where S_o and S are the interface areas in the unit volume of the blend having monodisperse spherical particles, respectively, before and after coalescence. The experimental data confirmed the linearity of $(S/S_o)^{-3/2}$ as a function of $t^{1/2}$. However, it is to be noted that Brownian motion affects particles that usually are below the size of dispersions in polymer blends. Furthermore, coalescence should be independent of the stress field intensity and magnitude of the interfacial energy. The efficiency of particle collisions due to Brownian motion leading to coalescence should also be taken into account.

Coagulation is a result of collision between two spherical drops of diameter, d, that approach each other with certain velocity gradient to a distance smaller than their radius. Coalescence can occur only if the liquid remaining between two flattened drops will be removed sooner than the global velocity field will force the drops to separate. The instabilities in the layer of the entrapped film will break it when the separation between drops is smaller than the critical separation distance, $h_c \cong 5$ nm, the critical coalescence time for systems with mobile interface is expected to follow the relation: $t_c = 3\kappa[\ln(d/4h_c)]/4\dot{\gamma}^2$ (Elmendorp 1986; Chesters 1991a). The relation was derived for isolated pairs of drops, and as such it does not take into account the concentration effect. It predicts that, in shear, the coalescence of two isolated drops is proportional to the exerted stress and it is easier for larger spheres with high surface energy. It was observed that $t_c \propto \dot{\gamma}^{-2}$, in agreement with Eq. 7.65. Experimentally, coalescence probability was found to rapidly decrease with increasing κ and d.

7.3.2.3 Non-Newtonian Flows

Only dilute emulsions or systems undergoing slow deformation show Newtonian, deformation rate-independent flow. As the concentration and deformation rate increases, the flow progressively changes into pseudoplastic. Since the rheological response is a reflection of the inner structure of the material, modifications of the emulsion morphology accompany such a change.

Morphology

Even in the dilute region, individual emulsion droplets rarely exist. In most cases, droplets are polydisperse in size, forming doublets, chain structures, or aggregates. Two types of emulsion morphology can be distinguished: (A) formed by the shear field (e.g., skin-core structures developed during flows through long tubes) and (B) formed by particle–particle interaction. Knowledge of type A structures is important for proper interpretation of the flow phenomena. Their formation is influenced by the differences in the flow behavior of the components, as well as by shear coagulation. Knowledge of type B structures is important for the utilization of suspension rheology in processing. Since the effective volume fraction of dispersed particles increases with increase of association, the relative viscosity of emulsion is strongly influenced by these variables.

By contrast with polymer blends, emulsions are prepared by carefully designing the interface system and by sequential addition of ingredients. Both elements are essential when 96 vol% of one liquid must be dispersed in 4 vol% of another. If, due to interactions of emulsifiers, the continuous phase becomes viscoelastic, the emulsion has high consistency or a *body*. There is gradual passage of structures, from rotating doublets in dilute systems to entrapment of the dispersed phase in a continuous network of interacting interfaces. Consequently, emulsions can show a Newtonian as well as a complex thixotropic and viscoelastic character (Nielsen 1977).

Theoretical Treatment

The theoretical treatment of two-phase flow was reviewed by Cox and Mason (1971), Leal (1980), and Barthès-Biesel (1988). As indicated before, dispersions of one Newtonian liquid in another result in systems that are characterized by elasticity and relaxation times, e.g., Eq. 7.57.

For dilute emulsions, with neither hydrodynamic interactions nor interfacial effects, Fröhlich and Sack (1946) developed the following time-dependent constitutive equation:

$$
\begin{aligned}
&[1 + \tau_1(d/dt)]\tau = 2\eta[1 + \tau_2(d/dt)]d \\
&\text{where} \quad \eta = \eta_m\big[1 + (5\phi/2) + 0\big(\phi^2\big)\big], \\
&\qquad \tau_1 = [3\eta_m/2G](1 + 5\phi/3), \\
&\qquad \tau_2 = [3\eta_m/2G](1 - 5\phi/2)
\end{aligned}
\tag{7.67}
$$

where G is the Hookean modulus of the elastic, dispersed spheres, while λ_i is the relaxation time of the emulsion. Thus, the theory considered viscoelasticity of dilute emulsions to originate in elastic deformability of the dispersed phase.

Nearly a decade later, Oldroyd (1953, 1955) proposed a constitutive model similar to that of Fröhlich and Sack, valid at small deformations. The model considered low concentration of monodisperse drops of one Newtonian liquid in another. The interfacial tension and the viscoelastic properties of the interfacial film

were incorporated by means of convected derivatives. The model provided the following relation for the complex modulus:

$$G^* = G_m^*[1 + 3\phi H]/[1 - 2\phi H]$$

$$H = \frac{(4/R')\left(2G_m^* + 5G_d^*\right) + \left(G_d^* - G_m^*\right)\left(16G_m^* + 19G_d^*\right)}{(40/R')\left(G_m^* + G_d^*\right) + \left(2G_d^* + 3G_m^*\right)\left(16G_m^* + 19G_d^*\right)} \quad (7.68)$$

$$G_i^* = G_i^*(\omega); \quad R' = R/v_{12}; \quad \text{thus:} \quad H = H(\omega; R')$$

where v_{12} the interfacial tension coefficient, R is the drop radius, $G_i^*(\omega)$ is the complex modulus, and subscripts i = m, d indicate matrix or disperse phase, respectively.

Oldroy's model was extended by Palierne (1990) to emulsions with polydisperse spherical drops. The model considered viscoelastic liquids, the concentration range was extended up to that at which drop–drop interactions start complicating the flow field. However, the drops must be spherical, undergoing small deformation, and the interfacial tension coefficient was considered constant, independent of stress and the interfacial area. The following relation was derived for the complex modulus:

$$G^* = G_m^*\left[1 + 3\sum_{i=1}^{n}\phi_i H_i\right]/\left[1 - 2\sum_{i=1}^{n}\phi_i H_i\right]$$

$$H_i = \frac{(4/R_i')\left(2G_m^* + 5G_d^*\right) + \left(G_d^* - G_m^*\right)\left(16G_m^* + 19G_d^*\right)}{(40/R_i')\left(G_m^* + G_d^*\right) + \left(2G_d^* + 3G_m^*\right)\left(16G_m^* + 19G_d^*\right)} \quad (7.69)$$

$$G_i^* = G_i^*(\omega); \quad R_i' = R_i/v_{12}; \quad \text{thus:} \quad H_i = H_i(\omega; R')$$

Here ϕ_i and R_i are, respectively, the volume fraction and the drop radius. The main feature of this model is the inclusion of a contribution from the interfacial tension to the viscoelastic properties and the inclusion of the effect of particle size polydispersity. For example, knowing $G_i^*(\omega)$ of the two main components of the blend, one can predict the dynamic moduli of the emulsion (as well as dilute polymer blends) from the knowledge of the interfacial tension coefficient and distribution of drop sizes. This model has been used extensively to determine the interfacial tension or droplet size of emulsions (Guschl and Otaigbe 2003; Mekhilef et al. 2000; Xing et al. 2000; Yoo et al. 2010). It has been shown that the volume average droplet radius could be employed instead of R_i, as long as the ratio of volume to number average radius of an emulsion is less than two (Graebling et al. 1993a). The theory is applicable to low strains and to the concentration range where yield stress is absent (Graebling and Muller 1990, 1991; Graebling et al. 1993b).

Low-viscosity mixtures of PDMS and PI, with $\lambda = 0.155$, 0.825, and 4.02 were studied at room temperature (Kitade et al. 1997). The dynamic data were analyzed using Eq. 7.69. Good agreement was found. However, for the $\lambda = 4.02$ system, the drops were insensitive to the flow field. They neither broke nor coalesced. Similar observations were reported for PDMS/PIB system (Vinckier et al. 1996). The latter

authors also observed that agreement with Palierne's model becomes weaker for blends pre-sheared at higher shear rate, i.e., blends with finer drop dispersion.

Palierne emulsion model failed to describe the dynamic modulus of the PP/EPDM blends after radiation, because the viscosity ratio increased significantly and the rubber phase changed from deformed droplets to hard domains after radiation (Cao et al. 2007). Interconnections among inclusions of the dispersed phase (Shi et al. 2006) and the existence of multiple emulsion (emulsion-in-emulsion) structure exhibiting different relaxation domains in compatibilized systems are other factors contributing to the failure of Palierne's model (Friedrich and Antonov 2007; Pal 2007).

Honerkamp and Weese (1990) reported on the use of Tikhonov's regularization for the determination of material functions. This method of data treatment was found particularly useful for the computation of the relaxation and retardation spectra (Elster et al. 1991; Honerkamp and Weese 1993). It has also been used to compute the sphere-size distribution of the dispersed phase in binary blends (Gleisner et al. 1994a), as well as the ratio of the dispersed drop diameter divided by the interfacial tension coefficient, d/ν_{12} (Gleisner et al. 1994b).

Friedrich et al. (1995) modified Palierne's Eq. 7.69 by a continuous function:

$$G^*(\omega) = G_M^*(\omega) \left[1 + 3 \int_{-\infty}^{\infty} H(\omega, R') u(R') R' d\ln R' \right] \Big/ \left[1 - 2 \int_{-\infty}^{\infty} H(\omega, R') u(R') R' d\ln R' \right]$$
(7.70)

where $R' = R/\nu_{12}$ and $u(R') = \nu_{12}v(R)$ is the scaled, volume-weighted distribution of sphere sizes. Using Tikhonov's regularization method, the distribution function, $u(R')$, could be computed. The experimental data (storage and loss shear moduli, G' and G'', respectively, within six decades of frequency and transmission electron microscopy, TEM) were determined for 2, 5, 10, and 20 wt% PS in the PMMA matrix. From the dynamic viscoelastic data of the neat components and the blends, the monomodal distribution of the distribution function $u(R')$ versus log $R' = \log (R/\nu_{12})$ was computed and compared with data obtained from TEM. Excellent agreement was found for blends containing 2 and 5 wt%, fair for 10 wt%, and poor for 20 wt% PS. In the latter case, TEM showed a bimodal distribution (possibly resulting from coalescence), whereas a monomodal distribution was obtained from the rheological data. The interfacial tension coefficient computed from these results varied from $\nu_{12} = 2.08$ to 3.10 mN/m. The average value, $\nu_{12} = 2.5$ mN/m at 190 °C, is comparable to the literature data $\nu_{12} = 0.8$ to 1.8 mN/m at 200 °C (Luciani et al. 1996).

For infinitely dilute viscoelastic emulsions, the shear dependence of inherent viscosity was derived as (Barthès-Biesel and Acrivos 1973)

$$\eta_{inh} \equiv (\eta_{rel} - 1)/\phi = [(5/2)\lambda + 1]/[\lambda + 1] - f(\lambda)(\sigma_{12}/E_{int})^2 + 0(\sigma_{12}^3) \quad (7.71)$$

where $f(\lambda) > 0$ is a rational function of λ. The relation predicts that in dilute emulsions subjected to small deformations, the η_{inh} should decrease with the square

of the shear stress. The effect of stress is moderated by interphase elasticity expressed as E_{int}. The theory was experimentally verified. Note the similarity of the first term on the rhs of Eq. 7.71 to the expression derived by Oldroyd for the intrinsic viscosity of emulsions, Eq. 7.50. Accordingly, Eq. 7.71 may be modified by replacing λ by Λ, as derived by Oldroyd.

Semi-concentrated emulsions were examined theoretically and experimentally only within the linear viscoelastic region (Oosterbroek and Mellema 1981; Oosterbroek et al. 1980, 1981; Eshuis and Mellema 1984). Recognizing that the interphase has a finite thickness (sometimes the total volume of the interphase is comparable to, or even exceeds, the volume of the dispersed phase), the authors postulated that the interphase should have two interfacial coefficients, v' and v'' facing the two principal polymer domains. Then, two models of the interphase were evaluated: (i) a two-dimensional viscoelastic film and (ii) the interphase of finite thickness. Both led to at least two relaxation times:

$$\begin{aligned} \tau_1 &= \left\{ (1 + R/\Delta L)^2 \eta (R + \Delta L)(1/v' + 1/v'') \right\} \\ \tau_2 &= \left\{ \eta(R + \Delta L)/(v' + v'') \right\}; \text{where } v_{12} = v' + v'' \end{aligned} \tag{7.72}$$

The experimental data employing dynamic testing in the kHz region for ionic emulsions was equally well described using either model. The emulsion elasticity was found to originate in droplet deformation. For nonionic emulsions, only one relaxation time was observed. The data were interpreted in terms of the second Oldroyd's model in which the interfacial tension is more important than the viscoelasticity of the interphase. The steady-state viscosities of both ionic and nonionic systems at the volume fraction $\phi \leq 0.2$ were found to follow Simha's Eq. 7.24.

For concentrated emulsions and foams, Princen (1983, 1985) proposed a stress–strain theory based on a two-dimensional cell model. Consider steady-state shearing of such a system. Initially, at small strains, the stress increases linearly as in an elastic body. As the strain increases, the stress reaches the yield value, then at still higher deformation, it catastrophically drops to negative values. The reason for the latter behavior is the creation of unstable cell structure that generates a recoil mechanism. The predicted dependencies for modulus and the yield stress were expressed as

$$\begin{aligned} G &\equiv \sigma/\gamma \quad \propto \quad v_{12}\phi^{1/3}/d \\ \text{and} \quad \sigma_y &\propto G\tilde{F}_{max}(\phi) \end{aligned} \tag{7.73}$$

where the function $\tilde{F}_{max}(\phi)$ is the concentration-dependent, dimensionless contribution to stress per single drop. The theory was evaluated using a concentrated oil-in-water system.

Princen's work was followed by (Reinelt 1993), who considered theoretical aspects of shearing three-dimensional, highly concentrated foams and emulsions. Initially, the structure is an assembly of interlocked tetrakaidecahedra (which have

six square surfaces and eight hexagonal ones). An explicit relation for the stress tensor up to the elastic limit was derived. When the elastic limit is exceeded, the stress–strain dependence is discontinuous, made of a series of increasing parts of the dependence, displaced with a period of $\gamma = 2^{3/2}$.

The validity of Princen's theory for concentrated water-in-oil emulsions was also investigated by Ponton et al. (2001), using the droplet size distribution determined by laser diffractometry based on the Mie theory model. Comparing the surface–volume diameter and the mass fractions of emulsions depicted an increase in the particle size with the volume fraction reduction. They showed that their experimental data (as obtained by oscillatory measurements and droplet-size distribution) corroborated the expression of the elastic shear modulus for the two-dimensional model proposed by Princen and Kiss (1986). In this model, G′ is proportional to $(\sigma/R_{SV})\Phi_v^{1/3}(\Phi_v\text{-}\Phi_c)$ where σ is the interfacial tension, R_{SV} is the volume–surface radius (as obtained by laser diffractometry), and Φ_v and Φ_C are the volume fraction and the critical volume fraction, respectively (Ponton et al. 2001). The latter was found to be 0.714 experimentally, which is close to the value obtained by Princen ($\sim$0.712) (Ponton et al. 2001).

Paruta-Tuarez et al. (2011) analyzed the Princen and Kiss equation (Princen and Kiss 1986) associated with the linear form of the function $E(\Phi_v)$, ($E(\Phi_v) = A(\Phi_v - \Phi_c)$). This function was proposed to take into account the experimental dependence of storage modulus (G′) on the dispersed-phase volume fraction (Φ_v). However, it was found that the Princen and Kiss equation underestimates the storage modulus values in some cases, due to the particular set of experimental data used for derivation of $E(\Phi_v)$. Thus, despite the applicability of the linear form of the function $E(\Phi_v)$ as proposed by Princen and Kiss, it is not universal and another choice of experimental data could lead to other mathematical functions (Paruta-Tuarez et al. 2011).

Experimental Data

Experimentally, there are three concentration regions of emulsion flow: (i) dilute for $\phi < 0.3$, characterized by nearly Newtonian behavior; semi-concentrated at $0.3 < \phi < \phi_m$ with mainly pseudoplastic character; and concentrated at $\phi_m < \phi < 1.0$, showing solid-like properties with modulus and yield.

The necessary condition for non-Newtonian flow to occur is droplet deformation, expressed either by the deformability parameter, $D = (a_1 - a_2)/(a_1 + a_2)$, or by the aspect ratio, $p = a_1/a_2$.

Figure 7.16 illustrates the effect of shear rate, initial drop diameter, and the viscosity ratio on the droplet aspect ratio, p. For low and high values of λ, a pseudoplastic dependence has been observed (Talstoguzov et al. 1974).

The shear viscosity of polymer-thickened oil-in-water emulsions was studied by Pal (1992). Addition of polyethyleneglycol, PEG, made it possible to vary the matrix liquid viscosity. The flow was pseudoplastic, following Ellis dependence:

$$\eta_r = 1/\left[1 + A\eta_o\sigma_{12}^{\alpha-1}\right] \tag{7.74}$$

Fig. 7.16 Effect of the shear
rate (*top*), the initial drop
diameter (*middle*), and the
viscosity ratio (*bottom*)
on the drop aspect
ratio for the systems:
water–gelatin–dextran
(W–G–D, *circles*) and
water–gelatin–polyvinyl
alcohol (W-G-P, *squares*)
(Talstoguzov et al. 1974)

Drop deformability in water-gelatine
systems with either PVAl or dextran
where A and α are equation parameters. The zero-shear viscosity, η_o, was found to follow a modified Mooney dependence (see Eq. 7.28):

$$\ln\eta_r = 2.5K_1\phi/[1 - K_2\phi] \tag{7.75}$$

where K_i are equation parameters. It was observed that η_r of the thickened emulsions is lower than that for the emulsions without PEG.

In liquid–liquid systems, upon increase of concentration of the dispersed phase, at certain concentration suddenly the dispersed and continuous liquids exchange roles. This is known as a *phase inversion*. Salager et al. (1983) and Minana-Perez et al. (1986) reported two types of phase transition in ionic emulsions – in the first, viscosity goes through a minimum, whereas in the second it goes through a maximum. The first type of transition (normal) is associated with a decrease of the interfacial tension coefficient and formation of a microemulsion. The second (catastrophic) transition is associated with an inversion of unstable structure to a stable one.

The extensional viscosity of non-Newtonian emulsions, η_E, at the dispersed phase volume fraction $\phi = 0.3$–0.8, was measured using the opposed nozzles configuration. For more diluted emulsions, $\phi < 0.6$, the elongational viscosity, η_E, was found to decrease with the rate of elongation, $\dot{\varepsilon}$, mimicking the flow curves in a shear field, η versus $\dot{\gamma}$. Furthermore, the Trouton rule, $\eta_E \cong 3\eta$, was found to be reasonably obeyed. However, for more concentrated emulsions, $\phi \geq 0.7$, owing to the presence of yield stress, η_E was found to depend on the test geometry, viz., nozzle diameters and their separation (Anklam et al. 1994). Since in more concentrated emulsions, the structure is engendered by close packing of interacting spheres, its destruction must depend on the type of imposed deformation as well as on strain. In consequence, the lack of correlation between the shear flow and extensional flow data was expected.

Compliance, J, of concentrated oil-in-water emulsions at $0.4 \leq \phi \leq 0.7$ was found to follow a two-retardation time process:

$$J(t) - J_0 + J_1\exp\{-t/\tau_1^*\} + J_2\exp\{-t/\tau_2^*\} \tag{7.76}$$

where J_o and J_i are, respectively, instantaneous compliance and retarded values, all three decreasing with concentration of the dispersed phase (Gladwell et al. 1986).

For a similar system, the shear viscosity was found to follow the power law model with yield (Pal et al. 1986). Owing to the presence of yield stress, the flow of concentrated emulsion was found to be facilitated by superposition of 10 Hz oscillation on the steady-state shear flow – up to 40 % energy saving was reported (Jezequel et al. 1985). More recently, the relative viscosity of emulsions was described in terms of scaling parameters (Pal 1997). Ten principal variables were incorporated into six dimensionless groups: λ, κ, reduced time, $t_r = t/(\eta_m d^3/8\,k_B\,T)$, relative density, $\rho_r = \rho_d/\rho_m$, Peclet number, $Pe = \eta_m\dot{\gamma}d^3/8k_BT$, and Reynolds number, $Re = \rho_m\dot{\gamma}d^2/4\eta_m$. For the steady-state flow of well-stabilized emulsions, it was argued that the relative viscosity of emulsions should depend only on two

parameters: volume fraction of the dispersed phase and Re, i.e., $\eta_r = f(\phi, Re)$. At constant composition, the experimental data for coarse and fine oil-in-water emulsions plotted versus the deformation rate, $\dot{\gamma}$, showed different dependencies (higher η_r for finer dispersion), but when plotted versus Re, a single dependence was found.

The understanding rheology of dilute and concentrated multiple emulsions is necessary to provide information related to mixing, processing, and storage of such systems. To predict the relative viscosity of multiple emulsions of type B, containing several small internal droplets, and type C, containing a large number of small internal droplets, four variables were introduced in the proposed viscosity models (Pal 2008) : K_{21} (viscosity ratio of primary-emulsion matrix to multiple-emulsion matrix), K_{32} (viscosity ratio of internal droplet to primary-emulsion matrix), φ^{PE} (volume fraction of internal droplets within a multiple emulsion droplet), and φ^{ME} (volume fraction of total dispersed phase in the whole multiple emulsion). Based on experimental data and model predictions, it was shown that the viscosity generally increases with increase in any of these variables. Comparison between experimental data and predictions of various models showed that the model based on the Yaron and Gal-Or equation (Yaron and Gal-Or 1972) was reasonably in agreement with experimental data. However, the model based on the Oldroyd equation under predicted and the model obtained using the Choi–Schowalter equation (Choi and Schowalter 1975) overestimated the viscosity of multiple emulsion systems (Pal 2008).

7.3.2.4 Melt Flow of Block Copolymers

Block copolymers, BC, are macromolecular species in which long chains of one polymer are joined to long chains of another polymer. Thus, BCs are made of at least two chemically different chains arranged linearly, in form of multi-branch stars, combs, etc. Linear block copolymers are the most common – diblock, AB, triblock, ABA, or multiblock, $A(BA)_n$.

Commercial BCs are prepared from monomers that, upon polymerization, yield immiscible macromolecular blocks, one rigid and the other flexible, that separate into a two-phase system with "rigid" and "soft" domains. The concentration and molecular weights provide control of the size of the separated domains, thus the morphology and the interconnection between the domains. The existence of a dispersed rigid phase in an elastomeric matrix is responsible for its *thermoplastic elastomer* behavior. For symmetric block copolymers, Leibler (1980) showed that a sufficient condition for microphase separation is $(\chi_{AB}N) = 10.5$, where χ_{AB} is the binary thermodynamic interaction parameter and N is the degree of BC polymerization (Folkes 1985).

As in polymer blends, also in BC the phase transition is affected by flow. Theoretically it was predicted that homogeneous melt can be obtained at $T < UCST$, provided that the stress field exceeds the critical value for the phase demixing, $\sigma_{12} > \sigma_{12, \text{ crit}}$ (Lyngaae-Jørgensen 1989).

For most BCs the phase diagram is characterized by the presence of an upper critical solution temperature, UCST, also known as an order–disorder transition temperature or a microphase separation temperature. Below UCST the block

copolymers phase separate, while above it, an isotropic melt is obtained. Owing to the chemical link between the blocks, during phase separation in BCs, micro-domains instead of macroscopic phases are usually obtained. Furthermore, since the micro-morphology depends on the concentration as well as on the temperature, the phase diagram is complex, similar to those of metallic alloys. Under thermodynamic equilibrium conditions, depending on the composition, magnitude of the interaction parameter, and temperature, spherical, cylindrical, lamellar, or some other structures are formed. There are three elements to BC morphology: domain size, domain shape, and the interfacial thickness – they lead to a wide variety of rheological responses (Inoue et al. 1969; Meir 1969; Hashimoto et al. 1980a,b; Krause 1980).

For A-B block copolymers, the thickness of the interphase, Δl, is theoretically derived by Helfand and Wasserman (1976, 1978, 1980):

$$\Delta l = 2\sqrt{(\beta_A^2 + \beta_B^2)/2\chi_{AB}}$$
$$\text{where}: \quad \beta_i^2 = (\rho_{oi} b_i^2)/6; \quad \text{and} \quad b_i = <R_i^2>/Z_i \tag{7.77}$$

where b_i is length of Kuhn's statistical segment, Z_i is degree of polymerization, ρ_{oi} is density, and $<R_i^2>$ is the radius of gyration of the block. For immiscible systems $\chi_{AB} \geq 0$; thus as the "antipathy" of the two types of blocks toward each other decreases and $\chi_{AB} \to 0$, the interphase thickness increases.

Recently, another theoretical expression for Δl was derived for symmetric diblock copolymer with $N_A = N_B = N/2$ with lamellar morphology (Spontak and Zielinski 1993):

$$\Delta l = \Delta l_\infty [1 - (8\ln2)/(\chi_{AB}N)]^{-1/2} \tag{7.78}$$

where N is the degree of BC polymerization and Δl_∞ is the interface thickness when $N \to \infty$. The dependence should only be used for $\chi_{AB}N \geq 20$. The theory predicts that as $\chi_{AB}N$ decreases, the thickness of the interphase increases – nearly three times more rapidly for block copolymers than for homopolymer blends.

Considering melt flow of BCs, it is usually assumed that the test temperature is $UCST > T > T_{gc}$, where T_{gc} stands for glass transition temperature of the continuous phase. However, at $T_{gc} < T < T_{gd}$ (T_{gd} is T_g of the dispersed phase), the system behaves as a cross-linked rubber with strong viscoelastic character. At $UCST > T > T_{gd,}$ the viscosity of BC is much greater than would be expected from its composition. The reason for this behavior is the need to deform the domain structure and pull filaments of one polymer through domains of the other. Viscosity increases with increase of the interaction parameter between the BC components, in a similar way as the increase of the interfacial tension coefficient in concentrated emulsions causes viscosity to rise (Henderson and Williams 1979).

In shear, the block copolymers exhibit time-dependent flow with yield stress (Liu et al. 1983):

$$\sigma_{12}(t) = \sigma_y + \eta_0\dot{\gamma}\{\beta + [(1 - \beta)/(1 + b\dot{\gamma}^m)][1 + b\dot{\gamma}^m\exp\{-kt(1/b = \dot{\gamma}^m)\}]\}$$
(7.79)

where β represents the relative residual viscous dissipation parameter, b and m are parameters originating from the structural breakdown and reformation of structure, while k is the loss rate constant. The relation can describe multiple phenomena: yield, upper and lower Newtonian plateaus, pseudoplasticity, stress growth and overshoot, thixotropy, hysteresis, etc.

The multiplicity of rheological phenomena observed in BC is related to sensitivity of the melt structure to independent molecular and rheological variables. For example, for styrene-butadiene-styrene (SBS), the activation energy of flow $\Delta E_\eta = 80$ or 160 kJ/mol for compositions containing less or more that 31 vol% of styrene. The difference originates in the structure; it is dispersed below 31 % and interconnected above (Arnold and Meier 1970).

Block polymers, owing to the tendency for formation of regular structures tailored by molecular design, are ideal models for compatibilized, two-phase polymer blends or alloys. Blends do show similar rheological behaviors, e.g., yield, pseudoplasticity, thixotropy, structural rearrangements, but since the morphology is more difficult to control, the interpretation of data could present serious difficulties.

7.4 Rheology of Miscible Blends

7.4.1 General Observations

Miscible polymer blends are less common that immiscible ones. The miscibility is usually confined to a specific range of independent variables, such as chain configuration, molecular weight, composition (viz., for alternate copolymers), temperature, pressure, etc. Nevertheless, Krause reported that 1680 two-, three, or four-component polymeric mixtures were identified as miscible in 780 publications (Krause 1980).

It is noteworthy that even in miscible polymers of similar molecular structure, viz., 1,4-polyisoprene with 1,2-polybutadiene, time–temperature superposition fails. With the glass transition temperatures separated by 60 °C, the polymers preserve their different dynamics in the blends (Kannan and Kornfield 1994). Thus, even miscible systems can be rheologically complex. The rheological behavior of blends in the vicinity of phase separation is of great fundamental importance. It will be discussed in Sect. 7.4.3.

PPE/PS mixtures are considered classical examples of miscible polymer blends. Within the accessible range of temperatures, single-phase melts have been observed with the size of homogeneity below 20 nm. Dynamic flow behavior of PPE/PS blends, with molecular weight ratio MW(PS)/MW(PPE) $\cong$ 1, was studied in a wide range of temperatures and compositions (Prest and Porter 1972). The authors assumed additivity of the free volumes of the components and characterized the blend flow behavior under iso-free volume conditions. Increasing PPE content

resulted in higher values of the storage and loss shear moduli, G′ and G″. The same blends, but with MW(PS)/MW(PPE) = 100 were studied by Araujo and Stadler (1988).

Blends of atactic polymethylmethacrylate with polyethyleneglycol, PMMA/PEG, were reported miscible (Colby 1989). Their rheology, PMMA/PEG = 50/50 and 80/20 at T = 160–210 °C, was studied in a dynamic shear field (Booij and Palmen 1992). By contrast with homopolymers, the blends did not follow the time–temperature superposition. The deviation was particularly poor at low temperatures. The reason for the deviation is most likely based on the different temperature dependence of the relaxation functions. The authors concluded that in miscible blends, the temperature dependence of the relaxation times of individual macromolecules depends on composition. This leads to different degree of mutual entanglement and hence the rubber plateau moduli.

In contrast with PPE/PS blends, those of PS with PVME are known to have lower critical solution temperature, LCST, in the middle of the experimentally accessible temperature range, LCST = 100–180 °C (depending on composition and MW of the components). Rheology of these systems was studied within the miscible and immiscible as well as across the phase separation region. Within the miscible region, addition of PVME was reported to plasticize PS, thus shifting the terminal zone of G′ and G″ to higher frequencies (Schneider and Brekner 1985; Brekner et al. 1985; Yang et al. 1986). It was also reported that the time–temperature superposition principle for the blends breaks down as the temperature approaches the glass transition temperature, T_g (Cavaille et al. 1987). For the PS/PVME blends, with molecular weight ratio MW(PS)/MW(PVME) $\cong$ 40, separate relaxation times were found in the entanglement region (Stadler et al. 1988) (in homologous polymer blends having significantly different molecular weights, the relaxation spectra also show separate relaxation times for the components). Time–temperature superposition was obtained up to T = LCST + 40 °C (Stadler et al. 1988). For the PS/PVME blends, with molecular weight ratio MW(PS)/MW (PVME) $\cong$ 2, phase separation was found to increase G′ but not G″; thus the time–temperature superposition breaks down (Ajji et al. 1989; Ajji and Choplin 1991). For similar blends, with MW(PS)/MW(PVME) $\cong$ 0.8, total breakdown of the time–temperature superposition principle was reported for the phase-separated region. Large increases in both G′ and G″ were observed (Mani et al. 1992).

Sharma and Clarke (2004) reported experiments on a lower critical solution temperature blend of PSD and PVME, in order to determine the miscibility of the blend based purely on rheology. The investigation was done in the temperature range of T_g (glass-transition temperature) + 45 K to T_g + 155 K in which the blend morphology was expected to change from homogeneous to two-phase structure. Dynamic temperature sweep was found to be sensitive to the phase-separation temperature and the miscibility region. They suggested that the first change in the slope of the smoothly varying storage modulus is associated with the binodal temperature. Three different zones identified in the tan δ-temperature curve (peak zone and off-peak zones) were shown to correspond to the miscible, metastable, and phase-separated regions of the phase diagram (Sharma and Clarke 2004).
Fig. 7.17 Master curves of storage modulus (G′) and loss modulus (G″) for a 50:50 PSD/PVME blend, as a function of frequency ω (Sharma and Clarke 2004)

Time–temperature superposition works well in the homogeneous region of LCST (e.g., polystyrene and poly(vinyl methyl ether)) or UCST (e.g., polystyrene and poly(α-methylstyrene))systems. This suggests scaling behavior of $G' \sim \omega^2$ and $G'' \sim \omega^1$ at low frequencies. However, time–temperature superposition fails in the metastable region of these blends, which exhibit an increase in the magnitude of G′ in the terminal zone (Kim et al. 1998; Sharma and Clarke 2004). Figure 7.17 depicts clear deviation from scaling behavior of homogeneous blends of PSD/PVME, just after the rheologically determined binodal temperature (only the temperatures at which the time–temperature superposition failure occurs are listed in the fig., i.e., above 104 °C). It was suggested that the observed thermo-rheological complexity is related to the different morphologies formed by different coarsening kinetics. It seems that concentration fluctuation induced stress, which is mostly of elastic origin, causes storage modulus to be more sensitive to phase transitions than loss modulus (Kapnistos et al. 1996; Sharma and Clarke 2004).

The investigation of the Han plots, which is the log–log plot of storage modulus versus loss modulus, is another effective method to determine the onset of phase separation. This method is more sensitive to concentration fluctuations than data obtained from time–temperature superposition. The Han plot of homogeneous phases shows two main features: temperature independence and terminal slope of two (Han et al. 1990, 1995). Deviations from these two criteria were reported only for Han plots above the LCST and below the UCST (Kim et al. 1998; Sharma and Clarke 2004). Therefore, it has been suggested to use this method to infer the phase-separation (binodal) temperature rheologically.

There are other fingerprints that may be used to track the critical point of the phase transition in polymer blends, using the linear regime of rheological

Fig. 7.18 Cole–Cole plot
of the 80:20 blend at
different temperatures
(Ajji et al. 1988a)
experiments. One method is the so-called Cole–Cole diagram showing the
relationship between the dynamic viscosity (η') and the loss viscosity (η'').
For example, Ajji et al. (1988a) used the Cole–Cole representations to estimate
the phase-transition temperature of the 80:20 PS/PVME blend, as shown in
Fig. 7.18 at different temperatures. The characteristic of the Cole–Cole plot for
homogeneous blends is the presence of only one circular arc. Therefore, the
temperature at which a second circular arc begins to appear is the phase-transition
temperature of the system. Close to this temperature on the right-hand side of the
first arc, a tail develops and forms a second arc. Phase-transition temperature was
found to be about 140 °C by this technique, which was close to the value of 138 °C
found by cloud point measurements (Ajji et al. 1988a,b). Phase separation of
polymer blends can be also identified in the relaxation spectrum $H(\tau)$ of polymer
blends in the form of an additional relaxation (Bousmina et al. 2002; Zuo and
Zheng 2006).

According to Onuki (1987), the shear viscosity increases in phase-separating
fluids near the critical point. However, Sharma and Clarke (2004) claimed that
Onuki's prediction of features specific to the transition from a homogeneous to
a two-phase regime was not observed for PSD/PVME blends.

Blends of tetramethyl polycarbonate, TMPC, with PS were reported miscible
(Wisniewsky et al. 1984). Couchman (1996) demonstrated that the concentration
dependence of η_o at 230 °C can be predicted from the characteristic parameters of
the two components, assuming absence of specific interactions.

Fig. 7.19 The experimental (points) and computed from Eq. 7.80 relation between viscosity and composition for polypropylene blends with styrene-ethylene-butene-styrene block copolymer (Steller and Zuchowska 1990)
In miscible blends, flow behavior depends on free volume, entanglements, and specific interactions. From Doolittle's equation, assuming additivity of the occupied volume and non-additivity of the free volume, Steller and Zuchowska (1990) derived:

$$\ln\eta_b = \sum_{i=1}^{n}\phi_i\ln\eta_i = \frac{\sum_{i=1}^{n}w_i[(\delta_i-1)/(\delta_{i+1})]V_i}{2\sum_{i=1}^{n}w_iV_i/(\delta_i+1)} - (1/2)\sum_{i=1}^{n}\phi_i(\delta_i-1)$$

$$\delta \equiv [1-4(\partial\ln\eta/\partial T)/(\partial\ln V/\partial T)/B]^{1/2} = (2V_0+V_f)/V_f \tag{7.80}$$

where w_i and V_i are, respectively, weight fraction and specific volume of i-th component, while V_o and V_f are the occupied and free volume, respectively. Since the parameter δ can be determined experimentally (from the temperature gradient of the viscosity and specific volume – see Eq. 7.80), the dependence is fully predictive, as shown in Fig. 7.19.

The reptation model provides simple mixing rules for miscible systems (Doi and Edwards 1986):

$$G_N^o = \sum G_{Ni}^o\phi_i; \quad \eta_o = \sum \eta_{oi}\phi_i; \quad J_e^o\eta_o^2 = \sum J_{ei}^o\eta_{oi}^2\phi_i \tag{7.81}$$

where G_N^o is the plateau modulus, η_o is the zero-shear viscosity, and J_e^o is the recoverable shear compliance. This "single reptation model" neglects the thermodynamic interactions and constraints release. Viscoelasticity of miscible polymer blends was also analyzed by Tsenoglou (1988). The "double reptation model" resulted in the following mixing rules for the miscible blends:

$$G_N^o = \left[\sum_{i=1}^{2} \left(G_{Ni}^o \right)^{1/2} \phi_i \right]^2$$

$$\eta_o = \eta_{o1} \phi_1^2 + \eta_{o2} \phi_2^2 + 4 \left(G_{N1}^o G_{N2}^o \right)^{1/2} \phi_1 \phi_2 \left[\left(G_{N1}^o / \eta_{o1} \right) + \left(G_{N2}^o / \eta_{o2} \right) \right]^{-1} \quad (7.82)$$

$$J_e^o \eta_o^2 = J_{e1}^o \eta_{o1}^2 \phi_1^2 + J_{e2}^o \eta_{o2}^2 \phi_2^2 + 8 \phi_1 \phi_2 \left[\frac{\left(G_{N1}^o / G_{N2}^o \right)^{1/4}}{\left(J_{e1}^o \eta_{o1}^2 \right)^{1/2}} + \frac{\left(G_{N2}^o / G_{N1}^o \right)^{1/4}}{\left(J_{e2}^o \eta_{o2}^2 \right)^{1/2}} \right]^{-1}$$

Validity of Eqs. 7.81 and 7.82 was examined for mixtures of entangled, nearly monodisperse blends of poly(ethylene-*alt*-propylene) with head-to-head PP (Gell et al. 1997). The viscoelastic properties, compared at constant distances from the respective glass transition temperatures of each component, were found to obey the time–temperature superposition principle. The data agreed better with the predictions of Eq. 7.82 than Eq. 7.81. However, for blends of linear and branched PE, the relations were found valid only when MW and rheological properties of the two components were similar (Groves et al. 1996).

The double reptation model was used to evaluate viscoelastic behavior of metallocene-catalyzed polyethylene and low-density polyethylene blends by Peon et al. (2003). They compared their results with those obtained for HDPE/BPE blends prepared under similar conditions. Since this model assumes miscibility between the mixed species, the experimental viscosity of HDPE/BPE blends showed only small deviation compared to that expected according to the reputation miscible model. However, the model underestimated the compositional dependence of the zero-shear viscosity for mPE/LDPE blends, especially at intermediate levels. The enhanced zero-shear viscosity in immiscible blends such as PETG/EVA, PP/EVA, or EVA/PE blends was found to be more abrupt than it is for mPE/LDPE blends (Lacroix et al. 1996, 1997; Peon et al. 2003).

The enhanced viscoelastic functions are attributable to additional relaxation processes that occur at low frequencies associated with deformation of the dispersed phase. Therefore, for cases such as mPE/LDPE, where partial miscibility at high LDPE content and the extremely different relaxation times of the phases in the blends rich in mPE are observed, a hybrid model including the double reptation approach for the matrix and the linear Palierne approach for the whole system could successfully explain the viscoelastic response of these blends (Peon et al. 2003).

Yu et al. (2011) studied rheology and phase separation of polymer blends with weak dynamic asymmetry ((poly(Me methacrylate)/poly(styrene-*co*-maleic anhydride)). They showed that the failure of methods, such as the time–temperature superposition principle in isothermal experiments or the deviation of the storage modulus from the apparent extrapolation of modulus in the miscible regime in non-isothermal tests, to predict the binodal temperature is not always applicable in systems with weak dynamic asymmetry. Therefore, they proposed a rheological model, which is an integration of the double reptation model and the self-concentration model to describe the linear viscoelasticity of miscible blends. Then, the deviation of experimental data from the model predictions for miscible

blends determines the binodal temperature. This method was successfully applied in PMMA/SMA blend with weak dynamic asymmetry (Yu et al. 2011).

7.4.2 Relaxation Spectrum and Linear Viscoelasticity

Substituting Eq. 7.42 into Gross frequency relaxation spectrum, H_G, results in the following expression:

$$\tilde{H}_G \equiv H_G/\eta_0 = (2/\pi)r^{-m_2}\sin(m_2\Theta)$$
$$r = \left[1 + 2(\omega\tau)^{m_1}\cos(m_1\pi/2) + (\omega\tau)^{2m_1}\right]^{\frac{1}{2}} \tag{7.83}$$
$$\Theta \equiv \text{arc}\sin\left\{(\omega\tau)^{m_1}r^{-1}\sin(m_1\pi/2)\right\}$$

Thus, once the four parameters of Eq. 7.42 are known, the relaxation spectrum and then any linear viscoelastic function can be calculated. For example, the experimental data of the dynamic storage and loss shear moduli, respectively G' and G'', or the linear viscoelastic stress growth function in shear or uniaxial elongation can be computed from the following relations (Utracki and Schlund 1987):

$$G'(\omega) = \int_{-\infty}^{+\infty}\left\{sH_G(s)/\left[1 + (s/\omega)^2\right]\right\}d\ln s$$
$$G''(\omega) = \int_{-\infty}^{+\infty}\left\{\omega H_G(s)/\left[1 + (\omega/s)^2\right]\right\}d\ln s \tag{7.84}$$
$$\eta_E^+(t) = \int_{-\infty}^{+\infty}\{H_G(\omega)[1 - \exp(-\omega t)]\}d\ln\omega$$

Since Gross frequency relaxation spectrum can be computed from η', i.e., from the loss modulus, $G'' = \eta'\omega$, the agreement between the computed and measured G' values provides good means of verifying both the computational and experimental procedures. It has been found that Eqs. 7.83 and 7.84 are useful to evaluate the rheological performance of systems that obey linear viscoelastic principles.

According to the definition of the reduced relaxation spectrum, the integral:

$$\int_{-\infty}^{+\infty}\tilde{H}_G(s)d\ln s \equiv 1 \tag{7.85}$$

Thus, the coordinates of the maximum, $\tilde{H}_{G,\max}; \omega_{\max}$, are related respectively to the system polydispersity and molecular weight. However, if the system is miscible,

these functions are fully predictable from the composition, polydispersity, and molecular weight of the components. Note that in miscible blends, the general relation between the relaxation spectrum of a mixture and its composition follows the third-order blending rule:

$$H(\tau) = \sum w_{ijk} H_{ijk}\left(t/\tau_{ijk}\right) \qquad (7.86)$$

The dependence can be significantly simplified, when all fractions are either entangled or not (the situation that exists in most polymer blends):

$$H_G(\omega) = \sum w_i H_{Gi}(\omega) \qquad (7.87)$$

Thus, for miscible polymer blends, the relaxation spectrum is a linear function of the relaxation spectra of the components and their weight fractions, w_i. Hence, one may use rheological functions to detect miscibility/immiscibility of polymer blends. An example is presented in Fig. 7.20 (Utracki and Schlund 1987).

Two principles can be used for the rheological methods of miscibility detection:
1. Effect of polydispersity on the rheological functions
2. Effect of the inherent nature of the two-phase flow

The first principle makes it possible to draw conclusions about miscibility from, e.g.:
- Coordinates of the relaxation spectrum maximum (Utracki and Schlund 1987)
- Cross-point coordinates (G_x, ω_x) (Zeichner and Patel 1981)
- Free volume gradient of viscosity: $\alpha = d(\ln\eta)/df$
- Initial slope of the stress growth function: $S \equiv d\ln\eta_E^+/d \ln t$ (Schlund and Utracki 1987)
- The power-law exponent $n \equiv d\ln\sigma_{12}/d\ln\dot{\gamma} \cong S$

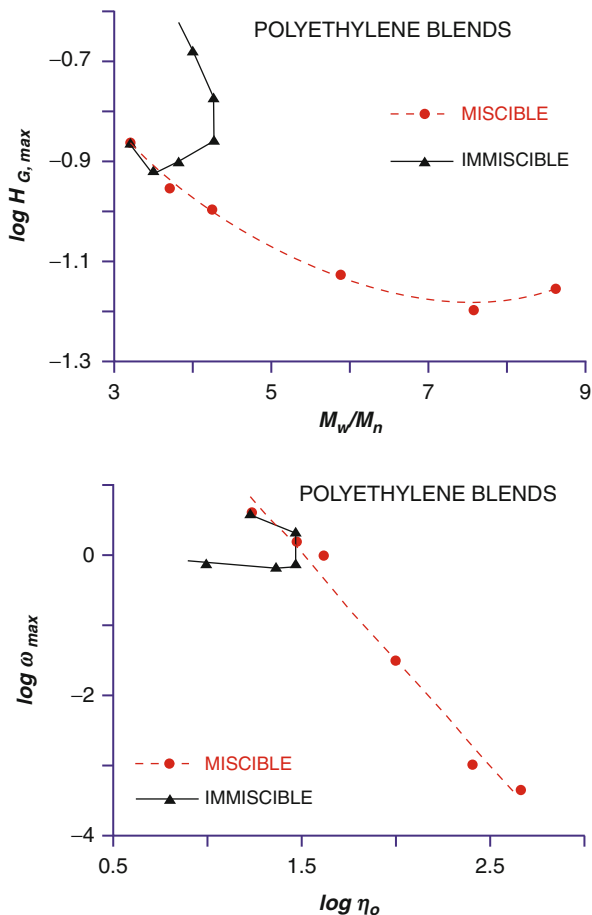
The second principle involves evaluation of, e.g.:
- Extrudate swell parameter, $B = D/D_o$
- Strain (form) recovery
- Yield stress

These effects, associated with immiscibility, will be discussed in later in this chapter.

7.4.3 Phase Separation and Flow

The phase behavior of polymer blends under flow was reviewed by Kammer et al. (1993).

For most polymer blends, the phase diagram is characterized by the presence of the lower critical solution temperature, LCST. Thus, as the temperature increases, miscible polymer blends may phase-separate. Theoretically, the miscibility region stretches up to the binodal. However, as the system approaches the binodal,

Fig. 7.20 Coordinates of the maximum of the Gross frequency relaxation function, $\tilde{H}_{G,max}$ (*top*), and, ω_{max} (*bottom*), versus, respectively, the polydispersity index, M_w/M_n, and the zero shear viscosity, η_o, a measure of the molecular weight (Utracki and Schlund 1987)


there is strong mutual interaction between the rheology and thermodynamics (Rangel-Nafaile et al. 1984; Larson 1992).

For systems of small molecules, the phase diagram does not change by the kinetic energy. However, due to the viscoelastic nature of polymer blends, a part of the flow energy could be stored as the free elastic energy. This influences the Gibbs free energy of the blend. Therefore, the phase diagram and miscibility would change. Various studies attempted to correlate this energy to the properties and the conditions of flow. One approach involves modification of the free energy of the system by the addition of the elastic free energy, which is expressed in terms of the viscosity and the shear modulus. Berrayah and Maschke (2011) considered the effects of shear on the phase diagram of binary polymer blends of poly(styrene acrylonitrile) copolymer and poly(methyl methacrylate) characterized by a lower critical solution temperature (LCST). Using the above theoretical formulism, they showed that predictions are in good agreement with cloud point data of the PSAN/PMMA

Fig. 7.21 The equilibrium phase diagram of PSAN/ PMMA under shear flow at several shear rates. Symbols represent the cloud point data of the system PSAN/PMMA in the quiescent (Berrayah and Maschke 2011)
blend in the quiescent state and the miscibility was enhanced with increasing shear rate (Fig. 7.21) (Berrayah and Maschke 2011).

The interaction between stress and composition in single-phase polymer solutions and blends is of theoretical and experimental concern. Flow-induced encapsulation has been known for a long time. Recently, the focus has shifted to miscible systems of nonuniform compositions placed in a nonuniform stress field. Two mechanisms have been proposed: the first postulating that long chains migrate to lower stress regions to decrease the elastic energy stored by deformation of the macromolecular coil (Metzner et al. 1979), the second assumes that long chains can support stress more than the short ones, creating imbalance of stresses and relative motion of the components (Doi and Onuki 1992). The latter theory makes it possible to calculate the concentration gradients in sheared blends. For example, in cone-and-plate geometry, the theory predicts migration of the high molecular weight fractions toward the center. Phenomenologically, the effect may be considered to originate from the hoop stress created in shearing of the larger polymeric chains that force them to migrate toward the center, engendering what is known as *Weissenberg effect*. The effect is related to the normal stress, $\sigma_N = N_1 + 2\,N_2$, and the osmotic pressure gradient, $d\pi/d\phi$, while the diffusion time is determined by the ratio (l/D_m), where l is the diffusion length scale and D_m is the mutual diffusion coefficient – the process is rather slow.

7.4.3.1 Influence of Thermodynamics on Rheology

For linear viscoelastic functions near phase separation at low strains, Larson and Fredrickson (1987) derived:

$$G'(\omega) = \omega^2 \Delta^{-5/2}; \quad \psi_1 = \psi_2 = \Delta^{-5/2} \atop G''(\omega) = \omega \Delta^{-3/2}; \quad \eta(\dot{\gamma}) = \Delta^{-3/2} \left.\right\} \tag{7.88}$$

where $\Delta = 2((\chi N)_s - (\chi N))$ is a measure of thermodynamic distance from the spinodal. The theory indicates that, at spinodal, the linear viscoelastic functions go to infinity or, in other words, the system becomes rheologically nonlinear. Numerically, near the spinodal, the theory predicts that the ratio $\Psi_2/\Psi_1 \cong -1.35$, instead of the usual $\Psi_2/\Psi_1 = -0.05$ to -0.20. All the data for diverse liquid systems indicate that when approaching phase separation, the viscosity should increase with the correlation length, but the rate of the increase and the absolute magnitude may vary from one system to another. The effect depends on the deformation rate and is more pronounced in high molecular weight systems.

This prediction was found qualitatively valid for blends of low density polyethylene, LDPE, with linear low density polyethylene, LLDPE. At about 20 wt% of LDPE, a sharp peak in the plot of $a_1 \equiv dln\eta/dlnY$ (where $Y = 1/(f + 0.07)$ with f being the free volume fraction) versus composition. This behavior was associated with the phase separation in the blends (Utracki and Schlund 1987).

In contrast to the predictions of Eq. 7.88, the effective viscosity at the spinodal was described by the fluidity additivity relation (Onuki 1994, 1997):

$$1/\eta_{eff} = \phi_1/\eta_1 + \phi_2/\eta_2; \quad N_1 \propto \dot{\gamma}(\phi_1\eta_2/\phi_2) \atop \text{at SD}: \quad \phi_1/\eta_1 \approx \phi_2/\eta_2; \quad \text{where} \quad \phi_1 = 1 - \phi_2 \tag{7.89}$$

Similarly, the first normal stress difference, N_1, is also predicted to be proportional to the shear stress. The phase co-continuity condition was derived from the equal shear stress principle between two phase-separating phases. The dependence is the same as empirically derived by Paul and Barlow – see Eq. 7.6.

The effect of phase separation on the dynamic shear flow of PS/PVME blends was frequently studied (Schneider and Brekner 1985; Brekner et al. 1985; Yang et al. 1986; Cavaille et al. 1987; Stadler et al. 1988; Ajji et al. 1989; Ajji and Choplin 1991; Mani et al. 1992). The results seem to differ, depending on the relative magnitude on the molecular weight, MW(PS)/MW(PVME). When the ratio was large, PVME acts as a plasticizer. When the ratio was about 2, a passage through the phase-separation region affected the dynamic storage shear modulus, G', but not the loss modulus, G''. Finally, for ratios less than one, it was reported that neither the storage nor loss dynamic shear modulus, G' and G'', respectively, indicated any significant change near the phase separation region, but upon entering the phase separation region both functions increased. By measuring the fluorescence intensity, the authors were able to map the phase separation region well. The time–temperature superposition principle was found to be valid only within the miscible blends region (Mani et al. 1992).

Dynamic shear flow within the linear viscoelastic region was used to determine binodal and spinodal temperatures (T_b and T_s, respectively) in LCST-type

blends (Vlassopoulos 1996). The system of interest was PMMA (containing 12 wt% ethyl acrylate) with 10–60 wt% SMA. The demixing temperature was determined in temperature sweeps, by plotting log G′ versus T – departure from a straight line was taken as T_b. Determination of T_s involved plotting $[G''(\omega)]^2/[TG'(\omega)]^{2/3}$ versus 1/T. Again, linear extrapolation was used to determine T_s. The rheologically determined data were found to correspond reasonably well to those determined by turbidity and light scattering.

The viscoelastic properties of model blends with UCST were studied in dynamic and steady-state shearing (Vlassopoulos et al. 1997). Low molecular weight PS and poly(methyl phenyl siloxane), PMPS, were used – the neat resins showed Newtonian behavior. The equilibrium phase diagram was determined by optical means. Within the miscible region, blend viscosity followed the log-additivity rule, provided that the concentration was corrected for the difference in the surfaces (Mertsch and Wolf 1994):

$$\ln\eta = w_1\ln\eta_1 + w_2\ln\eta_2 + \left\{\ln(\eta_1/\eta_2)\frac{\varsigma w_1 w_2}{1 + \varsigma w_1}\right\}$$
$$\text{where}: \quad \varsigma(\text{Bondi}) = \left.\frac{S_1/S_2}{V_1/V_2}\right|_{\text{Bondi}} - 1 \tag{7.90}$$

where w_i is the weight fraction of polymer i. The correcting factor, ς, can either be treated as a fitting parameter ($\varsigma = -0.54$ was determined for PS/PMPS system) or it can be calculated using Bondi's values of the surface, S_i, and volume, V_i, for each component ($\varsigma = -0.5$ was calculated). The phase separation resulted in rheologically complex behavior. However, the rapid increases of the rheological functions near SD, predicted by Eq. 7.88, were not observed.

7.4.3.2 Influence of Rheology on Thermodynamics

The response of heterogeneous systems to a stress field allows them to be placed in two categories: (i) those in which stress induces irreversible changes (e.g., precipitation, denaturation of protein, crystallization, etc.) and (ii) those in which the changes are reversible. The classification is not perfect, as the type and magnitude of stress field can be crucial, but it provides a guide: in most cases, miscibility in systems (i) is reduced by stress, while in systems (ii) it is increased. In other words, if a system can be irreversibly modified by rheological means, its solubility will be reduced. An excellent review on the phase transition in shear flow has been published (Onuki 1997).

Microrheology indicates that drops burst when the capillarity parameter $\kappa \approx 1$ (see Eq. 7.52). Thus, in shear, the equilibrium drop diameter $d \propto \nu_{12}/\sigma_{12}$ – the higher is the shear stress in the matrix or the lower is the interfacial tension coefficient, the smaller is the drop size. In other words, it is natural to expect that shearing improves dispersion. When the drop diameter becomes comparable to the radius of gyration of the macromolecules, miscibility is achieved (Silberberg and Kuhn 1952; Wolf 1980, 1984).

The above argument is correct for infinitely diluted systems. In the practical case at finite concentrations, drop coalescence may limit the dispersion process. However, when shearing takes place near the critical point, phase separation can only occur when the rate of shear is smaller than $1/\tau_c$, where τ_c is the thermodynamic relaxation time for the concentration fluctuations.

Strain compatibilization at low, steady-state stress was considered by Lyngaae-Jørgensen (1985):

$$\sigma_{cr}^2 \cong a_o T(T_s - T); \quad T \leq T_s \tag{7.91}$$

where a_o is a material parameter. Subjecting block copolymers to above-critical stresses at low deformation rates made it possible to change T_s by $\Delta T = 29\ ^\circ C$. For systems with lower critical solution temperature, LCST, the spinodal was shifted to higher temperatures. The values $a_o = 0.26$ and 0.53 $(kPa/K)^2$ were calculated, for block copolymers and poly(styrene-*co*-acrylonitrile)/poly(methyl methacrylate) blends, respectively. Equation 7.91 is in qualitative agreement with experimental observations that, in polystyrene/polybutadiene/dioctylphthalate systems, the critical point shifted as according to $\Delta T_o(\dot\gamma) \approx a_o T_o \dot\gamma^{1/2}$, where a_o is a numerical (Hashimoto et al. 1990).

A thermodynamic theory of strain demixing was proposed (Horst and Wolf 1991, 1992, 1994). The authors postulated that the Gibbs free energy of mixing for flowing blends can be expressed as a sum of the equilibrium thermodynamic free energy of mixing, ΔG_m, and the flow-induced stored energy term ΔE_S:

$$\Delta G\dot\gamma = \Delta G_m - \Delta E_s = \left(\sum_{i=1}^{n} x_i V_i\right)\langle J_e^o\rangle[\langle\eta_o\rangle\dot\gamma]^{2n} \tag{7.92}$$

where the averaged values of the zero-shear viscosity and the steady-state shear compliance can be calculated from, respectively

$$\langle\eta_o\rangle = \left(\sum_{i=1}^{n} w_i\eta_i^{1/3.4}\right)^{3.4}$$
$$\langle J_e^o\rangle\langle\eta_o\rangle^{4.4/3.4} = \sum_{i=1}^{n} w_i J_{ei}^o\eta_i^{4.4/3.4} \tag{7.93}$$

The theory was found to predict complex behavior near the phase-separation conditions. As the rate of shear increases, first, the system undergoes homogenization, then demixing, followed by another homogenization and demixing. At high rates of shear, the system should behave similarly as in the quiescent state. These predictions were found to be in qualitative agreement with experimental data, e.g., for blends of ethylene-vinyl acetate copolymer with chlorinated polyethylene, EVAc/CPE, or polystyrene with poly(vinylmethylether), PS/PVME (Hindawi et al. 1992; Fernandez et al. 1993a, 1995).

The first observation of shear-induced increase of the LCST was reported for PS/PVME by Mazich and Carr (1983). The authors concluded that shear stress can enhance miscibility by 2–7 °C. Larger effects, $\Delta T \leq 12$ °C, were reported for the same system in hyperbolic flow (Katsaros et al. 1986). In a planar extensional flow at $\dot{\varepsilon} = 0.012 - 26$ s^{-1}, the phase-separated PS/PVME was homogenized at temperatures 3 to 6 °C above T_s. The critical parameter of homogenization was found to be the extensional strain, $\varepsilon = \dot{\varepsilon} t_c = 44 \pm 14$, where t_c is the critical time to achieve miscibility at various levels of ϕ, T, and $\dot{\varepsilon}$. The constancy of ε_c indicates that the main mechanism of flow-induced miscibility is related to deformation; after cessation of flow, the deformation dissipates and the homogenized blend phase separates within 20–70 s. By contrast, large stresses can cause demixing in colloidal (e.g., denaturation of proteins) and polymeric systems. In the latter case, precipitation from poor solvent solution, shear crystallization, and stress-related phase separation, are known. For example, PS/PVME under planar stresses at $\sigma_{11} < 10$ MPa shows the previously discussed strain compatibilization, whereas at $\sigma_{11} \geq 30$ MPa it exhibits stress demixing (Katsaros et al. 1986). The demixing may be related to differences in the rheological behavior of the two blend components.

The correlation between rheology and thermodynamics in polymer blends is not straightforward. The concept of stored energy is useful in describing the interaction of rheology with thermodynamics in partially miscible polymer blends (Soontaranum et al. 1996). Flow-induced stored energy determines the deviation of the stored energy of the blend from the linear additivity rule ($\Delta E_S = E_s (\phi_1 E_1 + \phi_2 E_2)$. It is reasonable to consider that the miscibility region of the system is extended when flow-induced stored energy is negative ($\Delta G \gamma = \Delta G_m + \Delta E_s$). This is called flow-induced mixing (shear-induced mixing) and has been observed in a number of systems, such as PS/PIB blends exhibiting UCST (Wu et al. 1992), PSAN-PMMA blends exhibiting LCST (Kammer et al. 1991), and PSAN-PMMA blends in which the spinodal curve is shifted upward upon imposition of shear (Soontaranum et al. 1996). In contrast, positive deviation of the flow-induced stored energy from additivity leads to flow-induced phase separation (de-mixing) (Fernandez et al. 1993b).

For true shifting of the critical point to occur, the suppression of long-range concentration fluctuation must be anisotropic. This has not been observed in PS/PVME blends. Using neutron scattering, it was demonstrated that shearing suppresses the fluctuations only parallel to the flow, leaving the concentration gradients in other directions unchanged (Nakatani et al. 1990). Viscoelastic effects (caused by the presence of a high-MW polymer) during the early stage of spinodal decomposition (SD) were discussed (Clarke et al. 1997). The data were verified using PVME blended with PS having MW = 1,610 kg/mol. Good agreement was observed.

The relation between rheology and morphology during late stages of SD in PS/PVME blends was investigated by means of several techniques (Polios et al. 1997). The results were interpreted using Doi-Ohta (1991) theory.

Shear-induced mixing was reported for polystyrene/polyisobutylene, PS/PIB, blends (Wu et al. 1992). Optical measurements indicated that shearing within the

miscible blend region did not cause demixing, while shearing within the two-phase region reduced turbidity. The latter observation was interpreted as most probably resulting from the shear-induced mixing of the blends.

Blends of PI with PB were dynamically sheared at large amplitude ($\gamma_o = 0.8$) and frequency $\omega = 0.63$ and 6.3 rad/s (Matsuzaka et al. 1997). After a temperature jump, the spinodal decomposition (SD) was in situ observed at the lower frequency, but not at the higher frequency. In the latter case, after stopping the oscillation, a modified SD pattern emerged. The authors postulated that the dynamic flow induced a structure in the miscible system, quite different from that which exists in the non-sheared specimens.

7.5   Rheology of Immiscible Blends

7.5.1   Rheological Equation of State

Based on the principles of the flow behavior of simpler systems, viz., suspensions, emulsions, and block copolymers, as well as an understanding of the mutual interactions between rheology and thermodynamics near phase separation, it may be possible to consider the flow of more complex systems where all these elements may play a role. Evidently, any constitutive equation to describe flow of immiscible polymer blends should combine three elements: (i) the stress-induced effects on the concentration gradient, (ii) an orientation function, and (iii) the stress–strain description of the systems, including the flow-generated morphology. The first steps toward a theory of blend flow behavior were proposed by Helfand and Fredrickson (1989), then by Doi and Onuki (1992). A greatly simplified constitutive equation for immiscible 1:1 mixture of two Newtonian fluids having the same viscosity and density was also derived (Doi and Ohta 1991). The derivation considered time evolution of the area and orientation of the interface in flow, as well as the interfacial tension effects. The relation predicted scaling behavior for the stress and the velocity gradient tensors:

$$\sigma(t,[\widetilde{\kappa}(t)]) = c\sigma(ct, [\kappa(t)]) \quad \text{and} \quad \widetilde{\kappa}(t) = c\kappa(ct)$$
$$\sigma(c\dot{\gamma}) = c\sigma(\dot{\gamma}); \quad \sigma_{12} \propto \dot{\gamma} \quad \text{and} \quad (\sigma_{11} - \sigma_{22}) \propto \dot{\gamma} \tag{7.94}$$

Experimental verification of Eqs. 7.94 indicated that the scaling relationships are valid, but the shape of the experimental transient stress curves, after a step-change of shear rate, did not agree with Doi-Ohta's theory (Takahashi et al. 1994). Similar conclusions were reported for PA-66 blends with 25 wt% PET (Guenther and Baird 1996). For steady shear flow, the agreement was poor, even when the strain-rate dependence of the viscosities of the components was incorporated. Similarly, the recovery of the overshoot (or that of undershoot for step-down experiments) and the shear thinning were not predicted by that theory. However, the theory could predict the extra stress arising from the interfacial tension. Also, the transients (η and N_1) at the start-up of steady-state flow agreed qualitatively with the theory. Doi-Ohta's theory was also compared to the experimental data of semi-concentrated mixtures

of PIB in PDMS (Vinckier et al. 1997). The theory described reasonably well the transient effects at the start-up of steady-state shearing. The scaling laws were also obeyed by these slightly viscoelastic blends.

Following the work of Doi and Ohta, a more general theory was derived for immiscible polymer blends by Lee and Park (1994). A constitutive equation for immiscible blends was proposed. The model and the implied blending laws were verified by comparison with dynamic shear data of PS/LLDPE blends in oscillatory shear flow. This new approach considered the influence of morphology in determining the rheological behavior in a given flow field. Thus, instead of formulating a single droplet problem, as microrheology does for the dilute dispersions, the authors considered the complex interfaces formed between two phases of immiscible fluids created by deformations, breakup, and coalescence of drops (caused by flow and interfacial tension). A semi-phenomenological kinetic equation was derived that described the time evolution of the interfacial area per unit volume, Q, and its anisotropy in a given flow field, q_{ij}:

$$Q = (1/V)\int ds; \quad q_{ij} = (1/V)\int \left[n_i n_j - (1/3)\delta_{ij}\right]ds \tag{7.95}$$

where n_i denotes the unit normal vector to the interfaces, V the total system volume, and dS an interface element. The time evolutions of Q and q_{ij} are affected by the flow that deforms the interface to an anisotropic state:

$$dQ/dt = -d_{ij}q_{ij}$$
$$dq_{ij}/dt = -q_{ik}d_{kj} - q_{jk}d_{ik} + (2/3)d_{ij}d_{lm}q_{lm} - (Q/3)(d_{ij} + d_{ji}) + (q_{lm}d_{lm})/Qq_{ij} \tag{7.96}$$

where $d_{ij} = \partial u_i/\partial x_j$ is the macroscopic velocity gradient tensor. For a mixture of fluids with equal viscosity, the stress tensor may be expressed as

$$\sigma_{ij} = \eta_m\left(d_{ij} + d_{ji}\right) - v_{12}q_{ij} - Pd_{ij}; \quad d_{ij} \equiv du_i/dx_j \tag{7.97}$$

where η_m is the matrix viscosity and v_{12} is the interfacial tension coefficient. In Eq. 7.97, the excess shear stress is proportional to the spatial anisotropy of the interfaces, q_{ij}, and the structure of the interface distorted by the competition between flow and interfacial tension.

The resulting constitutive equation can be used not only for arbitrary volume fractions but also for arbitrary flow fields. It is advantageous to consider that the time evolution of Q and q_{ij} originates in the external flow as well as in the interfacial tension:

$$dQ/dt = (dQ/dt)_{\text{flow}} + (dQ/dt)_{\text{interf.tens.}}$$
$$dq_{ij}/dt = (dq_{ij}/dt)_{\text{flow}} + (dq_{ij}/dt)_{\text{intenf.tens.}} \tag{7.98}$$

For concentrated systems, dimensional analysis of the retraction caused by interfacial tension makes it possible to express the second terms in Eq. 7.98 as

$$dQ/dt = -c_1 c_2 (v_{12}/\eta_m)Q^2 - c_1 c_3 (v_{12}/\eta_m)q_{ij}q_{ij} \tag{7.99}$$

$$dq_{ij}/dt = -c_1(v_{12}/\eta_m)Qq_{ij} - c_1 c_3(v_{12}/\eta_m)(q_{lm}q_{lm}/Q)q_{ij} \tag{7.100}$$

where the dimensionless parameters, c_i, are, respectively, the total relaxation, the size relaxation, and the breakup and shape relaxation. They all depend on the volume fraction ϕ.

The macroscopic stress tensor for the two-phase fluid can be expressed as σ_{ij} = (pressure term) + $\eta_m(d_{ij} + d_{ji})$ + (viscosity ratio term) + (morphology-dependent term) or respectively

$$\sigma_{ij} = -P\delta_{ij} + [1 + 3\phi(\lambda - 1)/5(\lambda + 1)]\eta_m\left(d_{ij} + d_{ji}\right) - v_{12}q_{ij} \tag{7.101}$$

To complete the constitutive equation, contributions originating from flow must be incorporated. These are expressed as

$$dQ/dt = -d_{ij}q_{ij} \tag{7.102}$$

$$dq_{ij}/dt = -q_{ik}d_{kj} - q_{jk}d_{ki} + (2/3)\delta_{ij}d_{lm}q_{lm} - (Q/3)(d_{ij} + d_{ji}) + (q_{lm}d_{lm}/Q)q_{ij} \tag{7.103}$$

Substitution of Eqs. 7.99, 7.100, 7.102, and 7.103 into the two dependencies in Eq. 7.98 provides two relations that, when combined with Eq. 7.101, form the rheological equation of state. Note that at t = 0: $Q = Q_o$ and $q_{ij} = q_{ijo}$. For dynamic oscillatory flow, the relationships between the complex shear moduli $G^* = i\omega\eta^*$ can be written as

$$G_b^* = \left\{1 + \left[6\phi\left(G_i^* - G_m^*\right)/10\left(G_i^* + G_m^*\right)\right]G_m^* + G_{int}^*\right\} \tag{7.104}$$

where G_b^*, G_m^*, and G_i^* are the complex moduli of the blend, the matrix, and the dispersed phase, respectively. The term G_{int}^* is the complex modulus attributed to the interfaces. Imposition of sinusoidally varying strain, $\gamma(\omega) = \gamma_o \sin(\omega t)$ results in frequency-dependent stress at the interface $v_{12}q_{ij}$. The latter also sinusoidally changes with the stress amplitude, δ_{int}, and is out of phase with the strain. The interfacial stress amplitude σ_{int} and its phase lag by δ_{int} can be calculated by solving Eqs. 7.102, and 7.103 assuming the initial values of Q_o, q_{ijo} as well as of the parameters, c_i. The interfacial moduli G_{int}^*, G'_{int}, and G''_{int} can be expressed as

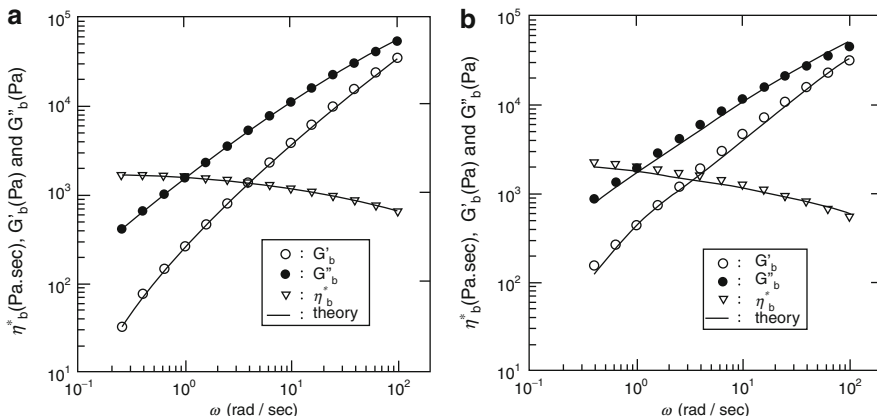
$$G_{int}^*(i\omega) = G'_{int}(\omega) + iG''_{int}(\omega) \tag{7.105}$$


Fig. 7.22 Comparison of model predictions with experimental results for (**a**) 10 wt% and (**b**) 30 wt% of PS in LLDPE (After Lee and Park 1994)

$$G' = (\sigma_{int}/\gamma_0) \cos(\delta_{int}) \tag{7.106}$$

$$G'' = (\sigma_{int}/\gamma_0) \sin(\delta_{int}) \tag{7.107}$$

where γ_o is the strain amplitude.

The effects of shear flow on the PS/LLDPE morphology were investigated by observing the structure of quenched samples under the scanning electron microscope, SEM. Predictions based on the constitutive equations were compared with observations from the dynamic shear experiments at 200 °C (see Fig. 7.22). The frequency variations of G_b', G_b'', and η_b^* were found to be in good agreement with computations based on Eqs. 7.101, 7.102, and 7.103. However, to get such agreement, seven parameters (viz., ν_{12}, ϕ, initial value of the anisotropy parameter, q_{ijo}, initial size of the dispersion, and three dimensionless equation parameters) were required (Lee and Park 1994).

It should be noted that the Doi and Ohta theory predicts only an enhancement of viscosity, the so-called emulsion-like behavior that results in the positive deviation from the log-additivity rule, PDB. However, the theory does not have a mechanism that may generate an opposite behavior that may result in a negative deviation from the log-additivity rule, NDB. The latter deviation has been reported for the viscosity versus concentration dependencies of PET/PA-66 blends (Utracki et al. 1982). The NDB deviation was introduced into the viscosity–concentration dependence of immiscible polymer blends in form of an interlayer slip caused by steady-state shearing at large strains that modify the morphology (Utracki 1991).

A complete set of governing relationships was derived from the requirements of the compatibility of dynamics and thermodynamics (Grmela and Ait-Kadi 1994, 1998; Grmela et al. 1998). The authors developed a set of equations governing the

time evolution of the functions Q and q_{ij} (see Eqs. 7.95), as well as the extra stress tensor expressed in their terms. The rheological and morphological behavior was expressed as controlled by two potentials: thermodynamic and dissipative. Under specific conditions for these potentials, the Lee and Park formalism can be recovered.

Lacroix et al. (1997, 1998) attempted to evaluate three approaches (those of Palierne, Lee and Park, and Grmela and Aït-Kadi). They are capable in describing the experimental data of different types of polymer blends, viz., PS/PE, PETG/EVAc, PP/EVAc, and PP with EVAc and poly(ethyl methacrylate) (PEMA). Since EVAc is miscible with PEMA, the latter blend is also a two-phase blend with PP being the matrix. All blends were prepared within the concentration range that assured dispersed morphology. The Palierne model was found to describe well the linear viscoelastic behavior, whereas the model of Lee and Park was found useful for describing the rheological behavior under large strains. In the later paper, it was shown that the overshoot at the start-up of shearing was described well using either the Lee and Park or Grmela and Aït-Kadi model.

Based on the morphological features, the proposed models can be divided into two categories (Yu and Zhou 2007). The first group is based on local coarse-grained morphology such as the models of Doi and Ohta, Lee and Park, and Grmela. The second group includes the models based on droplet morphology, such as the models proposed by Maffettone and Minale (1998), Jackson and Tucker Iii (2003), and Yu and Bousmina (2003).

The first group used a statistical area tensor or interfacial anisotropic tensor to explain the complex interface by applying some modification on the Doi and Ohta model. The general advantage of these models is their ability to describe the blends with co-continuous structure or irregular phase morphology. On the other hand, the main drawback is attributed to the model parameters that can be used for a specific system and are non-generalizable. More quantitative morphological studies should be done to extend their applications.

The second group involves an ellipsoidal shape tensor representing the shape of the droplets. They lead to good description of droplet deformation, droplet relaxation, and rheological properties, along with the ability to incorporate the viscoelastic effects of components (Maffettone and Greco 2004; Yu et al. 2004; Yu et al. 2005). However, they fail to describe the systems that undergo droplet breakup and coalescence phenomena. To overcome this problem, Dressler and Edwards (2004) assumed that the variable droplet distribution can be considered in terms of two thermodynamic variables: the droplet shape tensor and the number density of representative droplets. They used a single time scale for breakup and coalescence to track droplet numbers. However, while this approach worked well for the PIB/PDMS blend, it was suggested that more quantitative rheological and morphological studies are needed to compare model predictions and experiments, especially for systems in which the breakup process dominates (e.g., transient process under large step shear) (Yu and Zhou 2007).

As another approach to predict the rheological behavior of immiscible blends, Almusallam et al. (2003) and Zkiek et al. (2004) constructed "hybrid" models based

on local coarse-grained morphology by casting Tomotika's theory to consider thread breakup under quiescent conditions. Yu and Zhou (2007) proposed a simple constitutive equation for immiscible blends. The theory predicts the overshoot in the first normal stress difference in the transient start-up of shear and morphology of droplets under varying shear histories. This model is based on the ellipsoidal description of droplets and includes the breakup and coalescence processes. The main assumption is that the discrete droplet breakup/coalescence process can affect droplet size only and it can be approximated by a continuous dynamic equation. A simple mapping approach was suggested to unify the variation of droplet volume due to the breakup/coalescence process and the conservation of droplet volume during the deformation (Yu and Zhou 2007).

7.5.2 Morphology of Immiscible Blends

In immiscible blends, the properties are related to the interface as well as to the size and shape of the dispersed phase. The morphology is controlled by both equilibrium and nonequilibrium thermodynamics, as well as by the flow field. As discussed in Sect. 7.1.2.2, at equilibrium and within the region of low volume fraction of the dispersed phase, $\phi < \phi_{perc} = 0.16$, droplets are expected, while at $\phi > \phi_{perc} = 0.16$ a co-continuous morphology, e.g., fibers or lamellae, are usually observed.

When the polymers are miscible under one set of conditions (e.g., within a specified range of concentration (ϕ), pressure (P), and temperature (T)), but immiscible under other conditions, the nonequilibrium morphology depends on the quench depth and time scale. Shallow quenching into the metastable region (between the binodal and spinodal curves) results in nucleation of the dispersed drops, followed by their growth. The mechanism of this phase separation is appropriately called *nucleation and growth*, NG. By contrast, deep quenching into the spinodal region results in *spinodal decomposition*, SD. Here there is an instantaneous generation of regularly spaced co-continuous structures, with progressive increase of the concentration difference between the two adjacent regions and increased spacing. The co-continuity of structures has been reported for scales varying from a few nanometers to hundreds of micrometers.

Both the NG and SD morphologies are transient, progressively coarsening. At a late stage, both NG and SD mechanisms follow similar ripening patterns, leading to an appropriate equilibrium morphology. Without compatibilization, the two phases may totally separate into two layers. In the case of well-compatibilized blends, the action of a compatibilizing agent is similar to that of surfactants in emulsions – one may assign specific surface area coverage per single molecule of the compatibilizer. However, dimensions of the dispersed, compatibilized phase do change with time after cessation of flow. By contrast, addition of a stabilizing agent (e.g., a third polymer immiscible in the two others) may prevent coalescence, preserving the degree of dispersion (but not the orientation) generated during the flow.

7.5.3 Microrheology of Polymer Blends

In this part, the breakup of polymer drops will be discussed, initially dealing with diluted systems (isolated drops) and subsequently with concentrated dispersions where coalescence is of equal importance. Dispersion in Newtonian systems was discussed in Sect. 7.3.2.2.

The mechanisms governing deformation and breakup of drops in Newtonian liquid systems are well understood. The viscosity ratio, λ, critical capillary number, κ_{crit}, and the reduced time, t^*, are the controlling parameters. Within the entire range of λ, it was found that elongational flow is more effective than shear flow for breaking the drops. However, it is always important to realize that both rheological and thermodynamic considerations play an important role in the development of morphology in polymer blends. The role of thermodynamics is illustrated in the following example. Ravati and Favis (2013) reported three completely different interfacial tension-driven structures for the ternary blends: partial wetting for PBS/PLA/PCL, complete wetting tri-continuous morphology for PBS/PLA/PBAT, and combined partial-complete wetting cases for the PBS/PBAT/PCL blend. The variety of structures was achieved since the interfacial tensions between the phases were very low and the spreading coefficients were close to zero. Simply replacing one component with another changed the sign of the spreading coefficient and led to a different wetting behavior, as shown in Fig. 7.23. The observed partial and complete wetting cases were supported by Harkins theory of the spreading of liquids (Harkins 1941).

7.5.3.1 Deformation and Breakup of Viscoelastic Drops

The shear deformation of viscoelastic drops in a Newtonian medium has been the subject of several studies. Gauthier et al. (1971) found higher values of the critical capillary number than those determined for Newtonian drops. Prabodh and Stroeve (1991) observed that, during shearing, some drops are greatly extended and only break when the flow is stopped. The authors concluded that, at $\lambda < 0.5$, the drop elasticity has a stabilizing effect, but for $\lambda > 0.5$ the opposite is true. Interestingly, the experimental observations of De Bruijn (1989) seem to contradict the latter conclusion. He found that the critical capillary number for the viscoelastic droplets is always higher (sometimes much higher) than for the Newtonian drops, whatever the λ-value. De Bruijn concluded that drop elasticity always hinders drop breakup.

For Newtonian drops suspended in a viscoelastic fluid, Flumerfelt (1972) reported the existence of a minimum drop size below which breakup cannot be achieved. The author pointed out that the elasticity of the medium tends to increase this minimum value for breakup, that is, to stabilize the droplets.

In the case when both the droplets and the suspending medium are viscoelastic liquids, Wu (1987) reported that drops can break up during extrusion even when $\lambda > 4$. However, owing to the complex nature of the deformation during flow through an extruder, it was difficult to even speculate on the origin of this phenomenon. Van Oene (1978) studied the mechanisms of two-phase formation in a mixture of two viscoelastic fluids. He pointed out that, besides the viscosity ratio and the equilibrium interfacial tension of the two liquids, the elasticity of the liquids plays an important
Fig. 7.23 Micrographs and schematics of combined partial-complete wetting morphology for ternary PBS/PBAT/PCL blends showing the effect of composition. (**a**, **b**) 25%PBS/25%PBAT/50%PCL after extraction of the PCL phase by acetic acid and annealing; (**c**) schematic of 25% PBS/25%PBAT/50%PCL; (**d**) schematic of 10%PBS/40%PBAT/50%PCL; (**e**, **f**) 10%PBS/40% PBAT/50%PCL after extraction of PCL phase by acetic acid and annealing. The *white bar* indicates 10 μm except for (**b**) which is 1 μm (Ravati and Favis 2013)

role in deformability of drops. Thermodynamic considerations led to the following relation for the dynamic interfacial tension coefficient:

$$v_{12} = v_{12}^0 + (d_0/12)\left[(\sigma_{11} - \sigma_{22})_d - (\sigma_{11} - \sigma_{22})_m\right] \tag{7.108}$$

where v_{12}^0 is the interfacial tension in a quiescent polymer blend, d_o is the initial diameter of the dispersed drop, and $(\sigma_{11} - \sigma_{22})_i$ is the first normal stress difference of

the dispersed (i = d) and of the matrix (i = m) phase, respectively. For $(\sigma_{11} - \sigma_{22})_d > (\sigma_{11} - \sigma_{22})_m$ the dependence predicts that higher elasticity of the dispersed than the continuous phase results in more stable drops. On the other hand, for $(\sigma_{11} - \sigma_{22})_d < (\sigma_{11} - \sigma_{22})_m$ Eq. 7.108 predicts that $\nu_{12} < \nu_{12}^o$; thus the flow tends to enhance the dispersing process (flow compatibilization). Note that ν_{12} cannot be negative; for large differences of the normal stress difference and for large drop diameters (thus, for higher concentration of the dispersed phase), this translates into co-continuous morphology, for which the above relation is no longer valid.

Since flow affects miscibility of blends near the spinodal, the interfacial tension coefficient must also change with the flow conditions. This theory leads to $\nu_{12}(\dot{\gamma}) = \nu_{12}^o \left[1 - a\kappa^{1/3b}\right]^{2b}$, where a and b are parameters (Onuki 1986).

Han and Funatsu (1978) studied droplet deformation and breakup for viscoelastic liquid systems in extensional and nonuniform shear flow. The authors found that viscoelastic droplets are more stable than the Newtonian ones; in both Newtonian and viscoelastic media, they require higher shear stress for breaking. The critical shear rate for droplet breakup was found to depend on the viscosity ratio; it was lower for $\lambda < 1$ than for $\lambda > 1$. In a steady extensional flow field, the viscoelastic droplets were also found less deformable than the Newtonian ones. In the viscoelastic matrix, elongation led to large deformation of droplets (Chin and Han 1979).

Bousfield et al. (1986) studied the surface-tension-driven breakup of Newtonian and viscoelastic filaments. The authors found that disturbances grow more rapidly in viscoelastic filaments than in the Newtonian ones but that there is a retardation of the growth and stabilization at long times, resulting from large extensional stresses (see Fig. 7.24). The formation of satellite drops was found to be retarded by the elasticity. The authors analyzed the problem using the Galerkin finite element method, as well as a one-dimensional theory for viscoelastic filaments. Their findings were successfully used to interpret existing experimental data on Newtonian and viscoelastic jet disintegration, where the initial disturbance was imposed by nozzle vibration. For viscoelastic jets, an asymptotic solution was offered for the later stages of the process:

$$\ln(R/R_0) = a_0 - t/3\tau; \quad \text{for} \quad t >> \tau \qquad (7.109)$$

where a_o and τ are, respectively, the numerical constant and the relaxation time. This work should have direct bearing on disintegration of viscoelastic filaments in a Newtonian matrix, but application of these findings to polymer blends is more difficult.

Lyngaae-Jørgensen et al. (1993) developed a predictive model of morphology variation during simple shear flow of diluted polymer blends. The model considers the balance between the rate of breakup and the rate of drop coalescence. It was assumed that (i) the viscosity and elasticity of the dispersed phase are significantly lower than those of the matrix, (ii) only the cylindrical, large drops (defined by the long and short semiaxes a_1 and a_2) are able to break and form small drops, and

Fig. 7.24 Computed radius at the neck for disintegrating jet stream of Newtonian (*solid line*) and Maxwell fluid (*dashed line*) (Bousfield et al. 1986)
(iii) the coalescence can occur between all types of the dispersed entities. The dynamics of drop formation and breakup can be described by

$$dN_S/dt = N_b R_{Lb} - 2R_{SSC} - R_{LSC}$$
$$dN_L/dt = R_{SSC} - R_{Lb} - R_{LSC}$$
$$da_2/dt = (a_2/dt)_{V,\,\text{flow}} + (a_2/dt)_{\text{coalescense}}$$

(7.110)

where dN_S/dt, dN_L/dt, and da_2/dt are the rates of change of the numbers of small drops and large drops and the rate of change of drop dimension correspondingly; R_{Lb} is the rate at which the number of small drops, N_b, are produced by breakage of the large drops; R_{LSC} and R_{SSC} are the number rates at which small drops are destroyed by coalescence with large and small drops, respectively; R_{LSC} is the number rate of coalescence between large drops. The first term on the right side of the last relation in Eq. 7.110 describes the contribution due to the flow process, and the second reflects that the average thickness of the large domains increases during coalescence.

The theory makes it possible to compute the drop aspect ratio, $p = a_1/a_2$, a parameter that can be directly measured in either a transient or steady-state flow. Following the derivation by Hinch and Acrivos (1980), the flow-induced changes to the drop aspect ratio were assumed to be proportional to the first normal stress coefficient of the matrix fluid. The coalescence was assumed to follow the Silberberg and Kuhn (1954) mechanism. These assumptions substituted into Eq. 7.110 gave a simple dependence for the aspect ratio:

$$p = 4\phi_d p_r \eta_m \dot{\gamma}/\pi a_1 (\sigma_{11} - \sigma_{12})_m - a_2$$

(7.111)

where a_i are adjustable parameters.

Fig. 7.25 Deformability of PS drops in PMMA during steady-state shear flow at 180 °C. The points are experimental; the line is to guide an eye (Lyngaae-Jørgensen et al. 1993)
A special unit, equipped for light-scattering measurements, was attached to a Rheometrics Mechanical Spectrometer with cone and plate to follow the transitional events during shearing of polymer blend melts. The predictions of p obtained by the proposed model were found to be in a reasonable agreement with the experimental observations for poly(methyl methacrylate) blends with either 8 or 10 wt% polystyrene, PMMA/PS. The most interesting finding that came out of this work was that, both theoretically and experimentally, under steady-state flow conditions, the aspect ratio plotted versus shear stress showed a sharp peak at the stresses corresponding to transition of PMMA viscosity from the Newtonian plateau to the power-law flow, i.e., to the onset of the elastic behavior. The dependence is presented in Fig. 7.25.

Mighri and Huneault (2002) investigated the drop deformation and breakup mechanisms in Boger fluid in PDMS as a viscoelastic model fluid system and PPS/PE and EPR/PP polymer blends under high shear rate conditions. Flow visualization was carried out in a transparent Couette shearing setup. Two non-Newtonian deformation and breakup mechanisms were presented. The first one was attributed to normal force buildup in the droplet. It was manifested in contraction of the dispersed droplet in the flow direction and its elongation in the vorticity direction at high deformation rates. The second deformation/breakup mechanism was the erosion mechanism. Erosion at the drop surface would occur only in highly viscous molten polymer systems, in which shear stresses could reach the required level. It was suggested that the ends of highly elongated particles would be located in different planes due to flow disturbance. Consequently, clouds of very small ribbons and sheets were formed around the drop, which then elongated and broke into very small droplets (Mighri and Huneault 2002). They also mentioned that the breakup process for the high interfacial tension PS/PE blends was very similar to that of low interfacial tension the EPR/PP system, probably due to the fact that viscosity ratio of both blends was very high.

