tenfold increase in toughness compared to neat PLA with little or no decrease in tensile strength and modulus. Note that with time, low molecular weight additives can migrate to the surface of a part due to reasons such as physical aging and this phenomenon may be accompanied by an increase in polymer crystallinity (Auras et al. 2010; Rasal et al. 2010); an increase in crystallinity is usually accompanied by a reduction in ductility.

A lowering in PLA modulus and T_g can be avoided if PLA is blended with other polymers. However, it is not miscible with many plastics, and the use of block copolymers or the use of reactive blending is generally necessary. Candidate poly-mers may be biodegradable or nonbiodegradable. In the former category are starch,

PGA, and PHA (Yu et al. 2006), while in the latter category are polyolefins, vinyl and vinylidene polymers, and elastomers and rubber (Detyothin et al. 2010). PLA has been blended extensively with starch due to its plentiful supply, low cost, and biodegradable nature (Yu et al. 2010). However, it is hydrophilic, and it tends to swell in the presence of water. To promote compatibility of starch with the hydrophobic PLA, one may use coupling agents such as methylene diphenyl diisocyanate (MDI) or functionalize the polyester by grafting highly reactive groups such as maleic anhydride with the expectation that covalent bonds will be formed by reaction with the hydroxyl groups on starch (Rzayev 2011). It is found that mechanical properties of PLA such as modulus, yield strength, and impact strength can all be improved by blending with starch in the presence of MDI. The use of other additives, such as resorcinol di(phenyl phosphate), can endow the blends with flame retardancy (Pack et al. 2012). Several PLA blends have now been commercialized, and these find application mainly in packaging and agriculture. The recent review by Imre and Pukanszky (2013) may be consulted for details.

Approaches that can be employed to toughen PLA with the use of different blend constituents and how the toughening protocols modify mechanical properties have been described by Anderson et al. (2008). The most significant improvement in toughness of PLA has been reported by McCarthy et al. (1999) who made blends of PLA with polybutylene-succinate adipate (PBSA). PBSA is a biodegradable polymer, but it is not biobased. A 70/30 (weight%) PLA/PBSA blend exhibited about a 5-fold increase in tensile elongation to break and about a 25-fold increase in tensile toughness. More recently, Krishnaswamy (2013) and Krishnaswamy et al. (2013) have described blends of PLA and PHA which have about 31–58 % increase in tensile elongation and 21–35 % greater tensile toughness than PLA alone.

As mentioned earlier, a major application of PLA is in food packaging. Cheung et al. (2012) have described blends of PLA with styrenic polymers compatilbilized with styrene-based copolymers like SEBS, SMA, and SMMA that can be extruded and thermoformed to produce very low-density food service foam articles with good mechanical properties. Li et al. (2012) have described the development of a biodegradable gloss film that contains 60–99 % PLA and the rest PP. In general, biodegradable polymer blends are prepared by blending a thermoplastic resin with a biodegradable one. Specific examples are given in Table 1.79. Blending must produce dispersion that after disintegration of the biodegradable part, the thermoplastic powder will not contaminate the environment.

1.9   Blending and Recycling

Recycling is becoming increasingly important. Its methods depend on the polymer type and source. Within the resin manufacturers' plant recycling is the easiest. This is known as postindustrial recycling. In processing plants, where commingled polymeric scrap is generated, it is more difficult, but it is still possible by separating the different components (Jody et al. 1997). The most difficult is recycling of

Table 1.79 Biodegradable polymer blends

Composition	Comments	References
PVAl/vinylacetate grafted starch	Biodegradable, better properties than PVAl	Yoshitake et al. 1978
PHBA, with 10–40 wt% CPE	Biodegradability, impact properties and HDT	Holmes et al. 1982
PLA/PEO, EVAc, EVAl, EPDM, SBR, etc.	Biodegradable, flexible alloys	Kharas and Nemphos 1992
EVAl/poly(hydroxybutyrate-valerate)	Biodegradability and good impact properties	Webb et al. 1992
PS, PO, NR, SBR, PI, PB, or CA, a polysaccharide and bioagent	Cellulose with 1 wt% of bacteria, fungi, and/or enzymes	Guttag 1992, 1994
LDPE, starch, and a copolyacrylate	Biodegradable blends	Willett 1992

TPU and/or *phenoxy*, EVAl, COPO, cellulose, and/or polyalkylene oxide	Attractive physical, optical, and barrier properties and were melt processable without PVAl degradation	La Fleur et al. 1994
Starch with biologically degradable aliphatic polyesters, hydrophobic protein, PVAl, or cellulose esters and a hygroscopic material	Absorbed water was released during either extrusion or injection molding at T = 200 °C, causing the mixture to foam to density ρ = 160 kg/m³	Tomka 1998

postconsumer polymers which show up in municipal solid waste (MSW) and ultimately end up in landfills. Indeed, the magnitude of the problem has been increasing at a rapid rate. The plastic component of MSW in the USA has risen from 390,000 t in 1960 to 30.7 million tons in 2007 (Merrington 2011). Three basic methods of recycling have been used: (i) direct, where cleaned resins are incorporated into virgin material, (ii) reprocessing the commingled plastics either by blending or transforming into plastic wood or plastic concrete, and (iii) feedstock type that may involve depolymerization or pyrolysis. To the following text, only the method (ii) is important. It can be subdivided into (1) compatibilization and upgrading of resins in direct recycling, (2) compatibilization and upgrading of commingled plastics for reprocessing, and (3) recycling of polymer blends (Akovali et al. 1998).

The essential difficulty in recycling commingled plastic is the fact that mixed plastics have poor mechanical, thermal, and flow properties even when the individual components have very desirable ones. In particular, plastic mixtures have low ductility and poor impact strength (Liang and Gupta 2001). This limits their use to less demanding applications such as flower pots, park benches, and plastic lumber. To reuse postconsumer plastics in high-value applications, it is necessary to first separate plastic waste by chemical type. A variety of techniques, such as float-sink tanks and hydrocyclones, can be used to separate mixed plastics based on differences in density. For plastics with overlapping density, other methods, such as froth flotation, can be employed (Merrington 2011). A relevant question then is the purity level that must be attained in such a separation process. The higher the purity, the better is the performance, but the higher also is the cost of the separation process.

One way to address the issue of residual contaminants present in polymer recovered from postconsumer waste is to use regrind in an inner layer in a multilayer article. Shelby et al. (2012) have described several such transparent polymer compositions made from a variety of polymer pairs that exhibit excellent barrier properties while retaining processability and good mechanical property. Another approach is to blend the separated plastic with virgin plastic. This procedure also allows one to standardize the flow properties if the virgin polymer is available in different molecular weights (Liang and Gupta 2002). Even so, it is necessary to compatibilize the recycled material since it remains a multicomponent blend.

To do this, one may (i) add at least one ingredient with highly reactive groups that can interact with several polymeric components, e.g., ethylene-acrylate-maleic anhydride, glycidyl methacrylate-ethylene-vinylacetate, and ethylene-glycidyl methacrylate-methylmethacrylate (the copolymer may compatibilize and toughen); (ii) add a low molecular weight additive that at different stages of the reactive blending binds to different components, viz., ethylene-glycidyl methacrylate, triglycidyliso-cyanurate, etc.; and (iii) add a cosolvent, for example, *phenoxy*. A significant penetration of properly designed copolymer into the homopolymer phases has been reported (Brown 1989).

The morphology can be stabilized by (i) thick interphase, (ii) partial cross-linking, or (iii) addition of an immiscible polymer with a suitable spreading coefficient (Yeung et al. 1994). The adhesion between the phases in the solid state is improved by (i) addition of a copolymer that covalently bonds the phases, (ii) reduction of size of the crystalline domains, (iii) adequate adhesion, e.g., by the use of polyetherimine, PEIm (Bjoerkengren and Joensson 1980), and (iv) dispersing at high stresses, either in the melt (Patfoort 1976) or in solid state (Shaw 1993; Khait 1994, 1995).

Chemical re-stabilization of recycled material against the thermal- and light-induced degradation is essential. Addition of 0.1–0.5 wt% of a sterically hindered phenol and a phosphite at a ratio varying from 10:1 to 1:10 is recommended (Pauquet et al. 1994). For outdoor applications, hindered amine light stabilizers with UV absorbers of the benzotriazole type are to be used (Herbst et al. 1995, 1998). Examples of blends used for polymer recycling are listed in Table 1.80. For more details, see ▶ Chap. 20, "Recycling Polymer Blends" in this book.

1.10   Conclusions and Outlook

Blends like composites are integral parts of the plastic industry. Their sales are estimated at more than US$ 100 billion per annum. The blends provide widening selection of performance characteristics, tunable for specific applications at a reasonable cost. In effect, this technology is a shortcut to development of complex polymeric species.

Considering the range of possibilities and constraints, polymer blends provide a fertile field of polymer research. Polymer blending not only requires understanding of intrinsic properties of polymers but also a broad knowledge of numerous disciplines such as thermodynamic principles of miscibility and compatibilization, surface and interfacial properties, morphology, rheology, processing, and performance during the service life of the material. Decades of research have enriched our understanding about the science and technology of polymer blends. As a result, polymer blends and blending techniques are finding applications in multidisciplinary fields.

Performance during its service life is crucial to the widespread application of any material. It has been estimated, for example, that at least 15–25 % of all failures of plastic materials in commercial use are related to the problem of environmental

Table 1.80 Polymer blends for recycling

Composition	Comments	References
PS with 1–10 wt% PE and CSR	Improved impact, elongation, and strength (CPE or CSR is a compatibilizer for scrap)	Herbing and Salyer 1963
LLDPE/PS shear-compatibilized	Blends with good mechanical properties	Patfoort 1976
PS or HIPS, with PP and SEBS	SEBS is expensive but useful in recycling	Holden and Gouw 1979
PS with PO, S-b-B stabilizers	Recycling requires higher concentration of stabilizers than virgin resins	Sadrmohaghegh et al. 1985
sPS and sPS copolymer with MA or GMA and an elastomer reactive with it	Recyclable, impact resistant, good elongation, and retention of physical properties	Okada 1994
PO with 30–40 wt% PS recycled without compatibilization	High properties due to stable co-continuous morphology	Morrow et al. 1994
PA with PA/LDPE, EGMA	Recyclable blends, good performance	Timmermann et al. 1994
$\geq$ 2 PO, PS, polydienes – either virgin, recycled, or both	Blending at T in between the melting points of the components	Lai and Edmondson 1995
Rubber scrap with rosin and fatty acids, esters and unsaponifiables, and PE, PET, TPU, PU, PVC, etc.	Cryogenically comminuting rubber, drying it, blending with plasticizer/binding agent, heating, and blending with polymers	Segrest 1995
Automotive scrap plastic parts comprising PC, PEST, ABS, PA, etc., with 5–15 wt% MBS	Compounding in a TSE, devolatilization, filtering of paint flakes; closed-loop control system for properties	Lieberman 1995
Branched PET with recycled PET and a chain extender or a cross-linking agent	Foaming and extruding the mixture	Muschiatti and Smillie 1995
Recycling of manufactured polymer blends	Recent concepts in polymer blends recycling	Jose et al. 2011

stress cracking (ESCR) (Arnold 1996). The development of polymer blends technology has provided a strategic route to avoid ESCR of amorphous engineering polymers and allowed these engineering blends (Xenoy®, Noryl®, Gemax®, Triax, Elemid, Macroblend) to be used in various aggressive environments. For automotive applications, blends have been formulated with high T_g polymers (PC, PPO) with crystalline polymers (PBT, PA 66) (Robeson 2007). As applications of amorphous polymers expand in adverse environments, newer commercial blends will be developed, and the reader is referred to the recent review by Robeson (2013). This effort is likely to be aided by computational methods that have been developed in the science and technology of polymer blends. Molecular dynamics provide means of computation of the specific interactions and miscibility (Coleman et al. 1991) or the interfacial energy in a polymer blend (Yao and Kamei 1995).

Indeed, commercial computer programs are available for designing blends with specific sets of properties.

The phase behavior and morphology of phase-separated polymer blends play a vital role in the design of membrane transport properties (Robeson 2010). Numerous applications of polymeric membranes involving gas and liquids are known. Although different transport models have been utilized successfully to relate morphology with transport properties, there is enough room for improvements as membrane applications continue to grow in such areas as gas separation.

Formulation of biodegradable polymer blends is already on the rise, and these blends are being used successfully in applications ranging from agriculture to consumer goods, to packaging, and to automotives. Blends of biodegradable polymers, however, behave differently than those of commodity polymers. Miscibility-structure-property relationship of these blends will continue to emerge. Progress has been made in developing self-extinguishing biodegradable polymer blends (PLA/ECOFLEX). As the use of biodegradable polymer blends increases, demand for flame-retardant formulations will rise as well.

Another rapidly evolving field is biomedical engineering and particularly tissue engineering that seeks to regenerate or repair damaged or diseased tissues and organs. Scaffolds are being fabricated by combining the solid-state foaming and immiscible polymer blending methods. Biodegradable dipeptide-based polyphosphazene-PLAGA blends have been reported to be a promising material for mechanically competent scaffolds for bone tissue engineering (Deng et al. 2010). Undoubtedly, biodegradable and biocompatible polymer blends will play an increasing role in the fabrication of tissue engineering scaffolds in the future.

One usually wishes to know what would be the final properties of a polymer blend once it has been conceptually designed but before it is actually made. That is what molecular modeling does. However, there is always a compromise between simulation complexity, accuracy, and speed of prediction. Studies are being carried out which could open up the possibility of computer-aided design of polymer blends with desired physical and mechanical properties.

Although great strides have been made in the past, opportunities still exist to improve and solve numerous polymer blend problems. Research and technical innovation will continue to impact polymer blend development and production. We are confident that polymer blends will continue to contribute to the development of our modern society.

MWD Molecular weight distribution
NBR Elastomeric copolymer from butadiene and acrylonitrile; nitrile rubber
NC Nitrocellulose
NDB Negatively deviating blend
NPDB Negative and positive deviating blend
NR Natural rubber
P4MP Poly(4-methyl-1-pentene)
PA Polyamides, nylon
PAc Polyacetylene
PACE Polyacetylene
PAE Polyarylether
PAEB Poly(*p*-aminoethyl benzoate)
PAEK Polyaryletherketone
PAES Polyarylethersulfone
PAI Polyamide-imide
PAN Polyacrylonitrile
PANI Polyaniline
PAr Polyarylate

PARA Polyarylamide; aromatic amorphous polyamide
ParSi Poly(aryloxysiloxane)
PB Polymer blend; polybutadiene
PB-1 Poly-1-butene
PBA Polybutylacrylate
PBG Polybutyleneglycol
PBI Polybenzimidazole
PBMA Poly(butyl methacrylate)
PBSA Polybutylene-succinate adipate
PBT Polybutylene terephthalate
PC Polycarbonate
PCHA Polycyclohexyl acrylate
PCHE Polycyclohexylethylene
PCHMA Polycyclohexyl methacrylate
PCL Polycaprolactone
PCO Polycycloolefin
PCS Poly-2-chlorostyrene
PCTF Polychlorotrifluoroethylene
PCTFE Polychlorotrifluoroethylene
PCTG Copolymer of cyclohexanedimethanol, terephthalic acid and ethylene glycol
PDB Positively deviating blend
PDMDPhS Poly(dimethyl-diphenyl siloxane)
PDMS Polydimethylsiloxane, polysiloxane
PDPS Polydiphenylsiloxane
PE Polyethylene
PEA Polyethylacrylate; polyesteramide; polyether-amide
PEBA Polyether-block-amide
PEC Polyestercarbonate
PEEI Copolyesteretherimide
PEEK Polyether ether ketone; polyaryletherketone
PEG Polyethylene glycol
PEI Polyetherimide
PEIm Polyetherimine
PEK Polyetherketone
PEKK Polyetherketone
PEMA Polyethylmethylacrylate
PEN Poly(ethylene-2,6-naphthalene dicarboxylate)
PEO Polyethylene oxide
PEOX Poly(2-ethyl-2-oxazoline)
PES Polyethersulfone
PEST Thermoplastic polyester
PET Polyethylene terephthalate
PETG Polyethyleneterephthalateglycol

PF   Phenol-formaldehyde
PGA   Polyglycolic acid
PGI   Polyglutarimide
PHA   Polyhydroxyalcanoate
PHB   Poly-3-hydroxybutyrate
PHBA   Poly(β-hydroxybutyric acid)
PHT   Polyhexamethyleneterephthalate
PHZ   Polyphosphazene
PI   Polyimide
PIB   Polyisobutylene
PISO   Polyimide-sulfone
PLA   Polylactic acid
PMA   Polymethacrylate
PMB   Poly*p*-methylenebenzoate
PMI   Polymethacrylimide
PMMA   Poly(methylmethacrylate), acrylic
PMP   Poly-4-methyl-1-pentene
PMPhS   Polymethylphenylsiloxane
PMS   Polymethylstyrene
PNDB   Positive and negative deviating blend
PO   Polyolefin
POBA   Polyoxybenzoyl acid, rigid-rod polymer
POCA   Polyoxycyanoarylene
POD   Polyoctadecene
POM   Polyoxymethylene
POT   Poly-3-octyl thiophene
PP   Polypropylene
PPA   Polyphthalamide
PPBA   Polyparabanic acid
PPCO   Polypropylene carbonate
PPE   Polyphenylene ether
PPG   Propylene glycol
PPhA   Polyphthalamide
PPMA   Poly-*n*-propyl methacrylate
PpMS   Poly-*p*-methylstyrene
PPP   Polyparaphenylene
PPS   Polyphenylenesulfide
PPSS   Polyphenylenesulfidesulfone
PPT   Polypropylene terephthalate
PPTA   Poly(*p*-phenylene terephthalamide)
PPy   Polypyrrole
PS   Polystyrene, styrenic
PSF   Polysulfide; polysulfone
PSIB   Polyisobutylene-block-polystyrene

PSOX Polystyrene grafted with 2-oxazoline
PSS Poly(styrene sulfonic acid)
PSU Polyarylsulfone
PTES Polythioethersulfone
PTFE Polytetrafluoroethylene
PTO Polytransoctanamer
PVA Polyvinylacetate
PVAl Polyvinyl alcohol
PVB Polyvinyl bromide
PVC Polyvinyl chloride, vinyl
PVCAc Poly(vinylchloride-co-vinylacetate)
PVDC Polyvinylidenechloride
PVDC-MeA Vinylidenechloride-methylacrylate copolymer
PVDF Polyvinylidene fluoride
PVF Polyvinyl fluoride
PVFO Polyvinyl formal
PVME Poly vinyl methyl ether
PVP Polyvinylpyrrolidone
PVPh Polyvinylphenol
SAA Poly(styrene-acrylic acid)
SAN Styrene-acrylonitrile copolymer
SAN-MAc Copolymer of SAN and methacrylic acid
SB Styrene-butadiene block copolymer
SBR Styrene-butadiene rubber
SBS Styrene-butadiene-styrene block copolymer
SEB Styrene-ethylene/butylene
SEBS Styrene-ethylene-butylene-styrene block copolymer
SEP Styrene-ethylene-propylene block copolymer
SH Strain hardening
SI Styrene-isoprene block copolymer
SIS Styrene-isoprene-styrene block copolymer
SMA Poly(styrene-co-maleic anhydride)
SMI Copolymer from styrene and maleimide
SMM Styrene-methylmethacrylate copolymer
SMMA Styrene methylmethacrylate
sPhPS Syndiotactic poly(*p*-phenyl styrene)
sPP Syndiotactic polypropylene
sPS Syndiotactic polystyrene
SSE Single-screw extruder
TM Thio-rubber
TMPC Polycarbonate of tetramethyl bisphenol-A
TPE Thermoplastic elastomer
TPU Thermoplastic polyurethane
TPV Thermoplastic vulcanizate

TS Thermoset polyester
TSE Twin-screw extruder
UF Urea-formaldehyde
UHMWPE Ultra-high molecular weight polyethylene
UHMW-PMMA Ultra-high molecular weight poly(methylmethacrylate)
UHMW-PS Ultra-high molecular weight polystyrene
ULDPE Ultra low-density polyethylene
VCM Vinyl chloride monomer
VPh Vinylphenol
VLDPE Very low-density polyethylene
XLPE Cross-linked polyethylene

F. Buehler, E. Schmid, H.J. Schultze, Europ. Pat. Appl. 536,679, 14 Apr 1993, to Ems-Inventa

F. Buehler, E. Schmid, H.J. Schultze, U.S. Patent 5,346,936, 13 Sept 1994, to Ems-Inventa

A.L. Bull, G. Holden, J. Elastom. Plast. **9**, 281 (1977)

K. Burg, E. Wolters, H. Cherdron, Ger. Offen. 2,037,823, 03 Feb 1972, to Hoechst

W.E. Burgert, Europ. Pat. Appl. 215,150, 25 Mar 1987, to Dow Chemical

A.M. Burnell, U.S. Patent 5,272,182, 21 Dec 1993, to General Electric Co.

P.M. Buschbaum, Polym. J. **45**, 34 (2013)

W.F. Busse, J. Phys. Chem. **36**, 2862 (1932)

J.D. Bussink, J.W.J. De Munck, P.C.A.M. van Abeelen, U.S. Patent 4,122,131, 24 Oct 1978, to General Electric Co.

S. Bywater, Adv. Polym. Sci. **4**, 66 (1965)

D.W. Caird, U.S. Patent 3,087,908, 30 Apr 1961, to Osaka Kinzoku Kogyo

M. Cakmak, A. Dutta, U.S. Patent 5,114,987, 19 May 1992, to Edison Polymer Innovation Corp.

G.W. Calundann, F. Herold, E.C. Chenevey, T.S. Chung, Europ. Pat. Appl. 510,818, 28 Oct 1992, to Hoechst Celanese Corp.

G.W. Calundann, F. Herold, E.C. Chenevey, T.S. Chung, U.S. Patent 5,290,884, 01 Mar 1994, to Hoechst Celanese Corp.

R. Camargo, F. Mercer, T.-C. Cheng, PCT. Intl. Appl. WO 86 04,079, 17 July 1986, to Raychem Corp.

G.A. Campbell, D.H. Rasmussen, U.S. Patent 5,358,675, 25 Oct 1994; U.S. Patent 5,369,135, 29 Nov 1994, to Mobil Oil Corp.

J.R. Campbell, J.R. Presley, U.S. Patent 5,380,796, 10 Jan 1995, to General Electric Co.

P.J. Canterino, J.P. Freudemann, Europ. Pat. Appl. 148,567, 17 July 1985, to Mobil Oil

P.J. Canterino, D.V. Dobreski, R.G. Shaw, U.S. Patent 4,579,912, 01 Apr 1986, to Mobil Oil

W.H. Carothers, Chem. Rev. **8**, 353 (1931)

W.H. Carothers, U.S. Patent 2,071,250; 2,071,251; 2,071,252; 2,071,253, 16 Feb 1937, to E. I. du Pont

W.H. Carothers, I. Williams, A.M. Collins, J.E. Kirby, J. Am. Chem. Soc. **53**, 4203 (1931)

J. Castelein, Europ. Pat. Appl. 060,525, 22 Sept 1982, to Montefina

J.Y. Cavaille, J. Perez, C. Jourdan, G.P. Johari, J. Polym. Sci. B Polym. Phys. **25**, 1847 (1987)

G. Cecchin, F. Guglielmi, Europ. Pat. Appl. 373,660, 20 June 1990, to Himont

Celanese Corporation, Fr. Demand, 2,484,430, 18 Dec 1981

Celanese Corporation, U.S. Patent 4,489,190, 30 June 1984

Ceramer™ Hoechst-Ticona, Techn. Inf. (1996)

R.J. Ceresa, N.E. Davenport, T.L. Trudgian, Brit. Pat. 1,112,024, 01 May 1968, to W. R. Grace & Co.

J. Cerny, R. Troncy, Fr. Pat. 2,473,534, 17 July 1981, to Rhône-Poulenc

G.R. Chambers, G.F. Smith, J.B. Yates III, U.S. Patent 5,384,359, 24 Jan 1995, to General Electric Co.

M.F. Champagne, M.M. Dumoulin, L.A. Utracki, J.P. Szabo, Polym. Eng. Sci. **36**, 1636 (1996)

G.M. Chapman, R.H. Downie, U.S. Patent 5,352,716, 04 Oct 1994, to Ecostar International

L.F. Charbonneau, B. Gupta, H.C. Linstid, L.C. Sawyer, J.P. Shepherd, U.S. Patent 5,393,848, 28 Feb 1995, to Hoechst Celanese Corp.

J.J. Charles, E.A. Coleman, Europ. Pat. Appl. 033,393, 12 Aug 1981, to GAF Corp.

J.J. Charles, R.C. Gasman, Ger. Offen. 2,825, 236, 25 Jan 1979, to GAF Corp.

D.E. Henton, A. Chen, P.J. Moses, B.S. Ehrlich, D.E. Beyer, PCT Int. Appl. WO 92 20,744, 26 Nov 1992, to Dow Chemical

D.E. Henton, D.M. Naeger, F.M. Plaver, U.S. Patent 5,219,933, 15 June 1993, to Dow Chemical

L.R. Hepp, Europ. Pat. Appl. 113,096, 11 July 1984, to General Electric Co.

S.J. Hepworth, J.D. Seddon, J.E. Priddle, Ger. Offen. 2,011,608, 01 Oct 1970, to ICI

J.A. Herbing, I.O. Salyer, U.S. Patent 3,092,607, 4 June 1963, to Monsanto Chemical Co.

H. Herbst, K. Hoffmann, R. Pfaendner, F. Sitek, *Proceed. of National Seminar on Emerging Trends in Plastic Recycling Technologies and Waste Management*, Goa, 27–28 May 1995

H. Herbst, K. Hoffmann, R. Pfaendner, H. Zweifel, in *Frontiers in the Science and Technology of Polymer Recycling*, ed. by G. Akovali, C.A. Bernardo, J. Leidner, L.A. Utracki, M. Xanthos. NATO ASI Series, vol. 351 (Kluver, Dordrecht, 1998)

O. Herrmann-Schoenherr, H.T. Land, Eur. Pat. Appl. 568,917, 10 Nov 1993, to Hoechst

O. Herrmann-Schoenherr, H.T. Land, Jap. Pat. 60 57,160, 01 Mar 1994, to Hoechst

A. Heslinga, P.J. Greidanus, U.S. Patent 4,332,917, 01 June 1982; U.S. Patent 4,338,417, 06 June 1982, to Nederlandse Centrale Organisatie voor Toegepast-Natuurwetenschappelijk Onderzoek

H. Heywang, Ger. Offen. 1,221,323, 21 July 1966, to Siemens and Halske

T. Hikasa, H. Mendori, T. Hamanaka, T. Igarashi, Y. Shida, U.S. Patent 5,308,700, 03 May 1994, to Sumitomo Chem.

R.W. Hill, R.P. Anderson, S.V. Scroggins, U.S. Patent 3,539,662, 10 Nov 1970, to Gulf R&D Co.

S. Himei, M. Takine, K. Akita, Jap. Pat. 000,949, 18 Jan 1967, to Kanegafuchi Chem.

M.H. Hindi, M.W. Woods, N. Harry, T. Wakida, U.S. Patent 5,300,552, 05 Apr 1994, to Phillips

K. Hinselmann, V. Ladenberger, K. Bronstert, G. Fahrbach, Ger. Offen. 2,137,274, 08 Feb 1973, to BASF

M. Hirai, T. Tatsuda, T. Yoshida, Europ. Pat. Appl. 284,086, 28 Sept 1988, to Sumitomo Naugatuck

M. Hirai, T. Tatsuda, T. Yoshida, U.S. Patent 4,855,355, 08 Aug 1989, to Sumitomo Naugatuck

M. Hirai, T. Tatsuda, T. Yoshida, Can. Pat. 1,307,863, 22 Sept 1992, to Sumitomo Naugatuck

T. Hirai, N. Amano, SPE Techn. Pap. **39**, 1256 (1993)

T. Hiri, H. Kotama, Jap. Pat. 005,224, 09 Feb 1971, to Toray Industries

Hitachi Chemical Company, Ltd., Jap. Pat. 052,348, 28 Mar 1983

N. Hizasumi, T. Uehara, H. Ohba, K. Hirose, Europ. Pat. Appl. 336,680, 11 Oct 1989, to Kureha Chem.

K.-S. Ho, K. Levon, U.S. Patent 5,391,622, 21 Feb 1995, to Neste Oy

S.Y. Hobbs, R.C. Bopp, V.H. Watkins, Polym. Eng. Sci. **23**, 380 (1983)

A. Hodzic, in *Natural Fibers, Biopolymers and Biocomposites*, ed. by A.K. Mohanty, M. Misra, L.T. Drzal (Taylor and Francis, Boca Raton, 2005)

S.M. Hoenig, D.P. Flores, S.P. Ginter, U.S. Patent 4,474,928, 02 Oct 1984, to Dow Chemical

H. Hoenl, A. Jung, P. Klaerner, B. Ostermayer, S. Seelert, Europ. Pat. Appl. 545,181, 09 June 1993, to BASF

G.H. Hofmann, U.S. Patent 5,352,735, 04 Oct 1994, to E. I. du Pont

G.H. Hofmann, Plast. Technol. **55** (1998)

J.P. Hogan, R.L. Banks, U. S. Pat. Appl. 333,576, 27 Jan 1953, to Phillips

J.P. Hogan, R.L. Banks, Belg. Pat. 530,617, 24 Jan 1955, to Phillips

T. Hoki, N. Miura, U.S. Patent 4,652,590, 24 Mar 1987, to Dow Chemical Co.

G. Holden, L.H. Gouw, Europ. Pat. Appl. 004,685, 17 Oct 1979, to Shell.

G. Holden, D.R. Hansen, Europ. Pat. Appl. 308,001, 22 Mar 1989, to Shell

W.D. Holland, J.M. Schmitt, R.M. Griffith, Ger. Offen. 2,018,606, 29 Oct 1970, to American Cyanamid

P.A. Holmes, A.B.. Newton, F.M. Willmouth, Europ. Pat. Appl. 052,460, 26 May 1982, to ICI

F.F. Holub, U.S. Patent 4,908,418; 13 Mar 1990, to General Electric Co.

F.F. Holub, G.A. Mellinger, U.S. Patent 4,258,155, 24 Mar 1981, to General Electric Co.

F.F. Holub, J.A. Rock, Europ. Pat. Appl. 325,718; 325,719, 02 Aug 1989, to General Electric Co.

R. Holzer, K. Mehnert, Ger. Offen. 1,145,792, 21 Mar 1963, to Hoechst

R. Holzer, K. Mehnert, U.S. Patent 3,262,292, 1966, to Hoechst

S.M. Hong, B.C. Kim, K.U. Kim, I.J. Chung, Polym. J. **24**, 727 (1992)

M. Hongo, H. Shigemitsu, N. Yamamoto, A. Yanagase, Europ. Pat. Appl. 249,964, 23 Dec 1987, to Mitsubishi Rayon

A. Honkanen, M. Arina, R. Holstii, Finn. Pat. 064,805, 30 Sept 1983, to Neste Oy

J.F. Hoover, Europ. Pat. Appl. 524,731, 27 Jan 1993, to General Electric Co.

K. Horiuchi, T. Kamiya, Jap. Pat. 001,639, 16 Jan 1974, to Teijin Chem.

Y. Hoshi, A. Kaneko, Jap. Pat. 014,220, 17 Sept 1962, to Kureha Chemical Works

Y. Hoshi, A. Kaneko, Brit. Pat. 928,799, 12 June 1963, to Kureha Chemical Works

Y. Hoshi, A. Kaneko, Belg. Pat. 635,851, 01 Feb 1965, to Kureha Chemical Works

N. Hosoi, Jap. Pat. 03 167,258, 19 July 1991, to Sumitomo Electric Industries

R.J. Hoxmeier, U.S. Patent 5,276,095, 04 Jan 1994, to Shell Oil

H.-W. Hsu, S.-C. Liuo, S.-F. Jiang, J.-H. Chen, H.-M. Lin, H.-D. Hwu, M.-L. Chen, M.-S. Lee, T. Hu, U.S. Patent 5,308,897, 14 Jan 1994, to Industrial Technology Research Institute, Taiwan

G.-H. Hu, H. Cartier, Intl. Polym. Process. **13**, 111 (1998)

J. Huang, GP. Kipouras, U.S. Patent 8,273,268, 25 Sept 2012, to PolyOne Corp.

H.H. Hub, G. Blinne, H. Reimann, P. Neumann, G. Schaefer, Ger. Offen. 3,444,339, 05 June 1986, to BASF

Huels., Brit Pat., 1,247,068, 22 Sept 1971

T. Huff, U.S. Patent 4,087,485, 02 May 1978, to Exxon

T. Huff, Europ. Pat. Appl. 015,066, 03 Sept 1980, to Exxon

M.L. Huggins, G. Natta, V. Desreux, H. Mark, J. Polym. Sci. **56**, 153 (1962)

H.G. Karian (ed.), *Handbook of Polypropylene and Polypropylene Composites* (Marcel Dekker, New York, 2003)

T.P. Karjala, Y.W. Cheung, M.J. Guest, in *Metallocene-Catalyzed Polymers*, ed. by G.M. Benedict, B.L. Goodall (SPE Plastics Design Library, Norwich, 1998)

T. Karna, J. Laakso, T. Niemi, H. Ruohonen, E. Savolainen, H. Lindstrom, E. Virtanen, O. Ikkala, A. Andreatta, U.S. Patent 5,340,499, 23 Aug 1994, to Neste Oy

H. Kasahara, K. Fukuda, H. Suzuki, Europ. Pat. Appl. 046,040, 17 Feb 1982, to Asahi-Dow

T. Kasuya, T. O. Omichi, H. Maehara, Jap. Pat. 011,546, 27 May 1969, to Asahi Chem.

R. Kato, I. Soematsu, T. Mori, Jap. Pat. 003,108, 09 Feb 1967, to Toa Gosei Chem.

T. Katsumata, Jap. Pat. 03 119,048, 21 May 1991, to Polyplastics

T. Katsumata, N. Matsunaga, Europ. Pat. Appl. 519,749, 23 Dec 1992, to Polyplastics

T. Katsumata, N. Matsunaga, Europ. Pat. Appl. 549,338, 30 June 1993, to Polyplastics

T. Katsumata, N. Matsunaga, U.S. Patent 5,378,748, 03 Jan 1995, to Polyplastics

S. Katsura, Jap. Pat. 028,539, 08 Feb 1986, to Mitsubishi Petrochem.

H.S. Kaufman, U.S. Patent 3,105,827, 01 Oct 1963, to Minnesota Mining and Manufacturing

M. Kawai, M. Miyauchi, Jap. Pat. 124,150, 27 Nov 1974, to Teijin Chem.

H. Kawai, T. Munemaru, T. Inoue, R. Kimura, Jap. Pat. 043,539, 21 Nov 1978, to Institute for Production and Development Science

T. Kawaki, A. Amagai, M. Ishikawa, T. Yamada, Y. Hirai, H. Ban, Eur. Pat. Appl. 492,947, 01 July 1992, to Mitsubishi Gas Chem.

T. Kawaki, A. Amagai, M. Ishikawa, T. Yamada, Y. Hirai, H. Ban, U.S. Patent 5,321,097, 14 June 1994, to Mitsubishi Gas Chem.

T. Kawaki, A. Amagai, T. Yamada, H. Harada, H. Ban, U.S. Patent 5,387,652, 07 Feb 1995, to Mitsubishi Gas Chem.

T. Kawauzra, S. Aibe, M. Kawazoe, U.S. Patent 5,679,744, 21 Oct 1997, to The Yokohama Rubber Co., Ltd.

C. Kennedy, *ICI, The Company That Changed Our Lives* (Hutchinson Limited, London, 1986)

A. Képes, Fr. Pat. 1,175,241, 23 Mar 1959, to Soc. anon. des manufacturers des glaces et produits chimiques de Saint-Gobain, Chauny & Cirey

R.J. Kern, U.S. Patent 2,806,015, 10 Sept 1957, to Monsanto Chem.

H. Keskkula, D.A. Maass, K.M. McCreedy, U.S. Patent 4,460,744, 17 July 1984, to Dow Chemical

K. Khait, SPE Techn. Pap. **40**, 3006 (1994)

K. Khait, SPE Techn. Pap. **41**, 2066 (1995)

M.M.K. Khan, R.F. Liang, R.K. Gupta, S. Agarwal, Korea Australia Rheol. J. **17**, 1 (2005)

G.B. Kharas, S.P. Nemphos, Europ. Pat. Appl. 515,203, 25 Nov 1992, to Novacor Chem.

W.N. Kim, C.M. Burns, Polym. Eng. Sci. **28**, 1115 (1988)

W.N. Kim, C.M. Burns, J. Polym. Sci. Polym. Phys. **28**, 1409 (1990)

S.-K. Kim, J.-W. Choi, U.S. Patent 5,747,587, 05 May 1998, to Cheil Industries

B.K. Kim, M.S. Kim, H.M. Jeong, K.J. Kim, J.K. Jang, Angew. Makromol. Chem. **194**, 91 (1992)

H.S. Kim, B.S. Jin, Y.C. Kwon, K. Seong, in *Encyclopaedic Dictionary of Commercial Polymer Blends*, ed. by L.A. Utracki (ChemTec, Toronto, 1994)

K. Kishida, J. Kobayashi, N. Ohsaka, Jap. Pat. 077,858, 26 Nov 1977, to Mitsubishi Rayon

K. Kishida, H. Mori, M. Kaneta, Jap. Pat. 001,246, 09 Jan 1978a, to Mitsubishi Rayon

K. Kishida, H. Mori, H. Fukunaga, H. Nakanishi, Jap. Pat. 018,661, 21 Feb 1978b, to Mitsubishi Rayon

H. Kishikawa, K. Yasuno, S. Kitamura, Ger. Offen. 2,119,376, 11 Nov 1971, to Sumitomo Chem.

T. Kishimoto, Jap. Pat. 059,952, 25 May 1976, to Mitsui Petrochem.

M. Kita, K. Hashimoto, Jap. Pat. 131,043, 13 June 1987, to Daicel Huels

K. Kitamura, Jap. Pat. 002,748, 08 Jan 1986, to Teijin Chem.

N. Kitayama, H. Keskkula, D.R. Paul, Polymer **41**, 8041 (2000a)

N. Kitayama, H. Keskkula, D.R. Paul, Polymer **41**, 8053 (2000b)

N. Kitayama, H. Keskkula, D.R. Paul, Polymer **42**, 3751 (2001)

T. Kobayashi, K. Shinohara, PCT Int. Appl. WO 93 05,107, 18 Mar 1993, to E. I. du Pont

T. Kobayashi, K. Tanaka, Can. Pat. 2,064,301, 29 Sept 1992, to Toray

T. Kobayashi, K. Miyazaki, M. Nakamura, U.S. Patent 5,594,038, 14 Jan 1997; U.S. Patent 5,646,194, 08 July 1997, to Sekisui Chemical

Y. Kobayashi, W. Zheng, E.F. Meyer, J.D. McGervey, A.M. Jamieson, R. Simha, Macromolecules **22**, 2302 (1989)

F.F. Koblitz, R.G. Petrella, A.A. Dukert, A. Christofas, U.S. Patent 3,253,060, 28 Nov 1966, to Pennwalt Chemical

J.E. Kochanowski, U.S. Patent 4,334,030, 08 Jun 1982, to General Electric Co.

T. Kodaira, H. Ishida, H. Kabaya, U.S. Patent 5,310,821, 10 May 1994, to GE Plastics Japan

H. Koenig, G. Wick, F. Thomczik, A. Thielemann, Ger. Offen. 1,165,255, 12 May 1964, to Hüls

P. Koetzing, K. Diebold, Kunststoffe **85**, 2046 (1995)

M.I. Kohan, U.S. Patent 4,351,916, 28 Sept 1982; Europ. Pat. Appl. 047,529, 17 Mar 1982, to E. I. du Pont

B. Köhler, W. Rüsseler, B. Sarabi, K. Reinking, F. Jonas, Europ. Pat. Appl. 510,475, 28 Oct 1992, to Bayer

H. Kojima, A. Taoka, K. Takiguchi, Jap. Pat. 027,905, 11 Sept 1970, to Mitsubishi Monsanto Chem.

M. Kojima, M. Tanahashi, Jap. Pat. 014,710, 02 May 1972, to Chisso

T. Kokkonen, T. Karna, J. Laakso, P. Nuholm, J.-E. Sterholm, H. Stubb, U.S. Patent 5,279,769, 18 Jan 1994, to Neste Oy

H. Komoto, Jap. Pat. 020,243, 28 Sept 1972, to Asahi Chem.

M. Kondo, K. Tominari, Jap. Pat. 079,260, 11 Apr 1987, to Mitsui Petrochem.

C.E. Koning, J.A.J. Kingma, L. Prinsen, Europ. Pat. Appl. 365,101, 25 Apr 1990, to Stamicarbon

C.E. Koning, H.J. Vroomans, Europ. Pat. Appl. 463,238, 02 Jan 1992, to Stamicarbon

E. Konrad, E. Tschunkur, U.S. Patent 1,973,000, 1934, to I. G. Farbenindustrie

R.M. Kopchik, U.S. Patent 4,255,322, 10 Mar 1981, to Rohm & Haas

A. Koshimo, Jap. Pat. 025,053, 02 Apr 1973, to Unitika

A. Koshimo, H. Sakata, T. Okamoto, H. Hasegawa, Jap. Pat. 051,945, 051,946, 051,947, 051,948, 21 July 1973, to Unitika

A. Koshirai, A. Nakata, N. Yamamoto, Europ. Pat. Appl. 468,772, 11 Mar 1992, to Mitsubishi Rayon

A. Koshirai, A. Nakata, N. Yamamoto, U.S. Patent 5,288,798, 22 Feb 1994, to Mitsubishi Rayon

T. Kotaka, *International Symposium on Elongational Flow of Polymeric Systems*, Yamagata U., Yonezawa, 13–15 June 1998

K. Kotama, Jap. Pat. 009,740, 23 Mar 1972, to Mitsubishi Rayon

A.M. Kotliar, J. Polym. Sci. Macromol. Rev. **16**, 367 (1981)

K. Koyama, T. Takahashi, Y. Naka, J. Takimoto, *13th International Annual Meeting* (Polymer Processing Society, New York, 1997)

S. Kozakura, S. Kuze, K. Tanaka, Europ. Pat. Appl. 496,257; 496,258, 29 July 1992, to Idemitsu Petrochem.

S. Kozakura, S. Kuze, K. Tanaka, U.S. Patent 5,314,949, 24 May 1994, to Idemitsu Petrochem.

M. Kozlowski, Polym. Networks Blends **4**, 39 (1994)

M. Kozlowski, Polym. Networks Blends **5**, 163 (1995)

E.O. Kraemer, W.D. Lansing, J. Am. Chem. Soc. **55**, 4319 (1933)

N.P. Krasnikova, E.V. Kotova, E.P. Plotnikova, M.P. Zabugina, G.V. Vinogradov, V.E. Dreval, Z. Pelzbauer, Kompoz. Polim. Mater. **21**, 37 (1984)

M. Kraus, I. Katsnelson, M. Heisler, PCT Int. Appl. 018,664, 12 Dec 1991, to Gelman Sci.

H.J. Kress, C. Lindner, L. Morbitzer, H. Peters, K.H. Ott, J. Schoeps, Ger. Offen. 3,514,185, 23 Oct 1986, to Bayer

J. Kressler, N. Higashida, T. Inoue, W. Heckmann, F. Seitz, Macromolecules **26**, 2090 (1993)

R.K. Krishnaswamy, U.S. Patent Appl. 2013006546, Mar 2013

R.K. Krishnaswamy, J. van Walsem, O.P. Peoples, Y. Shabtai, A.R. Padwa, U.S. Patent Appl., June 2013

W. Kuhn, Kolloid Z. **68**, 2 (1930)

W. Kuhnel, P. Spielau, U.S. Patent 4,255,372, 10 Mar 1981, to Dynamit Nobel

V.G. Kulkarni, B. Wessling, Europ. Pat. Appl. 497,514, 05 Aug 1992, to Americhem.

V.G. Kulkarni, B. Wessling, Europ. Pat. Appl. 536,915, 14 Apr 1993, to Americhem.

V.G. Kulkarni, B. Wessling, U.S. Patent 5,290,483, 01 Mar 1994, to Americhem.

H. Kumabe, A. Morimoto, Y. Kitagawa, N. Shiraishi, Fr. Pat. 2,151,639, 25 May 1973, to Japan Synthetic Rubber

A. Kumar, R.K. Gupta, *Fundamentals of Polymer Engineering*, 2nd edn. (Marcel Dekker, New York, 2003)

V. Kumar, N.P. Suh, Polym. Eng. Sci. **30**, 1323 (1990)

V. Kumar, J.E. Weller, R. Murray, SPE Techn. Pap. **41**, 2202 (1995)

J.A. Kuphal, L.M. Robeson, J.G. Santangelo, U.S. Patent 4,940,733, 10 July 1990, to Air Products & Chem.

K. Kyo, Y. Asai, Jap Pat. 129,248, 11 Nov 1978, to Unitika

T. Kyu, Europ. Pat. Appl. 392,763, 17 Oct 1990, to Edison Polym. Innov. Corp.

E.E. La Fleur, R.M. Amici, W.T. Freed, W.J. Work, W.G. Carson, U.S. Patent 5,147,930, 1992, to Rohm & Haas

E.E. La Fleur, R.M. Amici, W.J. Work, U.S. Patent 5,189,097, U.S. Patent 5,322,892, 21 June 1994a, to Rohm & Haas

E.E. La Fleur, R.M. Amici, W.T. Freed, W.J. Work, W.G. Carson, U.S. Patent 5,296,537, 22 Mar 1994b, to Rohm & Haas

E.E. La Fleur, W.J. Work, R.M. Amici, N.M. Bortnick, N.L. Holy, Eur. Pat. Appl. 583,109, 16 Feb 1994c, to Rohm & Haas

F.P. La Mantia (ed.), *Thermotropic Liquid Crystal Polymer Blends* (Technomics, Lancaster, 1993)

S.-Y. Lai, M.S. Edmondson, U.S. Patent 5,408,004, 18 Apr 1995, to Dow Chemical

X.-Y. Lai, D.-F. Zhao, F. Lai, U.S. Patent 5,344,895, 06 Sept 1994, to University of Massachusetts Lowell

R. Langworth, U.S. Patent 3,299,176, 17 Jan 1967, to E. I. du Pont

H.H. Lank, E.L. Williams, *The Du Pont Canada History* (Du Pont Canada, Montréal, 1982)

O.E. Larsen, Can. Pat. 1,120,630, 23 Mar 1982, to Phillips

R.L. Lauchlan, Ger. Offen. 2,035,147, 28 Jan 1971, to Uniroyal

R.L. Lauchlan, G.A. Shaw, Fr. Pat. 2,011,783, 06 Mar 1970, to Uniroyal

R.L. Lauchlan, H.E. Snodgrass, Ger. Pat. 2,312,971, 27 Sept 1973, to Uniroyal

M.K. Laughner, PCT Int. Appl. WO 93 19,128, 30 Sept 1993; U.S. Patent 5,262,476, 16 Nov 1993, to Dow Chemical

M.K. Laughner, U.S. Patent 5,286,790, 15 Feb 1994, to Dow Chemical

M.K. Laughner, C.P. Bosnyak, B.N. Herron, PCT Int. Appl. 003,504, 05 Mar 1992, to Dow Chemical

D. Lausberg, C. Taubitz, M. Knoll, Ger. Offen. 3,617,070, 26 Nov 1987, to BASF

R.E. Lavengood, A.F. Harris, A.R. Padwa, Europ. Pat. Appl. 202,214, 20 Nov 1986, to Monsanto

R.E. Lavengood, R. Patel, A.R. Padwa, U.S. Patent 4,777,211, 11 Oct 1988, to Monsanto

A. Lazzeri, C.B. Bucknall, J. Mater. Sci. **28**, 6788 (1993)

G.F. Lee Jr., U.S. Patent 4,123,410, 31 Oct 1978; U.S. Patent 4,128,602; 4,128,603; 4,128,604; 05 Dec 1978, to General Electric Co.

G.F. Lee Jr., U.S. Patent 4,143,095, 06 Mar 1979, to General Electric Co.

G.F. Lee Jr., U.S. Patent 4,242,263, 39 Dec 1980, to General Electric Co.

G.F. Lee Jr., U.S. Patent 4,311,633, 19 Jan 1982, to General Electric Co.

G.F. Lee Jr., U.S. Patent 4,383,082, 10 May 1983, to General Electric Co.

G.F. Lee Jr., Europ. Pat. Appl. 133,487, 27 Feb 1985, to General Electric Co.

G.F. Lee Jr., U.S. Patent 4,972,021, Nov 20, 1990, to General Electric Co.

G.F. Lee Jr., U.S. Patent 5,324,782, 28 June 1994, to General Electric Co.

S.-T. Lee, SPE Techn. Pap. **42**, 1948 (1996)

S.-T. Lee, U.S. Patent 5,428,093, 27 June 1995, to Sealed Air Corp.

Y.S. Lee, K.H. Char, Macromolecules **27**, 2603 (1994)

Y.C. Lee, Q.A. Trementozzi, Europ. Pat. Appl. 002,961, 11 July 1979, to Monsanto

Y.C. Lee, Q.A. Trementozzi, Europ. Pat. Appl. 007,931, 20 Feb 1980; U.S. Patent 4,223,096, 16 Sept 1980, to Monsanto

Y.C. Lee, Q.A. Trementozzi, U.S. Patent 4,305,869, 1981, to Monsanto

Y.C. Lee, Q.A. Trementozzi, U.S. Patent 4,341,695, 27 July 1982, to Monsanto

R.W. Lee, M.S. Ott, C.O. Castro, U.S. Patent 5,281,670, 25 Jan 1994, to Shell Oil

M.-H. Lee, C. Tzoganakis, C.B. Park, Polym. Eng. Sci. **38**, 1112 (1998)

J.P. Lehane Jr., U.S. Patent 3,137,672, 16 June 1964, to Hercules Powder

R. Leibler, W. Ringenberg, Ger. Offen. 3,518,538, 27 Nov 1986, to Roehm

J. Mayumi, H., Omori, Europ. Pat. Appl. 268,981, 01 June 1988, to Mitsubishi Petrochem.

F.B. McAndrew, Ger. Pat. 2,051,028, 29 Apr 1971, to Celanese Corp.

S.P. McCarthy, R.A. Gross, W. Ma, U.S. Patent 5,883,199, 1999

W.J. McCracken, J. Cellular. Plast. **20**(2), 150 (1984)

J.E. McCready, U.S. Patent 3,947,403, 30 Mar 1976, to Goodyear Tire and Rubber

T.W. McCullough, B.D. Stevens, U.S. Patent 4,515,907, 07 May 1985, to Dow Chemical

J.E. McGrath, M. Matzner, U.S. Patent 3,655,822, 11 Apr 1972, to Union Carbide Corp.

G.H. McKee, F. Haaf, J. Hambrecht, K. Benker, R. Stephan, H. Breurer, Ger. Offen. 3,113,627, 21 Oct 1982, to BASF

A.K. Mehta, M.C. Chen, U.S. Patent 5,358,792, 25 Oct 1994, to Exxon

P. Meier, Ger. Pat. 4,139,468, 03 June 1993, to Ems-Inventa

J.L. Melmquist, U.S. Patent 5,189,115, 23 Feb 1993, to Amoco Corp.

N.A. Memon, C.S. Myers, U.S. Patent 4,391,938, 05 July 1983, to Rohm & Haas

A. Merrington, in *Applied Plastics Engineering Handbook*, ed. by M. Kutz (Elsevier, Amsterdam, 2011)

R.B. Mesrobian, C.J. Ammondson, Brit. Pat. 889,354, 14 Feb 1962, to Continental Can Company

V. Metanomski (ed.), *Compendium of Macromolecular Nomenclature*, IUPAC Macromol. Div. (Blackwell, Oxford, 1991)

R.V. Meyer, P. Tacke, Ger. Offen. 2,654,168, 01 June 1978, to Bayer

J.M. Michel, Fr. Pat. 1,566,235, 09 May 1969, to Pechiney-Saint Gobain

E.A. Militskova, E.A. Pavlova, I.O. Stalnova, V.B. Cherkashin, USSR. Pat. 1,788,958, 15 Jan 1993, to USSR

A. Miller, N.G. Reddeman, Belg. Pat. 620,703, 14 Nov 1962, to Miliprint

G.W. Miller, U.S. Patent 3,646,159, 29 Feb 1972, to Baychem Corp.

A. Minegishi, Y. Naka, T. Takahashi, Y. Masubuchi, J. Takimoto, K. Koyama, Nihon Reor. Gakk. **25**, 215 (1997)

A. Minegishi, A. Nishioka, T. Takahashi, Y. Masubuchi, J. Takimoto, K. Koyama, *International Symposium on Elongational Flow of Polymeric Systems*, Yamagata U., Yonezawa, 13–15 June 1998

S. Minekawa, K. Yamaguchi, K. Toyomoto, E. Fujimoto, Y. Takeuchi, Jap. Pat. 008,585, 12 Sept 1969, to Asahi Chem.

S. Minekawa, K. Yamaguchi, K. Toyomoto, E. Fujimoto, Y. Takeuchi, Jap. Pat. 016,429, 06 May 1971, to Asahi Chem.

L.I. Minkova, M. Paci, M. Pracella, P. Magagnini, Polym. Eng. Sci. **32**, 57 (1992)

Mitsubishi Chem. Ind. Co., Jap. Pat. 157,648, 08 Dec 1980

Mitsubishi Chem. Ind. Co., Jap. Pat. 137,347, 24 Aug 1982

Mitsubishi Chem. Ind. Co., Jap. Pat. 076,448, 09 May 1983

Mitsubishi Chem. Ind. Co., Jap. Pat. 020,351, 02 Feb 1984

Mitsubishi Gas Chem. Co., Jap. Pat. 174,344, 27 Oct 1982

Mitsubishi Gas Chem. Co., Jap. Pat. 020,953, 02 Feb 1985

Mitsubishi Petrochem. Co., Jap. Pat. 195,147, 30 Nov 1982

Mitsubishi Petrochem. Co., Jap. Jap. Pat. 007,448, 17 Jan 1983; Jap. Pat. 162,653, 27 Sept 1983

Mitsubishi Petrochem. Co., Jap. Pat. 022,956, 06 Feb 1984

Mitsubishi Petrochem. Co., Jap. Pat. 086,161; 086,164, 15 May 1985

Mitsui Petrochem. Ind., Jap. Pat. 168,646, 05 Oct 1983; Jap. Pat. 213,039, 10 Dec 1983

K. Miyanishi, Y. Manabe, Jap Pat., 047,043, 22 Apr 1976, to Teijin Chemicals

Y. Mizuno, T. Maruyama, Europ. Pat. Appl. 349,339, 03 Jan 1990, to Sumitomo Chem.

M. J. Modic, R. Gelles, Europ. Pat. Appl. 255,184, 03 Feb 1988, to Shell

A.K. Mohanty, M. Misra, L.T. Drzal (eds.), *Natural Fibers, Biopolymers and Biocomposites* (Taylor and Francis, Boca Raton, 2005)

R.N. Mohn, D.R. Paul, J.W. Barlow, C.A. Cruz, J. Appl. Polym. Sci. **23**, 575 (1979)

A.N. Mollison, U.S. Patent 4,461,808, 24 July 1984, to DuPont Canada

H. Moncure Jr., U.S. Patent 3,480,694, 25 Nov 1969, to E. I. du Pont

C.W. Montgomery, Fr. Pat. 1,445,876, 15 July 1966, to Ethyl Corp.

D.Y. Moon, O.O. Park, Adv. Polym. Technol. **17**, 203 (1998)

D. Moorwessel, R. Glasser, G. Pfirrmann, Ger. Offen. 2,306,893, 22 Aug 1974, to BASF

A.W. Morgan, R.G., Ribaudo, U.S. Patent 4,228,245, 14 Oct 1980, to Bayer

Y. Morita, N. Kashiwa, Europ. Pat. Appl. 022,376, 14 Jan 1981, to Mitsui Petrochem.

K. Morita, K. Uchiki, H. Shinoda, U.S. Patent 5,223,546, 29 June 1993a; U.S. Patent 5,238,968, 24 Aug 1993b, to Mitsui Toatsu Chemicals

P.J.T. Morris, *The American Synthetic Rubber Research Program* (University of Pennsylvania Press, Philadelphia, 1989)

D.R. Morrow, T.J. Nosker, K.E. VanNess, R.W. Renfree, U.S. Patent 5,298,214, 29 Mar 1994, to Rutgers State University

M. Morton, in *History of Polymer Science and Technology*, ed. by R.B. Seymour (Marcel Dekker, New York, 1982)

G.S. Motz, U.S. Patent 4,226,961, 07 Oct 1980, to General Electric Co.

C.T. Movak, P.N. Nelson, S. Nam, W. DeMoully, K.D. Goebel, U.S. Patent 5,371,143, 06 Dec 1994, to Minnesota Mining & Manufacturing

P. Mukhopadhyay, C.K. Das, Polym. Plast. Technol. Eng. **28**, 537 (1989)

P. Mukhopadhyay, C.K. Das, J. Appl. Polym. Sci. **39**, 49 (1990)

P. Mukhopadhyay, C.K. Das, Int. J. Polym. Mater. **15**, 57 (1991)

P. Mukhopadhyay, H.P. Schreiber, Colloids Surf. A Physicochem. Eng. Asp. **100**, 47 (1995)

P. Mukhopadhyay, G. Chowdhury, C.K. Das, Kautschuk Gummi Kunststoffe **42**, 308 (1989)

P. Mukhopadhyay, G. Chowdhury, C.K. Das, J. Appl. Polym. Sci. **40**, 1833 (1990)

A. Mukohyama, Int. Pat. Appl. 08,233, 29 Apr 1993, to E. I. du Pont

R. Mülhaupt, J. Rosch, S. Hopperdietzel, E. Weinberg, H. Klein, U.S. Patent 5,312,875, 17 May 1994, to Rehau

D.H. Mullins, Brit. Pat. 958,399, 21 May 1964, to Union Carbide Corp.

W.G. Munk, Ger. Offen. 4,204,083 A1, 04 Mar 1993, to Nordmann Rassmann GmbH & Co.

H. Münstedt, S. Kurzbeck, *International Symposium on Elongational Flow of Polymeric Systems*, Yamagata U., Yonezawa, 13–15 June 1998

S. Murakami, H. Higuchi, S. Matsuo, Jap. Pat. 03 190,961, 20 Aug 1991, to Idemitsu Kosan

J.D. Murdock, N. Nelan, G.H. Segall, Ger. Offen. 1,217,606, 26 May 1960, to Canadian Industries

J.D. Murdock, N. Nelan, G.H. Segall, Brit. Pat. 901,386, 18 July 1962, to Canadian Industries

J.G. Murray, U.S. Patent 4,352,908, 05 Oct 1982, to Mobil Oil Corp.

L.C. Muschiatti, B.A. Smillie, U.S. Patent 5,391,582, 21 Feb 1995, to E. I. Du Pont

V.M. Nadkarni, J.P. Jog, in *Two – Phase Polymer Systems*, ed. by L.A. Utracki (Hanser, Munich, 1991)

S. Nagai, M. Hasegawa, H. Mimura, M. Kobayashi, Eur. Pat. Appl. 565,304, 13 Oct 1993, to Mitsubishi Gas Chem.

S. Nagai, M. Hasegawa, H. Mimura, M. Kobayashi, U.S. Patent 5,326,846, 05 July 1994, to Mitsubishi Gas Chem.

K. Nagasaki, T. Hata, K. Matsuzaki, Jap. Pat. 03 263,454, 22 Nov 1991, to Asahi Chem.

Y. Nagase, M. Kobayashi, T. Kato, S. Imuta, U.S. Patent 5,338,792, 16 Aug 1994, to Mitsui Petrochem.

S.V. Nair, A. Subramaniam, L.A. Goettler, J. Material Sci. **32**, 5347 (1997)

S.V. Nair, A. Subramaniam, L.A. Goettler, J. Material Sci. **33**, 3455 (1998)

K. Nakamura, K. Neki, Europ. Pat. Appl. 039,155, 04 Nov 1981, to Asahi Chem.

K. Nakamura, K. Toyomoto, Jap. Pat. 075,662, 22 July 1974, to Asahi Chem.

K. Nakamura, T. Kimura, H. Tsunoda, Jap. Pat. 083,174, 06 Nov 1973, to Sanyo Pulp.

H. Nakano, T. Inoue, S. Gotoh, M. Kihira, Europ. Pat. Appl. 484,941, 13 May 1992, to Mitsubishi Petrochem.

K.M. Nampoothiri, N.R. Nair, R.P. John, Bioresource Technol. **101**, 8493 (2010)

K.M. Natarajan, R. Mininni, Europ. Pat. Appl. 428,178, 22 May 1991, to Enichem.

K.M. Natarajan, P. Arjunan, D. Elwood, Europ. Pat. Appl. 540,120, 05 May 1993, to Enichem.

K.M. Natarajan, P. Arjunan, D. Elwood, U.S. Patent 5,296,550, 22 Mar 1994, to Enichem.

G. Natta, F. Danusso (eds.), *Stereoregular Polymers and Stereospecific Polymerization* (Pergamon Press, New York, 1967)

S.P. Nemphos, G.B. Kharas, Eur. Pat. Appl. 540,182, 05 May 1993, to Novacor Chem.

S.P. Nemphos, G.B. Kharas, U.S. Patent 5,300,576, 05 Apr 1994, to Novacor Chem.

D. Neuray, W. Nouverte, R. Binsack, D. Rempel, P.R. Mueller, Europ. Pat. Appl. 064,648, 17 Nov 1982, to Bayer

R. Newe, E. Lange, H. Hoffmann, K. Wetzel, East Ger. Offen. 207,381, 29 Feb 1984, to VEB Chemiekombinat Bitterfeld

S. Newman, D.R. Paul, *Polymer Blends*, vol. I and II (Academic, New York, 1978)

A.B.. Newton, Europ. Pat. Appl. 037,181, 07 Oct 1981, to ICI

K.L. Ngai, D.J. Plazek, Macromolecules **23**, 4282 (1990)

X.Q. Nguyen, L.A. Utracki, U.S. Patent 5,451,106, 19 Sept 1995, to National Research Council Canada

E. Nield, Ger. Offen. 2,122,735, 25 Nov 1971, to ICI

N. Niessner, G.E. Mac Kee, K. Ruppmich, Ger. Pat. 4,200,247, 15 July 1993, to BASF

N. Niessner, F. Seitz, W. Fischer, N. Guentherberg, K. Ruppmich, R. Moors, R. Weiss, Europ. Pat. Appl. 576,960, 05 Jan 1994, to BASF

Nippon Zeon Co., Jap. Pat. 129,245, 25 July 1984

T. Nishio, T. Sanada, T. Okada, Europ. Pat. Appl. 270,247, 08 June 1988, to Sumitomo Chem.

T. Nishio, Y. Suzuki, K. Kojima, M. Kakugo, Kobunshi Robunshu **47**, 331 (1990)

T. Nishio, T. Nomura, N. Kawamura, H. Sato, A. Uchikawa, I. Tsutsumi, Y. Goto, Europ. Pat. Appl. 519,725, 23 Dec 1992, to Mitsubishi Petrochem.

T. Nishio, T. Sanada, S. Hosoda, K. Nagaoka, T. Okada, U.S. Patent 5,288,786, 22 Feb 1994, to Sumitomo Chem.

A. Nishioka, S. Kato, Y. Kiyomatsu, M. Ichikawa, Y. Kitagawa, Jap. Pat. 074,552, 08 Oct 1973, to Japan Synthetic Rubber

A. Nishiyama, T. Nakakita, Jap. Pat. 03 252,455, 11 Nov 1991, to Ube Industries

M. Nishiyama, K. Ohtsuki, Y. Nakakita, H. Ozawa, Europ. Pat. Appl. 360,544, 28 Mar 1990, to Ube

M. Nishiyama, T. Nakakita, K. Ohtsuka, Jap. Pat. 03 100,055, 25 Apr 1991a, to Ube

M. Nishiyama, K. Ohtsuka, T. Nakakita, Jap. Pat. 03 91,562, 17 Apr 1991b, to Ube

G.E. Nizik, U.S. Patent 4,097,425, 27 Jan 1978, to General Electric Co.

G.E. Nizik, U.S. Patent 4,174,432, 13 Nov 1979, to General Electric Co.

K. Nyori, A. Kinoshita, I. Hatano, Jap. Pat. 010,928; 012,919, 04 Sept 1962, to Kanegafuchi Chem.

W.J.J. O'Connell, Fr. Dem. 2,213,959, 09 Aug 1974, to General Electric Co.

W.J.J. O'Connell, Jap. Pat. 076,450, 09 May 1983, to General Electric Co.

A.O. Ogah, J.L. Afikuwa, Int. J. Eng. Management Sci. **3**, 85 (2012)

T. Ogawa, N. Ito, K. Ohishi, R. Samejima, Jap. Pat. 031,241, 24 Apr 1973, to Sumitomo Chem.

T. Ohmae, Y. Toyoshima, K. Mashita, N. Yamaguchi, J. Nambu, U.S. Patent 5,010,136, 23 Apr 1991, to Sumitomo Chem.

T. Ohmae, Y. Toyoshima, K. Mashita, N. Yamaguchi, J. Nambu, Europ. Pat. Appl. 480,770, 15 Apr 1992, to Sumitomo Chem.

M. Ohta, K. Iiyama, S. Kawashima, S. Tamai, H. Oikawa, A. Yamaguchi, Europ. Patent Appl. 294,144, 07 Dec 1988, to Mitsui Toatsu Chem.

T. Ohta, O. Urakawa, Q. Tran-Cong, Macromolecules **31**, 6845 (1998)

T. Oita, T. Hara, R. Samejima, K. Tanabe, Jap Pat. 108,146, 20 Sept 1978, to Sumitomo Chem.

A. Okada, U.S. Patent 5,352,727, 04 Oct 1994, to Idemitsu Kosan

A. Okada, A. Masuyama, U.S. Patent 5,326,813, 05 July 1994, to Idemitsu Kosan

K. Okada, M. Karaiwa, A. Uchiyama, U.S. Patent 5,728,744, 17 Apr 1998a, to Mitsui Petrochem.

K. Okada, M. Karaiwa, A. Uchiyama, U.S. Patent 5,786,403, 28 July 1998b, to Mitsui Petrochem

O. Okada, H. Keskkula, D.R. Paul, J. Polym. Sci. Part B Polym. Phys. **42**, 1739 (2004)

K.T. Okamoto, K.D. Eastenson, S.C. Guyaniyogi, Europ. Pat. Appl. 566,106, 20 Oct 1993, to Himont

K.T. Okamoto, K.D. Eastenson, S.C. Guyaniyogi, U.S. Patent 5,290,856, 01 Mar 1994, to Himont

M. Okamoto, A. Kojima, T. Kotaka, Polymer **39**, 2149 (1998a)

M. Okamoto, H. Kubo, T. Kotaka, *14th International Polymer Processing Society Meeting*, *PPS-14*, Yokohama, 08–12 June 1998b

Y. Okawa, N. Koga, H. Oikawa, T. Asanuma, A. Yamaguchi, U.S. Patent 5,321,096, 14 June 1994, to Mitsui Toatsu Chem.

S. Okuda, Europ. Pat. Appl. 356,167, 28 Feb 1990, to Polyplastics

T. Okuzono, M. Kifune, Jap. Pat. 001,147, 08 Jan 1975, to Mitsubishi Gas Chem.

T. Okuzono, M. Kifune, Jap. Pat. 030,255; 030,256, 11 Sept 1976, to Mitsubishi Gas Chem

J. O'Leary, S. Musgrave, PCT Int. Appl. WO 93 21,269, 28 Oct 1993, to ICI, Australia

Y. Ono, K. Iida, K. Murata, Y. Noto, Jap Pat. 03 97,756, 23 Apr 1991, to Dainippon Ink & Chem.

Y. Orikasa, S. Sakazume, Europ. Pat. Appl. 361,400, 04 Apr 1990, to Nippon Petrochem.

Y. Orikasa, S. Sakazume, Europ. Pat. Appl. 506,006, 30 Sept 1992, to Nippon Petrochem.

Y. Orikasa, S. Sakazume, U.S. Patent 5,296,538, 22 Mar 1994, to Nippon Petrochem.

Y. Orikasa, S. Sakazume, S. Nishimura, Y. Maki, Europ. Pat. Appl. 314,188, 03 May 1989, to Nippon Petrochem.

I.I. Ostromislensky, J. Russ. Phys. Chem. Soc. **44**, 204 (1911)

Abstract

This chapter summarizes the thermodynamics of multicomponent polymer systems, with special emphasis on polymer blends and mixtures. After a brief introduction of the relevant thermodynamic principles – laws of thermodynamics, definitions, and interrelations of thermodynamic variables and potentials – selected theories of liquid and polymer mixtures are provided: Specifically, both *lattice theories* (such as the Flory-Huggins model, Equation of State theories, and the gas-lattice models) and *off-lattice theories* (such as the strong interaction model, heat of mixing approaches, and solubility parameter models) are discussed and compared. Model parameters are also tabulated for the each theory for common or representative polymer blends. In the second half of this chapter, the thermodynamics of phase separation are discussed, and experimental methods – for determining phase diagrams or for quantifying the theoretical model parameters – are mentioned.

2.1   Introduction

Performance of polymer blends depends on the properties of polymeric components, as well as how they are arranged in space. The spatial arrangement is controlled by the thermodynamics and flow-imposed morphology. The word "thermodynamics" invariably brings to mind "miscibility." However, thermodynamics has a broader use for the practitioners of polymer science and technology than predicting miscibility. The aim of this chapter is to describe how to measure, interpret, and predict the thermodynamic properties of polymer blends, as well as where to find the relevant information and/or numerical values.

Determination of such thermodynamic properties as the phase diagram or the Flory-Huggins binary interaction parameter, χ_{12}, is in principle difficult. The difficulties originate in high viscosity of macromolecular species, thus slow diffusion toward the equilibrium, heat generation when mixing, and thermal degradation at processing relevant temperatures.

For these reasons, there is a tendency to use values obtained from low molecular homologues or solutions. Furthermore, it is an accepted practice to purify the polymers before measuring their thermodynamic properties. However, most industrial polymers are modified by incorporating low molecular weight additives. Furthermore, they are processed under high flow rates and stresses that preclude the possibility of thermodynamic equilibrium. For these and other reasons, a direct application of the laboratory data to industrial systems may not always be appropriate or advisable.

Another difficulty originates in the lack of theories able to predict variation of thermodynamic properties for commercially relevant systems with modifiers. Different additive compositions are used by different manufacturers of the same polymer. Some of these are even being "used up" during processing or during the products' lifetime, their content, and chemical structure change. They may significantly affect the thermodynamic properties of a polymeric mixture, by the physical, viz., that of a cosolvent, and the chemical effects. For example, additives of one polymeric component of a blend may chemically react with additives of another polymeric component, mutually neutralizing each other. In particular, these effects may be large as far as the surface and interface energies are concerned.

2.2 Thermodynamic Principles

2.2.1 Definitions

For convenience, thermodynamic systems are usually assumed closed, isolated from the surroundings. The laws that govern such systems are written in terms of two types of variables: *intensive* (or intrinsic) that do not depend on the mass and *extensive* that do. By definition, extensive variables are additive, that is, their value for the whole system is the sum of their values for the individual parts. For example, volume, entropy, and total energy of a system are extensive variables, but the specific volume (or its reciprocity – the density), molar volume, or molar free energy of mixing are intensive. It is advisable to use, whenever possible, intensive variables.

The main independent variables are the temperature (T), pressure (P), and composition (expressed as number of molecules, N_i, for each component molecule species, i, or through the respective molar fractions, x_i, or volume fractions, ϕ_i). The principal thermodynamic terms are listed in Table 2.1, whereas Table 2.2 provides values of constants often used in thermodynamic calculations.

2.2.1.1 Thermodynamic Potentials and the Concept of Free Energy

In thermodynamics, any energy definition for a system is expressed in terms of pairs of thermodynamic variables, termed as *conjugate variables*. Conjugate pairs are T and S (with TS relating to heat), P and V (with PV related to mechanical work), μ and N, and so on. In each pair, one of the variables is an *intensive variable* (e.g., T, P, μ, etc., that can be considered as a "generalized force"), and the other variable is *extensive* (e.g., S, V, N, respectively, that is considered as the respective "generalized displacement"). The construction of all energy expressions, i.e., thermodynamic potentials, is based on conjugate variables pairs, and all energy changes are associated with products of the absolute value of one conjugate variable multiplied by the change of the other from each pair, i.e., $T \Delta S$, $S \Delta T$, $P \Delta V$, $V \Delta P$, $\mu \Delta N$, and so on.

For every thermodynamic system, there is a finite number of D conjugate pairs describing it (Alberty 2001), or, equivalently, D independent variables are needed to describe the extensive state of the system (*natural variables*). D is also called the "thermodynamic dimensionality" of the system, or, equivalently, the thermodynamic

Table 2.1 Definition of principal thermodynamic terms

Term	Symbol	Definition
Internal energy	U	$U = U(N, V, S)$ comprises of heat, Q, work, W
Entropy	S	$S = S(N, V, U)$ with $S = k \ln \Omega$; where Ω is a measure of the multiplicity of states
Enthalpy	H	$H = H(N, P, S)$ with $H = U + PV$
Helmholtz potential	F	$F = F(N, V, T)$ with $F = U - TS = H - PV - TS$
Gibbs potential	G	$G = G(N, P, T)$ with $G = U + PV - TS = H - TS$
Landau potential	Ω	$\Omega = \Omega(T, V, \mu)$ with $\Omega = U - TS - \mu N$
Extensive properties of a mixture	Z_m	Z_m can be E_m or S_m or F_m or H_m, etc.
Change of an extensive property due to mixing	ΔZ_m	$\Delta Z_m = Z_m - \Sigma x_i Z_i = \Sigma x_i (Z_i - Z_i^0) = \Sigma x_i \Delta Z_i$
Ideal solutions	ΔG^I	$\Delta G^I = -T\Delta S^I = kTN\Sigma x_i \ln x_i$, thus no interactions, $\Delta H^I = 0$, and total randomness of molecular placement, $\Delta V^I = 0$
Regular solutions	ΔG^R	$\Delta G^R = \Delta H^P - T\Delta S^I$; $\Delta H^R \propto \frac{1}{2}(\varepsilon_{11} + \varepsilon_{22}) - \varepsilon_{12}$. The molecular interactions are nonspecific, without associations, hydrogen or dipole-dipole bonding, distribution, orientation, etc.
Excess properties	ΔZ^E	$\Delta Z^E = \Delta Z - \Delta Z^I$
Athermal solutions	ΔG^A	$\Delta G^A = -T\Delta S$; $\Delta H^A = 0$
Combinatorial entropy	ΔS^{comb}	That part that originates from the number of possible placements of molecules in the lattice of an athermal solution (the latter assumption usually is abandoned in the following derivations)
Equation of state (EoS)	PVT	The relation between P, V, and T for a material
Reducing variables	P^*, V^*, T^*	Reducing variables are characteristic materials' parameters used to reduce the corresponding independent variables, making them to follow respective corresponding state equation(s)
Corresponding states	$\tilde{P}\tilde{V}\tilde{T}$	Describing behavior of material by relations of its reduced variables, e.g., $\tilde{P} \equiv P/P^*, \tilde{V} \equiv V/V^*, \tilde{T} \equiv T/T^*$
Free volume	V_f	$V_f = V - V_o$, where $V_o \simeq \lim_{T \to 0} V$
Solubility parameter	δ	Can be calculated from the heat of vaporization ΔH^V $(\Delta H^V = RT^2(\partial \ln P/\partial T)_{sat})$ by $\delta = \sqrt{(\Delta H^V - RT)/V}$ or can also be calculated from the molecular structure

space of the system has D dimensions. For example, in the simplest case of a single-phase ideal gas, there are three pairs of conjugate variables and, thus, $D=3$. By definition of the thermodynamic energy functions (thermodynamic potentials, cf. Table 2.1), this means that there will be 2^D unique thermodynamic potentials. The various thermodynamic potentials are defined considering as its independent variables one thermodynamic parameter from each conjugate pair; these are the D *natural variables* of this thermodynamic potential (e.g., $U = U(N, V, S)$, $F = F(N, V, T)$, $G = G(N, P, T)$, etc., see also Table 2.1). For the same example as above, the single-phase ideal gas, there will be $2^3 = 8$ thermodynamic potentials that can be

Table 2.2 Useful constants

Constant	Symbol	Value
Avogadro's number	N_A	6.02205×10^{23} [mol^{-1}]
Boltzmann constant	k_B	1.38065×10^{-23} [JK^{-1}]
Molar gas constant	$R = N_A k_B$	8.31441 [JK^{-1}mol^{-1}]
Molar volume at standard conditions	$V_o = RT_o/P_o$	22.41383×10^{-3} [m^{3}mol^{-1}]
Origin of Celsius scale	T_o	273.15 [K]
Planck's constant	h	6.62618×10^{-34} [Js]
Standard atmospheric pressure	P_o	1.01325×10^5 [Nm^{-2}]

defined to quantify its energy at a given state, or its energy change upon undergoing any arbitrary thermodynamic process. All 2^D thermodynamic potentials can be calculated for any system, and its corresponding differential can be calculated for any arbitrary process to quantify the corresponding energy change for this process (Alberty 2001). However, only one of these 2^D energy definitions adopts appropriate values and has appropriate behaviors/changes for each thermodynamic process, and this energy (thermodynamic potential) is the *free energy* of the system for this thermodynamic process. For a system undergoing a thermodynamic process, by definition:

1. The free energy adopts a minimum value at equilibrium.
2. The free energy change is negative for spontaneous processes.

Both the above are satisfied by a thermodynamic potential, when the thermodynamic process happens under conditions where its *natural variables* remain constant. For example, for a closed system ($N = $ constant) undergoing a process under controlled temperature and volume (T, V are also constant), the Helmholtz potential $F = F(N, V, T)$ is the corresponding free energy; similarly, for the same system undergoing a process where NPT are constant, the Gibbs potential $G = G(N, P, T)$ is now the free energy in this case; and so on.

New energy terms need to be added in the form of conjugate pairs when the system has additional energy contributions: e.g., if there exist more than one species of molecules, a separate $\mu_i N_i$ term is needed for each species i; if there are magnetic dipoles or spins, a BM term is needed (B is the magnetic field, M the system magnetization, and $B \, dM$ would be the associated energy change contribution in dU); and so on. Also, there may be additional mechanical work terms (beyond $P \, dV$), such as work associated with interfaces, $\gamma \, dA_{inter}$; work associated with mechanical deformation, $V \sum_{ij}\tau_{ij}d\varepsilon_{ij}$; or work associated for uniaxial deformation, $F \, dl$.

2.2.2 The Three Laws of Thermodynamics

Thermodynamics focuses on the state of material, usually in *a closed system*. Historically, the laws were empirically formulated using the well-accepted process of hypothesis, observation, and analysis. However, since the energetic state of a closed system is a sum of all the molecular and atomic motions, the statistical physics re-derived these laws from the first principles (Waldram 1985; Gupta 1990).

2.2.2.1 The First Law (Conservation of Energy)

In a closed system, the total energy remains constant (also known as *sine perpetuum mobile*). Thus, for a closed system, the change of internal energy (dU):

$$dU = dW + dQ = 0 \tag{2.1}$$

where dW represents the work done on or by the system and dQ represents the change of the thermal energy content. Note that there are several forms of energy that can be classified as "work," for example, compression, friction, electromagnetic interaction, etc.

For a perfect gas at constant pressure, $P = $ const., Eq. 2.1 gives the relationship between the heat capacities at constant pressure and at constant volume, viz., $C_P - C_V = R$ (R is the gas constant). Similarly, at $T = $ const., Eq. 2.1 predicts that the external work can only be performed at a cost of the internal energy: $PdV = -dU$.

2.2.2.2 The Second Law (The Principle of Entropy Increase)

The energy always flows from a higher to a lower level; hence, the system tends to move toward a more uniform distribution of the local energetic states. Since the entropy provides a measure of randomness, in a closed system, the entropy never decreases:

$$dS = \frac{dQ}{T} \geq 0 \tag{2.2}$$

The second law of thermodynamics is also known as the Carnot cycle principle that specifies that "heat can never pass from a colder to a warmer body without some other changes, connected therewith, occurring at the same time" (Clausius).

Equation 2.2 can also be written as:

$$
\begin{aligned}
\left(\frac{\partial S}{\partial V}\right)_T &= \frac{1}{T}\left(\frac{\partial Q}{\partial V}\right)_T = \left(\frac{\partial P}{\partial T}\right)_V \\
\left(\frac{\partial S}{\partial P}\right)_V &= \frac{1}{T}\left(\frac{\partial Q}{\partial P}\right)_V = \left(\frac{\partial V}{\partial T}\right)_S
\end{aligned}
\tag{2.2a}
$$

2.2.2.3 The Third Law (Entropy Vanishes at Absolute Zero)

In 1906, Nernst showed (experimentally) that the equilibrium entropy tends toward zero as the absolute temperature approaches zero:

$$
\begin{aligned}
&\lim_{T \to 0} S = \lim_{T \to 0} dS = 0, \quad \text{or equivalently} \\
&S = \int_0^T \frac{dQ_{rev}}{T}\left(\text{assuming } S_{T=0} \overset{emp}{=} 0\right)
\end{aligned}
\tag{2.3}
$$

As a corollary, near zero K the change of entropy in any process is negligibly small. Thus, the third law is empirical, but so far no contradictory observation was reported. As a consequence of Eq. 2.3, near the absolute zero the coefficient of thermal expansion and the pressure coefficient are expected to vanish:

$$\lim_{T \to 0} \left(\frac{\partial S}{\partial P} \right)_T = \lim_{T \to 0} \left(\frac{\partial S}{\partial V} \right)_T = 0$$

$$\lim_{T \to 0} \left(\frac{\partial V}{\partial T} \right)_P = -\lim_{T \to 0} \left(\frac{\partial P}{\partial T} \right)_V = 0$$

(2.3a)

In summary, the first law is simply a statement of the law of conservation of energy, the second law is concerned only with differences in the entropy between (two) states, and the third law allows for the calculation of the absolute entropy of a state (assuming knowledge of the system's entropy at the absolute zero of temperature, that is at $T = 0$ K).

2.2.3   Interrelations Between Thermodynamic Variables

The full differentials (or the total changes) of the principal thermodynamic potentials for a closed system ($N = $ const.) cast in terms of their natural variables are

$$
\begin{aligned}
dF &= -SdT - PdV \\
dH &= TdS + VdP \\
dG &= -SdT + VdP
\end{aligned}
$$

(2.4)

Note that Eq. 2.4 implies that $F = F(T, V)$, $H = H(S, P)$, and $G = G(T, P)$ and that the thermodynamic definitions of pressure, P, and temperature, T, are

$$
\begin{aligned}
P &= \frac{(\partial S/\partial V)_U}{(\partial S/\partial U)_V} = \left(\frac{\partial F}{\partial V} \right)_T \\
T &= \left(\frac{\partial H}{\partial S} \right)_P = \left(\frac{\partial U}{\partial S} \right)_V
\end{aligned}
$$

(2.5)

These relations are important when deriving an equation of state by statistical methods. In addition, they can naturally lead to another set of useful identities through the derivation of the mixed second derivatives of the thermodynamic potentials (known as Maxwell relations):

$$
\begin{aligned}
\frac{\partial^2 U}{\partial S \partial V} &= + \left(\frac{\partial T}{\partial V} \right)_S = - \left(\frac{\partial P}{\partial S} \right)_V \\
\frac{\partial^2 H}{\partial S \partial P} &= + \left(\frac{\partial T}{\partial P} \right)_S = + \left(\frac{\partial V}{\partial S} \right)_P \\
\frac{\partial^2 F}{\partial T \partial V} &= - \left(\frac{\partial S}{\partial V} \right)_T = - \left(\frac{\partial P}{\partial T} \right)_V \\
\frac{\partial^2 G}{\partial T \partial P} &= - \left(\frac{\partial S}{\partial P} \right)_T = + \left(\frac{\partial V}{\partial T} \right)_P
\end{aligned}
$$

(2.6)

Whereas, since the heat capacity C is $\delta Q \equiv C\delta T$, using the second law of thermodynamics ($\delta S = \delta Q/T$, or $\delta Q = T\delta S$) and Eq. 2.4 the heat capacities at

constant pressure (or at constant volume) can directly connect the enthalpy and entropy gradients between two temperatures, for example,

$$C_P \equiv T\left(\frac{\partial S}{\partial T}\right)_P = -\left(\frac{\partial H}{\partial T}\right)_P \quad \text{and} \quad C_V \equiv T\left(\frac{\partial S}{\partial T}\right)_V = -\left(\frac{\partial H}{\partial T}\right)_V \qquad (2.7)$$

Based on the Maxwell relations, the definitions of the isothermal compressibility (K_T or β_T), the isoentropic compressibility (K_S or β_T), and the thermal expansion coefficient (α) can be written with the ln V removed as, respectively,

$$
\begin{aligned}
K_T \text{ or } \beta_T &\equiv \left(\frac{\partial P}{\partial \ln V}\right)_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T \\
K_S \text{ or } \beta_S &\equiv \left(\frac{\partial P}{\partial \ln V}\right)_S = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_S \\
\alpha &\equiv \left(\frac{\partial \ln V}{\partial T}\right)_P = +\frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P
\end{aligned}
\qquad (2.8)
$$

The parameter K_T is also known as the isothermal bulk modulus and α as the volume expansion coefficient; these are interrelated by means of the Grüneisen constant, γ:

$$\gamma = -\frac{V}{C_V}\frac{(\partial V/\partial T)_P}{(\partial V/\partial P)_T} = \frac{\alpha V}{C_V \beta_T} \qquad (2.9)$$

Similarly, through the definition of isothermal and isoentropic compressibility, the ratio and difference of C_P and C_V can also be simplified to

$$
\begin{aligned}
\frac{C_P}{C_V} &= \frac{(\partial P/\partial V)_S}{(\partial P/\partial V)_T} = \frac{\beta_T}{\beta_S} \\
C_P - C_V &= T\left(\frac{\partial S}{\partial T}\right)_P - T\left(\frac{\partial S}{\partial T}\right)_V = VT\frac{\alpha^2}{\beta_T}
\end{aligned}
\qquad (2.7a)
$$

2.2.4 Multicomponent Systems

In a multicomponent, closed system comprising N_i moles of component i, the changes dX in an extensive function of state X (e.g., U, F, G, S, H, C_P, C_V, etc.) caused by the variation of composition are given by

$$
\begin{aligned}
dX &= \sum_i X_i dN_i \\
\text{defining } X_i &\equiv \left(\frac{\partial X}{\partial N_i}\right)_{N_{j \neq i}} \quad \text{and, thus: } X = \sum_i X_i N_i
\end{aligned}
\qquad (2.10)
$$

where the functions X_i are known as partial molar quantities. Thus, the full differentials of the state functions (viz., Eq. 2.4) can be expressed as

$$
\begin{aligned}
dU &= TdS - PdV + \sum_i \mu_i dN_i \\
dF &= -SdT - PdV + \sum_i \mu_i dN_i \\
dH &= TdS + VdP + \sum_i \mu_i dN_i \\
dG &= -SdT + VdP + \sum_i \mu_i dN_i
\end{aligned}
\tag{2.11}
$$

where $\mu_i = \partial G / \partial N_i$ is the chemical potential of component i and N_i being a natural variable for all four above state functions, that is, $U = U(S, V, N)$, $F = F(T, V, N)$, $H = H(S, P, N)$, and $G = G(T, P, N)$. The relationships in Eq. 2.11 indicate that in a closed multicomponent system (N_i = const.) any change of the independent variables must be reflected in a change of the chemical potentials (μ_i):

$$
-SdT + VdP - \sum_i N_i d\mu_i = 0
\tag{2.12}
$$

Equation 2.12 is known as the Gibbs-Duhem relationship and is a depiction that the free energy of this grand canonical ensemble remains unchanged.

2.3 Thermodynamics of a Single-Component System

2.3.1 Equation of State (EoS) or PVT Relationships

2.3.1.1 Equation of State (EoS)

All theoretical equations of state suggest a corresponding state behavior of PVT properties that requires three scaling parameters (P^*, V^*, and T^*). These define the corresponding state and are used to scale/reduce the PVT toward $\tilde{P} \equiv P/P^*, \tilde{V} \equiv V/V^*, \tilde{T} \equiv T/T^*$. In his Ph.D. thesis of 1873, van der Waals proposed the first EoS formulated in terms of corresponding state (reduced) variables. The relation can be written in terms of PVT or in terms of reduced variables $\tilde{P}\tilde{V}\tilde{T}$, indicating expected observance of the corresponding state principle:

$$
\begin{aligned}
P &= \frac{RT}{V - b} - \frac{a}{V^2} \\
\frac{\tilde{P}}{\tilde{T}} &= \frac{8}{3\tilde{V} - 1} - \frac{3}{\tilde{T}\tilde{V}^2}
\end{aligned}
\tag{2.13}
$$

$$
\left(\text{where}\, \tilde{P} \equiv P/P^*, \tilde{V} \equiv V/V^*, \tilde{T} \equiv T/T^*, \right.
$$
$$
\left. \text{with}\, V^* = 3b; P^* = a/27b^2; T^* = 8a/27Rb \right)
$$

This approach demonstrated that the V^* and P^* are related to the van der Waals excluded volume (b) and the cohesive energy density ($\propto a$) of a system, a fact that has been largely used thereafter in subsequent EoS theories. Equation 2.13 also introduced the free volume concept; note that as $T \to 0$, $V \to b$. van der Waals

considered that molecules move in "cells" defined by the surrounding molecules with a uniform potential. Furthermore, Eq. 2.13 allows, through the definition of the critical point (P_c, T_c) in the P-T phase diagram (*vide infra*), to connect a and b to the critical values of pressure and temperature, P_c and T_c, which can be found tabulated from experimental data for various systems (viz., $a = 27R^2T_c^2/64P_c$, and $b = RT_c/8P_c$). This enables improved predictive capability over the ideal gas EoS. Finally, van der Walls also proposed a method to extend the single-component EoS of Eq. 2.13 to multicomponent mixtures by using the same relation with weight-averaged values of a_m, b_m of the mixture calculated based on the mole compositions (y_i) and the single-component a_i, b_i of each component i: $a_m = \sum_i \sum_j y_i y_j \sqrt{a_i a_j}$ and $b_m = \sum_i y_i b_i$. Thus, although the van der Walls EoS is not used today for any practical purpose, it is purely pedagogical, it does clearly demonstrate the corresponding state principle, it predicts continuity of matter between gas and liquid phases, it provides a mixture rule for EoS application in multicomponent mixtures, and it laid the foundations for modern EoS theories.

The volume, within which the center of a molecule can freely move, is what defines its free volume (or, more accurately, free volume relates to the excess empty volume beyond the per-molecule unoccupied volume). Thus, one may distinguish and define:

1. Total volume, V.
2. Occupied volume, V_o (usually defined as the V at $T = 0$ K).
3. Free volume, $V_f = V - V_o$.
4. Doolittle's free volume fraction, $f_D = V_f/V_o$.
5. Free volume fraction, $f = V_f/V = 1/(1 + 1/f_D)$ (to be used here).

Detailed methods of computation of the van der Waals excluded volume (for any chemical structure) have been developed (van Krevelen 1976). Thermodynamically, the free volume is expressed in terms of the entropy of vaporization:

$$P = \frac{RT}{V_f}\exp\left(-\frac{\Delta H^V}{RT}\right) = \frac{RT}{V_f}\exp\left(-\frac{\Delta S^V}{R}\right) = \frac{RT}{V}$$
$$\text{or} : \Delta S^V = R\ln\left(V/V_f\right) \text{ and } \Delta H^V = T^V \Delta S^V$$

(2.14)

Over the years, many versions of the EoS theories have been proposed (see, e.g., Table 2.3). Several comprehensive reviews of the EoS used in polymer thermodynamics have been published. For example, one review (Curro 1974) discussed applications of EoS within a full range of materials and variables, viz., to crystals, glasses, molten polymers, and monatomic liquids. This review discusses fundamentals of the theories and it provides a list of available experimental data. The comparison between different EoS was made on two levels, first by comparing the derived expressions for physical quantities (e.g., the characteristic reducing parameters, cohesive energy density, or internal pressure) and then comparing how well the EoS describes the observed PVT dependencies for polymers. A second type of reviews focused on summarizing PVT parameters for the molten state of polymers (Zoller 1989; Rodgers 1993a, b; Cho 1999). The authors here examined and compared several EoS theories, e.g., Spencer and Gilmore (1949) (S-G),

Table 2.3 A summary of a few EoS, mentioned in this section

Cell models

Flory-Orwoll-Vrij (FOV)

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = \frac{\tilde{V}^{1/3}}{\left(\tilde{V}^{1/3}-1\right)} - \frac{1}{\tilde{T}\tilde{V}}$$

$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ Eq. 2.15

Prigogine (P)

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = \frac{\tilde{V}^{1/3}}{\left(\tilde{V}^{1/3}-2^{-1/6}\right)} - \frac{2}{\tilde{T}}\left(\frac{1.2045}{\tilde{V}^2} - \frac{1.011}{\tilde{V}^4}\right)$$

$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ Eq. 2.17

Dee and Walsh (D-W)

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = \frac{\tilde{V}^{1/3}}{\left(\tilde{V}^{1/3}-2^{-1/6}q\right)} - \frac{2}{\tilde{T}}\left(\frac{1.2045}{\tilde{V}^2} - \frac{1.011}{\tilde{V}^4}\right)$$

$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ $q = 1.07$

Simha and Somcynsky (S-S) hole model

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = \frac{y\tilde{V}^{1/3}}{\left[(y\tilde{V})^{1/3}-\vartheta y\right]} - \frac{2y}{\tilde{T}}\left(\frac{1.2045}{(y\tilde{V})^2} - \frac{1.011}{(y\tilde{V})^4}\right)$$

$$\frac{s}{3c}\left[1+\frac{\ln(1-y)}{y}\right] = \frac{\frac{1}{3}(y\tilde{V})^{1/3}-\vartheta y}{(y\tilde{V})^{1/3}-\vartheta y} - \frac{y}{6\tilde{T}}\left(\frac{2.409}{(y\tilde{V})^2} - \frac{3.033}{(y\tilde{V})^4}\right)$$

System of two equations; $\vartheta = 2^{-1/6}$ cf. hexagonal cells; y = fraction of occupied sites; $s/3c \simeq 1$ for polymers
$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ Eq. 2.19

Lattice fluid models

Sanchez and Lacombe (S-L)

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = -\tilde{V}\left[\ln\left(1-\frac{1}{\tilde{V}}\right) - \frac{1}{\tilde{V}}\right] - \frac{1}{\tilde{T}\tilde{V}}$$

$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ Eq. 2.16

Jung

$$\frac{\tilde{P}\tilde{V}}{\tilde{T}} = -\tilde{V}\left[\ln\left(1-\frac{1}{\tilde{V}}\right) + \frac{1}{\tilde{V}}\right] - \frac{4}{\tilde{T}}\left(\frac{1.2045}{\tilde{V}^2} - \frac{1.011}{\tilde{V}^4}\right)$$

$\tilde{P} \equiv \frac{P}{P^*}, \tilde{V} \equiv \frac{V}{V^*}, \tilde{T} \equiv \frac{T}{T^*}$ Eq. 2.18

Empirical PVT relations

Tait equation (4-parameter)

$$V(P,T) = V(0,T)\left[1 - C\ln\left(1 + \frac{P}{B(T)}\right)\right]$$

with $C = 0.0894$; $V(0,T) = V_o e^{\alpha T}$; $B(T) = B_o e^{-B_1 T}$ Eq. 2.22

Hartmann and Haque (H-H)

$$\tilde{P}\tilde{V}^5 = \tilde{T}^{3/2} - \ln\tilde{V}$$

$P^* = B_o, V^* = V_o, T^* = T_o$ Eq. 2.23

Sanchez and Cho (S-C)

$$\tilde{V} = \frac{1}{1-\tilde{T}}\exp\left[\frac{\omega}{(1-\omega)B_1}\left\{1 - \left(1 + \frac{B_1\tilde{P}\exp(9\tilde{T})}{\omega}\right)^{1-\omega}\right\}\right]$$

$B_1 = 10.2$; $\omega = 0.9$ Eq. 2.24

Flory et al. (1964) (FOV), Sanchez-Lacombe (1976, 1977, 1978) (S-L), Simha and Somcynsky (1969) (S-S), Prigogine et al. (1953, 1957) (P), Dee and Walsh (1988) (D-W), Hartmann and Haque (1985) (H-H), and Sanchez and Cho (1995) (S-C), and tabulated the respective corresponding state values (P^*, V^*, and T^*) for most common polymers. These comparisons span across the different types of EoS models, from cell models (FOV, P, D-W), to lattice-fluid (S-L) and hole (S-S) models, to semiempirical approaches (H-H, S-C), comparing the validity of distinctly different EoS approaches across large numbers of different homopolymers and copolymers. All reviews seem to build a consensus on the comparative accuracy of the various EoS: Zoller (1989) reported large deviations (≤ 0.01 mL/g)

for S-G, the FOV and S-L were useful only at low P and over small P ranges, whereas S-S and S-C consistently provided the best representation of data over extended ranges of T and P, with average deviations in volume of ≤ 0.003 mL/g (S-S) and ≤ 0.0004 mL/g (S-C), compared to the experimental values. Rodgers (1993a, b) and Cho (1999) reach similar comparative conclusions, based on additional experimental PVT data, reporting that the D-H modified cell, the S-S hole, the P cell models, and the semiempirical H-H and S-C models, were all found to provide good fits of polymer liquid PVT data over the full range of experimental pressures, whereas the FOV and the S-L EoS were both significantly less accurate when applied over wide pressure ranges.

The FOV model can be summarized as

$$\frac{\tilde{P}}{\tilde{T}} = \frac{1}{\tilde{V}^{2/3}\left(\tilde{V}^{1/3} - 1\right)} - \frac{1}{\tilde{T}} \cdot \frac{1}{\tilde{V}^2} \tag{2.15}$$

with: $\quad V^* = \rho_*^3; \quad P^* = ck_BT^*/V^*; \quad T^* = s_*\eta_*/(2cV^*k_B)$

where ρ_* is the "hard-sphere" radius, s_* the number of contacts per segment, η_* the segment-segment interaction energy, and c the coordination number (k_B is the Boltzmann constant).

The S-L model, better known as the "lattice-fluid model," introduces vacancies into the classical incompressible Flory-Huggins model (*vide infra*). The lattice vacancy is treated as a pseudoparticle in the system. This model can be summarized as

$$\frac{\tilde{P}}{\tilde{T}} = -\left[\ln\left(1 - \frac{1}{\tilde{V}}\right) + \frac{1}{\tilde{V}}\right] - \frac{1}{\tilde{T}} \cdot \frac{1}{\tilde{V}^2} \tag{2.16}$$

with $V^* = M_W/r\rho^*$ (where M_W is the weight-averaged molecular weight, while ρ^* is the characteristic density parameter, $\rho^* = 1/V^*$), $P^* = rN_1\varepsilon^*/V^*$, and $T^* = \varepsilon^*/k_B$ (where ε^* is the van der Walls interaction energy). The parameter r represents the number of lattice sites occupied by the r-mer – its presence in the EoS negates the principle of corresponding states. The latter can be recovered only for $r \rightarrow \infty$.

The Prigogine simple cell model (P) considers each monomer in the system to be trapped in the cell created by its surroundings. The general cell potential, generated by the surroundings, is simplified to be athermal (cf. free volume theory), whereas the mean potential between the centers of different cells are described by the Lennard-Jones 6–12 potential. The P model EoS can be summarized as

$$\frac{\tilde{P}}{\tilde{T}} = \frac{1}{\tilde{V}^{2/3}\left(\tilde{V}^{1/3} - 2^{-1/6}\right)} - \frac{2}{\tilde{T}} \cdot \left(\frac{1.2045}{\tilde{V}^3} - \frac{1.011}{\tilde{V}^5}\right) \tag{2.17}$$

where the factor $2^{-1/6}$ originates from the hexagonal close packing lattice used as a cell geometry and the factors 1.2045 and 1.011 correct the effects of higher coordination shells on the internal energy. Another, largely unnoticed,

EoS was proposed (Jung 1996), by employing a continuous lattice and using a Lennard-Jones 6–12 potential to modify the S-L simple lattice fluid. This method combines elements from both S-L and P models, and the obtained EoS can be summarized as

$$\frac{\tilde{P}}{\tilde{T}} = -\left[\ln\left(1 - \frac{1}{\tilde{V}}\right) + \frac{1}{\tilde{V}}\right] + \frac{4}{\tilde{T}} \cdot \left(\frac{1.2045}{\tilde{V}^3} - \frac{1.011}{\tilde{V}^5}\right) \qquad (2.18)$$

with the same definitions as the S-L simple lattice-fluid EoS. To examine the ability of this EoS to describe *PVT* dependencies, the author used experimental data of eight polymers and compared with the FOV, S-L, S-S, and D-W relations. The evaluation was performed computing errors in describing the volume (ΔV), as well as thermal expansivity and isothermal compressibility. As in the previous evaluations, S-S dependence performed the best. For the description of *PVT*, the new EoS performed as well as that of D-W, but for the expansivity and compressibility, it outperformed the latter EoS.

The S-S EoS derived by Simha and Somcynsky (1969) is based on the Prigogine cell model by introducing lattice imperfections (holes, unoccupied sites). In S-S, a liquid is represented as a mixture of *y* occupied and *h* ($=1 - y$) unoccupied sites; thus, following the "Significant Liquid Structures" nomenclature (Eyring and Jhon 1969), the model considers a liquid as being an intermediate between solid and gas. To derive the EoS, the authors first calculated the partition function, *Z*, for all possible number of arrangements of occupied sites and empty holes in a lattice with *z* coordination number. The Helmholtz free energy is directly given, $F = -k_B T \ln Z$, and its differentiation gives the pressure and, thus, the equation of state. Minimization of the Helmholtz free energy *F* provides a second relation that must be solved simultaneously with the EoS:

$$\frac{\tilde{P}}{\tilde{T}} = \frac{y}{\tilde{V}^{2/3}\left[(y\tilde{V})^{1/3} - 2^{-1/6}y\right]} - \frac{2y^2}{\tilde{T}} \cdot \left(\frac{1.2045}{(y\tilde{V})^3} - \frac{1.011}{(y\tilde{V})^5}\right)$$

$$\frac{s}{3c}\left[1 + \frac{\ln(1-y)}{y}\right] = \frac{\frac{1}{3}(y\tilde{V})^{1/3} - 2^{-1/6}y}{(y\tilde{V})^{1/3} - 2^{-1/6}y} - \frac{y}{6\tilde{T}}\left(\frac{2.409}{(y\tilde{V})^2} - \frac{3.033}{(y\tilde{V})^4}\right) \qquad (2.19)$$

with : y = fraction of occupied sites;

$s/3c \simeq 1$ in normal practice for polymers

Of all the EoS used for polymeric species, the one derived by S-S was the first to explicitly consider the hole fraction, $h = 1-y$. Equation 2.19 provides a corresponding state description of *PVT* behavior of any liquid. Once the four characteristic parameters: *P**, *V**, *T**, and *3c/s* are known, the specific volume and all its derivatives are known in the full range of *P* and *T*. For linear polymers, where $3c/s \simeq 1$, only the three usual parameters (*P**, *V**, and *T**) are required. Values of

P^*, V^*, and T^* for selected polymers are listed in Table 2.4. At atmospheric pressure, $\tilde{P} = 0$, and within the range of reduced volumes, $0.95 < \tilde{V} 1.40$, Eq. 2.19 predicts that the volume expansion with T should follow the dependence (Simha and Weil 1970):

$$\ln \tilde{V}_i = S_1(s_i, c_i) + S_2(s_i, c_i)\tilde{T}_i^{3/2} \tag{2.20}$$

2.3.1.2 Frozen Free Volume Fraction

The S-S EoS theory defined through Eq. 2.19 is valid for any liquid. However, upon cooling when the temperature reaches the glass transition region, part of the free volume fraction is no longer accessible for the molecular motion. The S-S theory can also be used in this glassy region, if it can be estimated what part of the free volume is frozen as T approaches the glass transition temperature, T_g. Experimentally, the frozen fraction of the free volume, FF, depends on the absolute value of T_g. This finding was first reported for several polymers at ambient pressure (Simha and Wilson 1973). Subsequently, the generality of this observation was confirmed by analyzing isobaric thermal expansion of PS for a wide range of pressures (Utracki and Simha 1997).

As shown in Fig. 2.1, the frozen fraction of the free volume, FF, follows the same dependence whether T_g changes are caused by the polymeric chemical structure or by imposed pressure. The observed, general dependence follows the empirical relation:

$$FF = 0.997 - 4.75 \times 10^{-4} \; T_g - 1.52 \times 10^{-6} \; T_g^2 \quad (R_{\text{fit}} = 0.975) \tag{2.21}$$

It is gratifying to see that as the glass transition temperature approaches the absolute zero, $T_g \rightarrow 0\text{K}$, Eq. 2.21 predicts that all free volume should freeze, $FF(T_g = 0\text{K}) = 1$. On the other hand, at the high-temperature range, as T_g exceeds 669 K (396 °C), all free volume should be accessible to thermal motion in the glassy state, i.e., $FF(T_g \geq 400\,°\text{C}) = 0$. Thus, it is to be expected that polymers at high temperature will have the same thermal expansion coefficient across the glass transition temperature, viz., $\alpha_L = \alpha_G$, where subscripts L and G indicate liquid and glassy state, respectively.

2.3.1.3 Empirical PVT Relations

Starting from a different viewpoint, one can reach empirically justified EoS by phenomenological arguments used to build universal behaviors (functions) and fit them to experimental PVT data. The most common such approach for polymers is an isothermal compressibility V-P model (Tait 1888) known as the Tait equation:

$$\begin{aligned} &V(P,T) = V(0,T)\left[1 - C \ln\left(1 + P/B(T)\right)\right] \\ &\text{with } V(0,T) = V_o\exp(\alpha T); \quad B(T) = B_o\exp(-B_1 T) \end{aligned} \tag{2.22}$$

where $C = 0.0894$ is treated as a universal constant, α is the thermal expansion coefficient, and $B(T)$ is known as the Tait parameter. This renders the Tait

Table 2.4 A list of polymers (homopolymers and random copolymers), the S-S characteristic parameters (P^*, V^*, and T^*), as well as the difference between the measured and computed volumes (ΔV) averaged over the data's temperature range (ΔT) and pressure range (ΔP) (Rodgers 1993a, b)

equation as a 4-parameter (V_o, α, B_o, B_1) representation of the *PVT* behavior. About a century later, the H-H empirical PVT relation was proposed (Hartmann and Haque 1985), which is a three-parameter empirical EoS approach, that is, it has the form of a dimensionless EoS connecting $\tilde{P}\tilde{V}\tilde{T}$, with the usual definition of $\tilde{P} \equiv P/P^*$, $\tilde{V} \equiv V/V^*$, $\tilde{T} \equiv T/T^*$ and by using characteristic state values (P^*, V^*, and T^*) for a given polymer. The H-H relation is noteworthy due to the simplicity of its form and respectable agreement with the experimental data:

$$\tilde{P}\tilde{V}^5 = \tilde{T}^{3/2} - \ln\tilde{V}$$
$$\text{with:} \quad V^* = V_o; \quad P^* = B_o; \quad T^* = T_o \tag{2.23}$$

In Eq. 2.23, the characteristic pressure-reducing parameter, B_o, has been identified as the isothermal bulk modulus extrapolated to $T = 0$ and $P = 0$. Subsequently, Sanchez et al. (Sanchez 1993; Sanchez and Cho 1995) used a temperature-pressure (T-P) superposition which allows for the compressional strain, $\ln(V/V_o)$, to be written as a function of the reduced pressure, $\Delta P = (P - P_o)/B_o$, following the same general curve independent of T (here, B is again the bulk modulus, and B_o is its isothermal value evaluated at a reference pressure, P_o). The Sanchez-Cho (S-C) relation seems to provide the most faithful reproduction of experimental data among empirical three-parameter models. The S-C relation can be summarized as

$$\tilde{V} = \frac{1}{1-\tilde{T}}\exp\left[\frac{\omega}{(1-\omega)B_1}\left\{1 - \left(1 + \frac{B_1\tilde{P}}{\omega}\exp(9\tilde{T})\right)^{1-\omega}\right\}\right] \tag{2.24}$$
$$\text{with:} \quad B_1 = 10.2; \quad \omega = 0.9$$

the corresponding P^*, V^*, and T^* are tabulated for various polymers in Table 2.5. An excellent agreement with experimental data was achieved, indicating validity of the relation.

2.3.2 Solid–Liquid and Vapor–Liquid Equilibria

For a single component, the phase diagram provides a map of the solid, liquid, and vapor states, as well as their coexistence regions. It is customary to construct such single-component phase diagrams as log-log plots of P versus V relation at constant T. Fig. 2.2 shows a phase diagram of argon. Dividing the three variables by the corresponding reducing parameters, the dependence can be cast in a general plot of reduced pressure versus reduced volume, $\tilde{P}$ versus $\tilde{V}$, at constant reduced temperature, $\tilde{T}$. For simple low molecular weight liquids, the van der Waals equation, Eq. 2.13, provides a reasonable description.

Guggenheim further demonstrated that near the critical point the coexistence curve of liquid and vapor follows a simple proportionality:

$$\tilde{T} - 1 \propto |(1 - \tilde{\rho})^3|/3 \tag{2.25}$$

This dependence is shown in Fig. 2.3 as a solid line – the dashed line represents the van der Waals parabolic prediction.

2.3.3 Gibbs Phase Rule

The state variables are those intensive or extensive quantities that describe a system, for example, by means of the "equation of state." The total number of variables required to describe a system with i number of components is $i+2$ (cf. Eq. 2.11, i accounts for the i composition variables, N_i, and 2 accounts for, e.g., P and T). For the discussions of phase diagrams, it is important to know how many of the state variables can be varied without going through a phase transition. For a closed system with i number of components and Π number of phases, the number of intensive variables (cf. thermodynamic degrees of freedom, #f) is given by the "Gibbs phase rule":

$$\#f = i + 2 - \Pi \tag{2.26}$$

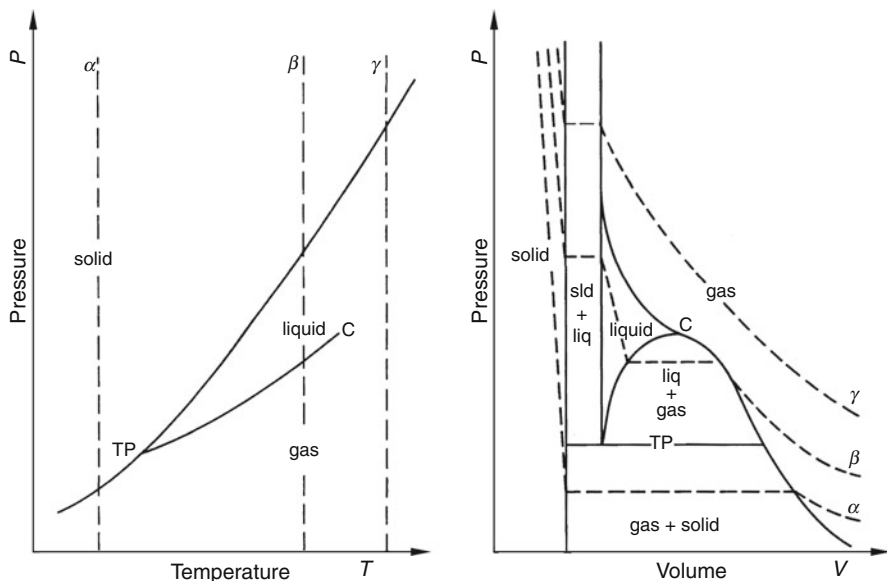
For example, for a phase equilibrium of a two-component blend ($i = 2$), in order to follow the two-phase ($\Pi = 2$) coexistence, Eq. 2.26 predicts #$f = 2$, i.e., two


Fig. 2.2 The van der Waals-type phase diagram in T-P (*left*) and P-V (*right*) axes. *C* is the critical point; *TP* is the triple point of the coexistence between solid, liquid, and vapor (TP is a line in the P-V phase diagram). *Solid lines* are the phase boundaries, whereas the *dashed lines* are isotherms at different temperatures (α below T_C, β slightly below T_C, and γ above T_C). The liquid–gas, solid–liquid, and solid-vapor coexistence regions are also shown (After Flowers and Mendoza 1970)
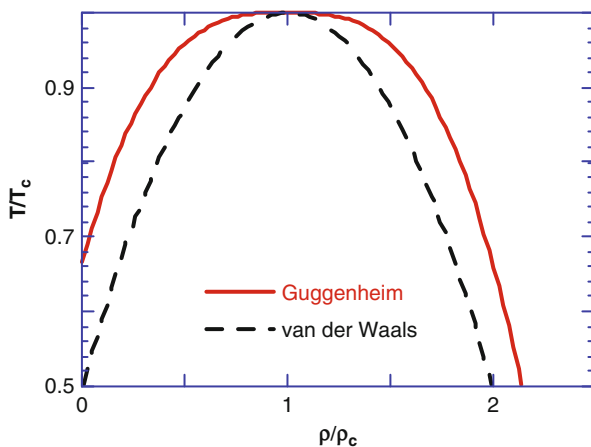

Fig. 2.3 The liquid–vapor coexistence curves, $\tilde{T}$ versus $\tilde{\rho}$, as predicted by Guggenheim (*solid line*) and by van der Waals

variables must be simultaneously changed (e.g., T and composition), whereas, for the same system within the single-phase ($\Pi = 1$) miscible region, three variables are available (e.g., composition, T and P). For a discussion based on general phase equilibria conditions, see Sect. 1.2.3 (Klenin 1999).

2.4 Polymeric Mixtures

Polymeric mixtures are conveniently divided into *polymer solutions* (containing one or more low molecular weight liquids, termed as solvent) and *polymer blends* (containing only macromolecular species). They will be briefly described in the following Sects. 2.5.1 and 2.5.2, respectively. More detailed discussion of the theoretical foundations is given in Sect. 2.6.

2.4.1 Polymer Solutions

In contrast to the mixtures of low molecular weight species, where composition is customarily expressed as a concentration or mole fraction, x_i, in the case of polymer solutions, composition must be given as volume fraction, ϕ_i, to correctly account for the much larger space (volume) occupied by a given concentration of a polymer, cf. for a polymer with degree of polymerization n, $\phi_i \sim x_i n$. For dilute solutions, the wt/vol concentration, c, can be also used accounting for weight of polymer per volume of solvent (e.g., in g/100 mL). As in mixtures of small molecules, also in polymer solutions, the solubility originates mainly from entropic reasons (Yamakawa 1971).

Traditionally, solutions have been used in polymer characterization, e.g., to measure its molecular weight averages (number, weight, and z-averaged molecular weight, M_n, M_w, and M_z), or the size of its macromolecular coil. The latter may be expressed as the unperturbed end-to-end distance (R_o), or through the related radius of gyration ($R_{g,\,o}$), viz.,

$$\langle R_o^2 \rangle = 6 \left\langle R_{g,o}^2 \right\rangle = \sigma^2 n l^2 \frac{1 + \langle \cos\theta \rangle}{1 - \langle \cos\theta \rangle} \tag{2.27}$$

In Eq. 2.31, σ is the steric hindrance factor of the macromolecular chain, n is the number of statistical segments (each statistical segment having a length l and the bond angle between two consecutive segments is equal to θ).

Solutions can also be used to measure of the thermodynamic interactions between polymer segments and solvent molecules. These intermolecular interactions are best discussed in terms of the virial coefficients, A_i. The change of the solvent chemical potential upon dissolution of a polymer is given by

$$\Delta\mu = \left(\frac{\partial G_m}{\partial N_2}\right)_{T,P,N_1} = RT \ \ln a_o = -V_1 \Pi \tag{2.28}$$

where a_o is the activity and Π the osmotic pressure, usually expressed as

$$\frac{\Pi}{c} = RT\left(\frac{1}{M_n} + A_2 c + A_3 c^2 + \dots\right) \quad \text{with} \quad A_2 = \frac{4\pi^{3/2} N_A}{M_n^2} \left\langle R_g^2 \right\rangle^{3/2} \Psi(z) \tag{2.29}$$

The second virial coefficient in Eq. 2.29 contains two functionals that depend on the binary interactions, the perturbed radius of gyration R_g, and the function $\Psi(z)$, which is

$$\Psi = \frac{1 - \exp(-5.73z)}{5.73} \quad \text{with} \quad z = \frac{4}{3^{3/2}} C_M \left(\frac{1}{2} - \chi \right) M_n^{1/2} \qquad (2.30)$$

As z increases from 0 (*theta conditions*) to 2 (*good solvent*), the Ψ function also increases from 0 to about 0.2. For simplicity, dilute solutions are used to avoid the need for determination of higher-order virial coefficients. In this case, A_2 provides a direct measure of the intermolecular interactions in polymer solutions and can be directly related to the respective Flory-Huggins parameter (χ, *vide infra*, Sect. 2.6.1.1). However, since $A_3 \propto A_2 M_n$, Eq. 2.29 can be written as

$$\left(\frac{\Pi M_n}{RT} \right)^{1/2} = 1 + \frac{M_n A_2}{2} \qquad (2.31)$$

In another approach, light scattering also makes it possible to determine A_2, viz.,

$$\frac{Kc}{R_\theta} = \frac{1}{M_w \ \langle P_1(\theta) \rangle} + 2A_2'c + 3A_3'c^2 + \dots \qquad (2.32)$$

where K is an experimental quantity ($K = 4\pi^2(dn/dc)^2\eta_o^2(1+\cos^2\theta)/N_A\lambda^4$), c is the concentration of the solution, $R_\Theta(c)$ is the Rayleigh ratio, and $\langle P_1(\theta) \rangle$ is the intramolecular interference factor, i.e., the angular dependence of the scattered light. Equation 2.32 provides the polymer's molecular weight, M_w, from the dilute solution limit where all higher-order terms of the virial expansion become negligible: $\lim_{c \to 0, \ \theta \to 0}(Kc/R_\theta) = 1/M_w$. Similar to the osmotic pressure (Eq. 2.29), light scattering (Eq. 2.32) also allows to calculate virial coefficients, with the second virial coefficient again being related to the solvent-solute interactions.

The thermodynamic interactions and the size of polymer coil also enter dependencies that describe the transport behavior of polymer solutions, viz., viscosity, diffusion, sedimentation, etc. To complete this short summary, the viscosity relations should be mentioned. Defining η as the solution viscosity and η_o as the solvent viscosity, the following, relative (η_r), specific (η_{sp}), and intrinsic ($[\eta]$) viscosities, are typically expressed as

$$
\begin{aligned}
\eta_r \quad &\equiv \quad \eta/\eta_o \\
\eta_{sp} \quad &\equiv \quad (\eta - \eta_o)/\eta_o = \eta_r - 1 \\
[\eta] \quad &\equiv \quad \lim_{c \to 0} \left(\eta_{sp}/c \right) = \lim_{c \to 0} \frac{\ln \eta_r}{c} \\
\eta_{sp}/c \quad &\cong \quad [\eta] + k_H[\eta]^2 c \qquad \text{(Huggins equation)}
\end{aligned}
\qquad (2.33)
$$

which can also be fitted to a virial-type expansion (e.g., $\eta_r = 1 + [\eta]c + k'([\eta]\,c)^2 + \cdots$). Many relations have been proposed connecting the intrinsic viscosity, $[\eta]$, to the polymer/solvent interaction parameters. One of the better known is that credited to Inagaki et al. (1966):

$$[\eta]^{4/5}/M_v^{2/5} = 0.786K^{4/5} + 0.454K^{2/15}\Phi_o^{2/3}B^{2/3}M_v^{1/3} \qquad (2.34)$$

where $K = 2.5 \times 10^{23}[\langle R_o^2 \rangle/M_v]^{3/2}$ and $B = (2\rho_s^2/V_o)(0.5 - \chi)$, with ρ_s and V_o being the segmental density and the molar volume of the solvent.

It is worth noting that the three methods of evaluation of the solution behavior, osmometry, light scattering, and intrinsic viscosity, provide different molecular weight averages, respectively, number average, M_n, weight average M_w, and "viscosity" average, M_v. Knowing at least two of them, one can also estimate the width of the molecular weight distribution through polydispersity factors, e.g., through M_w/M_n.

2.4.2 Polymer Blends: Definitions and Miscibility

In contrast to solutions, polymer blends are mostly immiscible. As shown in Appendix 2 by Krause and Goh, over 1,000 cases of miscibility have been found; however, these are so infrequent and poorly defined that one may consider them as exceptions to the general rule of polymer/polymer immiscibility.

While the thermodynamic definition of miscibility is unambiguous (see Table 2.6), there is a significant amount of discussion as to the methods of miscibility detection and the size of heterogeneity in miscible blends.

The methods of miscibility detection (sometimes wrongly labeled as "compatibility" experiments) will be discussed later in this chapter. Opacity (turbidity) can provide limited only information on miscibility – since light scattering manifests when the size of heterogeneity becomes larger than 100 nm and the difference in refractive index is greater than about 0.01; further complications arise when one or both polymer phases are semicrystalline. The most widely used tool for the "detection of miscibility" relates to measurement of the glass transition temperature, T_g. There is a widely accepted belief that blends which display a single T_g are miscible. The glass transition temperature is relatively simple to measure, but there are inherent uncertainties of the measurements that need to be carefully examined (Utracki 1989). For example, T_g is insensitive when the amount of one component is less than about 10 wt% or when the component T_g's occur at similar temperatures. On the latter, the T_g method should not be used for blends containing polymers whose T_g's differ by less than 10 °C from each other.

Along these lines, it has been shown, first by Schultz and Young (1980) and then by many others, that T_g is not sensitive to the thermodynamic miscibility of the components, but rather to the degree of dispersion. For example, in solvent-mixed PS/PMMA blends that were not allowed to phase separate, a single T_g has been detected, but when the specimens were annealed, double peaks were observed. In another example, solvent cast blends of PVC with caprolactone-grafted lignin showed a single T_g, while the measured domain size ranged between 10 and 30 nm, indicating immiscibility (De Oliveira and Glasser 1994).

Table 2.6 Terms related to polymer blend miscibility (see also ▶ Chap. 1, "Polymer Blends: Introduction")

Miscible polymer blend: polymer blend, homogenous down to the molecular level, in which the domain size is comparable to the macromolecular dimension; associated with negative value of the free energy of mixing, $\Delta G_m \simeq \Delta H_m \leq 0$, and within the phase stability condition $\partial^2 \Delta G_{ml}/\partial^2 \phi > 0$

Immiscible blends: polymer blends whose free energy increases upon mixing, i.e., $\Delta G_m \simeq \Delta H_m > 0$

Polymer alloy: immiscible but compatibilized polymer blend; implies a modified interphase and, thus, morphology

Interphase: a nominal third phase in binary polymer alloys, engendered by interdiffusion or compatibilization at the interfaces between the two polymer domains. The interphase thickness Δl varies between 1 and 60 nm depending on polymers' miscibility and compatibilization

Compatibilization: process of modification of the interphase in immiscible polymer blends, resulting in reduction of the interfacial energy, development, and stabilization of a desired morphology, leading to the creation of a polymer alloy with enhanced performance

Fig. 2.4 The glass transition temperature versus composition for PEK/N-TPI blends. The two *black squares*, connected by a *straight line*, are the T_g's of the two polymers; open circles are data for blends prepared at 455 °C; *solid circles* are for the same blends prepared at 400 °C. The lines are only guides to the eye (Data from Sauer et al. 1996)
For PEK/PI blends, the T_g's of the neat components are separated by about 90 °C; however, depending on the chemical nature of the components, as well as on the blend composition and blending conditions, three types of the glass transition behavior were observed: Specifically, three T_g behaviors for PEK blended with N-TPI were obtained, as shown in Fig. 2.4 after (Sauer et al. 1996) (N-TPI stands for: "new thermoplastic polyimide," obtained from condensation of 4,4-bis (3-aminophenoxy)biphenyl with pyromellitic dianhydride). At "low" blending temperature, of 400 °C, the mixture showed two T_g's, but when the same polymers were blended at $T = 440$ °C, the blend showed a single T_g; interestingly, when the two polymers were blended at intermediate temperatures, 400 °C$< T <$440 °C, a single, broad, overlapping T_g was obtained. Clearly, the glass transition behavior reflected different degrees of dispersion for the PEK/PI system, rather than phase miscibility (the degradation temperature is 410 °C). Finally, it is frequent that blends of rubber-containing copolymers (such as SBS or ABS type), e.g., PPE/SBS,

PC/ABS, or PPE/MBS, are identified as miscible, on the basis of T_g measurements. Obviously, this T_g measurement probes the mixing of the viscoelastic components of the blend, effectively neglecting the elastomeric (rubber) domains. The elastomeric domains remain immiscible in the blends, much like they were in the copolymers, and may show (or not, depending on their content) another T_g at much lower temperatures.

In any liquid, either single or multicomponent one, there is a significant amount of heterogeneity, usually expressed by density/composition fluctuation functions. Thus, along the above discussion, it is justified to ask two questions:

1. What is the maximum size, d_d, of heterogeneity in a polymer blend that fulfills the conditions of the thermodynamic miscibility (viz., $\Delta G_m \leq 0$ and $\partial^2 \Delta G_m / \partial^2 \phi \geq 0$)?
2. At what level of heterogeneity T_g is a monotonic function of composition?

Various answers have been given to the first question. On the basis of the size of the cooperative segmental motion required at T_g, it was estimated that d_d is 2–3 nm (Boyer 1966; Warfield and Hartmann 1980). The local segmental dynamics of a flexible polymer chain was found to be affected by the neighboring chains lying within 2–7 nm (Callaghan and Paul 1994a, b). Other authors consider that miscibility is achieved when the heterogeneity diameter becomes comparable to the unperturbed radius of gyration of the macromolecule, thus $d_d = \langle R_{g,\,o}^2 \rangle^{1/2}$ typically 3–10 nm (Silberberg and Kuhn 1952; Wolf 1980, 1984). Many others' estimates fall within these limits (e.g., Kaplan 1976; Bair and Warren 1980; Cowie 1989). Thus, it seems that the thermodynamic miscibility is associated with a size of compositional heterogeneity d_d smaller than about 10 nm, cf. smaller than the polymer size, an intuitively expected answer for intimate mixing of chain-type objects.

The answer to the second question has been given as well. Depending on the chemical nature of the system and its morphology, double peak of T_g has been reported to appear for domain sizes d_d as small as 15–20 nm (Frisch et al. 1982; Utracki 1989; De Oliveira and Glasser 1994).

From a fundamental point of view, the glass transition reflects a change in the molecular mobility upon cooling and can be viewed as associated with "freezing" of a portion of the free volume. However, the frozen fraction depends on the absolute value of T_g – as the T_g absolute value increases, more free volume becomes accessible to the thermal motion in the glassy state. Judging by data presented in Fig. 2.1, for organic macromolecules, the fundamental mechanism of the glass transition is not expected to be valid for T_g larger than about 400 °C. In short, even under the most favorable conditions, T_g should be unable to discriminate between the presence and absence of thermodynamic miscibility, i.e., when a system is miscible, a single T_g will indeed be found, but also a single T_g will also be manifested for immiscible systems having finely dispersed phases. In many cases, T_g may be able to detect the "technological miscibility," i.e., to identify systems that are so well homogenized that the phase domains will not be affected by the processing conditions. The method may be used as a pragmatic scan for industrially useful blends, or evaluation of a compatibilization scheme.

It is noteworthy that "homogeneity at fairly fine level is necessary for optimum performance, but some degree of microheterogeneity is usually desirable to preserve the individual properties of respective polymer components" (Hess et al. 1993). Note that nearly all commercial polymer blends (with the notable exception of the PVDF/PMMA blend) are immiscible. One tends to study miscibility not so much as to develop single-phase commercial blends, but mainly to design better compatibilizers and compatibilization strategies.

Since the standard test methods for detecting miscibility, viz., T_g measurements, microscopy, small-angle X-ray scattering, etc., are limited to $d_d \geq 15$ nm, other methods should be used for studies of true thermodynamic miscibility. Such approaches mostly capitalize on advanced scattering methods, such as high-resolution or multidimensional nuclear magnetic resonance (NMR) techniques, spin-diffusion NMR measurements, non-radiative energy transfer, excimer fluorescence, thermally stimulated depolarization current, small-angle neutron scattering (SANS), Fourier transfer infrared spectroscopy (FTIR), etc. Even simple NMR measurement of spin–lattice relaxation times, T_1, is capable to distinguish down to domain sizes of 2–3 nm. The method can be used for either molten or solidified mixture specimens. For example, these methods produced the following results:

a-PVC/PMMA: Homogenous at 20 nm, but heterogeneous at 2 nm. After deuteration of PMMA, the miscibility extended down to 1–2 nm.

PS/PVME, PnBMA/PS (2 mol% –OH): Homogenous at 20 nm.

SAN/PMMA: Homogenous at 20 nm, but heterogeneous at 2–15 nm (McBrierty et al. 1978).

a-PET/PC, a-PVDF/PMMA, a-PCL/PVC: Homogenous at 2 nm (Douglass and McBrierty 1978; Douglass 1979).

PS/PPE: Only about 30 wt% blend components participate in intimate interactions on the scale of less than 2 nm. The rest show the same nuclear resonance pattern as the one recorded for the two homopolymers (Stejskal et al. 1981; Takahashi et al. 1990).

2.5 Theories of Liquid Mixtures

2.5.1 Lattice, Cell, and Hole Theories

The statistical mechanics methods that use a pseudocrystalline model of regularly placed elements on a "lattice" are known as lattice theories. Many theories, known under the names of free volume, cell-hole, tunnel, Monte Carlo, or molecular dynamics belong here. Of these, only two will be mentioned. The first, and the best known, was originally developed by Huggins (1941) and, independently, by Flory (1941), then extended by many authors (Utracki 1962; Koningsveld 1967). The second is the cell-hole Simha and Somcynsky (1969) theory that has been incessantly evolving during the intervening years. The theory makes it possible to interpret and predict different material's behavior in a wide range of

states and independent variables, viz., gases, low molecular weight organic liquids, metals, and polymers in a glassy or molten state, to determine miscibility of gases or liquids in polymers, to compute the phase diagrams of polymer blends, etc.

2.5.1.1 Flory-Huggins Theory

For binary systems that contain two components denoted as i (i.e., $i=1$ or 2 and, traditionally, for polymer solutions the subscript 1 indicates solvent, and 2 polymer) the Flory-Huggins, FH, relation has been expressed in several equivalent forms:

$$\frac{\Delta G_m}{RT} = \frac{\phi_1}{V_1}\ln \phi_1 + \frac{\phi_2}{V_2}\ln \phi_2 + \chi'_{12}\phi_1\phi_2 \quad \left[\text{with} \quad \chi'_{12} \equiv \chi_{12}/V_{ref}\right]$$

$$\Delta G_m = RTV \left[\frac{\phi_1}{V_1}\ln \phi_1 + \frac{\phi_2}{V_2}\ln \phi_2\right] + B\phi_1\phi_2 \quad \left[\text{with} \quad B \equiv \chi_{12}RT\left(V/V_{ref}\right)\right]$$

$$(2.35)$$

In Eq. 2.35, ϕ_i is the volume fraction and V_i is the molar volume of component "i." The first two logarithmic terms give the combinatorial entropy of mixing, which are by definition of ϕ negative and always promote mixing, while the third term is the enthalpy of mixing. For polymer blends V_i are both large; thus the combinatorial entropy becomes vanishingly small, and, therefore, the miscibility or immiscibility of the system is determined by the value of the last term, $\chi'_{12}\phi_1\phi_2$. Using $\phi_2 + \phi_1 = 1$ and the monomeric volume as a reference volume, the free energy of mixing ΔG_m, expressed now in a per monomer basis, can be rewritten as

$$\frac{\Delta G_m}{kT} = \frac{\phi}{N_1}\ln \phi + \frac{1-\phi}{N_2}\ln(1-\phi) + \chi'_{12}\phi(1-\phi) \qquad (2.35a)$$

where N_i is the degree of polymerization of the i component ($N_i = 1$ for i being a solvent). For the purposes of determining phase behavior or miscibility, it does not matter if one uses the change in free energy of mixing expressed per unit volume, per mole of lattice sites, or per monomeric volume. Due to the assumption of the FH model, in its unaltered original form, the model predicts UCST only behavior (Fig. 2.5).