Aggarwal and Sarkar (2008) used a three-dimensional front-tracking finite-difference method to study the effects of matrix viscoelasticity on viscous and viscoelastic drop deformation in shear flow. They used the Oldroyd-B constitutive equation to model the viscoelasticity of the system and to predict numerically the drop deformation and orientation. It was observed that increasing matrix viscoelasticity changed the drop inclination angle with the flow direction significantly. Also the steady-state drop deformation first decreased and then increased with increasing Deborah number. The change in drop orientation angle along with localized stretching of the polymer molecules at the drop tips was shown to play a critical role in the observed non-monotonic behavior. It was mentioned that the breakup of a viscous drop in a viscoelastic matrix is more pronounced for high De and restricted at smaller De. They showed that polymer to total viscosity ratio (β) affects the drop inclination angle through the combined parameter βDe, pointing out the effect of the first normal stress difference in a steady shear ($N_1 = 2\beta De$) (Aggarwal and Sarkar 2008).

In another attempt, Sirivat et al. (2011) investigated the effects of three different parameters on droplet oscillatory deformation and breakup in polystyrene/high-density polyethylene by using a flow cell mounted on an optical microscope: (i) the effect of time scale ratio (4.0, 16.6, 33.2, and 63.8), (ii) the effect of viscosity ratio (0.58, 0.12, and 0.06), and (iii) the effect of droplet elasticity. The authors defined a modified deformation parameter as Def* $= (a^* - c)/(a^* + c)$ where a^* and c denote the apparent drop principal axes and the minor axes of the droplets as obtained from the droplet image projected onto the flow-vorticity plane from the time series of images. The difference between the maximum and minimum values of Def* divided by two (as a measure of amplitudes of deformation parameters) showed the linear correlation with small capillary numbers, whereas the dependences became nonlinear at large capillary numbers. The increase in critical capillary number was considerable with increasing viscosity ratio, but capillary number changed slightly with the time scale ratio. On the other hand, at a fixed capillary number, amplitudes of deformation parameters increased with decreasing the droplet elasticity (Sirivat et al. 2011) which is in agreement with the main conclusion of the previous studies showing the elasticity of the droplet suppresses droplet deformation and breakup (Lerdwijitjarud et al. 2003, 2004). Furthermore, Sirivat et al. suggested two different drop breakup patterns for PS/HDPE blends; (i) the nonsymmetric one-end tearing pattern that forms many smaller drops for the high-viscosity ratio system and (ii) the two-end stretching and twisting pattern that makes only few satellite drops at each end for the lower-viscosity ratio blend (Sirivat et al. 2011). Lee et al. (2009, 2010) studied the effect of steady shear on the phase separation in LCP/PC blends, using a shear stage, in conjunction with polarized light microscopy (Linkam stage). The phase diagram was divided into three regions with two phase-separation temperatures, Tsp1 and Tsp2, as the internal boundaries. Below Tsp1, phase separation can hardly occur. Between Tsp1 and Tsp2, phase separation can occur to a small extent. Above Tsp2, phase separation in the blends can proceed to a large extent. At low shear rates, both Tsp1 and Tsp2 are shifted to a lower position

(relative to the quiescent conditions) on the phase diagram, indicating that the LCP/PC blends exhibited shear-induced phase-separation behavior. The phase-separated morphology of the blends showed significant changes under shear. For low LCP contents (10 wt%), the blends did not form the droplet-type morphology under shear, as was observed under quiescent conditions. Instead, the blends formed interconnected-type structure, and the network-like LCP-rich domains were transformed to short and thick fragments, due to the breakup of the network. For moderate LCP contents (20–30 wt%), the blends exhibited interconnected structure. However, the LCP-rich domains were thicker and shorter than those formed under quiescent conditions. For high LCP content (40–60 wt%), the blend exhibited droplet-type morphology, with the PC-rich phase appearing as dispersed domains. However, these dispersed domains were not distributed uniformly spatially. The effect of shear, at a shear rate of 0.40 s^{-1}, on the temporal morphological development in 50 wt% LCP/PC blends at 290 °C was examined and compared to the situation under quiescent conditions. Both cases showed that phase separation started quickly and then slowed down at the later stages of the process. The speed and magnitude of phase separation in the blend was enhanced significantly under shear, because of the shift of the phase diagram.

The dynamic mechanical shear behavior of several blends, viz., PS with PMMA, PDMS with PEG, and PS with PEMA, were studied by Graebling et al. (1989, 1993b). The linear viscoelastic behavior of these blends with the volume fraction of the dispersed phase $\phi \leq 0.15$ was found to follow predictions of Palierne's emulsion model, which makes use of the viscoelastic behavior of component polymers and a single parameter that characterizes the interface, i.e., the ratio of the interfacial tension coefficient and drop radius, ν_{12}/R. The values of the interfacial tension coefficient determined from the viscoelastic measurements were found to be in good agreement with results obtained from the pendant drop method. However, the theory seems to break down for polymer blends with $\phi \geq 0.2$. The observed agreement between the experimental data and the theory means that the emulsion model can indeed be used for interpretation of the viscoelastic behavior of polymer blends. The noted deviations at higher concentration range are not in conflict with the basic premises of the approach. They originate from the imposed limitations of the model (see Sect. 7.3.2.3.2).

7.5.3.2 Coalescence of Viscoelastic Drops

For diluted Newtonian systems, the size of the smallest drop that can be broken is calculable from Taylor's theory. However, for polymer systems, many studies have shown that equilibrium drop size is usually larger than predicted and the deviation increases with concentration of the dispersed phase, $\phi_1 - \phi_o$, where ϕ_1 is the volume fraction of the dispersed phase and $\phi_o \approx 0.005$ is the smallest concentration for which the deviation occurs. Roland and Bohm (1984) studied the shear-induced coalescence in two-phase polymeric fluids by small-angle neutron scattering. The coalescence rate was high, dependant on the rheological properties of the two phases and the flow field.

Coalescence occurs in shear as well as quiescent systems. In the latter case, the effect can be caused by molecular diffusion to regions of lower free energy, by Brownian motion, dynamics of concentration fluctuation, etc. Diffusion is the mechanism responsible for coalescence known as *Ostwald ripening*. The process involves diffusion from smaller drops (high interfacial energy) to the larger ones. Shear flow enhances the process (Ratke and Thieringer 1985):

$$(d/d_0)^n = 1 + a_0 t, \quad n = n(y) = 3/2 \text{ to } 3 \tag{7.112}$$

where d_o is the drop diameter at the moment of imposition of stress and a_o is a constant. The exponent n decreases from the classical value of 3, for quiescent systems, to 3/2 at high shear rates.

Flow-induced coalescence is accelerated by the same factors that favor drop breakup, e.g., higher shear rates, reduced dispersed-phase viscosity, etc. Most theories start with calculation of probabilities for the drops to collide, for the liquid separating them to be squeezed out, and for the new enlarged drop to survive the parallel process of drop breakup. As a result, at dynamic equilibrium, the relations between drop diameter and the independent variables can be derived.

Tokita (1977) calculated the total number of collisions per unit volume and time. The author assumed that coalescence is proportional to this number and to the number of particles. The latter was assumed to increase with mixing time, being proportional to the shearing energy, $\dot{\gamma}\sigma_{12}$, and inversely proportional to the interfacial tension coefficient, v_{12}. At equilibrium, the rates of coalescence and breakup are equal. Thus, the equilibrium drop size can be expressed as

$$d = (24/\pi)p_r v_{12}\phi_1 / [\sigma_{12}\dot{\gamma} - (4/\pi)p_r E\phi_1] \tag{7.113}$$

where p_r is the probability of collision and E is the macroscopic bulk breaking energy. In agreement with experimental findings, the relation predicts that the equilibrium drop diameter increases with concentration and the interfacial tension coefficient, but it decreases with shear stress. At the low concentration limit, $\phi_1 \leq \phi_o$, Eq. 7.113 also agrees with the conclusions of Taylor's theory, but for $\phi_{d\to0}$, it predicts an unrealistic limit, $d \to 0$.

Under steady-state flow conditions, the morphology is fully defined by the dynamic breakup and coalescence processes. However, behind is an implicit assumption that the flow conditions are strong enough to erase the initial morphology. The presence of the critical value of shear rate, $\dot{\gamma}_{cr}$, has been documented (Minale et al. 1997). The authors reported that the unique morphology was observed only above $\dot{\gamma}_{cr}$. Below this limit, multiple pseudo-steady-state structures were observed for the model PDMS/PIB system. No attempt was made to generalize this observation. In principle, the phenomenon should be related to the critical value of the capillary number, κ_{cr}, and a ratio of the polymer(s) relaxation time to

the rate of shearing. The presence of $\dot{\gamma}_{cr}$ can also be used to explain observations on morphology evolution of PDMS/PIB blends (Grizzuti and Bifulco 1997).

Following a procedure similar to that of Tokita (1977), for equilibrium drop diameter in steady simple shear flow, the following dependence was proposed (Fortelny et al. 1988, 1990):

$$d = d_T + [(v_{12}p_r\phi_1)/\eta_2 f(\kappa)] \tag{7.114}$$

where d_T is Taylor's equilibrium diameter (e.g., calculable from Eq. 7.52) and $f(\kappa)$ is a function of the capillary number and the rheological properties of the system. Equation 7.114 predicts that as $\phi_{1\to0}$, the drop diameter is determined by the Taylor breakup conditions. As the concentration increases, d becomes proportional to the expression in square bracket. The authors reported that, in the system PP/EPDM, coalescence was more intense than predicted by the dependence.

A theory for the dynamic equilibrium drop diameter also started from separate calculations of the drop breakup and coalescence during steady-state shearing. The rate of particle generation was taken to be determined by microrheology, viz., Eq. 7.52, (Huneault et al. 1995a):

$$(dN_d/dt)_{\text{break-up}} = \dot{\gamma} N_d/\kappa_{cr}t_b^* \tag{7.115}$$

Since the dispersed phase volume is constant, the number of drops, N_d, can be related to the volume fraction of the dispersed phase, ϕ, and to the drop diameter, $N_d = 6\phi V/\pi d^3$. The coalescence rate is a function of the collision probability and the dynamics of the collision process. From Eq. 7.65 coalescence rate can be written as

$$(dN_d/dt)_{\text{coalescence}} = -C\dot{\gamma} N_d\phi^{8/3}/d^2 \tag{7.116}$$

where C is a coalescence constant. At equilibrium, the diameter rate of change is zero.

From Eqs. 7.115, and 7.116, the dynamic drop diameter is

$$d_{eq} = d_{eq}^0 + \left(6C\kappa_{cr}t_b^*\phi^{8/3}\right)^{1/2} \tag{7.117}$$

where d_{eq} is the equilibrium drop diameter (at steady-state shearing), in a blend with the volume fraction of the dispersed phase, ϕ, mixed under a given set of processing conditions, while $d_{eq}^o = d_T$ is its value extrapolated to zero concentration. The only unknown in Eq. 7.117 is the coalescence constant, C. Its value can be determined from a plot of d_{eq} versus ϕ (Fig. 7.26).

Domingues et al. (2010) developed a model to predict the morphology of immiscible systems in a single screw extruder. This model considers the stretching, breakup, and coalescence phenomena. The authors followed the approach proposed

Table 7.7 Expressions for the probabilities of collision and expulsion h* and the new particle size after coalescence R* (Delamare and Vergnes 1996)

$P_{col} = \exp\left(-\frac{\pi}{8\gamma\varphi t_{loc}}\right)$	For all the cases
$P_{\exp} = \exp\left[-\frac{9}{8}\left(\frac{R}{h^*}\right)^2\kappa^2\right]$	For immobile interfaces ($\lambda \gg 1$)
$P_{\exp} = \exp\left[-\frac{\sqrt{3}}{4}\left(\frac{R}{h^*}\right)\lambda\kappa^{3/2}\right]$	For partially mobile interfaces
$P_{\exp} = \exp\left[-\frac{3}{2}Ln\left(\frac{R}{h^*}\right)\kappa\right]$	For mobile interfaces ($\lambda \ll 1$)
$h^* = \left(\frac{10^{-20}R}{8\pi v_{12}}\right)^{1/3}$	For all the cases
$R^* = R\left(\frac{2}{2-P_{Coal}}\right)^{1/3}$	For all the cases

by Chesters (1991b) and Delamare and Vergnes (1996). They assumed that coalescence occurs by collision of two identical spherical drops in a shear flow, while the polymer film between them will be excluded and flow into the main stream. Therefore, the probability of the coalescence was defined as the product of the probability for expulsing the film separating the drops (P_{exp}) and the probability of the two drops colliding (P_{col}). P_{col} increases exponentially with the local residence time (t_{loc}), the volume fraction of the dispersed phase (ϕ), and shear rate. On the other hand, the probability for expulsing the liquid film depends on the viscosity ratio determining the type of interface. As seen in Table 7.7, P_{exp} is expressed differently using h*, the critical value for the breaking of the liquid film, the viscosity ratio (λ), capillary number (κ), the droplet radius (R), and the interfacial tension (v_{12}). Finally the new particle size after coalescence, R*, was computed from volume conservation to develop a model of morphology evolution (Delamare and Vergnes 1996).

The coarsening of the phase structure due to the matrix crystallization process is an important issue to be considered. Dimzoski et al. (2013) attempted to clarify the coalescence of dispersed phase particles induced by crystallizing matrix domains

during the cooling of an immiscible polymer blend in the quiescent state. The study was carried out using PP/EPR blends for which the coalescence during annealing in the quiescent state was studied in detail (Dimzoski et al. 2011). It is known that changes in the size of the rubber particles, during the cooling of the melt mixed blend, determine the effectiveness of EPR in the toughening of the PP matrix. Therefore, the authors investigated the possible changes in blend morphology during the crystallization of PP via the rejection of the EPR domains from the spherulites growth front, which consequently could lead to collision and coalescence. They suggested that molecular forces and/or coalescence induced by the Brownian motion caused a primary coarsening of the phase structure before reaching the temperature of PP crystallization. The contribution of crystallization to coalescence of the dispersed phase particles was found to be largest at a finite rate of cooling. This was explained by the rejection energy required to exclude particle from the growing spherulite (Dimzoski et al. 2013).

7.5.3.3 Predicting Drop Size Changes During Processing

Mohr et al. (1957) analyzed the degree of mixing in a single screw extruder (SSE), using the concept of striation thickness suggested by Spencer and Wiley (1957). The amount of shear strain experienced by an element of fluid in the extruder screw channel was calculated for a number of flow paths. Decreased helix angle, increased ratio of pressure flow to drag flow, and an increased flight height were predicted to improve mixing. The ratio of the viscosities of the minor and matrix phases significantly influenced the degree of mixing.

Schrenk et al. (1963) analyzed the degree of mixing in a simple annular mixer, which might be helpful for understanding mixing in a SSE. To evaluate the mixedness of the two-component polymers, the striation thickness was measured, when the inner shaft was rotated and the outer cylinder was stationary. Near the shaft, the thickness was substantially reduced, but only slightly near the external cylinder.

Bigg and Middleman (1974) studied the transverse flow in a rectangular cavity, similar to that in an SSE. They used the Marker and Cell technique to calculate the degree of mixing, which was described by the interfacial perimeter per cavity width. As the viscosity ratio decreased, the degree of mixing was enhanced.

Chella and Ottino (1985) studied the degree of mixing in an SSE by theoretical analysis of the kinematics of mixing. They evaluated the degree of mixing as a function of the ratio of screw length to height of flight, helix angle, the ratio of pressure flow and drag flow, and the direction of the shearing plane. The stretch of the minor phase increased with axial distance. Mixing was relatively insensitive to the initial feed conditions. The results of the studies on the dependence of mixing on extruder dimensions and operating conditions were in qualitative agreement with Mohr's analysis (Mohr et al. 1957).

The initial morphology generated during the melting and mixing stages in an extruder is important in the development of the final morphology of the extrudate. Lindt and Ghosh (1992) suggested that an abrupt morphological change occurs during the simultaneous melting and striation formation in the melting zone in an SSE. Within a fraction of a second, the scale of mixing drops by several orders of

magnitude. High stress in the thin molten film in the melting zone causes a reduction of striation thickness of the minor phase. The lamellar layers may be developed when the minor component pellets melt at the interface between the melt film and the solid bed. The layers could become threads as they undergo breakup. Finally, the threads change into droplets, as they are broken.

Scott and Macosko (1991) proposed a mechanism of morphology development based on experiments carried out in a batch mixer. When the minor component pellet melts, sheets or ribbons of the dispersed phase are formed, due to dragging of the pellets on the hot surface of the mixing equipment. Next, holes are formed in the sheets or ribbons of the dispersed phase, as the interfacial instability starts, and sheet or ribbon morphology changes into a lace structure. Then, the lace breaks into irregularly shaped pieces with diameters equal to the ultimate sphere morphology.

The above two proposed mechanisms incorporate concepts involving distributive and dispersive mixing. Layer or sheet morphology development is mainly due to distributive mixing. Distributive mixing refers to the physical process of blending two fluids such that the physical separation distances are reduced to a scale where diffusion or a chemical reaction can occur (Bigio and Conner 1995). Breakup of layers into threads, laces, or spheres could be attributed to dispersive mixing which is related to instability of the minor phases.

Other studies attempted to develop a model describe morphology evolution during polymer blending in a twin screw extruder. The first model (Shi and Utracki 1992) was based on a simplified flow analysis, and the microrheological considerations of the dispersed-phase drop disintegration. The effects of coalescence were neglected. A later model comprised more refined flow analysis, two mechanisms of dispersion (the fibrillation mechanism and a drop splitting mechanism for low supercritical capillary numbers, with the choice of breakup mechanism based on locally computed microrheological criteria), as well as coalescence effects (Huneault et al. 1995a). The latter effects were taken into account by determining the coalescence constant in Eq. 7.117 from the plot shown in Fig. 7.26. Thus, this model was self-consistent, fully predictive, without any adjustable parameters. The validity of the theoretical assumptions was evaluated by comparing the two model predictions with the experimentally measured drop diameters at different axial positions in the twin screw extruder. Experimentally, after the extrusion reached steady state, the screw rotation was stopped and the molten blend was quenched within a specially designed extruder barrel. It was estimated that the PS/PE blends were quenched within 7–10 s. The second model yielded reasonable predictions of morphology evolution of non-compatibilized blends of PS in PE and of PE in PS.

Based on microrheology, it is possible to expect that (i) the drop size is influenced by the following variables: viscosity and elasticity ratios, dynamic interfacial tension coefficient, critical capillary number, composition, flow field type, and flow field intensity; (ii) in Newtonian liquid systems subjected to a simple shear field, the drop breaks most easily when the viscosity ratio falls within the

range $0.3 < \lambda < 1.5$, while drops having $\lambda \geq 3.8$ do not break under shear; (iii) droplet breakup is easier in an elongational flow field than in a shear flow field; the relative efficiency of the elongational field dramatically increases for large values of $\lambda \geq 1$; (iv) drop deformation and breakup in viscoelastic systems seems to be more difficult than that observed for Newtonian systems; (v) when the concentration of the minor phase exceeds a critical value, $\phi_d > \phi_c \approx 0.005$, the effect of coalescence must be taken into account; (vi) even when the theoretical predictions of droplet deformation and breakup are limited to infinitely dilute, monodispersed Newtonian systems, they can be successfully used for predicting the development of blend morphology during compounding in twin-screw extruders.

Other experiments were conducted in a corotating, intermeshing twin-screw extruder using the same PE/PS system as described above (Huneault et al. 1995b). The screw geometry consisted of five zones: melting, melt conveying (no pressure), mixing (kneading), pumping, and flow through a die. The specimens were scooped from three ports and quenched within a second. After dissolution of the matrix, the dispersed phase was divided into fibers and droplets, characterized separately. Immediately after melting, the dispersed phase formed into fibers and droplets, both with diameters below 10 μm. Contrary to the previous model assumptions, fibers did not break in the unfilled conveying region that followed the melting section. Instead, they were mainly destroyed in the kneading section. Fibers were present after melting even at concentrations of the dispersed phase as low as 2 wt%. The effect of increasing the concentration was not only to increase the final diameter of droplets but also to increase the fiber content. The observations indicated that coalescence was not limited to drops. However, near the die, the average drop diameter did decrease to about $d \cong 1$ μm range (as observed earlier).

Cho and Kamal (2002) derived equations for the affine deformation of the dispersed phase, using a stratified, steady, simple shear flow model. It includes the effects of viscosity ratio and volume fraction. According to the equation, for viscosity ratio > 1, the deformation of the dispersed phase increases with the increase of the dispersed phase fraction. For compatibilized PE/PA-6 blends at high RPM (i.e., 100, 150, and 200 RPM) in the Haake mixer, the particle size decreases with concentration of the dispersed phase up to 20 wt%. This occurs because the total deformation of the dispersed phase before breakup increases as the volume fraction increases, and coalescence is suppressed. The increase of the particle sizes between 20 and 30 wt% results from the increase of coalescence due to the high dispersed phase fractions. The data for 1 wt% blends suggest that mixing in the Haake mixer follows the transient deformation and breakup mechanism, and that shear flow is dominant in the mixer.

Clearly, the microrheology of polymeric systems is more complex than the classical microrheology of Newtonian, low viscosity liquids. Near the liquefaction point (either T_m or T_g) the viscosity is of the order of 10^{12} Pas, and the relaxation time is of the order of 100 s (Angell 1997). As temperature

increases along the barrel, these values decrease according to the Vogel–Tamman–Fulcher relation:

$$\eta = \eta_o \exp\{B/(T - T_o)\}$$
$$\tau = \tau_o \exp\{B/(T - T_o)\}$$
$$\text{where}: \quad T_o \approx T_g + 50 \tag{7.118}$$

The long relaxation times are responsible for nonequilibrium structures, generated by the mechanical action of the compounding equipment that is not taken into account by microrheology. The microrheological model provided good agreement with the experimental data obtained after 7–10 s quenching. However, these data were on purpose collected from the second half of the TSE barrel, where the temperature was reasonably stable (isothermal model). Evidently, evolution of blend morphology is more complex than a simple, "steady-state" model can predict. The rapid variations of morphology will be particularly important for computations of reactive compatibilization.

The evolution of morphology along the extrusion direction, in a twin screw extruder, for thermoplastic vulcanizates (TPVs) and TPV nanocomposites at high EPDM content during dynamic vulcanization was studied by Mirzadeh et al. (2013). Figure 7.27 shows that the coarse co-continuous morphology in the first mixing zone changed to droplet matrix structure, as a result of cross-linking of the rubber phase. The breakup of highly elongated threads observed in the second mixing zone led to a line of small rubber droplets in the third mixing zone. It seems that the TPV nanocomposites reach this morphological state sooner due to the faster cross-linking reaction. Morphology evolution continued by the transition of the droplets into a network made by irregular rubber particles in the second and third mixing zones. The SEM micrographs of the samples taken from the die exit showed the coexistence of a small number of rubber droplets in the vicinity of the smaller irregular rubber particles connected to each other by some rubber fibrils. The existence of irregular shape rubber particles was also observed by Shahbikian et al. using the AFM technique (Shahbikian 2010). The evolution of morphology in this case is in agreement with the conceptual mechanism of morphology evolution in thermoplastic vulcanizates proposed by Bhadane et al. (2006). They suggested that a network (namely, β-network) forms due to the viscosity mismatch between the non-cross-linked rubber (in the center of rubber domains) and cross-linked rubber (at the outer envelope of the rubber phase), during the dynamic cross-linking. Again, it is obvious that the drop size changes during processing in the case of reactive blends are also complex.

Different morphological changes during blending were reported by Sundararaj et al. (1992, 1995). Similar morphological features were observed for reactive or nonreactive blends in an extruder, internal mixer, or a miniature cup-and-rotor mixer. Initially, during melting, the polymers were stretched into sheets and ribbons, which broke into fibers, then in turn into drops. However, the two studies reported different morphologies, most likely due to differences in the concentration of the dispersed phase (5 % and 20 %, respectively).

7.5.3.4 Mixing and Blending in Extensional Flow Field

Most works on liquid mixing in the extensional flow field considered convergent flow of a Newtonian liquid from a reservoir to a capillary (Tsebrenko et al. 1974, 1976; Ablazova et al. 1975; Krasnikova et al. 1978; Han and Funatsu 1978; Chin and Han 1979, 1980; Han 1981; Han and Yu 1981; Suzaka 1982; Vinogradov et al. 1982; Utracki et al. 1986). A device capable of mixing polymeric liquids (having widely ranging viscosity ratios) in an extensional field was constructed (Nguyen and Utracki 1995). The extensional flow mixer, EFM, was designed incorporating the following principles, based on the microrheological analysis:

1. The blend must be exposed to the extensional flow fields and to semi-quiescent zones.
2. The convergences and divergences should be of progressively increasing intensity.
3. The convergent–divergent flow should be generated in the radial not axial direction.
4. To reduce the pressure drop, and to prevent blockage, slit restrictions should be used.
5. The extensional flow mixer must be adjustable.
6. The rate of flow, upstream from the plates, should be approximately constant.

In EFM, the material flows from the rim between two facing each other circular convergent–divergent plates with ridges, toward the opening in the center of the lower plate. To assess the relative merit of the extensional mixing, EFM was attached to an SSE. For comparison, the blends were also prepared in a corotating, intermeshing TSE. The same temperature profiles were used for SSE + EFM as for TSE. In all cases the dispersed phase was significantly more viscous than the matrix, $\lambda \geq 4$. The efficiency was judged considering:

1. The degree of dispersion in PS/PE blends of PS with either 5 or 10 wt% HDPE. At the exit from SSE + EFM, either fibrillar or nodular morphology was observed. The number average fiber diameter decreased with pressure across the c–d plates from $d_n = 1.2$–0.7 μm to d = 0.2–3 μm, at respectively P = 10.3 to 18.6 MPa. The blends prepared in a TSE showed much coarser morphology, containing mainly infinitely long HDPE fibers with diameter varying from d = 1 to 10 μm.
2. The results of PP impact strength improvement by incorporation of EPR are summarized in Fig. 7.28. As evident, impact strength at room temperature increased with EPR content. Clearly, SSE + EFM compounding resulted in higher impact strength (points) than that obtained from TSE (broken line).
3. The ability to homogenize resins with widely different molecular weight can be exemplified by UHMWPE/HDPE blends. Addition of high MW polymer is expected to increase G′, G″, η, and the first normal stress coefficient, Ψ_1. For the linear polymers, these parameters at low deformation rates, η_o and Ψ_{1o}, are proportional to $M_w^{3.5}$ and M_w^7, respectively. Thus, the elasticity is more sensitive to the high MW fractions. For this reason, the frequency dependence of the storage modulus ratio G′(blend)/G′(PE), at 200 °C, for HDPE and its blends with 3 wt% UHMWPE was measured. The blends prepared in TSE had the worst
Fig. 7.28 Effect of EPR addition on PP's notched impact strength at room temperature. The specimens were prepared either in a TSE (*horizontal lines*) or in an SSE/EFM with c–d plates #2. In the latter case the results depended on the pressure drop across EFM (Utracki and Luciani 1996)

performance: G′ at ω = 0.01 rad/s increased by 90 %, while in EFM + SSE the increase was up to 210 % at P = 18.6 MPa.

4. Elimination of gel particles in the reactor powder. The gel particles can form during polymerization of EVAc or TPO. Since they may be considered very high molecular weight fractions of the same resins, SSE + EFM was used to eliminate or reduce the blemishes and improve the mechanical performance. On both counts, the performance was found at least equivalent to that obtained using a TSE.

One may calculate the pressure drop, ΔP, in EFM starting with well-known expressions (Cogswell 1972; Binding 1988; Tremblay 1989). An expression derived from Binding's theory was found to provide excellent prediction (no adjustable parameters) of the pressure across EFM.

Historically, the counterrotating TSEs were known as "calendaring" extruders, with high stresses existing between the two screws and low stresses outside this region. Owing to the high calendering pressures, the screws could rub against the barrel causing premature wear. Thus, slower speeds (up to 150 rpm) and large intermeshing gaps were recommended. One of the advantages of these counterrotating machines has been the presence of the elongational flow field within the calendering zone. The machines have been successfully used in numerous applications requiring high dispersive stresses.

The analysis of TSE performance resulted in modification of the screw profiles (higher free volume of the process), as well as in development of new mixing (or kneading) elements. The increased free volume (thus slender screw profile) resulted in lowering the average shear rate; thus the screw speeds needed to be

increased. New kneading and mixing elements have been designed to improve either the distributive or dispersive mixing. The kneading blocks (mono- and bi-lobal, to be used either in co- or counterrotating TSE, the tri- and hexa-lobal only in counterrotating TSE) were designed to maximize the extensional flow field within the lobal pools and reduce the shear field in the intermeshing and overflight regions. These designs improved mixing capabilities greatly, even for polymeric systems having large differences in the rheological flow parameters (Thiele 1995).

The influence of these complex flow fields on morphology development in blends of HDPE/PA6 (Wang 2005) and also immiscible polymer blends of PS/PMMA (Mours et al. 2003) was investigated. Droplet formation, breakup, and coalescence in these flows were studied by different microscopic techniques. The results showed that drop deformation and breakup were sensitive to both shear and extensional flow fields. However, extensional flow was more effective than shear flow in generating well-developed laminar phase. The main conclusion of these attempts points out the significant effect of the elongational flow fields on the final morphology. Therefore, it should be emphasized that the description of shear flow alone is insufficient for modeling purposes in processing machines (Mours et al. 2003).

7.5.4   Flow-Imposed Morphology

In this part, focus will be on the changes of morphology imposed by different flow fields and on the influence of variations in morphology on flow behavior. It must be evident that the degree of dispersion and the type of structure strongly relate to the type and intensity of imposed stresses during flow. Note that both concentrated suspensions and emulsions show yield stress and time-dependent flow. These macroscopic observations are related to the structural changes occurring on the microscale. Similar behavior of polymer blends is to be expected. One has to keep in mind that, during polymer processing, neither the thermodynamic miscibility, the macromolecular configuration (e.g., entanglement), nor the morphology is in an equilibrium state.

Most models of the morphological changes in polymer blends assume that an average response (e.g., an average size drop is being broken, or average size drops coalesce) provides good representation of the whole system. This assumption should be reasonably correct for blends with narrow distribution of drop sizes. However, there are reports in which (e.g., during the initial stages of blending in a twin-screw extruder) the domain sizes may differ by three orders of magnitude. Here the "average size" response may not be valid. A kinetic theory of structure development in moderately concentrated polymer blends was proposed (Patlazhan and Lindt 1996). The breakup and coalescence under steady-state shearing were considered, assuming a temporal population balance. This development provides a framework for incorporation of the elementary phenomena of drop breakup and coalescence to an overall model.

The effect of flow on miscibility of polymer blends is another area of industrial importance. There is evidence that during processing, the imposed stresses can change the critical temperature by at least 60 °C, causing miscibility inside the processing equipment. The blends, upon release of pressure, may undergo spinodal decomposition that results in superior performance (Inoue 1993).

Flow may also result in mechanochemical degradation processes that generate reactive sites, viz., radicals, peroxides, acids, etc. Furthermore, transesterification and ester–amide exchange reactions are well documented. These reactions affect the phase equilibrium as well as the regularity of the chain structure, thus dispersion in the blend and its crystallinity.

Blend morphology refers to the spatial arrangement of the blend components forming either a dispersed, a stratified (e.g., lamellar or a sandwich-type), or a co-continuous structure. Generation of morphology depends on the viscosity and elasticity ratios of the polymeric blend components (at constant stress). Both ratios vary with the type and the intensity of the flow field. While the viscosity ratio seems to control the ease of dispersing the component, thus the degree of dispersion, the elasticity ratio contributes to shaping the phases – the type of morphology. Two other pertinent parameters are the concentration and the level of interfacial interactions. To modify the interfacial energy, blends are usually compatibilized either by the addition of compatibilizer or by reactive blending. Once formed, the morphology needs to be stabilized against a possible destruction during the forming steps.

The rheological properties of a two-phase system depend not only on the rheological behavior of the components but also on the size, size distribution, and the shape of the discrete phase droplets dispersed in the continuous matrix phase. Flow affects morphology in two different ways:

- It changes the degree and type of dispersion at the local level, viz., drop breakup and coalescence.
- It causes migration of the dispersed phase, thus imposing global changes of morphology in the formed parts, viz., skin-core structures, weld lines, blush lines, etc.

In consequence, the flow-imposed morphologies can be classified as (i) dispersion (mechanical compatibilization), (ii) fibrillation, (iii) lamellae formation, (iv) coalescence, (v) interlayer slip, (vi) encapsulation, etc. These types will be discussed below under appropriate headings.

There is a reciprocal relation between morphology and flow behavior. Plochocki (1978, 1983) defined the particular rheological composition (PRC) most frequently observed in polyolefin blends. At PRC the $\eta = \eta(\phi)$ function reaches a local maximum or minimum. The existence of the maximum is related to a change of the dispersed phase, e.g., from spherical to fibrillar or from dispersed to co-continuous, while that of the minimum is related to a reciprocal change and/or to variation of the specific volume.

Table 7.8 provides a partial reference to studies on the effects of flow on the morphology of polymer blends (Lohfink 1990; Walling 1995). The dispersed phase morphology development has been mainly studied in a capillary flow. To explain the fibrillation processes, not only the viscosity ratio but also the elasticity effects and the interfacial properties have to be considered. In agreement with the microrheology of

Newtonian systems, an upper bound for the viscosity ratio, λ, has also been reported for polymer blends – above certain value of λ (which could be significantly larger than the Newtonian value of 3.8) the dispersed phase could not be deformed. By contrast, lower bounds of λ were not established for polymer blends.

Incorporation of compatibilizers (a third phase) into immiscible blends improves the adhesion between blend phases and helps to achieve mechanical properties comparable to those of homopolymers. The formation of lamellar structures with specifically designed arrangement of the dispersed phase in the matrix phase could provide barrier properties comparable to those achieved in multilayer parts.

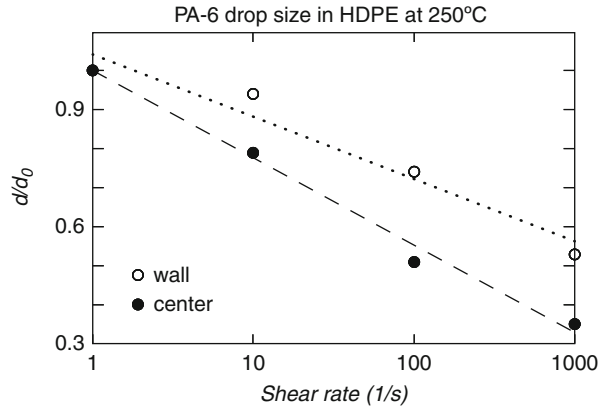
7.5.4.1 Dispersion

Microrheology can provide information regarding the temporal evolution of the drop diameter, d, under steady-state shearing, in the absence of coalescence. Assume that drops breakup occurs only if the shearing time at each appropriate shear stress exceeds the required time to break, $t > t_b$ (for shearing times $t < t_b$ the average drop remains unchanged). Then, Eq. 7.115 yields the following expression for the relative change of drop diameter as

$$
\begin{aligned}
&\ln(d_o/d) = \dot{\gamma}\,(t - t_b)/3\kappa_{cr}t_b^* = [(\gamma/\gamma_b) - 1]/3 \\
&\text{since}: \quad \gamma_b \cong 2 \quad \rightarrow \quad \therefore d = d_o\exp\{(1 - \gamma/2)/3\}
\end{aligned}
\tag{7.119}
$$

Since derivation of this relation considered only the drop-splitting mechanism and neglected coalescence, its validity may be limited to small capillary numbers, $\kappa^* = 1\text{–}2$, and low concentrations.

The drop diameter usually decreases with an increase of shear rate (see Fig. 7.29). However, microrheology indicates that there are different mechanisms operating in different flow types (e.g., shear and elongation) or at different field intensity. Furthermore, there is usually a difference in the quench time between the outer layer and the core of specimen. The data in Fig. 7.29 were obtained using capillary flow. The morphology was affected by the extensional flow field upstream

Fig. 7.29 Reduced drop diameter versus rate of shear at 250 °C. The blend comprising 10 wt% PA-6 in HDPE was extruded through a capillary with the L/D = 40 (Utracki et al. 1986)


from the die, shear flow (and flow-induced encapsulation) inside the die, and slower cooling in the center than at the core of the extrudate. After such complex morphological changes, empirically the drop diameter decreases with logarithm of the deformation rate, $d/d_o = 1 - a_o \ln \dot{\gamma}$, where $a_o \cong 0.3$–0.6 is a material parameter.

Huang et al. (2008) simulated the effect of three different screw geometries on morphology development of an immiscible polymer blend based on polypropylene/polyamide-6 (PP/PA 6). Samples collected from four different points along the extruder using a specially designed sampling device during blending by conventional screw elements, a fluted mixing element, and also by pineapple mixing element. Morphology evolution was evaluated using scanning electron microscopy, and it was interpreted considering the flow fields occurring along screw elements. The coarsest and most nonuniform morphology at the exit of the extruder was produced with the screw with conventional screw elements, whereas the finest and most uniform morphology was produced using the screw with a fluted mixing element. The chaotic mixing characteristic of the pineapple mixing element produced thin laminar layers of dispersed phase (Huang et al. 2008).

7.5.4.2 Fibrillation

The mechanism responsible for formation of fibers or fibrils is extensional, e.g., at the entrance to a capillary. Once inside the capillary, the blend undergoes shear flow, with intensity dependent on the radial position. The evolution of morphology of PMMA blends with core-shell elastomeric latex particles, poly(butylacrylate-*co*-styrene) was studied (Bousmina and Muller 1996). It was found that, within the plug flow region, the particles were randomly distributed, but in the outer part of the extrudate the particles were aligned into straight pearl strings. Had coalescence been possible, these would form fibers. The authors proposed a mechanism for string formation within the steady-state shear zone of the flow field. It is possible to postulate that there are at least two possible fibrillation mechanisms: the extensional flow at the entrance to capillary and the "stringing" process described by Bousmina and Muller.

Fig. 7.30 Stress-dependent values of the orthogonal axis of deformed polypropylene drops in shear at 250 °C. The blend comprised PP/PA-6 = 1:5, with and without an acrylic compatibilizer, AA (Søndergaard et al. 1992)
Stress-induced fibrillation occurs under steady-state shearing or elongation when $\kappa > 2$. Under these conditions, the dispersed phase is co-deformational with the matrix. Since the capillary parameter is proportional to diameter (viz., Eq. 7.52), it is easier to fibrillate coarser dispersions at concentrations exceeding a limited value: $\phi_{\text{limit}} \approx a\lambda^b$, where the numerical values of a, b depend on the blend (Krasnikova et al. 1984).

Fibrillation is also affected by the presence of a compatibilizer. From the perspective of the capillary parameter, κ, addition of a surface tension modifier has two effects: it lowers the interfacial tension coefficient (thus increasing κ) and decreasing the initial drop diameter (thus increasing κ) – the net result is difficult to predict. An illustration is provided in Fig. 7.30. Here PP drops in PA-6 matrix were observed during shearing in a cone-and-plate geometry, without and with an acrylic compatibilizer, AA. For both systems, the dimensions (long and short axes of a prolate ellipsoid) were approached a plateau at shear stress $\sigma_{12} \geq 10$ kPa. Evidently, the plateau value of the long axis, $a_1 = L$, was higher for the system without AA than that with it. However, the rate of elongation indicates that AA facilitated the fibrillation process (Søndergaard et al. 1992).

Tsebrenko et al. (1976) reported on fibrillation of POM in a copolyamide (CPA) matrix as a result of flow through a capillary. Fine fibrils with diameters of about 20 μm and length 3.2 mm were obtained during extrusion at $T = T_m(\text{POM}) + 6$ °C. The low extrusion temperature facilitated stress-induced crystallization of the POM fibers, preserving the morphology engendered at the entrance to the spinneret.

As evident from data in Table 7.9, fibrillation of POM in poly(ethylene-*co*-vinyl acetate), PEVAc, strongly depended on the viscosity ratio, λ (Tsebrenko et al. 1982). These data also indicate that for low-viscosity dispersed phase, the coalescence that results in formation of plate-like objects complicates the blend morphology. Furthermore, since the diameter of the fibrils remains virtually constant, low-viscosity ratios result in short fibers. On the other hand, for $\lambda \geq 1.7$, the diameter drops again and platelets were detected. In short, for the best results $\lambda \cong 1$ is preferred.

Table 7.9 Effect of viscosity ratio on fibrillation of POM in POM/PEVAc = 20/80 (Tsebrenko et al. 1982)

| λ = ηd/η_m | d ± σ (μm) | Number of fibrils | POM dispersion form (wt%) | | |
			drops	Fibers	plates
0.35	5.3 ± 2.5	61,500	0	83	17
0.91	4.2 ± 1.8	13,200	0	100	0
1.05	5.5 ± 3.6	6,800	0	100	0
1.70	6.2 ± 3.6	4,300	0	80	20
4.10	7.3 ± 5.8	4,400	48	50	2

Polymer blends were prepared comprising a poly(etheresteramide) block copolymer, PEBA, with liquid crystalline copolymers, LCP (Champagne et al. 1996). The minor component was deformed into fibrillar-type morphology that enhanced the mechanical properties in the draw direction, in a manner comparable to unidirectional continuous-fiber reinforced composites. Films prepared using a single screw extruder were melt drawn on calendering rolls. The storage modulus of blends containing 30 wt% LCP increased with draw ratio, DR ≤ 12, nearly 50-fold in comparison to neat PEBA (from 18 MPa to almost 1 GPa). The blend morphology was characterized by dissolving the PEBA matrix, followed by gravimetric and microscopic analysis of the LCP phase. As expected, the average fiber diameter decreased as a function of $DR^{-0.5}$. It was noted that only relatively large drops were deformed into fibers, leaving nearly 50 % of LCP in the form of small dispersed nodules. The fiber content as a function of DR followed a trend parallel to that of the mechanical properties. Longitudinal and transverse moduli followed the Halpin-Tsai predictions for unidirectional fiber composites. Properties of compression-molded specimens prepared from these blends compared favorably with glass fiber composites.

Drop deformation in shear that leads to fibrillation was examined using microscopy, light scattering, and fluorescence (Kim et al. 1997). They selected systems near the critical conditions of miscibility, thus where the flow affects miscibility and reduces the value of ν_{12}. The drop aspect ratio, p, plotted as a function of the capillary number, κ, showed two distinct regimes. For $\kappa < \kappa_{cr}$, p was directly proportional to κ, whereas for $\kappa > \kappa_{cr}$, p followed more complex behavior, with an asymptote that corresponds to flow-induced homogenization.

7.5.4.3 Lamellar Morphology

Lamellar morphology occurs in flow regimes where the dispersed phase undergoes two dimensional stretching with the formation of multilayers. In immiscible blends, such a structure may enhance barrier properties when the dispersed phase is a barrier material (e.g., PA, EVAl) and the matrix phase is a commodity polymer (e.g., PE, PP, etc.). Well-developed lamellas increase the length of the pathway for permeants diffusing through the blend. The longer path causes a lowering of the concentration gradient across the blend material, thus reducing the mass flux or permeability.

Subramanian (1985, 1987) was the first to develop a method for generating lamellar morphologies in polymer blends during melt processing. The method has been used to impart permeability barriers to low-cost polyolefins, PO, using small amounts of a barrier polymer. For example, blending under controlled conditions HDPE and a modified polyamide, either PA-6 or PA-66, led to compositions that during the subsequent blow molding or film blowing, generated lamellar PA dispersions. In particular, the lamellar morphology blends of PE and PA-6 were produced in a blow-molding machine. The product exhibited good barrier properties. The optimum performance was obtained using 18 wt% PA. The work resulted in commercialization of the *Selar*™ technology.

PP/EVAl blends with lamellar morphology were produced either in a single screw extruder with a specially designed die (Lohfink and Kamal 1993), using the injection molding machine (Walling 1995; Walling and Kamal 1996), or in an extruder with an annular blown film die (Lee and Kim 1997). To produce PP/EVAl sheets with lamellar morphology, Lohfink and Kamal (1993) designed and constructed a biaxially stretching slit die, which had converging and diverging sections to achieve the desirable extensional flow. In the PP matrix, EVAl lamellae were formed in the sheet core. The optimum barrier performance for oxygen transmission was obtained using 25 wt% EVAl. The barrier properties of the blends were superior to those obtained later in the blow molding process (Walling and Kamal 1996). During the injection molding of PP/EVAl blends, a complex morphology was obtained. In the core region, small relatively undeformed EVAl particles were found. By contrast, in the high shear zone near the skin, lamellas were present. Formation of the lamellar structure was enhanced by increasing EVAl concentration, compatibilization, and reduced mold thickness (Walling 1995; Walling and Kamal 1996).

The study by Kamal et al. (1995) showed that it is possible to control the flow-induced morphology to generate discontinuous overlapping platelets of PA-6 or EVOH dispersed phase in a polyolefin matrix phase. They considered the effects of feeding order, melt temperature, composition, compatibilizer level, die design, screw type, and cooling conditions. The results confirmed that screw type and processing conditions are key factors in developing a laminar morphology. For example, the combination of metering screw, 1.0 mm die exit gap, and 270 °C die temperature results in a laminar morphology. However, a mixing screw, 0.5 mm die exit gap, and 250 °C die temperature lead only to an alignment of the PA-6 domains in the flow direction without well-developed laminar morphology. For the optimized case, the toluene permeability of extruded ribbons of HDPE/PA-6 blends was found to be in the range of values obtained only with multilayer systems (Kamal et al. 1995).

In another attempt, the effects of processing conditions, such as different screw speeds, screw geometries, metering and mixing screws, on the morphology of the extruded ribbons of HDPE/PA-6 blends prepared by single screw extruder equipped with a convergent die were studied by Huang et al. (2005). The results showed that, in contrast to previous studies, even with a viscosity ratio larger than one, a laminar morphology with an aspect ratio of about 100 could be generated by appropriate combination of the screw type and shear intensity. Also, the formation of

well-developed laminar PA-6 phase is more effective using an extensional flow field rather than shear flow (Huang et al. 2005).

Morphology of blends is strongly influenced by the mixing mechanism. Well-developed lamellar morphology is produced when deformation of the minor phase is high, and its breakup is minimized. Coalescence of the deformed minor phase could also contribute to lamellar morphology (Lohfink and Kamal 1993). Thus, from the microrheological point of view, the best results are to be expected from systems where (1) the domain size of the dispersed phase is relatively homogeneous, with d $\cong$ 50 μm; (2) the viscosity of the dispersed phase is lower than that of the matrix, i.e., $\lambda < 1$ (which is not in agreement with the work done by Huang et al. (2005)); (3) the dispersed phase shows a strain hardening behavior. Breakup of the minor phase has been discussed in detail in the former sections.

Kinematics of Mixing

Spencer and Wiley (1957) found that the deformation of an interface, subject to large unidirectional shear, is proportional to the imposed shear and that the proportionality factor depends on the orientation of the surface prior to deformation. Erwin (1978) developed an expression, which described the stretch of area under deformation. The stretch ratio (i.e., deformed area to initial area) is a function of the principal values of the strain tensor and the orientation of the fluid. Deformation of a plane in a fluid is a transient phenomenon. So, the Eulerian frame of deformation that is traditionally used in fluid mechanical analysis is not suitable for the general analysis of deformation of a plane, and a local Lagrangian frame is more convenient (Chella 1994).

A general equation for the kinematics of distributive mixing was developed in a Lagrangian frame. The degree of mixing was described in terms of inter-material area density, or striation thickness, which could be obtained experimentally. Using an ideal laminar mixing model, the thickness of an individual particle of the minor phase was expressed as $\delta_d = 2\phi_1/a_v$, where ϕ_1 is the volume fraction of the minor phase and a_v is the interfacial area density (Ottino et al. 1981). As a result of deformation, the lamellar thickness and the interfacial area density change with the local strain, γ_l, viz., $\delta_d = \delta_d^o/\gamma_l$; $a_v = a_v^o \gamma_l$, where the symbols with upperscript "o" indicate the initial conditions. For simple shear flow deformation, when the deforming interface has the same direction as the flow, the local area strain is related to the linear strain of the flow field, $\gamma = t\dot{\gamma}$:

$$\delta_d = \delta_d^o \left[1 + (t\dot{\gamma})^2 \right]^{-1/2} \tag{7.120}$$

The above equation could be used for the interpretation of lamellar morphology development, when breakup of the minor phase is excluded, and the interfacial tension coefficient is vanishingly small.

Parameters Determining Lamellar Morphology Development

Distributive lamellar mixing depends on the deformation rate, deformation time, and the initial direction of the interface. The degree of mixing increases as the

deformation rate and time increase. The initial direction of the interface, favorable for maximum mixing, is also needed for achieving a high degree of mixing (Ottino et al. 1981).

Lohfink and Kamal (1993) observed that, in single screw extrusion through a flat die, an increase of die gap size yielded fewer, but thicker layers. On the other hand, a smaller die gap size resulted in an increased number of stacked thin layers. Higher screw rpm produced a more pronounced lamellar structure. In real mixing equipment, such as an SSE, deformation time (residence time) could be limited by the deformation rate (screw speed). Lee and Kim (1997) reported that an increase in screw speed reduced the degree of mixing, because the residence time decreased and the minor phase melting was insufficient.

The viscosity ratio, λ, is one of the major parameters in determining the deformation of the minor phase layer. When the viscosity ratio varies from zero to infinity, Taylor's Eq. 7.49 predicts that deformability of a small drop would change from 1.0λ to 1.18λ. For viscoelastic systems, Gonzalez-Nunez et al. (1993) and Lee and Kim (1997) obtained higher deformation for lower viscosity ratio, when they changed the viscosity ratio by changing the viscosity of matrix material.

Lamellar morphology development also depends on the volume fraction of the minor phase. The individual thickness of EVAl phase in PP matrix phase decreased when the concentration of EVAl phase decreased from 30 to 20 vol% (Kamal et al. 1995). In the experiment, for the processing conditions the viscosity ratio was $\lambda > 1$.

The minor phase layers become thinner as interfacial tension coefficient, v_{12}, decreases (Kamal et al. 1995; Lee and Kim 1997). This confirms that the decrease of v_{12} results in a more efficient transfer of stress from the matrix to the minor phase layer (Gopalakrishnan et al. 1995). As the v_{12} is reduced further, the layers of minor phase transform into fibers (Kamal et al. 1995). These results are in agreement with the morphology development mechanisms (Ottino et al. 1981; Lindt and Ghosh 1992; Scott and Macosko 1991).

7.5.4.4 Coalescence

Droplet–droplet coalescence was already discussed in Part 9.4.2.2. Here, the effects of coalescence on morphology will be summarized. Under normal circumstances, there is a dynamic equilibrium between coalescence and dispersion processes; thus it is difficult to assign a particular effect as due to coalescence. However, during flow at temperatures near the melting point, the effects of coalescence dominate the final morphology. For example, blends of HDPE with up to 30 wt% of PA-6 were extruded using a capillary viscometer at T = 150, 200 and 250 °C. All the extrudates contained PA-6 fibrils, independently at T below or above the melting point of PA-6, $T_m = 219$ °C (Utracki et al. 1986). Judging by the diameter of the resulting PA-6 domains and their internal structure, the fibrillation originated mainly from the flow-induced coalescence.

For capillary flow at 150 °C, the extensional stress, $\sigma_{11} = 50$–800 kPa, at the entrance to capillary was calculated from (Cogswell 1972)

$$\eta/\eta_E = 2\tan^{-2}\alpha; \quad \alpha = \arctan(2\dot{\varepsilon}/\dot{\gamma});$$
$$\sigma_{12}\dot{\gamma} = 2\sigma_{12}\dot{\varepsilon} \tag{7.121}$$

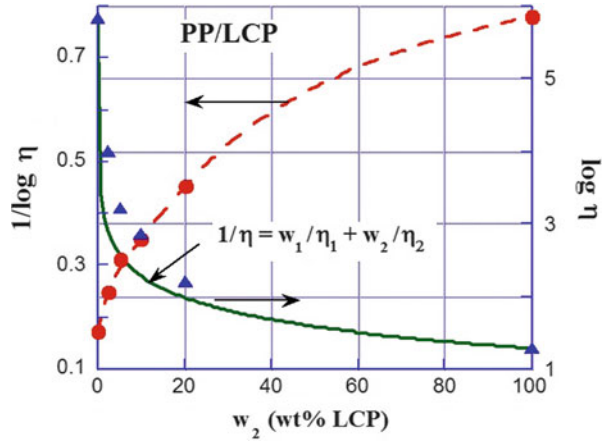
Since the tensile yield stress for "solid" PA-6 at 150 °C was determined as $\sigma_y = 15$ kPa, independent of the rate of straining, the extensional stress in the capillary entrance was more than sufficient to deform the amorphous part of PA-6. Owing to crystallization, the elongated structures, once created, could neither disintegrate nor elastically retract to spherical shapes.

Similarly, at $T > T_m$, coalescence of semicrystalline dispersed domains combined with stress-induced crystallization leads to formation of long fibers. This effect was explored for the improvement of performance of blends comprising liquid crystal polymers, LCP (La Mantia 1993).

Velankar et al. (2001) conducted shear-induced coalescence experiments on immiscible polymer blends with a droplet–matrix morphology. The study was carried out on model blends of polyisobutylene (PIB) and polydimethylsiloxane (PDMS), with various amounts of a PIB–PDMS diblock copolymer as a compatibilizer. This kind of compatibilizer promotes intimate mixing of thermodynamically immiscible homopolymers through their effect on the interfacial tension between them. The authors determined the mean capillary number of the droplets using dynamic mechanical measurements. The results showed that increasing the amount of a surface-active compatibilizer increased the steady shear capillary number of droplets to values well above the Ca_{cr} required for breakup of uncompatibilized droplets. This suggests that a simple decrease in interfacial tension is not the only effect of adding the compatibilizer to these immiscible blends. The hydrodynamic stress required for breakup of uncompatibilized blends, based on interfacial tension arguments, is lower than that required for breaking compatibilized droplets. Previous simulations by Stone and Leal (1990) and Li and Pozrikidis (1997) indicated the flow-induced gradients in the concentration of the compatibilizer on the droplet surface. Therefore, Valenkar et al. explained their results by assuming the existence of gradients in interfacial tension induced by the gradients of compatibilizer concentration due to flow. Microscopy experiments were in agreement with this interpretation (Velankar et al. 2001).

7.5.4.5 Interlayer Slip

The interlayer slip originates in the low entanglement density region at the interface (Helfand and Tagami 1971, 1972). There is a preponderance of chain ends and the low molecular weight species in the interphase. This leads to the low viscosity – in binary PS/PMMA blends, the interphase viscosity was determined as $\eta_{Interph} \approx 90$ Pas, hence three orders of magnitude smaller than viscosities of the two comprised polymers (Valenza et al. 1991). The net result of the interlayer slip is a drastic reduction of viscosity for mixtures of two immiscible liquids. The phenomenon, first observed for mixtures of low molecular weight liquids, was empirically described, using the fluidity additivity equation. The latter dependence was first derived by Bingham (1922):

Fig. 7.31 Concentration dependence of shear viscosity of PP/LCP blends; dotted line represents the fluidity equation, Eq. 7.122 (Data from Ye et al. 1991)


$$1/\eta = (w_1/\eta_1) + (w_2/\eta_2)$$
$$\text{or general,} \quad 1/\eta = \sum_{1=1}^{n} w_i/\eta_i \tag{7.122}$$

where w_i and η_i are the volume or weight fraction and the viscosity of the component i, respectively (see Fig.. 7.31).

The dependence was re-derived later for a telescopic flow of two polymers through a pipe (Heitmiller et al. 1964). The two liquids formed a large number of concentric layers, each of the same cross-sectional areas. The fundamental condition that leads to the fluidity additivity relation was the continuity of the shear stress across the multi-stratified structure. Lin (1979) followed this derivation with an additional assumption that the shear stress of each layer can be modified by the presence of an additional frictional stress, $Z = (\beta - 1)(R\Delta P/2L)$, where R is the capillary radius, ΔP is the pressure drop, and β is a characteristic material parameter (interlayer slip factor) in

$$1/\eta = \beta[(w_1/\eta_1) + (w_2/\eta_2)] \tag{7.123}$$

For a mixture of two liquids having the same viscosity, $\eta_1 = \eta_2$, Eq. 7.122 predicts additivity, while Eq. 7.123 with $\beta > 0$ predicts a negative deviation form additivity (NDB). For $\beta = 1$ Bingham's relation is recovered. However, there are serious reservations about the fundamental consequences of the frictional extra stress Z (Bousmina et al. 1999). In a rigorous derivation for a telescopic flow with the interfacial slip, the following dependence was obtained:

Table 7.10 Calculated viscosity of the interphase

Blend (1/2)	η_1 (Pas)	η_2 (Pas)	$\eta_{Interphase}$ (Pas)	Reference
POM/CPA	349	583	0.69	Bousmina et al. 1999
PP/PS	214	693	1.64	Bousmina et al. 1999
PE/PS	4000	582	25.22	Bousmina et al. 1999
PS/PMMA	1172	4610	13.31	Bousmina et al. 1999
PS/PMMA	3400	15500	90.00	Valenza et al. 1991

$$1/\eta = (w_1/\eta_1) + (w_2/\eta_2) + \theta\sqrt{\phi_1\phi_2}$$
$$\text{where}: \quad \theta \propto 1/\Delta l\eta_{Interphase} \tag{7.124}$$

Equations 7.123 and 7.124 predict a negative deviation from the log-additivity rule.

The material parameter θ in Eq. 7.124 governs the NDB behavior. It was shown that its value is inversely proportional to the thickness of the interphase, Δl, and its viscosity, $\eta_{Interphase}$ (Bousmina et al. 1999). Theoretically, the same molecular mechanism should be responsible for both factors, viz., better miscibility, better interdiffusion, thus higher Δl and $\eta_{Interphase}$. However, the low molecular weight components of the blend, that are forced by the thermodynamics to diffuse to the interphase, may not change much the former parameter, but drastically reduce the latter. For immiscible blends, Δl is small, typically 2–6 nm. Thus θ is large, and interlayer slip takes place. For compatibilized blends, the macromolecules of the two phases interact and interlace, which increases both factors; thus, the slip effects are negligible. Measured or calculated values of the interphase viscosity are listed in Table 7.10.

Interlayer slip creates a tree-ring structure in extrusion, e.g., observed in samples containing 30 wt% PA-6 in HDPE matrix, extruded at T = 250 °C. The HDPE/PA-6 capillary viscosities at 250 °C followed Lin's Eq. 7.123 (Utracki et al. 1986). The simplest fluidity equation, Eq. 7.122, may be useful in describing steady-state viscosity of antagonistically immiscible polymer blends, such as PP/LCP shown in Fig. 7.31. When the volume of the interphase is known, the general form of the Bingham formula in Eq. 7.122 can be used to calculate the interphase viscosity. This indeed has been done, in the case of shear flow of a multilayer PS/PMMA sandwich (Lyngaae-Jørgensen et al. 1988).

Yang et al. (2003) investigated the rheological behavior of PBT/LLDPE and PBT/LLDPE-*g*-acrylic acid, using a capillary rheometer. They used an equation proposed by Utracki (1991) successfully to depict the viscosity–composition dependence of the blends at low shear stresses. Morphological studies showed a droplet–matrix morphology at low shear rates. On the other hand, at high shear rates, the droplet–matrix morphology at the center of the extruded bar was observed in vicinity of a stratified PBT phase (co-continuous morphology) which contributed to lowering the viscosity of the blending system. This also caused the above equation to fail to predict the rheological behavior of these two systems. It was

concluded that the parameter β (interlayer slip factor) in the equation (see Eqs. 7.123 and 7.125) was related not only to the shear stress but also to the elasticity difference of the two components of the blend, the composition, and the interactions of the blend components at high shear stresses (Yang et al. 2003).

7.5.4.6 Encapsulation

Shear-induced segregation of polymer domains is related to differences in the magnitudes of the rheological properties of blend components. During large strain flow, segregation takes place not only in immiscible blends, in which the viscosities and elasticity of the two phases differ, but also in miscible blends comprising components of different MW. In the latter case, it is the difference in chain lengths that causes an imbalance of stresses and relative motion of the components (Doi and Onuki 1992).

Migration of the low viscosity component toward the high stress regions results in flow encapsulation of one phase by another. The effect has been well documented and successfully explored in polymer processing. For example, this mechanism is responsible for the lubricated, high-throughput flow of POs upon addition of either fluoro- or siloxane polymers. Similarly, enhancement of flow of engineering and specialty resins by incorporation of low viscosity (when molten) LCP is attributed to flow segregation (Utracki 1987, 1988, 1989).

7.5.5   Shear Flows

The easiest way to discuss flow of polymer blends is to compare them to simpler, low molecular weight homologues, viz., Sect. 7.3. For immiscible blends, the best model is that of emulsions. Like blends, emulsions comprise one liquid dispersed in another. The emulsion morphology is stabilized by addition of a surfactant or an emulsifier, similarly as immiscible blend is stabilized by addition of a compatibilizer. Both systems, emulsions and blends, show phase inversion, viz., Sect. 7.3.2. In emulsions, the phase inversion concentration, ϕ_{I1}, depends mainly on the type and concentration of emulsifier, while in blends it is dominated by relative rheological properties of the two polymers. In emulsion technology, by carefully selecting surfactants and the sequence of liquid addition, it is possible to generate (at the same concentration) two emulsions having different morphologies, viscosities, and other properties (Utracki 1989).

7.5.5.1 Concentration Dependence of Viscosity

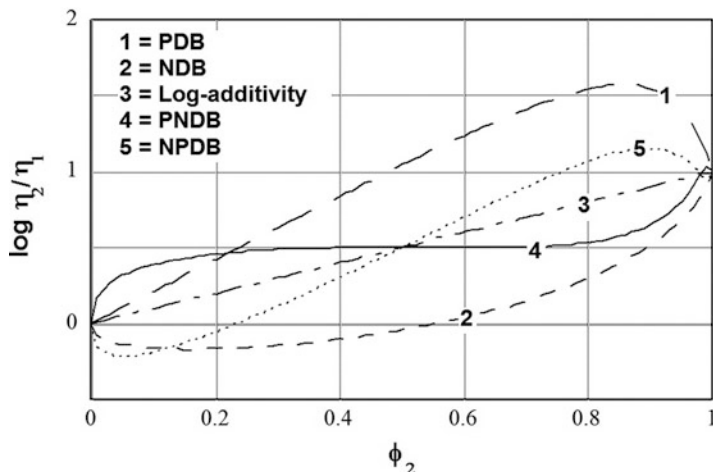
In miscible blends, where the free energy of mixing is negative, $\Delta G_m < 0$, experimental data indicate that, in most system, either the log-additivity rule (see Eq. 7.18) or small positive deviations from it are generally observed. Near the phase separation region, where $\Delta G_m \approx 0$, the rheological response is complex as the free energy of mixing is precariously balanced by the term describing the energy input by the flow. Finally, in immiscible systems, where $\Delta G_m > 0$, five different types of behavior have been identified. In Fig. 7.32, curves


Fig. 7.32 Five types of the relation between shear viscosity and concentration for immiscible polymer blends: *1*. PDB, *2*. NDB, *3*. additivity, *4*. PNDB, and *5*. NPDB (Utracki 1991)

1–5 represent, respectively, (i)) positively deviating blend (PDB), (ii) negatively deviating blends (NDB), (iii) log-additivity, (iv) PNDB, and (v) NPDB (Utracki 1991). To understand the origins of these types of behavior, it is necessary first to evaluate morphology and flow-imposed morphology in polymer blends.

From the discussion of phase inversion in Sect. 7.1.2, the emulsion model predicts that immiscible blends should show positive deviation, PDB, from the log-additivity rule: $\ln \eta = \sum w_i \ln \eta_i$. However, while PDB has been found in about 60 % of such blends, the remaining four types (see Fig. 7.32) must also be accounted for. This means that at least one other mechanism must be considered when modeling the viscosity–concentration dependence of polymer blends. This second mechanism should lead to the opposite effect, which is to the negative deviation from the log-additivity rule, NDB.

The simplest mechanism that explains the NDB behavior is interlayer slip, which leads to derivation of Eq. 7.123 and Eq. 7.124. One may postulate that at constant stress, the net η versus ϕ dependence can be written as a sum of two contributions: the interlayer slip, expressed by η_Λ (calculated from either Eq. 7.123 or Eq. 7.124), and the emulsion-like viscosity enhancement given by an excess term, $\Delta \log \eta^E$ (Utracki 1991):

$$\ln \eta = \ln \eta_L + \Delta \ln \eta^E$$
$$\Delta \ln \eta^E = \eta_{\max} \left\{ 1 - \left[(\phi_1 - \phi_{1I})^2 / \left(\phi_1 \phi_{2I}^2 + \phi_2 \phi_{1I}^2 \right) \right] \right\} \tag{7.125}$$

As mentioned in Sect. 7.1 for polymer blends, the relation between the steady-state shear viscosity and concentration can be quite complex. In the following discussion, the *constant stress* (not the constant rate) *viscosity*, corrected for the

yield and time effects, will be considered. To illustrate flexibility of Eq. 7.125 to
describe (and thus to facilitate interpretation of the rheological results) η versus ϕ,
dependence examples of computations are shown in Figures 7.33, 7.34, 7.35, 7.36,
7.37, 7.38, 7.39, and 7.40.

The numerical values of the phase inversion concentration, ϕ_{2I}, as well as the
two material parameters that enter Eq. 7.125 are listed in Table 7.11.

7.5.5.2 Dynamic Flow

Blend structure changes with flow conditions. Therefore, the observed rheological
responses must be sensitive to method of measurement. Since modification of
structure is related to strain, responses measured at high and low strain values
will be different. For this reason, the selected type of test procedure should reflect
the final use of the data. When simulation of flow through a die is considered, large
strain capillary flow is useful. On the other hand, if material characterization is
important, low strain dynamic testing should be used. Because of morphology

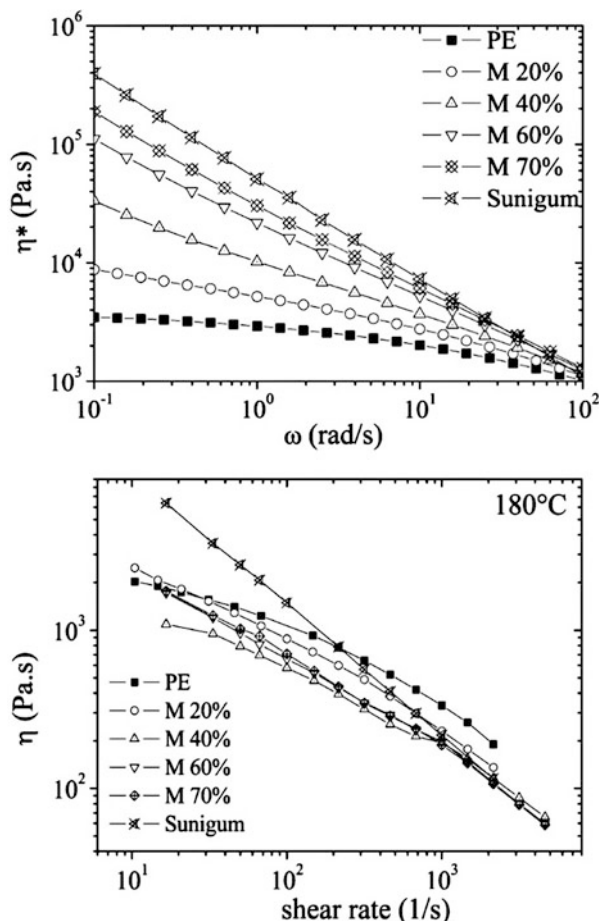
Table 7.12 Comparison of continuum-based predictions for simple fluid with experimental observations for polymer blends

Rheological function	Simple fluid	Polymer blend
Viscosity at vanishing deformation rates	$\eta(\dot{\gamma}) = \eta'(\omega) = \eta_E(\dot{\varepsilon})/3$	$\eta(\dot{\gamma}) \neq \eta'(\omega) = \eta_E(\dot{\varepsilon})/3$
Extensional viscosity (from entrance effects)	$\eta_E = \eta_E(Cogswell)$	$\eta_E \neq \eta_E(Cogswell)$
First normal stress difference (from extrudate swell)	$N_1 = N_1$(B-swell); Tanner 1970	$N_1 \neq N_1$(B-swell)

sensitivity to test conditions, there is a serious disagreement between predictions of the continuum-based theories and experiments. This is summarized in Table 7.12.

A study using confocal Raman spectrometry was carried out to determine the concentration profile within the extrudate of rubbery particles in a polyethylene matrix during capillary flow (Chartier et al. 2010). Chartier et al. reported that the effect of the concentration of particles on the apparent viscosity of polymer melts measured using capillary flow was the opposite of that based on observations made using linear dynamic viscosity measurements (Fig. 7.41). Shear-induced migration can be detected from the concentration profile of the components of the

Fig. 7.41 (*top*) the dynamic viscosity versus frequency and (*bottom*) apparent capillary viscosity of various concentrations of rubber in uncompatibilized PE/Sunigum blends at 180 °C (Chartier et al. 2010)


blends inside the material. They discovered that the lowest viscosity component migrates toward the capillary wall. The addition of a compatibilizers inhibited this migration.

Dynamic testing of polymer blends at small amplitude is a relatively simple and reliable procedure. The resulting storage and loss shear moduli, G' and G'', respectively, should be first corrected for yield stress then the loss data can be fitted to Eq. 7.42 to determine the value of the four parameters, η_o, τ, m_1, and m_2. Once these parameters are known, the Gross frequency relaxation spectrum, and as a result all linear viscoelastic functions, can be calculated (see Eqs. 7.85, 7.86, and 7.87).

The dependence of rheological functions of liquid mixtures on the content and the rheological functions of neat ingredients has been discussed, to some extent, in Sect. 7.3.2.3. A summary of these results is given in Table 7.13.

Table 7.13 Blend viscoelasticity from emulsion models (Graebling and Muller 1991)

Author	Concentration	Liquids	Drops	Results
Taylor 1932	Dilute	Newtonian	Undeformable	$\eta = \eta(\lambda, \phi)$
Oldroyd 1953	Dilute	Newtonian	Deformable	$G', G'', \eta = f(\lambda, \phi, \nu)$
Palierne 1990	Moderately concentrate	Viscoelastic	Deformable, polydispersed	$G^*, H = f(G^*_m, G^*_d, \nu_{12}/d, \phi)$

The last entry in Table 7.13 refers to the theory by Palierne (1990). The theory is based on the following assumptions: (i) the system consists of two viscoelastic liquids; (ii) the concentration of the dispersed phase is moderate; (iii) the drops are spherical, polydisperse, and deformable; (iv) the drop deformation is small, so the blend behavior is linear viscoelastic; and (v) the interfacial tension coefficient, ν_{12}, is constant, independent of stress and interfacial area. The theoretical analysis leads to Eq. 7.70. Note that the ratio ν_{12}/d is the only parameter of the equation. The model was found to provide good description of the dynamic behavior for several blends, supporting the idea that the long relaxation times in blends originate from geometrical relaxation of droplets (Graebling et al. 1989, 1993b).

7.5.5.3 Compatibilization Effects

Most immiscible polymer blends require compatibilization to reduce the interfacial tension. This helps to increase the degree of dispersion to stabilize the morphology developed during compounding against extensive damage during high stress and strain processing (e.g., during injection molding) and to enhance adhesion between the phases in the solid state, facilitating the stress transfer and improving the mechanical properties of the product. Compatibilization is achieved either by addition of a small quantity, 0.5–2 wt%, of a precisely tailored (usually) block copolymer; an addition of a multipurpose core-shell copolymer, ≤ 35 wt%, that also improves toughness of the blend; or by reactive processing.

Compatibilization strategy for either addition or reactive blending requires that the copolymer migrates to the interface, thus, on the one hand, lowering the thermodynamic immiscibility barrier between the two phases, and, on the other, engendering formation of the third phase, the interphase.

From the point of view of blend morphology in the molten state, compatibilization enhances the dispersion, increases the total apparent volume of the dispersed phase, rigidifies the interface, and increases interaction not only between the two phases, but also between the dispersed drops. Furthermore, reactive compatibilization may involve chemical bonding between the two polymer macromolecules, resulting in significant increase of the molecular weight at the interface.

The rheological consequences of these changes can be predicted from a model system. The emulsion model indicates that making the interface more rigid causes the intrinsic viscosity of the emulsion to increase (see Eq. 7.50). Similarly, an increase of the apparent volume of the dispersed phase causes the relative viscosity to increase (see Eqs. 7.24 and 7.25). Furthermore, enhanced interactions between

the phases will reduce the possibility of the interlayer slip and increase formation of associative network formation, which may result in the yield stress. In short, compatibilization is expected to increase melt viscosity, elasticity, and the yield stress.

There are two mechanisms that may invalidate this prediction: (i) In spite of the best efforts of researchers and technologist the added copolymer may prefer to form micelles inside one of the polymeric phases than to migrate to the interphase. This has been frequently observed in blends with block copolymers, e.g., for blends of PS with PE, "compatibilized" by addition of a hydrogenated styrene-butadiene block copolymer, SEBS (Utracki and Sammut 1988, 1990). (ii) Depending on the blend composition, an addition of compatibilizer may affect the total free volume of the system. These changes are difficult to predict. An increase of the free volume (evidenced by reduction of melt density) is expected to result in increased fluidity of the system.

Effects of addition of hydrogenated styrene-butadiene di-block copolymers (one strictly di-block and the other tapered) on properties of HDPE/HIPS blends were investigated (Brahimi et al. 1991). The rheological behavior of the blends, especially in the low-frequency region, was sensitive to the copolymer content. However, at high frequencies, the copolymer only slightly affected the flow. Furthermore, addition of a small amount of compatibilizer reduced the zero-shear viscosity, η_o, while higher loading had an opposite effect. This behavior was interpreted as due to the change in the copolymer state in the blend, i.e., saturation of the interface followed by micelle formation.

The results were compared with prediction of Palierne model, viz., Eq. 7.39. For diluted, uncompatibilized blends, PS/PE = 10/90 or 90/10, relatively good agreement was found. The agreement was poor for blends containing 3 wt% of the tapered di-block copolymer. In the latter case, the reduction of storage and loss shear moduli, especially at low frequencies, could not be explained by the emulsion model. The effect of the interfacial tension and particle size over a relatively wide range did not significantly affect the model predictions. These observations confirmed an earlier report for the same system (Aït-Kadi et al. 1992). Since, at low frequencies, slip is less likely to occur than at high frequencies, low values of G' and G'' could not be explained by this mechanism. The most likely explanation is an increase of the free volume by incorporation of the copolymer. The nonlinear variation of specific volume as a function of composition has been frequently observed for systems with limited miscibility.

Blends of PS with LDPE were compatibilized by addition of di- and tri-block copolymers, *Kraton*™ G 1701 and G 1605 (Pascault et al. 1994). A continuous decrease of PS-drop size and an increase of shear viscosity with addition of copolymer were reported.

Blends of PP with a polyamide (PA-6, PA-66, or PA-12) were the object of intensive studies. Linear viscoelastic shear moduli were measured for PP/PA-6 blends comprising different amount of PP-g-PA-6 copolymer. It was reported that, in spite of the expected reduction of the particle size with increase of the compatibilizer content, no qualitative effect of the flow was observed (Scholz et al. 1989).

In a thorough study, PP, PA-6, and their compatibilized blends were studied at 225–250 °C, in steady-state and dynamic shear, as well as extensional flow conditions (Utracki and Sammut 1992). The dynamic flow curves for the blend were significantly higher than what could be predicted from the component flow behavior. The blends showed a regular, pseudoplastic flow behavior, without yield stress. By contrast, capillary flow was found to be insensitive to temperature, suggesting a major modification of morphology during these large strain tests. Similarly, the extensional viscosity of the blends was one order of magnitude higher than what could be expected from the component polymer behavior. During extensional flow, the blends showed strain hardening, absent for either PP or PA-6. This could be explained by postulating that reactive compatibilization significantly increased the molecular weight of the system – strain hardening is to be expected for highly entangled, high MW systems. It was also reported that the measured elongational viscosity, η_E, for two homopolymers agreed quite well with the value calculated from the entrance pressure drop in capillary flow, P_e. However, for the blend, the calculated value of η_E was one order of magnitude higher than measured.

Reactive compatibilization in a specially designed twin-screw extruder was carried out during compounding maleated polypropylene, PP-MA (0–0.14 wt% MA), with PA-6. During the reaction a di-block copolymer was formed at the interface. As the copolymer content increases from zero to 20 wt%, the number average diameter of PA-6 drops decreased from the initial value $d_o = 20$ to $d = 0.14$ μm at 20 wt% copolymer. The concentration dependence of shear viscosity also changed with compatibilization from negative deviation from the log additivity rule, NDB, to positive deviation, PDB (Nishio et al. 1992).

The effect of compatibilization on the shear flow of PP/PA-6 and PP/PA-12 blends was also studied (Germain et al. 1994). Here the copolymer flow curve was one order of magnitude lower than that of PA. The authors reported that, at low deformation rates, emulsion-type morphology dominated the flow, whereas, at higher rates, concentric layered-type morphology, with appropriate flow behavior, was observed. At low shear rates, the blend viscosity was higher than the viscosity of the matrix, while at high shear rates the contrary was observed. The low shear rate behavior was analyzed by means of Palierne theory, assuming that the copolymer is located at the interface. Good agreement was obtained for the low-concentration blends. For high stress (and strain) deformation, a model of lamellar telescopic flow for power-law fluid was derived. The skin-core model represented the flow of blends well. Thus, it can be postulated that, in blends with low MW copolymeric compatibilizers, the stress may cause its disentanglement from at least one phase, forming a layered morphology, and resulting in flow lubricated by the presence of the low molecular weight compatibilizer.

Effects of addition of a compatibilizing block copolymer, poly(styrene-b-methyl methacrylate), P(S-b-MMA) on the rheological behavior of an immiscible blend of PS with SAN were studied by dynamic mechanical spectroscopy (Gleisner et al. 1994a). Upon addition of the compatibilizer, the average diameter of PS particles decreased from $d \cong 400$ to 120 nm. The data were analyzed using

weighted relaxation-time spectra. A modified emulsion model, originally proposed by Choi and Schowalter (1975), made it possible to correlate the particle size and the interfacial tension coefficient with the compatibilizer concentration. It was reported that the particle size reduction and the reduction of ν_{12} occur at different block copolymer concentrations.

In another attempt, TPVs based on ENR/PP blends were prepared by melt mixing via dynamic vulcanization, using two different types of compatibilizers: phenolic-modified polypropylene (Ph-PP) and graft copolymer of maleic anhydride on polypropylene molecules (PP-g-MA) (Nakason et al. 2006). A high compatibilizing effect was found because of the chemical interaction between the polar groups in ENR and Ph-PP or PP-g-MA. The TPVs prepared from ENR/PP with Ph-PP as a compatibilizer showed the highest rheological and mechanical properties, while those based on ENR/PP exhibited the lowest values. Moreover, the TPV, compatibilized with Ph-PP, showed smaller rubber particles dispersed in the PP matrix, compared to the corresponding TPV based on ENR/PP-g-MA (Nakason et al. 2006).

Huitric et al. (2007) studied the effect of different concentrations of polyethylene-graft-maleic anhydride on the morphology evolution of blends of low density polyethylene and nylon 12, using a method based on quenching following deformation of the samples, which were kept between the parallel plates of a rheometer. They determined droplet size and transient viscosity of the blends as functions of the total strain. The results revealed that the droplet size was governed by coalescence at low strain values. Due to the important interfacial coverage of the interface by the grafted copolymer chains, a significant coalescence inhibition was observed for the blends with high concentration of compatibilizer. In that case, the intensity of the coalescence did not change by the applied shear rate. On the contrary, increasing shear rate favored the coalescence for the blends without compatibilizer or with low compatibilizer concentration. The authors introduced an additional parameter for non-affine deformation (slip parameter) in a modified version of the Lee and Park model. The results showed great improvement in the predictions of droplet size evolution by this adjustment.

Kordjazi and Ebrahimi (2010) investigated the rheological properties and morphology of compatibilized and noncompatibilized PP/PET blends, using SEBS-g-MA as a compatibilizer. They suggested that the behavioral changes of rheological properties by increasing the compatibilizer are related to the aggregation of the dispersed particles encapsulated with elastomeric shell, which is responsible for the failure of Palierne's model predictions. Based on frequency sweep and step strain experiments in the linear region, after pre-shearing using various shear rates, the authors also suggested that the aggregated structure was destroyed and replaced by an alignment in the flow direction (Kordjazi and Ebrahimi 2010).

DeLeo et al. (2011) considered the formation of a compatibilizer between two multifunctional reactive polymers that leads to a cross-linked copolymer at the interface. The study was conducted on model blends PDMS/PI. In this case a chemical reaction between amine-functional PDMS and maleic anhydride-functional PI formed the compatibilizer. The effects of interfacial cross-linking

on rheological behavior and morphological characteristics were found to be highly asymmetric for the samples with PI:PDMS ratio of 30:70 or 70:30. The PI-continuous blends showed unusual features including drop clusters, nonspherical drops, and "gel-like" behavior, which increased by increasing reactive compatibilizer loading. Contrarily, PDMS-continuous blends displayed typical droplet–matrix morphology with round drops and showed liquid-like behavior that was qualitatively similar to that of compatibilizer-free blends. The authors speculated that the asymmetry of the compatibilizer architecture on the two sides of the interface is the factor causing the structural and rheological asymmetry (DeLeo et al. 2011).

Entezam et al. (2012) studied the effect of interfacial activity and micelle formation on rheological behavior and microstructure of reactively compatibilized PP/PET blends. They used different interfacial modifiers, i.e., PTW or PP-g-MAH. They also used dynamic and start-up shear flow experiments as well as their subsequent recovery. Reactive compatibilization, in concentrations close to the critical micelle concentration, at which the interface is saturated with the compatibilizer, changed the rheological behavior from emulsion to solid-like behavior due to the interconnectivity between dispersed phase domains. They suggested that PTW micelles in the bulk phase of the blend favored physical network-like structure formation and enhanced the time and intensity of the relaxation process. However, the PP-g-MAH micelles restricted interconnectivity between the dispersed domains. The analysis of fractional Zener models (FZMs) showed nonzero value of G_e (the elastic modulus of spring element of FZM) for the compatibilized blends with network-like structure. It was suggested that the increase of G_e with formation of PTW micelles and its zero value for the blends consisting of PP-g-MAH micelles indicate a dual role for micelles influencing rheological and morphological properties of PP/PET blends (Entezam et al. 2012).

7.5.5.4 Time–Temperature Superposition

The time–temperature superposition principle, t-T, has been a cornerstone of viscoelastometry. It has been invariably used to determine the viscoelastic properties of materials over the required 10 to 15 decades of reduced frequency, ωa_T (Ferry 1980). Measuring the rheological properties at several levels of temperature, T, over the experimentally accessible frequency range (usually two to four decades wide), then using the t-T shifting, has made it possible to construct the complete isothermal function.

As demonstrated before, the shifting involves three shift factors, one horizontal, usually expressed as $a_T = b_T \eta_o(T)/\eta_o(T_o)$, where $b_T = \rho_o T_o/\rho T$ is the first vertical shift factor that originates in the thermal expansion of the system (ρ is density). The subscript o indicates the reference conditions, defined by the selected reference temperature T_o, usually taken in the middle of the explored T-range. For homopolymer melts as well as for amorphous resins, the two shift factors, a_T and b_T, are sufficient. However, for semicrystalline polymers the second vertical factor v_T has been found necessary – it accounts for variation of

the crystallinity content during frequency scans at different temperatures (Ninomiya and Ferry 1967; Dumoulin 1988).

Only when all the relaxation times in a given system are multiplied by the same factor, when the temperature is changed, the t-T principle can be observed. In single-phase homologous polymer blends, the relaxations are mainly controlled by the segmental mobility; thus the t-T superposition has been observed in a wide range of conditions. Similarly, for polymers filled with high modulus particles, the filler is responsible for enhancement of modulus without affecting the relaxation spectrum, and as a consequence t-T superposition is obeyed. However, in rheologically complex heterogeneous systems, individual polymeric components contribute to the relaxation and since their activation energies are usually different, a change of temperature affects them differently – lack of t-T is a result.

Fesko and Tschoegl (1971) demonstrated that the simplest form of the time–temperature superposition relation for a function $G(t, T) = G[t, a(T)]$ is

$$
\begin{aligned}
[\partial G(t,T)/\partial T]_t &= \left\{[\partial G(t,T)]/[\partial \ln t]_T\right\}\{d[\ln a(t,T)]/dT\} \\
d[\ln a(t,T)]/dt &= \sum_i N_i(t)d[\ln a_i(T)]/dT; i = 1, \ldots, n \\
N_i(t) &= \phi_i L_i(t,T_0)/\sum_i \phi_i L_i(t,T_0) \\
L_i(t,T_0) &= \partial G_i[(\ln t),T_0]/\partial \ln t
\end{aligned}
\tag{7.126}
$$

where the summation extends over every species in the system. Equation 7.126 assumes that the effects of time and temperature can be separated, $G(t, T) = G[t \cdot a(t, T)]$. Similar derivation was published by Goldman et al. (1977).

There is growing evidence that t-T superposition is not valid even in miscible blends well above the glass transition temperature. For example, Cavaille et al. (1987) reported lack of superposition for the classical miscible blends – PS/PVME. The deviation was particularly evident in the loss tangent versus frequency plot. Lack of t-T superposition was also observed in PI/PB systems (Roovers and Toporowski 1992). By contrast, mixtures of entangled, nearly monodispersed blends of poly(ethylene-*alt*-propylene) with head-to-head PP were evaluated at constant distance from the glass transition temperature of each system, homopolymer or blend (Gell et al. 1997). The viscoelastic properties were best described by the "double reptation model," viz., Eq. 7.82. The data were found to obey the time–temperature superposition principle.

The explanation proposed by Ngai and Plazek (1990) was based on the postulate that the number of couplings between the macromolecules varies with concentration and temperature of the blend. The number of couplings, n, can be calculated from the shift factor, $a_T = [\varsigma_o(T)/\varsigma_o(T_o)]^{1/(1 - n)}$, where $\varsigma_o(T)$ is the Rouse friction coefficient. Thus, in miscible, single-phase systems, as either the concentration or temperature changes, the chain mobility changes and relaxation spectra of polymeric components in the blends show different temperature dependence, i.e., the t-T principle cannot be obeyed. Similar conclusions were reached from a postulate

that the deviation originates from different temperature dependence of the relaxation functions of the blend components (Booij and Palmen 1992).

In immiscible blends, the t-T principle does not hold. For immiscible amorphous blends, it was postulated that two processes must be taken into account: the t-T superposition and the aging time (Maurer et al. 1985). On the other hand, in immiscible blends, at the test temperature, the polymeric components are at different distances from their respective glass transition temperatures, $T - T_{g1} \neq T - T_{g2}$. In blends of semicrystalline polymers, such as PE/PP, the superposition is limited to the molten state, within a narrow, high temperature range (Dumoulin 1988).