Applying to Eq. 2.35 the critical point conditions (the critical point is located on the spinodal, thus, $\partial^2\Delta G_m/\partial^2\phi = 0$, and is the extremum of the spinodal curve, thus, $\partial^3\Delta G_m/\partial^3\phi = 0$) and treating the so-called binary interaction parameter, χ_{12} or B, as composition independent, the critical conditions for phase separation can be expressed as

$$\chi'_{12,cr} = \frac{1}{2}\left(\frac{1}{\sqrt{V_1}} + \frac{1}{\sqrt{V_2}}\right)^2 = \frac{1}{2}\left(\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}}\right)^2$$

$$B_{cr} = \frac{RTV}{2}\left(\frac{1}{\sqrt{V_1}} + \frac{1}{\sqrt{V_2}}\right)^2 = \frac{RT}{2}\left(\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}}\right)^2$$

$$(2.36)$$
Fig. 2.5 Phase diagrams predicted by the Flory-Huggins (*FH*) model for various ratios of molar sizes (N_1/N_2, as indicated): *solid lines* are *binodals* and *dashed lines* are *spinodals*; for all phase diagrams, a generic $\chi_{12} = -0.6 + 300/T$ was assumed; see right-side y-axis. Three groups of phase diagrams are distinguished: the group in the *bottom* corresponds to solutions, with component 1 being the solvent ($N_1 = 1$); the *middle* group corresponds to mixtures of oligomeric molecules; and only for the *top* three phase diagrams correspond to mixtures that resemble polymer blends ($N_1 N_2 \gg 1$). All spinodals, UCST critical points, and the binodals of the symmetric, $N_1 = N_2$, mixtures were analytically calculated from the derivatives of Eq. 2.35 (critical points from Eq. 2.36), and the rest of the binodals are from numerical solutions

Equation 2.36 gives the miscibility conditions for systems with species of different molecular weight. The relations are rather accurate, as they are markedly insensitive to the FH assumptions and approximations (Fig. 2.6). Three special cases can be distinguished:

1. Small molecule mixtures ($V_1 \simeq V_2$ or $N_1 = N_2 \approx 1$) are miscible when $\chi_{12} < 2$, viz., $\chi_{12} < \chi_{12, \, cr}$ and from Eq. 2.36 $\chi_{12,cr} = 2$ (for $N_1 = N_2 = 1$).

Fig. 2.6 Critical temperatures, both UCST and LCST, as a function of polymer M_w, for polystyrene solutions in methyl-cyclohexane. In the inset, the critical temperatures are fitted to Eqs. 2.36 and 2.39 (*vide infra*) showing an excellent agreement over the whole ensemble of data (Data from Wohlfarth (2008); collected from 71 systems, from 18 independent studies published from 1963 to 2002)

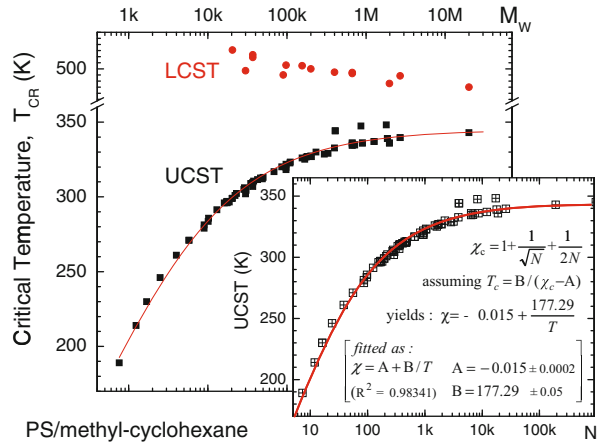
In the inset:

$$\chi_c = 1 + \frac{1}{\sqrt{N}} + \frac{1}{2N}$$

assuming $T_c = B/(\chi_c - A)$

yields : $\chi = -0.015 + \frac{177.29}{T}$

fitted as :
$\chi = A + B/T$ $A = -0.015 \pm 0.0002$
$(R^2 = 0.98341)$ $B = 177.29 \pm 0.05$

PS/methyl-cyclohexane


2. Polymer solutions ($V_1 \gg V_2$ or $N_2 \gg N_2 \approx 1$) are miscible when $\chi_{12} < 1/2$, viz., $\chi_{12} < \chi_{12,cr}$ and from Eq. 2.36 $\chi_{12,cr} = 1/2 + 1/\sqrt{N} + 1/2N \approx 1/2$ (for $N = N_2$).
3. Polymer blends (V_1 and $V_2 \gg 1$, or $N_1 \approx N_2 \gg 1$) are miscible when $\chi_{12} < 0$, viz., $\chi_{12} < \chi_{12,cr}$ and from Eq. 2.36 $\chi_{12,cr} = 2/N \approx 0$ (for $N = N_1 = N_2$).

Originally, after Hildebrand, the parameter χ_{12} was assumed to have a single, characteristic value for a given mixture. However, it was soon found that even for polymer solutions χ_{12} is a complex function of many independent variables, viz., concentration, temperature, pressure, molecular weight, molecular weight distribution, etc. For calculating isobaric phase diagram, the influence of the first two variables should be expressed as (Koningsveld 1967) $\chi_{12} = \sum_{j=0}^{j \leq 2} a_j \phi_2^j$ with $a_j = \sum_{k=1}^{m \leq 2} a_{jk} T^k$. Thus, at constant pressure, it takes nine parameters to describe variation of χ_{12} with concentration and temperature.

In a first approximation, the temperature dependence of χ_{12} can be simplified by keeping only one temperature term, i.e., $\chi_{12} = A + B/T$, which for polymer solutions most often gives a rather good estimation. For example, in Fig. 2.6, we fitted tabulated UCST's PS/methyl-cyclohexane solutions from 71 different PS M_w's from 22 different studies, obtaining $\chi_{12} = -0.015 + 117.29/T$ with a pretty good accuracy across multiple works and experiments. For polymer blends and for less demanding thermodynamic calculations, the concentration dependence must also be included, and most often χ_{12} is simplified by keeping one composition term and one temperature term. Thus, to express conditions of miscibility in PS blends with poly(styrene-*co*-4-bromostyrene), the binary interaction parameter per mer of styrene (when T within the 440–500 K region) was expressed as $\chi_{12}/N = -0.02208 + 20/T - 0.01482\phi_2$ (Strobl et al. 1986). Similarly, for PS blends, the following relation was proposed (Ahn et al. 1997a, b): $B_{12}(\phi_2, T) = B_0 + B_1\phi_2 + B_2 T/1{,}000$ where experimental/fitted or calculated values can be used for the B_i parameters. However, in polymer blends, there is typically a nonnegligible concentration dependence of the binary interaction parameter, i.e., $\chi = \chi(T, \phi)$, and in order to model blends by FH a relation of the form $\chi(T, \phi) = D(T) \cdot B(\phi)$ is used (the

separation of variables is for simplifying the fittings to experimental data series). For example, for PS/PVME, setting

$$\chi(T, \phi) = (1 - 0.4\phi) \; (0.02215 - 8.0/T) \qquad (2.37)$$

provided reasonable prediction of the phase behavior across various M_w's (Qian et al. 1991); more accurate prediction of the spinodals, for the same PS/PVME blends, necessitated the concentration term to be expanded to $(1 - 1.5\phi + 0.815\phi^2)$ and the T term to be adjusted for each polystyrene M_w (Qian et al. 1991):

$$
\begin{aligned}
\chi(T, \phi) &= \left(1 - 1.5\phi + 0.815\phi^2\right) \; \left(0.02754 - 9.0/T\right) \; \text{low } M_W \\
\chi(T, \phi) &= \left(1 - 1.5\phi + 0.815\phi^2\right) \; \left(0.0436 - 18.0/T\right) \; \text{medium } M_W \quad (2.37a) \\
\chi(T, \phi) &= \left(1 - 1.5\phi + 0.815\phi^2\right) \; \left(0.00644 - 2.5/T\right) \; \text{high } M_W
\end{aligned}
$$

The above compare well with results from a prior experimental approach, which employed SANS to map out the spinodal for d-PS/PVME, albeit parameterized using different functionals, with a linear ϕ dependence for both the $\chi_H \propto 1/T$ and the χ_S terms (Schwahn et al. 1987), which are based on a EoS model.

By redefining the T dependence of $\chi(T)$, e.g., to include $1/T^2$ or $\ln T$ terms, one can use the FH equation to predict other type of phase diagrams, such as LCST, closed-loop, chimney, etc. (Qian et al. 1991; Eitouni and Balsara 2007). In fact, a number of reasonably accurate, within the applicable T range, FH model $\chi(T)$ relations exist in literature for a number of polymer blends (often including a second T term (i.e., C/T^2), see Table 2.8).

More generally, the interaction parameter dependencies on T and ϕ can be written as

$$
\begin{aligned}
\chi_{12}(\phi_2, T, M_1, M_2, \ldots) &= \chi_H(\phi_2, M_1, M_2, \ldots) &+& \chi_S(\phi_2, M_1, M_2, \ldots)/T \\
B_{12}(\phi_2, T, M_1, M_2, \ldots) &= B_H(\phi_2, M_1, M_2, \ldots)T &+& B_S(\phi_2, M_1, M_2, \ldots)
\end{aligned}
\qquad (2.38)
$$

In this notation, the T dependence is explicitly provided using the standard second virial coefficient functionality, i.e., $\chi \propto 1/T$, and χ_{12} is now expressed in terms of enthalpic and entropic parts, i.e., χ_H and χ_S, respectively, each being a function of concentration, molecular weight of both polymers, and other independent variables. In other words, Eq. 2.38 attempts to account for nonrandom mixing, i.e., contribution of the non-combinatorial entropy to the interactions. This idea is particularly important for polymer blends. Here, the miscibility mainly originates from strong interactions that are expected to cause changes of intersegmental orientation, hence nonrandom mixing that entails strong entropic effects. Table 2.7 gives a few example values of Eq. 2.38 parameters for selected, simple polymer blends.

As one would expect from the definition of χ_{12} (cf. viewed as the excess enthalpy/interaction between monomers in a mixed pair vs. in their single phase)

Table 2.7 Enthalpic, χ_H, and entropic, χ_S, contributions to the Flory-Huggins binary interaction parameter, χ_{12}, see Eq. 2.38

there is marked independence of χ_{12} on the molecular weight of the polymers, N. However, large variability of χ_{12} has been observed with the concentration of the polymer blends, showing often linear and, in some cases, quadratic dependencies of χ_{12} on ϕ (e.g., Han et al. 1988; Krishnamoorti et al. 1994a) and on T (e.g., Eitouni and Balsara 2007, and references therein).

A compilation of $\chi_{12}(T)$ parameters, spanning numerous polymer blends, showed that it is often necessary that a second T term is added to Eq. 2.38 to obtain satisfactory accuracy; thus, the following the empirical dependence of χ_{12} on T

$$\chi_{12}(T) = A + B/T + C/T^2 \tag{2.39}$$

is obtained, and a compilation of $\chi_{12}(T)$ such functions for about 120 polymer blends can be found in the second edition of "Physical Properties of Polymers Handbook" (Eitouni and Balsara 2007) (see also Table 2.8). Most of these data were obtained by applying RPA (random phase approximation) to small-angle neutron scattering (SANS) profiles measured from homogenous homopolymer blends. This approach was pioneered by Hadziioannou and Stein (1983, 1984), Murray et al. (1985), and Herkt-Maetzky and Schelten (1983). In these cases, one needs to consider also the dependence of χ_{12} on the deuteration effects of polymers, whereby there can be appreciable changes in χ depending on deuteration (see Tables 2.7, 2.8); indicatively, appreciable interaction parameters can manifest even between the hydrogenated and deuterated homologues of the same polymer,

Table 2.8 Temperature dependence of $\chi_{12}(T)$ parameterized as $\chi_{12}(T) = A + B/T + C/T^2$ (Eq. 2.39), including the temperature range of parameter validity. Selected polystyrene (PS) and polypropylene (PP) blends are tabulated here. A much more extensive compilation can be found in (Eitouni and Balsara 2007)

Notes: The values of A, B, and C and thus χ are based on a reference volume $V_{ref} = 0.1$ nm^3

Polymer notation: A d- label preceding the polymer acronym indicates a per-deuterated polymer; partially deuterated polymers are labeled as d_3-, d_4-, etc., for selective deuteration of 3, 4, etc., hydrogens. Numbers in subscripted parentheses after the polymer name indicate the primary comonomer fraction, e.g., SPB$_{(66)}$ is a saturated polybutadiene with 66 mol% butadiene

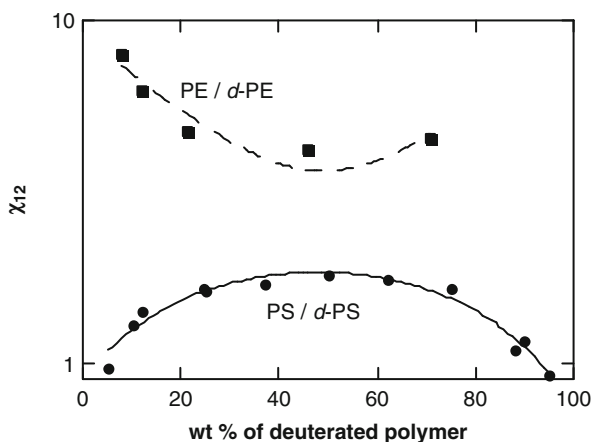
Polymer acronyms: *P2VP* poly(2-vinyl pyridine), *P4MS* poly(4-methylstyrene), *PBMA* poly(*n*-butyl methacrylate), *PCHA* poly(cyclohexyl acrylate), *PEB* poly(ethyl butylene), *PIB* polyisobutylene, *PI* polyisoprene, *PMMA* poly(methyl methacrylate), *PPMA* poly(*n*-pentyl methacrylate), *PP* polypropylene, *HHPP* head-to-head polypropylene, *PS* polystyrene, *PVME* poly(vinyl methyl ether), *PXE* poly(2,6-dimethyl-1,4-phenylene oxide), *SPB* saturated polybutadiene, *SPI* saturated polyisoprene


Fig. 2.7 The binary interaction parameter for blends of PS with d-PS at $T = 433$ K and for PE with d-PE at $T = 443$ K (Londono et al. 1994)

oftentimes leading to phase separation of such, especially at large molecular weights. For example, in Fig. 2.7, the experimental values of this parameter are shown for blends of a hydrogenated polymer with its deuterated homologue, i.e., PE with d-PE at $T = 443$ K and PS with d-PS at $T = 433$ K (Londono et al. 1994). The data can be described in terms of Eq. 2.38. A formal analysis of these data was published by Bidkar and Sanchez (1995).

Even at a superficial view, it is rather obvious that the FH theory has limitations, even when all its restrictive assumptions (weak interactions, entropy-independent enthalpy, etc.) are satisfied. For example, the χ for polymers, as defined by FH ($\chi = z\Delta\varepsilon/kT$; z is coordination number and $\Delta\varepsilon$ the excess enthalpy of interaction for one mixed pair) allows for z solvent neighbors around each monomer, neglecting that

Table 2.9 Structural parameters for model polyolefins (Dudowicz and Freed 1996a, b)

there are always (at least) two other monomers of either side of an internal monomer; this leads to a gross overestimation of the nearest neighbor heterocontacts, which, however, can be addressed by a simple correction, replacing z by $z - 2$ (Guggenheim 1944, 1952). A number of other extensions of the FH theory also address the type and geometry of monomer, the stiffness of the backbone, the existence of unsaturated carbons, etc.; the reader is referred to a recent review (Freed and Dudowicz 2005, and references cited therein). More arguments along these same lines led to correction terms or extensions in the FH theory that can address, beyond chain connectivity, also monomer size, monomer geometry including pending groups, restricted bond rotations, etc., details that can become very important when comparing to sensitive experimental data, such as SANS measurements of χ. The details of such corrections go beyond the scope of this chapter; the interested reader is again referred to Freed and Dudowicz (2005); in most cases, such extensions retain the FH equation for the free energy of mixing, Eq. 2.35, and redefine the χ' parameter as an appropriate function, rather than a system-specific constant. Thus, such corrections lead to a binary interaction parameters with functionals such as

$$\chi'(\phi, T) = a + \frac{b + c\phi}{T} \quad \text{or} \quad \chi'(\phi, T) = a' + \frac{b'}{T} + c'\phi \qquad (2.40)$$

where a, b, and c are corrections due to monomer geometry, packing (see also Table 2.9 *ff.*), and other (b', c') considerations, often rather involved in their definition (e.g., Eq. 11a vs. Eq. 2.10 in Freed and Dudowicz 2005). Finally, another drawback of the FH theory is the assumption of a fully occupied lattice, i.e., the assumption that all space is occupied by units, either solvent molecules or polymeric segments, of equal and constant size. As a consequence, the free volume contributions are largely neglected. It was pointed out that dissolution of polymer is associated with volume changes (Maron 1959), leading to a modification of the FH theory extended to account for ternary systems comprising of polydispersed polymers (Utracki 1962).

2.5.1.2 Equation of State Theories

Starting in the early 1960s considerable effort was made to develop what become known as the equation of state theories (Flory et al. 1964; Eichinger and Flory 1968;

Simha and Somcynsky 1969; Patterson 1969, 1982; Patterson and Robard 1978; Sanchez and Lacombe 1976, 1977; Sanchez 1983, 1984). The equation of state (EoS) theories of mixtures are based on the principles discussed in Sect. 2.4.1. Formally, the computation of the partition function for a single component or for a mixture of components is similar, yielding the Helmholtz free energy of mixing.

Different EoS use different measures of the binary interactions between components. For example, in Flory's extension of the FH approach, the binary interaction parameter, χ_{12}, is still present (Flory 1970). In S-L EoS (see Eq. 2.16), the characteristic pressures for the mixture of species are assumed to be pairwise additive:

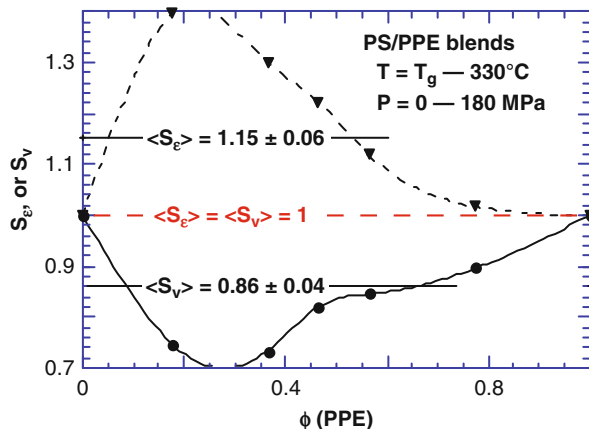
$$P^* = \sum_i \phi_i P_i^* - \sum_{i<j} \sum_j \phi_i \phi_j \Delta P^* \qquad (2.41)$$

For such systems, the difference of the interaction energy density, ΔP^*, has been considered a measure of the binary interactions between polymeric segments, proportional to either χ_{12} or B (Sanchez 1989).

The most successful statistical thermodynamic theory of liquids is that proposed by Simha and Somcynsky, S-S (Simha and Somcynsky 1969; Jain and Simha 1980, 1981, 1982, 1984). From the corresponding partition function, the Helmholtz free energy and then the pressure were computed using the general derivatives, Eq. 2.5. For a single-component system, the S-S yielded PVT relationships (Eq. 2.19). Initially, the theory has been used to compute PVT behavior of homopolymers. Later, it was extended to full thermodynamic description of multicomponent systems, viz., thermodynamics of mixtures, gas-liquid and liquid-liquid phase equilibria, etc. Thus, using the derived expression for the free energy of neat components, the molar Helmholtz free energy was derived for a binary mixture (Jain and Simha 1980; 1984; Stroeks and Nies 1988):

$$
\begin{aligned}
\frac{F_m}{RT} = \quad & x_1 \ln x_1 + x_2 \ln x_2 + \frac{\langle s \rangle}{y}(1-y)\ln(1-y) - (\langle s \rangle - 1)\ln\frac{z-1}{e} \\
& -\langle c \rangle \left[\ln \frac{\langle V^* \rangle (1-\eta)^3}{Q} - \left(\frac{yQ^2}{2T^*} \right)\left(AQ^2 - 2B \right) \right] \\
& -\frac{3}{2}\left[x_1 c_1 \ln\left(2\pi \frac{\langle M_{o1} \rangle}{(N_A h)^2} \right) + x_2 c_2 \ln\left(2\pi \frac{\langle M_{o2} \rangle}{(N_A h)^2} \right) \right]
\end{aligned}
\qquad (2.42)
$$

where N_A and h are Avogadro's and Planck's constants, respectively and the nomenclature follows the typical variables of the S-S EoS, such as y the fraction of occupied lattice cells; Q the dimensionless quantity $1/(yV^*)$; η the dimensionless quantity $2^{-1/6}yQ^{1/3}$; s_i the number of segments per chain of molar mass M_i; M_{oi} the segmental molar mass, $M_{oi} = M_i/s_i$; as well as the three principal reducing variables $P_i^* (= zq_i\epsilon_{ii}^*/s_i v_{ii}^*)$, $T_i^* (= zq_i\epsilon_{ii}^*/Rc_i)$, and $V_i^* (= v_{ii}^*/M_{oi})$, which relate to the component's maximum molar intermolecular attraction energy per segment (ϵ_{ii}^*) and the number of intermolecular contacts ($q_i z = s_i(z-2) + 2$), with the subscripts i, in all

Fig. 2.8 The binary
interaction parameters S_ε and
S_v of the Simha-Somcynsky
(S-S) EoS for PS/PPE blends
(T range, T_g to 330 °C;
P range, 0–180 MPa) (Jain
et al. 1982)


cases, indicating the value for component i. And the mixture variables, the values in
angle brackets, $\langle\rangle$, which are compositional averages based on the components'
properties and their molar fractions, x_i, in the mixture:

$$\langle s \rangle = x_1 s_1 + x_2 s_2 \quad \text{and} \quad \langle c \rangle = x_1 c_1 + x_2 c_2$$
$$\langle M_o \rangle = (x_1 s_1 M_{o1} + x_2 s_2 M_{o2})/(x_1 s_1 + x_2 s_2)$$
$$\langle \epsilon^* \rangle \langle v^* \rangle^k = X_1^2 \epsilon_{11}^* v_{11}^{*\,k} + X_2^2 \epsilon_{22}^* v_{22}^{*\,k} + 2X_1 X_2 \epsilon_{12}^* v_{12}^{*\,k} \quad (k = 2, 4)$$
$$\text{where} \quad X_1 = 1 - X_2 = x_1 [s_1(z-2) + 2]/\langle qz \rangle$$

$$(2.43)$$

In Eq. 2.43, there are two cross-interaction parameters, quantified through
weight-averaged mixing rules, that characterize the binary system:

1. The interaction energy, $\epsilon_{12}^* = S_\epsilon \sqrt{\epsilon_{11}^* \epsilon_{22}^*}$
2. The repulsion volume, $v_{12}^* = S_v [(v_{11}^{*\,1/3} + v_{22}^{*\,1/3})/2]^3$

For nearly athermal systems, the proportionality factors, S_ε and S_v, are taken as
equal to 1. Thus, for the systems without strong interactions, the binary parameters
are well approximated by the geometric and algebraic averages. For example, for
PS/PVME blends, the assumption $S_\varepsilon = S_v = 1$ resulted in 0.1 % deviation for the
experimental values of the cross-parameters (Xie et al. 1992; Xie and Simha, 1997,
"private communication"). In contrast, it is to be expected that for systems with
strong intermolecular interactions such mixture rules may fail and experimental
values for the cross-factors may have to be found. However, least squares fit of
Eqs. 2.42 and 2.43 to experimental values of CO_2 miscibilities in PS (in a wide
range of P and T) yielded values for S_ε and S_v close to 1 (Xie et al. 1997).

The S-S equations were used for the description of *PVT* dependencies for PS,
PPE, and their blends (Jain et al. 1982). The data are presented in Fig. 2.8, where the
best-fit values for each composition: $S_\varepsilon(P, T, \phi)$ and S_v (P, T, ϕ) are plotted
versus PPE volume fraction, ϕ(PPE). The plot shows concentration, a nontypical
dependence for these two parameters, i.e., a behavior not previously observed for
mixtures of solvents or for polymer solutions; the variation is not large – the

averages of S_ε and S_v are, respectively, 1.15 ± 0.06 and 0.86 ± 0.04. From a theoretical point of view, it is highly satisfying that these values are not far from unity. Furthermore, the larger (than 1) value of S_ε and the smaller (than 1) value of S_v indicate the presence of specific interactions between PS and PPE, larger than the geometric average energetic interactions, and a contraction of the binary volume contribution, smaller than the algebraic mean. It should be stressed that, as shown by the original authors, the S_ε and S_v values provided excellent description of the *PVT* dependencies over the full range of variables. The observed compositional variability may, thus, be caused by inadequacies of the theory, or the computational method, or the experimental data. Analysis of these and other blends by means of the S-S EoS is continuously being pursued.

2.5.1.3 Gas-Lattice Model

The gas-lattice model considers liquids to be a mixture of randomly distributed occupied and vacant sites. P and T can change the concentration of holes, but not their size. A molecule may occupy m sites. Binary liquid mixtures are treated as ternary systems of two liquids (subscripts "1" and "2") with holes (subscript "0"). The derived equations were used to describe the vapor-liquid equilibrium of *n*-alkanes; they also predicted well the phase behavior of *n*-alkanes/PE systems. The gas-lattice model gives the non-combinatorial Helmotz free energy of mixing expressed in terms of composition and binary interaction parameters, quantified through interaction energies per unit contact area (Kleintjens 1983; Nies et al. 1983):

$$
\begin{aligned}
\Delta F_m/N_\phi kT = \quad & \phi_0 \ln \phi_0 + (\phi_1/m_1) \ln \phi_1 + (\phi_2/m_2) \ln \phi_2 + \\
& \left[\alpha_{11} + g_{11}^L(1-\gamma_1)/(1-\gamma_1\phi_1-\gamma_2\phi_2)\right]\phi_0\phi_1 + \\
& \left[\alpha_{22} + g_{22}^L(1-\gamma_2)/(1-\gamma_1\phi_1-\gamma_2\phi_2)\right]\phi_0\phi_2 + \\
& \left[\alpha_{12} + g_{12}^L(1-\gamma_1)/(1-\gamma_1\phi_1-\gamma_2\phi_2)\right]\phi_1\phi_2
\end{aligned}
\tag{2.44}
$$

with $N_\phi = n_0 + n_1 m_1 + n_2 m_2$ and $\gamma_i = 1 - \sigma_i/\sigma_0$; the superscript L is used to indicate that the relation was derived from the gas-lattice model; the parameter s_i is the interacting surface area of species "i"; the binary interaction parameters include two terms, as usual, the α_{ij} empirical entropy corrections and the g_{ij} temperature dependencies ($g_{ij} = -w_{ij}/2\sigma_0 kT$, with w_{ij} is the interaction energy per unit contact surface area involved in $i - j$ contact, $i = j$ corresponds to same-species interactions). This approach is rather versatile, and, among other, it has been extended and adapted to describe the empirical parameters through a molecular basis (Koningsveld et al. 1987), as well as orientation-dependent interactions (Besseling and Scheutjens 1994). According to the gas-lattice theory, four factors determine the polymer/polymer miscibility (Koningsveld et al. 1982: Koningsveld 1986):

1. Interacting surface areas of segments
2. Coil dimensions (dependent on T, ϕ, and M_W)
3. Molecular weight polydispersity
4. Free volume fraction

   In an effort to address some of the FH and gas-lattice models simplifications, the lattice cluster theory (LCT) was developed (Dudowicz et al. 1991; Dudowicz

and Freed 1991, 1993, 1995, 1996a, b; Freed and Dudowicz 1995; 1996a, b; 2005).
LCT is a mean-field lattice-based model, but in comparison to FH theory, it
incorporates two modifications: (1) It includes local packing and interactions,
and (2) it distinguishes different structures of the monomeric units, allowing the
monomeric units to occupy different adjacent sites, as dictated by their structure
(e.g., pending side groups). The theory represents polymer chains as strings of beads,
called *united atoms*, freely jointed by flexible bonds. For example, it considers CH_x
(x = 0, 1, 2, or 3) as a single bead (or group) that occupies one lattice site. LCT also
incorporates vacant sites (free volume) and uses the nonrandom mixing principle.
Thus, the free energy of mixing is given by

$$\frac{\Delta F_m}{NkT} = \sum_i \frac{\phi_i}{M_i} \ln \phi_i + \phi_v \ln \phi_v + \sum_i g_i(\phi_i)\phi_i\phi_v + \sum_{i \neq j} g_{ij}\left(\phi_i, \phi_j\right)\phi_i\phi_j \quad (2.45)$$

The first two terms of Eq. 2.45 are the combinatorial entropy contributions, one
for each species i and one, the second term, for the free volume contribution to
the entropy of mixing (where the subscript v indicates the free volume fraction).
The third term represents the non-combinatorial contribution ($g_i(\phi_i)$ is the
non-combinatorial energy of a molten state of polymer i having the free volume
fraction ϕ_v). The fourth term represents the energetic contribution originating from
interaction between unlike species, $i \neq j$. Here, $g_{ij}(\phi_i, \phi_j)$ is the interaction term
expressed as a polynomial with coefficients that depend on the structure of the
polymer chains; these coefficients are computed as double expansions in $1/z$ (z is
the lattice coordination number) and ε_{ij}/kT (ε_{ij} is the van der Waals interaction
energies between groups i and j). Through curve fitting to experimental data, it has
been shown that the binary interaction parameter, Flory-Huggins' χ_{12} or g_{12} above,
is a thermodynamic function of such independent variables as T, P, ϕ_i, molecular
weight, and others. LCT shows that the binary interaction parameter has strong
sensitivity also to composition, monomeric structure, and local correlation. The
theory was quite successful describing observed dependencies for PS/PVME blends
using four parameters: $\varepsilon_{S/S}$, $\varepsilon_{VME/VME}$, $\varepsilon_{S/VME}$, and the cell volume. Except for the
heterocontact parameter $\varepsilon_{S/VME}$ (which must be determined by a fitting procedure),
the values of the other three parameters are determined from the *PVT* dependencies
of neat resins and are not adjustable in the blend phase calculations.

LCT, originally developed for di-block copolymers, was found to be particularly
useful to explain miscibility of polyolefin blends, where the two resins differ in the
type and size of short-chain branching. These polymers comprise of structural units
with two carbons in the main chain (backbone), i.e., polyethylene, PE = $[CH_2–CH_2]_n$;
polypropylene, PP = $[CH_2–CH (CH_3)]_n$; poly-2-butene, P2B = $[CH (CH_3)–CH$
$(CH_3)]_n$; polyisobutylene, PIB = $[CH_2–C (CH_3)_2]_n$; poly(4,4-dimethyl 1-butene),
PDMB = $[CH_2–CH (C_4H_9)]_n$; etc. Structural parameters (e.g., ratio of end to interior
groups, number of bonds, volume of submonomer units, etc.) are used to distinguish
between different monomer structures and geometries and account for differences in
the blend phase behavior by redefining $\chi(\phi, T)$ (see Eq. 2.40). For example, three such

Table 2.10 Binary interaction parameters, $\chi = \chi_s + \chi_H/T$, for model polyolefin 1:1 blends at 500 K (Freed and Dudowicz 1996a, b). See also Tables 2.9 and 2.8

Blends	T_c (K)	r	$1,000\chi_s$	χ_H (K)	100χ

PP/P2B	328	0.167	0.5463	0.0569	0.061
PEP/PP	311	0.133	0.3249	0.0424	0.037

parameters, r, p, and q, were used for the polyolefins above (values for model polyolefin macromolecules are summarized in Table 2.9). A number of derivative models (simplified-LCT, basic-LCT, etc.) were also developed by the same scientists (Freed and Dudowicz 2005).

Miscibility is expected for blends of polyolefins having similar values of these structural parameters. In Table 2.10, examples of the computed binary interaction parameters for 1:1 composition polyolefin blends at 500 K are shown (Freed and Dudowicz 1996a, b). The experimental values of these parameters have also been measured (Balsara et al. 1992, 1994; Graessley et al. 1993, 1994a, b, 1995; Krishnamoorti et al. 1994a, b, 1995, 1996; Lin et al. 1996; Schipp et al. 1996; Reichart et al. 1997). Experimental data were determined using either small-angle neutron scattering (SANS), cloud-point curve determination (CPC), or *PVT* measurements. The experimental results will be discussed later, *vide infra* SANS measurements.

2.5.2 Off-Lattice Theories

2.5.2.1 Strong Interactions Model

For incompressible systems having strong interactions, e.g., acid–base type, the directional-specific model of segmental interactions may be used (Walker and Vause 1982; ten Brinke and Karasz 1984). By appropriate definition of $\chi(T)$, the familiar FH expression was derived for a symmetric ($N_1 = N_2 = N$) blend:

$$\frac{\Delta G_m}{RT} = \frac{\phi_1}{N} \ln \phi_1 + \frac{\phi_2}{N} \ln \phi_2 + \chi(T)\phi_1\phi_2$$
$$\text{with } \chi = \frac{U_2}{RT} + \ln(1 - \lambda) + \ln\left(1 + \frac{1}{q}\right) \text{ and } \lambda = \left[1 + qe^{(U_1 - U_2)/RT}\right]^{-1} \quad (2.46)$$

where U_1 and U_2 are the attractive and repulsive energies, respectively, and q is the degeneracy number; the familiar FH expression was obtained by splitting the binary interaction parameter χ in an enthalpic and an entropic term:

$$
\begin{aligned}
\chi_H/z &= [\lambda U_1 + (1 - \lambda U_2)]/RT \text{ and} \\
\chi_S/z &= \ln(1 - \lambda) + \ln(1 + 1/q) - \lambda(U_1 - U_2)/RT
\end{aligned}
\tag{2.46a}
$$

respectively, with q and λ as above. Depending on the relative magnitudes of U_1 and U_2, Eq. 2.46 predicts either UCST or LCST.

2.5.2.2 Heat of Mixing Approach

For most polymers, $N \gg 1$ and the configurational entropy of a polymer blend become vanishingly small; thus, to a very good approximation $\Delta G_m \approx \Delta H_m$ (the enthalpic effects dominate) and, hence, adiabatic calorimetry should be able to predict polymer/polymer miscibility (Cruz et al. 1979).

$$
\Delta G_m \approx \Delta H_m = B\phi_1\phi_2 = \chi_{12}RT(V/V_1)\phi_1\phi_2
\tag{2.47}
$$

After experimentally confirming the validity of this idea, the principal authors attempted to use this approach for explanation of the so-called miscibility windows (Paul and Barlow 1984). The latter term refers either to polymer/copolymer blends that show miscibility only within a limited range of copolymer compositions (e.g., Balazs et al. 1985; Fernandes et al. 1986; Goh and Lee 1987) or to blends of two copolymers having a common monomer (Shiomi et al. 1986). As earlier, in Koningsveld's treatment of χ_{12}, here also the parameter B has an enthalpic contribution and a non-combinatorial entropic contribution. For multicomponent systems, Eq. 2.47 can be generalized (Barlow and Paul 1987):

$$
\frac{\Delta G_m}{V} \approx \frac{\Delta H_m}{V} = \sum_i \sum_{j \neq i} B_{ij}\phi_i\phi_j - \sum_k \Psi_k \sum_i \sum_{j \neq i} B_{ij}\phi_i^k\phi_j^k
\tag{2.48}
$$

where Ψ_k is the volume fraction of polymer k and the usual constraints for the component volume fractions are extended to $\sum \phi_i \equiv 1$ and $\sum \phi_i^k \equiv 1$. For simple systems, containing a copolymer A (mers #1 and #2) and either a homopolymer B (mers #3) or a copolymer B (mers #1 and #3), Eq. 2.48 can be simplified to read:

$$
\frac{\Delta G_m}{V} \approx \frac{\Delta H_m}{V} = B\Psi_1\Psi_2
\tag{2.49}
$$

where B is now, respectively,

$$
\begin{aligned}
B &= B_{13}\phi_1' + B_{23}\phi_2' - B_{12}\phi_1'\phi_2' \text{ or} \\
B &= B_{12}\phi_2(\phi_2' - \phi_3'') + B_{13}\phi_3(\phi_3' - \phi_2'') + B_{23}\phi_2'\phi_3''
\end{aligned}
\tag{2.49a}
$$

where ϕ_i' and ϕ_i' ′ denote the volume fraction of i-type monomer in copolymers A and B, respectively. Over the years, values of the parameter B for many polymer mixtures have been published. As shown in Table 2.11, similar to χ_{12}, also the binary B varies with composition, temperature, and other blend variables.

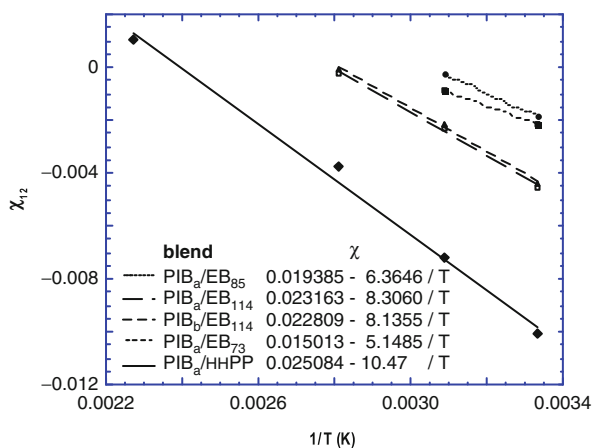
Determination of *B* for a series of blends made it possible to establish empirical rules for the observed miscibilities. Thus, for example, Prud'homme (1982) reported a systematic variation of miscibility in a series of halogenated polymer blends with aliphatic polyesters. The highest miscibility was observed for

Fig. 2.9 The binary interaction parameter B for PVDC/aliphatic polyester blends plotted as a function of the number of methylene groups ($-CH_2-$) per ester group ($-COO-$) in the second polymer (Data from Woo et al. 1986)

Fig. 2.10 The binary interaction parameters for two PIB resins ($M_w = 81.6$ and 114 kg/mol) with either ethylene-butene copolymers (of different M_w and composition) or with an atactic head-to-head polypropylene (HHPP), based on SANS data (Krishnamoorti et al. 1995)


chlorinated polymers, e.g., PVC, and the lowest for fluorinated, e.g., PVF, with the brominated PVB, having an intermediate behavior. Furthermore, when the chlorinated polymer was mixed with a series of polyesters, the highest miscibility was observed when the ratio of the $-CH_2-$ to $-COO-$ groups reached an optimum value. This optimum value depended on the chemical nature of the halogenated polymer – as shown in Fig. 2.9, for PVDC blends with aliphatic polyesters this optimum value is between 5 and 6.

In Table 2.11 along the parameters χ_{12} and B, the available values of ΔP^* are also listed. The latter parameter originates from S-L EoS, and it has been considered a measure if the interaction energy is proportional to χ_{12} or B (Sanchez 1989). All these parameters, being proportional to each other, are expected to show similar variability with the independent variables; for example, see the variation with composition and temperature of χ_{12} in Figs. 2.10 and 2.11 and of ΔP^* in Fig. 2.12.

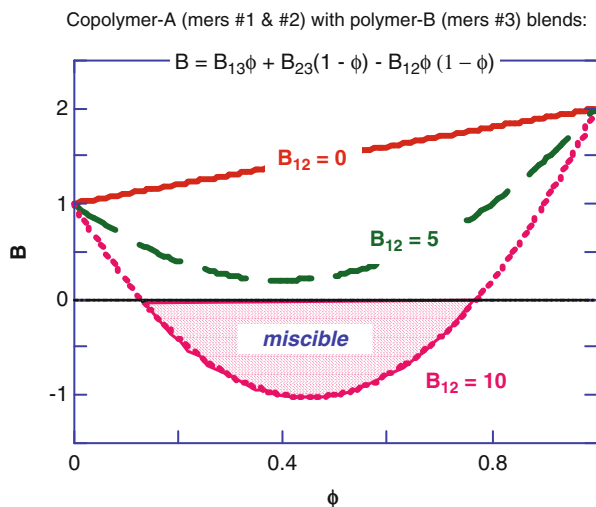
ether blends at the spinodal
temperature, T_s. (*bottom*)
Temperature dependence of
ΔP^* (Data after Etxeberria
et al. 1997)

Fig. 2.13 Compositional variation of the interaction parameter, B, in a copolymer (mers #1 and #2)/ homopolymer (mers #3) blend. Even when all three binary interaction parameters are positive ($B_{23} = 1$, $B_{13} = 2$, and $B_{12} = 0-10$), for a copolymer with strong repulsive interactions, $B_{12} = 10$, a "window of miscibility" is predicted

Copolymer-A (mers #1 & #2) with polymer-B (mers #3) blends:

$$B = B_{13}\phi + B_{23}(1 - \phi) - B_{12}\phi (1 - \phi)$$


The observed regularity in the miscibility behavior of polymers can be understood considering the polymers as composed of individual interacting groups. For example, taking the case illustrated in Fig. 2.9, one may consider that PVDC is an alternating copolymer of units, $-CH_2-$ and $-CCl_2-$, whereas the aliphatic polyester is composed of $-CH_2-$ and $-COO-$ units. Equations 2.48 and 2.49 predict that even systems with all positive values of the binary interaction parameter, $B_{ij} > 0$, (repulsive interactions) may have a window of miscibility, where the overall parameter B becomes negative. The magnitude of this effect depends primarily on the value of the repulsive interactions within the copolymer molecule, $B_{12} > 0$; a schematic representation of Eq. 2.49 is shown in Fig. 2.13.

Since B_{ij} characterizes the enthalpic and non-configurational entropy of interaction between segments i and j, they should be pairwise and additive, to a good approximation; thus, one could tabulate these parameters per group and, in turn, use them for predicting miscibility in any arbitrary system composed of polymers and/or copolymers built from these groups/segments (Paul and Barlow 1984). This idea is similar in concept with the group-contribution approach of calculating solubility parameters. Table 2.12 provides examples of B_{ij} values published over the years, as well as χ_{ij}. The χ_{ij} dimensionless parameter is directly proportional to B_{ij} (Eq. 2.47), whereas ΔP^* is the binary interaction energy density calculated from S-L EoS. Since ΔP^* is also proportional to B_{ij} (Sanchez 1989), one may apply S-L theory to experimental data and compute the segmental contributions, ΔP_{ij}^*, in analogy to B_{ij}:

$$\Delta P^* = \Delta P_{12}^* \phi_2' \left(\phi_2' - \phi_3''\right) + \Delta P_{13}^* \phi_3'' \left(\phi_3'' - \phi_2'\right) + \Delta P_{23}^* \phi_2' \phi_3'' \qquad (2.50)$$

The segmental interaction parameters have been also used to explain the "miscibility window" or "miscibility chimney" in polymer/copolymer or

copolymer/copolymer blends (Lath and Cowie 1988). These parameters have been found useful to predict miscibility of blends containing one component whose structure is systematically varied, e.g., polyesters with either halogenated polymers or phenoxy (Prud'homme 1982; Harris et al. 1983; Woo et al. 1985, 1986), polyamide blends (Ellis 1989), ternary blends (Shah et al. 1986), and other systems, viz., SAN/PMMA, SAN/PC, polyethyloxazoline/polyester, PPE with a mixture of P*o*ClS and P*p*ClS, PC/PCL/phenoxy, and many more.

Ellis (1988, 1989, 1990a, b) used the same approach to evaluate miscibility of polyamide blends. He treated the polyamide molecules as copolymers, viz., comprised of units A, B, and C in the form $A_xB_yC_{1-x-y}$, where A, –CH₂–; B, –NHCO–; and C, $–C_6H_4–$ (phenyl). The analysis made it possible to systematize the experimental observations and predict conditions of miscibility for aliphatic and semi-aromatic polyamides. The method was applied to a 1:1 composition of blends, and χ_{12} values were assumed to be temperature independent. Examples of the segmental interaction parameters, χ_{ij}, used are given in Table 2.13. For binary mixtures of aliphatic polyamides A_xB_{1-x} with A_yB_{1-y} (where A and B groups were as defined above), the binary interaction parameter of the blend was expressed as $\chi_{12} = 7.984(x-y)^2$, a positive number; thus, these polymers are expected to be immiscible. The miscibility, if observed, may be explained by either the presence of hydrogen bonding or *trans*-reactions (transamidation) resulting in rapid homogenization of the system (e.g., PA-6/PA-46 at 310 °C becomes homogenous in 4 min) (Ellis 1992).

Table 2.13 Segmental interaction parameters, χ_{ij}, for polyamide blends (Ellis 1990b, 1993, 1995, 1997)

Segment-1	Segment-2	χ_{12}
$-CH_2-$	$-NHCO-$	7.984; 8.534

$-mC_6H_4-$	$-NHCO-mC_6H_4-NHCO-$	1.680

It has been known since the early days that behavior of the aromatic polyamides (aramids) depends critically on the type of isomeric substitutions – *para*-substitutions result in crystalline, while *meta*-substitutions in amorphous polymers (Kwolek et al. 1962). Similarly, the two aramids: poly(*m*-xylene adipamide) and poly (hexamethylene isophthalamide), MXD6 and PA-6I, respectively, show different miscibility, e.g., with aliphatic polyamides. Clearly, blind application of the segmental interaction strategy to aromatic or semi-aromatic polyamides leads to conflicts. However, the problem can be resolved considering *p*- and *m*-substituted phenyl as two different statistical segments (Ellis 1995). This idea is indeed evident in the segmental contributions listed in Table 2.14.

The segmental interaction values of χ_{ij} from Table 2.13 were used to compute the binary interaction parameters, χ_{12}, for blends of a semi-aromatic polyamide, PA-3Me6T (Trogamid^{TM} T) with aliphatic polyamides, PA-4 to PA-12. These values are listed in Table 2.14, along with the observations of miscibility, in good agreement (Ellis 1989). The data of Table 2.14 were used to construct Fig. 2.14. Similar to the case for the miscibility of halogenated polymers with polyesters, here also the miscibility depends on the CH_2/NHCO ratio – with the best miscibility found when the group ratio was 7, e.g., for PA-410.

Later, this analysis was extended to PA blends with polyesters (Ellis 1993, 1995; 1997). Thus, in the simplest case of PA blends with aliphatic polyesters, i.e., blends of A_xB_{1-x} with A_yD_{1-y}, where the units are A, $-CH_2-$; B, $-NHCO-$; and

Table 2.14 Calculated binary interaction parameters, χ_{12}, based on segmental contributions values (from Table 2.13) for blends of aliphatic polyamides with PA-3Me6T and experimental observation of miscibility (Ellis 1989)

Aliphatic PA	Aromatic PA	χ_{12}	Observation
PA-4	PA-3Me6T	0.0400	Immiscible
PA-46	PA-3Me6T	0.0065	Immiscible
PA-6	PA-3Me6T	−0.0050	Miscible
PA-66	PA-3Me6T	−0.0050	Miscible

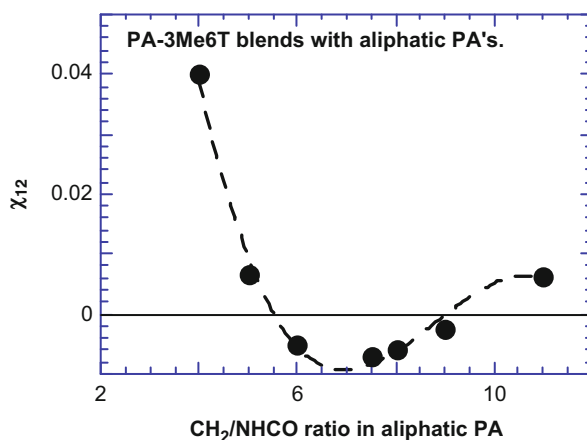
PA-610	PA-3Me6T	−0.0058	Miscible
PA-612	PA-3Me6T	−0.0023	Miscible
PA-11	PA-3Me6T	0.0061	Immiscible
PA-12	PA-3Me6T	0.0104	Immiscible


Fig. 2.14 The calculated binary interaction parameter for blends of PA-3Me6T with aliphatic polyamides as a function of the –CH$_2$–/–NHCO– group ratio of the aliphatic polyamide (Data from Ellis 1989)

D, –COO– (ester) and the subscripts x, y refer to the polymers' mer volume fractions, the binary χ based on segmental contributions is (Ellis 1993) $\chi_{12} = (y-x)(1-x) \chi_{AB} + (x-y)(1-y) \chi_{AD} + (1-x)(1-y) \chi_{BD}$. The values of χ_{ij} are also listed in Table 2.13. A similar principle was used to apply the LCT to polyolefin copolymer blends (Freed and Dudowicz 2005).

After 30 years since its conception, the heat of mixing (or analog calorimetry) method for the determination of polymer/polymer miscibility is becoming increasingly sophisticated. The low molecular weight analogs are selected on the basis of detailed calculations of the electrostatic charges on the atoms and molecules, using molecular orbital theories. The following principles have been formulated (Sandler and Wu 1991; Ziaee and Paul 1996; 1997):

The geometry of a functional group (in the polymer and selected analog molecule) should be the same.

The electrostatic charge of each atom in a functional group should be approximately the same.

Table 2.15 Segmental binary interaction parameters, B_{ij}, at 0.5 volume fraction, for polar groups related to bisphenol-A carbonates and acrylonitriles (Ziaee and Paul 1996, 1997)

Group-1	Group-2	T (°C)	B_{ij} (cal/mL)
$-C_6H_5$	$-CH_2-$	30	8.74 ± 0.16
$-C_6H_5$	$-CH_2-$	80	7.74 ± 0.16
$-C_6H_5$	$-CH_2-$	130	5.93 ± 0.20
$-C_6H_5$	C_6H_5-O-	80	-2.11 ± 0.30
$-CH_2-$	C_6H_5-O-	80	5.44 ± 0.15
$-C_6H_4-O-$	C_6H_5-	80	-0.60 ± 0.45
$-C_6H_4-O-$	$-CH_2-$	80	7.24 ± 0.26
$-C_6H_5$	$-mXO-$	80	-0.91 ± 0.14
$-CH_2-$	$-mXO-$	80	3.13 ± 0.18
$-C_6H_5$	$-CO-$	80	-36.9 ± 18
$-C_6H_5$	$-CO-$	90	15.1
$-CH_2-$	$-CO-$	80	-19.1 ± 15
$-CH_2-$	$-CO-$	90	41.4
C_6H_5-O-	$-CO-$	90	-8.97
$-C_6H_5$	$-Ph_2OCOO-$	90	0.55 ± 0.21
$-CH_2-$	$-Ph_2OCOO-$	90	10.1 ± 0.2
$-C_6H_5$	$-mX_2OCOO-$	130	0.40 ± 0.06
$-CH_2-$	$-mX_2OCOO-$	130	4.56 ± 0.06
$-C_6H_5$	$-CH_2-CN$	30	19.1 ± 0.2
$-CH_2-$	$-CH_2-CN$	30	60.8 ± 0.5

Notes: Most groups are the obvious common compounds (methylene, $-CH_2-$ (cf. alkyl); phenyl, $-C_6H_5$; carbonyl, $-CO-$; phenol, C_6H_5-O-; etc.). The rest of the groups relate to the segments of bisphenol-A polycarbonate and tetramethyl bisphenol-A polycarbonate: mX is m-xylyl: $-C_6H_2(CH_3)_2-$ (cf. di(2,6-dimethyl)phenyl); mXO, m-xylyl ether: $-C_6H_2(CH_3)_2-O-$; Ph_2OCOO, diphenyl carbonate: $-C_6H_4-O-CO-O-C_6H_4-$; mX_2OCOO, di(m-xylyl)carbonate, viz., di (2,6-dimethyl)phenyl carbonate, $-[C_6H_2(CH_3)_2]-O-CO-O-[C_6H_2(CH_3)_2]-$, i.e., a diphenyl carbonate with each of the two phenyls being a 2,6-dimethyl substituted phenyl (m-xylyl)

The functional group should be approximately electroneutral.

The functional group should be the smallest entity, identified by dividing the analog molecule into a collection of electroneutral groups.

Going beyond effectively apolar polymers – those whose miscibility is determined by van der Walls interactions (dispersion forces) – for polar polymer, the partial charges can also be accounted for and incorporated in segmental binary interaction parameters. A careful analysis of such data makes it possible to determine binary interaction parameters, B_{ij}, as those listed in Table 2.15. For these data, the authors calculated the (enthalpic) binary interaction parameters for several polymer/oligomer pairs, from Eq. 2.49 using the B_{ij} values, where the heat of mixing was determined at $T = 80$ °C for 1:1 blend/mixture compositions (Ziaee and Paul 1996; 1997). The calculated values were in good agreement with the measured ones, based mostly on polystyrene blends with bisphenol-A polycarbonate and tetramethyl bisphenol-A polycarbonate, as well as with acrylonitrile-containing polymers.

In summary, the heat of mixing approach and the corresponding segmental binary interaction parameters entail several simplifying assumptions. The numerical values of the parameters do vary depending on method of evaluation, selected system/pair, concentration, temperature, etc. However, the method has been found useful for the identification of potentially miscible systems and conditions. Furthermore, the approach provided a valid tool for interpretation of the blends' behavior at higher concentration, viz., 1:1 compositions, where the interaction parameters are relatively insensitive to the variability of concentration. Under these conditions, the segmental binary interaction parameters have been successfully employed to describe:

Miscibility in systems without strong specific interactions

Behavior of blends of a homopolymer with copolymer

Miscibility of polymer series (chemically similar polymers, e.g., polyamides, polycarbonates)

Window of miscibility in two- or three-component systems

Chimney of miscibility in two- or three-component systems

2.5.2.3 Solubility Parameter Approach

The concept of the solubility parameter originates from Hildebrand's work on enthalpy of regular solutions (Hildebrand and Scott 1950, 1962; Shinoda 1978) and was defined as the square root of the cohesive energy density $\left(\delta \equiv \sqrt{E/V}\right)$. Accordingly, in a strict sense, the molecular interactions should be nonspecific, without forming associations or orientation, hence not polar or hydrogen-bonding interactions. Another fundamental assumption was that the intermolecular interactions 1-2 are geometric mean of the intramolecular interactions, 1-1 and 2-2:

$$\Delta H_m \approx \Delta G_m^{non\ comb} = \phi_1 \phi_2 V_m (\delta_1 - \delta_2)^2 \geq 0$$

$$\Delta H_m \approx \phi_1 \phi_2 V_m \left[\sqrt{\frac{E_1^V}{V_1}} - \sqrt{\frac{E_2^V}{V_2}} \right]^2 = \left[\frac{E_1^V}{V_1} - \frac{2E_{12}^V}{\sqrt{V_1 V_2}} + \frac{E_2^V}{V_2} \right] \quad (2.51)$$

where E_i^V is the molar energy of vaporization of substance i and δ_i is its solubility parameter. Comparing Eq. 2.51 to Eq. 2.35 makes it evident that the binary interaction parameter *chi* can be written in solubility parameter terms:

$$\chi'_{12} \approx \left(V_{ref}/RT \right) (\delta_1 - \delta_2)^2 \quad (2.52)$$

where the reference volume is usually taken as $V_{ref} = 100$ mL/mol (viz., the liquid density is 1). It is important to note that, as stated by Eq. 2.51, the above interaction parameter is limited to the enthalpic part of binary interaction parameter, i.e.,

$$\chi'_{12} = \chi_S + \chi_H = \chi_S + \left(V_{ref}/RT \right) (\delta_1 - \delta_2)^2 \quad (2.53)$$

The entropic term in Eq. 2.53, χ_S, originates from local configurational effects, as well as combinatorial entropy contributions. When Eq. 2.52 is used, then χ_S must be accounted for through other means.

For molecules without polar groups, the solubility parameter δ_i may be determined or approximated:

1. From the δ_i definition (see Eq. 2.51):

$$\delta_i^2 = E_i^V/V = \left(\Delta H_i^V - PV\right)/V \approx \left(\Delta H_i^V - RT\right)/V \qquad (2.54)$$

2. From empirical correlation, as, for example, with the surface tension coefficient (γ_i) or the dipole moment (μ_i):

$$\delta_i^2 = 14\gamma_i/V^{1/3} \quad \text{or} \quad \delta_i = 37.4\mu_i/V^{1/2} \qquad (2.55)$$

3. By solving Eq. 2.51 for δ_1, knowing the experimental values of ΔH_m for material 1 in a series of solvents with known values of δ_2

For small molecules without strong interactions, the values of the solubility parameter vary from 5.9 (for C_6F_{14}) to 14.1 (for I_2), whereas it is about 30 for H_2O (Hansen 2000); the standard error of these estimates is ± 0.2, much larger for water. Given that polymer (melt) evaporation experiments are impossible, the solubility parameter of a polymer is usually determined by measurements of its oligomeric liquids or by indirect measurements of its behavior in a solvent of known solubility parameter. The solvent approach allows for the polymer to be cross-linked (the degree of swelling (D_s) is measured) or simply dissolved in the solvent (the intrinsic viscosity ($[\eta]$) is usually measured). From the plot of either D_s or $[\eta]$ versus $\delta_{solvent}$, the value of $\delta_{polymer}$ is determined as the value that corresponds to the peak location (Utracki 1972), or by appropriately fitting the whole curve (Hansen 2000). For copolymers, the volume additivity of the monomeric solubility parameters is assumed, i.e., $\delta = \sum \phi_i \delta_i$. This assumption also follows from the group-contribution method used to compute δ from the chemical and structural characteristics of polymeric chain, *vide infra* (Grulke 1989; van Krevelen 1992; Coleman et al. 1992, 2006). Correlation between the solubility parameter theory and the EoS based on the Flory model was also explored (Biros et al. 1971). The authors demonstrated that $\delta = P^{*1/2}V^*/V$, where P^* and V^* are the pressure-reducing and volume-reducing parameters, respectively.

Given the definition of δ, the temperature and pressure gradients of the solubility parameter can be approximated by

$$\left.\frac{\partial \ln\delta}{\partial T}\right|_P \cong -\alpha_P \quad \text{and} \quad \left.\frac{\partial \ln\delta}{\partial P}\right|_T \cong +\beta_T \qquad (2.56)$$

where α_P is the isobaric thermal expansion coefficient and β_T is the isothermal compressibility. These relations can be used to correct/extrapolate the value of δ to any temperature and pressure of interest (δ values are usually given at 298 K and ambient pressure).

For completeness of the above discussion, a few examples of solubility parameters for selected polymers are given in Table 2.16. More extensive listings can be found in the source literature (Shinoda 1978; Van Krevelen 1976; Grulke 1989;

Table 2.16 Solubility parameters, experimental and calculated, for various common polymers at 298 K. All δ values are in $(J/mL)^{1/2}$ the calculated values have a nominal error of ± 0.8 $(J/mL)^{1/2}$

Polymer	Experimental δ			Calculated δ

Note: The calculated values of δ in the last column can be reproduced by the CD-ROM tool provided in (Coleman and Painter [2006a], [b]). Although the tool allows for the input of almost any arbitrary polymer, and even provides a calculated δ value for these, care must be given to the uncertainty associated with certain groups' contributions, e.g., $-CF_2-$, $>Si<$, etc., whose attraction values are denoted as "rough estimates"; rather inaccurate numbers for δ are obtained for polymers that are comprised primarily by such groups, e.g., using $-CF_2-$ group contributions for PTFE above would result in $\delta = 10.2$, but this value is with ± 5 uncertainty. Calculated δ's with large uncertainties are omitted above. These limitation are outlined in the accompanying booklet (Coleman and Painter [2006a], [b])

Coleman et al. [1990]). As evident, by comparing data from different studies, cf. Table [2.16], one complication of the solubility parameter method is poor reproducibility of the measured values. Selection of different commercial polymers and solvents, or using different sets of solvents, may significantly change the value of the measured δ. Also, more recent and arguably more accurate calculated δ values exist (Hansen [2000]; Coleman and Painter [2006a], [b]), *vide infra*.

The biggest drawback of the solubility parameter approach, as described above, is the omission of the entropic and specific interactions' effects. Furthermore, the fundamental dependencies do not take into account either the structural (isomeric), orientation, or the neighboring group effects (e.g., steric effects, intermolecular screening, functional group accessibility) (Coleman and Painter [2006a], [b]). However, solubility parameters can provide a guide toward miscibility: Since the contributions that are included in the solubility parameter calculation are indeed detrimental to miscibility, minimizing their value must but help the miscibility.

In the simplest approach, the solubility parameter of a polymer can be calculated by a summation of group contributions (Coleman and Painter 1988, 1989, 1990, [2006a], [b]). The essence of this approach is to assume pairwise additivity for the interaction of sub-monomeric building blocks, "groups," which can be added to

Table 2.17 Selected group contributions for the calculation of solubility parameters based on Eq. 2.57; molar volume V_i^g [cm^3/mole] and molar attraction F_i^g [(cal · cm^3)$^{1/2}$/mole] (Coleman and Painter 2006a, b). The source contains additional groups and important instructions of how, and when, meaningful solubility parameters for polymers can be obtained

>NH	8.5	143
>N–	−5.0	−3

form the monomer units. For example, a simple hydrocarbon, such as *n*-octane, is assumed to consist of six –CH$_2$– and two –CH$_3$ groups; using the energy of vaporization for a series of such paraffins with varied length, Coleman and Painter estimated molar attraction constants for –CH$_2$– and –CH$_3$.

Further, by including branched hydrocarbons, and molecules containing other functional groups (ether oxygens, esters, nitriles, etc.), a table of constants was obtained (Table 2.17) and, subsequently, used to calculate the solubility parameter for various polymers, using the relationship:

$$\delta = \frac{\sum_i F_i^g}{\sum_i V_i^g} \tag{2.57}$$

In the late 1980s, a new approach to the solubility parameter concept was developed (Painter et al. 1988, 1989a, b, 1990, Coleman et al. 1988, 1989, 1990, 1991, 1995), which was later further refined to address some of the drawbacks mentioned above (Coleman and Painter 2006a, b). The authors start by recasting Flory-Huggins Eq. 2.35 into the form (Painter et al. 1988):

$$\frac{\Delta G_m}{RT} = \frac{V}{V_{ref}} \left[\frac{\phi_1}{N_1} \ln\phi + \frac{\phi_2}{N_2} \ln\phi_2 + \chi'_{12}\phi_1\phi_2 \right] + \frac{\Delta G_H}{RT} \tag{2.35b}$$

where V is the total molar volume of the two components and $V_{ref} = 100$ mL/mol is the reference volume. Originally, the new term, ΔG_H, was introduced to express the effects of hydrogen bonding in blends (where one polymer self-associates, the other does not – but it is capable to hydrogen bond to the first one). Since then, this term has been extended to describe all specific interactions (hydrogen bonding, ion-ion, ion-dipole, charge transfer, $\pi-\pi$ electron interactions, etc.) that provide negative contributions to the free energy of mixing. Equation 2.35b distinguishes three contributions to the free energy of mixing: the configurational entropy (given by the two logarithmic terms), the dispersive or van der Waals interactions (given by the positive $\chi'_{12}\phi_1\phi_2$ term), and the strong interaction term, ΔG_H. For systems with no specific interactions ($\Delta G_H \approx 0$), Eq. 2.35b becomes the FH equation. The interactions of the van der Waals type are accounted for by the $\chi'_{12}\phi_1\phi_2 \geq 0$ term, with χ'_{12} quantified through Hildebrand's solubility parameters via Eq. 2.52. The degree of polymerization dependence of miscibility was assumed to follow Eq. 2.36.

The novelty of the Coleman-Painter theory is the calculation of the hydrogen-bonding contributions in the free energy of mixing (Painter et al. 1988, 1995, 2000). Previous attempts to describe blends with specific interactions, including hydrogen bonds, usually employed the FH theory and allowed the χ parameter to become negative. However, such an approach is rather unsatisfactory because:

1. The hydrogen-bonded contacts are not random (i.e., the interaction term cannot take the usual $\chi\phi_1\,\phi_2$ form, because only for strictly random mixing the term $\phi_1\phi_2$ provide the probability of a 1–2 contact).
2. The formation of hydrogen bonds results in a high loss of degrees of rotational freedom in the molecules or segments involved and, hence, introduces significant entropic as well as enthalpic changes in ΔG_m.
3. It is rather unreasonable to lump both specific and nonspecific interactions into one overall interaction parameter, not only because they are very different in character (composition dependence, temperature dependence, etc.), but also because it is often the balance between the two, i.e., specific and nonspecific interactions, that determines the blend phase behavior.

In contrast, the Coleman-Painter theory quantified the hydrogen-bonding contributions implicitly by re-enumerating an "equilibrium distribution" of the various species in the mixture after accounting for hydrogen-bonding formation (in pairs, hydrogen-bonded dimers, or longer sequences h-mers). Specifically, starting from Eq. 2.35b, the final result for the specific interaction term ΔG_H can be written as

$$\frac{\Delta G_H}{RT} = \begin{aligned} &\frac{\phi_1}{r}\ln\phi_{01} + \phi_2\ln\frac{\phi_{21}}{\phi_{21}^0} \\ &+ K\phi_2\left(\phi_{21} - \phi_{21}^0\right) + \phi_2(1 - K\phi_{21})\frac{X}{1+X} \\ &- \left[\frac{\phi_2}{n_H^0}\ln\phi_2 + \frac{\phi_1}{r}\ln\phi_1\right] \end{aligned} \qquad (2.58)$$

with

$$r = V_1/V_2 \quad \left(\text{equiv. } V_{ref} = V_2\right) \quad \text{and} \quad X = K_1\phi_{01}/r$$

where the volume fractions ϕ_1 and ϕ_2 are the usual volume fraction of polymer 1 and 2, respectively, in the blend; ϕ_{01} is the volume fraction of polymer 1 that remains unassociated; ϕ_{21} and ϕ_{21}^0 represent the nonbonded monomers of polymer 2 in the blend and in the neat state, respectively; and n_H^0 is the equilibrium length of the hydrogen-bonded sequence of monomers. Note that a term describing the energy of hydrogen bond formation does not appear explicitly in the result (Eq. 2.58). To compute the thermodynamic contribution of the strong interactions to the overall thermodynamic behavior of a blend, one must first determine the three principal constants: K_A, K_B, and K_2; these are defined as association equilibrium constants for the formation of hydrogen bond between B and A units (of polymer 2 and 1), respectively, the formation of self-association between sequences of multiple B units, and the formation of doublets of the hydrogen-bonded B units (Coleman and Painter 1995; Painter and Coleman 2000). The K_A, K_B, and K_2 can be quantified experimentally, e.g., by IR spectroscopy, they are interrelated (only two of the three Ks need to be determined independently) and are constrained by stoichiometry (the total number of i-type mers is the sum of the associated and non-associated mers); the fraction of hydrogen-bonded A groups, f_A^{HB} which can be determined experimentally, can yield

$$f_A^{HB} = 1 - \frac{\phi_{0A}}{\phi_A} = 1 - \left[\frac{1}{1 + K_A\phi_B\Gamma_1}\right] \quad \text{with} \quad \Gamma_1 = 1 - \frac{K_2}{K_B} + \frac{K_2/K_B}{1 - K_B\phi_{0B}}$$
and
$$\phi_B = \phi_{0B}\Gamma_2\left[1 + \frac{K_A\phi_{0A}}{r}\right] \quad \text{with} \quad \Gamma_2 = 1 - \frac{K_2}{K_B} + \frac{K_2/K_B}{(1 - K_B\phi_{0B})^2}$$

$$\text{(2.58b)}$$

For the computation of an isobaric phase diagram, the temperature dependence of the association constants has to be known: $K_A(T)$, $K_B(T)$, and $K_2(T)$; the polymer-specific T dependence follows an Arrhenius-type dependence:

$$K_i = K_i^o \exp\left(\frac{-h_i}{R}\left[\frac{1}{T} - \frac{1}{T^o}\right]\right) \quad\quad\quad \text{(2.58c)}$$

where h_i is the enthalpy of formation of a hydrogen bond, which can be determined from experimental data (Painter and Coleman 2000). When the pressure influence on blend miscibility is of interest, the K_i functions must be evaluated within the appropriate range of pressures as well: $K_A(T, P)$, $K_B(T, P)$, and $K_2(T, P)$.

As mentioned, one of the strong points of this theory is that, since the three equilibrium association constants are defined in terms of chemical repeating units, these constants can, thus, be measured by spectroscopic means (Painter et al. 1989a, b, 2000). Infrared spectroscopy is sensitive to hydrogen bonding, but selection of the

most appropriate vibration band is essential. For example, instead of N-H or O-H stretching, the carbonyl group (C=O) may be a better choice. Examples of the association constants for blends of poly(4-vinyl phenol), PVPh, with acrylic polymers are given in Table 2.18. These values were used to compute the phase diagrams for blends of styrene-*co*-vinyl phenol (comprising of 2–100 % VPh), with either acrylic polymers, poly(alkyl$_{i\,=\,1..6}$-methacrylates), or polyethers (Serman et al. 1989, 1991; Xu et al. 1991). The experimental data confirmed the theoretical prediction, thus corroborating the validity of the model. Since then, more blends, as well as polymer solutions, have been investigated experimentally and compared favorably against the theoretical predictions (Painter et al. 2000).

As stated before, the Hildebrand solubility parameter concept was developed for nonpolar, low molecular weight liquids at room temperature. For polar molecules, the method did not provide consistent information. To avoid trouble, initially all liquids were divided into three categories for poorly, moderately, and strongly interacting systems. Another route was taken by Hansen (1967) who postulated that all intermolecular forces:

• London dispersion forces between nonpolar molecules
• Repulsive forces between nonpolar molecules
• Coulombic ion/ion interactions
• Dipole/dipole interactions between the permanent dipoles
• Permanent dipole/ion interactions
• Induced dipole/ion interactions
• Permanent dipole/induced dipole interactions
• Charge-transfer forces
• Hydrogen bonding
• Coordination bonding
• Metallic bonding, etc.

Fig. 2.15 Schematic representation of Hansen's miscibility sphere, Eq. 2.60
can be combined and grouped into three types of interactions, dispersive, polar, and hydrogen bonding, and a substance's total solubility parameter can thus be written as

$$\delta_i^2 = \delta_{id}^2 + \delta_{ip}^2 + \delta_{ih}^2 \tag{2.59}$$

where the subscripts d, p, and h represent the dispersive, polar, and hydrogen-bonding interactions, respectively. Accordingly, two substances would be miscible only when their solubility parameters place them within the critical radius of a spheroid, defined as (Hansen 1967, 1995)

$$R_{12}^2\text{crit} = \Theta(\delta_{1d} - \delta_{2d})^2 + \left(\delta_{1p} - \delta_{2p}\right)^2 + \left(\delta_{1h} - \delta_{2h}\right)^2 = \chi_{12} \geq 0 \tag{2.60}$$

where the semiempirical fudge parameter: Θ assumes values of 4–5 and accounts for the dominant role that the dispersion forces play in binary solubility. The concept is illustrated in Fig. 2.15. Examples of the numerical value of the Hansen's parameters are given in Table 2.16 (Hansen 1967, 1994, 1995; Hansen and Beerbower 1971; Grulke 1989; Luciani et al. 1996b), whereas a comprehensive collection of values has been compiled in a handbook (Hansen 2000). As reported by Hansen (1995, 2000), values of these parameters may greatly vary from one commercial polymer resin to another, reflecting diversity of molecular weights,

molecular weight distribution, the presence or absence of catalyst, and a great diversity of additives (caution is advised for their use). The values of the solubility parameters for solvents are considered more dependable.

Much like the Coleman-Painter approach, the solubility method also allows for the values of the Hansen's partial solubility parameters, δ_{id}, δ_{ip}, and δ_{ih}, to be calculated from the molecular structure of a polymer by using additive group contributions. van Krevelen (1976) demonstrated usefulness of the method using contributions from individual atoms, structural groups, and configurations. However, care must be given when such solubilities are employed in mixture that contain dissimilar in interactions polymers. For example, comparing to the calculations of interfacial surface tensions based on dispersive and polar components, it becomes necessary for the polar component to be further broken down in an electron-donor and an electron-acceptor component, e.g., $\delta_{ip} \propto \delta_{ip}^{+}\delta_{ip}^{-}$, and enter Eq. 2.60 as $(\delta_{1p}^{+}-\delta_{2p}^{+})(\delta_{1p}^{-}-\delta_{2p}^{-})$, rather than as $(\delta_{1p}-\delta_{2p})^2$, otherwise one is led to rather unreasonable predictions (van Oss et al. 1988); thus, it becomes obvious that Eq. 2.60 is a simplification, which works well for polar substances 1 and 2 that are similar in polarity, but it becomes problematic when, for example, an electronegative and an electropositive substance are considered (Table 2.19).

While the tabulated data for the group contributions are given for amorphous materials at room temperature, $T = 25\ {}^{\circ}\text{C}$ (298 K), miscibility at processing temperatures (200–300 $^{\circ}$C) is most often of interest; thus, it is necessary to correct the solubility parameter values for any temperature effects. The solubility parameters are, in principle, insensitive to temperature. However, although interaction energies are not expected to be a function of T, the corresponding interaction volumes, either for the polymers or for the corresponding groups, are indeed T dependent. To account for the T dependence, either Eq. 2.20 or 2.56 can be used. The calculated values of δ_{id}, δ_{ip}, and δ_{ih} at 150 $^{\circ}$C (423 K) for selected polymers are listed in Table 2.20.

Equation 2.60 was also used to calculate the interfacial (interphasial) tension coefficients, γ_{12}, for two polymers forming an immiscible blend, based on their chemical structures.

$$\begin{aligned}
\gamma_{12} &= k_1(\rho RT)^{n-1}\left[\Theta(\delta_{1d} - \delta_{2d})^2 + (\delta_{1p} - \delta_{2p})^2 + (\delta_{1h} - \delta_{2h})^2\right]^n \\
&= k\left[\Theta(\delta_{1d} - \delta_{2d})^2 + (\delta_{1p} - \delta_{2p})^2 + (\delta_{1h} - \delta_{2h})^2\right]
\end{aligned} \quad (2.61)$$

where k, k_1 are constants and ρ is the density. Good agreement was found between the computed and experimental values of the coefficient for 46 polymer blends (Fig. 2.16). The best correlation was found for the values $0.3 \le \Theta \le 0.5$. Thus, contrary to the dissolution processes dominated by the dispersive forces ($\Theta = 4\sim5$), for interphasial phenomena, the dispersive forces seem less important than the polar ones (Luciani et al. 1996a, 1997). A more detailed experimental approach, providing also M_w and T dependencies of the interfacial

Table 2.19 Hansen solubility parameters for selected polymers at 25 °C. All values are in $(J/mL)^2$. For some polymers, more than one set of δ values are provided (a, b, etc.), indicating variability in experiments/fittings or polymer structure effects (comonomer, M_w, additives, etc.). A much more comprehensive collection of such values can be found in the relevant handbook (Hansen 2000)

tension in immiscible blends, scattering or pendant drop approaches can be applied (Anastasiadis et al. 1988); this work showed good agreement with interfacial tension theoretical approaches, based on lattice models in the spirit of the Flory-Huggins approach (Helfand 1975a, b, c, Roe 1975). on the thermodynamics of interfacial tension in polymer blends, see Anastasiadis (2011).

A pragmatic modification of the solubility parameter approach was proposed by Bush et al. (1996). Recognizing that ΔH_m can be negative, the authors wrote

$$\Delta G_m \approx \Delta H_m = \phi_1 \phi_2 \left[(\delta_1 - \delta_2)^2 - e_h \right] \qquad (2.62)$$

where the correction e_h is a positive number, associated with the energy density that originates from specific interactions. In other words, Eq. 2.62 implies that, in the presence of favorable specific interactions, in order to maximize miscibility the solubility parameters of the two blend components should be the same.

2.5.3 Polymer Reference Interaction Site Model (PRISM)

Thermodynamic properties of a system can also be obtained from atomistic considerations. Molecular dynamics or Monte Carlo methods have been successfully used to study polymers. The success stems from the fact that many properties can be projected from dynamics of relatively simple, oligomeric models. Unfortunately, miscibility strongly depends on the molecular weight, and so far it cannot be examined by these methods.

Another similar route that considers interactions between individual elements of a system is the reference interaction site model (RISM). The theory involves computations of the system structure by means of the probability density function, which describes location of all N particles of the system. The binary interactions define the pair-density function:

$$\rho_N^{(2)} = \frac{N!}{(N-2)!} \int P_N \, dr^{(N-2)} = \rho^2 \, g(r) \qquad (2.63)$$

P_N is the probability density of N particles, r is the particle coordinate, and $g(r)$ is the radial distribution function. The potential energy of the system is given as a product of the potential energy of a single particle with all others, multiplied by a factor $N/2$:

$$U = \frac{N\rho}{2} \int_0^\infty 4\pi r^2 \, u(r)g(r) \, dr \qquad (2.64)$$

Thus, the total description of the thermodynamic state hinges on accurate quantification of $g(r)$. Ornstein and Zernike suggested separating the influence of this parameter into direct and indirect parts. The first describes direct interaction of the reference particle 1 with particle 2, while the indirect one that of particle 1 with particle 3, which in turn interacts with particle 2:

$$g_{12}(r) = c_{12}(r) + \rho \int c_{13}(r)[g_{13}(r) - 1] \, dr_3 \qquad (2.65)$$

where $c(r)$ is the direct correlation function. The advantage of the Ornstein-Zernike equation is that it can be readily generalized to more complex systems with inter- and

intramolecular interactions. RISM has been applied to progressively more complex liquids, from monatomic to diatomic, CCl_4, C_6H_6, etc. (Chandler and Andersen 1972). In the late 1980s, RISM has been applied to polymers, termed PRISM (Curro and Schweizer 1987; Schweizer and Curro 1989). The PRISM requires less computing time than atomistic simulations, but still makes it possible to incorporate structural details of polymeric molecules that the lattice models have been unable to account for. For example, bond lengths, their angles, chain conformation statistics, and different interaction potentials can be included in the mathematical simulations (Honeycutt 1992a, b, Curro 1994).

For polymer blends, PRISM provides good correlation with the experimental data obtained by SANS and light scattering (Eitouni and Balsara 2007). The agreement very much depends on selection of the "closure" approximation. Initial selection of the most appropriate closure for a given system can be quite difficult. Nevertheless, the method gave encouraging results, predicting details of phase separation in PO blends (Schweizer 1993). The deuteration effects as well as these related to structural differences between homopolymer and copolymers were well described (Schweizer 1993; Eitouni and Balsara 2007). The PRISM approach for polymer blends is still undergoing development and expansion; thus, more details here would simply be a snapshot at the moment of writing; the interested reader is therefore referred to seek a recent review or book chapter on PRISM.

2.5.4 Summary of Theoretical Approaches

Three theoretical approaches to the thermodynamics of polymer blends were briefly discussed: (1) the lattice theories, including the newer equation of state theories, (2) the off-lattice theories, and (3) the computational methods.

The lattice theories are the oldest and most frequently used to interpret and to predict the thermodynamic properties of multicomponent systems containing polymers. The Flory-Huggins theory is the best known. To use the theory, one must know the temperature, pressure, and concentration dependence of the enthalpic and entropic contributions to the binary interaction parameter, $\chi_{12} = \chi_H (T, P, \phi, \ldots) + \chi_s (P, \phi, \ldots)/T$. Two types of extension of the FH theory were discussed, the first that evolved from Paul and Barlow is a heat of mixing approach, and the second was a solubility approach developed by Coleman and Painter. The first of these two makes it possible to treat a homopolymer as a copolymer composed of subunits of the chain, thus to generalize and predict behavior of a great number of polymer blends. The second divides all thermodynamic influences into three groups: the configurational entropy, the van der Waals interactions, and the specific interactions. The novelty of this modification is the method of treatment of the latter interactions that combines the FTIR-measured kinetics of associations with the FH theory. All these approaches suffer from the fundamental drawbacks of the FH theory: inability to take into account the fine structure of polymeric chains, nonrandomness, orientation, and free volume. The interaction parameters depend on many variables, and the reported numerical values vary widely.

Fig. 2.17 Pressure dependence of the binodal and spinodal temperatures for the three *d*-PB/PS blends, with varied butadiene monomer structure. All phase boundaries increase with *P*, as expected from reduced free volume effects, but those for *d*-PB(1,2)/PS blends increase with a parabolic shape, while the increase is linear for the other two blends (Schwahn 2005)
The theories based on the equation of state are more versatile. The model developed by Simha and many of his collaborators is most useful. By contrast with the FH theory, it leads to two binary interaction parameters, one energetic, the other volumetric, that are constant in the full range of independent variables. Furthermore, it has been found that the numerical values of these two parameters can be approximated by the geometric and algebraic averages, respectively. The nonrandom mixing can easily be incorporated into the theory. The non-lattice approaches, viz., strong interactions, heat of mixing, and solubility parameter approaches have more limited use. Their application should be confined to cases where the assumptions used in the derivations are well fulfilled.

The influence of pressure, *P*, on the miscibility needs a comment. Since pressure reduces the effects of the free volume contributions, for most blends the miscibility increase with *P* (Walsh and Zoller 1987; Schwahn 2005). The effects are very sensitive to the monomer structure, as one would expect from free volume considerations, as, for example, in PB/PS blends (Fig. 2.17): In the case of *d*-PB/PS blends, the general trend of an increase of the phase boundaries with pressure is observed for all systems (viz., increased binodal and spinodal temperatures with *P*, due to the reduction of free volume), but the shapes of $T_{binodal}(P)$ and $T_s(P)$ are linear for *d*-PB(1,4)/PS and *d*-PB(1,4-*co*-1,2)/PS blends and are more parabolic for the blend with *d*-PB(1,2)/PS; also the compatibility of PS is best for *d*-PB(1,4) and worst for *d*-PB(1,2), with the *d*-PB(1,4-*co*-1,2) copolymer being in between the two, as expected (Fig. 2.17). The *P* effect generally depends on the magnitude of the heat of mixing: For systems with $\Delta H_m < 0$, the miscibility is enhanced by compression, whereas for those with $\Delta H_m > 0$ it is reduced (Rostami and Walsh, 1984, 1985; Walsh and Rostami 1985). For PS solutions, the pressure gradient of

the critical solution temperature was found to be a function of the molecular weight – the higher the M_w, the more negative the gradient value (Stroeks and Nies 1990). For polymer blends, the gradient is usually positive: for PPE blends with a random copolymer of o- and p-fluorostyrene, the gradient $d(UCST)/dP = 64$ to 108 °C/GPa (Maeda et al. 1986), and for PS/PVME, $d(LCST)/dP = 300$ °C/GPa (Hiramatsu et al. 1983), whereas for blends of PEA/PVF the LCST showed a complex dependence (Suzuki et al. 1982). The prediction of the pressure effects on solubility poses great challenges for the precision of the theoretical description. It should be noted that, according to the conditions for phase separation (*vide infra*, e.g., Eq. 2.66, Fig. 2.20), the critical point is given by third partial derivative of the free energy of mixing, and its pressure gradient – the stability condition – by the forth partial derivative.

2.6 Phase Separation

2.6.1 Thermodynamics of Phase Separation

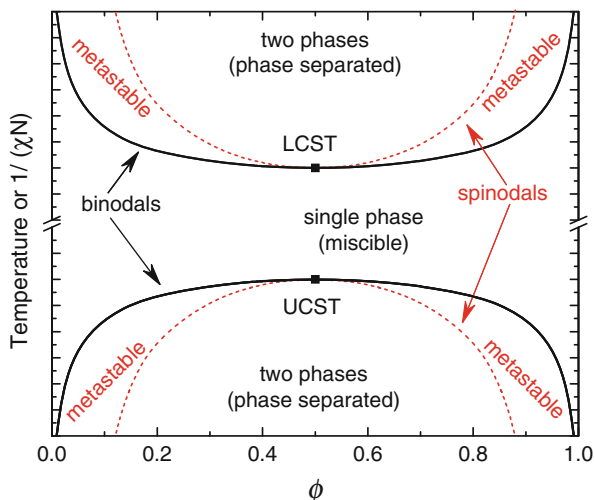
The thermodynamic conditions for phase separation and, also, the definitions of the respective phase diagram are given by

$$
\begin{aligned}
&\text{binodal}: (\partial \Delta G_m / \partial \phi_i)_{P,T,n_j}^{\text{phase 1}} = (\partial \Delta G_m / \partial \phi_i)_{P,T,n_j}^{\text{phase2}} \left(cf. \mu_i^{\text{phase 1}} = \mu_i^{\text{phase 2}} \right) \\
&\text{spinodal}: \left(\partial^2 \Delta G_m / \partial \phi_2^2 \right)_{P,T} = 0 \\
&\text{critical point}: \left(\partial^3 \Delta G_m / \partial \phi_2^3 \right)_{P,T} = 0 \\
&\text{stability condition}: \left(\partial^4 \Delta G_m / \partial \phi_2^4 \right)_{P,T} > 0
\end{aligned}
$$

$$(2.66)$$

Schematic of a phase diagram of a binary system is shown in Fig. 2.18. There are three regions of different degree of miscibility: (1) the single-phase miscible region between the two binodals, (2) the four fragmented metastable regions between binodals and spinodals, and (3) the two-phase separated "spinodal" regions of immiscibility bordered by the spinodals. The diagram also shows two critical solution temperatures, the lower, LCST (at higher temperature), and the upper, UCST (at lower temperature). The phase diagram with two critical points is a rule for measurements of mixtures with low molecular weight component(s). Whereas for polymer blends usually only one critical point is accessible for normal conditions, e.g., P, and typically shows either the LCST (most often) or the UCST. A few blends having UCST are PS blends with SBS, PoClS, PBrS, or poly(methyl-phenyl siloxane), and BR blends with SBR, SAN with NBR (Utracki 1989).

The origin of the critical point can be traced to the temperature effects on miscibility: In a first approach, one can distinguish three principal contributions to the binary interaction parameter, χ_{12} (Patterson 1982), with rather distinct T dependences: in general, the dispersive forces contributions in χ_{12}, with a $1/T$

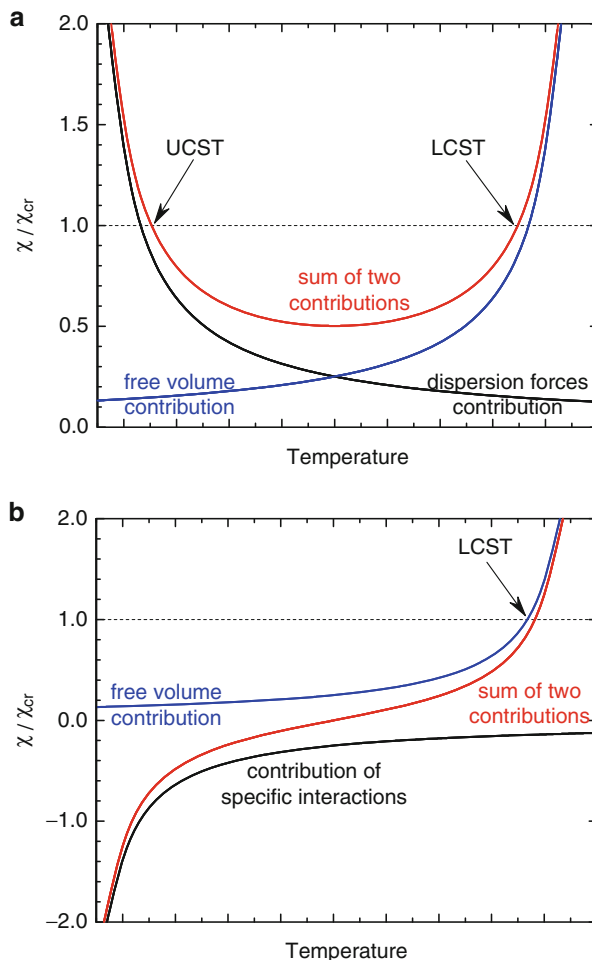
Fig. 2.18 A schematic of the phase diagram for liquid mixtures with the upper and lower critical solution temperature, UCST and LCST, respectively. The placement of the critical compositions at about $\phi_{cr} = 0.5$ denotes that this is a symmetric blend ($N_1 = N_2$). In the general case, the phase diagram is qualitatively the same, but much less symmetric with respect to ϕ, with a ϕ_{cr} appearing in very small polymer concentrations, e.g., $\phi_{cr} \approx 1/\sqrt{N}$, cf. FH theory


dependence; the free volume contributions, increasing with T; and the specific interaction contributions in χ_{12}, typically increasing with T (e.g., Arrhenius). As schematically illustrated in Fig. 2.19, the different temperature dependencies of these contributions affect χ_{12} in very different manner. For low molecular weight systems, where the dispersion interactions and free volume effects dominate the χ_{12}, the sum of these two has a U-shape, intersecting the critical value of the binary interaction parameter in two places – hence, two critical points, UCST and LCST (Fig. 2.19a). In contrast, most polymer blends owe their miscibility to the presence of specific interactions that contribute a negative value in the interaction parameter, but increase with T until they are balanced out by the free volume contributions (as well as by the ubiquitous dispersion forces, which in this case can be ignored). The sum of the two most important contributions in χ_{12} reaches the critical value at one temperature (e.g., an LCST, Fig. 2.19b).

To predict the phase behavior for a given system, the following steps are typically taken:

1. Select the most appropriate theoretical model for the free energy of mixing, ΔG_m.
2. Determine values of the characteristic material parameters required by the selected theory.
3. Solve Eq. 2.66 for the selected theory.
4. Readjust the fitting parameters of the theory to optimize the fit.
5. Make predictions of the thermodynamic behavior and then verify experimentally.

The most important step is the selection of the theoretical model, i.e., the form of ΔG_m. The balance between the complexity of its form and the adequacy of the description of experimental behavior must be preserved, also its applicability to the relevant P and T ranges must be checked, e.g., the existence of parameters with

Fig. 2.19 Interactions in polymer solutions and blends usually comprise of dispersive forces, the free volume effects, and specific interactions. (**a**) The χ_{12} of polymer solutions are typically dominated by the contributions from dispersive forces and free volume, whose T dependence can result in a UCST and LCST. (**b**) In polymer blends, the contributions from the free volume and the contributions from specific interactions usually control the T dependence of χ_{12}, giving rise to an LCST


values of confidence in these ranges. One fundamental question is whether the pressure dependence of the phase diagram is important or not. Most data in literature deal with ambient pressures, whereas most industrial applications, viz., processing, compounding, and forming, are done at high pressures (e.g., extrusion $P \sim 70$ MPa, injection molding $P \sim 500$ MPa, etc.). The accuracy demanded from the theory to account for large variations of pressure is severe. It suffices to note that according to Eq. 2.66 the critical point is given by the third derivative of the free energy of mixing – its pressure dependence (stability criterion) is given by the fourth derivative!

The sometimes complicated forms of the free energy equations require, in most cases, that Eq. 2.66 are solved numerically, especially for the binodal determination (Jain and Simha 1984; Nies et al. 1990; Kisselev and Manias 2007). Often authors described the computational procedures, e.g., Nies et al. (1990), for the modified

Fig. 2.20 Calculated phase diagrams for *n*-hexane/PE systems at varied pressures ($P = 1$, 50, and 100 bar); x_2 is the mole fraction of PE with $M_w = 8$ kg/mol (Nies et al. 1990)
S-S theory giving Eqs. 2.42 and 2.43, and Kisselev and Manias (2007), for the LF theory with specific interactions. In the case of the S-S theory, the Helmholtz free energy is explicitly provided, which, in turn, can easily be converted into Gibbs free energy, viz., $G = F + PV$, or $\Delta G_m = \Delta F_m + P\Delta V_m$, where the terms with Δ represent the excess values due to mixing (differences from the single-phase values for each component, i.e., the function values of the mixture less the contributions of the pure components). Results of these computations are exemplified by the three isobaric phase diagrams of PE solutions in *n*-hexane, shown in Fig. 2.14, whereas a number of examples of polymer phase diagrams are available in literature (e.g., Koningsveld et al. 2001) (Fig. 2.20).

2.6.2 Mechanisms of Phase Separation

Phase separation takes place when a single-phase system undergoes either a change of composition or, more usually, a change in T or P that forces it to move from the single-phase region and enter either the metastable or the two-phase/spinodal region (Fig. 2.18). There is a substantial difference between the phase separation mechanisms that take place for moving from single phase to metastable and for moving from single phase to two phase. When the system enters from the single-phase region into the metastable region, phase separation typically occurs by mechanisms resembling crystallization, i.e., slow nucleation followed by growth of the phase separated domains. Thus, this process is known as the "nucleation and growth," or NG for short. In contrast, when the system is forced to jump from a single phase into the spinodal/two-phase immiscible region, the phases separate
Fig. 2.21 Schematic representation of the density fluctuations during the spinodal decomposition mechanism (*SD*, *bottom*) and the nucleation and growth (*NG*, *top*). Three stages are shown: early, where in SD the wavelength is constant but the amplitude increases; intermediate, where both the wavelength and the amplitude change; and final, where the concentration amplitude is at maximum and the wavelength increases only due to coarsening processes

spontaneously: This process starts with instantaneous segmental density fluctuation that progressively increases in amplitude and later in wavelength. The process is known as the "spinodal decomposition," or SD for short.

These two processes are schematically illustrated in Fig. 2.21, as composition versus distance. Three stages of the phase separation process are distinguished: early, intermediate, and late/final. The upper and lower limits of the concentration are given by the tie-line limits intersecting the binodal at $T = $ constant, for the temperature of the experiment (Fig. 2.18). Following the late stage of phase separation, the process continues into a series of coalescence steps, which increase the lateral dimension d of the phases: Coalescence starts with Ostwald ripening ($d \propto t^{1/3}$; see Eq. 2.67), followed by surface tension-controlled coarsening ($d \propto t$; see Eq. 2.68), ending with gravitational or divergent coalescence that leads to formation of large size (macroscopic) separate phases.

$$d \; V_d \propto \frac{\gamma_{12}\phi_c V D_t}{RT}dt \Rightarrow (d/d_o)^{n_c} = 1 + K_c t \qquad (2.67)$$

where V_d is the drop volume, γ_{12} is the interfacial tension, ϕ_c is the equilibrium concentration of the phase separated system (binodal concentration at T), V is the molar volume of the drop fluid, n_c is the coarsening exponent, and K_c is the coarsening rate constant. For a steady-state coarsening, $n_c = 3$, whereas for sheared systems $n_c = 3/2$ (Ratke and Thieringer 1985). Subsequently,

$$\frac{RT}{\gamma_{12}} \le d^2 \le \frac{\gamma_{12}}{g\Delta\rho} \Rightarrow d \propto t \qquad (2.68)$$

where g is the gravitational constant (acceleration) and $\Delta\rho$ is the density difference between the two phases.

For fundamental studies of phase separation, to ensure that phase separation will proceed by the SD mechanism, a composition near the critical point is usually selected. The blend is then quenched (temperature jump) from the miscible to the spinodal region passing through or near the critical point. For this reason, SD studies are often called "critical quenching." Conversely, to study the NG mechanism (a significantly less popular subject), compositions for temperature jumps are selected away from the critical concentration; these studies are then known as "off critical." Reviews on phase separation are continuously published (the reader is strongly encouraged to do a fresh literature search); some such reviews were used next to highlight phase separation behaviors (Kwei and Wang 1978; Olabisi et al. 1979; Herkt-Maetzky 1984; Aifantis 1986, 1987; Hashimoto 1987; Nose 1987; Binder 1987; Hashimoto 1988; Han et al. 1988; Utracki 1989, 1994; etc.).

2.6.2.1 Spinodal Decomposition (SD)

Early theories of the phase separation dynamics are based on a mean-field approach developed for metallurgical applications (Cahn and Hilliard 1958; Cahn 1978). In the spinodal region, the concentration fluctuations are delocalized, leading to long-range spontaneous phase separation by SD. This type of mean-field theory is not adequate to describe the phase dynamics of small molecule liquids (especially near the critical point), but it has been successful in describing phase separation in polymeric systems, due to the slow diffusion rates owing to the large-chain dimension. The time-dependent probability distribution function for concentration can be determined directly by digital image analysis method (Tanaka and Nishi 1987).

For SD, three stages and three mechanisms of domain growth are traditionally identified (Siggia, 1979): diffusion, liquid flow, and coalescence. The earliest diffusion stage follows the Ostwald equation, Eq. 2.67, and is limited to the period when $d_o \leq d \leq 5d_o$, where d_o is the initial diameter of the segregated region ($d_o \approx$ 2–9 nm Voigt-Martin et al. 1986). The subsequent flow region dominates when $5d_o \leq d \approx 1$ μm. Within these two regions, the SD structure is regular and the growth can be observed by scattering methods. At the last, coalescence, stage of SD, diffusion becomes bimodal and then irregular. Thus, at this stage, the kinetics of phase separation has been studied using time-resolved scattering techniques, with light, neutrons, or other irradiation sources. There is a direct relation between the virtual structure function, $S(q, t)$, and the scattering intensity function, $I(q, t)$:

$$
\begin{aligned}
I(q,t) &= I_b + K\ S^2(q,t) \\
&= (I_b + K\ S_\infty) + K(S_o - S_\infty)\exp\big[2R(q)t\big] \\
&= I_\infty + (I_o + I_\infty)\exp\big[2R(q)t\big]
\end{aligned}
\tag{2.69}
$$

where I_b is the background scattering intensity, K is a constant, and S_o and S are the values of the structure function at time 0 and at time t. To extract the concentration

fluctuation function $R(q)$, a semilogarithmic plot of $\ln(I - I_\infty)$ versus t is used. However, in many cases, since the scattering intensity at equilibrium is low, the concentration fluctuation function is determined as

$$R(q) \cong \frac{1}{2} \frac{d \; \ln I(q,t)/I_o(q,t)}{dt} \tag{2.70}$$

As Eq. 2.69 indicates, the scattering intensity $I(q, t)$ is proportional to $S^2(q, t)$. For this reason, the plot of $I(q, t)$ versus q (at constant decomposition time and temperature) already provides evidence of the dynamics of phase separation in polymer blends.

The mechanism of phase separation is analyzed from the R versus q dependence. The dynamics of phase separation within the SD domain starts with a balance between the thermodynamics and material flux. The mean-field theory of phase separation leads to the following simple form of the structure function, $S(q)$ (Cahn and Hilliard 1958):

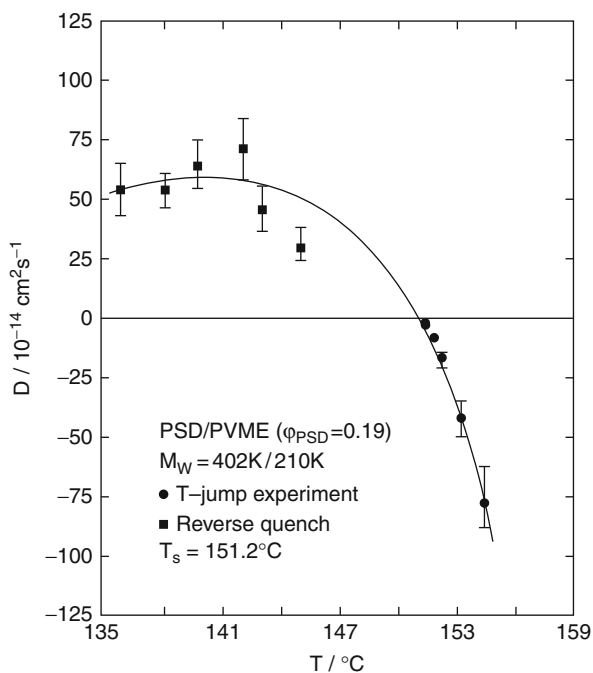
$$\begin{aligned}
S(q) &= S_o \exp\left[R(q)t\right] \\
R(q) &= -Mq^2 \left[\frac{\partial^2 G}{\partial \phi^2} + 2q^2 k\right] \\
q &= \frac{4\pi}{\lambda} \sin\left(\Theta/2\right) = \frac{2\pi}{\Lambda}
\end{aligned} \tag{2.71}$$

where M is the Onsager mobility factor, G is the free energy for the homogenous system, ϕ is the segmental volume fraction, and κ is the gradient energy coefficient arising from local composition fluctuations; the wavevector, q, is a function of the wavelength, λ, and the scattering angle, Θ. It has been shown that near the spinodal $\partial^2 G/\partial \phi^2 \propto 1 - (T/T_s)$, where T_s is the spinodal temperature, whereas the maximum wavelength for SD phase separation is $\lambda_{\max} \propto [1 - (T/T_s)]^{-1/2}$ (van Aarsten 1970). According to Eq. 2.71, the concentration fluctuation function, $R(q)$, can be linearized by plotting $R(q)/q^2$ versus q^2. The linearity provides evidence of the SD mechanism independently of the scale of the phase separation.

From the intersection at $q = 0$, the mutual diffusion coefficient D_M is obtained:

$$\begin{aligned}
\lim_{q\to 0} \left(\frac{R(q)}{q^2}\right) &= D_M = -M\frac{\partial^2 G}{\partial \phi^2} \\
D_M &= 2\phi_1\phi_2(\chi_{12s} - \chi_{12})(N_1 D_1 \phi_2 + N_2 D_2 \phi_1) \\
\chi_{12\ s} &= (N_1\phi_1)^{-1} + (N_2\phi_2)^{-1}
\end{aligned} \tag{2.72}$$

Evidently, D_M depends on the second derivative of the free energy, which in turn can be expressed in terms of the self-diffusion coefficients of polymers, D_1 and D_2, and the $\chi(T)$-distance from spinodal. The method of determining D_M is presented in Fig. 2.22, whereas its dependence on T across the spinodal is shown in Fig. 2.23. From D_M, one may calculate the binary interaction parameter and,
Fig. 2.22 Determination of the mutual diffusion coefficient, D_M, from the early stage data of the spinodal decomposition, SD, in SBS/PBD blends (Izumitani and Hashimoto 1985)

Fig. 2.23 Mutual diffusion coefficient D_M versus T for a PS/PVME blend undergoing spinodal decomposition. T-jumps, across the spinodal temperature $T_s = 151.2\ °C$, were performed in both directions, quenching into SD region, and reverse, quenching from the SD region (Sato and Han 1988)


hence, determine conditions for the thermodynamic miscibility. Fig. 2.24 shows the χ_{12} dependence on T and ϕ.

Coarsening of the structure continues through a series of steps that lead to a gross (macroscopic) phase separation. However, under certain conditions, the coarsening progresses only up to a certain stage, where the structure becomes fixed or "pinned." The pinning originates in a transition from the percolation to cluster formation then freezing-in of the molecular diffusion. In simple term, the generated structure is relatively regular; thus, there is little energetic incentive for the molecules to diffuse from one drop, through "unfriendly" territory of the other phase, to another drop. An example of this has been given for blends of PI containing 20, 30, and 50 wt% of SBR (Takenaka et al. 1989). Evidently, stirring the mixture disrupts the fine balance of forces that make the pinning process possible; thus, pinning is not expected to take place during processing.

Most work on SD focuses on the effects of temperature and composition on phase equilibria in binary polymer mixtures. However, in industrial processes, other

variables may be of equal importance, e.g., the shear stress, shear stress rate, and pressure. It is known that these variables are important for miscibility and, hence, for the morphology and performance. For example, during extrusion of PC/PBT blends the LCST was increased by at least 60 °C, causing miscibility; the blend, upon exit from the extruder, phase separated by the SD mechanism, which resulted in co-continuity of phases and excellent performance. Solvent casting of polymer blends and controlled evaporation can also lead to SD. This technology has been used for industrial production of semipermeable, selective membranes. The product characterized by co-continuity of phases also showed excellent mechanical performance. The type of solvent, concentration, temperature, and method of casting are used to control the blend morphology and its final performance (Inoue et al. 1985, 1987; Nauman et al. 1986).

Phase separation was computer simulated using finite-difference in time and space Runge–Kutta and Monte Carlo with a Hamiltonian methods (Petschek and Metiu 1983; Meakin and Reich 1982; Meakin et al. 1983). Both methods were found equivalent, reproducing the observed pattern of phase separation in both NG and SD regions. The unity of the phase separation dynamics on both sides of the spinodal has been emphasized (Leibler 1980; Yerukhimovich 1982).

2.6.2.2 Nucleation and Growth (NG)

As shown in Fig. 2.25, there is a significant difference in the scattering pattern evolution for NG and SD mechanisms, especially during the early stages of phase separation: SD follows a semilogarithmic time dependence (see Eq. 2.71), whereas NG follows a linear time dependence.

When the concentration of the minor phase is above 10–15 %, SD occurs by rapid growth of regularly spaced concentration waves, while NG is a slower and more random process. On the other hand, at low concentrations of the minor phase, neglecting the fine structure of the dispersed phase, phase separation by NG and SD mechanism looks similar. Also the reverse quenching of SD and NG morphologies is similar, both being controlled by (Kumaki and Hashimoto 1986):

$$\left(\frac{\partial^2 G}{\partial \phi^2}\right)_{\text{spinodal}} = -\lim_{q \to 0} \frac{R(q)}{Mq^2} = \text{constant} \tag{2.73}$$

The relation shows that the rate depends on the conditions for SD, the same for systems on both sides of the spinodal.

The NG is an activated process with a linear growth rate (Matsuda 1991):

$$\begin{aligned}
\text{Nucleation}: \quad & \frac{dN}{dt} = k_N \exp[-\Delta E_{aN}/k_B T] \\
& \Delta E_{aN} = \frac{4}{3}\pi r_{N,cr}^3 \Delta G_m + 4\pi r_{N,cr}^3 \gamma_{12} = \frac{16\pi}{3}\gamma_{12}^3 \Delta G_m^2 \\
\text{Growth}: \quad & \frac{\partial \phi}{\partial t} = D\nabla^2 \phi
\end{aligned} \tag{2.74}$$

Fig. 2.25 A plot of the scattering intensity versus time for 70 % PVME/30 % PS blends (SE-70), at wavevector $q = 5.6 \times 10^4$ cm^{-1} (the spinodal temperature was estimated at $T_s = 99.2$ °C); the data at higher T (99.7 °C, 100 °C, and 101 °C) are for the SD regime, and the data for 99 °C are for the ND regime (Hashimoto et al. 1983)
where $r_{N,cr}$ is the critical radius of the nucleating particle and D is the diffusion constant. Accordingly, the nucleation process requires activation energy for nucleation (ΔE_{aN}). However, once nucleated, the phases separate and grow spontaneously. The nucleation is initiated by the local fluctuations of density. The activation energy ΔE_{aN} depends on the local gradient of the free energy of mixing (ΔG_m) and the interfacial tension (γ_{12}). Once formed, the drops grow by diffusion of macromolecules into the nucleated domains, with the rate given by the Ostwald ripening. The diffusion stage is followed by coalescence (Hashimoto et al. 1986; Hashimoto 1988).

In principle, during the initial stage of phase separation the NG mechanism leads to a drop/matrix morphology over the full range of concentrations. However, the morphology at the later stages depends on the volume fraction of the dispersed phase, as well as the method and extent of stabilization. Furthermore, since nucleation depends on the local density fluctuations, whose amplitude depends on the distance from the critical conditions, near the spinodal, phase separation can occur either by the NG or SD mechanism (Langer 1977, 1980). This ambiguity is further exacerbated in applications by compounding and by processing stresses.

Table 2.21 Phase equilibrium studies for polymer/solvent systems, including mixed solvents

Polymer	Solvent
PE	Diphenyl-ether, *n*-hexane, ethylene, nitrobenzene, amyl acetate, xylene, 1,2,4,5-tetrachlorobenzene (TCB), xylene/glycol, toluene, petroleum ether, bromonaphthalene
PP	Benzene, *o*-dichlorobenzene, isopropyl ether, *n*-heptane, tetralin/butyl carbitol, TCB
PDMS	Oligo-isobutylene, carbon tetrachloride/cyclohexane/methanol
PS	Cyclohexane, methyl-cyclohexane, acetone, *tert*-butyl acetate, ethyl acetate, ethyl oxalate, vinyl acetate, ethyl malonate, methyl acetate, methyl succinate, octene, polyvinyl acetal/chloroform, rubber/benzene, toluene/ethanol
PVC	Tetrahydrofuran/water, cyclohexanone/methanol, chlorobenzene, cyclohexane/acetone
PVP	Water/acetone
PVAc	Acetone, water, methyl-isobutyl ketone, dioxane/isopropanol
PVA1	Water, water/acetone, water/propanol
PMMA	Benzene, toluene, 3-heptanone, *n*-propanol, *p*-cymene, MEK/isopropanol, acetone/hexane, butanone/cyclohexane
PBMA	Benzene
PCHMA	Dioxane/methanol
PEG	Water, chloroform/hexane
PPG	Water, isopropanol/water, isooctane
PIB	Di-isobutyl ketone, benzene/acetone, tri-methyl pentene, 2-methylheptane, toluene/methanol
CR	Benzene, benzene/acetone, benzene/methanol
PIP	Acetone/ethanol
PAN	Dimethyl formamide, dimethyl sulfoxide/toluene
PC	Methylene chloride/methanol
PET	Phenol/cyclohexane, dimethyl formamide, trifluoroacetic acid/chloroform
PA-6	*m*-Cresol/cyclohexane, phenol, formic acid
NC	Acetone, butyl acetate, acetone/water, ethyl acetate/heptane
SBR	Benzene

2.6.3 Phase Diagrams

There is a large body of literature on phase diagrams for binary and ternary polymer solutions (Flory 1953; Tompa 1956; Cantow 1967; Utracki 1989) and extensive compilations of data (phase diagrams, cloud points, critical temperatures) for numerous systems (e.g., Wohlfarth 2004, 2008; Koningsveld et al. 2001). A few examples of such systems are listed in Table 2.21.

Phase diagrams of polymer blends, including binary polymer/polymer systems and ternary polymer/polymer/solvent systems, are scarcer (Koningsveld 2001). Furthermore, owing to the recognized difficulties in determination of the equilibrium properties, the diagrams are oftentimes either partial or approximate or built using low molecular weight polymers. Examples are listed in Table 2.22.

Table 2.22 Phase equilibrium studies for polymer/polymer blend systems. CST stands for critical solution temperature: L indicates lower CST, while U indicates upper CST (see Fig. 2.18)

2.7 Experimental Methods

The thermodynamic properties of a polymer blend determine its performance. Many authors have focused on miscibility – this aspect has been extensively discussed in the literature (Olabisi et al. 1979; Solc 1982; Utracki 1989; Coleman et al. 1991; Paul and Bucknall 2000; Koningsveld et al. 2001), and few selected results, with the emphasis of what is not covered in details in the following chapters, are briefly mentioned here. The characterization methods of the thermodynamic behavior of polymer blends can be divided into groups:

Thermodynamic studies not directly related to miscibility (e.g., PVT measurements)

Determination of the interaction parameter (χ_{12} quantified through SAXS, SANS, melting point depression, from the Hess cycle, etc.)

Direct methods of miscibility determination (turbidity measurements, microscopy, combinatorial approaches, etc.)

Studies of the phase equilibria (determined by scattering methods, viz., turbidity, PICS, SAXS, and SANS; fluorescence techniques; ultrasonic measurements; etc.).

Indirect methods of miscibility determination (e.g., from the glass transition temperature, viz., T_g from thermal, dielectric, or mechanical tests, NMR, spectroscopic methods, ODT through rheology, etc.)

2.7.1 PVT and Related Measurements

Equilibrium thermodynamics controls the PVT behavior of any system and its thermal expansion coefficient, compressibility, bulk modulus, hardness, etc. The thermodynamic pressure, which can be defined as a partial derivative of the Helmholtz free energy (see Eq. 2.5), for multicomponent systems, comprises of two interaction parameters, e.g., $\langle \varepsilon^* \rangle \langle v^* \rangle^k$; $k = 2,4$. These values can as easily be determined from dilatometric measurements as from the phase diagram (Jain et al. 1982). With the advance of other methods, dilatometry has been largely neglected: It is still being used to characterize the compressibility of neat resins, but rarely nowadays to study the behavior of polymeric blends (Plochocki 1982, 1983, 1986; Zoller 1989; Steller and Zuchowska 1990; Zoller and Walsh 1995).

The interaction parameters can be calculated from the PVT data of polymer blends (Jain et al. 1982; Privalko et al. 1985); however, due to the need for subtraction of two large numbers, the resulting values were often erratic, with errors up to ± 6 %. Such errors may be acceptable for some applications, but not for the construction of phase diagrams. A more straightforward experimental route is the computation of the reducing parameters, P^*, V^*, and T^*, by, e.g., two possible approaches:

1. Experimental values are compared with theoretical predictions, assuming an EoS and an averaging scheme, e.g., Eq. 2.43. This approach was used, for example, to interpret the thermodynamic behavior of PS/PVME blends, for T, 25–200 °C, and P, 0–200 MPa (Ougizawa et al. 1991), and for a series of polyolefins (EPR, a-PP, PP, PEP, PEB, i-PB, PIB, etc.) whose miscibility was studied using PVT and SANS measurements (Krishnamoorti et al. 1996). The results were interpreted using Hildebrand's solubility parameter formalism. For regular blends, a close agreement was found.
2. From P^*, V^*, and T^*, the molar attractive energy, ε_{12}, and repulsion volume, v_{12}, can be calculated and, subsequently, compared with theoretically derived averages, viz., the geometric mean for the former and the algebraic mean for radius for the latter (see Sect. 2.4.1). For miscible systems, the dependence of these values on composition can be easily derived. Usually, these compare reasonably well with the experimental data, since immiscibility causes large variations from the monotonic dependence.

Several interesting observations relate to such thermodynamic measurements. For example, the exothermic effects, associated with phase separation in LCST-type polymer blends, showed a correlation between the exothermic enthalpy and the interactions between the components (Natansohn 1985); however, the specific interaction parameter χ_{12} was not calculated. In another example, there are definitive correlations between the thermodynamic and the transport properties (see ▶ Chap. 7, "Rheology of Polymer Alloys and Blends"). Thermodynamic properties of multiphase polymeric systems affect the flow, and vice versa. As discussed in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends", the effects of stress can engender significant shift of the spinodal temperature, $\Delta T_s = 16$ °C. While at low stresses the effects can vary, i.e., the miscibility can either increase or decrease,

at higher stress values an enhancement of miscibility is expected. Flow has also been used to establish whether the molten blends are miscible or not (Schlund and Utracki 1987a, b, Utracki and Schlund 1987a, b).

Finally, thermodynamics also plays a dominant role in interfacial phenomena, viz., value of interfacial tension, thickness of the interphase, Δl, rheological properties, adhesion, compatibilization, etc. It is worth recalling that most lattice theories directly relate the magnitudes of γ_{12} and Δl to the value of the binary interaction parameter, χ_{12} (Helfand and Tagami 1971a, b, 1972; Helfand 1975a, b, c; Helfand and Sapse 1975; Roe 1975; Joanny and Leibler 1978; Broseta et al. 1990; Anastasiadis 2011). For example, the interfacial tension, as measured from pedant drop or scattering experiments, can be used to obtain binary interaction parameters, χ_{ij} (Anastasiadis 2011). In another example, the equilibrium interfacial thickness, Δl, in PMMA blends with PS and SAN was determined by ellipsometry (Higashida et al. 1995); from the Δl values, the authors computed the temperature dependence of the binary interaction parameter, $\chi_{ij}(T)$, and then the phase diagrams. However, since these topics are of prime importance for Chap. 4, they will not be discussed here.

2.7.2   Determination of Interaction Parameters

2.7.2.1 Binary Systems

All types of radiation scattering techniques, viz., light, X-ray, and neutron, have been used to measure the interaction parameters and study the phase equilibria in polymer blends and solutions. Using the relations derived for polymer solutions (see Eqs. 2.27, 2.28, 2.29, 2.30, 2.31, and 2.32), scattering methods can be used to measure molecular weight, M_w; end-to-end distance or radius of gyration, $\langle s_o^2 \rangle^{1/2}$; and the second virial coefficient, A_2, thus χ_{12}.

The relation between the characteristic dimension of the scattering phase, d_{av}; the wavelength of irradiation, λ; and the scattering angle, Θ, is given by (see Eq. 2.71)

$$d_{av} = \Lambda = \frac{\lambda}{2} \sin\left(\Theta/2\right) \tag{2.71a}$$

Depending on the experimental values of λ and Θ, the experimentally accessible values of d_{av} vary accordingly. Approximate ranges of the dimensions of scattering phases for the light, neutron, and X-ray techniques are given in Table 2.23.

The great majority of polymer blends have domain sizes in the range of 50 nm to 5 µm. Thus, LS and SAXS methods albeit more proliferated have limited use for studies of phase morphology, while SANS is much better suited. SANS has been used to study macromolecular size and conformation, morphology, in a single or multicomponent system, in molten or solid state. Since the contrast, phase discrimination, is based on the mass number, it is very useful to replace the hydrogen atoms in one polymer, or parts of a polymer, by deuterium. The deuterated polymer is mixed with its hydrogenated homologue at a selected low concentration, usually ∼0.1 %, providing a means to control contrast. The mixture can be then used as one of the

Table 2.23 Spatial ranges for the scattering phase dimensions accessible to various scattering methods

Method	Origin of contrast	Scattering domain size (μm)
Light scattering (LS)	Refractive index	1–100
Small-angle neutron scattering (SANS)	Mass number	0.01–3
Small-angle X-ray scattering (SAXS)	Electron density	1–100
Wide-angle X-ray scattering (WAXS)	Electron density	0.1–1

blend's components, or for the study of homopolymer properties. Several reviews of the SANS application for the characterization of polymer conformation and morphology have been published (Sperling 1984; Rennie 1992; Balsara et al. 1992; Lohse 1994; Krishnamoorti et al. 1995; Takeno et al. 1996; Hammouda 2010).

It should be noted that deuteration will change the conformation of macromolecules and also their miscibility/solubility, especially for high M_w (Utracki 1989). Theory predicts phase separation (with UCST) for a blend of hydrogenated with deuterated polymer (Buckingham and Hentschel 1980; Edwards 1983; Honeycutt 1992a, b); see also Fig. 2.7, a behavior that has been experimentally observed in multiple systems (Eitouni 2007): Phase separation of poly-1,4-butadiene with its deuterated analog confirmed the prediction (Bates et al. 1985, 1986; Bates and Wignall 1986; Bates and Wilzinius 1989; Schelten et al. 1977; Yang et al. 1983; Atkin et al. 1984). Similarly, blends of hydrogenated with deuterated PDMS show immiscibility (Lapp et al. 1985). Apparently, there are three principle origins for these isotopic effects: (i) position of the isotope, (ii) conditions for SANS measurements, and (iii) difference in segmental volume upon deuteration. In conclusion, SANS is an excellent method for determination of molecular size and intermolecular interaction in polymer blends, provided that the isotopic effects are either absent or appropriately corrected for. The method is precise in quantifying the dependencies on molecular weight, molecular structure, macromolecular architecture, chemical substituents and additives, as well as on independent variables, P, T, deformation, etc. In Table 2.24, a few examples of blend studies are summarized. The interested reader is referred to consult specialized publications (Utracki 1989; Balsara et al. 1992; Lohse 1994; Krishnamoorti et al. 1995; Eitouni 2007; Hammouda 2010) or books.

SANS has been used extensively to determine χ_{12} of polymer blends, by fitting SANS profiles measured from blends to RPA. This approach was pioneered by Hadziioannou and Stein (1983, 1984), Murray and Stein (1985), and Herkt-Maetzky and Schelten (1983). In particular, the phase diagram in PVME/d-PS was among the first blends studied and has been extensively studied since then (Hadziioannou et al. 1983, 1984; Schwahn et al. 1987; Hammouda et al. 1995; Takeno et al. 1996; Choi et al. 1998, 2000; etc.), partly due to its well-documented LCST and the small difference in LCST ($\Delta T_{cr}^{LCST} \approx 40\,^\circ$C) upon deuteration. In the vicinity of the critical point, a non-mean-field behavior was observed. The SANS results can be summarized as follows (Utracki 1989):

- The M_w determined by the solution methods agreed with values obtained by SANS; the average ratio $M_w^{(sol)}$ to $M_w^{(SANS)}$ was found to be 1.02;

Table 2.24 Example SANS studies of polymer blends (*d* before an acronym indicates a deuterated polymer). See also Table 2.8 for selected $\chi_{12}(T)$ based on SANS data

- Increasing the blends' temperature causes the second virial coefficient, A_2, to decrease, thus, leading to an LCST as a rule for the studied systems.
- The radius of gyration, $\langle s_o^2 \rangle^{1/2}$, of the deuterated polymer decreased with M_w, in the matrix of the same chemical character. In most cases, the coil size of the probe molecules was found to be slightly increasing with A_2.
- Given the small positive values of A_2, blends of PMMA/SAN, PVC/PMMA, PPE/PS, and PVME/PS are miscible. However, in each system, the value of A_2

decreased with M_w, indicating worsening miscibility. In these systems $\langle s_o^2 \rangle^{1/2} \propto M_W^n$, with the exponent n depended on the system and temperature. Specifically, for PS/PVME, $n = 0.57$ (25 °C) or 0.52 (120 °C); for PPE/PS, $n = 0.55$; whereas, for PS in PS and for PMMA in PMMA, $n = 0.5$; and for PMMA in PSAN-19, $n = 0.60$, and for PSAN-19 in PMMA, $n = 0.64$.

SAXS and SANS were used to study PMMA with PVDF blends (Wendorff 1980, 1982; Hadziioannou and Stein 1984). The binary interaction parameter χ_{12} was plotted versus PVDF content, and the isothermal data (at $T = 200$ °C) could be expressed by a linear dependence (Wendorff 1980, 1982): $-1/(\chi_{12} + 0.0035) = -0.72 + 0.76\phi_{PVDF}$. Several authors reported data of $\langle s_o^2 \rangle^{1/2}$ and A_2 for polymer blends (Hadziioannou et al. 1983; Ree 1987; Maconnachie et al. 1984). The binary interaction parameter χ_{12} can be extracted from the second virial parameter A_2. As discussed in Sect. 2.5.1, $\langle s_o^2 \rangle^{1/2}$ and A_2 are measured using scattering methods, including light scattering (LS). One innovative way of using LS involves polymer/polymer/solvent ternary systems: This approach requires either that one of the polymers is iso-refractive with the solvent or that the polymers have equal contrast (Pinder 1997). The method was successfully used to measure χ_{12} for PS/PMMA blends of different M_w. Similarly, A_2 can be determined from osmotic pressure measurements of polymer/polymer/solvent ternary systems, yielding $\chi_{12}(\phi)$ for PVCVAc with acrylic copolymers in cyclohexanone (Sato et al. 1997).

SAXS has been mainly used to study morphology of the semicrystalline blends, cf. how it is affected by composition, crystallization rate, compatibilization, additives, etc. However, it can also be used to study local structures in molten polymer blends, for example, within the interphasial region. The method has been used for liquid, glassy, and crystalline systems to determine the spinodal and binodal temperatures as well as to measure χ_{12}. A reasonable agreement between the values measured by different methods was obtained (Harris et al. 1983; Riedl and Prud'homme 1984; Barlow and Paul 1987).

The depression of the melting point, T_m, has also been used to determine χ_{12}. Development of the method is credited to Nishi and Wang (1975, 1977). T_m depends on two factors: (1) the unit cell geometry, as well as the type and dimensions of the crystals/crystallites, and (2) the interactions between the crystalline polymer and other ingredients. To determine χ_{12} from T_m, it is important that there are no chemical reactions and all specimens (e.g., representing different compositions) are identically treated (identical thermal history), as well as that the mutual solubility of low molecular weight fractions is either small or independent of the blend composition.

However, it is important to ascertain that incorporation of other ingredients changes crystallinity only through thermodynamic interactions, while other effects on crystallinity are negligibly small. Blending can affect crystallinity in diverse ways, due to the effects of added components on nucleation and growth rates. Thus, blending method and parameters, especially rates, can have serious effects on crystallizability and crystal size. Experimentally, the presence of a miscible amorphous polymer in the blend usually slows down, or even prevents, crystallization of the semicrystalline polymer. For fewer systems, enhancement of crystallinity and increase in T_m upon blending have also been reported (Harris and Robeson 1987;

Table 2.25 Examples of determination of χ_{12} from melting point depression studies

Blend	Comment	References
PCL/PVDC-x	PCL blends with PVDC, PVDC-VC, PVDC-VAc, or PVDC-AN: $\chi_{12}(\phi_{PCL})$ showed a maximum at ca. 30 wt% and small T dependence	1
PVDF/acrylates	PVDF blends with PMMA, PEMA, PMHA copolymers: B_{12} was negative for all PVDC/acrylate blends	2
PVDF/PMMA	PVDF blends with PMMA and review of procedures used to determine χ_{12}	3
PVDF/PMA PVF-VDF/PMA	T dependence of $\chi_{12}(\phi)$ was determined; miscibility turns into immiscibility with increased PVF content	4
PVDF/PBA	PVDF blends with poly(1,4-butylene adipate) were miscible over full range of compositions: $\chi_{12} = -0.19$	5
PA/M-sPS	PA blends with Mn- or Zn-sulfonated PS were miscible (with $\chi_{12} < 0$); results confirmed by FTIR and SAXS	6
PBT/PAr	PAr depressed PBT's T_m by 17 °C; calculated χ_{12} varied from -0.65 (20 wt% PAr) to -0.22 (80 wt% of PAr)	7
PBT/ester-ethers	PBT blends with segmented/block poly(ester-co-ether): miscibility depended on the copolymer composition	8
PA/MXD	PA-g blends with poly(m-xylene adipamide): $\chi_{12} < 0$ indicated miscibility in amorphous phase; miscibility increased with transamidation during aging.	9
PP/SEBS/oil PP/EPR/oil	Miscibility was concluded for PP/SEBS/oil, $\chi_{12} = -0.043$, and immiscibility for PP/EPR/oil	10
PCL/P4HS	PCL blends with poly(4-hydroxy styrene): $\chi_{12}/V = -0.013$ and single T_g indicated miscibility	11
CR/PEMA	Miscibility concluded from the negative χ_{12}: -0.030 to -0.122, and from FTIR	12
PET/PETG	Miscibility concluded from the negative $\chi_{12} = -0.122$ (280 °C)	13

References: **1.** Zhang and Prud'homme 1987; **2.** Goh and Siow 1988; **3.** Runt and Gallagher 1991; **4.** Maiti and Nandi 1996; **5.** Pennings and Manley 1996; **6.** Lu and Weiss 1991, 1992; **7.** Huo and Cebe 1993; **8.** Gallagher et al. 1993; **9.** Shibayama et al. 1995; **10.** Ohlsson and Tørnell 1996; **11.** Lezcano et al. 1996; **12.** Kundu et al. 1996; **13.** Papadopoulou and Kalfoglu 1997

Dumoulin et al. 1987). As a result, despite its simplicity, obtained values of χ_{12} from the T_m method should be confirmed by other techniques (Utracki 1989; Groeninckx et al. 1998). Enthalpic interaction parameters determined for low molecular analogs via direct calorimetric measurements of the enthalpy of melting, ΔH_m, provide data which correlate well with χ_{12} determined by other methods (Barlow and Paul 1987; Rana et al. 1996; Ziaee and Paul 1996, 1997). The most crucial aspect here is the selection of suitable analogs. In this task, consideration of the partial charges of the atoms in each molecule can be used as guide (Ziaee and Paul 1996, 1997); as discussed in the heat of mixing Sect. 2.6.2.2, there are several disadvantages in such an approach, for example, inability to account for structural and/or polydispersity effects. Another method that can address some of these concerns is the microcalorimetric determination of ΔH_m using low viscosity oligomeric mixtures (Singh and Walsh 1986; Sham and Walsh 1987) (Table 2.25).

2.7.2.2 Ternary Systems Containing Solvent

The difficulties in the calorimetric determination of the interaction parameters are caused by the high viscosity of most commercially relevant or academically interesting polymers and the accompanying slow diffusion rates, heat generation during mixing or processing, etc. These problems do not exist for solutions.

One way to overcome such problems is to consider solvent(1)/polymer(2)/ polymer(3) ternary systems; any method that determines either ΔG_m or its derivatives should make it possible to calculate χ_{23}. Thus, for example, osmotic pressure measurements were used to characterize PS/PVME blends dissolved in either toluene or ethylbenzene (Shiomi et al. 1985). The χ_{23} was found to depend on the blends' composition. Elimination of the solvent effects gave $\chi_{23}/V_1 = -10^4$ $(7.41-11.01\phi_3)$. Thus, the system was expected to remain miscible up to a PVME volume fraction of $\phi_3 = 0.67$. Osmotic pressure has also been used to determine $\chi_{23} = 0.070$ for PS with poly(p-chloro styrene) in toluene, 2-butanone, and cumene (Ogawa et al. 1986). For the same system, $\chi_{23} = 0.087$ was calculated from intrinsic viscosity measurements. Thus, the system is thermodynamically immiscible. More recently, osmotic pressure measurements in cyclohexanone of a ternary system resulted in $\chi_{23}(\phi)$ for poly(vinylchloride-co-vinylacetate) blends with a series of acrylic copolymers (Sato et al. 1997).

Vapor sorption of PS/poly(α-methylstyrene) gave $\chi_{23} = 0.504$, varying with T and polymer concentration, indicating that this system is immiscible with UCST > 100 °C (Saeki et al. 1981). Light-scattering measurements of ternary systems, polymer(1)/polymer(2)/solvent(3), were also successfully used to determine polymer/polymer interaction parameters, $\chi_{12}(\phi)$. The method is particularly easy to use either if one of the two polymers is iso-refractive with the solvent or if the polymers have equal contrast (Pinder 1997). The method was successfully used to measure χ_{12} for PS/PMMA blends of different M_w.

Over the years, several authors tried to correlate polymer/polymer miscibility with solution viscosity in a common solvent (e.g., Bohdanecky and Kovar 1982). An interesting report in this field was (Chee 1990) considered that the parameter $b = k_H[\eta]^2$ (k_H is the Huggins constant of Eq. 2.33, and $[\eta]$ is the intrinsic viscosity) can be set as a measure of the interactions between the solvent and the polymeric species. For polymer blends, the author wrote

$$\left. \begin{array}{l} [\eta]_{blend} = w_2[\eta]_2 + w_3[\eta]_3 \\ b_{blend} = w_2^2 b_{22} + w_3^2 b_{33} + 2w_2 w_3 b_{23} \end{array} \right\} \Rightarrow \mu \equiv \frac{[b_{23} - (b_{22} + b_{33})/2]}{\left([\eta]_3 - [\eta]_2\right)^2} \quad (2.75)$$

where the parameter μ as defined in Eq. 2.75 is a measure of the polymer/polymer miscibility (viz., negative μ values indicate immiscibility, and positive μ miscibility). Three series of blends were examined: (1) PVC/PMMA, (2) PiBMA/PMMA, and (3) PiBMA/PVC. In agreement with the calculated values of the parameter μ, the first of these three blends was found miscible, whereas the two other immiscible in the full range of composition. However, the method is, at best, qualitative. For example, the effect of the common solvent on the parameter μ was not investigated,

but fundamentals of intermolecular interactions make it dubious that nonpolar solvents will lead to the same value of the parameter μ as strongly polar ones. The author observed that the method breaks down for polymer pairs that can form associations. Intrinsic viscosity measurements were also used to evaluate intermolecular interactions in blends of cellulose diacetate with poly(vinyl pyrrolidone) (Jinghua et al. 1997).