As an alternative to t-T superposition, plot of the elastic stress tensor component as a function of the viscous one has been used, e.g., $(\sigma_{11} - \sigma_{22})$ versus σ_{12} or G' versus G''. For systems in which the t-T is obeyed, such plots provide a temperature-independent master curve, without the need for data shifting and calculating the three shift factors. Indeed, from Doi and Edwards tube model, the following relation was derived:

$$\ln G' = 2\ln G'' + \ln(6M_e/5\rho RT) \qquad (7.127)$$

where M_e is the entanglement molecular weight (Han and Kim 1993). The dependence suggests that a plot of G' versus G'' should be insensitive to temperature. Indeed, good superposition was obtained for several blends where the structure remained unchanged within the range of independent variables, e.g., in such miscible systems as PS/PVME and PEO/PMMA, or even in some immiscible blends whose components have similar glass transition temperature, viz., PS/PMMA. However, lack of superposition was noted in other systems, where the structure did change, viz., PS/PVME heated across the binodal, block copolymer across the microphase separation temperature, LCP across the nematic transition temperature, etc.

7.5.5.5 Steady-State Versus Dynamic Viscosities

For most blends, the morphology changes with the imposed strain. Thus, it is expected that the dynamic low strain data will not follow the pattern observed for steady-state flow. One may formulate it more strongly: in polymer blends, the morphology and the flow behavior depend on the deformation field; thus under different flow conditions, different structures are being tested. Even if low strain dynamic data can be generalized using the t-T principle, those determined in steady state will not follow the pattern.

Chuang and Han (1984) reported that, for miscible and immiscible blends at constant composition, the plots of N_1 versus σ_{12} and G' versus G'' are independent of T. However, while for single phase systems, the two dependencies are approximately parallel, the steady-state relation may be quite different from the dynamic one for immiscible blends, such as PS/PMMA.

The agreement can be improved by means of the Sprigg's theory (1965). The general theory leads to the conclusion that

$$\eta(\dot{\gamma}) = \eta'(\omega), \quad \text{or} \quad \sigma_{12}(\dot{\gamma}) = G''(\omega)/C$$
$$\psi_1(\dot{\gamma}) = 2G'(\omega)/\omega^2, \quad \text{or} \quad N_1(\dot{\gamma}) = 2G'(\omega)/C^2 \tag{7.128}$$

where $C \equiv \omega/\dot{\gamma} = [(2 - 2e - e^2)/3]^{1/2}$ and e is a model parameter. For a series of PMMA/ABS blends, the plot of C versus composition was nonlinear, with C = 1 found only for PMMA homopolymer. Variation of this structural parameter seems to be related to differences of morphology existing in dynamic and steady-state flow fields (Utracki 1989).

Capillary flow of EPDM with poly(vinylidene-*co*-hexafluoropropylene), *Viton*™, showed a sixfold reduction of shear viscosity upon addition of about 2 % of the other component (Shih 1976, 1979), whereas in dynamic tests, the complex viscosity behavior of EPDM and EPDM with 5 % Viton™ was similar over a wide range of frequency and strain (Kanu and Shaw 1982). The latter authors postulated accumulation of the second component at the capillary entrance, which periodically feeds into the capillary, lubricating the main stream by a sort of roll bearing effect. In this particular case, the difference is related not only to material properties but also to a flow segregation enhanced by the geometry of the measuring device. Since the effect is strongly affected by flow geometry, the data obtained in capillary flow have little value for process design requirements.

The phenomenon of flow segregation has been exploited commercially. For example, high viscosity engineering resin that has poor resistance to solvents, e.g., polycarbonate or polyetheretherketone (PC or PEEK, respectively), can be blended with low melt viscosity liquid crystal polymer, LCP. Extruding such a blend through die with long enough land forces LCP to migrate toward the high stress surface, thus lubricating die flow and in addition engendering a protective layer on the surface of PC or PEEK. The reduction of viscosity of a polymer melt upon addition of LCP was originally described in 1979, in a patent deposition from ICI (Cogswell et al. 1981, 1983, 1984). The rheological behavior of LCP blends with polyether imide *Ultem*™ was studied by Nobile et al. (1990) in steady-state capillary and dynamic mechanical modes of deformation. The flow of LCP was reported to be sensitive to pressure; thus the flow of blends was carried out using a short capillary.

Another, more common commercial use of the phenomenon is addition of fluoropolymers to polyolefins. In this case, a small amount of fluoropolymer progressively migrates to the die surface, reducing the die pressure drop and making it possible to extrude the resin at high throughput without melt fracture. It has been shown that this approach also works for other polymers, viz., PEEK. Thus blends of PEEK with polytetrafluoroethylene, 1–5 wt% PTFE, were extruded. The pressure drop across the die was reported to decrease with time to an equilibrium value, P_{lim}. The value of P_{lim} depended on PTFE content, whereas the time to reach it depended on the rate of extrusion – the higher was the rate, the shorter was the saturation time (Chan et al. 1992).

Over the years, dynamic testing has become the preferred method of testing the rheological behavior of the multiphase systems. For example, Nishi et al. (1981) carried out careful studies on the dynamic behavior of PS/PVME. The specimens were cast at temperatures either below or above the lower critical solution temperature, LCST $\cong$ 95 °C. While those prepared at T < LCST (single-phase system) showed superimposition of dynamic data onto a master curve, those that were cast at T > LCST did not.

7.5.5.6 Blend Elasticity

Four measures of melt elasticity are commonly used: in steady-state shearing, the first normal stress difference (N_1); in dynamic tests, the storage modulus (G'); and the two indirect and controversial ones, namely, entrance–exit pressure drop (Bagley correction) (P_e) and the extrudate swell (B). In homogeneous melts, the four measurements are in qualitative agreement. More complex behavior is expected for blends. If the blend can be regarded as an emulsion, without interlayer slip the PDB behavior for the elastic measurements is to be expected. On the other hand, in systems where the dispersed phase is difficult to deform (as in suspensions), extrudate swell should be small. Deformation and recovery of the dispersed phase shape provides a potent mechanism for the elastic energy that result in large elastic response – this does not have anything to do with the molecular energy storage.

The direct measurements of N_1 and σ_{12} indicate a parallel dependence of both these functions plotted versus ϕ, even when they have a sigmoidal form. Considering the steady shear flow of a two-phase system, it is generally accepted that the rate of deformation may be discontinuous at the interface, and it is more appropriate to consider variation of the rheological functions at constant stress than at constant rate, i.e., $N_1 = N_1 (\sigma_{12})$. Using a similar argument for the dynamic functions, it should be concluded that $G' = G'(G'')$ should be used. Note that, as discussed above, the steady-state and dynamic data for polymer blends rarely superimpose.

Another method for estimating the elasticity contribution is through the Bagley entrance–exit pressure drop correction, P_e. For single-phase systems, the plot of P_e versus σ_{12} is independent of capillary diameter, temperature, and molecular weight, but rather sensitive to changes in flow profile (Utracki 1985). The plot was found to be useful for interpretation of the stress, temperature, and composition-dependent morphological changes in immiscible polymer blends (Dumoulin et al. 1985). However, it could not be used to estimate the elasticity of blends.

Extrudate swell, B, has been used to calculate the recoverable shear strain, γ_R, for single-phase materials (Utracki et al. 1975). Introduction of the interface negates the basic theoretical assumptions on which the calculation of γ_R was based. In addition, presence of the yield stress, frequently observed in multiphase systems, prevents B from reaching its equilibrium value required to calculate γ_R and then N_1. Nevertheless, B is used as a qualitative measure of blend elasticity.

Note that the presence of the dispersed, deformable phase leads to *form recovery*, i.e., shrinkage of the prolate ellipsoids motivated by the interfacial energy, which results in unduly large enhancement of B. The phenomenon has little to do with deformability of macromolecular coil – the postulated mechanism of swelling

in single-phase polymeric system. The main origin of blend swelling is the elastic recovery of domains extended during the convergent flow in the capillary entrance. The observed *form swelling* of blends could be large, giving strain recovery, $\gamma_R \leq 6.5$.

It is worth pointing out that strain recovery can be nonsymmetrical as far as the blend composition is concerned. In the case when the viscosity ratio at low deformation rate exceeds the limiting value $\lambda_{cr} = 3.8$, there is a significant difference in the mechanism of dispersion. During compounding in a twin-screw or twin-shaft instrument, the material undergoes stretching in shear and extensional flow fields. Depending on the composition, the stretched forms undergo different recovery. For blends with $\lambda > \lambda_{cr}$ the prolate ellipsoids cannot be broken; thus they slowly retract into large spheres. For blends with $\lambda < 1/\lambda_{cr}$ the prolate ellipsoids will disintegrate by the capillarity instability mechanism (El Khadi et al. 1995).

Similar observations were reported for PMMA/PS blends (Gramespacher and Meissner 1995). The elastic creep compliance for PMMA/PS = 16/84 behaved regularly, similar to what has been observed for single-phase polymers. However, when the composition was reversed, i.e., PMMA/PS = 84/16, the recovery creep compliance showed a maximum at which the recovery direction was reversed. The authors attributed the dissymmetry of behavior to different retardation times of the blend components.

7.5.6 Elongational Flows

Owing to experimental difficulties, there are but few publications on uniaxial deformation of blends. To prepare specimens for testing, samples usually are transfer molded and relaxed, both operations requiring relatively long heating time, during which only well-stabilized blends will not coarsen.

It is convenient to distinguish two contributions to the tensile stress growth function, η_E^+, one due to the linear viscoelastic response, η_{EL}^+, and the other originating in the structural change of the specimen during deformation, η_{ES}^+. The first can be calculated from any linear viscoelastic response, while the second (which originates in either intermolecular interactions or entanglements) depends on both the total strain, $\varepsilon = \dot{\varepsilon}t$, and either strain rate $\dot{\varepsilon}$ or straining time t. Owing to the industrial importance of strain hardening (SH), a large body of literature focuses on the optimization of blend composition to maximize SH. Since SH depends on the entanglements, blending branched polymers usually affects SH even in the low concentration range.

Most of the work on uniaxial extensional flow of immiscible polymer blends has focused on the behavior of systems containing PE. The main reason is the need for better, easier-to-process film resins, moreover for a relative stability of polyolefin blend morphology. Film blowing conceptually involves two different engineering operations, extrusion and blowing. For most production lines the latter limits productivity. For low density LDPE resins, strain hardening provides a self-regulating, self-healing mechanism. For HDPE and LLDPE, only small SH

can be obtained for the high MW and MWD resins. As a result, most LLDPE resins on the market are blends with LDPE, rubbers, copolymers, or another type of LLDPE. SH was also found to be an important resin characteristic for wire coating. Here the surface finish and uniformity of the deposited layer were superior for blends with high strain hardening and low shear viscosity (Utracki 1988).

Among biodegradable polymers, poly(lactic acid) (PLA) is a popular candidate for a wide variety of packaging applications because of its excellent gloss and clarity, high tensile strength, good heat sealability, and low coefficient of friction. However, drawbacks, including a low melt strength and brittleness, limit its end-use applications. Eslami and Kamal (2012) examined three different potential approaches to overcome these limitation by proper rheological and mechanical experiments: (i) the blending of PLA with poly((butylene succinate)-*co*-adipate) (PBSA) as another biodegradable polymer, (ii) the modification of the clay by formation of a blend/clay nanocomposite (Eslami and Kamal 2013b), and (iii) the introduction of by branching using chain extender (Eslami and Kamal 2013a). In the first approach, a series of blends based on poly(lactic acid) (PLA) and biode-gradable poly((butylene succinate)-*co*-adipate) (PBSA) and their nanocomposites with nanoclay (PLA/PBSA/Clay ternary nanocomposites) were prepared using a twin-screw extruder. The morphology and structure of the blends and the nanocomposites were examined using field emission scanning electron micros-copy, transmission electron microscopy, and X-ray diffraction. Rheological prop-erties of the blends, nanocomposites, and pure components were also studied in dynamic oscillatory shear measurements and elongational mode at different Hencky rate.

The authors calculated the strain hardening intensity values as a measure of melt strength using the ratio of $\eta_{E,nonlinear}/\eta_{E,linear}$ (λ_n). The slope of log λ_n versus Hencky strain defines the strain hardening intensity. As seen in Fig. 7.42 (a), effective improvements in melt strength required over 50 wt% PBSA which decreases the tensile modulus.

It was mentioned that the incorporation of nanoclay had only a minor effect on melt strength; however it increased the tensile modulus. On the other hand, Cole–Cole plot of the melts showed that the chain extender can promote the development of chain branching by time. The use of an epoxy based multifunctional chain extender resulted in significant enhancement of the melt strength and processability of the blends even at 30 wt% PBSA (Fig. 7.39b). These blends also exhibited interesting mechanical properties (Eslami and Kamal 2013a).

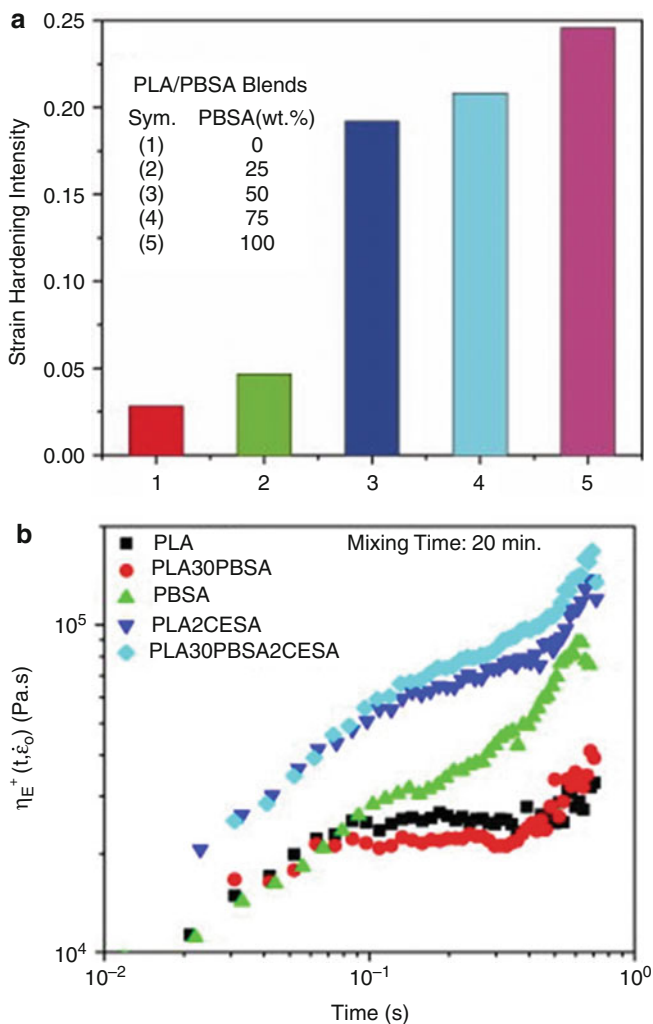
Blends of LLDPE/PP = 50:50, with or without compatibilizing ethylene-propylene copolymer, EPR, was studied by Dumoulin et al. (1984a, b, c). In spite of the expected immiscibility, the blends showed additivity of properties with good superposition of the stress growth functions in shear and elongation, as well as with the zero deformation rate Trouton ratio, $R_T \cong 1$. In earlier work, blends of medium density PE (MDPE) with small quantities of ultra-high molecular weight polyethylene (UHMWPE) were studied in shear and extension. Again, SH and $R_T \cong 1$ was observed.


Fig. 7.42 (**a**) Rheological properties of PLA/PBSA blends without chain extender (**b**) with chain extender (Eslami and Kamal 2013a, b)

It has been shown that the stress growth function, in uniaxial extension, provides three important pieces of information on the polymer. The initial slope of the stress growth function

$$S_i = \lim_{t \to 0} d\ln\eta_E^+ / d\ln t \qquad (7.129)$$

was found to correlate with polydispersity of the molecular weights, M_z/M_n, where M_z and M_n are respectively z- and number average molecular

weights (Schlund and Utracki 1987). The observation agrees with Gleissle's principle (1980):

$$
\eta(\dot{\gamma}) = \eta^{+}(t) \quad \text{for} \quad \dot{\gamma} = 1/t
$$
$$
\therefore \quad \lim_{t \to 0} \partial \ln \eta^{+}(t)/\partial \ln t = \lim_{t \to 0} \partial \ln \eta(\dot{\gamma})/\partial \ln \dot{\gamma} = n - 1 \tag{7.130}
$$

The plateau or equilibrium value provides information on the weight average molecular weight, M_w, and the stress hardening part, $\eta_{ES}^{+}(t)$ on the entanglements, i.e., branching, association, etc. The parameter S_i could provide information regarding blend miscibility. Solubility usually broadens the width of the MW distribution, causing S_i to increase. By contrast, immiscibility causes separation of high molecular weight fractions and narrowing MWD. The miscibility can also be reflected in a maximum strain at break, ε_b. In "antagonistically" immiscible blends of PA-6 in LLDPE, a sharp decrease of ε_b was observed. However, in blends with co-continuous morphology ε_b may increase to an average value, with negative deviations on both sides (Min 1984).

Li et al. (1990) studied the elongational viscosity of specially prepared blends of styrene-acrylonitrile copolymer, SAN, with different loadings of cross-linked polybutadiene, BR, particles having diameter, $d = 170$ nm. At higher rates of extension, the SAN showed strong strain hardening behavior. As the volume of rubber particles in the system increased, the strain hardening became less evident. By contrast, the low deformation rate elongational viscosity was shown to increase with BR loading, and as its content increased, the system progressively showed increased sensitivity to strain.

Delaby et al. (1994) attempted to experimentally examine the relation between droplet deformability and the extensional viscosity ratio, $D_E = D_E(\lambda_E)$. The authors demonstrated that the theories proposed by Taylor (1932, 1934) and Palierne (1990) predict the same dependence:

$$
(\gamma_d - 1)/(\gamma_m - 1) = 5/(2\lambda_E + 3) \tag{7.131}
$$

where γ_d and γ_m are respectively strain of the dispersed phase (defined as a ratio of the long axis to the original drop diameter) and the matrix. Only for $\lambda_E = 1$ co-deformation of drop is to be expected. The dependence is shown in Fig. 7.43. The experiments show good agreement with the behavior predicted by Eq. 7.131 in the full range of the viscosity ratios used in the studies, $\lambda_E = 0.005$ to 13. Drop deformability computed in 2D, using the boundary element method, resulted in higher value than 5/3, given for 3D by Eq. 7.131; independently, two research teams found the limit for $\lambda_E \to 0$ to be 2 (Khayat et al. 1996; Stradins and Osswald 1996).

Convergent flow at the die entrance provides strong elongational flow. Laun and Schuch [1989 derived the following relation between the entrance pressure drop in capillary flow and the shear stress at the capillary wall:

Fig. 7.43 Relative deformation of the dispersed phase versus the viscosity ratio (Delaby et al. 1994)

Drop-to-Matrix Deformation in Elongational Flow

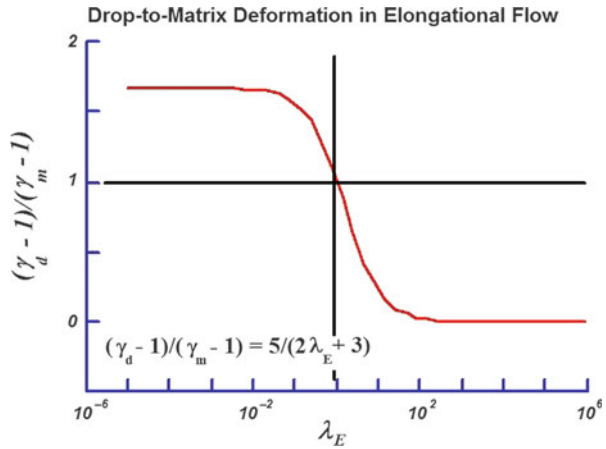
$(\gamma_d - 1)/(\gamma_m - 1) = 5/(2\lambda_E + 3)$


Fig. 7.44 Entrance–exit pressure drop in capillary flow of polypropylene, polyamide-6, and commercial PP/PA-6 blend, Orgalloy at 230 °C – line computed from Eq. 7.132
$P_e = 1.89(\eta_E/\eta)^{1/2}\sigma_{12}/(n+1)$

$$P_e = 1.89(\eta_E/\eta)^{1/2}\sigma_{12}/(n+1) \tag{7.132}$$

For Newtonian liquids Eq. 7.132 predicts $P_e \approx 1.64\sigma_{12}$, This proportionality is shown in Fig. 7.44 along with the experimental values determined for ORGALLOY™, PP, and PA-6. Evidently, Eq. 7.132 provides satisfactory approximation for the homopolymers, but for the blend, the prediction is again about one decade too low. Similarly, as for the shear flows, here also the elongational properties of blends show a different behavior under different extensional flow field conditions.

Extensional flow is important for the dispersion process. As the microrheology indicates, the minimum of the κ versus λ curve is very narrow for the shear flow, but very broad (and lower) for the extensional flow (see Fig. 7.45). This suggests that it should be much easier to disperse fluids in extensional than in shear flow fields.
Fig. 7.45 Critical capillary number versus viscosity ratio is shear flow (*solid lines*) and extension (*dash line*)

In particular, the benefits are obvious for high and low values of the viscosity ratio. It has been demonstrated theoretically and experimentally that drops can be deformed but not broken by shear flow if $\lambda > 3.8$. This is not the case for the inverse ratio, but the drop spinning mechanism in this region is slow, which makes the dispersion process inefficient. These theoretical findings have been confirmed by constructing an extensional flow mixer, EFM, and performing experiments with polymer blends having large difference of viscosity (Luciani and Utracki 1996; Utracki and Luciani 1996).

7.6   Concluding Remarks

The rheological behavior of polymer blends is a complex phenomenon that is not only an extension of the rheological behavior of simple multicomponent systems, such as solutions, emulsions, and suspensions. Also, it is not the combination of the rheological behavior of the individual polymeric components or additive. However, the rheological behavior of polymer blends is governed by the same general rules of thermodynamics, mechanics, surface science, and other physical and chemical principles that govern the behavior of all materials, when they respond to stress or strain or forces that produce a rheological response.

In this chapter, we have attempted to provide some of the fundamental background regarding the behavior of simpler systems and to indicate how polymer blends behave similarly to these systems in some respects, while in many other respects they behave in a much more complex manner. Much of our discussion related to simple two-component blend systems. However, there are many

multicomponent systems that are of commercial interest in many applications. Even more complex blends, such as those involving biosystems and systems involving natural polymers, are gaining interest. The understanding of the flow and rheological behavior of these systems is certainly very difficult. However, in the final analysis, these materials must obey the same laws of physics and chemistry. Complex as they might be, it is certain that the modern tools of science and technology will deal with the relevant issues.

It should be apparent from the aspects covered in this chapter that the rheological behavior of polymer blends, as many aspects of the behavior of polymer systems, cannot be understood or explained in terms of fundamentals and observations associated with rheology alone. Many aspects of polymer and blend behavior are involved. Therefore, we suggest to the reader to refer to other chapters in this handbook for a more complete understanding of the issues involved.

Notation and Abbreviations

Notations (Roman Letters)

a, b, k, K, n, u, β Equation constants
a_v Interfacial area density
B_{AB} Reduced binary thermodynamic interaction parameter, $B_{AB} = \chi_{AB}RT/V$
B Droplet width
b_i Segment length
c_i Lee and Park relaxation parameters
D Deformation
d Droplet diameter
d^* Equilibrium droplet diameter
D, D_M, D_s Diffusion, inter diffusion and self diffusion coefficient, respectively
D_p Particle diffusion coefficient
E^+ Threshold energy of coagulation
E_{DK} Macroscopic bulk breaking energy

F Intrinsic thermodynamic function

f Frequency

G*, G′, G″ Complex, storage and loss shear modulus, respectively

H(τ) Relaxation time spectrum

H̃(ω) Reduced frequency relaxation spectrum

H̃$_G$(ω) Gross' frequency relaxation spectrum

H$_{max}$ Maximum of the relaxation spectrum

h$_c$ Critical separation distance

k$_B$ Boltzmann constant

L Droplet length

M Onsager-type mobility factor

M$_n$, M$_w$, M$_z$ Number, weight and z-average molecular weight, respectively

N$_1$ = σ$_{11}$ − σ$_{22}$ First normal stress difference

N$_{o,N}$ Initial and final number of particles respectively

N^o, N$^+$ Number of coagulating drops, initially and at t = t$_c$

N$_T$ Total number of collisions per unit time

n Number of particles

n$_i$ Number of moles unit volume

P Pressure

Pe Peclet number

p$_r$ Probability that two particles that have collided result in coalescence

q Wave vector, or sinusoidal distortion

R Ideal gas constant

Re Reynolds number or real part of a complex function

R(q) Fluctuation function

r̄ Reduced drop radius

⟨r$_\Theta^2$⟩$^{1/2}$ Unperturbed, average radius of gyration

rad Radian

r$_N$ Radius of the critical nucleus

S(q), S$_0$ Virtual structure function

S$_o$, S Interfacial area per unit volume of the blend for monodispersed spherical particles before and after coalescence, respectively

s Spinodal

T Absolute temperature

T$_g$ Glass transition temperature

t Time

t$_b$ Necessary time for breakup of droplets

t$_b$* Dimensionless breakup time

t$_c$ Coalescence time

UCST Upper critical solubility temperature

V Volume

V$_x$/V Volume fraction of emulsion undergoing uniform shear

z Reduced frequency, $f \cdot \tau$

Notation (Greek Letters)

$\boldsymbol{\alpha}$ Orientation angle

$\boldsymbol{\alpha_o}$ The distortion at $t = 0$

$\boldsymbol{\beta_{12}}$ Interlayer slip factor

$\boldsymbol{\chi_{AB}}$ Binary thermodynamic interaction parameter between polymers A and B

$\boldsymbol{\Delta}$ Thermodynamic distance from the spinodal; $\Delta \equiv 2((\chi_{AB}N)_{s-} (\chi_{AB}N))$

$\boldsymbol{\Delta E}$ Activation energy, e.g., of flow: ΔE_η

$\boldsymbol{\Delta G_m}$ Gibbs free energy of mixing

$\boldsymbol{\Delta H_m, \Delta S_m}$ Enthalpy and entropy of mixing, respectively

$\boldsymbol{\varepsilon, \dot{\varepsilon}}$ Hencky strain and Hencky strain rate in extension, respectively

$\boldsymbol{\phi_1, \phi_2}$ Volume fraction of dispersed and matrix phase, respectively

$\boldsymbol{\phi_c}$ Volume fraction of the cross-linked monomer units

$\boldsymbol{\phi_i}$ Volume fraction of phase i at phase inversion

$\boldsymbol{\phi_m}$ Maximum packing volume fraction

$\boldsymbol{\phi_{perc}}$ Percolation threshold

$\boldsymbol{\gamma, \dot{\gamma}}$ Shear strain and rate of shearing, respectively

$\boldsymbol{\eta}$ Viscosity

$\boldsymbol{\eta_o}$ Zero-shear viscosity

$\boldsymbol{\eta_r}$ Relative viscosity

$\boldsymbol{[\eta]}$ Intrinsic viscosity

$\boldsymbol{\eta'}$ Dynamic viscosity

$\boldsymbol{\eta^*}$ Complex viscosity

$\boldsymbol{\eta_1, \eta_2}$ Viscosity of dispersed and matrix phase, respectively

$\boldsymbol{\kappa = \sigma_{\iota\varphi}d/\nu_{12}}$ Capillary number

$\boldsymbol{\kappa_{crit}}$ Critical capillary number

$\boldsymbol{\Lambda}$ Distortion wavelength

$\boldsymbol{\lambda = \eta_1/\eta_2}$ Viscosity ratio

$\boldsymbol{\lambda_s}$ Wavelength

$\boldsymbol{\nu_{12}^o}$ Interfacial tension in a quiescent blends

$\boldsymbol{\nu_{12}}$ Interfacial tension coefficient between phase 1 and 2

$\boldsymbol{\rho}$ Density

$\boldsymbol{\rho_d}$ Droplet density

$\boldsymbol{\sigma}$ Stress

$\boldsymbol{\sigma_{11}}$ Extensional stress

$\boldsymbol{\sigma_{11} - \sigma_{22} = N_1}$ First normal stress difference

$\boldsymbol{\sigma_{12}}$ Shear stress

$\boldsymbol{s_m}$ Stress in the matrix phase

$\boldsymbol{\sigma_y}$ Yield stress

$\boldsymbol{\sigma_y^o}$ Permanent yield stress

$\boldsymbol{\tau}$ Relaxation time

$\boldsymbol{t^*}$ Mean relaxation time

$\boldsymbol{\Omega(\Lambda, \lambda)}$ Tabulated function for capillary instability

ω Angular frequency
ω_max Frequency at which $\tilde{H}(\omega)$ is maximum
ω_x Crossover frequency
ψ_1, ψ_2 First and second normal stress difference coefficient, respectively

Abstract

In this chapter, as a guideline to control the phase separation morphology, the morphology formation mechanism is primarily explained. First the phase diagram and the phase separation mechanism are briefly explained to provide basic knowledge on controlling the morphology of polymer blends. Then, the effect of the shear flow on the phase diagram as a factor that influences the formation of the phase separation morphology is explained and the relation to the morphology control is shown. This is especially important in the polymer processing of polymer blends. Finally, as a control of the phase separation morphology using reactions, reaction-induced phase separation and reactive blending are explained. Because most polymer blends are immiscible, it is necessary to use some methods to obtain polymer blends that show good physical properties. Therefore, these are powerful tools for controlling the morphology in the polymer blends.

8.1   Introduction

It is not easy to satisfy the wide range of performance and function demanded of a material by using only one kind of polymer. Therefore, it is proper to satisfy these demands with polymer blends. Moreover, it is much easier to obtain a material that has the target characteristics by blending different polymers instead of designing and synthesizing really new polymers. Consequently, polymer blends which are composed of structurally and functionally different polymers have received much attention in terms of improving, e.g., mechanical, optical, and thermal properties, and numerous investigations have been done with these blends. However, most polymer blends are immiscible systems with dispersions of one polymer in the matrix of another, and it is not easy to improve their performance or function by simply mixing them. Hence, an effective control of the blend morphology is essential (Favis and Willis 1990; Bucknall 1977; Utracki 1982; Coran and Patel 1983).

The size level at which both polymers mix is very important, because it has a strong influence on the physical properties of the material. Whether a polymer blend that has mixed at the molecular level is better depends on its demanded performance. However, it is rare for a polymer blend to mix at a molecular level, because most polymer blends are immiscible and phase separation takes place. In addition, in the case where phase separation occurs, the physical properties greatly depend on the phase-separated morphology. Therefore, control of the phase-separated morphology is important. For example, the impact strength of polymer blends is generally controlled by the dispersed particle size, the ligament thickness, and the interfacial adhesion. If the morphology of polymer blends is altered by shear forces and the reaction during mixing, the material performance also changes. Thus, the morphology also greatly depends on how it is mixed.

In this chapter, morphology control using various mixing methods is described.

8.2   Phase Diagram and Phase Separation Mechanism

Generally, most polymer pairs of high molecular weight are immiscible in the range from glass transition temperature (T_{g}) to thermal decomposition temperature (T_{d}). It is difficult to mix polymers at a molecular level even for polymer pairs with similar structures, e.g., polyethylene (PE) and polypropylene (PP). To discuss the thermodynamics for the miscibility and the phase diagram of polymer blends, the Flory-Huggins equation has been widely used (Flory 1953),

$$\frac{\Delta G_M}{RT\,(V/V_{\mathrm{r}})} = \frac{\phi_1}{r_1}\ln\phi_1 + \frac{\phi_2}{r_2}\ln\phi_2 + \phi_1\phi_2\chi_{12} \tag{8.1}$$

where ΔG_M is the Gibbs free energy of mixing and R is the gas constant. V and V_{r} are the total and reference volumes, respectively. The first two terms on the right-hand side of Eq. 8.1 represent the combinatorial entropy of mixing and negative value, where ϕ_i is the volume fraction and r_i is the segment number of a polymer chain of component i. The third term contains the interaction parameter χ_{12}, which generally takes into account all contributions to the free energy that are not given by the combinatorial entropy. Using this Flory-Huggins equation, the miscibility of polymer blends can be described. In polymer blends, the combinatorial entropy of mixing the two polymers is a smaller negative than that of mixing two low molecular weight compounds, and the contribution to ΔG_M is very small. The miscibility tends to become better when ΔG_M decreases as χ_{12} becomes smaller. Therefore, pairs of dissimilar polymers are only miscible if there are favorable specific interactions between them leading to a negative contribution for ΔG_M.

   Miscible polymer blends can be classified into several categories. A blend that tends to phase-separate at low temperatures is termed an upper critical solution temperature (UCST) system, and one that separates at elevated temperatures is classified as a lower critical solution temperature (LCST) system. In addition, there are some pairs that are completely miscible and have both UCST and LCST characteristics. Figure 8.1a and b show the phase diagrams of a binary blend having LCST- and UCST-type phase behavior, respectively. The solid line is a "binodal line," which is a boundary between the one-phase and two-phase regions in the equilibrium state. The dashed line is called a "spinodal line," which satisfies the condition that the second derivative of the Gibbs free energy of mixing by composition is equal to zero ($\partial^2\Delta G/\partial\phi^2 = 0$). It is understood as a boundary that divides the style of the phase separation in a mixture, i.e., nucleation and growth (NG) type and spinodal decomposition (SD) type. The phase separation by NG takes place in the metastable region between the spinodal and the binodal lines on the phase diagram. SD occurs in the unstable region framed by the spinodal lines ($\partial^2\Delta G/\partial\phi^2 < 0$).

   In NG, a small particle (nucleus) with almost equilibrium concentration from the uniform solution is generated accidentally and grows gradually with time. There is no typical periodicity in the phase-separated morphology. Some domains having different sizes and positions are observed, as shown in Fig. 8.2a. In an SD process, on the other hand, a periodic fluctuation of the concentration in the system spontaneously

Fig. 8.1 LCST and UCST-type phase diagrams
Fig. 8.2 Schematic phase-separated morphology induced by (**a**) NG and (**b**) SD mechanism

arises. Then, the fluctuation gradually increases and separates into a coexistence composition ϕ_{B1} and ϕ_{B2}. In SD, there is structural periodicity, and each phase connects mutually in three dimensions, as shown in Fig. 8.2b. Furthermore, a dissimilarity also exists in the diffusion of molecules between NG and SD. The diffusion takes place from low concentration to high concentration in the process of SD. This is the opposite direction for ordinary diffusion, which takes place in the NG mechanism (see Fig. 8.3, Cahn 1968).
Fig. 8.3 Growth of concentration fluctuation in (**a**) NG and (**b**) SD mechanism

SD can be divided into three stages: the initial stage, middle stage, and late stage. In the initial stage (van Aartsen 1970; Binder and Stauffer 1973), the fluctuation of the concentration is gradually generated as a monochromatic wavelength and has a constant wavelength (Cahn 1965). A co-continuous morphology having the period distance Λ_m is formed as a consequence of the superimposed waves in various directions. The wavelength of the concentration fluctuation does not depend on time (constant), and the amplitude of the fluctuation increases exponentially. In the middle stage of SD, the periodic structure grows self-similarly, while the amplitude of the fluctuation increases gradually. In the late stage, the amplitude of the concentration fluctuation almost reaches the equilibrium concentration determined by the equilibrium composition of the blend, and then only the wavelength of the concentration fluctuation grows with self-similarity as time passes. Finally, the morphology with the dispersed particles phase (domain) in the continuous phase (matrix) is formed to reduce the interfacial tension at the late stage of SD. In this type of a system with dispersed particles, the domain size is also comparatively uniform, maintaining the regularity of the co-continuous morphology in the early stage. It can be said that the morphology after the SD is a characteristic structure.

8.3   Shear-Induced Phase Separation and Morphology

The effect of flow is of industrial relevance in the processing of polymer blends where high deformation rates are encountered, as in melt extrusion or injection molding.

Thus, the behavior of polymer blends in a flow field is of fundamental interest and is also technologically important, since deformation and related stresses are unavoidable in many processing steps. Recently, it has been reported that the shear flow can change the thermodynamic state of the system and perturb the phase diagram of the polymer mixtures, where it is now well established that the shear flow can shift the phase boundary a few degrees to higher or lower temperatures depending on the characterization of the blends under the shear (Mazich and Carr 1983; Lyngaae-Jorgensenn and Sondegaard 1987; Larbi et al. 1988; Katsaros et al. 1989; Nakatani et al. 1990; Kammer et al. 1991; Wu et al. 1991; Hindawi et al. 1992; Fernandez et al. 1995; Madbouly et al. 1999a). This also influences the morphologies that develop during polymer processing.

The effect of a simple shear flow on the phase behavior and morphology was investigated with the use of a parallel-plate apparatus (Fig. 8.4, Madbouly et al. 1999a) for some polymer mixtures: poly(methyl methacrylate) (PMMA)/poly(styrene-co-acrylonitrile) (SAN-29.5) and polystyrene (PS)/poly(vinyl methyl ether) (PVME), which have an LCST-type phase diagram; PS/PMMA, which has a UCST-type phase diagram; and polycarbonate (PC)/SAN and nylon4, 6(PA4,6)/poly(phenylene sulfide) (PPS), which are immiscible in the whole measurable region under the quiescent state.

8.3.1 PMMA/SAN-29.5 (AN:29.5 wt%) Mixture (LCST System)

This mixture phase-separates in the higher temperature region. Figure 8.5 shows the shear rate dependence of the cloud point at some compositions (Madbouly et al. 1999b). Since the cloud points increased monotonically for all of the measured compositions, only shear-induced mixing was observed. The shear flow can affect the phase behavior of the blend significantly; i.e., it suppresses the phase separation and enlarges the one-phase region of the polymer blend. Changes in the phase diagram of the polymer blends at different shear rates are represented in Fig. 8.6 (Madbouly et al. 1999b). The cloud points are affected by the values of the applied shear, as they gradually increase with shear rate values. Figure 8.7 represents the normalized shift in the cloud points $|\Delta T(\dot{\gamma})/T(0)| = |\{T(\dot{\gamma}) - T(0)\}/T(0)|$ versus shear rate $(\dot{\gamma})$ for different blend compositions. The following relation was given for the experimental data (Beysens and Gbadamassi 1979; Beysens and Perrot 1984):

$$|\Delta T(\dot{\gamma})/T(0)| = k\dot{\gamma}^n \tag{8.2}$$

where k and n are material constants that depend on composition. The experimental results can be fitted to Eq. 8.2 by using a nonlinear regression method. The constants k and n are used as fitting parameters. A good description of the data was obtained in Fig. 8.7, and Table 8.1 (Madbouly et al. 1999b) represents the values of the fitting parameters obtained from the regression. The values of the exponent n were almost constant regardless of the composition ratio of the blend, while the values of the prefactor k were greatly dependent on the composition of the
Fig. 8.4 Schematic representation of the shear apparatus used in this work: (**a**) general drawing; (**b**) sample between two parallel glass plates

blend. The value of k is a maximum for the critical composition (PMMA/ SAN $= 75/25$) and decreases on either side of this composition. This is attributed to the critical composition being more sensitive to the shear rate effect than the other compositions, as can be seen in Figs. 8.5 and 8.6. Note that Eq. 8.2 is applicable only at small shear rate values for this system ($\dot{\gamma} \leq 12\ \mathrm{s}^{-1}$) and deviated at higher shear rates. The cloud points become almost constant at higher shear rates, as shown in Fig. 8.5.

The phase-separated morphology under a flow field has also attracted considerable attention. The morphology of this system (PMMA/SAN $= 75/25$) was analyzed

85	0.032	0.501
75	0.045	0.501
50	0.022	0.502
25	0.015	0.501
Fig. 8.8 TEM pictures of PMMNSAN (75/25) samples that were sheared at 185 °C (20 °C above their quiescent cloud point) at 0.5 rad/s for 3 min and then quenched in a water bath. Samples were then taken from different radial positions and consequently different shear rates: (**a**) $\dot{\gamma} \sim 0~\text{s}^{-1}$; (**b**) 1.17 s^{-1}; (**c**) 2.33 s^{-1}; (**d**) 4.7 s^{-1}; and (**e**) 7 s^{-1}

relative to the shear rate effect. The sheared sample was quickly quenched in a water bath just after the shear cessation, and the morphology was observed using a transmission electron microscope (TEM) in the sample, which was cut parallel to the flow direction. A typical observed morphology of the samples is shown in Fig. 8.8 (Madbouly et al. 1999b). The phase-separated morphology is clearly observed; the dark and bright regions correspond to SAN-rich and PMMA-rich phases, respectively. One can see a well-defined phase separation; a co-continuous two-phase morphology of the blend can be clearly observed at nearly zero shear rate. Under the shear flow, the two SAN-rich and PMMA-rich phases are elongated and highly oriented parallel to the flow direction. These TEM results indicate that the size and amplitude of the concentration fluctuations were strongly

Fig. 8.9 Phase diagrams at various shear rates of PS/PVME blend
suppressed, as indicated by the decreasing intensity and contrast of the elongated phases. Lastly, no morphology was observed, which can be attributed to the shear-induced mixing of the polymer blend at the critical shear rate value ($10 \, \text{s}^{-1}$). The highly oriented phases are considered to be due to the nearly equal viscosity of SAN and PMMA. According to these results, it seems that macroscopic phase separation of the polymer blends cannot occur under the steady shear flow. With increasing shear rate, the macroscopic phase boundary is broken into pieces, generating smaller domains that can be elongated in the flow direction, resulting in a decrease in contrast (i.e., decreasing concentration fluctuations). Consequently, mixing of the unlike segments is enhanced.

8.3.2 PS/PVME Mixture (LCST System)

Changes of the cloud points on the shear rate in the PS/PVME system are shown in Fig. 8.9, which was measured by the same method as for the PMMA/SAN system (Madbouly et al. 1999a). This phase behavior is not simpler than that of the PMMA/SAN system. At low shear rates, the cloud point curve shifts to low temperature with increasing shear rate; i.e., the two-phase region becomes larger and a maximum decrease occurs when the applied shear rate value is around $5 \, \text{s}^{-1}$. Then the cloud point curve shifts to higher temperature with increasing shear rate up to $\dot{\gamma} = 14 \, \text{s}^{-1}$, at which point the cloud point curve is higher than that of the quiescent state. For larger shear rates than $\dot{\gamma} = 14 \, \text{s}^{-1}$, the cloud point curve does not change and becomes constant regardless of an increase in applied shear rate. This large effect of the shear rate on the miscibility behavior of this system is attributed to the large mismatch in the viscosity of the PS and PVME components: the bigger the mismatch in viscosity, the larger the effect of shear.

Based on this result, it appears that the shear flow can induce both phase demixing and mixing, as in the case of polymer solutions (Takebe et al. 1989). The fact that both were observed in the same blend suggests that two competing effects occur during

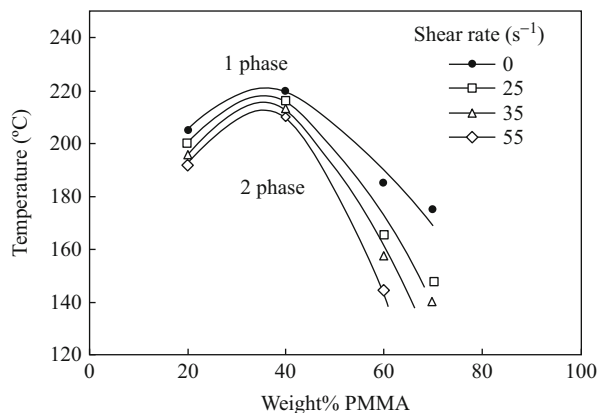
Fig. 8.10 Phase diagrams at various shear rates of PS/PMMA blend


Table 8.2 Values of prefactor k and exponent n for different systems

System	k	n
Cyclohexane/Aniline[3,4]	$(5.9 \pm 0.66) \times 10^{-7}$	0.53 ± 0.03
Polymer solution (PS/PB/DOP)[10]	$(2.6 \pm 0.6) \times 10^{-3}$	0.5 ± 0.02
Oligomer mixture (PMMA/PS)	$0.0075 - 0.031$	0.5 ± 0.02
Polymer mixture (PMMA/SAN)	$0.015 - 0.045$	0.5 ± 0.02

flow. One of these effects tends to suppress growing spatial composition fluctuation, and this effect would tend to promote phase mixing. The other effect causes the growth of composition fluctuation with consequent phase demixing. This effect can be attributed to elastic deformation, which may act to enhance some concentration fluctuation, promoting the uphill diffusion that occurs in the phase separation, as has been reported by Helfand and Fredrickson (1989) and Onuki et al. (1989). Thus, the first effect could dominate at high shear rate and high temperature, while the second effect could dominate at low shear rate and low temperature.

8.3.3   PS/PMMA Mixture (UCST System)

This is an oligomer mixture (Mw (PS) = 2,500, Mw (PMMA) = 6,000), and the phase separation takes place in a lower temperature region (UCST-type phase diagram; Madbouly et al. 2001). Changes in the phase diagram of the blends at different shear rates are represented in Fig. 8.10. The cloud points decreased monotonically with the shear rate. Though the results were opposite to the case of PMMA/SAN, shear-induced mixing took place. The shear effect was found to be largely composition-dependent. The shear flow can suppress the phase separation and enlarge the single-phase region of the blend.

It is important to compare the effect of the shear flow on the phase behavior for different systems. Table 8.2 summarizes the values of the prefactor (k) and the

exponent (n) in Eq. 8.2 for the four different systems. The values of n are almost constant (0.5) in all cases, regardless of the type of system under shear. However, the values of k greatly depend on the system under consideration; the k values decrease from high molecular weight polymer blends (PMMA/SAN) to simple liquid mixtures. This may be attributed to the fact that the effect of shear on the cloud points is much more sensitive in the high molecular weight polymer blends and that the sensitivity decreases in the simple liquid mixtures. From this result one can say that the sensitivity of the cloud points to the effect of applied shear rate in the different systems moves with the same order as the prefactor value in the different cases, with a greater value of the prefactor giving greater sensitivity of the cloud points to the application of shear rate. These reported results are in good agreement with a renormalization group theory of Onuki and Kawasaki (Onuki and Kawasaki 1979a, b; Onuki et al. 1981), who predicated the following equation for small molecular systems:

$$|\Delta T(\dot{\gamma})/T(0)| = p\dot{\gamma}^{1/3v} \qquad (3)$$

where the prefactor p is given by

$$p = 0.0832\varepsilon\tau_\xi^{1/3v} \qquad (4)$$

and $\varepsilon = 4-d_s$ $1/3v = 0.5$ v is a universal constant which depends on the spatial dimensionality d_s τ_ξ is the characteristic relaxation time for the concentration fluctuations of the mixture. Equation 8.4 predicts that the larger the characteristic time (τ_ξ) for the concentration fluctuations, the larger the change of the cloud point will be. This general principle can also be applied to a polymeric system, since the relaxation time decreases from the high molecular weight polymer mixtures to the simple liquid mixtures and becomes very small. Therefore, the large difference in the prefactor value, which reflects the sensitivity of the different systems to the shear rate, is not surprising at all.

According to this experimental fact, one can say that the phase behavior of the blend under shear flow can be changed due to the difference in the relaxation time, which reflects the different sensitivities of the cloud point to change under the shear flow.

8.3.4 PC/SAN Mixture (Immiscible System)

The blend of bisphenol-A polycarbonate (PC) and acrylonitrile-butadiene-styrene (ABS) resin is a useful industrial material. One reason is that the miscibility between PC and poly(styrene-*co*-acrylonitrile) (SAN), which is a matrix of ABS resin, is not too bad, though it is immiscible. In particular, a blend of PC and SAN-25 with 25 wt% AN is useful, because the miscibility is the best in PC/SAN systems and the blend shows the lowest value of χ in the system (Li et al. 1999). The blend has been used without any compatibilizers. It would be expected that the
Fig. 8.11 TEM pictures of PC/SAN-25 = 70/30 samples that were sheared at 240 °C by different shear rates for 5 min and then quenched in water bath. Five pieces were then taken from different radial positions and consequently different shear rates (**a**) $\dot{\gamma} \approx 0$ s^{-1}; (**b**) 7.5 s^{-1}; (**c**) 15 s^{-1}; (**d**) 30 s^{-1} and (**e**) 90 s^{-1}

miscibility of the blend might be more enhanced under the shear flow. The two-phase morphology under a controlled shear condition has attracted considerable attention in recent years. For this reason, the effect of simple shear flow on the morphology and miscibility of the PC/SAN-25 blend was investigated. A typical morphological observation of the blend samples (PC/SAN-25 = 70/30) under different values of the shear rate at 240 °C is shown in Fig. 8.11 (Hanafy et al. 2004). The bright dispersed phase and dark matrix correspond to the SAN-rich (not stained) and PC-rich (stained by RuO$_4$) regions, respectively. It is apparent that a well-defined phase separation of the blend at nearly zero shear rate can be obtained. For the samples under the shear flow, particles oriented to the flow direction were formed, and the size decreased with the shear rate. These results of TEM observation indicate that the size and amplitude of the concentration fluctuations between the domains and the surrounding matrix were strongly suppressed as a result of decreasing the contrast of the elongated domains. According to these results, one can say that the miscibility of the PC/SAN-25 mixture is enhanced to a great extent under the shear flow; i.e., the shear suppresses the concentration fluctuations and enhances the miscibility between different polymers. However, no shear-induced one-phase morphology was detected even under higher shear rate values. We must state here that the morphology under higher shear rate values (higher than 30 s^{-1}) does not change very much; see, for example, that at 90 s^{-1} in Fig. 8.11e the morphology is almost similar to that at 30 s^{-1} in Fig. 8.11d. This may be attributed to the fact that the sample under a higher shear rate seems to be

Fig. 8.12 Shear rate
dependence of the total area
of SAN-rich phase
under a quasi-equilibrium condition. Based on this experimental fact, it is apparent
that the morphology might be controlled by two competitive factors. One is trying to
break up the domains into smaller ones, i.e., a shear-induced breakup of the dispersed
domains. The other tends to increase the rate of domain growth, i.e., a shear-induced
coalescence. The competition between the two factors is responsible for the
obtained morphology. Therefore, the breakup is not a unique phenomenon involved
during the shear flow, since coalescence of the dispersed particles also occurs, and the
finally obtained morphology is the result of these two opposite effects.

Figure 8.12 shows the total area of the individual particles of the SAN-rich
region as a function of the shear rate calculated from the image analysis of the
previous TEM images (Fig. 8.11). Obviously, the area of the dispersed domains
remarkably decreased with the shear rate and leveled off at high shear rates. As
mentioned above, this is due to a competition of particle breakup and coalescence
which may occur at high shear rate values.

Though the bisphenol-A PC is immiscible with SAN, as mentioned above, it was
reported that a blend of a PC copolymer (cPC) and SAN-23 had a miscible region
and showed an LCST-type phase diagram; see Fig. 8.13 (Okamoto et al. 1995). It
was understood that the miscibility with SAN was enhanced by using random
copolymer PC in comparison with the PC/SAN system. The LCST phase boundary
shifts to higher temperatures by shearing, as shown in the figure, and the miscible
region is enlarged, though the accurate amount is not clear quantitatively. The
kinetic results provided a plausible scenario for the development of a co-continuous
two-phase morphology in the melt-processed blend as follows. When the cold
pellets of both polymers are heated to above the glass transition temperature
(Tg) of the polymers in the extruder, the dissolution starts. Even after attaining
the spinodal temperature of the quiescent state (Ts = 223 °C) the dissolution occurs
continuously, since Ts can be elevated under the shear flow to above the barrel
temperature (260 °C), shown as a dotted line in the figure. The homogeneous melt is
extruded and quenched quickly in water. When the single-phase blend is heated
under high shear in an injection machine (at 290 °C) and injected into a cold mold,

Fig. 8.13 Phase diagram of cPC/SAN blend and processing conditions
the polymer blend is thrust into the two-phase region from the single-phase region, since the phase boundary returns to the lower temperature of the quiescent state without shearing. Then the spinodal decomposition proceeds until the melt is cooled to Tg. The dissolution below Ts is negligible, and so the co-continuous morphology attained via the spinodal decomposition is frozen in the molded blend by vitrification near Tg. Thus, one can obtain the co-continuous morphology in the polymer blends by controlling the shear field.

Figure 8.14 shows a TEM picture of an injection molding sample in the bisphenol-A PC/ABS blend (Inoue 1996). The black particles are rubber in the ABS-rich region. When one draws the boundary line between the rubber particle-rich region (ABS-rich) and the rubber particle-poor region (PC-rich), a co-continuous morphology appears. This may show that the morphology formation occurs via spinodal decomposition after single-phase formation by shearing in the PC/ABS blend. It might be the reason why the PC/ABS blend shows nice physical properties. This morphology control is extremely interesting.

8.3.5   PA4,6/PPS Mixture (Immiscible System)

Both nylon 4,6 (PA4,6) and poly(phenylene sulfide) (PPS) are useful industrial materials and have a high melting temperature of the crystals ($T_m = 295$ °C and

Fig. 8.14 TEM picture of injection molding sample in PC/ABS (50/50). It is partitioned between overcrowdedness area (ABS-rich) of the rubber particle and white ground (PC-rich) by the line
280 °C, respectively). Therefore, we expect them to have the advantage that their polymer blend can maintain high temperature properties. The polymer blend of PA4,6/PPS has been used industrially without any compatibilizers; nevertheless, the blend is immiscible. Thus, it is considered that the shear flow during processing plays an important role for the formation of the phase-separated morphology related to the appearance of desirable properties.

The phase diagram at a quiescent state was confirmed in a liquid state from the melting temperature of the crystal to 400 °C by the cloud point measurement (An et al. 2002). The specimens were opaque and two-phase for every composition and measurable temperature. This means that the blend of PA4,6/PPS is immiscible in all processable regions. However, the specimen of PA4,6/PPS (80/20) in the higher shear rate region became transparent at 310 °C. The shear rate in the boundary of the opaque-transparent region was calculated ($\dot{\gamma} = 150$ s^{-1}), and at higher shear rates than this value, the blend become miscible. This means that a shear-induced mixing took place in this blend. But a miscible region in other compositions could not be found. Figure 8.15 shows a phase diagram at $\dot{\gamma} = 150$ s^{-1} and $\dot{\gamma} = 189$ s^{-1}. A miscibility region (window) can open by the shear flow, though it is very narrow.

Figure 8.16a shows an optical micrograph of a PA4,6/PPS(80/20) specimen annealed at 310 °C for 10 min after the cessation of the shear flow, which was one phase under shear flow ($\dot{\gamma} > 150$ s^{-1}) at the same temperature. A regularly and co-continuously phase-separated structure appears. Figure 8.16b shows a light scattering profile exhibiting a peak due to the regular morphology. It seems that phase separation took place via spinodal decomposition from one phase state after the cessation of shear flow. Such a fine morphology in polymer blends often causes good physical properties.

Fig. 8.15 Phase diagram of PA4,6/PPS blend under simple shear flow. The lines of phase boundary at $\dot{\gamma} = 150\ \text{s}^{-1}$ and $\dot{\gamma} = 189\ \text{s}^{-1}$ are drawn arbitrarily because the shape of phase diagram is not clear at present
Fig. 8.16 (a) Optical micrograph of PA4,6/PPS (=80/20) blend annealed in hot chamber for 10 min at 310 °C after shear cessation. Co-continuous morphology appeared. (b) Light scattering profile of this sample

To conclude, the miscibility of the PA4,6/PPS blend changed with the shear flow, and a miscible region appeared. By using this phenomenon, a specimen with a fine morphology and good physical properties could be obtained.

8.4   Reaction-Induced Phase Separation

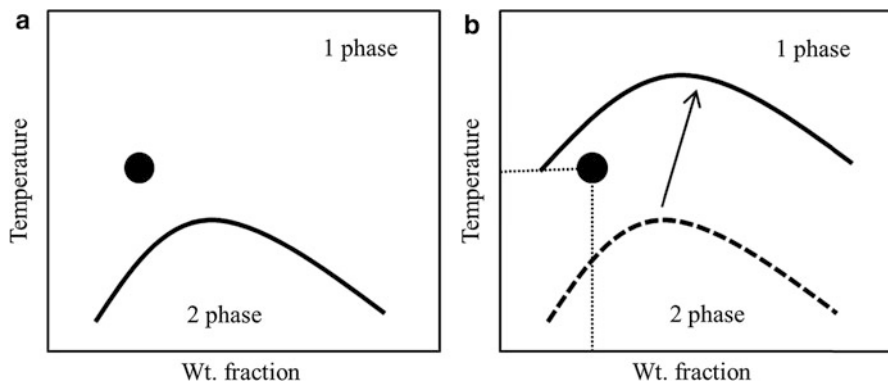
There are several methods used to mix polymers. Reaction-induced phase separation (RIPS) is one way to make useful polymer blends, and much research has been previously done on this topic (Visconti and Marchessault 1974; Manzione et al. 1981; Yamanaka and Inoue 1989, 1990; Yamanaka et al. 1989; Chen et al. 1994; Okada et al. 1995; Kojima et al. 1995; Inoue 1995). As explained before, many polymer blends are immiscible, and it is difficult to make them form a desirable


Fig. 8.17 Schematic representation of phase diagram in polymer blend with polymerization; (**a**) monomer/polymer blend before polymerization, (**b**) polymer/polymer blend after polymerization. *Solid circle* (●) represents polymerization condition

phase-separated morphology. RIPS occurs as a result of a curing reaction (c-RIPS) and polymerization of a monomer (p-RIPS) after one polymer is dissolved in another monomer forming a homogeneous solution initially. The phase separation is induced in the process of curing or polymerization of the monomer. Because the phase separation occurs from one phase state, it often occurs by the spinodal decomposition (SD) mechanism, and a regular phase-separated morphology is formed in the initial stage of the phase separation. Therefore, it is easy to obtain a material with a better performance. However, in RIPS, the obtained final morphology is remarkably different from that obtained by the usual phase separation of the binary polymer-polymer blends. Interest in the morphology of the blends obtained by RIPS has led to many research studies in this area.

Here the phase separation phenomenon by p-RIPS is explained by using the Flory-Huggins equation expressed by Eq. 8.1. Generally, if the interaction parameter χ_{12} is independent of the number of segments per chain, the miscibility during the polymerization is dominated by the number of segments in the combinatorial entropy terms on the right side of Eq. 8.1. That is, the larger the degree of polymerization, the narrower the miscible region becomes. Figure 8.17 shows the schematic representation of a UCST-type phase diagram in a blend: (a) the monomer/polymer blend before polymerization and (b) the polymer/polymer blend after polymerization. The solid circle in the phase diagram represents the position of the polymerization condition. When the degree of polymerization in a polymerized component is small, the system locates at the miscible state before the polymerization (Fig. 8.17a). The degree of polymerization becomes large as the polymerization proceeds, and the combinatorial entropy terms become negligible. Because the free energy of mixing becomes larger, the phase boundary shifts to the higher temperature with polymerization, as shown in Fig. 8.17b. Consequently, the system is thrust into a two-phase region from a one-phase region. Then, the phase separation occurs.

Fig. 8.18 TEM micrograph
of PMMA/EVAc(80/20)
blend polymerized at 60 °C
It has been reported that this phenomenon has been observed in the radical polymerization of methyl methacrylate (MMA) in the presence of poly(ethylene-*co*-vinyl acetate) (EVAc) (Chen et al. 1994). The MMA/EVAc blend shows a UCST phase diagram, and the shift of the phase diagram with polymerization of MMA is the same as that in Fig. 8.17. Figure 8.18 shows a TEM micrograph of the PMMA/EVAc (80/20) blend prepared by p-RIPS. The bright region is assigned to the polymerized PMMA region. The phase-separated structure shows a unique morphology in which the particles of the major component (PMMA) were dispersed in a matrix of the minor component (EVAc). Also, this blend prepared by polymerization shows a high impact strength. Figure 8.19 shows the notched Izod impact strength of PMMA/EVAc blends obtained by p-RIPS and melt-blending (Kojima et al. 1995). The blends obtained by polymerization show much higher impact strength than those by melt-blending. This result may be caused by the phase separation morphology in which the EVAc region with a rubbery property forms a matrix regardless of the minor component. This PMMA/EVAc blend obtained by polymerization is put to practical use because of its good physical properties.

As an example of c-RIPS, an epoxy/poly(ether sulfone) (PES) system with a phase diagram exhibiting an LCST behavior was demonstrated in Fig. 8.20 (Yamanaka and Inoue 1989). The binary mixture was first homogeneous at the curing temperature (below LCST). During the curing process, the system was thrust into a two-phase region by the LCST depression caused by increase of the molecular weight or the conversion, and the phase separation was expected to take place via SD. In this particular system, the progress of decomposition will eventually be suppressed by the vitrification, as shown by the approaching T_g line and by gelation in the epoxy-rich region. The morphology of the phase-separated structure in c-RIPS yields a variety of two-phase structures – interconnected globule structure, droplet structure with uniform domain size, and bimodal domain structure, depending on the relative rates of the chemical reaction and the phase separation (Yamanaka and Inoue 1989). Figure 8.21a shows a scanning electron

Fig. 8.19 Notched Izod impact strength of PMMA/EVA blend prepared by p-RIPS and melt blending

Fig. 8.21 SEM micrograph of cured resin epoxy/PES; PES 50 phr, 170 °C, 3 h
Fig. 8.22 Schematic representation of phase separation process resulting in connected-globule structure

microscope (SEM) micrograph for the cured resin in the epoxy/PES (100/50) system. Fine globules which are fairly uniform in size (a few micrometers) are seen. Furthermore, the particles seem to be connected to each other (Fig. 8.21b). This connected-globule structure implies a two-phase morphology of the interconnected spherical domains of the epoxy-rich phase of a major component dispersed regularly in a matrix of PES. This kind of morphology can never be obtained by mixing two polymers with an asymmetrical blend composition. The schematic representation of the changes in the phase separation structure is shown in Fig. 8.22 (Yamanaka and Inoue 1989). The dark region is assigned to the epoxy-rich region. During this curing reaction the homogeneous blend starts to phase-separate by SD (Fig. 8.22a). When the phase separation proceeds, the dispersed droplet-type
Fig. 8.23 TEM micrographs of the blends mixed by the mechanical blending at 200 °C for 5 min (**a**) PS/PMMA(80/20), (**b**) PMMA/PS(80/20)

morphology (Fig. 8.22b, c) or network morphology which is established with droplets (Fig. 8.22d) appears. The coarsening of domains then proceeds, eventually resulting in the connected-globule structure (Fig. 8.22e). The epoxy-rich region and PES-rich region form the domain and matrix, respectively. In polymer/polymer blend systems, generally the major component becomes the matrix while the minor component becomes the domain. However, in c-RIPS, the domain phase is formed by the cured component even if the cured component is major. This epoxy/PES system has good adhesive properties such as high peel strength because of this morphology.

Thus, the scenarios are plausible in the explanation of c-RIPS with the curing process. However, there was no explanation why the major component could form the domain in both of p-RIPS and c-RIPS. Also, so far the formation mechanism of the phase-separated morphology has apparently not been elucidated. Therefore, the following model experiments were carried out.

8.4.1 p-RIPS in PS/PMMA Systems

As a model blend of p-RIPS, the PS/PMMA systems were investigated. Both polymers are easily synthesized by radical polymerization from the monomer (Ono et al. 2008). This polymer blend is immiscible, but shows a small value of the positive interaction parameter, χ. The morphologies of the polymer blends mixed mechanically at 200 °C for 5 min are shown in Fig. 8.23a and b. The TEM micrographs are of PS/PMMA (80/20) and PMMA/PS (80/20), respectively. The darker regions correspond to the PS-rich phase and the brighter regions are associated with the PMMA-rich phase, because the phenyl group of PS is more stained by RuO_4. As shown in the figures, the minor component forms the domain in the major component matrix. In fact, in the case of PS/PMMA (80/20), PMMA, the minor component, was dispersed in the PS matrix as small domains after the mechanical melt blending. Phase inversion occurred in PMMA/PS (80/20) as a matter of course. The minor component of PS then formed many small domains. This phenomenon occurred predictably as is known in the field of polymer blends.

Fig. 8.24 TEM micrographs of the phase-separated structure of styrene/PMMA/AIBN(80/20/0.2) blend after polymerization at 80 °C in polymerization-induced phase separation

1.0 um
The final morphology of the binary blend prepared via p-RIPS is greatly different from that prepared via mechanical melt blending with the polymers, as stated above. The polymerized component tends to form the domains regardless of the varieties of monomer and reaction.

Here, not only styrene/PMMA (80/20) but also MMA/PS (80/20) could be prepared to observe the morphology obtained by p-RIPS. The process of the phase separation was observed by optical microscopy (OM) and light scattering (LS) measurements during the polymerization. The final morphology was observed by TEM, and image processing was carried out for the micrographs obtained by OM and TEM.

8.4.1.1 Styrene/PMMA Mixture

PMMA was dissolved in the styrene monomer with a radical initiator, α,α'-azobis (isobutyronitrile) (AIBN). Figure 8.24 shows the TEM micrograph for PS/PMMA/AIBN (80/20/0.2) after a polymerization of styrene completely finished at 80 °C. The brighter regions are associated with the PMMA-rich phase and the darker regions correspond to the PS-rich phase. According to this micrograph, the PS-rich phase formed the domains, although PS is the major component in this blend system, and the PMMA-rich phase formed the continuous phase in spite of being 20 wt% in content. This unique morphology can never be obtained by mechanical melt blending in binary polymers. As mentioned above, the minor component will form domains in mechanical melt blending. To confirm the particularity, the polymerized specimen was blended again by melt mixing. Of course, it was observed that the PMMA-rich phase of the minor component formed small domains in the PS-rich phase matrix of the major component, quite the same as in Fig. 8.23a. Furthermore, referring in detail to Fig. 8.24, there are several types of domains with different sizes, of which the larger domain is 10 μm and the smaller domain is 10 nm in diameter.

To investigate the formation process of the phase-separated morphology, the LS measurement and the observation by OM were carried out during the polymerization
Fig. 8.25 Change of light scattering profiles in the process of the polymerization of sty/PMMA/AIBN (80/20/0.2) mixture at 80 °C

at 80 °C for a styrene/PMMA/AIBN (80/20/0.2) mixture. This mixture was homogeneous in solution between room temperature and the polymerization temperature (80 °C).

Figure 8.25 shows the time-resolved LS profiles during the process of the polymerization of the styrene/PMMA/AIBN (80/20/0.2) mixture at 80 °C. The scattering vector is defined by

$$q = \frac{4\pi}{\lambda} \sin \frac{\theta}{2} \tag{5}$$

where λ and θ are the wavelength of light in the medium and the scattering angle, respectively. The light scattering occurred slightly after a certain time lag of $\sim$9 min, then one peak started to appear at $q = 0.7$ μm^{-1} after 11 min. The peak implied the development of a regularly phase-separated morphology. From these profiles, one can estimate the periodic distance, Λ_m, in the phase-separated morphology using a Bragg equation and the scattering vector:

$$\Lambda_m = \frac{2\pi}{q} \tag{6}$$

The periodic distance was estimated to be 9 μm when the peak appeared first. However, this distance is too large for that in the initial stage of spinodal decomposition (SD) because the periodic distance in a typical SD is usually of submicron order in the case of polymer-solvent and polymer-polymer systems. This implies that this phase separation may not be occurring via SD. Therefore, an observation by OM was carried out to investigate the morphology at the early stage of the phase separation.

Figure 8.26 shows the optical micrographs observed at the various stages of polymerization at 80 °C. After about 8 min from the starting of polymerization of styrene monomer, the phase separation started to occur but with low contrast. A domain having a uniform particle size was generated at irregular positions like a morphology formed by the nucleation and growth (NG) mechanism. A co-continuous morphology was not observed in this blend system. Coarsening of the domains took place with time up to 15 min. In addition, the second phase separation was observed to occur in the matrix phase at 15 min. After that, collision and coalescence between the domains took place, and the two types of domains simultaneously coarsened with time. These optical micrographs indicated that the several phase separations took place in many stages in this blend system. Furthermore, it was confirmed that these step-by-step phase separations do not occur via SD-type but rather by NG-type processes.

The size distribution of domains in the phase-separated morphology in the picture of OM or TEM was estimated after threshold by image processing with the software Image J in order to investigate the change of the volume fraction and particle size with time. From this image analysis, the small domains generated at the initial stage (8 min) coarsened gradually, and then another phase separation was observed at 15 min with the advent of the bimodal distribution. Therefore, this indicates that the two phase separations occurred in steps in this system. Figure 8.27 shows the time dependence of particle diameter in a two-step phase separation. The smaller particle size generated in the second phase separation agreed with that of the domains generated in the first phase separation. Figure 8.28 shows the time dependence of the volume fraction of the polymerized major component, the PS-rich phase, by adding the values of each phase separation step. Because the area of the PS-rich region is almost 73 % of the TEM image of Fig. 8.24, which is a final morphology, it is considered that at least three steps of the phase separation occur.

It is possible to think about the phase separation in this system from the above discussion by looking at Fig. 8.29, which is the schematic diagram showing the triangle phase diagram of the styrene/PMMA/PS system at 80 °C. Since the PMMA content was fixed at 20 wt%, the initial binary solution of styrene/PMMA is indicated by the black filled circle. The polymerization process can be described by the arrow. Polymerization of styrene causes the solution to enter the two-phase region in which it separates into two phases, one rich in polymer PMMA and the other rich in generated polymer PS. The phase separation in the metastable region should proceed by the NG mechanism. Furthermore, the second phase separation took place in the PMMA-rich phase via NG. In this way, the several processes in the step-by-step phase separation are assumed to induce the unique phase-separated morphology. From this phase diagram, in the first phase separation, the PS-rich phase is minor and the PMMA-rich phase is major by the principle of leverage. The second phase separation occurs in the PMMA-rich phase, which is major, and it is repeated. Therefore, it is difficult for the domains to collide and coalesce with each other, and the coarsening of domains might be suppressed. As a result, the many PS-rich domains disperse in the matrix regardless of the major component until the polymerization finishes completely. Perhaps this is a reason why the PS which is a major component forms a domain.

8.4.1.2 MMA/PS Mixture

Figure 8.30 shows a TEM micrograph for MMA/PS/AIBN (80/20/0.2) after polymerization of MMA completely finished at 80 °C. The brighter regions are associated with the PMMA-rich phase and the darker regions correspond to the PS-rich phase. According to this micrograph, the PMMA-rich phase formed the domains, although PMMA was a major component in this blend system, and the PS-rich phase formed the continuous matrix phase in spite of being 20 wt% content. This morphology is opposite to the morphology seen in the styrene/PMMA/AIBN (80/20/0.2) system as shown in Fig. 8.24.

Fig. 8.30 TEM micrograph
of the phase-separated
structure of MMA/PS/AIBN
(80/20/0.2) blend after
polymerization at 80 °C in
p-RIPS

To investigate the formation process of the phase-separated morphology, the
measurement of LS and the observation by OM were carried out. Figure 8.31 shows
the time-resolved LS profiles during the process of the polymerization. The periodic
distance Λ_m was estimated to be about 2.1 μm. The position of the peak started to
shift toward a smaller angle as the polymerization progressed. The phenomenon
revealed the occurrence of coarsening of the periodic structure at the late stage of
the SD mechanism.

The change of the volume fraction of the PMMA-rich phase and the periodic
distance Λ_m of the co-continuous morphology versus time can be estimated
from the optical and TEM micrographs after threshold by the image processing
with the software Image J (see Fig. 8.32). The black region is associated with the
PMMA-rich phase. The pictures after the image processing clearly represent

Fig. 8.34 Triangle phase diagram of MMA/PS/PMMA system at 80 °C. Spinodal and binodal curves are by *broken* and *solid lines*, respectively. *Arrow* indicates the polymerization process
the co-continuous structure via the SD. Furthermore, the coarsening behavior of the periodic morphology was observed. This indicates that the volume fraction of the PMMA-rich phase increased gradually with time (Fig. 8.33). The volume fraction should approach 80 % of the mixing composition if the phase separates to pure PS and pure PMMA completely. However, it does not completely correspond because there are many small particles which were not recognized by the image processing, or perhaps the phases do not separate pure components.

It is possible to think about the phase separation in this system from the above discussion by looking at Fig. 8.34, which is the schematic diagram showing a triangle phase diagram of the MMA/PMMA/PS system at 80 °C. Since the PS weight fraction was fixed at 20 wt%, the initial binary solution of MMA/PS is

indicated by a black filled circle. The polymerization process can be described by the arrow. The binodal and spinodal lines shift to the PS-rich side in some measure, as shown in Fig. 8.34, because the MMA/PS/AIBN (90/10/0.225) system did not show phase separation after polymerization of MMA at 80 °C. However, we suppose that the blend system did not cause the phase separation and was frozen at the miscible state because the sample entered the two-phase region late during the process of polymerization which is a low mobility stage. From the above results, this phase separation took place in the spinodal region in the triangle phase diagram. Therefore, the volume fraction of the formed domain is supposed to be almost 50 % derived from the concentration fluctuation in the co-continuous morphology at the initial stage of SD. After that, the volume fraction of the PMMA-rich phase increases up to near 80 % that is the mixing composition. However, the PMMA-rich phase, which is the major component, forms domains in the late stage of the phase separation. Because the volume fraction of each phase in the initial stage of the phase separation should be almost even, one cannot explain this result as explained in the NG mechanism for styrene/PMMA/AIBN (80/20/0.2). Therefore, it is considered that the polymerization process induced the change of the coarsening mechanism and the formation of a unique morphology in p-RIPS.

Which phase wants to form domains after the co-continuity is lost? Considering that this unique morphology is never formed by conventional thermal-induced phase separation, it is thought that changes of some kind of physical properties induced by the polymerization cause it. There are changes in physical properties, such as viscoelasticity and volume shrinkage. The answer is not clear at present.

8.5 Reactive Blending

The reactive blending of immiscible polymers yields a block or graft copolymer at the interface. By an emulsifying effect of the in situ-formed copolymer, the dispersed particles can be reduced down to submicrometer size, and the interfacial adhesion can be improved. Then, the material properties are improved. It may be a commonly accepted story for compatibilization (Baker et al. 2001). In addition to the emulsifying effect, new interfacial behaviors of the in situ-formed copolymers have been found recently; such as pull-out and pull-in of copolymers by the external shear forces. These render a series of high-performance materials with new morphologies. Further, a new approach has been explored by combining many reactions, e.g., coupling and exchange reactions.

8.5.1 Coupling Reaction at Polymer-Polymer Interface

The first example of reactive blending is a system containing polyamide (PA-6) and polypropylene (PP) with a small amount of maleic anhydride (MAH) (Ide and Hasegawa 1974). A coupling reaction between the amino chain end of PA with MAH leads to the in situ formation of a PA-PP graft copolymer at the interface (see Fig. 8.35).

Fig. 8.35 Polymer-polymer
interface as the reaction site

X=MHA, $\diagdown_0$ Y=NH$_2$, COOH
The coupling reaction proceeds very quickly, caused by concentrating the reactive
moieties (MAH, epoxide, NH$_2$, COOH, etc.) at the interface. The polymer chain end
generally prefers to locate at the interface, because such a chain conformation is more
probable, compared with the case where a mid-segment locates near the interface.
Then, the amino chain ends of PA may be concentrated at the interface. The MAH
unit is highly polar and is unstable in the non-polar PP-MAH phase, and it tends to
segregate at the interface to contact with the polar chain of PA. Thus, both reactive
sites may be concentrated near the interface to provide a favorable situation for the
coupling reaction.

This type of blending has been used to produce the "super-tough nylon" PA/poly
(phenylene ether) (PPE) alloy (Baker et al. 2001). Similar reactive blending of PPE
with poly(ethylene-*co*-glycidyl methacrylate) (EGMA) yields a high-temperature
engineering plastic with low dielectric loss and nice melt-processability (Furuta
et al. 2007). It can be classified as a super-engineering plastic, like poly(ether
sulfone) and poly(ether imide). A super-ductile alloy with excellent high-
temperature resistance was also developed by reactive blending of poly(butylene
terephthalate) (PBT) with EGMA (Hashima et al. 2008).

8.5.2   In situ-formed Copolymer as an Emulsifier

The in situ-formed copolymers locate at the interface to prevent coalescence of the
dispersed particles. The brush chains (the B chains of the in situ-formed A-B
copolymer; see Fig. 8.35) on the dispersed particles overlap when neighboring
particles approach each other. By the chain overlap, the conformational entropy
decreases to generate a repulsive interaction between the particles, which is different
from the electrostatic repulsion in low molecular weight systems (oil/water/soap).

The emulsifying effect of the in situ-formed copolymers allows a fine dispersion
to be achieved by reactive blending. The particle size during reactive blending of
PA-6 and MAH-functionalized polystyrene (PS) decreased by two orders of magnitude, in comparison to the nonreactive PA-6/PS = 80/20 (Park et al. 1992). The change in the morphological parameters, such as the mean radius of dispersed particles and the specific interfacial area, with mixing time was quantitatively shown as a function of reaction time via light scattering analysis (Okamoto and Inoue 1993).

The in situ-formed copolymer reduces the interfacial tension. In ternary systems of a major component (3) and two minor components (1 and 2), as schematically shown in Fig. 8.36, component 2 spreads over the component 1 particles when the spreading coefficient S, determined by a balance between the interfacial tensions $\Gamma_{i/j}$, is positive. The S in a ternary system of EPR (ethylene-propylene rubber) (1)/PA(2)/PPS (poly(phenylene sulfide)) (3) defined by

$$S = \Gamma_{PPS/EPR} - \Gamma_{PA/EPR} - \Gamma_{PPS/PA}$$

can be positive when the value of $\Gamma_{PPS/PA}$ is reduced by the formation of an in situ-formed copolymer of PPS and PA. Then, PA shell-EPR core particles are dispersed in a PPS matrix, as shown in Fig. 8.36. The formation of the core-shell particles gives the ternary alloy high toughness, even when the surface-to-surface interparticle distance τ is fairly large ($\tau = 500$ nm) (An et al. 2001).

8.5.3   Pull-out of in situ-formed Copolymer

During reactive blending, the in situ-formed copolymers are sometimes pulled out from the interface and dispersed as micelles (domains) in the matrix, as shown in Fig. 8.37. The micelles are typically 20 nm in diameter (Ibuki et al. 1999). The pull-out does not occur at the static state; i.e., it is not caused by the interfacial instability of the highly crowded copolymers themselves. The pull-out takes place mechanically under the shear fields (Charoensirisomboon et al. 1999).

Fig. 8.37 Pull-out of in situ-formed block copolymer
Fig. 8.38 In situ-formed copolymers are pulled out (YES) or not pulled out but stay at interface (NO), depending on the molecular architecture. Figures are number average molecular weight of component polymers

Whether pull-out occurs or not highly depends on the molecular architecture, as shown in Fig. 8.38 (Charoensirisomboon et al. 2000). A block copolymer with a linear structure is easily pulled out (YES, Fig. 8.38a). An in situ-formed graft copolymer with a trunk chain located in the dispersed particle (inverse-Y shape) is hardly pulled out and plays the role of emulsifier (NO, Fig. 8.38b). By contrast, a graft copolymer with a trunk chain in the matrix (Y shape) can be pulled out easily (Fig. 8.38c). An inverse-Y shaped graft copolymer is hardly pulled out, even in the case of a short trunk (Fig. 8.38d). A Y-shaped graft copolymer with a long anchoring chain is hardly pulled out (Fig. 8.38e). Following thermodynamic theory (equilibrium under quiescent conditions), an asymmetric copolymer is unstable at the interface. The results in Fig. 8.38 show that the external shear effect prevails over the thermodynamic effect.

Super-tough nylon is a case of the inverse-Y-type graft copolymer, which is hardly pulled out at all and stays at the interface to act as the emulsifier. It seems to be a clever and reasonable choice.

The pull-out occurs even at the very early stages of mixing in which the dispersed particles are large (∼10 μm). By continuing the mixing, the large particles shrink and the number of micelles increases. Eventually, the large particles
Fig. 8.39 Bimodal particle distribution by the pull-out of in situ-formed graft copolymer

disappear, leading to a pure copolymer domain system; that is, 100 % conversion is achieved. In other words, a solvent-free synthesis of the block or graft copolymer is realized by the dry process.

If the reactive blending is stopped at an intermediate stage, the micelles and the shrunken particles coexist and a bimodal particle distribution is realized, as shown in Fig. 8.39. In the case of Fig. 8.39, PA-6 was mixed with polyethylene (PE) modified with a small amount of MAH (0.1 wt%) and glycidyl methacrylate (3–12 wt%), at a 70/30 (PA/PE) blend ratio. The bimodal system can be easily crosslinked by electron beam irradiation at a low dose level, the same as that used for neat PE (Pan et al. 2002). The crosslinked PA/PE alloy shows good heat resistance in a lead-free solder test; thus, it may be applied in making construction parts with melt-down resistance in fires, e.g., a window frame.

8.5.4 Pull-in of in situ-formed Copolymer

As discussed in Fig. 8.38, an in situ-formed inverse-Y shaped copolymer is hardly pulled out of the matrix. However, "pull-out into the dispersed particles" (pull-in) takes place in reactive blending by the use of an extremely long (L/D = 100, L: screw length, D: screw diameter) twin screw extruder (Sato et al. 2007). Under the intensive shear fields in the extruder, the dispersed particles can be highly deformed, as shown in Fig. 8.40. The deformation to ellipsoids and the recovery to spherical particles would be repeated in the extruder, which implies that, from the shear fields in the dispersed particles, the in situ-formed graft copolymers would pull into the dispersed particles.

The pull-in leads to a fine "salami" morphology of 20 nm occlusion, as shown in Fig. 8.40. A PA/EGMA 70/30 alloy with a fine salami morphology showed ultra-high toughness (non-break under the Izod impact test) and a non-viscoelastic tensile property: the higher deformation rate leads to a lower modulus and a larger elongation at break (Sato et al. 2007). These results suggest a potential application in energy-absorbing car parts, designed to be friendly for both pedestrian and

Fig. 8.40 Pull-in of the in situ-formed inverse Y-type graft copolymer to form fine salami particle

20 nm PA domain

300 nm EGMA particle
Fig. 8.41 Video images during the falling weight impact test for neat PA (*above*) and PA/EGMA alloy (*below*)

driver. Actually, the alloy showed super-ductile behavior in a high-speed crash test. The results of a high-speed falling weight impact test are shown in Fig. 8.41 (Inoue and Kobayashi 2011). A 193 kg weight fell from a 0.5 m height (impact speed = 11.2 km/h) on a pipe sample (50 mm diameter, 150 mm height, 2 mm thick). The neat PA crashes into tiny fragments immediately after the weight hits the pipe sample. The impact condition is so severe that this typical engineering
Fig. 8.42 Improvement of toughness, heat resistance (HDT), and ageing resistance of PLA

plastic, PA, breaks in a very brittle manner. However, even for such a severe impact test, the PA/EGMA alloy never breaks, but only deforms. It looks like a beer can and a rubber hose.

8.5.5 Blending by Combining Many Reactions

As shown in Fig. 8.42, the toughness of poly(lactic acid) (PLA) is improved by blending a hydrogenated styrene-butadiene-styrene block copolymer (polystyrene-*b*-poly(ethylene-co-butylene)-*b*-polystyrene; SEBS). By adding EGMA as the third component, the toughness can be improved further. However, the toughness of both binary and ternary alloys decreases by annealing at 80 °C for 48 h. By adding polycarbonate (PC) as the fourth component, the heat resistance is improved; i.e., the high toughness is maintained even after the annealing (Hashima et al. 2010). The four-component alloy may be classified as an engineering plastic, as shown in Fig. 8.43.

In the TEM micrographs of Fig. 8.44, the gray region is assigned to PC and the dark region to SEBS particles in which the microdomain structure of the block copolymer is seen. SEBS particles are covered by a thin layer of EGMA. The coupling reaction between PLA and EGMA may lead to a fine dispersion of SEBS-core/EGMA-shell particles. The right micrograph is a magnified one. A gray boundary is seen between the elongated PC particles and the PLA matrix. The boundary is assigned to a multi-block or random copolymer formed by an exchange reaction between PC and PLA. The copolymer is expected to enhance the interfacial adhesive strength.
Fig. 8.43 PLA alloy on impact strength-HDT map, as compared with other plastics
Fig. 8.44 TEM of four component PLA alloy

Thus, the morphology of the four-component alloy seems to be generated by combining two reactions: the coupling reaction between EGMA and PLA and the exchange reaction between PC and PLA.

A high-performance PP/PLA alloy is successfully developed by reactive blending with the aid of EGMA and organic peroxide (dicumyl peroxide, DCP),

Fig. 8.45 TEM of PLA/PP alloy
Fig. 8.46 Impact strength and fluidity of PLA/PP alloy

e.g., PP/DCP/EGMA/PLA = 50/0.1/10/40 (Ito et al. 2012). As shown in Fig. 8.45, PLA particles are coated with EGMA shell and dispersed in a PLA matrix. The rubber (EGMA) shell seems to help the cold drawing of the brittle occlusion (PLA) in the ductile matrix (PP) (Angola et al. 1988). It showed high Izod impact strength, large elongation at break (75 %), and nice fluidity (Fig. 8.46). The three reactions involved in this reactive blending, (1) coupling between the epoxide of EGMA and the carboxyl acid and/or hydroxyl chain ends of PLA, (2) chain scission of PP, and (3) radical grafting of PP onto EGMA, may generate a desirable morphology of fine particles of PLA-core/EGMA-shell, dispersed in a PP matrix of low viscosity (see Fig. 8.47).

Fig. 8.47 Chain scission of PP, PP-EGMA radical grafting, and EGMA-PLA coupling
8.5.6 Blending with the aid of Reactive Plasticizer

It was quite difficult to develop a high-performance PP/PC blend. The difficulty is caused by the big differences in melt viscosity (the viscosity of PC is two decades higher than that of PP) and polarity (PP: non-polar vs. PC: polar). A new approach has been presented that uses a reactive plasticizer which is preferentially soluble with PC and polymerizable by organic peroxide (Matsumoto et al. 2012). As plasticizers, diallyl phthalate (DAP) and triallyl cyanurate (TAC) are used. For example, by adding 20 wt% of DAP, the melt viscosity of PC decreases to the same level of neat PP. By the reactive extrusion of PP/PC/plasticizer/dicumyl peroxide (e.g., 80/14/6/0.12 wt. ratio), a reaction-induced phase decomposition takes place in the dispersed PC particles to develop a regularly phase-separated nanostructure, and the graft copolymer of PP and polymerized plasticizer seems to be generated in situ at the interface. The extruded blend shows an excellent ductile behavior with ca. 500 %-elongation at break. TAC is shown to be more effective at elevating the heat resistance than DAP.

8.6 Concluding Remarks

Here, three important phenomena to control the phase separation morphology were explained: the phase diagram and the phase separation in a shear flow field, reaction-induced phase separation, and reactive blending.

Information about the phase diagram and the phase separation in the shear flow field is very important in polymer processing. For instance, it is important to know how the miscibility and the phase diagram change in a shear flow field. As shown in this chapter, the miscible area might extend by the shear flow, and there might be a case in which a two-phase region becomes a one-phase region. After the cessation of the shear flow, the miscible area reduces and the phase separation from the one-phase state might take place by spinodal decomposition. Control of the

phase-separated morphology using such a phenomenon must exist in other systems. Moreover, it may be that the physical properties are improved by increasing the adhesion between both separated phases due to the partial dissolution even if both polymers do not mix completely.

Reaction-induced phase separation is a very useful method because of a peculiar morphology in which the major component forms the domain and the minor component the matrix (occasionally a co-continuous morphology is formed). The utility value of this morphology is high. Because there are not very many miscible polymer blends, the method of controlling the morphology by using the phase separation from the one-phase state which is obtained by using the low molecular weight one as one component of polymer blend is useful. Therefore, another effect may be assumed to induce the phase separation and the unique morphology in RIPS. Regarding the change of physical properties by polymerization, it is known that volume shrinkage occurs in the process of polymerization from monomers to polymer. Considering that the polymerized component is sure to form domains in RIPS, this volume shrinkage is assumed to induce the unique morphology. Therefore, the shrinkage stress during polymerization may be assumed to affect the formation mechanism and also bring the differential in the coarsening mechanism.

Regarding the reactive blends, control of the molecules in the interfacial region is important, because they affect the morphology and the properties. The role of the in situ-formed copolymers is related to many phenomena. Therefore, the molecular design of the copolymer, including the type of copolymer, functional group, position of functional group, block length, and molecular weight, is important.