Another method is based on the principle that the change in any thermodynamic state function depends only on the initial and final states (Hess cycle). For example, in path I, two polymers are dissolved separately in the same solvent and then mixed together; in path II, polymers are first blended together and then dissolved in the same solvent. From the balance of the dissolution enthalpies, the heat of mixing of two polymers, ΔH_m, can be calculated at the corresponding temperature. However, since ΔH_m, in the above example, is a small number determined by subtracting two large values from each other, the error of these estimation can be large. Furthermore, χ_{23} determined from ΔH_m above is from dilute systems, and its extrapolation to melt may be impractical (Koningsveld et al. 1974). ΔH_m measurements have been used to characterize PPE blends with either PS, halogenated PS, or copolymers (Zacharius et al. 1983). At 34.8 °C, the heat of mixing of PS/PPE blend was small and negative, indicating weak specific interactions. By contrast, in blends of PS with poly(2-chloro styrene), ΔH_m was small and positive, dependent on molecular weight and temperature. In agreement with the observations, for PS/poly (2-chloro styrene-*co*-4-chloro styrene), $\Delta H_m = 0.31$ J/g was found in the full range of copolymer compositions, confirming immiscibility.

Size exclusion chromatography, SEC, has also been used for the determination of polymer/polymer interaction coefficients in solvent/polymer/polymer three-component systems (Narasimhan et al. 1979, 1983, 1984). The method was found precise and thermodynamically significant. Strong solvent concentration dependence of $\chi_{23} > 0$ was reported from tests of toluene/PMMA/PS system (Lau et al. 1984, 1985).

In conclusion, it is important to note that the determination of χ_{23} is of dubious value for predicting polymer/polymer miscibility, especially for processing conditions. The chi parameter is a complex function of many variables, including T and P that can become extreme during processing. The solution methods require high polymer dilution and low temperatures, significantly lower than those used for compounding or forming of polymer blends. Methods capable to accurately extrapolate solution data to the processing conditions do not exist. The above comments are pertinent to any of the ternary solvent methods of χ_{23} determination.

2.7.3 Phase Diagrams

2.7.3.1 Turbidity Measurements

The method consists of preparation of a series of mixtures of varied concentrations (near the phase separation condition) then causing the separation to occur, e.g., by ramping the temperature. The onset of turbidity is observed visually, using

a photoelectric cell, or by a UV-visible spectrophotometer. The ensemble of the cloud points defines the cloud-point curves (CPC) that closely follow the system's binodal. The method can be extended to rigorous studies of phase separation by measuring the light-scattering intensity.

For polymer blends, the CPC is usually determined by preparing films under conditions of miscibility, in a wide range of compositions. The films are then heated through the cloud point at a rate not exceeding 0.1 °C/min. Depending on the rate, type of system, and polydispersity, the hysteresis (difference between CPC on heating and cooling) can be significant. Examples of blends whose phase diagrams were determined are listed in Table 2.26.

The scattered intensity of light due to concentration fluctuations, extrapolated to zero-scattering angle, is inversely proportional to the second derivative of ΔG_m. Thus, it can be used to determine the location of a spinodal, i.e., the spinodal temperature, T_s, for the given mixture. As Eq. 2.32 indicates, LS makes it possible to determine also the second virial coefficient (A_2) and from it the binary interaction parameter (χ or B). However, this technique is applicable only to homogenous systems, i.e., at temperatures $T \leq T_s$ for LCST systems or at $T \geq T_s$ for those having UCST. As mentioned in Sect. 2.8.2.2, the LS methods has been used primarily to study the phase equilibria of polymer solutions.

Pulse-induced critical scattering, PICS, is an elegant method of LS measurements that makes it possible to extend the measurements closer to the spinodal. It uses a small mass of a homogenous liquid mixture very rapidly heated or cooled into the metastable region. The laser light-scattering intensity is measured after thermal equilibrium is reached, but before the system can phase separate, the mixture is brought out into the homogenous region and the cycle repeated (Gordon et al. 1973). The temperature change can be accomplished in milliseconds, afforded by the small specimen size, and the time of one full cycle is less than a minute.

One of the most serious obstacles in the phase equilibrium studies of polymer blends is the viscosity of the system. At the accessible temperatures, between softening point and thermal degradation, the self-diffusion coefficient of macromolecules is of the order of 10^{-4} to $10^{-6} \text{m}^2/\text{s}$ (Kausch and Tirrell 1989). As a result, phase separation is very slow. To accelerate the process, a low-speed centrifuge, the "centrifugal homogenizer" (CH), with PICS has been used (Koningsveld et al. 1982). In short, centrifugation within the immiscibility zone permits determination of binodal and critical points, while use of the PICS mode allows location of the spinodal.

2.7.3.2 Scattering Methods

Turbidity, light scattering, and PICS methods, discussed in the preceding paragraphs, are based on the scattering of light by liquid systems with optical heterogeneities. These principles have been extended to other types of radiation, e.g., X-rays and neutrons, cf. SAXS and SANS, which have been used to study polymer blend structures. In contrast to light scattering, SAXS uses the regularity of crystalline, or pseudocrystalline arrays of atoms, whereas SANS that of different mass of atoms. The data are treated via a relation derived for the conventional light-scattering equation (Eq. 2.32):

Table 2.26 Examples of polymer blends with known phase diagram(s)

Blend	Comment	References
PS/PVME	LCST. A rare case of miscible homopolymers. M_w only slightly affects the critical concentration (about 10 wt% of PS), but strongly changes the critical temperature 102–145 °C	Nishi and Kwei 1975

$$\frac{K\ c_2}{R(q)} = \frac{A_1}{M_{w,2}\ P(q)} + 2A_2\ c^2 + \dots \tag{2.76}$$

where $q \equiv (4\pi/\lambda)\sin\theta$ is the scattering vector (cf. Eq. 2.71); c_2 is the polymer concentration, $M_{W,2}$ the polymer molecular weight, and A_2 the polymer second virial coefficient (the subscript 2 indicates that the polymer is present in lower concentration); $R(q) \equiv I(q)\omega^2/I_o V_{sc}$ is the ratio of scattered to incident intensities (Rayleigh ratio); $P(q)$ is Debye's one-particle scattering form function, same with the one used in light scattering; λ is the neutron wavelength; and θ is the scattering

half-angle. The constant K contains the scattering lengths of hydrogen (^{1}H) and deuterium (^{2}H) as the most important quantities, whereas the average scattering radius of the polymer, cf. R_g^{sc} or $(R_g^{2\ sc}/M_W)^{1/2}$, is calculated from $P(q)$.

The phase equilibria in systems containing di-block poly(styrene-*b*-butadiene), SB, mixed with either a homopolymer or a random copolymer were established by plotting the reciprocal of the intensity of the main SAXS peak as a function of 1/T; thus, the spinodal, T_s, and binodal, T_B, temperatures were measured (Zin and Roe 1984). SAXS has been typically used to study the morphology of polymer blends in the solid state (Khambatta 1976; Russel, 1979; Russel and Stein, 1982, 1983). For example, in the interlamellar regions of PCL/PVC blend, the system is miscible on a molecular scale. Addition of PVC impeded crystallization of PCL. At high PVC concentration, PCL remained in solution. The radius of gyration was larger than that under unperturbed conditions, in spite of the fact that the second virial coefficient, A_2, was virtually zero. SAXS was also used to study the morphology of LDPE/HDPE blends (Reckinger et al. 1984, 1985). It was found that during the crystallization, macromolecules segregate. This segregation was also observed during rapid quenching at about 100 °C/min; at the high rates associated with the process, the segregation distance was comparable to coil dimension in the melt.

2.7.3.3 Fluorescence Techniques

"Excitation fluorescence" is the principle of the fluorescence techniques used for studying polymer blends. The method comprises of three steps: incorporation of an excimer, its excitation, and recording the excitation delay. The excimer can be an aromatic polymer component of the blend (viz., PS, poly(vinyl-dibenzyl), polyvinylnaphthalene, an aromatic group grafted onto the macromolecular chain, etc.), or it can be added as "probe" molecule (e.g., anthracene). There are three possibilities for the aromatic rings to form excimers: intramolecular adjacent, intramolecular nonadjacent, and intermolecular types. Each of these types is sensitive to different aspects of the chain conformation and environment, thus, sensitive to blend miscibility effects. The most important of these for studies of polymer blends is the intermolecular, usually identified from concentration measurements (Winnik et al. 1988).

In a second method, the "non-radiative energy transfer" method (NRET), the energy is transferred from a donor to a receptor chromophore, when the distance between them is of the order of 2–5 nm. Phase separation is concluded from a decrease of the chromophore energy transfer. The method has been used to study PVC miscibility with PMMA or with SAN; PS or poly-α-methylstyrene (PαMS) with PS-αMS copolymer; PS or PαMS or PBS [poly(tert-butyl styrene)] or PS + PBS with PS-BS copolymer; etc. (Morawetz 1980, 1981, 1983; Albert et al. 1986).

2.7.3.4 Ultrasonic Velocity

For homogenous systems, the ultrasonic velocity is related to the ratio of modulus to density. Thus, one may expect that any method that determines density changes with adequate precision can provide a measurement or an indication of

miscibility (Singh and Singh 1983). The ultrasonics can also be used as a fast screening method for the optimization of processing and its parameters, e.g., employed as online characterization of polymers blends (Piau and Verdier 1993; Verdier and Piau 1995; Gendron et al. 1995).

The compressive ultrasonic velocity (6 MHz, at room temperature) was used to study cast blend films of PMMA/PVAc, PMMA/PS, PVC/CR, and PS/EPDM (Singh and Singh 1983; Shaw and Singh 1987). A linear correlation between the sound velocity and the composition was observed for miscible blends, whereas immiscibility, viz., in PMMA/PS blends, the same dependence was irregular. Phase separation in PVC/CR was detected at $w = 70$ wt% of CR, indicated by a sudden departure from linear correlation. The ultrasonic absorption versus composition gave even stronger evidence of immiscibility. Ultrasonics have been also successfully used to study the phase behavior in polyurethanes (Volkova 1981).

Acoustic emission has been frequently used in studies of the fracture behavior of fiber-reinforced composites. This method was also adopted to studies of blends. Since the sound is most frequently generated by debonding of two phases, there should be a drastic difference in the acoustic activity for blends located on the two sides of spinodal. To quantify miscibility between PVC and EVAc, acoustic emission measurements during a peel test of a-PVC/EVAc/PVC sandwich were carried out (Muniz et al. 1992). The authors considered that the acoustic emissions at slow rates of peeling are related not to the viscoelastic dissipation processes, but rather to the work necessary to pull apart polymeric chains or break bonds. The highest acoustic emission was obtained for VAc content in EVAc of 18 and 29 wt%.

2.7.4 Indirect Methods for Polymer/Polymer Miscibility

These methods do not provide data for the binodal, spinodal, or the numerical value of the interaction parameter, but general information about the polymer/polymer miscibility. However, the information can frequently be used, e.g., to construct a map of miscibility – a simplified phase diagram.

2.7.4.1 Glass Transition Temperature (T_g) Measurements

When polymer is cooled, from either the liquid or rubbery state, its molecular motion slows down, and eventually it undergoes a glass transition, or vitrification, preceeded by crystallization for semicrystalline polymers. The glass formation is a nonequilibrium phenomenon and is kinetic in nature, i.e., not a genuine first-order thermodynamic transition; thus, its characteristic temperature, T_g, is detected at different temperature values depending on the cooling rate, the probing method, the thermal history, etc. Nevertheless, most theoretical treatments consider the glass to be at a pseudo-equilibrium state, endowing T_g with characteristics of a critical temperature of a second-order thermodynamic transition. The thermodynamics of such a state demands knowledge of "order parameters," z_i:

$$dG = \left(\frac{\partial G}{\partial T}\right)_{P,z_i} dT + \left(\frac{\partial G}{\partial P}\right)_{T,z_i} dP + \sum_{i=1}^{n} \left(\frac{\partial G}{\partial z_i}\right)_{P,T,z_j} dz_i \qquad (2.77)$$

At equilibrium, the affinity coefficients, $A_i \equiv (\partial G/\partial z_i)_{P,T,z_j} \rightarrow 0$, and the equilibrium equation, Eq. 2.11, regain validity.

When liquids are viewed as collections of inherently non-crystallizable macromolecules, they are expected to show equilibrium amorphous properties in all T ranges. Furthermore, in the thermodynamic description of the glassy state, it was postulated that cooling a liquid causes its configurational entropy to decrease, becoming zero at T_g (DiMarzio and Gibbs 1958; Dong and Fried 1997). This concept gives legitimacy to the pseudo- or semi-equilibrium theories of the glassy state, viz., Couchman's theories (Couchman 1978, 1979a, b). It is widely accepted that when the test methods are slow enough (usually less than 1 °C/min and/or 1 Hz) the glass behaves in a semi-equilibrium manner and its behavior can be generalized.

In a first approximation, the polymer's glass transition is related to the cooperative segmental motion involving 50–100 backbone chain carbon atoms, or 15–30 statistical segments, i.e., a domain of a size $d_d = 2$–3 nm (Boyer 1966; Warfield and Hartmann 1980). However, the glass transition is not a phenomenon occurring at constant free volume. Along these lines, the most common use of T_g in determination of polymer/polymer miscibility is based on the premise that a single T_g indicates that a uniform blend domain size comparable to the macromolecular cooperative length or to the macromolecular radius of gyration, i.e., $2 \leq d_d \leq 15$ nm. This approach has already been discussed in Sect. 2.5.2. It is important to recognize that a single T_g is not a measure of miscibility, but rather an indication of the state of dispersion. There are several equations relating T_g to composition (Utracki 1989). One approach (Couchman 1978) proposed the following relation for the T_g of miscible systems:

$$\ln T_g = \frac{\sum_i w_i \Delta C_{Pi} \ln T_{gi}}{\sum_i w_i \Delta C_{Pi}} \qquad \left(\text{with } \Delta C_{Pi} \equiv C_P^{\text{liquid}} - C_P^{\text{glass}} \text{ for polymer } i\right) \quad (2.78)$$

where w_i and T_{gi} are, respectively, the weight fraction and glass transition temperature of polymer i in the blend and ΔC_{Pi} is a difference of the isobaric heat capacity, C_P, in the liquid and glass states of polymer i, assumed to be independent of T. From this relationship, several empirical and semiempirical formulas were derived, including the Gordon-Taylor equation, as well as the Fox equation. Note that these relations are valid only for miscible systems. The latter one

$$\frac{1}{T_g} = \sum_i \frac{w_i}{T_{gi}} \qquad \left(\text{or}: \quad \sum_i w_i \left(1 - \frac{T_g}{T_{gi}}\right) = 0\right) \qquad (2.79)$$

is particularly simple and ubiquitously used, even applied to calculate blends' composition from measured values of T_g (this use should be limited to situations where

the T_g versus composition was "calibrated" and confirmed to follow Eq. 2.79). Comparing Eqs. 2.78 and 2.79, it is obvious that the Fox equation ignores the contributions of ΔC_{Pi}. To account for this omission, a different relation can be derived, also for miscible blends, for example, in a two-component system (Lu and Weiss 1991, 1992):

$$T_g = \frac{w_1 T_{g1} + k\ w_2 T_{g2}}{w_1 + k\ w_2} - \frac{\chi_{12}\ R\big(T_{g2} - T_{g1}\big)b\ w_1 w_2}{\Delta C_{P1}(w_1 + k\ w_2)(w_1 + b\ w_2)^2} \qquad (2.80)$$

where k and b are ratios of, respectively, ΔC_P's and densities of polymers 1 and 2 and χ_{12} is the binary interaction parameter. Thus, the relation makes it possible to compute the interaction parameter of miscible blends from T_g versus composition dependencies.

In a different approach, starting from Eq. 2.78, the following dependence was derived for binary blends (Utracki and Jukes 1984):

$$w_1 \ln\big(T_g/T_{g1}\big) + k\ w_2 \ln\big(T_g/T_{g2}\big) = 0 \qquad (2.81)$$

For a miscible blend, the parameter k is equal to $k = \Delta C_{P1}/\Delta C_{P2}$ (relaxing this condition, transforms Eq. 2.81 into a semiempirical one, valid for either miscible or immiscible systems). The dependence should be symmetrical, i.e., it must be valid when the indices are exchanged. Thus, miscibility requires that $k = 1/k = 1$. The larger the difference between k and $1/k$, the larger is the immiscibility of the system. The dependence should not be used for strongly associating polymer blends where blend T_g may reach values higher than those observed for either pure component. Such miscible, hydrogen-bonded, or donor-acceptor pairs are well described by a single parameter relation (Utracki 1989):

$$T_g = (1 + K^*\ w_1 w_2)\Big[w_1 T_{g1}^{3/2} + w_2 T_{g2}^{3/2}\Big]^{2/3} \qquad (2.82)$$

where K^* is a material parameter, with a value that increases with stronger polymer/polymer association.

Several methods of T_g determination make it possible to measure the width of the glass transition temperature (TW). The value of TW can be more reliable in assessing the degree of miscibility than T_g. For example, TW of 6 °C was determined for neat polymers, TW = 10 °C for miscible blends, and TW = 32 °C for blends approaching immiscibility (Fried et al. 1978). By measuring T_g and TW for samples annealed at different temperatures and then quenched, one may be able to determine the level of miscibility and hence construct a simplified phase diagram. This has been done for numerous blends, like those listed in Table 2.26, and others, e.g., for PS/PTMPC, PVC/poly(α-methylstyrene-co-methylmethacrylate-co-acrylonitrile), and NBR/EVAc (Casper and Morbitzer 1977) (vide infra, Table 2.27).

To construct the phase diagram, thin blend specimens should be prepared. The preferred method is to cast film from a common solvent. However, it has been

Table 2.27 A few examples of T_g measurements of polymer blends

Blend	Comment	References
PVDC/aliphatic polyesters	THF cast films; T_g measured by DSC on samples annealed at 460 K	1
Oligo(styrene-*co*-allyl alcohol)/ aliphatic polyesters	Specimens mechanically mixed at $T = T_g +$ 70 °C; DSC at 20 °C/min; UCST directly observed	2
PS/poly(styrene-*co*-4-bromostyrene)	Films cast from $CHCl_3$ of CH_2Cl_2; DSC (10 mg) at 20 °C/min. UCST reported	3
Poly(aryl ether ketone) blends	T_g linear dependence on mole fraction of ketone groups	4
PMMA/SAN/SMA PEM/SAN/SMA MAN/SAN/SMA	Samples were either cast from MEK or melt blended; DSC at 20 °C/min; T_g from the onset during the second heating cycle	5
1,2-PB/1,4-PI	Polymers co-dissolved in benzene, then freeze-dried; DSC at 10 °C/min' T_g and TW measured in duplicate or triplicate	6
SAN/SMMA/MAN	Ternary blends prepared in THF, precipitated by MeOH, then dried; DSC at 20 °C/min over $T = 310–430$ K	7
PC/TMPC/SAN/SMMA	Samples cast from THF; DSC at 20 °C/min; T_g taken at onset. Phase diagrams constructed	8
SMMA/poly(butyl-*co*-hexafluoro-carbonate)	Samples dissolved in CH_2Cl_2, precipitated by MeOH, and dried. T_g taken at onset during the second heating	9
Poly(α-MSAN)/SAN, TMPC, PVC, PPE or PMMA; PMMA-GMA/SAN or TMPC	Samples either cast from THF, or hot cast from DMF or acetonitrile, dried at 150 °C for 2 days; DSC at 20 °C/min. Diverse phase diagrams	10
PC/poly(ET-*co*-caprolactone)	Samples cast from $CHCl_3$; DSC at 20 °C/min $T \leq 530$ K. T_g taken at half-height	11
PMMA-GMA/PVDF	Samples cast from DMF; DSC at 20 °C/min to 190 °C; miscibility only for PMMA-GMA with GMA <35.7 wt%	12
PS/PC or oligo(cyclic-carbonate)	Samples hot cast from *o*-dichlorobenzene; DSC at 20 °C; samples annealed at 200 °C for 5 min	13
PS/PCHMA	Dissolved in THF, precipitated by MeOH; DSC at 10 °C/min; T_g taken at midpoint of inflection	14
PBT/Poly(ester carbonate)	DSC at 20 °C/min; T_g from second scan. Solution cast samples gave two T_g's; precipitated from solution or melt mixed (at 250 °C) systems had only one T_g	15
PEI/PAr	Melt mixed at 300 °C; DSC at 20 °C/min. T_g taken at onset	16
CR/PEMA	Melt mixed at 100 °C; DSC at 20 °C/min	17

observed that the blend thermograms depend on the type of solvent used for casting the film. For example, PVC/PHMT blends cast from toluene had a single T_g, whereas when cast from 1,4-dioxane it exhibited two T_g's, a fact that it is not completely unexpected, since small differences in the polymer/solvent χ results in quite substantial enthalpic contributions in the free energy of mixing, in the order of χN, N being the size (degree of polymerization) of the polymer, which would cause in a better dissolution of one of the two polymers in any given solvent and, in turn, would result in differences in the miscibility of the cast blend. Clearly, caution is advised: Preferably the procedure should be carried out using specimens prepared by different methods; specimens should be annealed at temperatures located on both sides of the expected spinodal and then quenched. The most popular method for detecting T_g is the differential scanning calorimetry (DSC), owing to the simplicity of the experiments and the small specimen sizes required (a few mg). Using substantially more complex experiments and analysis, more information can be obtained from a dynamic test: either dielectric relaxation spectroscopy, or dynamic mechanical analysis (shear, bending or tensile, preferably at low and

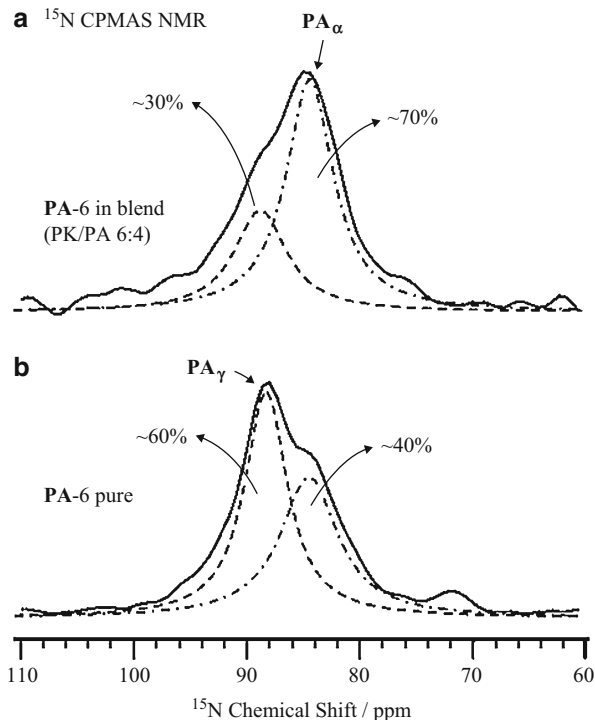
constant test frequency). T_g can also be determined by dilatometry. The method extends testing of the blend miscibility to higher pressures, as those expected during processing (Jain et al. 1982; Walsh and Zoller 1987; Zoller and Walsh 1995). The pressure effects are not negligible, for example, for PPE/PS system, the pressure gradient of T_g (dT_g/dP) was reported to range from 4.3 to 8.2 °C/GPa, depending on the composition (Zoller and Hoehn 1982).

One shortcoming of the method can be demonstrated by the fact that, even for immiscible blends, rarely two T_g's can be detected for compositions containing less than 20 wt% of the dispersed phase. Beyond any instrumental detection limits, the experimental range of resolution depends also on the difference between the T_g's of the two polymers ($\Delta T_g = T_{g1} - T_{g2}$). Since the width of the glass transition can be as large as TW = 40 °C, this method of assessment of miscibility should not be used for systems with $\Delta T_g \leq TW/2 \approx 20$ °C. Table 2.27 provides some examples studies of blend miscibility by means of T_g measurements; older data can be found in Utracki (1989).

2.7.4.2 Spectroscopic Methods: NMR

For the studies of interactions in polymer blends, nuclear magnetic resonance (NMR) and Fourier transform infrared spectroscopy (FTIR) are of principal significance. The NMR methods for the studies of polymer blends are well described in textbooks as well as in several reviews (Olabisi et al. 1979; Robeson 1980; Martuscelli et al. 1983; Kaplan 1984; McBrierty and Packer 1993; Cheng et al. 2011). The NMR parameters used in the determination of polymer/polymer miscibility are mainly the times related to the half-life of the spin relaxation, such as the spin–lattice relaxation time (T_1), the spin-spin (T_2), and the spin–lattice in the rotating frame ($T_{1\rho}$). The shorter the relaxation time, the broader is the NMR line width (for solid samples the lines are broad, a manifestation of slow reorientation of bonds, whereas for liquids and solution they are narrow, as expected from faster bond reorientation). The position of the lines, i.e., the precessional frequency of the nucleus, depends on its chemical environment, spatial configuration, and interactions. The position of the peak or the so-called chemical shift (usually quoted as d in parts-per-million, ppm) is a reflection of the energetic state of the nucleus, while the line intensity is that of its population. For example, $T_{1\rho}$ was used to analyze interactions between PVC and polymethacrylates: poly(cyclohexyl methacrylate) (PCHMA), poly(phenyl methacrylate) (PPMA), and poly(benzyl methacrylate) (PBzMA) (Sankarapandian and Kishore 1996). The NMR-detected domain size was between 3 and 15 nm. The miscibility of the same systems was also analyzed by measuring T_g. Both methods indicated miscibility for the PVC/PCHMA blends and immiscibility for the PVC/PBzMA system; however, for the PVC/PPMA 1:1 blends, while T_g indicated miscibility, the $T_{1\rho}$ NMR data showed that the same system is immiscible.

Modern solid-state NMR involves the use of very short radio-frequency pulses (of variable duration from 1 to 200 ms) and can be complemented with real-time Fourier transform analysis and multiple scan capability. Standard NMR enhancements nowadays, such as scalar (low power, ca. 4 kHz) and dipolar (about 45 kHz) decoupling, magic angle spinning, spectra of multiple elemental isotopes beyond

Fig. 2.26 An example of NMR used to probe local environment of a polymer in a blend. [15]N CPMAS (cross-polarization, magic angle spinning) NMR spectra of polyamide-6 in a blend with polyketone. PA-6 in a PK/PA 6:4 blend (**a**) shows primarily (70 %) its α-crystal phase, whereas in its pure form (**b**) PA-6 shows a 60 % γ and 40 % α crystal (Data from Asano, Chap. 5 in Cheng et al. 2011)


[1]H and ^{13}C, multi-pulse (multidimensional NMR), and cross-polarization methods, enable spectra for solid samples with resolutions similar to those known for liquids (Webb 2006; White and Wachowicz 2008). Such spectra provide precise information on the local environment of selected nuclei, configuration, interactions, and sample morphology (Fig. 2.26).

The interactions between PVDF with PMMA, PVAc, or PVME were studied by dipolar-dipolar decoupling, cross-polarization, magic angle spinning, and high-resolution ^{13}C NMR (Lin 1983; Ward and Lin 1984). Clear peak assignment for each carbon was made, and peak intensities were measured. It was found that blending has little effect on the peak frequency but a significant effect on its intensity. For example, the attenuation (A_t as a % of the observed to the expected intensities) varied with the method of blend preparation. For PVDF/PMMA 1:1 blends, when cast from DMF A_t was 100 % (immiscible), while when cast from MEK A_t was 60–75 %, and for extruded blends A_t was 26–49 % (miscible). Much clearer differences were obtained in PMAA/PVAc blends studied by ^{13}C CPMAS (cross-polarization, magic angle spinning) NMR (Fig. 2.27).

Information on short-distance spatial proximity between different segments of molecules can be obtained using the proton spin-diffusion NMR method. This is a particularly valuable method for the characterization of polymer blends. For example, in case of PS/PVME cast films, the method provided information on blend composition, fraction of interacting groups (phenyl from PS with ether from
Fig. 2.27 ^{13}C CPMAS NMR spectra of PMAA (*top line*), PVAc (*bottom line*), and several PMAA/PVAc blends. (**a**) carboxyl regions of PMAA and carbonyl regions of PVAc; (**b**) aliphatic regions. The weighted sums (of the pure PMAA and pure PVAc ^{13}C NMR spectra) are also depicted on the right of the corresponding observed spectra (*left columns*). The blend formation results in strong qualitative changes in the OC=O carbon, but not so much in the carbons of the aliphatic region (Data from Asano et al. 2002)

PVME), and group mobility within each of the three domains (PS, PVME, and PS-PVME). Again, it was found that different degree of dispersion is obtained when casting films from different solvents (Caravatti et al. 1985; 1986).

Miscibility of PEEKK/PEI 1:1 blend was analyzed using solid-state NMR (Schmidt-Rohr et al. 1990). This work involved tagging of ^{1}H magnetization, based on chemical shift difference, ^{1}H spin diffusion for controlled mixing times (tuned to probe 0.5–50 nm length scales), and high-resolution ^{13}C detection. The sample was prepared by compounding at 653 K. Intimate mixing on a molecular scale was concluded. An extension of this method employed 2D ^{13}C-^{13}C CPMAS NMR combined with multiple alternating depolarization (MAD) ^{13}C(HH) ^{13}C pulses, to probe PS/PXE blends (Hou et al. 2004); albeit tedious and lengthy, this method yielded substantially improved sensitivity in unlabeled samples and much better contrast between blend components compared to ^{1}H spin-diffusion NMR.

Two-dimensional ^{2}H NMR was used to analyze miscibility in blends of poly-1,4-polyisoprene with polyvinylethylene (PI/PVE) (Arendt et al. 1994; Chung et al. 1994). The blends were prepared by casting 3 wt% toluene solution. The rate of reorientation as a function of temperature near T_g was determined for both components. It was found that the system is miscible, but the glass transition is

broad owing to the wide distribution of segmental motions arising from the differences in the rates of the two polymers. As a result, the PIP/PVE blends were found to be rheologically complex: In spite of miscibility, the time-temperature superposition was found to be invalid.

High-resolution ^{13}C NMR spectroscopy was used to analyze miscibility of POM with terphenol ($M_w = 600$ g/mol). The size of the heterogeneity in the amorphous phase was estimated as 1 nm. The ^{1}H spin-diffusion analysis indicated a homogenous mixing on the molecular level (Egawa et al. 1996).

2.7.4.3 Spectroscopic Methods: Infrared

The use of infrared spectroscopy for the characterization of polymer blends is extensive (Olabisi et al. 1979; Coleman and Painter 1984; Utracki 1989; He et al. 2004 and references therein; Coleman et al. 1991, 2006). The applicability, fundamental aspects, as well as principles of experimentation using infrared dispersive double-beam spectrophotometer (IR) or computerized Fourier transform interferometers (FTIR) were well described (e.g., Klopffer 1984).

FTIR has been extensively used to study hydrogen bonding in polymer blends (Ting 1980; Cangelosi 1982; Moskala 1984; Pennacchia 1986; He et al. 2004; Coleman et al. 1991, 2006). These interactions affect not only the –OH absorption region (3,500–3,600 cm^{-1}), but also the =CO stretching (1,737 cm^{-1}), the –CH$_2$ symmetric stretching (2,886 cm^{-1}), as well as the fingerprint frequency region (1,300–650 cm^{-1}). As discussed in Sect. 2.6.2.3, FTIR has been used to calculate the strong interaction term of the free energy of mixing, ΔG_H (see Eqs. 2.35b and 2.58) (Painter et al. 1988, 2006). The combination of FTIR spectra, which can yield a miscibility map for specific systems, with the fitted model parameters, which can give "theoretical" phase boundaries, can be combined to construct phase diagrams for specific polymer blend systems (Fig. 2.28).

FTIR was also used to analyze the mechanism of interactions in blends of aliphatic polyesters with chlorinated polymers, viz., PVC, PVDC, or PVC-DC. In miscible blends, the polyesters' carbonyl stretching absorption frequency (1,700–1,775 cm^{-1}) was shifted – the shift was absent in immiscible systems – revealing hydrogen bonding between C–O and α- or β-hydrogen. However, there are indications that the interaction mechanism does vary from system to system, e.g., the dipolar C=O with C–Cl interactions have been also identified (Coleman et al. 1983; Prud'homme 1982; Garton et al. 1983; Morra and Stein 1984; Albert et al. 1986). A typical approach to construct a miscibility map from FTIR data is shown in Fig. 2.28, and a short summary of FTIR studies of polymer blends in Table 2.28.

There are publications on the use of other spectroscopic techniques, such as Brillouin scattering, photoacoustic, and Raman spectroscopy. The primary application of these has been to study the heterogeneities in polymer blends, viz., crystallization or phase separation.

2.7.4.4 Microscopy

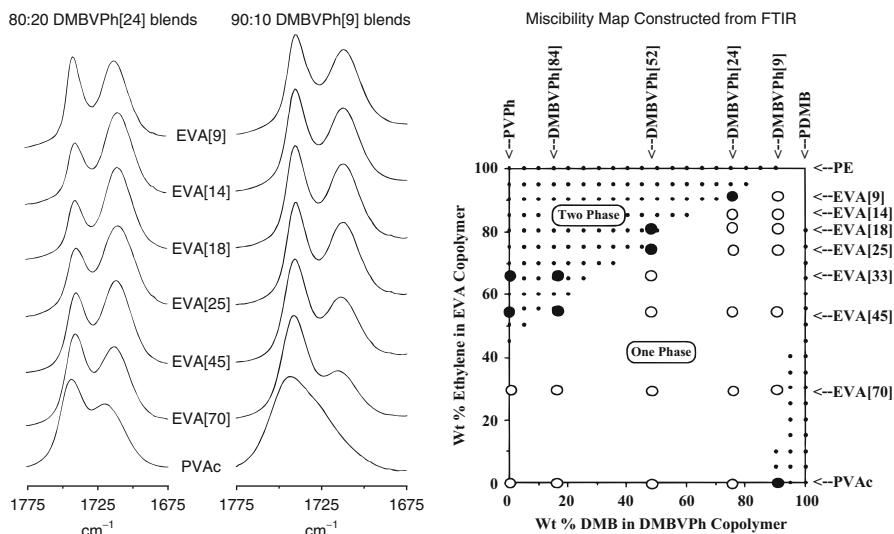
Microscopy methods, in the broader sense of methods that provide direct morphology imaging, can be divided into several categories: optical microscopy (OM),


Fig. 2.28 IR spectra in the carbonyl stretching region for blends of 2,3-dimethylbutadiene-*co*-4-vinylphenol (DMBVPh) with PVAc, EVA[70], EVA[45], EVA[25], EVA[18], EVA[14], and EVA[9] recorded at 100 °C; numbers in brackets indicate the % of the comonomer, Ph or VA, in each polymer. (*Left*) IR spectra of 80:20 wt% DMBVPh-[24] blends; (*Middle*) IR spectra of 90:10 wt% DMBVPh-[9] blends; (*Right*) Miscibility map calculated at 100 °C for DMBVPh/EVA blends: areas encompassed by small black dots denote the predicted two-phase regions; experimentally determined single- and two-phase blends are denoted by the open and filled large circles, respectively (Data from Pehlert et al. (1997)

scanning electron microscopy (SEM), transmission electron microscopy (TEM), atomic force microscopy (AFM), and several modifications of these techniques. For example, the scanning transmission electron microscopy (STEM) and low-voltage scanning electron microscopy (LVSEM, at 0.1–2 kV accelerating voltage) are particularly useful for polymer blends (Vesely and Finch 1988). STEM uses ultrathin stained films, providing images with a few nanometers resolution. LVSEM provides about tenfold increased image contrast (in comparison to the conventional SEM) with almost no charging problem (Berry 1988). Owing to shallow sampling depth and low energy of the secondary electrons, conductive coating is not needed. The method uses flat, microtomed specimens providing image quality comparable to that of TEM (Vesely 1996; a nice review of microscopy methods for blends). In all cases, microscopy is considered a necessary second method of characterization for polymer blends, since it provides the required morphological information needed to explain results from spectroscopy, T_g, or other measurements.

In most cases, some mode of sample "preparation" has to be used after the blend formation, viz., staining, swelling, fracturing, or etching. These are very appropriate for and have been extensively used to characterize morphology of immiscible blends, but they have obvious severe shortcomings in miscible or partially miscible

Table 2.28 A few examples of FTIR measurements of polymer blends

Blend	Comment	References
PVDF/PMMA	Blending slightly affected the carbonyl stretching near 1,735 cm^{-1}	1
PPE/PS	FTIR peak ratio 1,030/700 cm^{-1} used for the determination of composition	2
PPE/PS	Strongest interactions for 30 wt% PPE	3
PPE/PS	FTIR was used for characterizing macromolecular orientation in solid state	4
PC/PCL	Miscibility in the amorphous phase	5
PC/PBT	Miscibility in the amorphous phase	6
PCL/Phenoxy	H-bonding between the -OH group of phenoxy and C=O of PCL	7
PS/PVME	Changes in molecular environment were easiest detected using the vibrations: in PS the out-of-plane CH, and in PVME the COCH$_3$ at 700 and 1,100 cm^{-1}	8
PF (Novolac)/PS, SAN, PEA, PVAc, PEMA, PMMA, PMPS, PC, or PVME	Novolac (PF) blends: frequency shifts in CO vibration from 1,774 to 1,752 cm^{-1} due to hydrogen bonding in miscible blends	9
PET/PC	FTIR used to study transesterification	10
PET/PA-6	Studies of ester-amide exchange reactions	11
PU/poly(EG-co-PG)	The N-H stretching (3,500–3,100 cm^{-1}) was found sensitive to interactions	12
PVPh/PVAc, EVAc, PCL, PPL, PMA, PEA, PBA, or P2EHA	Poly(4-vinyl phenol) blends: the amount of free and bonded C=O vibrations were determined fort the PVPh/hydrogen-bonding polymer blends, using a curve fitting procedure	13
poly(DMB-co-VPh)/ EVA	2,3-dimethylbutadiene-co-4-vinylphenol (DMBVPh) blends with EVA (VA comonomer: 0 % to 100 %). Miscibility map constructed (see also Fig. 2.28)	14
poly(S-co-VPh)/ PBMA, PHMA, or PTHF	Poly(styrene-co-4-vinyl phenol) blends: the hydroxyl stretching (3,100–3,700 cm^{-1}) and "fingerprint" (600–1,650 cm^{-1}) regions were analyzed. The bands 3,525 and 3,100–3,500 cm^{-1} were assigned, respectively, to free and hydrogen-bonded structures	15
PVC/SAN	Nitrile stretch vibration region (2,260–2,220 cm^{-1}) and C-Cl absorption (660–580 cm^{-1}) were used to characterize the interactions	16
PPE/PS	New method of IR-data treatment was proposed. Weight fraction of polymer-1 in the blend: $x_1 = a_o + a_1R/(1 + a_2R)$, where a_i are parameters, and $R = A_1/(A_1 + A_2)$ is the absorbency fraction	17
PVPh/PMMA	Measurements of solvent cast films showed the H-bonding extent depended on solvent	18

blends. There are numerous factors that reduce resolution in blends, well above instrumental capabilities, and several sources for introduction of artifacts in electron microscopy, e.g., metallization in SEM and OsO_4 staining in TEM, introduce an artificial grain structure, especially under greater magnifications. However, even at the highest resolution, it is difficult to obtain sufficient confidence to declare whether the blend is thermodynamically miscible. One of the better sources of this information comes from studies of the diffusion rate of one polymer into another using any of the previously mentioned techniques. Preparation of samples for the observation under TEM is more tedious and exacting than that used for SEM. The specimens have to be hardened and microtomed into ca. 200 nm thin slices, and most often stained with Br_2, OsO_4, or RuO_4. Frequently, the SEM and TEM methods are being used in parallel (Karger-Kocsis and Kiss 1987; Kyotani and Kanetsuna 1987; Hsu and Geil 1987; Vesely 1996).

For example, the effects of AN content on miscibility of SAN with PMMA were studied by measuring the thickness of the interphase (Higashida et al. 1995). The effects of concentration, compatibilization, and annealing for PA with either PS or PE (compatibilized by 5 wt% of PP-MAh or SMA) were studied by SEM (Chen et al. 1988). Compatibilization reduced the diameter of dispersed phases by a factor of ten and stabilized the system against coalescence at the annealing temperature ($T = 200$–$230\ ^\circ C$, for at least 1.5 h).

Interesting studies of phase coarsening in PMMA/SMMA blends were followed using interference contrast light microscopy and/or TEM (Andradi and Hellmann 1993). Films, cast from toluene, were homogenized at low temperature and then brought to the spinodal region for phase separation and coarsening; owing to the difference in the refractive indices, good contrast was obtained without etching. The kinetics of phase coarsening in blends of PS with poly(sila-α-methylstyrene) was followed under an optical microscope (Maier et al. 1996). The blends have UCST that depends on M_w. Annealing within the single-phase region, and then jumping to the spinodal region, causes SD and phase coarsening. Similarly, optical and SEM methods were used to study phase separation in blends of PP with isotactic poly(1-butene) (Cham et al. 1994); this system was found to have an UCST.

Reactive compatibilization of PA/SAN blends was followed with careful TEM (Mujumdar et al. 1994a, b). Better contrast was obtained using phosphotungstic acid than RuO_4. The binary interaction parameter, χ_{12}, was calculated from the micelle spacing in microphase-separated PS-b-PVP system (Clarke et al. 1997). The spacing was determined using an AFM. Details of the polymer blends' morphology and the methods of its characterization were discussed in ▶ Chap. 8, "Morphology of Polymer Blends" in the first edition of this handbook.

Finally, a creative approach employing optical microscopy involved high-throughput (combinatorial) methods: Here, a single sample was made with a gradient of blend composition in one direction and a linear change in temperature in the normal direction. After sufficient annealing of the samples, the LCST phase diagram can be directly observed with optical microscopy (Meredith et al. 2000, 2002; Karim et al. 2002; Yurekli et al. 2004); see also Fig. 2.29.

Fig. 2.29 Optical microscopy photograph of a PS and poly(vinyl methyl ether) (PS/PVME) T-ϕ combinatorial sample (library) after 16 h of annealing, showing the lower critical solution temperature (*LCST*) cloud-point curve. *White points* are conventional *light*-scattering cloud points measured independently on separate uniform samples (Meredith et al. 2000)
2.8 Summary and Conclusions

The information provided in this chapter can be divided into four parts: 1. introduction, 2. thermodynamic theories of polymer blends, 3. characteristic thermodynamic parameters for polymer blends, and 4. experimental methods. The introduction presents the basic principles of the classical equilibrium thermodynamics, describes behavior of the single-component materials, and then focuses on the two-component systems: solutions and polymer blends. The main focus of the second part is on the theories (and experimental parameters related to them) for the thermodynamic behavior of polymer blends. Several theoretical approaches are presented, starting with the classical Flory-Huggins lattice theory and, those evolving from it, solubility parameter and analog calorimetry approaches. Also, equation of state (EoS) types of theories were summarized. Finally, descriptions based on the atomistic considerations, in particular the polymer reference interaction site model (PRISM), were briefly outlined.

As the volume of tabulated values of thermodynamic parameters indicates, the largest pool of data is based on Flory-Huggins type of relations. This is only to be expected since the theory, and the related concept of the binary interaction parameters, either B or χ_{12}, was introduced to polymer science very early, more than a half century ago, in 1941 to be precise. Even with its rather limited applicability, due to its strict assumptions, and the well-recognized complexity of functional dependence [viz., $\chi = chi(T, P, \phi, M_w, \text{MWD, molecular}$

structure, stresses, ...), needed for most practical applications] the FH model remains to broadest used and continually developed theoretical framework for blend thermodynamics.

In hindsight, due to its ability to address high T and P, the EoS approach has been used with growing frequency to describe the thermodynamic behavior of multicomponent polymer-based systems. Such problems as the temperature- and pressure-dependent miscibility of low molecular weight liquids or polymeric liquids in selected polymers have been successfully solved. For binary blends, the EoS uses two parameters, the first related to the change of specific volume and the other to the energetic interactions. It has been shown that for many cases the values of these experimental constants can be well predicted using the algebraic and geometric means, respectively. Since during polymer processing pressure plays a major role, the EoS is potentially a very valuable tool for polymer researchers and engineers.

Biography The second edition of this chapter was written after Les Utracki had passed away. In an effort to maintain the look and feel of the chapter's first edition, we retained the structure of the original chapter and only updated the content to reflect developments within the last decade. All shortcomings and concerns regarding this chapter should be addressed to manias@psu.edu.

EM would like to dedicate this chapter to the memory of Les Utracki, as well as to my Ph.D. advisors Gerrit ten Brinke and Georges Hadziioannou; all three of these exceptional scientists have seminal and pioneering accomplishments in the field of polymer blends, as reflected in the contents of this chapter, and made invaluable contributions to the first author's education in thermodynamics and blends.

Abstract

When the melt of a crystalline polymer is cooled to a temperature between the glass transition and the equilibrium melting point, the thermodynamic requirement for crystallization is fulfilled.

In a crystallizable miscible blend, however, the presence of an amorphous component, either thermoplastic or thermosetting, can either increase or decrease the tendency to crystallize depending on the effect of the composition of the blend on its glass transition and on the equilibrium melting point of the crystallizable component and also on the curing extent and conditions in case of thermosetting amorphous component. The type of segregation of the amorphous component, influenced by parameters such as crystallization conditions, chain microstructure, molecular weight, blend composition, and curing extent, determines to a large extent the crystalline morphology of a crystallizable binary blend. Separate crystallization, concurrent crystallization, or cocrystallization can occur in a blend of two crystallizable components. The spherulite growth of the crystallizable component in miscible blends is influenced by the type and molecular weight of the amorphous component, the former affecting the intermolecular interactions between both components and the latter the diffusion of the amorphous component. The blend composition, the crystallization conditions, the degree of miscibility and the mobility of both blend components, and the nucleation activity of the amorphous component are important factors with respect to the crystallization kinetics. The melting behavior of crystallizable miscible blends often reveals multiple DSC endotherms, which can be ascribed to recrystallization, secondary crystallization, or liquid-liquid phase separation. Complex crystallization behavior develops in miscible blends containing a crystallizable thermoplastic and a curable thermosetting component. That depends on the temperature and time of curing the thermosetting and also on whether crystallization is initiated before, during, or after the curing process.

For the discussion of the crystallization and melting behavior in immiscible polymer blends, a division into three main classes is proposed.

In blends with a crystallizable matrix and an amorphous dispersed phase, both the nucleation behavior and the spherulite growth rate of the matrix can be affected. Nucleation of the matrix always remains heterogeneous; however, the amount of nuclei can be altered due to migration of heterogeneous nuclei during melt-mixing. Blending can also influence the spherulite growth rate of the matrix. During their growth, the spherulites can have to reject, occlude, or deform the dispersed droplets. In general, the major influence of blending is a change in the spherulite size and semicrystalline morphology of the matrix.

A completely different behavior is reported for blends in which the *crystallizable phase is dispersed*. Fractionated crystallization of the dispersed droplets, associated with different degrees of undercooling and types of nuclei, is the rule. The most important reason is a lack of primary heterogeneous nuclei within each crystallizable droplet. An important consequence of fractionated crystallization may be a drastic reduction in the degree of crystallinity.

When two crystallizable components are blended, a more complex behavior due to the influence of both phases on each other is expected. In general, the discussion for matrix crystallization and droplet crystallization can be combined. However, crystallization of one of the phases can sometimes directly induce crystallization in the second phase. As a consequence, the discussion of blends of this type has been subdivided with respect to the physical state of the second phase during crystallization. The special case of "coincident crystallization," in which the two phases crystallize at the same time, is discussed. Finally, the effect of compatibilization of crystalline/crystalline polymer blends is briefly reviewed.

A new section has been added, introduced to deal with crystallization phenomena in immiscible polymer blends containing nanoparticles. Recent reports, although few, discuss the effect of nanoparticles on crystallization and melting in immiscible polymer blends.

3.1   General Introduction

The study of the processing-morphology-property relations of polymer blends has become a topic of major scientific importance during the past three decades mainly because of intensified technological interest in this area.

The science and technology of polymer blends has now acquired an important position in the area of development of new polymeric materials. Moreover, the application of polymer blends has increased significantly and is expected to continue to grow. Of the total consumption of engineering polymers, more than 20 % is currently thought to be composed of blends with important and various applications in the automotive, electrical, and electronic industry, in computer and business equipment housings, in medical components, etc. Annually about 4,900 patents related to polymer blends are published worldwide.

These are various reasons for today's focus on polymer blends. Design of new polymers with special properties by chemical synthesis is always more expensive than the costs of the constituent existing polymers and the blending operation. A proper selection and combination of polymeric components in a certain ratio might result in a blend material with optimal properties for a specific application. The resulting blend will be the more successful; the more of the desired properties of the components are expressed in its property profile. A remarkable broad spectrum of properties can often be achieved by blending. These properties include mostly mechanical strength and stiffness, toughness, processability, heat distortion

temperature, chemical and weathering resistance, flame retardancy, thermal and dimensional stability, aging resistance, elongation, permeability, transparency, and gloss.

A fundamental question, which has to be addressed first about any blend system of interest, is of course whether the components are miscible or not. Polymer mixtures of chemically dissimilar polymers can be divided on the basis of the miscibility of their components being miscible, partially miscible, or fully immiscible.

While miscibility of polymers was considered as rather rare three decades ago, it is now recognized as an achievable phenomenon with probably well over 500 noted miscible combinations. The conceptual key toward forming miscible polymer blends is to choose polymer pairs with chemical structures capable of specific interactions leading to exothermic heats of mixing. Miscibility studies on homopolymer/copolymer blends indicate that strong repulsive interactions between the segments of the copolymer larger than those between its segments and the homopolymer might also lead to miscibility.

Miscible polymer blends behave similar to what is expected of a single-phase system. Their properties are a combination of the properties of the pure components, and in many cases, they are intermediate between those of the components. The characteristics of the components affecting the properties of miscible blends are their chemical structure and molecular weight, their concentration, and their intermolecular interactions, including crystallizability.

While miscible blend systems are of considerable scientific and practical interest, it should not be concluded that miscibility is always the preferred situation with respect to the properties. In fact, immiscibility leading to two or multiple phases during blending is desired in various cases since the property combinations that one seeks require essentially a system in which each phase can contribute its own characteristics to the blend material.

For thermodynamic reasons, i.e., small entropy gain on mixing, most arbitrary selected polymer pairs are immiscible and, as a consequence, display a two-phase behavior. Melt-mixing of immiscible polymers can result in a variety of phase morphologies depending on the blend composition, the rheological characteristics of the components such as viscosity and elasticity, the interfacial tension between the phases, and the intensity and type of flow that is applied. In the case of immiscible polymer blends, important characteristics with respect to their properties are the chemical nature of the components, the blend composition, the phase morphology (size and shape), the degree of crystallinity and semicrystalline structure of the phases in the case of crystallizable components, and the interfacial interactions between the phases.

A number of miscible polymer blends are only completely miscible and form one-phase systems over a limited concentration, temperature, and pressure range. Under certain conditions of temperature, pressure, and composition, miscible binary blends may phase separate into two liquid phases with different compositions, called partially miscible blends. Important characteristics of this type of blends are the overall blend composition, the morphology, and the composition of the different phases as well as the nature of the interface between the phases.

A large number of polymer blends contain one or two crystallizable components. The crystallization behavior of a polymer component in a blend is expected to be altered by the presence of the second blend component, whether both are completely miscible, partially miscible, or totally immiscible. Therefore, a profound scientific understanding of the crystallization behavior and the resulting semicrystalline structure in polymer blends is necessary for effective manipulation and control of their properties.

There are a number of important factors governing the change of the crystallization rate and semicrystalline structure of a polymer in blend systems. Those include the degree of miscibility of the constituent polymers, their concentration, their glass-transition and melting temperature, the phase morphology and the interface structure in the case of immiscible blends, etc.

This chapter, related to the crystallization, morphological structure, and melting of polymer blends, has been divided into two main parts. The first part (Sect. 3.2) deals with the crystallization kinetics, semicrystalline morphology, and melting behavior of miscible polymer blends. The crystallization, morphological structure, and melting properties of immiscible polymer blends are described in the second part of this chapter (Sect. 3.3).

3.2 Crystallization, Morphological Structure, and Melting Behavior of Miscible Polymer Blends

The crystallization of miscible and immiscible polymer blends can differ remarkably from that of the neat crystallizable component(s). In the case of crystallizable miscible blends (discussed in this section), important polymer characteristics with respect to crystallization are the chemical nature and molecular mass of the components, their concentration in the blend, and the intermolecular interactions between the components.

The thermodynamic requirement for crystallization in a miscible blend is that the blend exhibits a free energy on crystallization that is more negative than the free energy of the liquid-liquid mixture. A liquid-solid phase separation can occur when the miscible melt is cooled to a temperature between the glass transition of the blend and the equilibrium melting point of the crystallizable component(s) (Sect. 3.2.1). The presence of an amorphous component in a crystallizable binary blend can either increase or decrease the tendency to crystallize, depending on the effect of composition on the glass transition of the blend and on the equilibrium melting point of the crystallizable component.

The morphology of a semicrystalline polymer blend is largely determined by the type of segregation of the amorphous component (Sect. 3.2.2.1). In the case of interspherulitic segregation of the amorphous component, where the spherulites of the crystalline component are imbedded in an amorphous matrix, the semicrystalline morphology will be influenced to a lesser extent than when the amorphous component is located within the spherulites (interlamellar and interfibrillar segregation). The parameters determining the type of segregation are not fully understood.

Recent studies (Defieuw 1989) indicate that the crystallization conditions, blend composition, chain rigidity and microstructure, and molecular weight of the components are important. Blends consisting of two crystallizable components (Sect. 3.2.2.2) can exhibit separate crystallization or concurrent crystallization (cocrystallization).

Spherulite growth of the crystallizable component in miscible blend (Sect. 3.2.3) will be influenced by the type and molecular weight of the amorphous component (the former affecting the intermolecular interactions between both components and the latter the diffusion of the amorphous component).

The blend composition, the crystallization condition, the degree of miscibility and the mobility of both blend components, and the nucleation activity of the amorphous component are important factors with respect to the crystallization kinetics (Sect. 3.2.4).

The melting behavior of miscible crystallizable blends (Sect. 3.2.5) is often complex, revealing multiple DSC endotherms, which can be ascribed to several causes such as recrystallization, secondary crystallization, liquid-liquid phase separation (Sect. 3.2.6), etc.

3.2.1 Crystallization Temperature Range of Crystallizable Miscible Blends

The crystallization of a polymer can only proceed in a temperature range limited on the low temperature side by the glass-transition temperature (T_g) and on the high temperature side by the equilibrium melting point ($T_m°$). Below T_g the mobility of the polymer chains is hindered, while in the proximity of $T_m°$, crystal nucleation is inhibited.

When dealing with crystallizable miscible blends, the glass transition is located in between those of the neat components (Fig. 3.1). The presence of an amorphous component in a crystallizable miscible polymer blend can increase or decrease the tendency to crystallize depending on the T_g of the amorphous component with respect to that of the crystallizable one. If the T_g of the amorphous component is lower than that of the crystallizable one, the crystallization envelope ($T_m° - T_g$) is widened, and the crystallization is facilitated. In the opposite case, where the T_g of the amorphous component is higher than that of the crystallizable one, the blend T_g is increased and the temperature range over which crystallization can occur becomes smaller. A limiting case of this is the inhibition of crystallization due to the fact that the blend T_g is higher than the $T_m°$ of the crystallizing component, a phenomenon that is often seen in blends with a high concentration of amorphous component. An even more complex situation is observed when two miscible components are crystallizable.

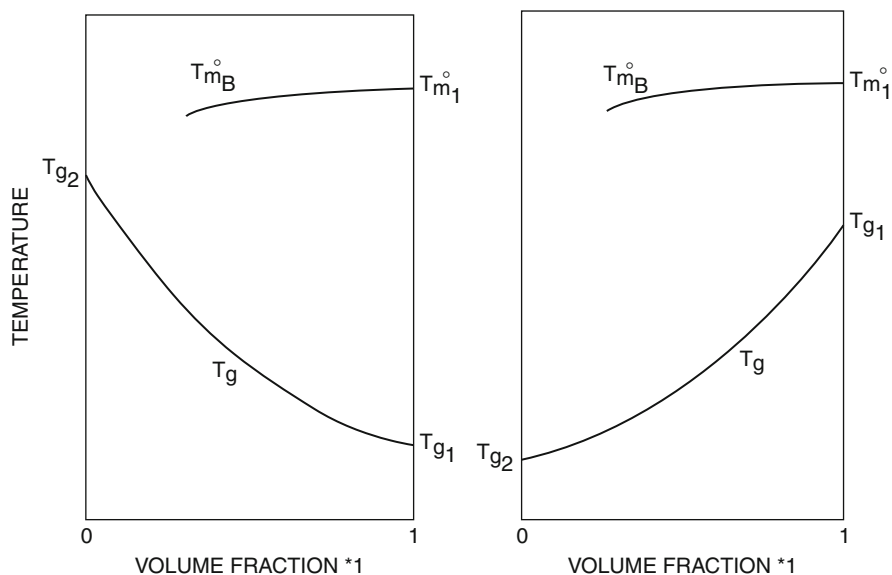
Some examples are given in Table 3.1. In PCL/CPE blends, the PCL crystallization is enhanced when CPE is added (Defieuw et al. 1989a). The crystallization range becomes narrower in blends such as PCL/PECH (Runt and Martynowicz 1986), PEG/PEMA (Cimmino et al. 1989), PCL/SAN (Defieuw et al. 1989d), and


Fig. 3.1 Possible crystallization temperature ranges for a crystallizable miscible polymer blend (*1* crystallizable component, *2* amorphous component) (Runt and Martynowicz 1986)

PBT/PAr (Iruin et al. 1989), PEO/Aramide 34I (Dreezen et al. 1999a), and PEO/PES (Dreezen et al. 1999b). It should be noted that the PBT/PAr 10/90 blend does not show any tendency to crystallize although the blend's T_g is located beneath the melting point of PBT. A possible explanation for this observation is that crystallization is too slow to be noticed within the observation time limit.

3.2.2 Crystallization Phenomena in Miscible Polymer Blends

When crystallized from the melt, most polymers show a spherulitic texture (Fig. 3.2). The spherulites then consist of lamellar stacks of alternating crystalline and amorphous layers, radiating from the center (the primary nucleus).

3.2.2.1 Modes of Segregation of the Amorphous Component During Crystallization in Crystalline/Amorphous blends

In blends of a crystallizable polymer with an amorphous one, the morphology is largely determined by the type of segregation of the amorphous component. Crystallization in a miscible blend involves two types of polymer transport: diffusion of the crystallizable component toward the crystallization front and simultaneous rejection of the amorphous component. This latter phenomenon is called segregation; it can take place at three different levels: interspherulitic, interfibrillar, and interlamellar (Fig. 3.3).

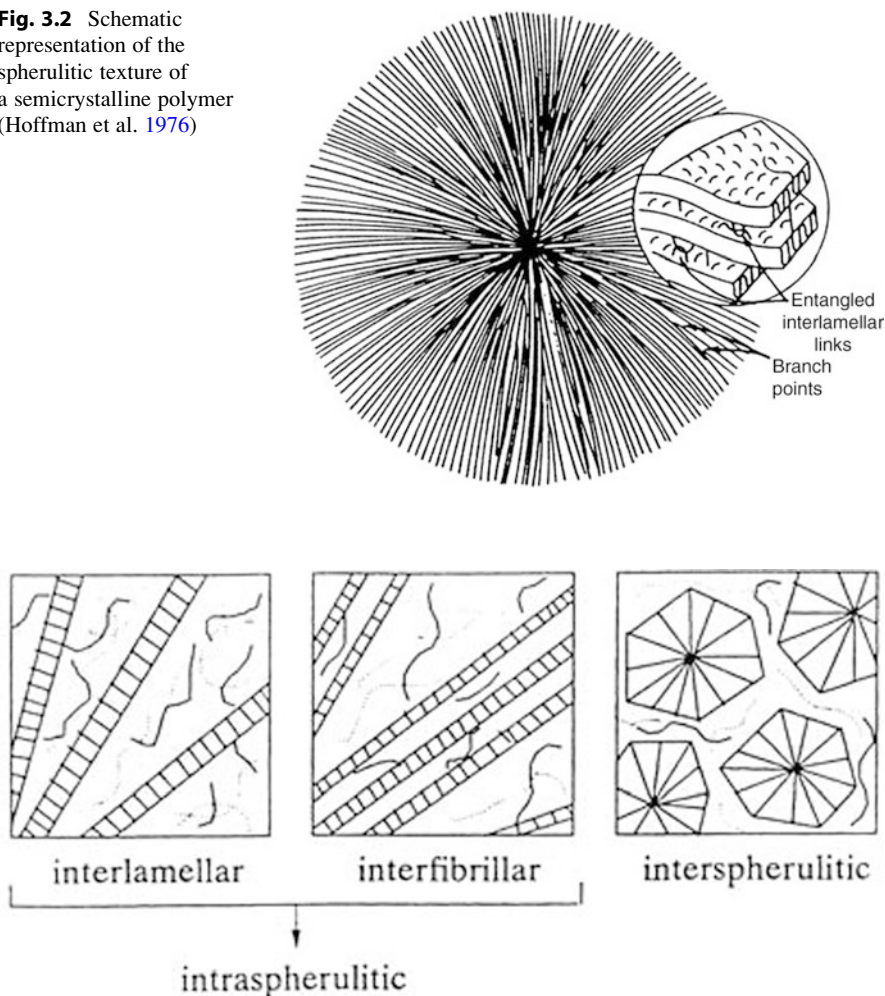

Fig. 3.3 Schematic representation of the different types of segregation of the amorphous component in crystallizable miscible polymer blends (*full lines*: crystallizable component, *dotted lines*: amorphous component)

Interspherulitic segregation, in which the spherulites are imbedded in an amorphous matrix, can be distinguished from the other two types using optical microscopy. In the case of intraspherulitic segregation, a volume-filling texture is observed; the amorphous components can be located either between the lamellae (interlamellar) or between stacks of lamellae (interfibrillar). To find out whether or not interlamellar segregation occurs, small-angle X-ray scattering (SAXS) can be used. The increase of the long spacing, which is the sum of the average thickness of the crystalline and amorphous layers, as well as the increase of the thickness of the

amorphous layers between the crystalline lamellae, with increasing concentration of the amorphous component, are parameters that are often used as indications for interlamellar segregation. In Table 3.2 some examples are presented together with the parameter and/or technique used to make conclusions about the type of segregation.

Most studies concerning the segregation behavior of amorphous components in a miscible crystallizable blend deal with PCL as the crystallizable component. In their blends with PCL, PVC has shown to segregate interlamellar (Stein et al. 1978, 1981; Khambatta et al. 1976a, b; Ong and Price 1978a; Russell and Stein 1980, 1983), PC interfibrillar or interspherulitic (Vandermarliere 1986; Cruz et al. 1979; Fernandez et al. 1986), CPE either interfibrillar or interspherulitic (depending on the amount of amorphous component) (Defieuw et al. 1989a), SMA interlamellar (Defieuw et al. 1989a; Defieuw et al. 1989b, c; Vanneste et al. 1995), SAN interlamellar (Defieuw et al. 1989c; Vanneste et al. 1995), and Phenoxy interlamellar/interfibrillar (Defieuw et al. 1989d; Vanneste 1993).

An intensively studied blend is the PEEK/PEI blend for which interlamellar (Chen and Porter 1994), interfibrillar (Crevecoeur and Groeninckx 1991: Hsiao and Sauer 1993), and interspherulitic segregations (Crevecoeur and Groeninckx 1991) were reported. In PEKK/PEI blends, PEI is segregated interspherulitically (Hsiao and Sauer 1993).

Warner et al. (1977) have shown that in iPS/PS blends the noncrystallizable atactic PS was mainly segregated between the fibrils inside the spherulites. Similar observations have been reported recently by Chi Wang et al. (2006) by using TEM and SEM tools on 50 wt% atactic PS/50 wt% syndiotactic PS miscible blends. On the other hand, Wenig et al. (1975) determined the segregation of PPE to be interlamellar region in the iPS/PPE blends. The influence of the tacticity of PMMA on segregation in PEG/PMMA blends was investigated by Silvestre et al. (1987a). Atactic and syndiotactic PMMA were found located in between the lamellae of PEG, whereas isotactic PMMA was reported to segregate interfibrillar or interspherulitic. It should, however, be noted that a low molecular weight iPMMA was used in this study. In other PEG blends, the amorphous component resided in the interlamellar (EVAc; Cimmino et al. 1994), interspherulitic (PEMA; Cimmino et al. 1989), and interlamellar and interfibrillar regions (PVAc; Silvestre et al. 1987b; Kalfoglou et al. 1988). Atactic PMMA (Canetti et al. 1994) and atactic polyhydroxybutyrate (PBH; Abe et al. 1994) were located between the lamellae in blends with iPHB. Interlamellar segregation was also reported in blends of 1-octene LLDPE fractions with different short-chain branching contents (Defoor et al. 1993).

Blends of PVDF with PMMA have been studied by several authors. All three types of segregation were detected, which was attributed to variation of the crystallization temperature by Stein et al. (1981) and Morra and Stein (1982). Hahn et al. (1987) reported the existence of a compositional interphase (a region of varying polymer composition) between the lamellae and the amorphous interlayer. The order-disorder interphase seemed to contain pure PMMA, while in the remaining interlamellar region, a homogeneous mixture of PMMA and amorphous PVDF was located.

[k] Rapid crystallization conditions, interfibrillar segregation occurred in blends with a PEI concentration below 50 %; at higher contents of the amorphous component, interspherulitic segregation was observed

[l] Slow crystallization conditions

Miscibility, isothermal crystallization kinetics, crystal structure, and microstructure of biodegradable PBSA/PVPh blends were investigated with DSC, Polarized OM, WAXD, and SAXS (Yang et al. 2009).

The investigation revealed the following features with respect to the crystallization of PBSA in the presence of PVPh:

1. PBSA and PVPh are miscible crystalline/amorphous polymer blends. Miscibility of PBSA/PVPh blends was evidenced by the single composition-dependent glass-transition temperature over the entire blend compositions. The negative polymer-polymer interaction parameter, obtained from the melting depression of PBSA, indicates that PBSA/PVPh blends are thermodynamically miscible.
2. Isothermal crystallization kinetics study of neat and blended PBSA indicates that the crystallization mechanism of PBSA does not change, but the crystallization rate decreases with increasing the PVPh content in the blends.
3. The crystal structure of PBSA is not modified in the PBSA/PVPh blends. However, the values of LP, Lc, and La become larger with increasing the PVPh content, indicating that PVPh mainly resides in the interlamellar region of PBSA spherulites.

## Typical Examples of Supramolecular and Semicrystalline Morphology

PEO (semicrystalline)/Aramide 34I (amorphous) blend was observed by polarized microscope to identify the supramolecular structure and characterized by SAXS to identify the type of semicrystalline morphology (Dreezen et al. 1999). The supramolecular structure of pure PEO consists of different types depending on the molecular weight and the crystallization temperature. Allen and Mandelkern (1982) compiled a morphological map for PEO in which three different supramolecular structures are present: a spherulitic, a hedritic, and an intermediate spherulitic-hedritic structure. Figure 3.4 reveals that pure PEO displays a non-structured-birefringence structure. Blending PEO with Aramide 34I results in the formation of well-defined Maltese-cross spherulites above 15 % Aramide 34I. Figure 3.4a represents an intermediate pattern of spherulitic-hedritic structure. All the blends containing up to 25 % amorphous Aramide 34I exhibit volume-filling spherulites indicating intraspherulitic segregation of the amorphous component. This change was attributed to lower diffusion rate and increased secondary nucleation when crystallizing PEO in blends with Aramide 34I, the T_g of which is very high. Calculation from SAXS reveals that both the long period and the amorphous thickness increase with the amount of the amorphous component, whereas the crystalline lamellae thickness slightly decreases; this effect is synonymous of interlamellar segregation. A model in which thin lamellae are located between the primary formed thick lamellae in the same stack was proposed to describe the secondary crystallization of PEO in PEO/Aramide 34I blends (Fig. 3.4). Similar crystallization, melting, and supramolecular structure and mode of segregation behavior were also reported when PEO is blended with polyethersulfone (Dreezen et al. 1999b; Fig. 3.5).

The concept of a crystal-amorphous (also order-disorder) interface was first proposed by Flory (1962) for binary semicrystalline/amorphous blends.
Fig. 3.4 Optical micrographs of PEO/Aramide 34I blends: (**a**) 100/0 $T_c = 47$ °C, magn. 5×; (**b**) 95/5 $T_c = 42$ °C, magn. 5×; (**c**) 90/10 $T_c = 44$ °C, magn. 10×; (**d**) 85/15 $T_c = 32$ °C, magn. 10×; (**e**) 80/20 $T_c = 28$ °C, magn. 10×; (**f**) 75/25 $T_c = 28$ °C, magn. 10× (Dreezen et al. 1999)

The *order-disorder interphase* was defined as the region of loss of crystalline order. Kumar and Yoon (1991) examined this interface and found that in blends the thickness of this transition zone was essentially independent of the interaction parameter between the two polymers (when χ_{12} varied from -1 to -0.005). Following the theoretical predictions, the thickness of this region increases only slightly when stiffer chains are considered. Due to the higher degree of order of segments of the crystallizable component in this zone, the penetration of the amorphous component is limited. The *compositional interphase*, however, is influenced by the stiffness of both chains and by the interaction parameter (the interfacial thickness varies with the reciprocal of $|\chi_{12}|^{1/2}$). This prediction seems to be confirmed by experiments. Blends of iPS and PS as well as HDPE/LDPE blends (at a temperature above the melting point for the latter blend) have a χ_{12} that is
Fig. 3.5 Model describing the crystallization behavior of (**a**) 80/20 PEO/Aramide 34I blend; (**b**) after fast primary crystallization; (**c**) secondary crystallization; and (**d**) a 65/35 PEO/Aramide blend after crystallization (Dreezen et al. 1999)

nearly zero; as a consequence, they will not form a mixed phase in the interlamellar region – the amorphous polymer will be excluded from the interlamellar zone. This seems to be in agreement with the experimental observations for iPS/PS (Warner et al. 1977) and HDPE/LDPE (Song et al. 1988). The presence of a pure order-disorder interphase has been observed in PVDF/PMMA blends (Wenig et al. 1975) using small-angle X-ray scattering and dielectric relaxation experiments. Jonas et al. (1995) estimated the spatial extension of the order-disorder interphase of PEEK in its blends with PEI.

A check of the theoretical predictions of Kumar and Yoon can be made comparing several miscible crystallizable blends with components having a similar stiffness but exhibiting variable interactions (i.e., different values of χ_{12}). Such experimental work was done by Runt et al. (1991) who examined blends of crystallizable PEG with three different amorphous components (PMMA, PVAc and polyhydroxystyrene, PHS). The first two amorphous polymers (PMMA and PVAc) exhibited a small interaction with PEG, while PHS (being able to form hydrogen bonds with PEG) displayed large interactions. A pure PEG interphase was found for the PEG blends with PMMA and PVAc, whereas a relaxation suggestive for the presence of a mixed interphase for the PEG/PHS blend was observed. Barron et al. (1992) studied strongly interacting PCL blends with PC, PVC, Phenoxy, etc., by means of dielectric relaxation measurements. The blends exhibit a dielectric relaxation in between the relaxation of the pure components, indicating the presence of a mixed amorphous interphase. The possibility to observe this transitional behavior depended on the frequency used; a frequency of 10 Hz was used in this case. Therefore, it was impossible to study these transitions by means of dynamic mechanical experiments (DMA, usually 1 Hz is used) or differential scanning calorimetry (DSC). For the PCL/PVC blends (PVC segregates interlamellar (Russell and Stein 1983), three transitions were noticed: (1) a pure amorphous PCL region (γ-relaxation); (2) a mixed amorphous phase,

located at a higher temperature than the former and which shifts to higher temperatures with increasing PVC content; and (3) an interphase transition that shifts to higher temperatures the stronger the interaction between both polymers. A frequency lower than 10Hz results in an overlap of the transitions associated with the mixed and phase and with the interphase, while at higher frequencies, the γ-relaxation merges with the interphase transition.

Excellent work was reported by Balsamo et al. (2006) on the semicrystalline morphology of PCL/PSMA14 miscible blends as well as on their crystallization kinetics. The authors used a combination of dielectric, calorimetric, and microscopy characterization tools to investigate crystallization features of PCL in miscible PCL/PSMA14 blends over the whole composition range. The results achieved allowed to draw the following conclusions with respect to the miscibility effect on the blend relaxation dynamics and crystallization kinetics of PCL:

(a) Crystallization of PCL in the blend occurs when the PCL content reaches 30 wt% or more. A depression of the PCL melting point and a significant cold crystallization process are detected for the 40/60 blend, showing the intimate mixing of the components with the existence of interactions on a molecular level. This is supported by the interlamellar insertion of the PSMA14, the formation of ring-banded spherulites, and the significant increase in the half-crystallization times.

(b) The existence of a miscible interlamellar region leads to a spherulitic extinction ring spacing that becomes larger upon increasing crystallization temperature. Interestingly, it also increases with PSMA14 content. The latter differentiates the PSMA14/PCL system from other PCL blends.

(c) With respect to the chain dynamics, the thermally stimulated depolarization current (TSDC) results indicate that even the short-range reorientations of the PCL dipoles are affected by blending. The addition of the rigid PSMA14 to PCL causes the hindering of the pre-cooperative motions usually assigned to the β relaxation in the presence of PCL crystalline regions.

For example, Fig. 3.6 shows the spherulites formed after isothermal crystallization at the indicated temperatures. Indeed, in addition to the typical Maltese-cross, extinction rings appear, leading to ring-banded spherulites. This kind of superstructures has been observed, for example, in blends of PCL with SAN (Wang and Jiang 1997; Li et al. 1992; Wang et al. 1998) and PVC (Eastmond 2000) as well as in block copolymers (Balsamo et al. 1996; Albuerne et al. 2003; Nojima et al. 1991). Note that the spherulites fill all the space, indicating the absence of interspherulitic segregation. In all cases, a linear increase of the radii of the spherulites with time was found until their impingement, evidencing that the growth rate is not controlled by diffusion. These results are in agreement with the interlamellar location of the PSMA14 evidenced here with TEM and are the consequence of the low flexibility of the PSMA chains and its affinity toward the PCL.

It is well known that banding is the result of the cooperative twisting of the lamellae during growth. Although such twisting has been associated with internal stresses produced on the lamellae surfaces, the reason for its occurrence is still controversial (Lotz and Cheng 2005). It has also been reported in case of polymer
Fig. 3.6 POM images obtained during isothermal crystallization of PSMA14/PCL blends at the indicated crystallization temperatures. The *bars* represent 100 μm. Top left: PCL Tc = 46 °C, Top right: 10/90 Tc = 44 °C, Bottom left: 20/80 Tc = 44 °C, Bottom right: 30/70 Tc = 44 °C. (Balsamo et al. 2006 with Permission)

blends that the periodicity of the rings depends on composition (Morin et al. 2001). To characterize the superstructure, the periodicity of the rings was measured in PSMA14/PCL 20/80 and 30/70. The results presented in Fig. 3.7 reveal that the periodicity increases with the content of the amorphous component, a fact that is contrary to the results obtained by other authors in blends containing PCL (Nojima et al. 1991; Wang et al. 1996; Schulze et al. 1993). Nevertheless, Briber and Khoury (1987, 1993) reported a similar trend in poly(vinylene fluoride)/poly(ethyl acrylate) blends. This could be related to the dependence of the interaction parameter on composition. Additionally, the periodicity markedly increases with the crystallization temperature, due to the higher segmental mobility within the blend.

3.2.2.2 Modes of Crystallization in Crystalline/Crystalline Blends

When dealing with miscible blends containing two crystalline components, several modes of crystallization are possible: separate crystallization, concurrent crystallization, cocrystallization, etc. Only those blends in which both components are miscible in the melt are considered here (Table 3.3). PET/PBT blends were reported to be an example of separate crystallization (Escala and Stein 1979;

Fig. 3.7 Dependence of the ring periodicity measured from POM micrographs as a function of crystallization temperature for PSMA14/PCL 30/70 and 20/80 (Balsamo et al. 2006)
Stein et al. 1981). A spherulitic crystallization was observed for the neat components as well as for blends with small amounts of one component, and the crystals of the minor component were included within the spherulites of the major component, which results in a coarsening of the spherulitic texture. Transesterification is, however, the reason for the homogenous amorphous phase.

Run et al. (2009) have recently shown that in the miscible blends of PET and PTT, PET component will crystallize first, and the formed crystallites serve as the nucleating agent for PTT crystallization at higher temperatures. The content of each component in the blend affects the crystallization growth rate of the other blend partner. PTT constitutes a diluting agent for the PET crystallization process. The spherulite's size, however, is much smaller than that of those formed in pure PTT. A completely different situation was reported by Chen et al. (2009) when the crystallization of miscible PET/PLA blend was considered. Due to the phenomenon of rigid amorphous fraction (RAF) formed by one component, the crystallization of the other partner is perturbed or even altered. PET can crystallize in all blends, regardless of whether PLA is amorphous or crystalline, and the degree of crystallinity of PET decreased as the fraction of PLA was increased in the blend. Whereas, the PLA crystallization is strongly affected by the mobility of the PET fraction. In the presence of an amorphous PET, PLA can crystallize, albeit weakly, even in a 70PLA/30PET blend. But when the PET is crystalline, PLA cannot crystallize below a 0.9 fraction in the blend. This phenomenon has been attributed of the ability of PET and PLA to form rigid amorphous fractions (RAF) which, like crystals, may inhibit the growth of crystals of the other blend partner.

A simultaneous (or concurrent) crystallization can only occur when the crystallization temperature ranges overlap and if the crystallizability of both blend's

[a]It should be noted that not all authors use the same terminology concerning the type of crystallization. Especially the terms "cocrystallization" and "concurrent crystallization" are often confused. Since some authors did not examine whether the lattice parameters change or not, it is not possible to decide if they mean cocrystallization or concurrent crystallization

[b]Depending on the blend preparation: cocrystallization when sequentially mixed and separate crystallization when simultaneously mixed

[c]Different molecular weight fractions

[d]Ethylene/propylene/1,4-hexadiene with an ethylene/propylene ratio of 4.5 mol%

[e]LLDPE: ethylene butene-1 copolymer, 18 branches/1,000 C

[f]Valid as well for slowly as rapidly (quenched) cooled blends

[g]DHDPE: deuterated HDPE

[h]LLDPE with a branching content of ca. 17 ethyl groups/1,000 carbons

[i]The lattice parameters vary continuously with composition of the blend, and the cocrystallization process is ascribed to the closeness of the crystallization rate of both species

[j]LLDPE with a branching content of ca. 41 ethyl groups/1,000 carbons

[k]The tendency to cocrystallize increases with increasing HDPE concentration

[l]Cocrystallization occurs when the blends are quenched rapidly from the melt (± 100 °C/min); separate crystallites are formed when isothermally crystallized, annealed at high temperatures, precipitated from solution, or slowly cooled from the melt (1 °C/min)

[m]$P(E)_{0.43}(K)_{0.57}$ is a random copolymer composed of phenyl ether and phenyl ketone units

[n]The type of crystallization depends on the thermal treatment of the samples: cocrystallization takes place in samples that are quenched or annealed at 110 °C for 6 h; separate crystallization is observed when annealed at 100 °C for 6 h. This is due to the existence of an UCST phase behavior between 100°C and 110 °C

[o]Copolymer of styrene and *p*-methyl styrene containing 30 mol% of the latter comonomer

[p]Miscibility of PBT/PEE depends on the copolymer composition of PEE, and cocrystallization occurs under all crystallization conditions and is possible because the unit cell parameters of PBT and PEE are the same. To avoid interchain chemical reactions, the blends were prepared by solvent casting

[q]EVAc has a molar ratio of ethylene to vinyl acetate of 7:1 and is amorphous, an increase of the lattice parameters was noticed when adding EVAc

components is similar. Cocrystallization is only possible when the components are isomorphic or miscible in the amorphous as well as in the crystalline phase. In both cases, mixed crystals can result, but in the case of concurrent crystallization, no changes in crystal structure may be induced. Cocrystallization requires chemical

compatibility, close matching of the chain conformations, lattice symmetry, and comparable lattice dimensions (Olabisi et al. 1979). Some examples of miscible polymer blends with two crystalline components are given in Table 3.3 together with the type of crystallization.

3.2.3   Spherulite Growth of the Crystallizable Component

3.2.3.1 Spherulite Growth Rate in Homopolymers

In the case of homopolymers, the growth rate of a lamellar crystal is controlled by two processes: on the one hand by the ability of forming a surface nucleus (determined by the degree of undercooling, $\Delta T = T_m{}^\circ - T_g$) and on the other hand by the ability of diffusion of the chain molecules toward the crystal growth front (determined by the difference between the crystallization temperature, T_c, and the glass-transition temperature, T_g). Both processes are inversely dependent on temperature; a maximum rate of crystal growth is usually observed at temperatures close to $T_{\max} \approx (T_g + T_m)/2$.

The growth rate kinetics of bulk semicrystalline homopolymers have been described in the past by Mandelkern et al. (1954) and Hoffman and Lauritzen (1976, 1973), using a modified version of the theory of nucleation of Turnbull and Fisher (1949):

$$G = G^\circ \exp[-\Delta E/R(T_c - T_o)]\exp[-\Delta F^*/k_B T] \tag{3.1}$$

G° is a constant dependent on the regime of crystallization, independent of temperature, and inversely proportional to the polymer molecular weight (Van Antwerpen and Van Krevelen 1972); T_o is the temperature at which motions necessary for the transport of molecules through the liquid-solid boundary cease; T_c is the temperature of crystallization; and k_B is the Boltzmann constant.

The rate of growth of a crystal, G, is governed by two processes: the activation energy required to transport crystalline molecules across the solid-liquid interface (ΔE) and the work necessary to form a critical nucleus (ΔF^*). At low supercooling, the growth rate is nucleation controlled, while at high supercooling, it is diffusion controlled; as a consequence, Eq. 3.1 produces a bell-shaped curve. Such a behavior for iPS (curve a) is shown in Fig. 3.8.

3.2.3.2 Spherulite Growth Rate in Miscible Polymer Blends

When dealing with crystallizable miscible polymer blends containing a noncrystallizable component, some refinements had to be made. Some modifications were proposed by Alfonso and Russell (1986) and by Cimmino et al. (1989) for blends in which the amorphous component is segregated into the interlamellar region (see also Sect. 3.2.2.1). First, the chemical potential of the liquid phase might be altered by the specific interactions that are often responsible for the miscibility of polymers (Olabisi et al. 1979). Such interactions may change the free energy required to form a critical nucleus as well as the mobility of both the crystalline and amorphous components. Second, the noncrystallizable component has to

Fig. 3.8 Spherulitic growth rate in iPS and iPS/PS blends (the values represent the percentage of atactic PS present in the blend) (Keith and Padden 1964)
diffuse away from the crystal growth front into the interlamellar region. Thus, the rate at which the growth front progresses depends on the competition between the inherent capability of the crystal to grow and on the rate of rejection (segregation) of the amorphous component. The kinetics of crystal growth will ultimately be determined by the slower of these two phenomena. A direct consequence of this consideration is the dependence of the crystal growth rate on the molecular weight of both components. Third, the concentration of the crystallizable component at the growth front will decrease during crystallization. And finally, the glass-transition temperature and the melting temperature can be influenced by addition of an amorphous polymer. As already mentioned in Sect. 3.2.1, the T_g of miscible blend lies in between the glass-transition temperatures of the neat components, its value being a function of the blend's composition. Depending on the T_g value of the noncrystallizable component (higher or lower than the T_g of the crystallizable component), the crystallization temperature range will be, respectively, narrowed or widened.

Incorporating the concepts discussed above, the equation describing the crystal growth rate in a miscible polymer blend can be expressed as

$$G_m = (\phi_2 k_1 k_2)/(k_1 + k_2)\exp(-\Delta F_m{}^*/k_B T_c) \tag{3.2}$$

ϕ_2 is the volume fraction of the crystallizable component; T_c is the crystallization temperature; k_1 is the rate of transport of the crystallizable molecules across the liquid-solid boundary:

$$k_1 = G° \exp[-\Delta E/R(T_c - T_o{}')] \tag{3.3}$$

$T_o{}'$ is the value of T_o in the blend and can be written in terms of the glass transition and a constant C (associated with the WLF constant C_2) (Rostami 1990); and k_2 is the rate at which the amorphous component segregates

$$k_2 = D/d = 2\overline{D}/L \tag{3.4}$$

d is the maximum distance over which the amorphous component has to diffuse away during crystallization ($d = L/2$, with L the crystal lamellae thickness), and D is the diffusion coefficient. Since a simultaneous diffusion of the amorphous and the crystalline component takes place, the diffusion coefficient of interest is the mutual diffusion coefficient, $\overline{D}$; $\Delta F_m{}^*$ is the free energy of nucleus formation (secondary nucleation) in the presence of a noncrystallizable component.

The rate of crystal growth in a semicrystalline blend, G_m, will depend on the magnitude of k_1, k_2, and $\Delta F_m{}^*$. At low undercooling, $\Delta T = T_m° - T_c$, $\Delta F_m{}^*$ is high and hence G_m is small. However, if the blend T_g approaches or exceeds the melting point ($T_m°$), k_2 can prohibit crystallization regardless of the value of $\Delta F_m{}^*$.

Table 3.4 refers to a number of crystallizable miscible polymer blends for which the spherulite growth rate as a function of the crystallization temperature has been investigated. For most blends, only a part of the bell-shaped curve could be measured. In Fig. 3.8, the complete bell-shaped spherulitic growth rate curve of iPS in iPS/PS blends containing 0, 15, and 30 wt% PS is shown. Due to the addition of impurity (e.g., the amorphous PS), a suppression of the growth rate is observed, which is greater than the concentration of the impurity added. Important parameters of the impurity added to the crystallizable component are the type, concentration, and molecular weight (Keith and Padden 1964).

By means of several optical techniques, viz., small-angle laser light scattering (SALLS), optical microscopy, etc., the spherulite structure can be studied. From the photographic scattering pattern, the spherulitic radius, R, can be calculated as a function of the crystallization time and/or blend composition (Stein 1964):

$$R = 4.1\lambda/4\pi\{1/\sin(0.5\ \theta_m)\} \tag{3.5}$$

θ_m represents the azimuthal angle of the intensity maximum; R the spherulite radius; and λ the light wavelength in the medium.

A general observation is a decrease of the spherulitic radius with increasing content of the amorphous polymer when a same crystallization time is used (see Fig. 3.9 and Table 3.5: PCL/PVC).

3.2.3.3 Determination of the Lateral and Fold Surface Free Energies from the Growth Rate

Alfonso and Russell (1986) related the different terms in Eq. 3.2 to the measurable or characteristic properties of the blend, which resulted in the following relation for blends in which the amorphous component segregated into the interlamellar regions:

$$G_m = \left\{\phi_2 G\degree \exp[-\Delta E / R(T_c - T_o{}')] 2\overline{D}/L\right\} / \left\{G\degree \exp[-\Delta E / R(T_c - T_o{}')] + 2\overline{D}/L\right\}$$
$$\exp\left\{(-2b\sigma\sigma_e)/\left(k_B T \Delta h_u f\left[1 - T_c/T_m\degree - RTV_{2u}\chi(1 - \phi_2)^2 / \Delta h_u f\, V_{1u}\right]\right)\right\} \quad (3.6)$$

where b is the thickness of a monomolecular layer; $\sigma\sigma_e$ is the product of the lateral and fold surface free energies; V_{iu} is the molar volume of component i; χ is the Huggins-Flory interaction parameter; and Δh_u is the heat of fusion per mole of monomer of the crystallizable component, the temperature dependence of which is taken into account by the parameter f:

$$f = \left[2T_c/\left(T_c + T_m\degree\right)\right] \quad (3.7)$$

Both $\sigma\sigma_e$ and χ are assumed to be independent of temperature and composition.
Fig. 3.9 Spherulite growth of PCL/Phenoxy blends at $T_c = 45\ ^\circ$C (Defieuw et al. 1989d)

In Eq. 3.6 the ratio $\overline{D}/G$, a modified version of the δ-parameter (Keith and Padden, 1963, 1964), appears. This length, relative to the thickness of the crystalline lamellae (L), is critical for the consideration of the crystal growth in crystallizable miscible polymer blends.

Equation 3.6 can be written as

$$\alpha = -\sigma\sigma_{ei}\beta \tag{3.8}$$

where

$$\begin{aligned}\alpha = \ln G_m - \ln\phi_2 - \ln G^\circ + \Delta E/R(T_c - T_o') \\ + \ln\{1 + [G^\circ L \exp[-\Delta E/R(T_c - T_o')]/2\overline{D}]\}\end{aligned} \tag{3.9}$$

and

$$\alpha = \ln G^\circ - (K_g/T_c\Delta Tf) \tag{3.10}$$

with

$$K_g = (n\, b\, \sigma\sigma_e T_m^\circ)/(\Delta h_u k_B) \tag{3.11}$$

Table 3.5 Maximum spherulite radius, R, as a function of crystallization time (t_c) and blend composition

where n is 2 or 4 depending on the regime of crystallization (Hoffman 1982; Ong and Price 1978b; Runt and Martynowicz 1986). The value of $n = 2$ refers to intermediate growth behavior (regime II), while the value of $n = 4$ corresponds with regime I and III in which low and high undercooling, respectively, is taking place. Furthermore, based on the WLF relation (Williams et al. 1955), the growth rate can be written as (Ong and Price 1978b)

Fig. 3.10 Plot of α versus $T_m/(T_c\Delta T)$ for various compositions of a PEG/PMMA blend (*triangles*, 100/0; *circles*, 90/10; *squares*, 80/20; *crosses*, 70/30; *filled circles*, 60/40) (Calahorra et al. 1982)
$$\alpha = \ln G^\circ - C_3\left\{T_m^\circ/T_c\left(T_m^\circ - T_c\right)\right\} \tag{3.12}$$

where

$$C_3 = (4\,b\,\sigma\sigma_e)/(k_B\,\Delta h_u) \tag{3.13}$$

Note that $K = C_3\,T_m$ when $n = 4$ (regime I or III)
and

$$\beta = (2b/k_B T_c)\left\{\left(\Delta h_u f\Delta T/Tm^\circ\right) - \left[RTV_{2u}\chi(1 - \phi_2)^2\right]/V_{1u}\right\}^{-1} \tag{3.14}$$

α contains parameters associated with the kinetic processes, while thermodynamic variables are met in β. If the product $\sigma\sigma_e$ is independent of the blend composition and temperature, then, according to Eq. 3.8, a curve of α versus β should produce a straight line, regardless of the concentration and molecular weight of the amorphous component. The slope of such a plot is a measure of the product $\sigma\sigma_e$.

Another way to rewrite Eq. 3.6 is (Cimmino et al. 1989)

$$\alpha = \ln G_m - \ln\phi_2 + C_1/[R(C_2 + T_c - T_o] - \left[\left(0.2T_m^\circ\ln\phi_2\right)/\left(T_m^\circ - T_c\right)\right] \tag{3.15}$$

Although equilibrium melting points, $T_m^\circ = T_c$, should be used in Eq. 3.13, generally the experimental T_m values are used.

Considering the Eqs. 3.11 and 3.13, a plot of α versus $1/(T_c\Delta Tf)$ and $T_m^\circ/(T_c\Delta T)$, respectively, should result in a straight line from which $\sigma\sigma_e$ can be obtained – see Fig. 3.10 where a plot of α as a function of $T_m^\circ/(T_c\Delta T)$ is shown.

The straight line in Fig. 3.10 represents a fit of Eq. 3.13 to the experimental values using the WLF constants, $C_1 = 17,250$ cal/mol and $C_2 = 72$ K (see Eq. 3.15), the latter value being higher than the true WLF value of 51.6. Other authors,

however, also had to use higher C_2 values to fit their growth rate data (Hoffman and Weeks [1962a](); Magill [1964](); Boon et al. [1968]()). The good fit in Fig. [3.10]() indicates that the temperature dependence of the spherulite growth rate of a crystallizable component in miscible blends is quite similar to that of homopolymers. It is also obvious from this figure that σ_e is independent of the concentration of the amorphous component (PMMA). Caution should be taken to generalize these data since (1) the high concentration diluent was not investigated and (2) the temperature range was near the melting point. The same observations were, however, made by Ong and Price ([1978b]()) and by Wang and Nishi ([1977]()).

3.2.3.4 Influence of the Molecular Weight of the Amorphous Component

Alfonso and Russell ([1986]()) found a significant curvature in the α versus β plots of PEG/PMMA blends (see Eq. [3.8]()) while they were linear for neat PEG. The curvature could be due to an increase of $\sigma\sigma_e$ with a decreasing temperature. These authors also studied the influence of the molecular weight of the amorphous component (PMMA) on the spherulite growth rate of PEG. Noteworthy is the discrepancy seen at low undercooling for one of the blends containing PMMA with a molecular weight corresponding to the critical molecular weight for entanglement. Superposing all data for different molecular weights (above the critical value) results in a true master curve (see Fig. [3.11]()), which shows that Eq. [3.8]() accounts quite well for the effect of molecular weight.

3.2.3.5 Influence of the Molecular Weight of the Crystallizable Component

Martuscelli ([1984]()) studied the influence of the molecular weight of the crystallizable component (PEG) on the spherulite growth rate of PEG/PMMA blend. In contrary to Calahorra et al. ([1982]()), they found that the fold surface free energy, σ_e, decreases with increasing PMMA content in the blend. It should be mentioned, however, that the molecular weight of PEG used by Calahorra is much higher ($M_w = 400$ kg/mol) compared to the PEG used by Martuscelli (2 and 10 kg/mol). The value of σ_e was seen to depend on the molecular weight of PEG (Martuscelli [1984]()), being smaller in the case of blends containing PEG with lower molecular weight (see Fig. [3.12]()).

Several authors (Ong and Price [1978b](); Alfonso and Russell [1986](); Runt and Martynowicz [1986](); Cimmino et al. [1989]()) used one of the equations mentioned above to calculate $G°$, σ, σ_o, and/or $\sigma\sigma_o$ (see Table [3.6]()). The following empirical relationship (Thomas and Staveley [1952](); Geil [1963](); Vidotto et al. [1969]()) was developed:

$$\sigma = 0.1\, b\, \Delta h_u \tag{3.16}$$

3.2.3.6 Influence of Copolymer Composition

The influence of the SAN copolymer composition on the spherulitic growth rate of PCL has been studied at a fixed crystallization temperature by

Fig. 3.11 Master curve of α
versus β for blends of PEG
(145) with PMMA (125) and
PMMA (525) (values between

content for PEG/PMMA
blends using two PEG
polymers differing in
molecular weight (2 and
10 kg/mol) (Martuscelli 1984)

Kressler et al. (1992, 1993). A minimum has been observed at about 20 wt% AN in
SAN for several compositions (see Fig. 3.13), due to a minimum in the value of the
interaction parameter, χ, at the same copolymer composition that is responsible for
a reduced chain mobility.

[a]Several molecular weight PEG polymers were used

[b]Other compositions have been studied too

[c]This parameter has been calculated using a modified version of Eq 3.16: $\sigma = 0.1\,(\Delta h_u)\,(a_o b_o)^{0.5}$, where $a_o = 5.43$ A, $b_o = 4.45$ A, and $\Delta h_u = 1.986 \times 10^6$ J/m³

[d]σ was calculated by Eq. 3.16, using $b = 4.65$ A (Vidotto et al. 1969)

[f]σ was calculated by Eq. 3.16, using $b = 4.38$ A and $\Delta h_u = 1.48 \times 10^{+8}$ J/m³

[g]Since all compositions could be superposed on one straight line in the α versus $T_m/T\Delta T$ plot, all blend compositions have the same value for $G°$, σ, σ_e, and $\sigma\sigma_e$

[h]SAN with 19.5% AN; other copolymers have been used by the author leading to the same tendencies

[i]The first value is calculated from the spherulitic growth rate data of PEG(10)/PMMA, the second one from the overall crystallization data of PEG(10)/PMMA, and the third one from the spherulitic growth rate data of PEG(2)/PMMA (Martuscelli and Demma 1980) (the value between brackets refers to the molecular weight of PEG in kg/mol)

[j]This parameter has been calculated using Eq. 3.16 where $b_o = 4.65$A and $\Delta h_u = 2.13 \times 10^6$ J/m³ (Van Krevelen 1976)

Fig. 3.13 Dependence of the spherulite growth rate G on the copolymer composition of SAN in PCL/SAN blends at 45 °C (Kressler et al. 1992, 1993)
Fig. 3.14 Values of $(\sigma\sigma_e)^{1/2}$ versus the copolymer composition of SAN in PCL/SAN blends (Kressler et al. 1992, 1993)
The same authors also investigated the influence of the copolymer composition of SAN in PCL/SAN blends on $G°$ and $(\sigma\sigma_e)^{1/2}$. The plot of $(\sigma\sigma_e)^{1/2}$ versus the acrylonitrile content in SAN shows a minimum (Fig. 3.14), suggesting that the addition of SAN results in a stabilization of the growing PCL crystallites. This effect was more pronounced when the interactions between SAN and PCL, indicated by χ, are more favorable. Since $G°$ is proportional to $\left|\chi - \chi_s\right|$ (Saito et al. 1991), with χ_s the interaction parameter at the spinodal, a minimum was also noticed in the $G°$ versus the copolymer composition of SAN (see Figs. 3.14 and 3.15).

Fig. 3.15 The pre-exponential factor G° SAN in PCL/SAN blends (Kressler et al. 1992, 1993)
3.2.3.7 Other Aspects Related to Crystallization in Miscible Blends

(a) Chen et al. (2001) are among the few authors who considered the study of the effect of chain branching on the crystallization behavior of polyethylenes blends. Simple DSC techniques were used to differentiate, in terms of crystallization and melting, between blends of LDPE and VLDPE containing short branches. A stepwise isothermal crystallization was applied to thermally fractionate species based on their branching densities. The fractionated curves were used to determine the short-chain branching distribution, crystallization, and miscibility of the blends. When the two blend partners have similar unbranched segments, they may cocrystallize provided miscibility exists in the melt. Cocrystallization was found in all series of blends investigated but to varying extent depending on the branches densities of each blend couple.

(b) Svoboda et al. (2008) by choosing PCL/SAN containing 27.5 wt% AN could elucidate an interesting phenomenon of the competition between the phase dissolution and the crystallization of PCL in the blend. The authors qualified the crystallization as the liquid-solid phase transition and the phase dissolution as the liquid-liquid phase transition. A blend of 80/20 PCL/SAN phase separates via spinodal decomposition (SD) above the LCST, yielding a regularly phase-separated SD structure. By quenching a sample at temperatures below the Tm of the crystallizable PCL component, it was possible to have both crystallization and phase separation. TEM observations revealed that during isothermal annealing (after quenching to temperature as 51 °C close to T_m of PCL), the SD structure disappeared, and then the crystallization started from a single-phase mixture to yield normal crystalline structure similar to a neat PCL phase. At lower temperatures (e.g., 40 °C), crystallization set in quickly, and the SD was preserved implying the crystallization prevailed over the dissolution process, resulting in a bi-continuous structure consisting of amorphous (SAN-rich) and crystalline (PCL-rich) regions. At intermediate temperatures (e.g., 45 °C), the phase dissolution competed with the crystallization,

Fig. 5.16 Crystallization isotherms for the PEG/PEMA 80/20 blend crystallized at different T_c (Cimmino et al. 1989)
resulting in a bi-continuous structure with longer periodic distance and a broad boundary having a gradient in composition of amorphous region between PCL lamellae crystals.

3.2.4   Overall Crystallization Kinetics

3.2.4.1 General Aspects of the Avrami Theory Under Isothermal Conditions

The overall crystallization kinetics of blends can often be described by the Avrami equation (Avrami 1939):

$$\alpha = 1 - \exp\{-kt^n\} \tag{3.17}$$

α is the weight fraction of crystallinity at time t, n is the Avrami index depending on the type of nucleation and the crystal growth geometry, and k is the Avrami constant related to the crystallization rate:

$$k = \ln\left(2/t^n_{1/2}\right) \tag{3.18}$$

where $t^n_{1/2}$ is the halftime of crystallization (the time for half the crystallinity to develop), which is often used as a measure for the overall rate of crystallization. The theory was applied to polymer systems, e.g., by Morgan (1954) and Mandelkern et al. (1954).

In Fig. 3.16 typical crystallization isotherms were obtained by plotting α versus the crystallization time for the PEG/PEMA 80/20 blend at different crystallization temperatures. From such curves, the halftime of crystallization, $t^n_{1/2}$, can be deduced.

Equation 3.17 can be rewritten as

$$\log\{-\ln(1-\alpha)\} = \log k + n\log t \tag{3.19}$$

Plotting the left part of this equation against log t should result in a straight line, from which both Avrami parameters, n (slope) and k (intercept), can be obtained.

In Table 3.7 some literature data on the Avrami constants and the halftime of crystallization are presented. The Avrami n index (smaller than three for all the crystallization temperatures studied) of PCL/PBT system as investigated recently by Righetti et al. (2007) suggests a not fully three-dimensional crystalline growth. For the calculation of the crystallization growth rate, the authors plotted the reciprocal of the crystallization time needed to reach 20 % (and not half) of the crystallinity as a function of undercooling. As illustrated in Fig. 3.17, the dependence of the crystallization rate on the PCL molecular weight for both miscible and phase-separated PBT/PCL 80/20 blends, at the undercoolings accessible to DSC, parallels perfectly the trends exhibited by the linear growth rate curves that refer to lower undercoolings. Indeed and in contrast to many miscible systems, the low molecular weight PCL induces an increase in the crystallization rate of the PBT because of the higher molecular mobility the PCL oligomer causes as a plasticizer.

Cimmino et al. (1989) calculated the halftime of crystallization ($t_{1/2}$) for some PEG blends, PEG/PEMA, PEG/PVAc, and PEG/PMMA, using the same blend composition and the crystallization temperature. Blends of PEG with PVAc had the smallest $t_{1/2}$, while the PEG/PEMA blends showed the highest values for the halftime of crystallization. The type of amorphous component added to PEG seems to be important. The differences observed in $t_{1/2}$ (and also in the values of G) depend on:

– The degree of miscibility and mobility of the crystallizable and amorphous components
– The influence of the amorphous component on the nucleation of PEG
– Influence of the noncrystallizable component on the secondary nucleation or the crystallization regime (neat PEG and PEG/PEMA crystallize in regime I, whereas PEG/PVAc and PEG/PMMA crystallize in regime II)

Adding PMMA to PEG results in a decrease of $k = \ln 2/t^{n}_{1/2}$ (see Eq. 3.18), an effect that is clearly seen in Fig. 3.18 where $1/t_{1/2}$ is plotted against crystallization temperature (Martuscelli et al. 1984).

3.2.4.2 Modified Avrami Expression

It was often found that, contrary to the theoretical prediction, the value of n is noninteger (Avrami 1939). The Avrami model is based on several assumptions, such as constancy in shape of the growing crystal, constant rate of radial growth, lack of induction time, uniqueness of the nucleation mode, complete crystallinity of the sample, random distribution of nuclei, constant value of radial density, primary nucleation process (no secondary nucleation), and absence of overlap between the growing crystallization fronts. These assumptions are often not met in polymer (blend) crystallization. Also, erroneous determination of the "zero" time and an overestimation of the enthalpy of fusion of the polymer at a given time can lead to noninteger values for n (Grenier and Prud'homme 1980).

Pérez-Cardenas et al. (1991) developed a modified Avrami expression, taking into account the secondary crystallization effects. The weight fraction of crystallinity, α, can be written as the sum of two terms:

Table 3.7 Overall kinetic rate constant, k; Avrami index, n; and halftime of crystallization, $t^n_{1/2}$; as function of the crystallization temperature and blend composition for some crystallizable miscible blends

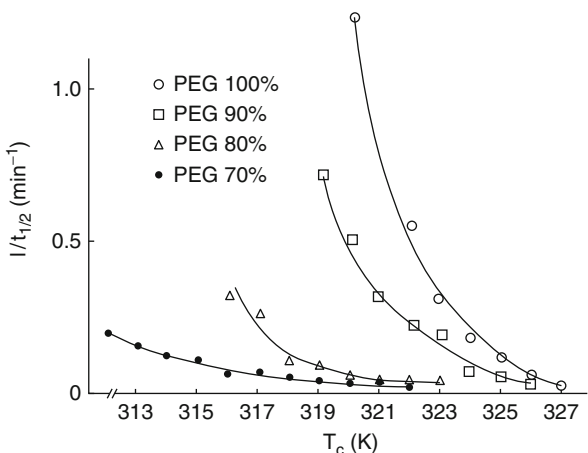
[b]The halftime of crystallization is expressed in seconds (!)
[c]The overall kinetic rate constant is expressed in $\min^{-n}$ (!)

Fig. 3.17 Reciprocal of the time needed to reach 20 % of the final crystallinity ($1/\tau 0.2$) for PBT and PBT/PCL blends, plotted as a function of the undercooling. The *lines* are a guide for eyes (Righetti et al. 2007)
Fig. 3.18 Reciprocal of the halftime of crystallization, $t_{1/2}$, versus T_c for neat PEG (10) and PEG (10) blends with PMMA (the value between brackets refers to the molecular weight of PEG in kg/mol) (Martuscelli 1984)


$$\alpha = \alpha_p + \alpha_s \qquad (3.20)$$

where the subscripts "*p*" and "*s*" refer to primary and secondary crystallization, respectively.

The crystallization process is divided in three regions (Fig. 3.19): (I) the initial primary crystallization region, (II) a region in which both primary and secondary crystallization takes place, and finally (III) a region in which only secondary crystallization occurs.

A parameter, ζ, was introduced, which is the weight fraction of the polymer crystallized by primary and secondary crystallization at the moment that the primary crystallization has ended (end of region II). The whole crystallization process is then described by two equations:

Fig. 3.19 Comparison between a typical experimental crystallization isotherm (*solid line*) and the Avrami equation (Eq. 3.17, *broken line*). The three regions I, II, and III correspond to primary, primary and secondary, and secondary crystallization, respectively (Pérez-Cardenas et al. 1991)
$$1 - \alpha = \exp\left(-kt^{n} - k't^{n'}\right)\left[kn(1 - \zeta)\int_{o}^{t}\exp\left(k\tau^{n} + k'\tau^{n'}\right)\tau^{n-1}d\tau + 1\right] \quad (3.21)$$

$$1 - \alpha = (1 - \zeta)\exp(k't^{*n'})\exp\left(-k't^{n'}\right) \quad (3.22)$$

Equation 3.21 is valid for $\alpha \leq \zeta$ and Eq. 3.22 for $\alpha > \zeta$. Instead of two Avrami parameters, five parameters are required to describe the process. They have the following physical meaning: k and n (the primary crystallization parameters) depend on crystallization temperature, nature of primary nucleation, and the fast growth; the secondary crystallization parameters, k' and n', depend on the conditions under which the slow crystallization of the remaining amorphous regions takes place; and a fifth parameter, ζ, indicates the weight fraction of material crystallized up to the moment the primary crystallization ends. t^* is the moment at which the third region starts (e.g., pure secondary crystallization).

Some literature data concerning isothermal crystallization experiments of linear PE at 128 °C (Doremus et al. 1958) have been fitted using different values for the parameters in Eqs. 3.21 and 3.22 (Fig. 3.20). The most accurate fit was obtained using the following parameters: $n = 4$, $k = 3.7 \times 10^{-10}$, $n' = 2$, $k' = 4 \times 10^{-6}$, and $\zeta = 0.68$.

Fig. 3.20 Theoretical isotherms (*solid lines*) using Eqs. 3.21 and 3.22 for three different sets of values of the five parameters (Pérez-Gardenas et al. 1991) fitted to the experimental values (*points*) of Doremus et al. (1958)
In the case of miscible polymer blends, the temperature dependence of the overall kinetic rate constant, k, can be calculated from (Boon and Azcue 1968; Wunderlich 1973; Hoffman 1982)

$$1/n \ln k - \ln \phi_2 + \Delta E / \{R(T_c - T_o)\} - \{(0.2 T_m^\circ \ln \phi_2)/\Delta T\} = \alpha_2$$
$$= \ln A_n - \{K_g / T_c \Delta T f\} \tag{3.23}$$

with K_g the same as in Eq. 3.12

3.2.4.3 Determination of the Surface Free Energy of Folding from Overall Kinetic Data

A plot of α_2 versus $1/(T_c \Delta T f)$ results in a straight line and from the slope, values of σ_e can be obtained. In Table 3.8 and Fig. 3.21, the free energy of folding, σ_e, for some PEG/PEMA and PEG/PMMA blends, respectively, derived from the overall kinetics of crystallization (Eq. 3.23), is compared with the values obtained from the radial growth rate data (Eq. 3.11). The compositional dependence of σ_e derived from both methods is similar, although higher values were obtained using Eq. 3.23 (overall kinetics of crystallization).

The σ_e values obtained from both analyses almost coincide. The dependence of σ_e on the composition of the PEG/PMMA blends may be partly accounted for by the effect of concentration, since the concentration-dependent part of σ_e is only a few joule per square meter (Martuscelli 1984). It is possible that PMMA molecules located in the interlamellar regions easily form entanglements with PEG molecules, favoring the formation of large loops on the surface of the PEG crystals.

Table 3.8 Free energy of folding (σ_e) for some PEG/PEMA blends calculated using Eqs. 3.11 and 3.23

Polymer blend	Composition (wt%)	σ_e ($\times 10^3$J/m^2) (Eq. 3.11)	σ_e ($\times 10^3$J/m^2) (Eq. 3.23)	References
PEG/PEMA	100/0	58	75	Cimmino et al. (1989)

	80/20	24	34	
	70/30	14	29	
PEG/PMMA	100/0	58	60	Martuscelli et al. (1984)
	90/10	43	48	
	80/20	38	39	
	70/30	36	39	
	60/40	36	37	
Fig. 3.21 Surface free energy of folding, σ_e, versus the volume fraction of the crystallizable component, ϕ_2, for blends of PEG (10) with PMMA from spherulite growth rate data (*circles*) and from overall rates of crystallization data (*triangles*) (the value between brackets refers to the molecular weight of PEG in kg/mol) (Martuscelli et al. 1984)

This can lead to an increase of both the surface enthalpy and the entropy of folding which contribute to σ_e ($\sigma_e = H_e - TS_e$). The decrease of σ_e when adding PMMA suggests that the entropic term overwhelms the enthalpic one.

3.2.4.4 Nonisothermal Kinetics

The theory of Avrami is limited to isothermal processes. Since polymer processing is mostly performed under nonisothermal conditions, the theory has been extended (Ziabicki 1967; Ozawa 1971; Ziabicki 1976).

According to Ozawa ([1971](#)), the crystallinity at any temperature is given by

$$-\ln(1 - \alpha) = C(t)/q^{n''} \tag{3.24}$$

where q is the heating or cooling rate; $C(t)$ is a cooling function of the process; and n'' is the Ozawa exponent.

Ziabicki ([1967](#), [1976](#)) based his analysis on the assumption that any nonisothermal process can be treated as a combination of several isothermal crystallization steps:

$$E(t) = kt^n = \ln2\left\{\int_0^t ds/t_{1/2}[\alpha(s)]\right\}^n \tag{3.25}$$

This equation is an analogue of Eq. [3.18](#).

Under nonisothermal conditions, the ultimate Avrami parameters will be averages of the parameters of the subsequent steps.

Gupta et al. ([1994](#)) used the following equation, based on the theory described by Ziabicki ([1967](#), [1976](#)) and by Kamal and Chu ([1983](#)), to describe the nonisothermal behavior of cocrystallizing HDPE/LLDPE blends.

$$\left[\alpha_p' \left(T_p - T_{ons}\right)\right]/\left[\beta\left(1 - \alpha_p\right)\right] = (n - 1) - \left[E\left(T_p - T_{ons}\right)\right]/\left[RT_p^2\right] \tag{3.26}$$

where $\alpha' = d\alpha/dt = nkt^{(n-1)}\left(1 - \alpha\right)$ and β is the heating rate. In the case of a cooling experiment, β will be negative and β should be replaced by $-\beta$ in the equation.

T_{ons} is the onset temperature and T_p is the temperature after time t $(T_p - T_{ons} = \beta t)$, where the subscript "p" denotes the peak temperature and E is the activation energy of the crystallization process.

A plot of the left part of Eq. [3.26](#) against $(T_p - T_{ons})/T_p^2$ should be linear with slope and intercept equal to E/R and $(n - 1)$, respectively (see Fig. [3.22](#)). The quantity α was evaluated from the ratio of the area under the crystallization peak per unit mass of the sample. α_p is the extent of crystallization at the peak maximum and is determined by the fractional area under the exotherm from the onset temperature T_{ons} to the peak temperature T_p relative to the total area under the exotherm.

The Avrami exponent and the activation energy decrease with increasing LLDPE content (see Table [3.9](#)).

The authors suggested that the Avrami constant could be seen as the sum of two processes: a contribution due to nucleation and a contribution due to growth:

$$n = n_{\text{ucleation}} + n_{\text{growth}} \tag{3.27}$$

Since both components cocrystallize (Edward [1986](#); Hu et al. [1987](#); Gupta et al. [1994](#)), the crystalline growth can be considered to be identical. As a consequence, the differences seen in the Avrami exponent, n, in the blends

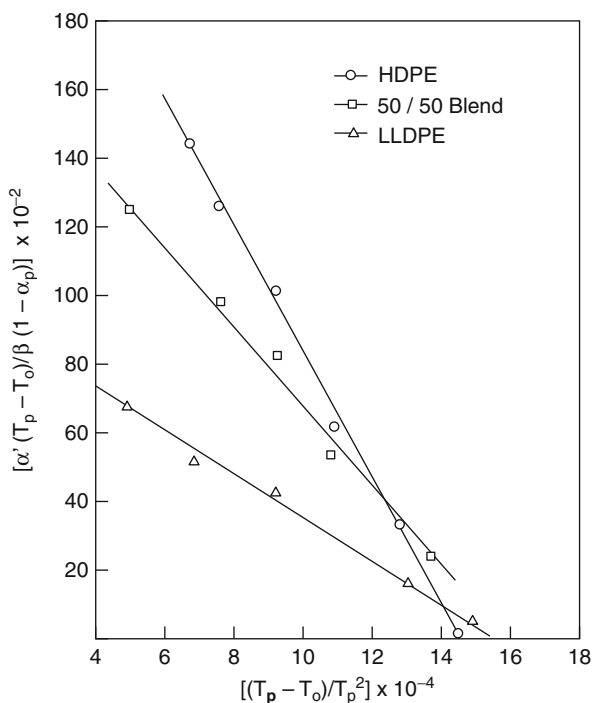
Fig. 3.22 Plot of $[\alpha_p' (T_p - T_o)]/[\beta (1 - \alpha_p)]$ versus $(T_p - T_o)/T_p^2$ for HDPE, LLDPE, and the 50/50 blend (Gupta et al. 1994)


Table 3.9 Avrami exponent, n, for HDPE, LLDPE, and their blends

Blend composition (wt%)[a] HDPE/LLDPE	Avrami exponent, n	Activation energy, E (kJ/mol)
100/0	2.94	121.67
75/25	2.65	99.44
50/50	2.30	85.83
20/80	1.93	59.04
0/100	1.72	49.16

[a]More compositions were mentioned in the article (Gupta et al. 1994)

must be due to a difference in the nucleation behavior that depends on the blend composition. A value varying from 0 (instantaneous nucleation) to 1 (sporadic nucleation) was attributed to the contribution of the nucleation of LLDPE and HDPE, respectively, to the Avrami constant, n. The remaining part of n (e.g., 1.94 for HDPE and 1.74 for LLDPE) represents the value for the growth process.

The lower activation energy for LLDPE compared to HDPE seems to be due to a storage of thermal energy by the crystallites caused by the presence of bulky pendant groups at the crystalline boundary that exert repulsive forces. Cocrystallization enhances these forces due to the greater abundance of the bulky groups that results in a decrease of the activation energy.

3.2.5   Melting Behavior of Crystallizable Miscible Blends

3.2.5.1 The Equilibrium Melting Temperature in Miscible Blends: Hoffman-Weeks Plot

In a semicrystalline homopolymer, the change in free energy of melting per mole of monomer unit is given by

$$\Delta G_u(T) = \Delta H_u - T\Delta S_u \tag{3.28}$$

where ΔH_u and ΔS_u are the enthalpy and the entropy changes on melting, respectively. For blends, the difference in free energy of the crystalline unit can be written as (Sanchez and Di Marzio 1971)

$$\Delta G_{ub}(T) = \Delta G_u(T) + \Delta g_M = \Delta H_u - T\Delta S_u + \Delta h_M - T\Delta s_M \tag{3.29}$$

where $\Delta G_u(T)$ has the same meaning as in Eq. 3.28, i.e., the heat of fusion of the crystalline component in the blend is assumed to be equal to that of the homopolymer. For athermal blends ($\Delta h_M = 0$) Eq. 3.29 becomes

$$\Delta G_{ub}(T) = \Delta H_u - T\Delta S_u - T\Delta s_M = \Delta H_u - T\Delta S_{ub} \tag{3.30}$$

For an infinitely thick crystal with an equilibrium melting temperature in the blend of $T_{mb}°$, $\Delta G_{ub}(T_{mb}°)$ is equal to 0 and

$$T_{mb}° = \Delta H_u/\Delta S_{ub} \tag{3.31}$$

substituting Eq. 3.31 into Eq. 3.30 results in

$$\Delta G_{ub}(T_{mb}) = \Delta H_u(1 - T_{mb}/T_{mb}°) - T_{mb}\Delta s_M \tag{3.32}$$

At T_m:

$$\Delta G_{ub}(T_{mb}) = 2(\sigma_{eb}/n_b) \tag{3.33}$$

Combining and rearranging Eqs. 3.32 and 3.33 gives a relation between the experimental and equilibrium melting point in athermal polymer blends:

$$1/T_{mb} = \{1/T_{mb}° + \Delta s_M/\Delta H_u\}\{1/[1 - (2\sigma_{eb}/\Delta H_u n_b)]\} \tag{3.34}$$

with $\sigma_{eb} = \phi_1^{\alpha} \sigma_e$ and $n_b = (1 - \phi_1)^{\beta} n$ with α and β constants which need to be evaluated for each system (Cimmino et al. 1988). For $\Delta s_M \to 0$, the dependence can be simplified to

$$T_{mb} = T_{mb}°[1 - (2\sigma_{eb}/\Delta H_u n_b)] \tag{3.35}$$

If the heat of mixing is not ignored ($\Delta h_M \neq 0$), then the same treatment of Eq. 3.29 as used to obtain Eq. 3.35 results in

Fig. 3.23 Hoffman-Weeks plot for PCL-rich PCL/PC blends (the data are displaced by 5 °C to discern the different blend compositions) (Jonza and Porter 1986)
$$T_{mb} = T_{mb}°\{1 - [(2\sigma_{eb}/\Delta H_u n_b) + (\Delta g_M/\Delta H_u)]\} \tag{3.36}$$

This equation is a general form of the relation between the experimental and equilibrium melting temperature of the blend.

The equilibrium temperature of a polymer (blend) can experimentally be determined by a Hoffman-Weeks plot, which is a plot of the experimental melting point versus the crystallization temperature (T_m vs. T_c) as presented in Fig. 3.23. Extrapolation from experimental data to the $T_m = T_c$ line results in the value of $T_{mb}°$.

The influence of T_c on T_m is due to morphological contributions such as degree of perfection and the finite size of crystals (Hoffman and Weeks 1962b; Mandelkern 1964). If the crystals are perfect, of finite size and no recrystallization takes place during the melting, the T_m versus T_c data can be described by Nishi and Wang (1975)

$$T_m° - T_m = \phi(T_m° - T_c) \tag{3.37}$$

or

$$T_m = T_m°(1 - \phi) + \phi T_c \tag{3.38}$$

$T_m°$ and T_m are the equilibrium and observed melting point, respectively; ϕ is the stability parameter that depends on the crystal thickness and assumes

Fig. 3.24 Hoffman-Weeks plot for PVDF/PMMA blends with 50.1 vol% of PVDF (Stein et al. 1981)

values between 0 and 1 (sometimes ϕ is replaced by $1/\gamma$, where γ is the thickening factor of the crystal).

The value of $\phi = 0$ implies $T_m = T_m^\circ$ for all T_c, whereas $\phi = 1$ implies $T_m = T_c$. Therefore, the crystals are most stable at $\phi = 0$ and inherently unstable at $\phi = 1$. Nishi and Wang (1975) examined the polymer system PVDF/PMMA and found a value for $\phi = 0.2$ for all compositions studied, which suggests that the crystals are fairly stable. A comparable value has been found for other polymer crystals (Hoffman and Weeks 1962b).

The same polymer blend was studied by Stein et al. (1981), Morra and Stein (1984). Since PVDF crystallizes into several types of morphologies, different lines are shown in the Hoffman-Weeks plot (Fig. 3.24). The curve representing the melting point of PVDF as a function of the crystallization temperature for the α modification shows a break that was associated with defect exclusion from the crystal (Stein et al. 1981) and by entrapment of head-to-head defects of the PVDF chains into the crystals during rapid crystallization at large undercooling (Morra and Stein 1984).

Hoffman-Weeks plots have also been drawn for several other amorphous/crystalline miscible blends, such as PVDF/PEMA (Eshuis et al. 1982), PEG/PMMA (Martuscelli 1984), PCL/SARAN (Zhang and Prud'homme 1987), as well as for some miscible blends containing two semicrystalline components, PCL/PC (Jonza and Porter 1986) and PCL/Penton (Guo 1990). Table 3.10 represents equilibrium melting points derived from T_m versus T_c plots for some of these systems.

In Fig. 3.25 Hoffman-Weeks plot for PCL/PBT blends is compared to pure PBT sample. A nonlinear extrapolation procedure was applied for the determination of the equilibrium melting temperature of the crystallizing phase. The linear extrapolation as proposed initially by Hoffman-Weeks neglects the contribution of the increment of the lamellar thickness. Note that the PCL is miscible with PBT only when the PCL molecular weight is equal or lower than MW = 1,250. The blend samples having a PCL molecular weight of 10,000 or 50,000 form immiscible mixture for which the crystallization behavior of pure PBT is recovered. The T_m° of

[b]Both polymers crystallize in this blend, but no $T_m - T_c$ plots could be made for PC since the blends are reactive at the higher crystallization temperatures required for this component
[c]Both polymers crystallize in this blend

Fig. 3.25 Melting temperature of non-thickened crystals ($\beta = 1$) as a function of T_c for PBT and PBT/PCL blends. The *curved* lines are the nonlinear fit to the experimental data. The *straight* line $T_m = T_c$ is also depicted. The *inset* shows an enlargement of the plot (Righetti et al. 2007)
the PBT/PCL1250 is equal to 501 °K, much lower than that of pure PBT (522 °K) or its blends with higher MW PCL samples (PCL10000: $T_m° = 519$°K; PCL50000: $T_m° = 521$ °K).

It should, however, be noted that several blends do not show a linear T_m versus T_c relation (Rim and Runt 1984; Jonza and Porter 1986). The absence of linearity originates from several effects, such as recrystallization, crystal defects, etc.

Fig. 3.26 Schematic diagram of the free energy of a crystalline phase (G_c) and the free energy of a melt phase of a homopolymer (G_m°) and a miscible blend (G_{mb}°) as function of the temperature
3.2.5.2 Melting-Point Depression

The melting behavior of a semicrystalline component in a miscible blend strongly depends on the blend composition. In several blends, a depression of the melting point has been observed after addition of an amorphous polymer. This behavior results from the kinetic, morphological, and thermodynamic factors (Cimmino et al. 1989). *Kinetic* effects originate from the crystal formation at temperatures below the equilibrium melting point. They can be avoided by using equilibrium values derived from Hoffman-Weeks plots. Melting-point depression, caused by *morphological* effects (see Eq. 3.38), is associated with changes in crystal thickness, perfection and geometry, as well as different thermal histories of the samples. When a miscible diluent is added to a semicrystalline polymer, the equilibrium melting point of the crystallizable component can be depressed due to interaction between both components. The free energy of the crystallizable component will decrease from G_m° to G_{mb}°, when the crystallites are surrounded by a mixed melt phase. The free energy of the crystalline phase, G_c, is not affected by mixing. The melting temperature, defined as the cross section of G_c and G_m (e.g., when $\Delta G = 0$), may be depressed (Fig. 3.26).

The melting-point depression resulting from *thermodynamic* effects can be described by the following equation (Flory 1953; Nishi and Wang 1975):

$$\left(1/T_{mb}^\circ\right) - \left(1/T_m^\circ\right) = -[(RV_{2u})/(\Delta h_u V_{1u})]$$
$$\left[(\ln\phi_2/m_2) + (1/m_2 - 1/m_1)(1 - \phi_2) + \chi_{12}(1 - \phi_2)^2\right] \tag{3.39}$$

T_{mb}° and T_m° are the equilibrium melting point of the blend and the neat crystallizable component, respectively; V_u is the molar volume of the repeating unit of the components (1 = amorphous component and 2 = crystallizable component); Δh_u is the heat of fusion per mole of repeating unit; m is the number of units in the molecule, i.e., the degree of polymerization; ϕ is the volume fraction; and χ_{12} is the polymer-polymer interaction parameter.

Since, for polymers $m \to \infty$, Eq. 3.39 can be reduced to

$$\left(1/T_{mb}^{\circ}\right) - \left(1/T_{m}^{\circ}\right) = -[(RV_{2u})/(\Delta h_u V_{1u})]\chi_{12}(1 - \phi_2)^2 \qquad (3.40)$$

Instead of χ_{12}, the interaction energy density, B_{12}, can be used; both parameters are related by

$$\chi_{12} = B_{12}V_{1u}/RT \qquad (3.41)$$

Melting-point depression data are often used to determine the Huggins-Flory interaction parameter, χ_{12} (see Table 3.11), that is a measure for the miscibility of the blend, i.e., χ_{12} is negative for a miscible blend. A lack of melting-point depression means that χ_{12} is zero. Equation 3.39 is only valid for systems in which the crystalline morphology is not affected by the composition.

Many authors (Hay 1976; Kwei and Frisch 1978; Rim and Runt 1984; Plans et al. 1984; Alfonso and Russell 1986), however, encountered difficulties when fitting Eq. 3.40 to their experimental data, due to (Rostami 1990):

– The use of observable melting temperatures instead of the thermodynamic equilibrium temperatures.
– The plot of the left-hand side of Eq. 3.40 versus the right-hand side has no zero-intercept. The intercept contains information about the crystalline morphology (Kwei and Frisch 1978; Walsh et al. 1985) that has been ignored. Following Eq. 3.39 the intercept should equal $1/m_1$. When high molecular weight polymers are used, $1/m_1$ equals zero. This was observed for PVDF/PMMA and PVDF/PEMA blends (Kwei and Frisch 1978).
– The concentration dependence of the interaction parameter adds a restriction on plotting the left-hand side of Eq. 3.40 versus ϕ_1 to obtain a single value for χ_{12} (Kwei and Frisch 1978; Plans et al. 1984; Walsh et al. 1985).

A modified version of this equation has been used by some other authors (Kwei and Frisch 1978; Walsh et al. 1985), who added a constant that is related to the morphology of the crystalline region:

$$\Delta h_u\left(T_m^{\circ} - T_{mb}^{\circ}\right)/\phi_1 RT_m^{\circ} - T_{mb}^{\circ}/m_1 - \phi_1 T_{mb}^{\circ}/2m_2 = C/R - b\phi_1 \qquad (3.42)$$

where C is a constant taking into account the morphological contributions (which were assumed to be proportional to ϕ_1) and b is a constant derived from the equation relating the interaction parameter with temperature: $\chi_{12} = a + b/T$ with $a \ll b/T$ near the melting point. This approach was, however, not satisfactory (Walsh et al. 1985).

It should be noted that in Eq. 3.42 the assumption of infinite molecular weights has not been included as was done in Eq. 3.40.

Balsamo et al. (2006) presented a nice comparison in Fig. 3.27 of the effect of equilibrium melting-point depression in miscible blends of PCL with various partners including PVC, PSMA14 (14 wt% MA), Phenoxy, and SAN19,5 (19,5 wt% AN). It is clear that PSMA14 caused the greatest depression of the T_m° of PCL compared to the other partners. The authors ascribed this effect to the

highest interaction PCL develops with PSMA14 and that hinders the formation of perfect and complete lamellae. The peak temperature was used for the calculations instead of the onset due to the presence of a low melting endotherm that introduces some error in the determination of the onset of the melting point corresponding to the primary crystallization. Using at least eight experimental points, a linear dependence was observed in the T_c range used in this work. Thus, the extrapolation to $T_c = T_m$ by a linear least squares fit could be performed to calculate T_m°. For neat PCL, a T_m° of 69.9 °C, was observed in agreement with values reported in the

[a]The absolute value of χ_{12} is too large in comparison with the other literature data on miscible blends. The authors (Martuscelli et al. 1984) suggested that for this blend non-negligible entropic effects occur during mixing of the two polymers, noncompliance with the assumption inherent in the extrapolation of T_m (observed melting point) by using the Hoffman-Weeks plot and the inadequacies of the Huggins-Flory theory to describe the melting behavior of such polymer-polymer system

literature (Balsamo et al. 2001; Wang and Jian 1997; Jonza and Porter 1986; Neo and Goh 1991). The melting-point depression exhibited by the PCL fraction with increasing PSMA14 (68.3 ± 2.2 °C and 64.2±1.4 °C for PSMA14/PCL 10/90 and 30/70, respectively) indicates miscibility between PCL and PSMA14 as was previously discussed from the standard DSC scans.
Fig. 3.28 Schematic representation of the melting mechanism proposed to account for the heating rate dependence of recrystallizing material. The *top* of the figure shows the melting of the original crystals (M), recrystallization (C), and remelting (M_r). The *bottom* portion of the figure shows the resultant thermograms that are experimentally observed (Rim and Runt 1983)

For some miscible blends, a melting-point elevation has been reported with respect to that of the neat crystallizable component, both crystallized at the same temperature (Eshuis et al. 1982; Rim and Runt 1983, 1984). These observations may originate from recrystallization, enhanced crystal perfection, and increased crystal size.

3.2.5.3 Multiple Melting Endotherms

The melting behavior of binary crystallizable blends often reveals multiple melting endotherms that can be ascribed to recrystallization, secondary crystallization effects, phase separation, etc.

Recrystallization is a process in which the initial, rather imperfect, lamellae melt and recrystallize to produce thicker and more perfect lamellae that as a consequence melt at a higher temperature. As a result of this process, a double melting behavior may be observed. Recrystallization has been observed for neat polymers and blends.

A method that is often used to determine if the dual melting behavior is caused by recrystallization is the variation of the heating rate in DSC experiments. It is suggested that during the DSC run, an annealing of the crystalline lamellae occurs (see Fig. 3.28; Rim and Runt 1983). At slow heating rates, the original crystals are given sufficient time to reorganize, and the melting behavior is then mainly caused by lamellae originating from recrystallization (C) and melting of the recrystallized material (M_r). The resulting behavior is a composite of the peaks due to the melting of the original crystals (M), the recrystallization exotherm, and the melting of the recrystallized material. As the heating rate is increased, the crystals have less time to reorganize, thus C and M decrease in magnitude.

A plot of the observed melting point of both melting endotherms as function of the crystallization temperature (Hoffman-Weeks plot) is another method to detect whether recrystallization occurs. The melting point of recrystallized material is independent of T_c; thus a horizontal line is observed in the T_m versus T_c plot.

During crystallization of a miscible polymer blend, the composition of the amorphous phase changes, i.e., becomes poorer on the crystallizable component. In some cases, a liquid-liquid phase separation can take place as a result of the crystallization. This phenomenon will be discussed more in detail in the next section.

A complex melting behavior is also observed when a semicrystalline polymer exhibits two different types of crystal structure. A second crystal structure can be introduced by a variation in temperature, pressure, elongation, etc. This phenomenon is known for neat PE. Adding an amorphous polymer to a crystallizable component can result in a change of the unit cell dimensions of the crystal structure. This has been observed for LDPE blended with EPDM (Starkweather 1980), where the unit cell expanded in the a-direction (a raises from 7.515–8.350 A) when increasing the amount of EPDM, while the b- and c-directions remained almost unchanged. The composition of EPDM plays also an important role. EPDM with an ethylene/propylene mole ratio of 4:5 (EPDM-1) exhibits the behavior as mentioned above. Decreasing the ethylene content in the EPDM copolymer results in an amorphous polymer (designated EPDM-2 and EPDM-3; Starkweather 1980) that do not alter the unit cell dimensions as much as EPDM-1 does. The latter copolymer is thought to cocrystallize (at least partially) with LDPE.

Several blends prepared by coprecipitation followed by crystallization from the melt exhibit a double melting behavior, due to the occurrence of the secondary crystallization process. The amorphous component causes a retarded crystallization of some of the crystallizable chains, which form lamellae smaller than and located between the primary ones constituting the spherulites (see Fig. 3.29).

This is a phenomenon often observed in PCL blends. In DSC scans as a function of crystallization time (t_c), a single melting behavior is observed after short t_c, while a second melting endotherm is noticed at long t_c (see Fig. 3.30). This second melting endotherm becomes more important as the more amorphous component is added (Vanneste and Groeninckx 1995; Fig. 3.31).

In Table 3.12 some blends are presented exhibiting a complex melting behavior due to one or more of the abovementioned reasons.

It should be mentioned that several homopolymers (of which polyethylene is probably the best known sample) also exhibit a complex melting behavior. Branched polyethylenes (LDPE, LLDPE, and VLDPE) show multiple melting endotherms, due to the presence of fractions with different branching contents (Schouterden et al. 1985; Defoor et al. 1993). This was clearly illustrated by Defoor et al. who fractionated LLDPE with respect to the short-chain branching content and blended the fractions with the highest and the lowest branching content. It was shown that they both crystallized and melted separately. Both fractions determined the spherulitic morphology in a cooperative way.

Fig. 3.29 Schematic presentation illustrating the secondary crystallization process (*thin lines*: crystallizable component, *thick lines*: amorphous component)
Fig. 3.30 Influence of the crystallization time on the melting behavior of the ternary PCL/Phenoxy/SAN 15 = 90/05/05 blend (Vanneste and Groeninckx 1994)

Other examples are PPS (which shows a double melting behavior due to the obstructive effect of branching or cross-linking of the molecules on crystallization at high temperature; Mai et al. 1994) and PEEK. Much controversy exists about the cause of the double melting behavior of PEEK – recrystallization or secondary crystallization. According to one group of authors (Prasad et al. 1991; Hudson et al. 1991; Bassett et al. 1992; Lattimer et al. 1992), PEEK that was crystallized

Fig. 3.31 Influence of the concentration of the amorphous component on the amount of secondary crystallization in PCL/SAN 15/SMA 14 polymer blends (Vanneste and Groeninckx 1995)
from the melt contains crystals with two types of lamellar thickness. The thicker ones grow first, while the smaller ones grow later within the thicker lamellae. Thermal analysis, however, indicates that a process of melting, recrystallization, and remelting occurs (Cheng et al. 1986; Lee and Porter 1987; Lee et al. 1989; Crevecoeur and Groeninckx 1991).

PEO/amorphous polyamide (Aramide 34I) blends investigated by Dreezen et al. (1999) displayed a double melting behavior. By varying the crystallization time of a 85 wt% PEO/15 wt% Aramide 34I from 33 to 451 h, the authors could demonstrate that the primary melting endotherm visible at 65 °C does not change, whereas the second melting endotherm increased in intensity and shifted to higher temperatures (from 41 °C to 50 °C) with increasing crystallization time (Fig. 3.32). They attributed the presence of a second melting endotherm, situated at lower temperatures than the main peak, to secondary crystallization of PEO after the primary crystallization process. The crystallization of some PEO-chains was retarded and crystallized slowly after the formation of the spherulitic structure. With time the thin lamellae thicken and melt at higher temperatures. During heating at low heating rates,

3.2.6 Crystallization Phenomenon in Miscible Thermoplastic/ Thermosetting Blends

Because of the additional parameter of curing a phase, crystallization of blends of a curable amorphous thermosetting with a crystallizable thermoplastic has been poorly reported in literature. Nevertheless, the few blend systems covered are very interesting and show attractive phenomena in terms of crystallization, melting, and phase separation when the thermosetting is cured. Crystallization in thermosetting polymer blends containing a crystallizable thermoplastic component will be affected by the miscibility of the components, the phase behavior of the cross-linked blends, and the topological effect of the formed network. Except for the particular three-dimensional network formed upon chemical curing, the effect of thermosetting curing is almost similar to that of a solidifying phase (cooling below T_g for an amorphous phase or crystallization of a crystallizable phase) in thermo-plastic/thermoplastic blend system. Therefore, we can consider that the utmost effect of the cured phase on the crystallizable phase is the chain mobility restriction. How does the segregation of the cured thermosetting component take place during the crystallization of the semicrystalline component? Prior to any deep investigation of the crystallization phenomenon, a deep understanding of the miscibility of the thermosetting/thermoplastic blends is crucial. The determination of the glass

Fig. 3.33 Schematic representation of the melting mechanism proposed to account for the heating rate dependence of recrystallizing blends. The *left* side of the figure shows the melting of the original crystals (*full line*) and the recrystallization, remelting phenomenon (*dashed line*), while the *right* side shows the resulting experimentally observed thermogram: (**a**) for an 80/20 PEO/Aramide blend; (**b**) for a 65/35 PEO/Aramide blend at fast, intermediate, and slow heating rates (Dreezen et al. 1999)
transition as a function of the extent of curing of the thermosetting resin helps for the interpretation of the crystallization results. Other questions remain poorly elucidated including, e.g., to which extent the chains of the thermoplastic component remain intimately in contact to the thermosetting network when curing is achieved. One can expect that a part of the crystallizable phase is entrapped in the formed network of the thermosetting and does not participate to the overall crystallization.

Blends of bisphenol A type epoxy resin (ER) with PEO (Guo et al. 2001a), PCL (Guo et al. 2001b), and POM (Goossens et al. 2006a, b, 2007) are typical examples of thermosetting/thermoplastic blend system studied. The curing of the epoxy resin is usually ensured by using MCDEA curing agent. In Fig. 3.34 the T_g of the blend and the T_c and T_m of the PEO component as a function of the ER/PEO blend composition are plotted. It is clear that the presence of PEO phase reduces the cross-linking density of the ER resin, and hence it is T_g via a dilution and eventually a plasticizing mechanism. Blends with 60 wt% or more ER do not exhibit any crystallization and behave as an amorphous phase. Blends with 50–60 wt% PEO crystallize at higher T_c, indicating chain mobility constraints imposed by the formation of a cross-linked ER network.

Fig. 3.34 Thermal properties of the second scan of the MCDEA-cured ER/PEO blends. (●) Experimental plot of T_g versus overall blend composition, (□) plot of T_g versus calculated amorphous composition, and (————) theoretical curve of T_g versus composition as predicted by the Gordon-Taylor equation using a k value of 0.25. The T_c (cooling) (□) as a function of composition is also given (Guo et al. 2001)
Blends of uncured thermosetting component DGEBA with PCL were compared to blends of cured resin ER with PCL (Guo et al. 2001). In Fig. 3.35 are plotted the measured experimental T_g of the uncured DGEBA/PCL blends as a function of composition. The curve exhibits a mixing rule trend indicating a strong miscibility of the two components. Note that in blends containing 70 wt% or more PCL, the T_g exhibits a positive deviation with respect to the fox mixing rule (broken line), indicating a high crystallinity of the PCL phase. Figure 3.36 shows the T_g of the cured ER/PCL blends, the T_c and T_m as a function of the blend composition. Comparison of the two figures reveals that the uncured DGEBA resin is less constraining the crystallinity of the PCL phase than the cured ER resin. Indeed, the crystallization temperature, T_c, increases with increasing ER content synonymous of the difficult crystallization of PCL in the presence of the cured resin.

The melting depression is less pronounced in the uncured blend than in the cured one. A smaller difference of the Tm's of the two endothermic peaks is depicted between the cured and the uncured DGEBA/PCL blend system. Big differences with respect to the melting behavior compared to classical thermoplastic/thermoplastic miscible blends are revealed. The crystallization of the crystallizable phase was found to be very sensitive to the thermal history as manifested by crystallization peaks observed during the first heating scan, the second heating scan, or the phenomenon of the double melting behavior. Figure 3.37 illustrates these effects for the degree of crystallinity as a function of the PCL content in the cured ER/blend. Substantial differences exist between samples as-prepared, cooled from the melt or quenched. No significant effect is depicted for the cooled or the quenched samples when the content

of PCL is equal or above 80 wt%. A drastic decrease of crystallinity is however
registered below this critical concentration. The as-prepared samples exhibit
a decreasing degree of crystallinity when the concentration of PCL is between
100 and 40 wt%.

3.2.6.1 Crystallization Kinetics

The overall crystallization rate of the crystallizable phase in thermosetting/thermo-
plastic miscible blends is greatly affected by the presence of the thermosetting resin
either cured or not (ER cured with MCDEA or uncured DGEBA resin). The
crystallinity of PCL in the cured ER/PCL blend decreases much more rapidly
with increasing amorphous cured ER content than that of the uncured amorphous
DGEBA/PCL blends. The authors ascribed this behavior to the higher T_g of the
cured ER restraining the chain mobility for the PCL and thus limiting the extent and
rate of crystallization ($T_g = 138\ °C$ for the cured ER and $T_g = -11\ °C$ for the
uncured DGEBA system).

Halftime of crystallization $t_{1/2}$ as a function of crystallization T_c for cured
ER/EO blend reveals that addition of cured ER resin to PEO crystallizable ther-
moplastic depresses the overall crystallization rate of PEO, and at a fixed T_c, the
overall crystallization rate decreases significantly with increasing the concentration
of the cured resin ER (Fig. 3.38). Application of the Avrami extrapolation resulted
in *n* values comprised between 3.5 and 5, not changing as the content of ER in the
blend is increased. That means the incorporation of cured ER does not affect
significantly the nucleation, and growth process is under the conditions the authors
selected for the crystallization of PEO.

Fig. 3.38 Halftime of crystallization $t_{1/2}$ as a function of crystallization temperature T_c (Guo et al. 2001)
Goossens et al. (2006b, 2007) studied the most challenging aspect which consists of curing the DGEBA and monitoring the crystallization of the POM phase in the DGEBA thermosetting/POM thermoplastic blends system.

The influence of the curing reaction and the resulting reaction-induced phase separation on the crystallization and melting of POM in POM/DGEBA has been studied at two different cure temperatures (180 °C situated above the melting point of POM and 145 °C below it). Various phase morphologies have been generated which allows to investigate the POM crystallization in either a particle-in-matrix or in a phase-inverted phase morphology of POM/DGEBA blends. By using DSC and OM characterization techniques, the authors could demonstrate that at the curing temperature of 180 °C, large differences exist between particle-in-matrix (for 10 wt% POM blends) and phase-inverted structures (20 wt% POM blends) with respect to crystallization behavior. The melting temperatures were almost similar, indicating reorganization in the small POM-rich droplets in the 10 wt% POM blend upon heating. When lowering the curing temperature to 145 °C, isothermal crystallization was induced followed by interspherulitic reaction-induced phase separation (RIPS). Substantial differences were noticed between dynamically and isothermally crystallized POM.

3.2.6.2 Semicrystalline Morphology Development

As in classical amorphous thermoplastic/crystallizable thermoplastic miscible blends, the chains of the thermosetting are rejected from the crystallizing front when the crystallizable thermoplastic is crystallizing in thermosetting/thermoplastic blends. The curing process allows the formation of a network that is not involved
Fig. 3.39 Optical micrographs of ER/PEO blends crystallized at 23 °C. ER/PEO: (**a**) 0/100; (**b**) 10/90; (**c**) 20/80; (**d**) 30/70; (**e**) 40/60; and (**f**) 50/50 (Guo et al. 2001)

in crystallization and is segregated in own domain upon crystallization. The liquid-solid phase separation occurring during the crystallization process of PEO in miscible MCDEA-cured ER/PEO blends requires the segregation and diffusion of amorphous ER away from the crystalline nucleus. The cured ER molecules have a rather limited mobility compared to the linear polymer diluents. Well-defined spherulites were observed in cured ER/PEO blends with ER content up to 50 wt% isothermally crystallized at 23 °C (Fig. 3.39). The spherulitic morphology does not become irregular or coarser with increasing ER content as revealed by OM characterization tools. That indicates that the MCDEA-cured ER is not segregated in the interspherulitic space but must be interlamellarly or interfibrillarly segregated during the process of PEO crystallization. This semicrystalline morphology has been confirmed by using SAXS characterization. The long period increased

Fig. 3.40 Long period, L, as a function of composition for MCDEA-cured ER/PCL blends (Guo et al. 2001)
drastically with increasing ER content at all crystallization temperatures. The interlamellar segregation resulting in an increase of the long period has been reported in a number of cases of miscible polymer blends as, e.g., PVC/PCL (Khambatta et al. 1976a, b) or PSMA/PCL (Defieuw et al. 1989a). In contrast to linear (not cross-linked) polymers, cured resins exhibit high viscosity and slow chain mobility which makes its diffusion at the crystallizing front difficult. Similar trends of the long period increase have been reported for PCL/MCDEA-cured ER blends using SAXS techniques (Guo et al. 2001). When the content of the cured ER was increased from 0 to 25 wt%, the long period was increased by almost 1.5 nm at all crystallization temperatures (Fig. 3.40). That is synonymous of interlamellar segregation of the ER resin upon crystallization of PCL.

3.2.7 Coupling of Demixing and Crystallization Phenomena

3.2.7.1 Thermoplastic/Thermoplastic Blends

Tanaka and Nishi (1985) were the first to report about the existence of coupling between crystallization and demixing in crystallizable blends. A competition between demixing and crystallization is seen in binary blends of a semicrystalline and an amorphous polymer when the crystallization curve and the miscibility gap intersect. The morphology of blends exhibiting such behavior is determined by the ratio of the rate of crystallization and of demixing. Four important situations can be distinguished (Fig. 3.41):

Fig. 3.41 Phase diagram of a binary polymer blend with miscibility gap (UCST) and intersecting crystal/melt coexistence curve. The $T_m{}^\circ$ curve is extrapolated into the miscibility gap. Quenching routes *A* to *D* are explained in the text. For routes *B* and *C*, the quenching-induced phase separation and crystallization are indicated. —— binodal, ——— spinodal, and —. crystal/melt coexistence curve (Li et al. 1991)
A. **Simultaneous spinodal decomposition and crystallization**
   The blend is quenched into the unstable region of the miscibility gap and to a temperature below the crystallization/melt coexistence curve.
B. **Simultaneous binodal decomposition and crystallization**
   This type is similar to spinodal decomposition, but a composition is quenched into the metastable region of the miscibility gap.
C. **Crystallization induced decomposition**
   The blend is quenched outside the miscibility gap to a temperature below the crystallization/melt coexistence curve. The concentration of the noncrystallizable component increases with crystallization until the miscibility gap is reached inducing demixing.
D. **Decomposition-induced crystallization**
   The blend is quenched into the miscibility gap to a temperature that lies above the crystallization/melt coexistence curve for the actual composition but lies below the crystallization curve for the binodal composition. When the blend is quenched, demixing occurs resulting in two coexisting phases of which one is able to crystallize. The demixing can result in spinodally as well as in binodally decomposed material.

Only few experimental studies have been performed on polymer blends exhibiting one or more of the phenomena described above (see Table 3.13).

Routes A and C of Fig. 3.41 were discussed by Tanaka and Nishi (1985, 1989) for a system consisting of PCL and PS. In case A coarse spherulite results including PS droplets, while in case C the spherulites are separated and show large droplets on their surface (see Fig. 3.42).

Li et al. (1991, 1993) investigated case B and C for the same system, i.e., PCL/low molecular weight PS, for which the phase diagram is presented in Fig. 3.43.

Table 3.13 Polymer blends showing coupling of demixing and crystallization. The routes describing the type of coupling are explained in the text

Polymer blend	Composition	Type of coupling	References

PEG/PPG	88/12	Route B	Shibanov and Godovsky (1991)
	54/46	Route A	
	10.3/89.7	Route B	
Fig. 3.42 Phase separation behavior at the growth front of the spherulites of PCL during the crystallization process in the PCL/PS 70/30 blend at $T_c = 50$ °C. These morphologies were observed at (**a**) 1,860 min, (**b**) 2,790 min, (**c**) 3,250 min, and (**d**) 4,230 min after quenching (bars: 20 μm) (Tanaka and Nishi 1989)

For route C three different regimes (Fig. 3.44) can still be distinguished depending upon the rate of crystallization, $G = dR/dt$, and the rate of diffusion of the noncrystallizable component, $v_d = (D/t_c)^{1/2}$ (D = diffusion constant and t_c is the correlation time of the macromolecules). Parameters, v_d and G, show a different dependence on temperature (see Fig. 3.45). The growth rate, G, has a maximum

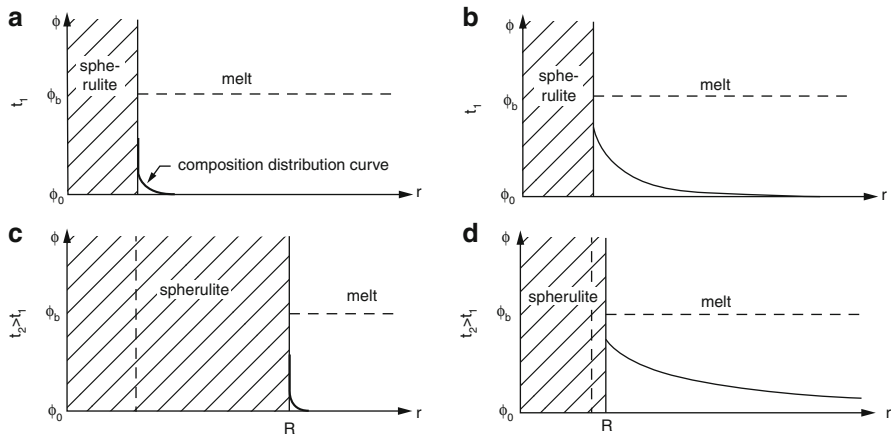
Fig. 3.43 Phase diagram of the PCL/PS blend (*triangles*: homogeneous melt/PCL crystal coexistence curve, *filled circles*: glass-transition curve, *open circles*: spinodal, and *squares*: binodal) (Li et al. 1991)


Fig. 3.44 Concentration distribution of PS around a spherulite at different times t and for different ratios G/v_d. ϕ_o, start composition; ϕ_b, binodal composition; and r, local coordinate. (**a**) Regime 1, (**b**) regime 2: the binodal composition is not exceeded, (**c**) as in (**b**) but the binodal composition is exceeded, (**d**) superposition of the concentration distribution curves (*dashed lines*) according to the transition between regime 2 and 3 of two adjacent spherulites (Li et al. 1991)

between the melting temperature and the glass-transition temperature of the blend, whereas the diffusion rate of the amorphous component, v_d, increases with temperature.

1. $v_d \ll G$: the noncrystallizable component is trapped within the growing crystals. Depending on the composition of the amorphous phase, liquid-liquid

Fig. 3.45 Temperature dependence of the diffusion-driven displacement of the noncrystallizing component, v_d, and the spherulitic growth rate G (Li et al. 1991)
demixing may occur resulting in droplets of noncrystallizing polymer inside the spherulites.

2. $v_d \approx G$: a part of the amorphous component is trapped and another part is segregated from the growing crystals. The concentration of this component increases with crystallization, and finally demixing occurs resulting in the formation of droplets at the spherulite surface.

3. $v_d >> G$: the noncrystalline component is fully segregated into the bulk melt. When the miscibility gap is reached, the melt phase separates homogeneously and binodally.

The crystallization rate is retarded for all regimes, but the extent of hindrance increases from regime 1 to 3. It should be noted that the diffusion of the crystalline polymer occurs on a lamellar scale (about 10 nm), whereas the diffusion of the amorphous component, induced by demixing, takes place on a spherulitic scale (10–20 μm). Under normal processing conditions, crystallization presumably takes place at a higher rate than the demixing.

The morphology resulting from the three regimes are presented in the Fig. 3.46 (regime 1), Fig. 3.47 (regime 2), and Fig. 3.48 (transition from regime 2 to 3) for the PCL/PS system.

A demixing-induced crystallization is shown in Fig. 3.49 (route B in Fig. 3.41) for the binary PCL/PS 40/60 blend.

3.2.7.2 Thermoplastic/Thermosetting Blends

Curing of the thermosetting component and crystallization of the semicrystalline thermoplastic blend partner are two processes that induce phase separation in thermosetting/thermoplastic miscible blend. The new phase morphology that could be generated from the intimately miscible molecules of both components depends on the temperature and kinetics of the curing reaction of the thermosetting resin and of the crystallization of the thermoplastic phase. Semicrystalline thermoplastics like PCL (Guo et al. 2001a, b), PBT (Kulshreshtha et al. 2003a, b), and syndiotactic polystyrene (Schut et al. 2003; Salmon et al. 2005) have been used with curable thermosetting partners with which they form miscible blends before
Fig. 3.46 Morphology development in a PS blend with 60 wt% PCL at 44 °C after (**a**) 55 min and (**b**) 126 min (bar: 50 μm) (Li et al. 1991)
Fig. 3.47 Morphology development in a PS blend with 60 wt% PCL at 49 °C after (**a**) 92 h and (**b**) 142 h (bar: 25 μm) (Li et al. 1991)

any curing or crystallization. Crystallization in thermosetting blends containing a crystallizable thermoplastic component will be affected by the miscibility, the phase behavior and the morphology of the cross-linked blends, and the topological effect of the network (Guo et al. 1991, 2004; Lu et al. 2003; Zheng et al. 2003).
Fig. 3.48 Morphology development in a PS blend with 60 wt% PCL at 51 °C after (**a**) 91.5 h, (**b**) 100 h, and (**c**) 109 h (Li et al. 1991)
Fig. 3.49 Phase separation followed by crystallization in a PS blend of 40 wt% PCL at 46 °C after (**a**) 2.5 h, (**b**) 13.5 h, and (**c**) 27 h (Li et al. 1991)

By selecting POM/DGEBA/DDS thermosetting/thermoplastic miscible blends, Goossens et al. (2006a, b) could elucidate how the phases are reorganized upon curing of the thermosetting and crystallization of the thermoplastic. Depending on the experimental conditions chosen, crystallization of POM can be investigated before or after the reaction (curing)-induced phase separation (RIPS), i.e., crystallization in homogeneous blend or in a phase-separated one. Three cure temperatures (150, 145, and 140) situated below the melting point of POM were examined. Curing at these temperatures will alter the starting order of the RIPS and crystallization of POM. Both processes will mutually affect each other, leading to complex blend morphologies. Curing at 150 °C is a situation where:
Fig. 3.50 OM pictures of a blend with 10 wt% POM cured at 150 °C for different times: (**a**) 29 min, (**b**) 44 min, and (**c**) 120 min (Goossens et al. 2006a)
Fig. 3.51 OM pictures of a blend with 20 wt% POM cured at 150 °C for different times: (**a**) 31 min, (**b**) 35 min, (**c**) 41 min, (**d**) 45 min, (**e**) 66 min, and (**f**) 71 min (Goossens et al. 2006a)

(i) *Phase separation precedes the isothermal crystallization* (*curing at* 150 °C).
As a consequence of RIPS due to curing, the three initially miscible blends, containing 10, 20, and 30 wt% POM, evolved to a co-continuous and then to a droplet (POM rich)-in-matrix (epoxy rich) phase morphologies (Figs. 3.50, 3.51 and 3.52). For the blends with 10 wt% POM, no isothermal crystallization was depicted because the difference between the cure temperature (150 °C) and the homogeneous crystallization temperature (85 °C) was too large to induce homogeneous crystallization in the dispersed POM-rich droplets. In contrast, at a content of 20 wt%, POM isothermal crystallization was observed after phase separation has set in via successive spinodal demixing, break up into epoxy-rich droplets dispersed in a POM-rich matrix and coalescence which increased particle size. Fifteen minutes after, the liquid-liquid demixing has set in, and growing spherulites were observed in the POM-rich matrix phase in between the epoxy droplets. The growth of spherulites in the POM-rich matrix was also observed during the phase separation process of a 30 wt% POM blend, cured at 150 °C.
Fig. 3.52 OM pictures of a blend with 30 wt% POM cured at 150 °C for different times: (**a**) 50 min, (**b**) 66 min, and (**c**) 92 min (Goossens et al. 2006a)

(ii) *Isothermal crystallization followed by phase separation* (*curing at* 145 °C).
At this curing temperature, isothermal crystallization starts before the liquid-liquid phase separation as caused by the curing of the epoxy resin. Homogeneous blends containing 5 wt% POM developed spherulites after 22 min. Thirty three minutes later, interspherulitic zone starts to phase separate leading to a co-continuous phase structure. While the liquid-liquid phase separation proceeds, the spherulites continue to grow through the POM-rich continuous part of the co-continuous structure. Crystallization stops as the phase structure evolved to a droplet-matrix as POM molecules need to diffuse through the highly viscous cured epoxy. The authors could differentiate between three zones within the POM spherulite: zone 1 is the spherulite growth in the homogeneous sample where no RIPS occurs yet, zone 2 is the spherulite growth in the co-continuous structure, zone 3 is limited because of the slow diffusion of very diluted POM molecules in the epoxy-rich matrix, and, finally, zone 4 which represents the volume hat has been phase separated but did not undergo crystallization at 145 °C. Blends containing 10 wt% POM exhibits the same trend. In contrast, increasing the POM content beyond 10 wt% gave a different phase-separated process. For example, the co-continuous structure was found to break up in a phase-inverted structure instead of a particle/matrix structure. Increasing the amount of POM resulted in higher nucleation density and an increased crystallization growth rate.

(iii) *Isothermal crystallization without phase separation* (*curing at* 140 °C).
Decreasing the cure temperature to 140 °C will increase the supercooling and consequently the nucleation density. Indeed, when a blend with 20 wt% POM was cured at 140 °C, spherulites appeared as early as 1 min which is a direct result of the higher supercooling. After 20 min the spherulites are almost volume filling due to higher nucleation density and the higher local crystallization rate. This suggests that nearly all the epoxy resin is rejected interlamellar or interfibrillar.

3.2.8 Conclusions

Most of the fundamental and experimental aspects related to the crystallization phenomena occurring in miscible polymer blends are relatively well known. Much research has been done in the 1970s and 1980s, especially the development of the

general theory concerning the crystallization process itself and the concomitant kinetics. These theories could be adapted to simple systems under quiescent conditions. Later, modifications have been made to the original concepts to take into account the effects occurring under processing conditions (for instance, the nonisothermal Avrami theory), unusual phenomena not responding to the simple theory (for instance, the nonlinearity of Hoffman-Weeks plots), coupling of the crystallization with demixing processes, etc.

The addition of a second component to a crystallizable polymer has several profound consequences:

1. Depending on the glass-transition temperature of the added component, the crystallization window is widened or narrowed.
2. The type of added component is also important. Crystallization in the presence of an amorphous component is paralleled to segregation. The segregation can occur into three regions: interspherulitic, interfibrillar, and interlamellar, depending on the ratio of the diffusion rate of the amorphous component and of the crystallization rate of the crystallizable component. In blends of two crystallizable polymers, the phenomena such as separate crystallization, concurrent crystallization, and cocrystallization may take place.
3. The spherulite growth rate changes by blending due to interactions between the components, the necessity of diffusion of both components, the concentration change in the amorphous phase during crystallization, and the possible changes of the glass-transition and melting temperature.
4. The overall kinetics are strongly affected by the type of amorphous component, its influence on the nucleation of the crystallizable component, the degree of miscibility, the presence of secondary nucleation effects, and the molecular weight of both components.
5. The melting behavior is often complex due to phenomena such as reorganization, secondary crystallization, demixing, etc. A depression of the equilibrium melting temperature is often observed.
6. In case of thermosetting/thermoplastic initially miscible blends, the duration and the curing temperature of the thermosetting are crucial conditions which determine the crystallization kinetics, the type of semicrystalline phase morphology generated, as well as the melting behavior of the semicrystalline partner of the blend. Depending on the temperature at which crystallization is carried out, competition between demixing and crystallization can take place.

3.3 Crystallization, Morphological Structure, and Melting Behavior of Immiscible Polymer Blends

3.3.1 Introduction

From a commercial point of view, semicrystalline polymers are of prime importance. Among the four mostly used commodity plastics (PE, PS, PVC, and PP), only PS is completely amorphous. The three semicrystalline polymers account for the

largest volume of the commercial polymer blends. A majority of the polymer blends contains at least one crystalline component. Most polymer blends are immiscible.

The immiscible semicrystalline polymer blends may be classified in terms of crystalline/crystalline systems in which both components are crystallizable and crystalline/amorphous systems in which only one component can crystallize, being either the matrix or the dispersed phase (Utracki 1989). Numerous authors have been investigating the crystallization behavior of immiscible blends. In Tables 3.14 and 3.15, an overview is given of a number of important immiscible crystallizable blend systems.

The properties of the finished articles made from immiscible blends are governed by the morphology created as a result of the interplay of processing conditions and inherent polymer characteristics, including crystallizability. Therefore, a scientific understanding of the crystallization behavior in immiscible polymer blends is necessary for the effective manipulation and control of properties by compounding and processing of these blends.

In the following part, a discussion on the crystallization behavior in immiscible polymer blends is given, including the nucleation behavior, spherulite growth, overall crystallization kinetics, and final semicrystalline morphology. Each topic is illustrated with several examples from the literature to allow the reader to find enough references on the discussed subject for further information.

3.3.2 Factors Affecting the Crystallization Behavior of Immiscible Polymer Blends

The discussion on the crystallization behavior of neat polymers would be expected to be applicable to immiscible polymer blends, where the crystallization takes place within domains of nearly neat component, largely unaffected by the presence of other polymers. However, although both phases are physically separated, they can exert a profound influence on each other. The presence of the second component can disturb the normal crystallization process, thus influencing crystallization kinetics, spherulite growth rate, semicrystalline morphology, etc.

Important factors are:
– Molecular structure and molecular mass of the components
– Blend composition
– Type and degree of dispersion of the phases in the melt state
– Phase interactions (e.g., nature of the interface, migration of nuclei, etc.)
– Melt history (T_{melt}, t_{melt}, etc.)
– Crystallization conditions (e.g., T_c, cooling rate, etc.)
– Physical crystallization conditions (surrounded by melt or solidified material)

These factors influence the crystalline morphology development, resulting in changes of crystallization parameters such as:
– Nucleation density, N
– Spherulite growth rate, G

[a]EPDM and EPR copolymers are crystalline if block copolymer and depending on the ethylene/propylene ratio; in blends with PE or PP, they can extract to some extent (depending on the ethylene/propylene ratio) amorphous low molecular weight molecules from the PP or PE phase that slightly influence the crystallization and melting behavior

[b]Study done on fibers

[c]Sometimes coincident crystallization occurs in finely dispersed morphology

– Overall crystallization rate, K
– Total degree of crystallinity, X_c
– Semicrystalline morphology, i.e., shape, size, and texture of the spherulites, interspherulitic boundaries, etc.

To discuss these topics in a systematic way, a distinction will be made between three main blend categories, namely:
1. Blends with a crystallizable matrix and an amorphous dispersed phase
2. Blends with an amorphous matrix and a crystallizable dispersed phase
3. Blends containing two crystallizable components

3.3.3 Blends with a Crystallizable Matrix and an Amorphous Dispersed Phase

In immiscible blends, the phases are separated in the molten state, thus before crystallization of the matrix starts. The dispersed amorphous phase is assumed to be homogeneously distributed in the melt in droplet-like domains.

3.3.3.1 Nucleation Behavior of the Crystallizable Matrix
General Considerations Related to Heterogeneous Nucleation
When a crystallizable component forms the matrix phase in a polymer blend, nucleation can occur via *heterogeneous nucleation* by heterogeneities in a similar way as in the pure component. The heterogeneities, available in the melt, can be residual catalysts, fillers, impurities, crystalline residues (due to incomplete melting), etc. Each type of "heterogeneity" has its own typical activation energy for the formation of an "active nucleus of critical size," corresponding to a certain degree of undercooling $(T_m - T_c)$. When $T_{c,1}$ is reached during cooling from the melt, all heterogeneities of type 1 (which have the lowest activation energy) become active and the nucleation of the crystallizable phase is induced. Once the crystallization is initiated by the primary nucleation, it can further spread over the whole available material via secondary nucleation, before any other type of heterogeneity can become active.

Since in immiscible blends the phases are physically separated, the same heterogeneities that nucleate the homopolymer at $T_{c,pure}$ may nucleate the crystallizable matrix. As a result, the crystallization temperature, T_c, of the blend during cooling from the melt will in general not differ that much from the T_c of the pure component.

Some general principles governing the crystallization behavior of homopolymers also remain valid for immiscible polymer blends in which the crystallizable component forms the continuous phase.

The *premelting temperature*, T_{melt}, may have a profound influence on the crystallization temperature of the matrix, T_c, during cooling from the melt (Table 3.16).

The higher the temperature at which the blend is kept in the melt prior to crystallization, the less residual crystalline parts (otherwise leading to self-seeded

[a]sPS/PVME is only immiscible in those blends where the amount PVME exceeds 10 %

nucleation) remain in the melt. As a result, fewer nuclei are available to nucleate the melt phase, thus leading to the formation of fewer but larger spherulites.

Another less important factor is the *isothermal crystallization temperature*, $T_{c,iso}$, when the crystallization is carried out at a constant temperature (Table 3.16). When a crystallization experiment is performed at lower temperatures, the activation energy for nucleation of several types of heterogeneities can be overcome. At that $T_{c,iso}$, more nuclei become active, leading to the formation of a larger number of smaller spherulites.

Although most principles for the crystallization of homopolymers remain valid for immiscible blends with a crystallizable matrix, the crystallization behavior can be altered by two phenomena, inherently correlated with immiscible two-phase systems, namely, migration of impurities during melt-mixing and the nucleating activity of the interface between two phases.

Migration of Impurities During the Melt-Mixing Process
During the melt-mixing process, heterogeneous impurities can migrate across the interface between both blend phases (Bartczak et al. 1986). The driving force for this migration is the interfacial free energy of the impurity with respect to its melt phase, $\sigma_{i,1}$. If this interfacial free energy is higher than the interfacial free energy of that impurity within the second melt phase, $\sigma_{i,2}$, it is energetically more favorable for the impurity to move to the second phase. As soon as it has the "possibility," it will migrate across the interface (Galeski et al. 1984).

Several factors determine the "possibility" for the impurities to migrate from one phase to the other phase during the melt-mixing process.

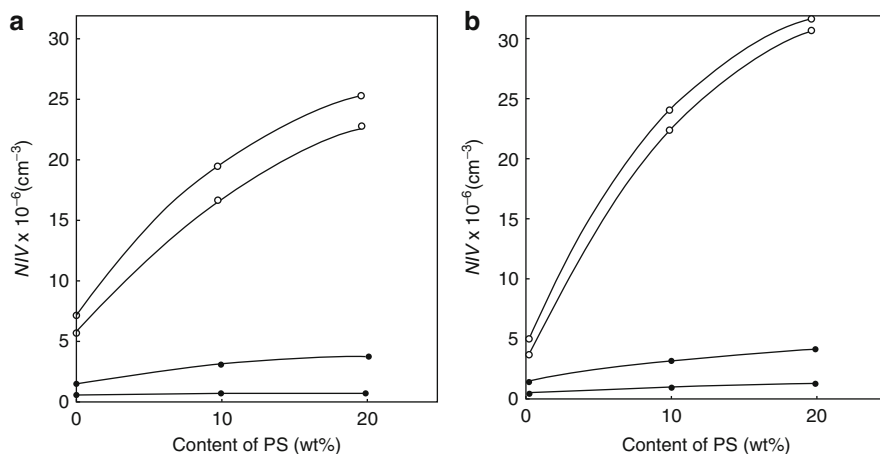
Because the migration of heterogeneities can only occur when they find themselves close enough to the interface, the melt-mixing conditions play an important role (Bartczak et al. 1987; Fig. 3.53). It must be clear that the longer the mixing or the more intense the mixing, the higher the probability that nuclei find themselves somewhere at an interface, where they can easily migrate. Thus, the effect of migration on the crystallization behavior will be more pronounced – migration of


Fig. 3.53 Influence of the amount of dispersed phase, mixing time, and crystallization temperature, T_c, on the amount primary nuclei active for crystallization at T_c in a PP/PS blend. All samples have been molten up at 220 °C; (**a**) 2× mixing, (**b**) 3× mixing; $T_{c,iso}$ was set to 119 °C (∇), 123 °C (Δ), 125 °C ($\bigcirc$), and 130 °C ($\square$) (Bartczak et al. 1987)

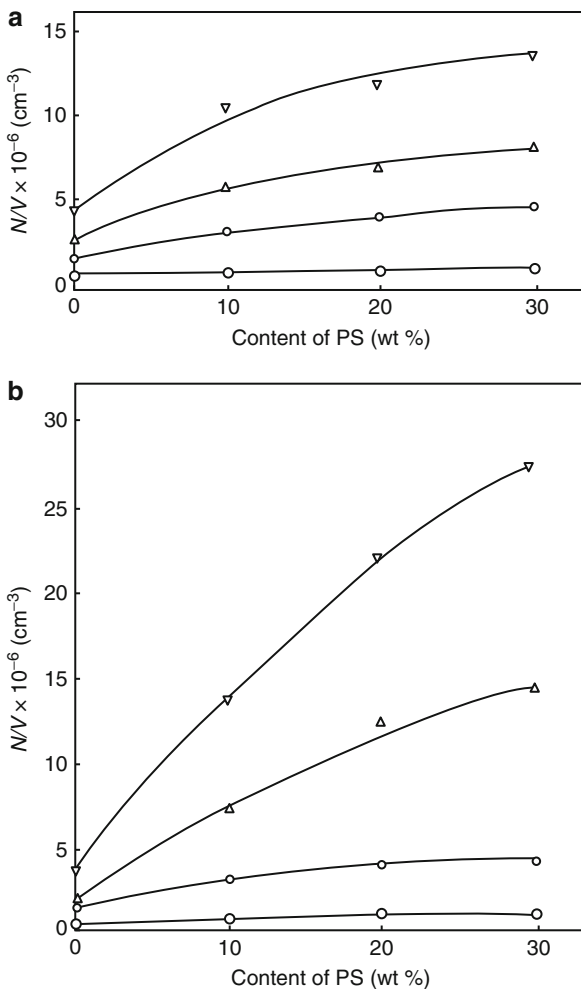
heterogeneities across the interface will not proceed in the absence of mechanical mixing (Bartczak et al. 1987). Furthermore, the possibility for impurities to be located close enough to an interface stands in direct relation to the phase morphology generated during the melt-mixing (Bartczak et al. 1987).

As the relative amount of the phases changes, the amount of nuclei that can migrate varies, and the effect of these migrating nuclei on the crystallization behavior changes. This can be understood if one assumes an amorphous/crystalline blend system in which heterogeneities migrate from the crystallizable matrix toward the second phase. With increasing amount of the second phase, the total amount of available nuclei is lower, and they will migrate toward a larger volume of the second phase, which may lead to a more than proportional decrease of the nucleation density in the crystallizable phase.

However, the melt morphology also changes with varying content of the phases. By increasing the amount of the second phase, the dispersion becomes coarser due to coalescence of droplets. This implies that larger droplets are formed, and as a consequence, a lower total interfacial contact area is available. Hence, less impurities will find themselves located close enough to the interface to be able to migrate. It should be remarked that a critical volume fraction of the second component could exist, which is able to absorb all active nuclei of the crystallizable matrix. Adding higher amounts of the second component will no longer decrease the number of active nuclei per volume unit of the crystallizable matrix. An example is given for the PP/LLDPE blend, where LLDPE is in the molten state during PP crystallization (and thus can be considered as an amorphous melt) (Fig. 3.54).

Fig. 3.54 Influence of LLDPE on the nucleation of PP at various temperatures: (**a**) measured as blend volume and (**b**) calculated as PP volume fraction (Long et al. 1991)


Finally, a factor that also may influence the degree of migration is found to be the *interfacial free energy between both phases of the blend in the melt*, $\sigma_{1,2}$. If $\sigma_{1,2}$ is high, due to a high degree of immiscibility between the phases, a sharper interface will be formed. Nuclei close to such a sharp interface are found to migrate fast and efficient (Bartczak et al. 1987), in contrary to partially miscible blends where no evidence could be found for such a fast migration (Galeski et al. 1984; Bartczak et al. 1986).

In general, the migration of heterogeneities from one phase to the other in blends with a crystallizable matrix only slightly affects the crystallization temperature of the matrix during cooling from the melt (Bartczak et al. 1987). More important should be the influence of migration on the final semicrystalline morphology. This aspect will be discussed in Sect. 3.3.3.4.

Nucleating Activity of the Interface

The second phenomenon found to influence the crystallization behavior in immiscible polymer blends is the nucleating activity of the interface (Bartczak et al. 1987; Wenig et al. 1990; Wei-Berk 1993).

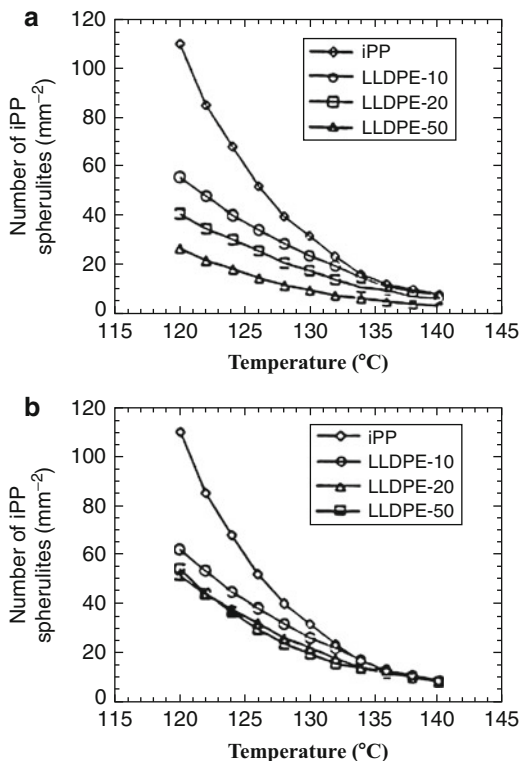
In immiscible polymer blends with a high degree of immiscibility such as PP/PS, it has been shown that nucleation at the interface affects the crystallization behavior. Wenig et al. (1990) showed that with increasing the amount of PS in a blend with PP, the nucleation shifted from preferentially thermal (related to the degree of undercooling) to more athermal. This was explained by the effect of heterogeneous surface nucleation at PS interfaces (Fig. 3.53).

However, not all interfaces can produce additional nucleating centers. For immiscible and highly incompatible polymer blends, since their interfacial tension is higher, the interface is very sharp (Helfand and Tagami 1972). Such interfaces can rarely induce new nuclei. Furthermore, on a molecularly smooth surface, a new layer can only be grown after secondary nucleation, and a somewhat lower energy barrier is present, since the surface area which must be created is smaller (Hoffmann et al. 1992). Only an interface which wets well with the crystallizable matrix, so that a crystalline chain can deposit on it, can cause heterogeneous nucleation (Turnbull 1950; Geil 1973). The wetting ability between two melt phases can be calculated from the spreading coefficient F_{12}. An example can be given by the immiscible polymer blend pair PP/PS (Bartczak et al. 1987; Fig. 3.53).

Furthermore, the *physical state* of the second component at the time of matrix nucleation is of importance. It may be presumed that the mode of nucleation of a polymer in the presence of solidified domains of the second polymeric phase is heterogeneous, and therefore the nucleation rate should be higher than in the pure homopolymer. The effect of blending on the nucleation behavior is more subtle and complex in the presence of a molten second component. Factors such as miscibility, relative melt viscosity, and inherent crystallizability all influence the formation of critical size nuclei (Nadkarni and Jog 1991).

Nucleation by the interfaces contributes to the crystallization behavior proportionally to the *total amount of interface* in the blend system. The finer the amorphous droplets are dispersed, the larger the total interfacial contact surface, and thus the higher is the possibility of nucleation at these interfaces.

The main factors determining the melt morphology are the blend composition, the difference in melt viscosity between both phases, and the interfacial tension. Hence, the nucleation effect on the crystallization behavior should be more pronounced in blends containing a higher amount of the dispersed phase, or in blends composed of components with nearly equal melt viscosities. It has to be noticed that due to coalescence, upon increasing the amount of the amorphous component, larger domains are formed. As a result, the total interfacial contact area may not increase proportionally, leading to a less-than-linear increase of T_c with increasing amount of the amorphous component (see Figs. 3.55 and 3.53).

Fig. 3.55 Influence of the amount of dispersed phase, mixing time, T_{melt} and $T_{c,iso}$ on the amount of nuclei per volume unit in the immiscible PP/PS blend (**a**) after $2\times$ mixing, (**b**) after $3\times$ mixing; T_{melt} was set to 190 °C (*open symbols*) or 220 °C (*filled symbols*); $T_{c,iso}$ for experiments was 125 °C (*circles*) or 130 °C (*blocks*) (Bartczak et al. 1987)


An interesting application of the direct relationship between nucleating interfaces and the total amount of the interfacial contact surface can be found in *compatibilized* immiscible blends. In these systems, the dispersed phase size becomes much smaller, strongly increasing the total amount of interface at which nucleation can occur. Some authors reported that this could cause an upward shift in the T_c by up to 10 °C (Wei-Berk 1993). However, other studies in which the crystallization behavior of a compatibilized blend was investigated did not always mention such a clear nucleating activity (Table 3.17).

Finally, the degree of nucleation at the amorphous/semicrystalline interfaces was found to be *temperature dependent*. When the crystallization temperature was raised, the nucleating efficiency of the interface was found to decrease (Bartczak et al. 1987).

In conclusion, the polymer interface can induce some limited number of nucleation events, but does not cause transcrystallinity, as some other crystal surfaces do. Consequently, the amorphous droplet surfaces, either in the solid or molten state, only act as a weak nucleating agent (Bartczak et al. 1987).

Nucleation Behavior of Some Selected Polymer blends
See Table 3.18

Table 3.17 Influence of compatibilizers on the nucleation behavior of the semicrystalline matrix in crystalline/amorphous polymer blends

Blend system	Observations	Explanation	Reference
PA-6/EPR + g-SA	Compatibilization ↓ spherulite size (which was not found in PA-6/EPR blends) + serious ↑ of the interfacial adhesion	Strong nucleation effect of EPR-g-SA on the PP phase	Martuscelli (1984)
PP/PS +PP/PS block	T_c increased (116 → 126 °C) (DSC) along with copolymer content up to 20–25 % of PS phase	Copolymer lowers the interfacial tension → finer dispersion → more surface available for nucleation at interface + more formation of α-phase PP crystals as T_c rises above 125 °C	Wei-Berk (1993)

3.3.3.2 Spherulite Growth of the Crystallizable Matrix

For homopolymers, the temperature dependence of the isothermal spherulite growth rate, G, is described by Eq. 3.43 (Turnbull and Fischer 1949):

$$G_I = G^{\circ} \exp[-\Delta E / kT_c [\exp] - \Delta F^* / kT_c] \tag{3.43}$$

In the case of immiscible blends with a crystallizable matrix, the spherulite growth can be disturbed to a certain degree by the presence of an amorphous phase component, dispersed in the crystallizable melt.

Phenomena Affecting the Spherulite Growth Rate: Energetic Considerations
Prior to crystallization, the amorphous component exists in the form of droplet-like domains, which at T_c can either be in the molten or glassy state. During the spherulite growth of the crystallizable matrix, small domains may be rejected by the spherulitic growth front either completely to the amorphous interspherulitic zone or only partly over some distance. Furthermore, somewhat larger domains can be occluded by the growing stacks of lamellae after which they eventually can be deformed (Martuscelli 1984; Bartczak et al. 1984). In most cases, a combination of the above-described processes is observed; small droplets are rejected over some distance, coagulate at the growth front, and are engulfed and/or deformed subsequently by the growing lamellar stacks.

The presence of droplet-like domains along the path of the crystallizing growth front can markedly disturb the spherulite growth. The outlined processes require the growth front to perform work against the interfaces, thus dissipating energy. Such energies constitute new energy barriers, controlling the spherulite growth in immiscible blends.

The spherulite growth rate depression is proportional to the type of energy barrier that has to be overcome and can be quantitatively expressed by a modified equation of the spherulite growth rate (Martuscelli 1984):

Table 3.18 Examples of the nucleation behavior of the crystallizable matrix in crystalline/amorphous polymer blends

Blend system (preparation)	Comp.[a]	Observed nucleation behavior (technique used)	Explanation	Reference
LDPE/PS (melt-mix)	90/10 80/20 70/30 60/40	No change		Baïtoul et al. (1981)
HDPE/PS (melt-mix)	90/10 80/20	No change		Aref-Azar et al. (1980)
PP/EPR (melt-mix)	95/5 90/10	Spherulite size ↓ to less than 1/2 size of PP pure with (EPR)↑ (SALS, O. M.)	EPR is nucleating agent for the production of α-type spherulites (most stable and dense packed)	Karger-Kocsis et al. (1979)
	80/20	Formation of more α-type spherulites with (EPR) ↑ (WAXS, O. M.)		
	60/40	T_c ↑ with (EPR) ↑ (DSC)		
PP/EPR (solvent-mix + melt-mix)	90/10 80/20 (70/30)	N/S in PP phase ↑ with (EPR) ↑, mainly at higher (EPR) ⇒ spherulite size ↓ (O. M.)		Martuscelli et al. (1982), Coppola et al. (1987), Kalfoglou (1985)
PP/EPR (melt-mix)	95/5 90/10 80/20 70/30	N/S with (EPR) ↑ (5–7x) This effect is more pronounced when the % ethylene ↑ or the MW ↓ of the used EPR (O. M.)	EPR acts as a nucleating agent, probably due to migration of nuclei from EPR to PP phase	Martuscelli (1985)
PP/EPDM (solvent cast film)	90/10 80/20 70/30	N/S in PP phase ↑ with (EPDM) ↑, mainly at higher (EPDM) ⇒ spherulite size ↓ (O. M.)		Martuscelli et al. (1983)

Table 3.18 (continued)

Blend system (preparation)	Comp.[a]	Observed nucleation behavior (technique used)	Explanation	Reference
PP/PIB (melt-mix)	90/10 80/20 70/30	N/S is not affected by addition of PIB (O. M., thick sheet cross section)	No additional nucleation effects	Bianchi et al. (1985), Martuscelli (1985)
PP/PIB (solvent-mix)	90/10	N/S seriously ⇈ with addition of PIB up to 30 times N/S in PP pure (O. M., thin film)	PIB seems to be an effective nucleating agent	Martuscelli et al. (1983), Martuscelli (1985)
PP/SBS (melt-mix)	75/25 50/50	T_c ↑ slightly ($\pm2\,^\circ$C) with addition of SBS (DSC)	SBS is a weak nucleating agent for PP	Ghijsels et al. (1982)
PP/SBS (melt-mix)	95/5 90/10	Spherulite radius ↓ with addition of SBS (O. M., SALS)	SBS is a weak nucleating agent for PP	Karger-Kocsis (1979)
PP/PS (melt-mix)	90/10 80/20	N/V ↑ with (PS)↑ (up to 7x N/V found in pure PP)	Mainly migration of nuclei from PS phase to PP phase	Bartczak et al. (1987)
	70/30	This effect is more pronounced with longer mixing times (O. M.)	Some limited nucleating activity of PS droplets at interface because of their high interfacial tension	
PP/PS (solvent-mix)	90/10	N/S ↑ due to addition of PS up to 20 % PS (4×)	Nucleating activity of PS at the interface	Wenig et al. (1990)
	80/20 70/30	This increase becomes less pronounced with further (PS)↑ (O. M.)	When (PS) > 20%, coalescence of droplets occurs ⇒ less ↑ interfacial area	
	60/40 50/50	Avrami exponent n ↓ from 3 to 2 (DSC)	Nucleation changes from thermal to athermal due to nucleation at interfaces	

PP/PS (melt-mix)	96/4 77/23 65/35 60/40	$T_c \uparrow$ from 121°C (4%PS) to 127°C (40% PS) (DSC)	Nucleating activity of the PS interface on PP	Wei-Berk (1993)
PP/PS (melt-mix)	90/10 80/20 70/30 50/50	No significant change in T_c visible		Santana and Müller (1994)
sPS/PVME[b] (solvent-mix and molten up)	80/20	Formation of larger spherulites with (PVME) $\uparrow$ (O. M.)	Migration of impurities during mixing from sPS to PVME phase	Cimmino et al. (1993a)
	70/30 50/50	$t_{0.5} \uparrow$ during isothermal crystallization (DSC)		

[a]Other compositions than the ones mentioned have been investigated sometimes
[b]PVME and sPS are immiscible as long as the concentration PVME remains larger than 10 % of the blend

Table 3.19 Expressions for the dissipation energy terms and corresponding spherulite growth rates in a crystalline/amorphous polymer blend system (Martuscelli 1984; Bartczak et al. 1984)

Rejection of droplets by growing spherulites	Occlusion of droplets in growing lamellae	Deformation of occluded droplets[a]
$E_1 = 1.5 \, (EGR_s\mu_Mc/\rho_Mr^2)$	$E_3 = 3C\mu_M\Delta F/\rho_Mr$	$E_4 = U(K) \, (3C\mu_M\gamma_{PS}/\rho_Mr)$
$G = G_1/(1 + (3\mu_McEG_1R_s/2\rho_M{}^2RT))$	$G = G_1 \exp(-3C\mu_M\Delta F/\rho_MrRT)$	$G = G_1 \exp(-U(K). (3C\mu_M\gamma_{PS}/\rho_MrRT))$
$E_2 = C\mu_M\rho_PG^2/2\rho_M$		
$G = G_1 \exp(-C\mu_M\rho_PG^2/2\rho_MRT)$		

G_1 is the undisturbed spherulite growth rate

μ_M is the molecular mass of the repetitive unit of the macromolecular chain of the crystallizable matrix

γ_{PS} is the interfacial free energy between the crystallizing solid and the inclusions

ρ_M and ρ_P is the density of the matrix and of the dispersed component

R_s and r is the radius of spherulite and of the dispersed particles, respectively

c is the volume concentration of the noncrystallizable component

R is the gas constant

E is the kinetic energy supply required to move the dispersed droplet along with the motion of the crystallizing front $= 2/3 \, G^2 \, \Pi r^2 \, \rho_P$

[a]The energy of deformation is the sum of two terms: the first is related to change of the surface of particles and the second to deformation of viscoelastic material. U(K) is a complicated function of the coefficient of deformation K of the particles. In the expression of E_4, only the change in surface is taken into consideration with reference to the case where $\Delta F > 0$

$$G = G_1\exp[-(E_1 + E_2 + E_3 + E_4)/kT_c] \qquad (3.44)$$

where G_1 is the spherulite growth rate of the plain crystallizable polymer (theoretically described by the Turnbull-Fisher equation); E_1 is the energy dissipated for rejection (proportional to the melt viscosity); E_2 is the energy needed to overcome the inertia of the drops; E_3 is the energy needed to form a new interface if drops are engulfed; and E_4 is the energy dissipated for deformation of occluded particles.

Theories for the description of these energies for a non-polymeric solidification front were developed by Cissé and Bolling (1971) and by Omenyi et al. (1981). Bartczak et al. (1984) have modified these theories in order to apply them to the case of a crystalline polymeric front that grows according to a spherulite-like morphology, while in the melt, noncrystallizable polymeric domains of spherical shape are present (Table 3.19).

The driving force for rejection, occlusion, or deformation processes is equal to the difference of interfacial free energies (Martuscelli 1984):

$$\Delta F = \gamma_{PS} - \gamma_{PL} \qquad (3.45)$$

where γ_{PS} is the interfacial free energy between crystallizing solid and the inclusions, and γ_{PL} is the interfacial free energy between the melt and the inclusions. When ΔF is positive, the particle droplet will be rejected (Wei-Berk 1993).

Table 3.20 Energy dissipated in PP/TR blends for rejection, occlusion, and deformation of the TR droplets by the growing PP lamellae (Martuscelli 1984; Bartczak et al. 1984)

Process	Energy (J/mol PP repeating units)
Rejection	10^1–10^4
Kinetic energy of rejection	10^{-15}–10^{-14}
Occlusion	10^{-2}–10^{-1}
Deformation: surface change term	10^{-1}–10^0
Deformation: viscous term	10^{-7}–10^{-6}

Martuscelli (1984) and Bartczak et al. (1984) have calculated the energies dissipated by growing PP spherulites in a blend with dispersed rubber particles for all the abovementioned phenomena that may disturb the spherulite growth (Table 3.20).

It can be concluded that mainly rejection of small particles and to a lesser extent deformation of large engulfed droplets (requiring the formation of new surface boundaries) cause a depression in the spherulite growth rate.

Factors Influencing the Spherulite Growth Rate, *G*

Several factors determine the amount of energy required by the growth front to be overcome in order to allow the crystallizable matrix to form spherulites.

The first and most important of these is the *crystallization temperature*, T_c. The higher the isothermal crystallization temperature above $T_{c,\text{max}}$, the slower the spherulites will grow. However, higher T_c also implies a lower melt viscosity. In such case, small droplets will be rejected easier, consuming less energy. This is reflected in a spherulite growth rate, nearly independent on the total amount of small amorphous droplets to be rejected, while at lower T_c, it could be clearly seen that the growth rate is much affected by the amount of fine droplets (Fig. 3.56)

The temperature dependence of the spherulitic growth rate has been theoretically treated (Wenig et al. 1990), for several blends composed of a PP matrix in which PS droplets were dispersed. This temperature dependence could be calculated based on the work done by Hoffmann (1983) and by Suzuki and Kovacs (1970) and is defined as follows (Fig. 3.57a):

$$\text{for } T < T_g - C_2 : G(T) = 0$$
$$\text{for } T_g - C_2 < T < T_m{}^\circ : G(T) = G{}^\circ \exp\left[-C_1 C_2 / (C_2 + T - T_g)\right] \exp\left[(-C_3)/T(T_m{}^\circ - T)\right]$$
$$\text{for } T > T_m{}^\circ : G(T) = 0$$

$$(3.46)$$

where T_g is the glass-transition temperature of the crystallizable component; $T_m{}^\circ$ is the theoretical melting temperature of the crystalline component; G°, C_1, C_2, and C_3 are parameters describing the growth rate behavior in the blends.

For the crystalline component, the parameters from the WLF equation, C_1 and C_2, can be found from literature (Icenogle 1985). T_g and $T_m{}^\circ$ can be measured for pure crystallizable component. The parameters G° and C_3 can be calculated from the experiments that give the spherulite growth rate G as

Fig. 3.56 Theoretical estimation for spherulite growth rate depression in immiscible PP-based blends in the case of *rejection* of particles: influence of particle size, $T_{c,iso}$, and volume concentration of the second component (Martuscelli 1984)
a function of temperature T. By plotting the value $\ln G + C_1C_2/(C_2 + T - T_g)$ versus $1/(T(T_m - T))$ for the entire crystallization temperature range, a linear plot is obtained from which the values of $G°$ (intercept) and C_3 (slope) for all the blend compositions can be determined (Fig. 3.57b). Once all these parameters are known, the growth rate can be estimated as a function of temperature for all blend compositions, according to Eq. 3.46.

Secondly, the *blend composition* is of importance as well. The finer the dispersion (i.e., at low content of the amorphous phase, nearby equal melt viscosities of matrix and dispersed phase, etc.), the more droplets need to be rejected. This high energy-consuming process reduces the spherulite growth rate (see Fig. 3.57).

Fig. 3.57 (**a**) Temperature dependence of the spherulite growth rate, G, for PP (experimental values were fitted using the function defined in Eq. 3.46); (**b**) plot to determine the parameters $G°$ and C_3 ($C_1 = 25$, $C_2 = 30$ K, $T_g = 260$ K, $T_m° = 460.5$ K) (Wenig et al. 1990)
Spherulite Growth Rate Investigations in Some Typical Polymer Blends
See Table 3.21

3.3.3.3 Overall Crystallization Kinetics

The effect of blending on the overall crystallization rate is the net combined effect of the nucleation and spherulite growth. Martuscelli (1984) observed that in blends of PP with LDPE, crystallized at a T_c high enough to prevent any LDPE crystallization, the overall rate of crystallization of the PP matrix phase (thus in the presence of the LDPE molten droplets) was progressively depressed with increasing content of LDPE (Fig. 3.58).

This can be seen in the plot of $t_{1/2}$ (halftime of crystallization at a fixed $T_{c,iso}$) versus blend composition. The observations agree very well with the findings that the growth rate of the PP spherulites is almost unaffected, while the nuclei density decreases with increasing LDPE content due to impurity migration from PP to LDPE phase.

A different case has also been explored by Martuscelli (1984) for PA-6 blended with an EPR-rubber. As shown in Fig. 3.59, $t_{1/2}$ of the PA-6/EPR blend decreased (faster overall crystallization rate) as the content of the rubbery phase increased, especially at lower concentrations of the EPR phase.

Table 3.21 Examples of the spherulite growth rate, G, of the crystallizable matrix in crystalline/amorphous polymer blends

Blend system	Comp.	G (µm/min)[a] (from O. M.)	$\neq T_c$[b]	Final semicrystalline morphology	Comments	Reference
PP/EPR (thin film)	100/0	32	x	Some droplets are ejected interspherulitically	Small ↓ of G which is composition dependent	Martuscelli et al. (1982)
	90/10	±30				
	80/20	±27		At low (EPR): droplets are ejected for a short distance and then occluded intraspherulitically		Martuscelli (1985)
	70/30	±27				
		at 121 °C				
PP/EPDM (thin film)	100/0	15	x	Droplets are occluded intraspherulitic	Only small ↓ of G independent of the blend composition	Martuscelli et al. (1983)
	90/10	11				
	80/20	12		Droplets are aligned along radial direction due to coalescence of droplets upon rejection for short distance, followed by deformation		Martuscelli (1985)
	60/40	13				
		at 125 °C				
PP/PIB (thin film)	100/0	32	x	Most droplets (3–5 µm) are occluded intraspherulitically	Clear depression of G on addition of PIB which is strongly dependent on MW PIB and composition[c]	Martuscelli et al. (1982)
						Martuscelli et al. (1983)
	90/10	23		Sometimes droplets are rejected (for short distance or even interspherul.) if MW PIB low (PIB) low (<10 %)		Martuscelli (1985)

	80/20	6.0			
	70/30	7.0			G↑ with (PVME) ↑ due to facilitated transport of chains (PVME and PS chains are partially miscible ⇒ Tg↓)	Cimmino et al. (1993)
	50/50	–			
		at 244 °C			

[a]Some of the listed data were extracted from plots presented in the article

[b]x indicates that the influence of different crystallization temperatures T_c has been investigated

[c]PIB is shown to be partially miscible with the amorphous phase of PP at low concentrations. Hence, the behavior can deviate and exhibit some typical characteristics as in miscible systems
Fig. 3.58 Global crystallization kinetics in immiscible PP/LDPE blends; influence of the amount dispersed phase and the crystallization temperature, T_c, on the halftime for crystallization, $t_{1/2}$ (Martuscelli 1984)
Fig. 3.59 Variation of the halftime of crystallization, $t_{1/2}$, with the percent of added rubber component (EPR) and T_c for PA-6/Dutral and the compatibilized blend PA-6/Dutral-g-SA (Martuscelli 1984)

Fig. 3.60 Evolution of DSC crystallinity from cooling (▼) and melting curves (■) versus PA6 droplet size for various (PS/SMA2)/PA6 blend compositions (Tol et al. 2005c)
The reverse could be observed in a compatibilized blend. Because in these blends a serious decrease of the spherulite size was observed, the authors concluded that the compatibilizer acted as a nucleating agent for the PP phase. However, due to the increase of the melt viscosity upon compatibilization, the overall crystallization kinetics was retarded. Additionally, they observed experimentally that ΔF^* (free energy for the formation of a nucleus of critical size) and σ_e (surface free energy of folding) in compatibilized blends were larger than in PA-6 homopolymer. An opposite trend was observed for the physical PA-6/EPR blends. No further investigations have been done to elucidate this phenomenon.

The crystallization kinetics of PA6 in immiscible blends of PS/PA6 and (PS/SMA2)/PA6 have been investigated over very broad temperature range using high cooling rates (Tol et al. 2005c). For immiscible blends with PA6 droplets of micrometer size, exhibiting moderate decrease of crystallization temperature compared to the PA6 bulk crystallization, an athermal nucleation mechanism was suggested based on nucleation process in a very small temperature interval. Blends of PA6/PS compatibilized using SMA2 having submicrometer-sized PA6 droplets, crystallizing at 90 °C (i.e., a supercooling of 100 °C compared to Tc bulk), a random nucleation event was found using isothermal DSC experiments, which is characteristic of a homogeneous nucleation process. This effect was persistent up to 40 wt% PA6 (Fig. 3.60). This concentration is the highest concentrated heterogeneous system reported, exhibiting homogeneous nucleation kinetics. Crystallinities were strongly affected by the confining conditions of the droplets. For 1–30 μm-sized PA6 droplets crystallizing at intermediate temperatures, the crystallinity decreased with decreasing PA6 droplets size from 36 % for bulk PA6 to 22 %. For the submicrometer-sized PA6 droplets, a very strong decrease in crystallinity was found down to 10 %.

3.3.3.4 Final Semicrystalline Morphology

The addition of a second noncrystallizable component to a crystallizable matrix can cause drastic variations of important morphological and structural parameters of the
Fig. 3.61 Optical micrographs of melt-crystallized films of PP/EPDM blends at $T_c = 135\,^{\circ}\mathrm{C}$; (**a**) 90/10, crossed polarizers; (**b**) 90/10, parallel polarizers; (**c**) 60/40, crossed polarizers (Martuscelli et al. 1983)

semicrystalline phase, such as the shape, size, regularity of spherulites and interspherulitic boundary regions, lateral dimensions of the lamellae, etc. These factors may greatly influence the mechanical behavior and, in particular, the fracture mechanisms and thus are of great importance, especially when the toughening of semicrystalline polymer blends is considered.

The first important parameter determining the final crystalline morphology is the *nucleation density*, N (see Sect. 3.3.3.1). An increase in the nucleation density (per volume unit of the crystallizable material) due to migration of nuclei from one phase toward the other, or due to a nucleating activity at the polymer/polymer interface, results in the formation of more numerous but smaller spherulites.

The spherulite *growth rate*, G, also plays a role.

- At low G values, there is a higher probability that all dispersed particles can diffuse fast enough away from the growth front and be pushed along until complete crystallization. The second phase component will then be found mainly in the interspherulitic regions.
- At high G values, even small particles will not be rejected anymore. Hence, the homogeneously distributed droplets will be as such engulfed, rejected into newly formed boundaries behind occluded particles, and eventually deformed. This results in a radial-like distribution of the droplets within the spherulite (Fig. 3.61).
- At intermediate growth rates, the dispersed drops will first be pushed along, but due to an increase of the amount of droplets at the solidification front, they will coagulate and subsequently be engulfed. This results in a spherulite center consisting of pure crystalline material and an outer layer in which dispersed particles are occluded.
Fig. 3.62 Optical micrographs of isothermally ($T_c = 135$ °C) crystallized thin films of PP/PIB (HM) blends with different compositions (Martuscelli et al. 1983)

Another parameter strongly influencing the final crystalline morphology is the *blend composition* (Fig. 3.62).

The higher the amount of the amorphous phase, the higher the chance to have a coarse melt morphology containing lots of large, easily coalescing amorphous droplets. In such a case, the crystallizing growth front will mainly engulf and deform these droplets. The resulting crystalline morphology will be heavily disturbed by the second phase component.

Some examples of the final semicrystalline morphology in several immiscible crystalline/amorphous blend systems have already been given in Tables 3.21 and 3.22 for the discussion of the spherulite growth rate (Sect. 3.3.3.2). Some more information about this topic can be found in the articles listed in Table 3.23.

3.3.3.5 Melting Behavior of the Crystalline Matrix in Crystalline/ Amorphous Blends

The behavior of binary blends with only one crystallizable component has been studied by several authors, who have investigated different systems. The crystals of the crystallizable matrix have grown in equilibrium with their own melt phase. The presence of separate domains of noncrystallizable component, dispersed in the molten matrix during the crystallization process (owing to the kinetic and morphological effects), may cause a depression of the observed melting temperature, T_m' (Martuscelli 1984). However, the changes in T_m' will be only in the range of a few degrees C.

Some binary systems do not show any depression at all, indicating that T_m' and T_m do not depend on blend composition. This is found when the second dispersed

melt viscosity of the dispersed phase and the matrix, the viscosity ratio, the interfacial tension, and the processing conditions (Utracki 1989; Folkes and Hope 1993).

The crystallization behavior of a dispersed melt phase, for example, discrete melt droplets, in an amorphous matrix can be dramatically affected compared to that of the bulk polymer. It has been reported by several authors that crystallizable dispersed droplets can exhibit the phenomenon of *fractionated crystallization* originating from the primary nucleation of isolated melt particles by species with different nucleating activities (heterogeneities, local chain ordering)

Table 3.24 Examples of the melting behavior of the crystallizable matrix in some crystalline/amorphous blend systems

Blend system	$T_{m\downarrow}$	$T_m \uparrow$	References
PP/EPR		$T_m \uparrow$ with (EPR) ↑	Martuscelli et al. (1982)
		Effect is largest at high ethylene content and low MW of EPR	Martuscelli (1984)

3.3.4.1 The Phenomenon of Fractionated Crystallization of a Dispersed Phase

Crystallization is a phase transition that is controlled by nucleation and growth (Wunderlich 1976). As it has been outlined in Sect. 3.2.2, crystallization during cooling from the melt in homopolymers is initiated by impurities (primary heterogeneous nucleation), after which the crystallizing front spreads over the whole material via the secondary nucleation, before other heterogeneities, requiring a larger degree of undercooling, $\Delta T_{c,i} = T_{mo} - T_{c,i}$, can become active. A single crystallization exotherm is generally observed in DSC thermograms. So, the primary nucleation is the rate-determining step of crystallization. The dynamics of the process depend for a given component only on the temperature.

However, for polymer blends in which the crystallizable phase is dispersed into fine droplets in the matrix, crystallization upon cooling from the melt can sometimes occur in several steps (fractionated crystallization) that are initiated at different undercooling, often ending up with a crystallization at the homogeneous crystallization temperature $T_{c,hom}$ (Aref-Azar et al. 1980; Baïltoul et al. 1981; Ghijsels et al. 1982; Santana and Müller 1994).

The first investigations concerning the crystallization in discrete droplets date from 1880; Van Riemsdyk reported that small gold melt droplets solidify at much

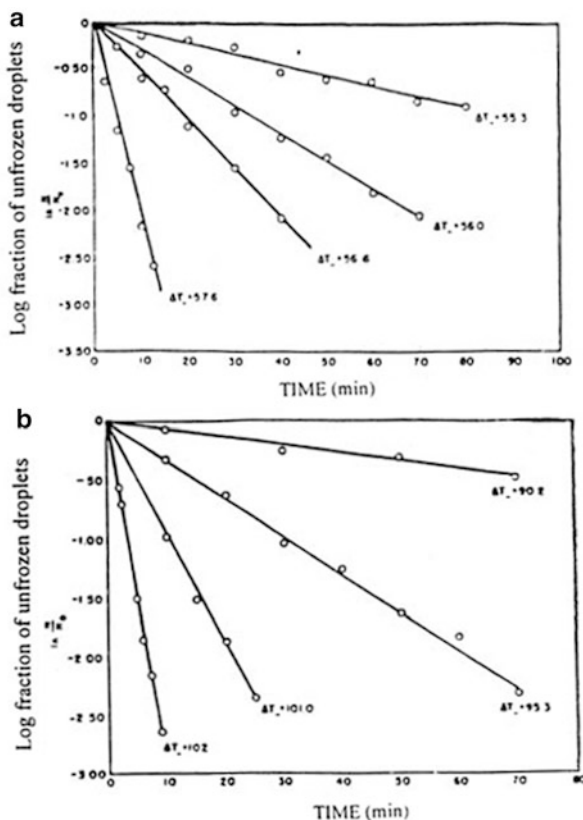
[b]Nucleating activity of the suspending medium prevents to detect the real undercooling needed to obtain a homogeneous crystallization

larger undercoolings than the bulk material (Van Riemsdyk 1880). Similar observations were made later for other metals (Perepezko and Paik 1982), indicating this to be a basic crystallization phenomenon.

The creation of sufficiently small polymer droplets as a stable suspension was much more difficult. It was therefore only first in 1959 that similar experiments have been reported for polymers (Frensch et al. 1989; Table 3.25).

It was clearly observed that the phenomenon of delayed crystallization was directly related to the size of the dispersed droplets (Koutsky et al. 1967). Only the smallest droplets showed crystallization at much larger undercooling, droplets having a sufficiently large diameter crystallized at temperatures approaching the bulk crystallization temperature, T_c. The explanation for this behavior is obvious: the spectrum of undercoolings at which several crystallization steps occur reflects the difference in nucleating activity of the various heterogeneities available in the melt (Frensch et al. 1989). It can be assumed that if the dispersion of the polymer is so fine that not every droplet contains at least one heterogeneity of type 1, only those droplets containing the latter will crystallize at an undercooling $\Delta T_{c,1}$. Since the droplets are physically not in contact with each other, further growth via secondary nucleation in other crystallizable droplets is impossible. During further cooling, heterogeneities of type 2 requiring the second lowest degree of undercooling, $\Delta T_{c,2}$, can become active in some of the remaining droplets, resulting

Fig. 3.64 Isothermal homogeneous crystallization of finely dispersed polymer droplets as a function of time (**a**) linear PE, (**b**) PP (Koutsky et al. 1967)


in a second crystallization exotherm. This process goes on until finally some very fine droplets that have not yet been nucleated by the heterogeneous species will crystallize in a homogeneous mode.

In isothermal experiments, the fractionated crystallization of finely dispersed crystallizable droplets is reflected by longer crystallization times before the same degree of crystallinity X_c is obtained. This has been illustrated clearly by Koutsky et al. (1967) in experiments (see Table 3.25) in which finely dispersed droplets of PE and PP in a suspension of silicon oil were crystallized at different undercoolings ΔT_c (Fig. 3.64).

It should be mentioned that the occurrence of a fractionated crystallization is related only to the number densities of dispersed polymer particles and primary heterogeneous nuclei. No direct physical relationship has been found with the number or size of spherulites. These parameters are additionally influenced by the cooling rate and the crystallization temperature (Frensch et al. 1989).

Several factors can influence the fractionated crystallization behavior. An important parameter that has already been discussed is the thermal history of the sample. Crystallizable dispersed droplets that were submitted to premelting at higher temperatures or longer times generally display a shift in the heterogeneous

Table 3.26 Influence of compatibilization on the crystallization behavior of the dispersed phase in amorphous/crystalline polymer blends

nucleation spectrum to greater undercooling. The homogeneous crystallization temperature however is not displaced and thus independent of the thermal history (Koutsky et al. 1967). This may become less evident for blends with unstable phase morphology (rapid phase coarsening upon annealing); long residence times in the melt will cause fine droplets to coarsen. Consequently, the newly formed larger droplets have a higher probability to crystallize close to the bulk crystallization temperature of the homopolymer.

The degree of dispersion of the minor phase plays a crucial role. Important factors here are the blend composition, the interfacial tension between both components, the melt viscosity of both components, the processing device and mixing conditions, the blend preparation method, etc.

In this context, it is interesting to evaluate also the influence of compatibilization on the crystallization behavior of the dispersed phase. Since compatibilization reduces the droplet size of the minor phase even more drastically, it can be expected that this can lead to a serious shift of the crystallization temperature toward lower temperatures, resulting in more pronounced fractionated crystallization or even in a homogeneous crystallization. However, this issue is more complex due to numerous other factors involved in the nucleation process. Some examples from the literature are listed in Table 3.26. They illustrate how differently the compatibilization can influence the crystallization behavior of the dispersed phase.

3.3.4.2 Theoretical Considerations of the Fractionated Crystallization

In crystallizable dispersed droplets, several different nucleating heterogeneities (type i) can be present, each having a typical free energy for the formation of a nucleus of critical size, ΔF^*, at an undercooling $\Delta T_{c,i}$:

$$\Delta F^* \approx \Delta y_{pn}/\left(\Delta T_{c,i}\right)^2 \tag{3.47}$$

This free energy is proportional to the specific interfacial free energy difference Δy_{pn} defined as (Wunderlich 1976)

$$\Delta y_{pn} = y_p(m, c) - y_{pn}(m) + y_{pn}(c) \tag{3.48}$$

where the indices refer to polymer (p), melt (m), crystal (c), and nucleus (n); $y_{pn}(m)$ is the interfacial energy between the nucleating species and the polymer melt; $y_{pn}(c)$ is the interfacial energy between the nucleating species and the polymer crystal; and $y_p(m, c)$ is the lateral surface free energy between the crystal and its own melt.

In the case of a homogeneous nucleation, the expression for Δy_{pn} can be simplified to read: $\Delta y_{pn} = 2\, y_p(m, c)$

If one assumes that for the onset of crystallization $\Delta F^*/kT$ must be smaller than a certain critical value (i.e., a nucleus of critical size can be formed at the given temperature), independent of the material, and if one neglects that the crystallization also depends on the temperature-dependent mobility of the crystallizable segments, the following expression for the relation between Δy and the degree of undercooling for two heterogeneities of type 1 and type 2 can be given (Frensch et al. 1989):

$$\Delta y1/\Delta y2 \approx \left(T_{c,1}/T_{c,2}\right)\cdot\left(\Delta T_{c,1}/\Delta T_{c,2}\right)^2 \tag{3.49}$$

where $T_{c,1}$ and $T_{c,2}$ represent the temperatures at which nucleation is induced by the heterogeneity of type 1 and 2, respectively (Fig. 3.65).

In the special case of a homogeneous nucleation, Eq. 3.49 can be simplified to read

$$\Delta T_{c,\,hom} = T_c^\circ - T_{c,\,hom} = T_c^\circ/5;\ \ i.e., T_{c,\,hom} = 0.8 T_c^\circ \tag{3.50}$$

where T_c° is the crystallization temperature in the bulk polymer (in K).

From the latter (Eq. 3.50), the homogeneous crystallization temperature for each polymer can be estimated in a simple way.

Furthermore, from Eq. 3.49 for heterogeneity of type 1, one may write

$$\Delta y1/y_p(m, c) \approx 62.5\, \left(T_{c,1}/T_c^\circ\right)\left(\Delta T_{c,1}/T_c^\circ\right)^2 \tag{3.51}$$

From this dependence, the relative values of Δy for different heterogeneities can be calculated at the corresponding degrees of undercooling.

Fig. 3.65 Plots of the relative specific interfacial energy difference $\Delta y/y$ versus the relative undercooling $\Delta T/T°_m$ at which a heterogeneity nucleates the polymer; (1) and (2), two different heterogeneous nucleations; (3) homogeneous nucleation (Frensch and Jungnickel 1989)
From the fractionated crystallization behavior and the blend morphology, one can determine the number density of the nucleating active species. Among a large number of small polymer droplets, each having a volume V_D, the fraction of droplets that contain exactly z heterogeneities of type 1 (inducing normally crystallization in the bulk polymer at $T_c°$) follows a Poisson distribution function (Pound and LaMer 1952):

$$f_z^{(1)} = \left[\left(M^{(1)} \cdot V_D \right)^Z / z! \right] \exp\left(-M^{(1)} \cdot V_D \right) \tag{3.52}$$

where $M^{(1)}$ is the concentration of heterogeneities of type 1 and $M^{(1)}.V_D$ is the mean number of heterogeneities of type 1 per droplet with volume V_D.

Hence, the fraction of droplets that contain at least one heterogeneity of type 1 can be given by

$$f_{z>0}^{(1)} = 1 - f_0^{(1)} = 1 - \exp\left(-M^{(1)} \cdot V_D \right) \tag{3.53}$$

Now considering that not all droplets have the same size, $f_{z>0}^{(1)}$ describes that fraction of the droplets (with average volume V_D) that crystallize induced by heterogeneity of type 1. The other droplets will crystallize at a different crystallization step. From the relative intensities of the fractionated crystallization steps, one can estimate the concentration of the different heterogeneities, if the mean size of these droplets is known.

In the special case where the usual crystallization from heterogeneity of type 1 is completely suppressed, Eq. 3.52 can be written as

$$M^{(1)} \cdot V_D << 1 \tag{3.54}$$

Table 3.27 Evaluation of the blend morphology and thermal behavior in immiscible PS/HDPE blends in which HDPE was the minor phase (Aref-Azar et al. 1980)

wt% HDPE	Size-dispersed phase (μm)	Number droplets (cm^{-3})	ΔH_m^a (J/g)	X_c^b (%)

[a]ΔH_m for pure HDPE is 293 J/g
[b]Degree of crystallinity, X_c, for HDPE homopolymer is 80 %

3.3.4.3 Droplet Crystallization in the Presence of a Matrix Melt

In most immiscible crystalline/amorphous polymer blends, the crystallization of the dispersed phase occurs in the presence of a molten matrix phase. In the following description, examples will be categorized according to the major classes, as listed in Table 3.14.

Polyethylene Blends

Blends of PS/HDPE have been investigated by Aref-Azar et al. (1980). Table 3.27 gives an overview of the crystallization behavior in the crystallizable dispersed phase.

It should be noted that the crystallization kinetics is related to the size of the dispersed HDPE droplets and the nucleation density. An increase in the amount amorphous PS caused the HDPE phase to be dispersed into finer droplets that, as a result, exhibited a lower degree of crystallinity, X_c, when isothermally crystallized. Furthermore, a higher degree of undercooling was needed to reach the same X_c in blends where the HDPE phase was dispersed into finer droplets, indicating that crystallization depends on the temperature. The melting behavior of the HDPE phase did not seem to be affected by blending.

Recently, Müller et al. (1995) and Morales et al. (1995) have reported on the crystallization of LLDPE that was finely dispersed in a PS matrix. A good correlation was found between the size of the LLDPE phase and the tendency to crystallize in a fractionated way. The authors showed that the relationship is only sensitive to the volume of the dispersed crystallizable droplets and not to the shape of the droplets.

Polypropylene Blends

Numerous studies have been performed on the crystallization behavior of PP in blends with an amorphous component. However, only few authors paid attention to the crystallization behavior of the PP phase when it formed the minor phase of the blend.

Ghijsels et al. (1982) investigated the multiple crystallization behavior of blends in which the crystallizable PP phase was finely dispersed into a SBS-rubber (TR). In the case where the latter was finely dispersed, the authors found the PP phase to crystallize at much higher undercooling. A serious drop in the degree of crystallinity, X_c, was also reported. The melting behavior of the fractionated crystallized blend did not seem to be markedly affected, e.g., ΔH_m and T_m remained constant, independent of the amount TR added.

Wei-Berk (1993) reported on the crystallization behavior of PP droplets dispersed in a PS matrix. A slight drop in $T_{c,PP}$ (as the PP phase became the minor phase) was observed. However, the author only investigated the behavior in blends containing more than 35 % PP, and did not correlate the crystallization behavior with the blend morphology.

Recently, Santana and Müller (1994) investigated the same polymer blend. These authors reported that droplets having a diameter of less than 6 μm crystallized at higher undercooling ($T_c \approx 78$ °C), while the larger droplets crystallized at $T_c \approx 105$ °C – the latter temperature corresponding to the bulk T_c for the PP used in the studies. The authors referred to the fractionated crystallization behavior caused by a lack of heterogeneities in some of the finely dispersed PP droplets, ending up with the appearance of the homogeneous crystallization peak. Hence, the nucleation mechanism was found to be strongly influenced by the blend morphology.

Polyester Blends

Quirk et al. (1989) investigated the crystallization behavior of PET in a PET/PS 25/75 blend. The PET particle diameter as determined by SEM was found to be in the range of 5 μm, being quite large due to the large difference in interfacial tension between both phases (hindering easy droplet breakup during mixing). Suppression of the cold crystallization in the PET droplets quenched from the melt was observed, along with serious depression of the total degree of crystallinity with increasing content of the amorphous phase.

PBS/PBA crystalline/crystalline miscible blends were recently studied for their crystallization behavior by Yang et al. (2011). Upon blending with PBS, PBA was found to exhibit fractionated crystallization during the nonisothermal crystallization process. The higher isothermal crystallization temperature (TIC) of PBS (e.g., 100 °C) was favorable for the fractionated crystallization of PBA, which was probably attributed to the distribution of PBA in the preexisting PBS matrix. At high TIC of PBS, the phase segregation of PBA was more obvious, that is, PBA can be distributed in the interspherulitic region as well as interfibrillar/interlamellar region of the PBS matrix. However, at low TIC of PBS, the phase segregation was not obvious. The parameters of the crystallization kinetics suggest that PBS suppresses the crystallization of PBA, which was mainly ascribed to the physical confinement effect of PBS on PBA. From the WAXD and FTIR analyses, it was concluded that PBS facilitates the formation of the PBA α-crystal, namely, the PBA polymorphic crystallization can be regulated. From polarized OM observation, the spherulite growth direction and morphology of PBA were found to be controlled by those of PBS. This was mainly ascribed to the induction effect of growth direction of PBS lamellae on PBA ones.

Polyamide Blends

Tol et al. (2005a) intensively described the crystallization phenomenon of polyamide (PA6) semicrystalline component in an immiscible blend with pure PS or (PPE/PS) amorphous miscible mixture. The idea was to have a controlled and a varying glass-transition temperature of the amorphous phase. Two situations

were studied: uncompatibilized blends and reactively compatibilized blends using SMA reactive copolymer. The composition and viscosity ratios of the blend have been selected to generate versatile phase morphologies including the most important ones for the study, i.e., PA6 droplets in (PPE/PS) matrix.

Uncompatibilized PA6/(PPE/PS) Blends

Multiple crystallization peaks were observed in blend systems where PA6 constitutes the dispersed droplets (s 65 and 66). The blends having continuous PA6 phase do not show significant differences in crystallization behavior compared to pure PA6 homopolymer. In contrast, as PA6 content decreases, it forms discrete droplet in the matrix. The multiple crystallization peaks correspond to different degrees of supercooling. As the size of the droplet exceeds a critical size, the PA6 crystallizes around its bulk crystallization temperature (188 °C). When the morphology becomes finer and the concentration of PA6 droplets per unit volume increases, a significant part of the droplets crystallize at higher degree of supercooling as translated by the intensity of the new crystallization peaks. This was ascribed to a heterogeneous nucleation of nuclei having different activities. Three crystallization peaks have been identified in blends with (PPE/PS) matrix. One of these peaks has been formed below ($T_c = 90$ °C), the average vitrification temperature of the matrix ($T_g = 150$ °C). It has been ascribed to a homogeneous nucleation after all the heterogeneities in the droplets have been exhausted. The authors concluded that:

- When the droplet size is small enough and the number of PA6 droplets exceeds the number of nuclei active at T_c bulk, crystallization takes place in different steps, at larger degrees of supercooling, via nucleation by different types of nuclei that need a larger supercooling to become active.
- The crystallization can be affected by the thermal history.
- Self-nucleation experiments generating a larger number of nuclei crystallizing at T_c bulk can lead to a complete suppression of the fractionated crystallization phenomena.
- When the amorphous phase is vitrified prior to crystallization, the nucleation densities increase, leading to less fractionated crystallization in the dispersed droplets.
- The overall crystallization rate, determined after self-nucleation, decreases with decreasing PA6 droplet size (20–1 μm), indicating the disturbing effect of the small dimensions of the micrometer-sized PA6 particles.
- The degree of fractionated crystallization, characterized by the fraction of the droplets that crystallized at temperature below T_c bulk, can be fairly related to the volume average droplet diameter.
- The number of crystallization peaks T_c bulk is very dependent on the droplet size distribution, leading to more peaks for broader distributions (Figs. 3.66 and 3.67).

Reactively Compatibilized PA6/(PPE/PS) Blends

The authors used SMA reactive copolymer that reacts via the anhydride group with the amine groups of the PA6 semicrystalline component of the blend and the

Fig. 3.66 DSC cooling curves for a number of (PPE/PS)/PA6 blend compositions with PA6 droplets (Tol et al. 2005a)
styrene segment ensures miscibility with the PS/PPE mixture. The effects of two copolymers, SMA2 (2 % MA content) and SMA17 (17 % MA), on the crystallization of PA6 in the immiscible (PA6/(PPE/PS)) blends were compared. Figure 3.68 is very illustrative of the effect of the SMA copolymer on the crystallization behavior of the blend. A very strong transition in crystallization behavior is observed when the blend phase morphology evolves from a co-continuous to a PA6-dispersed droplets. Reactive compatibilization with SMA2 strongly decreases the PA6 droplet size in the blend by a factor of 10 (from 1–2 to 0.1–0.2 μm on average). In addition, due to compatibilization, the droplet distribution is less polydisperse compared to uncompatibilized blends. An enormous retardation of the crystallization is induced by the reactive compatibilization. The bulk crystallization around 188 °C (peak1) is completely suppressed, and a crystallization peak emerges around 85 °C (peak 3 in Fig. 3.68a, peak4 in Fig. 3.68b), about 100 °C lower than the bulk crystallization temperature. The authors performed additional experiments combining the phase morphology (droplet size and distribution measurement) and crystallization phenomena and draw the following conclusions on the effect of the reactive compatibilization on crystallization of PA6 in compatibilized immiscible PA6/(PPE/PS) blends:

– Fractionated crystallization is strongly enhanced in the submicron-sized PA6 droplets per unit volume leading to a marked delay of crystallization to very high supercooling and ultimately to crystallization at temperatures as low as 85 °C.
– A clear relation between the number of dispersed PA6 droplets per unit volume and the intensity of the homogeneous nucleation peak at this very low crystallization temperature has been found.
– Abundant reaction of the reactive copolymer with the PA6 seems to reduce the mobility of PA6 chain segments, leading to an increased fractionated crystallization in the PA6 droplets.

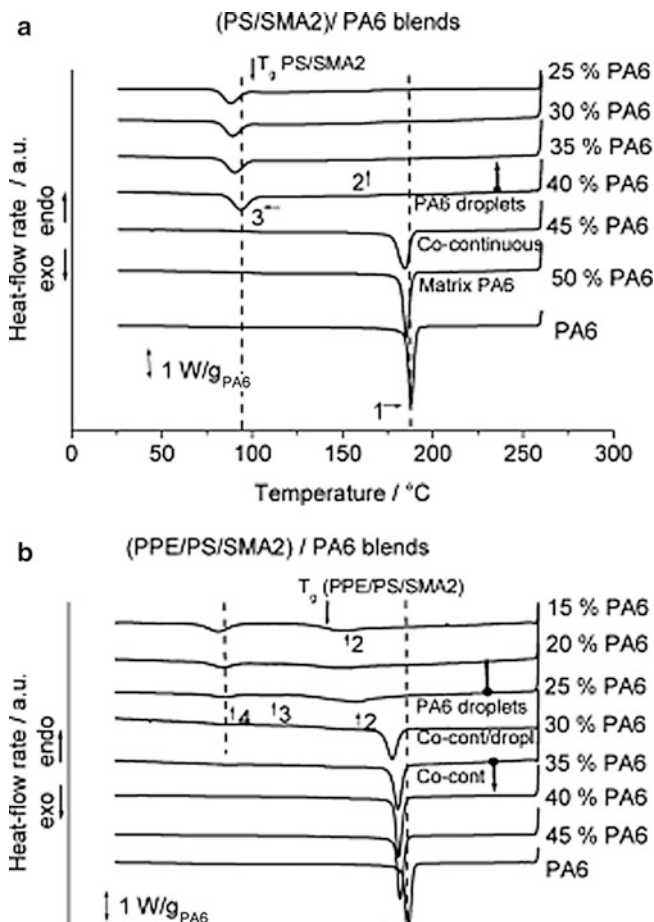
Ethylene-1-octene copolymer was also used as an amorphous blend partner of PA6 in PA6/ethylene-1-octene blend reactively compatibilized using PE-g-MA reactive copolymer (Sanchez et al. 2006). Because of the dispersed phase


Fig. 3.67 DSC cooling curves at 10 K/min for (**a**) PS/PA6 and (**b**) (PPE/PS)/PA6 blend compositions (Tol et al. 2005a)

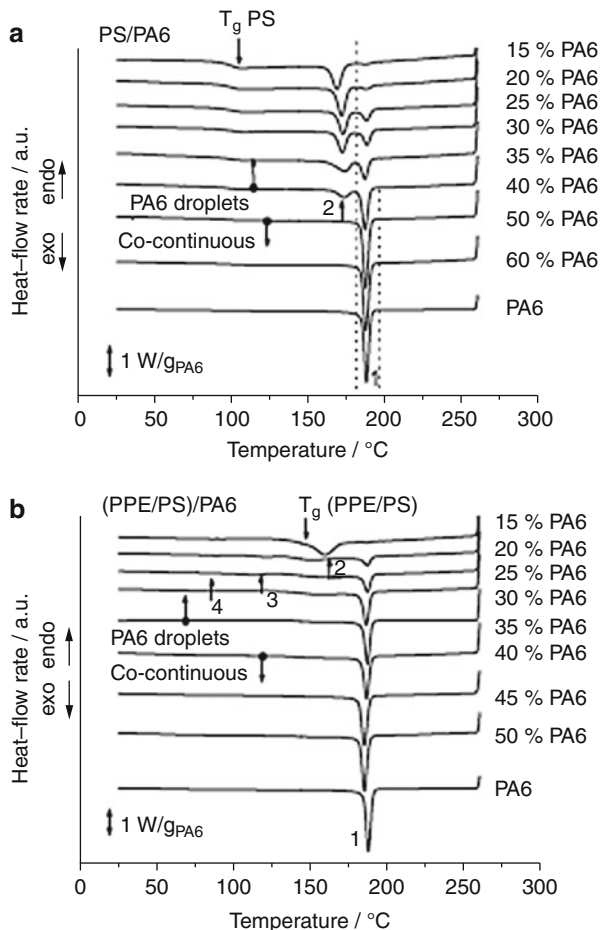
morphology, fractionated crystallization was observed, leading to an extra supercooling of PA6 (50 °C compared to bulk crystallization temperature). Self-nucleation experiments the authors used were able to demonstrate, as expected, that a lack of heterogeneities is at the origin of the fractionated crystallization.

Yordanov et al. (2005) have considered fractionated crystallization in blends of LDPE/PA6 reactively compatibilized using each of the three different types of reactive copolymers: EAA, EGMA, and SEBS-g-MA. As expected the SEBS-MA, owing to the efficient reaction of the maleic anhydride groups with the amine groups of PA6, resulted in the most significant particle size reduction of the dispersed phase. As a direct consequence, the most visible fractionated crystallization was obtained with this copolymer. Compatibilization with EGMA could not lead to PA6/LDPE blends that exhibit fractionated crystallization because of a lack of interfacial

Fig. 3.68 DSC crystallization curves for different compositions of (**a**) (PS/SMA2)/PA6 blends and (**b**) (PPE/PS/SMA2)/PA6 blends. (PS/SMA2 ratio 92/8 w/w, (PPE/PS/SMA2)/PA6 80/20, and 85/15: 95/5 w/w (PPE/PS)/SMA2 (Tol et al. 2005b)


reaction and thus inefficiency in reducing particle size. The authors performed self-nucleation experiments and concluded that the lack of nuclei is responsible for the fractionated crystallization at high supercooling and not the absolute particle size reduction.

Other Blends

Robitaille and Prud'homme (1983) studied the crystallization in the liquid/liquid phase-separated melt of the triblock copolymer PEG-PI-PEG having a minor amount of PEG. The authors reported a lower degree of crystallinity of the PEG domains along with a slight melting-point depression. Due to the fine dispersion of PEG, the droplets only crystallized at much higher undercoolings (up to 60 °C lower than the bulk T_c), and less perfect crystalline lamellae were formed. These lamellae consequently melted at lower temperatures than the usual T_m. The bulk T_c has disappeared completely. The authors related this behavior to the
Fig. 3.69 DSC cooling and heating curves for the PEG-PI-PEG block copolymer, a pure PEG sample, and PI; the homogeneous crystallization of the PEG segment at much higher degrees of undercooling does not really influence its melting behavior (Robitaille and Prud'homme 1983)

lack of heterogeneities available in the PEG microdomains, which are hence nucleated at much lower temperatures by a homogeneous nucleation mechanism (Fig. 3.69).

Tang and Huang (1994a) investigated that the crystallization behavior of PA-6 is an EPDM matrix. The fractionated crystallization of the PA-6 occurs when the PA-6 content decreased below 15 wt%. Two crystallization peaks were observed, one around the bulk $T_{c,PA-6}$ and another at about 25 °C lower, caused by the smaller PA-6 droplets having a lack in heterogeneous nuclei. The ratio of the α/γ crystalline form was not altered by the fractionated crystallization, indicating that the lower crystallizing droplets do not crystallize in another crystalline form as in the bulk.

Fractionated crystallization of the POM crystalline phase in (PS/PPE) miscible amorphous phase has been investigated by DSC, and the results were correlated to the blend phase morphology (Everaert et al. 2000). This model blend was selected to investigate both the influence of the blend phase morphology and of the physical state of the amorphous PS/PPE matrix on the crystallization behavior of the minor POM phase. To have a varying Tg of the amorphous matrix, the PS/PPE composition has been varied as 85/15, 60/40, 50/50, and 40/60 wt:wt% to have tg's of 114 °C, 134 °C, 144 °C, and 156 °C, respectively. Interesting relationships were established between the crystallization features and the parameters of the phase morphologies developed in the blend. Figure 3.70 shows the absolute degree of crystallinity of the POM crystalline phase as a function of the average particle diameter of the POM dispersed as minor phase in PS/PPE amorphous matrix (the composition of Ha4 and Ha7 are 85/15 and 50/50 PS/PPE, respectively). The authors could not correlate the degree of crystallinity to the POM particle diameter. In contrast, as the fraction of POM droplets should reflect all homogeneously crystallized material, a correlation between both parameters could be found (Fig. 3.71). To elucidate a possible effect of the phase morphology of the blend on the crystallization of the crystalline polymer, the authors have asked and discussed the following key questions: (i) What determines the onset of fractionated crystallization and/or the offset of heterogeneous nucleation at T_c, bulk?

Fig. 3.70 Relationship between the absolute degree of crystallinity, X_c, of the POM phase and the average particle diameter of the POM droplets (Everaert et al. 2000)
Fig. 3.71 Correlation between the fraction of POM droplets in POM/Ha7 blends with a composite-like phase morphology and the intensity of the homogeneous crystallization peak (Everaert et al. 2000)
(ii) Is fractionated crystallization solely related to the blend phase morphology? (iii) Under what conditions are multiple crystallization peaks possible, and what determines their number and extent? (iv) What causes the decrease of the crystallinity in fractionated crystallizing samples? The onset of fractionated crystallization was found to coincide with the center of the phase inversion region. In contrast, the morphological parameters and blend composition that could influence the offset of fractionated crystallization were less evidenced. The data presented in Table 3.28 reveal the effect of the POM content in POM/(PS/PPE) blend systems on the final degree of crystallinity, X_c, as calculated directly from fractionated crystallization.

The semicrystalline phase morphology and crystallinity of POM in POM/(PS/PPE) blends were studied with respect to fractionated crystallization (Everaert et al. 2003). The degree of crystallinity decreases with decreasing POM content with a visible shift from bulk to homogeneous crystallization. Analysis of WAXD reflections indicate that the decrease in X_c is not solely due to the formation of thinner lamellae at higher degrees of undercooling.

Table 3.28 Influence of the POM content in POM/(PS/PPE) blend systems on the final degree of crystallinity, X_c, as calculated directly from fractionated crystallization curves. X_c for POM is 54 %

3.3.4.4 Droplet Crystallization in the Presence of a Glassy Amorphous Matrix

The crystallization of dispersed domains in the presence of a solidified matrix has not yet been a field of active research. Some examples are given below.

Polyethylene Blends

The thermal behavior of PS/LDPE blends has been investigated by Baitoul et al. (1981). A clear indication of the fractionated crystallization was deduced from the appearance of two additional crystallization peaks around 71 °C and 64 °C in all blends in which LDPE was the dispersed phase. Furthermore, the crystallization kinetics was found to slow down severely when the content of PS was raised.

Kunori and Geil (1980) investigated the melting behavior of the binary PC/HDPE blends, in which the weight percentage PE varied between 2 % and 10 %. The melting temperature of the HDPE droplets did not seem to be affected.

Polypropylene Blends

The majority of published papers on the crystallization of PP in blends concerns those blends in which the T_g of the amorphous component falls below the crystallization temperature of PP. The crystallization of PP in the presence of a glassy amorphous matrix has seldom been reported.

The well-known blend PC/PP has been intensively investigated by Favis and his co-workers (1987, 1988, 1990, 1992). Morphology development, rheology, compatibilization, etc., were studied, but no results on the thermal behavior of these blends were reported.

Polyester Blends

Quirk et al. (1989) have reported the crystallization behavior in blends of PPE with PET. Since the blend components showed only a small difference in the interfacial tension, quite small dispersions could be obtained ($d \approx 4$ μm). The authors reported that the glassy PPE matrix enhanced the cold crystallization of PET after being quenched. Decreasing the PPE content from 75 to 50 wt% resulted in the nearly

disappearance of the cold crystallization exotherm. This behavior was found to be opposite to that in a PS/PET blend (where PET crystallizes surrounded by a PS melt). No clear explanation has been given here.

A similar result for PPE/PET blends has been reported by Liang and Pan (1994). The authors found the cold crystallization temperature, $T_{c, cold}$, in the dispersed PET phase to be markedly lower than that of the virgin PET, indicating that PPE may partly act as nucleating agent to promote the nucleation of the PET component.

Other Blends

O'Malley et al. (1969) described the thermal behavior of PEG/PS blends in which PEG was dispersed into fine droplets. A clear indication of fractionated crystallization combined with a simultaneous decrease in the total degree of crystallinity with increasing weight fraction of PS has been observed. Again, a slight decrease of the melting temperature, T_m, with about 2 °C was detected, although ΔH_m remained unaffected. This was attributed by the authors to the formation of less perfect crystalline lamellae during the crystallization at higher undercooling.

Chang et al. (1991) reported on the melting behavior in PC/POM blends. The blends were found to behave in a similar way as the above-described PEG/PS blend.

3.3.5 Conclusions

It can be stated that the crystallization behavior of a semicrystalline polymer phase, dispersed into an amorphous matrix, is characterized by:

 (i) Fractionated crystallization or homogeneous nucleation if the minor phase is finely dispersed. Annealing or large droplets resulted in the appearance of a crystallization peak close to the bulk T_c° of the homopolymer.
 (ii) A decrease in the overall degree of crystallinity, X_c, after cooling from the melt, most pronounced in finely dispersed blend morphologies.
(iii) A slight decrease of the melting temperature due to the formation of less perfect crystalline lamellae at higher undercoolings. A decrease of the overall melting enthalpy, ΔH_m, could be observed clearly, only in blends where the crystallizable dispersed phase did not undergo recrystallization upon heating.

3.3.6 Binary Polymer Blends Containing Two Crystallizable Phases

A large number of polymer blends consists of two crystallizable phases (Table 3.15); hence, more studies have been carried out on the thermal behavior of crystalline/crystalline polymer blends.

The morphology of a polyblend consisting of two crystallizable polymers can vary depending on the processing conditions and the relative rates and temperature of crystallization of the constituent polymers. These can either crystallize at the same time (coincident crystallization, see further) or separately in a sequential

manner, leading to different morphologies and hence different properties. As such, in blends of two semicrystalline polymers, the physical properties may be altered not only by the blend composition and the phase morphology but also by changing their relative crystallization behavior. Therefore, it is important to study the effect of blending on the crystallization behavior of each component in the blend, to understand the structure development as influenced by melt-processing.

Because the phases are physically separated in the melt, the theory concerning the crystallization behavior as discussed above can be combined to understand the crystallization and melting behavior of most crystalline/crystalline polymer blends. In general, both crystallizable phases crystallize separately around their characteristic bulk T_c-value (as long as the minor phase is not dispersed into very fine droplets). The T_c-values can be somewhat shifted due to the migration of heterogeneities from one phase toward the other phase or due to the nucleating activity of one – crystalline or crystallizing – phase at the interface with the second phase. However, changes in the nucleation density of both phases will be more clearly reflected in the spherulite size of each blend component with respect to the homopolymer. This can have important consequences for the final mechanical properties of the blend (Friedrich 1978, 1979).

In the following overview, a survey of the most important topics concerning crystallization behavior in immiscible crystalline/crystalline polymer blends is given. Because the physical state of the second phase affects the crystallization mode of the phase under consideration, a distinction has been made for blends crystallizing in a melt environment and those crystallizing when the second phase has solidified.

3.3.6.1 Crystallization of the Matrix in the Presence of a Molten Dispersed Phase

For most commonly studied polymer blends, crystallization of the matrix occurs in the presence of a molten dispersed phase. The crystallization behavior of the continuous phase can be compared to that found for crystalline/amorphous blend systems in which the dispersed amorphous phase was in the molten state.

Polyethylene Blends

Because of the low crystallization temperature of the polyethylenes (HDPE, LDPE, LLDPE, etc.) (see Table 3.15), in most commonly used blends, the dispersed phase has already solidified before the PE matrix starts crystallizing. However, Greco et al. (1987a) studied the crystallization of HDPE ($T_c \approx 118\ ^\circ\text{C}$) in an 80/20 binary blend with EPR elastomers containing a different ethylene/propylene ratio. The HDPE phase was reported to exhibit higher T_c-values during cooling from the melt, indicating enhanced nucleation, due to the nucleating effect of the EPR copolymers on the HDPE matrix. Furthermore, the melting point, T_m, shifted to slightly higher temperatures relative to the homopolymer due to better crystal perfection as a result of the dissolution of some low molecular weight ("defective") HDPE molecules into the EPR copolymer phase during the melt-mixing process. The latter phenomenon was directly related to the ethylene content in the copolymer.

Polypropylene Blends

Blends of isotactic polypropylene, PP, with a polyethylene are immiscible and, owing to their commercial importance, have been the subject of intensive studies. In these blends, PP crystallization mostly takes place in the presence of molten PE droplets.

Long et al. (1991) investigated the crystallization behavior in blends of PP with LLDPE. They found the crystallization temperature of the PP matrix, T_c, to decrease slightly upon the addition of LLDPE. However, the degree of crystallinity, X_c, and the spherulite growth rate, G, were not affected. The authors concluded that the overall crystallization rate of PP in the matrix decreased due to a decreasing primary nuclei density. The latter was confirmed in O. M. experiments by the increased size of the PP spherulites upon the addition of LLDPE. However, Zhou and Hay (1993) reported that with the addition of LLDPE to PP, the crystallization rate remained similar as for the PP homopolymer.

Flaris et al. (1993) investigated also the same blend system and reported that blending had a pronounced effect on the lamellar morphology. Furthermore, the isothermal crystallization experiments indicated that the spherulite growth rate, G, and the nucleation density of the PP phase were enhanced. The authors suggested that these observations could be related to the formation of additional nucleation sites, which arise from the polymer-polymer interfaces created by the blending.

Because three different observations were reported on the crystallization of the PP matrix in which LLDPE droplets are dispersed, no unambiguous conclusions on this matter can be given. A serious investigation of all factors playing a role here is necessary in the future.

Blends composed of a PP matrix with LDPE as the minor dispersed phase have been intensively investigated by Teh (1983), Bartczak et al. (1984), Galeski et al. (1984), and recently Teh et al. (1994a). All authors found LDPE to act primarily as an efficient nucleating agent for the PP matrix, reducing the average PP spherulite size, and to induce the formation of some large β-form PP crystals at the interface with the LDPE phase that melt at a lower temperature, $T_m = 155\,°C$ as compared to normal α-form PP crystals with $T_m = 165\,°C$. Galeski et al. (1984) and Bartczak et al. (1984) revealed that the nucleating activity of the LDPE phase was mainly attributed to the migration of heterogeneous impurities from LDPE to PP during the melt-mixing process. Furthermore, Galeski et al. (1984) showed the spherulite growth rate of the PP matrix to be unaffected by the dispersed molten LDPE droplets and showed that these droplets were not rejected by the growing PP spherulites.

In the case of PP/HDPE blends, the influence of the HDPE component was more complex and dependent on the physical state of the dispersed HDPE droplets. At a T_c high enough to prevent any HDPE crystallization, the overall rate of crystallization of the PP matrix in isothermal crystallization was found to be strongly reduced by the addition of HDPE (Bartczak et al. 1986). Since the spherulite growth rate of PP was found to be constant and independent of the blend composition (Teh et al. 1994a), this decrease has been attributed to a decrease in the nucleation density of the PP phase. Bartczak et al. (1986) related this to the migration of heterogeneous nuclei from the PP phase toward the HDPE melt during

melt-blending. As a result, the PP spherulite size was found to increase (Bartczak et al. 1986; Teh et al. 1994b). The same observations were reported for PP/HDPE blends cooled slowly from the melt (Plesek and Malac 1986).

However, in the case of either an isothermal crystallization at temperatures below the crystallization temperature of HDPE or crystallization at a higher cooling rate, there may have been migration of nuclei from the PP toward the HDPE phase, but the overall number of heterogeneous nuclei was increased due to the presence of HDPE crystallites that may have acted as additional nucleating centers for PP (Lovinger and Williams 1980; Gupta et al. 1982; Bartczak et al. 1986; Plesek and Malac 1986; Teh et al. 1994a, b). This results in a drastic reduction of the PP spherulite size (Noel and Carley 1984; Lovinger and Williams 1980; Plesek and Malac 1986). Moreover, Bartczak and Galeski (1986) reported that spherulitic crystallization of a polymer near the interface can cause its deformation, increasing the interfacial area, and can lead to an improvement of toughness and impact properties.

Greco et al. (1987b) studied the crystallization in immiscible PP/EPR blends. The average spherulite size in the PP phase was smaller than in the homopolymer. The higher the PP contents (C-3) in EPR, the stronger the nucleating effect for the matrix. The authors experimentally showed that migration of impurities could not cause this effect and that the copolymer composition was the most important factor. An increase in the PP content of the EPR caused a higher miscibility (defective PP molecules could be partially dissolved in the EPR phase), leading to more perfect PP crystallites melting at a higher T_m, and also caused a stronger nucleating effect.

Pukansky et al. (1989) investigated both the crystallization and melting behavior and the global blend morphology in PP/EPDM blends over the whole composition range. Blends quickly cooled from the melt did not show significant changes in the crystallization behavior of the PP matrix. However, blends crystallized at a fixed rate of 10 °C/min behaved differently. Thermograms of the blends containing between 5 and 50 vol% EPDM showed a second melting peak at lower temperature, corresponding to the melting of the β-form of PP. Furthermore, the authors reported that small amounts of EPDM slightly increased the $T_{c,PP}$, but did not affect the degree of crystallinity. Dispersed EPDM droplets thus seem to promote the formation of the hexagonal β-form of PP.

An overview of the effects affecting the primary nucleation in immiscible PP-based blends is provided in Table 3.29.

Polyethylene Terephthalate Blends

Wilfong et al. (1986) reported on the effects of blending low concentrations (1–10 wt%) **polyolefin** with PET on the crystallization and toughening behavior of the latter. The authors studied blends of PET with LLDPE, HDPE, PP, and poly (4-methylpentene-1), all of them having a lower melting point than PET (Table 3.15). Polyolefin melts did not enhance the nucleation of PET, although the spherulite size of the PET matrix was found to be 2.5–3 times larger than for the homopolymer, with a broader spherulite size distribution. Both the crystallization

rate and the degree of crystallinity were found to be reduced by blending. This was attributed to the expense of energy that was required by the crystallizing growth front to reject and deform the polyolefin dispersed molten droplets. Martuscelli (1984) and Bartczak et al. (1984) have calculated that the rejection and/or deformation of dispersed droplets by the crystallizing growth front can cause a marked depression of the spherulite growth rate, G.

Poly(phenylene sulfide) Blends
Poly(phenylene sulfide), PPS, is an expensive, high-performance but brittle specialty resin. Blending can offer a good alternative both in toughness improvement and cost reduction (Nadkarni and Jog 1991).

Shingankuli et al. (1988) and Jog et al. (1993) investigated the influence of blending PPS with PET on its thermal and crystallization behavior. Blending was found to enhance the PPS nucleation. Isothermal crystallization experiments revealed that the crystallization time of PPS decreases along with the crystallization induction time. Both parameters were found to depend on composition. Optical microscopy confirmed this and revealed that the size of PPS spherulites in PPS/PET blends was drastically reduced as compared to the homopolymer. Furthermore, the degree of crystallinity of the PPS phase decreased with increasing PET concentration. However, dynamic crystallization experiments showed a constant value of $T_{c,PPS}$. The authors have related the accelerated crystallization of PPS in a blend with PET to the nucleation at the interface of the PET droplets. Owing to its supercooled state, the PPS matrix consists of highly ordered chains.

Nadkarni and Jog (1986), Nadkarni et al. (1987), and Jog et al. (1993) investigated the crystallization in blends of PPS with three types of HDPE, having a different melt flow index. In contrast to the PPS/PET blends, PPS crystallizes now in a superheated HDPE melt environment. From the dynamic cooling experiments, it was found that the presence of the HDPE melt suppresses the crystallization of PPS. The crystal growth rate, G, of PPS was found to remain unchanged, but its nucleation density was reduced as the concentration of HDPE in the blend increased or when the melt viscosity of the HDPE phase decreased. As a consequence, the overall crystallization rate of PPS was found to be retarded.

Other Blends
Chen et al. (1988) reported about blends of polyamides with a polyolefin. PA-11/LDPE blends and PA/HDPE blends both showed an increase of the melting temperature of the PA-11 matrix due to the addition of the polyolefin. No further attention was paid to this phenomenon.

Holsti-Miettinen et al. (1992) and Ikkala et al. (1993) recently studied the crystallization behavior of PA-6 blended with PP. No shift of the crystallization temperature of the PA-6 matrix was observed in the blends; the dispersed PP droplets did not influence the crystallization behavior of the matrix.

Frensch and Jungnickel (1989) investigated the influence of blend composition on the crystallization and melting behavior of PA-6/PVDF blends and PBT/PVDF blends. The crystallization of the PA-6 matrix and PBT matrix was promoted by the dispersed molten PVDF phase, as indicated by the rise in their T_c in the blends, while their relative crystallinity remained unaffected. The authors assigned this increase in T_c to migration of nucleating heterogeneities from the dispersed PVDF phase toward the matrix phase during melt-mixing of the blends.

3.3.6.2 Crystallization of the Matrix in the Presence of a Solidified Dispersed Phase

The crystallization of a polymer in the presence of solidified domains of the second phase takes place through a heterogeneous nucleation process. Since the rate of heterogeneous nucleation is higher than that of homogeneous nucleation, and since primary nucleation is the rate-controlling step for polymer crystallization, the crystallization rate is expected to be higher in such blends when compared to homopolymers (Nadkarni and Jog 1991).

Polyethylene Blends
On account of their commercial interest, the crystallization of HDPE, LDPE, and LLDPE in blends with PP has been extensively investigated. In these systems, the PP phase solidified already before the PE matrix starts crystallizing.

In the case of LDPE/PP blends, not much attention has been focused on the case where the LDPE phase forms the matrix. Teh (1983) reported no shift in the melting temperature of the LDPE matrix in the presence of solidified PP domains. Bartczak and Galeski (1986) observed that the LDPE crystallinity remained unaffected by blending.

Zhou and Hay (1993) investigated the crystallization behavior in LLDPE/PP blends. The crystallization rate of the LLDPE matrix, measured from isothermal DSC experiments, was not really affected by the dispersed PP domains. However, its degree of crystallinity slightly decreased with increasing PP content in the blend. According to the authors, this could be ascribed to the lower degree of perfection of the LLDPE crystals.

More extensive investigations have been performed on HDPE/PP blends by Martuscelli et al. (1980) and Bartczak and Galeski (1986). From the isothermal crystallization experiments, it was found that the rate of crystallization of the HDPE matrix was markedly reduced upon addition of small amounts of PP (10 wt%). The authors attributed this phenomenon to the increased melt viscosity of the sample caused by the presence of solidified PP domains. Moreover, Plesek and Malac (1986) have calculated from the surface tensions of the homopolymers at T_c that PP crystallization will not cause the nucleation of the HDPE phase, while in the reverse case HDPE crystals will induce the nucleation of PP.

Similar results were reported by Nadkarni and Jog (1986) and Nadkarni et al. (1987) for HDPE/PPS blends. The degree of crystallinity of HDPE in blends with a HDPE matrix was not affected by blending. The degree of supercooling required for initiating nonisothermal crystallization of HDPE was surprisingly not affected by the presence of solid PPS domains. However, isothermal crystallization halftimes for HDPE in the blends containing more than 10 wt% PPS were longer than for the HDPE homopolymer. Again, this has been attributed by the authors to the increased melt viscosity due to the presence of solidified PPS domains.

Frensch et al. (1989) reported on the crystallization of HDPE in a blend with POM. The HDPE matrix crystallized in all samples at almost the same temperature and to the same extent, independent of the extrusion time.

Polypropylene Blends
The majority of papers related to the crystallization of isotactic polypropylene(PP)-based blends concern those where the PP matrix crystallizes in the presence of a molten dispersed phase of polyethylenes and olefinic elastomers. As a result, crystallization of a PP matrix in the presence of a solidified dispersed polymer has seldom been reported (Nadkarni and Jog 1991).

Shingankuli (1990) studied the crystallization behavior of PP in the presence of solidified PVDF domains. A higher crystallization temperature of the PP matrix phase was observed, indicating an enhanced nucleation in the blends. The degree of crystallinity of PP was found to increase by about 30 % to 40 % with increasing PVDF content. Isothermal crystallization studies also confirmed the acceleration of the overall crystallization rate in terms of shorter crystallization halftimes for PP.

More efforts have recently been dedicated in understanding the crystallization behavior in PP/PA-6 blends. Holsti-Miettinen et al. (1992), Moon et al. (1994), and Ikkala et al. (1993) found that the crystallization temperature of the PP matrix by cooling from the melt rises by about 10 °C by adding PA-6. Ikkala et al. (1993) observed that the largest temperature increase was caused at a PA-6 concentration of about 20 wt%; in this case, the PA-6 dispersion size was quite small (2.5 μm).

Moon et al. (1994) have related this temperature shift to the migration of heterogeneous nuclei toward the PP matrix during the melt-mixing process, together with the nucleating agent-like behavior of the solidified PA-6 domains. No change of the melting peak has been noticed (Park et al., 1990). Grof et al. (1989) performed some isothermal crystallization experiments on fibers of the PP/PA-6 blend. In accordance with the cited findings, the latter authors reported a decrease both in the crystallization halftime and the induction time for crystallization of PP in PP/PA-6 blends, while no change in the degree of crystallinity was observed.

Tang and co-workers (1994) investigated briefly the crystallization behavior of PP in blends with PA-12. The melting point remained unaffected by blending. However, a slight shift of the crystallization peak (about 2.5 °C), upon cooling from the melt, was reported for blends comprising 33 wt% PA, along with an increase of the height of the T_c peak. The PP matrix has been nucleated by the dispersed PA-12 domains. The authors related this to the fine morphology; at the interface of the phases, epitaxial crystallization had also been observed. This was also the reason why the PA-12 phase in the blends only existed in the γ-form. However, it should be mentioned that these PP/PA-12 blends were prepared from solution.

Polyethylene Terephthalate Blends

Only few papers related to the crystallization of a PET matrix in immiscible crystalline/crystalline blends have been published.

Shingankuli et al. (1988) investigated the thermal behavior of PET blends with the glass fiber-reinforced polymer PPS. Dynamic crystallization experiments revealed that the PET crystallization behavior was significantly altered by blending. Upon the addition of PPS, both the onset temperature for crystallization and the peak value, T_c, showed a dramatic shift to higher temperatures (up to 20 °C). Also, the degree of crystallinity significantly increased in the blends. The author attributed the phenomenon to the heterogeneous nucleation induced by the glass fibers in the PPS phase and the nucleating activity of the already solidified PPS domains. As a result, the PET matrix in the blends became richer in heterogeneous nucleating sites as compared to virgin PET. Isothermal experiments confirmed these conclusions and showed that the crystallization halftime of PET decreased drastically in the blends (attributed to the enhanced nucleation). Furthermore, an increase of the onset of melting of the PET matrix (15 °C) with increasing content of PPS in the blends has been observed. The melting behavior PET in the blends has been explained by the formation of larger and more perfect crystallites (due to the nucleation at higher temperatures) with a narrower size distribution and by an increased degree of crystallinity.

Other Blends

Frensch and Jungnickel (1989, 1991) and Frensch et al. (1989) have investigated the thermal behavior of polyvinylidene fluoride, PVDF, in blends with polyamides, in relation to the blend morphology. PA-6 droplets could be finely dispersed into the PVDF matrix. The crystallization temperature of the PVDF matrix did not seem to be affected in the blends. A similar behavior was observed in PVDF/PA-66 blends.

Investigations on the crystallization behavior of PVDF in a blend with polybutyleneterephthalate, PBT, have been reported by Frensch and Jungnickel (1989) and Frensch et al. (1989). PBT dispersed droplet size was found to be an order of magnitude larger than the dispersed PA droplets in PVDF blends. However, in this case, the $T_{c,PVDF}$ displayed a shift to higher temperatures (2–8 °C) upon blending with PBT, which was attributed to the nucleating efficiency of amorphous or crystallizing PBT domains (which subsequently crystallized coincidentally with the PVDF matrix).

3.3.6.3 Crystallization of the Dispersed Phase in the Presence of a Matrix Melt

Immiscible blends most often show a two-phase morphology consisting of a continuous matrix and a droplet-like dispersed phase beyond the phase inversion region. From Sect. 3.2.3, it is clear that the crystallization behavior of droplets can be dramatically affected as compared to the homopolymer.

In summary, (i) dispersed drops can have an altered nucleation density, caused by the migration of heterogeneous nuclei during the melt-mixing process, they can be nucleated by a crystallizing or solidified matrix, the interface can induce some additional nucleating centers, etc. (ii) The smallest dispersed droplets can suffer from the lack of heterogeneous impurities in each droplet, what may result in a fractionated crystallization. In some cases, this can give rise to the coincident crystallization of the dispersed phase with the (lower crystallizing) matrix (see Sect. 3.2.4.6).

Polyethylene as Dispersed Phase

Because of the low crystallization temperature of all polyethylenes as compared to most other commonly used thermoplastics, crystallization will proceed most often in an already solidified matrix. No literature could be found on the crystallization behavior of PE in a molten matrix environment.

Polypropylene as Dispersed Phase

Typical polymer blends with isotactic polypropylene, PP, are the PP/PE blends, in which PP is the first crystallizing component.

Zhou and Hay (1993) investigated the crystallization in LLDPE/PP blends. They reported that the extent of crystallization in PP droplets is seriously hindered by the low nucleation density of PP, resulting in a serious drop of the degree of crystallinity during the isothermal measurements. From these experiments, it could be predicted that cooling from the melt would result in a fractionated crystallization (30 wt% PP) or even homogeneous crystallization (10 wt% PP). Similar results had already been reported by Long et al. (1991), Pukanszky et al. (1989), and recently Müller et al. (1995) and Morales et al. (1995). The latter authors even mentioned that the retarded crystallization of PP droplets in some cases finally resulted in the coincident crystallization of PP with the LLDPE matrix. Furthermore, a partial change in the crystallographic form from α to the lower melting β-form was observed. Lovinger et al. (1977) reported that the β-form is nucleated at a lower rate than the α-form and hence promoted on homogeneous nucleation.

Teh (1983) reported only the melting behavior of LDPE/PP blends – no shift in $T_{m,PP}$ was seen. An enhancement in the formation of the β-form PP spherulites in the LDPE melt was observed.

Blends of HDPE with PP have been studied by several authors. However, not much attention has been focused on the crystallization behavior of the dispersed phase yet.

Polyamide as Dispersed Phase

Several blends with polyamides, crystallizing at high temperatures, have been studied. Chen et al. (1988) investigated the phase morphology and melting behavior of HDPE/PA-11 and LDPE/PA-11 75/25 blends. The melting point of the dispersed PA-11 phase was found to be unaffected by blending.

Several studies have been performed on the thermal behavior of PP/PA-6 blends. Park et al. (1990) reported a melting-point depression for the dispersed PA-6 phase (about 4 °C), having an average particle size of 2–5 μm at 25 wt% PA-6 in the blend. However, the relations between the crystallization phenomena and the blend morphology were not explored. Ikkala et al. (1993) have investigated the correlation between the blend morphology, crystallization, and melting behavior of the minor component in PP/PA-6 blends. The PA-6 phase was reported to crystallize at its bulk temperature. However, compatibilization (resulting in the formation of a finer dispersion) did not show any crystallization exotherm around the bulk $T_{c,PA\text{-}6}$. This could be explained by the retarded crystallization caused by a lack of heterogeneous nuclei in the PA-6 droplets. Finally, the nucleating activity of both blend components on each other caused the coincidental crystallization of the PA-6 with the PP matrix.

Moon et al. (1994) also investigated the thermal behavior of PP/PA-6 70/30 blends. The authors reported the T_c of the PA-6 droplets to rise remarkably (by about 14 °C) as compared to the T_c of the virgin PA-6. This rise in $T_{c,PA\text{-}6}$ was explained by analogy to findings of Khanna et al. (1988a, b) on pure virgin PA-6 homopolymer, suggesting that melt extrusion of PA-6 would lead to a more ordered molecular arrangement that persisted in the molten state due to hydrogen bonding, and as such caused a faster crystallization. This has been confirmed by crystallization experiments on melt-extruded PA-6 homopolymer. The results of the blends as compared to melt-mixed pure PA-6 agree with those reported by Ikkala et al. (1993) – no shift in the $T_{c,PA\text{-}6}$ was caused by blending. Furthermore, they also reported that compatibilization of the blends caused a decrease of the dispersed phase size, leading to fractionated and subsequently coincident crystallization.

Frensch and Jungnickel (1989) and Frensch et al. (1989) tried to elucidate the crystallization behavior of the minor phase in the binary PVDF/PA-6 blends, in relation to the final blend morphology. They reported that the crystallization of the PA-6 droplets was fractionated and/or retarded, depending on the number of mixing cycles and dispersion size. The smaller the PA-6 droplets, the more pronounced the retardation of the crystallization peak ($\Delta T \approx 40$ °C). Nevertheless, the melting endotherm remained unaffected. They concluded that part or all of the PA-6 phase finally coincidentally crystallized with the PVDF matrix due to the specific mutual nucleating efficiency of both components.

A similar behavior has been reported by Frensch and Jungnickel (1991) for PVDF/PA-66 blends. In this case, the undercooling associated with the retarded crystallization was about 90 °C higher than the one for the bulk crystallization! The size of the dispersed PA-66 droplets has been found to be only about 0.3 μm. The authors concluded that the appearance of fractionated and coincident crystallization is correlated with the low interfacial energies between the amorphous melt phases, providing a high level of dispersion, and between the crystalline phases, providing a nucleating efficiency.

Other Blends

Shingankuli et al. (1988) reported on the crystallization of dispersed PPS domains in a PET matrix. The onset of crystallization of the dispersed PPS domains decreased (by about 7 °C) with decreasing PPS content, together with the crystallization peak and the degree of crystallinity. The authors concluded that the PPS crystallization was retarded mainly when the PPS content in the blends was below 20 wt%. Furthermore, the onset of melting of the PPS fraction remained nearly unaffected, except for those blends containing less than 20 wt% PPS. In the latter case, the onset of melting seriously decreased (by about 30 °C), whereas the melting peak temperature and heat of fusion remained constant. This can be attributed to the lower crystallization temperature of the PPS droplets leading to the formation of less perfect, lower melting crystallites.

Klemmer and Jungnickel (1984) have reported on the fractionated crystallization of POM in an HDPE matrix. They found an additional crystallization peak of POM to occur 14 °C lower than the bulk crystallization peak. This was attributed to the fractionated crystallization of POM, caused by an interface-induced additional inhomogeneous nucleation and crystallization. It was shown that this phenomenon only occurs in those blends where the number of the dispersed particles was higher than the number of available heterogeneous particles. Moreover, the preparation method clearly influenced the fractionation due to the change of the particle sizes – fractionated crystallization has been observed only in melt-mixed blends.

Frensch and Jungnickel (1989) and French et al. (1989) have investigated PVDF/PBT blends and related their thermal behavior with the blend morphology. Similar to PVDF/PA-6 blends, the PBT droplet crystallization was completely suppressed in an 85/15 blend and finally crystallized coincidentally with the PVDF matrix. Again this phenomenon could be related to the fine dispersion of PBT droplets, in number exceeding the available nuclei. Shorter melt-mixing cycles caused a coarser dispersion leading only to a fractionated crystallization of PBT at $T_{c,bulk}$ and at $T_{c,PVDF}$.

3.3.6.4 Crystallization of the Dispersed Phase in the Presence of an Already Solidified Matrix

Polyethylene as Dispersed Phase

PP/PE blends have been studied extensively by several authors. Zhou and Hay (1993) reported that the dispersed LLDPE droplets in PP/LLDPE blends showed problems in nucleating at the normally expected bulk crystallization temperature, T_c. Also, a serious decrease of the degree of crystallinity from isothermal measurements, as the LLDPE content decreased, could be observed. Contrary to these

observations, Müller et al. (1995) recently stated that the LLDPE droplets do not exhibit fractionated crystallization when they are dispersed in a PP matrix (although they do in a PS matrix), because of the nucleating effect of the solidified PP matrix on the LLDPE droplets.

Galeski et al. (1984) and Teh et al. (1983) have investigated PP/LDPE blends. No shift of the melting peak for LDPE has been observed. Both authors showed migration of the impurities during the melt-mixing process from the PP toward the LDPE phase. No further details on the crystallization behavior of the LDPE droplets themselves were reported.

Nadkarni and Jog (1986) have reported on PPS/HDPE blends. The degree of crystallinity of HDPE was reduced when HDPE was the minor phase. Furthermore, the $T_{c,HDPE}$ shifted to somewhat lower temperatures (by about 5 °C) but only in those blends with a low HDPE content. Isothermal crystallization halftimes for HDPE in its blends with PPS decreased as the HDPE content decreased, indicating an enhanced nucleation from the solidified PPS interfaces.

Chen et al. (1988) have investigated the melting behavior of 75/25 PA-6/HDPE and PA/LDPE **blends**. No shift has been observed in the melting point. No attention has been focused to the crystallization of the PE droplets.

Polypropylene Blends

Blends of PA-6 with PP dispersed as fine droplets have been examined recently by several authors.