The formation of a phase separation morphology with crystallization is also important, though it was not described in this chapter.

The control of the phase separation morphology is just a key technology in polymer blends. In order to achieve good performance of the materials, it is important to handle the processing-morphology-properties relationship.

Abstract

In processing polymer blends, equipment selection, conditions, and formulation are highly important to control the final morphology. In this chapter, a review of the fundamentals in mixing (laminar, chaotic, dispersive, and distributive) is given before presenting the main limitations/problems related to interfacial properties, coalescence, and measure of mixing quality. Then, different methods and equipments are presented for lab-scale and industrial applications. A special focus is made on reactive system and phase compatibilization to improve the properties of the final blends. Also, nonmechanical techniques (solutions) are presented.

9.1   Introduction

The cost of polymer alloys is mainly determined by the composition. By contrast, the profit that is based on the alloys' performance is controlled by the way the material is processed, i.e., by morphology and stability. The compounding process must ascertain that the alloy has the desired spectrum of the performance characteristics.

Undoubtedly, compounding is the most critical and difficult step in polymer blends' technology. It must combine the fundamental knowledge of thermodynamic and rheological material behavior, with engineering aspects of flow inside mixing devices. Furthermore, since nowadays about 90 % of blends are reactively compatibilized, good knowledge of polymer chemistry is also essential.

This chapter has four parts: fundamentals of polymer mixing, blending methods and equipment, nonmechanical methods of polymer blending, and reactive processing. The information is presented in a concise form, with tables of data and references to the source literature. Owing to the complex nature of the topic, interested readers are encouraged to consult other chapters in this book dedicated to specific topics that impact on the *Compounding of Polymer Blends* via compatibilization (▶ Chaps. 4, "Interphase and Compatibilization by Addition of a Compatibilizer" and ▶ 5, "Reactive Compatibilization") and rheology (▶ Chap. 7, "Rheology of Polymer Alloys and Blends").

9.2   **Fundamentals of Polymer Mixing**

According to English dictionaries, *mixing*, *blending*, *and compounding* are synonyms, indicating "an action to combine ingredients into one mass, so that the constituent parts are indistinguishable." However, in the plastic processing, these terms have different meanings: *mixing* indicates the physical act of homogenization (i.e., mixing of fractions), and *blending* usually indicates preparation of polymer blends or alloys, while *compounding* that of *a compound*, i.e., incorporation of additives into a polymeric matrix like antioxidants, lubricants, pigments, fillers, or reinforcements (Utracki 1994, 1998).

9.2.1   **The Reasons for Mixing**

Mixing is the most important operation in polymer processing. Uniformity of the molecular weight, degree of entanglement, temperature, and composition is the key to good plastics' performance. For example, fusion of rigid PVC formulation by heating, but without mechanical mixing, results in bad mechanical properties, poor thermal stability, and weatherability. Similarly, poor performance is obtained from compression molding of a dry blend of LLDPE reactor powder where low level of intermolecular entanglements result in low strength of molded parts.

Hydrodynamics recognize two kinds of a fluid motion: (1) laminar, in which the streamlines are smooth, and (2) turbulent, in which the motion is irregular or disorganized. These two types are separated by the critical value of the Reynolds number ($Re_{critical} \cong 2{,}000$ in a circular tube). The Reynolds number is defined as

$$\mathrm{Re} \equiv \mathrm{L}\overline{\mathrm{V}}\rho/\eta \tag{9.1}$$

where L is the channel size, $\overline{\mathrm{V}}$ is the flow velocity, ρ is the fluid density, and η is its viscosity. For a typical molten polymer with $\eta = 1$ kPa·s, $\rho = 10^3$ kg/m^3, flowing through a one centimeter channel in diameter (L $= 10^{-2}$ m), turbulence starts when the flow velocity exceeds the critical value of $\overline{\mathrm{V}} = 200$ km/s. Evidently, the turbulent flow is not to be expected for liquids with such a high viscosity; hence, molten polymers flow by laminar mechanism. (Note that the term "laminar" is used in two different connotations: to characterize the flow (as in laminar vs. turbulent) and that of mixing, "laminar mixing model," as described below.)

It is convenient to distinguish two types of flow: dispersive and distributive, schematically shown in Fig. 9.1.

The dispersive (or intensive) mixing involves *application of stress* (shear and elongation) that breaks domains of the dispersed phase to the desired size. The dispersed phase may be composed of liquid drops, gel particles of the matrix material, aggregates of filler particles, etc.

The distributive (or extensive) mixing involves homogenization of a fluid, accomplished by the *application of strain* (shear and elongation). Homogenization
Fig. 9.1 Schematic representation of mixing (*top row*, *left* to *right*): bad dispersion and distribution; bad dispersion, but good distribution; (*bottom row*, *left* to *right*): good dispersion, but bad distribution, and good dispersion and distribution

may involve a single-phase fluid (i.e., homogenization of temperature), a miscible system (homogenization of concentration), or a multiphase system, blend or composite (homogenization of the dispersion).

Two other terms have also been used to describe mixing: the laminar and chaotic. In both types, the system is considered "passive," i.e., the rheological properties are identical and the interface is "invisible." Thus, flow-induced morphological changes do not affect the flow behavior, and the effects of flow and morphology are "decoupled." In real systems, the rheological and thermodynamic properties of two phases are different. In this case, the changes of morphology affect the flow, which in turn affect the morphology, and so on, until a steady state is reached and the effects are "coupled." Thus, laminar and chaotic mixing models are excellent to start with, but with the exception of special cases, they do not represent reality.

As indicated in Chap. ▶ 7, "Rheology of Polymer Alloys and Blends," the effects of flow on morphology have been described by micro-rheology. For highly diluted systems, a good agreement between experimental data and theoretical predictions has been reported. Furthermore, continuous efforts are made to incorporate the kinematics of the interface generation into the rheological description of the system (Doi and Ohta 1991; Grmela and Ait-Kadi 1994; Grmela et al. 1998; Lee and Park 1994; Roths et al. 2002; Keestra et al. 2003; Dressler and Edwards 2004; Das et al. 2005; Takahashi et al. 2007; Gu and Grmela 2008; Jelic et al. 2010).

9.2.2 Laminar Mixing

The following derivations for the laminar mixing are valid for the flow of passive mixtures. Neither the effects imposed by the interface nor those originating from the differences in the rheological properties of the fluid components

Table 9.1 Values of R for different types of deformation

Deformation	Elongation ratios	R	Comment
Plane elongation	$\lambda_x = \lambda_o;\ \lambda_y = 1/\lambda_o;\ \lambda_z = 1$	$\boldsymbol{\lambda_o}$	Regular, flow between rolls
Plane elongation	Averaging isotropic mixture	$\boldsymbol{\lambda_o/2}$	Random input orientation
Pure elongation	$\lambda_x = \lambda_o;\ \lambda_y = \lambda_z = \lambda_o^{-1/2}$	$\boldsymbol{\lambda_o^{1/2}}$	Uniaxial stretching
Pure elongation	$\lambda_x = \lambda_o;\ \lambda_y = \lambda_z = \lambda_o^{-1/2}$	$\boldsymbol{1/\lambda_o}$	Biaxial stretching
Simple shear	Expressed by shear strain, γ	$\boldsymbol{\gamma \cos \beta}$	Couette or Poiseuille flow

are taken into account. Thus, the laminar mixing (as presented below) provides the first approximation for the distributive (or homogenizing) mixing. The dispersive mixing has not been considered, and there is no need for it when there is no interface and the rheological properties of both fluids are the same (Edwards 1985).

9.2.2.1 Growth of the Interfacial Area

Laminar mixing depends on the strain tensor, which can be visualized as an ellipsoid formed upon straining a sphere. The strain magnitude is proportional to the relative size of the ellipsoidal axes while their relative positions to the orientational effects of the imposed flow. It can be shown that the interfacial area (A_o) will grow with the imposition of strain according to the relation (Erwin 1991):

$$R \equiv A/A_o = \left| \left\{ \left(\lambda_x \lambda_y \right)^2 + \lambda_y^2 \left(\lambda_z^2 - \lambda_x^2 \right) \cos^2\alpha + \lambda_x^2 \left(\lambda_z^2 - \lambda_y^2 \right) \cos^2\beta \right\}^{1/2} \right| \tag{9.2}$$

where λ_i ($i = x, y, z$) are the principal elongation ratios and α and β are the orientation angles. Depending on the type of deformation, the interfacial area ratio (R) takes on values listed in Table 9.1.

For example, the principal elongation ratios in simple shear can be expressed as

$$\begin{aligned}
\lambda_x &= \left[1 + \gamma^2/2 + (\gamma/2)(4 + \gamma^2)^{1/2} \right]^{1/2} \\
\lambda_y &= \left[1 + \gamma^2/2 - (\gamma/2)(4 + \gamma^2)^{1/2} \right]^{1/2} \\
\lambda_z &= 1
\end{aligned} \tag{9.3}$$

9.2.2.2 Energy of Mixing

It is important to be able to calculate how much energy is required to generate the same R in different flow fields, in particular in extension and in shear. The specific energy per unit volume (E) required to generate the aerial strain R in a passive liquid mixture with viscosity η for a time t_o is given by the following expressions (Erwin 1991):

Fig. 9.2 Energy
consumption as a function of
change of the interface area in
extensional (uniaxial, biaxial,
and plane strain) and simple
shear flows. The most
efficient is the biaxial stretch;
the worst (by a factor of
500,000!) is shear (after
Erwin 1991)

Mixing energy vs. interface growth for four types of flow
$$
\begin{aligned}
\text{Uniaxial extension}: \quad & E = (12\eta/t_o[\ln(5R/4)])^2 \\
\text{Biaxial extension}: \quad & E = (3\eta/t_o[\ln(5R/4)])^2 \\
\text{Planar extension}: \quad & E = (4\eta/t_o[\ln(2R)])^2 \\
\text{Simple shear}: \quad & E = (4\eta/t_o)R^2
\end{aligned}
\tag{9.4}
$$

These dependencies are shown in Fig. 9.2. Evidently, simple shear is inefficient for generation of a large interfacial area (for smaller deformations, $R \leq 10$, the inefficiency is not as dramatic). The inefficiency can be reduced if a large deformation is obtained not at once, but in a series of smaller deformation steps. The best formula is stretch–twist–fold, the second best is stretch-and-fold, and the third is stretch-and-randomize. Thus, to improve the mixing efficiency of the processing units that operate in the shear mode (like in a single-screw extruder), the flow should be interrupted and the flow lines randomized. For uniform shear strains of randomly oriented elements, the interfacial area increases linearly with strain, and when the process is repeated, the total increase of the interfacial area becomes proportional to the square of strain (γ^2), etc.:

$$
R_1 \cong \gamma/2 ; \quad R_2 \cong (\gamma/2)^2 ; \quad R_n \cong (\gamma/2)^n
\tag{9.5}
$$

The same approach may also be used to improve mixing in the extensional flow field. However, since the surface generation in extension is efficient to start with, the improvement is not as dramatic as that expected in shear.

The validity of Eq. 9.5 was experimentally confirmed using a specially designed mixer (Ng and Erwin 1981). Even if this device did not lend itself to be incorporated into a processing unit, the idea of the interrupted flow has been generally adopted by the designers of mixing equipment. The process would be even more efficient if the elements could be reoriented at 90° (biaxial stretching) or even 180° (folding and stretching). Several attempts have been made to incorporate these ideas into the extruders' design. Nowadays, this concept is successfully applied in so-called static mixers which are placed at the end of the screws in extruders.

Fig. 9.3 Kinematics of separation of two material points during laminar flow in the uniaxial elongation and in simple shear
9.2.2.3 Kinematics of Mixing

The strain between two material points M and M′ can be expressed as

$$\lambda \equiv \|MM'\| / \|M_oM'_o\| \tag{9.6}$$

The kinematics of the deformation is described by the following set of differential equations (Poitou 1988):

$$dX/dt = u; \quad dm/dt = [grad\,u]\,m - ([\varepsilon]\,m \bullet m)\,m; \quad d\ln\lambda/dt = [\dot{\varepsilon}]\,m \bullet m \tag{9.7}$$

where **X** is the coordinate of M, **u** is the velocity field, [grad **u**] is the velocity gradient tensor, [ε] is their strain rate tensor, and **m** is the unit vector of **MM′**. Figure 9.3 presents the kinematics of strain evolution in simple shear and uniaxial elongation.

9.2.2.4 Laminar Mixing: A Summary

The elongational deformation provides more efficient mixing than shear. On all three accounts, the magnitude of the interface increase, the energy required for mixing, and the rate of spatial separation of two material points, significantly better mixing (frequently by several orders of magnitude) is expected for extensional than for shear flow.

The fundamental assumptions in all these derivations have been that the system is rheologically decoupled, that there is neither an "active" interface nor a significant difference between viscosity of the mixture components. In consequence, coalescence does not exist and the flowing materials always are stretched, deformed, and the degree of mixedness continuously improves. By contrast with immiscible polymer blends, the model does not take into account either the shear coalescence or the thermodynamic coarsening.

Thus, the laminar mixing provides good guidance for the distributive homogenization of idealized polymer mixtures. The conclusions that come from this model may be directly applied for mixing of homologous polymer blends, temperature homogenization of polymer melt, or to mixing different batches of the same resin.

9.2.3 Chaotic Mixing

The term *chaotic mixing* was introduced by Ottino (1989) to describe laminar, distributive mixing with continuous or periodic translation of cavity walls. The phenomenon is universal, observed in many diverse branches of science and technology from aerodynamics to geology (Ottino 1989; Rauwendaal 1994). This type of mixing can be observed even in a simple geometry as a result of interplay of at least two velocity fields, which can be generated by either applying two type of forces (heating and shearing), imposing two types of motion, or imposing a specific type of flow geometry.

To illustrate the principle, a "two-dimensional" cavity was constructed. The boxlike geometry had a transparent front wall and movable top and bottom neoprene walls. An insertion of rod-shaped, fluorescent tracer drop (with only a cross section visible) made it possible to follow the laminar mixing as a function of time for diverse sequences of the top and bottom wall translations. As shown in Fig. 9.4, periodic translations resulted in stretching, folding, and transporting the drop much more effectively than the regular, steady-state translation. At the same strain, the mixedness index, expressed as a ratio of the generated interface to the initial one, was significantly higher for the periodic translations than for the steady state.

The experiments also demonstrated presence of the "mixing islands," where very little mixing took place. In consequence, the chaotic mixing could be schematically represented by the streamline diagram comprising the elliptic points located in the center of the "blinking vortex" and a hyperbolic point. Little mixing takes place around the elliptic points surrounded by circulating streamlines, while extensive mixing takes place at the hyperbolic points where the streamlines
Fig. 9.4 Mixing in a 2D cavity with *upper* and *lower* neoprene walls. *Left*, effect of continuous motion of both walls and, *right*, that of discontinuous motion (1/2 *top*, then 1/2 *bottom*, etc.). In both tests, the total walls' displacement was the same (Leong and Ottino 1989)

(leading in opposite directions) cross-link. Thus, the principle of chaotic mixing involves a non-steady-state translation of the material by stretching and folding that creates horseshoe-shaped domains of the dispersed phases (Smale 1967; Leong and Ottino 1989; Ottino 1990, 1991). Formally, it was described as originating from a "blinking" vortex that is periodically displaced by imposed strain on different cavity walls (Aref 1983).

As in the case of laminar mixing, here also it is advantageous to start consideration with a passive system. Imposition of periodic motion causes the domains to stretch and fold. Several 2D flows were explored and mathematically treated. Of these, the cavity flow (with two moving walls) and the journal bearing flow were investigated. For example, in the first geometry, good stretch-and-fold mixing was observed for the periodic, interrupted shearing of the upper then lower wall (see Fig. 9.4).

Three-dimensional chaotic mixing was studied by Liu and Zambrunnen (1995). A cylindrical cavity of the journal bearing type was constructed. The cylinder diameter was 79.0 mm, the height of the cavity was 23.7 mm, and the offset of the shearing wall centers was 27.6 mm. The disks were alternatively rotated, each for half period. The cavity was used to generate fine fibrillar structures (aspect ratio of about 1,000) of PE in either EVAc or PS. The authors observed that owing to extensional flow the mixing process is insensitive to the viscosity ratio. The principles of chaotic mixing are well established, but the development of mixing devices based on them still awaits real commercialization at large scale.

9.2.4 Dispersive Mixing: Micro-rheology

This topic has been already presented in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends." In the following section, only the aspects pertinent to mixing will be summarized (Utracki 1991, 1995).

It is important to recognize the advantages and the drawbacks of the micro-rheological approach. By contrast with the discussed above laminar mixing, the micro-rheology focuses on the physical differences between the two blends' components, the dispersed and the matrix fluids. Both the thermodynamic (expressed by the interfacial tension coefficient) and the rheological properties (expressed by the strain, stress, and the viscosity ratio) are important for the deformation and breakup of the dispersed phase. The drawbacks are numerous: assumptions of high dilution, low deformation rates, and that the systems are Newtonian. In spite of these, micro-rheology provides invaluable guidance for mixing of commercially interesting systems. For example, the use of these principles led to successful predictions of the blends' morphology evolution during flow in a twin-screw extruder (Utracki and Shi 1992; Huneault et al. 1995a).

9.2.4.1 Drop Deformability
When a neutrally buoyant, initially spherical droplet is suspended in another liquid and subjected to stress, it deforms into an ellipsoid and then breaks up into smaller

droplets. Taylor ([1932](#), [1934](#)) described the process (at low stress in a steady-state, uniform flow), using the following three dimensionless parameters: the viscosity ratio, the capillarity number, and the reduced time, respectively, defined as

$$\lambda \equiv \eta_d/\eta_m; \quad \kappa \equiv \sigma d/\nu_{12}; \quad t^* = t\dot{\gamma}/\kappa = \gamma/\kappa \tag{9.8}$$

where $\sigma = \dot{\gamma}\eta_m$ is the local stress; η_d and η_m are the dispersed phase and matrix viscosity, respectively; $\dot{\gamma}$ is the deformation rate; d is the droplet diameter; and ν_{12} is the interfacial tension coefficient.

During flow, the initially spherical drop deforms into a prolate ellipsoid with the long axis a_1 and two orthogonal short axes a_2. The drop deformability parameter (D) is a complex function. At low shear stress, it can be expressed as (Taylor [1934](#))

$$D_{shear} \equiv (a_1 - a_2)/(a_1 + a_2) = (\kappa/2)[(19\lambda + 16)/(16\lambda + 16)] \tag{9.9}$$

Since, for the full range of λ values from zero to infinity, the quantity in the square bracket in Eq. [9.9](#) ranges from 1.00 to 1.18, the drop deformability $D_{shear} \cong 0.55\,\kappa$. For highly viscous dispersed phase, i.e., $\lambda >> 1$, Taylor calculated that $D = 5/4\,\lambda$, but since the condition for drop break is $D \geq D_{crit} = 0.5$, this means that **shear flow can lead to drop breakage only when the viscosity ratio $\lambda < 3.8$** (Grace [1982](#)).

For the planar or the axisymmetric extensional flow, the theory predicts that the deformability is larger than in shear, respectively:

$$D_{planar} = 2D_{shear}; \quad D_{axisymmatric} = (3/2)D_{shear} \tag{9.10}$$

Cox ([1969](#)) derived the kinetic equation for the deformability of a drop in the planar flow:

$$D_{planar} = \kappa\left[(19\lambda + 16)/(16\lambda + 16)\right]\left[1 - \exp\left\{-(10\kappa/19\lambda)\,t^*_{planar}\right\} \right.$$
$$\text{where}: \quad t^*_{planar} \equiv (t\dot{\gamma}_{planar})\lambda/\kappa = \gamma_{planar}\lambda/\kappa \tag{11.11}$$

where γ_{planar} is the strain in planar flow and t^*_{planar} is the reduced time for planar deformation. It is worth noting that in the hyperbolic flow, the reduced time scale depends on the viscosity ratio. Unfortunately, Eq. [9.11](#) is valid only for small values of λ and κ. The exponential master curve is shown in Fig. [9.5](#). The effects of λ and κ on D are illustrated in Fig. [9.6](#).

The above relations are valid for Newtonian systems undergoing small, linear deformations, smaller than that which would lead to a breakup. As Fig. [9.4](#) indicates, in planar hyperbolic flow, about 10 units of strain is required to get into an equilibrium. In simple shear, $t^*_d \cong 25$ of the reduced time scale is required (Elemans et al. [1989](#)).

in hyperbolic planar flow [Cox, 1969]
9.2.4.2 Drop Breakup

From the point of view of the drop deformation and breakup, there are four
regions of the reduced capillarity numbers $\kappa^* \equiv \kappa/\kappa_{cr}$, both in shear and elongation:

For	$\kappa^* < 0.1$,	Droplets do not deform
For	$0.1 < \kappa^* < 1$,	Droplets deform, but do not break
For	$1 < \kappa^* < 2$,	Droplets deform then split into two primary droplets
For	$\kappa^* > 2$,	Droplets deform into stable filaments

The critical capillary number (κ_{cr}) is defined as the minimum capillarity number
sufficient to cause breakup of a deformed drop. It is customary to plot κ_{cr} as
a function of λ. For simple shear and uniaxial extension flow, De Bruijn
et al. (1989) found the following dependence (see Table 9.2 and Fig. 9.7):

$$\log(\kappa_{cr}/2) = c_1 + c_2 \log\lambda + c_3 (\log\lambda)^2 + c_4/(\log\lambda + c_5) \qquad (11.12)$$

Similarly as κ_{cr}, also the critical time for drop breakup (t_b^*) varies with λ. When
values of the capillarity number and the reduced time are within the region of drop
breakup, the mechanism of breakup depends on the viscosity ratio (λ). In shear, four
regions have been identified:

For	$\lambda << 0.1$,	Small droplets are shed from sigmoidal drops: *tip streaming*
For	$0.1 < \lambda < 1$,	Drop breaks into two principal and odd number of satellite droplets
For	$1 < \lambda < 3.8$,	Drop deforms into fiber then disintegrates into small droplets
For	$\lambda > 3.8$,	Drop may deform, but does not break

9.2.4.3 Drop Fibrillation and Breakup

For $\kappa^* > 2$, drops deform affinely with the matrix into long fibers. When subse-
quently the deforming stress decreases, causing the reduced capillarity number to

Table 9.2 Constants for drop breakup in Newtonian systems

Flow	$1000c_1$	$1000c_2$	$1000c_3$	$1000c_4$	$1000c_5$
Shear	−506.0	−99.4	124.0	−115.0	−611.0

fall below two ($\kappa^* < 2$), the fibers disintegrate under the influence of the interfacial tension (Tomotika 1935, 1936). The distortion amplitude α grows exponentially with time as

$$\alpha = \alpha_o \exp\{qt\} \qquad (11.13)$$

where α_o is the distortion at $t = 0$ and the growth rate parameter $q = \Omega(\Lambda, \lambda)(t^*/t)$, with $\Omega(\Lambda, \lambda)$ being a tabulated function of the distortion wavelength and the viscosity ratio. The thread breakup occurs when $\alpha = R \cong 0.81R_o$. The most serious obstacle for the quantitative use of Timotika's theory is the estimation of the initial distortion (α_o).

9.2.4.4 Micro-rheology of Viscoelastic Systems

The mechanisms governing deformation and breakup of drops in Newtonian liquid systems are relatively well understood. However, within the range of compounding and processing conditions, the molten polymers are viscoelastic liquids. In these systems, the shape of a droplet is determined not only by the dissipative (viscous) forces but also by the

pressure distribution around the droplet that originates from the elastic part of the stress tensor. Therefore, the characteristics of drop deformation and breakup in viscoelastic systems may be quite different from those in Newtonian ones. Some of the pertinent papers on the topic are listed in Table 9.3.

In summary, there is no theory capable to completely describe the deformability and breakup of viscoelastic drops in viscoelastic media or even one that provides explanation for the divergent observations. The complexity of the problem involves three-dimensionality, free surface, and nonstationary flow leading to complex constitutive equations. Furthermore, the role of fluid elasticity in the breakup process is still not well understood. In most experiments, the elasticity stabilized the deformed drops, thus making the dispersing process more difficult. However, there are also reports of the opposite effects. The micro-rheological behavior of two-phase liquid systems may provide but a general guidance for the drop deformation and breakup in polymer blends. For blends of industrial interest, the phenomenon is further complicated by higher concentration of the dispersed phase, as well as by the presence of numerous additives that affect the interfacial phenomena. The problem becomes even more complex for three-phase flows and for cases where surface active materials (surfactants, impurities, and particles) are present leading to Marangoni stresses and Pickering effect.

Nevertheless, one of the sources of confusion may originate from different types of liquids studied as large differences in deformability in convergent flow were observed for drop prepared from viscoelastic solutions or from Boger fluid (Bourry et al. 1999). Spiegelberg et al. (1996) have shown that a Boger fluid is strongly strain hardening. At Hencky strains larger than two, the elongational viscosity is larger than shear viscosity by three orders of magnitude. These high values of strain hardening may explain the large differences of deformability of two types of viscoelastic drops.

9.2.5 Distributive Mixing

Static mixers (SM), also called motionless mixers, operate on the principle of repetitive dividing of a flow channel into at least two new channels, reorienting them by 90° and dividing again. The flow is a pressure-driven, laminar shear. Mixing by SM is related to the numbers of striations (N_s) generated by a number of SM elements (n_e) and the number of divisions (new channels) engendered by each element (n_c):

$$N_s = n_c^{n_e} \tag{9.14}$$

Over 30 different SM designs have been commercialized (Rauwendaal 1986). Their efficiency is determined comparing (1) the length-to-diameter ratio

Table 9.3 Deformability of viscoelastic drop

Description	Reference
Higher κ_{crit} for viscoelastic system than for Newtonian drops	Gauthier et al. 1971
For Newtonian drops in viscoelastic fluid, elasticity of the medium stabilizes the drops	Flumerfelt 1972
$$\nu_{12} = \nu_{12}^o + (d_o/12)\big[(\sigma_{11} - \sigma_{22})_d - (\sigma_{11} - \sigma_{22})_m\big]$$ where ν^o_{12} is the interfacial tension in a quiescent polymer blend; d_o is the initial diameter of the dispersed drop; and the bracketed expressions are the first normal stress differences of the dispersed ($i = d$) and of the matrix ($i = m$) phase. For $(\sigma_{11} - \sigma_{22})_d > (\sigma_{11} - \sigma_{22})_m$, the above equation predicts that higher elasticity of the dispersed phase than that of the matrix causes the interfacial tension coefficient to increase, what leads to more stable drops. For $(\sigma_{11} - \sigma_{22})_d < (\sigma_{11} - \sigma_{22})_m$, it predicts that $0 < \nu_{12} < \nu^o_{12}$; thus the flow tends to enhance the dispersing process (flow compatibilization). However, as the shear stress increases, the above equation predicts a physically untenable condition: $\nu_{12} < 0$. To avoid this nonphysical situation, the system morphology changes from dispersed to lamellar	Van Oene 1978
Viscoelastic drops in either Newtonian or viscoelastic media were reported more stable (less deformable) than the Newtonian ones. The critical shear rate for droplet breakup was lower for $\lambda < 1$ than for $\lambda > 1$	Han and Funatsu 1978; Chin and Han 1979, 1980
Initially, disturbances grow more rapidly in viscoelastic filaments than in Newtonian ones, but at a later stage, there is stabilization, resulting from large extensional stresses (see Fig. 9.8). As a result, the time required to break the viscoelastic drop is longer than that for Newtonian. Formation of the satellite drops was found to be retarded by elasticity	Bousfield et al. 1986
Both the drop and the medium were viscoelastic. Drops did break during extrusion, even when $\lambda > 4$, but the mechanism is not clear	Wu 1987
In viscoelastic systems, κ_{crit} is always higher than in Newtonian: drop elasticity hinders drop breakup whatever the λ value	De Bruijn 1989
When $\lambda < 0.5$, the drop elasticity has stabilizing effect	Prabodh and Stroeve 1991
Predictive model for the morphology variation during simple shear flow under steady-state uniform shear field was developed. The model considers the balance between the rate of breakup and the rate of drop coalescence. The theory makes it possible to compute the drop aspect ratio ($p = a_1/a_2$), a parameter that was directly measured for PS/PMMA = 1:9 blends. Theoretically and experimentally, p vs. shear stress shows a sharp peak at the stresses corresponding to a transition from the Newtonian plateau to the power-law flow, i.e., to the onset of the elastic behavior (see Fig. 9.9)	Lyngaae-Jørgensen et al. 1993, 1999
Deformation of a single drop in a medium subjected to convergent flow was observed. Both liquids were of the Boger fluid type. For a given matrix, the drop deformability decreased with elasticity of the dispersed phase. For a given	Mighri et al. 1997

(*continued*)

Table 9.3 (continued)

Description	Reference
drop liquid, the drop deformability increased with the matrix elasticity. The following empirical equation was proposed: $$l_{d,E} = l_{d,N} - \Delta P(l_m - 1)$$ where l_d is the aspect ratio of the elastic (subscript E) or Newtonian (subscript N) drop, ΔP is a function of the elasticity ratio, and l_m is the matrix deformation expressed in Hencky terms	
The deformability of viscoelastic drops in a Newtonian matrix was studied in convergent slit flow. Both the experimental observations and the boundary element method computations were carried out. It was reported that deformation of Boger fluid drops was quite low: about 1/3 of that recorded for the deformability of a strongly shear-thinning, viscoelastic solution. The latter drops showed deformability similar to the ones observed for Newtonian drops of similar viscosities	Bourry et al. 1999
The steady-state deformation of isolated droplets decreases with increasing dispersed phase elasticity for the same imposed capillary number. A linear relationship between critical capillary number for droplet breakup (κ_{crit}) and dispersed-phase Weissenberg number (Wi_d) holds up to a value of Wi_d around unity, with a saturation at around $\kappa_{crit} = 0.95$ for high Wi_d	Lerdwijitjarud et al. 2002, 2004
In Newtonian fluids, drop deformation is dominated by the competition between interfacial tension and viscous forces due to flow. When the matrix is viscoelastic, however, drop deformation is suppressed when the Deborah number De is small, but increases with De for larger De	Yue et al. 2005
Viscoelastic effects alter the steady drop shape from being ellipsoidal to drop shapes with more blunt ends. The results reflect a balance between the direct tensile stress contribution of the viscoelastic fluid to the normal stress balance and modifications of the viscous (i.e., Newtonian) stress and pressure due to viscoelastic changes in the flow	Hsu and Leal 2009
The deformation of a viscoelastic drop suspended in a Newtonian fluid subjected to a steady shear is investigated using a front-tracking finite-difference method. The viscoelasticity is modeled using the Oldroyd-B constitutive equation. The drop shows slightly decreased alignment with the flow as viscoelasticity increases. κ_{crit} for drop breakup is observed to increase with De owing to the inhibitive effects of viscoelasticity	Aggarwal and Sarkar 2007
The breakup of confined droplets was studied systematically for systems with either interfacial or component viscoelasticity. κ_{crit} of Newtonian and compatibilized droplets showed a similar increase with increasing confinement ratio. However, a decrease in breakup length was observed in the compatibilized case, caused by the viscoelastic interface. Viscoelastic droplets experienced more stabilization by confinement compared to Newtonian droplets	Cardinaels et al. 2011

(L/D proportional to n_e) required to produce the same degree of homogeneity; (2) the associated pressure drop, ΔP_{rel}; (3) the holdup volume, ΔV_{rel}; and (4) the relative dimensions of the device, D_{rel} and L_{rel}. The efficiency of SM also depends on the type of liquid. For example, Ross mixer was found better for pseudoplastic polymer melts, whereas Kenics mixer for Newtonian fluids (Ottino 1983). An example of comparative evaluation of 11 earlier commercial SM is presented in Table 9.4. Comparative studies have been published for the emulsification of low-viscosity liquids in turbulent flows (Theron and Le Sauze 2011) and for highly viscous liquids in laminar flows (Meijer et al. 2012). The most known SM producers, besides the ones presented in Table 9.4, are Chemineer, Euromixers, Koflo, Nordson, Parker, Statiflo, StaMixCo, Sulzer, and Westfall.

9.2.6 Mixing in Extensional Flow Field

The elongational flow field exists anywhere where the streamlines are not parallel. This type of deformation is quite common during the processing like in foaming, fiber spinning, film blowing, blow molding, biaxial and uniaxial stretching, and similar operations carried out downstream from the die (calendering). However, these operations have little to do with mixing.

It is extremely rare to find a mixer where the energy dissipated in extension is nearly as large as that in shear and mixing is overwhelmingly carried out in the shear field. Since the easiest method for the generation of extensional flow is by means of convergence and divergence, the attention will be focused on these types of deformations.

9.2.6.1 Orientation of Solid Particles

The extensional flow field has been used to generate orientation either in homopolymers or in filled or reinforced systems. The convergent flow results in high fiber alignment in the flow direction, whereas the diverging flow causes the fibers to align 90° to the major flow direction. Shearing reduces the alignment. The early theoretical studies of the elongational flows were carried out by Takserman-Krozer and Ziabicki (1963). Molden (1969) developed a geometrical theory that showed the extensional strain to be more effective than shear for fiber alignment. Several other theoretical descriptions of the chopped fibers orientation in flow have been proposed (Lockett et al. 1972; Johnson et al. 1972; Vincent and Agassant 1985). For example, Goettler used the convergent–divergent die geometry to orient fibers in the transverse direction, greatly improving pipes' hoop strength (Goettler 1970; Goettler and Lambright 1977; Lee and George 1978; Crowson et al. 1980; Goettler et al. 1981; Goettler and Shen 1983).

9.2.6.2 Convergent Flow of Viscoelastic Fluids

The fundamental studies of drop deformation in convergent–divergent geometry were carried out using either axisymmetric (Mighri et al. 1997) or slit geometry (Bourry et al. 1999) (see Table 9.3). The analysis of converging flow of viscoelastic fluids using nonlinear viscoelastic models was carried out by several authors. The work is summarized in Table 9.5.

9.2.6.3 Blending in Extensional Flow Field

The use of extensional flow field for mixing is relatively unexplored, while a growing number of reports show that mixing in extensional flow field is more efficient than in shear, especially for blends with higher viscosity ratio, $\lambda \geq 3.8$, where the shear field is unable to cause drop breakup (Grace et al. 1971).

Most of the works on mixing in the extensional flow field consider convergent flow of Newtonian liquids, flowing from a reservoir to a capillary (Tsebrenko et al. 1974, 1976; Ablazova et al. 1975; Krasnikova et al. 1978; Vinogradov et al. 1982; Han and Funatsu 1978; Chin and Han 1979, 1980; Han and Yu 1981; Han 1981). The following factors affecting the quality of blends were identified:
  (i) Diameter of the convergence, d_c
 (ii) The ratio of the reservoir-to-convergence diameters, usually expressed as the convergence ratio, $C \equiv d_r/d_c$
(iii) The capillary length-to-diameter ratio, $R \equiv L/d$
 (iv) The initial drop size, d
  (v) Extensional viscosity ratio, $\lambda_\varepsilon \equiv \eta_{\varepsilon d}/\eta_{\varepsilon m}$ (extensional viscosities of the dispersed phase and that of the matrix, $\eta_{\varepsilon d}$ and $\eta_{\varepsilon m}$, respectively, to be taken at the conditions existing during the mixing, i.e., extensional stress (σ_{11}), temperature (T), pressure (P), etc.)
 (vi) Absolute value of the elongational stress, σ_{11}
(vii) The number of passages through the convergence
    These factors affect both the dispersive and distributive mixings.
    Suzaka (1982) patented an extensional flow mixer, composed of a series of plates placed across the flow channel. A polymer blend was forced to pass through a series of convergent and divergent orifices (or c-d for short) that elongated the drops and dispersed them. All the circular orifices had the same size; i.e., the convergence ratio was constant. The mixer provided good mixing for some systems but not for others. Furthermore, the device could be optimized only by trial and error. Any change in the blend composition required repetitive testing, the process had to be interrupted, and the mixing plates changed. In consequence, the mixer has not been commercially explored.

9.2.6.4 Extensional Flow Mixer

During the last few years, there has been significant progress in the fundamental understanding of micro-rheology and its role for polymer blending. Flow visualizations of the Newtonian and non-Newtonian systems have been carried out (Mighri et al. 1996; Picot 1997; Bourry et al. 1999). The boundary element method (BEM)

Table 9.5 Convergent flow of viscoelastic systems

Description	Reference
Kaloni used the Oldroyd model and Schümmer a fourth-order fluid model, while Wissler a nonlinear Maxwell model. Employing the perturbation method, the authors observed that the inclusion of second-order perturbation terms (which bring in the non-Newtonian effects) predicted velocity profiles with superimposed secondary circulation patterns	Kaloni 1965; Schümmer 1967; Wissler 1971
Normal stresses of HDPE and PP flowing through a converging channel were measured. Near the die exit, the wall normal stress rapidly increased. Relationships were derived for the wall shear stress, normal stress difference at the channel wall, and the wall normal stress gradient in the flow through a converging channel and through a conical duct. Contrary to viscometric flows, in the converging flow field, the normal stress alone does not permit to determine the pressure gradient of viscoelastic fluids	Han 1973, 1974, 1975
Flow into either sharp-edged or tapered die was studied using stress-optical measurements. Distribution of shear stress and normal stress difference was obtained for PS melt: neither stresses nor velocities showed secondary motion	Han and Drexler 1973
Flow through converging–diverging tubes has been computed (velocity fields, pressure distribution, and wall stresses). The velocity profiles were measured using laser Doppler anemometry	Theodorou et al. 1984
Flow through an axisymmetric pipe, whose diameter was slowly varying in the axial direction, was theoretically described. A converging flow rheometer was developed	Williams and Javadpour 1980; Williams and Williams 1985
Converging and diverging dies produced flat, biaxially oriented extrudates. Relationships between the die geometry and product orientation were established	Mascia and Zhao 1991; Lohfink and Kamal 1993
Flow of multilayer viscoelastic fluids in converging channel slit die was analyzed. The neutral stability contours were altered in the channel flow. The effect of convergence on interfacial stability was similar to that of the elasticity. Channel convergence can be used to stabilize the interface at low depth ratios provided that shear-thinning effects are more dominant in more viscous layers	Su and Khomami 1992
The interface of PP/HDPE system can become unstable in both converging and diverging channels when the layer/depth ratio and disturbance wave number lie in a certain region	Khomami and Wilson 1995
Flow along the central axis of a converging conical channel was used to investigate the contribution of elasticity on drop using a Boger fluid. Drop deformation decreases with increasing elasticity. For elasticity ratio, $k' < 0.2$, the matrix elasticity has more effect on the drop deformation than drop elasticity. However, for $k' > 0.2$, drop deformation is more affected by drop elasticity	Mighri et al. 1997

Table 9.5 (continued)

Description	Reference
Flow in cylindrical, converging die with semi-hyperbolic shape was used to measure the elongational viscosity of polymer melts	Collier et al. 1998; Feigl et al. 2003
Droplets of polymer blends flowing through convergent channels undergo collisions and coalescence. Compared with methods using simple shear flow, the convergent flow pattern combines both shear and extensional flows	Miroshnikov et al. 2011

provided important information on the evolution of drop shape during the flow through c-d channel (Luciani et al. 1997; Khayat et al. 1996). This led to designing of a new extensional flow mixer (EFM) in which the blend is repeatedly exposed to extensional flow fields and semi-quiescent zones. The c-d channels are of progressively increasing intensity, with flow in the radial not axial direction. To reduce the pressure drop and to prevent blockage, slit restrictions are used (Nguyen and Utracki 1995; Utracki and Luciani 1997).

The EFM is a fully adjustable, general-purpose, motionless mixer. The mixing action is provided by the development of extensional flow field through the c-d geometry. It is primarily a dispersive mixer that should be attached to a pressure-generating device. It efficiently homogenizes different liquid systems, even these where the components' viscosity ratios are large. The mixer attached to a single-screw extruder provided comparable or better mixing than a twin-screw extruder with the so-called mixing screw geometry (Bourry et al. 1995; Utracki and Luciani 1996; Luciani and Utracki 1996). EFM has been used for polymer blending, incorporation of elastomers into resins, and dispersion of high-viscosity resins or "gel particles."

Figure 9.10 shows a cross section of the EFM. The molten polymer blend enters the EFM from an extruder through an adapter plate #1. The melt is distributed by the distributing plate #3 to six slits, located between the cone and the mounting ring of the part #3. Next, the melt enters the annular space inside the EFM body #5 where it is directed to the space limited by the upper (part #4) and lower (part #6) c-d plates. There it flows from the rim toward the center, undergoing the convergent and divergent deformations before sorting out through the central passage in the lower plate #6 and the central bore in the plate holder #7. The magnitude of the stresses is controlled by the pressure (generated by the extruder) and by the gap between the two c-d plates (parts #4 and 6). The latter is adjusted by turning the adjusting plate #8.

The pressure drop (ΔP) across the EFM was calculated using an expression proposed by Binding (1988). The pressure loss across the c-d plates (ΔP) was computed for a series of blends with either PE, PP, or PS as matrix. The result can be either expressed by the proportionality or given by a linear fit:

$$\begin{aligned}
\Delta P_{exp} &= (1.026 \pm 0.195)\Delta P_{calc}; \quad \text{or} \\
\Delta P_{exp} &= 0.0512 + 1.044\Delta P_{calc}, \quad R = 0.9772
\end{aligned} \quad (9.15)$$

The computations made it possible to separate the pressure losses into the extension and shear contributions (PE and PS), respectively. As evident
Fig. 9.10 Cross section of the extensional flow mixer (EFM) assembly. The numbered parts are described in the text

from Fig. 9.11, in EFM the pressure drop caused by elongation is larger than that by shear.

The performance of EFM attached to a single-screw extruder (SSE) was examined in reference to the results obtained using a corotating, intermeshing twin-screw extruder (TSE) equipped with the recommended-by-the-manufacturer high-dispersion screws. Four types of mixing were studied: dispersion of a viscous polymeric blend component in at least four times less viscous polymer matrix, impact modification of engineering resins, elimination of gel particles from reactor powders, and homogenization of new metallocene polyolefin mixtures having very large ratios of melt flow index. The results showed that compounding in SSE + EFM resulted in finer dispersion of HDPE in PS and vice versa than in a TSE. Similarly, the impact properties of EPR/PP blends prepared in SSE + EFM were better than of the same compositions mixed in TSE. The SSE + EFM mixing unit was also superior to TSE as far as dissolution of very high molecular weight fractions (polymeric gel particles) was concerned (Utracki and Luciani 1996; Luciani and Utracki 1996). The original EFM was commercialized in 1999, but an improved version was presented 1 year later reporting better gel elimination and more uniform morphology leading to higher blend strength (Song 2000). Then, numerical simulations (finite element methods) on shear-thinning (Carreau model)
Fig. 9.11 Total pressure drop across the EFM c-d plates and its extensional and shear components vs. throughput of polypropylene, using a gap of one millimeter

and viscoelastic (Phan-Thien–Tanner model) fluids showed that possible stagnation regions in the c-d plates can be obtained for viscoelastic fluids. The size of the stagnation region increases for strain-thickening fluids, while it disappears when no elasticity is present (Tanoue and Iemoto 2003). Other versions, called EFM-3 and EFM-N, were shown to produce high-performance nano-composites based on PA-6 and PP with nanoclays (Cloisite C15A) due to increased dispersion and exfoliation (Tokihisa et al. 2006).

9.2.7 Interphase Properties

9.2.7.1 Importance of the Interfacial Tension Coefficient

At high dilution, the morphology of an immiscible blend is controlled by the viscosity ratio (λ), the capillarity number (κ), and the reduced time (t^*) as defined in Eq. 9.8. The interfacial and rheological properties enter into κ and t^*. As the concentration increases, the coalescence becomes increasingly important. This process is also controlled by the interphase properties.

Blending two immiscible polymers always creates a third phase called the interphase. In binary blends, thickness of this third phase (Δl) is inversely proportional to the interfacial tension coefficient (ν_{12}). When the blend approaches miscibility, ν_{12} approaches zero and Δl goes to infinity. Thus the interphase with its own set of characteristic parameters (viscoelasticity) may dominate the behavior of nearly miscible systems, as well as that of compatibilized blends. For further

details on this topic, see ▶ Chap. 4, "Interphase and Compatibilization by Addition of a Compatibilizer."

To modify the interphase properties, three strategies of compatibilization have been developed:

  (i) Addition of a small quantity of a third component that either is miscible with both phases (cosolvent), or it is a copolymer whose one part is miscible with one phase and another with the other phase (0.5–2 wt%, usually block-type or a graft one).
 (ii) Addition of a large quantity (less than 35 wt%) of a core-shell copolymer that behaves like a multipurpose compatibilizer-cum-impact modifier.
(iii) Reactive compatibilization designed to enhance domain interactions. The reactive blending may be employed to generate in situ the desired quantities of either block or graft copolymer(s) (see also in this book Chap. ▶ 5, "Reactive Compatibilization").

Different strategies lead to different alloys, having different sets of properties like addition of a small amount of block copolymer mainly affects the interfacial tension coefficient, thus the size of dispersion, but under normal circumstances, it only slightly affects the shear sensitivity of the blends' morphology or the solid-state behavior. Reactive compatibilization was found to produce thick interphase, which resulted in excellent stability during intense processing and good mechanical performance.

9.2.7.2 Theoretical Aspects of the Interface

The Helfand and Tagami (1971, 1972) model is based on self-consistent field that determines the configurational statistics of the macromolecules in the interfacial region. The interactions between the statistic segments of polymers A and B are determined by the thermodynamic binary interaction parameter (χ_{12}). The isothermal segmental density profile shown in Fig. 9.12, ρ_i (i = A or B), was calculated for infinitely long macromolecules, $M_w \to \infty$. The interfacial thickness (Δl_∞) and the interfacial tension coefficient (ν_∞) were expressed as

$$\Delta l_\infty = 2b/(6\chi_{12})^{1/2} \; ; \quad \nu_\infty = b\rho k_B T(\chi_{12}/6)^{1/2} \tag{9.16}$$

where b is a lattice parameter, k_B is the Boltzmann constant, and T is the absolute temperature. The Helfand–Tagami lattice theory predicted that (1) the product $\nu \Delta l|_\infty$ is independent of the thermodynamic binary interaction parameter, (2) the chain ends of both polymers concentrate at the interface, and (3) the low molecular weight components are repulsed to the interface.

Addition of a compatibilizer reduces ν_{12} to the level corresponding to the critical micelles concentration or CMC (Utracki and Shi 1992; Tang and Huang 1994). The radius of the dispersed drop (R) follows the same "titration curve" as the interfacial tension coefficient ν_{12}.

Segmental density profile across the interface
Fig. 9.12 Computed segmental density profile across the interface. The figure defines the interphase thickness Δl (after Helfand and Tagami 1971)

The amount of the interfacial agent required to saturate the interface (w_{cr}) per volume fraction of the dispersed phase (ϕ) can be expressed as (Paul 1978; Matos 1993)

$$w_{cr}/\phi = 3M/RN_{Av}\zeta \tag{9.17}$$

where M is the molecular weight, R is the radius of the dispersed drop, N_{Av} is the Avogadro number, and ζ is the area occupied by a copolymer molecule, taken either as a cross section of a copolymer chain (ca. 5 nm^2) or proportional to the square of the end-to-end distance of the copolymer chain, $\zeta = \langle r^2 \rangle/9$.

9.2.7.3 Calculations of the Interfacial Tension Coefficient

The interfacial tension coefficient can be calculated from the solubility parameters (δ) that comprises contributions from the dispersive, polar, and hydrogen bonding interactions. The following dependence was proposed (Luciani et al. 1996, 1997):

$$\nu_{12} = k(\rho RT)^{n-1} \left[\Theta(\delta_{1d} - \delta_{2d})^2 + (\delta_{1p} - \delta_{2p})^2 + (\delta_{1h} - \delta_{2h})^2 \right]^n \tag{9.18}$$

where k is a constant, $\Theta = 1$–4 is a parameter, and exponent n (depending on the adopted theoretical assumptions) $n = 1/2$–$3/2$. The expression $(\rho RT)^{n-1}$ is not sensitive to temperature. All available experimental values of ν_{12} were plotted as functions of the computed values for polymer blends, assuming that all factors have the same value, $\Theta_i = 1$ (see Fig. 9.13).
Fig. 9.13 Interfacial tension coefficient computed from the chain structure of the polymeric chains for 46 polymer blends vs. the computed solubility parameter difference (Luciani et al. 1996)

9.2.8 Coalescence

During mixing, the dispersed phase progressively breaks down until a minimum drop diameter, d, is reached. For Newtonian systems, the size of the smallest drop that can be broken can be calculated from the Taylor theory (see Eq. 9.9). However, many experimental studies (Tokita 1977; Roland and Bohm 1984; Plochocki et al. 1990; Willis et al. 1990, 1991; Favis et al. 1991) have shown that the final drop size is usually larger than predicted. For example, only when $\phi_d < \phi_o \approx 0.005$, the observed drop sizes approached the theoretical values (Elmendorp and Van der Vegt 1986). The source of the discrepancy is coalescence.

There are two types of coalescence mechanisms, the first being determined by the equilibrium thermodynamics and the second caused by flow. Thus, coalescence occurs in flowing as well as quiescent systems. To the latter type belongs the *Ostwald ripening*, characterized by the linear increase of the drop volume with time; i.e., $d^3 \sim t$. The process involves diffusion from smaller drops (high interfacial energy) to the larger ones. Flow modifies the rate of this process and the rate depends on the drop dynamic cross section, i.e., $d^n \sim t$, where $3/2 < n < 3$ (Ratke and Thieringer 1985).

Tokita (1977) suggested that the drop diameter in polymer blends originates from the two competitive processes: continuous breakup and coalescence of the dispersed particles. The equilibrium drop diameter should increase with concentration, number of drops, and the interfacial tension coefficient, but decrease with shear stress (σ_{12}). The dependence qualitatively agrees with experiments (Liang et al. 1983; White and Min 1985; Willis et al. 1991).

The coagulation time (t_c) of PVC lattices under steady-state shear flow followed the theoretical relation (Utracki 1973)

$$t_c \propto d^3 \phi_d^{-8/3} \dot{\gamma}^{-2} \qquad (9.19)$$

The coagulation rate was related to the projected area of the drop $d^* \propto \phi_d^{2/3}$. The relation separates the effects of the particle diameter, the concentration, and the rate of shear. When the other variables are constant, the coagulation time increases with particle diameter following the Ostwald ripening kinematics. It decreases with nearly a cube of concentration and with a square of the shear rate.

From Eq. 9.19, the rate of diameter change due to coalescence can be expressed as

$$(\mathrm{d}d/\mathrm{d}t)_{\text{coalescence}} \propto \dot{\gamma}\, \phi^{8/3}/d \qquad (9.20)$$

On the other hand, micro-rheology predicts that the rate of diameter change due to break is

$$(\mathrm{d}d/\mathrm{d}t)_{\text{break}} \propto \quad -\dot{\gamma}\, d/\kappa_{cr} t_b^* \qquad (9.21)$$

These two equations indicate which factors can be used to enhance either dispersion or coalescence. Clearly, the shear rate is expected to similarly affect coalescence and breakup. However, the flow-induced coalescence is a strong function of concentration, whereas the break is not; thus concentration may be used to discriminate between these two processes. Furthermore, the rate of break is proportional to d, whereas the coalescence is proportional to 1/d. Thus, coalescence is not expected to play a major role in the beginning of the dispersion process.

Equating Eqs. 9.20 and 9.21 leads to (Huneault et al. 1995a)

$$d_{eq} = d_{eq}^o + \left(6C\kappa_{cr} t_b^* \phi^{8/3}\right)^{1/2} \qquad (9.22)$$

where κ_{cr} is the critical capillary number for breakup, t_b^* is the time to break, ϕ is the volume fraction of the dispersed phase, d_{eq} is the equilibrium drop diameter, and d_{eq}^o is its value extrapolated to zero concentration (see Fig. 9.14).

9.2.9 Measures of Mixedness

As defined above, mixing is an operation that provides enhanced spatial homogeneity of a system. However, the homogeneity is not an absolute parameter. Depending on the scale of observation, one can always find domains belonging to a single component of the mixture. By definition, mixtures that show heterogeneity of composition on a scale not larger than the radius of gyration of a given polymeric chain are considered thermodynamically miscible. They may be considered as having the ultimate degree of mixedness.
Fig. 9.14 Average equilibrium diameter of polyethylene dispersed in polystyrene matrix as a function of PE volume fraction. The data were obtained blending the resins in an internal mixer at 200 °C until an equilibrium drop size was obtained after 300 s

Assessment of the quality of a mixture, or mixedness, is difficult and time consuming. Since the performance of blends is controlled by the optimum degree of dispersion, as well as by other factors (compatibilization, adhesion in solid state, the level of degradation engendered during the blending, etc.), the mixedness must be considered a separated quantity, to be determined independently of the blends' performance.

In a binary mixture of two polymers, A and B, their local concentration (in weight fraction) can be expressed as $a(\mathbf{x}) + b(\mathbf{x}) = 1$ (where $\mathbf{x}$ denotes vectorial location). Similarly, the sum of the average compositions $a_{av} + b_{av} = 1$. For such a system, the mixedness can be described by the binary frequency function. For fine dispersions, variance of the composition and the intensity of segregation can be defined as (Hold 1991; Tucker 1991)

$$\text{Variance}: \quad \sigma_a^2 = \left\langle [a(x) - a_{av}]^2 \right\rangle$$
$$\text{Segregation intensity}: \quad I_s = \sigma_a^2 / a_{av} b_{av}$$
(9.23)

Since segregation is not uniform, it is important to know the scale of segregation in the mixture. The volume scale of segregation is defined as (Danckwerts 1953)

$$S_v = 2\pi \int_0^\infty \{R(r)/\sigma_a^2\} dr; \quad where: \quad R(r) \equiv \langle [a(x) - a_{av}][a(x + r) - a_{av}] \rangle$$

(9.24)

The segregation intensity varies between 0 and 1. For the mechanical mixtures of immiscible polymers, the parameter I_S is close to 1; thus other measures of mixedness must be found.

An excellent measure of mixedness is the *specific interfacial area*, or the interfacial area per unit volume of the mixture (A_V). For completely separated phases, $A_V = 1\ m^2/1\ m^3 = 1\ m^{-1}$. As the mixing progresses, the value of A_V increases. The larger is the value, better is the blend's mixedness. In laminar shear mixing A_V of randomly oriented elements depends on strain (γ):

$$A_v = 4\lim_{r\to o}(dR(r)/dr) = (A_{v,o}/2)\exp\{\gamma/2\} \qquad (9.25)$$

where $A_{v,o}$ is the initial interfacial area at strain $\gamma = 0$. It was estimated that for adequate laminar mixing, 18,000 strain units is required, which gives $A_v/A_{v,o} \to \infty$ (Hold 1991).

For layered or laminar mixtures, one can also define mixedness by the striation thickness (s) defined as 1/2 of the layer thickness. It can be shown that in these systems there is a simple relation: $A_V = 1/s$. Since in real blends there is a variety of striation thickness, s should be expressed by a volume distribution function.

Another excellent description of mixedness is the power spectrum, derived by Fourier transformation of the correlation function:

$$P(n) = \int_{-\infty}^{\infty} R(r)\exp\{-2\pi inr\}dr \cong 2\int_{-\infty}^{\infty} R(r)\cos(2\pi nr)\,dr \qquad (9.26)$$

where n is the wave vector. The power spectrum can be used to calculate the variance and the linear scale of segregation as

$$\sigma_a^2 = \int_{-\infty}^{\infty} P(n)dn; \qquad S_L = \int_{0}^{\infty} R(r)dr / \int_{-\infty}^{\infty} P(n)dn \qquad (9.27)$$

Although several image analysis techniques based on optical, electronic (SEM, TEM), and atomic (AFM, STM) microscopy have been developed to study the morphology of polymer blends, they are usually time consuming and need tedious sample preparation. Hyperspectral image analysis (UV-VIS-NIR) was shown to be a powerful tool to get rapid information as online and off-line measurements can be performed, but usually with lower resolution. For example, PS/LDPE blends were successfully analyzed via film blowing (Gosselin et al. 2009). These multivariate image analysis (MIA) is usually combined with principal component analysis (PCA) to extract two-dimensional information on composition, homogeneity via texture analysis (Gosselin et al. 2009), and crystallinity (Gosselin et al. 2008) and with some previous modeling/calibration mechanical properties (Gosselin et al. 2011).

9.2.10 Morphology Evolution During Processing

Blending is an economically viable, versatile method of manufacturing new materials with a wide range of properties (Utracki 1987, 1993; Rauwendaal 1986). The parameters most frequently targeted for the improvement by blending are stiffness, strength, processability, heat deflection temperature, and cost-to-performance ratio.

When designing a blend, first, the polymers and their approximate concentrations must be selected and then the most appropriate blend morphology for the envisaged application. For example, the need to improve impact properties implies that the minor phase ought to be dispersed as spherical droplets with micron or submicron diameter. On the other hand, if the material is to be used in vapor on solvent barrier applications, the minor phase should be dispersed in the form of relatively large, thin lamellas. The desired morphology is obtained by selecting the appropriate compatibilization and compounding/processing methods (Utracki 1993, 1998).

9.2.10.1 Sample Collection for the Morphology Characterization

Several methods have been proposed to follow the morphology evolution in an extruder. Ideally, the method should make it possible to instantaneously freeze the structure, without imparting changes due to stress, stress relaxation, or coalescence. The frozen structure may then be analyzed for the degree of fusion, crystallinity, composition, degree and type of dispersion, etc. Table 9.6 lists some of the more popular methods used for the characterization of morphology evolution during blending in an internal mixer, an extruder, or a special mixing device. Blends' morphology has been studied by several research teams: Elemans et al. (1988, 1990), Lindt et al. (1992), Utracki and Shi (1992), Huneault et al. (1995b), Delamare and Vergnes (1996), Cho and White (1996), etc.

There are numerous small single- or twin-screw extruders developed for the preparation of small quantity of blends and evaluation of their morphology. These are particularly useful for compatibilizer optimization. The SSE-type recirculating devices are well represented by mini-extruders, *Microtruder*™, having throughput ≥ 10 g/h (Luker and Leistritz 1996). Recirculating TSE with a sampling port in the bypass line was originally developed at DSM. Later, the unit was commercialized. Owing to the small size, its specimens can be rapidly quenched.

Following on the success of the extensional flow mixer (see Sect. 9.2.6.4), an extensional mini-mixer was designed. The device consists of two reciprocating pistons with a convergent–divergent, c-d, restriction between them. The material to be mixed is introduced to the mixing chamber, heated under vacuum until the desired temperature is reached. Next, it is forced repeatedly through the c-d restriction, by the action of the reciprocating pistons (Utracki 1996).

9.2.10.2 Modeling of the Morphology Evolution

Several attempts were made to develop mathematical models capable of describing the morphology evolution during blending in different model flows and compounding machines. These efforts are summarized in Table 9.7 and briefly discussed below under separated headings.

Table 9.6 Experimental methods for morphology characterization

Mixer	Description	Reference
SSE, now used also for TSE	The oldest and the most primitive method is the so-called carcass method, viz., stopping the motor, cooling the compound, and removing either screw(s) or a barrel to access the solidified resin. Due to the thermal inertia of the system, the minimum time for the solidification is about 15–20 min. During this period, extensive changes of blends' morphology may take place. The observed structure can hardly reflect the structure existing during the blending	Maddock 1959
TSE	Not much better is the dead-stop method and sliding out the barrel (Clextral BC 45 mm extruder). Three methods were described: 1. Cooling the barrel with water requires at least 5 min. 2. Sliding out the barrel and then cooling by sprinkling water on the melt still requires several minutes. 3. The best choice is to slide out the barrel and then to take molten samples from the hot screws and quench them in cold water. The methods 2 and 3 may affect the morphology. Significant differences of the average drop size were reported between samples collected using the three methods	de Loor et al. 1994, 1996; Delamare and Vergnes 1996
TSE	Similar to the sliding barrel is the method that uses a clamshell barrel. The morphology is quenched by either pouring a cooling liquid (ice water or liquid nitrogen) or quenching the specimens taken from various locations in a cooling medium. Opening the barrel causes deformation of the molten blend. Here, the time lag is 2–5 min. Prior cooling of the extruder and opening it after reheating the surface require a comparable time lag to the carcass method, 15–20 min. A Baker Perkins 50.8 mm and Werner & Pfleiderer up to 70 mm are popular TSE used for this method	Kalyon et al. 1988; Sundararaj et al. 1992
TSE	A quenching double-barrel clamshell section was designed and manufactured for a ZSK-30, to replace two barrel segments. The section played the same role as the regular barrel elements, but it had extra quenching channels for chilled water (4 °C). Once blending reached a steady state, the screw rotation and heating were stopped and the quenching unit was switched on. It took 4–6 s to quench the polymer near the barrel wall and about one minute to quench the position near the screw root. It was calculated that in the kneading disks, quenching took about 10 s. The advantage of this method is the ability to quench a blend at any location along the screw, within seconds without deforming the material	Bordereau et al. 1992; Shi et al. 1992

(continued)

Table 9.6 (continued)

Mixer	Description	Reference
TSE	TEX extruders with sampling nozzles along the barrel were introduced. The nozzles have been designed to follow the chemical reactions during the blending, but they can be used as well to follow the morphological changes. The disadvantage of the system is that the sampling barrel elements can be placed only at the locations where sufficient pressure is generated to force the melt through the nozzle. Furthermore, depending on the morphology and stresses in the nozzle, the blend morphology may be modified. The quenching time was estimated at 3–5 s	Nishio et al. 1990, 1992; Sanada et al. 1991; Sakai 1993
TSE	The most rapid method of quenching involves scooping the specimens directly from an operating extruder and quenching these in either ice water or liquid nitrogen. It takes ca. 1 s to quench the sample. Furthermore, scooping does not impose extensive changes of morphology. Its disadvantage rests with the limited number of sampling ports. Large differences of morphology were observed within the first few seconds after TSE screws were stopped	Huneault et al. 1995b
Special	A "dispersion tester" consists of a rotating drum with a milled grove, in which a stationary spreader was placed. The gap, clearance, drum speed, temperature, pressure on, and the shape of the spreader could be controlled. The specimen could be subjected to repeated passages, with the morphology analysis after each passage. The device was used to analyze the morphology generation of PS/LDPE blends with and without compatibilizing SEB di-block copolymer. The observed morphological changes are summarized in Fig. 9.15	Tadmor 1988; Kozlowski 1994
Mini-Max	The mixer is capable of mixing less than 1 g of the resin. The device has been reported to produce similar dispersions of reactive blends as those prepared in industrial mixers, TSE or internal mixer. It was found that Mini-Max makes it possible to pre-evaluate blends, especially those of polymers having low viscosity and elasticity	Maxwell 1972; Sundararaj et al. 1995
TSE	Morphology development of polymer blends was studied in TSE. Samples were cooled in liquid nitrogen immediately after being taken from the screws. Morphology develops faster in compatibilized blends than that in their uncompatibilized counterparts	Li and Sundararaj 2009

Table 9.6 (continued)

Mixer	Description	Reference
Special mixer	A new laboratory-scale mixing device based on the geometry of Mackley's multipass rheometer. The flow in this mixer is characterized by a high contribution from elongational flow. Its efficiency for dispersive mixing is attributed to the combination of elongational flow in the convergent zone and shear flow in the die of the mixing element	Bouquey et al. 2010
TSE mixer	Morphological development of cross-linked blends was prepared both in an internal mixer and in a corotating TSE; despite the similar average apparent shear rate used in both mixing equipments, the intensive flow field inside the TSE resulted in a finer morphology in comparison to the internal mixer	Shahbikian et al. 2012

9.2.10.3 Morphology Evolution in Internal Mixers

A laboratory internal batch mixer was used by Shih et al. (1991, 1992) to simulate the progression of mixing in a compounding process of multicomponent polymer systems. A mixing bowl was modified with a glass window built into the front heating plate. A video picture taken through the glass window was recorded continuously. By using HDPE, PBT, and PAR, the authors distinguished four sequential characteristic states:

  I. Elastic solid pellets
 II. Deformable solid pellets
III. Transition material
    A. Fluid with suspended solid particles
    B. Fractured or semifluid material
    C. Doughlike material
IV. Viscoelastic fluid

The type of the transition material (No. III A, B, or C) mainly depends on the difference in the solid–liquid transition temperature of polymers. Furthermore, if the second polymer was crystalline, after melting, a phase inversion has been frequently observed.

For blends having widely different softening points (either melting point or glass transition temperature), the four stages were "shifted." Thus, the polymer having the lower softening temperature melted first and became matrix of a "highly filled composite." If the softening point and the concentration of the second polymer were high enough, the torque increased causing breakage of the shear pin in the mixer. In the extrusions, the consequences could be more serious. It was concluded that blends of polymers having widely different softening points should be fed consecutively, trying to match viscosities by judicious selection of the local temperature. Extensive studies of mixing in an internal mixer were carried out by Min and White (1985). The work combined the flow visualization with the modification of rotors and measurements of the pressure distribution. Detailed description of the blend morphology in an internal mixer is provided in a review chapter (Min 1994).

Single-screw extruder	Theoretical analysis of flow through a SSE using the "three-layer" model. Theoretical and experimental studies of the early stages of morphology development. Melting of two resins generated lamellas that during the flow through SSE were thinned out and then disintegrated into filament, which in turn broke into droplets	Lindt 1981; Gosh et al. 1991; Lindt and Ghosh 1992
Twin-screw extruder	Pressure flow model for Newtonian liquid in the pumping section	Vergnes et al. 1983, 1986
Twin-screw extruder	Flow of Newtonian fluids in kneading disk elements and (right- and left-handed) screw elements	Szydlowski et al. 1987
Twin-screw extruder	A simplified model was developed. It is based on the assumption that throughput is the same along the extruder as within the zone where the flights are full. Calculations of blend morphology evolution along an extruder and comparison with experimental data were published	Elemans et al. 1988, 1989, 1990
Twin-screw extruder	The groove model to describe the flow in axially open screw channels by introducing two parameters, dimensionless pressure gradient and dimensionless output	Potente et al. 1989
Twin-screw extruder	Dimensionless calculations of throughput and pressure gradients for flow of non-Newtonian fluids in screw and kneading disk elements of a modular intermeshing self-wiping corotating twin-screw extruder, as well as the temperature rise	Chen and White 1992, 1993
Twin-screw extruder	Experimental studies using Baker Perkins corotating TSE. During the melting stage, first sheets, then sheets with holes labeled "laces," and finally dispersed drops were observed	Sundararaj et al. 1992
Twin-screw extruder	Theoretical and experimental studies of morphology evolution during compounding of PS/PE blends. A quenching barrel section was designed for a corotating intermeshing TSE (W&P). A predictive model for morphology development was proposed	Bordereau et al. 1992; Utracki and Shi 1992; Utracki and Shi 1992, 1993

Table 9.7 (continued)

Compounder	Modeling	References
Twin-screw extruder	Morphology development along a corotating or counterrotating intermeshing TSE was observed. Different screw configurations were used. Increasing the number of kneading blocks enhanced the degree of dispersion	Lim and White 1993
Twin-screw extruder	Extension of the model developed by Shi and Utracki. Better fluid mechanics computations and micro-rheological drop fracture mechanisms were used. The model takes into account the coalescence	Huneault et al. 1995a
Corotating twin-screw extruder	Experimental work. Samples were scooped directly from the venting ports located between the melting and kneading block sections, as well as after the latter section. After melting, the dispersed phase consisted of fibers and droplets, both with diameters already below 10 μm. The kneading section (independently of its construction) further reduced the drop diameter by a factor of ten	Huneault et al. 1995b, 1996
Twin-screw extruder	Experimental and theoretical. Non-isothermal model with drop diameter computations based on micro-rheology and coalescence. Changes in polydispersity of sizes can also be computed	de Loor et al. 1994, 1996; Delamare and Vergnes 1996
Corotating twin-screw extruder (CORI)	A 3D modeling of flow was carried out by finite elements method. The flow profile, the backflow volume, pressure distribution, shear and elongation rates, and adiabatic T-gradient were computed for the conveying and kneading sections	Goffart et al. 1996; van der Wal et al. 1996
Co- or counterrotating twin-screw extruder	A 3D modeling of flow in full conveying screw elements of either a CORI or ICRR was reported. The flow velocity and stress fields were computed, as well as the residence time distribution. CORI was found to have better distributive mixing, whereas ICRR performed better as a dispersive mixer	Kajiwara et al. 1996
Twin-screw extruder	Experimental work using CORI. Blends of 10 and 30 wt% PS in HDPE were prepared either by feeding dry blended pellets or introducing molten PS to HDPE melt at different screw positions. The morphology was insensitive to the feeding method. The authors concluded that the blend morphology is determined by the melt mixing within the first 25 s	Bourry and Favis 1997

(continued)

Table 9.7 (continued)

Compounder	Modeling	References
Twin-screw extruder	Distributive mixing was experimentally measured during polymer melt blending along the length of a CORI. A mixing limited interfacial reaction between two reactive polymer tracers was used to gain direct evidence of the generation of interfacial area. Mixing in kneading blocks depended on the combination of the operating conditions and the stagger angle	Shearer and Tzoganakis 2001
Twin-screw extruder	In the melting section of CORI extruders, virtually all the degradation mechanisms that can essentially be distinguished, such as quasi-steady drop breakup, folding, end pinching, and decomposition through capillary instabilities, take place in parallel	Potente et al. 2001
Single-screw extruder	The evolution of the morphology of liquid–liquid systems along the axis of a single-screw extruder is predicted, from the onset of melting until the die outlet. The possibilities of stretching, breakup, and coalescence are taken into consideration. Melt flow was assumed as 2D (which is computationally advantageous), a simplified cross-channel helical pattern being adopted; full 3D analysis showed little difference in the results	Domingues et al. 2010
Twin-screw extruder	The melting and deformation mechanisms of polystyrene (PS) and polypropylene (PP) blends were investigated through online visualization of the corotating twin-screw extrusion process. A sliding barrel technique was used to perform online visualization using a glass window in the barrel. The axial temperature and pressure profiles along the screw channel were measured using the same sliding technique. The overall melting process was accelerated due to heating from viscous dissipation	Chen et al. 2004
Single-screw extruder, twin-screw extruder	A "screw pulling-out" technique was used to investigate polymer behavior along the screw axis in a single-screw extruder and an intermeshing counterrotating twin-screw extruder. In particular, solid conveying, melting positions, extent of starved character along the screw, and fully filled regions were observed	Wilczynski et al. 2012a, b

9.2.10.4 Blends' Morphology in a Single-Screw Extruder (SSE)

Lindt and Ghosh (1991, 1992) dealt with the early stages of blend morphology development in a SSE. According to the model, melting of two types of pellets having similar solid–liquid transition temperatures generates lamellas that during the flow through SSE progressively thin out and then disintegrate into filaments, which in turn break into droplets. Comparison between experimental data and theoretically simulated striation thickness of polymers in a SSE channel showed good agreement. Unfortunately, owing to theoretical difficulties, the model did not go beyond the lamellas thinning. The authors argued that the melting zone plays an important role during continuous blending of polymers. Within the residence time in the melting zone, the blend undergoes rapid morphological changes. Within a fraction of a second, the scale of mixing may decrease by several orders of magnitude.

9.2.10.5 Morphology Evolution in a Twin-Screw Extruder (TSE)

Twin-screw extruders are important tools for the plastic industry. Their principal advantages (over SSE) are better feeding and more positive conveying, self-wiping of the screws, short residence times, a narrow residence time distribution spectrum, better mixing, larger heat transfer area, an easier scale-up, and large output.

The predictive models of the morphology evolution during polymer blending in a TSE start with a description of the flow mechanics. The fundamental assumption is that there are "strong" and "weak" zones. Within the former, the screw elements are fully filled; there is a positive pressure, large deforming stresses, and usually material recirculation that offer a potential for modifications of the blends morphology. The "weak" zones are partially filled, made of mainly transport elements. Here the material is conveyed either at ambient pressure or under vacuum. The stresses are minimal. Within these regions, two mechanisms are expected (provided that the reduced time (t*) is sufficiently long): breakup of filaments by the Raleigh instability mechanism and coalescence. Table 9.7 summarizes the fluid mechanics models of flow through TSE. For a more detailed discussion on the early modeling of flow through co- or counterrotating TSE, see White (1990).

Utracki and Shi (1992) proposed the first model of the morphology changes in a corotating, intermeshing TSE, CORI. The model incorporated the microrheological dispersion mechanism, but coalescence was neglected. Its validity was evaluated comparing the predictions with the experimentally measured drop diameter at different axial positions in the twin-screw extruder. It was estimated that using the newly designed quenching barrel, the PS/PE blends were quenched within 7–10 s. The model well predicted the morphology evolution of these non-compatibilized blends but only to the last mixing block. In the assumed absence of coalescence, the model predicted continuous decrease of drop diameter, whereas the experiment indicated its stabilization. The second model refined these computations and introduced coalescence between drops (Huneault et al. 1995a). The model is fully predictive. Good agreement with experimental data was found (see Fig. 9.16).

Position along the screw, L (mm)
Some experiments were repeated using faster method for the samples' collection. The specimens were periodically "scooped" from open ports in the extruder and quenched in ice water. It was estimated that the quenching time was $t \leq 1$ s (Huneault et al. 1995b). Immediately after melting the dispersed phase consisted of fibers and droplets, both with diameters below 10 μm. The fibers were observed for $\phi \geq 0.02$ and were broken in the kneading section. The kneading blocks reduced the drop diameter to $d \cong 1$ μm. Its configuration had little influence on the resulting drop diameter. As the concentration increased, so did the final diameter of droplets, as well as the fiber content.

Evidently, in spite of the good agreement between the previous models and observations obtained after 7–10 s of the quenching time, the "incipient" blends' morphology is more complex than the models predicted. The morphology changes rapidly within the first few seconds after blending is stopped. This rapid variation of morphology would be particularly important for reactive blending. Furthermore, the morphology evolution during the melting stage may be

more important than initially assumed. During this stage, the viscosity ratio may vary by several orders of magnitude, both locally (stress and temperature gradients) and along the screw length. Furthermore, the coalescence affects not only the drops but fibrils as well.

Other types of morphological changes during blending in TSE were also observed (Sundararaj et al. 1992, 1995). The authors reported that both reactive and nonreactive blends in an extruder, internal mixer, or a miniature cup-and-rotor mixer show similar morphological features. Initially, during the melting, the polymers stretch into sheets and ribbons that first broke into fibers then into drops.

9.3   Blending Methods and Equipments

The term "processability" refers to the relative ease with which neat or compounded resin can be handled in production operation and equipment. In most cases, it is a synonym of a high throughput, low pressure at the die, and thus low viscosity. For the blending operations, another parameter is important: the energy consumed per mass or volume of the material, or the specific energy (E_{sp}). The polymer compounding or blending involves:

1. Preparation of ingredients (drying, sizing, heating, etc.)
2. Premixing (dry blending, homogenization, breakage of agglomerates, fluxing, etc.)
3. Melt mixing (usually with degassing)
4. Forming (granulation, pelletization, or dicing)

The most frequently applied operations are mixing, milling, extrusion, molding, and curing. The resin processability and the processability window are of main concern. Since they affect the material performance, their stability and control are of paramount importance.

9.3.1   Historical Evolution

Mixing is the oldest process. The first annular container with a spiked rotor (for rubber compounding) was developed in 1820 by Thomas Hancock. A more efficient, counterrotating twin shaft internal mixer with elliptical rotating disks was patented by Freyburger in 1876, while its sigma-blade versions 4 years later by Pfleiderer, and 40 years later by Banbury. These machines provided adequate mixing, but (owing to the batch mode) the production was slow and the performance erratic. An alternative was extrusion mixing.

Paul Troester started manufacturing single-screw extruders (SSE) in 1892, but it was only in 1935 that the first SSE for thermoplastics was introduced. Four years later, Paul Leistritz built electrically heated, air-cooled SSE, having L/D = 10, automatic temperature control, variable screw speed, and nitrided barrel. The machine is considered a prototype of the modern extruders. The SSE offered continuous processing capability, but it was notoriously poor as a mixer. Furthermore, under

the standard processing conditions, a significant nonuniformity in the shear history had resulted in large temperature differences of the melt, $\Delta T \cong 60\ °C$. To alleviate the problem, numerous types of mixing screws, mixing sections, or "add-ons" (inserted between the extruder barrel and the die) have been developed, for example:

1. Mixing screws: S-shaped kneader, Eagle mixing, turbine mixing, Cohen double wave, or Maillefer; screws with pin or blister ring and fluted or barrier screw, Dynamic Extensional Flow Mixer (DEFM), etc.
2. Mixing sections: Dulmage, Saxton, pineapple, Stratablend, and many others
3. Add-ons: Barmag add-on torpedo, *Staromix*™, Maddox, cavity transfer mixer (CTM), Twente Mixing Ring (TMR), the Extensional Flow Mixer (EFM), Dynamic Melt Mixer (DMX), and static or motionless mixers (SM) from Koch, Ross, or Kenics

Many of these devices were developed in parallel with the evolution of twin-screw extruders (TSE) in part to reduce the competitive advantage of TSE as far as their recognized capability for good mixing was concerned (Rauwendaal 1986; White 1990).

In 1937 Roberto Colombo and his associates developed an intermeshing, corotating TSE that during the early 1940s was used by I. G. Farbenindustrie for the continuous reactive extrusion of poly-ε-caprolactam. During the early 1940s, recognizing the need for improved compounding capability, Meskat and Erdmenger designed and manufactured intermeshing, corotating TSEs equipped with self-wiping corotating disks.

After the Second World War, the development of the TSE technology has been carried mainly in Germany and then in Japan. In 1959, Werner & Pfleiderer introduced ZSK – *Zwei Schnecken Kneter* – a CORI with segmented screws and barrel. The screws have been assembled from at least six different types of conveying and mixing elements. Japan Steel Works (JSW) started production of TSE in 1951. Thus, by the late 1950s, TSE technology has reached the end of the pioneering period: directions of the screw rotation, their intermeshing, principal left- and right-handed screw elements, and the kneading and mixing disks were designed, evaluated, and patented.

Over the years, significant improvement in the throughput capabilities was obtained by providing screws with higher "free volume," higher screw speeds (experimental machines operate at screw speeds exceeding 1,500 rpm), and higher torque. Several mixing elements as well as restrictors have also been introduced. However, probably the most significant is the progress in the construction of the intermeshing, counterrotating machines, ICRR. Several manufacturers offer TSEs in changeable configuration: CORI or ICRR, both capable of operating within similar ranges of the barrel lengths and screw speeds.

While developing either SSE or TSE machines for the mixing applications, the employed strategy was simple: when distributive mixing was required, the split-and-recombine flow stream was introduced; when dispersive mixing was needed, the high shear stress zones were incorporated. In spite of the recognized advantages of the extensional flow mixing, there has not been much effort to incorporate this concept into the processing equipment. The extensional flow mixer (EFM) is the only device that consciously utilizes the elongation flow for mixing.

Evaluating symbols: + means good, 0 means acceptable, and − means poor

9.3.2 Melt Mixers

The melt mixers are either batch or continuous type. The former require lower investment cost but are more labor-intensive and have low output and poor batch-to-batch reproducibility. Developments in process control and automation eliminated some of these disadvantages (Utracki 1991). The continuous melt mixers comprise extruders, continuous shaft mixers, and specialty machines, and these will be discussed in the following part of this chapter. A brief overview of the melt mixing devices is given in Table 9.8.

9.3.2.1 Batch Mixers

Before the introduction of the intensive internal mixers, the mixing was accomplished on open mills which are slow and dirty processes requiring skilled operators. An efficient, counterrotating twin shaft internal mixer with elliptical rotating disks was patented by Freyburger, while its sigma-blade versions by Pfleiderer and by Banbury. The latter two inventors started the manufacturing companies, Werner & Pfleiderer (W&P) and Farrel Corporation, respectively. An important feature of these machines is that they are enclosed and pressurized, so that fine powders and additives would mix into the compound, not drifting away.

Batch mixing is not efficient for handling large capacities, but it is well suited for short-run operations (manufacture of color-concentrate

masterbatches) and products that have to have tailored identity. Because of the high stresses, an internal mixer can complete a cycle in minutes. The residence time, shear, and temperature can be controlled since all of these are of critical importance in the compounding of heat-sensitive materials or in alloying two materials of varying melt indices. Batch mixing also encourages close monitoring of formulations that combine expensive ingredients produced in small quantities.

Several basic designs of the internal batch-type mixers are available. The most popular are the laboratory mixers manufactured by Brabender or Haake and their homologues on the larger scale manufactured by Banbury or Moriyama dispersion mixers.

The laboratory machines are often used for the evaluation of compounds on a small scale, prior to production. The test requires a small amount of materials, short time, little efforts, and operational expense. The scale-up of the test results to production size is usually done through the "unit work" concept. The mixer makes it possible to assess the effects of changes in temperature, torque, and shear characteristics.

The most serious drawback of these internal mixers is the heat conduction by the mixing shafts. The mixer chamber is only heated from the outside and the shafts conduct the heat away from the molten polymers. During mixing at relatively low temperatures, a dynamic equilibrium may be reached as heat from the heaters is transferred to the melt, then the shafts conduct it to the internal drive system of the mixer. The dynamic equilibrium means that higher temperature is at the chamber wall and lower on the shafts' surface. However, for blending engineering or specialty polymers with high melting points, temperature drop across the chamber can be as large as $100\,^{\circ}\mathrm{C}$.

In the Readco High-Intensity Mixers, the agitators ascertain that the material is continuously moved in a circular pattern from one side of the chamber to the other, undergoing compression and expansion. At the same time, due to the helical angle of the agitators and the offset between the outer and inner agitators, the material is moved from one end of the mixing chamber to the other. The mixer is recognized for providing good dispersive mixing.

9.3.2.2 Continuous Mixers

Continuous mixing involves the continuous loading and unloading of components. When properly performed, mixing decreases the compositional variations to the desired level. Continuous operations have the advantage of providing a stable process. The power consumption is usually lower than in batch operations. The stresses are imposed systematically, either in the shear or in the shear-and-elongation mode of deformation. In spite of high capital costs and complex mixing, the continuous mixing is easy to justify on the basis of the production volume (mixers with throughputs up to 80 t/h are available) and quality.

The continuous mixers make it possible to control the feed rate, screw speed, temperature, as well as the discharge orifice setting and temperature. Machines can operate at high screw or shaft speeds require a short residence time. However, care must

be taken that high speeds will not lead either to excessive specific energy consumption or thermal decomposition of the resin. The continuous mixers require high capital investment but are easy to automate and robotize, have high output, and can be run with a statistical quality loop control (Kearney 1991; Canedo and Valsamis 1994).

Extruders

Extrusion is one of the most important forming methods in polymer processing. Virtually, all polymers go through an extruder at least once: compounding and pelletizing reactor powders. Furthermore, most forming operations involve extrusion: profiles, films, sheets, fibers, wire or paper coating, injection or blow molding, thermoforming, etc. More thermoplastics are converted into useful products by extrusion than by any other method.

The word "extrude" originates in the Latin words "ex" (out) and "trudere" (to thrust), and thus it closely described the process itself as shaping by forcing through an exit opening called the "die." In the nineteenth century, extruders were slow, thus rightly called "plodders." Extrusion is accomplished by a screw rotating in a cylindrical barrel. The feed to the extruder may be either solid or liquid. In the plastic industry, the solid-fed machines are called "plasticating extruders," while that fed by melt are known as "melt extruders."

There are three layers of the basic functions that extruder must perform:
- Primary: melting, pumping, and forming.
- Secondary: devolatilize and mix.
- Tertiary: conduct chemical reactions.
  Extruders are classified according to the principal element of their construction as:
- Single-, twin-, and multi-screw extruders
- Single-, twin-, multi-shaft compounders
- Gear or disk extruders like Maxwell melt-elasticity extruder, Tadmor's disk extruder, etc.
- Special extruders like Gelimat, Patfoort, etc.

In a plasticating extruder, the homopolymers, copolymers, or their blends are introduced at one end. As they advance along the extruder length, they are melted, homogenized, reacted, devolatilized, and transported either to a die (profile or blow molding) or into the mold cavity (injection molding). The extrusion that aims to produce pelletized material is conducted at higher screw speeds, using more intensive mixing than that aimed to manufacture the finished product. Hence, it is appropriate to distinguish the compounding extrusion and the forming extrusion.

The extruder operation is supported by an army of ancillary equipment. Their type and quality depend on the specific machine, type of operation, and material to be extruded. It is advantageous to divide this equipment into pre-extrusion and post-extrusion type. To the first category belong dryers, dry mixers, pre-compounders, solid and liquid feeders, etc. To the second group of post-extrusion equipment belong gear pumps, add-on mixers, dies, pelletizers, coolers or chillers, dewatering systems, sizing equipment, and many others.

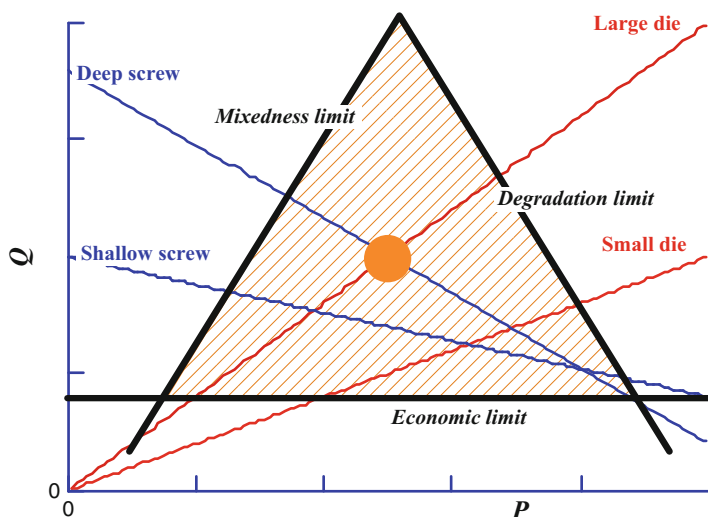
Operation of an extruder is conducted considering the throughput (Q) vs. the pressure drop at the die (P) relation, schematically illustrated in Fig. 9.17.


Fig. 9.17 The throughput (Q) vs. pressure drop at the die (P) dependence for a SSE. The operational triangle is defined by three limiting lines: the economy determined by the lowest acceptable value of Q, the mixing capability determined by the stresses (thus, by the screw speed, N, and P), and the degradability limit, also determined by N and P

Older SSEs have been equipped with minimum instrumentation: a pressure gauge at one point along the barrel (usually at the head) and a thermocouple in the hot melt region. For noncritical operations, the operator would record pressure, temperature, screw speed, and mass flow rates (typically determined by the sample weight–time method).

In operations requiring close tolerances of the extrudates, a greater degree of instrumentation and automation is employed. Usually, several pressure transducers and thermocouples along the barrel are used to ensure uniform extrusion and to control barrel and stock temperatures. Some designs may include thermocouple on the screw to monitor and control conveying flights. For specific applications, a closed-loop control may involve monitoring of composition, density, morphology, rheological performance, and other variables pertinent for the product. Standard methods of monitoring these variables may be used (radioisotopes, ultrasonics, rheological detectors, near and far infrared spectroscopy, mechanical testing, clarity scans, etc.).

Single-Screw Extruders (SSE)
The single-screw extruder is a relatively inexpensive machine for small- or medium-size production lines. For lines with the throughput exceeding 10 t/h, the capital costs of SSE and TSE are comparable. SSE that can produce 40 t/h can be custom-built by only few manufacturers. For example, in 1996 Berstorff demonstrated 600 mm machine for homogenization and degassing of LDPE at a throughput of 23 t/h. SSEs are characterized by a simple design, raggedness, and reliability, are easy to operate and maintain, and have favorable performance-to-cost ratio, and

theoretical description of their operation is well documented. On the other hand, they are difficult to scale-up and are notoriously poor mixers with broad residence time distribution and relatively long residence time (Hold 1982).