Ikkala et al. (1993) investigated the thermal behavior and morphology of blends of PA-6 in which PP had been dispersed. In binary blends, PP droplets crystallized even at somewhat higher temperature (by about 5 °C) than the PP homopolymer, attributed to the nucleating activity of the solidified PA-6 matrix toward the dispersed PP phase. Morphological investigations revealed that the PP dispersion in the blends was quite coarse; so nearly every droplet contained the heterogeneities that usually nucleate PP. However, upon compatibilization, this behavior changed. Compatibilizers that formed an immiscible interlayer between PA-6 and PP and caused a reduction of the dispersed particle size gave rise to a retarded crystallization of the PP phase in a PA-6/PP 80/20 blend, decreasing the $T_{c,PP}$ by 50° C! This behavior was directly caused by the small size of the dispersed phase and the prevented nucleation from the solidified matrix. Blends containing 40 wt% PP did not crystallize in a retarded way due to their coarser droplet size, but clearly were not nucleated by the PA-6 phase as seen from $T_{c,PA-6} = T°_{c,PA-6}$. Similar results have been presented by Holsti-Miettinen et al. (1992).

Other Blends

Tang and Huang (1994b) investigated the relation between blend morphology and crystallization behavior in PP/PEG blends, prepared by solution blending. They reported that the PEG phase crystallized fractionated at different degrees of undercooling, but was always nucleated heterogeneously. The authors related the different crystallized fractions to PEG droplets of different sizes; the largest droplets crystallized at the bulk crystallization temperature.

Shingankuli et al. (1988) studied the crystallization behavior of dispersed PET droplets in a PPS matrix. A serious increase of the crystallization temperature of the dispersed PET phase (by about 20° C) during cooling experiments from the melt was explained as a result of the nucleating activity of the glass fibers in the PPS matrix, but also from the solidified PPS itself. As a result, the crystallization became more heterogeneous and the crystallization peak width decreased drastically. A corresponding increase in the onset of melting for PET (about 15 °C) was attributed to the formation of thicker and more perfect PET crystallites in the blends.

Frensch and Jungnickel (1989) and Frensch et al. (1989) have studied PA-6/PVDF blends. The authors reported that the finely dispersed PVDF droplets crystallized fractionated at different undercoolings. Again this could be directly related to the lack of heterogeneous nuclei in some of the smallest droplets. Increasing the blend composition or decreasing the mixing cycles caused the crystallization of the PVDF droplets to shift to higher temperatures, due to the formation of a coarser morphology. A similar behavior has been reported for PA-66/PVDF blends (Frensch and Jungnickel 1991).

A reverse case however has been reported by the same authors for the crystallization of dispersed PVDF droplets in a solidified PBT matrix. In the latter case, $T_{c,PVDF}$ even shifted to higher temperatures (by about 5 °C) than for homopolymer crystallization. The shift seemed to become less pronounced as the number of mixing cycles increased. No explanation for this behavior was reported. The melting endotherm of the PBT droplets was not affected by the blending.

3.3.6.5 Coincident Crystallization in Crystalline/Crystalline Polymer Blends

A few authors have observed coincident crystallization of both phases in crystalline/crystalline immiscible blends. This phenomenon was reported for blends in which the minor phase exhibits a higher degree of undercooling for crystallization due to its fine dispersion (see Sect. 3.2.3) and the matrix phase crystallizes at its bulk T_c that is lower than that of the minor phase. An additional factor that should be taken into account is that a heterogeneous nucleation is promoted on surfaces with a high interfacial tension (Helfand and Sapse 1975) (i.e., a crystallizing phase boundary). This can lead to the "coincident crystallization" of both phases, as it has been reported by Frensch and Jungnickel (1989, 1991) and by Frensch et al. (1989).

Principle of Coincident Crystallization

It has been observed that this phenomenon is connected with the phase dispersion of the minor component and is enhanced when the dispersion becomes finer. Upon cooling from the melt, a finely dispersed phase can exhibit fractionated crystallization, what implies that none, or only part of the dispersed droplets crystallize at their bulk T_c. This type of crystallization is related to the lack of heterogeneities in the droplets, required for nucleation at the bulk T_c.

When the blend is now further cooled, two possible ways of primary nucleation are possible. In the first case, the matrix phase is nucleated by heterogeneous species present in this phase, and, instantly, newly created crystals appear. Hence,

the crystallization temperature of the matrix will be situated at its bulk T_c. The second possibility for coincident crystallization occurs in the case one finds again a single crystallization peak for the matrix phase, which however takes place above its bulk T_c. Some novel mutual nucleating mechanism was suggested in such blends; a molten component (minor phase) acts as nucleating substrate for the matrix, which instantaneously crystallizes (Frensch and Jungnickel 1989).

For both cases, when the Δy-value (see Sect. 3.2.3.2) between these newly formed crystals and the melt of the minor phase is smaller than that of all other heterogeneities present in the minor phase (except probably the nuclei of "type 1" normally nucleating around the bulk $T_{c,minor}$), its associated specific undercooling must be so small that the crystals can induce the crystallization of that minor phase from the instant of their own creation (Frensch et al. 1989). Consequently, a single *coincident* crystallization peak will be registered in DSC thermograms.

It is clear that this phenomenon is phase morphology-dependent. Only in those blends where the minor phase is dispersed into sufficiently fine droplets, this phase has the opportunity to exhibit fractionated crystallization. Hence, only at low blend compositions and/or good matching viscosities of both phases (where the capillary number C_a predicts droplet breakup being dominant above coalescence) the occurrence of coincident crystallization is possible.

Examples of Coincident Crystallization
Frensch and Jungnickel (1989, 1991) and Frensch et al. (1989) have investigated the crystallization behavior of PVDF/PA-6, PVDF/PA-66, and PVDF/PBT blends. The PVDF/PA-6 blends showed a composite droplet-type morphology (finely dispersed matrix droplets encapsulated in the minor phase droplets) that disappeared after sufficiently long mixing cycles. Along with these observations, coincident crystallization was found in PVDF/PA-6 blends for an 85/15 and 75/25 composition only. The influence of morphological changes could be significant; after four mixing cycles, the dispersed PA-6 droplets became finer and did not contain small PVDF inclusions anymore. Along with this observation, only one single coincident crystallization peak could be found from DSC. The small exotherm at 184 °C caused by some larger PA-6 domains containing the PVDF inclusions with a small exotherm at 113 °C had disappeared completely by the mixing (Fig. 3.72). PVDF crystallization was found to be initiated by nucleation from heterogeneities of "type 1" at the bulk $T_{c,PVDF}$. A similar behavior has been reported for PVDF/PA-66 blends by Frensch and Jungnickel (1991).

A second system investigated by the authors was the PVDF/PBT blend. Similar effects could be observed. However, coincident crystallization in the PVDF/PBT 85/15 blend occurred at a somewhat higher temperature than the bulk $T_{c,PVDF}$. It could be concluded that in this case, the PBT melt induced the crystallization of the PVDF matrix phase.

Besides the cases of coincident crystallization reported previously, recent investigations on PP/PA-6 blends in which a compatibilizing agent had been used to obtain finer and more homogeneous dispersed phase morphology also mentioned coincident crystallization of the PA-6 droplets with the PP matrix (Ikkala et al. 1993; Moon et al. 1994). However, this has not been observed in the binary blend.
Fig. 3.72 Retarded and/or fractionated crystallization causing coincident crystallization in PVDF/PA-6 and PVDF/PBT blends. Influence of the blend composition (**a**) and the number of extrusion cycles *Z* (**b**) (Frensch and Jungnickel 1989)

3.3.6.6 Effect of Compatibilization on the Crystallization Behavior in Crystalline/Crystalline Polymer Blends

Blending offers an interesting means of tailoring product properties to specific applications. However, in the case of immiscible polymer pairs, the desired properties are not achieved readily without a compatibilizer, which enhances the phase dispersion and stability, as well as a good adhesion between the phases. This can be effectuated by physical or reactive methods (Folkes and Hope 1993). Compatibilization strongly affects the blend phase morphology, and as such, it also may influence the crystallization behavior of the blend (Flaris et al. 1993). Because both factors are related to the final properties of the blend, it is worth paying attention to these phenomena.

Several authors have investigated the influence of compatibilization on the global blend morphology. However, only a few authors really tried to understand the effect of compatibilization in crystalline/crystalline polymer blends on the crystallization kinetics, melting behavior, and semicrystalline morphology of the components. In Table 3.30, some recent results on this topic are summarized.

From the data presented in this table, it appears that in contrast to binary blends without a compatibilizer, the crystallization of the minor component in compatibilized blends cannot be solely explained by the size of the dispersion (Ikkala et al. 1993; Flaris et al. 1993; Tang and Huang 1994a; Holsti-Miettinen et al. 1995). Other factors

Table 3.30 Influence of a compatibilizing agent on the crystallization behavior of binary crystalline/crystalline polymer blends

Blend system[a] +compatibilizer	Studies on the influence of	Crystallization	Explanation	Reference

(1993)

[a] All blend systems listed have been prepared by melt-mixing, except when indicated with

affecting the crystallization are the type of compatibilizer and its degree of miscibility with one or both of the blend components, the amount of compatibilizer added, the amount of interface created, and other effects.

The general influence of a compatibilizer on the crystallization behavior of an immiscible polymer blend system is still far from being well understood. However, abstract can be made between two main classes. A first class consists of compatibilizers that form a kind of "immiscible" interlayer between the two phases. Examples are given by Holsti-Miettinen et al. (1992) and Ikkala et al. (1993) for PP/PA-6 blends to which MAH-g-SEBS, FA-g-EBA, and GMA-g-E EA have been added. The compatibilizer prevents direct nucleating effects from one phase on the other. As such, only the size of the dispersion relative to the nucleation density of the dispersed phase and the nucleating effect of the compatibilizing agent itself play a role in the crystallization behavior (Fig. 3.73). Remark however that the size of the dispersion is often directly related to the concentration of the compatibilizer added (Moon et al. 1994).

A second class consists of compatibilizers that have an analogous chemical structure compared to one or two of the blend components. Here, the influence of a compatibilizer on the crystallization behavior of both phases is complex. Several factors have to be taken into account: nucleating effect of the matrix on the dispersed phase or from the dispersed phase on the matrix, the size of the dispersed phase relative to the nucleation density of that phase (and thus to the composition, content of the compatibilizer, etc.), nucleating effect of the compatibilizer itself, interactions of the compatibilizing agent and one or both phases which can impede the crystallization, cocrystallization of the compatibilizer with one of the phases, etc. An illustration is given in Figs. 3.72 and 3.73. Again, the concentration of compatibilizer plays a crucial role (Fig. 3.74).

Compatibilization seems to be of industrial interest in several ways: besides the improvement of the phase dispersion and adhesion, leading to superior mechanical properties, it also often can prevent the minor crystallizable dispersed phase from fractionated or retarded crystallization, which make faster production times and higher thermal stability of the products possible.

3.3.6.7 Conclusions on the Crystallization Behavior of Immiscible Crystalline/Crystalline Polymer Blends

The scientific literature on crystallization in polymer blends clearly indicates that the crystallization behavior and the semicrystalline morphology of a polymer are significantly modified by the presence of the second component even when both phases are physically separated due to their immiscibility. The presence of the second component, either in the molten or solid state, can affect both nucleation and crystal growth of the crystallizing polymer. The effect of blending on the overall crystallization rate is the net combined effect on nucleation and growth.

From the above literature survey, it is clear that the physical state of the second phase at the moment of crystallization is of utmost importance.

The crystallization of a *continuous matrix in which the dispersed phase is in the molten state* can be influenced by several phenomena. One of the most important
Fig. 3.73 Influence of compatibilization (10 wt%) on the crystallization and melting behavior of PA-6/PP blends with various blend compositions. Compatibilizer types used were EBA-g-FA (I), PP-g-MAH (II), SEBS-g-MAH (III), and E EA-GMA (IV) (Ikkala et al. 1993)

factors that play a role here is the possibility that impurities and nuclei migrate during the melt-mixing process, hence altering the nucleation density of the components. Furthermore, the interface may enhance the nucleation, mostly due to highly ordered structures in supercooled melt droplets.
It should however be mentioned that the crystal growth rate, G, is generally not affected. Only in some exceptional cases where the growing crystallizing front rejects and/or deforms finely dispersed melt droplets, a decrease of G has been reported. It can thus be concluded that the matrix always crystallizes around its bulk temperature. Migration of nuclei, nucleation effects, etc., result in a shift of the $T_{c,matrix}$ by 5–10 °C, on average. The melting behavior of the matrix remains in general unaffected.

In the case of the *crystallization of the matrix in the presence of already solidified or crystallizing particles*, migration of nuclei still can play an important role. However, several other phenomena have to be taken into account. First of all, the solidified domains can act as efficient nucleators. Furthermore, retarded crystallization of finely dispersed droplets can nucleate the matrix and leads to coincident crystallization of both phases. Finally, it has been reported that epitaxial crystallization at the interfaces sporadically occurs. All these phenomena lead to an increased heterogeneous nucleation of the matrix phase.

Although most often also here the crystal growth rate is not affected, some authors have reported that finely dispersed solidified domains can increase the melt viscosity of the matrix in such a way that the crystallization rate becomes depressed. Again, the matrix component will crystallize around its bulk temperature. The abovementioned phenomena can eventually alter the spherulite size and shift the T_c of the matrix on average by 5–10 °C. The melting behavior remains normally unaffected.

The crystallization and melting behavior of a dispersed phase is highly different from the behavior of the continuous phase and much more sensitive for changes.

Droplets crystallizing in a melt matrix can just crystallize at their bulk temperature or show shifts of their T_c as a result of migration of nuclei, as has been outlined for matrix crystallization in the melt.

However, an important additional factor that plays a role here is the size of the dispersed phase. When the number of finely dispersed droplets exceeds the available heterogeneities of "type 1," fractionated or even homogeneous crystallization will occur, leading to shifts in the crystallization temperature by sometimes up to 100 °C (as compared to the homopolymer). This can result in a change of the crystal polymorphic form, coincident crystallization with a lower crystallizing matrix component, etc. However, the melting peak in the latter case will only be slightly depressed (by 2–4 °C) due to the formation of less perfect crystallites at lower temperatures. Additionally, it has been demonstrated that compatibilization can induce drastic changes in the blend phase morphology and thus in the crystallization and melting behavior.

In the case where *dispersed droplets crystallize in an already solidified matrix*, the same phenomena as in the previously described case can influence the thermal behavior of the dispersed phase. Additionally, nucleation from the already solidified matrix will play a distinguished role. An induction of heterogeneous nuclei often can reduce the fractionated crystallization or even bring the T_c back at its bulk temperature.

3.3.7 Crystallization in Immiscible Polymer Blends Containing Nanoparticles

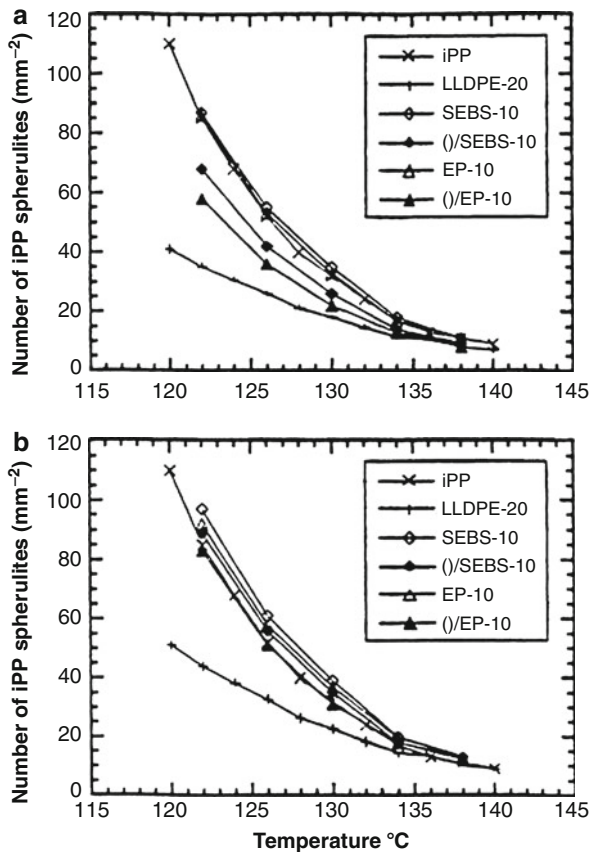
Solid particles can be used as fillers dispersed in a matrix composed of one polymer or copolymer but can also be added in a miscible and immiscible binary, ternary, or multicomponent blend. The objective of the addition of fillers is diverse. They can be used as fillers to reduce the price of the composite and to improve the properties of the material (mechanical, aspect, chemical, etc.). Nanoparticles are among the category of fillers, the particle size of which is in the nanometer scale. They are considered as a new generation of particles which is progressively occupying a strategic position in the area of material development. Carbon nanotubes (CNTs) are nanoparticles that have been widely used in various fields owing to their remarkable mechanical, thermal, and electrical properties. One of the most intriguing applications of CNTs is the polymer/CNTs composites. Because of the combination of low density,

nanometer scale diameter, high aspect ratio, and, more importantly, unique physical properties such as extremely high mechanical strength and modulus, CNTs have emerged as potential reinforcing filler in polymer composites with excellent performance and multifunction. Nanoparticles can also be added to polymer matrices for specific effect of modifying a single but discrete property such as crystallization of homopolymers. In this application, they are nucleating agents as they enhance the crystallization of the polymer matrix where they are dispersed via a heterogeneous nucleation process. The use of nanoparticles as nucleating agents and more generally as crystallization modifiers in polymer blends is poorly reported in literature. Only few reports deal with this particular application of nanoparticles. Bose et al. (2007) performed an interesting investigation on fractionated crystallization in reactively compatibilized PA6/(amorphous)ABS blends. They added multiwall carbon nanotubes (MWNT) as heterogeneous nucleating agents. SMA- or SMA-modified MWNT were able to reduce significantly the particle size of PA6 up to a concentration of 1 wt% SMA. Fractionated crystallization was observed in both reactively compatibilized and non-compatibilized 20 PA6/80ABS blends. Delayed crystallization was reported for both types of blends due to lack of heterogeneities because of indirect but crucial effect of particle size reduction.

Pillin and Feller (2006) investigated the crystallization of the PBT minor phase in an EEA continuous matrix by DSC and SEM. When PBT is the minor phase, PBT crystallizes at a lower temperature of 105°C. Introducing different CB nanoparticles into the EEA continuous phase at contents increasing from 0.02 to 5 wt% resulted in important modifications of the PBT crystallization. A new PBT exotherm appeared at $T_c = 144$ °C on the addition of CB, becoming really visible at $T_c = 158$ °C and finally moving to $T_c = 185$ °C at high content. The areas corresponding to the new peaks were found to increase to the detriment of that of the fractionated crystallization at $T_c = 105$ °C. Morphological studies and interfacial tension measurements were made to understand the surprising activity of the CB. Moreover, the substitution of the EEA phase with a less polar component as, e.g., LLDPE, confirmed the importance of the strong interactions developed by EEA with CB aggregates.

Liu et al. (2012) have recently investigated the morphology, melting, crystallization, and mechanical properties for similar blend combination of PA6/ABS with MWNT nanotubes. PA6/ABS blends (70/30 and 50/50 wt) with 0, 0.1, 0.25, 0.5, and 1 wt% MWNTs were studied. Figures 3.75 and 3.76 show the crystallization and melting behaviors of PA6/ABS (70/30 wt) and (50/50 wt) blends with different contents of MWNTs. By incorporating MWNTs, the crystallization peak of PA6 shifted to higher temperature regions, the same effect has been reported in various polymer/CNTs composites (Li et al. 2006; Assouline et al. 2003; Valentini et al. 2003). The crystallization onset temperature (Tco) and the crystallization peak temperature (Tcp) increase with increasing the content of MWNTs. In PA6/ABS (70/30 wt) blends, PA6 crystallized at 191.4 °C, and with the incorporation of 1 wt% MWNTs, PA6 started to crystallize at 203.6, i.e., 12.2 °C higher than that of PA6 in simple (nonmodified blends). In PA6/ABS (50/50 wt) blend, the increment in Tco is also 12.2 °C. The long fibrillar MWNTs provided ideal

Fig. 3.75 DSC (**a**) cooling and (**b**) heating curves of PA6/ABS (50/50 wt) blends with various contents of MWNTs (Liu et al. 2012)
nucleation sites for PA6 chains (Gong et al. 2000). Indeed, the nucleation ability of MWNTs was quite high and effective. When the content of MWNTs in PA6 increases, more heterogeneous nucleation sites are available, leading to higher Tco and Tcp. Additionally, a weak exotherm at about 110 °C is found in Fig. 3.75a, c, which is often referred to as fractionated crystallization. This phenomenon often appears when the crystallizable polymer exists as the minor phase in a dispersed droplets form. In the composition the authors selected, PA6 acts mainly as the matrix. Indeed, fractionated crystallization is less visible, because numerous new interfaces are introduced during melt-mixing which can cause heterogeneous nucleation (Turbull et al. 1950; Helfand et al. 1977). In the melting endotherms,

Fig. 3.76 The effect of compatibilizers (SEBS) and (EP) on the nucleation of isotactic PP at various temperatures: (**a**) measured as blend volume and (**b**) calculated as PP volume fraction (Long et al. 1995)


PA6 forms two melting peaks in both PA6/ABS (70/30 wt) and PA6/ABS (50/50 wt) simple blends. The double melting peaks were not due to the existence of two crystal forms but originated from the different distribution of the lamellar thickness (Helfand et al. 1977). According to the authors, the introduction of MWNTs in the blends provides a large amount of nucleation sites for end tethering of PA6 chains to form the α-phase crystals with similar lamellar thickness and restrain reorganization or recrystallization during the heating process in DSC scanning (Phang et al. 2006), which results in only one melting peak of PA6. The favorable formation of α-phase crystals in the presence of MWNTs also facilitates the enhancement of mechanical properties of the blends (Zhang et al. 2004).

The fractionated crystallization behavior of polypropylene (PP) droplets in its 20PP/80PS blends in the presence of hydrophilic or hydrophobic fumed silica nanoparticles was studied by using differential scanning calorimetry, scanning electron microscopy, and transmission electron microscopy by Huang et al. (2013). The fractionated crystallization of PP droplets in the PS matrix was promoted by adding a low content of hydrophobic or hydrophilic nanoparticles due

to their morphological refinement effect. However, discrepancies in the fractionated crystallization behavior of PP droplets occurred as the nanoparticle content increased. The crystallization became dominated by the heterogeneous nucleation effect of high content of hydrophilic nanoparticles. The authors ascribed this decrease to possible migration of the nanoparticles preferentially into PP droplets during mixing, significantly suppressing their fractionated crystallization (cause heterogeneous nucleation).

3.4   General Conclusion

Crystallization and melting phenomena in multicomponent polymer-based materials has been and is still a subject of scientific activity for a large number of academic and industrial research centers. That is because a wide spectrum of properties of many polymer materials depends on the crystallization process and on their extent of crystallinity as a result of the processing operations. The huge volume of literature of various types dealing with the crystallization and melting features is a strong witness of the above statements. The present chapter can be considered as a smart guide rather than an exclusive review work for people involved with the study of crystallization both for academic and applied research programs. The chapter has been split, although not really simple to achieve, into miscible, immiscible, and nanoparticles containing polymer blends. The miscible blends section has been divided into subsections of thermoplastic/thermoplastic and thermoplastic/thermosets. In the former system, the segregation of the molecules of the amorphous component from the crystallizing front is affected by the T_g, the kinetics of diffusion of the amorphous component, the crystallization kinetics, and the supercooling. In the latter blend system, the temperature and time of curing of the thermosetting affect strongly the crystallization features of the crystallizable thermoplastic component.

In miscible blends, segregation of the amorphous component competes with crystallization of the crystallizable one. Interspherulitic, interfibrillar, and interlamellar are the regions where segregation can take place during the crystallization of the crystallizable componenet. The balance between the diffusion rate of the amorphous component and the crystallization rate of the crystallizable component determines one or the other of the segregation type. In miscible blends of two crystallizable components, separate crystallization, concurrent crystallization, or cocrystallization may take place upon cooling from above the two individual melting temperatures of both blend components. Examples of blend systems leading to similar behavior were selected from literature and summarized herein. These phenomena were already reported in the first edition of the handbook and are maintained unmodified in the present chapter as no important new concepts were reported since then.

In immiscible blend systems, the accent was put on the fractionated crystallization features. A new and interesting work has been done since the first edition. This is extensively highlighted in the present chapter. The phenomenon is significant when the crystallizable phase is dispersed in the amorphous phase of the second blend component. Reactively compatibilized blends were compared to uncompatibilized

ones. The effect of compatibilization was shown to indirectly affect the crystallization behavior of the blends as it effects only and mainly causes particle size reduction. That results in more fractionated crystallization as the number of heterogeneities becomes insufficient to locate in all the crystallizable dispersed particles.

Dedication and Acknowledgments Professor Emeritus Dr. Gabriël Groeninckx would like to dedicate this chapter to all his former master and Ph.D. students, postdocs, and colleagues of the Laboratory for Macromolecular Structure Chemistry of the Catholic University of Leuven (KU Leuven, Heverlee, Belgium) for their valuable contribution in the field of polymer blends and related domains. He also would like to fully express his acknowledgments to the KU Leuven where he spent his scientific career from 1965 to 2010. And last but not least, he also has the great pleasure of dedicating this chapter 5 to his wife Anne-Marie and his children Christine, Filip, and Mark but also to his grandchildren Maartje, Nikolaas, Lineke, Noortje, and Luca. Each of them made him very happy in their own way.

SALS Small-angle light scattering (also SALLS)

SAXS Small-angle X-ray scattering

SEM Scanning electron microscopy

temp. Temperature

UCST Upper critical solution temperature

WAXS Wide-angle X-ray scattering

WLF Williams, Landel, and Ferry

C_1, C_2, C_3 WLF constants

C-2 Carbon chain with 2 C-atoms; i.e., ethylene

C-3 Carbon chain with 3 C-atoms; i.e., propylene

C_p Heat capacity under constant pressure

E_1 Energy dissipated for rejection of droplets during spherulite growth

E_2 Energy to overcome the inertia of droplets during spherulite growth

E_3 Energy required to form new interfaces when droplets are engulfed

E_4 Energy dissipated for deformation of occluded particles during spherulite growth

F_{12} Spreading coefficient

$f_z^{(1)}$ Fraction of dispersed droplets of volume V_D that contain z heterogeneities of type 1

G Isothermal spherulite growth rate

G^o Theoretical spherulite growth rate

G_1 Undisturbed spherulite growth rate of the homopolymer described by the Turnbull-Fisher equation

$M^{(1)}$ Concentration of heterogeneities of type 1

MW Molecular weight

n Avrami exponent

N Nucleation density

N/S Nucleation density normalized per unit area

K Overall crystallization rate

$t_{0.5}$ Halftime of crystallization at a fixed $T_{c,iso}$

T_c Bulk crystallization temperature upon cooling from the melt

T_c^o Crystallization temperature of the bulk homopolymer

$T_{c,cold}$ Cold crystallization temperature

$T_{c,hom}$ Homogeneous crystallization temperature

$T_{c,i}$ Crystallization temperature at which heterogeneities of type i become active

$T_{c,iso}$ Isothermal crystallization temperature

$T_{c,max}$ Optimal isothermal crystallization temperature which yields the highest overall crystallization

T_g Glass-transition temperature

T_m Measured melting temperature of the crystalline phase

T_m^o Theoretical melting temperature for crystalline lamellae of infinite thickness

T_m' Observed melting temperature of the crystalline phase in blends

T_{melt} Premelting temperature

t_{melt} Time the polymer is kept in the melt

V_D Average volume of dispersed polymer droplets

Vol% Volume percentage

wt% Weight percentage

X_c Total degree of crystallinity

y_p **(m, c)** Lateral surface free energy between the crystal and its own melt

y_{pn} **(m)** Interfacial energy between the nucleating species and the polymer melt

y_{pn} **(c)** Interfacial energy between the nucleating species and the polymer crystal

z Number of heterogeneities of type 1, inducing crystallization in the bulk polymer at $T_c{}^o$

Symbols: Greek Letters

$\boldsymbol{\Delta E}$ Activation free energy for the transport of chains through the liquid–solid interface

$\boldsymbol{\Delta F}$ Difference of interfacial energies; driving force for rejection, engulfing, and/or deformation of dispersed droplets during spherulite growth

$\boldsymbol{\Delta F^*}$ Free energy for the formation of a nucleus of critical size

$\boldsymbol{\Delta H_m}$ Total melting enthalpy of the crystalline polymer fraction

$\boldsymbol{\Delta T_{c,hom}}$ Degree of undercooling required for homogeneous crystallization

$\boldsymbol{\Delta T_{c,i}}$ Degree of undercooling required before a heterogeneity of type i can become active

$\boldsymbol{\Delta y_i}$ Specific interfacial energy difference between a nucleating species of type i and the polymer

$\boldsymbol{\Delta y_{pn}}$ Specific interfacial energy difference between a nucleating species and the polymer

$\boldsymbol{\gamma_{PS}}$ Interfacial free energy between the crystallizing solid and the inclusions

$\boldsymbol{\gamma_{PL}}$ Interfacial free energy between the liquid polymer melt and the inclusions

$\boldsymbol{\sigma_o}$ Surface free energy of folding

$\boldsymbol{\sigma_{1,2}}$ Interfacial free energy between two phases of a blend in the melt

$\boldsymbol{\sigma_{i,1}}$ Interfacial free energy of an impurity with respect to melt phase 1

$\boldsymbol{\sigma_{i,2}}$ Interfacial free energy of an impurity with respect to melt phase 2

Abstract

Polymer blends are mixtures of at least two macromolecular species, polymers
and/or copolymers. For practical reasons, the name *blend* is given to a system
only when the minor component content exceeds 2 wt%. Depending on the sign
of the free energy of mixing, blends are either miscible or immiscible. In
a general sense, the polymer/polymer miscibility does not exist – it is always
limited to a "miscibility window," a range of independent variables, such as
composition, molecular weight, temperature, pressure, etc. More than 1,600 of
these "miscibility windows" have been identified for two-, three-, or four-
component blends. The immiscibility dominates the field (Utracki 1989). For
more details on the thermodynamics of mixing and phase diagrams, the reader is
referred to ▶ Chap. 2, "Thermodynamics of Polymer Blends" in this volume.
This chapter is an updated version of the 1998 version and addresses the aspects
related to the interphase in immiscible polymer blends and their compatibi-
lization by the addition of a compatibilizer. In the first part, theoretical aspects
treating on the prediction of the distribution profiles, interface thickness, and
interfacial tension are presented for immiscible homopolymer blends, copoly-
mers, copolymer/homopolymer blends, and finally copolymer-added homopol-
ymer blends. The second part deals with experimental aspects such as
measurement techniques and comparisons of experimentally measured results
with theory for the interfacial tension and thickness for the systems mentioned
above. Finally, some information on patented polymer blends is presented in
table form. The first two parts are updated at their end with related information
from recent literature.

4.1 Introduction

4.1.1 Definition of the Surface and Interface Tension Coefficients

The surface tension is the reversible work required to create a unit surface area at
constant temperature (T), pressure (P), and composition (n) (Wu 1982):

$$v_i = (\partial G / \delta A)_{T,P,n} \tag{4.1}$$

where v_i is the surface tension coefficient of the substance i, G is Gibbs free energy
of the system, and A is the surface area. In immiscible liquids, interactions between

components are located at the physical boundary creating the interface. The energy required to reversibly separate the two liquids is expressed as the work of adhesion:

$$W = v_1 + v_2 - v_{12} \tag{4.2}$$

where v_1 and v_2 are surface tension coefficients of neat components and v_{12} is the interfacial tension coefficient between the liquids 1 and 2.

4.1.2 Importance of the Interfacial Properties in Polymer Blends

The structure and morphology of immiscible blends depends on many factors among which the flow history and the interfacial properties are the most important. At high dilution and at low flow rates, the morphology of polymer blends is controlled by three dimensionless microrheological parameters: (i) the viscosity ratio, $\lambda = \eta_1/\eta_2$, where η_1 is the viscosity of the dispersed liquid and η_2 that of the matrix; (ii) the capillarity number, $\kappa = \sigma_{12}\, d/v_{12}$, where σ_{12} and d are, respectively, the shear stress and the initial drop diameter; and (iii) the reduced time, $t^* = t\dot{\gamma}/\kappa$, where t is deformation time and $\dot{\gamma}$ is the rate of shear (Utracki 1989, 1994). Thus, the interfacial and rheological properties are keys for the morphological development in polymer blends, which in turn is the controlling factor for their performance.

To improve performance of immiscible blends, usually they need to be compatibilized. There are three aspects of compatibilization: (1) reduction of the interfacial tension that facilitates fine dispersion, (2) stabilization of morphology against its destructive modification during the subsequent high stress and strain processing (e.g., during the injection molding), and (3) enhancement of adhesion between phases in the solid state, facilitating the stress transfer, hence improving the mechanical properties of the product. Compatibilization can be either carried out by adding a compatibilizer to a polymer blend or prepared during the reactive processing or blending. During the latter process, the compatibilizing species are chemically formed in situ, directly across the interface.

In this chapter, compatibilization of polymer blends by means of the addition of a compatibilizer will be discussed. First, the theories will be summarized as follows: (i) interface, (ii) interphase, and (iii) compatibilization process. Reference to some recent work in the area will also be performed in this updated version. This brief summary is to provide a general framework for understanding the phenomena associated with compatibilization and guidance for optimization of the process to gain maximum performance. The theoretical part is followed by the experimental part, where the methods for the determination of interfacial properties are presented. Most of the chapter is dedicated to provide comprehensive information on the characteristic properties of blends compatibilized by the addition of a compatibilizing agent, also with updates from recent literature.

4.2   Theoretical Aspects of the Interface

4.2.1   Binary Immiscible Polymer Blends

Mixing two polymers usually results in an immiscible system, characterized by a coarse, easy to alter morphology, and poor adhesion between the phases. These blends have large size domains of dispersed phase and poor adhesion between them. As a result, their performance is poor and irreproducible. In particular the impact strength, maximum strain at break, and the yield strength are affected. The irreproducibility originates from instability of morphology – blend structure developed during the compounding step is unstable and irreproducible. To be able to solve these three problems (degree of dispersion, stability of morphology, and adhesion between the phases in solid state), one must learn about the region between the two phases in binary polymer blends, the interface or rather the interphase.

Let us consider a molten, immiscible, binary blend of polymers A and B, without compatibilizer. Helfand and Tagami (1971a, b), Helfand (1975a, b, c), Roe (1975), and Helfand and Sapse (1975) have developed a quantitative lattice theory of the interphase that 20 years later still provides good basis for understanding.

Helfand and Tagami model is based on self-consistent field that determines the configurational statistics of macromolecules in the interfacial region. At the interface, the interactions between statistic segments of polymers A and B are determined by the thermodynamic binary interaction parameter, χ_{12}. Since the polymers are immiscible, there are "repulsive" enthalpic effects that must be balanced by the entropic ones that cause chains A and B to intermingle.

In the first simplified mean-field approach, (i) the two homopolymers were assumed to have the same degree of polymerization; (ii) the complex set of equations derived for the segmental density profile, ρ_i (where $i = A$ or B), was solved for infinitely long macromolecules, $M_w \to \infty$; (iii) the isothermal compressibility was assumed to be negligibly low; and (iv) there was no volume change upon blending (i.e., the attractive or repulsive forces between two polymers were assumed weak).

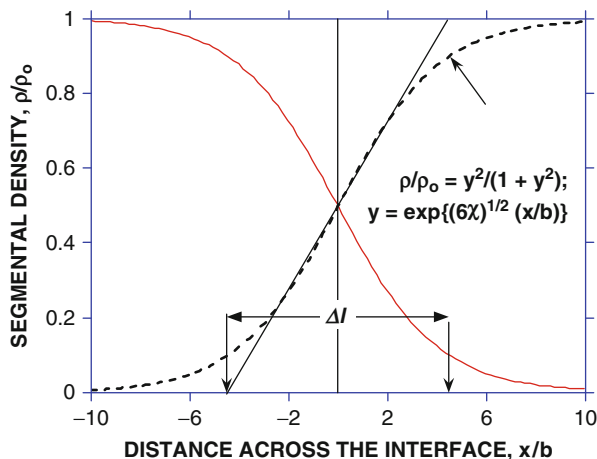
The analytical solution of the interfacial composition profile was found to follow an exponential decay function (Helfand and Tagami 1972):

$$
\begin{aligned}
\rho_i &= \rho_{i,o} y^2/(1+y^2) \\
y &\equiv \exp\left\{(6\chi_{AB})^{1/2}(x/b)\right\}
\end{aligned}
\tag{4.3}
$$

where b is the lattice parameter and i can be either A or B. A typical dependence is shown in Fig. 4.1 (Utracki 1994).

Similarly, for the symmetrical polymers A and B whose $M_w \to \infty$, the interfacial thickness, Δl_∞, and the interfacial tension coefficient, v_∞, were derived as:

$$
\Delta l_\infty = 2b(6\chi_{AB})^{-1/2}
\tag{4.4}
$$

Fig. 4.1 Representation of
the interface, with the
definition of the interphase
thickness, Δl; χ and b are,
respectively, the binary
interaction and the lattice
parameters


$$v_\infty = b\rho T k_b (\chi_{AB}/6)^{1/2} \tag{4.5}$$

where k_b is the Boltzmann constant and T is the absolute temperature.

Predictions of Eq. 4.5 were compared with the experimental data for three polymeric blends: polystyrene/polymethylmethacrylate, PS/PMMA; polybutyl methacrylate/polyvinylacetate, PBMA/PVAc; and PMMA/PBMA. It was found that v_∞ agreed with the experimental value of v_{12} determined for PBMA/PVAc. However, the agreement for PMMA/PBMA was not as good, while for PS/PMMA the difference was 50 %. In consequence, the authors postulated that for large values of χ_{12}, the thickness of the interphase is too small for the mean-field theory to be valid. Equation 4.5 also predicts that the interfacial tension coefficient is a linear function of the temperature. Furthermore, since to the first approximation $\chi_{AB} = a + b/T$, the slope dv_{12}/dT should be negative. Figure 4.2 indeed confirms these predictions.

The Helfand-Tagami lattice theory predicts that there is reciprocity between the interfacial tension coefficient and the interfacial thickness, and the product, $v_\infty \Delta l_\infty$, is independent of the thermodynamic binary interaction parameter, χ_{12}. Furthermore, the theory led to the conclusions that (i) the surface free energy is proportional to $\chi_{12}^{1/2}$; (ii) the chain ends of both polymers concentrate at the interface; (iii) any low molecular weight third component is repulsed to the interface; (iv) the interfacial tension coefficient is a linear function of temperature (see Eq. 4.5 and Fig. 4.2); and (v) the interfacial tension coefficient increases with molecular weight to an asymptotic value, v_∞, as illustrated in Fig. 4.3:

$$v = v_\infty - a_o M_n^{-2/3} \tag{4.6}$$

Four years later, Helfand and Sapse removed the restriction of the original theory for the symmetric character of both polymers, obtaining for v_∞ the following expression:
Fig. 4.2 Temperature dependence of the interfacial tension coefficient for PP/PS (data from Demarquette and Kamal 1994) and for PE/PA, LDPE/PS, and PVDF/EP
Fig. 4.3 Verification of the molecular weight dependence of the interfacial tension coefficient, as predicted by the Helfand-Tagami theory (see Eq. 4.6)

$$v_\infty = (2/3)k_b T\alpha^{1/2}(\beta_A^3 - \beta_B^3)/(\beta_A^2 - \beta_B^2)$$
$$\alpha \equiv \chi_{AB}(\rho_{oA}\rho_{oB})^{1/2} \tag{4.7}$$
$$\beta_i^2 = \rho_{oi}b_i^2/6$$

where $b_i^2 = \langle R_i^2\rangle/Z_i$ and b_i is the Kuhn statistical segment length.

Substituting in Eq. 4.7, $\rho_{oA} = \rho_{oB}$ and $\beta_A = \beta_B$ result in the recovery of Eq. 4.5.

A generalized gradient theory of the interface was developed by Anastasiadis et al. (1988). The approach is based on the assumption that the composition gradient is small compared to the reciprocity of the intermolecular distances. Under these circumstances the free energy density, g, can be written as a power series, truncated after the square term. In essence, the theory determines the difference in the density fluctuation per unit interfacial area between a polymer mixture and a system in which the properties are homogenous. The theory predicts that:

$$
\begin{aligned}
v_{12} &= \int_{\phi_\alpha}^{\phi_\beta} \left[\overline{\kappa} \Delta g(\phi) \right]^{1/2} d\phi \\
\overline{\kappa} &\equiv -\left[\partial^2 g / \partial\phi\partial\nabla^2\phi \right] + \left[\partial^2 g / \partial |\nabla\phi|^2 \right]
\end{aligned}
\tag{4.8}
$$

Thus, to calculate v_{12}, one has to select an appropriate expression for the energy density gradient and then integrate Eq. 4.8 within the limit of composition in both phases, ϕ_A and ϕ_B. Huggins-Flory and Cahn-Hilliard theories were used with good success to predict the temperature gradient, but poor as far as the effects of molecular weight were concerned.

Roe (1975) developed a quasicrystalline lattice model for conditions where $\chi_{12} >> \chi_{cr}$ (where χ_{cr} is the critical value of the interaction parameter at the phase separation) and for $\chi_{12} - \chi_{cr} << \chi_{cr}^2$. Under the first conditions (high immiscibility), the theory predicted a proportionality between v_{12} and χ_{12}, whereas under the second (near the phase separation), a proportionality between v_{12} and $\chi_{12}^{3/4}$ was predicted. By contrast with the previously summarized Helfand and Tagami predictions, Roe's theory indicates that the product $v_{12}\Delta l$ should be proportional to $\chi_{12}^{1/2}$.

Kammer (1977) considered the interface between two polymers from the basic thermodynamic point of view. He derived a simple relation: $v_{12} = \Delta\mu_{B/S}$, where $\Delta\mu_B$ is the excess chemical potential of polymer B in the mixture and S is the molar area of the interface. Near the spinodal decomposition, using the Cahn-Hilliard gradient theory, he calculated:

$$
\begin{aligned}
v_{12} &= v_o + RT\phi_B^{1/2}\varepsilon^{1/2} \\
\varepsilon &\equiv (\chi - \chi_{cr})/\chi_{cr}
\end{aligned}
\tag{4.9}
$$

The following year, from similar assumptions, Joanny and Leibler (1978) derived:

$$
\begin{aligned}
v_{12} &= (2/3)k_B T b^2 Z_B^{-1/2}\varepsilon^{3/2} \\
\Delta l &= (1/3)b Z_B^{1/2}\varepsilon^{-1/2} \\
\therefore v\Delta l &= (2k_B T/9b)\varepsilon
\end{aligned}
\tag{4.10}
$$

where $Z_B = Z_A$ is the degree of polymerization. The proportionality $v_{12} \sim \varepsilon^{3/2}$ and $\Delta l \sim \varepsilon^{-1/2}$ are in agreement with the classical approach to the interface (de Gennes 1977). Thus, it seems that the prediction of the Helfand-Tagami lattice

theory that the product, $v_{12}\Delta l$, is independent of the thermodynamic binary interaction parameter, χ_{12}, may not be correct in the whole range of variables. The authors observed that the relation breaks down in antagonistically immiscible blends where $\chi_{12} >> \chi_{cr}$. Nowadays, there is growing theoretical evidence that the prediction is not valid for $\chi_{12} \rightarrow \chi_{cr}$.

More recently, Eq. 4.4 was modified to account for finite M_w (Broseta et al. 1990). For blends of polystyrene with polyvinylpyridine, PS/PVP, the authors obtained:

$$\Delta l = 2b\,(6\chi_{12})^{-1/2}[1 + (\ln\ 2)(1/Z_{PS} + 1/Z_{PVP})/\chi_{12}] \tag{4.11}$$

where Z is the degree of polymerization. Equation 4.11 was corrected for entropic effects. For $M_w \rightarrow \infty$, Eq. 4.4 is recovered. Polydispersed systems were also considered by assuming the same bimodal distribution of chain lengths for both A and B components. As expected, chains of higher M_w tended to localize in the bulk phases rather than near the interfacial region. The loss of translational entropy associated with the confinement of the chain into half the space is more easily accepted by large chains than by small ones.

Muller and Binder investigated recently (Muller and Binder 2000) the structure and thermodynamics of interfaces in dense polymer blends using Monte Carlo (MC) simulations and self-consistent held (SCF) calculations. A quantitative agreement between the MC simulations and the SCF calculations was found for structurally symmetric blends for interfacial properties such as interfacial tension or enrichment of copolymers at the interface. Some capillary wave contributions had, however, to be taken into account for quantitative comparison of the profiles across the interface in the MC simulations and the SCF calculations. SCF calculations led to profiles of a perfectly fiat interface and the local, interfacial position fluctuated for the MC simulations. Asymmetric blends' interfacial properties were investigated by considering the polymers having different stiffnesses. At high incompatibilities, the interfacial width is not much larger than the persistence length of the stiffer component. Deviations from the predictions of the Gaussian chain model were found indicating that while the Gaussian chain model yields an increase of the interfacial width upon increasing the persistence length, no such increase was found in the MC simulations. The details of the chain architecture on all length scales could be taken into account using a partial enumeration technique in the SCF calculations, and a good agreement with the MC simulations was achieved.

There have been also some recent theoretical approaches addressing mainly the thermodynamic properties of binary and ternary polymer blends. Campos et al. (1996) extended the Flory-Huggins theory to predict the thermodynamic properties of binary polymer blends and blends in solution. Their approach was applied for PVDF/PS dry blend and in solution in dimethylformamide (DMF) with inclusion of an interaction function. It could be inferred that this blend behave as slightly incompatible under environmental conditions, in agreement with previously reported data. That incompatibility was suppressed when a low molar mass component, such as DMF, was added, reaching the semidilute regime (total

polymer volume fraction of about 0.35). Values of the Gibbs free energy of mixing as a function of the blend composition were also evaluated for both ternary solution and dry blend and discussed in terms of their stability.

Rudolf et al. (1998) used the modified cell model of Dee and Walsh and the Simha-Somcynsky theory to investigate the phase behavior, excess volumes, the influence of pressure on miscibility, and the causes of miscibility. It was found that the theory of Dee and Walsh yields results similar to the previously investigated theories, whereas the Simha-Somcynsky theory does not. A modification of the latter theory for mixtures again resulted in predictions similar to that of Dee and Walsh and the earlier investigated theories.

Buta et al. (2001) tested the Monte Carlo approach for the lattice cluster theory to derive the thermodynamic properties of binary polymer blends. They considered the two polymers to have the same polymerization indices, i.e., M = 40, 50, or 100. The results confirm that this lattice cluster theory had a higher accuracy compared to the Flory-Huggins theory and the Guggenheim's random mixing approximation. However, some predictions for the specific heat were found to be inaccurate because of the low order cutoff of the high temperature perturbative expansion.

Finally, a review was done by Higgins et al. (2005) in which they combined the experiments and a theory based on the lattice Born-Green-Yvon (BGY) approach to predict coexistence curves, neutron scattering intensities, and pressure-volume-temperature surfaces. This work allowed to better understand some of the correlations between the microscopic structure and macroscopic behavior of several common polymer mixtures.

4.2.2   Copolymers

Block copolymers are polymers constituted of at least two different monomers arranged in a specific manner – they could be diblock, triblock, multi-block, linear, star shaped, etc. Those based on styrene and butadiene, SB or SBS, are the earliest to be applied and studied, as well as the largest as far as the volume of production is concerned (Holden et al. 1967).

4.2.2.1 Block Copolymers: Fundamentals

To ascertain control of the molecular weight, structure, and composition, block copolymers are usually synthesized in anionic polymerization. The block copolymers of commercial interest are specifically prepared from monomers that upon polymerization yield immiscible macromolecular blocks, a smaller one rigid and the other flexible. The rigid blocks form physical cross-links that upon heating above the transition point make the copolymer flow. Thus, these materials belong to the growing family of thermoplastic elastomers.

There are two distinct differences between the phase diagram of a block copolymer and the one obtained for a mixture of two homopolymers. In block copolymers, owing to the chemical links between blocks, microdomains instead of macroscopic phases are observed. The size of microdomains can be

controlled by varying the molecular weight and composition. Furthermore, since the type of morphology depends on the concentration as well as on the transition temperatures of the individual phases, the phase diagram of block copolymers shows comparable complexity to those of metallic alloys.

The domain size and shape, as well as the interfacial thickness, depend on the following factors: (i) magnitude of the repulsive interactions between the A and B blocks, χ_{AB}; (ii) the conformation entropy loss necessary to maintain constant segment density; (iii) the localization entropy loss that causes the chemical links to be present at the interface; and (iv) the composition. These mutually compensating factors (i vs. ii + iii) depend on molecular weight of each block and the binary interaction parameter (Helfand 1975; Helfand and Wasserman 1976, 1978, 1980; Hashimoto et al. 1974, 1980a, b; Inoue et al. 1969; Krause 1980; Meir 1969, 1987; Hashimoto et al. 1983).

4.2.2.2 Interphase in Block Copolymers

Theories of block copolymers are usually complex, involving computation of the domain size, the interphase thickness between the blocks, the structure, and the order–disorder transitions. Helfand and Wasserman (1976, 1978, 1980), using the narrow interphase approximation, showed that Eq. 4.4 is valid in the limit of infinitely immiscible blocks having $M_w \to \infty$ (i.e., the strong segregation limit, SSL). The authors' approach was based on the confined chain statistics. Expressions for the free energy of different structure formation, interfacial tension, and interfacial thickness (in the case of an infinite M_w) were derived. For large $\chi_{12}Z_c$ values (Z_c is the copolymer degree of polymerization), the narrow interface approximation was assumed valid; thus, the boundary thickness should be similar to that in an A/B mixture. This interfacial thickness Δl was expressed as:

$$\Delta l = 2\left[\left(\beta_A^2 + \beta_B^2\right)/2\chi_{12}\right]^{1/2} \tag{4.12}$$

with $\beta_i^2 = (\rho_{oi}b_i^2)/6$ and $b_i^2 = <R_i^2>/Z_i$, where b_i is the Kuhn statistical segment length, Z_i is the degree of polymerization, ρ_{oi} is the density, and $<R_i^2>$ is the radius of gyration of the block i. For identical chains and the lattice size, $b^2 = b_i^2\rho_i$ and Eq. 4.12 converts to Eq. 4.4.

The thermodynamic properties of block copolymers in disordered state have been studied by Leibler (1980). Using the random phase approximation (de Gennes 1979), the author developed a relation between the segmental density correlation function and the scattering vector. An order parameter, related to the reduced segmental density, was introduced. In the disordered state, this order parameter is zero, whereas for the ordered phase, it is a periodic nonzero function. Leibler demonstrated that the critical condition for microphase separation in diblock copolymers is $\chi_{AB}Z_c = 10.5$.

The work was extended by Olvera de la Cruz and Sanchez (1986) to block copolymers with more complex architectures. For diblock copolymers, the authors confirmed Leibler's results, $\chi_{AB}Z_c = 10.5$. The same value was also found for the star copolymers having the same number of A and B arms, each of the same length:

Fig. 4.4 Interphase thickness in styrene-isoprene block copolymers versus total molecular weight. *Points* are experimental (Hashimoto et al. 1980; Richars and Thomason 1983); the *line* was computed from Eq. 4.13 using $\Delta l_o = 1.9$ nm and $\chi = 1,000$ $\chi_{AB}/M_o = 0.6$
$Z_A = Z_B$. Computations for triblock copolymers gave $\chi_{AB}Z_c = 8.86$, indicating poorer miscibility than that computed for diblocks.

More recently, a theory based on confined chain statistics (CCS) predicted that Δl should be a decreasing function of Z_c. Thus, the modification of Eq. 4.4 resulted in an expression valid for $\chi_{AB}Z_c \geq 20$ (Spontak and Zielinski 1993):

$$\Delta l = \Delta l_\infty [1 - (8\ln 2)/(\chi_{AB}Z_c)]^{-1/2} \tag{4.13}$$

Equations 4.12 and 4.13 are similar, but differences in the range of 40 % have been found in the low $\chi_{AB}Z_c$ region. The prediction of Eq. 4.13 is compared in Fig. 4.4 with the small-angle neutron scattering and small-angle X-ray scattering data (Hashimoto et al. 1980; Richars and Thomason 1983).

4.2.3   Copolymer/Homopolymer Blends

4.2.3.1 Blends of Block Copolymer with Homopolymer

Information on the phase diagrams of copolymer/homopolymer blends can be found in reviews by Ajji and Utracki (1996, 1997) and in ▶ Chap. 2, "Thermodynamics of Polymer Blends" in this handbook. The interface thickness of A/A-B mixtures was not theoretically calculated, but experimental measurements indicate that the presence of the homopolymer leaves the domain boundary unchanged (Bates et al. 1983; Hashimoto et al. 1990a; Tanaka et al. 1991; Zin and Roe 1984; Green et al. 1989). On the other hand, the part of the phase diagram where the concentration of the block copolymer in the mixture is low was studied in detail (Whitmore and Noolandi 1985; Leibler et al. 1983; Leibler 1988). The proposed models were similar. In both, the conditions for the formation of spherical micelles

were investigated and expressions of the critical micelle concentration, $\phi_{CMC}^{\text{spherical}}$, were derived. For example (Leibler 1988):

$$\phi_{CMC}^{\text{spherical}} = \exp\left\{ 1.72(\chi_{AB}Z_C)^{1/3}f^{4/9}\left(1.74f^{-1/3}-1\right)^{1/3} - f\chi_{AB}Z_C \right\} \qquad (4.14)$$

where f is the fraction of A-polymer in A-B copolymer.

The predictions of ϕ_{CMC} were extended to cylindrical and lamellar micelle morphologies (Shull et al. 1991). In all cases, geometric parameters, e.g., core radius and corona thickness, can be computed, assuming that the interfacial thickness between the core and the corona is equal to Δl_∞.

Experimental studies of micellar systems were carried out using scattering methods (Selb et al. 1983; Rigby and Roe 1984, 1986; Kinning et al. 1990, 1991). Theoretical simulations of the scattering curves have been based on the assumptions that either an infinitely sharp boundary thickness or a diffuse interfacial thickness is equal to Δl_∞. In spite of these seemingly diverse principles, the simulations were reasonably correct.

The enthalpy associated with the addition of a homopolymer having high M_w to a block copolymer in the disordered state is not compensated by sufficient entropic gains; hence, a mesophase is formed. This effect was observed by Cohen and Torradas (1984). This contrasts with other reports (Ptaszynski et al. 1975; Hashimoto et al. 1990; Winey et al. 1991) where upon the addition of a homopolymer with molecular weight smaller than that of the corresponding block, the average area per junction point was found to increase. SAXS scattering patterns obtained from samples having lamellar morphology followed an idealized model, in which layers of styrene and butadiene (with randomly varying thickness and a diffuse interface) were parallel.

Green and Russel (1991) theoretically and experimentally studied effects of the addition of a low molecular weight symmetric block copolymer of P(S-b-MMA) on the interfacial tension in blends comprising a high molecular weight homopolymer, either PS or PMMA. The theory was based on a mean-field argument (similar to that of Leibler), valid within the low compatibilizer concentration range. The theory predicted that:

$$v = v_o - k_B T[\rho\phi_C a\exp\{\chi_{AB}Z_C\}]/Z_C \qquad (4.15)$$

where ϕ_c is the volume fraction of the copolymer. The calculations were consistent with experimental data on similar systems. The estimated value of χ_{AB} compared well with that determined in neutron scattering experiments.

Floudas et al. (1997) studied theoretically and experimentally microphase segregation in block copolymer/homopolymer blends for an asymmetric diblock copolymer and homopolymer concentrations of less than 25 %. It was observed that the minority phase could solubilize only a small amount of added homopolymer. The addition of higher amounts resulted in the formation of nonequilibrium structures. Theoretical predictions in the strong segregation limit showed that $(\chi N)_c$,

where N is the degree of polymerization, always increases with the addition of the minority phase. Experiments agreed with experiments in the two extreme cases of N much larger than N_h (homopolymer degree of polymerization) and N much smaller than N_h. Their results showed that the degree of compatibility between the two blocks of the diblock AB can be effectively controlled by adding a small amount of homopolymer A or B.

Choksi and Ren (2005) derived a density functional theory for diblock copolymer/homopolymer blends. Their numerical results were shown to capture the multiscale separation in the system: (i) macrophase separation into homopolymer- and copolymer-rich macrodomains followed by (ii) microphase separation into A- and B-rich microdomains within the copolymer-rich macrodomains. They also demonstrated a result on local minimizers in one space dimension, confirming a lamellar multiscale phase separation.

More recently, Martinez-Veracoechea and Escobedo (2009) used a self-consistent theory and particle-based simulations for the case of bicontinuous phases in diblock copolymer/homopolymer blends. They were able to predict the spontaneous formation of double-diamond phase (DD) and plumber's nightmare phase (P) in the range of homopolymer volume fraction simulated via coarse-grained molecular dynamics for the first time. The self-consistent field theory was used to explore the DBC/homopolymer phase diagram in more detail. They showed that although the two-phase coexistence of a DBC-rich phase and a homopolymer-rich phase does precede the stability of complex bicontinuous phases in many cases, the DD phase can be stable in a relatively wide region of the phase diagram. The P phase was always metastable with respect to macrophase separation under the thermodynamic conditions explored with SCFT. It was sometimes nearly stable, suggesting that full stability could be achieved in other unexplored regions. Moreover, the predicted DD and P phases could be observed in experiments as "long-lived" metastable phases.

Finally, a comparison of self-consistent field theory (SCFT) results with experiments for micelle formation in block copolymer/homopolymer blends was performed by Greenall et al. (2009) for a blend of poly(styrene-butadiene) diblocks and homopolystyrene. They found that the micelle core radii R_c shape and variation with molecular parameters could be reproduced much more accurately than scaling theories. For the corona thickness, the accuracy of the predictions was at least as good as that of scaling theories. For copolymers with lighter core blocks, SCFT predictions for the critical micelle concentration improved over those of scaling theories by an order of magnitude. In the case of heavier core blocks, however, SCFT predicted the critical micelle concentration less well due to inaccuracies in the modeling of the bulk chemical potential.

4.2.3.2 Blends of Graft or Random Copolymer with Homopolymer

There are only few papers dealing with systems comprising a graft copolymer and a homopolymer. For example, blends of graft A-B copolymer with homopolymer A (identical with the backbone of the copolymer) were found to have unusual morphologies (Eastmond and Phillips 1977, 1979). The most common of these

were spherical structures (named *onions*) consisting of alternating concentric layers of *A* and *B* components. The conclusion was that the *onions* had their origin in the immiscibility of copolymer with homopolymer, even when the molecular weight of chemically identical blocks was comparable (Eastmond et al. 1987). Other studies reported similar findings, even when the molecular weight of homopolymer was lower than that of the corresponding block (Jiang et al. 1985). It was suggested that the immiscibility and the *onion*-type morphology originated in molecular structure of copolymer.

For the case of homopolymer blends with a random copolymer, Shimomai et al. (1996) studied their miscibility using the equation of state theory and compared the results for poly(methyl methacrylate) (PMMA) and styrene-acrylonitrile random copolymers (SAN) blends. They used the Flory-Orwoll-Vrij equation of state theory. To obtain the equation of state parameters (P*, V*(sp), T*: characteristic parameters), the pressure-volume-temperature (PVT) behavior was measured for PMMA and a series of SANs with various acrylonitrile contents. The Flory-Huggins interaction parameter X was separated into two contributions based on the equation of state theory for mixtures: an exchange energy term and a free volume term. Both their temperature and copolymer composition dependences were estimated by calculations using the equation of state parameters. There exists a region in which the part due to the exchange energy term is negative, leading to a miscibility window in PMMA/SAN blends. However, the immiscibility at high temperatures in the blends could not be explained only by term; it was caused by the free volume contribution.

4.2.4 Blends of Two Homopolymers with a Compatibilizer

4.2.4.1 Blends of Two Polymers with a Copolymer

Ternary blends that comprise two immiscible polymers and a copolymer are of a particular interest. They not only represent an ideal model for studying compatibilization of polymer blends, but also they have found direct commercial applications. Phase diagram information can be found in reviews by Ajji and Utracki (1996, 1997) and in ▶ Chap. 2, "Thermodynamics of Polymer Blends," ▶ Chap. 21, "Miscible Polymer Blends," and ▶ Chap. 8, "Morphology of Polymer Blends" in this handbook.

The theories discussed in Sect. 4.2.1 dealt with binary polymer blends without compatibilizer. Hong and Noolandi (1980, 1981a, b) developed a theory, similar to that of Helfand, for the interfacial region in three-component polymeric systems comprising polymers *A* and *B* and either a cosolvent or a block copolymer. The theory is based on the lattice model – it uses the mean-field approximation. It is formulated using the reduced equation of state variables. Finite molecular weights and conformational entropy effects were considered, but the excluded volume effects were not (this aspect was later treated by Broseta et al. (1987)). The resulting system of equations can be solved numerically for the interfacial composition profile, interfacial tension coefficient, thickness of the interphase, etc. At low values of M_w, the theory well predicts v_{12}, but for higher M_w, the prediction was up to 20 % too high.

Calculations of the Interfacial Tension Coefficient and CMC

The emulsifying effects of a small quantity of a block copolymer, *A-B*, added to immiscible blend of homopolymers *A* and *B*, were examined by Leibler (1988). The theory predicted the reduction of the interfacial tension coefficient, v_{12}, caused by equilibrium adsorption of a copolymer at the interface. For well-chosen compositions and molecular weights of the copolymer, low values of v_{12} are to be expected. This suggests a possible existence of thermodynamically controlled stable droplet phase, in which the minor phase homopolymer drops are protected by an interfacial film of the copolymer, interfacing the matrix polymer. The size distribution of the droplets is expected to depend on the rigidity and spontaneous radius of curvature of the interfacial film that can be controlled by molecular structure of the copolymer.

For long copolymer chains (in strongly immiscible, or the "wet brush case"), the reduction of the interfacial tension coefficient should follow the relation:

$$\Delta v \equiv v - v_o = -\left(k_B T/a^2\right)(3/4)^{1/3}\left(\Sigma/a^2\right)^{-5/3}\left[Z_{CA}Z_A^{-2/3} + Z_{CB}Z_B^{-2/3}\right] \quad (4.16)$$

where Z_{CA} and Z_{CB} are, respectively, the number of *A* and *B* monomeric segments in copolymer; $Z_c = Z_{CA} + Z_{CB}$ is the total number of segments in copolymer; Z_A and Z_B are the degrees of polymerization in homopolymer *A* and *B*, respectively; a is the monomer length; and Σ is the interfacial area per copolymer joint ($\Sigma = A/Q$, where Q is the number of copolymer chains at the interface between *A* and *B* and *A* is the total interface surface area). For short copolymer chains ($Z_c < Z_i^{-2/3}$ and $\Sigma < Z_c^{1/2}a^2$), Eq. 4.16 can be simplified to read:

$$\Delta v = -3Z_C\left(k_B T/a^2\right)\left(\Sigma/a^2\right)^{-3} \quad (4.17)$$

Both Eqs. 4.16 and 4.17 predict that when adsorption density (Σ/a^2) is high, the interfacial tension coefficient is low. For the same surface area per chain, longer copolymer chains are predicted to be more efficient. The expressions of Σ/a^2 can be obtained, for both "wet" and "dry" brushes, as a function of the copolymer chemical potential, μ. The ratio was found to depend on the logarithm of the copolymer concentration (Leibler 1988).

From Eq. 4.14, the critical micelle concentration, *CMC*, was derived:

$$\phi_{CMC}^+ = \exp\{\mu_{CMC} - f\chi_{AB}Z_C\} \quad (4.18)$$

where ϕ_{CMC}^+ is the volume fraction of copolymer in B-rich phase and μ_{CMC} is its chemical potential at *CMC*:

$$\mu_{CMC} = (3/2)^{4/3}f^{4/9}\left(1.74f^{-1/3} - 1\right)^{1/3}(\chi_{AB}Z_C)^{1/3} \quad (4.19)$$

As copolymers are added, v_{12} decreases until ϕ^+ reaches the ϕ_{CMC}^+ value, at which the limiting value of the interfacial tension coefficient, v_{CMC}, is obtained.

A question arises whether the copolymer can saturate the interface so that $\Delta v = v_o = (k_B T/a^2)(\chi/6)^{1/2}$, and effectively the interfacial tension vanishes. This saturation may occur when $\mu = \mu_{sat} = (3/4^{2/3})(\chi N)^{1/3}$. For a flat interface, v_{12} should vanish when $f > 0.31$. The theory also predicts that for $f < 0.31$, spherical micelles may appear. In the latter case, the limiting reduction of v_{12} is given by:

$$\Delta v/v_o = -3^{1/2} f^{2/3} \left(1.74 f^{-1/3} - 1\right)^{1/2} \tag{4.20}$$

Typically, for $f = 0.33, 0.2$, and 0.15, $\Delta v/v_o$ is expected to be $1.00, 0.83$, and 0.42 respectively; hence, $\Delta v = v_o$ for $f = 1/3$. Thus, the more asymmetric is the chain, the less it is efficient as an interfacial agent. Since the theory does not differentiate between polymers A and B, evidently the most efficient copolymer composition must be as follows: $1/3 < f_{opt} < 2/3$, or $f_{opt} = 1/2$.

For more symmetric chains $f > 0.31$, $v = 0$ can be reached when:

$$\phi_{sat}^+ = \exp\left\{ \left(3/4^{2/3}\right)(\chi_{AB} Z_C)^{1/3} - f\chi_{AB} Z_C \right\} \tag{4.21}$$

For a flat interface saturated by the copolymer, the copolymer film thickness was calculated as:

$$\Delta l = a Z_C^{2/3} \left(v_o a^2/3 k_B T\right)^{1/3} \tag{4.22}$$

The above expressions are valid for flat interface. For interface with a curvature R, e.g., for droplets having a radius $R \gg \Delta l$, the following expressions were derived (dry film) (Leibler 1988):

$$v(\mu, R) = v(\mu) - [K(\mu)/R\psi(\mu)] + K(\mu)/2R^2 \tag{4.23}$$

$$\Delta l = Z_C a^2/\Sigma \tag{4.24}$$

The droplet size is given by:

$$R = \{K(\mu)/[v(\mu)\psi(\mu)]\}\left[1 - \left(1 - v(\mu)\psi^2(\mu)/K(\mu)\right)^{1/2}\right] \tag{4.25}$$

For copolymer content close to the saturation of a flat interface, the R-value becomes:

$$R = K(\mu)/[v(\mu)\psi(\mu)] = (3/2)\psi(\mu) \tag{4.26}$$

The limiting value is obtained for the saturation value of μ.

In Eqs. 4.23, 4.24, 4.25, and 4.26:

$$
\begin{aligned}
K(\mu) &= 2\Sigma^{-5}[7\beta(f) - 32\varepsilon^2]Z_C^3 \\
\Sigma &= a^2(3/2^{1/2})(Z_C/\mu)^{1/2} \\
\psi(\mu) &= (L/3\varepsilon)[7\beta(f) - 32\varepsilon^2] \\
L &= Z_C a^3/\Sigma \\
\beta(f) &= f^3 + (1-f)^3 \\
\varepsilon &= (1/2) - f
\end{aligned}
\tag{4.27}
$$

Equations 4.23, 4.24, 4.25, and 4.26 are valid at equilibrium, without taking into account the kinetic effects. The latter effects may be important when comparing theoretical predictions with experimental data.

There are other theories of the interface, some of which lead to different dependencies. For example, Noolandi (1984; 1985) considered a binary polymer system compatibilized by addition of a diblock copolymer. For $\chi_{AB}Z_c\phi_p \leq 2$, he derived:

$$
\begin{aligned}
v_{12} &= v_o + \Delta l\phi_C\{\chi_{AB}\phi_P/2 + (1/Z_C)[1 - \exp(\chi_{AB}Z_C\phi_P/2)]\} \\
\therefore \Delta v_{12} &\cong -\exp(\chi_{AB}Z_C\phi_P/2)
\end{aligned}
\tag{4.28}
$$

where a_o is a numerical parameter, while ϕ_c, ϕ_p, and Z_c are, respectively, the volume fraction of the copolymer, the volume fraction of the polymer, and the degree of polymerization of the copolymer.

It is noteworthy that Leibler's (see Eqs. 4.20 and 4.22) and Noolandi's theories (see Eq. 4.28) predict that the product $v_{12}\Delta l$ depends on the binary interaction parameter χ_{12}. Thus, the reciprocity between v_{12} and Δl predicted by Helfand and Tagami for binary systems is not expected to exist in compatibilized binary blends.

Two semiempirical relations between the interfacial tension coefficient and compatibilizer concentration were derived. The first was obtained assuming an analogy between the addition of a block copolymer to a polymer blend and titration of an emulsion with surfactant (Utracki and Shi 1992):

$$
\begin{aligned}
v_{12} &= (\phi v_{CMC} + \phi_{\text{mean}}v_o)/(\phi + \phi_{\text{mean}}) \\
v_{CMC} &\equiv v_{12}(\phi_C = \phi_{CMC}) \\
\phi_{\text{mean}} &\equiv (\phi_{CMC} + \phi_o)/2
\end{aligned}
\tag{4.29}
$$

The other was proposed by Tang and Huang (1994):

$$
v = v_{CMC} + (v_o - v_{CMC})\exp\{-K\phi\}
\tag{4.30}
$$

The latter authors proposed a similar relation for the particle's radius:

$$
R = R_{CMC} + (R_o - R_{CMC})\exp\{-K\phi\}
\tag{4.31}
$$

In Eqs. 4.30 and 4.31, K is treated as an adjustable parameter. Its functional dependence can be deduced from the comparison with Noolandi's Eq. 4.28, since $K \propto \chi_{AB} Z_c$. These dependencies were found useful in describing the experimental data.

Cho et al. (2000) studied the segregation dynamics of block copolymers to the interface of an immiscible polymer blend and compared experimental results to the predictions of various theories for a poly(styrene-b-dimethylsiloxane) [P(S-b-DMS); $M_n = 13,000$] symmetric diblock copolymer system added to a molten blend of the corresponding immiscible homopolymers. They used the pendant drop technique at intermediate times and compared their results to the predictions of diffusion-limited segregation models proposed by Budkowski, Losch, and Klein (BLK) and by Semenov that have been modified to treat interfacial tension data. The apparent block copolymer diffusion coefficients obtained from the two analyses fall in the range of 10^{-5}–10^{-6} cm^2/s, in agreement with the estimated self-diffusion coefficient of the PDMS homopolymer matrix.

More recently, Reynolds et al. (2004) used mean-field theories and scattering to study the thermodynamic organization of a polymer blend by the addition of balanced block copolymers. They used parameters determined from binary experiments to predict the behavior of multicomponent A/B/A-C polymer blends, where A was saturated polybutadiene with 90 % 1,2-addition (sPB90), B was polyisobutylene (PIB), and C was also saturated polybutadiene but with 63 % 1,2-addition (sPB63). The polymers were chosen such that the binary interactions (A/B, A/C, and B/C) were similar to those in oil (A)/water (B)/nonionic surfactant (A-C) systems. The Flory-Huggins interaction parameters and the statistical segment lengths were all determined experimentally by fitting the random phase approximation (RPA) to small-angle neutron scattering (SANS) data from the three binary homopolymer blends. These parameters were successfully used to predict the scattering from concentration fluctuations in a homogeneous A/B/A-C blend using multicomponent RPA. These same binary parameters were also used as the only inputs to self-consistent field theory (SCFT) calculations of ordered multicomponent polymer blends. The SCFT calculations enabled quantitative interpretation of the SANS profiles from microphase-separated A/B/A-C blends. The phase separation temperatures predicted by the theory for the blends were within the experimental error, and the theoretical domain spacings were within 10 % of the experimental values.

Finally, a review of the experimental and theoretical investigations of the interfacial tension in phase-separated homopolymer blends with the effect of copolymers and emulsifying agents was published by Anastasiadis (2011) recently. The effects of temperature and molecular weight on the behavior were emphasized: interfacial tension γ decreases with increasing temperature (for polymer systems exhibiting upper critical solution temperature behavior) with a temperature coefficient of the order of 10^{-2} dyn/(cm.degrees C), whereas it increases with increasing molecular weight. The increase followed a dependence of the type:

$$\gamma = \gamma_{oo} \left(1 - k_{\text{int}}.Mn^{-z} \right)$$

(with z approximatively 1 for high molecular weights), where γ_{oo} is the limiting interfacial tension at infinite molecular weight and M_n the number average molecular weight.

The effects of concentration, molecular weight, composition, and macromolecular architecture of the copolymeric additives were discussed. An issue that could influence the efficient utilization of a copolymeric additive as an emulsifier is the possibility of micelle formation within the homopolymer matrices when the additive is mixed with one of the components. These micelles will compete with the interfacial region for copolymer chains. A second issue related to the possible trapping of copolymer chains at the interface, which could lead to stationary states of partial equilibrium. The in situ formation of copolymers by the interfacial reaction of functionalized homopolymers was also discussed.

Blends with an Arbitrary X-Y Block Copolymer

Vilgis and Noolandi (1988) investigated, by means of statistical thermodynamics, the use of an arbitrary block copolymer *X-Y* in *A/B* blends. The aim was to predict v_{12}, Δl, and the concentration profile across the interphase of the blocks. This was achieved by generalizing the theory of the interfacial properties of immiscible polymer blends in the presence of a block copolymer. The diffusion equations for the density profiles were solved numerically. Despite the use of chemically different blocks, their addition resulted in the reduction of v_{12}, increasing as M_w of the blocks increased. The computations were performed assuming different values of the binary interaction parameters and degree of polymerization. Strong localization effects of the *XY* emulsifier were observed when the interactions between the blocks and the homopolymers were increased. Thus, the competitive interactions of the blocks with different homopolymers were shown to promote strong interfacial activity. As a result, a selective orientation of the *XY* blocks in the *A/B* polymer mixture is expected to be similar to that computed for the *A/A-B/B* system.

A simplified analytical calculation for the case where the interaction parameters obey the assumed relationships led to the following relation for the reduction of the interfacial tension coefficient in the *A/B* blend upon the addition of copolymer *XY*:

$$\Delta v = -(1/Z_C)\exp\{Z_C[(\chi_1/2) + \chi_2]\}$$
$$\chi_1 \equiv \chi_{BY} = \chi_{AX} = \chi_{XY} = \chi_{AB} \qquad (4.32)$$
$$\chi_2 \equiv \chi_{AY} = \chi_{BX} > \chi_1$$

This suggests that it is possible to design a universal compatibilizer operating on the principle of competitive repulsive interactions between the homopolymers and the different blocks of the copolymer.

Critical Compatibilizer Concentration

Matos (1993) showed that the critical concentration of interfacial agents is directly related to the interfacial area of the dispersed phase, thus related to interface saturation. The chemical structure played an important role in the emulsification

ability of copolymers. Many block or graft copolymers were selected such that their segments were identical to those of the homopolymers. Alternatively, the blocks could be chemically different but miscible, each with different homopolymers. However, complete miscibility of all blocks in a single phase should be avoided.

The morphological analysis showed that diblock copolymers of the type polystyrene-b-hydrogenated polybutadiene, P(HB-b-S), have a higher interfacial activity than triblock or graft copolymers. It is possible that owing to the steric restriction at the interface, graft and triblock copolymers form micelles in the homopolymer phases. This adds to the complexity of the system morphology without fulfilling the basic functions of a copolymer. The diblock copolymer more readily interacts with the two homopolymeric phases, forming appropriate entanglements that result in the reduction of the interfacial tension coefficient, and enhanced interphasial adhesion in the solid state. These observations have been confirmed by measuring the mechanical properties. In blends prepared in solution, M_w of the homopolymers should be lower than those of the corresponding blocks. This rule seemed to be less critical for blends prepared in the molten state (Fayt et al. 1986a, b, 1989) – only one copolymer was reported to follow this rule.

The amount of the interfacial agent required to saturate the interface, w_{cr}, is related to its M_w, the total surface area of the interface, and the specific cross-sectional area of the copolymer macromolecule, a. Paul and Newman (1978) proposed the following relation for the critical amount of copolymer necessary to saturate the interface:

$$w_{cr} = 3\phi M_w/(RaN_{Av}) \tag{4.33}$$

where ϕ is the volume fraction of the dispersed phase, R is the radius of the dispersed drop, and N_{Av} is Avogadro's number. The authors also suggested (not derived from molecular parameters) that for a diblock copolymer, $a \geq 5$ nm^2.

Similarly, Matos (1993) developed an expression for the minimum copolymer amount required to cover the surface of spherical particles. The model was based on the division of an outer shell surrounding the particle into pseudo-cubic elements, each containing randomly oriented (random coil configuration) blocks of diblock copolymer:

$$w_{cr} = 9(3\phi/R)(M_A + M_B)/\left[N_{Av}\langle r^2 \rangle\right] = 3\phi M_w/\left[RN_{Av}\langle r^2 \rangle/9\right] \tag{4.34}$$

where M_A and M_B are molecular weights of the A and B blocks, respectively, $M_A + M_B = M_w$, and $< r^2 >$ is the square of the end-to-end distance of the copolymer chain. Since $< r^2 >$ is proportional to M_w, the above relation depends on the A/B ratio rather than on M_w's. Equations 4.33 and 4.34 are identical if $a = < r^2 >/9$. The density of A-blocks around the particle was expressed as:

$$\rho_A = 3^{5/2} M_A/\left[N_{Av}\langle r^2 \rangle^{3/2}\right] \tag{4.35}$$

In the most general case, the periphery of a drop contains A chains of the matrix and the copolymer. Since $< r^2 >$ is proportional to M_w, then the density should be proportional to $M_A^{-1/2}$. Clearly, for long copolymer chains, the segmental density will tend to zero, thus implying higher contribution from the A chains.

For blends containing diblock copolymers, interface enrichment by the copolymers as well as the potential reduction of the interfacial tension was investigated by Muller and Binder recently (Muller and Binder 2000). For weak segregation, the addition of copolymers led to compatibilization. At high incompatibilities, the homopolymer-rich phase could accommodate only a small fraction of the copolymer before the formation of a copolymer lamellar phase. The analysis of interfacial fluctuations yielded an estimate for the bending rigidity of the interface. The latter quantity is important for the formation of a polymeric microemulsion at intermediate segregation.

4.2.4.2 Blends of Two Polymers with "Cosolvent"

Another way of compatibilizing immiscible polymer blends is by the addition of a mutually miscible ingredient, a "cosolvent," usually polymeric in nature. The objective here is not to generate a wholly miscible three-component system but to add just enough mutually miscible polymers. The cosolvent is to induce interactions between the immiscible polymers, thus compatibilizing the blend but preserving its two-phase structure. To help in the judicious selection of appropriate cosolvent for a given immiscible blend, a partial list of miscible systems is given in Table 4.1.

In polymer blends, the thermodynamic miscibility depends primarily on specific interactions. For the entropic reasons, high molecular weight homopolymers are expected to be immiscible when the specific interactions are absent. Many types of interactions may exist between two polymers. These include London dispersion forces between nonpolar molecules, Coulombic ion/ion and ion/dipole interactions, dipole/dipole interactions between permanent or induced dipoles, charge-transfer forces, hydrogen bonding, etc. Polymer/polymer miscibility has been generally identified as mainly caused by hydrogen bonding (e.g., PPE/PS, PVME/PS, PVC/PCL, Phenoxy/PCL, PEG/PAA) and, for specific cases, by ionic and dipolar interactions.

Some polymers have been found miscible with many other resins, or in other words, there are many immiscible blends whose components are miscible with the same polymer. The addition of this polymer can be used to partially homogenize the system, i.e., to compatibilize the blend. The added polymer is a cosolvent. Of particular interest are systems in which the presence of a cosolvent makes it possible for the two immiscible components to form three-body interactions. In this case, the blend is indeed compatibilized, with the cosolvent being located in the interphase. For thermodynamic reasons, mostly copolymers belong to this type of cosolvents. In the left-hand side column of Table 4.1, there are polymers that may be used as cosolvents for pairs of resins listed in the other column. Some of the latter resins may show local miscibility (e.g., PS with styrenic copolymers), but the vast majority is immiscible.

Table 4.1 Some examples of miscible polymers

Potential cosolvent	Polymers miscible with the potential cosolvent
PEEK	PEK, PEI, PES, etc.
PEG	Phenoxy, PVC, TPU, EP, PAA, PES, EVAc, PVP, poly(meth)acrylates, etc.
Phenoxy	PES, PMMA, PVME, PVP, TPU, PBT, PET, etc.
PMMA	PC, MSAN, EPA, poly(meth)acrylates, PF, NC, PPG, PVAc, PVC, PVC-VAc, CPVC, PVDF, etc.
PPE	PS, CPS, SMA, P(α-MeS), SBS, SAN, ABS, etc.
PS	PC(TM-BPA), PPE, CHMA, PVME, etc.
PVAc	PVDF, halogenated-PMMA, etc.
PVC	PCL, EVAc, PVAc, PBT, poly(meth)acrylates, etc.
SAN	PCL, PVC, PPE, co-polymethacrylates, etc.
SMA	PCL, PVME, methacrylates, vinyl butyral, etc.
Co-polyacrylic acid	PVP, PAs, PEG, etc.
Epichlorohydrin	SAN, (meth-)acrylates, PVAc
NBR	Chloroprene, NC, PVC, PVCAc, etc.
PAr	Phenoxy, PET, PBT, PARA, PVC, etc.
PARA	PAs, PET, PBT, PAr
PB	EPDM, PI, etc.
PBT, PET	PEST, Phenoxy, PVC, PVDC-VAc, LCP, etc.
PC	Carbonates, adipates, (co-)polyesters, PCL, PMMA, SMA, etc.
PCL	Phenoxy, PC, PVC, PVB, CPE, NC, c-PP, PVDC-VAc, EPI, etc.

Note that according to the discussed strategy, the added polymer is to be *miscible* with the principal polymeric ingredients of the blend. On the other hand, it has been reported in the open and patent literature that the addition of a small amount of a third *immiscible* polymer to a blend of two immiscible ones also improves the degree of dispersion. A "classical" example is a blend of PE with $\leq$ 15 wt% PS – here the addition of $<$ 2 wt% of PMMA reduced the domain size of PS by a factor of ten. In this case, the drop size reduction originates from hindered coalescence. The immiscible polymer preferentially migrates to the interface between the two principal resins, providing protection to the dispersed phase against coalescence. This phenomenon has been commercially explored, e.g., in blends comprising PPE/SEBS drops dispersed in PBT matrix – an addition of immiscible PC improved the degree of dispersion and stabilized the morphology by reducing the risk of coalescence.

In principle, any polymer that is miscible with two others can be used as cosolvent. As the data in Table 4.1 indicate, Phenoxy, PMMA, PPE, PC, and PCL are miscible with several polymers; hence, they are the best candidates for cosolvents of many systems. It is noteworthy that acrylic multipolymers are often used as additives to many blends. Their role is to enhance compatibilization as well as to toughen the blends.

Table 4.2 Examples of *Phenoxy* compatibilized blends

Blend	Comments	References
PA with SEBS	0.5–3.0 wt% Phenoxy significantly improved the tensile and impact strength above the values for PA	Freed 1975
PC/PET/Akryloid™ KM660	10 wt% Phenoxy compatibilized the three-ingredient mixture. The materials showed excellent impact strength, ductility, and solvent resistance	Liu and Giles 1986
PA-6, PA-66, or PA-610, with either PET or PBT	0.5–15 wt% Phenoxy increased elongation, tensile strength, Izod impact strength, and uniformity	Robeson 1988
PSF/ABS	Either Phenoxy, EVAc-GMA, SMA copolymers, or MBS were used as compatibilizers. The blends showed good processability, toughness, plateability, and heat and water resistance	Gaafar 1990a; Orikasa and Sakazume 1990; Golovoy and Cheung 1994
LCP/PEST	Addition of Phenoxy™ was also found to provide good compatibilization	Dashevsky et al. 1993, 1994

Finally, in a very recent study, Pakravan Lonbani et al. (2012) used the rheological technique to investigate the phase separation and miscibility of chitosan/PEO solutions at different compositions in aqueous acetic acid solutions. Lower critical solution temperature (LCST) phase behavior was observed for chitosan/PEO solution blends. Phase separation temperature, miscibility range, and correlation length of the solutions were determined from isochronal dynamic temperature sweep experiments. The effect of the chitosan/PEO ratio on the binodal and spinodal decomposition temperatures was studied. Finding phase separation information on polymer solutions through rheological measurement was very promising. Isothermal steady shear rheological measurements were also carried out on chitosan/PEO solutions over a temperature range in which phase separation occurs. Viscosity increase was observed at low shear rates above the phase separation temperature (but in its vicinity), which confirms the validity of the theoretical approach employed to determine the critical temperatures through dynamic rheological measurements. Finally, the Flory-Huggins interaction parameters were estimated from critical solution temperature and concentration results.

One of the most frequently used cosolvents is the poly(hydroxy ether) of bisphenol-A, *Phenoxy*. Owing to the presence of the phenolic group, the resin forms strong hydrogen bonding with numerous polymers. In 1970, Mitsubishi Chemical discovered that toughness of engineering resin blends could be improved by incorporation of a Phenoxy. This commenced a widespread use of the resin. Phenoxy has been used as a compatibilizer in many blends (see Table 4.2). It is, however, to be noted that adding too much Phenoxy can make the blend miscible, which may reduce the mechanical performance, especially the impact strength. For

example, *Phenoxy* was reported to lead to single-phase blends, viz., PBT/PEST or PC; PCL/PVME, PC, or PEST; etc.

4.2.5 Conclusions and Outlook

In the case of binary A/B blends, Helfand and his coauthors provided the basic relations and the theoretical guidance to the properties of the interface, as well as to their modification by incorporation of a compatibilizer. The theory is based on strong, limiting assumptions (e.g., infinitely long macromolecules); thus, one should not expect a quantitative agreement with experimental data. However, the theoretical predictions offer a powerful guidance for the best compatibilization strategies.

The interfacial thickness, Δl_∞, and the interfacial tension coefficient, v_∞, are both related to the square root of the thermodynamic binary interaction parameter, $\chi_{AB} - \Delta l_\infty$ directly, whereas v_∞ inversely – thus, their product, $\Delta l_\infty \cdot v_\infty$, is to be independent of thermodynamic interactions. The latter conclusion may have limited validity, but the general tendency – the reciprocity between the interfacial tension coefficient and the interphase thickness – is correct. The theory correctly predicted the magnitude of the interphasial thickness, $\Delta l_\infty = 1–4$ nm. Note that the theory is for *A/B* binary systems, thus extending these predictions to compatibilized systems, where $\Delta l_\infty \leq 65$ nm may lead to erroneous expectations. For the latter system, the reciprocity between v_∞ and Δl_∞ is not to be expected.

For the strategies of compatibilization, Helfand's theory provides three important conclusions: (1) the chain ends of both polymers concentrate at the interface, (2) any low molecular weight third component is forced by the thermodynamic forces to the interface, and (3) the interfacial tension coefficient increases with molecular weight up to an asymptotic value.

Noolandi et al. developed a theory for the interfacial region in three-component polymeric systems comprising diblock copolymers. There are two aspects to consider: the phase separation in block copolymers upon the addition of one or two homopolymers and the modification of the *A/B* blend properties upon addition of a block copolymer (either *A-B* or *X-Y* type). The second aspect is more pertinent for the polymer blend technology. In particular, the ternary blends comprising two homopolymers and a copolymer, either *A/B/A-B* or *A/B/X-Y*, are of industrial interest.

The addition of a block copolymer, *A-B*, to an immiscible blend of homopolymers *A* and *B* reduces the interfacial tension coefficient similarly as the addition of a surfactant affects emulsions. Thus, the idea of the critical micelle concentration, *CMC*, and the limiting value of the interfacial tension coefficient, v_{CMC}, can be applied to polymer blends. This suggests possible existence of a thermodynamically controlled stable droplet phase, in which the minor phase homopolymer drops, protected by an interfacial film of copolymer, are dispersed within the major phase polymer. The theory

predicts that *CMC* depends exponentially on the product $\chi_{AB}Z_c$ – the larger are the repulsive interactions and/or the higher is the molecular weight of a copolymer, the lower is the concentration for saturation of the interface. Once the concentration of the added copolymer exceeds *CMC*, the micelles are formed. The interfacial tension coefficient exponentially decreases with $-\phi_c\chi_{AB}Z_c$, toward the limiting value at *CMC*, v_{CMC}.

Vilgis and Noolandi investigated the effects of the addition of a block copolymer *X-Y* to blends of *A* and *B* polymers. Similar dependencies as those derived for *A-B* copolymer were found. The work suggested that it is possible to design universal compatibilizers based on the principle of competitive repulsive interactions between the homopolymer and copolymer blocks.

4.3   Determination of the Interfacial Parameters

4.3.1   Interfacial Tension Coefficient

As seen in Sect. 4.2, several theoretical approaches have been proposed for the description of the interfacial phenomena. The lattice theories by Helfand, Roe, Noolandi, and their collaborators are based on the study of conformation and molecular environment. The derived relations are written in terms of the binary thermodynamic interaction parameter χ_{12} and the lattice constants. The theories do agree that the interfacial tension coefficient is a function of χ_{12}, but the predicted functional dependencies are different: $v_{12} \propto \chi_{12}^n$, with exponent $n = 1/2$ to $3/2$, depending on the assumptions.

These and more recent theories can be considered as guides for the expected dependencies, but they cannot be used directly to calculate either the interfacial tension coefficient or the interphase thickness. Since there is a significant disagreement between the theoretical relationships derived for the interfacial tension coefficient, several attempts were made to calculate its approximate values from other physical quantities. Two methods have been considered, the first using the surface tension coefficients, v_i, as an intermediate physical quantity, and the second the solubility parameters.

4.3.1.1 Calculations of the Interfacial Tension Coefficient
From Surface Tension Coefficients
Among the different approaches used to calculate the surface tension coefficient, v_i, the most useful seems to be the parachor method (Sugden 1924; Van Krevelen 1976; Wu 1982). This parameter was defined as (Sugden 1924):

$$P_i \equiv M_i v_i^{1/4}/\Delta\rho_i \tag{4.36}$$

where M_i is the molecular weight of a liquid i and $\Delta\rho_i$ is its liquid-minus-vapor density difference. The value of P_i can be calculated for any chemical compound
Fig. 4.5 Comparison between calculated and measured values of the interfacial tension coefficient from Girifalco and Good Eq. 4.37 and from the harmonic mean Eq. 4.38, incorporating the dispersive and polar contributions

from the contributions of structural elements. Once the surface tensions are known, the second step for calculating the interfacial tension coefficient, v_{12}, requires a relationship between v_i and v_{12}. Two dependencies have been proposed, first one by Girifalco and Good (1957):

$$v_{12} = v_1 + v_2 - 2\varphi(v_1 v_2)^{1/2} \tag{4.37}$$

(here φ is a semiempirical interaction parameter) and the second by Wu (1982). The latter one is based on the concept of fractional polarity that assumes the molecular forces originate from the polar and dispersive interactions:

$$
\begin{aligned}
v_{12} &= v_1 + v_2 - 4v_{1d}v_{2d}/(v_{1d} + v_{2d}) - 4v_{1p}v_{2p}/(v_{1p} + v_{2p}) \\
&= (v_{1d} - v_{2d})^2/(v_{1d} + v_{2d}) + (v_{1p} - v_{2p})^2/(v_{1p} + v_{2p})
\end{aligned}
\tag{4.38}
$$

The subscripts d and p refer to dispersive and polar components of the surface tension coefficients. Equation 4.38 is called the harmonic-mean equation. The idea can also be written in the form of a geometric mean equation:

$$v_{12} = v_1 + v_2 - 2\left(v_1^d v_2^d\right)^{1/2} - 2\left(v_1^p v_2^p\right)^{1/2} \tag{4.39}$$

In Fig. 4.5, the interfacial tension coefficients calculated from Eqs. 4.37 and 4.38 are compared with the experimental values. For the selected pairs of polymers, the latter seems to provide a better correlation with the measured values of v_{12}.

From the Solubility Parameters

The cohesive properties of a material are related to the solubility parameter, δ_i, that originates from different types of interactions: dispersive or atomic, molecular of the type polar and hydrogen bonding, induced dipoles, metallic, etc. The first three types are the most important; thus, respectively:

$$\delta_i^2 = \delta_{id}^2 + \delta_{ip}^2 + \delta_{ih}^2 \tag{4.40}$$

The values of the δ_i-components can be calculated for any chemical substance from the tabulated group and bond contributions. Once δ_i is known for both polymers in the blend, the Huggins-Flory binary thermodynamic interaction parameter, χ_{12}, can be calculated from:

$$\chi_{12} = (V/RT)[\delta_1 - \delta_2]^2 \tag{4.41}$$

From Eq. 4.41 and predictions of the lattice theories, the interfacial tension coefficient can be written as (Luciani et al. 1996):

$$v_{12} = kRT\chi_{12}^n = k_1(\rho RT)^{n-1}\left\{\left(\delta_{1,d} - \delta_{2,d}\right)^2 + \left(\delta_{1,p} - \delta_{2,p}\right)^2 + \left(\delta_{1,h} - \delta_{2,h}\right)^2\right\}^n$$

$$\therefore v_{12} = k_1(T)\left\{\left(\delta_{1,d} - \delta_{2,d}\right)^2 + \left(\delta_{1,p} - \delta_{2,p}\right)^2 + \left(\delta_{1,h} - \delta_{2,h}\right)^2\right\}^n \tag{4.42}$$

To evaluate the validity of Eq. 4.42, the experimental data of v_{12} for 46 polymer blends are plotted in Fig. 4.6 as a function of the computed values of the bracketed sum (Brandrup and Immergut 1989). The straight line represents the least squares fit. It is noteworthy that the exponent $n = 0.402$ is close to 1/2, predicted by Helfand et al.; lower than 3/4, predicted by Roe et al.; and significantly lower than the value of 3/2 derived by Joanny and Leibler.

4.3.1.2 Determination of the Interfacial Tension Coefficient

For low-viscosity Newtonian fluids, several methods for the measurements of v_{12} have been developed (Wu 1974). However, the high viscosity of industrial polymer melts makes most of them irrelevant. The few remaining ones that can be used for the determination of v_{12} in polymer blends can be divided into equilibrium and dynamic methods (Luciani et al. 1997).

Equilibrium Methods

Pendant Drop Method

The pendant drop method, schematically shown in Fig. 4.7, was used in many studies of polymeric blends, usually with low molecular weight fractions of given polymer pairs (Wu 1974). The technique is based on the analysis of the drop shape of component-1 emerging from the extremity of a capillary, immersed in component-2 (Anastasiadis et al. 1987, 1988, 1989b; Owens et al. 1989a, b).
Fig. 4.6 Interfacial tension coefficient at 150 °C for 46 polymer blends plotted versus the solubility parameter contributions (see Eq. 4.42)

The interfacial tension coefficient can be calculated from the drop shape using the relation:

$$v_{12} = g\Delta\rho d_e/H(S) \tag{4.43}$$

where g is the gravitational constant, $\Delta\rho$ is the density difference between the two molten polymers, and $H(S)$ is a function of the form factor S, defined as:

$$S \equiv d_s/d_e \tag{4.44}$$

where d_s and d_e are defined in Fig. 4.7. The values of $H(S)$ are tabulated (Adamson 1982). The application of this method requires the knowledge of the polymer melts' density at the processing temperature.

Sessile Drop Method
The sessile drop method is similar to the pendant drop one (Sakai 1965). The same scheme is used, but in this case, the droplet is resting on a plane surface immersed in the second component (see Fig. 4.8) – v_{12} is calculated from the analysis of the drop shape at equilibrium (characterized by the relative magnitude of the shape parameters, X and Z, defined in Fig. 4.8), knowing the densities of the polymeric fluids at the temperature of measurement.

Spinning Drop Method
In the spinning drop method, a droplet of polymer-1 immersed in polymer-2 is submitted to extensional deformation through the use of centrifugal forces

Fig. 4.7 Schematic representation of the interfacial tension measurements by the pendant drop method; d_e is the maximum drop diameter, and d_s is the diameter located at the distance d_e from the drop apex
Fig. 4.8 Schematic representation of the interfacial tension measurements by the sessile drop method; X is the equatorial radius, and Z is the distance from the equator to the drop apex
(Elmendorp and De Vos 1986). The extent of deformation is controlled by the rotational speed imposed on the system contained in a cylindrical tube (see Fig. 4.9). The rotational energy is balanced by the increased interfacial area. The interfacial tension coefficient is calculated from the equilibrium drop deformation. For drops with length to diameter ratio larger than 4, the following dependence was suggested (Vonnegut 1942):

$$v_{12} = \omega^2 d^3 \Delta\rho/32 \tag{4.45}$$

where d is diameter of the spinning drop and ω is the angular velocity of the cylinder. The technical difficulties of constructing an apparatus suitable for handling highly viscous polymer melts make this method too elaborate to be commonly used.

All these equilibrium techniques are rarely applicable for the measurements of the interfacial tension coefficient of common, industrial polymers. A long time is

Fig. 4.9 Schematic representation of the interfacial tension measurements by the spinning drop method; ω is the angular velocity, and d the deformed drop diameter
usually required to reach the equilibrium. Since the rate is determined by the ratio of the interfacial tension coefficient to viscosity, v_{12}/η, the time to reach an equilibrium can take either minutes or days – this may lead to the thermal degradation and uncertain validity of the measured v_{12}. As the degradation products are preferentially adsorbed at the interface, the determined interfacial tension coefficient may not reflect the blend behavior during compounding or forming. The influence of the equilibration time (thus degradation and contamination) on the v_{12} value is expected to be significant (Grace 1982).

The pendant and spinning drop methods were to determine v_{12} for different polymer pairs as well as the effect of temperature and compatibilizer (Garmabi and Kamal 1998). The authors found a linear relationship between the temperature (T) and v_{12} for PE/PA and PP/EVAl (see Fig. 4.2), as well as strong effect of compatibilizers. The pendant drop method and T-effects on v_{12} for different PS/PP blends were also described (Demarquette and Kamal 1994).

Dynamic Methods

In dynamic methods, determination of v_{12} is based on the time evolution of a fluid element shape, from a nonequilibrium to an equilibrium state. The evolution is driven by the interfacial tension, and depending on the initial shape of the element, it can follow different dependencies.

Capillary Breakup Method

The capillary breakup method is based on Tomotika's theory (Tomotika 1935, 1936). The author was the first to investigate the development of Rayleigh's instabilities in cylinders of one fluid imbedded in another (see Figs. 4.10 and 4.11) (Rayleigh 1879). The amplitude variations of the sinusoidal distortions, α, can be described by:

$$\alpha \equiv (b - a)/2d_0 = \alpha_0 \exp\{qt\} \qquad (4.46)$$

with

$$q = v_{12}\Omega(x, \lambda)/\eta_m d_0 \qquad (4.47)$$

where λ is the relative viscosity of the system ($\lambda = \eta_d/\eta_m$) and $\Omega(x, \lambda)$ is a complex function of λ and the observed wavelength, Λ, of the distortion, expressed as $x = \pi d_0/\Lambda$.
Fig. 4.10 Schematic representation of the interfacial tension measurements by the capillary breakup method; d_0 is the initial diameter of the fiber, b and a are the maximum and minimum diameters observed during the breakup process, respectively
Fig. 4.11 Optical micrographs of a PA-6 fiber imbedded in PS matrix at 230 °C. The initial diameter of the fiber was 46 μm. The photographs were taken (from the *top*) after: $t = 0$, 10, 19, 23, 25, and 29 min

The values of $\Omega(x, \lambda)$ can be calculated from Tomotika's equations. The linear dependence of $\ln(\alpha)$ on the fiber disintegration time enables estimation of q and, consequently, v_{12}.

Table 4.3 Interfacial tension coefficient as determined using the capillary breakup method (Luciani et al. 1997)

Matrix	Fiber	T(°C)	v_{12}(mN/m)
PS 103-300	PA-6 Z211	230	6.3
LDPE 1001	PA-6 Z211	230	8.9
PE 300	PA-6 C316	220	11.7
		250	10.9
		280	9.2

LDPE 1001 + 0.5 % Irganox MD 1024	PA-6 Z211	230	14.4

It seems that Chappelear (1964) was the first who applied this technique to measure the interfacial tension coefficient of polymer blends. Further refinements have been published (Elemans 1989; Elemans et al. 1990; Elmendorp 1986). The method is simple, not requiring special equipment, but the zero-shear viscosity of the investigated polymers at the processing temperature must be known. Typical results obtained through this method are shown in Table 4.3.

Deformed Drop Retraction Method (DDRM)

The deformed drop retraction method (DDRM) has been recently proposed. It makes it possible to determine v_{12} from the time evolution of deformed ellipsoidal drops toward its spherical equilibrium form (Luciani et al. 1997). Assuming an ellipsoidal shape for a drop of initial radius R_0 deformed under simple shear, the following relation was found:

$$D = D_o \exp\left\{ -t\left[\frac{40(\lambda + 1)}{(2\lambda + 3)(19\lambda + 16)} \frac{v_{12}(t_c)}{\eta_m R_o} \right] \right\} = D_o \exp\{-t/\tau\} \qquad (4.48)$$

with $D = (L - B)/(L + B)$ (where L and B represent the long and short diameters of the prolate ellipsoid, respectively), λ is the viscosity ratio, η_m is the matrix viscosity, $v_{12}(t_c)$ is the interfacial tension at the polymer-polymer contact time t_c, and D_0 is the initial value of D at $t = 0$. In principle, this relation is valid only for Newtonian systems. However, the method can be used to characterize viscoelastic materials

Fig. 4.12 Interfacial tension
coefficient in LDPE/PS
system as a function of the
contact time at 200 °C.
Vertical bars correspond
to ± 6 % error
provided that (1) the retraction rate is sufficiently slow to ensure that the material
behave as Newtonian and (2) the elastic relaxation of the materials after deforma-
tion is faster than the ellipsoidal droplet retraction, that is, a clear separation of the
two mechanisms is achieved.

DDRM is particularly useful for the binary polymer blends. The dynamic interfa-
cial tension coefficient, v_{12}, is determined from the time evolution of a distorted fluid
drop toward its equilibrium form. Measurements of either low-viscosity model
systems or high-viscosity industrial polymer mixtures led to a good agreement with
values obtained from the widely used breaking-thread method. DDRM enables to
measure v_{12} in polymeric blends of commercial interest – the high-viscosity systems
that frequently are impossible to characterize by other techniques. Furthermore, for
the first time, it is possible to follow the time dependence of v_{12} thus unambiguously
determining its dynamic and equilibrium values. For example, in LDPE/PS blends
v_{12}, presented in Fig. 4.12, decreased with the polymer-polymer contact time, t_c, from
$v_{12} = 6.9$ mN/m at $t_c = 12$ min to $v_{12} = 5.2$ mN/m at $t_c \geq 75$ min – the latter may
represent the true thermodynamic equilibrium value, $v_{12\varepsilon\theta}$. Such a large reduction of
v_{12} may be due to the thermodynamically driven migration of chain ends, low
molecular weight fractions and additives, as well as thermal degradation. The contact
time dependence of v_{12} explained some of the differences reported for the data
obtained using different measurement techniques, viz., pendant drop, capillary
breakup, or ellipsoid retraction techniques (Luciani et al. 1997).

4.3.2 Interphasial Thickness

Much less information is available on the methods for the determination of the
interphasial thickness in polymer blends, Δl, than that of v_{12}. For binary systems,
assuming that these two parameters are interrelated, one may estimate Δl from v_{12},
the latter determined using one of the above-described methods. To determine the
experimental value of Δl in any system, diverse methods have been used, viz.,

electronic microscopy, X-ray scattering, ellipsometry (Yukioka and Inoue 1991; Fayt et al. 1986a, b), light scattering, etc. Results of these measurements are presented in the next section (see Table 4.6).

4.3.2.1 Microscopy

Since the dimensions to be probed are of the order of few nanometers, the most useful microscopic method would be that of the transmission electron microscopy (TEM). Using this technique, Fayt et al. (1986a, b) observed the location of the P(S-b-HB) compatibilizer in PE/PS blends. The authors inserted a short sequence of isoprene between the styrenic and hydrogenated butadiene blocks. After staining the isoprene double bonds with OsO_4, the authors were able to observe the presence of the copolymer at the interface between the matrix and dispersed phase. The thickness of the interphase could then be measured. The experiments also demonstrated the presence of the added compatibilizer as dispersed micelles inside the PE phase. This technique is applicable, however, only when selective staining affects only the compatibilizer.

4.3.2.2 Ellipsometry

The ellipsometric method has been developed by Yukioka and Inoue (1991, 1994). The principles of the technique and the model used for calculating the thickness of the interphase are schematically illustrated in Figs. 4.13 and 4.14, respectively. The retardation (Δ) and reflection ratio ($\tan(\psi)$) can be determined from the ellipsometric readings. The adopted model assumes the existence of four layers: air, thin polymer-1, interphase, and thick polymer-2 (see Fig. 4.14). In the interphase the refractive index is assumed to be an average: $n_3 = (n_1 + n_2)/2$. Thus, one can compute the best value of the interfacial thickness, d_3, to fit the observed values of Δ and $\tan(\psi)$. The following relations were derived for the computation of d_3:

$$\rho = \frac{R_i^p}{R_i^s} = \frac{|R_i^p|\exp(i\Delta_p)}{|R_i^s|\exp(i\Delta_s)} = \frac{|R_i^p|}{|R_i^s|}\exp\left[i(\Delta_p - \Delta_s)\right] = \tan(\psi)\exp(i\Delta)$$

$$\text{where}: \quad R_i^j = \frac{r_i^j + R_{i+1}^j\exp(-iD_{i+1})}{1 + r_i^j R_{i+1}^j\exp(-iD_{i+1})}; \quad D_i = 4\pi n_i d_i \cos(\theta_i)/\lambda;$$

$$\text{and} \quad r_i^p = \frac{n_{i+1}\cos(\theta_i) - n_i\cos(\theta_{i+1})}{n_{i+1}\cos(\theta_i) + n_i\cos(\theta_{i+1})}; \quad r_i^s = \frac{n_i\cos(\theta_i) - n_{i+1}\cos(\theta_{i+1})}{n_i\cos(\theta_i) + n_{i+1}\cos(\theta_{i+1})}$$

$$n_1\sin(\theta_1) = n_2\sin(\theta_2) = n_3\sin(\theta_3) = n_4\sin(\theta_4)$$

$$(4.49)$$

In Eq. 4.49, superscripts p and s designate parallel and perpendicular polarization of light, and λ is the true interfacial thickness. The other quantities in these equations are defined in Fig. 4.14. The interface thickness needs to be corrected using the composition profile. The true interfacial thickness is then determined as $\Delta l = \lambda = d_3/1.7$.

For example, the ellipsometric technique was used to determine the interfacial thickness in SAN/PA blends, compatibilized by the addition of SMA
Fig. 4.13 Experimental setup for the ellipsometric measurements: *1.* is a He-Ne laser, *2.* is a chopper, *3.* is a polarizer, *4.* is a compensator, *5.* is a sample chamber, *6.* is an analyzer, and *7.* is a detector (e.g., a photodiode) (After Yukioka and Inoue)

Fig. 4.14 The four-layer model used for the calculations of the interfacial thickness. n_i designates the refractive index, θ_i the incidence angle, r_i the Fresnel reflection coefficient, R_i the reflection coefficient in the incident plane, and d_i the thickness of the layer
(Yukioka and Inoue 1991, 1994). A thin bilayer film of SMA/SAN was prepared and then mounted on a thick PA substrate. The interfacial thickness varied with the compatibilization time from $\Delta l = 2$ to 30 nm. The method was also used to study the interphasial thickness variation in PCL blends with CTBN or CTBR. Without a reactive modifier (aminopropyltriethoxysilane, APS), the measured thickness was $\Delta l = 3$ nm, upon addition increasing to 6 nm (Okamoto and Inoue 1993).

4.3.2.3 X-Ray Scattering

Small-angle X-ray scattering (SAXS) has been used by many authors to determine the interfacial thickness. An excellent review of this subject can be found in Perrin and Prud'homme (1994). Many methods of calculations can be used. One of these involves an analysis of the deviation from Porod's law, in which the desmearing procedure is avoided. This procedure was applied to blends of PS with PMMA added with a P(S-b-MMA) block copolymer. Upon the addition of a copolymer, the interface thickness changed from $\Delta l = 2$ to 6 nm (Perrin and Prud'homme 1994).

4.3.2.4 Atomic Force Microscopy

Another technique of interest is the atomic force microscopy (AFM). The method can be used to any system where properties of the separated phases significantly differ. For example, the method was used to determine the thickness of the interphase in blends of PA with soft elastomers. In this case the rigidity scanning procedure was the most appropriate. Since the difference in moduli between the dispersed phase and the matrix was large, scanning in this mode gave a rigidity profile across the thickness. The interfacial thickness was found to be about 20 nm (M. Champagne, private communication, 1996).

4.3.2.5 Other Methods

Several other methods, more or less tedious, have been described in the literature. They include welding cleavage experiments (Foster and Wool 1991), neutron reflectivity (Fernandez et al. 1988), etc.

4.3.3 Update on Recent Results on Interfacial Tension and Characteristics

In this section, some of the recent results reported in literature on the measurements of interfacial tension and characteristics are reported.

Sigillo et al. (1997) used several experimental methods for the measurement of interfacial tension of a model polymer blend. Common to all methods presented here are two main points. The first is that a is obtained from experiments where the shape of the interface between the liquids is directly observed by means of optical microscopy techniques. The second point is that the interface geometry is controlled by a balance between the interfacial force and the viscous stresses generated by some flow applied to the system. Measurements have been carried out on a model polymer blend, whose constituents are a polyisobutylene and a polydimethylsiloxane, both transparent and liquid at room temperature. When compared with each other, the values of interfacial tension obtained from the different methods show a good quantitative agreement. Excellent agreement is also found with results for the same system previously published in the literature.

Temperature dependence of interfacial tension of demixed polystyrene/poly (dimethylsiloxane) melts was studied by Nose (1997) using the sessile drop technique. The results were described as a scaled relation of reduced interfacial tension versus reduced segregation strength. The scaled relation was discussed on the basis of the mean-field theory, and a semiempirical expression has been presented for the scaled relation covering a wide temperature range.

The effect of molecular weight on the interfacial excess ($z(B)^*$), tension (γ_{ABC}), and width (w_{ABC}) in polystyrene/poly(d(8)-styrene-co-4-bromostyrene)/poly (styrene-co-4-bromostyrene) ($AB{:}C$) system was studied by Genzer and Composto (1998). Low-energy forward recoil spectrometry (LE-FRES) was used to measure $z(B)^*$ as a function of the B volume fraction in the $B{:}C$ blend. The experimental $z(B)^*$'s were found to be in excellent agreement with those calculated using the

self-consistent field (SCF) model of the $A/B{:}C$ interface. In addition, the SCF model was used to evaluate γ_{ABC} and the widths for the $A/B{:}C$, A/B, and A/C interfaces (i.e., $w(ABC)$, $w(AB)$, and $w(AC)$, respectively). Their results demonstrated that increasing the number of B segments, N_B, greatly increases the magnitude of $z(B)^*$, particularly at low B contents. On the other hand, varying N_A had only a minor effect on $z(B)^*$. Concurrent with the segregation of B, γ_{ABC} and $w(AB)$ rapidly decreased and increased, respectively, as B content initially increases. Upon calculation of the entanglement length, $w(e)$, for each component, $w(AB)$ was found to approach $w(e)$ when B content approximated 0.30. As a result, the mechanical strength of the interface should greatly improve. The optimum amount of B to achieve good compatibilization correlated with the B content at which $z(B)^*$ is a maximum.

Luciani et al. (1998) critically examined the experimental methods used for the measurements of the interfacial coefficient in polymer blends as well as the theoretical models for its evaluation. A new working relation was derived that makes it possible to compute the interfacial tension from the chemical structure of two polymers. The calculations involve the determination of the dispersive, polar, and hydrogen-bonding parts of the solubility parameter from the tabulated group and bond contributions. The computed values for 46 blends were found to follow the experimental ones with a reasonable scatter of $+/-$ 36 %. The authors mentioned also that since many experimental techniques have been developed for low-viscosity Newtonian fluids, most were irrelevant to industrial polymeric systems. For their studies, two were selected: capillary breakup method and a newly developed method based on the retraction rate of deformed drop.

The effect of a compatibilizer on interfacial tension reduction and coalescence suppression was also studied by Lepers and Favis (1999) on an 80 % polystyrene and 20 % ethylene-propylene copolymer compatibilized by diblock copolymers of poly (styrene-hydrogenated butadiene). The diblocks differed in that one contained 53 % styrene (symmetric diblock) and the other 30 % styrene (asymmetric diblock). The interfacial tension was measured using the breaking-thread technique, and the results were compared to both the theoretical predictions of Noolandi and Hong and Leibler. The morphology was tracked using an emulsification curve, comparison of which with the interfacial tension results made it possible to estimate the relative role of interfacial tension and coalescence reduction in particle-size reduction phenomena.

Willemse et al. (1999) studied the influence of interfacial tension on the composition range within which fully co-continuous polymer blend structures can exist for different blends with selected matrix viscosities and viscosity ratios. The critical composition for full co-continuity was found to increase with increasing interfacial tension, narrowing the composition range. The effect of the interfacial tension on the critical composition was found to be composed of two counteracting effects: the stability of the co-continuous morphology and the phase dimensions. The latter effect was smaller than the former.

Guerrica-Echevarria et al. (2000) used the interfacial tension as a parameter to characterize the miscibility level of polymer blends. Fourteen polymer pair interfacial tensions were determined by means of contact angle measurements

of the surface of each polymer component, with at least two liquids, and the relation with the different miscibility levels of the corresponding blends evaluated. Although exceptions were found, the values obtained appeared to be related to the miscibility level of the blend, immiscible blends giving high interfacial tension values that decreased as miscibility increased. The relation was possibly affected by additional parameters and was clearer when the components of the blends compared were similar.

Xing et al. (2000) compared five different techniques for the measurement of interfacial tension in a model polystyrene (PS)/polyamide-6 (PA-6) system at a constant temperature. The techniques include three dynamic methods (the breaking thread, the imbedded fiber retraction, and the retraction of deformed drop), one equilibrium method (the pendant drop), and a rheological method based on linear viscoelastic measurements. The advantages, the limitations, and the difficulties of each technique were discussed and compared.

The effect of copolymer molecular weight, architecture, and composition on the interfacial tension of a binary polymer blend was studied by Retsos et al. (2001, 2004). The system investigated was polystyrene/polyisoprene blends in the presence of polystyrene-block-polyisoprene copolymers using the pendant drop method. The interfacial tension decreased with the addition of small amounts of copolymer and reached a plateau at higher copolymer concentration, in agreement with previous studies. However, the reduction of the interfacial tension was a nonmonotonic function of the copolymer molecular weight at constant copolymer concentration in the plateau region. As the additive molecular weight increases, the interfacial tension reduction went through a maximum. This should be related with the increased tendency of micelle formation for high copolymer molecular weights, which was confirmed by small-angle X-ray scattering. The results were also discussed in relation to theoretical predictions for polymer/polymer/copolymer mixtures.

For the effect of architecture, graft copolymers with constant molecular weight and varying composition are utilized as additives (Retsos et al. (2004)). The interfacial tension decreased with the addition of small amounts of copolymer and reached also a plateau at higher copolymer concentration. The interfacial tension at interfacial saturation depended on copolymer composition exhibiting a minimum and was lower than that using a symmetric diblock with the same molecular weight. Moreover, the interfacial tension at saturation depended on the side of the interface the copolymer was introduced; its addition to the polyisoprene phase was much more efficient than to polystyrene. This was interpreted as due to the asymmetric architecture of the copolymer and pointed to the fact that a local equilibrium could only be attained in such systems: the copolymer reaching the interface from one homopolymer phase probably does not diffuse to the other phase. The fact that this behavior was not a kinetic effect was also verified.

For the interface thickness, there are also a number or recent studies that addressed this issue that was less studied before. Yeung and Shi (1999) performed a dynamic mean-field study on the formation of interfaces in immiscible polymer blends. They studied the interdiffusion dynamics of a polymer interface toward its

equilibrium profile using a dynamic mean-field method, in which the nonequilibrium chemical potentials were evaluated numerically using the full polymer mean-field free energy. Their results demonstrated that the interfacial width grows as $t^{1/4}$ at early times and saturates to the equilibrium thickness at long times, in agreement with previous, more approximate analyses based on Cahn-Hilliard-type theories. Furthermore, it was shown that the dynamic exponent can only be obtained unequivocally via a scaling analysis. The interdiffusion of a polymer interface in the single-phase regime was also studied.

Rharbi and Winnik (2001) and Yang et al. (2003) from the same research group studied the interface thickness of two systems: styrene-methyl methacrylate and isoprene-methyl methacrylate block copolymers using an energy transfer technique. First, films were prepared from mixtures of two PS-PMMA copolymers of identical length and compositions, labeled at their junctions with either a 9-phenanthryl or 2-anthryl group. The fluorescence decays were analyzed in terms of a model that takes account of the Helfand-Tagami distribution profile of polymer segments at the interface. An interface thickness of 4.8 nm was determined after careful corrections. A theoretical value of 4.2 nm was obtained when using Semenov's finite-chain correction to Helfand-Tagami prediction and the Flory-Huggins interaction parameter recovered by Russell for partially deuterated d-PS-PMMA copolymer. When the Callaghan and Paul interaction parameter value was employed for undeuterated PS + PMMA blends, an interfacial thickness of 4.9 nm was obtained.

In a second study, they evaluated the interfacial thickness of two poly(isoprene-b-methyl methacrylate) block copolymers (PI-PMMA) using the same approach. Small-angle X-ray scattering experiments showed that films of the mixed diblock copolymers have a lamellar morphology with a spacing that varies with composition from 24 to 26 nm. Fluorescence decay profiles from these films were analyzed in terms of an energy transfer model that takes into account the distribution of junctions across the interface and calculated an interface thickness of 1.6 +/− 0.1 nm. This value was independent of the acceptor/donor ratio (i.e., the acceptor concentration) in the films.

Farinha et al. (2000) used an energy transfer study to evaluate the interface thickness in blends of poly(butyl methacrylate) (PBMA) and poly(2-ethylhexyl methacrylate) (PEHMA). A model that describes the energy transfer between donors and accepters chemically attached to the two different components of a polymer blend is proposed. The model describes the case of one polymer dispersed as spheres of identical diameter in a continuous matrix of the second polymer. The model takes explicit account of the segment distribution of the two polymers at the interface region. This model was used to characterize the interface between PBMA and PEHMA domains in a binary blend. By using a 14:1 particle ratio of PEHMA to PBMA, films in which the 120 nm PBMA particles were surrounded by the PEHMA matrix were obtained. For the ion-exchanged latex blend, the interface thickness (Δ) in the film freshly prepared at room temperature was $\Delta = 21$ +/− 2 nm and upon annealing broadened to 25 +/− 2 nm. Because of the low degrees of polymerization for the samples, it was difficult to have

confidence in the value of the Flory-Huggins interaction parameter calculated from the experimental value of Δ because the correction for the finite length of the component was larger than the term that depends on the interface width. Keeping in mind the limitations of this calculation, the interaction parameter was estimated to 0.02–0.03.

Finally in two recent studies from the same research group (Meghala and Ranganathaiah 2012; Ramya and Ranganathaiah 2013), the interfaces of ternary and binary polymer blends were characterized. In the first study (Ramya and Ranganathaiah 2013), the interface widths in two immiscible polymer blends (polyvinyl chloride (PVC)/polystyrene (PS) and PVC/ethylene vinyl acetate (EVA)) were determined experimentally using hydrodynamic interaction approach through free volume measurement by positron annihilation lifetime spectroscopy. For comparison, the same study was performed on a miscible blend (styrene-acrylonitrile (SAN)/polymethyl methacrylate (PMMA)). The interfacial width (Δ) was evaluated from the hydrodynamic interaction (a) based on the Kirkwood-Riseman theory and friction coefficient from Stokes equation. Friction at the interface of a binary blend evidences how close the surfaces of the polymer chains come or stay apart, which in turn depends on the type of force/interaction at the interface. In this study, the interface width was defined from a different perspective of Flory-Huggins interaction approach. Measured composition-dependent interface widths in the three blends studied demonstrated the sensitivity of the method. In miscible blend, high friction at the interface resulted in stronger hydrodynamic interaction and hence smaller interface widths, whereas weak or no interaction in immiscible blends produce wider widths.

The second study (Meghala and Ranganathaiah 2012) was dedicated to the evaluation of interfaces in poly(styrene-co-acrylonitrile) (SAN)-based ternary polymer blends using also positron lifetime spectroscopy. The method successfully applied for binary blends (single interface), mentioned above, was theoretically modified for ternary blends and experimentally verified by measuring free volume content in blends and their constituents. They tested the efficacy of this method in two ternary blends: SAN/PVC/PMMA and SAN/EVA/PVC at different compositions. The effective hydrodynamic parameter evaluated using individual values turned out to be handy in predicting the overall miscibility level of a ternary blend.

4.4   Compatibilization by Addition of a Compatibilizer

There are several strategies of compatibilization, e.g., (i) the addition of a small quantity of a third component that either is miscible with both phases (a cosolvent) or is a precisely tailored copolymer whose one part is miscible with one phase and another with another phase (0.5–2 wt%, usually block-type, less frequently graft one); (ii) the addition of a large quantity, ≤ 35 wt%, of a core-shell copolymer(s) that behaves like a multipurpose compatibilizer-*cum*-impact modifier; and (iii) reactive compatibilization, designed to enhance

the domain interactions and generate finer morphology by creating chemical bonds between the two homopolymers during the compounding or forming processes. The latter type of compatibilization is treated in ▶ Chap. 5, "Reactive Compatibilization" in this handbook.

In the following part, aspects related to the morphology of the blends with and without an added compatibilizer (from the nm to the μm scale) will be presented. These include information on the interfacial characteristics (interfacial tension coefficient and thickness of the interphase), morphology, crystallization, and performance of the blends. This information will be presented mainly in a tabulated form, summarizing the main features from the referenced publications.

4.4.1 Interfacial Characteristics

Experimentally, it has been shown that diblock copolymers, especially of the type polystyrene-b-hydrogenated polybutadiene, P(S-b-HB), have a higher interfacial activity than triblock or graft copolymers. Diblocks more readily interact with the homopolymer phases, forming appropriate entanglements that result in the reduction of v_{12} in the melt and enhanced interphasial adhesion in the solid state. When properly selected and added in optimum quantity, they were also found to stabilize the morphology against the shear degradation during abusive processing. Experimental data are listed in Tables 4.4, 4.5, and 4.6.

The addition of graft copolymers is much less frequent. Some blends of this type were reported to have unusual onion-like morphology. This observation is not universally valid – the compatibilizing effect must depend on the structure and composition of the copolymer. Owing to the complexity of these structures, the theoretical analysis has not been attempted.

Effective compatibilization of binary polymer blends by the addition of a copolymer reduces the dispersed particles' size and v_{12} (Anastasiadis et al. 1987; Wu 1987; Patterson et al. 1971). An illustration is shown on Fig. 4.15. The effect of compatibilizer addition is similar to the emulsification of the classical emulsions. In the former systems, the compatibilizer effect on the drop size and v_{12} follows the same behavior as the emulsion drop size reduction upon the addition of a surfactant. The latter behavior is usually described as the "titration curve" that characterizes the surfactant efficiency. The shape of the titration curve depends on the type of emulsifier and the emulsification process, e.g., mixing time and equipment. However, the amount of emulsifier to saturate the interface also depends on the affinity of the emulsifier to the dispersed phase, the size of the dispersion, the orientation of the emulsifier at the interface, and its ability to prevent flocculation and coalescence (Djakovic et al. 1987). A similar behavior is to be expected for polymer blends upon the addition of a compatibilizer.

Recently, the effect of a reactively formed compatibilizer on v_{12} was studied using the pendant drop method (Garmabi and Kamal 1998). Their results are shown in Fig. 4.16. A small quantity of MAH drastically reduced the interfacial tension coefficient, but the amount of formed graft was not determined.

Table 4.4 General interfacial characteristics of blends

Blend system	Techniques and results	References
PE/PS with P(HB-b-S) or P(HB-b-I-S)	Used TEM and other methods. Copolymer located at the interface	Fayt et al. 1986a, b, 1989; Hobbs et al. 1983
PS/PMMA	Embedded fiber retraction technique at 190 °C. $v_{12} = v_{\infty} - C_1 M_n^z$, $z = 0.73 \pm 0.24$. For M_n exceeding 48 kg/mol, v_{12} was independent of M_n with a mean value of 1.2 mN/m	Ellingson et al. 1994

The efficiency of a block copolymer is limited by the formation of micelles in bulk phases and by the kinetic factors. Consequently, the block copolymer used as a compatibilizer should be designed by taking thermodynamic and kinetic parameters into account to achieve the desired effects. Thus, the structure and transitions in copolymers and homopolymer/copolymer systems are of great interest.

The formation of gradient interfaces between PS- and PB-rich microphases in SBS block copolymers was investigated by means of solid-state NMR and solution NMR as well as TEM, AFM, and SAXS by Thomann et al. (2009). Its molecular architecture, linear and star-shaped asymmetric block structures, and gradient as well as random incorporation of styrene comonomer into the PB-rich blocks were compared. Although all studied SBS possess a very similar total styrene content, different morphologies and mechanical properties were found in the extruded SBS/PS blends, whose origin could be related to the formation of a compositional interface gradient. Employing the sensitivity of solid-state NMR for hard (glassy) and soft (rubbery) phases as well as their respective chemical compositions, it was found that upon raising the temperature up to the PS glass transition, different amounts of polystyrene from the hard PS phase "soften" and integrate into the soft PB-rich phase ("PS softening"). The degree of "PS softening" characterizes the interfacial gradients of SBS block copolymers at elevated temperatures up to the melt. The softened PS was found to partially mix into the soft phase and partially remain at the interface, thus forming different gradient interfaces, depending primarily on the amount of styrene randomly incorporated in the PB mobile blocks and much less on a compositional gradient at the block linkages in SBS chains.

In SBS/PS blends, SBS with a substantial "PS softening" effect was found to preferentially form elongated PB lamellar morphologies, which led to improved mechanical ductility. The purpose of the study was to apply different characterization methods and correlate their results in order to gain important compositional and morphological information as well as their effects on the SBS/PS blend mechanical properties. Rapid and robust low-cost pulsed solid-state NMR methods were established as versatile analytical tools for the application in high-output polymer screening (HOPS) and quality control systems, enabling online monitoring of structure–property correlations as well as product quality of SBS-based materials.

Table 4.5 Copolymers and homopolymer with copolymer systems

System	Techniques and results	References
Homopolymer/copolymer	Solubilization of homopolymer by copolymer. The homopolymer A dissolves in microdomains of A-blocks of the A-B copolymer, until a limit of miscibility is reached. Above this limit, excess of homopolymer forms macroscopic domains	Hashimoto et al. 1990; Tanaka et al. 1991
PS with P(S-b-VP) copolymer	PS-block with $M_w = 9.5$ and PVP-block with $M_w = 10.6$ kg/mol. SAXS was used. Blends containing PS with $M_w < 9.5$ were transparent; those with $M_w > 13.7$ kg/mol were opaque. The solubility limit increased when M_w of PS decreased	Skoulios et al. 1971
PS with P(S-b-I) copolymer	SAXS. Polymer dissolved in domains of block of the same nature as long as its M_w is lower than that of the block	Ptaszynski et al. 1975
Copolymer	Used X-ray scattering. Microdomain measured repeat distance: $D \propto M_w^{0.643}$, theoretical $D \propto M_w^{2/3}$	Hashimoto et al. 1980; Matsushita et al. 1990; Ohta and Kawasaki 1986
PS/PMMA and symmetric P(S-b-MMA) copolymer	Used SAXS and TEM. Stabilization of the interface, the formation of micelles, and the micro- and macrophase separation. The same morphology was observed in solution and after solvent evaporation	Lowenhaupt and Hellmann 1990, 1991, 1994
Copolymer	The effect of temperature, M_w, preparation history, etc., on D. The interphasial thickness, ΔI, was found to remain constant	Spontak and Zielinski 1993; Ohta and Kawasaki 1986; Roe et al. 1981; Anastasiadis et al. 1989a, 1990; Bates et al. 1983; Hashimoto et al. 1977; Todo et al. 1977; Todo, Hashimoto and Kawai 1978
PS/SB/S-B	SALS, TEM, and SAXS were used to study PS-solubilization in S-b-B copolymer (50 wt% styrene). The solubility of PS in the S-block was governed by the ratio of the homopolymer M_w to the block's M_w. The lamellar repeat period increased linearly as more PS was added. The butadiene layer thickness remained constant	Jeon and Roe 1994
PPE, with SAN, SMMA, SAA, or SMA	Miscibility of copolymers with PPE when the amount of comonomer is small. The interfacial energy between the blend components was significantly reduced by adding either a PS-b-PMMA or PS-b-PEB-b-PMMA. The copolymers had a profound influence on the morphology, phase adhesion, and mechanical properties of the blend	Gottschalk et al. 1994

Table 4.6 Interfacial thickness in polymer blends

Polymer or blend	Copolymer	Techniques and results	References
Polymer A	P(A-b-B)	The interfacial thickness did not change upon the addition of homopolymer, $\Delta l \cong 2$ nm	Ptaszynski et al. 1975; Bates et al. 1983; Zin and Roe 1984; Hashimoto et al. 1990; Tanaka et al. 1991
PS/PMMA	P(S-b-MMA)	Neutron reflectivity using blends with high copolymer content and an equal amount of homopolymers. The microdomain boundary thickness was found to increase by 25 % from the pure copolymer to a mixture containing 17 % homopolymer; $\Delta l \cong 2$ nm	Russel et al. 1991b
PS	P(S-b-VP)	Studied M_w effects of diblock copolymer segregation at the interface using the segregation isotherms. A normalized interfacial thickness was found as a universal function of that portion of the block copolymer chemical potential due to chain stretching	Dai and Kramer 1994
PS/PVP	Poly(styrene-b-2-vinyl pyridine)	Forward recoil spectrometry, FRES, was used to study the diffusion of copolymer randomly dispersed in the PS layer of a PS/PVP bilayer sample. Free copolymer chains were detected at the interface below ϕ_{CMC}, whereas, above it, copolymer chains were also found at the PS/air surface as well as micellar segregation at the interface was visually confirmed	Shull et al. 1991
PS/PMMA		Determined $\Delta l = 6$ nm by the welding cleavage experiments	Foster and Wool 1991
		For spin-coated samples, $\Delta l = 5$ nm was determined by neutron reflectivity	Fernandez et al. 1988
		Similar experiments as above also gave $\Delta l = 5$ nm	Anastasiadis et al. 1989a
PS/PMMA	P(S-b-MMA)	Increasing thickness of the P(S-b-MMA) layer between PS and PMMA to 23.9 nm caused a gradual increase of Δl from 5 to 8.4 nm	Russel et al. 1991

Table 4.6 (continued)

Polymer or blend	Copolymer	Techniques and results	References
		Micellar segregation at the interface of samples was not observed by the elastic recoil detection method	Jeon and Roe 1994
		SAXS method was used. Upon addition of the copolymer, the interface thickness changed from $\Delta l = 2$ to 6 nm	Perrin and Prud'homme 1994
PCL with CTBN or CTBR	APS	Ellipsometric methods. $\Delta l = 3$ nm without APS and 6 nm with APS (a reactively generated copolymer)	Okamoto and Inoue 1993
PE/PP	EPR	The interfacial thickness was $\Delta l = 1.5$–2.8 nm without copolymer. The blend was compatibilized by adding EPR	Teh et al. 1994
PE/PS	P(HB-b-S) or P(HB-b-I-S)	Copolymer migrated to the interface. Observed a continuous layer around each dispersed particle, either of PE in PS or PS in PE. $\Delta l = 10$–12 nm was determined. 2 wt% of P(HB-b-S) was sufficient to reduce the v_{12}, the particles size, as well as prevent coalescence. At 5 wt%, the copolymer effect was stable	Fayt et al. 1986a, b, 1989; Hobbs et al. 1983

Fig. 4.15 Interfacial tension coefficient as a function of diblock copolymer in the minor phase. System: matrix, polybutadiene; dispersed phase (pendant drop technique), polystyrene with styrene-b-butadiene diblock copolymer (Data: Anastasiadis et al. 1988). *Dotted* and *solid lines* were computed from Eqs. 4.29 and 4.30, respectively
Fig. 4.16 Interfacial tension as a function of added maleic anhydride for PE/PA-6 blend

4.4.2 Thickness of the Interphase

In contrast to measurements of the interfacial tension coefficient, only few measurements of the interphase thickness have been reported (Wlochowicz and Janicki 1989; Janicki et al. 1986). For example, domain boundary thickness were measured in PS/PMMA blends (Foster and Wool 1991; Fernandez et al. 1988; Russel et al. 1991a; Perrin and Prud'homme 1994). Generally, values in the range of 2–6 nm were reported for the interface thickness.

4.4.3 Morphology

As shown in Tables 4.7 and 4.8, several methods have been used to characterize the morphology of polymer blends containing a block copolymer. In the pioneering works, transparency of films cast from solutions was used as a measure of the emulsifying agent efficiency (Riess et al. 1967; Banderet et al. 1967). Other studies have focused on the observation of phase size reduction in the scanning or transmission electron microscopy, SEM and TEM, respectively (Ouhadi et al. 1986; Fayt and Jerome 1990; Heuschen et al. 1990; Jo et al. 1991; Sakellariou et al. 1991). For block copolymers, the spherical, cylindrical, lamellar, and many other morphologies (including newly discovered ordered bicontinuous and grain boundary structures) have been reported for the copolymers' microphase-separated state and for their blends with homopolymers. New structures were characterized by hyperbolic interfaces (Hasegawa et al. 1993).

Table 4.7 Morphology in copolymer and homopolymer/copolymer blends

System	Techniques and results	References
P(S-b-I) blends with PS	Lamellar-catenoid or double-diamond morphologies as well as microstructural disorder have been reported	Spontak et al. 1993
PS with P(S-b-B), (K-resin)	Mesh-and-strut morphology consisting mostly of hyperbolic interfaces, found between the lamellar and spherical phases, was observed	Hashimoto et al. 1992
P(S-b-B-b-MMA) triblock copolymers and their hydrogenated analogs	At 17 % B-block, a "cylinder at the wall" morphology was observed – here PB and PHB cylinders were located at the lamellar PS/PMMA interface. At 6 % B-block, PB formed spheres at this interface. Hydrogenation of PB induced significant changes	Stadler et al. 1995
P(S-b-BMA) and blends with PPE	From dilute 2-propanol solutions, 42 wt% copolymer formed micelles with PS in the core. From THF solutions, ordered cylindrical structures were obtained. The addition of 10 wt% PPE turned the cylinders into spheres with PPE cores insulated by swollen PS blocks from a PBMA matrix. In PPE/P(S-b-BMA) 50/50 blends, multilayer vesicles and lamellar structures coexisted. In blends having less than 5 % of P(S-b-BMA), micelles with PBMA cores were observed in PPE matrix	Siqueira and Nunes 1994
PMMA or PS with P(S-b-MMA)	The microphase separation was observed only when low M_w homopolymers were used. Blends of a polymer C having strong specific interactions with A did not show any M_w limit for the microphase segregation	Lowenhaupt et al. 1994
PE with SB, SBS, SI, or SIS copolymers	In low-viscosity PE matrix, SB, SBS, and statistical SB copolymers formed spheres or ellipsoids. Broken filaments have been observed for SBS at 240 °C and for SIS at 270 °C. When PE was blended with high molecular weight of either SB or SIS, at 240 and 220 °C, respectively, co-continuous, elongated structures were observed	Getlichermann and David 1994

4.4.4   Crystallization

Another important aspect of compatibilization is the effect on blends' micromorphology, i.e., on the total crystallinity and the crystalline morphology (Utracki 1989; Xavier 1991; Nadkarni and Jog 1991).

Crystallization may take place only within the temperature region limited on the upper side by the melting point, T_m, and on the lower side by the glass transition temperature, T_g. The crystallization behavior very much depends on the state of

Table 4.8 Blends of two homopolymers with or without a copolymer

Blend	Additive	Techniques and results	References
PE/PP	EPR	Processing conditions, melt viscosity and elasticity ratios, M_w, and MWD affect the melt and solid morphology and hence the performance	Teh et al. 1994
PAr/PVDF	PAr-b-PMMA	PVDF/PMMA is a miscible blend. The addition of PAr to the PAr/PVDF/PAr-b-PMMA resulted in the reduction of PVDF T_m and an increase of PAr T_g. These effects were enhanced by the addition of PAr-b-PMMA. Finer dispersion was obtained for higher block copolymer content. Contact angle measurements showed that v_{12} was greatly influenced by the presence of block copolymer	Ahn et al. 1994
PP/PC	SEBS –*Kraton G*	Distinct changes of morphology were observed for 10–20 wt% PC, when the PP/SEBS ratio varied from 95/5 to 90/10. SEM studies showed composite PC droplets with SEBS envelopes, embedded in PP matrix. This suggests stronger interfacial interactions between SEBS and PP than between PC and PP	Srinivasan and Gupta 1994
PPE/PE ionomer	P(S-b-VP)	Melt mixing at 290 °C. The addition of a small amount of PS-b-PVP was found to reduce the domain size	Jo et al. 1994a
PBT/ PMMA	Phenoxy	When a small amount of polyhydroxy ether of bisphenol-A (*Phenoxy*) was added to the PBT/PMMA blends, the morphology changed into more regular and finer. For > 50 wt% *Phenoxy,* the blend converted to single phase	Jo et al. 1994b
PS/PP	PSiS	Excellent dispersions in PS with up to 5 % of polydimethylsilylene-co-phenylmethylsilylene (PSiS) were obtained. In PP at > 1 wt% PSiS, segregation was observed. The blending of PSiS with PS decreased surface resistance, increased hardness, and provided protection from degradation by sunlight	Asuke et al. 1994
PS/PVC	Graft copolymer	A block-graft copolymer was prepared by grafting a diblock copolymer of styrene and butadiene, with cyclohexyl methacrylate monomers. PS/PVC blends comprising a small amount of the block-graft copolymer showed excellent behavior. The copolymer had strong effect on the blends' morphology	Braun et al. 1994

miscibility, as well as on the nature of other blend's components. In miscible blends T_g is a monotonic function of the components' T_g's. When the second component is amorphous, its presence can either decrease or increase the tendency of the first resin to crystallize. The process depends on the blending effects on T_g and on the chain mobility (the free volume effect). When T_g of the amorphous component is

lower than that of the semicrystalline, the crystallization envelope is increased and the crystallization is facilitated. The effect is similar to the crystallization from a solvent – both the T_g and chain mobility tend to maximize the total crystallinity. Such blending may induce the crystallization of polymers that are known to be amorphous, e.g., PC. In the opposite case, the addition of an amorphous component increases T_g of the blend, reduces the crystallization envelope, and thus hinders crystallization.

When the blends are immiscible in the molten state, the crystallinity is an even more complex function of the ingredients' properties, compatibilization method, processing parameters, and post-processing treatments. The following factors have been identified to play a major role: (i) the molecular constitution and M_w of the components; (ii) composition; (iii) the type of phase morphology and the degree of dispersion; (iv) the interphase, thus interactions between the phases, nature of the interface, migration of nuclei from one phase to the other, etc.; (v) melt history, in particular the time the polymers were exposed to $T > T_m$; (vi) crystallization conditions, T_c, cooling rates, annealing, etc.; and (vii) physical conditions of crystallization, viz., presence of nucleating impurities; discontinuities, e.g., gas bubbles or filler particles; confinement by molten, crystalline, or glassy phase; etc.

As predicted by Helfand and Tagami, the interface is the locus of low molecular weight impurities that have been shown to nucleate crystallization, as, for example, in PS/PP blends (Wening et al. 1990). Compatibilization by the addition of a third component may either reduce or enhance the tendency for crystallization. On the one hand, the addition of a compatibilizer increases the interfacial area, thus increasing the nucleation rate – an increase of T_c by 10 °C was reported (Wei-Berk 1993). However, the compatibilization also may increase thickness of the interphase, Δl, thus hindering the diffusion of the nucleating agent to the crystallizable phase. It has been reported that when the size of domains containing the crystallizable polymer falls below certain limit, the crystallization rate is drastically reduced. In blends having widely different drop diameters, this may lead to fractionated crystallization with large undercooling required for the smallest drops. The presence of undercooling reflects the difference in nucleating activity of the heterogeneity existing in the dispersed phase. When the drop size is reduced beyond a certain limit, it may no longer have a nucleus for the heterogeneous crystallization – it may crystallize by the homogenous mechanism at much lower T_c (Frensch et al. 1989). Table 4.9 presents data on selected semicrystalline blends. More details on crystallization can be found in ▶ Chap. 3, "Crystallization, Micro- and Nano-structure, and Melting Behavior of Polymer Blends."

4.4.5 Mechanical Performance

Since blends are mainly used as structural materials, the most important properties are mechanical, especially the impact strength, stiffness, and elongation. Historically, blending was developed to improve these properties in the early

Table 4.9 Crystallization with and without compatibilizer

Blend	Additive	Technique and results	References
PA-6/EPR	EPR-g-SA	Compatibilizer had strong nucleating capability, reducing the spherulite size and increasing adhesion between the phases	Martuscelli 1984
PP/PA-6	Maleated PP (PP-MA)	Thermal analysis and optical microscopy. One or two crystallization peaks were affected by PP-MA. T_c of PA-6 initially decreased then leveled off with PP-MA content, whereas that of PP was not affected. Blends with PP-MA showed concurrent crystallization at the T_c of PP	Moon et al. 1994
PP/PS	P(P-b-S)	T_c increased from 116 °C to 126 °C upon the addition of PP-b-PS. Its presence lowered v_{12}, reduced PS drop diameter, and thus produced higher surface for nucleation of the α-PP crystals	Wei-Berk 1993
PP/PS	SBS	The drop size of PP did not change, but T_c increased, owing to the immiscibility of PP with polybutadiene block. SBS is a poor compatibilizer but capable to transfer nucleating heterogeneity to PP	Santana and Müller 1994
PP/HIPS	SB	WAXS and SAXS methods. The addition of an SB slightly reduced crystallinity of α-PP	Hlavata and Horak 1994
PET/PPE	P(ET-b-S)	The addition of a compatibilizer reduced the PS drop size (from $d = 5$ to 0.2 μm) as well as increased the total crystallinity	Quirk et al. 1995

resins, viz., PS, PVC, PMMA, PET, PA, etc. When blending started to involve mixtures of polymers, the impact modification has progressively changed into compatibilization. However, even today, many blends profit from the simultaneous compatibilization and impact modification by the addition of multicomponent modifiers. Many patents and papers in the open literature address this question, some of which will be presented in this section and the following one on patented blends. More information on various aspects of the mechanical performance can be found in ▶ Chap. 11, "Mechanical Properties of Polymer Blends" and ▶ Chap. 10, "Properties and Performance of Polymer Blends" in this handbook.

Two types of mechanical tests have been used: the low rate of deformation (tensile, compressive, or bending tests) and the high-speed impact tests. The immiscibility of polymers is reflected in both. For example, in tensile tests, the maximum strain at break (or the maximum elongation) and the yield stress (or the maximum strength) can be dramatically decreased by poor adhesion between the phases in the solid state. Similarly, this lack of adhesion is responsible for low values of impact strength – the specimens are brittle.

Polymeric systems can be classified as either brittle or pseudo-ductile. The first type tends to fail by the crazing mechanism and has low crack

Fig. 4.17 Izod impact strength at room temperature as a function of diameter of elastomeric particles in methyl methacrylate-butadiene-styrene copolymer used for toughening polyvinyl chloride resin
initiation as well as propagation energy – typical examples: PS, PMMA, and SAN. The second type tends to fail by yielding and has high crack initiation energy and low crack propagation energy – typical examples: PA, PEST, and PC. As usual, there are some polymers, e.g., POM and PVC, which show an intermediate behavior. The transition from brittle to ductile behavior depends on the intrinsic performance characteristics of the material as well as on external variables, such as the test temperature, rate of testing, geometry, loading mode, etc.

It is a common practice to toughen brittle resins by the addition of elastomeric particles. The effectiveness of the process depends on their diameter and concentration. It has been found that at constant concentration of the toughening agent, its effectiveness, i.e., the plot of toughness versus particle diameter, follows a bell-shaped curve, defining the optimum particle diameter. As shown in Fig. 4.17, the optimum does not change with concentration.

The optimum particle size, d_{opt}, was found to depend on the entanglement density of the matrix resin (see Fig. 4.18). However, the dependence can be used only as a general guide. Both the fracturing and toughening mechanisms change from one resin to the next. The determination of the d_{opt} also is ambiguous owing to the polydispersity of sizes as well as to the presence of other macromolecular chains. For example, it has been accepted that to toughen PS into HIPS, the optimum diameter is defined as a diameter of the elastomeric particles expanded by the occlusion of the PS matrix. In PVC the diameter of the elastomer was defined as the diameter of the original butadiene latex, before grafting it with styrene and methyl methacrylate. In PC the "optimum" diameter was defined rather from the point of view of availability of the core-shell toughening agent than the true optimum performance – it is becoming increasingly difficult to find tougheners with elastomeric particles having diameter $d < 100$ nm. Furthermore, the strategy of the preparation of polymer
blends with stable morphology demands that blends have a thick interphase, $\Delta l \leq 60$ nm. Frequently it is impossible to decide how far the toughening by rubber core extends to the interphase. Many impact-resistant engineering resin blends have been formulated using the core-shell multicomponent with rigid core and elastomeric shell whose thickness and affinity to the matrix resin can be adjusted.

By contrast with brittle resins where d_{opt} is independent of concentration, in pseudo-ductile, one of these two variables is related – when the concentration of the toughening agent decreases, the elastomeric particle size must be reduced. In other words, in the latter systems, it is the distance between the elastomeric particles that seems to control the fracture mechanism. Again, there are resins showing intermediate behavior between these two limits.

The above discussion focused on the addition of discrete elastomeric particles. However, there have been reports that the formation of co-continuous structures of brittle or pseudo-ductile resin and an elastomeric one can produce a quantum jump in toughness, without greatly affecting the key engineering properties of the high-performance resin. Commercial blends of this type, e.g., comprising POM, PA, PC, or PEST, are available. When the blends are formulated with relatively large content of two resins, it may be necessary to toughen both phases. This is often done using sequential reactive blending. Examples of mechanical properties of blends toughened by the addition of block copolymers are given in Table 4.10. More information on this topic is presented in the section on patented blends.

4.4.6   Solvent and Chemical Resistance

In many applications the chemical and solvent resistance is of paramount importance. To improve these properties, blending with a resin having the required performance characteristics is used. By nature, the modifying resins must have

Table 4.10 Examples of compatibilized and impact modified polymer blends

Blend	Additive	Comments	References
PE/PA-6	SEBS-MA, ≤ 10 wt%	Reactive blending, reduced v_{12}, increased adhesion	Armat and Moet 1993
PS/PP = 1:1	5 wt% of low MW SEBS	Threefold increase of the impact strength	Appleby et al. 1994
PPE/PE ionomer	PS-b-PVP	In PPE matrix blends, tensile strength and elongation increased	Jo et al. 1994
PS/PVC/CPE	#1. SEB-GMA #2. (SEB-GMA)3 #3. random S-r-EB-GMA	Compatibilization depends on GMA content and degree of chlorination of the CP; best #1, worst #3	Koklas and Kalfoglou 1994
PP + 0–30 wt% PC	SEBS (5, 10, and 20 wt%)	Improved impact, reduced tensile, and flexural moduli	Srinivasan and Gupta 1994
HIPS/PBT	PS-GMA	Reactive processing to form PBT-b-PS	Chang et al. 1994

very much different chemical compositions, which leads to antagonistic immiscibility and a need for compatibilization. The examples listed in Table 4.11 illustrate some commercial solutions.

4.4.7 Electrostatic Dissipating Blends

Polymer blends have been often used as electrical insulating materials. Polymers do not readily conduct electrical current, are inexpensive in comparison to other known insulating materials, and are sufficiently durable and heat resistant. However, in some applications, owing to the accumulation of surface charge that may discharge rapidly and cause damage to electronic components and cause fires or explosions, they may pose problems. A need has existed for electrostatic dissipating polymeric compositions, ESD.

The ESD compositions must have sufficient resistivity to cause slow dissipation of a static charge, but not too low as to allow the charge to move too quickly through the material, thereby causing an arc or spark. The surface resistivity $105 \leq R \leq 1,012 \ \Omega$ cm is considered desirable. Attempts have been made to coat an electrostatic dissipative material onto plastic, add graphite, or metal particles, but coating can easily be wiped out and the additives are expensive, make processing difficult, and often lower the mechanical performance of the plastic part. Incorporation of organic semiconducting materials, or other low molecular weight antistatic agents, also is disadvantageous. These additives must migrate to the surface and pose similar problems as coatings.

For ESD the surface resistivity should be $105 \leq R \leq 1,012 \ \Omega$ cm. The best strategy for development of such materials is by the incorporation of organic semiconducting polymers. Selected examples are listed in Table 4.12.

Table 4.11 Blends with enhanced chemical and solvent resistance

Blend	Additive	Comments	References
HIPS/HDPE	SBS or SIS	High impact strength and resistance to solvents	Swartzmiller et al. 1993
PA/ABS	SAN-MA	Excellent solvent resistance and toughness	Lavengood et al. 1988

PEST/ABS	AES-GMA, ABS-MA, or ABS-GMA	Outstanding heat, chemical, and impact resistance	Yasue et al. 1989; Hirai et al. 1988
PET/PO	PO-GMA or EEA-GMA	High heat and moisture absorption resistance	Mukohyama 1993; Natarajan et al. 1993

4.5   Patented Blends with Added Compatibilizer

Patented or commercial polymer blends are in most cases multiphase, compatibilized systems. In the old but still popular blends of polyvinyl chloride or polycarbonate with acrylonitrile-butadiene-styrene copolymer, PVC/ABS or PC/ABS, the styrene-acrylonitrile copolymer, SAN, ascertains adequate compatibilization in the systems. Note that ABS went through a series of process and composition modifications to enhance performance in blends.

In this brief description of selected patented and/or commercial blends, first the commodity then the engineering and specialty materials will be presented in a tabulated form (Utracki 1997). Further information on the topic can be found in ▶ Chap. 9, "Compounding Polymer Blends" in this handbook.

More than 550 patents were identified from 1976 to 2013 with the research term polymer blends in the abstract. The approximate number of patents found between 1995 and May 2013 were as follows:

2006–2013: 100 patents
2003–2013: 150 patents
2000–2013: 200 patents
1995–2013: 300 patents

Interested reader can consult the web site of the US patent office for the details on these patents.

Table 6.12 Examples of ESD blends

Blend	Additive	Comments	References
ABS/PMMA	5–25 wt% EO-CHR epihalohydrin copolymer	ESD, reduced delamination, and improved ductility	Gaggar et al. 1988
PS/PCL	2–50 wt% EO-ECH	Excellent ESD and elongation	Giles and Vilasagar 1994

4.5.1 Commodity Resin Blends

4.5.1.1 Polyolefin Blends
The information about polyolefin, styrenic, vinyl, and acrylic blends is presented in tabulated form in Tables 4.13, 4.14, and 4.15 below.

4.5.1.2 Styrenic Blends
See Table 4.14.

4.5.1.3 Vinyl and Acrylic Blends
See Table 4.15.

4.5.2 Engineering and Specialty Resin Blends

The information about engineering and specialty blends are presented in tabulated form in Table 4.16 below.

4.6 Conclusions and Outlook

To select proper compatibilizer, it is imperative to know whether the copolymer is capable to (i) engender a fine dispersion during blending, (ii) preferentially migrate to the homopolymers' interface, (iii) stabilize the morphology against segregation, and (iv) enhance the adhesion between the phases. It is only when all these conditions are satisfied that the idea of interfacial activity of classical emulsifiers can be applied to copolymers added to immiscible blends.

The effective compatibilization of binary polymer blends by the addition of a copolymer should reduce the interfacial tension coefficient. Often, it also alters the molecular structure of the interface (as measured by the scattering methods). The process is similar to the emulsification in the classical emulsions. The emulsifier effect on the droplet size follows generally the same behavior as the interfacial tension. This behavior is described by the emulsification curves (evolution of the particle's size with the emulsifier content) and characterizes the additives' efficiency. The shape of the emulsifying curve depends greatly on the type of emulsifier and the emulsification process. If the selected compatibilizer is miscible only with one component of the blend, its efficiency

Table 4.13 Typical polyolefin polymer blends and their characteristics

Blend	Additive	Comments	References
PP and/or LLDPE	EPR	Enhanced mechanical performance	Yamazaki and Fujimaki 1970, 1972
PCO/PE	Block copolymers with ethylene or propylene and norbornene blocks	Low melt viscosity, thus good processability, high elongation at break, impact strength, toughness, hardness, and modulus	Epple and Brekner 1994
PE/PPE	Styrenic copolymers (SB, SBS, SEBS)	Had excellent impact strength, good solvent resistance and aging characteristics	Haaf and Lee 1978
PE/PET	Block copolymer: n-butyl terephthalate/ ethyleneglycol and propylene glycol, Hytrel™4074, and a mixture of two aromatic phosphites	Improved impact strength and flame resistance, as well as low permeation to gasoline	Abu-Isa and Graham 1993
PE/POM	EVAc	Abrasion resistant, glossy moldings, high elongation, excellent impact strength, dimensional stability, and high environmental stress cracking	Ishida and Masamoto 1974
PE and PP	EPR	Good flow properties and a very good low-temperature impact strength	Schreck et al. 1994
PP/SBR	PP grafted with styrene	Useful as stand-alone structural materials	DeNicola and Conboy 1994
PE or PP with PS or HIPS	3-block copolymer of styrene and butadiene or isoprene	Good processability, stress cracking resistance, impermeability to water vapor, and improved impact resistance	Hoenl et al. 1993
PP/PC	EVAc	Good mechanical properties and excellent solvent resistance	Giles and Hirt 1986
PP with PET or PBT	Polyolefin-polyester graft copolymer	Excellent impact strength, flexural modulus, HDT, and peel resistance	Fujita et al. 1994
PP/LCP	Maleated PP	Compatibilization improved the performance well above that observed for two-component LCP/PP blends	Baird and Datta 1992

is negligible. The efficiency of a block copolymer is limited by the formation of micelles in bulk phases as well as by the kinetic factors.

The morphology of blends may be complex. The addition of compatibilizer not only affects the size and shape of the separated phases (the macro-morphology), but it may also affect the crystalline form, the size of crystalline entities, as well as the total crystallinity (the micromorphology). In a blend of two semicrystalline polymers, e.g., PE/PP, four phases may coexist:

Table 4.14 Typical blends with styrenic polymers and their characteristics

Blend	Additive	Comments	References
PS or HIPS with polyolefins	SEBS	2–30 wt% PP and 5–20 wt% SEBS. Good impact, flexural strength, and tensile yield retention were reported	Holden and Gouw 1979
PS/PP	$(SB)^n$ block copolymer	Thermoformable blends	Grancio et al. 1981
PS/LLDPE	SEBS	10–90 wt% PS, 10–90 wt% LLDPE, and 5–40 wt% SEBS – the system showed good resistance to impact and yellowing	Seelert et al. 1993
PS/EVAc	SB	Improved elasticity, tensile strength, and reduced die buildup. Further improvement by replacing a part of the EVAc with a low crystallinity PO	Djiauw and Mitchell 1990; Djiauw 1994
45–70 wt% HIPS with 15–40 wt% HDPE	5–25 wt% SBS or SIS	Thermoformable blends with good interfacial properties for refrigerator or freezer liners. They are easy to process into parts with high impact strength and solvent resistance	Swartzmiller et al. 1993

PE-crystalline, PP-crystalline, PE-amorphous, and PP-amorphous. The situation can be more complex if the polymorphism of PP (with four potential crystalline structures) is taken into account. The spherulites' size, lamellar thickness, interlamellar amorphous zones, perfection of the crystallites, total crystallinity, and a possibility of epitaxial crystallization are additional factors that affect the final morphology and performance. Processing conditions, such as the extent of shearing, the cooling rate, and annealing history, all affect the melt and solid morphology. The addition of a compatibilizer multiplies the factors that must be taken into account. More details on the effect of processing and compounding can be found in ▶ Chap. 9, "Compounding Polymer Blends" in this handbook.

Polymer blends must provide a variety of performance parameters. Usually it is a set of performance criteria that determines if the material can be used or not. For specific application more weight can be given to one or another material property. The most important properties of polymer blends are mechanical. Two types of tests have been used: the low rate of deformation (tensile, compressive, or bending) and the high-speed impact. Immiscibility affects primarily the maximum elongation at break and the yield stress.

Polymers are either brittle or pseudo-ductile. The first type tends to fail by the crazing mechanism and has low crack initiation as well as propagation energy, while the second tends to fail by yielding and has high crack initiation energy and low crack propagation energy. The transition from brittle to ductile behavior depends on the intrinsic performance characteristics of the material as well as on external variables, such as test temperature, rate of testing, geometry, loading

Table 4.15 Typical blends of vinyl and acrylic polymers

Blend	Additive	Comments	References
PVDC or PVC with 70–20 wt% CR	10–25 wt% NBR	Transparent blends, thermoplastic, heat sealable, printable, odorless, and tasteless, suitable for a wide range of applications	Signer and Beal 1953
PVC with 5–13 phr of SBR	NBR	The alloys showed improved impact strength at low temperature	Bataafse Petroleum 1960
PVC	MBS	Butadiene methyl methacrylate styrene copolymer, MBS as an impact modifier	Feuer 1958
PVC or PVCAc	Poly(B-co-BA-co-S), or poly(S-co-AN-co-MMA-g-BA-g-MMA)	3–40 wt% P(S-co-BA-co-S). The alloys were transparent, with good weatherability and high impact strength	Ide and Deguchi 1971
			Ide and Miura 1971
			Ide et al. 1972
PVC/SAN	ABS-type G	10 phr of SAN and 10 phr of ABS-type G. Give resins with *low sensitivity to mechanical working*. For vacuum forming the blend performance could be improved by addition of ≤ 20 % PVCAc	Parks and Jennings 1956
5–50 wt% PVC with 1–50 % ABS	Post-chlorinated PVC	The alloys showed improved processability, impact strength, and thermal stability	Kojima et al. 1970
PVC	5–30 wt% MABS	PVC with MABS showed high impact strength	Himei et al. 1967
PVC/ABS	ABS core and grafted with AN-co-Et- acrylate-co-styrene	Excellent mechanical properties, high impact strength, transparency, surface smoothness, and whitening resistance	Tanaka et al. 1971
PVC/ABS	ABS (core) grafted with PMMA	PMMA improved PVC/ABS miscibility. The alloys displayed excellent mechanical properties and impact strength	Michel 1969

mode, etc. To toughen a brittle polymer, elastomeric particles with optimum diameter, d_{opt}, should be used. It has been found that d_{opt} depends on the entanglement density of the matrix resin, $d_{opt} \propto v_e^n$, where the exponent $n = -2$ to -3. For pseudo-ductile polymers, a similar dependence is valid, but since for them the entanglement density is significantly higher, the required size of the elastomeric zones is small, in order of nm. Furthermore, it has been found that not only the size but also the separating distance between the elastomeric zones is important. Thus, for these polymers, the toughening strategy is based on the creation of proper size elastomeric interphase, with rigid core that provides

Table 4.16 Engineering and specialty polymer blends

Blend	Additive	Comments	References
PPE/PEST	SBS	Low viscosity, good impact, fire resistance, and tensile strength	Lee 1978
PC/ACM	Styrene-acrylic acid copolymer, SAA	High impact strength and HDT	Henton 1980, 1982, 1983, 1984, 1986
PC/ABS	SMMA-MA	Co-continuous morphology	Jones and Mendelson 1985
PC/MeABS	AN-co-α-methyl styrene-co-MMA, MeSAN	Good compatibility, toughness, and thermal stability	Kress et al. 1986
PC/PBT/LLDPE	MBA	Impact and solvent resistance	Boutni and Liu 1984, 1986
PPE/PA	Styrene-butadiene radial copolymer (*K-Resin*™) with citric acid or chloro-epoxytriazine or tapered block copolymer	Izod impact strength was improved (in comparison to blends with HIPS) by a factor of three	Gianchandai et al. 1993; Yates 1993
PA/PAr or PA/PEST	PA-co-PAr	Good processability, mechanical properties, UV stability, heat, solvent, and stress-crack resistance	Dean 1990
PA/PC or PA/PAr	EGMA	Impact modification	Yuichi and Suehiro 1989
PA/PVDF	A compatibilizer	Suitable for parts that are impact resistant and impermeable to gases	Hizasumi et al. 1989
PA/PEI	Phenolic compounds, e.g., a nonylphenolic	Have reduced water absorption, had less swelling, and have good dimensional stability	Gallucci 1988; Gallucci and Rock 1992

proper separation. The ultimate in the toughening method for pseudo-ductile polymers is the generation of co-continuous structure having proper size of the phases.

For brittle polymers the impact strength can be improved by engendering proper size heterogeneity in the matrix – rubber particles that may or may not be joined to the matrix or even gas bubbles. Toughening is accomplished by increasing the number of crazes, thus increasing the total energy of fracture. However, this strategy rarely leads to maximum improvement of impact strength, and as a rule, it decreases several other performance parameters. Thus, for good balance of properties, e.g., improved processability, dispersion, impact strength, and other mechanical properties, it is imperative that the impact modifier is well bonded to the polymeric phases, i.e., that it plays the broader role of compatibilizer.

In PO blends, the preferred compatibilizer has been EPR, while in styrenic blends, SBS or SEBS maintains high visibility in spite of the price. Both compatibilizers can also improve the impact strength. However, the excessive

amount of elastomer can lower the modulus and strength of the alloy; thus, the elastomeric particles' size should be optimized.

The PVC blends are usually compatibilized by the addition of an acrylic copolymer, viz., ABS, MABS, MBS, or a core-shell-type copolymer (consisting of ABS core and grafted with acrylonitrile-ethyl acrylate-styrene) was introduced by Japanese Geon in 1966.

Owing to miscibility, PPE has been compatibilized by adding a styrenic copolymer, capable of interacting with the other polymer, e.g., either PS or HIPS, SEBS, or SBS. Since the most interesting second polymer was either PA or PEST, in the early 1980s, the technology moved to reactive blending. The use of PC that preferentially migrated to the interface between the dispersed drops of PPE and SEBS, dispersed in PBT matrix, is an excellent example of the use of the third polymer to prevent coalescence, thus to stabilize the optimized morphology. In several engineering blends, e.g., ABS/PSF, the nearly universal cosolvent, *Phenoxy*, has been used. However, majority of modern commercial blends is prepared by reactive compatibilization.

Strong research and development activity is still ongoing on polymer blends, with a variety of new functional applications such as biomedical, energy, environment, etc.

Nomenclature

Notation

A	Total interface surface area
a, b, c, k, K, n, u	Equation constants
a, b_i	Segment or monomer length or lattice parameter
a_1, a_2	Long and short axis of a deforming particle
CMC	Critical micelles concentration
D	Domain period in copolymer
$\boldsymbol{D}$	Drop deformability parameter
d	Droplet diameter
d_{eq}	Equilibrium droplet diameter
ΔE_S	Elastic energy
f	Fraction of a component in copolymer
f^*	Transition concentration from microphase to macrophase separation
g	Energy density
ΔG_m	Gibbs free energy of mixing
ΔH_m	Heat of mixing
k_B	Boltzmann constant
l	Mean length of statistical skeletal segment
$\Delta l, \Delta l_o$	Interfacial thickness and initial interfacial thickness
Δl_∞	Interfacial thickness for infinite molecular weight
LCST	Lower critical solubility temperature
M_A, M_B, Mv	Molecular weight of monomer-A, monomer-B, and a statistical segment
M_e	Entanglement molecular weight
M_n, M_w, M_z	Number, weight, and z-average molecular weight
N_{Av}	Avogadro's number
N_v	Number of statistical skeletal segments
Q	Number of copolymer chains at the interface
R	Ideal gas constant, droplet radius
$\langle r^2 \rangle$	End-to-end distance of the polymer chains
$\langle R_i^2 \rangle$	Radius of gyration of chain i
S	Interfacial area per unit volume of the blend
t, t^*	Time and dimensionless breakup time
T, T_g, T_m	Temperature, glass transition temperature, and melting point
T_{cr}, T_s	Critical and spinodal temperature
UCST	Upper critical solubility temperature

V	Specific volume
w_{cr}	Minimum amount of copolymer to cover surface of spherical particle
w_i	Weight fraction of i
Z_i	Degree of polymerization of polymer i (or copolymer)
χ, χ_{AB}	Binary thermodynamic interaction parameter
ϕ_1, ϕ_2	Volume fraction of the dispersed and matrix phase, respectively
ϕ_d, ϕ_m	Volume concentration of dispersed phase and the matrix
ϕ_p	Polymer volume fraction
γ	Shear strain
$\dot{\gamma}$	Shear rate
η, η', η^*	Shear viscosity, dynamic viscosity, and complex viscosity
$[\eta]$	Intrinsic viscosity
η_1, η_2	Viscosity of the dispersed and matrix phase, respectively
η_d, η_m	Viscosity of the dispersed and matrix phase, respectively
$\eta_i, \eta_{Si}, \eta_{Ei}$	Interfacial, shear interfacial, and extensional interfacial viscosity
η_o, η_r	Zero-shear viscosity and relative viscosity
$\kappa = \sigma d/v_{12}$	Capillarity number
κ_{cr}	Critical capillarity number
$\lambda = \eta_1/\eta_2$	Viscosity ratio
μ	Chemical potential
$\Delta\mu$	Excess chemical potential
v	Surface tension coefficient
v_{12}	Interfacial tension coefficient between phases 1 and 2
v_e	Entanglement density
v_o	Initial interfacial tension
v_∞	Interfacial tension for infinite molecular weight
ρ	Density
Σ	Interfacial area per copolymer joint
σ	Stress
σ_{12}	Shear stress
s_m	Stress for the matrix phase
σ_y	Yield stress
τ, t_y	Relaxation or residence time, and characteristic relaxation time
ω	Angular frequency
ζ_o	Rouse friction coefficient

5.1   Introduction

Reactive compatibilization of immiscible polymer blends by in situ copolymer formation is reviewed using approximately 1,100 examples taken from both journal articles and patents. Selected references in English through approximately 2013 to early 2014 are included. Important chemical reactions are illustrated which are useful for copolymer formation across a melt-phase boundary during melt processing of the immiscible blends. Focus is on irreversible chemical reactions taking place within typical extrusion residence times for polymer processing. Examples of block, graft, cross-linked, and degradative copolymer formation are shown. The illustrated chemical reactions and processes are also generally useful for compatibilization of immiscible polymer blends either not illustrated or not yet conceived.

Commercial polymer products are frequently derived from blending two or more polymers to achieve a favorable balance of physical properties. As described in ▶ Chap. 2, "Thermodynamics of Polymer Blends" in this handbook, from the thermodynamic point of view, there are two basic types of polymer blends: miscible and immiscible. The vast majority of polymer pairs are immiscible. There are only a few commercially important polymer blends based on miscible or partially miscible (i.e., miscible within a low range of concentration) polymer pairs. It is seldom possible to mix two or more polymers and create a blend with useful properties. Instead, when preparing a new polymer blend from immiscible resins, it is necessary to devise a specific strategy for compatibilizing the mixture to provide for optimum physical performance and long-term stability. Although there do exist a very small number of commercial blends of immiscible polymers that are not compatibilized, most commercially available blends of immiscible polymers have been compatibilized by some specific mechanism.

The majority of polymer blends containing elastomeric, thermoplastic, and/or liquid crystalline polymers are processed by melt extrusion at some point in their history. After melt extrusion with intensive mixing, the morphology of an immiscible polymer blend on a microscopic scale will often consist of a dispersed phase of the more viscous polymer in a continuous matrix of the less viscous polymer (depending upon the relative amounts and viscosities of the two polymers in the blend). A good analogy from everyday experience is a dispersed mixture of viscous oil droplets in an immiscible water matrix.

The formation of optimum dispersed phase particle size and the long-term stabilization of the resulting blend morphology are critical if the blend is to have optimum properties and in particular good mechanical properties. If this

morphology is not stabilized, then the dispersed phase may coalesce during any subsequent heat and/or high stress treatment, such as injection molding. Coalescence may result in gross-phase segregation of the two polymers and delamination on a macroscopic scale and/or brittleness or poor surface appearance in the final molded part. Good analogies from everyday experience would be the separation on standing of a not stabilized oil-in-water dispersion into two separate liquid phases. Therefore, an important aspect of all compatibilization strategies is the promotion of morphology stabilization. Morphology stabilization may be provided by sufficient interfacial adhesion and/or lowered interfacial tension between the two polymer phases.

Of the various compatibilization strategies that have been devised, an increasingly common method is either to add a block, graft, or cross-linked copolymer of the two (or more) separate polymers in the blend or to form such copolymers through covalent or ionic bond formation in situ during a reactive compatibilization step. The first of these methods was described in ▶ Chap. 4, "Interphase and Compatibilization by Addition of a Compatibilizer," in this handbook, while the second method is the topic of this chapter.

The said copolymer can reside at the interface between the dispersed and matrix phases, acting as an emulsifying agent that effectively stabilizes the dispersed phase particles against coalescence and providing interfacial adhesion between dispersed and continuous phases in the solid state. In this manner such a copolymer can both promote optimum dispersed phase particle size formation during compounding and prevent phase coalescence of the dispersed phase during any subsequent heat treatment and/or high stress processes. Again, the analogy from everyday experience is the addition of a soap or other emulsifying agent to stabilize an oil-in-water emulsion. Often, as little as 0.5–2.0 wt% copolymer is sufficient to achieve morphology stabilization of an immiscible polymer blend. However, frequently higher amounts, for example, as much as 10–20 wt% copolymer, may be necessary to obtain optimum physical properties of the blend, e.g., impact strength.

The majority of commercially important, immiscible polymer blends rely for compatibilization on the presence of a copolymer of the blended polymers. However, such a copolymer is almost never synthesized in a separate step and then added as a distinct entity to the blend of immiscible polymers. Instead, a compatibilizing copolymer is most economically formed simultaneously with generation of morphology during extrusion processing, a process referred to as reactive compatibilization. The reactive compatibilization process is logically a subcategory of the broader class of interchain copolymer formation reactions performed by reactive extrusion (Brown 1992a), because there are other commercial reasons for preparing copolymers of immiscible polymers aside from using them as in situ generated compatibilizing agents for immiscible blends.

Copolymer formation by reactive compatibilization is a *heterogeneous reaction taking place across a melt-phase boundary*. Often this process occurs by direct reaction between chemical functionalities on some fraction of each of the two

polymers. In some cases a third reactive species may be added to the blend to promote copolymer formation by one of several mechanisms.

Reactive compatibilization has at least two advantages:

1. First, the compatibilizing copolymer is automatically formed at the interface between the two immiscible polymers where it is needed to stabilize morphology. In contrast, when a compatibilizing copolymer is added as a separate entity to a polymer blend, it must diffuse to the polymer-polymer interface to be effective for promoting morphology stabilization and interfacial adhesion between dispersed and continuous phases. However, that added copolymer may prefer to self-associate in micelles and form a separate phase that is useless for compatibilization.

2. A second advantage of in situ copolymer formation is that the molecular weight of each of the two distinct polymeric segments in the copolymer is usually the same as that of the individual bulk polymer phase in which the segment must dissolve. Even approximate molecular weight matching between copolymer segment and bulk phase can result in optimum copolymer/bulk phase interaction for maximum interfacial adhesion. See, for example, Jiao et al. (1999).

5.2   Purpose

Only a relatively small number of chemical reactions have been devised to form a compatibilizing copolymer during extrusion processing. Therefore, a purpose of this chapter is to identify these different chemical reactions and give selected examples illustrating their scope to form block, graft, or cross-linked copolymers as compatibilizers for immiscible polymer blends. The emphasis is on copolymer formation during melt reaction occurring during development of morphology. With few exceptions, the examples are limited to processes that require mixing in the molten state. This includes processes run in single-screw or twin-screw extruders, or similar continuous or semicontinuous processing equipment, as well as in batch mixers.

The references in this review include both journal articles and selected published or issued patents. A large number of reactive compatibilization examples are found in industrial research and are documented mostly in patents. Patent references are included in this chapter if they reveal a novel compatibilization strategy apparently not otherwise documented until later in the journal literature. Numerous examples of industrial compatibilization methods have also been provided in a book based on the patent literature (Utracki 1998).

It is not the purpose of this chapter to describe "compatibilization" of layers of immiscible polymers in laminates. Strategies similar to those used to compatibilize intimately mixed polymer blends have also been used to prepare stable laminates, and in those cases, where a chemical reaction takes place between laminate layers, similar types of chemical reaction have been used.

Nevertheless, laminate macroscopic morphology is essentially fixed, and formation of stable laminates is better treated as an adhesion problem. Similarly, composite compositions which may comprise a blend of one or more functionalized polymers with a second, less tractable component such as starch, lignin, clay, silica, POSS, carbon nanotubes, etc. are outside the scope of this chapter.

It is also not the purpose of this chapter to summarize examples of "compatible" polymer blends formed in a solution step involving dissolution of the polymer components, whether or not a chemical reaction takes place between them. In some cases, particularly when no reaction takes place, such blends are only "pseudo-stable," since they may not have been processed above the Tg of one or both of the polymer components. Also, mixing in solution followed by devolatilization is rarely economical for practice in industry, particularly since many commercially important compatibilized polymer blends comprise at least one semicrystalline component (e.g., PA) which is poorly soluble in common solvents. There are included in the Tables a small number of examples of solution blended polymer blends when these complement similar examples prepared by melt processing.

It is also not the purpose of this chapter to describe examples of compatibilized polymer blends formed by polymerization of a monomer in the presence of a second polymer. In these cases, the growing polymer chain may react with functionality on the second polymer to form a certain fraction of compatibilizing copolymer.

The coverage of this chapter is arranged by binary polymer *Blend Type*, in alphabetical order of the first polymeric component. Thus, "polyamide blend" is the first category discussed herein. Subcategories within each Blend Type category are arranged by the specific chemical reactions that have been described in the literature for reactive compatibilization processes.

The emphasis is on illustrating the scope of these particular reactions and not on presenting every known example of a particular compatibilization strategy. For example, polyamide-polyolefin (PA-PO) blends compatibilized by reaction of PA amine end-groups with anhydride-functionalized PO have been studied in hundreds of different published examples, as have immiscible pairs of polyesters (or polycarbonate) compatibilized by transesterification reactions and polyester-polyolefin blends compatibilized using anhydride-grafted PO. Although these studies contribute to understanding the physics and property optimization of such blends, the underlying chemistry is basically the same in each case, and limitations of space preclude comprehensively listing all such examples. It should also be noted that many published studies listed herein actually represent a series of papers or patents. In some cases, only one paper or patent in the series is referenced. Also included in this chapter are some examples of blends which illustrate simple copolymer formation between two functionalized polymers although a corresponding blend with either of the unfunctionalized polymers is not exemplified, because it is

perfectly possible that the said copolymer could be a compatibilizer in corresponding blends with one or both unfunctionalized polymers.

5.3   Definitions of Compatibilization and Polymer Alloys

As defined in the appendix "Dictionary of Terms Used in Polymer Science and Technology" in this handbook, compatibilization means "A process of modification of interfacial properties of an immiscible polymer blend, leading to creation of polymer alloy." A polymer alloy in turn is defined as "An immiscible polymer blend having a modified interface and/or morphology," whereas a polymer blend is simply "A mixture of at least two polymers or copolymers." In other words, all polymer alloys are blends, but not all polymer blends are alloys. A somewhat more elaborate definition of a polymer alloy would describe a blend of at least two immiscible polymers stabilized either by covalent bond or ionic bond formation between phases or by attractive intermolecular interaction, e.g., dipole-dipole, ion-dipole, charge-transfer, hydrogen-bonding, van der Waals forces, etc. Only stabilization by covalent bond formation or ionic association (including acid-base and ion-neutral donor group interaction) is covered in this chapter.

 Thermodynamic compatibility describes a miscible polymer blend that displays a single glass transition temperature, Tg, within the full range of composition of the two polymers. For the purposes of this chapter, we will be more concerned with *Technological Compatibility*. This term describes a polymer blend that does not separate into its individual components and does not lose useful technological properties over the expected lifetime of a molded part (which has been estimated by the Society of Plastics Engineers to be about 10 years) (Gaylord 1989; Rudin 1982). Taking a somewhat different view, Coran and Patel have defined compatibilization as a process for improving ultimate properties by making polymers in a blend less incompatible (Coran and Patel 1983b).

5.4   Types of Polymer Blends

The market for commercial polymer blends has grown steadily over the past four decades. A recent estimate of the polymer alloy/blend market by volume for 2012 was about 2.2 billion pounds. The market was projected to grow to about 2.6 billion pounds by 2018 (BCC Research 2013). The principal markets for all blends include the automotive industry; phone, computer, and other business machine housings; electrical components such as connectors; appliances; consumer products; recreational equipment; and construction and industrial applications.

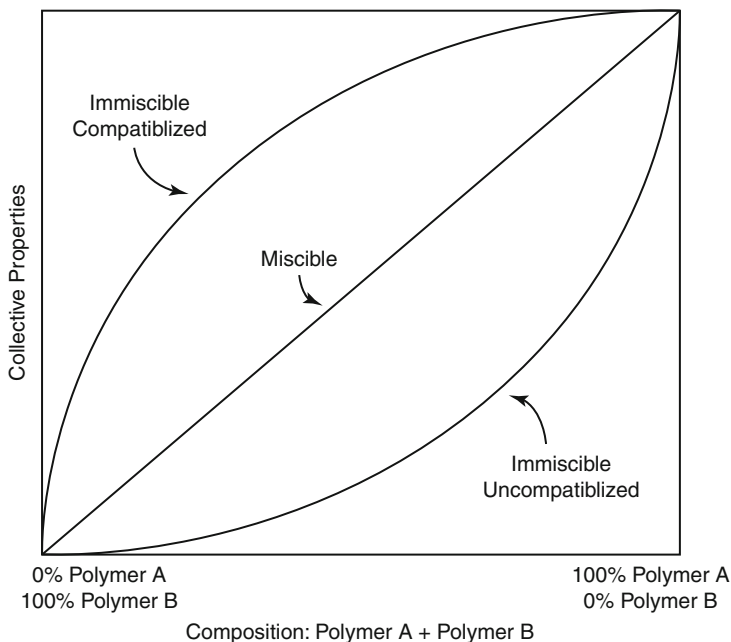
 Commercial activity is mirrored by technological activity. It was estimated that roughly 87,000 patents appeared worldwide on all aspects of polymer blends between 1970 and 1987 averaging almost 5,000 patents per year (Juliano 1988). The pace appears to have slowed little since then although the emphasis has


Fig. 5.1 Potential effect on polymer blend properties as component concentration changes

changed from simple blends (e.g., binary blends with additives) to more complex compositions for specialty applications.

Common polymer blend building blocks arranged in a hierarchy of price and performance are shown in Fig. 19.2 of ▶ Chap. 19, "Commercial Polymer Blends" in this handbook. As the price gets higher, one is typically paying for higher heat stability and higher modulus. High performance thermoplastics such as PPS, PEI, and LCP and engineering thermoplastics such as PPE, PBT, and PC have high heat stability and are often designed to take the place of metals in typical applications. Lower modulus, commodity plastics such as PE, EPDM, and modified styrenics have lower heat stability and are often used in applications requiring high flexibility.

The goal of combining two or more polymers such as polymer pairs from those categories described above (e.g., an engineering thermoplastic plus a commodity polyolefin) is to achieve in the blend a combination of favorable properties from each polymer. Figure 5.1 shows idealized expected properties from blending two polymers that are either miscible (straight center line), immiscible and uncompatibilized (curved bottom line), or immiscible and compatibilized (curved top line). In the case of polymers that are miscible in all proportions, one can only hope to obtain in their blend an average of their physical properties depending upon the proportion of each polymer present. In a common example, the Tg of a miscible blend will vary linearly from that of the lower Tg polymer to that of the higher Tg polymer as the higher Tg polymer increases in proportion in the blend.

When two immiscible polymers are blended without compatibilization, one generally obtains a mixture with physical properties worse than those of either individual polymer. Usually such a blend has poor structural integrity and poor heat stability since there is no mechanism for stabilizing a dispersion of one polymer in a matrix of the other. On a macroscopic scale, the blend may appear heterogeneous and in the extreme case grossly delaminated, e.g., in a molded part.

When two immiscible polymers are blended with compatibilization, one may expect a synergistic combination of properties derived from each polymer. A common example is a blend of a thermoplastic (to provide high heat stability) with an immiscible, rubbery impact modifier (to provide impact resistance), e.g., a rubber-toughened PA. A second common example is a blend of a semicrystalline thermoplastic with an amorphous thermoplastic. Because of their semicrystalline nature, polymers such as PA, PBT, PPS, or PP often have high chemical solvent resistance but low ductility, low dimensional stability, and low Tg. In contrast, amorphous polymers such as PPE, PEI, PC, and PE typically have poor solvent resistance and stress crack sensitivity but higher ductility, dimensional stability, and Tg. Often a binary blend includes a third, lower modulus polymer to provide optimum impact strength. A good example is a rubber-toughened blend of PPE with PA. In commercial examples, PPE and PA are combined in amounts such that PPE is the dispersed phase and PA is the continuous, matrix phase so that the blend possesses adequate solvent resistance (e.g., to common solvents used in automotive applications) but also higher heat stability compared to unmodified PA. Again, because of its inherent solvent resistance, this type of blend is prepared by melt processing and cannot economically be prepared by combining the components in solution.

Quite generally, the goal in preparing any polymer blend is to obtain one or all of the following benefits: higher heat distortion temperature (HDT), improved variable temperature impact resistance, solvent resistance, dimensional tolerance, higher flow, utilization of recycle/regrind, and lower cost.

5.5   Characteristics of Immiscible Polymer Blends

The general characteristics of immiscible polymer blends have been described in a large number of references (e.g., many of those listed in Sect. 5.6 on "General Stractegies for Compatibilization of Immiscible Polymer Blends"). Commercial polymer blends are most often prepared by some form of processing in a molten state, usually extrusion. Among the factors that determine which polymer will be the dispersed phase and the continuous matrix are the relative volume proportions and relative viscosities of the two polymers. During intensive mixing in a twin-screw or single-screw extruder, the less viscous molten polymer in a simple 1:1 mixture of two polymers will form an easily deformable matrix, while the more viscous polymer will form a difficultly deformable dispersed phase. Generally, the more viscous polymer will form the dispersed phase even in some cases when it represents more than 50 vol% of the blend.
Fig. 5.2 Morphology of PPE dispersed phase in a PBT matrix (**a**) as extruded and (**b**) after molding

Blend properties depend strongly on which polymer is the continuous phase. The majority of commercially important compatibilized blends of semicrystalline polymers with amorphous polymers are prepared in compositions such that the semicrystalline component is the matrix and the amorphous component is the dispersed phase. Such blends show adequate solvent resistance since in this morphology the surface consists largely of the dominant, matrix phase of semicrystalline polymer.

The formation of optimum dispersed phase particle size and the stabilization of the resulting blend morphology are critical if the blend is to have optimum properties and in particular good mechanical properties. Figure 5.2 shows a morphology generated by processing an uncompatibilized blend of PPE dispersed phase in a PBT matrix (Brown, unpublished results, 1988). Figure 5.2a shows that a reasonably uniform dispersion of PPE may be formed simply by suitable degree of mixing during extrusion. Figure 5.2b, however, demonstrates phase coalescence of PPE particles to form large, irregularly shaped islands when the extrudate of the uncompatibilized blend is molded at normal processing temperature. In this blend there is no interfacial adhesion between the two phases and, hence, no mechanism for morphology stabilization. Even in the presence of an impact modifier, the resulting molded parts are quite brittle since there are no uniform dispersed phase particles of proper size to dissipate impact energy.

Table 5.1 shows further examples of dispersed phase coalescence in blends of PA as the dispersed phase in a less viscous PE or PS matrix. The data show that the mean PA particle size increases dramatically with simple heating under static conditions in the absence of any mechanism for morphology stabilization. The same coalescence can occur in molded parts of uncompatibilized polymer blends

Table 5.1 Change of dispersed phase dimensions in uncompatibilized polymer blends upon annealing (Adapted from White and Min 1989)

Blend	Mean dimension after annealing (µm)		
	30 min	60 min	90 min
PS/PA-6 (60/40)	90	140	310
LDPE/PA-6 (50/50)	251	314	319
LDPE/PA-11 (50/50)	162	275	303

subjected to further thermal treatment after molding (e.g., in a paint drying oven). The mechanical properties of these blends are quite poor.

In summary, a frequent goal in making a technologically compatible blend of immiscible polymers is to stabilize an appropriate morphology of the dispersed phase polymer in the matrix polymer by promotion of interfacial adhesion and/or by lowering the interfacial tension. These conditions are critical for providing good mechanical properties, toughness, molded part dimensional integrity, and maximum solvent resistance in the blend.

5.6 General Strategies for Compatibilization of Immiscible Polymer Blends

Numerous reviews have been published which discuss general (or specific) aspects of strategies for compatibilization of immiscible polymer blends, including but not limited to those by Fink (2013), Imre and Pukanszky (2013) (bio-based and biodegradable polymer blends including reactive compatibilization), Karaağaç and Deniz (2013) (rubber based blends), Covas et al. (2011), Jiang et al. (2010) (reactive compatibilization), Nwabunma and Kyu (2008) (polyolefin blends), Robeson (2007), Yu et al. (2006) (polymer blends from renewable resources), Feldman (2005), Macosko et al. (2005) (reactive compatibilization), Mangaraj (2005) (recycling ground rubber waste), Harrats and Groeninckx (2004) (reactive compatibilization) Paul (2004) (reactive compatibilization), Platé et al. (2004) (theoretical considerations), Horák et al. (2002), Litmanovich et al. (2002) (theoretical considerations), Baker et al. (2001), Prut and Zelenetskii (2001), Bussink and van de Grampel (2000), Paul and Bucknall (2000), Fakirov (1999) (transreactions in condensation polymers), Shonaike and Simon (1999), Xanthos (1999) (polypropylene), Koning et al. (1998), Robeson et al. (1998) (PVAl-PO blends), Tran-Cong (1998), Al-Malaika (1997), Baranov (1997), Gao et al. (1997) (ionomer blends), Lohse et al. (1997), Datta and Lohse (1996), Utracki and Dumoulin (1995) (polypropylene), Folkes and Hope (1993), Brown (1992a) (reactive compatibilization). Liu and Baker (1992a) (reactive compatibilization), Elmendorf and Van der Vegt (1991), Xanthos and Dagli (1991) (reactive compatibilization), Menges (1989), Utracki (1989, 1998), Brown and Orlando (1988) (reactive compatibilization), Paul et al. (1988), Teyssie et al. (1988), Sperling (1987), Fox and Allen (1985), Solc (1981), Rudin (1980), Paul and Newman (1978), and Bucknall (1977). The basic strategies for compatibilization of two-phase polymer blends can be divided into at least four major categories.

5.6.1   Co-crystallization of Two Phases

This particular strategy is limited to those cases in which an immiscible polymer blend contains two semicrystalline polymers that can co-crystallize. Nadkarni and Jog (1989, 1991) have reviewed examples of this type of compatibilized blend. Co-crystallization may also occur as a secondary process in an intimately mixed blend containing a copolymer resulting in concomitant effects on blend properties as shown in a few of the examples of this review.

5.6.2   In Situ Immobilization of One Phase: Dynamic Vulcanization

In these examples a dispersed phase of a cross-linkable rubber is vulcanized in the presence of a matrix of a second, immiscible, non-vulcanizable polymer during the residence time of melt processing. Examples have also been reported in which a mixture of two vulcanizable polymers has been employed. Coran (1995) has summarized five key requirements for preparing optimum compositions by dynamic vulcanization:

1. Good match between surface energies of the dispersed phase and the matrix
2. Low entanglement molecular length (high entanglement density) of the rubber
3. Crystalline plastic matrix
4. Stable rubber and plastic at blend processing temperatures
5. Availability of appropriate curing system for rubber under desired processing conditions

Coran and others have reviewed work in this area (Coran and Patel 1995, 1996, 2004; Karger-Kocsis 1999; Abdou-Sabet et al. 1996; Coran 1987, 1990, 1995).

Most examples of dynamically vulcanized blends do not involve covalent bond formation between the immiscible phases. However, other work has shown that covalent bond formation between phases in conjunction with dynamic vulcanization of one phase can lead to blends with improved properties in certain cases. This is particularly true in blends where certain of Coran's five key requirements above are not met. Some examples of dynamically vulcanized blends that also feature copolymer formation between the two immiscible phases are summarized in this review under the appropriate categories.

5.6.3   Inclusion of a Third Material as a Compatibilizing Agent

5.6.3.1 Addition of a Separate Compatibilizing Agent

A separate compatibilizing agent included in a blend may be a third material not derived from either of the two immiscible polymers. Representative examples include certain plasticizers, random copolymers, and block copolymers, which may lower the interfacial tension between the two immiscible polymer components.

Table 5.2 Change of dispersed phase dimensions in compatibilized polymer blends upon annealing (Adapted from White and Min 1989)

Blend	Mean dimension after annealing (μm)		
	30 min	60 min	90 min
PS/PA-6/SMA (57/38/5)	4	5	5
PE/PA-6/PP-MA (47/47/5)	5	7	13
PE/PA-11/PP-MA (47/47/5)	5	6	4

Examples also exist where the separate compatibilizing agent is a chemically unreactive *analog* of one (or both) of the two immiscible polymers that has an attractive interaction with each polymer. In any case this is often a semiempirical compatibilization strategy since precedent may be the only basis for choosing an effective compatibilizer. Reviews on addition of this type of compatibilizing agent as a separate component to an immiscible polymer blend have appeared in addition to ▶ Chap. 4, "Interphase and Compatibilization by Addition of a Compatibilizer," in this handbook. They include but are not limited to those listed above in Sect. 5.6 and those by Gaylord (1989), Xanthos (1988), and Paul (1978).

5.6.3.2 Inclusion of a Copolymer of the Two Immiscible Polymers

As stated earlier, a copolymer of the two immiscible polymers themselves would seem to be ideally suited to act as a compatibilizing agent for an immiscible blend. If the copolymer is at the interface of the two phases, then the segments of the copolymer dissolve in the respective bulk phases of the same identity. The copolymer acts as emulsifying agent for the blend resulting in reduced interfacial energy and improved interfacial adhesion.

Table 5.2 shows dramatic examples of the stabilization of dispersed phase morphology in the presence of a compatibilizing copolymer, in these cases formed through reaction of PA amine end-groups with anhydride-functionalized matrix polymer. In all examples, essentially no change in dispersed phase particle size occurs after annealing under static conditions for up to 90 min. The data shown in Table 5.2 should be compared with those presented in Table 5.1, where the dispersed phase mean dimensions were presented for similar, uncompatibilized blends.

There are two basic options for inclusion of a copolymer compatibilizer in a blend of immiscible polymers. First, the copolymer can be synthesized in a separate step followed by addition to the blend. One disadvantage is that this requires a new product synthesis with expensive and time-consuming process development, and, hence, a significant number of years before profitability, since scale of copolymer manufacture will be initially low.

A second and more important disadvantage is that adding the copolymer as a separate species to the blend requires that the copolymer diffuse to the phase interface of the immiscible polymers to be effective as a compatibilizer.

Diffusion to the interface may not be efficient within the residence time of a typical extrusion blending process (usually 2–5 min). In addition, high concentrations of added copolymer may form micelles as a third, distinct phase that does not contribute to compatibilization (see, e.g., Jeon et al. 2005).

A third, potential disadvantage is that for optimum interfacial interaction, a copolymer synthesized in a separate reaction step must have carefully controlled segment lengths to best match the molecular weight of the bulk phase in which the segment must dissolve (see, e.g., Cercle and Favis 2012; see also Gani et al. 2010, for an approach to solving this dilemma). It is often desired to offer for different applications a series of commercial blends containing the same two polymers but with different molecular weights for the polymers in each blend. Any copolymer synthesis process would then have to be capable of producing a series of copolymers with a variety of controlled segment molecular weights for optimum compatibilization efficiency, an economically difficult task.

Commonly, the most economical and efficient process for including a copolymer in a blend of immiscible polymers is to form the copolymer in situ by a chemical reaction during the extrusion process during establishment of the immiscible phase morphology – the process known as reactive compatibilization. In summary the advantages of such a process include:

- The copolymer is made only as needed and a separate copolymer commercialization process need not be developed.
- The copolymer is formed directly at the phase interface where it can serve as a compatibilizer, and no diffusion process dependent on extruder residence time is involved.
- The copolymer, except when formed in a degradative process, typically has segment molecular weights similar to the molecular weights of the bulk phases in which the segments must dissolve, which should promote optimum interaction between copolymer and bulk phases. This also facilitates commercialization of a series of blends containing polymers with quite different molecular weight since the copolymer formed in situ will usually have ideal segment molecular weights.
- A disadvantage of forming copolymer in situ is that such a process often requires that each of the immiscible polymers bear an appropriate chemical functionality for reaction across a melt-phase boundary.

As practiced commercially, reactive compatibilization is a continuous extruder process with material residence time usually 1–5 min. Such a process permits large-scale preparation of a polymer blend as needed ("Just-In-Time" inventory control). Because reactive compatibilization involves a heterogeneous reaction across a phase boundary, the reaction is limited by the interfacial volume available at this phase boundary. Most often, twin-screw extruders (having screw diameter from about 20 to >120 mm) are employed. The screws are designed using an appropriate sequence of screw elements and auxiliary conditions (e.g., subsequent vacuum venting of volatiles) to promote generation of a large interfacial area for the desired chemical reaction to form copolymer.

5.7   Generic Processes and Specific Types of Reactions to Form Copolymer in a Reactive Compatibilization Process

When it is desired to form in situ a compatibilizing graft, block, or cross-linked copolymer, there are at least two distinct *generic* processes available for copolymer formation:

1. *Direct Reaction*, wherein reactive functionalities on each of the two immiscible polymers react with each other across the melt-phase boundary.

2. *Addition of a Third, Reactive Species* to effect or promote copolymer formation. This situation is a typical "three-body" reactive extrusion problem requiring that three chemical species (at least two of which are immiscible) react within the short residence time of extrusion processing. In some cases, the third, reactive species is simply a catalyst that activates functionality on one polymer for reaction with functionality on the second polymer. Such cases produce results similar to the direct reaction process. Frequently, however, the added reactive species is a *coupling agent* capable of reacting with each of the polymers individually (as opposed to reacting with and activating only one of the two polymers). If the coupling agent is preferentially soluble in one of the two phases (e.g., a polar coupling agent in the more polar polymer phase), it may give predominantly homogeneous reaction instead of promoting heterogeneous reaction (copolymer formation) across the melt-phase boundary. Hu et al. (1997) have studied one type of polymer melt reaction (carboxylic acid + epoxide) in which the kinetic efficiency depends upon the partition coefficient of reactant between two immiscible polymer phases. Such considerations must be applied to all reactive compatibilization processes involving three or more reactive species. Coupling agents are further discussed herein below.

As subcategories of the two generic processes, there are at least five *specific* processes for achieving interchain copolymer formation between two polymers during reactive compatibilization in an extruder. The following sections and their accompanying tables show these five processes starting with two idealized homopolymers, one derived from monomer "A" with structure AAAAAAAA and the other derived from monomer "B" with structure BBBBBBBB. Each process produces a specific type of copolymer compatibilizing agent by particular types of chemical reactions.

5.7.1   Compatibilization by a Redistribution Reaction to Produce Block and Random Copolymer: Reaction Type #1

As summarized in Table 5.3, redistribution reactions (often referred to as "transreactions") occur by chemical interchange of block segments of one polymer chain for corresponding segments of a second polymer chain. Such reactions may be homogeneous (self-reaction) or heterogeneous. In the homogeneous case, the molecular weight distribution of a polymer may reach equilibrium. In the heterogeneous case, redistribution reactions can form a copolymer between two

Table 5.3 Redistribution reaction ("transreaction") to form block and random copolymer (Adapted from Brown 1992a)

Reaction type	Characteristics	Type of copolymer obtained
1a	By reactive end-groups of one polymer attacking main chain of second polymer	**AAAAABBBBB + AABBBBBAAA + AABBAAABBB + BBB + BB, etc.**
1b	By chain cleavage/recombination involving each polymer	**(Same as from 1a)**
Summary of characteristics		
In theory all the chains of each polymer participate in the redistribution reaction. The reacting polymers can be diluted with different, nonreactive polymers. In process (a), the extent of reaction depends on concentration of reactive end-groups		
In processes (a) and (b), the initial reaction product is a block copolymer, which is often an effective compatibilizer. Further reaction leads to random copolymer with loss of phase integrity and loss of properties associated with uniform sequence distribution of each polymer (e.g., crystallinity)		
The reaction may be catalyzed. Preferably, the catalyst is one that may be easily quenched or thermally degraded before a significant amount of the random copolymer is formed		

different polymers. This type of reaction is typically dependent upon reaction time and temperature and is not often used to form polymer alloys in a reactive compatibilization process because the time for forming a stable compatibilizing copolymer may be longer than a typical extrusion process time.

Redistribution reactions can occur by several different mechanisms. In one common example, nucleophilic end-groups of one polymer react with electrophilic linkages in the main chain of a second polymer resulting in chain cleavage (e.g., acidolysis or alcoholysis). The initial product is a block copolymer of the two polymers along with a lower molecular weight fragment of the second polymer. Since the initial block copolymer can participate in further redistribution reactions, the net product after sufficient time may be a random copolymer. The propensity to form random copolymer is further increased if both polymers have nucleophilic end-groups and also electrophilic linkages in the main chain that can participate in redistribution. Redistribution during thermal processing is also a common self-reaction in condensation polymers such as PA, PEST, and PC that often contain nucleophilic amine, hydroxy, or phenolic end-groups, along with electrophilic groups such as amide, ester, or carbonate linking the individual monomer units.

In common examples, essentially all of the polymer chains in each of the immiscible polymers are capable of participating in the copolymer-forming reaction by redistribution. This is in contrast to many other processes for in situ copolymer formation where only those few chains bearing reactive functionality participate. Unless the redistribution process is carefully controlled, it is difficult to stop the process to make stable, compatibilized polymer blends. If the reaction is thermally initiated, the blend processing temperatures and residence times must be strictly and reproducibly controlled within narrow limits to achieve reproducible properties. For prolonged reaction times at a temperature above that necessary to initiate the reaction, one may obtain a broad distribution of block lengths and

eventually random copolymer. The random copolymer may not be as efficient a compatibilizer for the immiscible polymer blend as the block copolymer initially formed. More importantly, a high degree of random copolymer formation may destroy desirable properties in the polymer blend such as crystallinity in one of the polymers and, hence, solvent resistance in the final blend. In the extreme case, phase separation is lost and the mixture may become homogeneous and transparent. The problem of controlling the redistribution process does not necessarily stop at the manufacturing stage. After a compatibilized polymer blend leaves the manufacturer, it typically undergoes further thermal histories such as molding or paint-oven drying at the processing facilities of the final user. Continued redistribution reaction in the hands of a final user may cause deterioration and non-reproducibility in blend properties.

When applicable, a common method for controlling a redistribution process is to initiate the reaction with a catalyst. Control may then be achieved by quenching the catalyst at the desired extent of reaction. Certain types of redistribution catalyst may thermally decompose under controlled processing conditions that make quenching unnecessary. In these cases, a predominance of block copolymer may be formed that serves as an effective compatibilizer for an immiscible polymer blend. Just as importantly, only a relatively small fraction of the polymer chains may actually participate in the redistribution process so that phase separation and the properties attributable to the original sequence distribution may be maintained.

The redistribution reaction is a degradative process for making a compatibilizing copolymer. A common feature of all redistribution reactions to form copolymer between two different polymers is that the molecular weight of at least one segment of the initially formed block copolymer is less than that of the bulk polymer phase from which it is derived. Therefore, even when the redistribution process is carefully controlled to give predominantly block copolymer, the copolymer may not be as efficient a compatibilizer as a similar type of block copolymer formed by an end-group/end-group reaction (see herein below). With a low molecular weight block segment, one may have poor penetration into the corresponding bulk polymer phase and less than optimum interfacial adhesion between the immiscible phases with copolymer at the interface. As discussed before, an optimum interfacial adhesion is usually obtained when the segmental molecular weights of the block copolymer are similar to the molecular weights of the individual bulk polymer phases. A general review of "Interchange Reactions Involving Condensation Polymers" describes early work on redistribution reactions in the melt blends of polyesters, polyamides, and polyester + polyamide (Kotliar 1981).

5.7.2 Compatibilization by Graft Copolymer Formation: Reaction Type #2

Graft copolymer formation has been the most common method of forming a compatibilizing copolymer between two immiscible polymers during reactive compatibilization. As shown in Table 5.4, there are at least four processes for

Table 5.4 Graft copolymer formation processes (Adapted from Brown 1992a)

Reaction type	Characteristics	Type of copolymer obtained		
2a	By *direct reaction* of end-group of the 1st polymer with pendent groups of the 2nd polymer	A A - BBBBB A + A A	A A - BBBBB A A - BBBBB A	etc.
2b	By reaction of end-group of the 1st polymer with pendent group of the 2nd polymer in the presence of a *condensing agent*	**(Same as from process a)**		
2c	By reaction of end-group of the 1st polymer with pendent group of the 2nd polymer in the presence of a *coupling agent* ("c")	A A -c- BBBBB A + A A	A A -c- BBBBB A A -c- BBBBB A	
2d	By reaction of pendent groups of the 1st polymer with main chain of the 2nd polymer in a *degradative process*	A A - BBB A + A A	A A - BBB A A - BB A + BBB + BB	etc.

Summary of characteristics

Only chains bearing reactive functionality participate in the copolymer-forming reactions. A small amount of cross-linked copolymer may be formed when the end-group-functionalized polymer has functional groups at both ends

Graft copolymer formation between two polymers *each with different functionality* may occur either by *direct reaction* (e.g., A-acid end-group + B-pendent epoxy group) or by addition of a *condensing agent* that activates functionality of one polymer for reaction with functionality of the second polymer (e.g., A-acid end-group + B-pendent alcohol + triaryl phosphite)

Graft copolymer formation between two polymers *each with the same type of functionality* may be obtained using a *coupling agent* that links the two groups (e.g., A-acid + B-acid + diepoxide). The reaction may be inefficient if the coupling agent segregates into one phase, instead of concentrating at the interface. The coupling agent is incorporated into the final copolymer as a linking group

Graft copolymer formation may occur by a *degradative process* through reaction between a pendent functionality on one polymer and main-chain linkages on the second polymer. Small amounts of cross-linked copolymer may be formed if degradable segments of the graft copolymer react further

forming graft copolymer in a melt reaction. In the direct reaction process, the reaction occurs between one polymer containing reactive sites along its main chain and a second polymer with reactive sites only at end-groups. Depending upon stoichiometry and concentration of functional groups, copolymer structures of the general type 2a and 2b are obtained. In this particular type of graft copolymer formation, the average molecular weight of the copolymer is the simple sum of the average molecular weights of the two reacting species.

Graft copolymers may also be formed through reaction of a bi- or multifunctional coupling agent with one polymer containing reactive sites along its main chain and a second polymer with reactive sites only at end-groups (Type 2c). Typical coupling agents include multifunctional epoxy resins, oxazolines, carbodiimides, and isocyanates that react with nucleophilic end-groups of condensation polymers. The coupling agent is incorporated into the copolymer. When the coupling agent is an epoxide, a new secondary alcohol is formed when the epoxide ring is opened by a nucleophile. This alcohol may also be reactive to one or more polymeric components (particularly polyesters) similar to the reactivity of alcohol groups on phenoxy resin (see, e.g., Su et al. 1997).

A third, less common process for forming graft copolymer as shown in Table 5.4 is Type 2d. In this process, multiple reactive sites pendent on one polymer chain can bite into the linkages of a second type of polymer chain. The reaction creates a copolymer having segments with average molecular weight less than the sum of the two initial reacting species. This is a degradative method for forming a compatibilizing copolymer. A common example is the transesterification reaction between the poly(hydroxy ether) of bisphenol A (a phenoxy resin) and a polyester. Pendent hydroxy groups on phenoxy resin can undergo transesterification with ester linkages in the polyester chains resulting in graft copolymer formation accompanied by lower molecular weight polyester fragments. Because the molecular weight of the grafted polyester species is less than that of the homopolymer from which it was derived, the grafted chain segments may be below optimum molecular weight necessary for most efficient chain entanglement with the remaining homopolymer phase. This may result in less than optimum physical properties. Furthermore, if there is a large number of pendent reactive sites, then degradation of the second polymer may reach the point where it has lost the physical properties that made it useful for blending. Consequently, formation of a graft copolymer compatibilizing agent by a degradative process is not a common method for immiscible blend compatibilization.

Many commercial thermoplastics for high-impact strength applications are two-phase blends in which a higher modulus thermoplastic matrix is toughened by the presence of a lower modulus, dispersed phase polyolefin. In the majority of cases, such blends are compatibilized by graft copolymer formation between at least some fraction of the chains of the two immiscible polymers. Rubber-toughened PAs are the most common examples. In most of these cases, PA amine end-groups react with pendent anhydride or epoxy groups along the main chain of an immiscible rubbery polyolefin to form sufficient copolymer to compatibilize a dispersed polyolefin phase in a matrix phase of PA. Rubber-toughened PEST are also often compatibilized through graft copolymer formation formed through reaction between polyester acid end-groups and epoxy-functionalized polyolefins.

In rubber-toughened thermoplastic blends, the efficiency of compatibilization depends among other things upon sufficient concentrations of both thermoplastic reactive end-groups and polyolefin reactive pendent groups to give adequate levels of copolymer under the mixing, temperature, and residence time protocol of the extrusion process. Concentrations of thermoplastic reactive end-groups are

usually controlled during the manufacturing process, e.g., through control of stoichiometry in condensation polymerization and/or through addition of reactive or unfunctionalized chain-capping agents either during synthesis or in a subsequent processing step.

Functionality in rubbery polyolefins is usually introduced in one of two ways:

1. Copolymerization of olefin monomer(s) with another functionalized monomer (e.g., poly(ethylene-*co*-acrylic acid), poly(ethylene-*co*-glycidyl methacrylate), etc.)
2. Graft functionalization of polyolefin in a separate processing step (e.g., polyethylene-g-maleic anhydride, polypropylene-g-maleic anhydride, etc.)

Graft functionalization may be performed either by reactive extrusion in the molten state (see, e.g., Brown 1992a), in solution, or by solid-state processes. In these cases, concentration of functionality is controlled by temperature, physical phase of the polymer substrate, stoichiometry of functionalization agent, and (optional) catalyst among other factors.

When graft functionalization is performed by extrusion, the removal of unbound functionalization agent from functionalized PO is critical for success of subsequent copolymer formation with reactive thermoplastic end-groups. Unbound functionality (e.g., free maleic anhydride) in the PO phase may tie up reactive end-groups of the thermoplastic resin during subsequent reactive compatibilization processing, making these end-groups unavailable for copolymer formation. For functionalization during a separate extruder grafting reaction, unbound functionalization agent is removed by efficient devolatilization, and for solution functionalization, by solubilization of excess functionalization agent during isolation of solid, functionalized polymer.

5.7.3 Compatibilization by Block Copolymer Formation: Reaction Type #3

Compatibilized polymer blends have been prepared through block copolymer formation between immiscible polymers. In the direct reaction process, during melt processing, the functionalized end-groups on some fraction of chains in each of the polymers react across a melt-phase boundary to form block copolymers. Depending upon stoichiometry, either A-B or A-B-A or both copolymer structures may be obtained as shown in Table 5.5 (Type 3a or 3b). The average molecular weight of the copolymer corresponds to the sum of the average molecular weights of the reacting polymers.

Block copolymers may also be formed through reaction of the end-group on one polymer with a condensing agent which activates that end-group for reaction with a nucleophilic end-group on a second immiscible polymer. Typical condensing agents include phosphite esters that react with acid and hydroxy end-groups on condensation polymers. A by-product from the condensing agent is always formed in the copolymer reaction and is often removed by devolatilization of the blend melt. Since the condensing agent is not incorporated into the copolymer, the process is similar to that shown in Table 5.5, Type 3a.

Table 5.5 Block copolymer formation processes (Adapted from Brown 1992a)

Reaction type	Characteristics	Type of copolymer obtained
3a	By *direct reaction* of end-group of the 1st polymer with end-group of the 2nd polymer	**AAAAA-BBBBB**
3b	By reaction of end-group of the 1st polymer with end-group of the 2nd polymer in the presence of a *condensing agent*	**(Same as from process a)**
3c	By reaction of end-group of the 1st polymer with end-group of the 2nd polymer in the presence of a *coupling agent* ("c")	**AAAAA-c-BBBBB**
3d	By reaction of end-group of the 1st polymer with main chain of the 2nd polymer in a *degradative process*	**AAAAA-BBB + BB**
Summary of characteristics		

Only chains that bear reactive functionality participate in the copolymer-forming reaction. A-B-A block copolymer may result from the reaction if least one polymer is functional at both ends

Block copolymer formation between two polymers *each with different functionality* may occur either by *direct reaction* (e.g., A-acid end-group + B-epoxy end-group) or by addition of a *condensing agent* that activates functionality on one polymer for efficient reaction with functionality on the second polymer (e.g., A-acid end-group + B-alcohol end-group + triaryl phosphite)

Block copolymer formation between two polymers *each with the same type of functionality* may occur by adding a *coupling agent* capable of linking the two end-groups (e.g., A-acid + B-acid + diepoxide). The method may be inefficient if the coupling agent segregates to one phase instead of concentrating at the interface. The coupling agent is incorporated into the final copolymer as a linking group

Block copolymer formation may occur by a *degradative process* through reaction between end-group functionality on one polymer and main-chain linkages in the second polymer

    Block copolymers may also be formed through reaction of end-groups on each of the immiscible polymers with a coupling agent. Typical coupling agents are the same as for graft copolymer formation and include multifunctional epoxy resins, oxazolines, carbodiimides, and isocyanates that react with nucleophilic end-groups of condensation polymers. The coupling agent is incorporated into the copolymer. The process is shown in Table 5.5 (Type 3c). When the coupling agent is an epoxide, a new secondary alcohol is formed when the epoxide ring is opened by a nucleophile. This alcohol may also be reactive to one or more polymeric components (particularly polyesters) similar to the reactivity of alcohol groups on phenoxy resin.

    Block copolymers may also be formed by a degradative process in which end-groups on one polymer undergo transreaction with linkages in the main chain of a second, immiscible polymer. A low molecular weight fragment of the second polymer is formed as by-product. The block copolymer has lower average molecular weight than the sum of the average molecular weights of the reactants. The process shown in Table 5.5 (Type 3d) is essentially the same as Reaction Type 1a in Table 5.3 terminating at the block copolymer. A typical copolymer architecture in this process is an A-B block. An A-B-A block can form if the degradable segment is further degraded through transreaction with another end-group-functionalized polymer.

5.7.4 Compatibilization by Covalently Cross-Linked Copolymer Formation: Reaction Type #4

As shown in Table 5.6, compatibilizing copolymers may be formed in situ by a covalent cross-linking process.

The cross-linking reactions have been performed by at least five processes. In Reaction Type 4a, direct cross-linking occurs by covalent bond formation between functionalities on each of the two immiscible polymers without degradation of either polymer. The cross-linking is most often performed by reaction of pendent, nucleophilic sites of one multifunctional polymer with pendent, electrophilic sites of the second multifunctional polymer. Common examples include reactions of pendent acid or amine nucleophiles on one functionalized polymer with pendent electrophilic groups such as epoxide, oxazoline, or ortho ester on a second functionalized polymer.

Covalent cross-linking reactions mediated by a third, added reagent may give the same type of copolymer structure as that which results from direct cross-linking reactions (Table 5.6, Type 4b and 4c). In this case, the added reagent may be a radical initiator or other type of activating agent such as a condensing agent. Such activating agents are not incorporated into the final copolymer. Radical initiators may promote radical formation on each of two immiscible polymers. A cross-linked copolymer results through radical-radical coupling between the two polymers at a melt-phase interface. Self-coupling of each polymer may compete with cross-coupling as is the case with most three-body reactions in which an added reagent is capable of reacting with each of the two immiscible polymers.

Covalent cross-linking by covalent bond formation arising from mechanochemical radical generation and recombination in the absence of an added radical initiator may also be performed (Table 5.6, Type 4d). The method is less frequently used than other cross-linking reaction types. When two immiscible polymers can both form radicals on their main chains in the absence of added radical initiator, then a copolymer results when radical sites on the two different polymers recombine at the phase interface. If radical formation occurs without chain degradation, then the copolymer becomes cross-linked as multiple sites on each chain participate in the reaction. Alternatively, one radical-forming polymer can form a cross-linked copolymer with a second polymer containing a radical trap such as an unsaturated site (e.g., EPDM). This cross-linking process may be difficult to control since it only stops when thermal and/or shear conditions are below some threshold level. Casale and Porter (1975, 1978) and La Mantia and Valenza (1994) have briefly reviewed mechanochemical radical generation and its use to form copolymers in immiscible blends. Ahn et al. (1995) have described radical generation and copolymer formation in immiscible polymer blends subjected to elastic strain pulverization in specially modified extruders building on earlier Russian work. Pulverization occurs in an extruder section kept below the polymer melting points. The compatibilizing copolymer formed in these cases may be a block, graft, or cross-linked copolymer depending upon the polymers involved. See also the more recent review

Table 5.6 Covalently cross-linked copolymer formation processes (Adapted from Brown 1992a)

Reaction type	Characteristics	Type of copolymer obtained		
4a	Covalent cross-linking by *direct reaction* of pendent functionality of 1st polymer with pendent functionality of 2nd polymer	**A B** **A - - B** **A B** or **A - - B** **A B**	**A B A** **A B ----- A** **A ----- B A** **A B A** **A B A**	
4b	Covalent cross-linking by reaction of a pendent functionality of the 1st polymer with pendent functionality of the 2nd polymer in the presence of a *condensing agent*	**(same as from process a)**		
4c	Main chain of the 1st polymer reacts with main chain of the 2nd polymer in the presence of a *radical initiator*	**(same as from process a)**		
4d	Main chain of the 1st polymer reacts with main chain of the 2nd polymer through mechanochemical radical generation	**(same as from process a)**		
4e	Covalent cross-linking by reaction of pendent functionality of the 1st polymer with pendent functionality of the 2nd polymer in the presence of a *coupling agent* ("c")	**A B** **A -c- B** **A B** or **A -c- B** **A B**	**A B A** **A -c- B A** **A B A** **A B -c- A** **A B A**	

Summary of characteristics

Only chains bearing reactive functionality participate in copolymer-forming reactions

Cross-linked copolymer formation between two polymers *each with different functionality* may occur either by *direct reaction* (e.g., A-pendent acid + B-pendent epoxide) or by addition of a *condensing agent* that activates functionality on one polymer for efficient reaction with functionality on the second polymer (e.g., A-pendent acid + B-pendent alcohol + triaryl phosphite) (process 4a and 4b)

Cross-linked copolymer formation may also occur via *direct reaction* of mechanochemically generated free radicals of each polymer in the absence of added radical initiator, or through radical trapping by a reactive site, such as olefin or acetylene groups in the second polymer (process 4a) Alternatively, a radical initiator may be added to generate radical sites on one or both polymers (process 4c). A cross-linked copolymer results if the polymers involved are not degraded. When the polymers are degraded, then the copolymer structure may be as shown in Table 5.3

Cross-linked copolymer formation between two polymers *each with the same type of functionality* may occur by adding a *coupling agent* capable of linking the two pendent groups (e.g., A-pendent acid + B-pendent acid + diepoxide). The method may be inefficient if the coupling agent segregates to one phase instead of concentrating at the interface. The coupling agent is incorporated into the final copolymer as a linking group

In all the above cases, the initial copolymer formed is a *graft copolymer*, but this product may react further to form cross-linked copolymer as additional functionalities of one or both of the two segments of the copolymer react

by Beyer and Clausen-Schaumann (2005) concerning mechanochemical radical generation in polymers.

Covalent cross-linking reactions to form a compatibilizing copolymer may also be performed by addition of a coupling agent. Coupling agents react with the same

type of functionality in each of the immiscible polymers and remain bound in the cross-linked product as linking agents. Examples include diepoxide reaction with pendent carboxylic acid groups on each of two immiscible polymers. In this case, the structure of the cross-linked copolymer is shown in Table 5.6 (Type 4e). Most commonly, coupling agents are multifunctional reagents with molecular weights less than about 1,000. When immiscible polymer pairs are employed, each bearing multiple pendent nucleophilic groups (such as carboxylic acids), then low molecular weight coupling agents such as bis-, tris, tetra-, and higher epoxides; bis-oxazolines; and other multifunctional electrophilic species are used. A low molecular weight coupling agent bearing multiple olefinic sites may be used to promote cross-linking in blends containing POs. Common examples include commercially available tris-acrylates and triallyl isocyanurate. Often these cross-linking reactions are performed in the presence of radical initiator. Self-coupling of each polymer may compete with cross-coupling as is the case with most three-body reactions in which an added reagent is capable of reacting with each of the two immiscible polymers.

5.7.5 Compatibilization by Ionic Interaction to Form Copolymer: Reaction Type #5

Immiscible polymer blends have been compatibilized through formation of a compatibilizing copolymer linked by ionic association instead of by covalent bonding. Although many examples have been published, most of these involve solution mixing of the two immiscible polymers (see Natansohn et al. 1990). Most examples given in this chapter describe only such polymer blends prepared by melt mixing.

In theory, the possible architectures of a compatibilizing copolymer arising from ionic association may be the same as all those architectures arising from covalent bond formation that were previously discussed. However, in practice only a small number of copolymer architectures have been reported for compatibilizing agents arising from ionic association. In the most common examples (Table 5.7; Type #5a), ionizable groups such as carboxylic, sulfonic, or phosphonic acid are present in low concentrations (e.g., about 5 % or less) on both polymers. The ionizable groups may be at least partially neutralized by a mono-, di-, or trivalent metal cation, such as Na^{+1}, Zn^{+2}, or Al^{+3}. Multivalent cations may form a bridging linkage between the ionizable groups of the two immiscible polymers resulting in interchain copolymer formation by ion-ion association. Monovalent cations such as Na^{+1} or K^{+1} may also be used to promote association through ion-dipole association. With either type of cation, a morphology is formed in which there are concentrated domains of associated ionic species (ion clusters) in a matrix of the immiscible homopolymers.

In the first type of ionic association (Type #5a), the ionizable functionalities of the two polymers are located in the pendent side groups. These polymers are prepared either through copolymerization with ion-containing monomers (or latent ion-containing monomers) or through subsequent grafting with such

Table 5.7 Ionic copolymer formation processes (Adapted from Brown 1992a)

Summary of characteristics

Only chains bearing reactive functionality participate in copolymer-forming reactions

In theory, it is possible to form block, graft, or cross-linked copolymers by ionic associations. However, in practice, telechelic polymers with ionic functionality at the chain ends are uncommon. Therefore, the majority of reported examples involve *cross-linked copolymer formation* between two immiscible polymers bearing pendent ionic groups

Ionic groups include carboxylic, sulfonic, and (less frequently) phosphonic acid groups. The acidic groups may be at least partially neutralized with monovalent, divalent, or trivalent metal cations, e.g., Na^+, Zn^{+2}, Al^{+3}. Ionic cross-linking of immiscible polymers bearing acidic groups may be mediated by such metal cations or by low molecular weight dibasic molecules such as diamines. Both these agents may link ions of different polymers

Masked ionomeric groups may also be used. They generate ions during melt processing. Examples include phosphonate esters that form phosphonic acid salt in the melt by transesterification with a salt, e.g., zinc stearate

monomers. Consequently, the resulting compatibilizing agents are most often cross-linked copolymers with the structure shown in Table 5.7 as Type 5a.

In a second type of ionic association (Type #5b) metal cations may mediate association between ionic groups on one polymer and neutral donor groups on a second immiscible polymer. Typical ionic groups are again carboxylic, sulfonic, and phosphonic acids. Neutral donor groups contain atoms, usually nitrogen or phosphorus, having unshared pairs of electrons capable of coordinating to metal cations. Such groups include pyridine, quinoline, and phenanthroline. These are usually introduced into a polymer via copolymerization with the vinyl analog, e.g., vinylpyridine. Again, the structure of the compatibilizing copolymer is usually cross-linked.

In a third type of ionic association (Type #5c), acidic groups such as carboxylic acids bound to one polymer may mediate interchain copolymer formation by protonation of basic groups on a second, immiscible polymer. In this case, the compatibilizing agent is again most often a cross-linked copolymer.

General discussions of the properties of polymers containing ionizable groups (ionomers) have been published (see, e.g., Kim et al. 2002; Hara and Sauer 1994;

Lundberg 1987; Rees 1986). Ionic cross-links are usually thermally reversible, which may limit the usefulness of blends containing them in certain commercial applications. Since ionomers are initially self-associated through ionic bonds, thermal reversibility of ionic cross-links in the melt is necessary to overcome homogeneous, self-cross-linking within each homopolymer before heterogeneous, interchain cross-linking can occur. Often a high degree of plasticization of the ion-containing polymer melt is required so that high processing temperatures that might lead to polymer decomposition need not be used. In some cases, polymers containing masked ionomeric functionality, i.e., chemical groups that form ionic species during extrusion, have been used to form copolymers during reactive processing. Use of masked ionomers may require lower energy during extrusion since ionic self-association does not have to be overcome before interchain copolymer formation can occur.

5.8   Polyamide Blends

Examples of polyamide blends are listed in alphabetical order of the second polymer in the blend unless otherwise noted. When copolymer characterization was not performed, the structure of the compatibilizing copolymer is inferred from the functionality location on each of the two polymers. In some cases, more than one type of compatibilizing copolymer may have formed.

Many of the copolymer-forming reactions employed to compatibilize PA blends with a second immiscible polymer have been studied by Orr et al. (2001) who determined that the order of increasing reactivity in functionalized polymer pairs is acid/amine, hydroxyl/(anhydride or acid), aromatic amine/epoxy, aliphatic amine/epoxy, acid/oxazoline, acid/epoxy, aromatic amine/anhydride, and aliphatic amine/anhydride (most reactive).

5.8.1   Polyamide + Polyamide Blends

5.8.1.1 Copolymer Formation by Redistribution Reaction
Examples of copolymer formation by redistribution reactions (sometimes referred to as transreactions) in PA/PA blends are given in Table 5.8. In related work, Liu and Donovan (1995) failed to find evidence for transamidation in PA-6 blends with an aromatic polyamide during molding and annealing. Aspects of transreactions in PA/PA blends have been described in Eersels et al. (1999) and in portions of other chapters included in Fakirov (1999) (transreactions in condensation polymers).

5.8.1.2 Copolymer Formation by Amine + Carboxylic Acid Reaction: Blends Containing a Condensing Agent
Aharoni et al. (1984) and Aharoni (1983) have shown that blends of immiscible polyamides may be compatibilized through copolymer formation mediated by addition of a phosphite condensing agent. A block copolymer results when the phosphite-activated end-group of one PA reacts at the phase interface with a

nucleophilic end-group on the second PA. The reaction also produces a secondary phosphite by-product. The relative proportions of copolymer vs. simple chain-extended PA may depend upon the relative solubility of the condensing agent in each of the immiscible polymer phases. For example, blends of 95-50 parts PA-6 were extruded using an SSE at 265–315 °C with 5-50 parts PA-11 (or PA-12 or PA-66 or PA-6T) in the presence of 0-1 part triphenyl phosphite or other trialkyl phosphite. Copolymer-containing blends were characterized by selective solvent extraction, FTIR, ^{13}C NMR, and ^{31}P NMR. Model compound studies were done to understand the mechanism of copolymer formation.

5.8.1.3 Copolymer Formation by Amine + Anhydride Reaction: Blends Containing a Coupling Agent

Xie and Yang (2004) have prepared blends of PA-6 (70 parts) and PA-12,12 (30 parts) through addition of SEBS-g-MA (15 wt%) which may serve as a coupling agent between the two PA. Blend characterization included SEM.

5.8.2   Polyamide + Polyester (or Polycarbonate) Blends

5.8.2.1 Copolymer Formation by Amine + Anhydride Reaction

Qu et al. (2008) reported blends of PA-6 with PET compatibilized through addition of ethylene-acrylate-maleic anhydride terpolymer.

John and Bhattacharya (2000) reported that PBT may be modified by extrusion with MA. The modified PBT forms compatibilized blends with PA-66 characterized by FTIR, ^{13}C NMR, SEM, and mechanical properties.

PA/PC ternary blends have also been compatibilized through copolymer formation between PA amine end-groups and anhydride-functionalized styrene copolymer. Kim et al. (1999a) employed SAN-co-MA in PA-6,12/PC blends. Lee et al. (1999b) and Horiuchi et al. (1996, 1997a, b, c) employed SEBS-g-MA with PA-6/PC blends.

PA/PC blends have also been compatibilized by block copolymer formation through reaction of PA amine end-groups with PC anhydride end-groups (Hathaway and Pyles 1988, 1989). PC phenolic end-groups were anhydride-functionalized by reaction with trimellitic anhydride acid chloride. Extruded blends of PA-6 and PC were characterized by selective solvent extraction and mechanical properties of test parts. An amorphous polyamide could also be compatibilized with PC using this strategy.

5.8.2.2 Copolymer Formation by Amine + Carboxylic Acid Reaction: Blends Containing a Condensing Agent

PA/PEST blends have been compatibilized through block copolymer formation mediated by addition of a phosphite condensing agent (Aharoni et al. 1984; Aharoni 1983; Aharoni and Largman 1983). Block copolymer results when the phosphite-activated end-group of a PEST (or PA) reacts with a nucleophilic end-group on a PA (or PEST) at the phase interface with generation of secondary phosphite by-product. The relative proportions of copolymer vs. simple chain-extended PA or PEST may depend upon the relative solubility of condensing agent in each of the immiscible polymer phases. For example, blends of 95-5 parts PA-6 (or PA-66 or PA-12) were extruded using an SSE at 265–315 °C with 5-95 parts PET (or PBT or PCT) in the presence of 0-1 part triphenyl phosphite or trialkyl phosphite. Copolymer-containing blends were characterized by morphology, viscosity, selective solvent extraction, FTIR, ^{13}C NMR, and ^{31}P NMR. Model compound studies were done to understand the mechanism of copolymer formation. Various other PEST and PA resins were also used.

5.8.2.3 Copolymer Formation by Carboxylic Acid + Epoxide Reaction: Blends Containing a Coupling Agent

As shown in Table 5.9, PA/PEST blends can be compatibilized through block copolymer formation mediated by addition of a multifunctional epoxide coupling agent. The coupling agent may react with nucleophilic end-groups on each of the two immiscible polymers at the phase interface to give a block copolymer containing the coupling agent as linking group. The relative proportions of copolymer vs. simple chain-extended PA or PEST may depend upon the relative solubility of coupling agent in each of the immiscible polymer phases. See, e.g., Jeziórska (2005) wherein a bis-oxazoline coupling agent was used, but the predominant reaction was PEST chain extension.

5.8.2.4 Copolymer Formation by Degradative Process

Examples of compatibilizing copolymer formation in PA/PEST blends by reaction of PA end-groups with PEST main-chain units by a degradative process (including PA/PC blends) are given in Table 5.10. The degradative process in this instance may also be considered a transreaction. Reviews of transreactions in PA/PEST blends include those described in chapters of Fakirov (1999) (transreactions in condensation polymers).

5.8.3 Polyamide + Polyesteramide LCP + Polyolefin Blends

5.8.3.1 Copolymer Formation by Amine + Anhydride Reaction

Seo (1997) prepared compatibilized PA blends with LCP polyesteramide (Hoechst Vectra® B950) in the presence of anhydride-functionalized polyolefin. Specifically, 60 parts PA-6 was mixed with 25 parts LCP and 15 parts EPDM-g-MA in a TSE at 290 °C. The blend was characterized by SEM, optical microscopy, Raman spectroscopy, mechanical properties, selective solvent extraction, and FTIR.

5.8.4 Polyamide + Polyester LCP + Polypropylene Blends

5.8.4.1 Copolymer Formation by Amine + Anhydride Reaction

Tjong and Meng (1997) have described PA/LCP polyester blends with improved properties through addition of anhydride-terminated PP-MA. A block copolymer may form between PA amine end-groups and anhydride-terminated PP. For example, 86 parts PA-6 was mixed in an internal mixer with 14 parts PP-MA at 220 °C followed by injection molding with 5-40 parts LCP (Hoechst Vectra® A950). The blends were characterized by torque rheometry, mechanical properties, DMA, and SEM.

5.8.5 Polyamide + Polyethersulfone Blends

Kanomata et al. (2011) prepared compatibilized blends of PA-6 and polyethersulfone using PES having hydroxyphenyl end-groups. Blends prepared in a Brabender mixer were characterized using TEM and torque rheometry in comparison with control blends.

Weber and Güntherberg (1999) have prepared compatibilized blends of PA and polyethersulfone in the presence of S-MA-(N-phenylmaleimide) terpolymer. In the examples, the PA was derived either from hexamethylenediamine-isophthalic acid or from hexamethylenediamine-caprolactam-terephthalic acid. Blends comprising PA, an amine-terminated polyethersulfone, and S-MA-(N-phenylmaleimide) ter-polymer prepared in a Haake mixer were characterized using mechanical properties testing, selective solvent extraction, DSC, and Vicat B test. Blends optionally contained phenoxy resin.

5.8.6 Polyamide + Polyolefin Blends (Excepting Polypropylene)

Blends in these sections include those with either a single PA or a mixture of semicrystalline PAs or a mixture of amorphous and semicrystalline PAs.

5.8.6.1 Copolymer Formation by Amide-Ester Exchange
Graft copolymer compatibilizing agents have been prepared by direct reaction (Table 5.11) through amide-ester exchange reaction between polyamide amine end-groups and pendent ester groups on polyolefin copolymers such as EEA. In these cases, a low molecular weight alcohol is generated as a by-product.

5.8.6.2 Copolymer Formation by Amine + Anhydride Reaction
The most common method for compatibilizing PA/amorphous polyolefin blends involves graft copolymer formation by reaction of polyamide amine end-groups

with pendent anhydride groups on an appropriate polyolefin to form a compatibilizing copolymer linked through an imide bond. Anhydride groups may be incorporated into suitable POs through grafting or through copolymerization with maleic anhydride, citraconic anhydride, itaconic anhydride, and congeners or through grafting or copolymerization with potentially latent anhydrides such as vicinal diacids or acid-esters including fumaric acid, maleic acid monoalkyl ester, and congeners. Selected examples are listed in Table 5.12.

5.8.6.3 Copolymer Formation by Amine + Carboxylic Acid Reaction

As shown by examples listed in Table 5.13, PA/PO blends have been compatibilized through block copolymer formation between PA amine end-groups and terminal carboxylic acid groups of polyolefins. PA blends with oxidized PE should fall into this category since carboxylic acid groups are believed to be located at PE chain ends (see El'darov et al. 1996).

Compatibilized PA/PO blends have also been prepared by graft copolymer formation between the amine end-groups of PA and PO pendent carboxylic acid groups to give a new amide linkage (Table 5.14). Water is the by-product of this reaction. The work by Aharoni is noteworthy in that it employs a condensing agent to effect copolymer formation between polyamide end-groups and pendent carboxylic acid groups on EAA.

Mascia and Hashim (1997, 1998) have prepared compatibilized blends of PA with PVDF by using carboxylic acid-functionalized PVDF. In an example, 20 parts PA-6 was combined with 80 parts PVDF-g-methacrylic acid (10 % MAA) in an internal mixer at 240 °C. The graft copolymer-containing blend was characterized by SEM, FTIR, mechanical properties, selective solvent extraction, and rheology. The effects of adding zinc acetate were studied.

5.8.6.5 Copolymer Formation by Miscellaneous Reactions

Miscellaneous compatibilization methods belonging to this category are listed in Table 5.16. Chen and Wang (2001) reported that pan-milling a blend of PA-6 and PP resulted in chain scission and subsequent copolymer formation resulting in a blend with improved properties compared to the same blend prepared by extrusion. Li et al. (1993) have shown that PA-PO copolymer may be formed through displacement reaction between PA amine end-groups and benzylic bromide groups

PA-6 (100-0) or PA-6,66,610 terpolymer or PA-69/ chlorinated PE (0-100)/L101 RI	Internal mixer at 225 °C/selective solvent extraction/FTIR/mechanical properties/ also blends containing m-phenylene bismaleimide or trimethylolpropane triacrylate + RI	Coran and Patel 1983a
PA-66 (2.7 parts)/EA-BA-vinyl benzyl chloride copolymer (0.9 parts; 0.23–0.33 % reactive chloride)	SSE at 280 °C/multiple pass extrusion/ mechanical properties/also used vinyl chloroacetate as reactive chloride source	Moncur 1982

pendent on brominated poly(isobutylene-*co-p*-methylstyrene) (see also Bhadane et al. 2008, 2011; and Tsou et al. 2009, 2011). Coran and Patel (1983a) suggest that PA-PO copolymer may be formed by a displacement reaction between PA amine end-groups and PO chloride groups, simultaneous with dynamic vulcanization of the PO phase. Moncur (1982) reported that PA-PO copolymer may form through PA amine end-group displacement of chloride from a PO copolymer bearing reactive chloride.

5.8.7   Polyamide + Polyolefin + Polypropylene Blends

5.8.7.1 Copolymer Formation by Amine + Carboxylic Acid Reaction
Favis (1994) and Willis and Favis (1988) prepared compatibilized PA blends with PP and carboxylic acid-functionalized EMAA ionomer. Blends containing 90-10 parts PA-6, 0-30 parts EMAA ionomer, and 10-90 parts PP were combined in an internal mixer at 250 °C and characterized by torque rheometry and SEM. Dispersed phase particle size vs. interfacial modifier concentration was determined. Emulsification curves were constructed. Effects of mixing protocol on blend properties were studied. Blends were also prepared containing HDPE in place of PP.

5.8.7.2 Copolymer Formation by Amine + Anhydride Reaction
PA/PP blends have been compatibilized through graft copolymer formation between polyamide amine end-groups and pendent anhydride groups on a functionalized polyolefin as exemplified in Table 5.17.

Chen and White (1993) and Chen et al. (1988) have reported properties for blends containing 75-25 parts PA-6 (or PA-11), 25-75 parts LDPE (or HDPE), and 0-5 parts PP-MA. The blends were prepared in an SSE at 200–230 °C and characterized by mechanical properties and DSC. Morphology and capillary rheometry were done before and after annealing. Interfacial tension measurements for the blends were also reported.

5.8.7.3 Copolymer Formation by Amine or Carboxylic Acid + Epoxide Reaction
As shown in Table 5.18, PA/PP blends can be compatibilized through graft copolymer formation between polyamide amine end-groups and pendent epoxide groups

Table 5.17 PA/PO/PP blends: copolymer formation by amine + anhydride reaction

on a functionalized PO. Since there are multiple epoxide sites on the polyolefin, some cross-linked copolymer may result as well if the PA is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon blend composition and processing conditions.

5.8.8 Polyamide + Polyolefin + Styrene Copolymer Blends

5.8.8.1 Copolymer Formation by Amide-Ester Exchange

Horak et al. (1997) prepared compatibilized PA blends with ABS in the presence of polyacrylate copolymer bearing pendent ester groups. A graft copolymer is obtained when PA amine end-groups undergo transreaction with the pendent ester groups. In an example, 50-45 parts PA-6 was mixed with 45-50 parts ABS and 0-10 parts MMA-co-AN (80 % MMA) in an internal mixer at 240 °C. The blend was characterized by SEM, WAXS, and mechanical properties. The effects of premixing PA + MMA-co-AN or of adding dibutyltin dilaurate or Ti(OBu)$_4$ catalyst were examined.

5.8.8.2 Copolymer Formation by Amine + Anhydride Reaction

As shown in Table 5.19, PA/PO blends have been compatibilized through graft copolymer formation between polyamide amine end-groups and pendent anhydride groups on a functionalized styrene copolymer or alternatively through copolymer formation between PA and anhydride-functionalized PO in the presence of PS or a styrene copolymer.

5.8.8.3 Copolymer Formation by Amine or Carboxylic Acid + Epoxide Reaction

Huang et al. (2011) prepared blends of PA-6 with ABS in the presence of ethylene-acrylate-GMA copolymer. Characterization techniques included SEM, DSC, HDT, and mechanical properties.

Filippi et al. (2004) prepared blends of PA-6 with LDPE in the presence of SEBS-g-GMA. Inefficient compatibilization of PA/PE was observed in comparison to the use of SEBS-g-MA apparently due to cross-linking reactions involving both amine and carboxylic acid end-groups on PA.

An interesting study by Kudva et al. (1998) showed that PA-6/ABS blends were poorly compatibilized through graft copolymer formation between PA amine or carboxylic acid end-groups and MMA-co-GMA. Extensive characterization indicated that, although the epoxy-functionalized MMA is miscible with the SAN domain, the difunctionality of PA end-groups led to PA cross-linking rather than formation of a compatibilizing copolymer.

5.8.9 Polyamide + Polyphenylene Ether Blends

PA/PPE blends in these sections include those containing PPE-miscible PS or a functionalized PS. These blends often contain a rubbery impact modifier, such as SEBS.

5.8.9.1 Blends Containing PPE Melt Functionalized with Anhydride Groups: PA-PPE Copolymer Formation by Amine + Anhydride Reaction

Anhydride groups are readily introduced into polyphenylene ethers such as poly (2,6-dimethylphenylene ether) (PPE) by extrusion with maleic anhydride (MA) or

congeners such as fumaric acid (FA), itaconic acid, citraconic acid, and related compounds. Evidence has been presented that such anhydride groups are predominantly located along the PPE main chain and with a fraction also at chain ends (Glans and Akkapeddi 1991b). This functionality distribution depends on the type and level of functionalization agent and on the mixing protocol during extrusion processing. PPE that has been melt functionalized, for example, with FA or MA reacts with PA to give predominantly graft copolymer by reaction of anhydride pendent groups on PPE with amine end-groups of PA. There is certainly a proportion of block copolymer formation as well since some anhydride functionality may be present at the chain ends on PPE. In the examples given in Table 5.20, PPE was functionalized in either a separate extrusion step before mixing with PA or in the front section of an extruder with downstream feeding of PA.

Son et al. (2000a, b) have studied the effect of processing conditions on the morphology of PA blends with PPE compatibilized through addition of MA.

PPE has also been melt functionalized with various esters of trimellitic anhydride substituted in the 4-position (Sivavec and M?cCormick 1991). A phosphite catalyst

was used to promote transesterification and functionalization at PPE phenolic chain ends. As an example, 412 g PPE was extruded with 8 % 4-(*o*-carbophenoxyphenyl)-trimellitic anhydride and 0.5 % triphenyl phosphite on a TSE at 170–300 °C. Analysis of the extrudate showed 40 % carboxylation and 55 % capping of PPE phenolic end-groups. Extrusion of 49 parts capped PPE with 41 parts PA-66 and 10 parts SEBS provided molded test parts with Izod impact strength of 247 J/m. The PPE-PA copolymer in this case is primary block type. For melt functionalization of PPE with various trimellitamides and subsequent compatibilized blends with PA, see also Sivavec and Fukuyama (1992).

5.8.9.2 Blends Containing PPE Solution Functionalized with Anhydride Groups: PA-PPE Block Copolymer Formation by Amine + Anhydride Reaction

Campbell et al. (1990) have reported properties for compatibilized PA-PPE blends made using anhydride-terminated PPE. Anhydride-terminated PPE was made by capping PPE phenolic end-groups with trimellitic anhydride acid chloride in solution. A block copolymer may form between PA amine end-groups and PPE-anhydride during subsequent melt mixing. For example, a blend containing 49 parts

PPE-anhydride, 41 parts PA-6, and 10 parts SEBS impact modifier was extruded using a TSE at 280 °C. The copolymer-containing blend was characterized by selective solvent extraction, mechanical properties, SEM, and TEM. Ductile-brittle transition temperatures were determined. The same anhydride-terminated PPE was also used to prepare compatibilized blends with PA-66 (Aycock and Ting 1986, 1987).

5.8.9.3 Blends Containing PPE Solution or Melt Functionalized with Aryloxy Triazine Groups: PA-PPE Copolymer Formation by Amine + Ester Exchange Reaction

PPE has been functionalized in solution with a variety of chloro aryloxy triazine derivatives in the presence of a base to provide a reactive diaryloxy triazine-capped PPE (Brown 1991b, 1993). Diaryloxy triazine-capped PPE can also be prepared by melt functionalization through transesterification of the cyanuric acid phenyl ester (i.e., aryloxy triazine) with PPE phenolic end-groups (Brown 1992b). Extrusion of the functionalized PPE with an amine-functionalized polymer such as amine-terminated PA results in formation of a compatibilizing block copolymer through displacement of at least one aryloxy group from the diaryloxy triazine end-cap. Typically, a 2,6-unfunctionalized aryloxy group is displaced from the triazine end-cap during extrusion in preference to displacement of more hindered 2,6-dimethylphenoxy PPE terminal unit. The reaction may also be viewed as an esteramide exchange reaction between a cyanuric acid ester (i.e., the diaryloxy triazine terminal group on PPE) and PA-amine end-group. In one example, 41 % PA-66 extruded with 49 % diaryloxy triazine-capped PPE, and 10 % impact modifier showed Izod impact strength of 753 J/m and tensile elongation of 122 % compared to 37 J/m and 11 % for the same blend containing unfunctionalized PPE. The effect of PA amine end-group concentration on blend properties was examined.

5.8.9.4 Blends Containing PPE Functionalized with Carboxylic Acid: Copolymer Formation by Amine + Carboxylic Acid Reaction

Yates and White (1989) introduced carboxylic acid functionality into PPE by metalation in solution with alkyl lithium and treatment with carbon dioxide. Extrusion of this functionalized PPE (45 parts) with PA-66 (45 parts) and SEBS (10 parts) provided a composition which showed eightfold improvement in impact strength compared to a similar blend made with unfunctionalized PPE.

5.8.9.5 Blends Containing Functionalized PPE: PA-PPE Copolymer Formation by Amine or Carboxylic Acid + Electrophile Reaction

PA/PPE blends have been compatibilized through copolymer formation between PA amine or carboxylic acid end-groups and an electrophile-functionalized PPE (Table 5.21). Typically, the PPE is functionalized in a separate reaction either in the melt or in solution to introduce an electrophilic moiety (such as epoxide, carbodiimide, cyclic ortho ester, imide, or the like) at a phenolic end-group or along the PPE main chain or both.

5.8.9.6 Blends Containing Unfunctionalized PPE: Copolymer Formation by Coupling Agent Addition

Unfunctionalized PPE has been compatibilized with immiscible PA by addition of a coupling agent capable of reacting with both PPE and PA end-groups. In one example, 4,4′-methylenediphenyl diisocyanate (1 part) was used to compatibilize PPE (49 parts) with PA-6 (41 parts) in the presence of an impact modifier. Properties of compatibilized blends were compared to those without coupling agent and without impact modifier (Pernice et al. 1993). Similar work was performed by Chiang et al. (1998). Chiang and Chang (1998) employed a multifunctional epoxy resin for the same purpose.

5.8.9.7 Blends Containing Unfunctionalized PPE + Functionalized PS: PA-PS Copolymer Formation by Miscellaneous Reactions

Unfunctionalized PPE may be compatibilized with immiscible PA by addition of functionalized polystyrene capable of forming copolymer with PA (Table 5.22). This is a common compatibilization strategy for PPE blends since both PS itself and

functionalized polystyrenes with a relatively low level of functionality are miscible with PPE. The examples in the table include use of anhydride-, acid-, and epoxide-functionalized polystyrenes, all of which are capable of reacting with nucleophilic end-groups on PA to form a graft copolymer.

5.8.10 Polyamide + Polyphenylene Sulfide Blends

Gui et al. (2013) prepared blends of an elastomeric PA with PPS in the presence of an epoxy resin. Blend characterization techniques included rheology, FTIR, and mechanical properties.

Yamao and Kosaka (2000) have prepared compatibilized blends of PA-66 or PA-46 with an amine-functionalized PPS in the presence of either pyromellitic acid anhydride or a multifunctional epoxy resin as coupling agent. See also Ishio et al. (2011).

Blends containing PA and an anhydride-modified polyphenylene sulfide have been prepared by Kadoi et al. (1996). For example, PPS was extruded with either maleic anhydride, itaconic anhydride, or succinic anhydride to form a PPS shown to have carbonyl incorporation by FTIR after selective solvent extraction to remove unreacted anhydride. Blends of modified PPS and PA-66 were extruded at 290–310 °C and molded to provide test parts with improved properties compared to blends with unmodified PPS.

5.8.11 Polyamide + Polypropylene Blends

5.8.11.1 Copolymer Formation by Amine + Anhydride Reaction
Immiscible blends of PA and PP have been compatibilized through copolymer formation between PA amine end-groups and maleic anhydride-functionalized PP to form a new imide linkage (Table 5.23). The structure of maleic anhydride-functionalized PP has been discussed, e.g., by De Roover et al. (1995) and Sclavons et al. (1996). The authors demonstrated that the free radical initiated maleation of PP in the molten state leads to anhydride groups locating mainly at PP chain ends. Consequently, unless PP has been functionalized by a process that suppresses PP chain degradation, the reaction product of amine-terminated PA with MA-functionalized PP may be predominantly a block copolymer.

5.8.11.2 Copolymer Formation by Amine + Carboxylic Acid Reaction
As shown in Table 5.24, PA/PP blends can be compatibilized through graft copolymer formation between PA amine end-groups and pendent acid groups grafted at more than one site along the PP chain or with acid groups along a poly(acrylic acid) segment grafted at a single PP site.

5.8.11.3 Copolymer Formation by Amine or Carboxylic Acid + Epoxide or Oxazoline Reaction
Deng et al. (2007) compatibilized PA-66 blends with PP through addition of alpha-methylstyrene-GMA copolymer. Evidence was presented that the copolymer acts to functionalize PP in situ with GMA groups. PA-6 blends with PP or PE were also prepared using this method.

Pompe et al. (2002) have prepared compatibilized PA/PP blends using oxazoline-modified PP.

Zhang and Yin (1998), Xiaomin et al. (1997, 1998), and Zhang et al. (1996, 1997) have prepared compatibilized PA/PP blends by adding epoxide-grafted PP. Graft copolymers result from reaction between PA amine end-groups and pendent epoxide groups on PP (or with epoxide groups along a poly(GMA) segment grafted at a single PP site). For example, 100-15 parts PA-1010 was mixed with 0-85 parts PP and 0-25 parts PP-g-GMA in either an SSE or TSE at 200–210 °C. The resulting blends were characterized by selective solvent extraction, SEM, rheology, DSC, ESCA nitrogen analysis, FTIR, mechanical properties, and peel test. Since there may be multiple epoxide sites on the polypropylene, some cross-linked copolymer may result if the polyamide is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon blend composition and processing conditions.

5.8.11.4 Copolymer Formation by Miscellaneous Reactions

Lin and Isayev (2006) prepared blends of PA-6 and PP by treatment with high-intensity ultrasound during extrusion. Mechanical properties, crystallinity, and morphology were investigated. The competition between polymer degradation and partial in situ compatibilization was assessed.

5.8.12 Polyamide + Polypropylene + Styrene Copolymer Blends

5.8.12.1 Copolymer Formation by Amine + Anhydride Reaction

As shown by examples listed in Table 5.25, PA/PP blends have been compatibilized through graft copolymer formation between polyamide amine end-groups and pendent anhydride groups on a functionalized styrene copolymer.

5.8.13 Polyamide + Polysiloxane + Styrene Copolymer Blends

Maric et al. (2001) have studied PA blends with poly(dimethylsiloxane) (PDMS) either in binary blends of the functionalized polymers or in ternary blends with a functionalized styrene copolymer. The efficiency of copolymer formation concurrent with morphology development and stabilization was studied for reactions between PA-amine and PDMS-anhydride, between PA-amine and PDMS-epoxy, and between PA-carboxylic acid and PDMS-epoxy. The effects of relative melt viscosities on interfacial reactivity and resulting morphology were noted.

5.8.14 Polyamide + Polysulfone Blends

5.8.14.1 Copolymer Formation by Amine + Carboxylic Acid Reaction

PA blends with polysulfone have been compatibilized through graft copolymer formation between polyamide amine end-groups and pendent carboxylic acid groups on a polysulfone functionalized using 4,4′-bis(4-hydroxyphenyl)pentanoic acid (Marechal et al. 1998). Characterization was by mechanical properties and morphology. A similar strategy was used by Ibuki et al. (1999) who in addition studied anhydride-terminated or anhydride-grafted polysulfone. See also Charoensirisomboon et al. (1999a, b, 2000) and Koriyama et al. (1999) and further papers by these authors.

5.8.15 Polyamide + Polystyrene or Styrene Copolymer Blends

5.8.15.1 Copolymer Formation by Acid-Base Interaction

Villarreal et al. (2004) have prepared blends of PA-6 with PS compatibilized by addition of poly(styrene-*co*-sodium acrylate). Characterization techniques included mechanical properties and SEM. See also Rodríguez-Ríos et al. (2004) for related work.

Compatibilized blends of PA-6 with syndiotactic PS (sPS) were prepared by melt blending in the presence of sulfonated sPS (Li et al. 2002). Blends were characterized by morphology, mechanical properties, and DSC. Sulfonated sPS at a level of 20 wt% or less was reported to be miscible with sPS. For related work involving PA-6 and sulfonated PS, see Molnar and Eisenberg (1991, 1992).

5.8.15.2 Copolymer Formation by Amine + Anhydride Reaction

Immiscible blends of PA and PS or styrene copolymer have been compatibilized through graft copolymer formation between PA amine end-groups and anhydride-functionalized styrene copolymer to form a new imide linkage (Table 5.26).

PA/PS blends have also been compatibilized through block copolymer formation between amine-terminated PA and anhydride-terminated PS. Anhydride end-groups were introduced into PS through reaction of either anion-terminated PS or hydroxy-terminated PS with trimellitic anhydride acid chloride. For example, Park et al. (1992) blended 80 parts PA-6 with 10-16 parts PS and 4-10 parts anhydride-terminated PS in an internal mixer at 240 °C. The blends were characterized by torque rheometry, SEM, selective solvent extraction, DSC, morphological stability to annealing, and lap shear adhesion. The effect of mixing protocol on properties was studied. Properties were also compared to those for blends compatibilized by added PA-PS graft copolymer that had been synthesized in a separate step.

5.8.15.3 Copolymer Formation by Amine + Carboxylic Acid Reaction

Melt reactions between amine-terminated PA and carboxylic acid groups on styrene-acrylic acid copolymer have been demonstrated (Table 5.27). The initial reaction product is a graft copolymer, but longer reaction times may result in cross-linking, since the polyamides (PA-66 and PA-69) can have two amine end-groups per chain (Kuphal et al. 1991). Monoamine-terminated polyamides were reported in the same study to exhibit miscibility with SAA through hydrogen-bonding depending upon AA content. For PA-1010 blends with carboxylated PS, see Li and Li (1999).

Kausar et al. (2013) prepared blends of PS and amine-f-PS with an aramid prepared from 1,5-diaminonaphthalene and 1,4-phenylenediamine with isophthaloyl chloride. Morphological and thermophysical properties were investigated. Formation of an aramid-g-PS copolymer was proposed, perhaps through an amine-carboxylic acid reaction. For related blends of amine-f-PS and aramid, see Shabbir et al. (2008, 2010).

5.8.15.4 Copolymer Formation by Amine or Carboxylic Acid + Epoxide Reaction

Sun et al. (2005) prepared compatibilized blends of PA-6 with ABS-co-GMA. See also Singh and Gupta (2011).

Chen et al. (2003) have studied PA-6 blends with sPS compatibilized using S-co-GMA in a torque rheometer. Blends were characterized using SEM, mechanical properties, and DSC.

Chang and Hwu (1991) prepared compatibilized PA/PS blends through addition of epoxide-functionalized S-GMA copolymer. A graft copolymer

results from reaction of pendent epoxide groups with either amine or acid end-groups on PA. A blend of 50 parts PA-66, 50 parts PS, and 0-0.5 parts S-GMA (3 % GMA) was prepared on a TSE and characterized by rheology, SEM, and mechanical properties. Since there are multiple epoxide sites on S-GMA, some cross-linked copolymer may result if the polyamide is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon blend composition and processing conditions. See also Martens et al. (2004).

5.8.15.5 Copolymer Formation by Amine or Carboxylic Acid + Isocyanate Reaction

Zhang et al. (2013a) prepared compatibilized PA/PS blends through addition of an isocyanate-functionalized PS. For example, blends comprising PA-6 and PS-*co*-(3-isopropenyl-α,α-dimethylbenzene isocyanate) were characterized using FTIR, DSC, and morphology determination. The effects of different functionalized PS loading and the isocyanate level in the PS copolymer were investigated.

Yin et al. (2009b) prepared blends of PA-6 with SEBS which had been functionalized with ε-caprolactam-blocked allyl (3-isocyanate-4-tolyl) carbamate.

5.8.15.6 Copolymer Formation by Amine or Carboxylic Acid + Oxazoline Reaction

As shown in Table 5.28, blends of PA and PS have been compatibilized through graft copolymer formation between PA amine or acid end-groups and oxazoline-functionalized styrene copolymer.

5.8.16 Polyamide + Polyurethane Blends

5.8.16.1 Copolymer Formation by Carboxylic Acid or Amine + Isocyanate Reaction: Blends Containing a Coupling Agent

PA/TPU blends have been compatibilized by addition of a bis-isocyanate coupling agent that is capable of reacting with nucleophilic end-groups on both polymers to form a block copolymer. Franke et al. (1993) have extruded PA-6 (20-0 parts) with polyester-urethane (78-100 parts) using a TSE at 230 °C in the presence of 0.5-2 parts diphenylmethane diisocyanate. The coupling agent was added downstream of the extruder feed throat. The blends were characterized by TEM, SEC, DSC, DMA, and FTIR.

5.9 Polyester Blends

Examples of polyester blends not shown in earlier sections are listed in alphabetical order of the second polymer in the blend unless otherwise noted. Polycarbonate blends are also included as polyesters. When copolymer characterization was not performed, the structure of the compatibilizing copolymer is inferred from the

functionality location on each of the two polymers. In some cases, more than one type of compatibilizing copolymer may have formed.

Copolymer-forming reactions for compatibilizing immiscible blends, some of which are applicable to PEST blends, have been studied by Orr et al. (2001) who determined that the order of increasing reactivity in functionalized polymer pairs is acid/amine, hydroxyl/ (anhydride or acid), aromatic amine/epoxy, aliphatic amine/epoxy, acid/oxazoline, acid/ epoxy, aromatic amine/anhydride, and aliphatic amine/anhydride (most reactive).

For reviews of reactive compatibilization of poly(lactic acid) (sometimes referred to as polylactide) with other immiscible polymers, see Imre and Pukanszky (2013) and Liu and Zhang (2011).

5.9.1 Polyester + Polyester (or Polycarbonate) Blends

5.9.1.1 Copolymer Formation by Alcohol + Carboxylic Acid Reaction: Blends Containing a Condensing Agent

As shown in Table 5.29, blends of immiscible polyesters may be compatibilized through copolymer formation mediated by addition of a phosphite condensing agent. Block copolymer results when the phosphite-activated end-group of one PEST reacts with a nucleophilic end-group of another PEST. The reaction takes place at the phase interface. A secondary phosphite is a by-product. The relative proportions of copolymer vs. simple chain-extended PEST may depend upon the relative solubility of condensing agent in each of the immiscible polymer phases.

5.9.1.2 Copolymer Formation by Carboxylic Acid + Epoxide or Oxazoline or Isocyanate Reaction: Blends Containing a Coupling Agent

Blends of poly(lactic acid) and poly((butylene-adipate)-*co*-terephthalate) have been prepared with the addition of either 2,2′-(1,3-phenylene)-bis(2-oxazoline) or phthalic anhydride (Dong et al. 2013). Blends were characterized using DSC, SEM, and mechanical properties.

Polycarbonate blends with poly(lactic acid) have been compatibilized through addition of bis(isocyanate), bis(carbodiimide), oxazoline-f-PS, or epoxy resin (Wang et al. 2012e; Mukawa et al. 2011).

Blends of aliphatic-aromatic polyester (75-25 parts) and poly(lactic acid) (25-75 parts) have been compatibilized through extrusion with a copolymer of styrene, GMA, and isomethacrylates (0-5 parts) (Hale 2008). Polyesters included those derived from adipic acid-terephthalic acid-butanediol. Mechanical properties were greatly improved compared to those for blends with no compatibilizer.

Poly(ε-caprolactone) blends with poly(lactic acid) have been compatibilized in the presence of polyepoxide or either di- or trisisocyanate (Harada et al. 2008).

Harada et al. (2007) have prepared compatibilized blends of PLA with poly (butylene succinate) through addition of lysine trisisocyanate. Characterization techniques included MFR, mechanical properties, SEC, and laser scanning confocal microscopy.

The crystallization behavior of PTT-PC blends in the presence of either epoxy resin or EPDM-g-GMA has been studied by Xue et al. (2005).

PET-PEN blends have been compatibilized in the presence of a bis-oxazoline coupling agent (Yang et al. 2002b).

Ju et al. (2000) prepared compatibilized blends of polyarylate with an LCP in the presence of tetraglycidyl-4,4′-diaminodiphenyl methane coupling agent.

Chin and Chang (1997) and Chin et al. (1996) have compatibilized blends of immiscible PEST through addition of a multifunctional epoxide coupling agent capable of reacting with nucleophilic end-groups on each of the two immiscible PEST at the phase interface to give a block copolymer containing the coupling agent as linking group. In one example 100-85 parts PET was extruded using a TSE at 270–285 °C with 0-15 parts LCP (Hoechst Vectra® A900) and 0-2 parts tetrafunctional epoxy resin. The blends were characterized by torque rheometry, capillary rheometry, DSC, SEM, and FTIR. Mechanical properties were determined vs. composition and morphology. Ethyltriphenylphosphonium bromide was added as a catalyst to promote the reaction of polyester acid or alcohol end-groups with epoxy resin. The relative proportions of copolymer vs. simple chain-extended PEST depend at least partly upon the relative solubilities of coupling agent and catalyst in each of the immiscible polymer phases. See also Tjong and Meng (1999) and Dekkers et al. (1992).

5.9.1.3 Copolymer Formation by Radical Coupling

Krishnaswamy et al. (2013) prepared blends of poly(lactic acid) with poly (3-hydroxybutyrate-*co*-4-hydroxybutyrate) containing 17–40 wt% 4-hydroxybutyrate in the presence of radical initiator. Blends were characterized by melt strength, viscosity, and mechanical properties. Blend properties were compared to control blends without RI.

Wang et al. (2009a) have compatibilized the biodegradable polymers poly(L-lactic acid) and poly(butylene succinate) in the presence of DCP radical initiator (0.05–0.2 phr). For related work, see Lan et al. (2013).

For blends of poly(butylene succinate) with poly(hydroxybutyrate-*co*-hydroxyvalerate or poly(hydroxybutyrate) compatibilized in the presence of radical initiator, see Ma et al. (2012a).

Blends of poly(lactic acid) and poly(butylene-adipate-*co*-terephthalate) were prepared in the presence of varying concentrations of L101 RI by Coltelli et al. (2010). The blends were characterized by morphology, rheology, and mechanical properties.

Other radical-radical coupling reactions used to compatibilize blends of immiscible polyesters include those by Avella et al. (1996); Immirzi et al. (1994); and Cavallaro et al. (1993). Specifically, 70-30 parts poly(hydroxybutyrate-*co*-hydroxyvalerate) (4 mol% valerate) or poly(hydroxybutyrate) was mixed with 30-70 parts PCL in an internal mixer at 100 °C or 160 °C in the presence of 0-0.5 parts DCP or DBP radical initiator. Blends were characterized by SEM, mechanical properties, selective solvent extraction, and FTIR.

5.9.1.4 Copolymer Formation by Redistribution Reaction

Brief reviews covering redistribution reactions (often referred to as transesterification reactions or simply transreactions) in polyester and in polycarbonate binary blends have been prepared by Porter et al. (1989) and Porter and Wang (1992). Carrot et al. (2007) have surveyed more recent knowledge relating to PET/PC blends. Pesneau et al. (2001) have studied the relative effectiveness of different transesterification catalysts, finding that dibutyltin oxide had the highest activity of those studied. Other reviews of transreactions in polyester blends include Montaudo et al. (1999), Pilati et al. (1999), Economy et al. (1999), and also portions of other chapters in Fakirov (1999) (transreactions in condensation polymers).

Selected references for redistribution processes in PEST/PEST blends are listed in Table 5.30. Early studies of these processes focused on measuring the extent of redistribution under specific processing conditions rather than on producing compatibilized polymer blends with an attractive balance of properties. A number of other studies have reported the limits of miscibility for certain melt-mixed polyester pairs in the absence of transesterification – see, for example, the NMR study of PC/PET blends (Abis et al. 1994). Table 5.30 omits references in which transesterification in PEST/PEST blends is brought about under static conditions either by annealing or heating in a DSC chamber.

5.9.2 Polyester + Polyether Blends (Including Polycarbonate)

5.9.2.1 Copolymer Formation by Transesterification

A graft copolymer may be formed through transesterification between pendent hydroxy groups on phenoxy polyether resin and ester linkages in the chains of an immiscible polyester or polycarbonate phase (Table 5.31). Since the product is a graft copolymer accompanied by a low molecular weight fragment from the polyester, this is a degradative copolymer-forming process. The initial product of the transreaction is a graft copolymer as the alcohol reacts into the polyester chain. Longer reaction time may result in a cross-linked copolymer since the pendent polyester segment is capable of further reaction with OH on a different phenoxy chain. These types of blends have also been prepared by solution casting followed by annealing. Blends of LCP with phenoxy resin provide an example (Kodama 1992).

5.9.3 Polyester + Polyetherimide Blends

5.9.3.1 Copolymer Formation through Coupling Agent Addition
PEST blends with PEI (derived from 2,2-bis[4-(3,4-dicarboxyphenoxy)phenyl] propane dianhydride and meta-phenylene diamine) have been compatibilized in the presence of various multifunctional epoxy resins and a catalyst (Brown et al. 2000b). PEST types included mixtures of PCT and PETG; catalysts included sodium stearate. Mechanical properties and HDT were compared to properties for blends without either epoxy resin or catalyst.

Silvi et al. (1997) have compatibilized an immiscible blend of LCP and similar PEI through copolymer formation in the presence of a coupling agent. Representative coupling agents included PE-co-GMA and the *o*-cresol novolak reaction product with epichlorohydrin. Mechanical properties and HDT were compared to properties for blends without polyepoxide. PEI could be diluted with polyarylate, polyestercarbonate, PET, or PEN.