Over the years, SSEs have been made more versatile by introduction of special mixing screws, by using add-on mixing devices, by utilization of two or more extruders operating in tandem or as coextruders, etc. Refinements have been developed in feed preparation and feeding methods, including improved drying and premixing techniques, as well as downstream feeding of some formulation components (such as glass fibers).

The principal components of a single-screw extruder are illustrated in Fig. 9.18. The machine has a motor drive, a gear train, and a screw that is keyed into the gear-reducing train. The fluid layer between the screw flights and the barrel wall maintains the screw balanced and centered. Modern units are equipped with continuously variable speeds and electrically heated barrels. The barrel can be "zoned" according to the number of controllers or the heater bands. Depending on the application and type of service, the screw may be cored for heating or cooling.

The standard barrel (inside) diameter ranges from 12 to 600 mm. Larger extruders are available by special order. Standard screw has length-to-diameter ratio: L/D = 16–36, with $20 \leq$ L/D ≤ 24 being most common (feed length, 4–8D; transition length, 14–16D; and metering zone length, 6–10D). It has a single parallel flight, with pitch = 1D and pitch angle $\phi = 17.66°$. The flight width is usually about 0.1D; the channel depth in feed section is 0.1–0.15D. The channel depth ratio varies from less than 2 to 4. The compression ratio, CR, has been defined as a ratio of the screw flight volume at the entrance to that at the exit. The CR can be expressed as a function of the internal barrel diameter and external diameters of the screw as

$$
\begin{aligned}
CR &= \left[\left(\pi D_b^2/4 \right) - \left(\pi D_{s,feed}^2/4 \right) \right] / \left[\left(\pi D_b^2/4 \right) - \left(\pi D_{s,die}^2/4 \right) \right] \\
\therefore \ CR &= \left[\left(D_{s,feed} + H_1 \right)^2 - D_{s,feed}^2 \right] / \left[\left(D_{s,die} + H_1 \right)^2 - D_{s,die}^2 \right]
\end{aligned}
\tag{9.28}
$$

For the standard screw, CR varies from 1.5 (for rigid PVC) to 6 (for PA). The pressure generated at the die ranges from P = 70 to 200 MPa, or 10 to 30 kpsi. The rotational screw speed ranges from N = 20 (for rigid PVC) to 360 rpm (for PE).

There are three zones in the SSE: the solid conveying, the melting, and the melt conveying. In addition, there is the upstream (feeding) and downstream (cooling) zones. Owing to the importance of feeding to the extrusion process, it is appropriate to start with that zone.

Since SSE operates at the fully flooded conditions, the quality and throughput depend directly on the feed. **The feed zone** consists of a hopper or feed arrangement and a solid stock conveying region. Its purpose is to transfer a polymer from the feed hopper into the barrel, where it is initially compressed. This compression forces the air out from between the interstices of resin pellets or rubber chunks (air is expelled back through the hopper). It also breaks up lumps and polymer agglomerates, creating a more homogeneous feedstock that can be readily melted.
Fig. 9.18 Schematic representation of a single-screw extruder (SSE)

Flow in hoppers depends on their type (gravitational or forced), the bulk density of the material, the shape and location of the feed inlet (direct or tangential feed, straight or with a chamfer on the down-going side), as well as the type of screw and the barrel.

For good feeding, the flight volume in the feed zone must be as large as possible. Since the solids' conveying ability of an extruder depends on the ratio of the friction coefficients on the barrel and on the screw root, frequently grooved barrel (cooled by circulating cold water and thermally insulated from the rest of the barrel) is used in the feed zone. Its advantages are increased throughput, greater extrusion stability, and smaller effects of pressure variation at the die on the flow. For this, one pays by higher torque and pressure at the die and high wear and higher energy losses caused by the extra cooling.

The solid conveying zone begins at the feed inlet and extends to a point where the solid particles just begin to melt. The screw section is characterized by a deep flight between the root of the screw and the barrel wall. In most cases, the pitch (i.e., the screw length for a single turn of the screw flight) is 1D that means that the screw pitch angle is 17.66° (Darnell and Mol 1956). Here the solid bed is compressed and it moves forward as a plug. The flow causes the material to be compressed and to melt under the influence of frictional forces between the barrel surface and the solid plug. There are two important factors controlling these operations: the need to remove the entrapped air and to ascertain high friction coefficient on the barrel. Removal of air is an underrated activity that may seriously affect the performance of the extruder. Its importance depends on the type of feed as well as on the shape of the feed inlet. For powder feeding, a vacuum-assisted air removal may be required.

The melting zone follows the solid conveying zone. The purpose of this zone is to compress the solid bed and to provide intense friction between it and a barrel. Within this zone, the channel depth decreases, and the solid polymer coexists with its melt. In a SSE, this zone extends over a major part of the extruder: L(melt) = 10–14D. Melting is caused by the two principal forms of energy: the thermal, applied to the polymer by conduction from the external heaters through the barrel surface, and the mechanical converted to heat through friction and viscous dissipation. The friction coefficient of a polymer on the metal surface (f) depends of pressure (increasing P by a factor of 10 increases f by a factor of 3–4), temperature (for PE: $f = 0.6 - 0.002\ T°C$), and the sliding velocity. The effect of the friction coefficient ratio: f(barrel)/f(screw) is illustrated in Fig. 9.19. The conveying is controlled by the difference in the friction coefficient between the solid bed and either the barrel or the screw. It is important to maximize this difference.

Good balance of heating and shearing within this zone is crucial. For the heat-sensitive polymers such as PVC, too much shearing may cause degradation. For this reason, the frictional heat generation should be kept low by means of low screw rotational speed (N = 20–30 rpm). Good screw design should efficiently eliminate unmelted particles. Shallow screws and high pressure give better melting, but their throughput is relatively low and there are problems with scaling. Deep screws at
Fig. 9.19 Effects of the friction coefficient ratio on the pressure evolution within the feed zone (*left*) and on the throughput vs. screw speed (N)

low N provide better melt homogeneity and throughput stability at the cost of inefficient mixing. The best compromise seems to be high N and shallow screw.

The length of the melting zone should also take into account the type of feed as powder feeding requires a longer melting zone than pellets. However, vacuum-assisted removal of entrapped air significantly improves the melting rate and the melt homogeneity. The melting zone is particularly important for the generation of blends' morphology. The variation of temperature and high stresses encountered within this zone may profoundly affect the extrudate quality.

The melt conveying zone begins at the point where all solid particles are melted, and it extends to the outlet of the extruder; thus it encompasses the screen pack, the breaker plate, and the die. Once the resin is in the molten state, the extruder acts on it as a pump transferring and homogenizing the molten polymers and building up the pressure to the level required to force the material through a discharge nozzle or a die. SSE is capable of delivering up to 70 MPa or 10 kpsi of pressure.

In the classical approach to the mathematical modeling of flow through SSE, the screw and the barrel are unwound, the screw is assumed to be stationary, and the barrel moves over it at the correct gap height and the pitch angle, ϕ. Near the tip of the screw, there is the melt metering or the pumping zone, where the pressure builds up. In this region, the polymer melt is essentially homogenized and raised to the proper temperature for formation of the products.

Many types of screws have been developed. The screw configuration should be selected considering properties of the material being processed. A constant-pitch metering screw is usually employed in applications not requiring intensive mixing. Where mixing is important, for example, for color dispersion, a two-stage screw equipped with a letdown zone in the center of the screw is used. Mixing promoters can also be incorporated in the metering zone or near the tip of the screw (Gagliani 1991). Figure 9.20 shows two screws developed for improved dispersive mixing. All the material must pass through the narrow slit between the restriction and the barrel. To enter the slit, the material is exposed to an elongational flow field, while

Dray
Blister ring
Fig. 11.20 Two SSE screws with restrictions designed to improve dispersive mixing

within the slit it is subjected to high shear stress. Many other screw modifications have been developed to enhance mixing. In some applications with two-stage screws, venting at the letdown section may be needed (Rauwendaal 1991, 2001).

The Buss Kneader is one of specialty SSE-type mixing extruders. The machine has relatively narrow residence time distribution and relatively low residence time. Here, the constant channel depth screw consists of interrupted flights and three rows of stationary pins in the barrel. During extrusion, the screw rotates and axially oscillates providing good self-wiping of the blades. This periodic reciprocation minimizes the material flow in one direction only. The intensive shearing strain is periodic and the gaps tend to reduce the effective shear stress. The large surface areas of exposed materials are a result of shear stresses generated by high torque. There is a good deal of distributive mixing during the high-stress dispersive process. The clamshell barrel design makes it easy to clean, service, analyze, and optimize the process. The machine is used for polymer blending, compounding of PVC formulations, preparation of engineering resins (with and without reinforcement), and extrusion of foodstuffs, carbon electrode pastes, etc. (Jakopin and Franz 1989; Anonymous 1989h).

By contrast with SSEs, the twin-screw extruders operate with partially filled screws. The polymers from a feeder are transported toward the pressure zone, usually created by a flow restrictor like a left-handed or reverse screw element. Under the pressure, the resins are compressed into a solid plug. The plug fractures and melts mainly by friction between the fragments of the initially compressed solid bed. The process is highly efficient. Its length can be as short as less than one diameter, $L \leq D$. There is evidence that melting in a TSE differently affects the generation of morphology than that in a SSE.

Twin-Screw Extruders (TSE)

Introduction to TSE

The first patent on the precursor of the TSE dates from 1869. However, the first commercial CORI for handling polymers was marketed 70 years later. Several intermeshing counterrotating twin-screw extruders (ICRR) were developed in the 1920–1930s. After the Second World War, the corotating, fully intermeshing TSE (CORI) started to dominate the field. Originally, CORI was developed for dewatering, devolatilization, and conduction of chemical reactions. The names of Meskat and Erdmenger are prominent on the early patent. The latter author is credited with designing the kneading blocks for the dispersive mixing, sometimes called "Erdmenger eggs." The prototype modular CORI was built by Werner & Pfleiderer (W&P) in 1955.

The non-intermeshing counterrotating TSE (CRNI) also dates from the 1920s when it was first designed by Ahnhudt for mixing and pumping rubbers and plastics. However, already in 1930, the Welding Engineers started to develop CRNI compounding extruders. In the 1950s, the company introduced a modular design. An excellent record of the TSE history is part of the monograph on the twin-screw extrusion (White 1990).

The TSE development work was completed by the mid-1950. The modular design of screws and barrel was universally accepted. The main types of screw elements (conveying forward, conveying backward, mixing, and neutral) were developed. Looking at the screw elements from dozens of TSE manufacturers, one must but note how similar they are. For example, the bilobal (egg-shaped) Erdmenger's mixing elements are universally popular. They provide high shear stress in the overflight (between the mixing element and the barrel) as well as in the direct intermeshing (between two mixing elements) regions. Many TSE manufacturers still insist that to control the dispersive-to-distributive mixing ratio, simply, the width of the mixing block should be used as a set of narrower blocks resulted in more distributive and less dispersive mixing.

TSEs are classified according to the following three categories:

Screw rotation	Intermeshing	Confinement
1. Corotating	A. Separated	a. Lengthwise closed or open (L-closed or L-open)
2. Counterrotating	B. Tangential	b. Crosswise closed or open (C-closed or C-open)
	C. Intermeshed	

In total, seven types of twin-screw extruders are on the market:
  I. **Counterrotating: not intermeshing (mostly tangential), L- and C-open (CRNI)**
 II. Counterrotating: partially intermeshing, L- and C-open (rare)
III. Counterrotating: partially intermeshing, L-open and C-closed (rare)
 IV. **Counterrotating: fully intermeshing, L- and C-closed (ICRR)**
  V. Corotating: not intermeshing, L- and C-open (rare)
 VI. Corotating: partially intermeshing, L- and C-open
VII. **Corotating: fully intermeshing screw, L-open and C-closed; disks, L- and C-open (CORI – the most popular)**

Table 9.9 Selected manufacturers of TSE

No.	TSE type	Manufacturer
1.	CORI – low-to-medium speed	Bandera, Colombo, Creusot–Loire, Ikegai, JSW
2.	CORI – high speed	APV, B&P Process Equipment, Betol, Berstorff, Clextral, Davis-Standard, Delaware Extruder, Egan, Ermefa, Farrel, ICMA San Giorgio, Ikegai, IKG, JSW, Kobe Steel, Leistritz, Mapré, Maris, Mitsubishi, OMC, Pomini, Reifenhäuser, Rockstedt–Farrel, Teledyne Readco, Theyson, Toshiba, Werner & Pfleiderer
3.	ICRR – parallel screws; high speed and long L/D	Amut SpA, Bandera, Battenfeld, Bausano, Clextral, Ermefa, Ikegai, JSW, KraussMaffei, Leistritz, Maplan, Mapré, Reinhäuser, Toshiba, Weber
4.	ICRR – conical (mainly for PVC profiles)	AGM, Anger, Cincinnati Milacron, Haake, JSW, Maplan, Mitsubishi, Toshiba, Weber
5.	CRNI – equal-length screws; high speed and short L/D	Bandera, Bausano, Bolling, Farrel, Davis-Standard, JSW, Kobe Steel, Leistritz, Pomini
6.	CRNI – non-equal screws	JSW, Welding Engineers

The three most popular types are indicated in bold. In Table 9.9 a partial list of TSE manufacturers is provided.

Whether the screws are open or closed lengthwise or crosswise, have a direct effect on the conveying capability, mixing, and the pressure buildup capacity of the system. For example, the non-intermeshing systems are open lengthwise and crosswise. Fully intermeshing, counterrotating systems can be closed lengthwise and crosswise. Here the material is locked in closed chambers (this is also the case for the screw pumps). The theoretically impossible systems are (i) lengthwise- and crosswise-closed CORI and (ii) lengthwise-open and crosswise-closed ICRR. Thus, CORIs are open lengthwise (normal screw flights are closed crosswise and staggered screw disks are open crosswise), while ICRR are lengthwise and crosswise closed.

A screw system lengthwise open has a passage from the inlet to the outlet of the apparatus. This means that material exchange can take place lengthwise along the channel. In a closed arrangement, the screw flights in the longitudinal direction are closed at intervals. It is important that the cross section of the screw channel be open in order for the material exchange to take place from one flight to the other in a direction normal to the screw channel. There is usually some leakage over the screw crests and through the areas required for the mechanical clearances.

The great advantage of TSEs stems from the modular design of barrel and screws. The manufacturers provide a diversity of the barrel elements (usually their length, L = 4D, sometimes 3D) that can be assembled in the configuration required for specific applications, viz.:
- Gland (or sealing) barrel
- Feeding barrel
- Standard-closed barrel

- Venting barrel
- Side feeder unit barrel
- Injection-sampling barrel
- Melt pressure barrel
- Mixing barrel, e.g., with hexagonal channel or profiled grooves
- Main gate barrel (a closing unit)

Similarly, the screws are assembled on shafts from selected elements. These are usually classified according to their functions into three categories: conveying, neutral (end or centering disks, screw tip), and mixing. There is again diversity of elements within each of these categories, the greatest being for the mixing type.

The conveying elements may differ in (1) the number of treads, (2) the helix angle or pitch, (3) the length, and (4) the thread direction (forward moving the material, or right handed, and back moving, or left handed). The elements are usually provided with a pitch angle of 14, 20, 28, and 42° and reversed −14 and −20°. As the pitch increases, the material is pumped faster, but at the same time, the dwell time and the conveying capability decrease. The conveying elements exercise very little shearing and mixing action of the transported material.

The mixing elements are available as individual elements or as their assemblies. There is a great diversity of these elements, for example:

- Perforated or slotted restrictor elements
- Compression elements
- Shearing elements
- Mixing turbines
- Multilobal elements (bilobal for CORI, tri- and hexa-lobal for ICRR)
- Polygon shifting elements
- Continuous mixing block
- Erdmenger's bi- or trilobal kneading blocks
- Low energy distributive vane mixers (usually the last elements before the screw tip, for homogenization of the melt within the highest pressure zone)
- Many others

The multielement kneading blocks are assembled of disks of different thickness (to adjust the ratio of dispersive-to-distributive mixing) and displacement angle (see Table 9.10). Blocks constructed from the same number of elements but of different thickness also behave differently. Wide disks provide much greater sharing action than the narrow ones; i.e., the former provide dispersive mixing while the latter the distributive one. As the disk thickness in the block decreases, its conveying capability increases.

Main Types of TSE

Out of the seven types of twin-screw extruders, the following three are of principal interest (in order of increasing commercial importance): **intermeshing counterrotating (ICRR), counterrotating non-intermeshing (CRNI)**, and **corotating intermeshing (CORI).**

Table 9.10 Effect of the twist angle on the performance of a block made of six Erdmenger's kneading disks

Angle (°)	Mixing	Shearing	Conveying
+30	Low	Low	High forward
+60	Medium	Medium	Medium forward
+90	High	High	Nil
−30	Highest	Highest	Medium backward

Table 9.11 Specifications JSW TEX TSE (Japan Steel Works, 2013)

Model	D (mm)	N (rpm)[a]	Torque (Nm)	Drive (kW)
30 α	32	2,500	401	22
44 αII	47	1,750	1,520	90
54 αII	58	1,450	2,863	185
65 αII	69	1,150	4,803	250
77 αII	82.5	950	8,235	450
90 αII	96.5	850	13,159	750
105 αII	113	710	21,169	1,500
120 αII	129.5	620	31,817	2,000
140 α	152	440	42,953	1,980
140 αII	152	440	51,544	2,375
160 α	174	300	64,277	2,000
160 αII	174	300	77,072	2,400
180 α	196	300	92,089	2,875
180 αII	196	300	110,507	3,450
200	218	270	115,338	3,250
200 αII	218	270	138,406	3,900
230 α	251	270	178,972	5,050
250 α	274	270	230,676	6,500
280 α	308	270	326,128	9,200
305 α	335	270	421,580	11,900
350 α	387	240	640,324	16,100
400 α	443	215	963,400	21,700

[a]Maximum speed reported

For many years, CORI has been the universal compounder of choice. It operated at higher screw speeds with longer barrel than ICRR, advantageous especially for the reactive processing. However, several manufacturers of these two types of extruders demonstrated that unbiased test results frequently show better performance of ICRR as far as the compound quality and the throughputs are concerned. Even at lower screw speed, ICRR frequently outperformed CORI. This resulted in interest in redesigning ICRR. Tables 9.11 and 9.12 list specifications from JSW and American Leistritz, respectively, for their standard machines that can be operated either as co- or as counterrotating, fully intermeshing TSE. Since these

Table 9.12 Specifications of ZSE MAXX TSE (American Leistritz, 2013)

Model	D (mm)	N (rpm)[a]	Torque (Nm)
ZSE-18	18.5	1,200	71
ZSE-27	28.3	1,200	304
ZSE-40	41.1	1,200	1,128
ZSE-50	51.2	1,200	2,144
ZSE-60	61.9	1,200	3,750
ZSE-75	77.5	1,200	7,324
ZSE-87	90.0	1,000	11,432
ZSE-110	113.7	600	22,982
ZSE-135	139.3	500	42,150
ZSE-180	178.8	400	91,460

[a]Maximum speed reported

manufacturers provide a diversity of processing equipment, they neither have a bias toward one of these types of machines, nor they pretend that one type can do all operations equally well as for certain applications CORI may be better than ICRR and vice versa. However, it is important to recognize the enlarged selection of the compounding equipment available on today's market.

Counterrotating Non-Intermeshing (CRNI)

Originally developed for natural rubbers, foodstuffs, and elastomers, at present these machines are used as a *stirred tank reactor* or a *twin-rotor continuous mixer*. Their bearings are exposed mainly to radial, not axial, forces. By using one screw longer than the other, one can separate the mixing and pumping functions.

In CRNI the material flow is based on a drag, not positive pumping. There is a low shear stress field, responsible for the absence of dispersive mixing. However, the interchange of material between the screws provides good distributive mixing. The chemical reaction proceeds on the continuously renewed surfaces, related to reorientation of the laminar flow patterns and the total strain. CRNI is well suited for the polymerization of miscible, low-viscosity systems, viz., polymerization of monomers, grafting, halogenation, and PP-*visbreaking* (degradation by the addition of organic peroxides). The main advantage of CRNI is long enough residence time, sufficient to complete slow reactions. The molecular weight of the generated polymer was found to be virtually independent of Q and N. Mild mixing during compounding prevents the mechanical degradation of elastomers as well as of crushing glass micro-balloons.

CRNI can offer larger outputs and more interchange of material between the two screws than the other type TSEs. These machines are frequently used for the preparation of composites with fibrous fillers. In general, the closer the clearances and intermeshing the more rapid the buildup of pressure. The narrower the lands and the larger the clearances between the screws, the greater the longitudinal mixing (Wood 1979, 1980).

Intermeshing Counterrotating (ICRR)

ICRR was developed as a positive displacement screw pump for viscous, difficult fluids (coal-oil, ceramic, or rubber compounds). This is the only TSE type that is fully, axially and radially, closed. The extrusion speed depends on the intermeshing geometry and the screw speed. The fully intermeshing ICRR has narrower distribution of residence times and better precision in controlling rapid reactions between liquid reagent and molten polymer than a CORI. The low-speed ICRRs have been used for PVC compounding and forming. At higher screw separations and speeds, the machines can be used for the incorporation of high-viscosity toughening elastomer. For example, ICRRs have been used for the reactive extrusion of ABS.

During the 1990s, there has been a significant progress in making ICRR fully competitive with the more popular CORI. This has been done by opening the calendering gap and moving the shearing action toward the barrel. While the older ICRR operated at the maximum screw speed of 150 rpm, the new ones can turn at least at 500 rpm without excessive gap pressure. For some applications, ICRR offers unique advantage of strong extensional flow field, able to disperse high-viscosity ingredients in a low-viscosity matrix.

Corotating Intermeshing (CORI)

These are the most popular and commercially important twin-screw extruders. The machines were originally developed in the 1860s for pumping stone paste. Their advantage arises from the movement of the intermeshing surfaces in opposite directions; thus the melt-free surface is continuously renewed and the screws clean each other. In addition, since at the intermeshing the material passes from one screw to the other (change of the drag direction), there is low probability that the material would go through the gap. Thus, there is no calendering pressure that may cause the screws to bend (a possibility for the ICRR machines). This in turn permits to use higher screw speeds and longer barrels. In 1938 CORI was used for the polymerization of butadiene and PA-6. The latter resin was commercialized by I. G. Farbenindustrie in 1939.

During the 1950s and 1960s, the design criteria for these extruders were:

1. Incorporation without degradation
2. High shear stress for dispersing
3. Homogenization of materials with different viscosity
4. Uniform stress and heat history
5. Precise control of mixing process

The present tendency in CORI development is to (1) maximize throughput from the given size machine by maximization of the *extruder free volume* or the OD/ID screw ratio, (2) provide capability to efficiently transmit the required amount of power into the material, and (3) increase the extruder speeds. The modern machines from Werner & Pfleiderer are supplied with OD/ID = 1.55, those from Berstorff with 1.74 (for reactive compounding and degassing). The latter company also developed several mixing elements (*turbo* or *gear mixers*) well suited for mixing resins with different viscosities. Smaller industrial CORI machines are available from JSW with the screw speed of $N \leq 1,500$ rpm. Similar speeds are also offered

by Werner & Pfleiderer. There is also talk in the industry of superfast extruders operating at 3,000 rpm. Maris increased free volume of their 58 mm extruder from 84 mL/D to 103 mL/D, an increase by 23 %. To make use of this extra throughput capability, the machines must have high torque capabilities.

Screws are available with 1, 2, or 3 screw flights; the first has the highest solid conveying capacity (used mainly for feeding powders). Two-flight screws have large free volume per unit length and low average shear rate. They are mainly used for processing temperature-sensitive materials. The three-flight screws are used when high shear stress is required. CORIs are efficient in alternating the direction of applied stresses, providing distributive mixing by lamellae folding, as well as controllable shearing (dispersing mixing). They are operated in starve-fed mode that demands high-performance feeders. The material transport mainly depends on drag flow, with only local contribution from the screw pumping in the so-called pressure zones. The maximum conveying is achieved when the screw pitch is equal to screw diameter. CORIs are used for compounding, polymerization, and devolatilization.

CORIs are the prime machines for polymer blending and reactive extrusion (Brown 1992). They have been used as reactors for the addition polymerization (polyacrylates, SAN, S-MMA, PA-6, POM, or TPU) and for the polycondensation (PA-66, polyarylates, PEST, PEI). Polymer grafting (polyolefin + silane, maleic anhydride, acetic anhydride, etc.) and mechanical and chemical degradation of polypropylene have also been carried out.

The reaction is usually conducted within the pressure zone (in a kneading block section). This section is followed by left-handed (reversed) elements that control the residence time within the pressurized section. Devolatilization (removal of the reaction by-products) is usually carried out immediately following the left-handed screw section. The *sliced screw mixing elements* provide gentler mixing than the kneading ones (now two-lobed, not three-lobed). There is a trend toward development of an *intelligent compounding plant*, where the polymerization, compounding, and shaping will be carried out in sequence.

Comparison of CORI and ICRR TSE Performance

There are several publications dealing with the comparison of efficiency of compounding, mixing, or reactive extruding in different types of extruders. Most of these studies suffer from the same aspect: the evaluated machines were not operated at a comparable level of performance efficiency. A summary of the reported observations is given in Tables 9.13 and 9.14.

Historically, the corotating geometry has been preferred by the plastic industry, as having more even distribution of stresses, providing easier control of compounding, and operating at higher screw speeds and throughputs. The counterrotating TSEs were known as the "calendering" extruders, with high stresses existing between the two screws and low stresses outside. In ICRR, owing to the high calendering pressures, the screws could rub against the barrel causing premature wear. Thus, shorter barrels, slower speeds, and large intermeshing gaps have been recommended. One of the advantages of these machines has been the presence

Table 9.13 Advantages and disadvantages of CORI- and ICRR-type TSE

Extruder	Advantages	Disadvantages
Corotating, intermeshing, CORI	Self-cleaning	Capital cost
	Dispersive and distributive mixing in transverse and longitudinal direction	Only residence times below about 10 min are economic
	Lower than in ICRR, uniform and controllable stress	Limited ranges of pressure and vacuum are available
	Good control of resin degradability	
	Local pressure control	
	High screw speeds and throughputs	
	Local high-vacuum possibilities	
	Double-walled barrel for rapid temperature changes	
	High specific energy input possible	
	Residence time up to one hour	
Counterrotating, intermeshing, ICRR	Self-cleaning	Transverse mixing is moderate
	High dispersive mixing in the shear and extension	Longitudinal mixing is poor
	It can accommodate multilobal mixing elements of the gear type with excellent dispersive mixing capabilities	Only residence times below 10 min are economic
	It has better specific energy than CORI	Limited screw speed
	It has narrower residence time distribution than CORI	Capital cost
	High local pressures possible	
	High local vacuum possible	
	Better devolatilization capability than CORI	
	High specific energy input possible	
	Shorter screws than in corotating	
	Easy separation of desired functions like mixing, devolatilization, chemical reaction, compounding, etc.	

of the elongational flow field within the calendering zone. The machines have been successfully used in numerous applications requiring high dispersive stresses.

There has been renewed interest in upgrading the TSE performance. This was spurred by the advances in the theory and methods of analysis of elemental contributions. The analysis resulted in modification of the screw profiles (higher free volume of the process), separation of screws that made it possible for CORI and ICRR to operate at the same screw speeds, as well as development of new mixing (or kneading) elements (American Leistritz 1996). The increased free volume (thus slender screw profile) resulted in lowering the average shear rate; thus the screw speeds needed to be increased, hence higher power/torque motors, which in turn

Table 9.14 Comments on CORI vs. ICRR performance

CORI	ICRR	Reference
Better control of shear and of mixing than in ICRR	Less efficient control of shear and of mixing than in CORI	Murray 1978
Broader distribution of residence times and slower melting and cleaning but better for dispersing glass fibers. For the same screw speed and throughput, higher melt temperature was obtained (an indication of not-optimized screw configuration)	Narrower distribution of residence times, better dispersing agglomerates of small particles, and faster cleaning time (of TiO_2 trace). Owing to periodic compression–depression effects, better devolatilization can be obtained	Sakai 1978; Sakai et al. 1988, 1992
Material transfer from one screw to another, axially open extruders. Melt is conveyed by frictional forces, allowing for partially filled melting zone	There is no transfer of material from one screw to another; closed C-shape chambers are developed. Melt flow is plug type. Materials see a wide range of pressures	Herrmann and Burkhardt 1981
Screws suspended in melt allow for high rotational speeds. In an axially open system, the pressure is controlled by purposely placed restrictions: either left-handed side screw, valves, or die. Material is compressed by the first screw and conveyed to the other. The melting process is similar to ICRR, but particle-to-particle rubbing makes it more efficient	Pressure within the calendar gap forces the screws to rub on the barrel. Low screw speeds must be used. Calendering gap problems are exacerbated in the feed region, leading to severe wear. The melting process is similar to that in single-screw extruders. Unmelted particles are observed in the discharge	Herrmann and Burkhardt 1981
Broader distribution of residence times, better distributive mixing, and better for blending	Better pumping capability, dispersion of small particles, and devolatilization	Rauwendaal 1981
Higher screw speed and output than the ICRR. Corotating extruders are especially suitable for reactive processing	Calendering leakage results in high lubrication pressure which in turn forces the screws apart, causing barrel abrasion. High calendering pressure causes mechanical degradation of polymers	White 1990
Polyethylene/polyamide-11 blend was compatibilized by radical copolymerization using diverse organic peroxides	The best performing material was obtained using corotating fully intermeshing machine	Lambla and Seadan 1993
At N = 400 rpm comparative blending produced lower throughput and poorer quality. Produced the same maximum lubricant concentration at different output. More aggregates than in ICRR	At N = 400 rpm comparative blending produced higher throughput at lower T and better quality. Higher maximum lubricant concentration achieved at higher power consumption	Thiele 1995
Final morphology is the same in both CORI and ICRR	Melts and mixes faster for a blend of HDPE and PS. Phase morphology develops faster along screw length	Cho and White 1996
For blends of PP with Al flakes, larger distribution of residence time due to backflow	ICRR has shorter residence time due to near plug flow	Shon et al. 1999

(*continued*)

Table 9.14 (continued)

CORI	ICRR	Reference
For blends of PP with glass fibers, fiber breakup is highly dependent on their feeding position and screw configuration	Same as CORI, but final fiber length is shorter	Shon and White 1999
For the polymerization of caprolactam, broadest residence time distribution. Conversion depends on residence time at low flow rate (1 kg/h) but almost independent at high flow rate	Lowest average residence time. Conversion change is highly dependent on residence time	Lee and White 2001
For blends of SEBS with graphite powder, CORI produced better mixedness. Volume resistivity is higher for the final composites	Similar maximum pressure for both configurations. Narrower residence time distribution	Erol and Kalyon 2005

improved the throughput. New kneading and mixing elements have been designed to improve either the distributive or dispersive mixing. To the first category belong the turbine-and-gear mixing elements (ZME, SME, or TME from Werner & Pfleiderer).

The intermeshing TSEs have self-cleaning screws. The material that adheres to the screw root may degrade and eventually fall off and be carried out with the product, showing up as contaminants (Wood 1979, 1980; Salden 1978). Self-cleaning action is achieved in both counterrotating and corotating screws, through an opposite roll-off or the wiping motion. The calendering flow does not take place in CORI, and a more efficient and uniform self-cleaning action is achieved.

In CORI the material is transferred from one screw to another in a tangential path (Salden 1978). Here, edges of one screw crest wipe the flanks of the other screw with a tangentially oriented, constant relative velocity. There is a high relative velocity and hence sufficiently high shear velocity to wipe the boundary layers.

In ICRR the roll-off process between the screw crest and screw root and between the screw flanks simulates the action of a calender. The necessary shear velocity required to wipe the boundary layers is proportionately lower because of the low relative velocity. Counterrotating screws require greater clearances between them since their mode of action is rather like a two-roll mill, passing material through the nip between them (Schoengood 1973). The material is drawn into the roller gap and is squeezed onto the surface. Consequently, ICRR has less efficient self-cleaning action.

The shear stresses and their distributions are higher in ICRR than in CORI. In the former it only depends on the screw pitch, while in the latter the shear stress distribution changes with the pitch angles, the throughput, and the screw speed. In addition, the flow pattern in these two types is different, with a higher radial flow in ICRR.

CORIs are used for the reactive processing, compounding of alloys and blends, color masterbatches, and fiber-reinforced composition. The quality of the

product critically depends on the selection of screws and their configuration. However, optimization of screw configuration and operating conditions remains an art.

TSEs are indispensable in several applications like reactive processing, high devolatilization, high additive loading, and/or intensive dispersive melt mixing. Furthermore, they are the preferred extruders for high throughput lines with the extrusion rates exceeding 10 t/h.

Table 9.13 summarizes the relative advantages and disadvantages of the intermeshing co- and counterrotating TSE (respectively, CORI and ICRR). A summary of published comments about the advantages and disadvantages of ICRR in comparison to CORI is provided in Table 9.14.

Comparison Between SSE and TSE Performance

Within TSE the shear and extensional stresses are generated by virtue of interactions between two screws. The degree to which this occurs depends on the relative direction of the screw rotation (co- or counterrotating), shapes of the screw elements, the degree to which they intermesh, and the rotational speed of the screws (Fisher 1958; Matthews 1962).

Conventional TSEs are claimed to be superior to SSE as compounders because they can provide (Adams 1974; Murray 1978; Wood 1979, 1980; White 1990):

1. Better feeding and more positive conveying characteristics
2. Shorter residence times and narrower residence time distribution
3. Improved kinetics and melt temperature control
4. High and controlled deformational stresses
5. Positive pumping action
6. Reduced melt slippage
7. Self-wiping action
8. Lower power consumption
9. Generation of high extrusion pressures with a short backup length

Table 9.15 summarizes these differences. The extrusion characteristics are given in Table 9.16.

TSEs have also drawbacks, the main being their cost. Owing to complex design of the screws and the thrust bearings these machines are more expensive than SSE (Prause 1967, 1968; Gras 1972). Furthermore, they are susceptible to quick overloading. The low bulk densities of preblends influence the throughput rate and the die pressure.

Mechanically, a major difference between SSE and TSE is the type of transport that takes place within the extruder. The material transport in the former is drag-induced: frictional drag in the solid conveying zone and viscous drag in the melt conveying zone. There are many materials with unfavorable frictional properties that cannot be fed into a SSE without getting into severe feeding problems. On the other hand, the transport in an intermeshing TSE is by positive displacement. Its degree depends on how well the flight of one screw closes the opposing channel of the other screw. The most positive displacement is obtained in a closely intermeshing, counterrotating geometry.

Table 9.15 Fundamental differences between single (SSE)- and twin-screw extruders (TSE)

Function	SSE	TSE
Degree of channel fill	Fully filled	Partially filled
Throughput (Q) is determined by:	Screw speed, N	Feed rate
Total strain	Independent of Q and N	Dependent on Q
Shear strain	Low	High, controllable
Material transport	By friction (drag flow)	Positive conveying
Material flow path	Smooth, regular thinning	Tortuous, diverse
Heat transport	Ineffective	Effective
Liquid and powder additives	Present problems	Do not present problems
High-viscosity additives	Impossible to disperse	Can be dispersed
Mixing capability	Poor	Good, adjustable
Extruder length for melting	Long	Very short
Extruder length for mixing	Long	Short
Advantages	Easy to make, inexpensive, theoretical description of its function well developed, a lot of experience	High flexibility (modular design), effective feeding, devolatilization, mixing, reactive processing
Disadvantages	Lack of flexibility, poor feeding characteristics, ineffective devolatilizer and mixer, not suitable for reactive processing	Difficult fabrication, cost up to 10x that of SSE, early stage of the theoretical analysis, poor back mixing (narrow residence time distribution), require accurate feeders

Another difference is the velocity profiles in these machines. In SSE these are well defined and fairly easy to describe. The situation in TSE is considerably more complex. The complex flow patterns have several advantages, such as good mixing and heat transfer, large melting capacity, good devolatilization capacity, and control over the stock temperatures. The theory of TSE is not nearly as well developed as that of SSE.

The extruders are assumed to be nominally "once through equipment." This implies that preblending, or bulk mixing, is essential for good mixing. In SSE that operates under the flooded conditions, feeding is often difficult and preblending

Table 9.16 Summary of extrusion characteristics for SSE and TSE

Function	Single screw	Twin screw	
		Counterrotating	Corotating
Flow mechanism	Continuous shear	Discrete c-sections, lengthwise and crosswise closed	Figure of eight; more uniform shear history for all flow elements
Stress field	Shear in the overflight and in the channel	High shear and elongation in the calendering gap, low in channels	Uniform stress field, mainly shear; convergent–divergent flow in mixing blocks
Conveying	Drag flow	Positive conveying	Less positive conveying
Pumping efficiency	Variable	Good, positive	Good
Die pressure	High	Low	Lowest
Die restriction	Often severe	Smaller effects	Smaller effects
L/D ratios	>20	16–40	Various
Compression	Decrease channel	Various designs	Various designs
Air entrapment	Possible	Possible, thus larger clearances	No
Screw speeds	20–100 rpm	500 rpm	Up to 1,500 rpm
Heating mode	High proportion by shear	Controllable low shear	Near-adiabatic
Residence time	Large spread-wide distribution	Narrow distribution, often easy to control	Wider distribution at high die pressures
Pressure in the gap	Low	High, thus possible wear	Low, effective self-wiping

may be necessary. In counterrotating tangential TSE, the degree of fill is low and feeding is relatively easy (provided that feeding devices have sufficient accuracy). Thus, uniform product quality is obtained by feeding separate streams either at the same or sequentially into various axial locations.

Most TSEs are of a modular design, having removable screw and barrel elements. The screw design can be altered by changing the sequence and type of the screw elements along the shaft. In this way, almost an infinite number of screw configurations can be put together. The modular design, therefore, creates great flexibility and allows careful optimization of screw and barrel geometry to each particular application. This flexibility is not available for SSE.

The modular design of TSE makes it possible to adjust the relative magnitude of the distributive and dispersive mixing. The shear stress in normal melt pumping SSE channels is not sufficient to provide adequate dispersive mixing. Similarly, the laminar flow through SSE channel is not sufficient to distribute the flow elements having different performance characteristics. Often, high shear stress mixing devices, such as modified screw, screw torpedoes, or external high energy planetary roller mixers, are required. For the distributive mixing, a static mixer may be inserted between the end of the extruder screw and the extrusion die.

The modern technology often requires that TSE performs a series of different functions. Owing to limitation of L/D, even these universal machines may profit from additional, external, either dispersive or distributive mixers. These devices are discussed in the following parts.

There are 12 criteria for the economic, high-quality compounding (Herrmann 1988):

1. Sound fundamental design principles of the compounding machine
2. Flexibility of operation
3. High screw torque
4. Appropriate selection of the screw elements
5. A balanced combination of the high-shear dispersive and low-shear distributive screw elements
6. Low pressure at the die
7. Reliability of components and parts
8. Long lifetime of parts
9. Reliable feeding/dosing equipment
10. Reliable granulation method
11. Automation of the process
12. Online quality inspection and closed-loop control

Flexibility and user friendliness are the key words for many extruders (easy-to-use control systems and displays, quick access for repair, and quick changeover). Several of the new machines feature segmented barrel, the ability to change screw-rotation direction, and the ability to be modified in place (to compound, to extrude a product, or to recycle plant scrap).

Other Mixing Devices

Planetary Roller Extruder

In these extruders, six or more evenly spaced planetary screws revolve around the circumference of the central or so-called "sun" screw. The planetary screws inter-mesh with the sun screw and the barrel. The planetary barrel section has helical grooves corresponding to the helical flights on the planetary screws. This section is usually a separate barrel with a flange-type connection to the feed barrel section.

In the first part of the machine, before the planetary screws, the material is processed as in a SSE. As the plasticated composition reaches the planetary section, it is exposed to intensive mixing by the rolling action between the planetary screws, the sun screw, and the barrel. The helical design of the barrel, sun screw, and planetary screws leads to a large surface area relative to the barrel length. The clearance between the planetary screws and the mating surfaces is about 1/4 mm. This allows thin layers of the compound to be exposed to large surface areas, resulting in effective devolatilization, heat exchange (thus good temperature control), and efficient mixing.

The planetary roller extruders are mostly used for processing heat-sensitive compounds like rigid or plasticized PVC formulations (Anders 1979; Collins 1987). The planetary roller section can also be used as an add-on mixer to SSE to

improve the mixing performance (Rust 1983; Huszman 1983). Degassing and addition of fillers or reinforcements into melt has also been carried out.

Multi-Screw Extruders (MSE)

Over the years, several extruder designs have been proposed using more than two screws. This concept is not new and has been around for over 40 years (Hanslik 1972). Nevertheless, several developments have been done over the years (Eckart et al. 2011). The main idea is to improve mixing and have better control on residence time and for process intensification, i.e., performing several tasks in a single step. These machines are also used for solvent removal (Gras 1972; Gras and Eise 1975). Flash devolatilization occurs in a flash dome attached to a barrel. The polymer solution is delivered under pressure and at temperature above the boiling point of the solvent. The solution is then expanded through a nozzle into the flash dome. The foamy material resulting from the flash devolatilization is then transported away by the four screws. In many cases, downstream vent sections are also used to further reduce solvent content. It is also reported that MSE (12 screws) have better control over elongational strains leading to better mixing efficiency (Loukus et al. 2004).

Disk Extruders

There are several extruders that do not use an Archimedean screw for transportation of materials, but still belong to the category of continuous extruders. These machines are sometimes referred to as screwless extruders. Usually they employ a disk or a drum. Most disk extruders are based on a viscous drag transport principle. To this category belong stepped disk extruders (Raleigh 1879; Westover 1962), drum extruders, spiral extruders (Ingen Housz 1975), disk pack extruder (Tadmor 1979, 1980; Tadmor et al. 1979, 1983; Hold et al. 1979; Valsamis 1983), and many others.

A disk pack (Tadmor and Gogos 1979) has the inherent capability of performing the elementary steps of plastic processing by combination of differently shaped rotating disks in a drumlike housing. The wiping action is provided by stationary channel blocks that cause the material to transfer from one disk-gap to another. Melting, laminar mixing, venting, and the pumping functions are all separated. Disk pack has been used for reactive processing, blending, compounding, mixing, and devolatilizing (Tadmor et al. 1983). The devolatilization capabilities are limited in comparison to TSE. The mixing capability and die pressure are influenced by:

1. Method of feeding
2. Disk diameter
3. Gap between disks
4. Shape and size of the feeding zone
5. Diameter and length of discharge
6. Hydraulic resistance of forming device
7. Viscoelastic properties of the melt
8. Shape of material particles

Elastic Melt Extruder (EME)

In EME the polymer is sheared between two plates, one stationary and one rotating. The extruder makes use of the viscoelastic properties of polymer melts. When a viscoelastic fluid is sheared, the normal stresses develop in the fluid, trying to push the shearing plates apart. Thus, leaving a hole in the center of the stationary plate makes it possible for the melt to flow continuously from the rim toward the center then out (Maxwell and Scalora 1959; Blyler 1966; Fritz 1968, 1971; Macosko and Starita 1971; Kocherov et al. 1973; Good et al. 1974).

The EME mixers have been used for mixing and extruding plastic formulations. Despite the relatively low pressures (0.3–0.7 MPa) in many applications (melt blending and incorporation of carbon fibers), EME was found superior to the screw-type extruders. The machines provide good mixing and melt homogenization at short residence time (for a unit with 150 mm disk diameter and a capacity of 25 kg/h, the average residence time is about 15 s). EME is two to three times smaller than screw-type extruders of similar capacities. The flow is laminar dispersive, preferentially generating co-continuous blend morphology leading to good performance (Thornton et al. 1980). Unfortunately, neither the original EME nor its modifications found a general acceptance in the plastic industry (Westover 1962; Frederix 1978; Michaux 1979).

Ram Extruders

The ram extruders are divided into (1) single-ram extruders that operate discontinuously (Berzen and Braun 1979; Zachariades et al. 1979; Sperati 1983) and (2) multi-ram extruders that offer a continuous flow of materials (Westover 1963; Yi and Fenner 1975).

FN-Plastifier

This is a short (L/D = 5) single-screw extruder, developed for polymer blending and recycling, with a three-start screw extended from the feed zone 2/3 over the screw length. The frontal part of the screw is smooth ending with a flat disk. The material is transported and partially fluxed by the grooved part of the screw and barrel. The pumping is assured by the normal stresses between the flat part of the screw end and the die (Maxwell–Scalora's EME principle). The short screw assures short (and narrow distribution) residence time. Large thrust bearing makes it possible to control the die gap, thus the magnitude of the normal stresses, hence morphology and performance (Frederix 1978; Michaux 1979; Anonymous 1981).

The extruder was developed by Patfoort and then licensed to Fabrique Nationale (FN) Herstal, SA (Patfoort 1976; Fabrique Nationale Herstal 1977). The machines were found to be particularly suitable for recycling commingled polymers from municipal waste streams. Under high stresses developed between the smooth part of the screw and the barrel, the free radicals were generated compatibilizing in situ the polymeric mixture. The usual product was of the "plastic wood" type. It had excellent mechanical performance characteristics. The FN plastificator was used for recycling by the city of Liege and other parts of Europe and then exported to China under the UNIDO program. However, FN discontinued manufacturing these machines.

Several other machines of this type have been developed since. They all involve intensive mechanical shearing that produces extensive chain scission. Recombination of the free radicals in situ generates sufficient concentration of copolymer, to compatibilize the system. The generated-under-high-stress, nonequilibrium morphology is then locked by quenching. Best performance has been observed for systems with co-continuous morphology.

Gelimat, K-mixer, and Homomicronizer

The residence time in the discussed above Patfoort's extruder is $7 < \tau < 25$ s (Patfoort 1976). The machine was originally designed for the extrusion of the thermally unstable resins, in particular PVC. For similar applications, Carlew Chemicals developed its *Gelimat*, latter renamed *K-mixer* (K- for the kinetic energy) (Crocker 1981). The mixer uses high-speed rotor with staggered blades mounted on a horizontal shaft at different angles. The number and position of the blades vary with the mixer size. The mixing is carried out at the blade tip velocity of 30–45 m/s. There is no external heating as the kinetic energy generated by the particles impacting on each other and the mixer elements produces sufficient heat to flux the material within 8–150 s. Once the material reaches the desired temperature, the infrared sensor activates the bottom doors of the chamber. The discharged dough can be either fed to a short screw extruder or passed between rolls and diced. The mixing is batch-type. However, with two *Gelimat* units each providing a load of plastified resin every 10 s or so, the downstream operation (calendering) is continuous.

When preparing polymer blends, the starting resins should have similar particle size and dimensions. There is an obvious advantage of using fine powders. The high stresses developed during the plastification are often sufficient to generate compatibilizing copolymers. Similarly like in the Patfoort extruder, here also good performance of antagonistically immiscible polymer blends was obtained.

Newplast developed a recycling process line that is based on a *homomicronizer* which is a machine similar to *Gelimat* or *K-mixer*. The unit has short, stubby radial blades attached to a horizontal shaft that rotates at high speeds, melting and homogenizing the postconsumer waste within 35–120 s. The blades are of two types, pushing the material away from the side walls toward the center of the cylindrical mixing chamber. The clearance between the blades and the chamber wall is 0.5–1.0 mm (Dubrulle D'Orhcel 1996; La Mantia et al. 1996).

Mixing or *Calendering* Rolls

The mixing rolls subject pastes and deformable solids to intense shear by passing them between smooth or corrugated metal rolls that revolve at different speeds. The principal design consists of two horizontal rolls or cylinders, arranged side by side and rotating toward each other at different speeds. The ratio of the peripheral roll speeds (known as the function ratio) ranges from 1 to 2, but it is usually about 1.2. The rolls' temperature is controlled by circulating oil. The higher friction ratio leads to greater heat generation. Friction, speed, sizes of the rolls, and gap between them influence the material temperature and the intensity of mixing.

Usually, the results obtained from one unit are specific to this machine and cannot be applied to a different one.

The material enters the mixing rolls in a form of lumps, powder, or friable laminates. As a result of rotation, adhesion, and friction, the material is entrained into the gap between the rolls, and upon discharge, it sticks to one of them. In batch mixing, the mass after loading passes through the gap between the rolls several times. In continuous mixing, the mass enters continuously from one side of the machine and passes between the rolls in rotational and forward motion along the unit's axis. The mixed material is continuously discharged in form of a narrow strip. Both the shearing action and entertainment of material into the gap are important to the mixing process and transporting the material through the unit.

Ribbon Blenders and Planetary Mixers

There are a number of design variations of this type of machines, with differences primarily in the agitator configuration. Ribbon blenders are essentially self-contained mixers best suited for batch or semicontinuous mixing. They are mainly used for preblending like dry mixing a composition. The continuous ribbon agitator is standard, with inner and outer ribbons that may be arranged for center or end discharge.

Planetary mixers are well suited for a wide range of liquid and solid applications. Double planetary mixers consist of two regularly shaped stirrer blades revolving around the tank on a central axis. Each blade also revolves on its own axis at approximately the speed of the central rotation. With each revolution on its own axis, the blade advances along the tank wall. This movement ensures good homogeneity of the material within a short time. Double planetary mixers have no packing glands or bearings within the product zone, thus cleaning between batches is relatively simple.

Emulsifiers and Blenders

Mixer emulsifiers are sometimes used as an alternative to slow-speed impeller mixing or high-pressure homogenization for a wide range of processing requirements. These mixers are normally used in dished or conical-bottom vessels.

Internal (Blade) Mixers

The internal mixers are used for kneading and mixing accompanied by either heating or cooling. The operation involves compressing the fluid mass, folding it over, and then compressing it again. The material is usually torn apart by high shear stresses engendered between the moving and stationary elements.

The mixing is performed using two Z-shaped blades rotating in opposite directions on parallel horizontal shafts. There is great variety of the commercially available blade designs, ranging from lightweight to heavyweight constructions. Selection of the specific design depends on the consistency of the mix. The size of the mixer is limited by the power input, batch weight, speed of mixing, materials of construction, and methods of mix discharge. Many machines are equipped with tilting facilities to discharge the batch while the blades are turning. The mixers require heavy-drive mechanisms and large motors.

The agitator blades in the sigma-blade mixer may be mounted so that their paths are either tangential or overlapping (intermeshing). In the tangential arrangement, the two blades rotate side by side with their circular paths of rotation not quite touching. The blades can have any relative speed because their paths of rotation do not overlap. In the overlapping arrangement, the paths of rotation overlap. Consequently here the blades must be designed and the speed of rotation adjusted so that the blades always clear each other. Many manufacturers provide double-arm mixers with interchangeable blades. Examples of materials handled by double-arm kneaders of the sigma-blade type are resins, putty, adhesives, baker's dough, and cellulose additives. Sigma-type agitator blades are best for general-purpose use.

Dispersion-Type Screw Mixers

Dispersion-type screw mixers are in an entirely separate class from the extruder designs described above. They are applicable to processing of either dry materials or moderately viscous pastes, creams, or lotions. These machines normally consist of a conical vessel equipped with a conical or inclined screw. There are either single- or twin-screw models that provide a gentle mixing action and thus are used for handling materials sensitive to attrition or fiber disintegration (one example is in dry cell battery manufacturing, where acetylene black has lacelike structure that easily breaks down).

The twin-screw design, in addition to the axial, orbital, and gravitational action offered by the single-screw design, provides intermixing between the two screws. Depending on the material properties, the mixing times can be 90 % faster than the single-screw system. The Combimixer employs two intersecting conical tanks with two orbiting spiral agitators. The axial and orbiting motions of the two agitators, along with the additional intermixing currants occurring through the juncture of the two tanks, provide for greater blending action than the single-screw mixer. Two motors and two gear boxes drive the smaller Combimixer. One set drives both screw flights axially and the other drives the two orbiting arms. For larger Combimixer units, separate motors are used for each screw flight and a single motor drives both orbiting arms.

Add-Ons

A need for better mixing in a SSE was already evident in the 1950s. Large effort was spent to redesign the screw by either changing the flow profile (mixing screws like Eagle, Chief, Meltstar, ODM, Pulsar, Stratablend, Toss-and-Rock, Stat-Dyn, etc.), adding mixing elements (pins, rectangles, or trapezoids), or modifying the screw tip. In the latter category, quite a long series of designs has been proposed: Axon, Dulmage, Egan, Maddox, pineapple, turbine, etc. These devices are parts of the extruder technology and have been well described (Manas-Zloczower and Tadmor 1994; Rauwendaal 1994).

By definition, an add-on device is an optional part to be attached to a standard SSE. While some of these use the extruder torque, the others can be used either as an attachment or stand-alone units with their own power (CTM or DMX mixers).

Barmag 3DD torpedo mixer is a forerunner of this category of mixers. The unit was designed to improve the temperature homogeneity of the film and fiber spinning extrusion lines. The device is made of a torpedo (to be attached to the tip of the SSE screw) and a sleeve (to be attached to the extruder barrel). Both the torpedo and the sleeve have slot-shaped grooves, arranged in rows (usually 12). Significant improvement of the melt homogeneity was reported by the manufacturer.

Cavity transfer mixer (or CTM) was designed at RAPRA as an add-on distributive mixer (Gale et al. 1982). The device is made of a torpedo (to be attached to the tip of the SSE screw) and a sleeve (to be attached to the extruder barrel). Both the torpedo and the sleeve have semispherical indentation. The number of rows of indentations must be selected to satisfy the mixing needs of the production line. The polymer flowing between them is sheared and split into different indentations. Furthermore, the extensional flows generated at the entrance and exit from the indentations introduce additional dispersive action. The flow through a simplified CTM was analyzed experimentally and by means of a fluid dynamics analysis package like FIDAP (Manas-Zloczower and Tadmor 1994; Wang and Manas-Zloczower 1996).

The University of Twente developed the mixing ring (or TMR). This device is made of three parts: smooth wall barrel extension, a torpedo with semispherical indentations (similar to these in CTM), and a perforated sleeve that goes between them. The sleeve provides shallow indentations. It slowly rotates between the torpedo and the barrel by the virtue of a drag flow. The flow in TMR is both dispersive and distributive. The advantage of TMR is its suitability to improve mixing in injection or blow molding machines (Housz 1989).

Another in this series of add-on mixing torpedoes is the Dynamic Melt Mixer, DMX. The device consists of a series of mixing modules inside a tubular housing. Two types of modules are available. Each module is made of two components: a stationary ring fixed to the sleeve and veined rotor keyed to an axial shaft either attached to the SSE screw or independently powered. Part of the rotor that does not enter the sleeve provides the cutting action across the flow lines that induces the distributive action. The primarily distributive one consists of a stator and a rotor (keyed to the central shaft) without the rolling semicylindrical lugs. As the rotating modules turn, they provide dispersive and distributive mixing (Miller 1996; Petren 1997).

An interesting distributive add-on mixer was proposed by Jurkowski et al. (1992). The mixer is made of a short barrel attached to the front of SSE. Within the barrel, there are several plates with channels directing the melt to flow from the rim toward the center and vice versa.

Other mixers, viz., the "static (or motionless) mixers," were discussed in Sect. 9.2.5, "Distributive Mixing," while the Extensional Flow Mixer (EFM) and the Dynamic Extensional Flow Mixer (DEFM) were described in Sect. 9.2.6.4, "Extensional Flow Mixer."

9.4   Nonmechanical Methods of Polymer Blending

9.4.1   Latex Blending

Historically, the preferred method of mixing was the latex blending. The early emulsion polymerization of rubbers (natural lattices or synthetic ones) and thermoplastic acrylates, methacrylates, and vinyls provided raw ingredients for the latex blending. A wide range of blends was described in the early I. G. Farbenindustrie patents. Later on, owing to the development of loop technology (Lanthier 1966), the method was revived by Shawinigan Chemicals.

The latex blends were used either directly, for example, as paints, adhesives, or sealants, or they were spray-dried or pelletized. Spray drying has been the most frequently used method. Since emulsion polymerization was able to produce either a fine dispersion (drop diameter d = 100–200 nm) of homo- or copolymer or alternatively large drop aggregates, comparable to those generated in suspension polymerization (d < 15 μm), the latex blending offered not only a wide range of compositions but also diverse morphologies. The principal disadvantage of the latex blending was high content of contaminants: emulsifiers, residuals of the initiators, chain transfers, stabilizers, etc.

9.4.2   Solvent and Spin Casting

There are several methods for the production of polymeric films (see Table 9.17). The oldest is calendering, but the most common methods are the film blowing and sheet extrusion. Others can be made by posttreating the extruded sheet like polyimide films (Sweeting 1971). Polymer films can also be polymerized onto a substrate from monomers in the vapor state or formed by the coalescence of polymer dispersions. However, several polymers cannot be formed without dissolving them.

Solvent casting is an important commercial technique utilized to fabricate thin layered films for diverse applications (Sweeting 1971). Most familiar is the solution casting of CA for photographic films having good dimensional stability, clarity, flexibility, and fracture resistance. The following advantages of solution-casting method (as compared to the melt process) have been given (Ricklin 1983):
- Higher quality (uniformity) and thinner film
- Freedom from pinholes and gel marks
- Purity and clarity
- Lack of residual stresses
- Possible to produce patterns or dull finishes

The solution-cast process consists of dissolution of the film ingredients in a suitable carrier that conveys the solution through a drier where the solvent is evaporated. The resulting film is removed from the substrate and wound into rolls. Solvents and scrap materials are reprocessed. As illustrated by examples in

Table 9.17 Methods for production of polymeric films

Process	Method
Film blowing or sheet extrusion	Continuous melt extrusion through a flat or circular die (PE, ionomers, PP, PS, PMMA, PEST, PA, etc.)
Calendering	Usually it follows the sheet extrusion. However, there are commercial lines where plastified polymer (semirigid PVC formulations) is directly fed to the calendar mill
Batch PVC plastisol or organosol casting	Plastisol and organosol casting process involves melting the polymer or polymeric mixture by an action of the temperature and presence of either a plasticizer or solvent
Continuous solvent casting	Extrusion of a solution through a flat die (CA, cellulose xanthate, PMMA, PVF, blends)
Batch in situ polymerization	Monomer casting, followed by controlled (co)polymerization (PMMA, epoxies)
Continuous in situ polymerization	Extrusion of Polymer-1 containing monomer of Polymer-2, followed by post reaction to Polymer 2 (polyimides, electrically conductive polymer blends, reactive blends) with cross-linked elastomers), etc.
Casting onto a substrate	Electrodeposition, plasma deposition, or dispersive deposition (vapor deposition of polyxylylene)

Table 9.18, the drying process can be used to manipulate the final film properties. Commercial solution casting is continuous (see Fig. 9.21) (Roberts 1967; Sittig 1967; Park 1969; Chow et al. 1976; Heffelfinger 1978; Ricklin 1983; Powers and Collier 1990).

The mathematical modeling of the process is complicated by the diffusivity dependence on composition. Low boiling solvents exhibit high diffusivity and usually are preferred, but for polymers with high T_g, high-boiling solvents may be more appropriate. The drying step is rate-limiting. An early mathematical model predicts the temperature and concentration profiles in the film during the drying (Collier 1981; Roehner 1982; Roehner and Collier 1983).

As indicated in Table 9.18, casting may induce orientation of the polymeric chains. The process is caused by the polymer movement induced by the solvent removal. Solvent removal from a solution constrained in two dimensions by a substrate results in one-dimensional thickness reduction. The orientation is caused by effectively stretching the polymer in the planar directions during thickness reduction. The resulting orientation depends on the evaporation rate. The competing rates for molecular relaxation and solvent removal are best considered using the Deborah number, defined as

$$De = \tau/t_{1/2} \qquad (11.29)$$

where τ is the polymer relaxation time and $t_{1/2}$ is the time required for the removal of one half of the solvent. For constrained processes with De $\gg$ 1, orientation occurs; for De $\ll$ 1, solvent removal results in only thickness reduction

Table 9.18 Examples of solution casting of polymers

Polymer	Solvent	Remarks, methods, and references
Poly(g-methyl-D-glutamate)	Chloroform, DCA, MC, FA, TCE	Solvent controls the degree of α- and ß-configuration or random coil contents in the film and its mechanical behavior and morphology. Rheovibron, stress–strain measurements, WAXS, SAXS, polarizing photomicrography, IR (Mohadger and Wilkes 1976)
Poly-2,5 (6) benzimidazole	Methane sulfonic acid, HCOOH/cresol	Solvent nature affects the morphologies of polymer films thus the extensibility and mechanical properties of films. DSC, Rheovibron viscoelastometer, WAXS (Wereta et al. 1978)
PS, PC, PVK	CH_3Cl benzene, THF	Casting aligns polymeric chains preferentially in the plane direction. DSC, optical anisotropy (Prest and Luca 1980)
Polyvinyl acetate	Methanol, acetone, chloroform	Mechanical properties of the films depended on the solvent and the time of exposure of film at each temperature; $CHCl_3$ was recommended. Mechanical tests (Olayemi and Adeyeye 1982)
PE, PC, PET, PS, i-PS, PVP, PMMA, PTFE PVAc, PVC	Toluene, CCl_4, $CHCl_3$, xylene, decalin, EtOH, H_2O, MeOH	The casting solvent has a pronounced influence upon the friction coefficient which may confer either ductile or brittle failure. "Good" solvent generally tends to promote brittle mode of failure with little temperature dependence. Friction measurements (Briscoe and Smith 1983)
PVC	MeOH, CHX, toluene, THF, decane, CS_2	The slowest evaporating solvent has the greatest effect on the surface properties; annealing above Tg reduces the surface porosity. Inverse gas chromatography, DSC (Wildman and Hsu 1984)
Ether polysulfone, PVDF	A high-water-affinity solvent	Swelling and the viscosity of the casting solution were controlled by addition of small amounts of partially miscible polymers. SEM, contact angle measurements (Stengaard 1988)

(Collier 1981). Birefringence measurements confirmed that drying conditions can affect the level of orientation in the films, but the techniques could not detect an orientation gradient developed across the thickness (Prest and Luca 1980).

Today, a great deal of literature is available on solution casting of polymers for applications like packaging, separation membranes, sensors, and fuel cells. A review on the subject is available (Guillen et al. 2011).

Solvent casting of polymer mixtures (usually with additives) may affect the density, porosity, mechanical properties, mode of failure, etc. These effects are
Fig. 9.21 The solution-casting process

particularly pronounced in films of immiscible polymers. Before discussing these effects, it is appropriate to consider the intermediate step like solvent casting of copolymers. Table 9.19 provides few examples.

For multicomponent systems, solution casting provides means for generating the desired degree and type of morphology. Profiting from the different (and controllable) rates of the phase separation and solvent evaporation, one may generate either co-continuity of phases (spinodal decomposition, SD) or dispersed structure (nucleation and growth or late stage of SD). The solvent casting offers additional flexibility in producing precisely what is needed. It is not necessary to use a single component solution. One frequently uses a mixture of solvents having different evaporation rates and different miscibility with the polymeric components. Furthermore, the films can be annealed, selected polymeric components extracted to form the desired size and shape of domains.

For example, it is possible to generate semipermeable membranes with well-controlled morphology, pore size, flux, and mechanical performance. The method is preferred for industrial preparation of semipermeable membranes from polymer blends (see Table 9.20).

Another method of morphology control in multicomponent polymeric systems is by the use of mixed solvents having different affinity to the polymeric components. When the non-solvent is less volatile than the good solvent, evaporation results in a two-phase structure.

When solvents are removed solely by evaporation, the membrane formation is known as a dry phase inversion process (Kesting 1985). When the phase separation and structure formation are achieved by immersion of a cast membrane in a quench medium, the process is known as a wet phase inversion process (Heffelfinger 1978). The latter process is used to prepare asymmetric membranes for either microfiltration (Roesink 1989), ultrafiltration (Michaels 1971), reverse

Table 9.19 Examples of solution casting of copolymers

Material	Solvent	Remarks, methods, and references
SBR	CHX, toluene, Et acetate, tetralin, cyclohexanone	Film properties depended on the evaporation rate, but there was no evaporation rate dependence when the casting solvent was CHX. Density measurements, Rheovibron dynamic viscoelastometer, TMA, SEM (Beamish and Hourston 1976; Beamish et al. 1977)
SEBS and SEPS	n-Heptane, cyclohexane, toluene	Spherical, cylindrical, and lamellar PS structures were obtained in the order of increasing solvent affinity to PS. Density, DSC, tensile test, dynamic viscoelastometer, SAXS (Séguéla and Prud'homme 1978)
SEBS	THF, CHCl$_3$, toluene, CHX, bromobutane, C$_6$H$_{14}$, C$_7$H$_{16}$	The complex modulus varied from 4.4 MPa (cast from low δ-solvents) to 205 MPa (cast from high δ-solvents); the area under the damping peak also depended on solvent. DMA, DSC (Cowie and McEwen 1979, 1980; Cowie et al. 1979)
SBS block copolymer	Toluene, CCl$_4$, EtAc, MEK	The solvent nature influenced film morphology. Position annihilation technique (Djermouni and Ache 1980)
Silicone-PC block copolymers	C$_6$H$_{14}$, methylene chloride	Casting from a homogeneous solution that favors the hard segments yielded better results than from mixed solvents from which PC blocks preferentially separated to form a discontinuous dispersion or network. Capillary viscometer, GPC, TMA, DMA (Maung et al. 1983)
Poly(styrene-b-butadiene-b-4-vinylpyridine)	THF, benzene, MEK, EtOH, MMA, nitromethane, hydroxyethyl methacrylate	A ball-in-a-box structure morphology was formed when the solvent for poly (4-vinylpyridine) is lost; a lamellar structure morphology was formed when solvents were equally distributed into the three phases; a random structure was formed when the solvent for one or two of the three block segments vaporizes faster than other solvent. SEM, Mechanical test (Arai et al. 1984)
PDMS-b-PS copolymers	CH$_3$Cl, Toluene, Cyclohexane	The interactions between the casting solvent and polymer affected the phase separation and the final morphology. DSC (Feng et al. 1988)
Ter-copolymer of acrylonitrile methyl methacrylate	Glycerol, water	An increase of glycol in the casting solution resulted in the formation of membranes with high pore density and small pore size, thus increasing the selectivity with respect to low molecular weight components. Selectivity of membrane, SEM, porosimetry (Petrov et al. 1991)

Table 9.19 (continued)

Material	Solvent	Remarks, methods, and references
Disulfonated poly (arylene ether sulfone) multiblock copolymer	N-methyl-2-pyrrolidone (NMP), dimethylacetamide (DMAC)	Morphology via transmission electron microscopy and small angle X-ray scattering showed that as the block length increased, the interionic-domain distance increased, with a subsequent increase in lamellar ordering and long-range continuity. SEM, TEM, rheology, mechanical properties (Lee et al. 2009)
Poly(lactic-co-glycolic) acid (PLGA)	dichloromethane	Infrared and Raman spectroscopy used to study composition and degradation of the copolymer films in a phosphate buffer solution. Mass loss, FTIR, Raman (Vey et al. 2011)

osmosis (Strathmann et al. 1971), or gas separation (Henis and Tripodi 1980; Van't Hoff 1988). Posttreatment may be necessary to prepare ultrathin asymmetric membranes for gas separation (Henis and Tripodi 1980; Zampini 1984; Zampini and Malon 1987; Murphy et al. 1989; Ekiner et al. 1989).

Membrane structures can also be formed by a microphase separation process in which the outermost region of the cast membrane undergoes phase separation induced by solvent evaporation, while the bulk of the structure is formed by solvent/non-solvent exchange during a quench step. This type of structure formation is defined as a dry/wet phase inversion process (Pinnau et al. 1990).

9.4.3 Special Methods

9.4.3.1 Freeze Drying

The freeze-drying of co-solutions of thermodynamically immiscible polymer pairs is a method of capturing kinetically the unlike molecules in molecular or "segmental" mixtures. PMMA/PVAc blends freeze-dried from co-solutions in benzene were reported homogeneous by dynamic-mechanical and dilatometric observations. They showed a single T_g intermediate between those of the pure polymers (Miyata and Hata 1970). Further dilatometric and differential calorimetric data corroborated the findings of homogeneity (Ichihara et al. 1971).

Berghmans and Overbergh (1977) found that freeze-drying of dilute solutions containing two miscible polymers produced a system with three glass transition temperatures, corresponding to the T_g's of both polymeric species and an intermediate T_g, characterizing their blend. A comparison of the density of freeze-dried and

Table 9.20 Solution casting of polymer blends

Material	Casting solvent	Remarks, methods, and references
Grafted block copolymer blends	Divers	The soluble polymer usually was the matrix with the other resins forming isolated domains. Physical properties and morphology (Merrett 1957; Inoue et al. 1960; Beecher et al. 1969; Kawai et al. 1971; Pedemonte et al. 1975; Kraus and Rollman 1976)
PMMA/PS/SA terpolymer blends	n-Butanol, toluene, CHCl$_3$, ethylene dichloride, ethanol	Good solvent produced tightly packed films, while poorer solvent yielded more porous ones. IGC, surface tension (Schreiber and Croucher 1980)
Poly(alkyl methacrylates), PS/BR	Methanol, toluene, DMF	The Tg of polymers varied because of residual solvent, possibly due to the plasticizing effect, and thermal history. DSC (Brostrom et al. 1980)
PC, PS, PC–PS blends, PC–PS copolymer	Dichloromethane, acetone	Blend properties were found to be a combination of these of the constituent homopolymers. Segmental motions of the PS chains in the copolymer were enhanced even though those chains were attached to more rigid PC chains. SEM, Rheovibron viscoelastometer, mechanical properties (Eastmond and Haraguchi 1983)
PS/poly(α-methyl styrene)	Toluene, cyclohexane, propylene glycol	Regions of miscibility and immiscibility as functions of a casting solvent and molecular weight for both components were established based on Tg consideration. DSC (Saeki et al. 1983)
PVC/NBR or EVAc; CR/NBR or EVAc; BR/SBR or IR; ABS/NBR or PMMA; PS/PMMA	THF	Faster rates of solvent evaporation yielded a smaller periodic distance in the modulated structure. The rate of phase separation was lower and the periodic distance of the modulated structure smaller as the blend ratio deviated from 50/50. **For high MW polymers, the system failed to phase-separate during fast casting**, resulting in a homogeneous blend without appreciable composition fluctuations. Light scattering (Inoue et al. 1985)
Perfluorinated Nafion ionomer/ PVDF blends	Dimethylformamide, dimethylacetamide, 1-Methyl-2-pyrrolidinone	The spherulitic crystalline morphology of PVDF showed strong dependence on the casting temperature and compositions. Mixed α- and γ-form crystals were obtained. DSC, SAXS, microscope, dielectric thermal analyzer (Kyu and Yang 1990)

Table 9.20 (continued)

Material	Casting solvent	Remarks, methods, and references
PC, PS, PPE, t-methyl PC	Dichloromethane	Casting induced distinct molecular order in the solid films; birefringence was influenced by the solvent type, the casting temperature, the surface energy of the substance, and the timing of the peel-off step; non-birefringence films could be produced by setting proper operating conditions. Birefringence (Machell et al. 1990)
PS, PMMA	Chloroform	Surface analysis showed an enrichment of the surface by PMMA (phase separation). The behavior is related to differences in solubility and dewetting of PMMA-rich domains by PS-rich phases. XPS, AFM (Ton-That et al. 2001)
PMMA, PVAc	Chloroform, toluene, tetrahydrofuran	FTIR analysis in transmission showed that residual solvent molecules can be trapped in the films and have an effect on transparency, absorption coefficient and refractive index, UV–Vis, reflection, and FTIR (Ahmed 2008)
PES, PI	N-dimethylacetamide, tetrahydrofuran	Different PES/PI ration and solution concentration showed that asymmetric thin films can be produced by process optimization (evaporation time). SEM, gas permeation (Madaeni et al. 2012)
PVDF, PMMA, PVP	N,N-dimethylformamide	For this ternary blend, PVDF was mainly found on the surface, and hydrophobicity and crystallinity were enhanced by PMMA/PVP addition SEM, WAXD, FTIR, DSC, and contact angle (Cheng et al. 2013)
P(VDF-TrFE), PEO	N,N-dimethylformamide	Differences in crystallization speed (sequential crystallization) results in a P(VDF-TrFE) fibrillar structure leading to two dynamic-mechanical relaxations. SEM, AFM, FTIR, DSC, TGA, DMA (Costa et al. 2013)

bulk PS has also led to the inference that freeze-drying from dilute solution leads to a system in which individual polymer chains are collapsed to globular particles rather than being intertwined (Miyamoto et al. 1970).

Schultz and Young (1980) prepared homogeneous blends of immiscible PMMA/PS blends by freezing and sublimation. The solutions containing 5 wt% of polymer

or polymer mixture were dissolved in naphthalene at 100 °C with a magnetic stirrer, under N_2 blanket. The hot solution was poured slowly into ice water undergoing high-speed stirring in a blender. After filtration on a sintered-glass filter, the naphthalene powder "solutions" were dried in an airstream for 24 h. The powders were then transferred to round-bottom flasks, and naphthalene was sublimed from the polymer blends at room temperature on a high-vacuum rack for 10 days. The first DSC scans showed single T_g for these blends, intermediate between those of the two polymers, while the second and the following ones showed two T_g's, corresponding to those of the two polymers.

9.4.3.2 Spray Drying

Spray drying is by definition the transformation of feed from a fluid state into a dried particulate form by spraying the feed into a hot drying medium (Masters 1985). This is an ideal process where the end product must comply with precise quality standards regarding particle size distribution, residual moisture content, bulk density, and particle shape. It involves the atomization of a liquid feedstock into a spray of droplets and contacting the droplets with hot air in a drying chamber. The sprays are produced by either rotary (wheel) or nozzle atomizers. Evaporation of solvent of matrix liquid from the droplets and formation of dry particles proceed under controlled temperature and air flow conditions.

The initial contact between spray droplets and drying air controls the evaporation rate and the product temperatures. The drying-chamber and air-disperser design must create a flow pattern that prevents deposition of partially dried product to the walls and the atomizer. There are three modes of contact:

1. Cocurrent: Drying air and particles move through the drying chamber in the same direction. On discharge, the product temperatures are lower than the exhaust air temperature. This is an ideal mode for drying heat-sensitive products.
2. Countercurrent: Drying air and particles move through the drying chamber in opposite directions. This mode is suitable for products that require a high degree of heating.
3. Mixed flow: Particle movement through the drying chamber experiences both cocurrent and countercurrent phases.

Spray drying has been used to prepare polymer blends from mixed lattices or cosolvent solutions.

9.5 Reactive Processing (Compatibilization)

Details of the reactive compatibilization are discussed in ▶ Chap. 5, "Reactive Compatibilization" of this book. For this reason, the following text is only concerned with the mechanical aspects of the process.

The term "reactive processing" is used to describe a polymer processing that involves chemical reactions. In principle, any processing operation can be conducted as a reactive process like reactive injection molding (RIM). However,

most often, the term refers to reactive extrusion and, in particular, to the reactive compatibilization of immiscible polymer blends, usually conducted in a TSE. During the last 50 years, the latter machines have been used a chemical reactor for the polymerization, depolymerization (chemical recycling), polymer modification, and compatibilization (Brown 1992; Xanthos 1992; Utracki 1989, 1991, 1994, 1997).

Four features make TSE particularly well suited as a reactor for highly viscous polymeric reactants (Thiele 1996):

1. An ability to compartmentalize the reactive mass into small melt pools, bounded by the screw flights and barrel walls, with short mass and heat transfer distances
2. The possibility of conducting a series of operations in a logical well-controlled sequence along the length of the extruder: melting, mixing, reacting, devolatilization, homogenization, and forming
3. The ability to provide the desired extent of the interface renewal that controls the overall reaction rate
4. The continuity of the process

For example, between 1966 and 1987, over 1,000 patents on reactive extrusion were granted to 200 companies. In order of decreasing number of patents, they were Asahi Chem., Bayer, Kabel Metal Gatehoff, BASF, Showa Electric, Mitsubishi Petrochem., Hitachi Cable, DuPont, Exxon, and many others (Utracki 1997).

9.5.1 The Use of Twin-Screw Extruders in Reactive Polymer Processing

TSEs have been used to prepare new families of engineering materials of high performance, polymers, and their blends. Polycondensation, free radical, and anionic and cationic polymerizations were conducted to obtain for PA, PEST, POM, styrenic, or acrylic resins. When the reaction is conducted in a low molecular weight liquid (solution or emulsion polymerization), usually devolatilization and compounding are carried out in a cascade second extruder. Functionalization and chemical modifications have been performed in TSE on virtually all polymers.

9.5.1.1 Advantages and Disadvantages of Reactive Processing

Reactive processing is a continuous, flexible process offering the technical and economic **advantages** vis-a-vis other reactors (Kamal and Ryan 1984; Sneller 1985; Tzoganakis 1989; Kowalski 1990):

- Low production volume, hence, small losses for equipment breakdown.
- Rapid and precise control of pressure and temperature; good heat exchange.
- Ability to introduce reactants and catalysts at the desired locations.
- Working with 100 % of reactant content, using rapidly renewed interface, which leads to higher reaction rates than those possible in batch processes.
- Self-cleaning system, hence, narrow and adjustable distribution of residence time.

- Good control of the residence time and residence time distribution; the residence time distribution is narrowest for ICRR, CORI, and then NIRT.
- Control of the reaction environment (airtight configuration or inert gasses).
- Ability to ascertain sequential high reaction rates.
- Capability of rapid removal of a large volume of volatiles.
- Controllable amount of dispersive and distributive mixing.
- Ability to disperse high-viscosity materials without a solvent.
- Ability to combine polymerization (or copolymerization), degassing, compounding, and forming, what results in overall more economic industrial process.
- Possibility of automation via the closed-loop control of product quality.
- Discharge through a forming die.
  The **disadvantages** of the reactive extrusion are:
- High initial capital investment.
- High cost of the reactions that require long residence times (reactions requiring residence time greater than 1 h are not acceptable).
- All the contaminants, inhibitors, and possible sources of side reactions must be removed or deactivated. This includes moisture, residual monomers, catalysts, etc.
- Difficulties in rapid removal of locally generated large heats of reaction.
- A need for high accuracy of ingredient addition and precise control of the process parameters.
- The reaction may need to be carried out under a blanket of dry, inert gas.
- Product quality is influenced by the residence time distribution.
- Run-out reaction usually leads to high-viscosity product; thus for safety reason high torque machines are needed with capability for rapid feed reduction and increase of temperature in the final barrel sections.
- The process must be closed-loop controlled, using either rheological (MFM), infrared, or ultrasonic sensors.
- The mathematical models of the reactive extrusion are in early stage of development.

The reactive processing is controlled on two levels: by selection of equipment, screw configuration, and ingredients and by the control of process variables. Depending on the type of reaction, the most appropriate TSE type must be selected and the appropriate steel alloy for the inner barrel and screw elements selected. Most manufacturers offer a selection of alloys with different resistance to abrasion and corrosion (to acids or halogens). Similarly, there is a variety of the control systems that must be considered knowing the number of sensor to be used and a need for protocolling. It is important that the metering system is selected to deliver the materials with the required precision and continuity. For liquid injections, the check valves that prevent freeze-off during the startup or shutdown should be used.

Reactive compatibilization requires good dispersive and distributive mixing of reactants and sufficient residence time for the reaction to take place. The introduced components should be immediately uniformly mixed. Thus, appropriate mixing screw elements (kneading, turbine, etc.) should be placed in the reaction zone of the

extruder where the reactants are introduced. Furthermore, adequate heat removal capabilities must be provided for the zone where the exothermic reaction takes place. It has been found that barrel cooling is not always adequate and screw (shaft) cooling has been used. Usually, the venting zone immediately follows the reaction one. Since in the venting zone the screw is only partially filled, between the two zones, there is a restriction of reversed screw elements, kneading element, check valve, or a throttling ring. Within the venting zone, multiple flight elements should be introduced to provide rapid surface renewal.

Owing to milder operating conditions, corotating TSE (CORI) has been preferred. However, the counterrotating TSEs (ICRR) are used with increasing frequency for polymerization of either polymethacrylates or polyurethanes. In the latter case, owing to higher pressures and stresses than those in CORI, the reaction must be controlled with greater precision. For example, during PBT modification with epoxy, the reaction started before the liquid was properly distributed in the melt, what resulted in poor quality products.

In conventional TSE, the residence time of up to 10 min can be achieved (Dreiblatt 1989). Special TSE systems for slow reactions have also been developed. For example, a TSE with a pre-reactor vessel may offer the residence time up to 45 min. However, the modern tendency goes in the opposite direction. TSEs are offered with the screw speed of up to 2,000 rpm (laboratory experiments are run at speeds of up to 3,000 rpm) that results in the residence time of the order of seconds. Hence, there is a rush to accelerate the reaction rates by catalysis, intensive mixing, as well as temperature and pressure.

The residence time distribution depends on the screw configuration, the throughput (or the degree of fill), and the screw speed. All three factors need to be optimized considering the rate of reaction, degradability of materials, and productivity.

9.5.1.2 Development of Reactive Compatibilization Process
Reactive processing combines fine polymer chemistry with polymer processing. Thus, development of the reactive compatibilization process involves:
1. Studies of chemical kinetics in glassware and internal batch mixers
2. Determination of the rheological and thermal parameters of the reaction ingredients and products
3. Mathematical modeling of the reactive processing
4. Reactive extrusion
5. Detailed evaluation of the properties of reaction products
6. Scale-up to industrial scale

9.5.1.3 Laboratory Equipment
To develop reactive compatibilization, the laboratory extruder should match the production unit. Thus, a TSE, either CORI or ICRR, with segmented barrel and screw should be used. The machine should have the screw diameter D ≥ 30 mm, with length-to-diameter ratio L/D ≥ 40. The extruder must provide an easy access to the reactive medium as well as the quenching capability with either screw or

barrel removal. It must be fully instrumented with temperature and pressure sensors all along the barrel. It should offer the possibility of working under dry inert atmosphere and have the capability of closed-loop control operation with an appropriate set of sensors. The machine should be equipped with a minimum of three feeders for solid and two for liquid ingredients. At least one vacuum system with cold trap is necessary.

The laboratory should have a drying facility for all components that are to be used (drying tower with closed resin transfer facility), as well as preblending facilities that can be operated under controlled temperature and atmosphere. The extrudate is usually granulated (thus, a need for the appropriate dies, cooling facility, and either granulator or pelletizer) and subsequently must be formed into suitable specimens and tested. Forming is usually done by injection molding into a standard, multi-cavity test mold.

The reactive extrusion is a process demanding precise operation by well-trained personnel. The knowledge of the extruder, compounding and mixing principles, design of screw and temperature profile, local residence time distribution, etc., is required. For optimization of the reactive extrusion, in- or online process monitoring, control, and data logging are recommended. This imposes further demands on the extruder operator.

9.5.1.4 Reactive Compatibilization Strategy

The experience indicates that the best results are obtained if:

1. The chemical reaction has low activation energy.
2. The required residence time is short ($t_{0.5} \leq 75$ s), what implies high reaction rates, and frequently catalysis.
3. The process can be simpler if the reaction is insensitive to moisture or oxygen.

The kinetics of the process should be studied on a model system in glassware. The kinetic parameters should be determined within the full range of the expected process parameters. Sensitivity of the reaction to moisture and oxygen should be examined. Next, the kinetics should be verified using polymeric ingredients. It is essential to know the lifetime of the activated sites. This determines the sequence and location of the reactant feeds. For example, if the radical is unstable, one may be better off feeding the peroxide and grafting monomer at the same location. Factors affecting group reactivity are listed in Table 9.21.

Since reactive compatibilization is carried out across the interface, the screws of the selected TSE must provide a suitable geometry for the mixing, mass, and heat transfer. The length of the reaction zone and the mixing intensity must ascertain sufficient mixing for the reactive groups to meet but without the accompanying mechanochemical degradation. It is essential that there is adequate devolatilization. The reaction by-products should be identified, removed, or rendered harmless (catalyst deactivation may be needed) (Dagli et al. 1994; Maier and Lambla 1995; Sundararaj et al. 1995; Hu et al. 1996a).

In principle, high melting point polymer should be fed and melted first, then the second polymer and liquid(s) should be added. After the reaction zone, the vacuum line should remove the volatile reactants (unreacted monomers) and by-products. Finally,

Table 9.21 Factors affecting group reactivity during reactive extrusion

Factor	Influence
Molecular weight	No influence of chain length onto which a functional group is attached was observed. Exceptions occur in stiff chain polymers
Neighboring groups	May increase or decrease group reactivity
Molecular configuration	Depending on chain configuration, the functional groups may co-interact which alters their reactivity
Electrostatic effect	Polarity of the reactive groups leads to repulsion or attraction effects
Accessibility	Stereo-barriers between functional groups
Supramolecular effect	Aggregation, associations, or clustering slows down the reaction, but the extent of these effects is difficult to predict
Mechanical shearing	Straining the macromolecules results in generation of stresses that may activate some bonds. Mechanically induced chain scission has been explored for grafting polymers and rubbers

just before the die, a filler (glass fiber) and unstable ingredients should be added. The reaction must be terminated when the product leaves the extruder. It is important that the process is well monitored and controlled (Broadhead et al. 1996; Gendron et al. 1996).

During the development stage, it is essential that samples are frequently taken from the extruder and analyzed for the extent of reaction as well as for the morphology and the key properties. The sampling methods are discussed in Sect. 11.2.1.2, "Morphology Evolution in an Extruder." It may also be profitable to verify the whole reactive compatibilization process by the carcass method.

The initial strategy formulated on the basis of chemical kinetics can serve as a starting point for the mathematical modeling of reactive extrusion. However, to ascertain successful strategy, mathematical "experiments" must be carried out, using realistic models of the process. To optimize the process parameters and the screw design, the model requires information on kinetics, rheology, and thermal properties (Menges and Bartilla 1987; Polance and Jayaraman 1995). The type of required rheological and thermal information depends on complexity of the model. The minimum rheological information is the shear viscosity as a function of the deformation rate, temperature, and the degree of conversion, $\eta = \eta(\dot{\gamma}, T, k)$. The minimum thermal information is the heat of reaction, transition temperatures of the ingredients and their enthalpies, as well as heat capacities and heat conductivity coefficients. The model must provide information on the sequence of extrusion steps like melting, homogenization of ingredients, chemical reaction, devolatilization, morphology, and performance.

The reactive extrusion should be optimized using a computer modeling procedure. The mathematical model of the reactive extrusion should combine three subroutines:

1. Pressure and temperature profile as a function of the degree of fill and screw length (Michaeli et al. 1991, 1993, 1995; Michaeli and Grefenstein 1996)
2. Rheology and chemical reaction (heat balance) as a function of screw length (Chen et al. 1996; Kye and White 1996; Hu et al. 1996b)
3. Variation of morphology along the screw length (De Loor et al. 1996)

An analytical model based on the energy balance in CORI was proposed. Anionic polymerization of ε-caprolactam in CORI was modeled, considering continuity of the process from one screw element to another. The model took into account the heat of reaction, viscous dissipation and heat transfer across the barrel. The calculations were performed for three different screw configurations comprising the transport and kneading elements. The predicted total conversion agreed with the experimental values within ± 3 % (Kye and White 1996).

Effects of the reactive processing are usually assessed either by analytical means or by their effects on morphology and performance. The analytical methods usually involve selective either extraction or destruction of one polymeric ingredient, followed by GPC, rheology, DSC, ^{13}CNMR, FTIR, and other analyses (Polance and Jayaraman 1995; Maier and Lambla 1995; Miyoshi et al. 1996; Kye and White 1996). The morphological studies should be conducted on several levels of magnification, from the optical to the transmission electron microscopy, TEM (Vesely 1996). For detailed discussion of the methods used to characterize the morphology, see ▶ Chap. 8, "Morphology of Polymer Blends".

Table 9.22 (see also literature reviews by Cassagnau et al. 2007; Raquez et al. 2008) lists examples reactive extrusion studies conducted in laboratory TSEs, whereas Table 9.23 provides examples for compatibilization (see also reviews by Feldman 2005; Karger-Kocsis et al. 2013). It is noteworthy that about 90 % of patents on polymer blends published during the last few years specify a TSE as the preferred compounder. Exceptions are blends formulated for oriented fibers and films (with LCP) that require high die pressure and thus are usually prepared in a SSE. Similarly, elastomeric blends of either PO or PVC are preferably prepared using one of the older methods like roll mill or Banbury mixer.