5.9.3.2 Copolymer Formation by Transreaction
A copolymer may be formed through transreaction between a bisphenol A polyestercarbonate resin and imide linkages in the chains of an immiscible PEI phase in the presence of a catalyst (Brown et al. 1998b). This is a degradative

process initially forming block copolymer and eventually random copolymer as chains continue to react. The final product may be transparent. Various phosphite catalysts were used. PC and polyarylate could be used in place of polyestercarbonate. Bookbinder and Sybert (1992) prepared compatibilized blends of Hoechst Vectra® A950 with amine-terminated PEI. A copolymer may form through reaction of PEI amine groups with main-chain ester units of LCP in a degradative process.

5.9.4 Polyester + Polyethersulfone Blends

Kanomata et al. (2011) prepared compatibilized blends of either PBT or PET and polyethersulfone using PES having hydroxyphenyl end-groups. Blends prepared in a Brabender mixer were characterized using TEM and torque rheometry in comparison with control blends.

5.9.5 Polyester + Polyolefin Blends (Excepting Polypropylene)

5.9.5.1 Copolymer Formation by Alcohol + Anhydride Reaction
As shown in Table 5.32, PEST/PO blends have been compatibilized through copolymer formation between polyester alcohol end-groups and pendent anhydride

functionality on a polyolefin such as maleic anhydride-grafted polyolefin. Because this alcohol-anhydride reaction is reversible with the equilibrium lying on the side of unreacted anhydride, only a relatively small amount of copolymer may be formed. Consequently, the dispersed polymer phase may not be well stabilized against coalescence upon further thermal treatment (for a discussion, see, e.g., Sun et al. (1996) and Boyer et al. (2005)). Alternatively, at least some copolymer may be formed by a degradative mechanism through transesterification between polyester main-chain linkages and a low concentration of pendent acid groups in anhydride functionalized polyolefin. In addition copolymer may possibly form through anhydride exchange between PEST-CO_2H end-groups and PO-anhydride. Alternatively, it may also happen that compatibilization results from hydrogen-bonding interaction.

5.9.5.2 Copolymer Formation by Carboxylic Acid + Cyclic Ortho Ester or Epoxide Reaction

Table 5.33 shows examples of PEST/PO blends that have been compatibilized through graft copolymer formation either by reaction of polyester carboxylic acid end-groups with either pendent cyclic ortho ester or pendent epoxide groups on a polyolefin or by reaction of polycarbonate epoxide end-groups with carboxylic acid groups on a polyolefin. In any case, the copolymer is joined through a new ester linkage. Since there may be multiple electrophilic sites or multiple carboxylic acid sites on the polyolefin, some cross-linked copolymer may result if the polyester is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon blend composition and processing conditions.

When the new ester linkage is formed, a secondary alcohol group forms as well through ring opening of the epoxide group. The new secondary alcohol may also react with polyester main-chain linkages to form copolymer through a degradative transesterification process. Consequently, two very different types of copolymer may be formed in certain blends of this section.

Perret et al. (1996) have encapsulated a third polymer within a PO phase dispersed in a PEST matrix; the third polymer was PA-66, having higher Tm than the matrix. In this ternary blend, the epoxy-functionalized PO was capable of reacting with terminal functional groups on both of the other two polymers. The blend was formed either by preextrusion of PO with PA, followed by extrusion with PEST, or by feeding PO and PA to the feed throat of an extruder, then adding PEST downstream. The morphology showed a PEST matrix in which shells of PO

surround cores of PA. The blend was an impact-modified PEST with higher impact strength than the corresponding blend containing epoxy-functionalized PO alone. One reason for the improvement may be that the volume fraction of PO impact modifier was effectively increased by inclusion of PA core. Copolymer formation between PEST and PO may also be combined with subsequent dynamic vulcanization of the PO phase in either the same or a separate processing step (Okamoto et al. 1994; Moffett and Dekkers 1992).

5.9.5.3 Copolymer Formation by Carboxylic Acid + Oxazoline Reaction

PEST/PO blends have been compatibilized through graft copolymer formation by reaction of polyester carboxylic acid end-groups with pendent oxazoline groups on an appropriate PO. The copolymer contains a new esteramide linkage. Wörner et al. (1997) have blended 0-20 parts oxazoline-functionalized rubbers containing more than one oxazoline group per chain with 100-80 parts acid-terminated PBT in

an internal mixer at 240 °C. Oxazoline-functionalized B-AN or E-B-AN was used. The copolymer structure was initially a graft copolymer. However, if additional oxazoline groups on the rubber react with additional PBT acid groups, then a cross-linked copolymer structure can arise. The blends of Wörner et al. were characterized by torque rheometry, mechanical properties, DMA, SEM, DSC, and level of oxazoline groups on the rubber (fraction of nitrile groups on AN-containing rubber that had been converted to oxazoline groups). Improved blend properties were obtained through addition of a bis-oxazoline chain extender for PBT.

5.9.5.4 Copolymer Formation through Coupling Agent Addition

Zhang et al. (2013c) prepared compatibilized blends of poly(lactic acid) and EVAl in the presence of a multifunctional epoxy resin and zinc stearate. Characterization techniques included morphology, dynamic light scattering, and barrier properties.

Compatibilized blends of PBT with EVAc have been prepared through addition of 2,2′-(1,3-phenylene)-bis(2-oxazoline) coupling agent (Scaffaro and La Mantia 2006; Scaffaro et al. 2004). The effect of EAA addition was studied. Evidence was presented that chain extension of the reactive polymers by the coupling agent was negligible. Blends characterization included mechanical properties and morphology in comparison to uncompatibilized blends.

Zhang and Hourston (1999) prepared blends of PBT and either LDPE or EPDM in the presence of a bismaleimide in a Haake mixer. A copolymer formation mechanism involving radical coupling was proposed.

Okamoto and Inoue (1993) have compatibilized an immiscible blend of terminally functionalized PEST and PO through block copolymer formation in the presence of a coupling agent. For example, 80 parts hydroxy-terminated PCL was mixed in a custom melt reactor at 120 °C with 20 parts carboxyl-terminated butadiene oligomer (or carboxyl-terminated NBR) in the presence of 0-1 part aminopropyltriethoxysilane coupling agent. Morphology development could be followed through analysis of successive samples taken periodically from the reactor. Samples were characterized by light-scattering photometry, ellipsometric analysis, and GPC.

5.9.5.5 Copolymer Formation by Diels-Alder Reaction

The benzocyclobutene functionality can thermally form an intermediate that can function as the diene partner in a classical Diels-Alder ring-forming reaction with an olefin. When benzocyclobutene and olefin are located on two immiscible polymers, the reaction can in theory lead to copolymer formation. Dean (1993) has postulated that copolymer is formed when 50-15 parts benzocyclobutene-terminated polyarylate is mixed with olefin-containing EPDM in an internal mixer at 265 °C. Blends were characterized by mechanical properties and DMTA.

5.9.5.6 Copolymer Formation by Transesterification

Polyester-polyolefin copolymer compatibilizers have been made through catalyzed or thermal transesterification of polyester or polycarbonate or polyestercarbonate main-chain ester linkages with pendent ester or acid groups (acidolysis) in a polyolefin copolymer such as EVAc or EMAA (Table 5.34). In a separate example,

Poly(hydroxybutyrate) (80)/ EP-g-MA (4 % MA) (20) or EP-g-dibutyl maleate or partially hydrolyzed EVAc	Internal mixer at 180 °C/mechanical properties/SEM	Abbate et al. 1991

polyester-polyolefin copolymer has been formed through transesterification between a carbonate ester linkage and an anhydride in a second polymer chain. All these examples represent degradative copolymer formation since the PEST chains are cleaved and the average molecular weight of the new copolymer is less than the sum of the average molecular weights of the two immiscible polymers.

In Table 5.34, Debier et al. (1995, 1997) present evidence that copolymer formation occurs in PC + PMMA blends through transesterification between PC carbonate ester linkages and acid groups produced by hydrolysis on PMMA. The table omits references in which transesterification in appropriate polyester-polyolefin blends is brought about under static conditions either by annealing or heating in a DSC chamber.

A block copolymer may be formed through transesterification between nucleophilic end-groups of one polymer and ester linkages in the chains of an immiscible polyester phase. Sek and Kaczmarczyk (1997) and Minkova et al. (1996) used oxidized PE as the acid-terminated polymer and an LCP with ester linkages susceptible to transesterification with PE acid end-groups. Since the product is a block copolymer accompanied by low molecular weight fragments from the polyester, this type of copolymer-forming reaction is degradative. The process is not redistributive since the PE chain cannot participate in redistribution. In an example, 50 parts LCP polyester (a copolymer of sebacic acid, dihydroxybiphenyl, and p-hydroxybenzoic acid) and 50 parts oxidized PE were mixed in an internal mixer at 240 °C. The blend was characterized by selective solvent extraction, FTIR, DSC, and SEM. Optionally, $Ti(OBu)_4$ catalyst was added to promote reaction.

5.9.5.7 Copolymer Formation by Miscellaneous Reactions

Chen et al. (2013a) prepared blends of PCL with NR in the presence of peroxide which, in addition to cross-linking NR, served to enhance the compatibility of PCL and NR as shown by FTIR and SEM. The blend was studied as a shape-memory composition.

Hachemi et al. (2013) prepared blends of poly(lactic acid) with PVC in the presence of DCP RI and MA. Characterization techniques included DSC, TGA, SEM, and mechanical properties.

Gramlich et al. (2010) prepared blends of maleimide-terminated poly(lactic acid) with conjugated soybean oil. A compatibilizing copolymer was formed through Diels-Alder reaction between maleimide double bond and diene units in conjugated soybean chains. Blends were characterized by morphology and mechanical properties.

Pan et al. (2007) prepared compatibilized blends of PC with EMAc-g-GMA. Characterization concluded that copolymer was formed through reaction of PC phenolic end-groups and epoxy groups.

Jung et al. (2003) have prepared compatibilized blends of PET with LDPE comparing a variety of functionalized LDPEs as compatibilizing agents, including LDPE-co-AA, LDPE-f-MA, LDPE-f-GMA, and LDPE functionalized with either masked or naked NCO monomers.

Park et al. (1998b) have prepared compatibilized blends of PET with PE using PE grafted with 2-hydroxyethyl methacrylate-isophorone diisocyanate. See also Park et al. (2002), Bae et al. (2001), and Kim et al. (2000a, b). For PBT/ethylene-octene copolymer blends compatibilized using masked isocyanate, see Yin et al. (2009a).

Hourston et al. (1991) have prepared compositions of 60-0 parts PBT and 16-40 parts EPDM in the presence of 0-60 parts copolymer of PBT with maleate ester (3.5 % maleate) using a TSE at 255 °C. A compatibilizing copolymer was postulated from the cross-linking reaction between maleate olefinic groups and EPDM olefinic groups. Blends were characterized by mechanical properties and TEM. Model studies were performed to understand the cross-linking process. Blends were also prepared using an internal mixer at 250 °C.

5.9.6   Polyester + Polyolefin + Polypropylene Blends

5.9.6.1 Copolymer Formation by Carboxylic Acid + Epoxide Reaction

PEST/PP blends have been compatibilized through graft copolymer formation by reaction of polyester carboxylic acid end-groups with pendent epoxide groups on an appropriate PO with potentially some miscibility with PP (Table 5.35). The copolymer is joined through a new ester linkage. Some cross-linked copolymer may also form. When the new ester linkage is formed, a secondary alcohol group forms as well. The new secondary alcohol may also react with polyester main-chain linkages to form copolymer through a degradative transesterification process.

anhydride functionality on a styrene copolymer are shown in Table 5.36. Because the alcohol-anhydride reaction is reversible (with the equilibrium lying on the side of unreacted anhydride), only a relatively small amount of copolymer may be formed. In consequence, the dispersed phase polymer may not be well stabilized against coalescence upon further thermal treatment (for a discussion, see, e.g., Sun et al. (1996) and Boyer et al. (2005)). Alternatively, at least some copolymer may be formed by a degradative mechanism through transesterification between PEST main-chain linkages and a low concentration of pendent acid groups in anhydride-functionalized styrene copolymer or in anhydride-functionalized PO. In addition copolymer may possibly form through anhydride exchange between PEST-CO_2H end-groups and either anhydride-functionalized styrene copolymer or anhydride-functionalized PO. Alternatively, it may also happen that compatibilization results from H-bonding interaction. For related work in PET/PP blends compatibilized using SEBS-g-MA (or PP-g-MA), see Papadopoulou and Kalfoglou (2000).

5.9.7.2 Copolymer Formation by Carboxylic Acid + Epoxide Reaction

Larocca et al. (2010) prepared blends of PBT and SAN in the presence of MMA-co-EA-co-GMA. Blend characterization techniques included morphology. PBT samples with different molecular weight were used to change the PBT/SAN viscosity ratio. In related work, AES was used in place of SAN (Larocca et al. 2005).

5.9.8 Polyester + Polyphenylene Ether Blends

PEST/PPE blends in these sections include those containing PPE-miscible PS or a functionalized PS. These blends often contain a rubbery impact modifier, such as SEBS, as well.

5.9.8.1 Blends Containing Functionalized PPE: PEST-PPE Copolymer Formation by Degradative Process

Furuta et al. (1994) have prepared compatibilized blends of LCP with an amine-functionalized PPE. For example, an LCP derived from p-acetoxybenzoic acid, terephthalic acid, isophthalic acid, and 4,4′-diacetoxydiphenyl was blended with an amine-functionalized PPE to provide a blend with improved properties compared to those with unfunctionalized PPE. PPE was melt functionalized with either p-aminostyrene, diallylamine, allylamine, or vinylimidazole. Other LCP were also used.

5.9.8.2 Blends Containing Functionalized PPE: PEST-PPE Copolymer Formation by Carboxylic Acid + Electrophile Reaction

PEST/PPE blends have been compatibilized through copolymer formation between polyester and a functionalized PPE (Table 5.37). Typically, the PPE is functionalized in a separate reaction either in the melt or in solution to introduce an electrophilic moiety (such as epoxide, carbodiimide, cyclic ortho ester, or the like) at a phenolic end-group or along the PPE main chain or both. The electrophilic moiety can react with PEST carboxylic acid end-groups in the melt resulting in a compatibilizing copolymer.

PEST-PPE blends have been compatibilized through block copolymer formation between carboxylic acid end-groups on polyesters, such as PBT, and epoxy-terminated PPE (Brown and Lowry 1992a). PPE was functionalized in solution with a variety of chloro-epoxy triazine derivatives in the presence of a base to provide a reactive epoxy triazine-capped PPE (Brown and Lowry 1992b; Yates et al. 1992). Melt functionalization of PPE was also possible (Brown et al. 2009). Representative chloro-epoxy triazine capping agents included

PBT (45 %)/ carbodiimide-functionalized PPE (45 %)/SEBS (10 %)	TSE/PPE functionalized in solution with 4,4′-bis (4-cyclohexylcarbodiimido) diphenylmethane/ mechanical properties/copolymer analysis by selective solvent extraction/PET also used	Han and Gately 1987

2-chloro-4-(2,4,6-trimethylphenoxy)-6-glycidoxy-1,3,5-triazine. For example, blends containing PBT, PPE-epoxide, and SEBS impact modifier were prepared using a TSE and characterized by selective solvent extraction, morphology, and mechanical properties. Numerous other polyesters, polyestercarbonates, and polyesteramides were used in these blends (see, e.g., Brown and Lowry 1992b).

PEST-PPE blends have also been compatibilized through block copolymer formation between carboxylic acid end-groups on polyesters, such as PBT, and PPE bearing reactive dialkylphosphatoethoxy triazine terminal groups (Phanstiel and Brown 1991, 1992). In this case PPE was functionalized in solution with a variety of chloro dialkylphosphatoethoxy triazine derivatives in the presence of a base to provide a reactive triazine-capped PPE. Representative chloro dialkylphosphatoethoxy triazine capping agents included 2-chloro-4-(2-di-n-butylphosphatoethoxy)-6-(2,6-xylenoxy)-1,3,5-triazine. For example, a blend containing 60 parts PBT, 30 parts functionalized PPE, and 10 parts impact modifier was prepared using a TSE. Molded test parts showed Izod impact strength of 860 J/m compared to 48 J/m for a similar blend containing unfunctionalized PPE. 2-Chloro-4-(2-chloroethoxy)-6-(2,4,6-trimethylphenoxy)-1,3,5-triazine or 2-chloro-4-(2-bromoethoxy)-6-(2,4,6-trimethylphenoxy)-1,3,5-triazine could be used in place of phosphatoethoxy triazine (Phanstiel and Brown 1993). See also Schmidhauser and Longley (1991).

PEST-PPE blends have also been compatibilized through block or graft copolymer formation between carboxylic acid end-groups on polyesters, such as PBT, and PPE bearing cyclic ortho ester groups. PPE could be either end-capped in solution using a chloro ortho ester triazine derivative such as 2-chloro-4-(2-methoxy-2-methyl-1,3-dioxolanyl)methoxy-6-phenoxy-1,3,5-triazine) (Khouri et al. 1992; Khouri and Phanstiel 1992) or functionalized in the melt using a graftable cyclic ortho ester such as 4-methacryloyloxymethyl-2-methoxy-2-methyl-1,3-dioxolane

(Khouri et al. 1993). In either case, blends of various polyesters with cyclic ortho ester-functionalized PPE showed markedly better mechanical properties compared with control blends containing unfunctionalized PPE. Polyolefin grafted with cyclic ortho ester could also be used in PEST blends comprising PPE grafted with cyclic ortho ester (Khouri 1996).

5.9.8.3 Blends Containing Functionalized or Unfunctionalized PPE: PEST-PPE Copolymer Formation through Coupling Agent or Condensing Agent Addition

As illustrated in Table 5.38, coupling agents have been employed to compatibilize PEST-PPE blends through copolymer formation between PEST carboxylic acid

end-groups and either PPE phenolic end-groups (unfunctionalized PPE) or PPE-g-carboxylic acid or PPE-g-anhydride (functionalized PPE). Numerous similar examples using epoxide coupling agents in PEST-PPE blends have been patented. Tang et al. (1992) have employed a phosphite condensing agent in similar manner to form compatibilizing copolymer. See also van Aert et al. (2001). Chen et al. (1993) employed a catalyst of boric acid with either polyphosphoric acid or sulfuric acid as a condensing agent to link PPE phenolic end-groups with LCP carboxylic acid end-groups.

5.9.8.4 Blends Containing Unfunctionalized PPE + Functionalized PS: PEST-PS Copolymer Formation by Carboxylic Acid + Epoxide Reaction

PEST/PPE blends have been compatibilized through graft copolymer formation between polyester and a PPE-miscible functionalized styrene copolymer (Table 5.39). In this instance, the reaction is between polyester carboxylic acid

end-groups and pendent electrophilic groups on the styrene copolymer such as epoxide, oxazoline, cyclic ortho ester, and the like typically leading to a new ester linkage in the resulting copolymer. In the examples where the new ester linkage is formed from an epoxide group, a secondary alcohol group forms as well. The new secondary alcohol may also react with polyester main-chain linkages to form copolymer through a degradative transesterification process. Since there are typically multiple epoxide sites on the styrene copolymer, some cross-linked copolymer may result as well if the polyester is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon functionality concentration on both PEST and PS, blend composition, and processing conditions.

5.9.9 Polyester + Polyphenylene Sulfide Blends

Luo et al. (2013) employed a disulfide-modified PPS in compatibilized blends with LCP blend characterization techniques including rheological, mechanical, and thermal properties. Gopakumar et al. (1999) reported transesterification of thermotropic LCP with carboxylic acid-terminated PPS. Blends were characterized by morphology, mechanical properties, and DSC. Hanley et al. (1999) used a similar compatibilization strategy for blends of PET and carboxylic acid-terminated PPS. Chen et al. (1993) employed a catalyst of boric acid with either polyphosphoric acid or sulfuric acid as a condensing agent to link PPS thiol end-groups with LCP carboxylic acid end-groups.

5.9.10 Polyester + Polyphosphonate Blends

Kauth et al. (1988) have disclosed transesterification of aromatic polyesters and a polyphosphonate in a devolatilizing extruder. For example, a polyester derived from bisphenol A and 1:1 iso/terephthalic acid dissolved in dichloromethane/chlorobenzene was devolatilized along with a similar solution of a polyphosphonate derived from methanephosphonic acid and 4,4′-dihydroxybiphenyl in a TSE at 340 °C. The isolated transparent product had a single Tg by DSC and improved impact strength compared to test parts of the individual homopolymers. Polycarbonate and polyestercarbonates were also successfully transesterified with polyphosphonate using this procedure.

5.9.11 Polyester + Polypropylene Blends

5.9.11.1 Copolymer Formation by Alcohol + Anhydride Reaction
Bettini et al. (2013) prepared PET/PP blends in a TSE with addition of PP-g-MA, the latter grafted polymer prepared using MA alone or MA in the presence of styrene monomer. The extent of PP degradation and MA incorporation was measured as a function of styrene monomer level. The effect of styrene level in PP-g-(S)MA

on subsequent blend properties was assessed using rheology, mechanical properties, and SEM. A similar study was performed by Khonakdar et al. (2013). See also Zhidan et al. (2011) for PET/PP/PP-g-MA blends incorporating recycle PET.

Akbari et al. (2007) prepared PET/PP blends using 5, 10, or 15 wt% PP-g-MA, the latter grafted polymer being prepared by solid-state grafting. Characterization methods included DSC, optical microscopy, SEM, and EDXA.

Xue et al. (2007a, b) investigated the effects of PP-g-MA addition for compatibilizing blends of PTT and PP. Rheological, morphological, thermal and mechanical properties were measured. For blends of poly(esteramide) LCP with PP-g-MA, see Seo et al. (2006).

5.9.11.2 Copolymer Formation by Carboxylic Acid + Epoxide Reaction

PEST/PP blends have been compatibilized through graft copolymer formation by reaction of polyester carboxylic acid end-groups with pendent epoxide groups on an appropriate PP or on a PO or styrene-polyolefin copolymer showing some miscibility with PP (Table 5.40). The copolymer is joined through a new ester linkage. When the new ester linkage is formed, a secondary alcohol group forms as well through ring opening of the epoxide. It is theoretically possible that the new secondary alcohol may also react with polyester main-chain linkages to form copolymer through a degradative transesterification process. Since there are multiple reactive sites on the epoxide-containing polymers, some cross-linked copolymer may result if the acid-containing polymer is functionalized at both ends. The proportion of cross-linked copolymer formed also depends upon blend composition and processing conditions. An example is also included in this section where a compatibilizing copolymer is postulated to form by reaction between acidic phenolic end-groups on polycarbonate and epoxide groups grafted to PP (Zhihui et al. 1998, 1997).

Using a TSE at 180 °C, Vainio et al. (1996b) have prepared blends of 42 parts poly(butyl acrylate-*co*-GMA) (2–5 mol% GMA) with 53-58 parts PP and 0-5 parts PP-g-AA (6 % AA) as a compatibilizer. A cross-linked copolymer may result through reaction of epoxide groups along the copolyester main chain with acid groups grafted at more than one site along the PP chain (or with acid groups along a poly(acrylic acid) segment grafted at a single PP site). The blends were characterized by DMTA, gel content, FTIR, and TEM. Other functionalized poly(butylacrylate) copolymers for use in these blends were also prepared by copolymerization with olefinic oxazoline-, amine-, carboxylic acid-, and hydroxyl-containing monomers.

5.9.11.3 Copolymer Formation by Carboxylic Acid + Oxazoline Reaction

Vainio et al. (1997, 1996a) have compatibilized PEST/PP blends by graft copolymer formation between acid-terminated polyester and oxazoline-grafted PP. Specifically, 30 parts PBT was mixed with 0-70 parts PP and 0-70 parts PP-g-oxazoline in an internal mixer at 250 °C or TSE at 240 °C. Blends were characterized by SEM, torque rheometry, DMA, and DSC. Oxazoline-functionalized PP was prepared by grafting PP with ricinol oxazoline maleinate in the presence of styrene monomer + RI. The inclusion of styrene monomer suppresses radical-induced decomposition of PP. Some cross-linked copolymer

may also form in this blend if the polyester is acid-functionalized at both chain ends. See also Vocke et al. (1998) and Jeziórska (2001).

5.9.11.4 Copolymer Formation through Ionomeric Cross-Linking
Compatibilized blends of 90 parts PBT and 10 parts oxidized PP or its corresponding Na ionomer were prepared in TSE at 240 °C (Dang et al. 2005). Blends were characterized by mechanical properties, morphology, and MFR compared to blends with unfunctionalized PP.

5.9.11.5 Copolymer Formation by Radical Coupling
Li et al. (2012c) prepared blends of poly(lactic acid) with PP in the presence of radical initiator. Blend characterization techniques included DSC. The effects of different radical initiators and different concentrations of RI were studied.

5.9.12 Polyester + Polysulfone Blends

Zhang and He (2002) have compatibilized LCP polyester (Hoechst Vectra® B950) with polysulfone-g-MA, the functionalized polysulfone having been prepared in solution. Blend characterization techniques included XPS, DMA, morphology and melt viscosity.

5.9.13 Polyester + Styrene Copolymer Blends

5.9.13.1 Copolymer Formation by Alcohol + Anhydride or Carboxylic Acid Reaction

Studies have been made of PEST/styrene copolymer compatibilization in which a copolymer is formed between polyester alcohol end-groups and pendent anhydride functionality on a styrene copolymer (Table 5.41). Because the alcohol-anhydride reaction is reversible with the equilibrium lying on the side of unreacted anhydride, only a relatively small amount of copolymer may be formed. Thus, the dispersed phase polymer may not be well stabilized against coalescence upon further thermal treatment (for a discussion, see, e.g., Sun et al. 1996 and Boyer et al. 2005). Alternatively, at least some copolymer may be formed by a degradative mechanism through transesterification between polyester main-chain linkages and a low concentration of pendent acid groups in anhydride-functionalized styrene copolymer. See also the work of Wu et al. (2010) for blends comprising PBT and ultrafine, vulcanized ABS wherein a copolymer was postulated to form between PBT-OH groups and surface carboxyl groups on ABS.

5.9.13.2 Copolymer Formation by Carboxylic Acid + Epoxide Reaction

As the examples of Table 5.42 demonstrate, PEST/styrene copolymer blends may be compatibilized through graft copolymer formation by reaction of polyester carboxylic acid end-groups with pendent epoxide groups on an appropriate styrene copolymer. Also included in the table is an example of graft copolymer formation in PC-styrene copolymer blends through reaction of styrene copolymer carboxylic acid pendent groups with epoxide end-groups on an appropriately functionalized PC. In either case, the copolymer formed is joined through a new ester linkage. When the new ester linkage is formed, a secondary alcohol group is also formed through ring opening of the epoxide. The new secondary alcohol may also react with polyester main-chain linkages to generate copolymer through a degradative transesterification process. When there are multiple reactive sites on at least one of the two polymers, some cross-linked copolymer may result depending upon functionalized polymer type, blend composition, and processing conditions.

5.9.13.3 Copolymer Formation by Transreaction

Bolton et al. (2005) prepared a copolymer of S-AN and alpha-methyl-*p*-hydroxystyrene. The copolymer was shown to be an effective compatibilizer for PC/SAN blends extruded in the presence of tetraphenylphosphonium benzoate catalyst.

Su et al. (2001a, b) have prepared blends of PBT with hydroxy-functionalized polystyrenes which differed in the number of hydroxy groups per chain. The effects of triphenyl phosphite and titanium butoxide on PBT chain degradation and copolymer formation were studied. Blends were characterized by FTIR, DSC, GPC, morphology, rheology, and mechanical properties.

Wildes et al. (1999) have reported compatibilized blends of PC with amine-functionalized SAN.

In a study by Landry et al. (1994), 50 parts PBT (or PET) was extruded with 50 parts poly(vinylphenol) using a mini-SSE at 254 °C or 293 °C, followed by annealing at 265 °C or 290 °C. The blends were characterized by DSC. Copolymer formation evidently occurs through a degradative reaction between pendent phenolic groups on poly(vinylphenol) and ester linkages in the polyester main chain. A low molecular weight polyester fragment results from this process.

5.9.13.4 Copolymer Formation by Miscellaneous Reactions

Liu et al. (2011a) prepared compatibilized PBT-ASA blends by addition of epoxy resin coupling agent. Blends were characterized by mechanical properties and morphology (TEM and FESEM).

Lee and Park (2001) prepared compatibilized PC-PBT-PS blends through reacting PBT with oxazoline-functionalized PS. See Becker and Schmidt-Naake (2003) for compatibilized blends of PC with oxazoline-functionalized SAN and

Becker and Schmidt-Naake (2004) for compatibilized blends of PC with oxazoline- or benzoxazole-functionalized ABS.

Lee and Park (2000) found evidence for copolymer formation in blends of anhydride-terminated PC and oxazoline-functionalized PS prepared in a Haake mixer. Blends were characterized by torque rheometry, SEM, FTIR, NMR, and mechanical properties. Anhydride-terminated PC was prepared by reaction of PC phenolic end-groups with trimellitic anhydride acid chloride (cf. Hathaway and Pyles 1988, 1989).

Lee et al. (2000) prepared compatibilized PET-PS blends through reacting PET with carbamate-functionalized PS, the carbamate serving as a masked isocyanate.

Ju and Chang (1999) prepared compatibilized PET-PS blends through blending PET and PS with SMA in the presence of a tetra-epoxide coupling agent.

Krabbenhoft (1986) prepared copolymers of PC with SEBS by extrusion with a disulfonyl azide. In one example, a blend of PC (1 part), SEBS (2 parts), and 4,4′-biphenyl disulfonyl azide was extruded on an SSE at 182 °C. This extrudate was melt blended with EEA and additional PC to give a blend comprising 82.5 % PC, 7.5 % SEBS, and 10 % EEA. Copolymer formation was shown by selective solvent extraction. Improved impact strength was seen in comparison to blends prepared without disulfonyl azide.

5.9.14 Polyester + Polyurethane Blends

Dogan et al. (2013) prepared blends of poly(lactic acid) with TPU through addition of 1,4-phenylene diisocyanate coupling agent. Characterization techniques included mechanical, thermal, morphological, and rheological properties.

Imre et al. (2013) also prepared compatibilized blends of poly(lactic acid) with polyurethane elastomer by coupling reaction under extrusion conditions. Copolymer formation was shown by SEM, AFM, DMA, and mechanical property measurement.

Archondouli et al. (2003) studied blends of PC with polyester-type polyurethane using SEM, mechanical properties, DMA, DSC, TGA, FTIR, and NMR. Formation of copolymer was shown by selective solvent extraction and spectroscopic analysis.

Samios et al. (2000) prepared PET blends with polyester polyurethane. Blends were characterized by mechanical properties, DMA, NMR, and morphology. An esteramide interchange reaction was proposed as the mechanism for compatibilizing copolymer formation.

5.10   Polyether or Polyphenylene Ether Blends

Examples of polyether blends not shown in earlier sections are listed in alphabetical order of the second polymer in the blend unless otherwise noted. Included in this section are polyphenylene ether blends not described in sections on PA, PEST, or PO. When copolymer characterization was not performed, the structure of the compatibilizing copolymer is inferred from the functionality location on each of the two polymers. In some cases, more than one type of compatibilizing copolymer may have formed.

5.10.1   Polyether + Polyolefin Blends

5.10.1.1 Copolymer Formation by Alcohol + Anhydride Reaction

Compatibilizing copolymers have been formed by direct reaction between pendent alcohol groups of phenoxy resin and pendent anhydride groups on MA-grafted polyolefins. Again, the initial product of the reaction was a graft copolymer, but longer reaction time resulted in a cross-linked copolymer since the pendent phenoxy chain is capable of further reaction with MA on a different polyolefin chain. Mascia and Bellahdeb (1994a, b) have blended 75-25 parts phenoxy resin with 25-75 parts EP-g-MA (0.7 % MA) in either an internal mixer or a TSE at 180–200 °C. The blends were characterized by selective solvent extraction, SEM, DSC, and rheology. Increased cross-linking was observed with increasing MA-to-phenoxy ratio and with the addition of either NaOEt or sodium benzoate (2 %). The resulting copolymers were used to compatibilize PET + HDPE blends.

5.10.1.2 Copolymer Formation by Alcohol + Ester Transreaction

Kim and Choi (1996b) have compatibilized blends of phenoxy resin with PMMA. Compatibilizing cross-linked copolymer resulted from transreaction between phenoxy pendent alcohol groups and pendent PMMA ester groups.

Compositions of 100-0 parts phenoxy resin and 0-100 parts PMMA were prepared in an internal mixer at 240 °C. The blends were characterized by DSC, FTIR, mechanical properties, rheology, and DMA. Mascia and Bellahdeb (1994a, b) have compatibilized phenoxy polyether resin with an acid-functionalized polyacrylate resin through cross-linking. A base capable of forming alkoxide from the polyether hydroxy groups was used. Thus, 75-25 parts phenoxy resin and 25-75 parts E-tBA-AA terpolymer (or EMAA Na ionomer) were blended in an internal mixer or TSE at 180–200 °C in the presence of 2 parts NaOEt. Blends were characterized by selective solvent extraction, SEM, DSC, and rheology. The resulting cross-linked copolymers were used to compatibilize PET + HDPE.

5.10.1.3 Copolymer Formation by Miscellaneous Reactions
Frick et al. (2013) prepared compatibilized blends of PEEK and PTFE (component ratios 0-100 to 100-0) using melt-processable PTFE treated by electron beam radiation to introduce –COF and –COOH functional groups by chain scission. Blend characterization techniques included mechanical properties and morphology.

5.10.2   Polyether + Styrene Copolymer Blends

5.10.2.1 Copolymer Formation by Alcohol + Anhydride Reaction
Bayam and Yilmazer (2002) have reported compatibilization of poly (tetramethylene ether glycol) with SMA prepared in a batch mixer or in a TSE in the presence of zinc acetate hydrate. Blends were characterized using thermal, mechanical, morphological, and spectroscopic techniques. FTIR analysis indicated the presence of copolymer from ester formation.

5.10.2.2 Copolymer Formation by Alcohol + Epoxide Reaction
Compatibilizing copolymers have been formed by direct reaction between pendent alcohol groups of phenoxy resin and pendent epoxide groups on GMA-grafted styrene copolymer. Again, the initial product of the reaction was a graft copolymer, but longer reaction time resulted in a cross-linked copolymer since the pendent phenoxy chain was capable of further reaction with GMA. Furthermore, the new hydroxy group arising from ring-opened epoxy groups may also participate in cross-linking reactions. It is also possible that some cross-linked copolymer resulted from transesterification between pendent hydroxy groups on phenoxy resin and the GMA ester groups. Chen and Chang (1994) have prepared blends of 75-45 parts phenoxy resin and 25-50 parts ABS with addition of 0-10 parts SAN-GMA (5 % GMA) copolymer in an internal mixer or a TSE at 230 °C. The blends were characterized by torque rheometry, SEM, viscosity behavior, and mechanical properties. Sodium lauryl sulfonate (0.02-0.10 parts) was added as a catalyst to promote the copolymer-forming reaction.

5.10.2.3 Copolymer Formation by Amine + Anhydride Reaction
Schaefer et al. (1995) prepared blends of poly(tetrahydrofuran) with SMA in the presence of bis(amine)-terminated poly(tetrahydrofuran). Characterization

techniques included FTIR and microscopy. Reaction rate constants were determined. The effects of temperature and poly(tetrahydrofuran) MW were studied.

5.10.3   Polyetherimide + Polyphenylene Ether Blends

PEI-PPE blends have also been compatibilized through copolymer formation between functionalized PPE and PEI in the presence of a multifunctional epoxy resin such as PE-co-GMA (Brown et al. 2000a). Functionalized PPE included PPE-g-FA. Catalysts such as sodium stearate were optionally added.

PEI-PPE blends have also been compatibilized through copolymer formation between anhydride-functionalized PPE such as PPE-g-FA and amine-terminated PEI (White et al. 1989). Amine-terminated PEI was prepared from bisphenol A-diphthalic acid anhydride and m-phenylene diamine, the latter used in excess. Copolymer analysis was by selective solvent extraction. Mechanical properties and morphologies were compared to blends with unfunctionalized PPE and PEI.

5.10.4   Polyetherimide + Polyphenylene Sulfide Blends

PEI-PPS blends have also been compatibilized through copolymer formation between amine-containing PEI and PPS in the presence of a multifunctional epoxy resin such as epoxy cresol novolak (Nazareth 1996).

5.10.5   Polyphenylene Ether + Polyphenylene Sulfide Blends

Some early work on copolymer-compatibilized PPE-PPS blends is summarized in Arashiro et al. (1992). PPE-PPS blends have also been compatibilized through copolymer formation between citric acid-functionalized PPE (e.g., 162 parts) and PPS (e.g., 225-275 parts) in the presence of a multifunctional epoxy resin (0-17.5 parts) and a minor amount of PBT (25-50 parts) (Brown et al. 1997a) or in the presence of a epoxy-functionalized PO and a catalyst (Brown et al. 2001) or in the presence of a bifunctional cyclic ortho ester compound (Brown et al. 1998a). See also Dekkers (1989) and Inoue et al. (1990). Okabe et al. (1989) have prepared compatibilized blends comprising PPE-g-MA and amine-functionalized PPS in the presence of 4,4′-diphenylmethane diisocyanate coupling agent.

PPE-PPS blends have also been compatibilized through copolymer formation between a PPS bearing nucleophilic functional groups and either epoxy-functionalized PPE (Han et al. 1992) or cyclic ortho ester-functionalized PPE (Brown et al. 1996). In the former case, PPE was functionalized by reaction with a chloro-epoxy triazine and, in the latter, by reaction with either a chloro (cyclic ortho ester) triazine or a graftable cyclic ortho ester.

Kubo and Masamoto (2002) have prepared compatibilized blends of PPE and PPS through addition of styrene-co-GMA.

5.10.6 Polyphenylene Ether + Polysiloxane Blends

PPE-polysiloxane blends have also been compatibilized through copolymer formation between amine-terminated polydimethylsiloxane and either epoxy-functionalized PPE (Blohm et al. 1995) or anhydride-functionalized PPE (Shea et al. 1989). Compatibilized blends have also been formed by extrusion of PPE with epoxy-functionalized polydimethylsiloxane (Cella et al. 2002) and by kneading of anhydride-functionalized PPE with carboxylic acid-functionalized polydimethylsiloxane in the presence of a diamine coupling agent (Moritomi and Iji 2002).

5.10.7 Polyphenylene Ether + Styrene Copolymer Blends

PPE is not miscible with SMA containing as much as 28 % MA (Witteler et al. 1993). To compatibilize these two resins, Koning et al. (1993b, 1996) have added a monoamine-terminated PS that can form a graft copolymer with SMA. Since the amine-terminated PS is miscible with PPE, compatibilized PPE-SMA blends are obtained. Specifically, 30 parts of unfunctionalized PPE was blended (internal mixer at 220 °C, or mini-SSE at 280 °C, or TSE at 326 °C) with 56 parts SMA (28 % MA) and 14 parts amine-functionalized PS. The blend was characterized by TEM, SEM, mechanical and thermal properties, DMA, and GPC copolymer detection. The effect of pre-reacting amine-terminated PS with SMA was studied. The blend properties were compared to those for uncompatibilized blends. Blends were also made containing ABS + SEBS. Further examples of compatibilizing copolymer formation in PPE-styrene copolymer blends are shown in Table 5.43.

5.11 Polyolefin Blends

Examples of polyolefin blends not shown in earlier sections are listed in alphabetical order of the second polymer in the blend unless otherwise noted. PVC is included as a polyolefin. When copolymer characterization was not performed, the structure of the compatibilizing copolymer is inferred from the functionality location on each of the two polymers. In some cases, more than one type of compatibilizing copolymer may have formed.

5.11.1 Polyolefin + Polyolefin Blends (Excepting Polypropylene)

5.11.1.1 Copolymer Formation by Alcohol + Anhydride Reaction
Yang et al. (2013) prepared compatibilized blends of EVAl with maleic anhydride-grafted ethylene-octene copolymer (0–25 wt%). Blends were characterized using mechanical, thermal, FTIR, and morphological techniques.

Wang et al. (2007c) prepared blends of HDPE and EVAl compatibilized through addition of HDPE-g-MA. Characterization methods included mechanical, thermal, and rheological properties.

Boyer et al. (2005) have reported that hydroxy-functionalized oligomers have little tendency to form a stable graft to PP-g-MA under the conditions studied.

Lee and Kim (1998) prepared compatibilized blends of EVAl with LDPE by addition of LDPE-g-MA (1–12 phr).

Schmukler et al. (1986a, b) prepared compatibilized blends of PVAl with an anhydride-functionalized polyethylene. For example, 50 wt% PVAl was reacted at 325 °C in a Brabender mixer with 50 wt% HDPE grafted with 1.5 wt% methylbicyclo(2.2.1)-hept-5-ene-2,3-dicarboxylic anhydride. Characterization showed evidence for copolymer formation and no gross phase separation.

5.11.1.2 Copolymer Formation by Carboxylic Acid + Epoxide Reaction
As shown in Table 5.44, immiscible blends containing at least two polyolefins have been compatibilized through cross-linked copolymer formation between carboxylic acid groups at multiple sites on one polyolefin and epoxide groups at multiple sites on another polyolefin.

5.11.1.3 Copolymer Formation through Coupling Agent Addition
Examples in Table 5.45 show use of coupling agents that can, in theory, react at sites along the main chain of each of the two immiscible polyolefins. The work of Inoue (1994a, b) and of Naskar et al. (1994) involve concomitant dynamic vulcanization of an elastomeric phase with an added cross-linking agent.

5.11.1.5 Copolymer Formation Involving Mechanochemical Radical Formation

Radicals may be formed on polyolefins under high-shear mixing conditions in a process termed mechanochemical radical generation. Two immiscible polyolefins may both be subject to mechanochemical radical generation during extrusion processing. In blends of PO that are not prone to degradation upon radical formation, a cross-linked copolymer may result from the recombination of radicals from each polymer. As a result, a compatibilized blend with improved physical properties may be obtained. In blends of PO subject to chain scission under high-shear mixing conditions, radical recombination reactions may lead to block and eventually random copolymer formation similar to other degradative copolymer formation processes. The examples listed in Table 5.47 show cross-linked copolymer formation in PVC blends with PO. For a general review of polymer reactions under the action of mechanical forces, see Prut (2009). Other aspects of mechanochemical processes in polymers may be found in Beyer and Clausen-Schaumann (2005). For a study of similarities between mechanochemical and high-energy radiation processes in polymer processing, see, e.g., Smith et al. (2001).

Casale and Porter ([1975]) reported that copolymer formation between NBR and PVC may occur via mechanochemical radical generation on each polymer followed by recombination. The proposed mechanism was based on earlier studies by Akutin ([1968]). Later, Manoj et al. ([1993b]) postulated another mechanism for the same system involving hydrolysis of nitrile groups to amide or carboxylic acid followed by displacement of allylic chloride on PVC by amide-NH_2 or acid-OH.

5.11.1.6 Copolymer Formation by Miscellaneous Reactions

Song et al. ([2012a]) prepared blends of PMMA with various functionalized poly (propylene-ethylene) copolymers. Blends were characterized by mechanical, morphological, and adhesion tests. Compatibility was found to increase in the order of unfunctionalized poly(propylene-ethylene), MA-grafted poly(propylene-ethylene), hydroxy-grafted poly(propylene-ethylene), and secondary amine-grafted poly (propylene-ethylene) which latter species exhibited the best compatibilization efficiency.

Lopattananon et al. ([2007]) have prepared blends of maleated natural rubber and carboxylated nitrile rubber in the presence of zinc acetate to form a compatibilizing copolymer through ionic cross-links. The effect of different maleation levels was studied. Blend properties were compared to those for blends with unfunctionalized rubbers.

Oliveira et al. ([2004]) prepared compatibilized blends of EPDM and NBR using mercapto-modified EPDM with oxazoline-functionalized NBR. Mercapto-modified EVAc was also used. Blends were characterized by techniques including mechanical properties and morphology.

Soares et al. ([2004]) prepared blends of partially hydrolyzed EVAc and NBR using oxazoline-functionalized NBR. Blends were characterized by techniques including mechanical properties, morphology, selective solvent extraction, and FTIR.

Dalai and Wenxiu ([2002b, c]) have reported blends of either HDPE or LDPE with EVAc effected by radiation cross-linking. Blend characterization techniques included morphology and thermal properties.

Nugay and Nugay ([2000]) prepared blends of poly(methyl methacrylate)-b-poly(4-vinylpyridine) with poly(acrylic acid), possibly compatibilized through copolymer formation by ion-neutral donor group association.

Some unusual ester cross-linking reactions have been proposed as copolymer-forming processes for immiscible PO blends (Table [5.48]). Alternative mechanisms include consideration of the possible contributions of simpler processes such as IPN formation, radical-radical coupling, or ionomeric cross-linking.

5.11.1.7 Copolymer Formation through Radical Initiator Addition

As shown in the examples listed in Table [5.49], immiscible blends of polyolefins have been compatibilized by copolymer formation brought about by radical coupling in the presence of a radical initiator. The work of Kim et al. ([1997a]) and Xu et al. ([1997]) involved copolymer formation between immiscible rubber and plastic phases simultaneous with the dynamic vulcanization of the elastomeric phase.

5.11.1.8 Copolymer Formation by Transesterification of Pendent Ester Groups

Immiscible polyacrylates have been compatibilized through transesterification between pendent ester groups on one polyacrylate with pendent ester groups on another polyacrylate. Selected examples are listed in Table 5.50.

5.11.2 Polyolefin + Polyoxymethylene Blends

Compatibilized blends of hydroxylated polyoxymethylene (polyacetal) with carboxylic acid-functionalized PP have been prepared (Chen et al. 1991). The formation of ester linkages between the polymers was proposed. For example, blends comprising hydroxylated polyoxymethylene and muconic acid-grafted PP were made into film by calendering at 200 °C to provide compositions with markedly improved mechanical properties compared to similar blends containing unfunctionalized PP or unfunctionalized polyoxymethylene.

5.11.3 Polyolefin + Polyphenylene Ether Blends

5.11.3.1 Blends Containing Functionalized PPE: PO-PPE Copolymer Formation by Carboxylic Acid + Cyclic Ortho Ester or Epoxide Reaction

As shown in Table 5.51, immiscible blends containing a functionalized polyolefin and a functionalized polyphenylene ether have been compatibilized through cross-linked or graft copolymer formation between carboxylic acid groups at multiple sites on one polymer and either cyclic ortho ester groups or epoxide groups at sites on another polymer.

5.11.3.2 Blends Containing Functionalized PPE: PO-PPE Copolymer Formation through Coupling Agent Addition

Togo et al. (1988) compatibilized PP with PPE by combining carboxylic acid-functionalized PP with carboxylic acid-functionalized PPE in the presence of a diamine. For example, a 1:1 mixture of PP-g-MA and PPE-g-MA was melt kneaded with 1 wt% p-phenylenediamine at 270 °C. The product was formed into sheet with high tensile strength. PP was grafted with MA in the presence of styrene. BPA or a polyepoxide resin was also used in place of diamine.

5.11.4   Polyolefin + Polyphenylene Ether + Styrene Copolymer Blends

5.11.4.1 Blends Containing Unfunctionalized PPE + Functionalized PS: PO-PS Copolymer Formation by Carboxylic Acid + Epoxide Reaction

Immiscible blends containing a polyolefin, an unfunctionalized polyphenylene ether and a functionalized styrene copolymer, have been compatibilized through cross-linked

copolymer formation between carboxylic acid groups at multiple sites on polyolefin and epoxide groups at multiple sites on styrene copolymer. Fujii and Ting (1988) reported compatibilized blends of EMAA (15 parts), PPE (47 parts), HIPS (30 parts), SEBS (8 parts), and S-co-GMA (1 part) prepared on a TSE at 288 °C. Characterization included mechanical properties vs. blends without functionalized polymers. Abe et al. (1984) prepared blends of EVAc-co-GMA (1 part; 8 wt% VAc; 4 wt% GMA) with SMA (1 part; 8 wt% MA) in a kneader at 200 °C and characterized the copolymer by selective solvent extraction. Blends of the copolymer with PPE/PS had greatly improved mechanical properties compared to blends without copolymer.

5.11.4.2 Blends Containing Unfunctionalized PPE + Functionalized PS: PO-PS Copolymer Formation by Carboxylic Acid + Oxazoline Reaction

Hohlfeld (1986) prepared compatibilized blends of EAA and unfunctionalized PPE by extrusion with styrene-isopropenyl oxazoline copolymer (S-IPO). In one example, a blend of EAA (30 parts), PPE (35 parts), and S-IPO (35 parts) was mixed in a Brabender mixer at 280 °C. Torque level was higher and mechanical properties were significantly improved compared to blends with PS used in place of S-IPO. See also Xu et al. (1999b) for a study of similar blends.

5.11.4.3 Copolymer Formation through Ionomeric Cross-Linking Mediated by Metal Cations

Immiscible polyolefin impact modifiers have been compatibilized with PPE/PS blends by employing a polyolefin sulfonate ionomer and also including PS-sulfonate ionomer in the blend (Table 5.52). Alternatively, PPE-sulfonate ionomer could be used in place of PS-sulfonate ionomer. In these compositions, the polyolefin ionomer can cross-link with PS ionomer through metal cations. The PS-sulfonate ionomer is at least partially miscible with PS, which in turn is miscible with PPE. Simple ionomers have been used (Golba and Seeger 1987; Campbell et al. 1986, 1989). In similar blends, a masked ionomer, such as a polyolefin phosphonate ester, could also be used (Brown and McFay 1986, 1987). The masked ionomer is melt processable but generates a polyolefin phosphonate ionomer through ester hydrolysis in situ during extrusion in the presence of zinc stearate. The polyolefin phosphonate ionomer can cross-link with PS sulfonate ionomer that is miscible with PS which in turn is miscible with PPE.

5.11.5 Polyolefin + Polyphenylene Sulfide

5.11.5.1 Copolymer Formation by Nucleophile + Epoxide Reaction

Immiscible blends containing an epoxy-functionalized polyolefin and a polyphenylene sulfide have been compatibilized by Oyama et al. (2011) through graft copolymer formation between epoxide groups at multiple sites on either EMA-GMA or E-GMA-g-PMMA and nucleophilic end-groups such as amine,

carboxylic acid, or thiophenol on PPS. Blend characterization techniques included morphology and mechanical properties.

Horiuchi and Ishii (2000) prepared PPS blends with LDPE-g-MA and PE-f-GMA in a TSE. Blend characterization techniques included morphology, TEM, EELS, DSC, tribological tests, and mechanical properties.

Hwang et al. (1998) effected graft copolymer formation between epoxide groups at multiple sites on PE-co-GMA and nucleophilic end-groups on PPS (see also Bailly et al. (1997) and Sugie et al. (1985)). SEBS impact modifier was also used in these blends. Han (1991a, b) employed amine- and carboxylic acid-terminated PPS in similar blends. Numerous similar examples of this compatibilization strategy have appeared, as documented, for example, in patents assigned to Toray Industries.

5.11.5.2 Copolymer Formation by Miscellaneous Reactions

Lehmann (2011) prepared compatibilized blends of PPS and PTFE (component ratios 0-100 to 100-0) using melt-processable PTFE treated by radiation to introduce –COF and –COOH functional groups by chain scission. It was proposed that functional groups on PTFE may react with thiol end-groups on PPS. Blend characterization techniques included mechanical and tribological properties.

5.11.6   Polyolefin + Polypropylene Blends

5.11.6.1 Copolymer Formation by Alcohol + Anhydride Reaction

Cascone et al. (2001) prepared compatibilized blends of PP-g-MA with poly(vinyl butyral) having different content of vinyl alcohol units. Demarquette and Kamal (1998) have prepared compatibilized blends of EVAl and PP through inclusion of

PP-g-MA (0.1 mol% MA). Characterization methods included SEM, ESCA, and interfacial tension measurement. Tselios et al. (1998) have prepared compatibilized blends of LDPE and PP through inclusion of PP-g-MA (0.8 mol% MA) and EVAl (7.5 mol% vinyl alcohol). Blends were characterized using SEM, torque rheometry, mechanical properties, FTIR, and micro-Raman spectroscopy.

5.11.6.2 Copolymer Formation by Amine + Anhydride or Amine + Carboxylic Acid Reaction

Coran and Patel (1983b) have shown that the mechanical properties of dynamically vulcanized NBR-PP blends can be improved through copolymer formation between the two immiscible polymers concurrent with vulcanization. In the first example in Table 5.53, block copolymer resulted from reaction of amine-terminated NBR with anhydride-terminated PP. The latter was prepared through functionalization of PP with MA in the presence of radical initiator. In the second example, a block copolymer may have resulted from reaction of acid-terminated NBR with a primary amine-terminated PP. The latter was prepared in a prior reaction between maleic anhydride-terminated PP and triethylenetetramine. It is also possible that the block copolymer may be linked through ionomeric association resulting from protonation of PP-amine with NBR acid.

5.11.6.3 Copolymer Formation by Carboxylic Acid + Epoxide Reaction

A compatibilizing copolymer may be formed through reaction between carboxylic acid groups grafted onto a PO chain and acrylate epoxide groups grafted onto a PP chain. In an internal mixer, Liu et al. (1993) have prepared compositions comprising 20 parts NBR-g-AA, 0-75 parts PP, and 0-25 parts PP-g-GMA (0.8 % GMA). The blends were characterized by torque rheometry, SEM, FTIR, and mechanical properties. Control blends were made using either unfunctionalized NBR or PP

with different GMA levels. Although the exact structure of the copolymer is not known, it is convenient to consider that the reaction leads to a cross-linked copolymer based on the assumption that the acrylate epoxide groups are truly grafted onto the PP chains and are not all at terminal sites. Ao et al. (2006) compatibilized EPDM/PP blends using epoxidized EPDM and PP-g-AA.

Interestingly, Wang et al. (2012b) have reported that solid-state chlorination of PP in the presence of GMA results in high levels of GMA grafting. The PP-g-GMA was shown to form compatibilized blends with hydroxy-terminated butadiene-acrylonitrile rubber.

5.11.6.4 Copolymer Formation by Carboxylic Acid + Oxazoline Reaction

A compatibilizing copolymer may be formed through reaction of carboxylic acid groups grafted onto a PO chain and olefinic oxazoline groups grafted onto a PP chain. Again, it is reasonable to consider that this copolymer may be cross-linked based on the assumption that the oxazoline groups are truly grafted along the PP chains and are not all at terminal sites. Liu and Baker (1994) and Liu et al. (1993) have prepared PO-PP blends containing 20 parts NBR-g-AA, 0-80 parts PP, and 80-0 parts PP-g-IPO (0.2 % grafted isopropenyl oxazoline) in an internal mixer. The blends were characterized by torque rheometry, SEM, FTIR, and mechanical properties. Control blends were made using either unfunctionalized NBR or different IPO levels on PP.

5.11.6.5 Copolymer Formation through Coupling Agent Addition

As shown in Table 5.54, PO/PP blends have been compatibilized by copolymer formation formed through addition of a coupling agent such as a tris-acrylate and a radical initiator that can react with both PO and PP in an immiscible blend. Although PP may have at most one unsaturated site per chain (see Coran and Patel 1983b), the immiscible rubber phase may have multiple reactive sites. Depending upon stoichiometry of coupling agent and reactant polymers, the reaction may lead to a cross-linked copolymer. In the examples from Coran and coworkers, an additional coupling agent could be used to dynamically vulcanize the elastomeric phase following copolymer formation with the PP matrix.

5.11.6.6 Copolymer Formation by Displacement Reaction

Solid-state chlorination of PP may lead to low levels of chlorine incorporation along the PP chain with minimal PP molecular weight degradation. Coran and Patel (1983b) have blended (internal mixer at 190 °C) 50 parts chlorinated PP with 45 parts NBR containing 5 parts amine-terminated NBR. The blend was characterized by mechanical properties and compared to those for blends using unfunctionalized PP. Compatibilization resulted from copolymer formation through displacement reaction of chloride by amine groups. The blend was prepared in the presence of a vulcanization agent (3.75 % of dimethylol phenol plus 0.5 % of $SnCl_2$) to cause concomitant vulcanization of the rubber phase.

5.11.6.7 Copolymer Formation through Radical Coupling

PO/PP blends have been compatibilized by addition of a radical initiator. Early examples were summarized in a review by Teh et al. (1994); additional examples are listed in Table 5.55. PP can undergo chain scission in the presence of radical initiator to give a terminal radical site. Coupling of this PP radical with a PE radical located on the PE chain may initially yield a graft copolymer. Since the new copolymer may participate in further coupling reactions, a cross-linked copolymer may eventually be formed depending upon reaction time and radical concentration among other factors.

EPDM/PP blends have been compatibilized by exposure to high-intensity ultrasonic waves during extrusion (Feng and Isayev 2004; Chen and Li 2005), as have blends of PP with natural rubber (Oh et al. 2003). HDPE/PP (or HDPE/ground tire rubber) blends have been compatibilized through copolymer formation promoted by gamma irradiation (Sonnier et al. 2010). Dalai and Wenxiu (2002a) have reported blends of PP and EVAc with copolymer formation effected by radiation cross-linking. Blend characterization techniques included morphology and thermal properties.

5.11.7   Polyolefin + Polypropylene + Styrene Copolymer Blends

Dharmarajan et al. (1995) have prepared compatibilized blends of PP/styrene copolymer with or without functionalized PO. Blends of 100-0 parts PP, 0-100 parts SMA, 0-15 parts EP-g-(primary amine) (0.3 mol% amine), and 0-5 parts PP-(secondary amine) (0.4 wt% amine) were combined in an internal mixer at 220 °C. Blends were characterized by FTIR, DMTA, TEM, rheology, mechanical properties, lap shear adhesion, and paint adhesion. Properties were compared for blends containing either of the two amine-functionalized polymers alone. Reaction of EP-g-(primary amine) with SMA should result in a cross-linked copolymer because EP-g-(primary amine) contains randomly distributed amine functionality in the backbone. The secondary amine-terminated PP was prepared by first extruding PP with MA to form predominantly anhydride-terminated PP, followed by extrusion with N-methyl-1,3-propanediamine to give the secondary amine-terminated PP through reaction of

the primary amine of the diamine with the PP-anhydride. Dharmarajan et al. suggested that PP-MA is mostly end-group functionalized with a smaller portion of main-chain-functionalized species as the result of trapping PP radicals before chain scission. Chains with combinations of end-group and main-chain functionalization should also be present since the authors report that their PP-MA contains a significant amount of highly functionalized PP-MA oligomer. Therefore, in these examples, the copolymers prepared from PP-MA and SMA may consist of a mixture of cross-linked and grafted species.

5.11.8   Polyolefin + Polysiloxane Blends

5.11.8.1 Copolymer Formation by Amine + Anhydride Reaction

DeLeo et al. (2011) and DeLeo and Velankar (2008) prepared compatibilized blends of polyisoprene-PDMS (70-30 and 30-70) with addition of 0.1–3.0 wt% copolymer of MA-f-polyisoprene and amine-f-PDMS. Characterization methods included optical microscopy and rheology.

Kole et al. (1995) postulated the formation of a cross-linked copolymer through reaction between amine groups distributed along the main chain of a polysiloxane and anhydride groups distributed along the main chain of a PO. A unique feature of this example is the use of acrylamide-grafted siloxane rubber as the source of amine groups. Amine groups alpha to carbonyl groups (as in acrylamide) are much

EMAc (100-0)/vinyl-functionalized PDMS (3.8 % vinyl) (0-100)	Internal mixer at 85–180 °C/capillary rheometry/DMA/FTIR	Bhattacharya et al. 1995; Santra et al. 1993a
LDPE (50)/EMAc (0-10)/vinyl-functionalized PDMS (3.8 % vinyl) (50)	Internal mixer at 180 °C/mechanical properties/DMA/FTIR/SEM/WAXS/X-ray diffraction/lap shear adhesion	Santra et al. 1993b

less nucleophilic than typical amine functionality. In an example, 50/50 blends of EPDM-g-MA (1 % MA) with acrylamide-grafted silicone rubber were mixed in an internal mixer at 35 °C, 70 °C, or 150 °C. The blends were characterized by DMA, FTIR, mechanical properties, solvent swelling, and TGA.

5.11.8.2 Copolymer Formation Involving Mechanochemical Radical Formation

As shown in Table 5.56, copolymer formation was postulated between mechanochemically generated radicals at sites on EMAc and vinyl-functionalized PDMS during melt processing (Santra et al. 1993a, b). The substitution pattern of vinyl groups on PDMS was not reported. Assuming that the vinyl groups are distributed along the PDMS chains (and not present only as end-groups), then the compatibilizing copolymer formed is a cross-linked copolymer. EMAc-PDMS copolymer formed in situ has also been used to compatibilize PDMS with thermoplastic polyurethane (Santra et al. 1995).

5.11.8.3 Copolymer Formation by Acid-Base Interaction

Blends of carboxylic acid-terminated polybutadiene and amine-terminated PDMS have been prepared by Fleischer et al. (1994). A copolymer with block-like structure was postulated to form. Blends were characterized using pendant drop tensiometry and FTIR.

5.11.8.4 Copolymer Formation by Miscellaneous Reactions

PMMA/polydimethylsiloxane blends have been compatibilized in the presence of methacryloxypropyl trimethylsiloxane (dos Anjos et al. 2010). Formation of covalent bonds between PMMA and silane coupling agent was examined using FTIR. Modulus and tensile strength were improved in the compatibilized blends.

5.11.9 Polyolefin + Polystyrene or Styrene Copolymer Blends (Including Polypropylene)

An interesting publication by Martini et al. (2006) describes a method for separating a reactively compatibilized PP/PS blend into its individual polymeric components for analysis. The method involved use of high-temperature, high-pressure, near-critical

solvent extraction with n-alkane. The effects of different n-alkanes and different temperatures and the influence of blend morphology and composition on separation efficiency were studied. The compatibilizing copolymer could be isolated and quantified using this procedure.

5.11.9.1 Copolymer Formation by Acid-Base Interaction

Compatibilized blends of ethylene-methacrylic acid copolymer and PS were prepared by Kim et al. (1998) through addition of S-co-4-vinylpyridine. Similarly, blends of poly(isobutyl methacrylate) were compatibilized with poly(styrene-co-methacrylic acid) using poly(isobutyl methacrylate-co-2-(N,N-dimethylamino) ethyl methacrylate) or poly(isobutyl methacrylate-co-4-vinylpyridine) (Habi and Djadoun 1999). Turcsáyii (1995) has reported compatibilized blends of PE-g-(N-vinylimidazole) with acrylic acid-modified PP.

5.11.9.2 Copolymer Formation by Alcohol + Anhydride Reaction

Tang et al. (2002) prepared blends of PS and ethylene-vinyl acetate-vinyl alcohol in the presence of SMA using a TSE. Characterization techniques included morphology, mechanical properties, and FTIR.

Tselios et al. (1997) have compatibilized PO/styrene copolymer blends through cross-linked copolymer formation between PO alcohol groups and anhydride groups on styrene copolymer. Specifically, 50 parts EVAl (1.6–7.5 % VAl) was mixed with 50 parts SMA (8.4–14.7 mol% MA) in an internal mixer at 200 °C. The blends were characterized by torque rheometry, FTIR, DSC, TGA, selective solvent extraction, and mechanical properties as a function of mole ratio alcohol to anhydride. Blend properties were compared to those with EVAc in place of EVAl.

5.11.9.3 Copolymer Formation by Amine + Anhydride Reaction

As shown in Table 5.57, PO/styrene copolymer blends have been compatibilized through cross-linked copolymer formation between amine-functionalized PO and anhydride-functionalized styrene copolymer.

Dharmarajan et al. (1995) have compatibilized PP/styrene copolymer blends by formation of a graft copolymer through reaction of secondary amine-terminated PP (0.4 wt% amine) with SMA. The secondary amine-terminated PP was prepared by first extruding PP with MA to form anhydride-terminated PP followed by extrusion with N-methyl-1,3-propanediamine to give the secondary amine-terminated PP through reaction of the primary amine of the diamine with the PP-anhydride. Blends within the range PP to SMA from 0-100 to 100-0, containing 0-5 parts amine-terminated PP, were prepared in an internal mixer at less than 220 °C. They were characterized by FTIR, DMTA, TEM, mechanical properties, rheology, lap shear adhesion, and paint adhesion. Some cross-linked copolymer may be present if the PP-MA contains more than one anhydride group. A similar compatibilization strategy was used (Datta et al. 1993a) wherein EP-g-MA or PP-g-MA was extruded with an excess of diaminopropane to yield an amine-functionalized PO which was used in blends with SMA and also in combination with an engineering thermoplastic such as PPE, PBT, and SAN (Dekoninck 1993).

5.11.9.4 Copolymer Formation by Carboxylic Acid + Cyclic Ortho Ester or Epoxide Reaction

PO/styrene copolymer blends have been compatibilized through cross-linked or graft copolymer formation between acid-functionalized PO and epoxide-functionalized PS or vice versa (Table 5.58). Also, acid-functionalized styrene copolymer has been compatibilized with PO grafted with cyclic ortho ester. Anhydride-functionalized polymer is also effective in these blends since some acid groups are present from ring-opened anhydride. Epoxide groups are most frequently introduced into PO or PS by copolymerization with GMA, while cyclic ortho ester groups are introduced by grafting or copolymerization with olefinic cyclic ortho ester.

5.11.9.5 Copolymer Formation by Carboxylic Acid + Oxazoline Reaction

PO/styrene copolymer blends have been compatibilized through cross-linked copolymer formation between acid-functionalized PO and oxazoline-functionalized PS (Table 5.59). Anhydride-functionalized PO is also effective in these blends since some acid groups may be present from ring-opened anhydride. Oxazoline groups are most frequently introduced into PS by copolymerization of styrene with isopropenyl oxazoline (IPO).

Sundararaj et al. (1995) have prepared blends containing PP-MA and oxazoline-functionalized PS. A graft copolymer may form through reaction between pendent oxazoline groups on PS and terminal acid groups (from some hydrolysis of anhydride groups) on PP. Specifically, 80 parts S-IPO (1 % IPO) was blended with 20 parts PP-MA (0.1 % MA) in either an internal mixer at 200 °C or in a TSE. The blends were characterized by selective solvent extraction and SEM. Morphology

development in the different mixing equipment was studied in both reactive and nonreactive blends (i.e., unfunctionalized PS and PP).

5.11.9.6 Copolymer Formation through Coupling Agent Addition

PO/styrene copolymer blends have been compatibilized by cross-linked copolymer formation in the presence of coupling agent as shown in Table 5.60.

In addition, PP/styrene copolymer blends have also been compatibilized by addition of a bismaleimide coupling agent capable of reacting with both polymers. For example, Inoue (1994a, b) has prepared blends containing 80 parts PP and 20 parts SIS (or SBS) in the presence of 0-0.3 parts m-phenylene bismaleimide coupling agent using a TSE at 210 °C. The blends were characterized by mechanical properties, melt flow rate, DSC, morphology, and selective solvent extraction. Evidence was presented for PP-SIS copolymer formation.

Bromobutyl rubber and SMA blends have been compatibilized through addition of a bifunctional coupling agent (Willis et al. 1990). The authors assumed that a low molecular weight amino alcohol reacted with rubber bromo groups to form a quaternary ammonium salt. The resulting alcohol-functionalized rubber could form cross-linked copolymers through reaction of hydroxy groups with anhydride of SMA. Blends of 30-5 parts bromobutyl rubber with 70-95 parts SMA and 0-8 parts 2-dimethylaminoethanol coupling agent were prepared in an internal mixer at 150–200 °C, followed by TSE processing at 200 °C. The blends were characterized by FTIR, SEM, and mechanical properties. The effects of premixing rubber with amine and the effects of processing conditions were studied. Model reactions for the proposed copolymer-forming reaction were carried out in solution.

5.11.9.7 Copolymer Formation by Friedel-Crafts Coupling

The Friedel-Crafts alkylation reaction is one of the oldest known methods for attaching an alkyl group to an aromatic ring. The process typically proceeds by reaction between an alkyl cation precursor and an aromatic compound in the presence of a Lewis acid catalyst. In one example, Sun and Baker (1997) obtained copolymer in blends of 80-20 parts LLDPE with 20-80 parts PS and 0.3 parts aluminum chloride. The proposed mechanism involved cation formation on PE through Lewis acid-catalyzed degradation, followed by attachment of PE cation to aromatic rings of PS. Blends were prepared in an internal mixer at 180 °C and characterized by selective solvent extraction, GPC, SEM, FTIR, and mechanical properties. The effects of added styrene monomer were also studied. This process is an example of degradative copolymer formation since the PE graft segment attached to the PS chain has lower molecular weight than the PE phase from which it was derived. Although the initial copolymer formed in this process is a graft copolymer, the grafted PE segments may still be capable of reacting with catalyst with subsequent cation formation and attachment to a different PS chain leading potentially to a cross-linked copolymer. For related work, see also Sun et al. (1998), Diaz et al. (2002, 2005, 2007), Guo et al. (2007), Liu et al. (2009b), Jian-Ping et al. (2011), and Shahbazi et al. (2012). Li et al. (2009a, b, 2011b) employed aluminum chloride in compatibilized blends of PP and PS. A potential issue with any Friedel-Crafts process employed to form a compatibilizing copolymer is removal of residual catalyst from the blend to prevent adverse effects on blend properties during the lifetime of any formed plastic part.

5.11.9.8 Copolymer Formation by Ion-Neutral Donor Group Association

Compatibilized blends of 77 parts EPDM-SO$_3$Zn salt and 9 parts S-co-4-vinylpyridine with 4 parts zinc stearate (ZnSt) plasticizer were prepared in an internal mixer at 200 °C (Lundberg et al. 1988; Agarwal et al. 1987; Peiffer et al. 1986). The blends were characterized by FTIR, DMA, melt viscosity, DSC, and SEM. Mechanical properties were compared to blends containing unfunctionalized PS or containing EPDM-SO$_3$Na or Mg salts. A copolymer linked by ion-neutral donor group cross-links may form between sulfonate anion and pyridine nitrogen mediated by Zn cation. Related blends comprising sulfonated EPDM and styrene/maleimide/2-vinyl pyridine copolymer have been described by Dean (1986).

5.11.9.9 Copolymer Formation by Radical Coupling

As shown in Table 5.61, PO blends with either PS or styrene copolymer have been compatibilized through radical coupling reaction. In these examples, radicals were generated either through addition of radical initiators, through addition of a peroxide-containing polymer, through addition of an azide species, through use of ultrasonic oscillation during extrusion, through mechanochemical processing, or through preirradiation.

5.11.9.10 Copolymer Formation by Thiol-Alkene Coupling

In a series of papers by Soares and coworkers (see, e.g., Soares et al. 2001), compatibilized blends have been prepared through copolymer formation between a thiol-functionalized polymer (also termed a mercapto-functionalized polymer) and a second polymer comprising a double bond (alkene). In a specific example, styrene-butadiene copolymer/EVAc blends with different ratios of components were compatibilized through addition of mercapto-modified EVAc. Evidence for copolymer formation came from FTIR and DMA. Morphology, mechanical properties, and DSC results were also reported.

5.11.9.11 Copolymer Formation by Transesterification

Hu and Lambla (1995) have blended EMAc (90-65 parts) with monohydroxy-terminated PS (10-35 parts) in an internal mixer at 180–220 °C in the presence of dibutyltin dilaurate or dibutyltin oxide catalyst. A compatibilizing copolymer arises from transesterification between pendent ester groups of EMAc and terminal hydroxy groups of PS. The effects on blend properties of PS molecular weight were reported. The effects of processing conditions and addition of solvent on conversion kinetics were studied.

5.11.10 Polyolefin + Polyurethane Blends

Ma et al. (2012b) reported compatibilized PVDF-TPU blends comprising PVDF-g-acrylic acid. Farah and Lerma (2010) prepared hydroxy-functionalized PP by reaction of PP-g-MA with 2-aminoethanol and used this functionalized PP in blends with TPU and unfunctionalized PP. Ethylene-octene copolymer was also used in place of PP.

Wang et al. (2007a) prepared compatibilized ethylene-octene copolymer blends with polyurethane using maleated ethylene-octene copolymer and amine-functionalized polyurethane. However, a study by Stutz et al. (1996) found no evidence for copolymer formation between thermoplastic polyurethane and either EAA or SMA under the specific conditions studied.

Qureshi (2009) prepared PP/TPU blends compatibilized using an amine-functionalized PP, which functionalized PP had been prepared in a separate step by extrusion of PP-g-MA with either hexamethylenediamine or dodecamethyl-enediamine. Blends characterization techniques included SEM, rheology, and mechanical properties.

Lu and Macosko (2004) and Lu et al. (2003) have prepared compatibilized blends of polyurethane with functionalized PP characterizing the blends by rheology, DMA, tensile properties, and morphology. Primary and secondary amine-functionalized PP were more efficient compatibilizers than was PP-g-MA. A degradative mechanism for copolymer formation involving polyurethane chain cleavage was postulated. See also Kobayashi et al. (2011) for related PE/TPU blends.

With regard to reactively compatibilized TPU blends, Lu et al. (2002) determined the relative reactivity of various functionalities toward TPU using model compounds. The ranking of relative reactivity was found to be primary amine (most reactive) > secondary amine >> hydroxyl $\sim$ carboxylic acid $\sim$ anhydride >> epoxide (least reactive).

5.12   Polyphenylene Sulfide Blends

Examples of polyphenylene sulfide blends not shown in other sections are listed in alphabetical order of the second polymer in the blend unless otherwise noted. Included in this section are polyphenylene sulfide blends not containing PA, PEST, or PO. When copolymer characterization was not performed, the structure of the compatibilizing copolymer is inferred from the functionality location on each of the two polymers. In some cases, more than one type of compatibilizing copolymer may have formed.

5.12.1   Polyphenylene Sulfide + Polysiloxane Blends

5.12.1.1 Copolymer Formation by Amine + Epoxide Reaction
Compatibilized blends of polyarylene sulfide with epoxy-functionalized polydimethylsiloxane have been prepared by Han (1994). An amine-terminated polysiloxane was functioned in solution with a chloro-epoxy triazine. Blends of 95:5 PPS:polysiloxane were extruded at 130–290 °C to provide compositions with markedly improved mechanical properties compared to a similar blend containing unfunctionalized polysiloxane.

5.12.2   Polyphenylene Sulfide + Styrene Copolymer Blends

Compatibilized blends of polyarylene sulfide with SEBS-g-MA have been prepared by Hisamatsu et al. (2000). Possibly an amine-terminated PPS reacts with anhydride to form a compatibilizing copolymer. Blend properties were measured as a function of MA content on SEBS. Nam et al. (2003) prepared compatibilized blends of PPS with ABS-g-MA in a TSE. Blends were characterized using optical microscopy, SEM, FTIR, DMA, and heat distortion temperature.

5.13   Polystyrene or Styrene Copolymer Blends

Examples of polystyrene blends not shown in earlier sections are listed in alphabetical order of the second polymer in the blend unless otherwise noted.

5.13.1   Polystyrene + Styrene Copolymer Blends

Xu et al. (1999a) prepared compatibilized blends of PS and the Zn salt of sulfonated PS by addition of poly(styrene-b-4-vinylpyridine) diblock copolymer. Characterization methods included SEM, DSC, SAXS, and FTIR. The effect of block copolymer level was studied. Evidence was found for Zn-mediated cross-linking between sulfonate groups and pyridine nitrogen.

Taubitz et al. (1988e) prepared ABS-g-GMA by reactive extrusion and used the product to make compatibilized blends with carboxylic acid-terminated PS. In one example, ABS-g-GMA (40 parts; 1.5 % GMA) was extruded with carboxylic acid-terminated PS (40 parts) on a TSE at 210 °C. The product showed only 15 % unbound PS by selective solvent extraction and GPC. For comparison blends prepared with unfunctionalized ABS showed 96–100 % unbound PS.

5.13.2   Polystyrene + Polyurethane Blends

Cassu and Felisberti (2001) prepared compatibilized PS/polyurethane blends by reactive extrusion in the presence of SMA. Blends were characterized by rheology, solubility tests, GPC, and SEM to confirm the presence of copolymer.

5.13.3   Styrene Copolymer + Polysiloxane Blends

Livengood et al. (2002) prepared compatibilized blends of amine-terminated polydimethylsiloxane and SMA by extrusion at 135–210 °C. The products were formulated into toner compositions with improved properties.

5.14   Summary

This chapter has not presented every known example of a reactive compatibilization strategy, nor has it included every known polymer that has been compatibilized in an immiscible blend with one or more other polymers. However, the compatibilization strategies presented herein illustrate broadly general methods which may be applied to new polymer blends or applied to known polymer blends for a higher return on cost vs. performance ratio.

The papers cited in this chapter reach similar conclusions concerning the effects on immiscible blend properties of a copolymer formed by reactive compatibilization. In virtually all cases, the generated blend morphology shows a smaller dispersed phase particle size than that observed in the absence of copolymer formation. In the majority of cases, this morphology is stabilized against agglomeration and coalescence of the dispersed phase during subsequent thermal processing. The specific morphology size distribution and its stability result in improved mechanical properties, not observed in uncompatibilized blends. A few

efforts have been made to characterize the phase interface and to correlate the interfacial thickness with the level of copolymer formed. However, in most older papers, the existence of copolymer is simply inferred from secondary evidence and its level is not quantified.

Except for a few notable cases, there was seldom consideration in these papers about the architectures of copolymers generated and their possible effects on compatibilization efficiency and morphological stability. Furthermore, since morphological stability alone may not result in optimum physical properties, it is sometimes not possible to know if optimum physical properties have been obtained. In numerous papers, clearly more than one type of copolymer architecture can form. For example, in acid-epoxide reactions, a new secondary alcohol may form that may possibly equilibrate into polyester constituting one blend component (see, e.g., Su et al. 1997). Only a few papers discuss the consequences of using di- vs. mono-end-group-functionalized polymers and their possible effects on generating graft vs. cross-linked copolymers. In many papers, the level and type of functionality on the reacting polymers are not specified.

There are numerous cited examples of blends where at least one polymeric component is vulcanizable. Such systems may be quite difficult to analyze after processing. In some cases, formation of an interpenetrating network (IPN) may be mistaken for covalently bonded copolymer. This is particularly so when no deliberate effort has been made to promote vulcanization and its occurrence was adventitious. Selective solvent extraction experiments to detect copolymer can be misinterpreted if some polymer is physically occluded in a matrix of the second polymer.

Some polymers contain reactive functionality but are also themselves subject to mechanochemical radical generation. When such polymers are blended under high-shear mixing with a second functionalized polymer, the architectures of formed copolymer may derive both from the primary, expected reaction and also from an unexpected, radical-radical coupling process.

In some cited examples, a third, multifunctional reagent is added that reacts with both polymers, for example, as a coupling agent. The relative solubility of many such reagents in particular polymers is often unknown. In immiscible blends, the reagent may segregate into one phase and selectively couple or cross-link that phase, in competition with the desired interpolymer reaction at the phase interface. Again, IPN formation may result, leading to confusion when interpreting selective solvent extraction data. For some types of reagents the problem of phase segregation can be solved by preparing a masterbatch in which a slight stoichiometric excess of the reagent is added to one of the polymers. The reagent caps the reactive functionality, but it does not couple or chain extend the polymer in which it is selectively soluble. Thus, reaction of the newly functionalized polymer at a phase interface with a second polymer is facilitated when the two polymers are blended. This strategy often works when using a coupling agent and in certain cases when using a condensing agent but not always when using a nonselective activating agent. However, relative stoichiometries of reacting species are often not considered in older cited examples.

There have been only a few studies of kinetics of copolymer-forming reactions under melt processing conditions because it is quite difficult to generate these data. In the papers cited in this chapter, there are many examples where not only the level of copolymer formed but also the architecture of the copolymer strongly depends on the melt processing time. Many of the blends are "living" in the sense that more copolymer would be generated with additional time. In contrast, some types of copolymer linkage (e.g., the reaction product of an alcohol and a cyclic anhydride) may degrade, and copolymer may be lost with additional processing time or at higher processing temperature. Different copolymer architecture may form with additional processing time, particularly when a redistribution reaction is possible as either the primary or as the secondary reaction (e.g., when a reactive alcohol is generated from epoxide ring opening with acid). It is usually difficult to isolate and characterize a copolymer from a melt-processed polymer blend. Model studies of copolymer formation between immiscible polymers have been performed either in solution (where there is unlimited interfacial volume for reaction) or using hot-pressed films of the polymers (where the interfacial volume for reaction is strictly controlled at a fixed phase interface). Model studies using low molecular weight analogs of the reactive polymers are useful, but their applicability to high molecular weight reacting systems may be limited. Nevertheless, excellent insight into reactive compatibilization processes has been obtained in recent years (such as through bilayer film studies) in publications including, but limited to, those by Scott and Macosko (1994b) (model experiments for interfacial reaction between SMA and either PA-11 or amine-terminated butadiene-acrylonitrile copolymer during reactive polymer blending); Merfeld et al. (1998) (interfacial thickness in bilayers of PPE and styrenics copolymers), Karim et al. (1999) (transesterification at a polymer blend layer examined by multiple physical techniques), Hayashi et al. (2000) (study of interfacial reaction between PA and anhydride-terminated polysulfone by neutron reflectivity and small-angle neutron scattering), Schulze et al. (2000) (reaction kinetics of end-functionalized chains at an amino-terminated PS/anhydride-terminated PMMA interface), Koulic et al. (2001) (premade vs. in situ formed compatibilizer at the PS/PMMA interface), Schulze et al. (2001) (measuring copolymer formation from end-functionalized chains at anhydride-terminated PMMA and amino-terminated PS interface using forward recoil spectrometry and SEC/fluorescence detection), Cheng et al. (2003) (computational modeling of reactive extrusion process), Yeung and Herrmann (2003) (computational modeling of reactive extrusion process), Coote et al. (2003) (neutron reflectometry investigation of polymer-polymer reactions at the interface between immiscible polymers), Jones et al. (2003) (effect of thermodynamic interactions on reactions of anhydride-terminated PMMA and amino-terminated PS in bilayer film), Harton et al. (2005) (diffusion-controlled reactive coupling at polymer-polymer interfaces), Kho et al. (2005) (morphological development at a bilayer film interface of PMMA-GMA/PS-COOH under electric field), Yu et al. (2005) (interfacial reaction kinetics at a PA-6/SMA reactive interface), Zhang et al. (2005) (interfacial morphology development during reactive coupling of anhydride-terminated PMMA and amino-terminated PS in bilayer film),

Kim et al. (2006) (bilayer film study of COOH-terminated PS and PMMA-GMA reaction), Chi et al. (2007) (kinetics of interfacial reaction between carboxylic acid-terminated PB and amino-terminated PDMS studied by interfacial tension measurements), Wang et al. (2010a) (investigation of reactive polymer-polymer interface using nanomechanical mapping), and Wang et al. (2013b) (interfacial interchange reaction between PC and amorphous PA).

It is to be hoped that future work on reactive compatibilization will continue to combine the excellent materials science that has been done to date with additional investigations of the more exact nature of chemical processes occurring and their quantitative effect on blend properties. Such knowledge of the chemistry, coupled to fluid mechanics and morphology development models, would provide powerful tools for optimization of known and invention of new reactive compatibilization processes to prepare commercially valuable polymer blends.

Abstract

An interpenetrating polymer network, IPN, can be defined as a combination of two
polymers in network form, at least one of which is synthesized and/or cross-linked
in the immediate presence of the other. This chapter presents the synthesis, mor-
phology, and properties of IPNs made in different ways emphasizing bulk syntheses
and latex syntheses. Some of the most interesting materials have a glassy polymer
and a rubbery polymer combined. Usually, polymer I is synthesized, followed by
polymer 2. If the reactions are noninterfering, both monomers can be mixed with
their respective cross-linkers and initiators and polymerized simultaneously. Appli-
cations of IPN technology are broad, including sound and vibration damping,
biomedical applications, coatings, adhesives, and golf ball components.

The morphology of IPNs has been widely investigated via electron microscopy
and dynamical mechanical spectroscopy. Many IPNs have dual-phase continuity,
with phase domain sizes of the order of several hundred angstroms. For sound and
vibration damping over broad temperature ranges, the two polymers are mixed in
different extents in different parts of the material, usually in the submicron range.

As examples of the biomedical materials, films to cover serious skin burns are
used because of their capability of transporting moisture away from the burn site
by diffusion while simultaneously transporting in oxygen to help keep the still
living tissue cells alive and multiplying. The films are transparent, so that the
doctors can see how the healing is progressing. Quite different materials make
up false teeth, which are hard and tough and very crack resistant.

Structured latex particles were also introduced to provide multifunctional
properties. Three component latexes with IPN cores as impact and damping
improvers were prepared by three-stage emulsion polymerization. The IPN cores
were composed of one impact part and one damping part.

6.1   Introduction

An interpenetrating polymer network, IPN, is defined as a blend of two or more
polymers in a network form, at least one of which is synthesized and/or cross-linked
in the immediate presence of the other(s). An IPN can be distinguished from
polymer blends, blocks, or grafts in two ways: (1) An IPN swells, but does not
dissolve in solvents, and (2) creep and flow are suppressed.

6.1.1   Definitions

There are several kinds of IPNs:

Sequential IPN. First, polymer network I is synthesized. Then, monomer II plus cross-linker and activator are swollen into network I and polymerized in situ; see Fig. 6.1a.

Simultaneous Interpenetrating Network, SIN. The monomers and/or prepolymers plus cross-linkers and activators of both components are mixed, followed by simultaneous polymerization via noninterfering reactions; see Fig. 6.1b. Typical syntheses involve chain and step polymerization kinetics. While both polymerizations proceed simultaneously, the rates of the reaction are rarely identical.

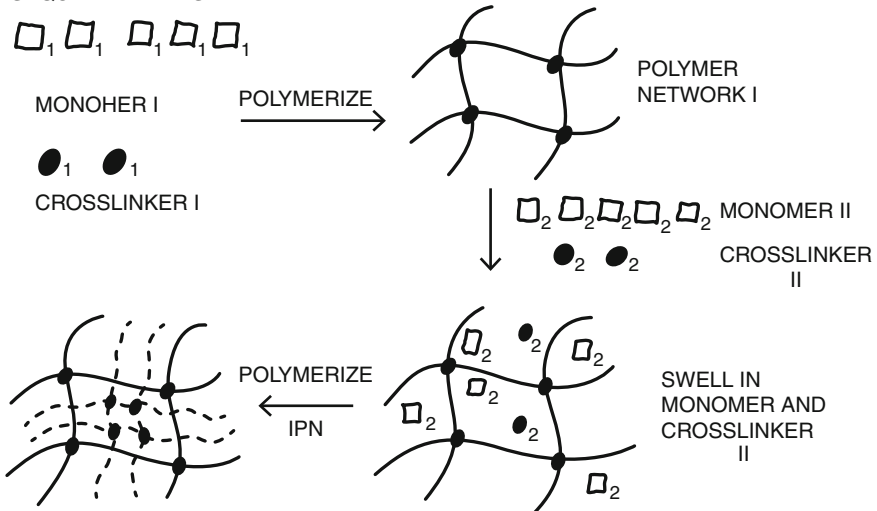
Latex IPN. The polymers are made in the form of latexes, each particle constituting a micro-IPN. Depending on the rates of monomer addition relative to the rates of


Fig. 6.1 Two synthetic methods for preparing interpenetrating polymer networks. (**a**), sequential IPNs and, (**b**), simultaneous interpenetrating networks, SINs

polymerization, various degrees of interpenetration and/or core/shell morphologies may develop. There are several kinds of latex IPNs; see Sect. 6.4.

Gradient IPN. In this case, the overall composition or cross-link density of the material varies from location to location on the macroscopic level. One way of preparing these materials involves partial swelling of polymer network I by the monomer II mix, followed by rapid polymerization before diffusional equilibrium takes place. Films can be made with polymer network I predominantly on the surface and polymer network II predominantly on the other surface with a gradient composition existing throughout the interior.

Thermoplastic IPN. When physical cross-links rather than chemical cross-links are utilized, the materials may flow at elevated temperatures. As such, they are hybrids between polymer blends and IPNs. Such cross-links commonly involve block copolymers, ionomers, and/or semicrystallinity.

Semi-IPN. These are compositions in which one or more polymers are cross-linked and one or more polymers are linear or branched.

6.1.2 History of IPNs

While the field of IPNs is considered younger than the corresponding field of polymer blends, blocks, and grafts, some of the early materials predated those commonly ascribed to the corresponding blend, block, and graft fields. To complicate the issue, the patent literature reveals that the topology of IPNs was invented over and over again. A brief summary is given in Table 6.1.

The first such invention was by Aylsworth (1914) (Table 6.1, No. 1), who was at the time the chief chemist of Thomas A. Edison in the latter's West Orange, NJ laboratory. He was also an independent inventor, working part time in his own laboratory (Sperling 1987).

Table 6.1 Early IPN patents

No.	Polymer 1	Polymer 2	Application	Inventor	Pat. No.
1	Phenol formaldehyde	Natural rubber	Toughen phonograph records	J. W. Aylsworth	*U.S. Pat.*, 1,111,284; 1914
2	Natural rubber	PVC	Plastic materials	H. Hopff	*Ger. Pat.*, 623,351; 1935
3	Poly(methyl methacrylate)	Poly(methyl methacrylate)	Smooth-surfaced plastics	J. J. P. Staudinger and H. M. Hutchinson	*U.S. Pat.*, 2,539,377; 1951
4	Positively charged network	Negatively charged network	Ion-exchange resin	G. S. Solt	*Br. Pat.*, 728,508; 1955

In those years, Edison had switched from the cylinder-type phonograph records to the platter type. The latter ones were made of the new phenol formaldehyde material, just invented by Leo Baekeland. The problem with the new material was that it was extremely brittle, hence the new platters needed to be very thick. Aylsworth's solution to the problem was to mix in natural rubber and sulfur, which on heating forms a network. Since the phenol formaldehyde compositions are all densely cross-linked, the overall composition was a simultaneous interpenetrating network.

In 1935, Dr. Heinrich Hopff of I. G. Farbenindustrie patented two major advances in emulsion polymerization and latex formation (see Table 6.1, No. 2):

1. Various vinyl monomers such as vinyl chloride were added to a natural rubber latex dispersion and polymerized to make a core-shell structure.
2. Various vinyl latexes, previously polymerized, were mixed with natural rubber latex, both still in aqueous dispersion, and then coagulated. Thus, core-shell latex and latex blend materials were known very early.
3. The coagulated masses of both (1) and (2) above could be masticated with sulfur and vulcanized, as mentioned in the patent, producing semi-IPNs.

Staudinger and Hutchinson (No. 3 in Table 6.1) were concerned with the surface unevenness of the new cast-polymerized plastics, as prepared between glass plates (Staudinger and Hutchinson, 1951). While the plastics were clear, objects behind them appeared distorted. They started with either cross-linked PMMA or cross-linked PS and added the same monomer mix as before and polymerized in situ. This creates a homo-IPN. The intent was that by stretching polymer network I taut via the swelling action of monomer mix II, the surface waviness would be reduced, thus improving the visual characteristics for windows, etc. It must be remarked that J. J. P. Staudinger was Herman Staudinger's son. The latter was the person who enunciated the now famous Macromolecular Hypothesis in 1920, stating that there was a certain class of colloids actually composed of long chains.

In 1955, Solt discovered that IPNs with one network charged negatively and the other charged positively made superior ion-exchange resins (Solt 1955). An important feature of these materials relates to having the two phases in juxtaposition on a very small scale. If the system is mutually miscible, however, efficiency declines due to the interactions between the opposite polymer ions, kicking out the mobile salt ions.

The term *interpenetrating polymer networks* was coined by John Millar in 1960, who prepared homo-IPNs (an IPN with both polymers identical) of polystyrene (Millar 1960). Millar knew about Solt's work, and his objective was to increase the size of suspension particles of polystyrene intended for ion-exchange applications.

Starting in the late 1960s, the field of IPNs was examined by three teams of investigators. Papers by Frisch et al. on IENs (1969a, b), Sperling and Friedman on sequential IPNs (1969), and Lipatov and Sergeeva (1967) on filled materials started systematic research to establish the field of IPNs. By the year 1979, there were

approximately 75 patents and 125 papers in the field (Lipatov and Sergeeva 1967; Sperling and Friedman 1969; Frisch et al. 1969a). Later on, that many IPN patents and papers are produced each year (Kim and Sperling 1997).

6.1.3 A Brief Literature Survey

Some of the IPN literature includes a book by Sperling (1981) and edited works by Klempner and Frisch (1993), Klempner et al. (1994), Sperling and Kim (1996), and Kim and Sperling (1996). A book by Sperling appeared in 1997 with a chapter on IPNs (Sperling 1997). Today, IPNs are widely accepted as a branch of multicomponent polymer materials and as such are discussed in many general polymer textbooks (Elias 1997) as well as more specialized monographs (Utracki 1989) and edited works (Gergen 1996).

A valuable review of IPN research was published by Yu. S. Lipatov and T. T. Alekeeva in 2007 (Lipatov and Alekeeva 2007). This review covers IPN research and development throughout the world from the beginning in the early twentieth century with 356 references. A good deal of theory is introduced relative to the problems of phase mixing and separation during the synthesis stage.

Sperling recently published a history of IPNs, going back to the early 1900s (Sperling 2011) as well. The first man known to invent an IPN was Jonas W. Aylsworth, who was associated at times with Thomas Edison. Aylsworth added natural rubber and sulfur to Leo Baekeland's Bakelite (Alysworth 1914), based on phenol and formaldehyde. As it was, Thomas Edison was using the original Bakelite for his phonograph records when he switched from spools to the platters. The platters needed to be very thick, lest they break on dropping, etc. Since both the Bakelite and the rubber and sulfur composition were cross-linked, they made an IPN, the first known such composition. Then, Edison's phonograph records suddenly got much thinner. The reader should note that this advance was carried out long before the idea of a polymer being a chain structure was considered. Sperling goes on to describe how IPNs were reinvented by several people, as revealed in the patent literature. Most of the works were largely forgotten, until the late 1960s.

6.2 Synthetic Methods

All interpenetrating polymer networks utilize two different polymers. The exception involves the homo-IPNs, where both polymers are identical (Millar 1960; Siegfried et al. 1979). While these polymers may be synthesized by any of the known methods of polymer synthesis, some methods clearly work better in given objectives than others. The principal kinetic methods used are chain and step polymerization.

Many sequential IPNs have used two chain polymerizations, where monomer mix I is polymerized and monomer mix II is swelled in, followed by polymerization

of monomer mix II. Typical examples involve poly(ethyl acrylate) and PS (Huelck et al. 1972) and SBR and PS (Curtius et al. 1972).

A host of cross-linkers have been employed; see Table 6.2. The mixed functionality cross-linkers often serve as grafting sites between networks of quite different nature, perhaps one network chain polymerized and the other step polymerized. Then, each type of functionality reacts with each type of monomer during polymerization.

Where a step polymerization is used, almost always it is for the first polymer synthesized in a sequential IPN. The reasons involve the slow diffusion into a preexisting network of most monomers used in step polymerization and the relatively high glass transition temperature of step-polymerized polymers. The latter reason is important because in order for diffusion and concomitant polymerization to occur rapidly, polymer network I should be above its glass transition at the temperature of polymerization of monomer mix II. Table 6.2 presents glycerol as a simple trifunctional cross-linker for step-polymerized materials, suitable for polyesters and polyurethanes.

For simultaneous interpenetrating networks (SINs), two independent, noninterfering reactions are required. Thus, a chain and a step polymerization have been the method of choice for many such polymerizations. Typical examples have involved PS, polyurethanes (Hourston and Schafer 1996; Mishra et al. 1995), and PMMA. A key factor in the kinetics of such polymerizations is the keeping of the system above the glass transition temperature of both components. If the glass transition of either the polymer network I or polymer network II rich phase vitrifies, the polymerization in that phase may slow dramatically.

There are several interesting polymerization schemes intermediate between a sequential IPN and an SIN. For example, in in situ prepared sequential IPNs, both monomers are polymerized via free radical reaction (He et al. 1993; Rouf et al. 1994). The two monomers must have quite different reactivities toward the free radicals. This situation arises with vinyl or acrylic double bonds and allylic double bonds. The allylic double bonds react about 100 times slower than acrylic or methacrylic bonds. Often, two initiators are used, one reacting at a lower temperature and the other at a higher temperature. In one of the systems studied, based on methyl methacrylate and diallyl carbonate of bisphenol-A (DACBA), first, cross-linked PMMA was formed at moderate temperatures. Then, by just increasing the temperature after completion of the first polymerization, the synthesis of the allylic network followed. In this case, the initiator azobisisobutyronitrile, AIBN, was used to polymerize the MMA at 60 °C, and then the sample was heated to 95 °C for the polymerization of the DACBA with t-butyl peroxy isononanoate (TBPIN).

Latex IPNs offer unique synthetic opportunities. Since an IPN double network, ideally, is contained in each submicroscopic latex particle, special effects are possible. The simplest case involves a cross-linked seed latex particle that is polymerized first. Then, monomer mix II is added. There are two subclasses. First, all of the monomer mix II can be added at once or at least far more rapidly than the polymerization takes place. In that case, the monomer will first swell the latex particle, and then the excess monomer forms a shell around the swollen core.

If the monomer mix II is added slowly, or more slowly than the initiator can polymerize the material, little monomer can swell into the particle, and a better defined core/shell structure develops.

There are other cases to consider, such as the polarity of the two polymers. Usually, the more polar polymer will prefer to be in contact with the aqueous phase (thermodynamics considerations). Without cross-linking, there can be a phase inversion from what was stated in the previous paragraphs. The presence of cross-linking, however, limits such inversion (where polymer network II forms the core) because of the swelling restrictions on polymer network I imposed by the cross-links. Then, in the general case, one must ask what relative rates of polymerization are taking place, what level of cross-linkers are employed, etc., leading to many current research topics (Lovell and El-Aasser 1997).

6.3   Morphology and Glass Transitions

The previous section showed how IPNs and related materials can be synthesized. The several synthetic methods, such as sequential, simultaneous, latex, and thermoplastic IPN formation, will result in different morphologies. One of the main advantages of IPN synthesis relates to the ease of promoting dual-phase continuity, i.e., for a two-component system, the two components will be phase separated, and each will exhibit phase continuity throughout the material.

Because most IPNs are phase separated, they usually exhibit multiple glass transition, one for each phase. However, since the phases are small with large volumes of interphase material, the glass transitions may be broadened or moved toward each other.

Another advantage of using IPNs involves its thermosetting characteristics. By definition, IPNs will not flow when heated. A partial exception is the thermoplastic IPNs, which behave cross-linked at ambient temperatures, but flow at elevated temperatures. While some IPNs are tough, impact-resistant plastics, the cross-linking permits many other types of applications, such as sound and vibration damping; biomedical, adhesive, and coating uses; etc. (see Sect. 6.5).

6.3.1   Morphology via Electron Microscopy

A powerful method of examining the morphology of many multicomponent polymer materials utilizes transmission electron microscopy (Woodward 1989). If the two phases are nearly equal in electron density, staining with osmium tetroxide or other agents can be used. For more detailed discussion on the methods of morphology characterization, see ▶ Chap. 8, "Morphology of Polymer Blends."

Donatelli et al. (1976) examined the morphology of *net*-polybutadiene-*internet*-polystyrene and compared these with those of the corresponding semi-IPNs and polymer blends; see Fig. 6.2. In the absence of cross-links, then a solution
Fig. 6.2 Selected morphologies of IPNs based on SBR and polystyrene, SBR stained with osmium tetroxide. *Upper left*, commercial high-impact polystyrene. *Upper right*, Ostromislensky's material, with no phase inversion; *middle left*, semi-IPN, SBR cross-linked; *middle right*, semi-II IPN, PS cross-linked; *lower left*, full IPN; *lower right*, full IPN, higher cross-linking in the SBR

graft copolymer develops. If the solution is stirred during the polymerization, and then a phase inversion takes place, see Fig. 6.2, upper left. This material is the well-known high-impact polystyrene, HIPS. On quiescent polymerization, the material fails to undergo phase inversion, and polybutadiene remains the continuous phase; see Fig. 6.2, upper right. This last material was invented by Ostromislensky (1927). The middle left and right compositions are, respectively, the semi-I and semi-II compositions of the polybutadiene and the polystyrene. The bottom left and right are the full sequential IPNs, with lower and high cross-link levels in the polybutadiene, as indicated.

The full IPNs shown here (as in numerous other cases) have dual-phase continuity. The domains, as cut in thin section for transmission electron microscopy, appear to be ellipsoidal. Actually, they are more probably thin sections of cylinders, cut at various angles. Other studies show that both phases may be continuous. Spinodal decomposition kinetics, thought to apply in many such cases, results in interconnected cylinders (Utracki 1994).

The upper left has an Izod impact resistance of approximately 80 J/m, the middle left about 150 J/m, and the bottom left about 250 J/m. These early results encouraged the development of these materials.

The domain size of sequential IPNs (such as shown in Fig. 6.2) is controlled by several features: the interfacial tension coefficient between the two polymers, γ; the volume fraction of polymers 1 and 2, v_1 and v_2, respectively; effective network concentration of the two polymers v_1 and v_2, respectively; and the gas constant times the absolute temperature, RT.

Basic equations were derived by Donatelli et al. 1977 and Yeo et al. 1983. Both assumed spheres of polymer 2 dispersed in polymer 1, although the spinodal decomposition model and much electron microscopy suggest that interconnected cylinders may be more prevalent, as discussed above. The Yeo et al. equation is the more general:

$$D_2 = \frac{4\gamma}{RT(Av_1 + Bv_2)} \tag{6.1}$$

where

$$A = \frac{1}{2v}\left(3v_1^{1/3} - 3v_1^{4/3} - v_1 \ln v_1\right)$$

and

$$B = \frac{1}{2}\left(\ln v_2 - 3v_2^{2/3} + 3\right)$$

For lightly cross-linked systems of 50/50 composition, the value of D_2 is of the order of several hundred angstroms. Even though spheres rather than cylinders were specified in the derivation, the numerical result is surprisingly accurate.

6.3.2   Phase Diagram Control of SIN Morphology

While the morphology of sequential IPNs is mainly controlled by the volume fractions of the two polymers and the thermodynamics of mixing, that of SINs depends primarily on the time order of three key events:

1. The gelation of polymer 1
2. The gelation of polymer 2
3. Phase separation of the two polymers

If gelation of one or both polymers precedes phase separation, the polymer gelling first will tend to be more continuous. If phase separation precedes gelation, then a rather coarse morphology may develop. Of course, both gelation and phase separation are controlled by the kinetics of polymerization and the concentration of the cross-linkers, as well as the thermodynamics of mixing.

To determine the time order of the three quantities indicated above, a metastable phase diagram was developed by Mishra et al. (1995). These authors studied polyurethane-based SINs, with poly(methyl methacrylate) constituting the other polymer. The system has proved very popular for research, over 50 papers now being in the literature on PU/PMMA and PU/PS SINs (Mishra and Sperling 1996). The morphologies of these systems vary widely, from two well-defined glass transitions to one broad glass transition or two glass transitions shifted inward toward each other. It appears that the differences in the morphology may have arisen through a different time sequence of the three critical events. (Mathematically, three factorial yields six different possibilities for the finished product.)

As shown in Fig. 6.3, Mishra et al. (1995) presented a tetrahedron as the spatial form of their metastable phase diagram, the corners of which represented MMA, PMMA, urethane prepolymer "U", and PU. The PMMA contained 0.5 % tetraethylene glycol dimethacrylate, causing it to gel after about 8 % conversion; see the G_1-"U"-PU plane. The phase separation curve for the ternary system MMA-PMMA-"U" (front triangle) on polymerization of only the MMA is indicated by the points C-D-A-E. Similarly, the phase separation curve for the MMA-PMMA-PU system (see rear triangle, Fig. 6.3) is represented by the points J-B-K-L. Thus, the entire tetrahedron volume is divided into two regions: one phase separated and the other single phased, separated by the curvilinear construction C-D-A-E-L-B-J. This surface exhibits a characteristic sail-like shape.

The inset in Fig. 6.3 illustrates the actual experimentally determined curve, C-D-A-E, of the tetrahedron. To the left of the diagram, the results were one phased and to the right, two phased. The curve down the middle of the triangle indicates where phase separation was first noted.

The intersection of the PMMA gelation plane with that of the phase separation sail-like surface, the curvilinear line A-B, represents the critical line along which simultaneous gelation of PMMA and phase separation of the PU from the PMMA exists. Reactions passing to the left of this curve will have the PMMA gel before phase separation, while reactions to the right of A-B will phase separate before gelation takes place.
Fig. 6.3 The metastable phase diagram for the polyurethane-poly(methyl methacrylate) SIN at 60 °C. The PMMA gels at and above the plane G_1-"U"-PU. The intersection of the PMMA gelation plane and the surface along the curve A represents the condition of simultaneous phase separation and PMMA gelation

The gelation plane of the polyurethane is illustrated in Fig. 6.4; see G_2-MMA-PMMA. For completeness, the gelation plane G_1 of the PMMA from Fig. 6.3 is also shown. The gelation plane G_2 occurred after about 67 % conversion of the PU. The intersection of the two planes, G_1-G_2, illustrates the line of simultaneous gelation of the two polymers. Reactions passing to one side or the other of this line will have one polymer or the other gelling first. It must be noted that the line G_1-G_2 also intersects the line A-B of Fig. 6.3, not shown. The intersection of these two curves expresses the presence of a triple critical point, where both polymers simultaneously gel and phase separate. While this triple critical point represents the ideal SIN synthesis condition, it would not, in general, produce the best physical or mechanical properties.

The tetrahedron construction represents the synthesis of sequential IPNs as well as the SINs. It must be noted that in real SIN syntheses, it is almost impossible to have the kinetics of polymerization of both polymers proceeding at identical rates. Sequential IPN polymerization represents the other extreme, where first one polymer is completely synthesized and then the other follows sequentially.

Fig. 6.4 The metastable phase diagram, same compositions as Fig. 6.3, illustrating the PU gelation plane, G_2-MMA-PMMA
Both sequential IPN and SIN polymerizations begin somewhere along the edge of the line connecting the two monomers, MMA-"U" in the present case. However, the polymerization lines need not be straight or even continue as single lines. When the polymerization line intersects the sail-like phase separation surface illustrated in Fig. 6.3, the line divides into two portions. Both these lines must conclude somewhere along the line connecting the two polymers, in this case the line PMMA-PU. Since it is impossible to have complete phase separation, the lines cannot be exactly at either apex. However, the more complete the phase separation will be, the closer to the apices the ends of the polymerization will be.

Sophiea et al. published the first classical composition-temperature phase diagram, working with the semi-IPN *net*-polyurethane-*inter*-poly(vinyl chloride) (Sophiea et al. 1994). They found a lower critical solution temperature, LCST $\cong 120\,^{\circ}\mathrm{C}$; below this temperature the system was one phased and above two phased. Such behavior is now known to be characteristic of most polymer blends (see ▶ Chap. 2, "Thermodynamics of Polymer Blends").

On the other hand, DuPrez et al., investigating the behavior of a poly(ethylene oxide)-*inter-net*-poly(methyl methacrylate) semi-II IPN, found what appears to be the lower-temperature portion of an upper critical solution temperature, UCST (DuPrez et al. 1996). However, since the temperatures were all below any possible critical temperature, conclusions are difficult to draw.

A TTT cure diagram was developed by Kim et al. for the system poly (ether sulfone)-*inter-net*-epoxy semi-II IPN (Kim et al. 1993). They showed that the transformation of the monomers to the polymers involved five steps: onset of phase separation, gelation of the epoxy component, a fixation of the domain size and shape morphology, end of phase separation, and (in this case)

vitrification of the epoxy component. In their system, the onset of phase separation preceded gelation.

Thermoplastic IPNs are defined above as being hybrid materials between the IPNs and the mechanical blends. Many of these materials consist of polypropylene, a semicrystalline polymer (the crystallinity contributing to the physical cross-linking of the system), and EPDM. The EPDM is lightly cross-linked during the mechanical blending, such that a dual-phase continuity is developed with the EPDM forming cylindrical structures inside of the polypropylene matrix. The basic physical requirements for dual-phase continuity in such blends were expressed by Paul and Barlow and by Jordhamo et al. (Paul and Barlow 1980; Jordhamo et al. 1986):

$$\frac{V_I}{V_{II}} x \frac{\eta_{II}}{\eta_I} = X \tag{6.2}$$

where if:

X > 1, phase I is continuous

X ≅ 1, dual-phase continuity or phase inversion is likely

X < 1, phase II is continuous

In Eq. 6.2, the quantity V is the volume fraction, and η represents the melt viscosity of phase I or phase II, depending on the subscript. Equation 6.2 represents the limiting case for zero shear. Utracki has proposed more complete relationships for finite shear stresses (Utracki 1989). However, although the forces involved in melt blending are large, the shear rates in blending are considerably smaller than on mixing lower viscosity fluids, such as oil and water. More information on this topic can be found in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends" in this handbook.

Davison and Gergen developed thermoplastic IPNs based on SEBS triblock copolymers (where the S hard blocks provide physical cross-linking) and semicrystalline polymers (Davison and Gergen 1977; Gergen and Davison 1978; Gergen et al. 1996). Figure 6.5 illustrates the dual-phase characteristics of a thermoplastic IPN of SEBS and PA-12, the latter having been extracted (Gergen et al. 1996).

The important points developed in this section are that sequential IPN synthesis tends to make dual-phase continuous materials. For both sequential and simultaneous syntheses, a metastable phase diagram can be developed to study the kinetics of phase separation and gelation, so that better control of the morphology can be attained. The thermoplastic IPNs depend on equal volume and viscosity ratios to attain the dual-phase continuity.

6.3.3   Glass Transition Behavior

Due to the small size of the domains, the glass transitions tend to be either broadened or moved toward one another on the temperature or frequency axis; see Table 6.3. This is a direct consequence of the greater extent of mixing and/or greater interphase volume fraction encountered in these materials. The glass transition temperatures

Fig. 6.5 An SEM fracture surface of an extracted thermoplastic IPN, 25/75 PA-11/SEBS. The SEBS phase was extracted

Table 6.3 Dynamic mechanical behavior of IPNs

No.	Observation	Comments
1	Two sharp T_gs near homopolymer values	Little or no mixing
2	T_gs moved toward each other	Molecular mixing in interphase and/or inside domains
3	One broad T_g spans both original T_g ranges	Extensive but incomplete mixing
4	One sharp T_g	Possibly miscible; T_g following the Fox equation
5	One or both T_gs increased	Cross-linking causes the T_g to increase. Can be part of no. 2

depend on the cross-linker level, as that influences the extent of mixing and/or interpenetration of the chains (Nemirovski et al. 1996). Of course, the glass transition temperature of any polymer increases slightly with increasing cross-link level. In this case, the polymer with the higher glass transition temperature may actually decrease as it is mixed with the other polymer. In such cases, within each phase, the Fox equation, often used for statistical copolymers, may be applied.

The volume fraction of the two polymers also plays critical roles; see Fig. 6.6 (Hsieh et al. 1996). This behavior is similar to many polymer blends, where the intensity of the transition depends on the volume fraction. In Fig. 6.6, an inward shift may also be observed. The glass transition temperature of three-polymer latex IPNs will be treated in Sect. 6.4.7.4.

6.4   Latex-Based Materials

Latex-based polymer materials can be either nature made, as natural rubber (Stern 1967; White 1995), or synthetically made. The synthetically made latexes are

Fig. 6.6 Loss modulus temperature behavior of PU (PTMO2000)/UPMI (PEG600) IPNs at various PU/UBMI ratios: _____ 100/0, __ __ __ 90/10, __.. __.. __.. 70/30, ... 0/100
commonly based on recipes of monomer, water, surfactant, and free radical initiator to induce chain polymerization (Lovell and El-Aasser 1997; Wickson 1993). However, recipes based on step polymerization are also well known, often resulting in cross-linked films (Walker and Shaffer 1996). The resulting latex material consists of small particles, usually spherical, of 50–500 nm in diameter, dispersed in water. Alternately, polymers are sometimes emulsified after polymerization (direct emulsification, the product sometimes called artificial latexes) via agitation of a melt in the presence of water and surfactant (emulsifier) and sometimes organic solvent or plasticizer (Piirma 1989).

6.4.1 Definitions

Latexes have long been used in IPNs and related materials. Some of the material types described in the literature are the following:

Latex Blends. These are combinations of two or more kinds of latexes, differing in chemical makeup. Blends of the same kind of latex, but differing in such characteristics as particle size, are of great interest, but will not be considered here (Gilicinski and Hegedus 1996). A latex blend used in coatings involves hard and soft latexes, serving to increase the modulus of the coating as well as improve block resistance (the ability to resist adhesion between two such films) (ASTM 1989; Friel 1992; Rajasingham et al. 2003), film formation properties (Robeson et al. 2003), dirt pickup resistance (Notta 2011), etc.

Core-Shell Latexes. First, a seed latex of polymer 1 is synthesized. Then, a second monomer is added to the system, usually with no added surfactant. Often, a starved polymerization route is employed, i.e., the rate of polymerization equals or exceeds the rate of monomer addition. This reduces the swelling of the seed latex by monomer 2, producing a two-layer latex having a spherical core and an overlaying shell. Obviously, multiple shells can be added.

Latex IPNs. A cross-linked seed latex of polymer 1 is synthesized first. Then, monomer 2 and cross-linker and initiator are added, usually without new surfactant. If the monomer 2 mix is added either all at once or rapidly, then swelling of polymer 1 by monomer 2 is encouraged, with subsequent greater interpenetration.

Latex IENs. Latex interpenetrating elastomer networks, latex IENs, are latex blends that have been cross-linked after film formation. They are named after the early works of Frisch and co-workers, who called these materials interpenetrating elastomer networks (Frisch et al. 1969b). Many latex blends, as used in coatings especially, are cross-linked as finally used in service.

Pre-cross-linked Latex Blends. In these materials the individual latexes are cross-linked during synthesis and then blended, and a film is formed. Because of limited deformation and/or interdiffusion capabilities, such films tend to be weak and only used for special purposes (Zosel and Lay 1993; Lesko and Sperry 1997). However, light cross-linking, as occurs in SBR latexes, may be tolerated. Pre-cross-linked latex blend materials are actually not IPNs, because the definition requires that at least one of the polymers be polymerized and/or cross-linked in the immediate presence of the other. An application of pre-cross-linked suspension-polymerized blends, in anionic and cationic form, is as ion-exchange resins. In suspensions, the particles are larger, usually of the order of 10–200 μm.

6.4.2   History of Latex Blends and Latex IPNs

The early research on core-shell and latex blend materials has already been mentioned; see Table 6.1. Hopff's materials (1935) were intended to be used vulcanized, in semi-IPN form.

A still earlier patent by I. G. Farbenindustrie prepared core/shell latexes from nitrocellulose and poly(ethyl acrylate) (Farbenindustrie 1931). Example 6 of the patent shows the level of sophistication already obtained 10 years after Staudinger's Macromolecular Hypothesis:

> 20 parts of nitrocellulose are dissolved in 80 parts of acrylic ethyl ester and emulsified in 200 parts of water, which contain 0.3 % of Marseilles soap (saponified from olive oil) and 0.5 % of sodium isopropylnaphthalene sulphonate and which has been adjusted with the aid of N/100 aqueous sulphuric acid to a hydrogen ion concentration corresponding to a pH value of 6.2. 2.5 parts of 30 %. aqueous hydrogen peroxide are added to the emulsion. After heating for 2 h at from 80 °C to 90 °C, the emulsion is freed from any non-polymerized ester with the aid of steam, and coagulated with the aid of aqueous 5 %. hydrochloric acid. The product is readily soluble in organic solvents and yields very elastic films.

While no cross-linker is mentioned in the patent, poly(ethyl acrylate) usually gels. That it was "readily soluble" suggests a low molecular weight. These early patents set the stage for today's latex blends and IPNs.

6.4.3 Types of Cross-Links

Klein and Daniels point out three basic categories of cross-linking in latexes (Klein and Daniels 1997): homogeneous or intraparticle cross-linking, interfacial cross-linking, and interstitial cross-linking. If two different polymer latexes are involved, the interfacial cross-linking actually constitutes a type of grafting. In interstitially cross-linked systems, cross-linking occurs in the aqueous phase, where water-soluble or water-swellable polymers undergo cross-linking (or grafting) reactions. These, for example, may involve melamine formaldehyde resins.

The principal types of cross-linking (or grafting) systems include carboxyl groups, hydroxyl groups, chloride (or other halogen) moieties, dimethyl meta-isopropyl benzyl isocyanate, TMI® or related materials, derivatives of acrylamide (such as N-methyl ethers), epoxy groups, and sulfonate groups. Ureido-functional monomers can also be used (Merger et al. 1988). Hydrogen and ionic bonding constitute effective physical cross-linking or grafting methods. Acetoacetoxyethyl methacrylate (AAEM) (Del Rector 1988) and diacetone acrylamide (DAAM)/adipic dihydrazide (ADH) (Kessel 2008; Zhang et al. 2012) are used extensively in coatings industry as well. Blocked cross-linking agents are also introduced by Yang et al. (2011) to be used in water-based coating.

A widely used self-condensable monomer is N-methylolacrylamide. This monomer undergoes a self-condensation reaction as well as reactions with hydroxyl and carboxyl moieties. The methylol functional groups can also react with epoxides or other methylol or methylol ether groups. Typically, N-methylol acrylamide is employed at concentrations of 3–7 wt% in latex coatings formulations (Daniels and Klein 1991).

6.4.4 Strategies for Low-VOC Latex Coatings

Low-VOC (volatile organic compounds, <50 g/l) and 0-VOC coatings (<5 g/l) are increasing in importance in the waterborne coating market due to increasing customer desire to minimize exposure to perceived chemical toxins in paint products and government regulations. To meet the needs, coating resins are moving toward lower T_g to achieve a good film formation property in the absence of a conventional coalescent (typically a VOC). However, this results in a softer film which impacts other coating properties, such as block resistance, hardness, and dirt pickup.

Feng et al. discussed some of the possibilities for producing low-VOC latex coatings (Feng et al. 1995). They pointed out that low-T_g latex materials produce low-T_g films, tacky to touch. The ability to resist adhesion (between two such films) is called *block resistance* in the coatings industry (ASTM 1989). Historically, people added organic solvents, transient plasticizers, etc., promoting particle deformation and interdiffusion, which on evaporation increased block resistance.

Reactive plasticizers that polymerize after film formation can also be used. They form an independent network (sometimes topologically resembling bailing wire) or

cross-link the polymer. Thus, the reaction results in a nonvolatile IPN. The chemistry of the latex surface region can be arranged such that it can be plasticized with water. This may be satisfactory for situations where the surface chemistry will be altered later or that water will not reach the final film in deleterious quantities. On the other hand, if still using higher-T_g IPN resin, high boiling-point ($>285\ ^{\circ}C$) coalescent can also be used in the formulation to improve the film formation property of the low- or near-zero VOC (0-VOC) coatings.

A newer alternative relates to the blending of hard and soft latex particles. The soft particles flow to form a film, while the hard ones tend to raise the modulus and, if on the surface, increase scratch resistance, etc.

Another alternate involves the post-drying of the film via cross-linking. Any number of reactions can be used, including double bonds pendent to the chain or condensable groups. Kessel et al. studied DAAM cross-linking reaction and its influence film formation of an acrylic latex (Kessel et al. 2008). They reported that the cross-linking reaction takes place during film formation process through "keto-hydrazide" reaction. They found that the cross-linking reaction is acid catalyzed and the reaction rate increases as pH decreases. Therefore, for ammonia-neutralized latex, the cross-linking reaction is favored by the loss of water during drying and the decrease in pH arising from the evaporation of ammonia. The cross-linking influences the later stages of film formation when particles are close packed. With the help of DAAM/ADH post cross-linking reaction, the film formation property can be improved. In some cases, heat, radiation, or high-temperature peroxides might be used. If two different latexes or core-shell structures are present, then the product will be an IPN.

6.4.5 Selected Patents in Latex Blends and Cross-Linked Systems

The field of latex blends and their cross-linked counterparts has been especially active; see Tables 6.4 and 6.5. Even in Table 6.4, where no cross-linkers are specified in the claims, it is likely that in many instances, the final product will contain some cross-linking. No. 4 in Table 6.4, for example, mentions a *gelling agent*. All the materials in Table 6.5 have a cross-linker in either one or both of the latexes. Both the N-methylol acrylamides and the ureido-functional groups described above appear in Table 6.5. The reader should note the use of both large and small latex pairs, as well as hard and soft latex pairs, in terms of making useful materials.

As defined in Sect. 6.1 and above, the compositions described in Table 6.5 are all latex IENs, where two latexes are blended and then cross-linked.

Patents rarely include the description of the system morphology. Patel et al. (1996) examined blends of hard and soft particles via atomic force microscopy, finding that when the soft component is present in amounts larger than 40 %, smoothed bumps were observed that appeared larger than either the hard or soft particles alone. The smoothness of each bump, supported by other evidences, suggests that the soft particles have coalesced into a virtual

continuum at the surface. The overall surface unevenness was thought to be indicative of underlying hard particles. The hard particles were thought to be submersed because of the lower surface energy of the soft polymer. Gilicinski and Hegedus (1996) also used atomic force microscopy to identify hard and soft domains by supplementing topographic data with mechanical property maps. A third such study by Geurts et al. examined the effect of blending two sizes of monodisperse poly(butyl methacrylate) latexes via minimum film formation techniques (Geurts et al. 1996). Usually, the addition of increasing amounts of small particles beyond a certain concentration level leads to a disruption of the particle matrix until the point at which the matrix changes from a continuous matrix of large particles into a continuous matrix of small particles. While these model materials were not cross-linked, it is easy to imagine the effects of cross-linking such materials, as indicated in Table 6.5.

6.4.6 Core/Shell Latexes

Core/shell latexes refer to systems with a submicroscopic particle morphology of one polymer forming the center part (the core) and the other polymer covering the core (the shell layer). Core/shell latexes are made via two consecutive emulsion polymerization stages, usually forming a particle structure with the initially polymerized material at the center and the later-formed polymer as the outer layer. If more than two stages are employed in the emulsion polymerization process, latex particles with multilayered morphology can be obtained.

The morphology of latex particles is controlled by the thermodynamic and kinetic factors. The thermodynamic factors determine the ultimate stability of the multiphase system, inherent in the production of a composite latex particle, while the kinetic factors determine the ease with which such a thermodynamically favored state can be achieved. The parameters affecting the thermodynamics of the system include the particle surface polarity, the relative phase volumes, and the

core particle size. The parameters affecting the kinetics of the morphological development include the mode of monomer addition (monomer starved or batch) and the use of cross-linking agents. Of course, cross-linked core/shell latexes constitute IPNs; see Sect. 6.4.1.

The core/shell morphology is usually more favorable if the latex contains a hydrophobic/hydrophilic polymer pair polymerized in that order, the volume fraction of the second-stage polymer is higher, the core particle size is larger (in the range from 100 to 900 nm), semicontinuous polymerization process (monomer-starved-feeding mode) for polymer 2 is employed, and cross-linking agents in both core and shell phases are used (Lee and Ishikawa 1983; Cho and Lee 1985; Berg et al. 1986; Lee and Rudin 1989, 1992; Jonsson et al. 1991; Xu et al. 1991; Lee 1981; Min et al. 1983; Hourston et al. 1986a; Sundberg et al. 1990; Winzor and Sungberg 1992; Durant and Sundberg 1995; Kong et al. 1996).

To a large degree, the physical and mechanical properties of the final product depend on the particle morphology. By properly selecting polymer pairs for the core and the shell stage, latex particles can be designed to have unique properties for a wide range of potential applications, from paints, coatings, adhesives, organic opacifiers, to impact modifiers for plastics or carriers for biomolecules (Kowalski et al. 1984; Dong et al. 1995; Qian et al. 1995; Segall et al. 1995; Hu et al. 1995, 1997c; Lindemann and Deacon 1993; Lee et al. 1986).

6.4.7   Latex IPNs (LIPNs)

LIPNs are also prepared through a two-stage emulsion polymerization (Kim and Sperling 1997; Nagarajan et al. 1996a; Sperling et al. 1972, 1973; Hourston and Satgurunathan 1984). First, a cross-linked seed latex is synthesized. For the second stage, one variation consists of swelling cross-linked latex particles (as the seed) with the second monomer, cross-linker, and initiator/catalyst, followed by polymerization. Another method is to feed the second monomer (together with a cross-linking agent and initiator/catalyst) slowly in a monomer-starved condition during the polymerization (Sperling 1997). The morphology of LIPNs is controlled by many factors, as will be discussed in Sect. 6.4.7.2.

The LIPNs are a special type of IPNs that combine both networks in a single latex particle, which differs from bulk IPNs, because the thermosetting character is limited to the size of the latex particles (of the order of several tens to a few hundred nanometers). Such IPNs have unique features in morphology, as well as in physical and mechanical properties (Zhong and Zhu 1991; Shu et al. 1990b; Zhang et al. 1991).

6.4.7.1 Cross-Linking and Grafting

For an ideal IPN, the two or more polymer networks are at least partially interlaced on a molecular scale but not covalently bonded to each other and cannot be separated unless chemical bonds are broken (Mita and Akiyama 1997).

The cross-linking of each polymer network is simply controlled by the type and concentration of the cross-linker employed in the system. The higher the cross-linker level (especially in polymer network I), the finer the morphology.

For a real IPN, however, especially for LIPNs, cross-linking or grafting of the polymer 1 with polymer 2 is likely to occur, based on the following three reasons:

1. The LIPNs are typically prepared through a two-stage emulsion polymerization process by a free radical polymerization mechanism. The cross-linking agents usually have two or more double bonds. Depending on the polymerization conditions, part of the double bonds from cross-linker I could be left during the first-stage polymerization, subject during the second-stage polymerization to act as graft sites.

2. If polymer 1 has residual double bonds, such as polybutadiene, part of the residual double bonds may be reacted in the second-stage free radical polymerization process, forming grafting sites for polymer 2.

3. If polymer 1 has an active α-hydrogen in the molecular structure, such as poly (butyl acrylate), hydrogen abstraction easily occurs in the second-stage polymerization. Actually, in many cases, to improve the compatibility between two networks, a graft site is intentionally added in polymer network I to enhance the grafting of polymer 2 on polymer 1.

The grafting reaction between two polymers can usually be minimized if the two polymer networks are formed through different polymerization mechanisms, such as polycondensation and free radical polymerization. In this case, a grafting agent may be needed in polymer 1 to improve the compatibility between the two networks. Again, the higher the graft site level, the higher the grafting efficiency of polymer 2 on polymer 1, the better the compatibility of the two phases. With very high graft levels, an AB-cross-linked copolymer may be created (Sperling 1997). However, for most purposes, the graft site concentration should be low enough to prevent miscibility of the two polymers.

6.4.7.2 Morphology

The morphology of latex IPNs refers to the degree of phase separation, the number of the phases, the shape and size and the domains, the degree of phase continuity, and the structure of the interface. On film formation, the ensemble of latex particles presents further unique morphologies. For LIPNs, the morphology is complicated because the swelling, polymerization, cross-linking, and phase separation are all taking place within the submicron polymer particles in an aqueous phase. Different LIPNs have different morphologies. Even for LIPNs with the same chemical composition, the morphology can be different when different synthesis processes are used (Peng and Li 1995). Since an LIPN is typically prepared by sequential emulsion polymerization, a core/shell morphology often forms, similar to that of the latex particles synthesized by a two-(or more)stage emulsion polymerization process (Sperling and Sarge 1972). However, if the cross-linking density of the first prepared polymer and the monomer 2 concentration are controlled properly, a cellular-type morphology can also be obtained (Silverstein et al. 1989; Hu et al. 1995; Sionakidis et al. 1979).

Similarly as in the core/shell latex particles, the LIPN morphology is controlled by the miscibility of the polymers, the volume fraction of each polymer, the cross-linking density of the polymers, and the sequence or the order of the synthesis (which polymer is synthesized first) (Sionakidis et al. 1979; Hourston and Satgurunathan 1987). The effects of those factors on the LIPN morphology are summarized as follows:

1. The more miscible the two polymer compositions, the less the phase separation between them and/or the smaller the domain size for each of them. The misci-bility is partially indicated by the solubility parameters (δ) of the two polymers. The closer the two δs, the more miscible the system (Yin et al. 1991).

2. Effect of the volume fraction of each phase in LIPN morphology depends on the nature of the two compositions. Phase separation can be reduced with increasing the content of the first component (Krause 1972) or with increasing the volume fraction of the second component (Geng 1992), i.e., by staying away from 50/50 compositions. If polymer 1 is hydrophobic (synthesized first) and polymer 2 is hydrophilic (synthesized later), a normal core/shell morphology is more easily formed; vice versa, an inverted core/shell morphology may result (Narkis et al. 1985, 1986). In addition, the longer the swelling time for the monomer 2 in polymer 1, the more nearly thermodynamic equilibrium is achieved for the system (Hourston et al. 1987).

3. Increasing the cross-linking density of polymer I (the seed) reduces the phase size (Sheu et al. 1990a). However, greater phase separation can occur when the cross-linking density of polymer I is high enough to reduce the diffusion of the monomer 2 into polymer 1. The higher the cross-linking density of polymer 2, the more efficient for the molecular interlocking, the less phase separation results (Sheu et al. 1990b; Yin et al. 1988).

The morphology of LIPNs can be investigated optically by either TEM or SEM and mechanically via the glass transition behavior. Nemirovski et al. studied elasto-meric LIPNs by a two-stage emulsion polymerization of styrene [with a comonomer to lightly cross-link the PS] upon a lightly cross-linked polyacrylate (PAcr) seed latex (75:25 PAcr:PS) (Nemirovski et al. 1996). The influence of the sequence and composition upon the morphology is schematically illustrated in Fig. 6.7 (Silverstein and Narkis 1989). They proposed a schematic diagram of the molded LIPN showing both the interparticle and the intraparticle microdomains and the bicontinuous IPN structure inside the particles; see Fig. 6.8 (Silverstein et al. 1989).

Wu and Zhao studied LIPN systems by a two-stage emulsion polymerization technique (Wu and Zhao 1995). A latex seed (polymer 1) was synthesized first in a semicontinuous emulsion polymerization, swollen by the second-stage monomer or monomer mixture (forming polymer 2), and followed by polymerization to form IPN materials. Six kinds of monomers were used: acrylonitrile (AN), vinyl acetate (VAc), n-butyl acrylate (nBA), methyl methacrylate (MMA), ethyl methacrylate (EMA), and ethyl acrylate (EA). The effect of composition, cross-linking level, feeding sequence of polymer 1 and polymer 2 on the IPN miscibility, and

EMA)
mechanical behavior were investigated via TEM, equilibrium swelling ratio, density, and DMS measurements. They found that the latex IPN particles had a core/shell-type morphology. Introduction of a third component as a comonomer (which had good miscibility with the original two polymers) improved the IPN miscibility. Their IPNs with higher cross-linking density had a higher phase miscibility. They also found that the IPNs with a hard core and a soft shell morphology, called an inverted IPN, had a higher miscibility than the IPNs with the opposite morphology, called normal IPNs (soft core and hard shell), as shown in Fig. 6.9.