9.5.2 Scale-Up to Industrial Size

Scale-up is one of the most difficult engineering tasks. The main source of difficulty originates in the multifunctional capabilities of TSE. In addition to the primary functions of an extruder (solid conveying, melting, and pumping), TSE is used to mix, devolatilize, and more and more often conduct the chemical reactions. For these reasons, several schemes for the scale-up have been developed, each focusing on one particular process variable like constant specific energy (CSE), constant thermal conduction (CTC), constant residence time (CRT), etc. Usually, the CTC forms the lower, whereas the CRT the upper boundary.

The scale-up starts with optimization of the compounding conditions in a laboratory-scale TSE, having the screw diameter D ≤ 35 mm. Owing to the difference in thickness of the molten polymer between this and commercial size extruders (D ≥ 100 mm), it is advisable that the scale-up involves an intermediate stage, a midsize TSE with D ≥ 50 mm. The experience also showed that it is more difficult to scale up from 30 to 50 mm than from 50 to 200 mm TSE. Thus, the intermediary step may save a large amount of time, material, and the plant production capability.

Table 9.22 Examples of reactions conducted in laboratory TSEs

Process	TSE	Comment	Reference
PP peroxide degradation	CORI or SSE	Melt flow monitor (MFM) is needed	Xanthos 1992; Fritz and Stöhrer 1986

In principle, good mathematical model that combines melting, fluid mechanics, morphology evolution, devolatilization, and chemical reactions should provide solid guidance for the scale-up. However, so far such a complex model has not been developed. In consequence, the methods are pragmatic and less formal. First, it must be decided which function is the most important and wherever possible, an appropriate mathematical model should be selected. At least three experiments must be conducted, both computer-type and extruder-type, using three sets of values like composition, throughput, and screw speed. For each composition, the nine specimens should be examined for the desired performance characteristics such as mechanical performance, permeability, solvent resistance, etc. Once the model is found to well describe the experiments, the exercise must be repeated for the larger diameter extruder, the model parameters readjusted, and the optimum screw configuration and the processing conditions computed and then experimentally verified.

Less formal method uses the power-law exponents. Here, the ratio of the screw diameters, $\delta = D_2/D_1 > 1$, is the principal variable. When scaling, the screw channel angle is to be kept constant, and the screw section length increased by δ. The channel depth is also increased as $H_2 = H_1 \delta^{0.92}$. If the ratio of heat transfer to throughput is assumed constant, then $Q_2 = Q_1 \delta^2$, and $N_2 = N_1/\delta$. On the other hand, if ESP is taken as constant, $Q_2 = Q_1 \delta^\alpha$, and $N_2 = N_1/\delta^\beta$, where the exponents $\alpha = 2.84-0.08/n$, and $\beta = -0.08(1 + 1/n)$, with n being the power-law exponent of the shear viscosity vs. rate of shear. Assuming CRT $N_2 = N_1$ and $Q_2 = Q_1 \delta^{2.92}$, the experimental data were found to closely follow the ESP = const. approximation (Potente 1985; Rauwendaal 1986).

For the applications where degassing is crucial, the degassing constant, K'', for specific TSE geometry must be established:

$$K'' = \left(Q/LN^{1/2}\right)\ln(\Delta c_o/\Delta c_f) \tag{11.30}$$

where Q is throughput, L is vent length, N is screw speed, and $\Delta c_o = c_o - c_{e,o}$, and $\Delta c_f = c_o - c_{e,f}$, c_o being the initial concentration of volatiles and c_e the equilibrium

Table 9.23 Examples of compatibilization in TSEs

Process	TSE	Comment	Reference

value (initially with subscript o and finally with subscript f) (Hashimoto et al. 1993). From the scale-up strategy, Q and N are computed; then Eq. 9.30 is used to determine the required vent length and/or the pressure of the vacuum line (that controls the equilibrium values, $c_{e,o}$, and $c_{e,f}$).

In applications where mixing efficiency is most critical, the scaling should be based on the total induced strain (γ) and its value (optimized in the small TSE) should be preserved in the larger machine (Manas-Zloczower 1991).

9.6   Conclusion

This chapter was divided into four parts: fundamentals of mixing, blending methods and equipment, nonmechanical blending, and reactive blending.

The theory of mixing distinguishes the dispersive and distributive mixing, the former dependent on stress, while the latter on strain. Both types of mixing are more efficient in the extensional than in shear flow field. The extensional flows more economically generate large dispersing fields and induce larger strains. Independently of the flow field, the best mixing strategy is generation of a series of deformation and folding steps.

A majority of commercial polymer blends are melt-blended, mostly in TSE, less frequently in SSE, and rarely in batch mixer and other specialty mixing devices. Around 1999, about 94 % of all patents on polymer blends described blends preparation in a TSE, and this number has not changed much since. This is particularly significant, since to make the invention more attractive, many of the texts claim that the blend "may also be prepared by other methods like solution blending, in a batch and SSE mixer." The high percentage of TSE being used to develop blends corresponds to the recent estimates of these machines used in the engineering alloys' production, and some analysts put the number as high as 90 %. This dominance of TSE most likely stems from the growing use of the reactive blending. Since SSE is not well suited for conducting chemical reactions, the demands gravitate toward the twin-screw machines (an abbreviated comparison of the SSE and TSE performance was given in Tables 9.15 and 9.16). The TSE selection is based on the production requirements. A summary of the performance characteristics is given in Table 9.24 (Rauwendaal 1993).

The single-screw extruders are being used for the preparation of blends that either do not require compatibilization or are compatibilized by addition of nonreactive compatibilizers. For both applications, SSE is frequently supplemented by additional mixing devices like mixing screws, add-ons, extensional flow mixer, etc. To the first category of blends also belong these systems that are produced as filaments or fibers. It has been found that creation of a large interface (by stretching) reduces the need for compatibilization (when the viscosity ratio is large, it may be difficult to transfer stress to the non-compatibilized dispersed phase). To the second category of blends belong these systems that are compatibilized and at the same time impact modified by the addition of multicomponent core and shell additives. To the third group of blends belong systems based on either PO or PVC with a large amount of elastomer. These highly viscous systems are prepared on roll mills, in a Banbury-type mixer, or non-intermeshing twin-shaft continuous mixers.

When selecting the mixing strategy, one must consider the thermomechanical degradability of the blend ingredients (including the compatibilizer), the time scale of the relaxation processes, as well as the stress-induced coalescence. Some polymers like PP are sensitive to degradation. For this reason, better performance may be obtained from PP/EPR blends using low dispersing energy, just sufficient to adequately disperse the elastomer without inducing too extensive degradation of the matrix.

One of the most efficient mechanisms of mixing is development of fibrils that upon reduction of stress disintegrate by the capillarity mechanism into thousands of micro-droplets. This mechanism, well known in the Newtonian systems, seems to be less efficient in systems comprising highly elastic dispersed phase and low interfacial tension coefficient like in R-TPO systems. The loss of efficiency is related to, on the one hand, small interfacial energy and, on the other, long relaxation times. However, it must be stressed that dispersion of high-viscosity polymer into a less viscous matrix is greatly facilitated by the extensional flow field.

When selecting mixing devices, it is important to remember that the final degree of dispersion is related to dynamic equilibrium between the dispersive and coalescing mechanisms. With the exception of dispersed phase concentration, they both depend on the same parameters. Thus, the rate of drop diameter decrease during dispersing is $\partial d/\partial t = -k_1 \dot{\gamma} d$, whereas that of coalescing $\partial d/\partial t = k_2 \dot{\gamma} \phi^{8/3}/d$. Hence, the rate of shear similarly affects the dispersion as the coalescence process. For this reason, when all other parameters are constant, the drop diameter is often found to be insensitive to the screw speed. It has been even reported that, owing to generation of very large interface and/or shear degradation of a compatibilizer, an increase of the shear rate may cause the drop size to grow.

Nomenclature

a   area occupied by a copolymer molecule
b   channel width in a rectangular flow channel
B   droplet width, or the smaller diameter of prolate ellipsoid
C, c_i   constants
C_L   screw center-to-center distance
D   deformability parameter
d   droplet diameter
d*   equilibrium droplet diameter
De   Deborah number
d_o   initial diameter of droplet
D_p   particle diffusion coefficient
dP/dz   pressure gradient
E   energy of mixing
e'   relative flight width $= e/(\pi D_s \sin\varphi)$
E_+   threshold energy of coagulation
E_{DK}   macroscopic bulk breaking energy
$\overline{F}_d, F_p$ correction shape factors
$\overline{h}$ mean channel depth
H   Hamaker constant of the system
h_c   critical separation distance
K''   degassing constant
k_B   Boltzmann constant
L   length of a drop
L   screw length, or vent length
L/D   length-to-diameter ratio (TSE barrels)
m   consistency index (power-law viscosity model)
n   power-law flow index, or number of particles
N   screw rotation speed
N_{av}   Avogadro's number
n_c   number of divisions in a static mixer
N_s   number of striations

p aspect ratio

P pressure

$\mathbf{p_r}$ probability that two particles that have collided result in coalescence

q sinusoidal distortion

$\mathbf{Q, Q_c}$ throughout, throughput capacity

R radius of a dispersed drop

R interfacial area ratio

Re Reynolds number

$\mathbf{R_i}$ interfacial area

T temperature

t time, or pitch

$\mathbf{t_b}$ necessary time for breakup of droplets

$\mathbf{t_b}^*$ dimensionless breakup time

$\mathbf{t_c}$ coalescence time

u velocity field

V free volume of the extruder

v velocity

$\mathbf{v_x}$ velocity in the x direction

$\mathbf{V_x/V}$ volume fraction of emulsion undergoing uniform shear

$\mathbf{\overline{V}}$ average flow velocity

x linear distance

$\mathbf{Wi_d}$ dispersed phase Weissenberg number

$\boldsymbol{\alpha}$ orientation or tip angle

$\boldsymbol{\alpha_i}$ breakup parameter

$\boldsymbol{\alpha_o}$ the distortion at t = 0

$\boldsymbol{\beta}$ orientation angle

$\boldsymbol{\chi_{12}}$ thermodynamic binary interaction parameter

$\boldsymbol{\delta}$ solubility parameter

$\boldsymbol{\Delta l_\infty}$ interphase thickness for MW $\rightarrow \infty$

$\boldsymbol{\Delta P}$ pressure drop

$[\dot{\boldsymbol{\varepsilon}}]$ velocity gradient tensor

$\boldsymbol{\phi_c}$ percolation threshold volume fraction

$\boldsymbol{\phi_d}$ volume fraction of dispersed phase

$\boldsymbol{\phi_m}$ maximum packing volume fraction

$\boldsymbol{\eta}$ viscosity

$\boldsymbol{\eta_d, \eta_m}$ viscosity of dispersed and matrix phase, respectively

$\boldsymbol{\gamma}$ shear rate

$\boldsymbol{\kappa}$ capillary (or Taylor) number

$\boldsymbol{\kappa_{crit}}$ critical capillary number

$\boldsymbol{\Lambda}$ distortion wavelength

$\boldsymbol{\lambda}$ viscosity ratio

$\boldsymbol{\nu_{12}}$ interfacial tension coefficient between phase 1 and 2

$\boldsymbol{\nu^\circ_{12}}$ interfacial tension in a quiescent polyblend

$\boldsymbol{\rho, \rho_d}$ density, droplet density

$\sigma_{11} - \sigma_{22}$ the first normal stress difference

σ_{12} shear stress

τ relaxation time

$\Omega(\Lambda, \lambda)$ Tomotika's tabulated function

Abstract

This chapter presents an overview of properties and performance of
polymer blends. It is structured into nine sections dealing with aspects required
for assessing the performance of a polymer blend. These are mechanical prop-
erties comprising of both low-speed and high-speed popularly studied proper-
ties; chemical and solvent effects; thermal and thermodynamic properties;
flammability; electrical, optical, and sound transmission properties; and
some special test methods which assumed prominence recently because of
their utility.

Each section opens up with standard test methods such as ASTM, BS, DIN, and ISO for each property evaluation and is summarized. Since presentation of all test methods for each property is beyond the scope of this chapter, one popular test method is described in detail while others are discussed with reference to it. The factors controlling each property are also examined. Each section concludes with an outline of the state of the art pertinent to the aspect in focus. Definitions of all terms from each section are grouped together in Table 10.36.

Toughening plays an important role in designing polymer blends. Due emphasis has been given to this aspect by presenting the different methods of determining blend toughness, specially using ductile fracture mechanics; the mechanisms of toughening; and also the factors influencing toughness. Flammability aspect assumed a great deal of interest ever since the US Federal Trade Commission's (FTC) action in 1972. Commercial exploitation of a polymer blend is regulated, since then, by its flammability characteristics. A brief review on factors affecting flammability is presented, and a list of fire-retardant chemicals is provided in Table 10.37.

The recent advances in optical properties, sound transmission properties, and certain "special testing methods" are presented at the closing of the chapter. These "special test methods" are not yet matured into international test methods but, nevertheless, are popularly used for meeting the requirements of certain applications. Hence, awareness of these methods is considered to be essential. The chapter concludes with perspectives for the future developments.

10.1   Introduction

Modern technology thrusts challenging demands on the performance capabilities of materials, including polymers and their blends. A new approach to the science and technology of polymer blends has emerged recently, i.e., polymer blends by design rather than by availability. These polymeric materials must perform under strenuous mechanical, chemical, thermal, and electrical conditions imposed by the requirements of a specific application. Service in these applications usually involves several criteria to be fulfilled without a loss of economic advantage. Indeed, performance requirements of polymer blends are often at the limit of the properties that can be achieved. Moreover, these materials are expected to endure complex environmental conditions for extended time. All these factors stress the need for in-depth studies of the properties and performance of polymer blends.

There are three aspects to material properties and performance:
1. The origin – identification of the mechanisms responsible for given performance characteristics
2. Methods of determination – the most reliable way that the properties should be measured
3. The numerical values of the characteristic parameters of the material

In principle, the entire handbook is dedicated to discussion of these three aspects. For example, in ▶ Chap. 2, "Thermodynamics of Polymer Blends," the molecular aspects of polymer–polymer interactions, the methods of

characterization, as well as the numerical values of the thermodynamic parameters are given. Similarly, in ▶ Chap. 3, "Crystallization, Morphological Structure, and Melting of Polymer Blends," the three aspects vis-à-vis nucleation, melting, etc., are presented. In ▶ Chap. 7, "Rheology of Polymer alloys and Blends," flow, generation of flow-imposed lamellar morphology was discussed. This morphology has been used to control permeability through polymeric membranes.

Another important aspect of the material performance characteristics that is growing in significance is the balance of properties – for many applications it is not so important what is the value of a single parameter, but how well the material combines a number of characteristic properties. Take, for example, the use of polymer alloys for automobile fenders. Here the general requirements (viz., weight reduction, part consolidation, cost, design flexibility, increased impact, crashworthiness) translate into requirements for stiffness, strength, impact resistance, low coefficient of linear thermal expansion, weight reduction, chemical, corrosion and heat resistance, finish, oven paintability, and cost. These aspects are well presented in ▶ Chap. 15, "Applications of Polymer Blends."

The third aspect of the properties, the numerical values of measured parameters, represents enormous challenge to authors of a chapter such as this ▶ Chap. 12, "Broadband Dielectric Spectroscopy on Polymer Blends". The polymer blend industry produces well over 500 generic name blends, each in dozens of grades (Utracki 1994, 1998). Physically, it is impossible and practically useless to attempt reproducing the data sheets of these thousands of blends. Furthermore, the industry is dynamic, continuously adding and/or removing grades from the market. The modern source of the numerical information must also be active, changing along with the variability of materials, viz., the Internet. Most of the major resin producers' offer updated data sheets on the Internet, for example, www.allied.com, www.amoco.com, www.basf.com, www.dow.com, www.dupont.com, www.eastman.com, www.ge.com, www.hoechst.com, www.solutia.com, etc.

This chapter presents an overview of properties and performance of polymer blends, focusing on these aspects that are outside the main domain of the other chapters in this handbook. Such properties as mechanical, chemical, and solvent effects and thermal, flame retardancy, electrical, and optical properties are discussed. Further, the developments in sound transmission, certain special test methods in aroma barrier, permeability test for liquids, and environment stress cracking are included in the second edition of this handbook. In addition, the data is updated and upgraded. And, finally, the relevant and useful websites for additional information are also provided towards the end of this chapter.

The response of a polymer blend to tensile, compressive, and flexural stresses is examined in the initial section. Its rigidity, fatigue, and failure characteristics are also studied. The toughened polymers have enhanced the status of polymer blends, thus the toughening mechanisms have received considerable attention from researchers. The fracture mechanics approach of testing and the fascinating toughening mechanisms prevailing in these wonderful materials are also examined.

Insufficient chemical resistance of a blend at times leads to its rejection for use in an aggressive chemical environment, although it possesses an excellent combination

of mechanical properties. Thus, chemical and solvent effects on polymer blends are important factors that frequently determine blends' applicability. Attention has been given to chemical resistance of blends starting from the fundamental concept of the solubility parameters. Apart from the chemical and environmental restrictions, thermal resistance of a polymer blend is often a major criterion for its applicability. Thus, the thermal conductivity, heat capacity, and heat deflection temperature of polymeric materials are discussed in separate sections.

In this second edition of handbook, discussions regarding low-temperature brittle point, Vicat softening point, oxidative induction time, melt and crystallization parameters using DSC, and thermal degradation using TGA are added in order to bring around completion of comprehension on thermal properties of polymers and blends.

Flame resistance has become a legal requirement for commercial utilization of polymers and their blends in many applications. Innumerable test methods for flammability have been developed in different countries, and several books and handbooks are exclusively dealing with this subject. Discussion of the test methods that are *en vogue* in various countries is beyond the scope of this chapter; thus only the most popular test methods are discussed. The fire-retardant chemicals and their suppliers are tabulated in Table 10.37.

The use of polymer blends in electrical as well as electronic applications has been increasing rapidly. The electrical insulation properties of these materials cannot be ignored. Moreover, conducting polymers are likely to make an industrial breakthrough. These types of blends are also briefly discussed.

In addition, oxidative induction time, an exclusive test method popularly engaged in checking the suitability of an insulation material for cables, is added in the second edition.

Optical clarity has received considerable attention from the research community, as well as industry, especially, since transparent ABS was introduced to the market. Although success in this area has been limited, nevertheless this property is pertinent when considering blend suitability to a particular application. Few significant innovations have come up in photoluminescence and thermoluminescence, but the subject is, however, not mature enough to make a comprehensive story of the subject.

Some special test methods which have illuminated the applications of polymer blends are grouped together towards the end, viz., aroma barrier test, permeation test for liquids, and environmental stress cracking, which are special in nature but not really obtained the status of ASTM or BS methods. Nevertheless, they are used in industry as they meet the special application requirements of these wonderful materials. The chapter concludes with a discussion of these aspects.

10.2 Low-Speed Mechanical Properties

10.2.1 Tensile Strength, Tensile Modulus, and Elongation

The tensile stress–strain test is most widely used. Owing to the viscoelastic nature of polymers, the test is only a rough guide to how a polymer will behave in

Fig. 10.1 Material in tension
a finished product. Often, results of a single test conducted at one temperature and speed of testing are published. To get a clear understanding of a polymer, it is required to have the tests at several temperatures, rates of testing, and other conditions (Dukes 1966).

There is no universally accepted set of definitions with regard to the tensile tests. The terms listed in Appendix 2 have been taken from the widely accepted norms (ISO/DIS 527; **BS 2782 Methods 320A to F; ASTM D638-95).

The most frequently applied stress–strain measurements are made in tension by stretching the specimen as shown in Fig. 10.1. A tensile stress can thus be defined as

$$\sigma_1 \quad = \quad \frac{F_1}{A_o} \tag{10.1}$$

where σ_1 is the tensile stress, F_1 is the tensile force, and A_o the cross-sectional area of the specimen. If the tensile stress stretches the specimen to length l_1, the tensile strain, ε_1, is defined as

$$\varepsilon_1 \quad = \quad \frac{(l_1 - l_o)}{l_o} \quad = \quad \frac{kt}{l_o} \tag{10.2}$$

where l_o is the initial length of the specimen, k is the rate of extension, and t is the time. Continuing the stressing operation to the ultimate, i.e., measuring the force until the material breaks, tensile strength, known as the ultimate tensile stress:

$$\sigma \quad = \quad \frac{F}{A} \tag{10.3}$$

where F is the force at failure and A is the cross section at failure.

During the process of stretching, the specimen's dimensions orthogonal to the axis of applied force decrease, and thus the area of cross section decreases. For experimental convenience, however, tensile strengths are usually based on the original cross section (A_o) which is easily measured at the beginning of the experiment:

$$\text{Elongation at break } (\%) \quad = \quad 100 \; \frac{(l - l_o)}{l_o} \tag{10.4}$$

From the point of view of mechanical performance, four types of materials have been identified. They are best discussed in terms of the stress–strain dependence:

1. Brittle, showing proportionality between stress and strain up to the point of rupture. Here, the modulus, $E = \sigma/\varepsilon$, is constant, independent of strain, ε.

2. Semi-ductile, showing decreasing proportionality between stress and strain up to the point of rupture. Here, the modulus, $E = \sigma/\varepsilon$, decreases with strain, ε.
3. Ductile, initially showing similar relationship between stress and strain as the semi-ductile materials. However, these materials deform further, causing the stress pass through a maximum (yield). The rupture takes place at lower values than the yield stress.
4. Ductile with flow. These materials show still greater deformability than the typical ductile materials. Initially, the stress–strain dependence resembles that described for ductile resin, but before the rupture, there is a zone of deformation where the stress remains about constant. Within this zone there is "flow" of material that usually leads to molecular alignment and/or to changes to the crystalline structure (viz., deformation of polyolefins).

10.2.1.1 Methods of Measurement

Stress–strain measurements for polymer blends can be conducted in one of two modes: using a constant rate of loading or a constant rate of stretching. The first method is very often used in adhesives testing. The latter method is the most extensively employed in polymer and blend testing. In tensile testers, a sample is clamped between grips or jaws that are pulled apart at constant strain rates varying from 0.5 to 500 mm/min. The stress on the sample is monitored with the load cells ranging between 2 g and 5,000 kg or more. The elongation must avoid errors arising out of sample slippage from the grips. There are a variety of jaws that can hold different samples. A review of grip systems is presented in "Handbook of Plastics Test Methods" (Brown 1981). Jaw design and specimen shape and preparation are selected so as to minimize the introduction of extraneous stress or strain.

Tensile tests on different polymer blends employ specimens of different sizes. To conduct a tensile test, a specimen capable of being gripped at both ends is required. The basic types of dumbbell configurations and dimensions recommended by ISO are illustrated in Fig. 10.2. The American specifications differ only in number of dimensional details and are based essentially on imperial units. In case of rigid polymer blends (such as engineering blends), the specimen can be molded, machined on a lathe, or simply cut out from thin, flat sheets.

The dumbbell specimen with narrow waist (Fig. 10.2a) is generally preferred in testing rubbers and their blends with thermoplastics. The dumbbell specimen with broad waist (Fig. 10.2b) is used for polymers and blends exhibiting low-to-moderate elongation at break. Dog-bone test specimens (Fig. 10.2c) are used for polymer blends that do not allow any elongation measurement to be made. The parallel strip specimens (Fig. 10.2d) are used for reinforced thermoplastics or blends. In order to avoid the problem of sample fracturing near the grips, the end pieces of the grips are normally bonded.

10.2.1.2 Standard Test Methods for Tensile Properties

The standard test methods for tensile properties are listed in Table 10.1 and the recommended test speeds in Table 10.2.

Fig. 10.2 (**a**) Tensile test
specimen: Narrow-waisted
dumbbell (ISO/DIS 527
Type A). (**b**) Tensile test
specimen: Broad-waisted
dumbbell (ISO/DIS 527
Type B). (**c**) Tensile test
specimen: Dog-bone
dumbbell (ISO/DIS 527
Type C). (**d**) Tensile test
specimen: Parallel-sided strip
(ISO/DIS 527 Type D)
Table 10.1 Standard test methods for the determination of the tensile properties of polymers

Test method	Materials	Specimen	Test speeds
ISO R527	Plastics	1 mm thick	See Table 10.2
ISO R1184		<1 mm thick	
BS 2782			
Method 320A	Flexible plastic sheets blends, filled or reinforced	Stamped from sheets	500 mm/min
Method 320B	Composites	Injection molded	1, 5, 25, 50 and 100 mm/min
Method 320C	Rigid thermoplastic, thermosets	Machined from sheets	As in Method-A

Table 10.2 Recommended test speeds according to DIS 527 (ISO/DIS 527)

Speed A	1 mm/min	±50 %
Speed Al	2 mm/min	±20 %
Speed B	5 mm/min	±20 %
Speed C	10 mm/min	±20 %
Speed D[a]	20 or 25 mm/min	±10 %
Speed E	50 mm/min	±10 %
Speed F	100 mm/min	±10 %
Speed G[a]	200 or 250 mm/min	±10 %
Speed H	500 mm/min	±10 %

[a]Both the mentioned speeds are allowed because they are popularly used throughout the world

Measurements of "Apparent" Strain
The elongation of specimen is followed by using gauge marks and measuring the distance between them preferably continuously or by making use of clip-on type of extensometer. In the case of blends exhibiting strains in excess of 50 %, optical extensometers are to be used. The merits and demerits involved in different methods of strain measurements are discussed in detail elsewhere (Brown 1981).

Measurement of Modulus
The standard test methods calculate the tensile modulus by drawing a tangent to the initial linear part of the stress–strain curve and calculating the slope of the line. In cases where no clearly defined linear portion exists, the "secant modulus" should be determined.

10.2.2 Compressive Strength

Stress–strain curves developed during tensile, flexural, and compression tests may be quite different from each other. The moduli determined in compression are generally higher than those determined in tension. Flaws and submicroscopic cracks significantly influence the tensile properties of brittle polymeric materials.

However, they do not play such an important role in compression tests as the stresses tend to close the cracks rather than open them. Thus, while tension tests are more characteristic of the defects in the material, compression tests are indicators of the material content of the specimen used. The ratio of compressive strength to tensile strength in the case of polymers is in the range 1.5–4 (Dukes 1966).

10.2.2.1 Standard Methods for Compressive Tests

The standard methods for compressive tests are listed in Table 10.3. For example, the ISO Standard 604 allows four types of test specimens: (1) the right square prism, (2) the right rectangular prism, (3) the right cylinder, and (4) the right circular crown tube. The test specifies for each of these test specimens, the load-bearing surfaces be parallel to each other within 0.1 % of the height of the test piece.

10.2.2.2 Plane-Strain Compression Test

Williams and Ford developed "plane-strain compression test" which was initially applied to metals (Williams and Ford 1964). It was based on the fact that strain is easier to measure in compression test. The same test method may be used for polymer blends to obtain total deformation curves up to high levels of strain that may be encountered in engineering applications. Williams had further explained the application of this technique to polymers (Williams 1964).

10.2.3 Flexural Strength and Flexural Modulus

Flexural tests may be carried out in tensile or compression test machines. In standard tests, three-point bending test is preferred, although it develops maximum stress localized opposite the center point (support). If the material in this region is not representative of the whole, this may lead to some errors. Four-point test offers equal stress distribution over the whole of the span between the inner two supports (points) and gives more realistic results for polymer blends (Fig. 10.3). Expressions for the calculation of flexural strength and modulus for differently shaped specimens are given in Table 10.4.

Standard test methods for flexural properties are listed in Table 10.5. They may be carried out in tensile or compression test machines. Three-point bending is often used. Four-point test offers equal stress distribution over the whole of the span between the inner two supports (points), and it is preferred for polymer blends. The curvature of the bearing rods is also important as too sharply curved rods lead to fracture of the specimen.

10.2.4 Rigidity and Rockwell Hardness

"Hardness" is not a fundamental property. Its measurement is subjected to the effects of temperature, time, and other test variables. Hardness measurement of

Table 10.3 Standard test methods for compressive tests

No.	Test method	Specimen	Materials
1.	ISO 604 (1973)	(1) The right square prism, (2) the right rectangular prism, (3) the right cylinder, and (4) the right circular crown tube	The load-bearing faces are to be parallel to each other within 0.1 % of the test piece height
2.	British standard BS 2782, Method 345A		
	Type 1	For sheets of thickness not less than 12 mm	Thermoplastics, including polymer blends and thermosets
	Type 2	For sheets of thickness less than 12 mm (for sheets of thickness >12 mm, the test piece is machined only on one face so as to reduce the thickness to 12 mm)	Thermoplastics, including polymer blends, and thermosets
	Type 3	For casting and lamination resin systems without fibrous reinforcement	
	Type 4	Test pieces are identical to ISO 604	Neat resins
	Type 5	For flat injection-molded or compression-molded thin sheets materials	Glass fiber-reinforced laminates
3.	USA standards ASTM D695-10[a] The method is the same as in BS, but specimen dimensions differ	For a right prism the preferred dimensions are 12.7 mm square by 25.4 mm height	For rod slenderness ratio should be in the range 11–15:1
4.	German standards DIN 53454 (1971)	Similar to British Standards in the form as well as dimensions of test specimens	

[a]ASTM standard test methods are available on web: http://enterprise.astm.org/
Fig. 10.3 Four point bending

Table 10.4 Expressions for calculation of flexural strength and modulus

No.	Geometry	Strength (MPa)	Modulus (MPa)	Comments
1.	**Four-point bending**			P = Load (N) at the moment of break
				P_Y = Maximum load (N) at yield or break
	ASTM D6109-97 (load span = 1/3 support span)	$S = PL/bd^2$	$E = 0.21\ L^3m/bd^3$	L = Support span (mm)
				B = Width of beam (mm)
				d = depth of beam (mm)
	ASTM D6272-98 (load span = 1/2 support span)	$S = 3PL/4bd^2$	$E = 0.17\ L^3m/bd^3$	m = slope of the secant (N/mm)
				For Unreinforced and reinforced plastics
2.	**Two-point bending**			For fiber-reinforced pultruded rods use ASTM D4476-97
	ASTM D790-99 (support span-to-depth ratio < 16:1)	$S = 3P_Y L/2bd^2$	$E = L^3m/4bd^3$	

plastics is similar to the traditional methods applied to metals. It usually employs a standard indenter (often a hardened steel ball), forcing it under known load into a flat surface of the plastic and then measuring the resultant degree of indentation.

Unlike other Rockwell scales, Rockwell R_α parameter correlates with the hardness as determined by ball indentation. Fett (1972) has shown that

$$H = \left[\frac{441.4}{(150\text{-}R_\alpha)}\right]^{1.23} \tag{10.5}$$

where H is the hardness by ball indentation and R_α is the Rockwell hardness parameter.

The standard test methods for determining Rockwell hardness are listed in Table 10.6, and the Rockwell scales are given in Table 10.7. For example, ISO 2039 employs a hardened steel ball, 5 mm diameter. The ball is pressed into the specimen under a specified load selected to give an indentation between 0.07 and 0.10 mm (Method A) or between 0.15 and 0.35 mm (Method B). The recommended thickness of the specimen is 4 mm and the suggested time of application of the load is 30 s before the depth reading is taken.

10.2.5 Fatigue Characteristics

Fatigue failure may occur when a specimen fractured into two parts was softened and/or its stiffness significantly reduced by thermal heating or cracking. Sometimes, for different reasons, a large number of cycles elapses from the first formation of microscopic cracks to complete fracture. In this case, the fatigue failure is

Table 10.5 Standard test methods for flexural properties

No.	Test method	Specimen	Material
1.	ISO standards	Standard test specimen dimensions: $80 \times 10 \pm 0.5 \times 4 \pm 0.2$ mm	For single-phase materials
	ISO 178	Length is 20 times the thickness and width is between l0 and 25 mm	For materials containing fillers
		Length is 20 times the thickness and width is between 20 and 50 mm	
2.	British standards BS 2782 Method 335A Method 336B	Identical to ISO 178.	
		It employs cantilever-bending mode. Standard test specimen (molded) dimensions are $70 \times 25.4 \times 1.5$ mm. A hole of diameter 2.0–2.02 mm is to be drilled centrally	
3.	USA standards ASTM[a] D790 Method I Procedure-A Procedure-B Method II Procedure A Procedure B	Three-point loading system	Procedure-A is for materials that fracture at small deflections
		Test specimen dimensions and rate of cross-head motion are to be selected based on support span-to-depth ratios ($1/d$ = 16 to 1, 32 to 1, 40 to 1 or 60 to 1)	
		Four-point loading system. Recommended test specimen dimensions and rate of crosshead motion are given based on support span-to depth ratios	Procedure-B is for materials that undergo large deflections
4.	German standards DIN 53452 DIN 53435	Similar to three-point loading for ISO 178 For four-point loading (using Dynstat apparatus)	

[a]ASTM standard test methods are available on web: http://enterprise.astm.org/

arbitrarily defined as having occurred when the specimen can no longer support the applied load within the deflection limits of the apparatus.

Plastics, including polymer blends, are relatively high damping and low thermal conductivity materials. Thus, repeated straining of an article leads to a temperature rise within and throughout its body. Rapid stress–strain cycling can significantly heat up the article and thereby induce thermal failure – the phenomenon is frequency dependent. Where the thermal effect is to be a minimized, much lower frequency, of the order of a few Hz, should be employed.

Fatigue data are usually presented in the form of S–N curves, in which stress amplitude S is plotted versus log N_f, where N_f is the number of cycles to fracture an unnotched specimen, either in bending or in tension. A typical example of such a curve is shown in Fig. 10.4. Here, the S–N curve for rubber-toughened PMMA provides the "endurance limit," which is defined as the lowest stress amplitude at which fracture occurs. In general, most S–N curves flatten out at $N_f = 10^7$. Rubber toughening, in the case of styrene polymers, is found to reduce fatigue resistance and causes a decrease in the endurance limit (Sauer and Chen 1983, 1984). This is due to promotion of crazing and reduction of stresses by the rubber particles. The cyclic loading then degrades the crazes into cracks.

Table 10.6 Standard test methods for determining Rockwell hardness

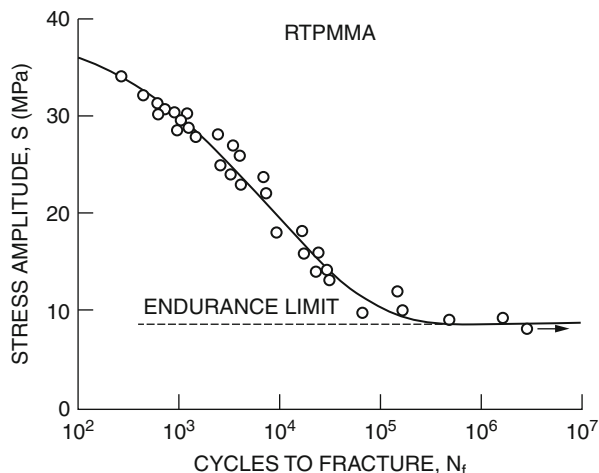
No.	Test method	Specimen	Indentation
1.	ISO standards: ISO 2039 Method A Method B Revised procedure follows that of ASTM D785-98.	4 mm thick specimen	Between 0.07 and 0.10 mm
			Between 0. 15 and 0.35 mm
			Time of load application is 30 s
2.	British standards	8 to 1 0 mm thickness	
	BS 2782	For "Softness Number"	
	Method 365A	As ISO 2039	
	Method 365D	As ASTM D2583-95	
	Method 1001	Measures Rockwell	
	Part 3 (Method 365C)	Hardness	
3.	USA standards ASTM D785-98[a]	Uses Rockwell hardness tester, and scales (see Table 10.7)	Minor load is applied for 10 s, then major load for 15 s; the hardness reading is taken off the scale 15 s after the major load is removed
	Procedure A Procedure B	6 mm thick specimen	Indentation is recorded 15 s after application of major load, but with minor load still on
4.	German standards DIN 53456	As in ISO 2039	Same as ISO 2039 except the major load must be selected from 49 N, 132 N, 358 N and 96IN, with a minor load of 9.81 N in all cases

[a]See: http://enterprise.astm.org/

Table 10.7 Rockwell scales (ASTM D785-98 (http://enterprise.astm.org/))

Rockwell hardness	Minor load (kg)	Major load (kg)	Indenter diameter	
			(in.)	(mm)
R	10	60	0.5000 ± 0.0001	12.7000 ± 0.0025
L	10	60	0.2500 ± 0.0001	6.3500 ± 0.0025
M	10	100	0.2500 ± 0.0001	6.3500 ± 0.0025
E	10	100	0.1250 ± 0.0001	3.1750 ± 0.0025
K	10	150	0.1250 ± 0.0001	3.1750 ± 0.0025

Fatigue-induced deformation mechanisms can be studied by measuring the volume changes. Another sensitive method is to monitor the hysteresis loops under tension–compression loading. This is illustrated in Fig. 10.5. All specimens initially show a small elliptical loop, indicating the viscoelastic response of the polymer (Bucknall and Stevens 1980; Sauer and Chen 1984; Bucknall and Marchetti 1983). Plots of tensile versus compressive loop area reflect the proportions of shear yielding and crazing. This method has been used to detect the onset of crazing in fatigue tests

Fig. 10.4 S-N curve for rubber-toughened PMMA (Bucknall 1988)


on ABS. Following the trend in metallurgy, fracture mechanics techniques are now widely used to study fatigue in polymers.

Standard test methods for fatigue testing are listed in Table 10.8. As an example, ASTM D671 makes use of the constant amplitude of force approach (Satake 1970). Two dumbbell-type test pieces, both of triangular form, are described. They are to be selected according to the thickness and stress range over which the measurements are to be made. The apparatus described operates only at a fixed frequency of 30 ± 5 % Hz.

10.2.6 Review of Low-Speed Mechanical Properties of Blends

The low-speed stress–strain dependence for PS and HIPS is shown in Fig. 10.6. These data well illustrate the change induced by incorporation of elastomeric particles into PS matrix. As shown, upon toughening, PS brittle behavior changes into ductile with flow.

The low-speed mechanical properties of polymer blends have been frequently used to discriminate between different formulations or methods of preparation. These tests have been often described in the literature. Examples of the results can be found in the references listed in Table 10.9. Measurements of tensile stress–strain behavior of polymer blends are essential (Borders et al. 1946; Satake 1970; Holden et al. 1969; Charrier and Ranchouse 1971). The rubber-modified polymer absorbs considerably more energy; thus higher extension to break can be achieved. By contrast, an addition of rigid resin to ductile polymer enhances the modulus and the heat deflection temperature. These effects are best determined measuring the stress–strain dependence.
Fig. 10.5 Hysteresis loops developed during fatigue tests of ABS and HIPS (Bucknall 1988)

Table 10.8 Standard methods for fatigue testing

No.	Test method	Approach	Specimen	Frequency of testing
1.	USA standards ASTM D671-93[a]	Constant amplitude of force	Two specimens of triangular form with rectangular cross section	Fixed frequency of 30 Hz
2.	German standards DIN 53442	Constant amplitude of deformation	Dumbbell shaped (tensile dumbbell) test specimens	Variable frequency

10.3   High-Speed Mechanical Properties

The subject of impact strength of plastics has received considerable attention in official standards, material data sheets, and literature at large. The result of an impact test is basically no more than one point on the general curve of studying strength properties as a function of speed of testing. One advantage an impact test can offer is a ready measure of the actual energy required to break a test piece, which information can also be calculated from stress–strain diagrams in tensile or flexural tests with some effort.

Fig. 10.6 Tensile stress–strain curves for PS and HIPS (Bucknall 1988)
All materials tend to fracture if stressed severely enough. Some materials fracture more easily than others and are thereby said to be "brittle." Brittleness is the property of a material manifested by fracture without appreciable prior plastic deformation. In ductile fracture significant plastic flow occurs before fracture. Strain at fracture is more than a few per cent, unlike brittle fracture, and may be several hundred per cent. However, a sharp distinction cannot be made between brittle and ductile fracture since even in glassy materials some deformations take place. Further, a given material will fail in a brittle manner under some conditions and a ductile manner under other conditions. Thus, brittle fracture is favored by the low temperature and fast loading and when the state of stress approaches a uniform, i.e., triaxial or dilatational, state. Materials with low T_g are more likely to suffer ductile fracture, but the mode of fracture also depends on the fracture conditions. Furthermore, any structural feature that raises T_g, such as bulky side groups or cross-linking, promotes brittle fracture. In a given material fracture may undergo brittle/ductile transition, depending upon the testing temperature. At this transition temperature, the mode of fracture changes from brittle to ductile fracture (Kinloch and Young 1983).

10.3.1 Impact Strength

In many applications a satisfactory resistance to impact loading is an important performance requirement, and, indeed, impact toughness is often the deciding

factor in materials selection (Vincent 1971; Bucknall et al. 1972; Turner 1973; Bucknall 1977; Reed 1979; Kinloch and Young 1983; Savadori 1985; Brostow and Corneliussen 1986; Havriliak et al. 1996). For the past several decades, ductile grades of usually brittle polymers, such as PS, PMMA, PVC, or PA, have been used. The most widely used test for impact assessment is the notched Izod impact test. A single operator can run up to 150,000 tests in a year (Havriliak et al. 1996).

The test is also an important material or product specification for toughness – it is often one of few material constants specified as a product development objective. It appears that the earliest reference to the subject of impact testing was in 1734 by Swedenborg who wrote that iron bars were tested by throwing them against a sharp edge (Lethersich 1948). If the blow marks the bar without breaking any part of it, this was a sign of tenacity. Further, experimental and theoretical works pointed out the dependence of the resistance of metals on the test speed and notches. Two devices were introduced by Charpy (in 1901) and by Izod (in 1903) for analyzing the impact performance of materials (see Fig. 10.7). The impact resistance is evaluated in energy terms, i.e., by evaluating the difference between the potential energy before and after impact, the energy absorbed by the specimen during the impact process is obtained.

From the physical point of view, the Izod equipment is equivalent to that of Charpy. However, the main differences between the two are the clamping system, the notch, the hammer speed, and its weight. Charpy adopted the keyhole form of notch. At such an early stage in the history of impact testing, Charpy found that correlations between static and dynamic tests were obtainable provided a notched bar was used. In 1925, the Izod and Charpy tests were extended to plastic materials, and many results on plastics were published a year later (Werring 1926).

The growth of fracture mechanics has placed greater emphasis on tests that use sharply notched specimens. These results were found to provide more fundamental information. Instrumented impact testing is a recent development that provides information on force – deflection curves. In addition to these notched bar tests, extensive use of falling dart tests is also being made. However, interpretation of the

Fig. 10.7 Cantilever beam (Izod type) impact machine (ASTM D256)
data from the latter is far from straightforward. The impact strength is not a fundamental material property. The results depend on the specimen geometry, test method, and the employed parameters. Thus, it is difficult to correlate the results obtained from different test techniques and extremely difficult to correlate the results from impact tests on specimens of the material to the impact performance of the manufactured article.

Correlation of results from one test to another for a given material becomes difficult because of different stress states of the specimen and the associated strain rates in different tests. In the tensile-impact test, the stress state is uniaxial and it measures the tensile property at a high strain rate. In Izod and Charpy tests, the presence of notch gives a triaxial state of stress. The falling-weight test is always in the forefront of high-speed testing for evaluating the strain rate sensitivity of materials. In this case, the stress is biaxial. Several attempts were made to relate fracture mechanics theories to impact test results (Brown 1973; Marshall et al. 1973; Plati and Williams 1975). The topic was also reviewed (Kinloch and Young 1983; Brostow and Corneliussen 1986).

10.3.1.1 Izod Impact

One of the most often used tests for impact assessment is the notched Izod impact test. The basic principle of the test is to allow a pendulum of known mass to fall

Fig. 10.8 Relationship of vise, specimen and striking edge to each other for Izod test methods A and C (ASTM D256)

WITHIN 0.025MM (0.001 IN.)
from a known height and strike a standard specimen at the lowest point of its swing, and to record the height to which the pendulum continues its swing (see Fig. 10.7). If the striking edge of the pendulum coincides with the center of the percussion of the pendulum, the bearings of the pendulum are frictionless, and there is no loss of energy to windage, then the product of the mass of the pendulum and the difference between the fall distance and the height it reaches after impacting the test specimen is the impact strength of the latter.

The test may be carried out on plane rectangular bars, but most often a carefully defined notch is molded or machined into the face to be struck (Fig. 10.8). The impact tests are often regarded as a means of assessing the resistance of a material to shock where notches or "stress raisers" generally are present. The ratio of impact strength of unnotched to that of notched specimen is sometimes regarded as a measure of the notch sensitivity of a material.

Despite the popularity of the test, it is still poorly understood in terms of generating an actual "material" property. The test reveals little about molecular dynamics and is not related to molecular structure. It is often criticized by fracture mechanics experts because of uncertainties about gauge length, complex state of stress, its dependence on thickness as well as a wide range of shear rates during the experiment, and the relationship of these factors to real situations (Havriliak 1996).

The test, nevertheless, does have several important features. First, it is accepted by a large technical audience and is in common use. Second, it is a reproducible test, mostly because of the work of the ASTM. Finally, the impact results for various materials are spread over two orders of magnitude. When this spread is compared with the signal-to-noise ratio, the material range is impressive. Attempts are made to set up this ubiquitous test method on a firm platform based on the principles of fracture mechanics.

Table 10.10 Standard test methods for the determination of Izod impact strength

No.	Test method	Impact energies	Test specimen	Notch
1.	ISO R180	1.0, 2.75, 5.5, 11.0 and 22.0 J	Four types permitted. Type 4 is preferred ($80 \pm 2 \times 10 \pm 0.2 \times 4 \pm 0.2$ mm)	Two types of cut notches allowed
2.	BS 2782 Method 306 A	1.36, 4.07 and 13.6 J	($63.5 \pm 2 \times 12.7 \pm 0.2 \times 12.7.0 \pm 0.3$ mm) or ($63.5 \pm 2 \times 12.7 \pm 0.2 \times 6.4 \pm 0.3$ mm)	Molded notch allowed in Type A. Cut notches allowed in Type B and C
3.	ASTM D 256-00	A range of pendulum energies from 2.710 to 21.680	Length: 63.50 mm (max.), 60.30 mm (min) Width: 12.7 mm (max), 3.00 mm (min). Breadth: 12.70 ± 0.15 mm	Cut notches allowed

Standard test methods for the determination of Izod impact strength are listed in Table 10.10. For example, ISO R180 normalizes the notch length. The velocity of the striker on impact has been standardized at 3.5 ± 10 % m/s with impact energies of 1.0, 2.75, 5.5, 11.0, and 22.0 J. Four types of test pieces are permitted.

10.3.1.2 Charpy Impact

The Charpy test is similar to the Izod impact test. In both the tests, flexural impact takes place by a pendulum (Fig. 10.9) striking a bar-shaped test piece (Fig. 10.10). However, as described before, there are quite significant differences between them, and no general correlation relating the data obtained from each have been developed.

Standard test methods for the determination of Charpy impact strength are listed in Table 10.11. For example, BS 2782 (Method 351A) uses a rectangular, notched or unnotched, bar supported at both ends in such a position that the pendulum strikes it in the center, directly behind the notch. The energy absorbed in the impact is read directly by means of a pointer from a scale calibrated to allow for frictional and windage errors. Three standard test pieces are defined – the preferred being $120 \times 15 \times 10$ mm with a span of 70 mm. The standard impact energies are 0.5, 1, 4, 15, and 50 J.

10.3.2 Fracture Mechanics

Griffith (1920) showed that brittle solid materials fail at lower strengths because of the presence of flaws acting as stress concentrators. The hypothesis has become the basis of "fracture mechanics," used to interpret the fracture of many solids, including polymers and their blends. The theoretical background is presented in standard texts (Kinloch and Young 1983; Williams 1984; Broek 1986; Brostow and Corneliussen 1986).

Linear elastic fracture mechanics (LEFM), which has grown out of the work of Griffith, provides the most satisfactory basis for characterizing the fracture process

Fig. 10.9 Simple beam
(Charpy-Type) impact
machine (ASTM D6110-97)
of polymer composites and multiphase polymers. It enables each of the factors contributing to fracture to be considered separately. Results obtained from the fracture mechanics analyses have thrown considerable light upon the behavior of polymers under tensile, impact, and fatigue loading. Unfortunately, the conditions of LEFM are very severe and require that the fracture process is nearly totally elastic. Only under such conditions the data can be used for large scale predictions. However, elastic behavior cannot always be obtained in a laboratory-scale test and some experimental or theoretical tools need to be available to help in predicting the brittleness of large-scale article. Furthermore, in case of rubber-toughened plastics, extensive yielding usually precedes fracture even in the presence of a sharp crack, so that LEFM techniques are Unsuitable.

A crack in a solid may be stressed in three different modes (Kinloch and Young 1983; Brostow and Corneliussen 1986). The cleavage or tensile-opening mode (Mode I) is technically the most important one since it is commonly encountered and usually results in failure. Two closely related approaches have been used (Williams 1984):

1. The first is an energy criterion that supposes that fracture takes place when sufficient energy is released (from the stress field) during crack growth to supply the energy requirements of the new fracture surfaces created (Orowan 1948).
Fig. 10.10 Relationship of anvil, specimen and striking edge to each other for Charpy test method (ASTM D6110-97)

The fracture of a material is thereby characterized by the material property G_c known as the "strain energy release rate" or "fracture energy" (Kinloch and Young 1983; Brostow and Corneliussen 1986).

2. Rivlin and Thomas (1953) developed the second approach. They showed that the stress field around a sharp crack in an elastic material could be uniquely defined by a parameter known as the "stress intensity factor," K. When K reaches a critical value K_c (which is a material property often called the "fracture toughness"), fracture takes place.

The criterion for crack propagation is that $K_I > K_{Ic}$. For plane strain in Mode I, values of G_{Ic} and K_{Ic} are related:

$$K_{Ic}^2 = \frac{E\,G_{Ic}}{(1 - \nu^2)} \qquad (10.6)$$

where E is Young's modulus and ν is Poisson's ratio. In SI units, K_{Ic} is usually given in $MPa.m^{0.5}$ and G_{Ic} in $kJ\ m^{-2}$. To make valid fracture mechanics

Table 10.11 Standard test methods for the determination of Charpy impact strength

No.	Test method	Impact energies	Test specimen	Notch
1.	BS 2782, Method 351 A	0.5, 1, 4, 15, and 50 J	Preferred test dimensions are $120 \times 15 \times 10$ mm	Type A (standard), square section, 2 mm wide and one-third specimen thickness in depth. Type B and C are V-shaped with base radii 0.25 mm and 1.00 mm respectively. The depth of these notches is set to one-fifth thickness
2.	ISO R179	Two striking energy levels	Four types of test pieces are allowed. First three are as in British standards. Fourth type is 125 mm long by 13 mm square	Same notch types as above. Molded notches are permitted. Machined notches are preferred
3.	DIN 53453 (Similar to BS Method)	As in BS Method	As in BS Method	Type A as given in BS Method (Type B-and C are not specified)
4.	ASTM D6110-97	2.710 ± 0.135 J	$(127.00$ to $124.50) \times (12.70 \pm 0.15) \times (12.70$ to 3.00 mm)	The included angle of the notch is $45 \pm 1°$, with a radius of curvature at the apex of 0.25 ± 0.05 mm

[a]ASTM standard test methods are available on web: http://enterprise.astm.org/

measurements, it is necessary to ensure that specimen dimensions are large in comparison with the plastic zone surrounding the crack tip. For metals, according to ASTM E399,

$$(w - a), \ a, \ B \ > \ 2.5 \ \left(\frac{K_{Ic}}{\sigma_y} \right)^2 \qquad (10.7)$$

where w is the width of the specimen, a is the crack length, B is the thickness, and σ_y is the uniaxial yield stress of the specimen. In the case of polymer blends, it is preferable to experimentally determine the effects of specimen dimensions upon G_c and K_c rather than rely upon the applicability of the above conditions.

The main experimental problem is to prepare specimens in which the plane-strain/plane-stress conditions are satisfied (Williams 1984; Kinloch and Young 1983). Apparent toughness values of K_c and G_c are higher in thin specimens than in thick ones. Measurements on several rubber-toughened plastics have shown a decrease in K_{Ic} with increasing thickness, B. The minimum value of B required, in the case of HIPS, for a valid determination of K_{Ic} at 296 K appears to be about four times higher than that given by Eq. 10.7 (Yap et al. 1983). Unfortunately, there is no reliable criterion for crazing under plane strain, and therefore it is difficult to suggest an alternative to the standard approach that has been used successfully for metals.

The toughness observed for rubber-toughened plastics is determined by the mechanism of deformation created by the plane strain at the tip of a sharp crack. There are two factors to be considered:

1. The fall in yield stress that occurs in ductile polymers as the temperature increases or the strain rate reduces. This fall results in a plane-strain to plane-stress transition, as indicated in Eq. 10.7 and therefore an increase in fracture resistance.
2. The release of constraint that results from cavitation in the matrix or void formation in the rubber particles (Bucknall 1988; Young 1988).

Linear elastic fracture mechanics studies on toughened brittle plastics at room temperature concentrated on thermosetting resins, which have sufficiently high yield stresses to meet the requirements of Eq. 10.7. There has been increasing emphasis on ductile fracture mechanics in testing the toughened thermoplastics. An alternative approach is to determine the parameter, J_{Ic}, which is the quantity corresponding to G_{Ic} in linear elastic fracture mechanics, as discussed below.

10.3.3 Fracture Mechanics Testing

10.3.3.1 Determination of G_c

The ductile fracture mechanics is gaining importance in testing polymer blends, especially the toughened thermoplastics. Some of the types of specimen which have been used to study the failure of ductile polymers whose deformation is elastic (but nonlinear) are shown in Fig. 10.11 (Kinloch and Young 1983). Formulae have been developed to determine G_c for these specimens, and examples are given in Table 10.12. Again, the parameter defining the fracture process G_c, is a function of applied load, crack length, and geometrical factor (Young 1988). Typical values of G_c and K_c are listed in Table 10.13.

The problem of defining conditions for crack propagation becomes more difficult when the material is sufficiently ductile to form a large plastic zone at the crack tip. The problem is encountered particularly while testing rubber-modified plastics. Two ductile fracture criteria have been developed for metals, one based on crack-tip opening displacement (CTOD) and the other upon the energy line integral (J-integral) around the crack tip. The crack-opening displacement (COD) criterion has been applied to a number of polymers and blends, but the J-integral method is receiving more attention. Physically, COD is measured between the outer edges of the crack whereas CTOD is defined as the distance between two crack walls at the end of the fatigue crack. Thus, while COD is easy to measure, the determination of CTOD is not simple.

The CTOD δ is the relative displacement of the two fracture surfaces at the crack tip. Critical values of CTOD δ_c may be measured by means of a mechanical clip gauge or recorded photographically. Furthermore, a cine camera may be used to follow the crack initiation and propagation as in HIPS (at 293 K) (Ferguson et al. 1973). The authors reported that both LEFM and CTOD criteria were applicable at different stages of the fracture. On application of load to the specimen, the crack began to extend at a fixed value of K_I, to give a value of K_{Ic}, for crack initiation. Then, at the crack tip, began to form a stress-whitened yield zone. The load on the

Fig. 10.11 Schematic diagrams of various specimens used for fracture mechanics testing of flexible polymeric materials. P = Applied load (Young 1988)
specimen continued to increase as both crack and yield zone extended, and a load maximum was observed at a fixed value of CTOD.

Precise determination of CTOD is often difficult. Furthermore, these measurements are unsuitable for use in design. For these reasons, models that enable CTOD to be calculated in terms of stresses have been developed (Dugdale 1960). In a wide plate with a central crack of length 2a with a narrow planar plastic zone of length L, extending from each of the crack tips, the applied stress σ is given by (Bucknall 1978)

$$\sigma = \frac{a}{(a+L)} = \cos\left(\frac{\pi\sigma}{2\,\sigma_y}\right) \tag{10.8}$$

The CTOD δ can be expressed as

$$\delta = \left[\frac{8\,\sigma_y\,a}{(\pi E)}\right]\ln\,\sec\,\left(\frac{\pi\sigma}{2\,\sigma_y}\right) \tag{10.9}$$

For small values of applied stress ($\sigma < 0.3\,\sigma_y$), the plastic zone size is small compared with the crack length and Eq. 10.9 can be simplified to read

Table 10.12 Expressions for G_C for fracture mechanics of crack growth in flexible polymers (Kinloch and Young 1983)

Geometry (see Fig. 10.11)	Expressions for G_C	Comments	References
Single-edge crack	$G_C = 2k_1 a W_C$	λ_c = extension ratio at onset of crack growth	Rivlin and Thomas 1953; Greensmith 1963; Lake 1979

$$\delta = \pi\sigma^2 \ \frac{a}{\left(E\sigma_y\right)} \tag{10.10}$$

Under these conditions, LEFM analysis is applicable to the specimen.

In the case of a brittle fracture in a wide and thick plate containing an edge crack of length a, the critical applied stress at fracture σ_c is related to the Young's modulus E, the Poisson's ratio ν, and the fracture surface energy G_{Ic}; the critical stress can be expressed from the Griffith equation as

$$\sigma_c^2 = \frac{E \ G_{Ic}}{\pi a \ (1 - \nu^2)} \tag{10.11}$$

From Eqs. 10.10 and 10.11, for plane-strain deformation,

$$G_{Ic} = \sigma_y \ \delta_c \ \left(1 - \nu^2\right) \tag{10.12}$$

Tests are conducted, in normal practice, on compact tension specimens rather than wide center-notched plates. Some allowance must be made for geometrical effects, including the finite width of the specimen, the difference between edge and center notches, and any rotations occurring at the grips.

In general, it is not possible to measure CTOD, but rather the crack-opening displacement (COD). The latter quantity can be determined at the outer end of the notch with a suitable clip gauge. Thus, for a notched three-point-bend specimen, it was shown that a "plastic hinge" can form around the tip of the crack (Brostow and Corneliussen 1986). If the center of rotation is known, the CTOD can be calculated from the measured COD. A standard has been published (BS 5762).

10.3.3.2 J-Integral Techniques
Single-Specimen Method
If there is extensive plasticity in a material under tension, it gives rise to a relatively large size of the crack-tip plastic zone, and solutions for elastic–plastic behavior are not readily available. J-integral provides a means of determining the energy release rate for such cases. This integral was applied to crack problems (Cherepynov 1967; Rice 1968). Rice showed that J-integral describes the flow of energy into the crack-tip region and that the dominant term in the description of stress and strain singularities at the crack tip could also be written in terms of J. He demonstrated that the value of J was independent of the integration path. In practice, J can be determined from changes in load displacement diagram with changes in crack length (ASTM E813). This method has been reviewed (Williams 1984; Landes and Begley 1979; Pascoe 1986). The J-integral is given by (Kinloch and Young 1983).
$$J = \int_{\Gamma} \left\{ Z\partial y - T\left(\frac{\partial u}{\partial x}\right) ds \right\} \tag{10.13}$$

where Γ is a closed contour in a stressed solid (Fig. 10.12), T is the tension vector perpendicular to the contour in an outward direction, u is the component of displacement of the contour in x-direction, ds is an element of the contour Γ, and Z is the strain energy (plastic and elastic) per unit volume.

In Fig. 10.13, a closed contour is taken as two curves surrounding the tip of the crack, one DEF inside the other ABC which are joined by two portions of the crack surface AF and CD. The integral around the contour is zero. Along the parts AF and CD which lie parallel to the x-axis and which have no normal stress on them, T = 0 and dy = 0. Therefore, the integral along ABC is equal and opposite in sign to that along DEF. For outward directed vectors, T, therefore, the integral is path independent. The J-integral method (ASTM E813) of

fracture toughness measurement has been applied to a variety of polymers (Theuer et al. 1988; Rimnac et al. 1988) and rubber-toughened polymers (Huang and Williams 1987; Huang 1988; Huang and Wang 1989; Hashemi and Williams 1985; Takemori and Narisawa 1989).

The multi-specimen J-integral technique (ASTM E813) also provides a method for determination of J_{Ic}, a measure of fracture toughness. A critical evaluation of ASTM E813-81 and E813-87 has been published (Narisawa and Takemori 1989; Huang and Wang 1989; Huang et al. 1990).

Multiple-Specimen Method

A major problem often encountered in the above described "single-specimen method" is that the crack growth measured from a side view may not be accurate, as the crack front may vary from the central region to the sides. A "multiple-specimen method" was developed to bypass this problem.

The method has been applied to numerous ductile polymeric materials (Begley and Landes 1972; Landes and Begley 1974). The critical J values obtained by using single-specimen method were greater than those obtained from the standard multiple-specimen method (Westerlind et al. 1991). Many workers have used the ASTM standards of E813-87 to characterize the fracture toughness of polymers (Chan and Williams 1981, 1983; Hashemi and Williams 1986; So and Broutman 1986; Huang and Williams 1987; Narisawa 1987; Rimnac et al. 1988; Narisawa and Takemori 1989; Huang and Williams 1990; Huang 1990; Moskala and Tant 1990).

Hysteresis Energy Method

When a pre-cracked specimen of a toughened polymer is under load, viscoelastic and inelastic micro-mechanisms such as crazing, cavitation, debonding, and shear yielding are expected to take place mainly around the crack tip. These micro-mechanisms occur during the process of crack-tip blunting (pre-crack) and during crack propagation. A portion of the storage energy is therefore consumed, and a relatively large crack-tip plastic zone is formed, which can be quantified by the corresponding hysteresis energy. For rubber-toughened polymeric materials, the crack tends to propagate within the plastic zone. A new J-integral method based on hysteresis properties of polymeric materials was proposed (Lee and Chang 1992; Lee et al. 1992).

In case of a cracked specimen, the material surrounding the crack tip can be divided into three parts: (1) the first plastic zone, (2) the second plastic zone, and (3) the elastic fracture surface (Lu et al. 1996). The specific energy balance equation for a cracked specimen can be expressed as

$$\left(\frac{1}{B}\right) \left(\frac{dU}{da} - \frac{dU_e}{da} - \frac{dU_k}{da}\right) = \left(\frac{1}{B}\right) \left(\frac{dU_p^{ppz}}{da} + \frac{dU_p^{spz}}{da}\right) + 2\gamma_s \quad (10.14)$$

where U is the input energy at different displacements, U_e is the elastic energy, U_k is the kinetic energy, U_p^{ppz} is the plastic energy for the primary plastic zone, U_p^{spz} is the

Fig. 10.14 Plots of critical J_{IC} value versus the strain rate (Lu et al. 1996)
plastic energy for the secondary plastic zone, and γ_s is the fracture surface energy and a is the initial crack length. The energy dissipated of the system is given by

$$\left(\frac{1}{B}\right) \frac{d(HE)}{da} = \left(\frac{1}{B}\right) \left(\frac{dU_p^{ppz}}{da} + \frac{dU_p^{spz}}{da}\right) + 2\ \gamma_s \qquad (10.15)$$

where HE is the hysteresis energy.

This approach assumes that there is a region surrounding the crack tip with local energy dissipation. This arises from viscoelasticity, plasticity, and bond rupture and can be considered the characteristic of the fracture process. For polymers the characteristic of this localized energy dissipation is considered to be independent of geometries.

The J_{Ic} values obtained based on hysteresis energy method were close to these obtained using E813-81 method, but significantly lower than those from E813-87 method. Experimentally the hysteresis energy method is relatively simple, because the tedious measurement of crack growth length is not necessary. Figure 10.14 shows variations of J_c values for PC/ABS blends obtained using different J-integral methods – as shown, the spread is $\pm 40\ \%$ (Lu et al. 1996).

The J-integral by hysteresis energy method was applied to elastomer modified PC (Lee and Chang 1992; Lee et al. 1992), HIPS (Lee et al. 1992, 1993), ABS (Lu et al. 1995), PC/ABS blend (Lu and Chang 1995; Lu et al. 1996), and PC/PBT blend (Lu and Chang 1995).

Essential Work of Fracture Method

The theoretical analysis of J-integral is well established (Rice 1968; Begley and Landes 1972), and the experimental procedure is standardized (ASTM E813-89). However, some aspects of the method still remain controversial (Hashemi and

Williams 1986; Huang and Williams 1987, 1990; Narisawa and Takemori 1989, 1990; Swei et al. 1991). For example, the procedure for J–R curve construction restricts the application of the J-integral method to only static loading tests. J-integral method is usually difficult and expensive (Bramuzzo 1989). The specimen size required by the J-integral method makes it impossible to characterize the toughness of polymeric thin films. It is also well recognized that using a blunting line to define the critical value of J-integral may not be proper for some ductile polymers (Hashemi and Williams 1986; Narisawa and Takemori 1989). The J-integral analysis based mainly on metals is not fully appropriate to polymers. This is particularly true when the heterogeneous and toughened polymer blends are involved.

To overcome the above drawbacks, a new method based on "essential work of fracture" concept was introduced (Broberg 1971, 1975). In this method, it is proposed that when a cracked ductile solid, such as a toughened polymer blend, is loaded, the fracture process and the plastic deformation take place in two different regions, viz., the inner process zone and the outer plastic zone. Much of the fracture work during crack propagation, dissipated in the plastic zone, is not directly associated with the fracture process. Only that work that goes into the fracture process zone is a material constant. Hence, the total fracture work, W_f, should be separated into two parts, i.e., the essential work of fracture (i.e., the work required to create two new fracture surfaces, W_e) and a nonessential work of fracture (W_p):

$$W_f = W_e \;+\; W_p \tag{10.16}$$

W_e is essentially a surface energy, and for a given thickness it is proportional to ligament length ($l = W - a$), while W_p is a volume energy and proportional to l^2. Thus, the total fracture work is rewritten as

$$W_f = w_e tl \;+\; \beta w_p tl^2 \tag{10.17}$$

where w_e and w_p are the specific essential work of fracture and nonessential work of fracture (or specific plastic work), respectively; β is the plastic zone shape factor; while t, W, and a are thickness, width, and initial crack length, respectively. Then, the specific total fracture work, w_f, is

$$w_f = \frac{W_f}{tl} = w_e \;+\; \beta w_p l \tag{10.18}$$

There are two kinds of specific essential work of fracture available, according to the stress state of the ligament area, viz., plane-stress-specific essential work of fracture (w_e) and plane-strain-specific essential work of fracture (w_{Ic}) (Wu and Mai 1996).

The w_e can be obtained if l/t ratio is large enough to ensure plane-stress condition in the ligament area, and it is proved to be a material constant for a given sheet thickness (Mai and Cotterell 1986a, b; Mai et al. 1987; Mai and Powell 1991). With a reduction of l/t ratio, plastic constraint increases and the plane-stress/plane-strain fracture transition may occur at a certain l/t ratio. Theoretical analysis shows that the specific essential work of fracture method is equivalent to the J-integral method for all three fracture modes (Mai and Powell 1991; Mai 1993).

The essential work of fracture approach has been applied to characterize the fracture properties of toughened polymer blends, such as PBT/PC/IM (where IM is the impact modifier) and ABS/PC. It is successfully used to determine the fracture toughness of a ductile LLDPE film (Wu and Mai 1996), and single-edge and double-edge notched different polymeric films (Hashemi 1993; Hashemi and Yuan 1994; Chan and Williams 1994; Karger-Kocsis and Czigany 1996; Karger-Kocsis and Varga 1996). It is also applied to study the effect of specimen size, geometry, and rate of tests in case of PBT/PC blends (Hashemi 1997).

10.3.4 Mechanisms of Toughening

Early investigations of the fracture of solids assumed that fracture involved only the creation of new surfaces (Griffith 1920; Kinloch and Young 1983). However, since measured values of G_c were well in excess of the surface energy of the material, it was soon realized that significant amounts of energy were also dissipated through other processes such as localized plastic deformation in the vicinity of the crack (Kinloch and Young 1983). In general, two mechanisms are responsible for this plastic deformation in rigid polymers, namely, "crazing" (Kausch 1983; Kambour 1973) and "shear yielding" (Ward 1983). The two mechanisms are not mutually exclusive. Under certain conditions both operate simultaneously.

10.3.4.1 Crazing

Crazing is an important source of toughness in rubber-modified thermoplastics. A craze can be described as a layer of polymer a nanometer to a few micrometers thick, which has undergone plastic deformation approximately in the direction normal to the craze plane as a response to tension applied in this direction (Kambour 1986). Crazing occurs without lateral contraction. As a result, the polymer volume fraction in the craze is proportional to $1/\lambda$, where λ is the draw ratio in the craze. The reduction in density occurs on such a small scale that the refractive index is markedly reduced, which accounts for the reflectivity of the craze (Kramer 1983).

Several methods of studies have been developed. Osmium-staining technique, pioneered by Kato (1967), is one of the most successful methods for observing crazing in rubber-toughened plastics. It depends upon a reaction between osmium tetroxide, OsO_4, and double bonds in PBD and other unsaturated polymers. But, it is not suitable for saturated rubbers.

Ruthenium tetroxide, RuO_4, is more reactive staining agent that can be used to differentiate between rubber and matrix when the former is essentially saturated. For example, clean glass slides (50×10 mm) were dipped in 2 wt% solutions of polymer, and the solvent was subsequently evaporated under vacuum at 50 °C (323 K) for 24 h. The films were removed from the glass substrate by immersing the slides in distilled water and then lifting the floating film from the water surface onto copper microscope grids. A 0.5 wt% solution of RuO_4 in distilled deionized water was used for staining. The aqueous solution (golden yellow when fresh) was found to

be effective for a considerable time (up to 6 months if kept in a firmly sealed glass container in a freezer). Film-covered grids were vapor stained in a glass-covered dish (Trent et al. 1981, 1983). Transmission electron micrographs, TEM, can be taken to illustrate detailed morphological features (at an accelerating voltage of 80 KV).

Recently, methods have been developed to characterize the relative amount of crazing and non-crazing that occurs in rubber-toughened glassy polymers, using the invariant obtained from small-angle X-ray scattering (SAXS) analysis. SAXS not only overcomes the disadvantages of transmission electron microscopy (e.g., the use of ultrathin samples), but the use of high intensity synchrotron radiation permits in situ deformation studies (Paredes and Fischer 1979; Brown and Kramer 1981). The new method of SAXS analysis leads to quantification of the contribution from crazing and non-crazing to the total deformation (He et al. 1998).

10.3.4.2 Shear Yielding

Yielding is a mechanism, in which a thin layer of polymer deforms in shear at constant volume. It is characterized by regions of sheared polymer oriented approximately at $45°$ to the tensile or compression stress. Unlike crazing, shear flow is essentially a process continuous in space, i.e., one that may spread through a much greater volume fraction of the stressed body and thus consume much more energy in total. Shear yielding is much less sensitive to environmental effects. In short, shear deformation is better than crazing, but crazing is better than no deformation at all (Kambour 1986).

Shear bands are highly birefringent and are most clearly observed in transmitted polarized light (Bucknall 1977). They are also visible as reflecting planes in ordinary transmitted light at glancing incidence, owing to refractive index differences between the band and the adjacent undeformed polymer (Kramer 1974, 1975). Both crazing and shear yielding involve the absorption of energy, and most methods of toughening polymers involve modifying the polymer such that more crazing and shear yielding take place. The rubber-modified polymer absorbs considerably more energy in a tensile test because of its higher extension to break, which can be achieved only as a result of yielding in the matrix. The rubber particles play only a secondary role but, nevertheless, a vital one.

Firstly, they accelerate yielding by acting as stress concentrators initiating deformation in the matrix; secondly, they respond to the hydrostatic component of stress by cavitating and increasing in volume, thus allowing the strain in the matrix to increase; and thirdly, in their cavitated and extended state, they stabilize the yielded polymer by carrying a share of the applied stress (Bucknall 1988). All three functions appear to be necessary for effective toughening, although their relative importance varies, depending upon the mechanisms contributing to toughening, and the kinetics of deformation, which in turn depend upon the material and the type of loading. Various types of response of the rubber particles have been observed experimentally as the polymer yields. They include (a) debonding between rubber and matrix (Haward and Bucknall 1976), (b) cavitation within the particle (Breuer et al. 1977; Kinloch 1985; Yee and Pearson 1986), (c) craze like fibrillation of the rubber
Fig. 10.15 Schematic rendering of craze moving in a field of encapsulated PB pools draining their content onto the craze surfaces when tapped by the advancing craze (Argon et al. 1990)

phase (Beahan et al. 1976; Donald and Kramer 1982), and (d) crazing within sub-inclusions (Seward 1970). Many polymers are toughened by blending or copolymerizing with a rubber (Kinloch and Young 1983; Bucknall 1977). This method of toughening is now well established for many thermoplastics, thermosets, and even adhesives.

10.3.4.3 Other Mechanisms

A new route for achieving a substantial lowering of stresses for craze growth without relying on potent craze initiators involves controlled local plasticization of a polymer by a low molecular weight diluent, distributed in a heterogeneous fashion throughout the material (Gebizlioglu et al. 1990; Argon and Cohen 1990). This mechanism is schematically shown in Fig. 10.15.

The advancing craze, nucleated from free surfaces or other occasional imperfections, cuts into the dispersed population of PB-2.76 K pools (which at this low molecular weight acts like a relatively low viscosity liquid) and drains the contents of these pools onto the surfaces of the craze. Although the solubility of the PB 2.76 K into PS under standard conditions of room temperature and atmospheric pressure is negligibly small (of the order of 4×10^{-3}), this should increase greatly in the presence of a negative pressure (Argon and Cohen 1990). The plasticization due to the increased sorption of the low molecular weight PB diluent into the craze surfaces is a highly interactive and complex process. The new mechanism offers considerable promise for practical industrial applications as only very small quantities of the plasticizing substance are needed, and thus subsidiary properties such as optical transparency and tensile modulus are less affected compared to the other methods of toughening.

Fig. 10.16 Influence of EPDM concentration on Izod impact strength of PPBC-EPDM blends
10.3.5 Factors Affecting Blend Toughness

Rubber toughening is the most often used method of improving the impact resistance of polymers (Bucknall 1977). The impact modified materials are usually the blends of a rigid matrix polymer with an elastomer. The composition of the constituents, their miscibility, and the morphology influence the deformation and failure mechanism in the blend. Particle size of the elastomer, its dispersion, and its adhesion with matrix are also the important factors determining the toughness.

10.3.5.1 Composition

The composition of individual constituents of a blend plays an important role in modifying the impact strength of the blend. The impact strength of polypropylene block copolymer (PPBC) blends with different concentrations of EPDM is shown in Fig. 10.16 (Xavier et al. 1994). Upon incorporation of the elastomer, the impact strength increases. EPDM was found to reduce the crystallinity of PPBC and significantly influence its failure mechanism. Both crazing and shear yielding were found to be responsible for the observed increase in impact strength. As shown in Fig. 10.16, above 10 wt% of EPDM, the increase in impact strength is more prominent. However, it was observed that such significant rise in impact strength adversely affected the other mechanical properties, such as flexural and tensile moduli of the blends.

In the case of PVC/ABS blend, the addition of ABS improved the impact strength of the blend (Sharma et al. 1988). At low concentrations of ABS, a small number of rubber particles (i.e., the butadiene particles in ABS) are insufficient to significantly improve the impact strength (Fig. 10.17). Increasing ABS concentration up to 50 wt% increased impact strength. The maximum impact strength obtained at the optimum blend composition is considerably higher than that of neat ABS itself. Since the particle size (Kulshreshtha et al. 1989) of the dispersed

Fig. 10.17 Influence of PVC/ABS blend composition on Izod impact strength
PBD (of ABS) phase is unlikely to change with blend composition, it is evident that there exists a critical volume fraction of rubber phase necessary for the maximum improvement in impact strength. When this critical concentration of rubber (or ABS) is exceeded, impact strength drops.

10.3.5.2 Morphology

The performance characteristics of a blend depend on its morphology, which in turn depends on the thermodynamic and rheological properties of the components (Plochocki 1983; Karger-Kocsis et al. 1984; Howe and Wolkowicz 1987; Wu 1987; Utracki 1989). However, due to nonequilibrium nature of the highly viscous polymer mixtures, often the processing conditions strongly influence the product morphology. The topic is discussed in the last part of Sect. 10.3.6: Low-Speed Mechanical Properties of Blends. Further details of the morphology-processing conditions can be found in ▶ Chap. 7, "Rheology of Polymer Alloys and Blends"; ▶ Chap. 8, "Morphology of Polymer Blends"; and ▶ Chap. 9, "Compounding Polymer Blends."

The properties of PPBC/EPDM blends strongly depend on the crystalline micromorphology of PPBC, as well as on the particle size and degree of dispersion of EPDM (Xavier et al. 1994). The DSC cooling thermograms indicated that the degree of crystallinity in PPBC decreased with increasing concentration of EPDM (Table 10.14 and Fig. 10.18).

Table 10.14 Crystallinity indices (A/m values) from DSC (Xavier et al. 1994)

No.	Blend	A/m (arbitrary units)
1.	PPBC (neat polymer)	232
2.	PPBC + EPDM (2.5 wt%)	216
3.	PPBC + EPDM (5.0 wt%)	208
4.	PPBC + EPDM (10.0 wt%)	206
5.	PPBC + EPDM (15.0 wt%)	197

Fig. 10.18 DSC thermograms recorded during cooling cycle for PPBC and its blends with EPDM (10 wt%)
As observed under optical microscope with crossed polarizers, incorporation of up to 10 wt% EPDM into PPBC does not affect the nucleation density or ultimate size of PPBC spherulites (Fig. 10.19). The EPDM particles act as inert inclusions, constituting geometrical obstacles to the PPBC spherulites' growth, thus changing their morphology. Nevertheless, some interfacial interactions are observed in the case of a blend with 10 wt% EPDM. The spherulites of PPBC are found to nucleate from the interface with EPDM (Fig. 10.19c). This resembles the transcrystalline structure observed in several glass or carbon fibers reinforced, semicrystalline polymers, such as PP, PE, PA-6, etc. (Xavier 1991). Such a structure was considered an indication of good interfacial interaction between the two constituents.

The EPDM particles were found either to initiate crazes or to terminate them, depending on the interfacial bonding, the particle size, the concentration, and the interparticle distances. The variation of notched Izod impact strength of PPBC blends with different EPDM concentrations is shown in Fig. 10.16. The fracture surface of a blend with 10 wt% EPDM, as examined under SEM, is shown in Fig. 10.20. The hemispherical embeddings and hollows (representing the removed EPDM particles) are clearly visible on the fracture surface. The ribbonlike structures visible on the fractured surfaces are probably the micro-shear bands in the blends.

Approximate ranges of the experimental techniques to study different blend morphologies are summarized in Table 10.15. See also ▶ Chap. 8, "Morphology of Polymer Blends" in this handbook.

10.3.5.3 Elastomer Particle Size

Elastomeric particle size plays a prominent role in controlling the toughening mechanisms of a polymer. It has been shown that particle size of an elastomer

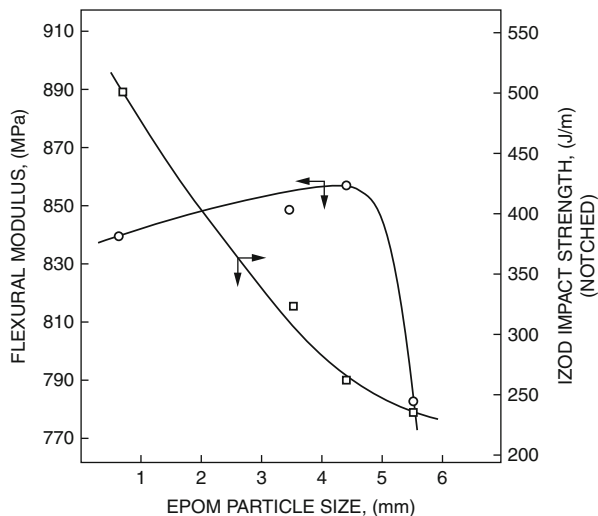
Fig. 10.21 Influence of EPDM particle size on tensile stress–strain curves of PPBC blends. EPDM particle sizes (*1*) 0.60 mm, (*2*) 3.45 mm, (*3*) 4.35 mm, (*4*) 5.50 mm

significantly influences the deformation and failure processes: small particles favor shear yielding, while coarser dispersions promote crazing (Jang et al. 1985). There is an optimal particle size resulting in maximum impact resistance (Speri and Patrick 1975; Stehling et al. 1981; Karger-Kocsis et al. 1981).

The tensile stress–strain curves of PPBC and its blends with EPDM of different particle sizes (for concentration equal 10 wt%) are shown in Fig. 10.21 (Xavier et al. 1994). The particle size of EPDM has considerably affected the post-yield behavior of the blends. Although the yield stress initially increases with reduction

Fig. 10.22 Influence of
EPDM particle size on
flexural modulus and Izod
impact strenght of PPBC/
EPDM (10 wt%)


of EPDM particle size (from 4.35 to 3.45 μm), with further reduction of size
(to 0.60 μm), it decreases. Earlier studies of the tensile properties of heterogeneous
polymer blends have shown that Young's modulus poorly reflects morphological
changes (Pukanszky et al. 1989; Pukanszky and Tudos 1990). Accordingly, the
particle size dependence of Young's modulus is weak.

By contrast (see Fig. 10.22), in the case of PPBC blend with EPDM, the flexural
modulus was found to significantly decrease when large EPDM particles (d ≥ 4 mm)
were used. The notched Izod impact strength was strongly affected by the particle
size. As usually it is the case, reducing it caused the impact strength to increase. With
the reduction in EPDM particle size, the number of particles has increased and the
interparticle distance was reduced. Thus, multiple crazing in the blend was enhanced
further with increased number of rubber particles and also reduced particle size.

The shear yielding also is influenced with change in particle size resulting in
increased impact strength. The notched Izod impact fracture surfaces examined
under SEM are shown in Fig. 10.23. Change in EPDM particle size had significantly
changed the fracture morphology. The fibrous sheets like structures are probably the
micro-shear bands in the blends. The number of these bands increases with reduction
of the rubber particle size as the smallest particle (at constant loading) corresponds to
their maximum number. The formation and break down of the micro-shear bands
absorb enormous energy, and hence it increases the Izod impact strength.

Both principal fracture mechanisms, shear yielding and crazing, are influenced
by the particle size. In PPBC matrix, where spherical elastomeric particles are
chemically bonded, the energy absorption takes place mainly by deformation of the
matrix. In such systems, a large amount of shear yielding is to be expected. The
shear yielding becomes more prominent upon increasing the concentration of
EPDM as well as reduction of their particle size. The micro-shear bands in the
fracture surface (Fig. 10.23e) clearly support these expectations.

10.3.5.4 Miscibility

The notion of polymer miscibility implies intimate mixing on the segmental level. A miscible blend is expected to have a homogeneous composition throughout. The understanding of chemical principles in polymer miscibility is getting refined as a result of the appearance of several reviews and books on the topic (Krause 1972; Olabisi et al. 1979; Paul and Barlow 1980; Paul 1982; Ottenbrite et al. 1987; Utracki 1989). The level of molecular mixing existing in polymer blends that exhibit macroscopic properties indicative of single-phase behavior is commanding

considerable attention. More detailed information on this topic can be found in ► Chap. 2, "Thermodynamics of Polymer Blends" in this handbook.

The best commercial advantages of a polymer blend can best be summarized by the word "versatility" (Olabisi et al. 1979). Unfortunately, miscible polymer–polymer blends usually show additivity of the component polymers properties, thus their versatility is limited. Furthermore, like any other single-phase resin, for most applications miscible blends need to be toughened and/or reinforced. Thus, with the exception of PMMA/PVDF blends (primarily used for coatings), there are no miscible blends on the market. The interest in miscible polymer blends is for the purpose of compatibilization and judicious selection of the processing conditions that may lead to the spinodal decomposition-type morphology (see ► Chap. 8, "Morphology of Polymer Blends" in this handbook).

Immiscibility dominates polymer blends. It reveals itself as opacity, delamination, double glass transition, or combination of these properties. Most immiscible polymer blends require compatibilization and toughening.

Owing to low values of the combinatorial entropy mixing, miscibility in polymer–polymer systems requires the existence of strong specific interactions between the components, such as hydrogen bonding (Olabisi et al. 1979; Solc 1982; Walsh and Rostami 1985; Utracki 1989). The thermodynamic characterization of the interactions in miscible polymer blends has been the subject of extensive studies (Deshpande et al. 1974; Olabisi 1975; Mandal et al. 1989; Lezcano et al. 1992, 1995, 1996; Farooque and Deshpande 1992; Juana et al. 1994).

Based on the Huggins–Flory theory, the polymer–polymer interaction parameter, χ_{12}, has been used to describe interactions between the two components. As a consequence, this "parameter" takes into account the enthalpic and non-combinatorial entropy of mixing contributions. Calorimetry, differential scanning calorimetry (DSC), Fourier transform infrared spectroscopy (FTIR), inverse gas chromatography, microscopy, etc., are used to investigate the miscibility and morphology of the blends (Zhong and Guo 1998; Lezcano et al. 1998). Comprehensive surveys of miscible polymer systems along with various methods of miscibility determination have been published (Olabisi et al. 1979; Utracki 1989; Coleman et al. 1991).

10.3.5.5 Other Factors

Temperature strongly influences the impact behavior of toughened plastics. Charpy impact energy measurements at different temperatures in the case of HIPS containing various concentrations of PBD showed two transitions, at 233 and 273 K (Bucknall 1988). At these temperatures, the material exhibited transitions from brittle to semi-ductile and then to ductile.

Newman and Williams (1978) carried out sharp-notch Charpy tests for ABS at $193 \leq T(K) \leq 333$ and showed that linear elastic fracture mechanics was applicable only up to 233 K. Above 273 K, the energy absorbed in impact was proportional to the fracture area and correlated well with the volume of the whitened zone. Mixed behavior occurred at the intermediate temperatures. More detailed study of the notched Izod impact behavior of ABS was carried out using instrumented

tests (Rink et al. 1978). The authors found that the force at peak load, F_m, decreased slowly with increasing temperature from 133 to 353 K; increased by a factor of two between 193 and 273 K; and then decreased again.

Because of the oxidative degradation of the main-chain double bonds, the plastics toughened by diene-type elastomers (e.g., PBD or other rubbers) are susceptible to aging. The UV radiation breaks the chemical bonds, initiating chain reactions in which the polymer is attacked by the atmospheric oxygen, becoming cross-linked or chemically degraded. Embrittlement of the surface has a similar effect to the introduction of a sharp crack. The effects are clearly seen in Charpy and Izod impact tests. Although the subsurface polymer is unaffected by the aging, a crack initiated at the surface can accelerate throughout the degraded layer and cause low-energy fracture of the specimen (see ▶ Chap. 14, "Degradation, Stabilization, and Flammability of Polymer Blends").

Geometry of a toughened plastic specimen also influences the impact strength and its mode of failure. The specimen's length, width, and thickness may affect the fracture behavior. Whether the specimen is notched or not, as well as the dimensions of the notch, may also influence the impact behavior (Kinloch and Young 1983). As discussed above in Sect. 10.3.3, "Fracture Mechanics Testing" – it is important to determine the material parameters (the initiation and the propagation energies) using the specimen geometry that reduces the effects of geometry to an acceptable level.

10.4   Miscibility and Solubility

10.4.1 Miscibility in Polymer Blends

Since physical properties of polymer blends are influenced strongly by blending conditions and processes that, in turn, affect the level of mixing of the blends, there is a growing interest in studying the miscibility and phase behavior of polymer blends. The most important factor leading to miscibility in low molecular weight materials is the combinatorial entropy contribution which is very large compared to high molecular weight polymers. For miscibility to occur, ΔG_m must be smaller than 0.

The properties of polymer blends are determined mainly by the miscibility of the components and structure. The miscibility of polymer blends is generally believed to originate from the specific interactions between polymers. The miscibility has been widely used to describe multicomponent polymer blends whose behavior is similar to that expected of a single-phase system. Many attempts have been made for the understanding of the miscibility of polymer blends, in which the determination of the crystallization behavior and the thermodynamic interaction between polymers are of central importance. Usually thermodynamic miscibility and homogeneity can be attained when the free energy of mixing, ΔG_m, is negative. (A more detailed discussion is available in ▶ Chap. 2, "Thermodynamics of Polymer Blends.")

The term ΔG_H has been used to describe all types of specific interactions (hydrogen bonding, ion–ion, ion–dipole, charge transfer, electron interactions, etc.) that provide negative contribution to the free energy of mixing. The interactions of

the van der Waals type are accounted for by the $\chi'_{12}\phi_1\phi_2 \geq 0$ term with χ'_{12} given by Hildebrand's solubility parameter (Hildebrand 1964).

Hildebrand pointed out that the order of solubility of a given solute in a series of solvents is determined by the internal pressures of the solvents. Later, Scatchard introduced the concept of "cohesive energy density" into Hildebrand's theories. The solubility parameter is a numerical value that indicates the relative solvency behavior of a specific solvent. It is derived from the **cohesive energy density** of the solvent, which in turn is derived from the **heat of vaporization.** In 1936 Joel, H. Hildebrand proposed the square root of the cohesive energy density as a numerical value indicating the solvency behavior of a specific solvent:

$$\delta = \sqrt{c} = \left(\frac{\Delta H - RT}{V_m}\right)^{\frac{1}{2}} \tag{10.19}$$

Hildebrand and Scott and Scatchard proposed that the enthalpy of mixing is given by

$$\Delta H_m = V_{mix}\left[\left(\frac{\Delta E_1^V}{V_1}\right)^{\frac{1}{2}} - \left(\frac{\Delta E_2^V}{V_2}\right)^{\frac{1}{2}}\right]^2 \Phi_1\Phi_2 \tag{10.20}$$

where V_{mix} is the volume of the mixture, ΔE_i^V is the energy of vaporization of species i, V_i is the molar volume of species i, and Φ_i is the volume fraction of i in the mixture. ΔE_1^V, i is the energy change upon isothermal vaporization of the saturated liquid to the ideal gas state at infinite volume.

The heat of mixing must be smaller than the entropic term ΔGm for polymer–solvent miscibility ($\Delta Gm \leq 0$). Therefore, the difference in solubility parameters ($\partial_1 - \partial_2$) must be small for miscibility or dissolution over the entire volume fraction range (Grulke et al. 1999).

The effect of polymer–polymer interactions on the miscibility and macroscopic properties of PVC/PMMA, PVC/PS, and PMMA/PS blends were studied and the miscibility of the components was characterized by the Flory–Huggins interaction parameter or by quantities related to it by Fekete et al. (Fekete et al. 2005). The comparison of interaction parameters determined by different methods indicates that PVC and PMMA are nearly miscible, while PS is immiscible either with PMMA or with PVC at all compositions. Flory–Huggins interaction parameters calculated from equilibrium methanol uptake (χ'_{12}) are plotted as a function of composition in Fig. 10.24. The negative values obtained for the PVC/PMMA blends hint at complete miscibility, although χ'_{12} depends on composition which indicates limited miscibility. The positive interaction parameters determined for the PVC/PS and PMMA/PS blends suggest immiscibility.

The influence of chemicals and solvents on a polymer blend depends on the nature of solvent and the blend components, as well as on morphology of the blends. The chemical/solvent resistance of an amorphous polymer is improved by the presence of semicrystalline polymer(s). For the best solvent resistance, the latter

Fig. 10.24 Relationship between composition and the Flory–Huggins interaction parameter determined from equilibrium solvent uptake; (□) PVC/PMMA, (○) PMMA/PS, (Δ) PVC/PS; component 2: PMMA in PVC/PMMA, PS in PMMA/PS, and PVC/PS blends (Fekete et al. 2005)
polymers should be the matrix. The semicrystalline polymers such as PA, POM, PBT, or PET contribute to the solvent and chemical resistance, high processability, and rigidity, while amorphous polymers (ABS, PC, and PSF) provide impact strength and elongation and often the cost reduction.

10.4.2 Solubility Parameter/Prediction of Miscibility

According to the solubility parameter approach at predicting compatibility, two polymers mix well if the difference in the pure component solubility parameter is small. In polymer systems where the interactions are dominated by the van der Waals forces, solubility is favored by chemical similarity of solvent and polymer. Molecular weight, chain branching, and cross-linking of individual polymers slightly influence the solubility parameter (for more details see ▶ Chap. 2, "Thermodynamics of Polymer Blends," Sect. 2.6.2.3).

For polymer molecules, the solubility parameter (δ) is best calculated using the table of molar attraction coefficients. Here, E is given as

$$\delta \; = \; e \; \Sigma \frac{E}{M} \tag{10.21}$$

where E is summed over the structural units of the polymer, M the "polymer" molecular weight, and "e" is the density.

In coating and in rubber industry, the solubility approach is used respectively to select the solvent or to study swelling of the cured rubber by solvents. The

approach was also useful in calculating the effects of pressure and temperature on free energy of mixing. However, the predictions with the Hildebrand solubility parameters are made in the absence of any specific interactions, especially hydrogen bonds. They also do not account for the effects of morphology (crystallinity) and cross-linking. In addition, there may be (non-ideal) changes with changes in temperature and, in many cases, with changes in concentration. Polymer blends with specific interaction include PMMA/PEO, PVAc/PEO, etc.

In a strict sense, the molecular interactions should be nonspecific, without forming associations or orientation, hence not of the hydrogen or polar type.

The solubility parameter approach is applicable to amorphous polymer systems. Highly crystalline polymers, viz., PE or PTFE, are insoluble at room temperature, but they obey the solubility principles at $T \geq 0.9\ T_m$, i.e., at temperatures not more than 10 % (in Kelvin) above their melting temperature.

The biggest drawback of the solubility parameter approach has been the omission of the specific and entropic interactions effects.

10.4.3 Binary Interaction Parameters

The binary interaction generally refers to the interactions between polymer–polymer and polymer–solvent. The nature of solvent–polymer interaction plays an important role in the miscibility of blends. Many thermodynamic properties of polymer solutions such as solubility, swelling behavior, etc., depend on the polymer–solvent interaction parameter (χ). The quantity was introduced by Flory and Huggins. Discussions of polymer miscibility usually start with Flory–Huggins equation for free energy of mixing of a blend (refer to ▶ Chap. 2, "Thermodynamics of Polymer Blends").

The Flory–Huggins theory is widely used still and has been successful, largely, in describing thermodynamics of polymer solutions.

It is also important to note that the Flory–Huggins is a mean-field theory (for the use of the formulation of the change in internal energy due to mixing).

The miscibility of ethylene–styrene copolymer blend was studied by the help of interaction parameters by Chen et al. (2001). They proposed that the interaction parameter for a blend of copolymers is a linear combination of the individual parameters. The nature of the polymer–solvent interaction plays an important role in deciding the influence of chemical and solvent effect on blends. For a compatible amorphous/crystalline blend, the Nishi–Wang equation (Nishi and Wang 1975) is commonly used to determine the polymer–polymer interaction parameter from the melting point depression experiments. Nishi and Wang equation is based on Flory–Huggins theory. The method involves a comparison of the equilibrium melting point of a neat semicrystalline polymer to that of the same polymer in blends of different compositions. For a binary mixture of two relatively high molecular weight polymers, one semicrystalline and one noncrystalline, Nishi and Wang showed that

Fig. 10.25 Nishi–Wang plot for semicrystalline PSMA14/PCL blends (Gouveia et al. 2011)

$$\frac{1}{T^0_{mb}} - \frac{1}{T^0_m} = -\frac{R V_{Bu}}{\Delta H^0_f V_{Au}} \ \chi_{AB} \phi^2_A \tag{10.22}$$
where T^0_m and T^0_{mb} are, respectively, the equilibrium melting points of the neat semicrystalline component and of the blend containing a volume fraction of amorphous component f. R is the universal gas constant, ΔH^0_f is the molar heat of fusion, V_{Au} and V are the molar volumes of the amorphous and crystalline units, respectively.

PSMA/PCL blends were analyzed by Gouveia et al. (2011) using Nishi–Wang equation. They plotted $(1/T^0_{mb} - 1/T^0_m)$ against ϕ^2_A and resulted in a straight line with slope proportional to χ_{AB} and zero y-intercept (Fig. 10.25).

10.4.4 Phase Separation Process

In polymer solutions and polymer blends, LCST, UCST, combined UCST and LCST, hourglass, and closed-loop shaped phase diagrams have been found experimentally. These five types of phase diagrams are the most commonly observed phase diagrams in polymer systems. An important role is played by temperature in the phase diagrams according to the equation:

$$T^* = \frac{d_1}{d_2} \tag{10.23}$$

Here d_1, d_2 are constant for a particular system. If the signs of d_1 and d_2 are opposite, then T^* is negative, and all miscibility gaps are of one type, for
Fig. 10.26 Schematic illustration of types of possible polymer blend phase diagrams, for binary blends where additional complications that can be introduced by competing processes (such as crystallization of a component) are absent. The coefficients d_1 and d_2 refer to a general functional form (as a function of temperature and component volume fractions) of the binary interaction parameter that quantifies deviations from ideal mixing (Courtesy: *Online resources*)

$d_1 > 0$, $d_2 < 0$ yielding exclusively the UCST type. In the opposite case of $d_1 < 0$ and $d_2 > 0$, leading exclusively to the LCST type. However, in the remaining cases where both the coefficients possess the same sign, the temperature T^* is physically important – with $d_1 > 0$ and $d_2 > 0$ (LCST type) for $T > T^*$ but changes to (UCST type) for $T < T^*$, resulting in an hourglass type of phase diagram for lower molecular weights. Finally, for $d_1 < 0$ and $d_2 < 0$, the pattern is switched and the diagram has the form of a closed loop. A simple schematic representation is given above (Fig. 10.26).

Diblock copolymers formed from polystyrene covalently linked to poly(*n*-pentylmethacrylate), P(S-b-*n*PMA), which have only weak segmental interactions, are shown to exhibit closed-loop phase behavior over a narrow range of molecular weight.

Liquid–liquid phase separation of a miscible blend system can occur either during heating (LCST type) or during cooling (UCST type) (Fig. 10.27). A detailed discussion on phase diagrams is presented in ► Chap. 2, "Thermodynamics of Polymer Blends."

Phase separation in polymer solutions may proceed either by nucleation and growth (NG) or by spinodal decomposition (SD). Spinodal decomposition is also of interest from a more practical standpoint, as it provides a means of producing a very

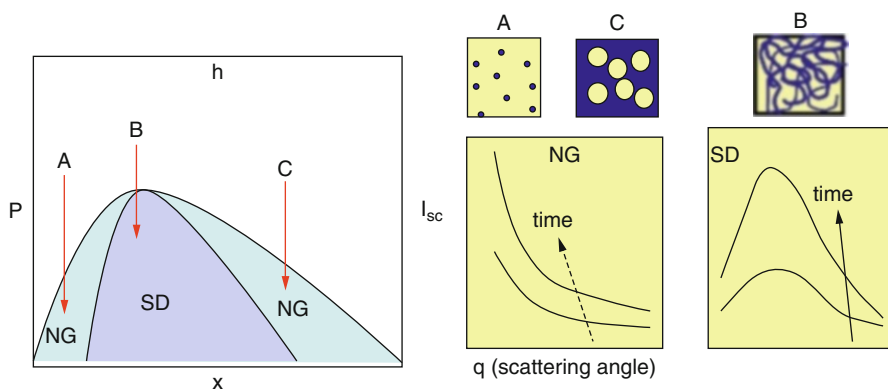
Fig. 10.27 Phase diagram showing LCST and UCST behavior for polymer blends (Courtesy: *Online resources*)


Fig. 10.28 Schematic illustration of the metastable (nucleation and growth) and unstable (spinodal decomposition) domains in polymer solutions and consequences of pressure quench at different polymer concentrations (Courtesy: *Online resources*)

finely dispersed microstructure that can significantly enhance the physical properties of the material. Nucleation and growth is the phase separation mechanism in the metastable regions which are schematically illustrated in Fig. 10.28 which shows the phase boundaries for a polymer solution in term of the miscibility pressures (or demixing pressures) at a given polymer concentration x.

A simple representation of the two mechanisms is given in Fig. 10.29.

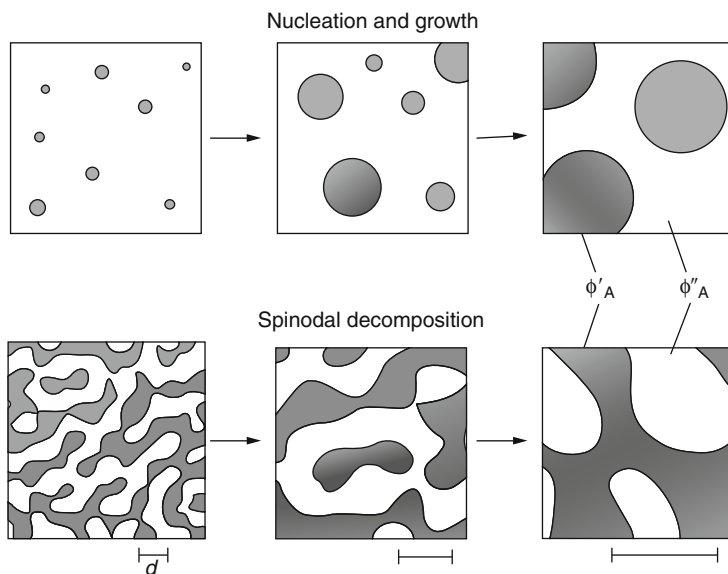
The phase boundaries and the kinetics of phase separation of polymer blends are very rich areas of investigation, with, additionally, important technological applications.


Fig. 10.29 Nucleation and growth and spinodal decomposition patterns in binary blends (Longjian Xue et al. 2012)

Figure 10.30 shows schematically the variation of the free energy of mixing, ΔG_m, with composition for a typical high molecular weight binary polymer blend and the corresponding phase diagram. The binodal denotes the limits of miscibility and is determined by the points of common tangent to the free energy curve, where the chemical potentials of the two coexisting phases will be equal. The spinodal denotes the limits of metastability of the system where the curvature changes from positive to negative and the second derivative of ΔG_m is zero. Inside the spinodal, the system is unstable to all concentration fluctuations and the blend spontaneously separates into coexisting phases via the process known as spinodal decomposition.

When mixing, most of the polymer mixtures get phase separated. Consider the example of polystyrene and polybutadiene. Mixing these two polymers results in an immiscible blend. When polystyrene is mixed with a small amount of polybutadiene, the two polymers will not blend; instead the polybutadiene will separate from the PS into little spherical blobs.

The determination of phase separation in partially miscible polymer blends by means of thermal analysis is often difficult because of the small demixing enthalpy and the slow rate of the diffusion-controlled process. Dreezen et al. (2001) studied the phase separation of PEO/PES and PEO/Aramid blends by optical microscopy, conventional DSC and MTDSC. The onset of phase separation from optical microscopy corresponds very well to the onset of a small stepwise increase in the MTDSC heat capacity (Fig. 10.31).

Phase separation process takes place in a number of ways. It may be thermally induced, reaction induced, crystallization induced, etc. Thermally induced phase

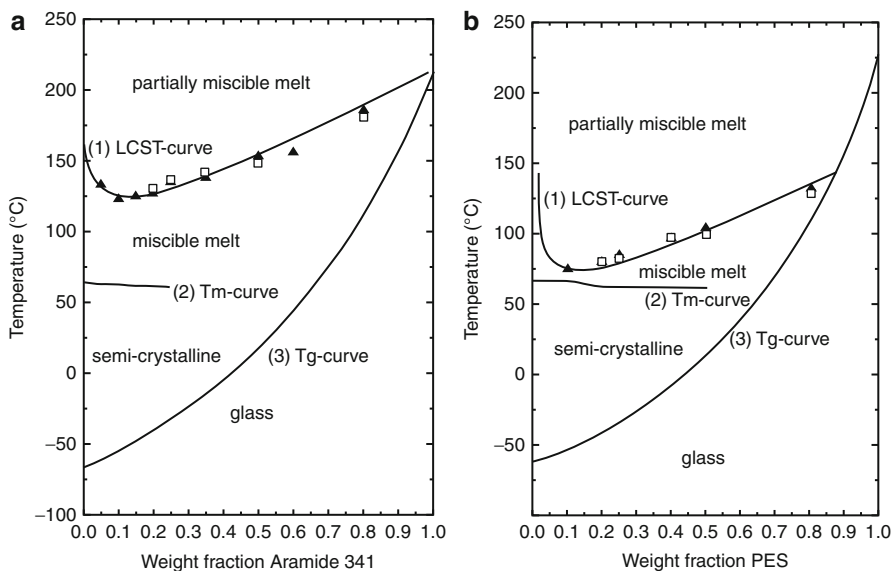
Fig. 10.30 Schematic showing the Gibbs free energy of mixing as a function of composition at a chosen temperature T_0 (*upper panel*). Given in the *lower panel* is the corresponding phase diagram showing the binodal (*outer, dark grey*) and spinodal (*inner, light grey*) curves; marked are the binodal and spinodal compositions at T_0 (B′, B″ and S′, S″) which are related to the features) (Courtesy: *Online resources*)


Fig. 10.31 Phase diagram of (**a**) PEO/Aramid and (**b**) PEO/PES blend system (▲) cloud point determined by optical microscopy, (□) onset of demixing obtained by modulated differential scanning calorimetry (Dreezen et al. 2001)

separation process is based on the phenomena that the solvent quality usually decreases when temperature is decreased. After demixing is induced, the solvent is removed by extraction, evaporation, or freeze-drying. The reaction-induced phase separation can be investigated by different observation techniques such as time-resolved small-angle light scattering (TRSALS), optical microscopy (OM), differential scanning calorimetry (DSC), digital image analysis (DIA), etc.

The phase separation process of blends has been studied by a number of researchers. Chaleat et al. investigated the phase separation of plasticized starch/PVA blends (Chaleat 2012) blends of vinylidene fluoride/trifluoroethylene copolymer and poly(1, 4-butylene adipate) was studied by Kap Jin Kim and Kyu (Kim and Kyu 1999). Fully biodegradable blends of poly(butylene succinate) and poly (butylene carbonate) and its phase behavior were studied by Wang (2012).

10.4.5 Factors Affecting Miscibility and Solubility

Miscibility can be influenced by various factors such as crystalline phase, intermolecular interaction, and reduction of surface tension.

10.4.5.1 Effect of Crystallinity

Growing numbers of commercial materials are blends of two or more polymers in which at least one of the components is a crystalline polymer. The crystallization in miscible blends is restricted to temperatures between the blend glass transition temperature and the equilibrium melting point, $T_{m,e}$, i.e., to the crystallization temperature, $T_c < T_{m,e}$. The difference, $D_c = T_{m,e} - T_c$, depends on the cooling rate and the nucleation process. There are three mechanisms of the crystallization nucleation (Utracki 1989):

1. Spontaneous, homogeneous nucleation – it rarely occurs in the supercooled homogeneous melt.
2. Orientation-induced nucleation, caused by alignment of macromolecules, e.g., in extensional flow field.
3. Heterogeneous nucleation on the surface of a foreign phase.

   In thermoplastic blends (2) and (3) are most important mechanisms.

   Miscible crystalline/amorphous polymer blends such as PLA/PVC blends have been widely investigated, and oriented crystallization has also been applied to some miscible crystalline/amorphous polymer blends. For miscible blends containing semicrystalline polymers, analysis of the melting point depression is widely used to estimate the Flory–Huggins interaction parameter (χ).

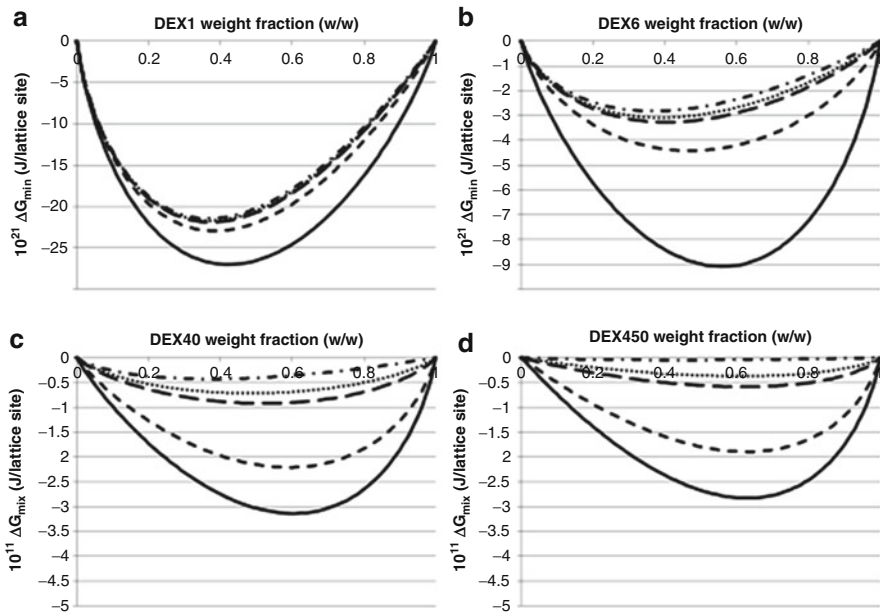
It has been known for more than a century that impurities reduce the melting point. This observation has been used to determine the molecular weight of the contaminant by Raoult. Nearly a hundred years later, this concept was used to calculate the thermodynamic binary interaction parameter χ_{12} from a melting point depression of a crystalline polymer in miscible blend with low concentration of another polymer. The relation is popularly used in the simplified form for very high molecular weight components (Nishi and Wang 1977):


Fig. 10.32 Entropic part of the free energy of mixing per lattice site as a function of DEX weight fraction (w/w): (**a**) DEX1 systems, (**b**) DEX6 systems, (**c**) DEX40 systems, and (**d**) DEX450 systems. Key: PVP12 (*solid*), PVP 17 (*short dash*), PVP25 (*long dash*), PVP30 (*dotted*), and PVP90 (*dash-dot*) (van Eerdebbrugh et al. 2012)

$$\frac{T_m}{T_{m,n}} = 1 + \left(\frac{\chi_{12}\, RT}{V_1}\right) \left(\frac{V_2}{\Delta H_m}\right) \phi^2 \tag{10.24}$$

where T_m is the melting point of crystalline polymer in miscible blend, $T_{m,n}$ is melting point of crystals of neat polymer, V_i is molar volume, and ΔH_m is the heat of fusion. But the determination of the experimental melting points using DSC or optical microscopy and substituting those values in the above equation gives erroneous values for χ.

10.4.5.2 Effect of Molecular Weight

It is well known that polymer molecular weight is a key factor that influences miscibility. Thus, by changing molecular weights of the polymers, systems with variable miscibility characteristics but virtually constant chemical composition potentially can be obtained. Bernard Van and Lynne Taylor applied this to their study and they took dextran and Maltodextrin with PVP (van Eerdebbrugh et al. 2012). Depending on the molecular weights used to prepare DEX-PVP blends, miscibility can vary from completely miscible to virtually immiscible. The higher the combined polymer molecular weight, the lower the miscibility of the resultant blends (Fig. 10.32).

Fig. 10.33 Phase homogenization temperature of the PS/P4MS blend system of (I) PS Mw = 192,000, (II) 250,000 g/mol, both as a function of composition. UCST (*critical point*) is also indicated (Chang and Woo 2001)
Polymer blends (like low molecular weight solvents) can exhibit miscibility or phase separation and various levels of mixing in between the extremes (e.g., partial miscibility). The most important factor leading to miscibility in low molecular weight materials is the combinatorial entropy contribution which is very large compared to high molecular weight polymers. This contribution is the reason that solvent–solvent mixtures offer a much broader range of miscibility than polymer–solvent combinations. The range of miscible combinations involving polymer–polymer mixtures is even much smaller. As an example compare the miscibility of hexane–ethanol mixtures with their high molecular weight analogs of polyolefins and poly(vinyl alcohol). The former is miscible, whereas the latter is highly immiscible.

Phase behavior of blends of polystyrene with poly(4-methylstyrene) has been studied by Chang and Woo (2001). Their study clearly indicates that an increase of molecular weight leads to a reduction in the entropic contribution to the Gibbs free energy of mixing, which is less favorable for miscibility (Fig. 10.33).

10.4.5.3 Effect of Copolymerization

In blends of random copolymers, or in blends of a polymer with random copolymer, the presence of repulsive forces among segments (other than specific interactions discussed before) may lead to miscibility (Wang et al. 2006). The effect of ethylene–styrene content on the miscibility and cocrystallization was studied extensively by Chen (2001). They showed that the miscibility of the system depends only on the comonomer content with composition expressed as weight fraction. Based on the experimental observations, they constructed a miscibility map for binary blends (Fig. 10.34).

The transition from miscibility to immiscibility occurs over a very small change in styrene content; which (difference from 9 to 11 wt%) is sufficient to change the system from miscible to immiscible for copolymers of this molecular weight.

Fig. 10.34 Miscibility map of ethylene–styrene copolymer blends (Chen 2001)
It has been found in the study of PVME and SBS triblock copolymer that solubility of PVME in PS block copolymer domains is larger than in PS homopolymer. This may indicate that the mixing enthalpy has an effect on the blend miscibility. The behavior has been attributed to the effect of PB segments in SBS. The phase equilibriums and miscibility in polymer blends containing random or block copolymer were reviewed. The solubility and miscibility of homopolymer/copolymer blends has been studied by Jiang and Xie (1991). They proposed that when increasing the amount of homopolymer A to the ordered state of block copolymer AB, initially the homopolymer will be dissolved in the microdomains of the block A of the copolymer until the solubility limit is reached beyond which macroscopic phase separation occurs. Results show that the solubility limit depends upon the relative lengths of the block copolymer and the corresponding homopolymer. The dependence of copolymer content on the miscibility of PMMA/SAN blend showed that the transition from miscibility to immiscibility increases with increase in AN copolymer content (Cameron 2002).

10.4.5.4 Effect of Solvents

The solvent effects on polymer blends can be estimated using the solubility parameter δ. The concept was originally used to characterize the strength of interactions in simple liquids, but later it was extended to polymer/polymer as well as polymer/solvent systems. Certain factors, such as structure, composition, and nature of the

Fig. 10.35 Tan δ of SF/PVA blend films cast from aqueous solution of various blend ratios: (**a**) 100/0, (**b**) 70/30, (**c**) 50/50, (**d**) 30/70, and (**e**) 0/100 (Um and Park 2007)
copolymer, influence the solvent effect. Chemical structure of polymers constituting the blend determines its solvent resistance. The polymers, having the backbone linkages involving oxygen, sulfur, and silicone exhibited enhanced chemical and solvent resistance. Thus, enhanced chemical and solvent resistance has been reported for polymer blends that comprise polymers with ether, thioether, oxymethylene linkages, siloxane and/or imide groups, fluorine, certain block polymers, etc.

The structure of repeat units of individual polymers constituting a blend and the nature of interactions between polymers in a blend are the factors that influence solubility characteristics of a blend. Thus, solubility is affected by cross-linking, hydrogen bonding, formation of donor–acceptor complexes, dipole–dipole interactions, ion–dipole interactions, ion–ion interactions, and segmental interactions.

The effect of casting solvent on the miscibility behavior of silk fibroin/PVF blends was investigated by Um et al. SF/PVA blend films cast from aqueous and formic acid solution. The β-sheet conformation of SF formed by formic acid casting was retained for all SF blends regardless of blend ratio. SF/PVA blends from aqueous solution exhibited a phase-separated morphology and immiscibility by SEM observation and DMTA (Dynamic Mechanical Thermal Analysis) measurement (Um and Park 2007) (Figs. 10.35 and 10.36).

Wu et al. (1997) used the DSC method to study the crystallization behavior of the PVAc/PEO blends using two solvents of chloroform and benzene. They observed that the crystallization of PEO was more suppressed in benzene (Fig. 10.37).

10.4.5.5 Effects of Compatibilizers and Interface Modification

A common method to enhance poor miscibility of two components in a blend is to add a third component to the blend that will have a favorable interaction with the precursor polymers. This third component, often termed a compatibilizer, is designed with the hope it will favorably affect the blend system by potentially changing a miscibility window, strengthening phase-separated domains, or by affecting the kinetics of phase separation thus causing a change in the phase-separated morphology.

A compatible blend is mixture of polymers with low repulsive forces between phases. Compatibilization is referred to any physical or chemical method that

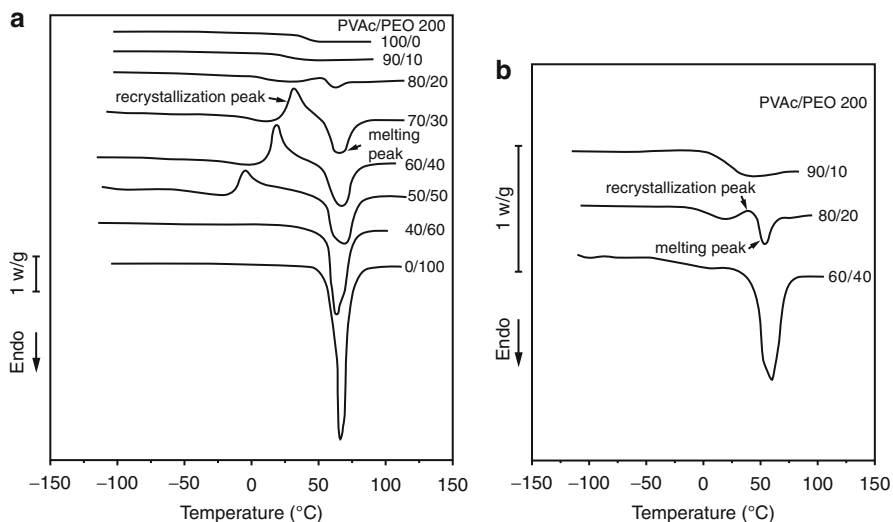
Fig. 10.36 Tan δ of SF/PVA blend films cast from formic acid solution of various blend ratios: (**a**) 100/0, (**b**) 70/30, (**c**) 50/50, (**d**)30/70, and (**e**) 0/100 (Um and Park 2007)


Fig. 10.37 DSC thermograms of (**a**) PVAc/PEO200 blends cast from chloroform and (**b**) benzene (Wu et al. 1997)

results in stabilization (prevention to separate) of polymer blends morphology and properties. Polymer blends are used to change impact or flex properties, chemical resistance, thermoformability, and printability, for example. Some properties of the compatibilized blend exceed that of either component alone. Compatibilizers act through a chemical reaction (reactive compatibilization) or through intermolecular forces of attraction such as van der Waals, hydrogen bonding, based on polarity of the materials (nonreactive compatibilization). In addition, a compatibilizer may function by more or less the same mechanism as a surfactant does to stabilize oil/water mixture, i.e., by being soluble in one or both major
Fig. 10.38 Qualitative comparison between the theory and the experimental phase diagram (*cloud points*) for the PVA/PMMA polymer blend without fillers (*filled diamonds*) and with 10 wt% fumed silica (*open squares*). The *two curves* correspond to the spinodals calculated using equations. It is assumed that both PVA and PMMA had degrees of polymerization (N) 1,000 and that (øN) a + bT, with (a)-10.0, (b) 0.026374. Finally, assumed that (F) 0.65. For the filled system, we took nanoparticle loading of 14 vol%, with the dimensionless particle radius (R) 20 (corresponding to the ªrealº particle radius of 10 nm) (Ginzburg 2005)

components of the blend. One such mechanism is by attaching itself to one of the blend components through chemical grafting and leaving a polymeric "tail" that is soluble in the other component.

Most polymers are not miscible and those having closely similar solubility parameter values are likely to be compatible. Two incompatible polymers can be compatibilized by the presence of a third component, which results in a good improvement in the physical and mechanical properties of the blend. The effect of the polyacrylonitrile compatibilizer, on the miscibility and properties of NBR/SBR blends, has been studied by Darwish et al. (2005).

Nowadays, nanoparticles have been widely used as fillers and compatibilizers. They exert certain effect on the miscibility of blends. Ginzburg applied a simple theory to study the effect of nanoparticles on the miscibility of PVA/PMMA blends and compared theoretical and experimental results for the same system with fillers and without fillers (Ginzburg 2005) when nanoparticle radius is smaller than polymer radius of gyration, the addition of nanoparticles increases the critical value of χ_N and stabilizes the homogeneity (Fig. 10.38).

Phase separation of poly(methyl methacrylate)/poly(styrene-co-acrylonitrile) blends in the presence of silica nanoparticles was studied by rheological method by Jianping Gao (2012). Rheology is a frequently used method to determine the phase separation temperature. However, unlike the optical method which can show the phase-separated morphology directly, no visual information can be obtained from rheology (Fig. 10.39).

Fig. 10.39 The binodal phase diagram of PMMA/SAN (*solid circles*) and PMMA/SAN/SiO (*solid squares*) by combining the gel-like method and Cole–Cole plot. The spinodal points of PMMA/SAN (*hollow circles*) and PMMA/SAN/SiO (*hollow squares*) are also shown. The *lines* are drawn to guide the eyes (Gao 2012)
10.4.6 Standard Methods of Evaluation of Miscibility, Solubility, and Interaction Parameter

The miscibility behavior of the blends can be determined by various techniques. Glass transition temperature (T_g)-based analysis using differential scanning calorimetry, dynamic mechanical analysis, spectroscopic techniques such as Fourier transform infrared (FTIR) spectroscopy and solid-state nuclear magnetic resonance (NMR), fluorescence spectroscopy, scattering techniques such as small-angle light scattering (SALS) and small-angle X-ray scattering (SAXS), morphology determination by transmission electron microscopy (TEM), scanning electron microscopy (SEM), etc., are the commonly used techniques for the miscibility studies in polymer blends. Each method has its own standard and sensitivity. The specific method used to determine the solubility and miscibility behavior is inverse gas chromatography (IGC); the effect of crystallinity is studied by DSC. The optical microscopy is used to study the spherulitic superstructure of polymer crystals from the melt and explain the relationship between morphology and crystal growth rate. In addition, small-angle light scattering (SALS) and small-angle X-ray scattering (SAXS) are used to study the morphology of crystalline/amorphous polymer blends.

10.4.6.1 Glass Transition Temperature (T_g) Analysis

Thermal methods are useful to study modern polymeric material, usually blends or composites with complex morphologies that are crucial to determining their material properties. The miscibility of polymer blends is often assessed by the measurement of a single glass transition temperature (T_g) as a function of composition. Two T_gs in a DSC thermogram indicates a two-phase system, and a single composition-dependent T_g is often taken as evidence of the formation of a miscible blend.

The differential scanning calorimetry (DSC) is the thermal analysis mainly used to determine a first-order transition (melting) and a second-order endothermic transition (glass transition). DSC has been extensively used for the characterization

Fig. 10.40 DSC *curves* of
PCP–PVC blends of different
composition. (*a*)–(*g*)
represent T_g of the blends
(Saha 2001)
of interchange reactions. Experimentally, the least ambiguous criterion for polymer
miscibility is the detection of a single glass transition temperature (T_g), which is
intermediate between those corresponding to the two component polymers. Phase
separation is judged by the existence of two distinct glass transition temperatures.

The effect of transesterification on the miscibility of the PC–PET blends was
studied by Zheng et al. using DSC (Zheng 2004). The binary interaction energies of
completely miscible binary pairs that do not phase separate like PPO/PS are studied
by small-angle neutron scattering (SANS). The miscibility of PEOx and PVPh
blends was investigated by Wang et al. (2001) using FTIR, DSC, high-resolution
solid-state NMR, etc. Compatibility of PCP–PVC blends was studied by DSC by
Saha (2001). He concluded that the compatibility increases with increase in PCP
content (Fig. 10.40). The difference in peaks gradually decreases and at 90 % PCP
content merges into single peak.

The phase behavior of blends of TMOS and SAN was investigated by means of
optical cloud point measurements and DSC by Pfefferkorn et al. (2012). The blends
display partial miscibility with an upper critical solution temperature (UCST).
Moreover, the SAN/TMOS blends show pronounced miscibility-window behavior,
i.e., the UCST depends strongly on SAN copolymer composition.

DSC technique was used to study polybenzoxazine/poly(ε-caprolactone) blends
(Huang 2005), poly([2-oxo-1,3-dioxolan-4-yl]methyl vinyl ether-co-acrylonitrile)/
poly(vinyl chloride) blend (Ha et al. 2002), polypropylene/polyethylene binary
blends (Wong et al. 2002), etc.

DMA is another technique, which is widely used for the determination of
miscibility of polymer blends. Generally for an immiscible blend, the tanδ curves
show the presence of two damping peaks corresponding to the T_gs of individual
polymers. For a highly miscible blend, the curves show only a single peak in
between the transition temperatures of the component polymers, whereas broaden-
ing of the transition occurs in the case of partially miscible systems. In the case of
miscible or partially miscible blends, the T_gs are shifted to higher or lower tem-
peratures as a function of composition. Perera et al. (2001) studied the miscibility of
polyvinyl chloride (PVC)/nitrile butadiene rubber (NBR) and PVC/epoxidized

natural rubber (ENR) blends using DMA. The tanδ curve for PVC/NBR and PVC/ENR blends appeared in between the respective homopolymers, indicating miscibility. The tanδ peaks for the blends were broader than the two homopolymer curves due to some degree of dynamic heterogeneity in the blend. In other words, the blends appeared to be miscible but had a wide range of relaxation times as a result of molecular proximity of the unlike chains.

10.4.6.2 Microscopic Measurements

The liquid–liquid decomposition of a blend of polycarbonate(PC)/polyethylene oxide(PEO) taking place via spinodal decomposition has been studied by optical microscope (Tsuburaya 2004) in Fig. 10.41.

Phase separation may proceed either by nucleation or growth or by spinodal decomposition when the changes in the conditions take the solution into metastable or unstable domains, respectively. Kiran (2009) studied solutions of poly(ε-caprolactone) in acetone/carbon dioxide fluid mixtures.

The structural morphology of a blend is a product of compositional variations formed in the micro-/nanoscales. Atomic force microscopy produces high-resolution images of the sample topography by monitoring the physical displacement of a cantilever interacting with a sample surface. Phase separation is observable in immiscible or partially miscible blends. High-resolution imaging provides useful information pertaining to the domain size and morphological character.

10.4.6.3 Scattering Techniques

Various light-scattering and optical techniques have been investigated as potential candidates for characterization of multiphase polymeric materials. Kinetics of phase separation and dissolution (demixing) of polymer blends, stress whitening process, photon migration in polymer composites, etc., are examined using light-scattering techniques. A light-scattering theory known as the Rayleigh–Gans theory was developed to extend Rayleigh theory to particles that are not optically small. The correction method involves extrapolation techniques that extrapolate light-scattering intensity to zero-scattering angle. This correction technique is important for analyzing results on polymer solutions.

The assessment of miscibility and phase separation conditions is relatively easy and is carried out in many laboratories employing view cells that allow visual or optical observations as phase separation is accompanied by a change in the transmitted light intensity. The assessment of phase separation needs special techniques that allow measurement of the scattered light intensities as a function of the scattering angle and time.

A pattern like the following one is observed after the liquid–liquid phase boundary. The scattered light intensities become brighter in time at all angles (Fig. 10.42).

Direct information on the χ value between blends can be obtained from small-angle neutron scattering (SANS). SANS studies usually involve studies on multiple pairs of deuterated samples, so the effect of deuteration on the interaction parameter can be evaluated quantitatively. Light-scattering techniques can be used to determine the miscibility of PE blends by slowly cooling or heating the blend from the
Fig. 10.41 Microscopic observation of the structural development in the 70/30 PC/HM-PEO blend during isothermal annealing at 180 °C. *Left*: unpolarized light. *Right*: polarized light (Tsuburaya 2004)

one-phase region. We can observe the cloud point at which the forward-scattered light intensity increases, indicating the onset of liquid–liquid phase separation.

Akpalu and Ping Peng (Akpalu et al. 2005) studied the melt miscibility of a commercial linear polyethylene and LLDPE system using SANS.

A similar technique called SAXS (small-angle X-ray scattering) is also used to study polymer blends. Small-angle X-ray scattering (SAXS) is a nondestructive scattering technique that records elastic scattering of X-rays at scattering angles
Fig. 10.42 Liquid–liquid phase boundary of blend observed in light-scattering experiment (Courtesy: *Online resources*)

close to the direction of the incident beam. SAXS, due to its q range, often proves useful to study the large structures in binary or ternary blends where one or more components crystallize. Mickiewicz studied extensively the application of SAXS with binary blends of four different high molecular weight poly(styrene-b-isoprene) diblock copolymers with a low molecular weight poly(styrene-b-isoprene-b-styrene) triblock copolymer (Mickiewicz et al. 2008).

Polymerization-induced binodal phase separation in rubber-modified epoxy system containing DGEBA and HTBN during curing was studied using time-resolved SANS. The following figure (Fig. 10.43) shows the pattern during polymerization-induced phase separation (PIPS). The PIPS at 160 °C is much higher (Zhang et al. 1999).

The quantitative analysis of the spectrum is also given. As the time passes from 9 to 11 min, the minimum appeared become closer to the second maxima and finally merged into one to give a broad peak, Fig. 10.44.

The phase separation behaviors of PMMA/SAN blends with and without fumed silica (SiO_2) have been investigated using time-resolved small-angle light-scattering and dynamic rheological measurements. It is found that the effect of SiO_2 on the phase separation behavior of PMMA/SAN blend obviously depends on the composition of the blend matrix (Du et al. 2013).

In the case of polymer blends, refractometric and viscometric methods are used to study the polymer–solvent and polymer–polymer miscibility. It is clear that
Fig. 10.43 Evolution of light-scattering pattern for the epoxy system cured at 160 °C. HTBN/E-51/MeTHPA/BDMA 5 40/90/70/0.056; (**a**) 9 min, (**b**) 10 min, (**c**) 11 min, (**d**) 12 min, (**e**) 15 min, (**f**) 18 min (Zhang et al. 1999)

behavior of viscosity and refractive index with blend composition is linear for the miscible blends and nonlinear for partially and immiscible blends.

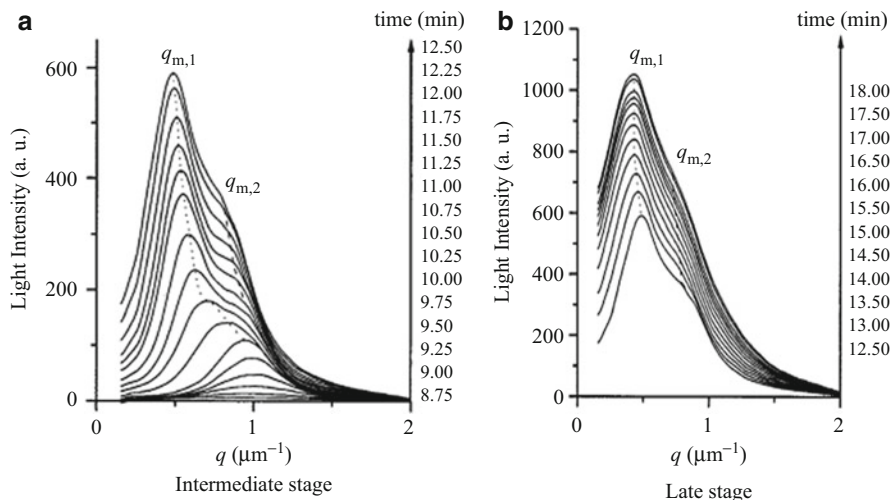
Radhakrishnan and Venkatachalapathy (Radhakrishnan et al. 1996) used the X-ray diffraction to study the crystallization, the PMMA/PEO blends cast from three solvents. The solvent effect is demonstrated from the large differences in the crystallinity values.


Fig. 10.44 Evolution of light-scattering profile for the epoxy system cured at 160 °C. HTBN/E-1/MeTHPA/BDMA 5 40/90/70/0.056; (**a**) intermediate stage, (**b**) late stage (Zhang et al. 1999)

10.4.6.4 Rheological Measurements

Rheological methods have been frequently used to study the phase separation behavior of partially miscible polymer blends. Rheology is generally sensitive to morphological changes during phase separation. Like optical methods rheological methods are not affected by the transparency of the blend. This method is strongly related to viscoelastic properties of the blend. It is said to have more resolution depending upon the applied oscillatory frequency. Rheological methods are used to get the phase diagram and to study the kinetics and mechanism of phase separation using some empirical rules.

The rheological properties of miscible blends under different temperatures can be obtained from some theoretical models. One such model is the double reptation self-concentration. The DRSC (double reptation self-concentration) model actually includes the temperature dependency and concentration dependency through a complex mixing rule given by the double reptation model and self-concentration model, which helps to exclude the complex contribution from miscible components under different temperatures in the experimental data and only illustrate the effect of the concentration fluctuation and interface formation. This model is applied to study PMMA/SMA (Wei 2011).

The frequency dependent apparent bimodal temperature is shown in Fig. 10.45. In this study, they showed that the storage modulus starts to deviate at the point of phase separation.

The rheological study was also done by Ceren Ozdilek et al. to investigate the thermally induced phase separation of PαMSAN/PMMA blends in presence of functionalized multiwall carbon nanotubes (Ozdilek 2011).

Fig. 10.45 Transition temperature as a function of oscillatory frequency during temperature ramp with a rate 1 °C/min. The triangle point at zero frequency is the transition temperature determined from isothermal frequency sweep (Wei et al. 2011)
10.4.6.5 Inverse Gas Chromatography

Inverse gas chromatography (I_{GC}) has been proven to be useful for the characterization of polymer blends in terms of polymer–polymer interaction parameters, polymer–solute interaction parameters, solubility parameters, molar heat of sorption and mixing, melting point depression as an indicator of miscibility, contact energy parameters, and surface characterization. I_{GC} has the capability of glass transition temperatures as a function of relative humidity. The technique involves creating within a column a stationary phase of the solid material of interest and determining its different physicochemical properties. The glass transition and polymer–polymer interactions are also studied using I_{GC}. Using the T_g detection by I_{GC}, Aouak and Alarifi showed the ability of this technique to study and confirm the miscibility of PBMA/PEO blends (Aouak and Alarifi 2009). It is well known that miscible blends have only one T_g, while immiscible blends have two or more T_g. Retention diagrams are constructed by two probes (solutes): chloroform as a common solvent and heptanes as a common nonsolvent to PBMA and PEO.

The miscibility of binary mixtures of poly(ether imide) (Ultem^{TM}) and a copolyester of bisphenol-A with terephthalic and isophthalic acids (50/50) (Ardel^{TM}) in three compositions (25/50, 50/50, and 75/25) was studied by F. Cakar et al. (2012).

10.4.6.6 Spectroscopic Analysis

Infrared spectroscopy has been widely used to investigate specific interactions in polymer blends in which the miscibility driving force is hydrogen bonding between components. Possibility of hydrogen bonding between hydroxyl groups of PVPh and carbonyl groups of PLLA in the blends of poly(L-lactide) with poly(vinylphenol) was reported by Meaurio et al. (2005). The miscibility and formation of hydrogen bond in the PMMA/CAB blends were studied. The carbonyl frequency of pure PMMA at 1,750 cm^{-1} is reduced to 1,740 cm^{-1} in the 50/50 blend indicating the formation of hydrogen bonding between the component polymers which contribute to the
Fig. 10.46 FTIR spectra of Pure PMMA and blend of PMMA/CAB of 50/50 composition (Meaurio et al. 2005)

miscibility of the blends. The FTIR data (Fig. 10.46) also compliments the solution techniques (Selvakumar et al. 2008).

The complete miscibility of the PMMA/DGEBA epoxy blends was confirmed by FTIR spectroscopy by Ritzenthaler et al. Increasing the heating time does not induce any shift or modification of the O–CH$_3$ (2,850–2,950 cm^{-1}) and the
Fig. 10.47 FT-IR spectra of DGEBA 30 wt% PMMA blend at 135 °C (Ritzenthaler et al. 2000)

C = O (1,725 cm^{-1}) peaks of PMMA. The results also confirm that there is no specific interaction between the PMMA and the thermoset components during curing (Fig. 10.47) (Ritzenthaler, et al. 2000).

^{1}H NMR was used to characterize the structure of the reactive and physical blend products of poly(lactic acid) and poly(ε-caprolactone) system by Wang et al. (1998). The investigation of EVA reject/phenolic resin from cashew nut shell liquid (CNSL) blends, using combined NE techniques at solid state, showed the range of compatibility as well as the domain structure present in the microdomains (Martins et al. 1996). The miscibility of poly(styrene-*co*-vinylphenol) containing 5 % vinylphenol monomer units (MPS-5) with syndiotactic poly(methyl methacrylate) (PMMA-s) and with isotactic poly(methyl methacrylate) (PMMA-i) was studied with ^{13}C solid-state n.m.r. complemented with cloud point and differential scanning calorimetry measurements (Lei Jong et al. 1993).

10.4.7 Influence of Miscibility on Final Properties of Blends

In general, a miscible blend of two polymers is likely to have properties somewhere between those of the two unblended polymers. The relative miscibility of polymers controls their phase behavior, which is of crucial importance for final properties. Polymer–polymer miscibility depends on a variety of independent variables, viz., composition, molecular weight, temperature, pressure, etc.

Jong-Han Chun studied the synergistic effect of impact strength and miscibility in polycarbonate PC/ABS blends (Chun et al. 1991). Positive deviations of the modulus

Fig. 10.48 Horizontal shift factors for the pure components and the single-phase 20/80 PS/PVME blend at a reference temperature of 1 °C (Polios 1997)
E_b and yield strength S of polymer blends consisting of partially miscible polymers are analyzed by combining models for miscible and immiscible blends by Jan Kolarík (2000). Several heterogeneous blends of partially miscible polymers, such as polycarbonate (PC)/poly(styrene-co-acrylonitrile) (PSAN) (Kolarik et al. 1997), poly(ether sulfone)/phenoxy (An et al. 1996a, b), and poly(ether-imide)/polyarylate, PC/poly(acrylonitrile-butadiene-styrene) (ABS), PC/PS, polyamide-6/ABS, and PC/poly(ether sulfone) (An et al. 1996) were found to show modulus E_b and/or yield strength S higher than predicted by the rule of mixing (additivity).

In the case of PS/PVME blends studied by Polis et al., the phase separation results initially in a large increase in the low-frequency complex moduli which is attributed to the highly interconnected PVME-rich and PS-rich phases, formed during the spinodal decomposition. The subsequent decrease is the result of the loss of interconnectivity between the two phases due to the breakup and coarsening of the phase-separated domains (Fig. 10.48) (Polios 1997).

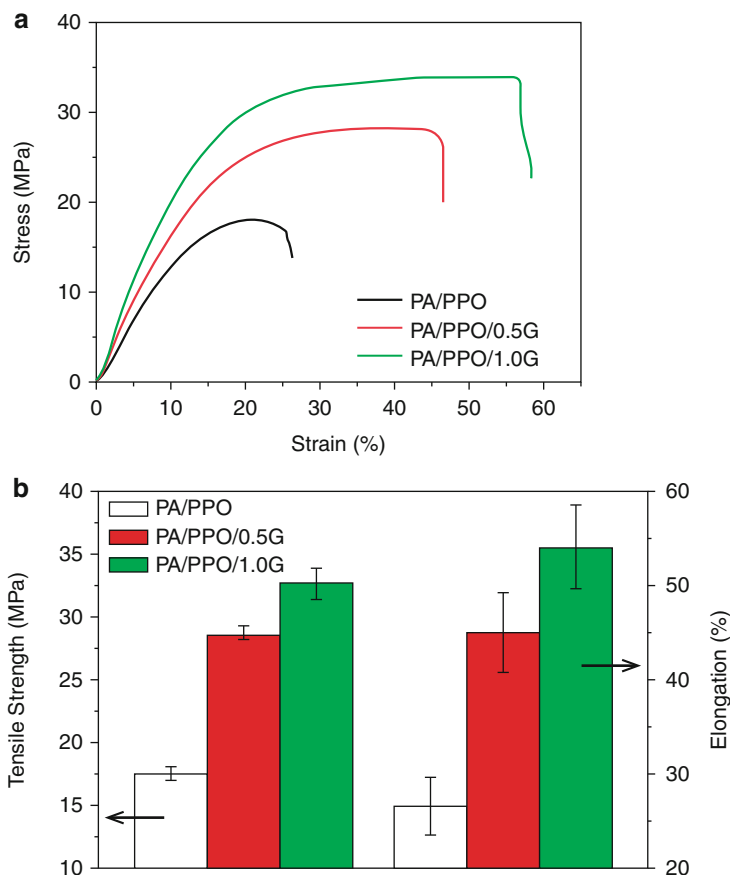
The influence of miscibility on the transport properties of polymer electrolyte blends composed of a proton conductor and an insulator was investigated by Jeffrey, Gasa, Weiss, and Montgomery Shaw (2006). The proton conductive component in the blends was SPEKK, while the nonconductive component was either PEI or PES. The phase behavior of PEI–SPEKK blends was strongly influenced by the sulfonation level of the SPEKK. At low sulfonation levels (ion-exchange capacity (IEC) = 0.8 meq/g), the blends were miscible, while at a slightly higher level (IEC = 1.1 meq/g), they were only partially miscible, and for IEC = 1.4 meq/g, they were effectively immiscible over the entire composition range. The PES–SPEKK blends were miscible over the entire range of SPEKK IEC considered in this study (0.8–2.2 meq/g). Poly(ether ketone ketone) (PEKK) itself is a relatively new engineering thermoplastic that has high-temperature stability, excellent chemical and solvent resistance, and excellent mechanical properties. The effect of compatibilization on the miscibility and final effect on the mechanical properties of PA/PPO blend have been studied by Cao et al. (2011). They used graphite oxide as a compatibilizer. Figure 10.49 represents the stress behavior and tensile strength data of the uncompatibilized and GO sheet compatibilized blends. They observed that the tensile strength of the blends increased by 87 %.


Fig. 10.49 (**a**) Stress–strain curve and (**b**) tensile strength and elongation data of uncompatibilized and GOS compatibilized PA/PPO blend (Cao et al. 2011)

10.5 Thermal Properties

10.5.1 Thermal Resistance (R)

For a flat slab, it is calculated as (ASTM C177)

$$R = A \ \frac{(T_1 - T_2)}{Q} \ = \ \frac{1}{\Gamma} \ = \ \frac{D}{\lambda} \tag{10.25}$$

where R = thermal resistance (Km^2W^{-1}), A = area measured on a selected isothermal surface (m^2), T_1 = temperature of warm surface of specimens (K), T_2 = temperature of cold surface of specimens (K), Q = heat flow rate (W), Γ = thermal conductance ($Wm^{-2} \ K^{-1}$), D = thickness of specimen measured

Table 10.16 Thermal conductivity units (Ives et al. 1971)

Units	Cal/(cm s °C)	W/(cm °C)	W/(m °C)	Kcal/(m h °C)	Btu in/(ft² h °F)
Cal cm/(cm² s °C) (or) cal/(cm s °C)	1	4.19	419	360	2900
J cm/(cm² s °C) (or) W/cm °C	0.230	1	100	86.0421	693
J cm/(m² s °C) (or) W/m °C	0.00239	0.01	1	0.860421	6.93
Kcal m/(m² h °C) (or) Kcal/m h °C	0.00278	0.0116	1.16	1	8.06
Btu in/ft² h °F	0.000345	0.00144	0.144	0.124	1

along a path normal to isothermal surfaces (m), and λ = thermal conductivity, (W/mK). The reciprocal of thermal resistance is known as thermal conductance, Γ.

10.5.2 Thermal Conductivity (λ)

Thermal conductivity of materials can only be defined for homogeneous materials, where the thickness is greater than that for which the apparent thermal resistivity of the material does not change by more than 2 % with further increase in thickness. The thermal resistance must be sufficiently independent of the area of the specimen, and for a flat slab specimen, the thermal resistance must be proportional to the thickness. When all these conditions are met,

$$\lambda = \frac{QD}{A}(T_1 - T_2) = \frac{D}{R} \qquad (10.26)$$

where the symbols are the same as in Eq. 10.25. The reciprocal of the thermal conductivity is called thermal resistivity (r).

The most common units for thermal conductivity are cal/cm °C and Btu in/ft² h°F. The SI unit for conductivity is W/mK. Since a variety of units has been in practice for thermal properties, the conversion factors are given in Table 10.16.

ASTM C177 and BS 874 recommend guarded plate method for materials of low conductivity. Two different types of guarded hot plate apparatus are described in ASTM C177. The low-temperature guarded hot plate is the most suitable method for determining the thermal conductivity of polymeric solid materials including foams. It is generally used for measurements where the temperature of the heating unit is not above 500 K. The second method is the high-temperature guarded hot plate which is ordinarily used for measurements where the heating unit temperature is greater than 550 K but less than 1,350 K. The schematic arrangement of the apparatus is shown in Fig. 10.50.

Three possible configurations to restrict edge heat flux are illustrated in Fig. 10.51. The apparatus consists of a heating unit, a cooling unit, and edge insulation. The heating and cooling units may be either round or square. The heating unit consists of a central metering section and a guard section.

Fig. 10.50 General features
of the metal surfaced hot plate
apparatus (ASTM C177)
The metering section consists of a metering area heater and metering area surface
plates. The guard section consists of one or more guard heaters and the guard
surface plates. The working surfaces of the heating unit and cooling plates should
be smoothly finished to conform to a true plane.

The heating unit has a separation (or gap) not greater than 4 mm between the
surface plates of the metering area and the guard. Two specimens should be selected
from each sample with their surfaces made plane. The temperature difference
between the hot and cold surfaces of the specimens should be not less than 5 K
(De Ponte and Di Filippo 1974).

The central heat source and the guard should have independent power supplies.
The cold surface heaters are to be adjusted so that the temperature drops through the
two specimens do not differ by more than 1 %. To attain a correct value for
properties, the time required should be adjusted – its magnitude depends on
the specific apparatus, control system and its operation, the test temperatures,
the thermal diffusivity, and thickness of the specimens (Shirtliffe 1974). The con-
ductivity is calculated using the Eq. 10.26. The attainment of equilibrium is important,
especially for polymer blends that have low conductivity. The equilibrium times, for
example, for cellular materials, are in the order of hours or tens of hours. For this
reason, stable over long time period power supplies are necessary.

Fig. 10.51 Possible configurations to restrict edge heat loss or gain (ASTM C177)
10.5.3 Heat Capacity

Specific heat of polymer blends is usually measured by differential thermal analysis (DTA) (Slade and Jenkins 1966) or differential scanning calorimetry (DSC) (Strella and Erhardt 1969; Richardson and Burrington 1974). DTA measures the difference in temperature between the sample and a standard for the same rate of heat input, while DSC compares the rate of heat inputs for the same rate of temperature rise. The results of DSC are easier to analyze as they give a direct measure of the rate of heat input.

Measurement of specific heat is made by heating a test specimen at a known and fixed rate (Blaine 1973). Once dynamic heating equilibrium of the specimen is reached, the heat flow is recorded as a function of temperature. This heat flow, normalized to specimen mass and heating rate, is directly proportional to the specimen's specific heat capacity.

In practice, two thermal experiments are required for each measurement. In the first, a baseline run is performed only on the empty pan and lid. In the second run, the test specimen is enclosed in the pan and lid. The specific heat capacity information is derived from the difference between the two resulting thermograms.

Heat flow calibration of the apparatus is also required. This is obtained by running baseline and experimental traces for a material whose specific heat capacity is well known. Sapphire is the calibration material of choice since it is easily available and its specific heat capacity is accurately known.

The relationship for calculation of specific heat capacity is given by

$$C_p \ = \ \frac{KEq}{m\beta} \tag{10.27}$$

where C_p is the specific heat capacity (J/kg K), E is the calibration coefficient (dimensionless), q is the heat flow (mW), β is the heating rate (K/min), m is the specimen mass (mg), and K (60,000) is the conversion constant. The calibration coefficient E is expressed as

$$E \ = \ \frac{C_p \ (lit)}{C_p \, (obs)} \tag{10.28}$$

where C_p (lit) is the reported literature value of specific heat capacity of the standard sample, while C_p (obs) is its experimentally observed value under the same conditions. The coefficient, E, is to be used for the determination of the unknown.

It is wise to calculate E for several temperatures over the region of interest – E should be constant. If it is not, particularly at low temperatures, it indicates that dynamic temperature equilibrium is not attained at the temperature and that the experimental temperature program needs to be started at a lower temperature. The overall accuracy of the method is found to be ± 5.5 %. Precision can be improved with large samples and higher heating rates, provided dynamic temperature equilibrium is achieved.

10.5.4 Heat Distortion Temperature (HDT)

ASTM D648 describes the determination of temperature of deflection under load for plastics and ebonite. ISO 75, BS 2782 Method 121 A and 121 B are equivalent. DIN 53461 is similarly related to the ISO method. Since these standards are similar, only the ASTM method will be described.

The heat distortion temperature (HDT), the deflection temperature under load (DTUL), or the softening temperature is a practical and important parameter of a polymeric material. They denote the upper temperature limit up to which the material can support a load for any appreciable time.

ASTM D648 provides a method for determining DTUL of plastics under flexural load. The method is applicable to molded and sheet materials available in thickness ≥ 3 mm, which are rigid at room temperature. The specimen is taken in the form of a rectangular bar with the load applied at its center to give maximum fiber stresses of 4.55 or 18.20 kPa (see below). The metal supports (rounded to a radius of mm) for the
Fig. 10.52 Apparatus for heat deflection temperature test [ASTM D648]

specimen are provided 100 mm apart (see Fig. 10.52) allowing the load to be applied on top of the specimen vertically and midway between the supports. The specimen is immersed under load in a heat-transfer medium. The temperature is raised at 275 ± 0.2 K/min. The load applied on the specimen to obtain a maximum fiber stress of 18.20 kPa $\pm$ 2.5 % is calculated using the formula below:

$$P = \frac{2\,S\,b\,d^2}{3L} \tag{10.29}$$

where P is the load (N), S is the maximum fiber stress in the specimen (18.20 or 4.55 kPa), b is the width of specimen (m), d is the depth of specimen (m), and L (0.1) m is width of span between supports. The load of 18.20 kPa is usually used for rigid polymers (e.g., PS) while 4.55 kPa is used for softer crystalline materials that have $T_g < 298$ K (e.g., PE).

ASTM D1637 provides tensile HDT test for plastic sheets. In this test a load of 345 kPa is applied to a strip, and the temperature is increased at a rate of 2 K/min. The HDT in this case is defined as the temperature at which the elongation becomes 2 %.

ASTM D1525 provides a third type of the softening temperature test. A flat-ended needle of 1 mm circular cross section is pressed into a thick sheet of the polymer with a load of 1.0 kg. The polymer is heated at a rate of either 50 or 120 K/h. The Vicat softening temperature, which is explained in detail below, in Sect. 10.5.5, is the temperature at which the needle has penetrated the polymer to a depth of

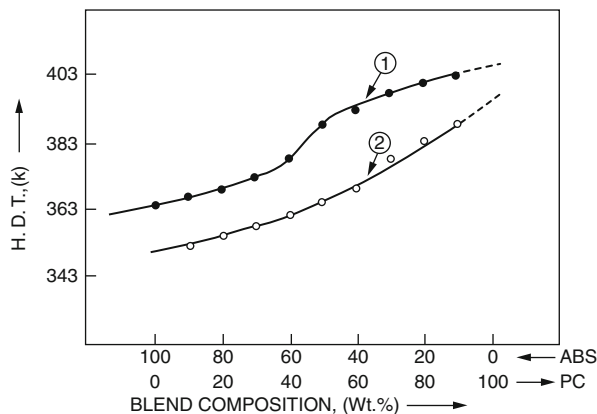
Fig. 10.53 Variation of heat deflection temperature with PC/ABS blend composition (curves 1 and 2 are obtained with loads 4.6 and 18.2 kg.f/cm^2, respectively)


Table 10.17 Variation of HDT with talc concentration in PPCP-EPDM blend (Xavier et al. 1994)

Blend composition	Talc (wt%)	HDT (K)
Neat PPCP	0	353
PPCP + EPDM (10 wt%)	8	355
PPCP + EPDM (10 wt%)	10	356
PPCP + EPDM (10 wt%)	12	359
PPCP + EPDM (10 wt%)	15	360

1 mm. For such a depth of penetration, the material must be very soft; hence, the Vicat softening temperature is higher than other HDT data.

Heat deflection temperature is influenced by (i) blend composition, (ii) fillers/reinforcing agents, (iii) annealing, and (iv) applied stress:

- HDT of a blend is influenced by its composition. Figure 10.53 shows variation of HDT (measured according to ASTM D648) with PC/ABS blend composition (Xavier and Pendyala unpublished). The observed variation is caused by changes in flexural modulus, which is also shown.
- Inorganic fillers (e.g., talc, mica, or CaCO$_3$) or reinforcements (e.g., glass or carbon fibers) increase HDT of neat polymers or blends (Nielsen 1974; Xavier and Sharma 1986). Table 10.17 illustrates the influence of talc concentration on HDT for a blend.
- Annealing of a crystalline polymer, either neat or in a blend, increases the degree of crystallinity, changes the crystallite morphology, and relieves built-in stresses in the amorphous phase. Table 10.18 shows the gradual increase of HDT with annealing time. Flexural modulus also increases. Similar effects were reported for amorphous polymers such as PS (Nielsen 1974).
- Polymer HDT decreases with applied stress. The major cause of this effect is the decrease of modulus with temperature with the consequent greater deformation at the higher temperature for a given load. HDT occurs, by definition, at

Table 10.18 Effect of annealing time on HDT and flexural modulus of PPCP: EPDM (10 wt%) blend (HDT was tested at 4.55 kPa) (Sarcar 1989)

Test	Value obtained after annealing (h)		
	0	3	6
Heat deflection temperature (K)	330.0	343.0	349.4
Flexural modulus (MPa)	805.2	882.2	889.8

Table 10.19 HDT of some alloys with and without reinforcement for car body panels and bumpers (Moro et al. 1988)

No.	Blend	HDT (K); ASTM[a] tests at 455 kPa
1.	PPE/PA (NORYL GTX 900)	456

a constant deformation. The deformation is proportional to the load and inversely proportional to the modulus. HDT values of some commercial polymer alloys are given in Table 10.19.

10.5.5 Vicat Softening Point

The effect of temperature on the mechanical properties of plastic materials has a fundamental role in the selection of materials. Unlike metals and ceramics, plastics are extremely sensitive to the slightest changes in temperature. The selection of plastics for applications under different temperatures is a complex task. The plastic material must be able to support a stress under operating conditions without getting distorted. The effect of temperature on geometrical stability and mechanical properties in general can be studied following different procedures and methods like at constant temperature or with a temperature ramp.

The Vicat softening temperature (VST) is standardized in ISO 306 and ASTM D 1525. It is very useful as a quality control or development tool (ASTM D1525-2009). (This test method is technically equivalent to ISO 306:1987(E)). The result is a measure of the temperature at which thermoplastics begin to rapidly soften. VST describes the temperature at which a circular indenter with a cross section of 1 mm^2 under a standardized loading of 10 N or 50 N penetrates exactly 1 mm into the specimen. VST was introduced to measurement technology as a substitute value for melting point. VST for some common polymers are presented in Table 10.20.

The apparatus for testing VST consists of a temperature regulated oil bath with a flat-ended needle penetrator so mounted as to register degree of penetration on

Table 10.20 Vicat softening temperatures for some common polymers

	(1 kg load)
Plastics	Measured value (K)
PS	375.5

Table 10.21 Four different methods used for testing VST

	Load (N)	Heating Rate (K/h)
A50	10	50
B50	50	50
A120	10	120
B120	50	120

a gauge. A specimen is placed with the needle resting on it. The temperature of the bath (preheated to about 323 K lower than anticipated Vicat softening point) is raised at the rate of 323.0 K/h. or 393.0 K/h. The temperature at which the needle penetrates 1 mm is the Vicat softening point. For the Vicat A test, a load of 10 N is used. For the Vicat B test, the load is 50 N. The test conditions are summarized above in Table 10.21.

The test specimen must be between 3 and 6.5 mm thick and at least 10 mm in width and length. No more than three layers may be stacked to achieve minimum thickness.

Traditionally silicone oil has been the most popular medium for performing HDT and VST tests on polymers. They can be used safely only up to a maximum temperature of 553 K.

An alternative medium is required to test high-temperature polymers, such as PEEK, PEI, etc., as they have HDTs and VSTs higher than the temperature at which silicone oil can be used. "CEAST HV500," which utilizes an aluminum oxide fluidized bath, is used to perform a range of HDT and VST tests for both high- and low-temperature applications. Engaging "CEAST HV500" different grades of PEEK, PS, PC, PA, and PPS incorporated with 40 % glass fillers and PP with 15 % glass fillers were tested, at temperature ramps of 323 K/h and 393 K/h:

- VST is a measure of how much a plastic material would soften with increasing temperature. The higher the VST, the higher the temperature necessary for lamination and higher is the service temperature.
- Standard PVC card films (homopolymer) have a VST of 349 K. To achieve high VST values, special blends of PVC/ABS card films (0.25–0.8 mm thick) are engaged. High-VST (364 ± 2 K) cards are required in environments with high temperatures and stress. Applications include SIM (GSM) cards and pay TV cards.
- Apart from its practical applicability, VST is also used in studying the "miscibility" of polymer blends. Miscibility of PVC/PMMA blends was studied by determining

Table 10.22   Glass transition temperatures of some common polymers

Polymer family	Glass transition temperature	
	(°C) (Approx.)	(K) (Approx.)
PCTFE	120–215	393–488
PTFE	130	403
PS	100	373
PMMA	100	373
PVC	90	363
PET	70	343
PA(nylon)	50	323
ROOM TEMP.	20	293
POM	−15	258
PP	−20	253
PVDF	−45	228
PE-LD	−120 to −100	153–173

the VST of blends. The plot of VST against composition exhibited a continuous curve which revealed miscibility of the blend. This was further confirmed from the study of viscometry, DSC, and FTIR analysis of the blends (Kamira and Naima 2006).

- α-Methylstyrene-acrylonitrile copolymers (AMSAN) are highly compatible with PVC and have a high glass transition temperature. Trials with proportions of AMSAN in the blend confirmed that the Vicat temperature of the blends can be raised by adding this copolymer. For every 10 % by weight of AMSAN added, the Vicat temperature increased by approximately 4 °C (Gottschalk 2006).

10.5.6   Low-Temperature Brittle Point

For most materials low temperatures present a challenging environment and plastics are no exception. Most polymers at room temperature show their familiar properties of flexibility (a low Young's modulus) and high resistance to cracking, but when the temperature decreases, this can change rapidly and many common polymers become brittle with low failure stresses. Low temperatures can be more harmful to plastics than high temperatures. Catastrophic failures can occur if materials selection does not take account of the low-temperature properties of plastics.

Brittle fracture takes place by rapid crack propagation. For most brittle crystalline materials, crack propagation corresponds to the successive and repeated breaking of atomic bonds along specific crystallographic planes, known as cleavage. Cleavage is essentially a low-temperature phenomenon, which can be eliminated if a sufficiently high deformation temperature is used.

The actual value of glass transition temperature (T_g) for real polymers will vary greatly with the specific molecular structure of the base polymer, the molecular weight and the molecular weight distribution of the polymer, the additives incorporated into the mix, and a variety of other factors. Table 10.22 above gives some

typical values of T_g for some common polymers (but these should be regarded as indicative rather than definitive). Polymers that have a T_g greater than room temperature are in glassy state at room temperature, and examples of these are plastics such as PS, PMMA, and PET. These polymers tend to be brittle and easy to break at room temperature. PVC is in the glassy state at room temperature but is a special case because it can be easily modified to be rubbery by the addition of plasticizers (Zeus 2005).

The brittle point test developed by the Bell Telephone Laboratories is simple and sensitive. It is believed that this test may be used to study all cold-resistance problems where damage to the rubber itself and not increase in stiffness is the first consideration.

The "slow-bend brittle point test" does not have the same practical significance as the Bell Telephone Laboratories' brittle point test because most rubber articles which are exposed to low temperatures in service are required to withstand fairly rapid flexing. If the slow-bend brittle point test were used as a criterion of the cold resistance of these rubber articles, it might qualify the rubbers for a lower temperature than they could safely withstand in service (Morris et al. 1944).

ASTM D746-07 describes the Standard Test Method for Brittleness Temperature of Plastics and Elastomers by Impact. It employs three types of specimens. In this method the brittleness temperature is determined by immersing the specimens in a bath containing a heat transfer that is cooled, usually by liquid nitrogen, carbon dioxide, or powdered dry ice, to a predetermined temperature for a period of three minutes. The specimens are then impacted by a device having a striker of a specific geometry, under defined conditions of velocity, distance, and energy. The test temperatures are varied over a range and the brittleness point is defined as that at which 50 % of the specimens fail. This test provides for the evaluation of long term effects, such as crystallization, or the incompatibility of plasticizers incorporated in the material when subjected to subnormal temperatures (ASTM D746-07). This test, however, does not, necessarily, determine the lowest temperature at which the subject material may be used. The results may be used to predict the behavior of plastic and elastomeric materials at low temperatures.

ASTM D1329-08 offers Standard Test Method for Evaluating Rubber Property–Retraction at Lower Temperatures (TR Test). The other related Methods for Temperature Retraction (TR) Test are ISO 2921, BS 903-A29 (UK), and NF T4NF T46-032 (France). This test method describes a temperature-retraction procedure for rapid evaluation of crystallization effects and for comparing viscoelastic properties of rubber and rubberlike materials at low temperatures. This test method is useful when employed in conjunction with other low-temperature tests for selection of materials suitable for low-temperature service (ASTM D1329-08). This is more commonly known as a TR-10; this temperature-retraction test is considered by many within the rubber industry to be the most useful indicator of a material's low-temperature performance. In a nutshell, the TR-10 measures material resilience. Samples are frozen in a stretched state and then gradually warmed until they lose 10 % of this stretch (i.e., retract by 10 %). The results of such tests are believed to provide a good basis for evaluating the effects of crystallization and the impact of low

temperatures on viscoelastic properties. TR-10 results are generally thought to be consistent with the capabilities of most dynamic seals. Static seals can often function at 15 °F/8 °C/281 K below the TR-10 temperature (Hudson 2011).

ASTM D2137-11 provides Standard Test Methods for Rubber Property – Brittleness Point of Flexible Polymers and Coated Fabrics. Related Methods for Brittleness Point Test are ISO 812, DIN ISO 812 (Germany), and BS 903-A25 (UK). These test methods cover the determination of the lowest temperature at which rubber vulcanizates and rubber-coated fabrics will not exhibit fractures or coating cracks when subjected to specified impact conditions (ASTM D2137-11).

Unlike the changes that result from exposure to high temperatures, changes brought about by low-temperature exposure are generally not permanent and can often be reversed once heat returns. For example, extended exposure to low temperatures will increase an elastomer's hardness, but the material will soften again when the temperature rises. Perhaps the most important consideration related to low temperatures involves seals which must also work in a low-pressure environment. Unless the selected seal compound is sufficiently soft and resilient, the combination of low temperature and low service pressure can cause leakage and failure (Hudson 2011).

The brittle–ductile transition temperatures of some commercial polymers, blends, and composites are given in Table 10.23.

10.5.7 Melt and Crystallization Parameters (Using DSC)

Differential scanning calorimeter (DSC) can be used to ascertain melting point, degree of crystallinity, and glass transition temperature or for component quantification of polymeric materials. For some materials – such as crystalline polymers and certain organic chemicals –DSC is used to measure melting points and degree of crystallinity. For amorphous polymers, rubbers, and cross-linked thermoset materials, DSC also provides a fast and accurate measure of the glass transition temperature or the degree of cure.

In a DSC experiment, when a polymer is heated, as it reaches its melting temperature (T_m), the polymer crystals begin to melt. The polymer chains come out of their ordered arrangements and begin to move around. When the polymer crystals melt, they absorb heat in order to do so. Melting is a first-order transition. This means when polymer reaches its melting point, the polymer's temperature does not rise until the crystals melt off. This also means that the furnace has to put up additional heat into polymer in order to melt both the crystals and keep the temperature rising at the same rate as that of the reference pan. This extra heat flow during melting shows up as a large dip in DSC plot as heat is absorbed by the polymer. The temperature at the apex of the peak is taken as the point where the polymer is completely melted. And the area under the peak gives the heat of melting of the polymer. As energy is added to the polymer to make it melt, melting is considered as an endothermic transition (Daniels 1973; Turi 1981).

An understanding of the degree of crystallinity for a polymer is important since crystallinity affects physical properties such as storage modulus, density,

Table 10.23 Low-temperature brittle point of some rubbers (Lindsay 2010)

Properties	Ethylene propylene diene	Nitrile rubber	Poly-chloroprene	Natural rubber	Poly-isoprene	Styrene butadiene rubber	Butyl rubber	Polybutadiene

Low-Temperature brittle point, K	215	222	219	215	215	215	215	200

permeability, and melting point. And melting point in turn influences the processing temperature. While most of these manifestations of crystallinity can be measured, a direct measure of degree of crystallinity provides a fundamental property from which these other physical properties can be predicted.

Polymer crystallinity can be determined with DSC by quantifying the heat associated with melting (fusion) of the polymer. This heat is reported as "% crystallinity" by taking ratio against the heat of fusion for a 100 % crystalline sample of the same material or more commonly by taking ratio against a polymer of known crystallinity to obtain relative values.

If ΔHf is equal to area under the melting peak, then ΔHf is proportional to % crystallinity:

$$\% \text{ Crystallinity} = \left[\frac{\Delta Hf}{\Delta H^* f}\right] \times 100 \tag{10.30}$$

where ΔH^*f is ΔHf of 100 % crystalline polymer.

In case of polyethylene, $\Delta H^*f = 68.4$ cal/g;

In case of polypropylene, $\Delta H^*f = 209.3 \pm 29.9$ J/g.

(These values of ΔH^*f are reported to be widely varying from one laboratory to another for the same polymer.)

An empirical relationship between T_g and T_m of a polymer is given as follows: $T_g/T_m \sim 0.6$

(Here, T_g and Tm are to be taken in Kelvin).

When a semicrystalline polymer, such as polypropylene, cools from melt, the polymer chains begin to form crystals at foreign particles in the melt (Wunderlich 1990). The completely solidified PP part is typically about 60 % crystalline and 40 % amorphous. These crystals exhibit a peak melting temperature (via DSC) of about 438 K. When nucleating agents are incorporated into the PP, the number of sites where crystal growth can start is dramatically increased. This means that the part will crystallize more rapidly in the mold and will also achieve a higher final level of crystallinity. The faster crystallization rate results in faster setup in the mold, and reduced cycle times, while the higher crystallinity results in increased part stiffness.

Another side benefit that accompanies with the use of certain nucleants is improved clarity. Since clarity or transparency is evidently related to the crystalline structure of the polymer and the structure is determined by the conditions of crystallization, parameters characterizing crystallization must be also connected with the optical properties of a PP product. The peak temperature of crystallization (T_c) is one of the quantities often used for the characterization of the crystallization process and efficiency of nucleating agents. With increased crystallization temperature, the thickness of the lamellae increases well. Higher efficiency and concentration of nucleating agent lead to an increase of T_c (as determined by DSC) and decrease of the size of the spherulites.

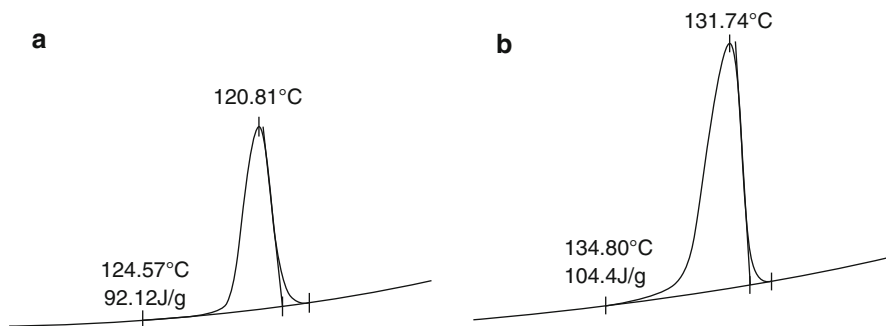
Figure 10.54a and b illustrate the shift in T_c for polypropylene homopolymer with the addition of a nucleating agent.


Fig. 10.54 Crystallization exotherm for (**a**) neat PP homopolymer and (**b**) PP with nucleating agent (Xavier 2002)

10.5.7.1 Crystallization of Polypropylene Homopolymer (PPHP)
Influence of Nucleating Agent, Millad-3988

Semicrystalline polymers, such as PPHP, display different microstructural features due to the factors like (i) the presence of various additives (Kopp et al. 1994), (ii) depending upon their processing history (Lotz 2003), and (iii) strain in solid (Butler and Donald 1997) as well as melt (Pople et al. 1999) phases. Many methods are being applied to modify the polymers in order to attain high-performance properties. Properties modification by incorporation of additives in polypropylene and its related polymers is observed to be particularly common.

In polypropylene, the crystallization results in large size spherulites, and hence inclusion of heterogeneous nucleating agents is often adopted to improve mechanical properties (Quande Gui and Weiping Zhu 2003) or to reduce optical haze (Gahleitner et al. 1996; Zhao and Dotson 2002). Hence, providing such heterogeneous nucleation is an essential consideration. Creation of various crystallographic phases, differed by the unit cells as well as by the spherulites, is known to be a result of the heterogeneous nucleation (Lotz 2003).

Nucleating efficiency is normally determined isothermally from crystallization half-time, by use of peak crystallization temperature of the nucleated system measured during cooling and compared with that of the neat polymer. The peak crystallization temperature technique is based on a single-point observation. Fillon et al. proposed alternate approach for the evaluation of nucleating efficiency using two dynamic reference points to understand the crystallization behavior of a polymer (Fillon et al. 1993). These two reference points include (i) polymer's crystallization temperature when crystallized normally and (ii) the same when polymer nucleated ideally.

In order to obtain an ideally nucleated polymer, it is heated to just above its melting point so that large number of residual crystal fragments exist in the melt and act as nuclei. This method is referred to as self-seeding or self-nucleation (Blundell 1966). Zhao et al. have evaluated crystallization behavior of propylene/ethylene copolymer by self-seeding approach (Zhao et al. 2001), which was found in good agreement with the earlier published DSC data (Laihonen et al. 1970, 1997).

Millad-3988 is a breakthrough "clarifying agent" for PP. Use of this additive in properly formulated and processed PP gives improved transparency, increased resin throughput, productivity gains, and enhanced physical properties.

DSC investigations were carried out (Fig. 10.55) using PPHP granules as well as fast cooled compression-molded sheets with three different concentrations of Millad-3988 (0.07, 0.14, and 0.21 wt%) in order to see whether the molding conditions would play a role and thus influence the DSC data in comparison to the data obtained using plant supplied granules. The properties of PPHP with different concentrations of Millad-3988 are shown in Table 10.24. From the Table 10.24, it is clear that T_m values for sections cut from the sheets were always less than their corresponding values obtained using granules. In fact, T_c also showed the same trend. The difference between T_m and T_c (i.e., $T_m - T_c$) gradually reduced with increasing concentration of Millad-3988. This behavior is more systematic in case of the sheets. However, T_{onset} which indicates the crystallization "onset" is found to be gradually enhanced with Millad-3988 concentration. The degree of crystallinity, as determined by X-ray diffraction, also gradually increased with increasing concentration of Millad-3988.

The crystallinity (%) of PPHP increases with increasing Millad-3988 concentration, which also influences the surface gloss of polymer sheets to increase (as observed in Haze meter measurements, not presented here). However, the transmission (%) (as measured by the Haze meter) does not undergo the same pattern of change. In fact the transmission (%) was found to be maximum for PPHP sheet with Millad-3988 concentration 0.07 wt% followed by the one with 0.14 and 0.21 wt%. It is interesting to note that the transmission (%) for neat PPHP (87.1 %) is not much different from that with maximum transmission (88.6 %) with Millad-3988 of 0.07 wt%.

10.5.8 Oxidative Induction Time

Oxidative induction time (OIT) provides an index useful in comparing the relative resistance to oxidation of a variety of hydrocarbon materials. The OIT procedure was first developed in 1975 by Gilroy and coworkers at Bell Laboratory as a test procedure to screen polyethylene insulation used in telephone wire and cable for its oxidation resistance. The method first became available as a Western Electric Specification and later as ASTM Test Method for Copper-Induced Oxidative Induction Time of Polyolefins. Polyolefin manufacturers quickly embraced the procedure and began to apply it to other applications including raw resins, finished pipes, wire and cable insulation, and, most recently, geosynthetic waste pit liners (ASTM D3895 2009).

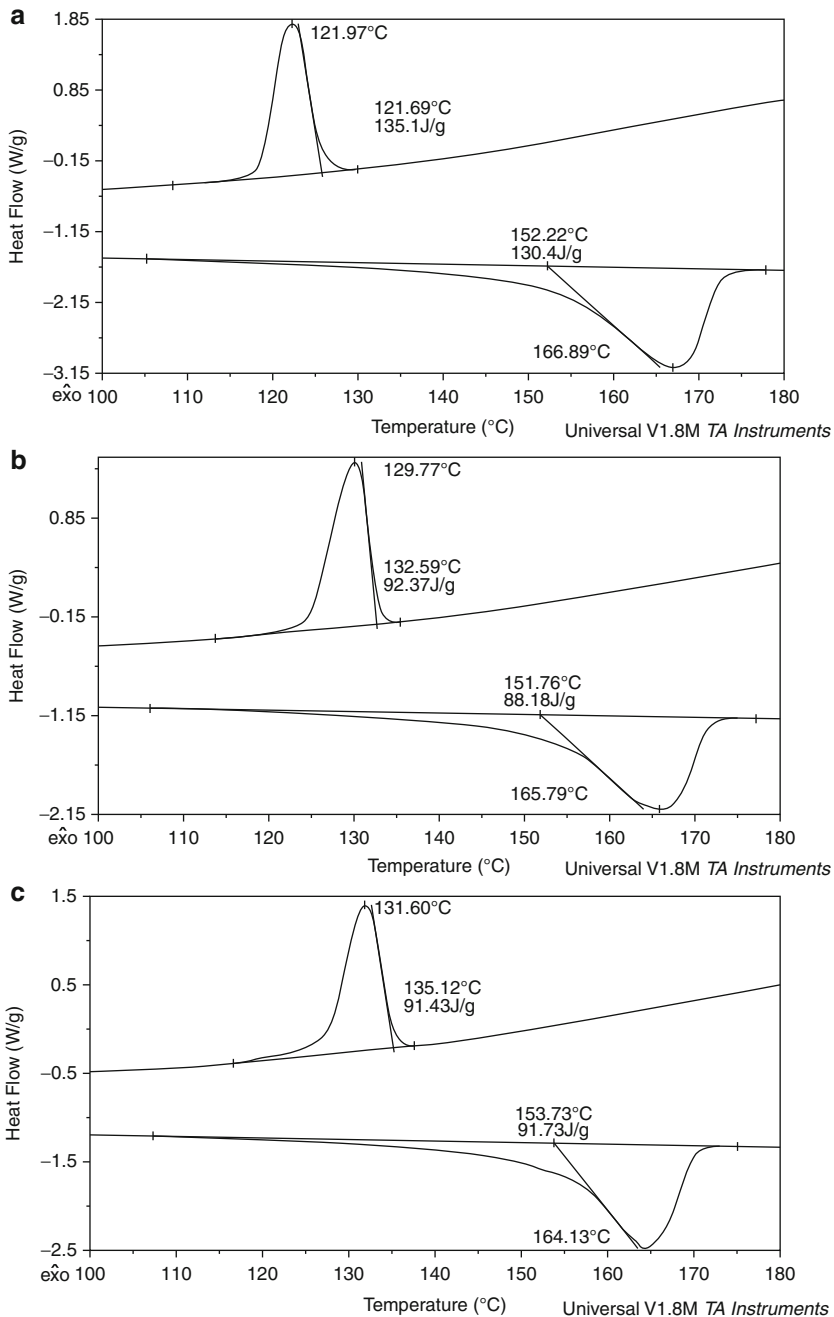
The test consists of heating a specimen to an elevated temperature (often 200 °C) in a DSC. Once temperature equilibrium is established, the specimen atmosphere is changed from inert nitrogen to oxidizing air or oxygen. The time from first oxygen exposure until the onset of oxidation is taken as the OIT value. This general procedure is applied, for example, to polyethylene wire insulation, edible oils, lubricating oils and greases, and geosynthetic barriers. Most materials are tested to measure the


Fig. 10.55 DSC thermograms of PPHP + Millad-3988 at different concentrations (**a**) 0.07 wt%, (**b**) 0.14 wt%, and (**c**) 0.21 wt%, carried out using sections cut from ∼0.7 mm thick, fast cooled, compression-molded sheets (Pendyala et al. 2004)

effectiveness of the antioxidant package added to improve lifetime, although a few materials (e.g., edible oils) are tested in their natural, non-fortified state.