Another kind of LIPN material, P(MMA-*stat*-S)/P(BA-*stat*-AA), with a core/shell structure, was synthesized by Chen and Wang (1995a, b). P(MMA-*stat*-S) seed was synthesized first by batch emulsion polymerization, and then PBA-PAA was semicontinuously polymerized. The effects of emulsifier concentration, cross-linking agent, and initiator on the final latex films were investigated. They found that the core was a hard MMA-S statistical copolymer with PBA located in the inner layer of the shell and the PAA located in the outer layer of the shell (due to a poor miscibility of PAA with P(MMA-*stat*-S) and the hydrogen bonding between PAA and water). An interpenetrated structure was formed at the interface of the core and the shell. These 0.1–0.2 μm latex particles were initially dispersed in the aqueous phase. After the evaporation of water, these latex particles formed a film, the particles coalescing with the soft shell becoming the continuous phase sticking these particles together. This kind of IPN can be used in coatings and adhesives. It was also shown that on increasing the core/shell ratio (hard to soft monomer weight ratio) from 2/8 to 8/2, the state of the film changed from an adhesive to one cracked into a powder. At the 1/1 core/shell ratio, increasing the AA concentration to 2.5 %, the film was still uniform and clear; but at higher AA levels, the latex stability decreases in the presence of electrolyte (due to a thinner electronic double layer) and higher water absorbance (due to the hydrophilicity of the –COOH). From DSC, the core/shell LIPN showed two broad T_gs at −36 and 103 °C and one small T_g at 10 °C.

Besides two-component LIPNs, three-component LIPNs have also been studied through three-stage emulsion polymerization processes (Zhang et al. 1991, 1994; Isao et al. 1992). These authors synthesized poly(n-butyl acrylate) cross-linked with ethylene glycol dimethacrylate as the seed latex. Styrene and divinylbenzene were added at the second stage. The third stage was linear poly(methyl methacrylate). Starved polymerization conditions resulted in more regular-shaped latex particles than batch addition of monomer.

Another interesting three-component LIPN consists of cross-linked polyorgano-siloxane (tetraethoxysilane as cross-linker) as the first stage, swollen by butyl acrylate monomer (allyl methacrylate as cross-linker) and then polymerized to form the second component, and finally, poly(methyl methacrylate) was grafted onto the IPN core as the shell layer (Isao et al. 1992). Such kind of LIPNs is found to be good impact modifiers in thermoplastics; i.e., they are toughened by the addition of finely divided low-T_g phase.

6.4.7.3 Damping

Polymers with sound and vibration damping properties are finding numerous applications, especially in the aircraft, automotive, tall buildings, and appliance industries (Aklonis and MacKnight 1983; Thurman and Miller 1986; Corsaro and Sperling 1990; Sophiea et al. 1994). The damping properties of polymers are dominated by their glass transitions. Usually, homopolymers or statistical copolymers possess efficient damping in a temperature range of only 20–30 °C around the T_g (Aklonis and MacKnight 1983). For most outdoor or machinery applications, however, good damping materials should exhibit a high loss factor (tan $\delta > 0.3$) over a temperature range of at least 60–80 °C (Yak 1994; Yao et al. 1991).

Why use IPNs as damping materials? It is because the introduction of cross-links in IPNs restricts the domain size to the order of 10–20 nm, which enhances the formation of a microheterogeneous morphology. This results in broad glass transitions, making them effective as broad temperature or frequency damping materials (Wang et al. 1996; Fay et al. 1991; Sperling and Fay 1991).

The damping behavior of LIPNs can be improved by proper design of the chemical composition in the system and effective control of the IPN morphology. The same factors should be considered as controlling core/shell LIPN morphology, such as the miscibility of the system, chemical structure of the polymer molecule, glass transition temperatures, cross-linking density of the two networks, and the feeding sequence in the polymerization. But here, to develop an LIPN with broad temperature damping behavior, a more miscible or microheterogeneous morphology is needed instead of a core/shell-type morphology. By contrast, if only a narrow temperature range is needed, such as an indoor, room temperature application, a homopolymer or simple statistical copolymer with a sharp T_g will serve better. An example would be slightly plasticized poly(vinyl acetate), $T_g = 25$ °C.

Based on damping theory (Kim and Sperling 1997; Sophiea et al. 1994a), the damping behavior of a polymer can be evaluated from its dynamic mechanical behavior by expressing it as the area under the tan δ versus temperature curve (Keskkula et al. 1971) or the area under the linear loss modulus versus temperature

curve (Fradkin et al. 1986a, b; Chang et al. 1987). The broad temperature damping performance improves if the polymer system is more miscible, the glass transition peak is broader, and the tan δ or loss modulus peak intensity is higher. The damping performance can also be predicted and improved via group contribution analysis (Fradkin et al. 1986b; Chang et al. 1987, 1988; Fay et al. 1990; Foster et al. 1987). However, the group contribution analysis may be unable to predict the partially miscible two-peaked (microheterogeneous) IPNs (Lipatov 1989), because the analysis is based only on molecular structure, not considering the interaction between the polymer phases.

Sperling et al. first developed a prototype "Silent Paint," which is a two-layer coating system, PEMA/PnBA LIPN, capable of attenuating noise and vibration over −30 °C to +100 °C (Sperling et al. 1974). Later, they further investigated P(EMA-EA)/P(BA-EA) and PVC/P(B-AN) LIPNs for more effective damping applications (Grates et al. 1975; Lorenz et al. 1976; Sperling et al. 1975). The damping capability was controlled by varying the chemical composition of the LIPN systems.

Liu et al. also studied LIPN systems for damping control in coating applications (Liu et al. 1995). A polystyrene (PS)/polyacrylate (PAcr) latex IPN was synthesized in a two-stage emulsion polymerization. Cross-linked PS was synthesized first as the seed polymer by a semicontinuous process, followed by an nBA-MA-BMA monomer mix with cross-linking agent, again feeding semicontinuously into the PS seed to polymerize, forming an IPN latex. The effect of PS and PAcr ratio and the addition of inorganic fillers, such as mica, graphite, $CaCO_3$, and TiO_2 on the damping of the final coating film, were studied. They found that the damping behavior of PS/PAcr IPN at room temperature was improved with increasing PS amount in the system, as shown in Table 6.6. This is because the presence of the benzene ring (from PS) enhances the friction of molecular chain movement. The introduction of a monomer with polar group to the PAcr backbone improved the miscibility of the IPN system and increased the adhesion of the coating film. This is because the polarity can increase the interchain attraction, favoring the permeation of the molecular chains, enhancing the mutual entanglement between the networks, and increasing the friction between the polymer molecular chains. Consequently, the damping property was improved. The addition of inorganic fillers increased the damping effective value, as well as expanded the temperature range for effective damping, with flake structure fillers, e.g., mica, showing the best result. This was confirmed by the DMS measurement, with the broadest tan δ peak and the highest valley value obtained.

Peng and Li synthesized a series of PS/P(EA-*stat*-nBA) LIPNs by two-stage emulsion polymerization method to investigate the effect on the damping properties of composition, cross-linker content, chain transfer agent, polar group, and feeding sequence (Peng and Li 1995). The results show that the PS/P(EA-*stat*-nBA) LIPNs are a partially miscible system. The effect of cross-linker content of network I on the damping properties is not the same as that of network II. The damping properties of the PS/P(EA-*stat*-nBA) LIPN (hard component synthesized first) are superior to that of P(EA-*stat*-nBA)/PS LIPN (soft component synthesized first). The introduction of

Table 6.6 Effect of PS/PAcr ratio on damping

Noise reduce, dB/mm	3.0	3.5	3.9	5.3

polar groups into the system can increase the damping properties by increasing the tan δ and broadening the damping range, while the addition of a chain transfer agent can broaden the damping temperature range.

6.4.7.4 Development of LIPNs with Multifunctional Properties

A type of three-component latex with IPN cores as impact and damping improvers was prepared by three-stage emulsion polymerization (Hu et al. 1995, 1997a). The IPN cores were composed of one impact part (polybutadiene based, with T_g around $-75\ ^\circ$C) and one damping part (acrylic based, with T_g around $+10\ ^\circ$C). The synthesis procedure was as follows: First, component A, a seed latex of poly (butadiene-*stat*-styrene), P(Bd/S) 90/10, was prepared at both 95 % and 40 % gel fraction. After stripping the residual monomer in the seed latex, a mixture of acrylate monomer (butyl acrylate or ethylhexyl methacrylate) and styrene or methyl methacrylate monomer together with tetraethylene glycol dimethacrylate and initiator was added and swollen for 24 h at room temperature and then polymerized to form an IPN hybrid core, A + B. Finally, the third component, C, poly(styrene-*stat*-acrylonitrile) (72/28) copolymer, was synthesized under monomer-starved conditions to form a uniform glassy shell layer covering on the IPN cores. This last made the latex particles compatible with a polycarbonate matrix (Tanrattanakul et al. 1996). A core/shell-type phase separation was observed for IPN particles when using P(Bd/S) with 95 % gel fraction, while a cellular IPN morphology with a distribution of polyacrylate-based copolymer in P(Bd/S) phase was formed with 40 % gel fraction P(Bd/S). Also, the domain size of the second polymer was larger when increasing the volume fraction of the second polymer. In order to study the effect of interfacial interaction between the two polymer components in an IPN particle (polymer A and polymer B), separate core/shell particles and multilayered structured particles were prepared, as molded in Fig. 6.10 (Hu et al. 1997b).

Dynamic mechanical spectroscopy (DMS) was used to characterize the glass transitions of the above LIPN particles. It was found that poly(butyl acrylate)-based copolymer provides higher miscibility with P(Bd/S) than poly(ethylhexyl methacrylate)-based copolymer, which has a longer side chain in the molecular structure. As a comparison to the IPN core/shell system, a blend of separate core/shell latex particles, A (poly(butadiene-*stat*-styrene) (90/10))/C (poly(styrene-*stat*-acrylonitrile) (72/28)) and B (poly(butyl acrylate)-based copolymer or poly (ethylhexyl methacrylate)-based copolymer)/C latexes were also synthesized and evaluated. Figure 6.11 (Hu et al. 1997a) shows three glass transitions for the IPN core/shell latex particles. Figure 6.12 (Hu et al. 1997a) shows a better-developed middle glass transition for component B and a lower-temperature P(Bd/S) glass transition. The polymer B appears more miscible with polymer A in the IPN form.

Fig. 6.10 Models of different types of core-shell modifiers: (**a**) traditional core/shell, (**b**) IPN core/shell, (**c**) blend of separate core/shell, and (**d**) multilayered core/shell. Possible polymer compositions are polybutadiene copolymer as polymer A, acrylic copolymer as polymer B, and SAN as polymer C
Fig. 6.11 DMS results for IPN core/shell latex film: (0.5 + 0.5)/1 (A + B)/C, A = P(Bd/S), B = P(EHMA/S), and C = SAN
In the same work, the damping behavior of those three-component LIPNs was evaluated from the integrals of the linear loss shear modulus versus temperature (loss area, LA) and linear tan δ versus temperature (tan δ area, TA) curves measured by DMS (Hu et al. 1997b). Baselines were used for subtraction, as is common in spectroscopy calculations (Fay et al. 1991). The IPN core/shell particles showed the highest damping, comparing with separate and multilayered core/shell particles. Also, normal synthesized (rubbery polymer was synthesized first) and inverted synthesized (glassy polymer was synthesized first) semi-I IPN and semi-II IPN latexes were compared for their damping performance. The inverted synthesized ones provided much higher LA and TA values, due to their finer morphology.

Tables 6.7 and 6.8 summarize selected LIPN systems developed for two- and three-stage systems, respectively. For the latter, polymer 3 is usually a linear overcoat. Of great interest throughout are morphology and concomitant behavior. Applications for coatings, damping, and impact improvement are discussed in many of the works.

6.5   Actual and Proposed Applications of IPNs

While the field of IPNs is relatively young compared with those of polymers, the
number of applications are growing rapidly. In 1979, the total number of scientific
papers was about 125; there were about 75 patents. Today, about that many are
published each year. Major advances include thermoplastic IPNs, renewable
resource materials, biomedical materials, and nonlinear optical materials.

6.5.1   Thermoplastic IPNs

The thermoplastic IPNs utilize physical cross-links, rather than chemical cross-
links. Usually, these materials will flow when heated to sufficiently high tempera-
ture (hence the terminology *thermoplastic*), but behave as thermosets at ambient
temperature, with IPN properties, often possessing dual-phase continuity. Most
often, physical cross-links are based on triblock copolymers (thermoplastic elasto-
mers being the leading material), ionomers, or semicrystalline materials.

Sometimes one of the components is chemically cross-linked. Usually, such mate-
rials undergo dynamic vulcanization, i.e., chemical cross-linking during melt shearing.
The resulting action yields a dual-phase continuity product, where the chemically
cross-linked component forms cylinders within the matrix of the other component.

Coran and Patel (1996) list several examples of the improvements possible:
Reduced permanent set
Improved ultimate mechanical behavior
Improved fatigue resistance
Improved fluid resistance, i.e., to hot oils
Improved high-temperature stability
Greater stability of phase morphology in the melt (i.e., the phase domain size does
    not increase)

Greater melt strength (i.e., green strength)

More reliable thermoplastic fabricability

Some materials that have achieved importance include EPDM/PP, NBR/PA, PU/PA, SEBS/PA, EPDM/PBT, and epichlorohydrin rubber/PA. Usually, these materials are made more processable through plasticizing oils. Holden (1996) provided trade names of selected compositions, emphasizing those based on hard polymer-elastomer combinations; see Table 6.9.

6.5.2 Renewable Resource IPNs

Renewable resources are those agricultural products that can be grown repeatedly. A closely related term is natural products. However, the latter may not be renewable, i.e., coal or petroleum oil. Renewable resource materials have long been based on

Table 6.9 Selected plastic-elastomer thermoplastic IPNs by trade name[b]

Trade name (manufacturer)	Synthetic method	Polymer	Elastomer	Notes
Ren-Flex[TM] (Dexter), Hifax[R] (Himont), Polytrope[R] (Schulman), Telcar[R] (Teknor Apex), Ferroflex[R] (Ferro), Flexothene[R] (Quantum)	Blend	PP	EPDM or EPR	Relatively hard, low density, not highly filled

[a]Dynamic vulcanizate: usually, the EPDM is cross-linked via free radical methods during a shearing action of the blend, often accompanied by a partial phase inversion to dual-phase continuity

[b]Based on Holden (1996), Chap. 16, Table 16.10; AES advanced elastomer systems

cellulose, triglyceride oils, and natural rubber, among other materials. Some IPNs based on renewable resources are summarized in Table 6.10. These materials suffer from two drawbacks in the current era: Research on them is passé and rather poorly funded. Secondly, the price of many renewable resources, such as castor oil and cellulose, is actually above the corresponding prices for petroleum-based products.

6.5.3 Biomedical IPNs

It has been said that people working on new applications are more willing to consider new materials than people working on established applications. This is certainly a truism when considering the biomedical applications of polymeric materials; see Table 6.11. The emphasis on soft contact lenses is remarkable.

Poly(ethylene glycol methyl ether methacrylate)	Poly(acrylic acid)	Body parts improvement or replacement	Naficy et al. (2012)

The first item, showing a gradient IPN being used to form a gradient refractive index material, is the most interesting. Of course, there are two ways to bend light, either to have a curved surface, the basis of most lenses, or to have a variable refractive index. This invention combines the two. The second item in Table 6.11 addresses burn dressings. In this case, a polytetrafluoroethylene film is filled with silicone rubber to prepare a dual-phase continuity structure. The silicone rubber provides high permeability allowing moisture to escape, while the polytetrafluoroethylene provides mechanical strength. Together, they are transparent, allowing better observation of the healing burn wound. A similar type of material is also used for applications, such as wound care, scar management, and others (Dillon 1997, 2006).

Over the years, the interest in IPNs for biomedical applications has increased. One "trick" being developed is to have one network with low cross-link density and the other with high cross-link density. The result has been shown to yield stronger, more fracture-resistant materials. As will be shown below, this idea works even if the two polymers are otherwise identical, i.e., homo-IPNs. Also, many of the new, proposed materials are versions of hydrogels. Since these materials are intended for improvement or replacement of body parts, many are studied at body pH: 7.4.

Waters et al. (2011) investigated IPN hydrogels based on a tightly cross-linked poly(ethylene glycol) network and a loosely cross-linked poly(acrylic acid) network, with emphasis on pH = 7.4. This idea of having one network tight and one loose was originated by Gong et al. (2003). This yields a self-reinforced material, with one network able to stretch under applied strain and the other able to stop crack growth. This idea dominates much of what follows for the hydrogels that will be mentioned below.

Another paper using the idea above as modified is a hydrogel based on poly (ethylene glycol methyl ether methacrylate) with poly(acrylic acid) (Naficy et al. 2012). Network I has a structure termed "bottle brush," signifying long chains attached to a master backbone chain. Poly(acrylic acid) constitutes the second network. Here, the second network contributes the larger part of the structure. These materials became transparent at a pH greater than 5. These materials are able to retain a large fraction of water. Due to their soft nature, etc., they are very similar to real biological systems.

An important possible application of these materials is as drug delivery systems with antibacterial properties (Silan et al. 2012). Compositions such as poly (acrylonitrile-co-(3-acrylamidoproplyl trimethyl ammonium chloride led to core-shell nanoparticles. Further, IPN microgels were prepared by mixing double quaternized poly(acrylonitrile-co-vinylpyridine). Suitable inherently antibacterial materials include silvery nanoparticles, copper nanoparticles, copper oxide nanoparticles, and chitosan, among many others. Also, the electrostatic interactions between positively charged polymers and the negative charges on the cell walls of bacteria cause disruption of the cell wall, leading to death of the bacteria.

Polycarbonate	Acrylic	Second-order nonlinear optics	Tripathy et al. (1996)

6.5.4 Nonlinear Optical Materials

Nonlinear optics is concerned with the manipulation of electromagnetic energy, particularly into different wavelengths than the original. For second-order nonlinear optics, an asymmetric molecule is required. While such molecules clearly do not need to be polymeric, the use of asymmetric polymer chains and side chains produces materials with spatial and temporal stability. Such asymmetric groups have the capability of holding one photon until another arrives, and then the energies may be added, with a single photon of twice the frequency produced, or other algebraic manipulations may be undertaken. As may be expected, a wider range of mechanical behavior patterns arise through the application of IPN technology; see Table 6.12. A leader in the field is Tripathy, with a patent (Tripathy et al. 1996) in nonlinear optic applications for IPNs.

6.5.5 Sound and Vibration Damping

One of the major effects of having extensive but incomplete mixing in two polymers, whether cross-linked or not, is that a very broad glass transition region may result, one that spans the temperature range between the two original glass transitions. Compared to their non-cross-linked counterparts, it is easier to prepare such materials with IPN technology; see Table 6.13. While the evidence is debatable whether such IPNs have more total damping (it seems to depend on the composition), having substantially the same damping level over a broad temperature range is good for outdoor and machinery applications. For example, a car door will be equally damped in winter and summer, and over broad frequency ranges, as well as at the standard 25 °C, 600 Hz standard conditions. However, the vinyl-phenolic composition (Yamamoto and Takahashi 1990) (in Table 6.13) damps specifically at the elevated temperatures at which machinery operates, but only weakly at room temperature.

6.5.6 Compatibilizing Phase-Separated IPNs

Most IPNs consist of two polymers that phase separate during synthesis. While the domains are usually very small, the dual network structure and positive heat of mixing result in two phases.

Table 6.13 Sound and vibration damping materials via IPN formation

There are, however, several pairs of IPN polymers that have been made miscible (Lipatov and Alekeeva 2007). The most useful way consists of introducing compatibilizers that react or interact at the interfaces of both polymers of the synthesis. These compatibilizers form an intermediate region between the two phases in question. Major results include a decrease in the interfacial tension between the two networks, allowing greater contact at the interfaces between the two networks, which permits greater contact at the interface between the two polymers. Depending on the IPN pair, frequently used compatibilizers include 2-hyroxyethylmethacrylate, oliourethane dimethacrylate, and triblock urethane with both ends containing $CH_3–CH_2–O–CH_2–CH_2–$.

These compatibilizers form an intermediate region between the two original phases in question. Major results include a decrease in the interfacial tension between the two networks, allowing greater contact at the interface between the two polymers. The compatibilizers should be distributed throughout the mix of the two polymers, improving the thermodynamics interactions. Note that the compatibilizer should have a negative value of the thermodynamic quantity X. However, Lipatov and Alekseeva (2007) point out that there are actually two types of compatibilization: non-equilibrium compatibilization and true thermodynamic stability of the two polymer components after network polymerization is complete. A simple test of the compatibilizer's success is via dynamic mechanical characterization. If the blend shows two tan (delta) maxima, and the compatibilized system only one maximum, that is a measure of success. In other words, if the polymer mix has only one glass transition, it is usually considered miscible (of course, the two polymers separated should have different glass transition temperatures). Sometimes, a range of glass transitions are noted, resulting in an apparent but incomplete miscibility.

There are other ways of increasing compatibilization. These may be through grafting reactions between the two networks, etc. On very rare occasions, true miscibility may exist without compatibilizers.

Some important ways of establishing compatibility include changing the polymerization sequences, introduction or prior presence of oppositely charged groups, and the formation of hydrogen bonds. Of course, one very broad glass transition range may be found, substantially running from T_{g1} to T_{g2} of the two polymers, representing partial mixing with all possible compositions coexisting in the mix. Some examples of compatibilized IPNs are collected in Table 6.14.

Table 6.14 Compatibilized IPNs

Polymer I	Polymer II	References
Poly(butyl acrylate) or poly(butyl methacrylate)	Diallyl network	Derrough et al. (1993)
Polyurethane	Polyacrylate	Yu et al. (1999)
Poly(dimethyl)siloxane urethane	Poly(methyl methacrylate)	Zhou et al. (1994)
Polyurethane	Unsaturated polyesters	Kim and Kim (1987)
Polyurethane	Poly(butyl methacrylate)	Lipatov et al. (2007)
Polyurethane	Polystyrene	Hourston and Schafer (1997)

6.5.7   Current Status of IPNs

Today, the rate of publications in the area of IPNs is approaching 100 papers per year. As may be expected, a relatively large fraction is devoted to applications (Sperling 2011). Some interesting examples relate to electronic devices. Plesse et al. (2004), for example, synthesized conducting IPNs, useful for actuators. The IPN synthesis was based on poly(ethylene oxide) and polybutadiene networks, containing a conducting polymer poly(3,4-ethylenedioxytheiophene (Plesse et al. 2004). High modulus and dimensionally stable polyimide IPN substrates were claimed to be used in flexible printed circuits, tape-automated bonding tapes, metal interconnectors for integrated circuits, and other similar types of electronic applications (Uhara 2004). Tran-Van et al. described IPNs for electrochromic devices (Tran-Van et al. 2008). Some other applications include fuel cell membranes (Morin. et al. 2010). The readers of this article may expect to see the list go on and on.

6.5.8   A Few More Exciting Materials

One interesting invention is a poly(2,6-dimethylphenylene oxide)-poly(styrene-HEMA)-based IPN that is useful for solar heating (Eck et al. 1995). The IPN has an adjustable lower critical solution temperature, so that when coated onto the glass panels, it clouds up if the temperatures inside get too hot. Polymer blends will not work so effectively for this application, because when they phase separate, the phases may continue to grow; thus the time to come back to a one-phased material may be long. The IPN structure restrains phase domain growth, so that the material, acting as a *smart material*, clouds and clears relatively rapidly, reacting to the temperature of the structure it is protecting.

Other areas of IPN application cover circuit boards (Tate and Varnell 1989; Takahashi et al. 1996) and, via gradient IPN technology, improved optical fibers (Bukhbinder and Kosjakov 1996). This last works by having a gradient refractive index from the axis to the surface, curving the light back away from the surface and

reducing the fraction of light leaving the fiber for the exterior. Another area of interest involves coatings and adhesives. An overcoat layer comprising a polyolefin/epoxy semi- or full IPN for a metal substrate was claimed in several patents (Ylitalo et al. 1997; Perez et al. 2007, 2010). The metal article can be a pipe, vessel, conduit, rod, profile-shaped article, or tube. Such kind of coating can provide a good resistance to various chemicals, such as petroleum, water, natural gas, methane, ammonia, gasoline, oxygen, hydrogen, as well as various industrial chemicals. Golf balls containing IPNs have also been claimed in several patents since 2007 (Kuntimaddi and Bulpett 2007; Kuntimaddi et al. 2008, 2010, 2011, 2013). Since a golf ball has multiple layers (up to 4 layers), the IPN technology is used to form one or more of the layers. At least two polymeric compounds are included. The first polymeric system may include a polyurethane-based or polyurea-based system and the second polymeric system may include an epoxy-based or acrylic-based system. For a golf ball, a high shear resistance, which indicates the ability of a material to maintain its mechanical stability and integrity upon the application of a shear stress to that material, is required. With IPN technology in the particular layer (e.g., core, intermediate, or cover layer), the shear resistance of that layer is increased. In addition, the resistance to moisture penetration of that layer is also increased. Consequently, the mechanical properties, such as tensile or flexural modulus and impact resistance, and durability of such golf ball will be less affected, resulting in longer lifetime. Some recent patents also claimed highly microporous thermoplastic/bismaleimide semi-IPNs to be used as a gas separation membrane (Kumar and Kurdi 2010) and porous IPNs to be used for chromatography and filtration of various compounds including biomolecules (Bonner et al. 2012).

   In summary, many of the IPN applications do not depend on high modulus or impact resistance (but some do!); these materials often show their best properties in the leathery, rubbery, or swollen states. Thus, it is seen that the applications for IPNs cover a broad range today.

6.6   Conclusions

The field of IPNs is simultaneously one of the oldest in multicomponent polymer literature and one of its newest and fastest growing fields. With IPNs, it is relatively easy to prepare very small domain sizes and/or materials with dual-phase continuity. IPNs can be made via a multitude of ways: sequential, simultaneous, latex, gradient, and thermoplastic, to name some of the more prominent materials.

   While IPNs can be and have been made extremely tough and impact resistant, many of the proposed applications involve such diverse fields and sound and vibration damping, biomedical materials, and nonlinear optics. This is because the presence of cross-links in both polymers reduces creep and flow, allowing relatively stable materials with a wide range of moduli to be prepared. Thus, those materials with leathery mechanical behavior, combinations of elastomers and plastics, are especially interesting to scientists, inventors, and engineers.

6.7   Cross-References

Abbreviations and Acronyms

AA   Acrylic acid
Bd   Butadiene
DACBA   Diallyl carbonate of bisphenol-A

Abstract

This chapter presents an overview of some of the important principles and characteristics associated with the rheological behavior of polymer blends. Initially, the chapter reports the observations and the scientific laws that illustrate and govern the rheological behavior of classical suspensions and emulsions of simple non-polymeric liquids. It is indicated that one of the main characteristics that differentiates the rheological behavior of polymer blends from that of simpler liquids is the viscoelastic nature of polymers and their blends. The discussion also points out the relationship between blend morphology and rheology and the importance of surface energy effects, such as interparticle and interfacial interactions. The general rheological characteristics of miscible polymer systems are considered. However, since the majority of polymers are immiscible, the rheological behavior of immiscible polymer blends is considered in more detail, with allowance for both thermodynamic and morphological factors. The influence of flow on morphology, as in phase separation, drop deformation, breakup, and fiber formation are discussed. Both viscous and viscoelastic characteristics of blend behavior are described, under the influence of shear and elongational flow fields. Various examples are presented, based on the study of rheological behavior of blends in both rheological testing devices (parallel plate, rotational, steady state, oscillatory, capillary, elongational, etc.) and processing equipment (extruders, mixers, molds, dies, etc.). In many cases, the observed rheological behavior is compared to the predictions of theoretical, computational, or empirical models.

7.1 Introduction

7.1.1 Rheology of Multiphase Systems

The rheology of multiphase systems is an extension of the general rheological dependencies observed for single component fluids. Obviously, the basic definitions of rheological functions, e.g., viscosity, η, dynamic shear moduli, G' and G'', dynamic shear compliance, J' and J'', etc., are identical. However, owing to the numerous influences, viz., concentration, morphology, flow geometry, time scale, type of flow field, thermodynamic interactions between the phases, and many others, more complex relationships prevail between the measured rheological functions of multiphase system and the intrinsic physical properties of the constituent fluids.

Table 7.1 Characteristics of flow fields

| No. | Type | γ | Vorticity | Uniformity of | | Comment |
				σ	γ	
1.	**Steady-state shear**					
1.1.	Sliding plate, and rotational cone-and-plate	Large	Yes	Homogeneous	Homogeneous	For small gap, or for cone angle $< 4°$
1.2.	Poiseuille (capillary or slit), Couette, and rotational parallel plates	Large	Yes	Functions of spatial coordinates	Functions of spatial coordinates	For laminar flows small measuring thickness is required
2.	**Dynamic shear**					
2.1.	Cone-and-plate	Small	Yes	Homogeneous	Homogeneous	For cone angle $< 4°$
2.2.	Parallel plates	Small	Yes	Linear	Linear	Gap 0.8–2.0 mm
2.3.	Couette	Small	Yes	Variable	Variable	Gap 0.2–0.5 mm
3.	**Extensional flows**					
3.1.	Uniaxial	Mid	No	Homogeneous	Homogeneous	
3.2.	Biaxial	Mid	No	Homogeneous	Homogeneous	

Rheological measurements in multiphase systems should be designed so that the length scale of flow is significantly larger than the size of the flow element. This makes it possible to treat the multiphase system as being homogeneous, having an average, "specific" rheological behavior. For example, Brenner (1970) showed that magnitude of relative viscosity, η_r, of diluted spherical suspensions, measured in capillary flows, depends on the $(d/D)^2$ factor, where d is the sphere diameter and D is the diameter of the capillary – for $D \cong 10d$, the error in η_r, was 1 %. Thus, if 1 % error is the acceptable limit, the size of the dispersion should be at least 10 times smaller than the characteristic dimension of the measuring device, viz., radius of a capillary in capillary viscometers, distance between stationary and rotating cylinders or plates in, respectively, the Couette or Weissenberg rheometer, etc. However, for many systems of industrial interest, the data are usually generated with a smaller factor, mainly for comparative purposes.

Another aspect of multiphase rheometry is related to the interrelations between the flow field and system morphology. In the present context, the term "morphology" will refer to the overall physical structure and/or arrangement of the components, usually described as a dispersed phase (particles or domains), co-continuous lamellae, fibrils, spherulites, etc. Furthermore, multiphase morphology deals with the distribution and orientation of the phases, the interfacial area, the volume of the interphase, etc. Flow may induce modifications of morphology, such as concentration gradients and orientation of domains.

Three types of flow are mainly used in rheological measurements: steady-state shearing, dynamic shearing, and elongation (Table 7.1). The three can be classified according to the strain, γ, vorticity, as well as uniformity of stress, σ, and strain within the measuring space.

Steady-state flows have a strong influence on the morphology, whereas dynamic flows have small influence. Extensional flows are characterized by uniform deformation with no vorticity; thus they are the most effective in changing the morphology and orientation of the system.

The rheological functions must be volume averaged (Hashin 1964). The averaged quantities are sometimes known as *bulk quantities*. For example, the bulk rate of strain tensor, $\langle \dot{\gamma}_{ij} \rangle$, is expressed as

$$\langle \gamma_{ij} \rangle = \frac{1}{2} \left(\left\langle \frac{\partial v_i}{\partial x_j} \right\rangle + \left\langle \frac{\partial v_j}{\partial x_i} \right\rangle \right) = \frac{1}{\Delta V} \int\limits_{\Delta v} \dot{\gamma}_{ij} dV \tag{7.1}$$

where $\left\langle \frac{\partial v_i}{\partial x_j} \right\rangle = \frac{1}{\Delta V} \int\limits_{\Delta V} \frac{\partial v_i}{\partial x_j} dV$

The stress tensor, $\langle \sigma_{ij} \rangle$, in multiphase systems, is given by

$$\langle \sigma_{ij} \rangle = -p \delta_{ij} + 2\eta_0 \langle \dot{\gamma}_{ij} \rangle + \frac{1}{\Delta V} \sum \left(S_{ij} - x_i F_j \right) \tag{7.2}$$

In Eqs. 7.1 and 7.2, v_i is local velocity, x_i is local coordinate, ΔV is an elementary volume, p is pressure, δ_{ij} is unit tensor, η_o is viscosity of the continuous phase, while S_{ij} and F_i represent hydrodynamic and non-hydrodynamic forces acting on a particle. These two functionals are usually coupled, as the thermodynamic interactions affect the hydrodynamic forces and vice versa.

The first two terms on the right-hand side (rhs) of Eq. 7.2 are identical to those for a homogeneous fluid. For a multiphase system, they represent the stress tensor of the matrix liquid, while the third term describes the perturbing influences of the dispersed phase (Batchelor 1974, 1977). Owing to difficulties in deriving exact forms of the S_{ij} and F_i functions in the full range of concentrations, Eq. 7.2 is usually written as a power series in volume fraction, ϕ, of the suspended particles.

The rheological behavior of multiphase systems within the linear, dilute region ($\phi < 0.05$) is relatively well described. For example, for dilute suspensions of spherical particles in Newtonian liquids, Eq. 7.2 reduces to Einstein's formula for the relative viscosity, η_r:

$$\begin{aligned} \langle \sigma_{ij} \rangle &= -p\delta_{ij} + 2\eta_0[1 + (5/2)\phi]\dot{\gamma}_{ij} \\ \text{or } \eta_r &= 1 + (5/2)\phi \end{aligned} \tag{7.3}$$

Equation 7.2 has been also solved for dilute suspension of anisometric particles (Hinch and Leal 1972), elastic spheres (Goddard and Miller 1967; Roscoe 1967), and emulsions (Oldroyd 1953, 1955; Barthès-Biesel and Chhim 1981). These works were reviewed by Barthès-Biesel (1988).

In the higher concentration range, where particle–particle interactions must be taken into account, Eq. 7.2 is often approximated by a second-order polynomial. However, even for hard-sphere suspensions, the theoretical extension of Eq. 7.3 has been found difficult:

$$\eta_r = 1 + (5/2)\phi + K\phi^2 + O(\phi^3)$$ (7.4)

where the second-order coefficient was calculated as K = 5.2–7.6. Such theoretical predictions should be compared with experimental results. Thomas (1965) compiled relative viscosity data, η_r versus ϕ, measured in 16 laboratories for different types of hard-sphere suspensions, e.g., pollen in water, steel balls in oil, etc. After correcting the data (e.g., for the immobilized adsorbed layer of the suspending liquid), the results superimposed and were fitted to the following relation (valid within the experimentally explored range of concentration, $\phi \leq 0.6$):

$$\eta_r = 1 + (5/2)\phi + 10.05\phi^2 + 0.00273\ \exp\{16.6\phi\}$$ (7.5)

Allowance for the last term in Eq. 7.5 yields K = 10.43 as the second-order coefficient of Eq. 7.4.

Owing to difficulties in deriving general constitutive equations for multiphase systems, rheologists had to resort to simplified theoretical or semiempirical dependencies derived for specific types of rheological tests and/or for specific multiphase systems. These, experimentally well-established relations, constitute the basic tools for the interpretation of rheological data for multiphase systems. They will be discussed in the following parts of the text.

7.1.2 Basic Concepts of Polymer Blends

The following standard definitions will be used (Utracki 1989a, 1991a; see also *Nomenclature* in ▶ Chap. 1, "Polymer Blends: Introduction" of this handbook).

7.1.2.1 Definitions
(a) **Polymer blend** is a mixture of two or more polymers and/or copolymers, terpolymers, etc., containing at least 2 wt% of the dispersed phase.
(b) **Miscible blend** is a blend with domain size comparable to the dimension of a macromolecular statistical segment, or in other words, whose free energy of mixing is negative, $\Delta G_m < 0$, and its second derivative of concentration with volume, is positive: $\partial^2 \Delta G_m / \partial \phi^2 > 0$. Usually, miscibility is restricted to a relatively narrow range of independent variables, viz., molecular weight, composition, temperature, pressure, etc. Thus, immiscibility dominates.
(c) **Polymer alloy** is an otherwise immiscible blend, which is compatibilized, with modified interphase and morphology.

Table 7.2 Rheological models for miscible and immiscible blends	**1. Miscible blends**	**2. Immiscible blends**
	1.1. Solutions	2.1. Suspensions
	1.2. Homologous polymer blends	2.2. Emulsions
		2.3. Block copolymers

Alloying involves several operations that must result in blends showing *stable* and *reproducible* properties. These processes comprise compatibilization, mixing, and stabilization. Compatibilization may be accomplished either by addition of a compatibilizer or by reactive processing. Its role is to facilitate dispersion, stabilization of the morphology, and enhancement of the interaction between phases in the solid state. Commercial alloys may comprise up to six polymeric ingredients. Development of such an alloy is complex, requiring knowledge of thermodynamics, rheology, and processing and their influences on morphology, thus performance.

If the rheology of suspensions and emulsions is difficult to describe theoretically and to determine experimentally, the difficulties increase substantially in the case of polymer blends. For example, both phases in polymer blends are likely to be viscoelastic, the viscosity ratio varies over a wide range, and morphology can be very complex. As a guide to characterization of the rheology of blends, it is useful to refer to the behavior of simpler systems, i.e., models that can offer important insight. The following systems (Table 7.2) are considered commonly. They will be treated in the following discussion.

7.1.2.2 Phase Co-continuity

When a small quantity of one polymer is intimately mixed with another polymer, the resulting system is a blend composed of a matrix (the major component) and the dispersed phase (the minor component). When the concentration of the dispersed phase is increased, the morphology may change from a discontinuous dispersion of nearly spherical drops to progressively interconnected drops, then rods, fibers, and sheets. At a certain concentration, labeled as *the phase inversion volume fraction*, ϕ_I, the distinction between the dispersed and matrix phases vanishes – the system morphology becomes co-continuous. Phase co-continuity is one of the most important aspects of blend morphology (Lyngaae-Jørgensen et al. 1999).

Since the morphology is strongly affected by large strain flow, it is expected that the method of specimen preparation influences the co-continuity. Both the phase inversion concentration and stability of the co-continuous phase structure depend on the strain and thermal history.

It has been reported that the onset of co-continuity occurs at an average volume fraction, $\phi_{onset} = 0.19 \pm 0.09$. In many branches of physics, the concept of percolation has been found useful. For example, when the concentration of conductive spheres in nonconductive medium exceeds the percolation threshold volume fraction, ϕ_{perc}, there is a sudden increase of electrical conductivity. For the three-dimensional case, 3D, theory predicts that $\phi_{perc} = 0.156$, while for 1D it is $\phi_{perc} = 0.019$. It has been postulated that the observed changes of morphology in polymer blends, when co-continuity occurs, belong to the group of percolation

Fig. 7.1 For immiscible blends the onset of phase co-continuity should coincide with the percolation threshold. Theoretically, $\phi_{perc} = 0.156$ for 3D flow of immiscible system. Experimentally, $\phi_{2perc} = 0.19 \pm 0.09$ was found (Lyngaae-Jørgensen and Utracki 1991)
phenomena (Lyngaae-Jørgensen and Utracki 1991). Figure 7.1 depicts the variation of phase co-continuity in blends of high-density polyethylene with polystyrene, HDPE/PS. The data (obtained by selective extraction of the matrix phase) indicate that the onset of phase co-continuity occurred at $\phi_{1perc} = 0.16$ and $\phi_{2perc} = 0.15$, whereas $\phi_I = 0.64$.

Co-continuity contributes to synergism of properties, e.g., advantageous combination of high modulus and high impact strength in commercial blends. Therefore, it is of interest to determine the composition at which co-continuity can be formed. Practically, the breadth of the co-continuity composition range depends on the experimental concentration step size used during the selective extraction tests. The following simple equation was proposed to relate the phase inversion composition to volume fractions and viscosity ratio:

$$\phi_{I1}/\phi_{I2} = \eta_1/\eta_2 \equiv \lambda \;\; \text{or} \;\; \phi_{I2} = (1 + \lambda)^{-1}$$
$$\phi_{I2} = (1 + F(\lambda)\lambda)^{-1} \tag{7.6}$$

where

$$F(\lambda) = 1 + 2.25\log\lambda + 1.81(\log\lambda)^2 \tag{7.7}$$

Note that $\phi_{I1} = 1 - \phi_{I2}$ and ϕ_{I1} and ϕ_{I2} are the volume fractions of liquids 1 and 2, respectively, at the phase inversion. Equation 7.6 is empirical, proposed by Paul and Barlow (1980) as a generalization of the experimental observations reported by Avgeropoulos et al. (1976). Equation 7.7 was derived from the filament instability equation by Metelkin and Blekht (1984). These relations are applicable to systems prepared at low stresses; thus in these equations, the viscosity ratio, λ, should correspond not to the ratio of the zero-shear viscosities, but to its value at the shear stress used to prepare the blends. The relations were found to describe the phase inversion for systems with nearly equal polymer viscosities, where $\lambda \to 1$. As the viscosity ratio increases, these equations predict more rapid change of ϕ_{I2}.

Fig. 7.2 Concentration dependence of emulsion viscosity. *Solid line* represents $\eta = \eta_1(\phi_2)$ while the other lines the same dependence for $\eta = \eta_2 \cdot \eta_r(\phi_1)$. To calculate these dependencies $[\eta] = 2$ and $\phi_m = 0.8$ were assumed. The intercepts correspond to the iso-viscous conditions defining the phase inversion concentration, $\phi_{2I} = 1 - \phi_{1I}$ (Utracki 1991)
To derive a more general relation for the phase inversion concentration, one may start by computing $\eta(A) = \eta_B^o \eta_r(\phi_A)$ and $\eta(B) = \eta_A^o \eta_r(\phi_B)$, where η_r is the relative viscosity. The latter dependence can be expressed as (Krieger and Dougherty 1959)

$$\eta_r = [1 - (\phi/\phi_m)]^{-[\eta]\phi_m} \qquad (7.8)$$

In Eq. 7.8, ϕ_m is the maximum packing volume fraction, and $[\eta]$ is the intrinsic viscosity. The computed curves are shown in Fig. 7.2. To calculate these dependencies, $\phi_m = 0.8$ and $[\eta] = 2$ were assumed. The six points of intersection represent the iso-viscous conditions for dispersion of liquid 1 in 2 and liquid 2 in 1, or in other words, the conditions for phase inversion.

Based on Eq. 7.8, the iso-viscous point can be expressed as

$$\lambda = [(\phi_m - \phi_{2I})/(\phi_m - \phi_{1I})]^{[\eta]\phi_m}; \quad \text{where} \quad \phi_m = 1 - \phi_{perc} \qquad (7.9)$$

Equation 7.9 can be expanded into MacLaurin's series, then truncated after the second term to give a simplified version, valid within the range $-1 < \phi_{Ii}/\phi_m < 1$:

$$\phi_{I2} = [1 - (\log\lambda)/[\eta]]/2 \qquad (7.10)$$

Figure 7.3 shows the experimental dependence of λ on ϕ_{2I} for thermoplastic polymer blends. The horizontal and vertical lines represent the conditions between which the phase inversion took place. The straight line represents Eq. 7.10. For most polymer blends the values of parameters in Eq. 7.9: $[\eta] \cong 1.9$; $\phi_m \cong 1 - \phi_{perc} = 0.84$ provide good approximation.

It should be noted that the steady-state viscosity ratio should be taken at a constant stress (not deformation rate). The "sharpness" of the phase inversion peak depends on the distribution of stresses within the mixing device, as well as on

Fig. 7.3 Experimental ϕ_{2I} versus λ dependence for mechanically prepared thermoplastics blends. The *dotted*, *solid*, and *broken lines* represent Eq. 7.6, 7.9, and Eq. 7.10, respectively; the values: $[\eta] = 1.9$ and $\phi_m = 0.84$ were used (Utracki 1991)
the absolute magnitude of polymer viscosity – the wider the distribution of stresses and/or the higher the viscosity, the wider the range of concentrations at which the phase inversion takes place. Since many experiments are conducted using an internal mixer known to possess a wide range of flow conditions, instead of a single point, usually a range of concentrations for the phase co-continuity has been reported (see Fig. 7.3).

Another relation was proposed for predicting the phase inversion concentration. It assumes that, at the phase inversion, the morphology of both phases is fibrillar and that the rate of fiber disintegration is the same for both components (Metelkin and Blekht 1984). The validity of the model is limited to viscosity ratios ranging from 0.25 to 4 (Luciani 1993, 1996):

$$\lambda \equiv \eta_1/\eta_2 = [\Omega_2(\Lambda,\lambda)/\Omega_1(\Lambda,\lambda)](R_{0,1}/R_{0,2})$$
$$= [\Omega(\eta_1/\eta_2)/\Omega(\eta_2/\eta_1)](\phi_1/\phi_2)^{1/2} \tag{7.11}$$

The significance of the function $\Omega(\Lambda, \lambda)$ will be discussed in the Sect. 7.3.1.2, dedicated to emulsion microrheology. Steinmann et al. suggested that, at the phase inversion point, the shape relaxation times of domains of the components meet at a maximum (Steinmann et al. 2002).

Since these models do not always completely agree with phase inversion compositions found experimentally, melt elasticity effects were examined to verify if the observed deviations could be attributed to elasticity effects. A model was proposed, using the storage moduli and loss tangent ratios instead of viscosity ratios in Eq. 7.6 (Table 7.3) (Bourry and Favis 1998). Based on their results, the more elastic component tends to encapsulate the less elastic one. Therefore, the elastic contribution of the blends was found to be an important factor in determination of co-continuity.

The validity of Cox–Merz rule should be verified by measuring G′ and tan δ at frequency ω corresponding to the shear rate γ_p. The use of the ratio of storage moduli for the experimental data evaluated at a constant matrix shear stress

Table 7.3 Summary of some available semiempirical phase inversion models

Viscosity ratio-based models	
$\frac{\phi_{I1}}{\phi_{I2}} \times \frac{\eta_2}{\eta_1} = 1$	Avgeropoulos et al. (1976)
$\phi_{I1}/\phi_{I2} = A(\eta_1/\eta_2)^B$	Paul and Barlow (1980)
$\phi_{I2} = (1 + F(\lambda) \times \lambda)^{-1}$ $F(\lambda) = 1 + 2.2g \log(\lambda) + 1.8[\log(\lambda)]^2$	Metelkin and Blekht (1984)
$\lambda = \left[\frac{(\phi_m - \phi_{2I})}{(\phi_m - \phi_{1I})}\right]^{[\eta]\phi_m}$	Utracki (1991)
$\phi_{2I} = \frac{1 - (\lambda^2 \Omega^2(\lambda))}{[\lambda^2 \Omega^2(\lambda) + \Omega^2(1/\lambda)]}$	Lucuani and Jarrin (1996)
$\Phi_I = k(\phi - \phi_{cr})^x$	Lyngaae-Jorgensen et al. (1999)
$\phi_{2I} = \frac{1}{(\lambda^{1/Z} + 1)}$	Steinmann et al. (2002)
Elasticity ratio-based models	
$\frac{\phi_{1I}}{\phi_{2I}} = \frac{G'_2(\omega)}{G'_1(\omega)}, \frac{\phi_{1I}}{\phi_{2I}} = \frac{\tan \delta_1(\omega)}{\tan \delta_2(\omega)}$	Bourry and Favis (1998)

(Sarazin and Favis 2003; Shahbikian et al. 2011) and the loss tangent ratio for the data obtained at a constant shear rate (Shahbikian et al. 2011; Steinmann et al. 2001) yields better agreement with the predictions of the Bourry and Favis model.

It should be noted that phase inversion prediction models focus on only a single composition, whereas in reality, co-continuous structures are observed over a composition range. Considering the definition of co-continuous structure and equations based on the percolation theory, a model was proposed to correlate a continuity index (Φ_I) with the volume fraction at onset of co-continuity (ϕ_{cr}) (see Table 7.3) (Lyngaae-Jorgensen et al. 1999). Numerical simulation predicted ϕ_{cr} to be about 0.2 for classical percolation in three-dimensional systems (Dietrich and Amnon 1994; Potschke and Paul 2003).

The co-continuous structure and the final rheological properties of an immiscible polymer blend are generally controlled by not only the viscoelastic and interfacial properties of the constituent polymers but also by the processing parameters. For example, the effect of plasticizer on co-continuity development in blends based on polypropylene and ethylene-propylene-diene-terpolymer (PP/EPDM), at various compositions, was studied using solvent extraction. The results showed more rapid percolation of the elastomeric component in the presence of plasticizer. However, the same fully co-continuous composition range was maintained, as for the non-plasticized counterparts (Shahbikian et al. 2011). It was also shown that the presence of nanoclay narrows the co-continuity composition range for non-plasticized thermoplastic elastomeric materials (TPEs) based on polypropylene and ethylene-propylene-diene-terpolymer and influences their symmetry. This effect was more pronounced in intercalated nanocomposites than in partially exfoliated nanocomposites with improved clay dispersion. It seems that the smaller, well-dispersed particles interfere less with thermoplastic phase continuity (Mirzadeh et al. 2010). A blend of polyamide 6 (PA6) and a co-polyester of

Fig. 7.4 Co-continuity index versus BioFlex concentration (Kucharczyk et al. 2012)
polylactide (BioFlex) was studied using scanning electron microscopy (SEM) and dynamic rheological measurements (Kucharczyk et al. 2012). SEM showed the formation of co-continuity for the blends containing 50–60 wt% of BioFlex. Rheological measurements and solvent extraction showed a broader co-continuity interval, even for blends with over 25 wt% BioFlex. All methods indicated maximum co-continuity at 60 wt% BioFlex. The best fit of experimental data was for the model including the contribution of elasticity to interfacial tension (Bourry and Favis 1998; Fig. 7.4).

7.1.2.3 The Interphase

Lattice theory predicts that the density profile across the interface follows the exponential decay function (Helfand and Tagami 1971, 1972):

$$\begin{aligned} \rho/\rho_o &= y^2/(1 + y^2) \\ \text{where} \quad y &\equiv \exp\left\{ (6\chi_{AB})^{1/2}(x/b) \right\} \end{aligned} \tag{7.12}$$

In Eq. 7.12, χ_{AB} is the thermodynamic binary interaction between polymers A and B, and b is a lattice parameter. The dependence is shown in Fig. 7.5. The intercept of the tangential line at the place of the steepest decline (or incline for the other component) defines thickness of the interphase, Δl.

The lattice theory of the interface predicts that there is a reciprocity between the interfacial tension coefficient and the interfacial thickness (Helfand and Sapse 1975):

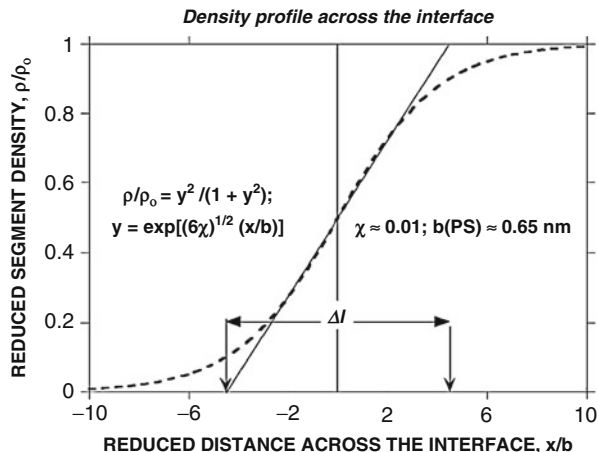
$$\begin{aligned} v_{12} &= k_B T a^{-1} (m\chi_{AB})^{1/2} \quad \text{and} \quad \Delta l = 2(m/\chi_{AB})^{1/2} \\ \therefore \Delta\lambda \cdot v_{12} &= 2mk_B T/a \end{aligned} \tag{7.13}$$

Density profile across the interface

$\rho/\rho_o = y^2/(1 + y^2)$;
$y = \exp[(6\chi)^{1/2}\,(x/b)]$ $\chi \approx 0.01$; $b(PS) \approx 0.65$ nm

Δl

REDUCED SEGMENT DENSITY, ρ/ρ_o

REDUCED DISTANCE ACROSS THE INTERFACE, x/b


where a, b, and m are lattice parameters. Notice that according to this theory, the product, $v_{12}\Delta l$, is independent of the thermodynamic binary interaction parameter, χ_{AB}. The theory leads to the conclusions that (i) surface free energy is proportional to the square root of χ_{AB}, (ii) the chain ends of both polymers concentrate at the interface, (iii) any small molecular weight third component will be repulsed to the interface, and (iv) interfacial tension coefficient increases with molecular weight to an asymptotic value: $v_{12} = v_\infty - a_o M_n^{-2/3}$. These conclusions were found to offer good guidance for development of compatibilization strategies.

There are several other theories of the interface, some of which lead to quantitatively different results (Ajji and Utracki 1996, 1997). For example, Noolandi (1984) considered a binary system compatibilized by addition of a block copolymer. For $\chi_{AB}N_c\phi_p \leq 2$ he derived:

$$v_{12} = v_{o|} + \Delta L\phi_c\{\chi_{AB}\phi_p/2 + (1/N_c)[1 - \exp\{\chi_{AB}N_c\phi_p/2\}]\}$$
$$\therefore \quad v_{12} \cong v_o - a_o\Delta L\phi_c + O(\phi_c^2) \tag{7.14}$$

where a_o is a numerical parameter, while ϕ_c, ϕ_p, and N_c are, respectively, volume fraction of copolymer, of polymer, and degree of polymerization of the copolymer. A semiempirical dependence of the interfacial tension coefficient on compatibilizer concentration can be derived from an analogy to titration of an emulsion with surfactants (Utracki 1992):

$$v_{12} = (\phi v_{CMC} + \phi_{mean}v_o)/(\phi + \phi_{mean})$$
$$\text{where;}$$
$$v_{CMC} = v_{12}(\phi_c = CMC) \tag{7.15}$$
$$\phi_{mean} = (v_{CMC} + v_o)/2$$

where v_o is the initial interfacial tension coefficient at zero concentration of copolymer, v_{CMC} is the interfacial tension at saturation of the interface, and

Fig. 7.6 Interfacial tension coefficient versus concentration of compatibilizer for polystyrene blends with polybutadiene, compatibilized with styrene-butadiene block copolymer. Data points (Anastasiadis and Koberstein 1988), line computed from Eq. 7.15
ϕ is the copolymer concentration. Eq. 7.15 adequately described the interfacial tension coefficient in the system polystyrene/polybutadiene compatibilized by addition of styrene-butadiene block copolymer; see Fig. 7.6 (Anastasiadis et al. 1988, 1989).

Recently an exponential decay relation was proposed (Tang and Huang 1994):

$$v_{12} = v_{CMC} + (v_o - v_{CMC})\exp\{-K\phi\} \tag{7.16}$$

where K is a parameter – from Eq. 7.14, its value should be proportional to $K \propto \chi_{AB}N_c$.

There have been several efforts to provide means for computation of the interfacial tension coefficient from characteristic parameters of the two fluids (Luciani et al. 1996). The most interesting relation was that found between the interfacial tension coefficient and the solubility parameter contributions that are calculable from the group contributions. The relation makes it possible to estimate the interfacial tension coefficient from the unit structure of macromolecules at any temperature. The correlation between the experimental and calculated data for 46 polymer blends were found to be good – the correlation coefficient R = 0.815 – especially when the computational and experimental errors are taken into account.

There are several methods for measuring the interfacial tension coefficient for low-viscosity liquids, e.g., spherical shape recovery after slight deformation, liquid thread breakup, rotating bubble or drop, pendant drop, sessile bubble or drop, du Nuouy ring, or light scattering. For high-viscosity polymeric melts, they can be used with decreasing reliability. The most recent and highly successful method involves spherical shape recovery of a drop deformed by about 15 % either in shear or (preferably) in elongation. Since the drop can be repetitively deformed and its shape recovery follows, this method is the only one that makes

Table 7.4 Interphase
thickness

Type of blend	Thickness (nm)
Immiscible blend	2
Block copolymer interphase	4–6
Immiscible blends filled with nanoclay	4–20
Polymer/copolymer	30
Reactive compatibilization	30–60
Radius of gyration, $\langle R_g^2 \rangle^{1/2}$	5–35

it possible to follow the time evolution of the interfacial tension coefficient. Furthermore, the method also makes it possible to examine whether, for a given polymer pair, the interfacial energy is symmetrical, i.e., if $\nu_{\alpha\beta} = \nu_{\beta\alpha}$ (Luciani et al. 1996).

There are fewer methods available to measure the interphase thickness, e.g., ellipsometry, microscopy, and scattering. For example, Ville et al. investigated the interphase in polyethylene (PE)/polyamide (PA) blends with nodular morphology, filled with modified montmorillonite, using morphological and rheological experimental techniques (Ville et al. 2012). The average interphase thickness was determined at several points (from more than 200 local interphase thickness measurements) by using an image analysis software. It was shown that the average interphase thickness increased with clay fraction, from about 7 nm at 1 % clay to about 20 nm at 4 % clay, which was expected since clay particles were localized exclusively at the interphase (Huitric et al. 2009; Khatua et al. 2004). However, based on rheological characterization, which showed not very long dominant relaxation times (nodule form relaxation time and interphase relaxation time), Ville et al. mentioned that using microscopy method to characterize the interphase is certainly insufficient due to the presence of a continuous rigid nanocomposite shell that misrepresents the physical reality of the interphase in these systems (Ville et al. 2012).

A summary of the measured Δl is given in Table 7.4. The temperature dependence of Δl in PMMA/SAN and PMMA/PS blends is presented in Fig. 7.7.

7.2   Rheological Models for Miscible Blends

By definition, miscible polymer blends are single-phase mixtures. Miscibility depends on the molecular weight, concentration, temperature, pressure, deformation rate, etc. Flow of these systems can be compared to that of solutions of low molecular weight, miscible components, or to flow of mixtures of polymeric fractions. Both models are far from perfect, but they serve to illustrate the basic behavior of miscible systems. In the first case one can learn about the effects of the thermodynamic interactions between chemically different components on the flow behavior. In the second case, it is the effect of molecular weight and molecular weight distribution that can be observed.

Fig. 7.7 Interphase thickness versus temperature for polymethylmethacrylate blends with (from *top*) styrene-acrylonitrile copolymer and polystyrene (Kressler et al. 1993)
7.2.1 Solutions

For solutions (Glasstone et al. 1941):

$$\ln[V\eta_0] = \sum_i x_i \ln[V_i \eta_{0i}] - \prod_i x_i \Delta H_m / 2.45RT \tag{7.17}$$

where V is the specific volume and x_i is the mole fraction. For miscible blends, $\Delta H_m < 0$ and the above relations predict a positive deviation from the log-additivity rule, PDB. The latter rule, the log-additivity, was formulated by Arrhenius (1887):

$$\ln\eta_0 = \sum_i x_i \ln \eta_{0i} + \ln\eta^E \tag{7.18}$$

with the excess viscosity term, $\ln \eta^E \to 0$.

There are several other blending rules for solution viscosity, e.g., (McAllister 1960):

$$
\begin{aligned}
\ln\eta_{k,b} = {} & x_1^3 \ln\eta_{k,1} + x_2^3 \ln\eta_{k,2} + 3x_1^2 x_2 \ln\eta_{k,12} \\
& + 3x_1 x_2^2 \ln\eta_{k,21} + 3x_1^2 x_2 \ln[(2M_1 + M_2)/3] \\
& + 3x_1 x_2^2 \ln[(M_1 + 2M_2)/3] + x_1^3 \ln M_1 \\
& + x_2^3 \ln M_2 - \ln(x_1 M_1 + x_2 M_2)
\end{aligned}
\tag{7.19}
$$

where $\eta_{k,i}$ indicates the kinematic viscosity, M_i is the molecular weight, and the two kinematic viscosities with double subscripts are the empirical interaction viscosities. Equation 7.19 was derived from a three-body model of a miscible mixture comprising two low molecular weight liquids with two interaction viscosities.

7.2.2   Homologous Polymer Blends

The homologous macromolecular blends are simply mixtures of fractions of the same polymer having the same molecular constitutions. On the one hand, any commercial polymer may be treated as a homologous macromolecular blend, and on the other, blending narrow molecular weight distribution fractions provides important information on the rheological behavior of commercial materials. Since the zero-shear viscosity for narrow molecular weight distribution samples can be expressed as

$$\eta_0 = KM_w^\alpha \quad \text{thus} \quad M_w = (\eta_0/K)^{1/\alpha} \tag{7.20}$$

(where K and $\alpha = 1$ or 3.4 are parameters), but since

$$M_w = \sum_i w_i M_i \tag{7.21}$$

then it follows that (Friedman and Porter 1975)

$$\eta_o = \left[\sum_i w_i \eta_{o,i}^{1/\alpha} \right]^\alpha \tag{7.22}$$

For binary mixtures, Eq. 7.22 predicts that viscosity should show a positive deviation from the log-additivity rule, PDB.

There is a mounting evidence that PDB is not a rule for miscible polymer blends. Depending on the system and method of preparation, polymer blends can show a positive deviation, negative deviation, or additivity. Note that miscibility in polymeric systems requires strong specific interactions, which in turn affect the free volume, thus the rheological behavior. It has been demonstrated that Newtonian viscosity can be described by the relation (Utracki 1983, 1985, 1986)

$$\ln\eta_0 = a_0 + a_1/(f + a_2) \tag{7.23}$$

where a_i are equation parameters $a_o \equiv \ln \eta_o^*$ with η_o^* being the iso-free volume viscosity, a_1 is a function of the molecular architecture and polydispersity ($a_1 = 0.79$ was found for all paraffin's and their mixtures), and $a_2 = 0.07$ is the linearization parameter. The key to Eq. 7.23 is the free volume fraction, f, computed from Simha's statistical theory (Simha and Somcynsky 1969; Simha and Jain 1984). This approach was successful in describing pressure, temperature, and concentration dependence of the viscosities of solvents and polymer melts (Utracki 1983, 1985, 1986).

7.3   Model Systems for Immiscible Blends

Most polymer blends are immiscible. Their flow is complex not only due to the presence of several phases having different rheological properties (as it will be

demonstrated later, even in blends of two polymers the third phase, the interphase, must be taken into account) but also due to strain sensitivity of blends' morphology. Such a complexity of flow behavior can be best put in perspective by comparing it to flow of better understood systems, suspensions, emulsions, and block copolymers.

Flow of suspensions of solid particles in Newtonian liquids is relatively well understood, and these systems provide good model for flow of polymer blends, where the viscosity of dispersed polymer is much higher than that of the matrix polymer.

Flow of emulsions provides the best model for polymer blends, where the viscosity of both polymers is comparable. The microrheology of emulsions provides the best, predictive approach to morphological changes that take place during flow of polymer blends. The effect of emulsifiers on the drop size and its stability in emulsions has direct equivalence in the compatibilization effects in polymer blends.

Finally, the rheological behavior of block copolymers serves as a model for well-compatibilized blends, with perfect adhesion between the phases. The copolymers provide important insight into the effects of the chemical nature of the two components and the origin of the yield phenomena.

7.3.1 Suspensions

The dispersions of solid particles in viscous fluids can be found in a wide range of natural and industrial applications. There are some interactions determining the microstructure of the suspension, such as interactions arising from Brownian, interparticle, and flow-induced forces. In the equilibrium state, there is a balance between Brownian and interparticle forces. Under the influence of flow, hydrodynamic interactions become considerable, in comparison with thermal and interparticle forces.

The rheological properties of the suspension are strongly influenced by the spatial distribution of the particles. The relationship between microstructure and rheology of suspensions has been studied extensively (Brader 2010; Morris 2009; Vermant and Solomon 2005). Most of earlier studies dealt with the simplest form of suspensions, in which dilute hard-sphere suspensions are subjected only to hydrodynamic and thermal forces near the equilibrium state (i.e., Péclet number $<< 1$) (Bergenholtz et al. 2002; Brady 1993; Brady and Vicic 1995). In shear flows of such suspensions, the structure is governed only by the particle volume fraction and the ratio of hydrodynamic to thermal forces, as given by the Péclet number.

The main problem in extending the microstructural theories to high Péclet number and volume fraction is related to the formulation of the many-body interactions. Recently, based on the Smoluchowski equation, Nazockdast and Morris (2012) developed a theory for concentrated hard-sphere suspensions under shear. The theory resulted in an integro-differential equation for the pair distribution function. It was used to capture the main features of the hard sphere structure and to predict the rheology of the suspension, over a wide range of volume fraction (≤ 0.55) for $0 < \mathrm{Pe} \leq 100$ (Nazockdast and Morris 2012).

There are two reasons for discussing the solid-in-liquid dispersions in the chapter dedicated to flow of polymer blends (Utracki 1995). Historically, the first

systematically studied multiphase systems were suspensions in Newtonian liquids, initially at infinite dilution (Einstein 1906, 1911), than at increasingly concentrated limits (Simha 1952). Knowledge of these derivations is fundamental to understanding the energy dissipation during flow in any multiphase system. Furthermore, the suspensions in viscoelastic matrix are good models for polymer blends having viscous polymer dispersed in a significantly less viscous matrix polymer.

7.3.1.1 Suspensions in Newtonian Liquids

The following assumptions are often used: (i) The size of a rigid particle is large in comparison to the suspending medium molecules, but small compared to the smallest characteristic diameter of the flow channel so the continuum theories are applicable. (ii) The flow is steady state, without inertia or sedimentation. (iii) The suspending medium perfectly adheres to the particles. Depending on the system (as well as the author), additional assumptions may be made, e.g., regarding interparticle interactions, orientation, etc.

Denisov et al. (1985) as well as Brady and Bossis (1985) reported on numerical simulation of suspension rheology. The first authors used the 6–12 *Lennard-Jones potential* with the usual meaning of ε^* and σ^* characteristic constants (with dimensions of energy and length, respectively) of the interacting species. Taking R_o as a measure of distance from the center of the particle at which action of the potential begins, the necessary conditions for dilatant behavior were: (i) $R_o \geq \sigma^*$ and (ii) particle concentration exceeding a critical value dependent on the system. The Stokesian dynamic's method was used by the other authors. The simulation provided valuable information on the influence of various microstructural elements on the macroscopic viscosity. The relative velocity of two particles in suspension provided the most important contribution to energy loss. As ϕ increased, the correlation of interparticle motion also increased. Hydrodynamic lubrication resulted in an increased number of particles acting as single agglomerate. The maximum packing volume fraction, ϕ_m, takes on a meaning as a percolation-like threshold for the viscosity to increase to infinity owing to the formation of infinite clusters.

Microstructural theories of suspensions appear to be particularly well suited to solve problems associated with time-dependent flows, thixotropy and rheopexy (anti-thixotropy) (Russel 1983; Utracki 1989, 1995).

Relative Viscosity of Suspensions

One of the most interesting derivations of the η versus ϕ dependence (covering the full range of concentration) was published by Simha (1952). He considered the effects of concentration on the hydrodynamic interactions between suspended particles of finite size. (Note that previously the particles were simply considered point centers of force that decayed with cube of the distance.) Simha adopted a cage model, placing each solid, spherical particle of radius a inside a spherical enclosure of radius b. At distances $x < b$, the presence of other particles does not influence

flow around the central sphere and the Stokes relation is satisfied. This assumption leads to a modified Einstein (1906, 1911) relation

$$\eta_r = 1 + (5/2)\lambda(y)\phi \tag{7.24}$$

where $\lambda(y)$ is the modifying (or shielding) function of the relative cage size, $y \equiv a/b$:

$$\lambda(y) = \frac{4(1 - y^7)}{4(1 + y^{10}) - 25y^3(1 + y^4) + 42y^5}$$
$$\text{with} \quad y = \left[2\left(1/\widetilde{\phi}\right)^{1/3} - 1\right]^{-1} \tag{7.25}$$

In Eq. 7.25, ϕ_m is the maximum packing volume fraction. Thus, the magnitude of the shielding function $\lambda(y)$ depends on the reduced volume fraction, $\widetilde{\phi} \equiv \phi/\phi_m$. At low concentration, $\widetilde{\phi} \to 0$, the shielding factor vanishes and Einstein's relation is recovered. However, at high concentration, $\widetilde{\phi} \to 1$, the shielding function and relative viscosity both go to infinity, $\lambda(y)$, $\eta_r \to \infty$. Substituting Eq. 7.25 into Eq. 7.24 and expanding it into power series make it possible to write simplified versions, valid respectively within the low (viz., Eq. 7.26) and high (viz., Eq. 7.27) concentration range:

$$\eta_{sp} \equiv \eta_r - 1 = (5\phi/2)\left[1 + \frac{25}{32}\widetilde{\phi} - \frac{21}{64}\widetilde{\phi}^{5/3} + \frac{625}{128}\widetilde{\phi}^2 + \ldots\right] \tag{7.26}$$

and

$$\lim_{\phi \to \phi_m} \eta_r = 27\phi/20\left[\widetilde{\phi}\left(1 - \widetilde{\phi}\right)^{-3}\right] \tag{7.27}$$

Two other semiempirical relations have been often used to describe the concentration dependence of suspension viscosity. The first was derived for the first time by Mooney (1951):

$$\ln\eta_r = [\eta]/\left(1 - \widetilde{\phi}\right) \tag{7.28}$$

where $[\eta]_s$ is the intrinsic viscosity. The subscript s indicates that the parameter refers to solid particles. The intrinsic viscosity is defined as

$$[\eta] = \lim_{\phi, \dot{\gamma} \to 0} (\eta - \eta_o)/\eta_o\phi = \lim_{\phi, \dot{\gamma} \to 0} d(\eta_r - 1)/d\phi = \lim_{\phi, \dot{\gamma} \to 0} d \ln \eta_r/d\phi \tag{7.29}$$
Fig. 7.8 Relative viscosity of hard-sphere suspension in Newtonian fluid as a function of the volume fraction. Thomas curve represents the generalized behavior of suspensions as measured in 19 laboratories. The remaining curves were computed from Simha's, Mooney's, and Krieger–Dougherty's relations assuming Einstein value for intrinsic viscosity of hard spheres, $[\eta] = 2.5$, but different values for the maximum packing volume fraction, $\phi_m = 0.78, 0.91$, and 0.62, respectively

The second dependence is the already cited Eq. 7.8, derived by Krieger and Dougherty (1959). The relation belongs to a large group of dependencies of the type, discussed in detail a few years back (Utracki 1989):

$$\eta_r = (1 + \alpha\phi)^{\beta} \tag{7.30}$$

In Eq. 7.30, the values of the semiempirical parameters, α and β, are usually constant, e.g., respectively 2.5 and 1, or -2.5 and -1, or -1.73 and -2.0, etc. However, in the Krieger–Dougherty relation, these two parameters depend on the system $\alpha = 1/\phi_m$ and $\beta = [\eta]\phi_m$.

In Fig. 7.8, the plots of η_r versus ϕ calculated from Simha's Eq. 7.24, Mooney's Eq. 7.28, and Krieger–Dougherty's Eq. 7.8 are compared with the empirical curve-fitted relation, Eq. 7.5. For all the relations, the intrinsic viscosity $[\eta]_s = 2.5$ was used. However, to optimize the fit, different values for the maximum packing volume fraction, $\phi_m = 0.78, 0.91$, and 0.62, respectively, had to be used. Detailed analysis of Thomas' data made it possible to conclude that Simha's relations provide the best fit with more realistic values of the physical parameters (Utracki and Fisa 1982).

To summarize, the dependence of relative viscosity on the volume fraction of suspended particles can be expressed by any of several theoretical or semiempirical relations. These can be written in terms of the two parameters, $[\eta]$ and ϕ_m; thus $\eta_r = \eta_r([\eta], \phi/\phi_m)$. As it will be shown, the generality of this dependence extends beyond the monodispersed hard-sphere suspensions.

The relationships between η_r and ϕ have been derived for suspensions of monodispersed hard spheres in Newtonian liquids. However, most real systems are polydispersed in size and do not necessarily consist of spherical particles. It has been found that here also Simha's Eq. 7.24, Mooney's Eq. 7.28, or Krieger–Dougherty's Eq. 7.8 are useful, provided that the intrinsic viscosity and the maximum packing volume fraction are defined as functions of particle shape and size polydispersity. For example, by allowing ϕ_m to vary with composition, it was possible to describe the η_r versus ϕ variation for bimodal suspensions (Chang and Powell 1994). Similarly, after values of $[\eta]$ and ϕ_m were experimentally determined, Eq. 7.24 provided good description for the η_r versus ϕ dependence of several multiphase systems, e.g., PVC emulsions and plastisols, mica-reinforced polyolefins, and sealant formulations (Utracki 1988, 1989).

The problem of packing a maximum volume of solids into a given space is common to numerous branches of physics and technology. It suffices to note that the relative viscosity of suspensions is a function of the reduced volume fraction, $\widetilde{\phi} \equiv \phi/\phi_m$, to realize the importance of ϕ_m. Experimentally, it was demonstrated that ϕ_m calculated from *dry packing* of solid particles agrees well with the value determined for a suspension.

Theoretically and experimentally polydispersity increases the ϕ_m value, for example, from 0.62 observed for random packing of uniform spheres to values exceeding 0.9. An interesting recipe for ϕ_m maximization requires four generations of nearly spherical particles with the diameter ratios 1:3:9:17. Blending them at the volume ratios 4:1:1:4 result in $\phi_m = 0.78$. However, what was important, the suspensions were found to be nonsedimenting, and when dried they gave solid bed with uniform porosity (Ritter 1971; Lord 1971).

In industrial practice it may be important to use mixtures of filler particles not only of spheroidal shape (as discussed above) but also of different shapes, e.g., filling and reinforcing polymer with $CaCO_3$ particles and glass fibers. The theoretical basis for optimization of such systems was developed by Wieckowski and Streg (1966) and later by Milewski (Milewski 1973, 1977, 1978; Milewski and Katz 1987). These studies are also important for polymer blends where at concentrations exceeding the percolation threshold the morphology is complex, comprising spheres, fibers, and lamellas.

For anisometric particles it is useful to use the particle aspect ratio, p, defined as a ratio of two orthogonal axes. For prolate ellipsoids (fibers) $p > 1$ is the length-to-diameter ratio, whereas for oblate ellipsoids (plates) $p < 1$ is the thickness divided by the largest dimension of the plate. It was observed that both, the intrinsic viscosity, $[\eta]$, and the inverse of the maximum packing volume fraction, $1/\phi_m$, increase linearly with p. Thus, the relative viscosity of suspensions of anisometric particles is higher than that observed for spheres. For example, Doi and Edwards predicted (1978) that for rods $\eta_r \propto \phi^3$.

In the extensional, irrotational field, under the steady-state conditions, the particles remain oriented in the direction of stress. In uniaxial flow they align with the main axis in the flow direction, while in biaxial they lie on the stretch

plane (Batchelor 1970, 1971). For dilute spherical suspensions in Newtonian liquid, the extensional viscosity follows the Trouton rule, i.e., $\eta_E \cong 3\eta$. However, for anisometric particles the Trouton ratio η_E/η is a strong function of p. For example, at $\phi = 0.01$ extensional viscosity of rods with aspect ratio p $= 1,000$ is 1,000 times higher than that for suspension of spheres.

Particle Orientation in Flow

The orientation of particles in flow is of particular interest to microrheology. To predict the macroscopic rheological properties of a multiphase system, a detailed description of each phase behavior is required. In this field, contributions from the Pulp and Paper Research Institute of Canada by Mason et al. and later by van de Ven and his coauthors are particularly valuable. The earlier results were summarized by Goldsmith and Mason (1967), the latter by Van de Ven (1989). The microrheology has been particularly well developed for infinitely dilute systems in Newtonian matrix – either solid particles or liquid drops. In the present part, only the former system will be summarized. More extensive discussion of microrheology of the liquid–liquid systems will be presented later, while considering the rheological behavior of polymer blends.

For suspension of solid particles in a liquid, the theoretical and experimental works indicate that the angle of orientation of a spheroid can be expressed as

$$\phi_1 = \arctan\left[p \tan\left(2\pi t/t_p\right)\right] \tag{7.31}$$

where the period of rotation of a particle with an aspect ratio, p, is given by

$$t_p = 2\pi\left(p + p^{-1}\right)/\dot{\gamma} \tag{7.32}$$

Accordingly, for rods, the maximum velocity of rotation occurs at $t/t_p = 0$, 1/2, 3/4, 5/4, ... For spheres with p $= 1$, $\phi_1 = 2\pi\,t/t_p$, i.e., constant rotational velocity. In nonuniform shear fields, such as that observed during flow through a capillary (Poiseuille flow), the particles rotate with velocity predicted by Eqs. 7.31 and 7.32, according to the value of the shear rate existing at the radial location of the sphere in the capillary. Near the wall, for finite diameter spheres, the immobile layer of the suspending medium causes a reduction of rotational and translational velocity. The effect scales with the square of the sphere diameter.

The wall also causes a geometric exclusion effect, i.e., a lower-than-average concentration of particles near the wall and a retardation of their motion. The phenomena are complicated by the axial migration of particles, dependent on the Reynolds number, $\mathrm{Re} = \rho\dot{\gamma}d^2/\eta_o$, where ρ and d are the particle density and diameter, respectively.

To control the orientation of the fibers during composites manufacturing, it is helpful to have an insight about the relation between the suspension structure and rheological properties. Determination of the position, orientation history, and shape of fibers due to bending and twisting in a fluid are the main stream of the studies in this area (Joung et al. 2001; Schmid et al. 2000; Switzer Iii and Klingenberg 2003).

There are a few studies about the role of the fiber flexibility. Recently, Keshtkar et al. (2009) investigated the effect of fiber flexibility on the rheological behavior and orientation of fibers suspended in a Newtonian fluid under simple shear flow using conventional rheometry and rheo-microscopy. The ability of the mesoscopic model of Rajabian et al. (2005) to predict the rheological behavior and orientation of the fibers was also examined (Keshtkar et al. 2010). The advantage of using the abovementioned mesoscopic model is related to the compatibility of thermodynamics with its equations. The results showed that by increasing the fiber flexibility, both the viscosity and first normal stress difference increased. The main conclusion based on rheo-microscopy of the various suspensions is that at low shear rates, the most rigid fibers are more easily oriented than flexible fibers. High shear rate data indicated negligible difference in the orientation state of the flexible and rigid fibers. However, the model predictions for the fiber orientation were qualitatively consistent with the experimental data; it was suggested that GENERIC model (Grmela and Öttinger 1997) should be extended to predict the formation of agglomerates in the fiber-filled suspensions (Keshtkar 2009).

Shear-Induced Particle Migration

There are at least two possible mechanisms for particle migration during shear flow, inhomogeneity of the stress field and strong interparticle interactions (Graham et al. 1991). In the first case, the particles tend to migrate to low shear stress regions, while in the second case the situation is more complex involving a coupled relationship between the thermodynamic and hydrodynamic forces.

The Newtonian behavior of suspensions in Newtonian liquids is limited to low concentrations. An exception seems to be the extensional flow of anisometric particles (irrotational flow field) where the rate of strain independent region extends to concentrations where strong non-Newtonian behavior would be expected in shear. This rate of deformation-dependent phenomena will be summarized below.

During the capillary flow of concentrated suspensions, the difference in velocities of particles located at different radial positions results in the formation of transient multiplets or stacks, behaving similarly to rods. Under these circumstances the rate of axial migration is accelerated, and the flow profile flattens. For example, experimentally, for $\phi = 1/3$ suspensions of spheres flowing through a tube at the Reynolds number Re $\equiv 2\rho Q/\pi R_1 \eta = 0.056$, a partial plug flow was observed. However, when Re reached the value of 0.112, a complete plug flow was observed – the flow was no longer Newtonian (Karnis et al. 1966; Vadas et al. 1973).

Matsumoto et al. (1986) reported that in the cone-and-plate geometry, the storage G' and loss G'' shear moduli of uniform, nonrigid spheres decrease monotonically with test time (or number of shearing cycles). G' and G'' were observed to decrease by four decades, but steady-state shearing for 15 s returned them to the initial values. Since the phenomenon depended on the rigidity as well as on the uniformity of shape and size, development of a structure during the dynamic test must be postulated.

In Couette flow the spheres migrate toward the outer cylinder. In shearing, a *shear fractionation* of spherical particles has been observed. For example, Giesekus (1981) observed that, during torsional shearing of binary sphere suspensions, the larger and the smaller spheres separated into two different annular volumes, i.e., for each sphere size a critical equilibrium radial distance had to be postulated. On the other hand, Prieve et al. (1984, 1985) reported that for each sphere diameter and speed of rotation there is a critical radius, r_c; in the parallel plate rheometer, a particle located at $r < r_c$ was observed to migrate inward, whereas that placed at $r > r_c$ migrated outward. There is no theoretical explanation for either observation.

In a wide-gap Couette rheometer, migration of spheres was followed by a nuclear magnetic resonance imaging (Abbott et al. 1991). Migration to the low shear rate region was found to be determined by the total strain, proportional to the shear rate and square of the particle diameter, but independent of the (Newtonian) viscosity of the matrix liquid. More recently, similar studies were undertaken for suspensions of rods with $p = 2$–18 and $\phi = 0.3$ or 0.4 (Mondy et al. 1994). At the same ϕ, the composition gradient of rods of different aspect ratios was indistinguishable, the same as the one earlier reported for spheres. The rate of migration was found to increase with concentration.

Owing to the periodically accelerated rotation of fibers in a shear field, alignment of fibers in Couette flow is to be expected. Theory indicates that the shear field is about half as efficient at causing fiber alignment as extension. However, the shear field is rarely homogeneous, and during the flow fibers undergo breaking, bending, or coiling, which causes further reduction of alignment efficiency. Further details on various modes of orientation behavior of flowing suspensions can be found in reviews by Cox and Mason (1971), Batchelor (1974), and Leal (1980).

The evidence accumulated so far indicates that there is a full spectrum of structures, from a liquid-like where the yield stress, $\sigma_y = 0$, to a solid-like with large σ_y. For anisometric particles at $\phi > 1/p$, yield may originate in mechanical interlocking of particles, but for spheres it stems from the interparticle interactions. When these interactions are weak, $\sigma_y \to 0$ is observed, with the arrow indicating the time effect. If the experiment is conducted at low rates of shear, no yield behavior would be noted.

In uniaxial extensional (convergent) flow, there is evidence of spherical particles moving toward the center of the stream. Convergent flow of a dilute suspension of glass fibers, $p = 200$–800, in Newtonian liquids was studied by Murty and Modlen (1977). The fiber orientation angle (defined as an average angle between the fiber axis and flow direction) changed from $45°$ (random) to about $15°$. The orientation started upstream from the convergence. For low viscosity liquids, jamming at the entrance region was responsible for as much as 60 % of fibers being "filtered out."

At higher fiber loading, $\phi_p > 1$, the rheological responses of aligned fiber suspensions resemble those of liquid crystals. Becraft and Metzner (1992) analyzed the rheological behavior and orientation of glass fibers (GF), in polyethylene (PE), and polypropylene (PP). The experimental data were interpreted using a modified

Doi theory for liquid crystalline fluids, LCF (Doraiswamy and Metzner 1986). The kinetics of the distribution function, f, is given by

$$\frac{Df}{Dt} = \nabla \cdot \overline{D}_r \nabla f + \nabla \cdot \overline{D}_r \frac{f \nabla V}{k_B T} - \nabla \cdot (uf) \qquad (7.33)$$

where $\overline{D}_r$ is the rotational diffusivity of the rods and u denotes a unit vector corresponding to rod orientation. The first term on the rhs of Eq. 7.33 accounts for the contribution of Brownian motion to the orientation distribution function, the second for the effects of the liquid crystalline interaction potential between the rods, while the third term for the effects of flow.

Doraiswamy and Metzner noted that use of the LCF approach is permissible at concentrations above that which would correspond to the transition from isotropic to aligned morphology, $\phi > 8/p$. The theory provided fair description of the stress–strain dependence for systems containing 10 wt% GF and excellent agreement for those with 40 wt% GF. Also, the approach gave good predictions of the diagonal terms of the second-order orientation tensor.

Aggregation and Yield Stress

One of the fundamental assumptions of the continuum theories is stability of structure (Newtonian behavior) or, alternatively, a well-defined process of structural changes (non-Newtonian behavior). However, as it was already mentioned, orientation effects in sheared layers of suspensions are responsible for either dilatant or pseudoplastic behavior, while strong interparticle interactions may lead to yield stress or a transient behavior. In short, there is an intimate relation between the liquid structure and its rheological response; change in one causes a corresponding change in the other. Some of these changes have been theoretically treated, viz., Eq. 7.32. The aggregation is the result of the attractive forces or the flow conditions. It could be categorized in two groups: flocculation which is the reversible aggregation and coagulation which is a fast irreversible aggregation (Larson 1999). A physical change in the system may cause flocculation. Flocculates can be re-dispersed in the suspension using mechanical processes such as shaking or stirring (deflocculation). Aggregation, agglomeration, and flocculation are structural phenomena ranging from transient rotating doublets observed within dilute region to a pseudo-solid-like behavior of flocculated suspensions with yield stress. Aggregation can occur due to thermodynamic interparticle interactions, chemical bonding, or geometric crowding. The latter type prevails in shear flows of suspensions of anisometric particles.

It was shown that even in the absence of attractive interparticle interactions, shear forces can make aggregates of the particles interacting by large friction forces (Switzer Iii and Klingenberg 2003). For example, flow-induced aggregation has been observed for stiff fibers (Schmid et al. 2000) and carbon nanotube suspensions (Khalkhal et al. 2011).

There are numerous theories based on structural models of suspensions (Mikami 1980). Wildemuth and Williams (1984) considered that the maximum packing

volume fraction, ϕ_m, is a function of *normalized* shear stress, $\widetilde{\sigma}_{12} \equiv \sigma_{12}/M$, where M is a numerical parameter. The authors derived the relation

$$\phi_m = \left(\phi_{m,o} + \phi_{m,\infty}\widetilde{\sigma}_{12}^m\right)/\left(1 + \widetilde{\sigma}_{12}^m\right) \tag{7.34}$$

where m = 1.00–1.17 is an experimental constant, while $\phi_{m,o}$ and $\phi_{m\infty}$ are values of the maximum packing volume fraction at $\widetilde{\sigma}_{12}$ and $\widetilde{\sigma}_{12} = \infty$, respectively. Defining the yield stress as $\widetilde{\sigma}_{12}$ when $\phi = \phi_m$, one can rearrange Eq. 7.34 to read

$$\widetilde{\sigma}_y = \left(\phi - \phi_{m,o}\right)/\left(\phi_{m,\infty} - \phi\right) \tag{7.35}$$

Hoffman (1972, 1974) also reported that at low rates of shear and high solid content, $\phi > 0.54$, the power law index $n = d\ln\sigma_{12}/d\ln\dot{\gamma}$ approaches zero.

For the system styrene-acrylonitrile (SAN) latex in ethylene glycol, addition of salt decreased *n* to zero. The experiment was performed to demonstrate that increased interparticle interaction causes the onset of dilatation to move to higher rate of shear. However, the work also demonstrated that at these high concentrations there is a yield stress, σ_y. Onogi and Matsumoto (1981) reported that in PS suspension with particles having strong attractive forces, the yield phenomenon was observed, while suspensions of PS particles having repulsive forces behaved like Newtonian liquids. Thus, the yield stress is associated with formation of a three-dimensional structure by interacting particles, resulting in a behavior similar to an elastic solid. Similarly, impact modification of PMMA by incorporation of 0–50 wt% of core-shell latex particles of poly(butylacrylate-co-styrene) demonstrated that the particles form a co-continuous network at $\phi \leq 0.2$ that result in a low frequency rubbery plateau. The high-frequency data were found independent of composition (Bousmina and Muller 1992). There are several methods for determining σ_y. Among these is the modified Casson equation (Utracki 1982):

$$F^{1/2} = F_y^{1/2} + aF_m^{1/2} \tag{7.36}$$

where F may be any rheological function (viz., shear stress σ_{12}, elongational stress σ_{11}, shear loss modulus G'', etc.), F_y indicates the yield value of F, F_m is the F-value of the matrix liquid at the same deformation rate as F, and a is a measure of the relative value of F. Another method requires a simultaneous fit of experimental data to a constitutive equation in which a parameter or parameters are related to σ_y (Utracki 1987).

Measurements of creep and elastic recovery also provide a sensitive, direct mean of detecting yield stress, either by simultaneous fit of time-dependent strain, $\gamma(\tau)$, at a constant stress, σ_{12}, to the compliance equation:

$$J(t) \equiv \gamma_{12}(t)/\sigma_{12} = J_0 + J_e^0\Psi(t) + t/\eta \tag{7.37}$$

(where $\Psi(t)$ is the retardation function), or by plotting the recoverable strain versus stress. In the latter case, the maximum value of stress below which the Hookean behavior is obtained gives the value of σ_y.

Polymer lattices and suspensions of carbon black in linseed oil and clay or calcium carbonate in aqueous media provide examples (Amari and Watanabe 1983). The values of σ_y determined from creep and those from shear viscosity were found to be in good agreement.

There are several direct methods of measurement of a yield stress. The constant stress rheometer is most frequently used to determine σ_y value in shear. Dzuy and Boger (1983, 1985) used a rotational vane viscometer. Yield stresses in compression can be calculated from the unrelaxed stress values in parallel plate geometry. Its value in elongation has been directly measured as the critical stress value below which no sample deformation was observed during 30 min of straining in an extensional rheometer.

Khalkhal and Carreau (2011) examined the linear viscoelastic properties as well as the evolution of the structure in multiwall carbon nanotube–epoxy suspensions at different concentration under the influence of flow history and temperature. Initially, based on the frequency sweep measurements, the critical concentration in which the storage and loss moduli shows a transition from liquid-like to solid-like behavior at low angular frequencies was found to be about 2 wt%. This transition indicates the formation of a percolated carbon nanotube network. Consequently, 2 wt% was considered as the rheological percolation threshold. The appearance of an apparent yield stress, at about 2 wt% and higher concentration in the steady shear measurements performed from the low shear of $0.01 \ s^{-1}$ to high shear of $100 \ s^{-1}$, confirmed the formation of a percolated network (Fig. 7.9). The authors used the Herschel–Bulkley model to estimate the apparent yield stress. As a result they showed that the apparent yield stress scales with concentration as $\tau_y \sim \varphi_v^{2.64\pm0.16}$ (Khalkhal and Carreau 2011).

For unoriented particle systems, the von Mises criterion for plastic flow of solids should be obeyed; the yield stress in elongation and compression should be equal to each other and larger by the factor of $\sqrt{3}$ than the yield stress in shear, σ_y. However, for highly concentrated suspensions of anisometric particles, von Mises criterion should not be used.

For suspensions, the concentration dependence of σ_y was found to follow either of the following two dependencies:

$$\sigma_y = a_1(\phi - \phi_0)^{a_2} \quad \text{and} \quad \sigma_y = a_3\exp\{a_4\phi\} \tag{7.38}$$

where a_i are adjustable parameters. The exponent a_2 depends on the particle geometry as well as the interparticle interactions. For human blood $\sigma_y = 26.87\phi^3$ (mPa) was reported (Picart et al. 1998).

It has been observed that for many systems the value of yield stress depends on the time scale of the measurements. Setting all controversies aside, pragmatically it is advantageous to consider that in these systems there are aggregates of different size, characterized by the dynamic interparticle interactions. For a given system these interactions have specific strength, σ_y^∞, and the aggregates have a characteristic relaxation time, τ_y. This model leads to the following relation:

$$\sigma_y(\xi) = \sigma_y^\infty \left[1 - \exp\{-\tau_y\xi\}\right]^u; \quad \text{for} \quad \xi = \omega, \ \dot{\gamma} \ \text{or} \ \dot{\varepsilon} \tag{7.39}$$

where u = 0.2–1.0 characterizes polydispersity of the aggregates. Equation 7.39 was found to be easy to use, and the parameters computed from curve fitting of the experimental data, $\sigma_{apparent} = \sigma_y + \sigma_{true}$, agreed quite well with the independently determined values.

Leonov (1994) introduced kinetics of interactions into his rheological equation of state. The new relation can describe systems with a dynamic yield stress, without resorting to a priori introducing the yield stress as a model parameter (as it has been done in earlier models).

Time-Dependent Flows

Two types of flow are recognized: thixotropy, defined as *a decrease of apparent viscosity under shear stress*, *followed by a gradual recovery when the stress is removed*, and its opposite, anti-thixotropy, or rheopexy. Both are related to molecular or macroscopic changes in interactions. In thixotropic liquids, the aggregate bonding must be weak enough to be broken by flow-induced hydrodynamic forces. If dispersion is fine, even slight interactions may produce thixotropic effects. When

Table 7.5 Definitions of viscoelastic and thixotropic systems

No.	Viscoelastic systems	Thixotropic systems
1.	Yield stress defined by the conditions: $\dot{\gamma} = 0$ when $\sigma_{12} < \sigma_y$	Critical stress defined by the conditions: $\dot{\gamma}(t) = 0$ when $\sigma_{12} < \sigma_{crit}(t)$
2.	Initial slope of the flow curve: $\lim_{\dot{\gamma} \to 0} \partial \ln \eta_{app} / \partial \ln \dot{\gamma} = 1$	Initial slope of the flow curve: $\lim_{\dot{\gamma} \to 0} \partial \ln \eta_{app} / \partial \ln \dot{\gamma} \leq 1$
3.	Elastic effects are present	Lack of elastic effects
4.	After step increase of $\dot{\gamma}$ the shear stress, σ_{12}^{+} increases	After step increase of $\dot{\gamma}$ the shear stress, σ_{12}^{+} decreases
5.	Smaller equilibrium strains than those for thixotropic systems	Larger equilibrium strains than those for viscoelastic systems

the dispersion coarsens, larger forces are required to engender the same effects. In the case of suspensions of anisometric particles, the interactions are particularly strong, while for spheres, the effect can be controlled by changing the type and concentration of ionic groups on the surface. Similarly, in polymer blends the interdomain interactions can be controlled by addition of a compatibilizer – its presence enhances the interphase interactions.

Breakup and recreation of the associated structure follow exponential decay kinetics. The simplest, single exponential relation representing thixotropic behavior is

$$\eta(t) - \eta_{\infty}^{t} = \left(\eta_0^{t} - \eta_{\infty}^{t} \right) \exp\{-t/\tau^{*}\} \qquad (7.40)$$

where t is the shearing time, η_0^t and η_∞^t are values of shear viscosity at $t = 0$ and ∞, respectively, and τ^* is the relaxation time of the system.

Time dependency also enters into the consideration of the rheological response of any viscoelastic system. In steady-state testing of materials such as molten polymers, the selected time scale should be sufficiently long for the system to reach equilibrium. Frequently, the required period, $t > 10^4$ s, is comparable to that in thixotropic experiments. More direct distinctions between these two types of flow are the usual lack of elastic effects and the larger strain values at equilibrium observed for thixotropic materials (see Table 7.4). There is a correlation between these two phenomena, and theories of viscoelasticity based on thixotropic models have been formulated by Leonov (1972, 1994). Inherent to the concept of thixotropy is the yield stress. Both the microstructural and continuum theories postulate that the material behaves as a Bingham body at stresses below a critical value (Table 7.5).

Steady-State Flows

There are three types of melt behavior in a simple shear flow: dilatant (D) (shear thickening); Newtonian (N), and pseudoplastic (P) (shear thinning). Similarly, in an extensional flow, the liquids may be stress hardening (SH), Troutonian (T), or stress softening (SS). By definition, the response considered here is taken at sufficiently

long times to ensure steady state, and the yield effect, Y, is subtracted. In consequence, within the experimental range of stress or deformation rate, several types of behavior may be observed. There exist a great variety of flow curves observed for different materials.

Pseudoplastic Flows

For suspensions, the most common type is a pseudoplastic flow curve with the so-called upper, η_o, and lower, η_∞, Newtonian plateaux (Cross 1965, 1970, 1973):

$$\eta - \eta_\infty = (\eta_0 - \eta_\infty)/(1 + a_0\dot{\gamma}^{a_1}) \tag{7.41}$$

In this relation a_o is the parameter describing how fast the viscosity changes between the two plateaux. In viscoelastic systems, the lower plateau is several orders of magnitude smaller than the upper one, $\eta_\infty << \eta_o$, and it is frequently neglected.

Equation 7.41 resembles the one derived by Carreau (1972) for monodispersed polymer melts, which later was generalized for polydispersed systems (Utracki 1984, 1989):

$$\eta = \eta_0[1 + (\tau\dot{\gamma})^{m_1}]^{-m_2} \tag{7.42}$$

In Eq. 7.42, τ is the relaxation time and m_1 and m_2 are polydispersity parameters, with a bound: $n = 1 - m_1 m_2$, where n is the power-law exponent in the relation:

$$\sigma_{12} = K\dot{\gamma}^n \tag{7.43}$$

Equation 7.42 well describes the flow behavior of polymeric systems, and it was found useful for polymer blends. It should be stressed that Eqs. 7.41, 7.42, and 7.43 describe the flow behavior of fluids without yield stress or thixotropicity.

Dilatant Flows

Krieger and Choi (1984) studied the viscosity behavior of sterically stabilized PMMA spheres in silicone oil. In high viscosity oils, thixotropy and yield stress were observed. The former is well described by Eq. 7.41. The magnitude of σ_y was found to depend on ϕ, the oil viscosity, and temperature. In most systems, lower Newtonian plateau was observed for the reduced shear stress value: $\sigma_r \equiv \sigma_{12}d^3/RT > 3$ (d is the sphere diameter, R is the gas constant, and T is the absolute temperature). However, when shear stress was further increased, dilatant behavior was observed. Dilatancy was found to depend on d, T, and silicone oil viscosity. The authors reported small and erratic normal stresses.

To describe the above behavior, the following relation was derived (Utracki 1989):

$$\eta - \eta_\infty = (\eta_0 - \eta_\infty)\left[1 + a_0\exp\{\tau\dot{\gamma} - a_1\}^{2a_2}\right]\left[1 + (\tau\dot{\gamma})^{m_1}\right]^{-m_2} \tag{7.44}$$

where a_i are equation parameters. Excepting the assumptions that $\eta_\infty \neq 0$ and insertion of the middle square bracket on the rhs of Eq. 7.44, the dependence is the same as Eq. 7.42.

Hoffman (1972, 1974), Strivens (1976), van de Ven (1984, 1985), Tomita et al. (1982, 1984), and Otsubo (1994) reported pseudoplastic/dilatant flow of concentrated suspensions of uniform and polydispersed spheres. A dramatic change in light diffraction pattern was systematically observed at the shear rate corresponding to the onset of dilatancy. Van de Ven and his collaborators demonstrated that, depending on concentration and shear rate, the distance between the sliding layers of uniform spheres in a parallel plate rheometer can vary by as much as 10 %.

The dilatant behavior of binary sphere suspensions in capillary flow was reported by Goto and Kuno (1982, 1984). At constant loading, dilatancy was observed only within a relatively narrow range of composition, $0.714 < x < 0.976$, where x represents the fraction of larger spheres.

Suspensions, even in Newtonian liquids, may exhibit elasticity. Hinch and Leal (1972) derived relations expressing the particle stresses in dilute suspensions with small Peclet number, $Pe = \dot{\gamma}/D_r \sim 1$ (D_r is the rotary diffusion coefficient), and small aspect ratio. The origin of the elastic effect lies in the anisometry of particles or their aggregates. Rotation of asymmetric entities provides a mechanism for energy storage, Brownian motion for its recovery. For suspensions of spheres, this mechanism does not exist and the first normal stress, N_1, is expected to vanish. However, when at higher ϕ the spherical particles aggregate into anisometric clusters, the system may and does show a viscoelastic behavior. Indeed, large N_1 (Kitano and Kataoka 1981), Weissenberg rod climbing (Nawab and Mason 1958), and large capillary entrance–exit pressure drops were reported (Goto et al. 1986). On the other hand, owing to the yield stress, no extrudate swell was observed in suspensions of anisometric particles in Newtonian liquids (Roberts 1973).

Theoretically, interparticle interactions contribute directly to the elastic stress component of spherical suspensions as well as by modification of the microstructure (Batchelor 1977):

$$\langle S^P \rangle N = \sum_{i=2}^{N} \sum_{j<i}^{N} r_{ij} F_{ij} \tag{7.45}$$

where N is the number of particles and r_{ij} center-to-center separation of i and j particles with pairwise interparticle interaction force F_{ij}. Gadala-Maria (1979) reported that, for suspensions of PS spheres in silicone oil, N_1 linearly increased with σ_{12}. Other theories have been discussed by Van Arsdale (1982), Bibbo et al. (1985), Brady (1993), Becraft and Metzner (1994), and many others.

The dynamic mechanical testing of suspensions is particularly suitable for studying systems with anisometric particles with well-defined structures (Ganani and Powell 1985). The authors studied the dynamic behavior of spheres in Newtonian liquids. They reported that dynamic viscosity, η', behaves similarly as the steady-state viscosity, η, while the storage modulus $G' \cong N_1 \cong 0$.

Transient Effects

In system where the structure changes with time upon imposition of stress, transient effects are important. For example, semi-concentrated fiber suspensions in shear and extension show large transient peaks in the first and the second normal stress differences (Dinh and Armstrong 1984; Bibbo et al. 1985). It is interesting that the peaks appear at different times, first for N_2, then for N_1, and finally for σ_{12}.

7.3.1.2 Suspensions in Non-Newtonian Liquids

Filled and reinforced polymer melts belong in this category. There are numerous reviews on the topic (Chaffey 1983; Goettler 1984; Metzner 1985; Utracki 1987, 1988; Utracki and Vu-Khanh 1992). There is particularly strong interest in flow of polymeric composites filled with anisometric, reinforcing particles, with properties that strongly depend on the flow-induced morphology and distribution of residual stresses.

In the absence of interlayer slip, addition of a second phase leads to an increase of viscosity. The simplest way to treat the system is to consider the relative viscosity as a function volume fraction of the solids, ϕ, particle aspect ratio and orientation.

There is no difference between the flow of suspensions in Newtonian liquids and that of polymeric composites, when the focus is on the Newtonian behavior phase. The non-Newtonian behavior of suspensions originates either from the non-Newtonian behavior of the medium or from the presence of filler particles. The problems associated with this behavior can originate in interparticle interactions (viz., yield stress) and orientation in flow (Leonov 1990; Mutel and Kamal 1991; Vincent and Agassant 1991; Shikata and Pearson 1994).

7.3.1.3 Flow-Induced Orientation

The most efficient orientation fields are extensional. Using convergent and divergent flow one may control orientation of anisometric particles. Most of the work in this area has been done with fiber-filled materials, but the effects are equally important for flow of neat semicrystalline polymer melts or liquid crystal polymers (Goettler and Shen 1983; Goettler 1984). In extensional flow, platelets are less susceptible to orientation. Two-stage orientation mechanism was observed in converging flow (Utracki 1988).

The nonlinear rheological behavior of platelet dispersions is a response to flow-induced rearrangements. Some methods have been developed to provide information on flow-induced orientation of platelets. These methods, generally, consist of performing in situ small-angle X-ray scattering (SAXS) (Bihannic et al. 2010) or small-angle neutron scattering (SANS) (Hanley et al. 1994; Kalman and Wagner 2009; Ramsay and Lindner 1993) experiments under shear flow applied in a Couette shear cell apparatus. For example, SAXS patterns obtained from radial and tangential incident beams relative to flow velocity field in a Couette apparatus showed biaxial orientation of natural clay particles (Bihannic et al. 2010). To correlate shear-induced particle orientation and the corresponding suspension viscosity, the effective volume fraction was first calculated based on parameters

Fig. 7.10 Comparison
between experimental and
calculated viscosities
(Bihannic et al. 2010)
derived from SAXS patterns (using an orientation distribution function) for differ-
ent shear rates. Then the viscosity was calculated using the model proposed by
Quemada (Quemada 1977; Quemada and Berli 2002) that relates suspension
viscosity to effective volume fraction. Figure 7.10 depicts the experimental and
calculated viscosities for the clay suspension. It reveals that the proposed approach
is successful in relating anisotropy of SAXS patterns to rheological behavior of the
suspension.

However, in shear-thinning dispersion, flow-induced orientation develops as
shear rate increases. Moreover, the shape factor of the particles affects the orien-
tational order. Evaluation of the shape factor effect on the orientation of particles
and, consequently, the rheological properties of suspensions showed that the shape
factor distribution provides more precise information than the median value of the
shape factor, specially at high shear rates (>105 s^{-1}) (Lohmander and Rigdahl
2000). Comparing two suspensions prepared using particles with a broad shape
factor distribution and a narrow one, with the same average value, showed higher
viscosity for the latter due to the different orientational order.

The orientation affects flow profoundly, hence processability, as well as the
product performance. It plays an important role in extrusion or injection molding
where the anisometric particles may become oriented in a complex manner.
Layered structures, weld lines, splice lines, swirls, and surface blemishes are well
known. Mold geometry (e.g., inserts) and transient effects make predictions diffi-
cult. It has been theoretically and experimentally shown that, when designing

a mold for composites with anisometric particles, the principles developed for single-phase melts do not apply (Crowson and Folkes 1980; Crowson et al. 1980, 1981; Folkes 1982; Vincent and Agassant 1986, 1991).

Yield Stress

Yield occurs as a result of structure formation due to physical crowding of particles, interparticle interactions, or steric–elastic effects of the medium. Depending on the stability of the structure, true or apparent (i.e., time-dependent) yield stress can be obtained. As a consequence, the magnitude of yield stress increases with aspect ratio of the particles, their rigidity, and concentration. The phenomenon is visible in steady-state shear, dynamic, or extensional flow, especially at low rates of deformation, where the slope of the flow curve, $\log\eta$ versus $\log\dot{\gamma}$, is often $\partial\log\eta/\partial\log\dot{\gamma} = -1$ (time-independent yield). Neglecting the yield stress may have serious consequences on interpretation of elasticity.

Yield stress and plug flow are interrelated. The viscous loss energy is dissipated in a relatively small volume of material, where the concentration of solids differs from average. This may lead to excessive shear heating (effects as large as $\Delta T \geq 80\,°C$ have been observed), degradation of polymeric matrix, strong change of skin morphology during polymer blends extrusion, as well as to attrition of anisometric particles, fibers, or flakes. Thus, the skin layer may not only have different concentration, but different chemical and physical composition as well. At high flow rates, this situation may lead to slip at the wall.

In capillary flow, slip velocity at the wall, s, can be calculated from (Reiner 1930, 1931)

$$
\begin{aligned}
&\dot{\gamma} = \dot{\gamma}_N(3 + 1/n) - (s/R)(n^* + 3) \\
&n \equiv \partial\ln\sigma_{12}/\partial\ln\dot{\gamma} \\
&n^* \equiv \partial\ln s/\partial\ln\sigma_{12} \\
&s = s_o(\sigma_{12} - \sigma_y)^{s_1}
\end{aligned}
\tag{7.46}
$$

where the first expression on the rhs of Eq. 7.46 is the well-known Rabinowitsch correction and the second expression represents the contribution of the slip. Here s is the slip velocity, R is the radius of the capillary, and s_i are parameters. Experimentally, it was observed that the slip velocity depends on the difference between shear stresses, $\sigma_{12} - \sigma_y$. Exponent values as large as $s_1 = 6.3$ were determined for rigid PVC. Slip may occur in any large strain flow, in capillary, cone-and-plate, or parallel plate flow (Kalyon et al. 1993, 1998).

Further consequences of the yield stress (i.e., plug flow) are (i) a drastic reduction of the extrudate swell, $B \equiv d/d_o$ (d is diameter of the extrudate, d_o that of the die) (see, e.g., Crowson and Folkes 1980; Utracki et al. 1984), and (ii) significant increase of the entrance–exit pressure drop, P_e (also known as Bagley correction). For single-phase fluids, these parameters have been related to elasticity by molecular mechanisms (Tanner 1970; Cogswell 1972; Laun and Schuch 1989). However, in multiphase systems, both B and P_e depend primarily on the

inter-domain interactions and morphology, not on deformation of the macromolec-
ular coils. Thus, in multiphase systems (i.e., blends, filled systems, or composites),
only direct measures of elasticity, such as that of N_1, N_2, or G' should be used. It is
customary to plot the measure of the elastic component versus that of the shear
components, viz., N_1 versus σ_{12}, or G' versus G'', etc. For rheologically simple
systems, the relationships are independent of temperature, but for the multiphase
systems the viscoelastic time–temperature principle does not hold.

A viscoelastic–plastic model for suspensions of small particles in polymer melts
was proposed (Sobhanie et al. 1997). The basic assumption is that the total stress is
divided into that in the matrix and the network of immersed interacting particles.
The model leads to nonlinear viscoelastic relations with the yield function, which is
defined in terms of structure rupture and restoration.

Many parameters like the size, size distribution, and shape of the particles along
with the particle–particle and particle–fluid interactions, viscoelastic properties of
the suspending fluid, and the flow geometry complicate the modeling of suspension
behavior. Chateau et al. proposed a homogenization approach to estimate the
behavior of suspensions of noncolloidal particles in an incompressible yield stress
fluids (Chateau et al. 2008). The study involve treats the non-Newtonian suspension
as a continuous medium based on the properties of its constituents. The problem is
simplified by using the secant method of Castañeda (1991) and Suquet (1993).
According to Chateau et al., where Herschel–Bulkey law is valid, the yield stress
($\tau_c{}^{hom}$) of the suspension may be estimated as the product of the suspending fluid
yield stress (τ_c) and a function of solid volume fraction, φ: ($\tau_c{}^{hom}/\tau_c = ((1 - \varphi)$
$g(\varphi))^{1/2}$). Using the Krieger–Dougherty law (Krieger and Dougherty 1959) to
determine the ratio of the macroscopic to the microscopic properties ($g(\varphi)$), it
was found that the experimental results are in a good agreement with the simple
law $\tau_c{}^{hom}/\tau_c = (1 - \varphi)^{1/2}(1 - \varphi/\varphi_m)^{-1.25\varphi m}$ (Chateau et al. 2008). This means that
as long as the noncolloidal particles are spherical, only the close packing density,
yield stress, and power law index of the suspending medium are necessary to
identify the macroscopic properties of these suspensions (Chateau et al. 2008).

Extensional Flows

The yield stress is also observed in extensional flows (Kamal et al. 1984a, b; Utracki
1988). Yield stress is manifested in two related ways: (i) as a vertical displacement
in the stress growth function at decreasing strain rates, contrasting with the normal
linear viscoelastic behavior of single-phase polymeric melts, and (ii) as a deviation
from the relation $\lim_{\dot{\varepsilon}\to0} \eta_E(\dot{\varepsilon}) = 3\eta_0$.

In qualitative agreement with the von Mises criterion, $\sigma_{11,y}/\sigma_{12,y} = 1.3 - 2.0$
was reported (Utracki 1984). The Trouton ratio

$$R_T \equiv \lim_{\dot{\varepsilon}\to0} \eta_E(\dot{\varepsilon})/3\eta_0 \qquad (7.47)$$

was found to decrease by half, as the concentration of glass beads in SAN increased
($\phi \leq 0.37$) (Martischius 1982). It was argued that in extensional flow only the liquid

undergoes deformation; thus both the extensional strains and viscosities should be corrected for the "diluting" effect of the filler volume (Nicodemo et al. 1975).

The relative extensional viscosity of suspensions in a power-law liquid can be expressed as (Goddard 1978)

$$\eta_{E,r} \equiv \eta_E(\phi,\dot{\varepsilon})/\eta_E(0\dot{\varepsilon}) = 1 + 2\phi R_T p^{n+1} \left\{ (1/n - 1)\left[1 - (\pi/\phi)^{(1-1/n)/2}\right] \right\}^{n/(2+n)}$$

(7.48)

Equation 7.48 described the extensional viscosity behavior of a PE/mica system well, after subtracting the yield stress using Casson's equation (Utracki and Lara 1984).

7.3.2 Emulsion Rheology

Liquid-in-liquid systems can be divided into three categories: those in which both liquids are Newtonian, those in which both phases are viscoelastic, and those systems comprising one Newtonian and one viscoelastic liquid. The first of these categories refers to emulsions (E), the second to polymer blends (B), and the third class is used as models (M) to gain some insight into the effects of elasticity on the flow and morphology. Some polymer blends may also be classified as M. Several reviews are available on emulsion rheology (Sherman 1963, 1968; Barry 1977; Nielsen 1977; Utracki 1988, 1989; Pal 1996) and on emulsions containing high volume fraction of the dispersed phase, $\phi > 0.74$ (Cameron and Sherrington 1996).

7.3.2.1 Newtonian Flow

Einstein's treatment of suspensions was extended to emulsions by Taylor (1932, 1934) who derived the following expression for the relative viscosity of emulsions:

$$\eta_r = 1 + (5/2)\sigma[\lambda + 2/5]/[\lambda + 1]$$
$$\therefore [\eta]_e = (5/2)\sigma[\lambda + 2/5]/[\lambda + 1]$$
$$\text{where} \quad \lambda \equiv \eta_d/\eta_\mu$$

(7.49)

Oldroyd (1953, 1955) modified this theory by incorporating effects of the interface:

$$[\eta]_e = (5/2)[\Lambda + 2/5]/[\Lambda + 1]$$
$$\text{where} \quad \Lambda \equiv (\eta_d + \eta_i/5d)/\eta_m$$
$$\text{and} \quad \eta_i = 2\eta_{Si} + 3\eta_{Ei}$$

(7.50)

In Eq. 7.50 the interfacial viscosity, η_i, is expressed in terms of the interfacial shear (subscript Si) and extensional (subscript Ei) components. The plot of emulsion viscosity as a function of the dimensionless viscosity ratio, Λ, is shown in Fig. 7.11.

Fig. 7.11 Intrinsic viscosity of emulsion versus the viscosity ratio (defined in the Figure) (Oldroyd 1953, 1955)
Note that the upper bound of the emulsion intrinsic viscosity is Einstein's value for hard-sphere suspension $[\eta] = 2.5$. This limit is observed for $\Lambda > 100$. For $\Lambda = 1$ (solutions), $[\eta] = 1.75$. The lower values are expected for emulsions of low viscosity liquids in highly viscous one – for $\Lambda < 0.01$, $[\eta] \approx 1$. Equation 7.50 was found valid in a wide range of $1.3 < \Lambda < \infty$.

Oldroyd (1953, 1955), Choi and Schowalter (1975), Oosterbroek et al. (1980, 1981), and many others considered the interphase between the dispersed phase and the matrix liquid to be a physical, three-dimensional entity endowed with its own specific rheological properties. These considerations led to calculations of two relaxation's times for Newtonian emulsions (Choi and Schowalter 1975)

$$\eta_r = 1 + \phi[(5\lambda + 2)/(2\lambda + 2)] + (5/8)[\phi(5\lambda + 2)/(\lambda + 1)]^2$$
$$\tau_1 = \tau_0[1 + 5\phi\{(19\lambda + 16)/[4(\lambda + 1)(2\lambda + 3)]\}]$$
$$\tau_2 = \tau_0[1 + 3\phi\{(19\lambda + 16)/[4(\lambda + 1)(2\lambda + 3)]\}]$$
$$\tau_0 = (\eta_2 R/\nu_{12})\{(19\lambda + 16)(2\lambda + 3)/[40(\lambda + 1)]\}$$

$$(7.51)$$

For the relative viscosity of emulsions, in the absence of deformation and coalescence, Eqs. 7.24, 7.25, 7.26, 7.27, 7.28, 7.29, and 7.30 may also be used, provided that the intrinsic viscosity is calculated from Eq. 7.50 and that the maximum packing volume fraction is treated as an adjustable parameter, dependent on the interphase. This pragmatic approach has been successfully used to describe $[\eta]$ versus ϕ variation for such complex systems as industrial lattices (at various stages of conversion), plastisols, and organosols.

Industrial emulsions are usually prepared as concentrated systems, containing $\phi_m \leq 0.94$. Owing to interface interactions and deformability of droplets, these systems behave rather like elastic, soft solids without any sign of Newtonian behavior. Between the highly concentrated and dilute regions, there is a wide zone of structural change reflected in a spectrum of non-Newtonian behavior.
Fig. 7.12 Deformation of drops in shear (**a**) and extensional (**b**) flow field (Taylor 1932, 1934)

7.3.2.2 Emulsion Microrheology
Drop Deformability

When a neutrally buoyant, initially spherical droplet is suspended in another liquid and subjected to shear or extensional stress, it deforms and then breaks up into smaller droplets. Taylor (1932, 1934) extended the work of Einstein (1906, 1911) on dilute suspensions of solid spheres in a Newtonian liquid to dispersions of single Newtonian liquid droplet in another Newtonian liquid, subjected to a well-defined deformational field. Taylor noted that, at low deformation rates in both uniform shear and planar hyperbolic fields, the sphere deforms into a spheroid (Fig. 7.12).

At low stress in steady uniform shearing flow, the deformation can be described by three dimensionless parameters: the viscosity ratio, the capillary number, and the reduced time:

$$\lambda \equiv \eta_1/\eta_2; \quad \kappa \equiv \sigma_{ij} d/v_{12} \quad \text{and} \quad t^* = \gamma/\kappa \tag{7.52}$$

where η_1 and η_2 are the viscosities of the dispersed and the matrix phases, respectively, σ_{ij} is the stress (either in shear $ij = 12$ or in extension $ij = 11$), d is the initial drop diameter, v_{12} is the interfacial tension coefficient between two phases, and γ is the generated strain.

During shear or uniaxial extensional flow, the initially spherical drop deforms into a prolate ellipsoid with the long axis, a_1, and two orthogonal short axes, a_2. It is convenient to define the drop deformability parameter, D, as

$$
\begin{aligned}
D &\equiv (a_1 - a_2)/(a_1 + a_2) \\
&= \left\{ \left[1 + \gamma^2/2 + (\gamma/2)(4 + \gamma^2)^{1/2} \right]^{3/4} - 1 \right\} \Big/ \left\{ \left[1 + \gamma^2/2 + (\gamma/2)(4 + \gamma^2)^{1/2} \right]^{3/4} + 1 \right\} \\
&= [\exp\{3\varepsilon/2\} - 1]/[\exp\{3\varepsilon/2\} + 1]
\end{aligned}
\tag{7.53}
$$

where γ and ε are shear and uniaxial extensional strains, respectively.

According to Taylor, the equilibrium deformability of drops is a complex function, which has simple solutions at two limits. On the one hand, at low stresses, when the interfacial tension effects dominate the viscous ones (low value *of* λ), the deformability D and the orientation angle α (see Fig. 7.12) of the droplet can be expressed as

$$D = (\kappa/2)[(19\lambda + 16)/(16\lambda + 16)] \quad \text{and} \quad \alpha = \pi/4 \qquad (7.54a)$$

Since, for $\lambda = 0$ to ∞, the quantity in the square bracket ranges from 1.00 to 1.18, the drop deformability $D \cong 0.55\kappa$. Thus, a small deformation of Newtonian drops in Newtonian matrix varies linearly with the capillary number. This proportionality was indeed demonstrated in Couette-type rheometer for a series of corn syrup/silicon oil emulsions (Elemans 1989).

On the other hand, when the interfacial tension is negligibly small in comparison to viscosity (high value of λ):

$$D = (\kappa/2)[(19\lambda + 16)/(16\lambda + 16)] \quad \text{and} \quad \alpha = \pi/4 \qquad (7.54b)$$

Taylor predicted that droplet breakup will occur at $D \geq D_{crit} = 0.5$.

Cox (1969) extended Taylor's theory to systems with the full range of viscosity ratios:

$$\begin{aligned} &D = (\kappa/2)[(19\lambda + 16)/(16\lambda + 16)]/\left[(19\lambda\kappa/40)^2 + 1\right]^{1/2} \\ &\alpha = (\pi/4) + (1/2)\arctan\{19\lambda\kappa/20\} \end{aligned} \qquad (7.55)$$

The above relations are valid for Newtonian systems undergoing small, linear deformation, smaller than that, which would lead to breakup. Furthermore, experimental data indicate that it takes time to reach the equilibrium deformation. It is convenient to use the reduced time scale (see Eq. 7.52), $t_d^* \cong 25$ is required to reach the equilibrium deformation (Elemans 1989).

Taylor's theory makes it also possible to predict the retraction of slightly deformed drops toward an equilibrium spherical form:

$$\begin{aligned} D(t) &= D_o\exp\{-[80(\lambda + 1)/(2\lambda + 3)(19\lambda + 16)](tv_{12}/\eta_2 d)\} \\ &= D_o\exp\{-t/\tau_{ret}\} \\ \text{where}: \quad &\tau_{ret} = \eta_{eq}d/v_{12}; \quad \eta_{eq} = \eta_2[(2\lambda + 3)(19\lambda + 16)/80(\lambda + 1)] \end{aligned} \qquad (7.56)$$

where t is the retraction time and the relaxation time, τ_{ret}, is expressed as a ratio of the equivalent viscosity, η_{eq}, divided by the interfacial tension coefficient scaled by drop diameter. Thus, knowing the time evolution of D and the viscosity of the

Drop Deformation in Shear Field
Fig. 7.13 Drop deformability versus shear rate (Silberberg and Kuhn 1954)

materials, one can calculate the interfacial tension coefficient. In principle, Eq. 7.56 is valid for Newtonian systems, but the method can also be used to characterize viscoelastic materials, provided that the following two conditions are valid: (1) the retraction rate is sufficiently slow to ensure that materials behave as Newtonian, and (2) the elastic relaxation of the materials after deformation is faster than the ellipsoidal droplet retraction, i.e., a clear separation of the two mechanisms is possible (Luciani et al. 1996).

The deformability of drops in a three-component Newtonian system (comprising 1.1 % PS and 1.7 % ethyl cellulose dissolved in benzene) was studied by Silberberg and Kuhn (1952, 1954). The authors reported that as the rate of shear increased, the spherical drops changed shape into prolate ellipsoids, with the long axis, a_1, and two orthogonal short semiaxes, a_2. The data are presented in Fig. 7.13. The observed maximum on the a_1 curve may be associated with the rheological effect on solubility.

Owing to elasticity of the interphase, the first normal stress difference and the relaxation time can be calculated as (Schowalter et al. 1968)

$$N_1 = \phi(\sigma_{12}d\kappa)^2/40v_{12}$$
$$\text{and} \quad \tau^* = \eta dD\kappa(2\lambda + 3)/40v_{12} \tag{7.57}$$

It is convenient to express the capillary number in its reduced form $\kappa^* \equiv \kappa/\kappa_{cr}$, where the critical capillary number, κ_{cr}, is defined as the minimum capillary number sufficient to cause breakup of the deformed drop. Many experimental studies have been carried out to establish dependency of κ_{cr} on λ. For simple

Table 7.6 Parameters of the critical capillary number for drop burst in shear and extension in Newtonian systems (R. A. de Bruijn 1989)

Flow	$1000c_1$	$1000c_2$	$1000c_3$	$1000c_4$	$1000c_5$
Shear	−506.0	−99.4	124.0	−115.0	−611.0
Elongational	−648.5	−24.42	22.21	−0.56	−6.45

shear and uniaxial extensional flow, De Bruijn (1989) found that droplets break most easily when $0.1 < \lambda < 1$, but do not break for $\lambda > 4$:

$$\log(\kappa_{cr}/2) = c_1 + c_2\log\lambda + c_3(\log\lambda)^2 + c_4(\log\lambda + c_5) \qquad (7.58)$$

Parameters of Eq. 7.58 are listed in Table 7.6 (see also Fig. 7.45).

Note that in shear for $\lambda = 1$, the critical capillary number $\kappa_{cr} = 1$, whereas for $\lambda > 1$, κ_{cr} increases with λ and becomes infinite for $\lambda > 3.8$. This means that breakup of the dispersed phase in pure shear flow becomes impossible for $\lambda > 3.8$. This limitation does not exist in extensional flows.

The deformation of dispersed drops in immiscible polymer blends with viscosity ratio $\lambda = 0.005$–13 during extensional flow was studied by Delaby et al. (1994, 1995). The time-dependent drop deformation during start-up flow at constant deformation rate was derived. The model is restricted to small drop deformations.

Milliken and Leal (1991) used a computer-controlled four-roll mill to investigate the deformation of polymeric drops in an imiscible Newtonian fluid in planar extensional flow. They showed that deformation curves differ, based on the viscosity ratio. Steady drop shapes were observed only for emulsions with viscosity ratio higher than one. However, for the low-viscosity polymeric dispersed phase, the deformation of drops does not follow that of Newtonian fluids anymore, and the critical capillary number was significantly smaller. For both cases, the transient deformation and breakup of polymeric drops were found to be different from Newtonian drops (Milliken and Leal 1991). Other geometries, such as Couette, torsional parallel plate, torsional cone and plate, and rectilinear parallel plate, have been used extensively (Fischer and Erni 2007). Comparison between these experimental results and numerical data regarding the deformation behavior arising from shear or elongational flow of emulsions verifies the consistency of the Volume of Fluid (VoF) method (Renardy et al. 2002) and the Boundary Integral Method (BIM) (Feigl et al. 2003) for the simulation of concentrated emulsion flow.

Drop Breakup

With regard to drop deformation and breakup, there are four regions of reduced capillary numbers, κ^*, both in shear and elongation:

For $-0.1 > \kappa^*$-droplets do not deform.

For $-0.1 < (\kappa^*) < 1$-droplets deform, but they do not break.

For $-1 < \kappa^* < 2$-droplets deform then split into two primary droplets.

For $-\kappa^* > 2$-droplets deform into stable filaments.
Fig. 7.14 Effect of the viscosity ratio on the critical time to break (Huneault et al. 1994)

As for κ_{cr}, Fig. 7.14 shows that the critical time for drop breakup t_b^* varies with λ.

When values of the capillary number and the reduced time are within the region of drop breakup, the mechanism of breakup depends on the viscosity ratio, λ.

In shear, four regions have been identified (Goldsmith and Mason 1967):

For $-0.1 >> \lambda$-small droplets are shed from sigmoidal drops – *tip spinning*.

For $-0.1 < \lambda < 1$-drop breaks into two principal and odd number of satellite droplets.

For $-1 < \lambda < 3.8$-drop deforms into fiber, which then disintegrates into small droplets.

For $-\lambda > 3.8$-drops may deform, but they do not break.

Critical capillary numbers for elongational flows are lower than for shear flows. In other words, the elongational flow field is much more effective for droplet breakup in a dispersive mixing regime (Grace 1982).

Drop Fibrillation and Breakup

In addition to the previously discussed drop breakup into two principal drops (and an odd number of small satellite droplets), there is another mechanism for dispersing one liquid in another. This is based on the "capillarity instability principle" of long cylindrical bodies. For $\kappa^* > 2$, drops deform affinely with the matrix into long fibers. When subsequently the deforming stress decreases, causing the reduced capillary number to fall below two, $\kappa^* < 2$, the fibers disintegrate under the influence of the interfacial tension. The problem was theoretically treated by Rayleigh (1879), Taylor (1932, 1934), and Tomotika (1935, 1936). The latter author showed that the degree of instability can be described by the growth rate parameter of a sinusoidal distortion:

$$q = v_{12}\Omega(\Lambda,\lambda)/2\eta_m R_0 \tag{7.59}$$

where Λ is the distortion wavelength, $\Omega(\Lambda, \lambda)$ is a function tabulated by Tomotika, and R_o is the initial fiber radius. The hydrodynamic instability is characterized by a maximum for the dominant wavelength Λ_m that leads to thread breakup. For $0.01 \leq \lambda \leq 10$:

$$\Omega(\Lambda_m, \lambda) = \exp\left\{ \sum_{i=0}^{4} b_i (\log \lambda)^i \right\} \tag{7.60}$$

where $b_0 = -2.588$, $b_1 = -1.154$, $b_2 = 0.03987$, $b_3 = 0.0889$, and $b_4 = 0.01154$. The distortion amplitude α grows exponentially with time, t:

$$\alpha = \alpha_0 \exp\{qt\} \tag{7.61}$$

where α_0 is the distortion at t = 0. Assuming that the initial distortion is due only to thermal fluctuations, Kuhn (1953) estimated that

$$\alpha_0 = (21k_B T)\left(8\pi^{3/2} v_{12}\right)^{-1/2} \tag{7.62}$$

where k_B is Boltzmann constant and T is the absolute temperature. The thread breakup occurs when $\alpha = R \cong 0.81 R_o$. The time required to reach this stage can be expressed as

$$t_b^* \equiv t_b \dot{\gamma}/\kappa = 2[\ln(0.81 R_0/\alpha_0)]/\Omega(\Lambda_m, \lambda) \tag{7.63}$$

Thus, t_b^* is an important parameter describing the breakup process for fibers subjected to lower stresses than those required for fibrillation, i.e., $\kappa^* < 2$. The above indicates that breakup is less likely at low interfacial tension. Since the matrix viscosity appears in the left side of the equation (in the capillary number), one may expect shorter breakup times with lower matrix viscosity, but it is noteworthy that this term also changes the Tomotika function on the right side of the equation. Figure 7.15 shows the distortion growth rate at the dominant wavelength as a function of viscosity ratio. To obtain a low value of $\Omega(l, \lambda)$, thread viscosity should be high and the matrix viscosity has to be low (Potschke and Paul 2003).

In practice, one of the most serious obstacles for quantitative use of Timotika's theory is estimation of the initial distortion, α_0.

The time corresponding to the complete breakup, t_b, was measured (Grace 1982; Elemans 1989). The data are presented in Fig. 7.14. Numerically they can be expressed as

$$t_b^* \cong 84 \lambda^{0.355} \kappa^{*-0.559} \tag{7.64}$$
Fig. 7.15 Distortion growth rate at dominant wavelength and dominant wave length versus λ (Potschke and Paul 2003)

Coalescence

During mixing, the dispersed phase progressively breaks down until a minimum drop diameter is reached. As the drop diameter decreases, further breakup becomes increasingly difficult. For emulsions, the size of the smallest drop that can be broken can be calculated from Taylor's theory, but experiments have shown that, in most cases, the equilibrium droplet size is larger than predicted. Furthermore, the deviation increases with concentration of the dispersed phase, $\phi_d - \phi_o$, where experimentally the smallest value for which the deviation occurs, $\phi_o \approx 0.005$ (Utracki and Shi 1992).

The fusion of the two or more droplets due to the local thinning and disruption of the matrix is called coalescence. Complete phase separation is expected as the limiting case of coalescence. Two types of coalescence must be recognized: the first is determined by equilibrium thermodynamics (e.g., liquid–liquid miscibility, interfacial tension coefficient, rheological conditions of the interphase, etc.); the second is determined by dynamics, and it is dominated by rheology and flow conditions. In the following text, only the second type will be discussed.

Utracki (1973) studied steady-state shear coagulation of PVC lattices for a wide range of variables. Assuming that the locus of coagulation is at the particle–matrix interface and that the rate of coagulation depends on the frequency of particle collisions, the critical time for coalescence was calculated as

$$
\begin{aligned}
t_c &= a_0 E^+ d^3 / \left[\rho_d \left(1 + N^+ + N^0 \right) \phi_d^{8/3} \dot{\gamma}^2 \right] \\
\text{or} \quad t_c &= 2.940 E^+ (\phi_m - \phi_d) / \left[\eta_m (V_x/V) \phi_d^{8/3} \dot{\gamma}^2 \right]
\end{aligned}
\tag{7.65}
$$

where a_o is a numerical parameter; E^+ is the threshold energy of coagulation; N^o and N^+ are the number of coagulating drops, respectively, initially and at $t = t_o$; V_x/V is the volume fraction of emulsion undergoing uniform shearing; and ρ_d is the drop density. Validity of these relations was confirmed on many lattices. In particular, $t_c \propto \dot{\gamma}^{-2}$ and $dt_c/d\phi_d < 0$ (thus, coagulation rate increases with ϕ_d) were experimentally confirmed. Since the coagulation was assumed to be related to the projected area of the drop, $d \propto \phi_d^{2/3}$ was implicitly assumed.

Fortelny et al. (1988, 1990) assumed that Brownian motion is the principal driving force for coalescence in polymer blends. Applying Smoluchowski's theory, the authors obtained:

$$S = S_0 \left\{ 1 + (2/3\pi)[k_B T/(\eta_m \phi_d)]^{1/2} S_0^{3/2} t^{1/2} \right\}^{-2/3} \tag{7.66}$$