The onset of oxidation is taken as the endpoint for the OIT measurement. Two means of determining the oxidation onset are in use (Blaine et al. 1997). The most common is the "extrapolated onset" in which the tangents are drawn at the point of maximum rate of oxidation and the baseline prior to oxidation (say 0.05 W/g). The endpoint for the OIT determination is taken at the point where the exothermic event crosses that threshold. If the oxidation exotherm is sharp, these two endpoint indicators produce similar results as seen in Fig. 10.56. However, some materials seem to have a multistaged oxidation, and the endpoint established by the two experimental procedures may be quite different as shown in Fig. 10.57 (Blaine et al. 1997). The selection of the method of determination of the OIT endpoint is the first parameter affecting the comparison of results from one laboratory to another. Apart from this, OIT values are influenced by temperature, oxygen flow rate, oxygen pressure, catalysts (sample pan materials), sample mass and form, and time, which will be discussed below.

10.5.8.1 Parameters Influencing OIT

OIT has been proved to be a useful diagnostic tool in assessing the extent of degradation in the polymer insulation of electric cables. Sample preparation and test conditions are parameters recognized to influence OIT results obtained by DSC. However, quantitative results on the variability of OIT as a function of these parameters have not been presented systematically in the literature.

Factors that influence OIT include test temperature, sample preparation, sample geometry, sample mass, particle size, thermogram interpretation, shelf life, heating rates to reach the isotherm, and oxygen flow. The influence of these parameters was investigated using a two level factorial design using HDPE samples (Rosa et al. 2000). Sample shape, amount of sample, and heating rate were the parameters that showed significant variability.

Fig. 10.56 Single stage
oxidation endpoint
determination (Xavier 2002)
Fig. 10.57 Multistage
oxidation endpoint
determination (Xavier 2002)
The effects of these parameters and cross-linking in polymer cable insulations, aged in radiation and thermal environments, were investigated. The results were then used to recommend standards for an OIT methodology suited for practical use, including the nuclear power industry. Techniques to estimate error in (O.I.T.) thermograms interpretation and reproducibility were also developed (Mason and Reynolds 1997).

A HDPE film, lightly stabilized with Irganox 1010 and a hindered phenol antioxidant, was proposed as a Standard Reference Material for OIT testing by Blain and Harris of TA Instruments, Inc. The mean OIT values, derived from nine interlaboratory studies and for a number of experimental conditions, were presented (Blaine et al. 1997). The material was found to be statistically homogeneous, a necessary condition for a reference material. The effects of temperature, oxygen pressure, and storage time on the proposed reference material were also explored. As a kinetic parameter, the OIT value appeared to be decreasing with time but in a well behaved and predictable manner. Because the material had been thoroughly tested in a wide variety of OIT conditions, it appeared to be the best available candidate and was offered for consideration as an OIT Reference Material (Blaine et al. 1997).

Oxidation is generally recognized as the key degradation mechanism regarding the long-term durability of HDPE geomembranes. For protection against oxidation during their service lifetime, antioxidants are added. A laboratory accelerated

aging program was conducted to assess the depletion of antioxidant from a Korean HDPE geomembrane subjected to air oven aging followed by incubation in acidic and alkaline buffer solutions at three different temperatures. The changes in OIT were monitored at selected time intervals. The results indicated that for samples subjected to oven aging incubation for 90 days, the OIT results showed that the geomembrane had enough antioxidants to ensure long-term oxidation stability. Immersion in the alkaline buffer solution was found to accelerate the antioxidant depletion rate relative to that observed in the acidic buffer solution. Greater depletion rates were recorded at higher temperature, indicating the temperature dependency of the depletion process. Conservative values of the depletion time ranged from 107 to 9 years depending on temperature and exposure condition. The estimated antioxidant depletion times were longest for exposure to acidic solutions and shortest for exposure to alkaline solutions (Jeon et al. 2008). These studies support the idea to use HDPE as a reference material for studying O.I.T.

10.5.8.2 O.I.T and O.O.T

Two different methods of studying O.I.T. are used in practice: dynamic and isothermal tests. In the dynamic technique, the sample is heated at a defined constant heating rate under oxidizing conditions until the reaction begins. The Oxidation Induction Temperature (O.I.T.) (also called Oxidation Onset Temperature (O.O.T.)) is the same as the extrapolated onset temperature of the exothermal DSC effect which occurs. In isothermal tests, the materials to be investigated are first heated under a protective gas and then held at a constant temperature for several minutes to establish equilibrium and subsequently exposed to an atmosphere of oxygen (or air). The time span from the first contact with oxygen until the beginning of oxidation is called the Oxidation Induction Time (OIT) (NETZSCH).

The procedure for the preparation, implementation, and evaluation of measurements is described in detail in national and international standards such as ASTM D3895 (polyethylene), DIN EN 728 (plastic pipelines), or ISO 11357-6 (plastics). Generally, either open crucibles or crucibles with multiple piercings in the lids are used. For polyolefins like PE or PP, a longer OIT allows one to conclude that the oxidation stability is better and the lifetime therefore longer.

10.5.8.3 OIT Measurements Using TGA

The measurement of OIT based on TGA was used for monitoring the re-stabilization of post-use LDPE samples, subjected to multiple extrusion cycles. This method has abilities and limitations as well which are discussed in literature (Kyriakou et al. 1999). The use of a re-stabilization system improved the oxidative stability of LDPE. A linear calibration curve correlating OIT values to the amount of re-stabilization system was obtained. Nevertheless, limitations concerning quantitative determinations appeared to exist, as a change in the behavior of re-stabilization system during subsequent re-melting cycles was observed.

10.5.8.4 TOIT: A New Method

OIT's oxidation condition is considered as very harsh especially in case of pure and irradiated polymers, particularly PP. PP undergoes pronounced molecular weight degradation in the course of processing and is prone to very fast oxidation and consequently very fast degradation, especially on samples submitted to previous aging and irradiation.

Lugao and his group had introduced a new procedure to determine OIT in non-stabilized, stabilized, irradiated, and nonirradiated PP. The new procedure was based on two main features: (1) starting the oxidation on melted samples at temperatures as low as possible and (2) oxidation under slow heating conditions. Since each sample has a set of two values of time and temperature, it is called as "temperature-dependent oxidative induction time." This new method is found to be reproducible, sensitive (to small changes in additive compositions), simple, and inexpensive (Lugao et al. 2002).

10.5.8.5 High Pressure OIT

A series of high pressure oxidative induction time measurements (HPOIT) were conducted on a PE geomembrane sheet in order to investigate the interaction of the pressure and temperature variables on the induction time. The experiments consisted of determining the HPOIT at constant cell volume employing a wide operational range of pressure and temperature values. The HPOIT test results were found to be inversely related to both variables, with temperature being the predominant factor (Tikuisis et al. 1985).

10.5.9 Thermal Degradation (Using TGA)

Thermogravimetry (or thermogravimetic analysis, TGA) is one of the oldest thermo-analytical procedures and has been used extensively in the study of polymeric systems. The technique involves monitoring the weight loss of the sample in a chosen atmosphere (usually nitrogen or air) as a function of temperature. It is a popular technique for the evaluation of the thermal decomposition kinetics of polymeric materials and hence provides information on thermal stability and shelf life. However, it is well known for its ability to provide information on the bulk composition of polymer compounds.

In the analysis of polymer compounds, the sample is initially heated in a nitrogen atmosphere. Heating under nitrogen ensures that no oxidation reactions take place. Additives are lost first, in order of decreasing volatility, and then the polymer fraction will undergo thermal degradation and volatilizes off. Once the entire polymer has thermally degraded, the species remaining in the TGA pan (which can include, carbon black, inorganic fillers and carbonaceous residue from the breakdown of the polymer) can be examined. This is achieved by changing the atmosphere to air and heating to around 1,273 K. Weight loss events can be
Fig. 10.58 TGA thermograms of ~0.7 mm thick compression-molded specimens of neat PPHP and its compositions with different nucleating agents carried out at a heating rate of 10 K/min in static air (Pendyala et al. 2004)

observed for the oxidation of carbonaceous residues and carbon black and the decomposition of inorganic fillers, such as calcium carbonate. At the end of the analysis an amount of stable inorganic residue will remain. This procedure will enable the amount of plasticizers, polymer, carbon black, and inorganic species to be quantified to an accuracy of at least ~0.5 %.

Although certain additives can be quantified by techniques such as solvent extraction and dry ashing, the advantage of TGA is that only 5–10 mg of sample is required. In recent years the benefits of coupling TGA instruments to either an infrared spectrometer or a mass spectrometer have been appreciated. This enables both qualitative and quantitative data to be obtained in a single analytical experiment. Here, how TGA can be used to evaluate different commercial nucleating agents by studying the thermal stability imparted to the polymer is illustrated below.

10.5.9.1 Thermal Degradation of Polypropylene Homopolymer (PPHP)

TGA of PPHP with and without commercial nucleating agents (Millad-3988 and three other selected nucleating agents) is shown as overlay in Fig. 10.58 and thermal characteristics are shown in Table 10.25. The thermal stability of a polymer is, generally, influenced by various factors such as bond strength, activation energy, cross-linking, presence of low molecular weight/volatile material and weak links, etc.

Table 10.25 Thermal characteristics of PPHP[a] and its compositions with different commercial nucleating agents (Pendyala et al. 2004)

	Composition	Decomposition temp. at K		T_{onset}		$T_{inflection}$	
		10 wt% loss	50 wt% loss	°C	K	°C	K
1	PPHP	247.00	288.20	219.96	492.96	279.01	552.01
2	PPHP + Millad-3988 (0.14 %)	249.70	309.92	213.43	486.43	297.68	570.68
3	PPHP + Millad-3988 (0.21 %)	250.10	303.24	215.00	488.00	297.68	570.68
4	PPHP + NA-11UH (0.07 %)	258.80	304.28	222.66	495.66	301.46	574.46
5	PPHP + Richyu-2868 (0.21 %)	262.60	297.40	221.28	494.28	276.09	549.09
6	PPHP + Kafrit-POA20 (0.21 %)	272.50	311.38	222.73	495.73	312.62	585.62

[a] ∼0.7 mm thick compression-molded sheets were used for analysis

The factors influencing thermal stability are to be considered prior to its evaluation. It is observed that the polymer may retain its "usefulness" when half of its strength is retained after one hour of exposure to a specified temperature and that the limit is reached with a weight loss of 10 wt% (Eirich and Mark 1961). This limit is based on many assumptions and it varies with the polymer. Polymer material's decomposition criterion is established by recording the temperatures: (a) at 10 % and 50 % decompositions and (b) at the maximum rate of decomposition (Mark and Gaylord 1971).

From Table 10.25, it is found that neat PPHP indicated loss of 10 % weight at 520 K. The incorporation of Millad-3988 in PPHP, in the concentration range of 0.14–0.21 wt%, showed a marginal increase in the temperatures for 10 % weight loss (∼523 K). However, PPHP in presence of the selected commercial nucleating agents (NA-11UH 0.07 %, Richyu-2868 0.21 %, and Kafrit-POA20, 0.21 %) exhibited significant increase in the temperatures (531.80–545.50 K) for 10 % weight loss. Similarly for the 50 % weight loss, PPHP degradation temperatures are found to be enhanced in the presence of Millad-3988 as well as the other selected nucleating agents. From their thermograms shown in Fig. 10.58, it is observed that the decomposition is occurring in single stage for PPHP and a similar behavior is observed in presence of Millad-3988 as well as the other selected commercial nucleating agents.

The onset of thermal decomposition, T_{onset}, of PPHP is found to be 492.96 K (Table 10.25). With the incorporation of commercial nucleating agents, it is observed Millad-3988, in the concentration range of 0.14–0.21 %, reduced the onset temperature of PPHP (∼5–7 K) while the other selected nucleating agents enhanced it and that enhancement is higher than that offered by PPHP with the incorporation of Millad-3988. $T_{inflection}$ temperatures, at which the rate of decomposition is maximum, for PPHP incorporated with Millad-3988 (555.54–570.68 K), are found to be higher than that of neat PPHP (552.01 K); among the selected three commercial nucleating agents, PPHP incorporated with NA-11UH (574.46 K), with Richyu-2868 (549.09 K), and with Kafrit-POA20 (585.62 K) indicated significant improvement in their thermal stability except Richyu-2868. It is observed that Kafrit-POA20 offered the highest improvement of thermal stability for PPHP

among the nucleating agents tried. From the above study, the commercial nucleating agents imparting thermal stability to PPHP is in the following order (Pendyala et al. 2004):

$$Kafrit - POA20(0.21\%) > NA - 11UH(0.07\%) > Millad - 3988\ (0.21\%) >$$
$$Millad - 3988(0.14\%) > Richyu - 2868(0.21\%).$$

10.5.10 Review of Blends' Thermal Properties

Owing to the absence of electronic effects in most polymers, heat conduction occurs as a result of lattice vibrations, similar to dielectrics. It is known that the thermal conductivity of an amorphous polymer increases to T_g with increasing temperature while it decreases above T_g (Godovsky 1992). Thermal conductivity is a fundamental and important factor in processing polymer blends (Agari 1992).

Influence of miscibility on thermal conductivity and diffusivity was studied (Agari 1993, Agari and Ueda 1994). In the blend of low molecular weight PS with coumarone–indene resin, which showed miscibility over all blend compositions, the thermal conductivity was approximately linearly dependent on composition (Agari 1993). Thermal conductivity, thermal diffusivity, and heat capacity of PMMA/PC blends were studied with respect to temperature and blend composition. The specific heat capacity of the two-phase 50/50 blend was larger than that of the one-phase blend. The thermal diffusivity and the conductivity of the 50/50 blend slightly decreased with the increase of temperature up to 450–460 K (LCST) and then decreased abruptly with increase of temperature (Agari et al. 1997).

Several investigators (Krause et al. 1982; Schultz and Young 1983; Rodriguez-Parada and Percec 1986) had used the specific heat increment (ΔC_p) to investigate the polymer–polymer miscibility by DSC.

The effect of molecular weight of PMMA on the miscibility of PMMA/PS blends was examined by studying the specific heat increment ΔC_p at T_g (Burns and Kim 1988). Using Couchman's equation, C_p for PMMA was calculated and was found to decrease with the composition of PS (Couchman 1978). The C_p for PS similarly decreased with PMMA composition. From these results the authors inferred that some of the PMMA dissolved in the PS phase and vice versa. Thus, the blends were found to be partially miscible. This result was found to be consistent with the polymer–polymer interaction parameter values. The authors also studied the PC/SAN blends miscibility by the thermal analysis (Kim and Burns 1988). The values of the specific heat increment ΔC_p at T_g for PC and SAN in PC/SAN blends were measured. For PC, C_p decreased linearly with addition of SAN. For SAN, C_p also linearly decreased with addition of PC. This suggested that some of the PC dissolved in the SAN-rich phase and *vice versa*.

Thermal studies have become important tools for understanding various basic phenomena in polymer blends and composites all over the world. The changes in crystallization kinetics of polymer blends in comparison to the

parent polymers involved the way a compatibilizing polymer interferes with the crystallization kinetics, and if a reinforcing filler or fiber is introduced into the same system, how the kinetics are getting affected is more a curious situation and it is not easy to make simple predictions without conducting experiments on DSC. The thermal stability of a blend after introducing a compatibilizer needs to be elucidated.

The literature available with such studies is also vast and also several books dedicated to thermal analysis alone are appearing time to time; hence, it is not possible to really justify such a presentation here. Nevertheless, some illustrative examples of such studies are given here in Table 10.26. The reader is advised to go through the desired literature.

10.6   Flammability

10.6.1 Standard Methods of Measurement

There are two types of tests, viz., burning and combustion toxicology tests. The burning tests aim at determining either the burning characteristics or the burning rate. The combustion toxicology tests aim at measuring the types and quantities of toxic gases that evolve during burning and smoldering of plastics and their effects on men and animals. A list of ASTM tests, the specimens, the purpose of each test, etc., is provided in Table 10.27.

Underwriters Laboratories (UL) provide Standards UL 94 Tests for Flammability of Plastic Materials for Parts in Devices and Appliances. The standard is important for classifying polymeric materials (including polymer blends and alloys) for the use in electrical applications. It is widely used and the results are reported in the literature and in company catalogues. However, the requirements are not applicable to polymeric materials used in building construction or finishing. The tests conducted under this standard are summarized below.

10.6.1.1 Horizontal Burning Test for Classifying Materials: 94 HB
The test uses small bar specimens: 127×12.7 mm. It is similar to ASTM D635. Materials classified under this test shall not have a burning rate exceeding either 38 or 75 mm/min over a 75 mm span, for specimen's thickness of, respectively, 12.7 or 3 mm. The materials must cease burning before reaching the 100 mm mark.

10.6.1.2 Vertical Burning Test for Classifying Materials: 94 V-0, V-1, V-2
The test specimen (127×12.7 mm, with maximum thickness 12.7 mm) is supported vertically by its upper end and is ignited at its lower end for 10 s by Bunsen/Tirril burner, in a draft-free area (see Fig. 10.59). If flaming or glowing combustion stops within 30 s after removal of the flame, the specimen is re-ignited for 10 s. The duration of the flame is again noted. In case the specimen drips flaming particles, they are allowed to fall into a layer of surgical cotton 0.3 m below the sample. The particles are considered significant if the cotton ignites.

Flammability ratings are based on the specimen behavior during the test, materials rated 94 V-0 being the most while those rated 94 V-2 being the least resistant to burning. Table 10.28 summarizes the test requirements.

10.6.1.3 Vertical Burning Test for Classifying Materials: 94 5 V

This test is more stringent than UL 94 V-0, V-1, and V-2. Here, 127 mm ignition flame is applied on specimen bars of dimensions 127×12.7 mm, with maximum thickness 12.7 mm. In Method A, a Tirril burner is positioned 20° from the vertical and the overall height of the flame is adjusted to 127 mm. The flame is applied for 5 s and removed for 5 s. The procedure is repeated five times. After the fifth removal of the flame, the duration of flaming and glowing, the distance the specimen burned, the

Table 10.27 Summary of ASTM test methods[a]

No	Test method	Specimen/sample	Purpose of the test	Comments
1.	ASTM D229-96 testing rigid sheet and plate materials used for electrical insulation	Flat sheet or plate form	Relative comparison of the ignition resistance of materials and the extent of burning	
2	ASTM D568 for rate of burning and/or extent of burning of flexible plastics in a vertical position	Flexible thin sheets or films	Relative comparison of rate of burning and/or extent and time of burning (of plastics)	Discontinued in 1991, not replaced
3.	ASTM D635-98 for rate of burning and/or extent of burning of self-supporting plastics in a horizontal position	Bars either molded or cut from sheets, plates, or panels	Relative comparison of average burning rate, average time of burning, and average extent of burning	This method combined with the best features of UL 94 resulted in writing of ASTM D3801
4.	ASTM D757 for incandescence resistance of rigid plastics in a horizontal position	Rigid plastic	Relative resistance to incandescent surface at $1,223 \pm 10$ K ($1,742 \pm 18$ °F)	Discontinued in 1966, no replacement
5.	ASTM D1433 for rate of burning of flexible thin plastic sheeting supported in a 45° incline	Flexible plastic in the form of film or thin sheeting	Relative rate of burning and/or extent and time of burning	Discontinued in 1987, replaced by D4549
6.	ASTM D1929-96 for ignition properties of plastics (Setchkin technique)		Determination of self-ignition, flash-ignition temperatures, and self-ignition by temporary glow	
7.	ASTM D2843-99 for density of smoke from the burning or decomposition of plastic		To measure smoke density across a 12 in. light path	For materials that excessively drip, auxiliary burner is used
8.	ASTM D2863-97 for measuring the minimum oxygen concentration to support candle-like combustion of plasticThe ratio $O_2/(O_2 + N_2)$ when multiplied by 100 is designated as the oxygen index (Imhof and Steuben 1974)	Various forms such as films, etc	To determine relative flammability of plastic by measuring the minimum concentration of oxygen in a flowing mixture of oxygen and nitrogen that will just support flaming combustion. The apparatus is shown in Fig. 10.60	Useful for determining the "Limiting Oxygen Index" of plastics. It has gone through several modifications

Table 10.27 (continued)

No	Test method	Specimen/sample	Purpose of the test	Comments
9.	ASTM D3014-99 for flame height, time of burning, and loss of weight of rigid cellular plastics in a vertical position	Rigid cellular plastics	Determining relative extent and time of burning	Revised to accommodate thermosets
10.	ASTM D3713 for measuring response of solid plastic to ignition by a small flame	A set of specimens of identical composition and geometry	To characterize the response of a plastic to a small flame of controlled intensity for quality control	Discontinued in 2000, no replacement
11.	ASTM D3801-96 for measuring the comparative extinguishing characteristics of solid plastics in a vertical position	Solid plastic material. A set of specimens with identical composition and geometry	Determination of comparative extinguishing characteristics	Combination of the best features of UL 94 and ASTM D635
12.	ASTM D3894 for evaluation of fire response of rigid cellular plastics using a small corner configuration	Rigid cellular plastic	Prediction of performance of a Factory Material Full-Scale Corner Wall Test	Discontinued in 1994 and not replaced
13.	ASTM D4100 for gravimetric determination of smoke particulates from combustion of plastic materials	Plastic material in a slab configuration	Gravimetric determination of smoke particulate matter produced from the pyrolysis of plastics	Discontinued in 1997 and not replaced
14.	ASTM E84-00 for surface burning characteristics of building materials	Any building material of dimensions 24 ft. × 20.25 in.	Determination of surface burning characteristics, e.g., of foam insulation	Suffers from several limitations. Also known as Steiner Tunnel Test
15.	ASTM E 119-00 methods of fire tests of building construction and materials	Full-size wall section	Determination of fire resistance of walls, floors, ceilings, roofs, etc	It is similar to UL 263 and NFPA 251
16.	ASTM E136-99 for behavior of materials in a vertical tube furnace at 705 °C	Building material test specimens of size 1.5 × 1.5 × 2 in.	Determination of combustion characteristics of building materials	
17.	ASTM E162-98 for surface flammability of materials using radiant heat energy source (Radiant Panel Test)	Specimen of dimensions 6 × 18 in.	Determination of flame spread index of a material	Intended for research and development only

[a]ASTM standard test methods are available on web: http://enterprise.astm.org/

Fig. 10.59 Test layout for classification in 94 V-0, 94 V-1 and 94 V-2 according to UL 94 (Troitzsch 1983)

SPECIMEN

BURNER

SURGICAL COTTON

(ca. 50•50•6.5)
dripping of particles from the specimen (during the test), and deformation of physical strength of the specimen immediately after burning (and when cooled) are observed.

When the specimen shrinks, elongates, melts, etc., additional tests are carried out using test plaques (152 × 152 mm) under Method B. These tests are conducted in various positions both vertical and horizontal positions of the plaques with flame applied to different places in the plaques, using the procedure as in Method A. The observations focus on the same items as in Method A.

Materials are classified 94-5V when:

- No specimen burns with flaming and/or glowing combustion (after the fifth flame) for more than 60 s.
- None specimen drips particles.

10.6.1.4 Flame Spread Index Test Using Radiant Panels

This test is conducted in accordance with ASTM E162 mentioned in Table 10.28.

10.6.1.5 Vertical Burning Test for Classifying Materials: 94 VTM-0, VTM-1, or VTM-2

Some materials due to their thickness distort, shrink, or get consumed up to the holding clamp, when tested according to the methods described above.

Table 10.28 UL 94 vertical burning test for classifying very thin materials (Landrock 1983)

No.	Requirement	Classification		
		94 V-0 (most severe)	94 V-1 (intermediate)	94 V-2 (least severe)
1.	Total flaming combustion time for 10 ignitions, maximum (sec)	50	250	250
2.	Individual flaming time, maximum (sec)	10	30	30
3.	Glowing combustion time (sec)	30	60	60
4.	Flame drippings	None	None	Allowed if burns briefly
Fig. 10.60 Oxygen index apparatus [Troitzsch, 1983]

VTM means "very thin materials" – test specimens are cut to 200 × 50 mm dimension. Each specimen is supported from the upper 6 mm of its length, with the longitudinal axis vertical using a heavy spring clamp. The lower end of the specimen is placed 9.5 mm above the top of the Bunsen burner tube and 0.3 m above a horizontal layer of dry surgical cotton. The test flame is placed under the lower end of the test specimen for 3 s. Then the flame is taken away from the specimen and the duration of specimen flaming is noted. When flaming of the specimen ceases, the test flame is applied once again for 3 s and then withdrawn.

The deviation of flaming and glowing of the specimen is noted. In case the specimen drips molten or flaming material, the burner may be lighted to angle up to 45°. The following are observed after the removal of the flame:

- Duration of flaming after first flame application
- Duration of flaming after second flame application
- Duration of flaming plus glowing after second flame application
- Whether or not specimens burn up to 127 mm
- Whether or not specimens drip flaming particles that ignite the cotton

94 VTM-0 classifies materials under most severe conditions. Table 10.28 summarizes the test requirements.

10.6.1.6 UL 746A-78 Polymeric Materials' Short-Term Property Evaluations

Test procedures for seven major areas are given in this standard. They are all applied for the determination of resistance of polymeric materials to ignition from electrical sources. The individual tests are Resistance to Hot Wire Ignition, Resistance to High-Current Arc Ignition, Resistance to High-Voltage Arc Ignition, and Resistance to Hot-Bar Ignition.

10.6.1.7 UL 746B-79 Polymeric Material Long-Term Property Evaluations

This standard deals with long-term tests for the evaluation of materials and parts of end products. Along with UL 94, UL 746A, and UL 746C, these tests provide data regarding the physical, electrical, flammability, thermal, and other properties of the materials under consideration.

10.6.1.8 UL 746C-78 Polymeric Materials' Use in Electrical Equipment Evaluations

This is the test procedure, including flammability, for parts of polymeric materials used in electrical equipment. It provides a table of short-term and long-term properties to be considered during evaluation of polymeric materials used in electrical equipment.

10.6.1.9 UL 746D-80 Polymeric Materials' Fabricated Parts

This standard is for blends of polymers, copolymers, terpolymers, and alloys. It considers plastic parts that have been produced under a material identity control system. Molders/fabricators are required not to employ such additives/flame retardants that would adversely affect critical material properties. A detailed discussion on national and international fire protection regulations and test methods for plastics is presented by Troitzsch (1983).

10.6.1.10 ASTM D2863 Measuring the Minimum Oxygen Concentration

The method provides means for the determination of relative flammability of plastics by varying the oxygen to nitrogen concentration. The oxygen indexer is shown in Fig. 10.60.

10.6.2 Factors Affecting Flammability

Application of a heat source, such as flame, raises the temperature of polymer and ultimately causes it to burn. Burning of a solid polymer has been divided into four stages: (i) heating, (ii) decomposition, (iii) ignition, and (iv) combustion (Landrock 1983). In the first stage, a thermoplastic material softens or melts and begins to flow. The temperature at which it melts can have a significant effect. In the second stage, gases or the volatile fragments of degraded polymer are removed. The temperature and the rate at which this occurs depend on the thermal stability of polymer and the chemical reactions occurring under those conditions. Ignition takes place as the flammable gases combine at appropriate ratios with oxygen from the air.

Sustaining the burning depends on the transfer of sufficient heat from the flame to polymer, capable to maintain supply of flammable decomposition byproducts. Supply of oxygen is also essential. If decomposition of the polymer requires more heat than it is supplied by the flame, or if solid nonflammable residues coat the surface and insulate the remainder of the flammable part, a continuous propagating flame will not be obtained. Thus, the last stage of the burning sequence very much depends on the polymer characteristics. It may be correlated with such energy factors as cohesive energy, hydrogen bonding, heat of combustion, and dissociation energy (Einhorn 1972).

An interesting relationship between polymer structure and polymer flammability has been observed. Commercial polymers that possess aromatic groups in the main chain (e.g., PPE, PC, PSF, phenolic resins) undergo char-forming condensed-phase reactions – as a result they have low flammability. Higher oxygen index of PC and PPE was apparently related to their higher charring tendency in comparison to the aliphatic hydrocarbon-type polymers. The greater thermal stability of aromatic-type polymer backbone leads to a higher tendency for condensation into aromatic chars and, therefore, to the less flammable products (Fenimore and Martin 1966).

Van Krevelen had confirmed the empirical relationship between polymer structure, char formation, and polymer flammability. A mathematical formula was proposed that (based on structural units) allows calculation of the oxygen index and char residue values for a wide variety of hydrocarbon polymers. The very existence of such a relationship indicates that pyrolytic condensed-phase process is of primary importance in determining polymer flammability at least in the studied cases (Van Krevelen 1975).

A relationship between the polymer structure and its flammability was related to unsaturation for co-polyterephthalates and co-polycarbonates (Quinn 1977). This work is an excellent illustration of the importance of condensed-phase pyrolytic mechanisms upon polymer flammability.

10.6.3 Prevention Methods

Since a thorough review of fire-retardant methods is beyond the scope of this chapter, only a brief summary is given below. The readers interested in a more

detailed discussion are referred to pertinent reviews (Einhorn 1972; Hilado 1972, 1981; Vandersall 1971). Four general methods for reduction of polymer flammability have been identified (Kuryla and Papa 1978):

- A nonflammable coating that prevents the normal pyrolytic or combustion mechanism is either applied to the polymer surface or produced in the presence of a flame.
- Appropriate chemicals are incorporated during polymer processing. Their role is either to alter the rate of pyrolytic fuel generation or to inhibit the exothermic gas-phase reactions.
- Gas-phase flame reaction can be prevented by the generation of nonflammable gases, which dilute the fuel gases below the flammability limits.
- Incorporated solid components consume sufficient heat during pyrolytic decomposition that they sufficiently cool the substrate to a temperature below the ignition point.

In any given fire retardant, one or more above methods may be used. The effect of a fire retardant strongly depends on the basic chemical structure of the polymeric material. Owing to complexity of the processes and the experimental limitations, it is difficult to predict which mechanism is most important or operative for any system. A list of commercially available fire retardants is given in Appendix 2 (Table 10.37). These materials are classified as organic, inorganic, and reactive types. A fact to be kept in mind is that for blends or alloys, the fire retardancy behavior is usually between those of the base resins; for example, consider Arylon and Kydene (acrylic/PVC) (Landrock 1983).

10.6.4 Review of Fire Retardancy in Polymeric Materials

The concept of fire retardancy is remarkably old. The Greek historian, Herodotus, in 484–431 BC recorded that the Egyptians imparted fire resistance to wood by soaking it in a solution of alum (potassium aluminum sulfate) (Browne 1958). The Romans added vinegar to the alum for the same purpose. Vitruvius in the first century BC described the natural fire-retardant properties of the larch tree and some military applications of fire-retardant materials such as plaster of clay reinforced with hair (Vitruvius 1960). In 1638, Circa recorded that Italian theaters were painted with a mixture of clay and gypsum (potassium aluminum silicate and hydrated calcium sulfate) to protect them from fire. Wild was issued a British patent in 1735 for his process of treating wood with a mixture of alum, ferrous sulfate, and borax (sodium tetraborate decahydrate). And Gay-Lussac in 1821 showed that a solution of ammonium phosphate, ammonium chloride, and borax acts as a fire retardant for wood.

In all these processes the key ingredients are the elements from group III (B and Al) of the periodic table. Now, at the end of the twentieth century, with so much of research activity for better fire retardants, the most effective elements are still found in groups III (B and Al), V (N_2, P, and Sb), and VII (Cl and Br). Research efforts to find new and improved fire-retardant agents for synthetic polymers and their blends have been concentrated on the same three groups of the periodic table, with the same seven elements. The search is for new ways of incorporating them into polymers

(Chamberlain 1978). Certain compounds based on Ba (group II), Zn (group II B), and Sn (group IV) are claimed to be effective in some polymers, especially when used in conjunction with one or more of the seven key elements mentioned above.

The burning or non-burning characteristics of plastics have been given a great deal of attention by the scientific community. After the Federal Trade Commission (FTC) announced inquiry into flammability of plastics in October, 1972, the suppliers started more carefully to describe flammability of their products. ASTM and other standard developing groups have given considerable effort to develop more meaningful tests and have dropped or modified certain tests. Thus, ASTM D1692 was discontinued (Hendersinn 1977).

A theory that certain flame retardants vaporize and produce an effect by acting as free-radical chain stoppers to extinguish the flame or to inhibit the flame speed of the burning gases was proposed. It is based on extensive studies for 30–40 years (Kuryla and Papa 1978). The research efforts devoted to understand the mechanisms of combustion and inhibition for solid materials burning with a diffusion flame in an air environment have multiplied rapidly in the last two decades.

Polymer matrix-based nanocomposites have become a prominent area of current research and development. Exfoliated clay-based nanocomposites have dominated the polymer literature, but there are a large number of other significant areas of current and emerging interest. Increased flammability resistance has been noted as an important property enhancement involving nanoplatelet/nanofiber modification of polymeric matrices. The primary advantage noted with nanofiller incorporation is the reduction in the maximum heat release rate (determined by cone calorimetry) (Morgan 2006; Bourbigot et al. 2006). The majority of the flame retardant studies on nanofiller incorporation in polymers involve exfoliated clay. Studies involving PA6 (Dasari et al. 2007; Kashiwagi et al. 2004) and PP (Qin et al. 2005) yielded similar observations with reduced peak heat release rate but no change in the total heat release with exfoliated clay addition. The primary advantage for nanofiller addition for these tests generally involves reduction in the flame retardant additives that need to be incorporated to pass the specific test (Morgan 2006; Schartel et al. 2006; Nazare et al. 2006). This has been observed in various nanoparticle modified composites including exfoliated clay with halogen-based flame retardants/Sb_2O_3 (Zanetti et al. 2002) and EVA nanocomposites with magnesium hydroxide nanoparticles and microcapsulated red phosphorus (Lv and Liu 2007).

Studies involving carbon nanotubes have also shown decrease in the peak heat release rate with no change in the total heat release (Kashiwagi et al. 2002, 2005) with effectiveness equal to or better than exfoliated clay. The level of dispersion of the carbon nanotubes in the polymer matrix was shown to be an important variable (Kashiwagi et al. 2005). Upon combustion, the surface layer was enriched with a protective nanotube network providing a thermal and structural barrier to the combustion process. Continuity of the network was important to achieve optimum performance as very low levels of nanotube incorporation or poor dispersion did not allow a continuous surface network during the combustion process. It is noted that the incorporation of nanoclay and carbon nanotubes often results in slightly earlier

ignition than the unmodified polymer presumably due to the increased thermal conductivity. However, at the later stages of combustion, the reinforcement of the char layer provides a stable thermal barrier preventing regeneration of polymer at the surface available for rapid combustion (Paul and Robeson 2008).

Fire retardancy behavior of PP/PA66 blends compatibilized with PP-g-MAH and modified with untreated and treated nanoclays was studied (Kouini and Serier 2012). It was found that the intercalation, exfoliation of nanoclays of nanocomposites, and the flame retardancy properties were improved significantly. In addition a good balance of impact strength and flame retardancy was obtained for PP/PA66 nanocomposites in the presence of PP-g-MA compatibilizer. The presence of the clay led to an increase in the flammability time. In addition, the treatment made a more pronounced effect. A 23 % increase was observed only when 4 wt% nanoclay was added and a longer flammability time was noticed with treated clay. This was attributed to the stacking of nanoclay which created a physical protective barrier on the surface of the material. Similar behavior has been reported by earlier workers (Kocsis and Apostolov 2004).

Thermal insulating materials are required to protect structural components of space vehicles during the reentry stage, missile launching systems, and solid rocket motors. A series of review papers were published (Koo et al. 2006, 2007; Ho et al. 2007) on using polymeric composites as ablative thermal protection systems for a variety of military and aerospace applications. Thermal protection materials such as char-forming phenolics and carbon–carbon composites are used for spacecraft heat shields, rocket motor insulation, and rocket nozzle assembly materials. The TPU nanocomposites (TPUNs), with the addition of nanoclays and carbon nanofibers, are prepared, and properties such as density, specific heat capacity, thermal diffusivity, and thermal conductivity of the different TPUN compositions were determined. Cone calorimetry was employed to study the flammability properties of these TPUNs. These novel materials were proposed to replace Kevlar-filled EPDM rubber, the current state-of-the-art solid rocket motor internal insulation (Ho et al. 2010).

10.6.5 Data on Blends

The flame retardancy properties of some commercial polymer blends are given in Table 10.29.

10.7   Electrical Properties

10.7.1 Standard Methods of Measurement

10.7.1.1 Resistivity of Insulating Plastics
Measurements of insulating polymers or polymer blends are usually carried out using a sheet specimen in form of a disc or a square (ASTM D257).

Table 10.29 Data on blends

Blend (trade name, grade, and manufacturer)	UL 94 Flame class			Oxygen index ASTM D 2863-97
	HB rating (inch)	V-0 rating (inch)	5 VB rating (inch)	
PC/ABS **Cycoloy**, GEC	**0.060**	**0.060**	0.098	<**21.0**
ASA/PC **Geloy**, XP 1001, XP 2003, XP 4001, GEC	**0.063**	**0.130 V-1**	0.130 VA	–
PC/PBT **Xenoy**, 6120, 6240, 6123, 6370, 6620, 6380, GEC	**0.061**	–	–	–
PC/ABS **Bayblend**, Miles; FR 1439	–	0.062	–	**28**
FR 1440, FR 1441	–	0.062	–	**30**

Commercially available resistance meters can measure resistance in the range from 10^6 to 10^{15} Ω. In the case of plastics, the method can be applied if the resistance values are of the same order or lower than the volume resistance and if the volume resistivity is $>10^8$ Ω. Flat plate metal electrodes, preferably guarded (Fig. 10.61), are used for testing flexible and compressible materials (at room or elevated temperatures).

Voltmeter–Ammeter Method

The DC voltmeter and the DC amplifier (or electrometers to increase the sensitivity) are connected to the voltage source and the specimen. The applied voltage, V_x, is measured by a DC voltmeter. The current, I_x, is measured in terms of voltage drop across a standard resistance R_s. The voltage drop is amplified by the DC amplifier and read on an indicating meter as V_s. The resistance R_x or the conductance G_x is calculated as

$$R_x \;=\; \frac{1}{G_x} \;=\; \frac{V_x}{I_x} \;=\; \left(\frac{V_x}{V_s}\right) R_s \tag{10.31}$$

The time of electrification, unless otherwise specified, should be 60 s and the applied direct voltage $V_x = 500 \pm 5$ V.

Volume Resistivity or Conductivity

Measure the dimensions of the electrodes and width of the guard gap, g, accurately. Unless otherwise specified, the time of electrification should be 60 s and the applied direct voltage 500 ± 5 V. Volume resistivity is expressed as (Ω-cm)

$$\rho_v \;=\; \frac{A}{t R_v} \tag{10.32}$$

where A = the effective area of the measuring electrode (see Fig. 10.61), t = average thickness of the specimen, R_v = measured volume resistance in Ω.

Fig. 10.61 Top view and side view of flat plate guarded metal electrodes [ASTM D257]
Volume conductivity is calculated as (S/cm)

$$\nu_v = \frac{t}{A G_v} \qquad (10.33)$$

where G_v = measured volume conductance in Siemens.

Surface Resistivity or Conductivity

The electrode dimensions and the distance between the electrodes, g, are to be measured accurately. The surface resistance or conductance between electrodes No. 1 and 2 is measured with a suitable device (Brown 1981). The time of electrification should be 60 s and the applied direct voltage shall be 500 ± 5 V.

Surface resistivity, per square cm is given by

$$\rho_s = \frac{P}{g R_s} \qquad (10.34)$$

where P is the effective perimeter of the guarded electrode (see Fig. 10.61), R_s is the measured surface resistance in Ω, and g is as indicated in Fig. 10.61. For specimens of square, rectangular, and tube forms, appropriate electrodes and mathematical relations are given in ASTM D257.

BS 4618 recommends preconditioning of the test specimens at not more than 1 % relative humidity (RH) for the study of effect of temperature. ASTM D257 covers resistivity measurements for insulating materials. Electrode sizes are not stipulated (round, square, and rectangular types are permitted). The gap between guard ring and center electrode is made approximately equal to twice the specimen thickness. The test voltage is usually 500 V applied for 60 s, as in the British test.

DIN 53482 uses methods similar to some of those in IEC 93, using silver or graphite painted electrodes for volume resistivity. A different electrode system was suggested for the measurements of surface and volume resistivity. A narrow guard gap of 1 mm makes it difficult to avoid short-circuiting the electrodes.

Power Factor and Permittivity

Measurements of dielectric constant and loss in polymeric solids and melts over a wide frequency range were described in detail elsewhere (Porter and Boyd 1972). An updated and detailed account of these topics may be found in ▶ Chap. 12, "Broadband Dielectric Spectroscopy on Polymer Blends" of this handbook (Andreas Schonhals 2014).

The measurement of power factor and permittivity and the related parameters such as dissipation factor, phase angle, etc., may need to be carried out over a wide range of frequencies from a few Hz to several tens of GHz. However, most measurements are made between 50 Hz and 100 MHz (Brown 1981).

Insulating materials, such as polymers and polymer blends, are used as dielectrics at commercial frequencies between approximately 50 Hz and 100 GHz. Two different techniques are adopted to study the dielectrics in two ranges, i.e., below and above 100 MHz. Dielectric measurements at ultralow frequencies are of some interest, as they reveal the basic structure of the material (McCrum et al. 1967). Bridge circuits are invariably employed for the measurements of power factor and permittivity.

The test specimen, whose dielectric constant and loss factor are to be measured, is cut or molded to a suitable shape and thickness determined by the material specifications or the test method. The thickness of the specimen must be accurately measured. The electrodes are selected, based on convenience and whether or not the specimen must be conditioned at high temperature and high relative humidity. The test specimen with its attached electrodes is placed in a suitable measuring cell, and its capacitance and a-c loss are measured using a suitable bridge. For routine work when either the highest accuracy is not required, or when neither terminal (of the specimen) is grounded, it is not necessary to place the solid specimen in a test cell.

In the Schering Bridge, one sets the ratio R_1/R_2 (range) and varies C_s and C_1 to obtain a balance (ASTM D150):

$$C_x = \left(\frac{R_1}{R_2}\right) C_s \qquad\qquad (10.35)$$

$$D_x = W.C_1R_1 \qquad\qquad (10.36)$$

The test method covers dielectric measurements from 1 Hz to several hundred MHz. It has few recommendations about the procedure or apparatus.

Size of the electrodes is not suggested and it is recommended that the guard gap should be as small as possible and the guard width should be at least twice the thickness of the specimen. An appendix is provided, which describes number of bridges and their circuits. The German standard for dielectric measurements is DIN 53483.

Dielectric Strength

Low-level conduction in insulating materials can originate in a variety of ways. Often it is attributed to impurities that provide small concentrations of charge carriers in the form of ions and/or electrons. At high fields, the electrodes may also inject new carriers into the polymer, causing the current to increase more rapidly with voltage. At very high fields, these and other processes inevitably lead to complete failure of the polymer as a dielectric. This localized, sudden, and catastrophic phenomenon is known as the dielectric breakdown (Ku and Liepins 1987). In many cases the dielectric breakdown or dielectric strength of a material can be the determining factor in the design of an apparatus in which it is to be used.

A method for determination of dielectric strength of solid electrical insulating materials at commercial power frequencies was developed (ASTM D149). The voltage can be applied at a fast uniform rate or step-by-step or at a slow rate of rise. At the dielectric breakdown voltage, an abrupt rupture through the specimen results in a visible puncture and decomposition of the material – the occurrence can be seen and heard. This form of breakdown is irreversible. Dielectric strength is calculated (in terms of KV/mm or V/mil) by noting the gradient at the highest voltage step at which breakdown did not occur. BS 2782 Method 201, deals with plastics breakdown voltage. Other British standards such as BS 3784, BS 3816, BS 3924, and BS 5102 directly invoke BS 2782.

10.7.2 Factors Affecting Electrical Properties

Factors such as improper mixing of polymer blends lead to variations in test specimens. Such compositional and/or structural changes from specimen to specimen often lead to widely divergent data.

10.7.2.1 Effect of Temperature

Resistivity depends on temperature – for nonmetallic materials it invariably decreases with T. Volume resistivity is markedly more sensitive to temperature than surface resistivity. In any measurement it is important to ensure that temperature is maintained constant during the test. Temperature fluctuations produce changes in measured current and lead to significant errors (Brown 1981; ASTM D257). In the case of power factor or permittivity determinations, the effects of temperature and frequency are interrelated. With nonpolar polymeric materials, the changes in properties with temperature and frequency are small, while with polar materials very large changes may take place.

10.7.2.2 Effect of Humidity

The insulation resistance of solid dielectric materials decreases with increasing humidity. Surface resistance is particularly sensitive to humidity changes. Insulation resistance or conductance is a function of both the volume and surface resistance or conductance of the specimen. Surface resistance changes almost instantaneously with a change of RH. Therefore, it is essential to maintain both T and RH within close limits during the conditioning and measuring of the specimens. In a humid environment, absorption of water into the volume of the insulating material as well as the formation of an ionized water film on the specimen surface takes place. These factors lead to significant rise in the insulating materials' permittivity and loss index. The process of dielectric breakdown in the case of neat polymers is not completely understood, and many unknowns are still remaining (Ku and Liepins 1987).

Still many uncertainties exist for polymer blends and alloys. However, it is clear that the chemical structure, the solid-state structure, degree of plasticization, the nature and concentration of filler, molecular weight and morphology of a polymer, etc., influence the electrical properties. For example, the dielectric breakdown of EVAc and its blends was studied in the low-temperature region (193 K) (Nagao et al. 1976, 1977). The dielectric breakdown voltage of EVAc and blends was found to rise with an increase in VAc content. This may be caused by increased electron scattering associated with the decrease of crystallinity and the increase of polar groups.

The process of polymer blending was used for improving the mechanical properties of electric wire insulation, as early as 1968 (Ku and Liepins 1987). In 1978, it was found that the use of a HDPE/LDPE blend enhanced the electrical treeing inception voltage (Nitta and Funayama 1978). This approach to electrical treeing inhibition and some of the experimental results on the use of SB/LDPE and HDPE/LDPE blends are given in Table 10.30 (Wu and Chen 1983).

10.7.3 Review of Blends' Electrical Properties

Most polymers have high electrical resistivity, are inexpensive in comparison to other known insulating materials, and are heat resistant and sufficiently durable. Owing to their sensitivity to oxidation and solvents, they are frequently blended to generate better electrical insulating alloys. In the past two decades, there has been serious effort to modify the electrical properties of polymers and their blends. The electrically conductive polymers can be broadly categorized as (i) electrostatic dissipating polymeric compositions and (ii) electrically conductive polymer blends. Utracki has reviewed evolution of these materials (Utracki 1998).

The electrostatic dissipating polymeric compositions (ESD) are developed to overcome problems related to the accumulation of surface charge and its rapid discharge leading to shocks, fire, explosions, damage to electronic components, etc. These compositions must provide surface resistivity $10^5 < R < 10^{12}$ (Ω cm).

Table 10.30 Effect of polymer blending on tree growth and length (Wu and Chen 1983)

Parameter	LDPE	SBR			HDPE		
Modifier wt%	100	10	20	30	10	15	20
Tl (min)	–	198	127	54	25	70	90
T2 (min)	300	100	200	230	156	170	160
T3 (min)	–	2,180	2,200	–	75	30	2,100
Tl + T2 + T3 (min)	2,300	2,478	2,527	2,284	250	270	2,350
Length §(μm)	1,300	300	600	1,400	450	500	400

T1, induction period for tree initiation in minutes; T2, growth period of the tree in minutes; T3, the saturation period of tree development in minutes; §, The length of the tree after saturation period

The early efforts to achieve the optimum surface resistivity, such as coating the polymeric parts with electrostatic dissipative materials, addition of either graphite, metal particles or fibers, incorporation of low molecular weight antistatic agents, etc., did not yield fruitful results (Kozlowski 1995). Antistatic properties are observed for materials having either -SH or –OH groups (e.g., phenolic, alcoholic, or acidic).

Since the mid-1980, the most frequently used ESD has been a copolymer of ethylene oxide and epichlorohydrin, EO-CHR. Many chemical companies (such as Borg-Warner, B.F. Goodrich, Asahi, and General Electric) came up with several ESD formulations containing EO-CHR for improving the electrostatic properties of PVC, CPC, PC, PEST, epoxy, phenolics, etc. (Federl and Kipouras 1986; Kipouras and Federl 1988; Yu 1988; Lee 1993; Shimamura and Suzuki 1991; Giles and Vilasagar 1994).

The second variety of materials, viz., electrically conducting polymer blends, ECPB, has been known since the early 1980s. These are prepared, in principle, by synthesis of the conducting polymer within the host or by simple blending (Billingham and Calvert 1989). Polyacetylene, PACE, blends were prepared by the polymerization of acetylene in LDPE films doped with Ziegler catalyst (Galvin and Wnek 1982, 1983; Galvin et al. 1984). PACE formed a particulate second phase with a size ranging from 60 to 200 nm. Addition of 7 % PACE LDPE increased the yield point of the latter resin from 7 to 10 MPa, but the extension to break was reduced. The effect was greater in blends produced by polymerization in solid PE.

Acetylene was polymerized in the presence of polybutadiene rubber, and the blends were investigated for their electrical conductivity (Rubner et al. 1983; Sichel and Rubner 1985). The electrical properties of these blends were explained in terms of the morphological features (Tripathy and Rubner 1984). In these investigations, a conductivity of 10 S/cm was achieved at PACE loadings above 30 %. Polymerization of acetylene in EPDM resulted in tough, conductive films (Lee and Jopson 1983, 1984). The conductivity of these films was found to be significantly enhanced by stretching.

Mechanical blending of various conducting polymers with thermoplastics was studied (Wessling and Volk 1987). These materials although processable showed low electrical conductivity ($<10^{-5}$ S/cm). They were prepared by blending an electrically

conductive polymer (such as polyacetylene or polypyrrole) with a polymer having strong anionic group (such as sulfonated PE, sulfonated SEBS, sulfonated PS, or sulfonated polyacrylamidomethylpropane) (Cross and Lines 1995).

Electrically conducting polymer blends are also produced by blending another conducting polymer (e.g., poly-3-octylthiophene) with a matrix polymer (e.g., PP, PVC, PS, PE, EVAc, PVC/ABS, etc.) introducing a dopant (e.g., iodine) (Kokkonen et al. 1994). Several strategies were adopted in preparing ECPBs. In one example, polyaniline was blended with dodecylbenzenesulfonic acid, mixed with PS, PE, or PP and then melt processed. In another case, polyaniline was mixed with protoning acid metallic salt. The conductive material was melt mixed with PE, PS, PP, or ABS (Karna et al. 1994a, b).

ECPBs were prepared by melt blending a matrix polymer (selected from between PE, PP, PB, PIB, PMP, EPR, CPE, CSR, PS, polyalkanes containing styrene, acryl, vinyl, or fluoroethyl groups and their blends) and an electrically conducting thermotropic liquid-crystal polymer, containing either ferric chloride or iodine as a dopant. The blend which could be manufactured into fibers and films was reported to have conductivity as 10^{-12}–10^2 S/cm (Ho and Levon 1995). Amine-terminated polyaniline was first grafted onto a thermoplastic polymer comprising a functional group capable of reacting with -NH$_2$, e.g., maleic anhydride. They were further compounded with polymers, fillers, and/or electrically conductive solids (Jongeling 1993). Blends of PVC with "doped" polyaniline and at least one other additive (e.g., impact modifier, plasticizer, acidic surfactant) were developed to give electrically conductive blends.

ECPBs were also prepared compounding polyaniline and a thermoplastic polymer (selected from PA-6, PA-66, PA-11, PA-12, PET, PC TPU, CPE, etc.) and 0–10 wt% carbon black (Kulkarni and Wessling 1992, 1993). Electrically conductive materials were prepared by dispersing pre-blends of aniline to sylate particles and poly(ethylene terephthalate glycol), PETG, and then diluting the pre-blend with PETG. The blends were useful for the manufacture of films, printing inks, and coatings, in shielding, antistatic, and adhesive applications (Shacklette et al. 1993). Curable blends, with good flame retardancy, comprising of fluorine-containing polycyanurates and a thermoplastic polymer (e.g., PSF, PPE, and PEEK) were patented by IBM in 1992. The filled materials were useful in several applications (fabrication of printed circuit boards, semiconductor chip carriers, metal-core boards, chip modules, and multilayer thin film circuits) (Ardakani et al. 1994).

Conducting polymer fibers were prepared by melt mixing and chemical coating on fibers. Different conductive materials were used in order to obtain conductive PP-based fibers with specific electrical and mechanical properties. The electrical conductivity and morphological characteristics of these fibers were investigated (Kim et al. 2004). The conductive fibers are intended for use in creating conductive yarns, conductive fabrics (which can be used as electromagnetic shields), and multifunctional textile structures for novel applications.

Melt-processed immiscible polymer blends of HIPS, LCP, and CB were prepared. Relationships between composition, electrical resistivity, and morphology of the blends produced by adopting different processing methods

were investigated. The LCP phase morphology in the blends was found sensitive to the processing conditions. An important role of the skin region in determining the resistivity of injection-molded samples was found. The study also revealed that shear rate effect on resistivity of capillary rheometer filaments might serve as a predictor of resistivity behavior in real processing procedures (Tchoudakov et al. 2004). Such studies are not frequent. In fact, processing–structure–property relationships in electrical properties of polymeric materials are rarely available.

A two-step method was used to prepare carbon nanotube (CNT)/(EVA)/(PE) and CNT/(PC)/PE composites. First, CNT–EVA and CNT–PC master batches were obtained by solution-phase processing, and second, the CNT master batches were melt mixed with PE. Phase morphological observations revealed decrease in the size of the dispersed particles in the composites (Li et al. 2007).

Pure polyaniline (PANI) and its blends with PVA and PEO were prepared by solution cast method. The blends were characterized by XRD, FTIR, and SEM techniques. The blends were prepared in order to combine the mechanical properties of PVA and PEO with conducting properties of PANI. It was found that the conductivity of pure PANI was more than PANI blends (Subrahmanyam et al. 2012).

Nunoshige et al. developed a novel low-dielectric-loss thermosetting material by blending poly(2-allyl-6-methylphenol-co-2,6-dimethylphenol) (Allyl-PPE) with 1,2-bis(vinylphenyl)ethane (BVPE). BVPE could be used effectively as a cross-linking agent for Allyl-PPE, decreasing the cured temperature to 523 K or lower. The cured products exhibited better thermal and thermomechanical properties. The effect of the composition of the blends on the dielectric constant and the dielectric loss were evaluated (Nunoshige et al. 2007).

Mao et al. had tuned the morphology to improve the electrical properties of graphene filled immiscible polymer blends. PS and PMMA blends filled with octadecylamine-functionalized graphene (GE-ODA) were fabricated to obtain conductive composites with a lower electrical percolation threshold. The dependence of the electrical properties of the composites on the morphology was examined by changing the proportion of PS and PMMA. The electrical conductivity of the composites was optimal when PS and PMMA phases formed a co-continuous structure. For the PS/PMMA blend (50 wt/50 wt), the composites exhibited an extremely low electrical percolation threshold (0.5 wt%) because of the formation of a perfect double percolated structure (Mao et al. 2012).

Advances in nano-material research have opened the door for transparent conductive materials, each with unique properties. These include CNTs, graphene, metal nanowires, and printable metal grids. Transparent electrodes are necessary components in many modern devices such as touch screens, LCDs, OLEDs, and solar cells, all of which are growing in demand. Traditionally, this role has been well served by doped metal oxides, such as indium tin oxide. A review exploring these innovations in transparent conductors and the emerging trends is presented recently (Hecht et al. 2011). Electrical conductivity in PS nanocomposites with ultralow graphene level was found to enhance significantly (Qi et al. 2011).

10.7.4 Data on Blends

Electrical properties of selected commercial polymer blends are listed in Table 10.31.

10.8   Optical Properties

10.8.1 Methods of Measurement

10.8.1.1 Haze and Luminous Transmittance
ASTM D1003 provides two methods for measuring light transmittance and haze in planar sections of transparent plastics. The method making use of a hazemeter is briefly described.

A spherical hazemeter, which is pivotable about a vertical axis through the entrance port (where the specimen is placed), is shown in Fig. 10.62. In the normal position the collimated incident light passes straight through the sphere, leaving through the exit port, which is closed by an absorbent light trap. When light is scattered either by the instrument alone or by the specimen and the instrument (when the specimen is loaded), it is reflected from the region around the edge of the exit port and finally collected by the photocell after multiple reflections from the highly reflecting walls of the sphere.

When the integrating sphere is rotated slightly so that the incident light hits the opposite highly reflecting wall of the sphere adjacent to the exit port, the measurements with and without a specimen give a measure of the total transmittance. The total transmittance, T_t, is given by

$$T_t \quad = \quad \frac{T_2}{T_1} \tag{10.37}$$

where T_2 = the total light transmitted by the specimen and T_1 = the incident light without the specimen. Diffuse transmittance, T_d, and % of haze are calculated as

$$T_d \quad = \quad \frac{\left[T_4 - T_3 \left(\frac{T_2}{T_1 I} \right) \right]}{T_1} \tag{10.38}$$

$$\text{Haze} \ (\%) \quad = \quad 100 \ \left(\frac{T_d}{T_t} \right) \tag{10.39}$$

where T_4 = light scattered by instrument and specimen and T_3 = light scattered by instrument (without specimen). BS 2782 Method 515 A is the British equivalent, which deals with only haze of films.

10.8.1.2 Refractive Index
When a ray of light passes from one isotropic medium into another, the sinus of the angle of incidence makes a constant ratio to the sinus of the angle of refraction (both

measured with respect to the normal) for all angles of incidence. This dimensionless ratio, while dependent on the wavelength of the light and temperature, characterizes the two media concerned.

ASTM D542 describes two methods, viz., (i) refractometric and (ii) microscopic, for the measurement of refractive index of transparent organic plastics. Both the methods require optically homogeneous specimens of uniform index. The ASTM recommends that refractometric method is to be preferred wherever possible, since it is capable of providing results with greater precision (up to four significant figures). The microscopic method depends on operator's skill, and it yields results accurate up to only three significant figures.

For the refractometric method, the apparatus consists of an Abbe refractometer, a suitable source of white light and a small quantity of suitable contacting liquid. The test specimen for refractometer method should be 12.7×6.3 mm, with one flat face and one perpendicular surface. The two surfaces (preferably polished) shall intersect along a sharp line (without a rounded edge). The test specimen is attached to the prism of the refractometer with a drop of liquid of refractive index higher than the test specimen by at least 0.01, and it should not soften or dissolve the specimen. ASTM D542 suggests a list of liquids for a variety of plastics. Measurements are to be carried out at specified conditions, 296 ± 2 K and 50 ± 5 % RH. Temperature is to be accurately controlled. For maximum accuracy, sodium D lines are recommended.

ISO R489 suggests two methods based on Abbe refractometer and the Becke line methods. It does not recommend any specimen conditioning procedure prior to the test. DIN 53491 provides practical details relevant to refractometer measurements. It recommends test temperature as 293 ± 5 K, like ISO R489. For maximum accuracy it suggests the use of sodium light. All these methods provide lists of liquids suitable for different plastics.
Fig. 10.63 Transmission (%) determined using Haze Meter and crystallinity (%) measured using X-ray diffraction are shown for polypropylene homopolymer mixed with different concentrations (0.07 wt%, 0.14 wt%, and 0.21 wt%) of Millad-3988 (Pendyala et al. 2004)

10.8.2 Transparency in Polypropylene

The degree of crystallinity and regularity of crystallite size have noticeable effects on properties of bulk isotactic polypropylene (PP). Clarity is commonly obtained in PP in two ways. First, resins with lower crystallinity will be clearer than those with higher, but a minimum level of crystallinity is necessary to provide the required strength, stiffness, and resistance to softening at elevated temperature expected of the PP. Second, certain nucleating agents greatly improve the clarity of PP by producing very small crystals in the polymers. These smaller crystals are below the size which scatters visible light that produces haze. Crystallinity vis-à-vis transmission in polypropylene homopolymer with different concentrations of Millad-3988 is illustrated in Fig. 10.63 (Pendyala et al. 2004).

Isotactic polypropylene can crystallize into three different forms: (i) α-phase, (ii) β-phase, and (iii) γ-phase. These spherulites satisfy two requirements to scatter light – they are larger than the wavelength of light and they have a refractive index different from that of the amorphous region. The refractive indices of the crystalline and amorphous regions of a polymer cannot be changed. So, in order to improve clarity, the average spherulites' size must be reduced. Since a spherulite grows until it meets another, their size is dependent on the number of nucleation sites (nucleation density) within the crystallizing polymer.

PP with improved clarity was commercialized in the 1980s by incorporating sorbitol-based clarifying agents by Milliken Chemical Co. and others (Carroll 1984). In PP, the crystallization results in large size spherulites, and hence inclusion of heterogeneous nucleating agents is often adopted to improve mechanical properties (Quande Gui and Weiping Zhu 2003) or to reduce optical haze (Sterzynski et al. 1994; Mannion 1994; Gahleitner et al. 1996; Amos et al. 1999; Zhao and Dotson 2002).

Hence, providing such heterogeneous nucleation is an essential consideration. Creation of various crystallographic phases, differed by the unit cells as well as by the spherulites, is known to be a result of the heterogeneous nucleation (Varga 1992; Lotz 1998).

10.8.3 Review of Blends' Optical Properties

Lack of transparency is a significant drawback in the commercially important toughened polymers such as HIPS or ABS (Manson and Sperling 1981). Transparency in these materials is lost due to the light scattering at the interface between the phases. The degree of light scattering (turbidity) was found to be a function of the amount of dispersed phase present, its particle size, the ratio of refractive indices of the phases, and the wavelength of light. In typical polymer pairs, at a given dispersed phase level, the maximum turbidity was observed in the range of particle sizes considered to be necessary for good impact strength (Conaghan and Rosen 1972). If the refractive indices are matched at a particular temperature, small particle sizes greatly increase the temperature range over which scattering is minimized. In other words, a clear blend can be obtained if both phases have identical refractive indices, regardless of the details of the phase morphology (Rosen 1967). Thus, for example, clarity in ABS and toughened acrylics was achieved by matching refractive indices of the continuous and dispersed phases (Gesner 1967). Impact modifiers for PVC that can impart toughness as well as clarity were described by several workers (Petrich 1972; Souder and Larson 1966; Ryan and Crochowski 1969; Ryan 1972).

Formation of transparent blend films cast from solutions of PVC and (PC-PDMS)$_n$ multiblock copolymer has created concern (Gorelova et al. 1992). The finding is interesting because the refractive indices of PVC, PC, and PDMS are different, and consequently, transparency of the blend films may suggest miscibility of their constituents, despite the fact that PVC is immiscible with PC and PDMS (Krause 1978). In other words, these blends are pseudo-miscible and their transparency is caused by the very small size of the dispersed block copolymer phase. PVC was also found to form transparent blends with other multiblock copolymers (Papkov et al. 1995). Several examples of the formation of transparent blends were reported. The constituents of these blends are homopolymers of various chemical compositions and flexibility, viz., PS, PMMA, and PVC, and the multiblock copolymers are PC-PDMS, PSF-PDMS, PSF-PB, and polytetramethylene oxide-PB (Papkov et al. 1998). For copolymers and homopolymers of various chemical structures, the composition range for each type of block copolymer, within which the formation of transparent blend film takes place, is relatively narrow.

The phenomenon appears to be similar to the so-called miscibility window in some blends with random copolymers (ten Brinke et al. 1983). Micro phase separation and the evolution of the multiblock copolymer phase in the form of small-sized particles (up to 100 nm in diameter) is the physical basis of their transparency. Thus, these transparent blends are considered microheterogeneous

systems (Papkov et al. 1998). Detailed theoretical and experimental investigations are required to understand details of this phenomenon (Sikora and Karasz 1993).

Blends of transparent polymers are generally hazy. However, transparency is required in many products. The miscible blends, PET/PBT, maintain transparency in almost all cases regardless of the blending ratio, whereas some immiscible blends become hazy. The reason for this haze is the number and size of the dispersed particles. Differences in the refractive indices of various polymers also have a large influence on haze. Stretching makes even the transparent blends hazy, because stretching increases the size of the dispersed particles in the sheet plane and also the difference in the anisotropic refractive indices of the matrix and the dispersed phase is increased by stretching, which is in agreement with the theory of light scattering (Maruhashi and Iida 2001).

The effect of added nanoclays to the morphological characteristics and the macroscopic properties in a blend of isotactic PP and PEO was examined. It was shown that strong interactions between the surfactant used for clay modification and the binary matrix effectively controlled the spatial organization of the suspended polymer droplets. The incorporation of a small amount of organically modified nanoclay induced a dramatic transformation from an opaque to a transparent system (Kelarakis and Yoon 2008).

Several blends of polymers that varied concentrations of PMMA and polyimides based on 2,20-bis(3,4-dicarboxyphenyl)hexafluoropropane dianhydride (6FDA) were prepared in film form by solution casting and using various solvents. The miscibility of the blended films was studied. DSC thermograms revealed two T_gs for specimens using THF as a solvent, indicating immiscibility; on the other hand, samples using methyl chloride and cyclohexanone showed a single T_g, indicating miscibility between the two polymers. The transmittance for 6FDA-6FpDA/PMMA had a value of about 85 % (according to ASTM D1003), in the visual light range. However, 6FDA–6FpDA:DABA 2:1/PMMA showed a low transmittance below wavelengths of 550 nm. For haze, all of the films were clear with values of less than 1 % (Im et al. 2009).

In a separate study immiscible blends were rendered transparent. The components of the immiscible blends were having refractive indices which differ by about 0.006 to about −0.0006. The small difference in the refractive indices enabled the incorporation of regrind into the polymer composition to produce transparent shaped articles (Gilliam et al. 2011; Cliffton et al. 2012).

Interesting advances are taking place in biopolymers with regard to optical transparency. An opaque polylactide/poly(ethylene-co-vinyl alcohol) (PLA/EVOH 90/10 w/w) blend was made transparent by reactive compatibilization. In the presence of a multifunctional epoxy compound and zinc stearate, the dispersed domain size of EVOH in the blend and its distribution decreased significantly. Consequently, the light transmission at 700 nm increased from 9.3 % to 83.5 % for the compatibilized sample. A significant difference in the transparency of the samples can also be confirmed by naked eye (Zhang et al. 2013). In a separate study, binary blends composed of biomass-based cellulose acetate propionate (CAP) and poly(epichloro-hydrin) (PECH) were studied. As a result of the interdiffusion, leading to fine

morphology, the blends exhibited high level of optical transparency although the individual pure components had different refractive index. Furthermore, the mechanical toughness of CAP was considerably improved by blending PECH. This will have a great impact on industries because the blend technique widens the application of CAP (Yamaguchi and Masuzava 2013).

10.9 Sound Transmission Properties

Sound retardant (acoustical) assemblies are one of the most commonly used in commercial building. An acoustical assembly is an acoustical door or window that maintains its basic operating function and is at the same time designed to be a significant barrier to the passage of sound. It is called an acoustical assembly because an entire system is involved. A sound retardant assembly encompasses not just the door or window itself but all the components around it. The wall, the frame which surrounds the door, the door itself, the hardware components, and finally the sealing system, whereby the passage of noise is minimized, all combine to create an acoustical assembly.

Sound ratings are typically based off the sound transmission class (STC) scale system, Table 10.32. This single rating system enables a designer to match up architectural products that when combined will create an STC rating for the entire assembly controlling the noise and vibration in room, office, or even an entire building.

10.9.1 Method of Measurement

The preferred method for determining the STC rating of a product is a test called the ASTM E-90, "Standard Method for Laboratory Measurement of Airborne Sound Transmission," which is summarized here below.

ASTM E90-09 provides a method covering the laboratory measurement of airborne sound transmission loss of building partitions such as walls of all kinds, operable partitions, floor–ceiling assemblies, doors, windows, roofs, panels, and other space-dividing elements (ASTM E90 2009). Laboratories are designed so the test specimen constitutes the primary sound transmission path between the two test rooms, and so approximately diffuse sound fields exist in the rooms.

Sound transmission loss refers to the response of specimens exposed to a diffuse incident sound field. The test results are therefore most directly relevant to the performance of similar specimens exposed to similar sound fields. They provide, however, a useful general measure of performance for the variety of sound fields to which a partition or element may typically be exposed. In laboratories designed to satisfy the requirements of this test method, the intent is that only significant path for sound transmission between the rooms is through the test specimen. Laboratories are designed so the test specimen constitutes the primary sound transmission path between the two test rooms and so approximately diffuse sound fields exist in the rooms.

This standard does not purport to address all of the safety concerns.

Table 10.32 Sound transmission class (ZERO International 2001)

Sound Transmission Class (STC) Table		
STC	Performance	Description
50–60	Excellent	Loud sounds heard faintly or not at all
40–50	Very good	Loud speech heard faintly. But not understood
35–40	Good	Loud speech heard but hardly intelligible
30–35	Fair	Loud speech understood fairly well.
25–30	Poor	Normal speech understood easily and distinctly
20–25	Very poor	Low speech audible

It is important to know the sound transmission loss of walls and floors in order to be able to compare different constructions, to calculate acoustic privacy between apartments or noise levels from outdoor sources such as road traffic, and to engineer optimum solutions to noise control problems. Laboratory measurements can be made for many different types of partitions, but it is impractical to test every possible design, and so it is necessary to have reliable methods for predicting the sound transmission loss of typical building constructions.

There are various methods for predicting the sound transmission loss of walls and floors that can be used by noise control engineers. It is important to know how accurate these methods are for typical constructions used in building acoustics (Ballagh 2004). As the standard grows in experience over the years, it reveals the complex variables that must be addressed in order to equalize the conditions that have a potential to affect results.

10.9.2 Factors Affecting Sound Transmission

During an ASTM E-90 test, a test specimen is mounted between a room containing an isolated source of noise and a receiving room. Sound transmission loss, the difference between the sound level in the source room and the receiving room, is measured at specific sound frequencies and used to arrive at the STC rating. The higher the STC rating calculated, the quieter it is in the receiving room.

When sound waves come in contact with a boundary obstacle, such as a wall or door, a portion of the sound wave energy is reflected, a portion is transmitted through the obstacle, and the rest is absorbed by the obstacle. One of the standard methods of measuring the effective sound absorption coefficient of an acoustical material is by finding its effect on the reverberation time, or decay rate, of the sound pressure level in the sound chamber. The total sound absorption in the receiving room is required to determine the noise reduction of the specimen being tested. The key here is to rule out the absorption of sound waves within the chamber that may be attributed to the door being tested.

Because the ASTM standard does not provide a resolution for measuring and standardizing absorption levels from one laboratory to the next, the same product tested in laboratories with different absorption levels can result in different STC ratings. Another variable that the standard does not currently address is the difference between a door and a partition. While the standard makes a provision that a door must be cycled (opened and shut) a number of times, prior to commencing the test, the operating force or the pressure required to release a tightly sealed door is not addressed.

STC values are used to define the performance requirements for achieving a specified reduction in sound transmission from a source room to a receiving room. The STC rating of an installed door also determines how much noise reduction is possible between a given source room and receiving room.

10.9.2.1 Salient Features of Sound Transmission

- Sound waves travel through any opening with very little loss. While the amount of air flowing through a gap increases in proportion with the size of the gap.
- A tiny hole transmits almost as much sound as a much larger gap. For example, a one square inch hole in 100 square feet of gypsum board partition can transmit as much sound as the rest of the partition. Air paths through gaps, cracks, or holes pose serious problems.
- Air trapped in a "sound lock" between a pair of doors, or between layered sets of seals in a gasket, is one of the best sound absorbers.
- It is important to understand that STC values are not proportionate units of measurement. To achieve increasingly higher levels of sound control, each 10 dB increment requires ten times as much improvement as the one before. While door openings rated in the range from STC of 30 to STC of 40 are common, achieving STC of 50 and higher ratings is extraordinarily difficult.
- Acoustical performance depends upon wall design, its thickness and weight, and ultimately cost. Frequently it is not possible to optimize one factor without seriously compromising the others.

10.9.3 Review of Blends in Noise Reduction

Noise has become an environmental issue, and legislation on noise regulation is under review and being drafted in industrialized countries, especially those in Europe. The reduction of noise from machinery, automobiles, and appliances has been studied extensively (Tokairin and Kitada 2005; Zhang et al. 2007; Jiang et al. 2007; Mazeaud and Galland 2007). The techniques using sound absorption and insulation materials to reduce ambient noise have received much attention in this area of research (Zhou et al. 2006; ASTM E413-10).

Traffic noise, which falls within the frequency range of 250 and 4,000 Hz (Lapcik 1998), has been a huge headache for the public, and the common practice to deal with it is to build concrete noise barriers along roads and highways.

The study done by American Acoustical and Insulation Materials Association (1974) showed that these concrete barriers are of very high acoustic reflectivity (95 % and above) and of low sound absorption. This means that concrete barriers are not effective in controlling and reducing traffic noise (Campbell 2000).

In recent years, some notable progress has been made in making non-concrete barriers. It has been reported that a section of polycarbonate noise wall was built in 1996 near Culver City Park in Los Angeles, California, USA. The polycarbonate noise reduction panels are developed by Quilite International (QUILITE Noise Barriers 1997). A jet engine testing shelter was installed by using Lexan (polycarbonate) plastic manufactured by General Electric (Anderson 1997).

Another development is a noise barrier system developed by Carsonite International based in the city of Early Branch, South Carolina, USA, and those noise barriers are lightweight hollow panels made of tongue-and-groove planks of reinforced composite material filled with crumbed tire rubber. A few sections of Carsonite noise barriers have been built in Long Beach, California. Traditional noise barriers have a flat surface. Now new designs are experimenting with nonflat surface textures (Watts and Morgan 1997).

Placing noise reducers on the top of highway noise barriers is another way that aims to reduce traffic noise (Shono et al. 1994). Numerical and/or analytical studies have also been reported on the estimate of noise reduction effect (Alfredson 1990; Tanaka et al. 1990).

These, abovementioned, noise barriers exhibit a much better performance than concrete with sound absorption and transmission loss. But noise reduction is not the only criterion dominating the decision to construct noise barriers. There are other crucial criteria, and they include (1) cost-effectiveness, (2) technology maturity, (3) durability, (4) low cost and convenience in installation, (5) low cost and convenience in maintenance and repair, and (6) aesthetics. Concrete noise barriers meet those criteria very much (Kay et al. 2000). Crumb rubber blends aiming at the application in noise reduction are also developed and are found to yield encouraging results (Han et al. 2008).

The sound insulation efficiency of ABS/carbon nanotube (CNT) composites was increased with an increase in the amount of CNT. Since the sound insulation of ABS/CNT composite was improved with higher stiffness due to CNT, it might be concluded that stiffness is one of principal factors influencing the improvement of transmission loss of polymer/CNT composites (Lee et al. 2008).

Particle boards (PB) from jute stick (JS), date palm leaf, and their blends offered higher sound transmission loss, higher thermal insulation, and lower swelling compared to plywood. Increase of JS in blend with date palm leaf increased sound loss as well as thermal insulation. Sound loss increased with increase in thickness of PB. Relationship between sound loss and thickness is found to be nonlinear. Sound loss reached maximum at board thickness of 19 mm for PB (Ghosh et al. 2010).

Noise inside a motor vehicle arises from various sources. External sources include rain and wind impacting on the vehicle body panels, and internal sources

include the engine of the vehicle. Vibration of the body panels, such as the bonnet, the roof, and door panels, is the source of considerable noise inside the vehicle. Attempts have been made to damp vibration of the body panels and hence reduce the noise inside the vehicle, by attaching layers of damping material to the surfaces of the panels. One traditional method has been to attach press-formed fibrous composite sheets. However, these sheets are prone to rotting when damp, as the material is not water resistant and is very difficult to clean.

More recently, viscoelastic materials have been used. One such material is a copolymer comprising ethylene, vinyl acetate, and acrylic and/or methacrylic acid. Another proposal has been to apply a viscoelastic adhesive composition comprising a polyepoxide, a polyether amine, a hetrocyclic amine, and a phenol, which is said to be useful as a damping material. A yet further proposal has been to use composite comprising an elastomeric butyl polymer sheet bonded to a thin layer of non-elastomeric material on the surface. Furthermore they are not particularly useful in preventing transmission of noise from other sources. Multilayered acoustic tiles for suppressing noise and also reducing its transmission were developed (Gunasekara and Alwis 2004; Bourcier et al. 2009). Improved materials that will not only effectively damp the vibration of the body panels but will also reduce sound transmission through the body panels would be a great advance in the art of vehicle sound proofing which is still evolving.

10.10 Special Test Methods

10.10.1 Aroma Barrier Test

Until the first half of the twentieth century, perishable food articles of daily life, such as meat or cheese, and also non-food articles like detergents or soap were mostly sold in shops and did not use packaging or were just wrapped in paper or cardboard. Glass and metal were the only packaging materials providing high barrier for the few applications which required long shelf life.

Modern lifestyle with self-service supermarkets, plus worldwide and year-round availability of all articles, would not be possible without adequate packaging of those articles. Processing, preservation, and distribution of those articles have created not only a huge growth of traditional packaging materials, e.g., glass, metal, and paper, but also the development of new packaging concepts, especially flexible packaging with plastic materials, for better economy, convenience of packaging, and quick transportation (Kemmer et al. 2008).

The food industry has long depended upon reliable, impermeable packaging materials such as glass and metal. Both suppliers and food manufacturers focus research efforts into lighter-weight, flexible, and semirigid packages, which are typical qualities of plastics. While parameters such as functionality, recyclability, and cost are critical characteristics, the lack of complete impermeability and inertness in these polymer materials can have important effects. Due to their size

and nature, the aroma compounds will interact with packaging materials often consisting of lipophilic hydrocarbons (Johansson 1996).

10.10.1.1 Factors Influencing Aroma Barrier Test

An aroma is a chemical substance sensed by the taste and/or the smell defined by parameters such as its volatility, its polarity, and its aromatic value. The aromas must be protected throughout the retail chain until its use. The conservation of these aromatic contents is mainly based on the packaging (Risch 2000).

Aroma compounds interact with the polymer matrix, leading to polymer structural changes. Plastic packages are made up of polymers that form a matrix of crystalline and amorphous regions, which contain submicroscopic voids. Aromas permeate through packaging by first being adsorbed onto the package's surfaces, diffusing through the voids (absorption), and, without a barrier material, desorbed to the package's exterior. A sorption–diffusion mechanism is thus applied.

The mass transfer phenomenon, commonly described by the sorption, the migration, and the permeation can be determined by three parameters: S, the solubility coefficient; D, the diffusion coefficient; and P, the permeability coefficient. When diffusion is Fickian and sorption follows Henry's law, the relationship $P = DS$ can be used (ASTM F 1769-97).

Literature and knowledge on mass transfer of aroma compounds are few and no standard procedure is recommended. Methods developed for aroma compounds permeability measurements are commonly approached by isostatic or quasi-isostatic methods and depend on the physical state (vapor or liquid) of the aroma compounds (Piringer and Baner 2000).

Aroma barrier is somewhat analogous to flavor barrier. Food products must be protected from outside aromas in the distribution chain, grocery store, and home. Other food and non-food products such as garlic, agricultural chemicals, pesticides, insecticides, or perfumes can be highly aromatic. The desire is to retain the aroma in the package and not let it escape into the surrounding environment (Eval Americas 2007).

Numerous apparatus have been designed, to different degrees of success, to obtain information regarding aroma permeability of packaging films in a reasonable time frame. Experimental setup for studying the permeability through polymeric films is presented in Fig. 10.64 (Vähä-Nissi et al. 2008).

Sensory evaluations of some common aromas packaged in a variety of film structures are presented in Table 10.33. And comparison of permeation rate of different film structures for some common aromas is shown in Table 10.34.

The area of "flavor" and "aroma" barrier is receiving growing attention in the field of plastics packaging. The permeation of flavors is difficult to measure quantitatively because they contain many components. Many times, only a simple component of a flavor is measured if a quantitative value must be determined. Gas chromatography and mass spectrophotometric (GC/MS) techniques have been developed that allow the analysis of complex flavors. However, in most cases, the use of organoleptic testing provides reliable and pertinent data at a greatly reduced cost.

As with flavor permeation, aroma permeation can be determined by sensory evaluation or gas chromatography.

Fig. 10.64 Permeation device with *1*, GC; *2*, test cell; *3*, test cell oven and sample transfer oven (Vähä-Nissi et al. 2008)
Table 10.33 Results of sensory evaluations for various aromas packaged in a variety of film structures. The numbers represent the time it takes the aroma to permeate the package at room temperature (Eval Americas 2007)

Aroma permeation						
PVDC						
Structure thickness (μ)	LDPE (50)	OPP/PE (20/50)	PET/PE (20/50)	Nylon (15)	F Series/ PE (15/50)	EF-XL/PE (15/50)
Orange essence	1	2	3	2	4	5
Strawberry essence	2	2	3	2	3	3
Curry powder	2	3	2	2	3	3
Garlic powder	2	2	2	2	3	3
Coffee powder	2	3	3	3	5	5
Linalol	1	3	3	4	5	5
Geraniol	1	3	3	4	5	5
Prenyl Benzoate	1	2	2	3	5	5
Methyl ionone	2	3	3	3	5	5

Key: 1: <1 h, 2: <1 day, 3: <1 week, 4: <2 weeks, 5: <2 weeks

Diffusion (D) and Permeability (P) Coefficients

For different aroma/synthetic material couples, the results of the D and P obtained by the HS-GC/MS and gravimetric methods are compared in the literature (Table 10.35).

D and P for the Limonene/LDPE Couple in Function of Relative Humidity

In view of the previous results, the study of the influence of the relative humidity on the mass transfer of an aroma through a packaging material was realized for the couple limonene/LDPE (Maki and Stevens 2002).

Table 10.34 Comparison of permeation rate of various film structures for common aromas (Eval Americas 2007)

Aroma permeation					
Days to Leakage					
Film construction	Thickness (mils)	Vanillin (Vanilla)	Menthol (Peppermint)	Piperonal (Heliotropin)	Camphor
PET/F Series/ PE	0.5/0.6/2.0	15	25	27	>30
OPP/F Series/ PE	0.7/0.6/2.0	30	>30	27	>30
PET/F Series	0.5/0.6	>30	>30	30	>30
ON/F Series	0.6/0.6	2	>30	27	30
PET/PE	0.5/2.0	2	16	5	>30
ON/PE	0.6/2.0	2	20	5	28
PVDC ct'd PET/PE	0.6/2.0	7	>30	6	30
PVDC ct'd/ OPP/PE	0.7/2.0	6	2	1	13
PVDC ct'd PET	0.9	5	6	1	7

Values in the table above indicate the number of days until leakage through the package is detected. The greater the values, higher the fragrance preservation

Table 10.35 Comparison of the diffusion and permeability coefficients of the HS-GC-MS and gravimetric methods for different relative humidity for the limonene/LDPE couple (Martine and Louvier 2010)

Method	Coefficient at 23 °C	20 % r.h.	50 % r.h.	90 % r.h.
HS-GC/MS	Mean diffusion (**D**) (cm^2/s)	5.34×10^{-9}	7.03×10^{-9}	5.23×10^{-9}
	Permeability (**P**) (g.μm/m2.d.Pa)	14 (n = 3)	20 (n = 7)	7 (n = 3)
		9 → 18	14 → 35	6 → 8
Gravimetry	Mean permeability (**P**) (g.μm/m^2.d.Pa)	13 (n = 3)	26 (n = 3)	13 (n = 3)
		13	26 → 27	12 → 15

Notice that D and P are lower for 20 % and 90 % relative humidity compared with those for a relative humidity of 50 % whatever the analytical methods used

10.10.1.2 Examples of Polymers as Barrier Films
Nylon 6
Nylon 6 is a good barrier material for nonpolar to slightly polar solvents and smaller organic molecules and a very good barrier to bulky aroma molecules of low to intermediate polarity. For some nonpolar materials, its barrier even exceeds that of EVOH, whereas EVOH has slight advantages for molecules of intermediate polarity. Only for highly polar migrants, as methanol or isopropanol, the barrier of nylon 6 is clearly lower than that of EVOH – a situation well known from oxygen and carbon dioxide permeation.

Due to its moderate price, good processability, and high mechanical and thermal properties, it is found to be a suitable material for packaging of many aroma-containing materials, such as menthol-flavored toothpaste. In case of detergent refill pouches, it further prevents contamination of the environment by the aroma migrating out of the package, an effect that may be undesirable when too many different flavors come together. Another application PA6 that is frequently used for is barrier layer in blow-molded containers as are used for packaging herbicides or pesticides with cyclohexane, xylene, or methyl ethyl ketone solution. Here, nylon provides another advantage over EVOH: nylon 6 may be processed as inner, sealing layer, thereby providing a continuous barrier layer in the container. EVOH however needs to be processed as a core layer, with a PE inner layer which is then in contact to the solvent and also forms the seal. This seal will then be a weak spot in the container for both migration and mechanical strength.

Cyclic Olefin Copolymer (COC)

COC has better aroma barrier than polyethylene and is found to reduce aroma/flavor loss from food when it is utilized as a barrier layer in food packaging. COC is also found to reduce the transmission of objectionable odors to surrounding areas and has utility in disposable food storage bags. Low extractables in COC reduce the possibility of generating an "off-taste" in water or susceptible foods when used as a contact layer or just under a seal layer in packaging (Jester et al. 2005).

10.10.2 Permeability Test for Liquids

There has been a trend to use more plastic-based packaging materials for different applications such as replacements for metal and glass containers. This situation has stimulated the industry to provide new and more efficient barrier solutions. A number of different technologies are being developed and are making their way into the market. Melt processable thermoplastic blends which allow injection molding, blow molding, thermoforming, and other conventional techniques to be applied for making products that are impermeable for diesel, petrol, and other organic liquids while possessing high-performance properties, even after recycling, are being focused.

Following the success story of the plastic bumpers, for automobiles, which commercially replaced the heavy metallic bumpers, the plastic fuel tanks are making inroads to replace metallic fuel tanks. The plastic tanks offer weight reduction, freedom from corrosion, and ease of fabrication.

The principal performance property required for HDPE blend (with polyamide-6) is the reduced permeability for diesel; hence, the morphology of the blends in the final product is extremely important. The morphology of the binary blends and the influence of different compatibilizers in different concentrations were also investigated using scanning electron microscope (SEM). Here, for morphology

studies, the injection-molded flexural bars were allowed to soak in liquid nitrogen and were fractured quickly after taking them out. The fractured surfaces were carefully cut and were studied under SEM, after making their surfaces conducting by depositing gold vapors in an ion sputtering unit.

The blends disclosed dispersed domains of polyamide within a continuous phase of HDPE. Since HDPE and polyamide are incompatible, use of a compatibilizer is essential. There are three main factors governing compatibilization and interfacial interactions, viz., reduction of the interfacial tension, increased interfacial adhesion, and achievement of a viscosity ratio conducive to efficient dispersion.

10.10.2.1 Factors Influencing Permeability Test

Permeation is a mass transport phenomenon in which molecules transfer through the polymer from one environment to another through diffusive processes. Mass transport proceeds through a combination of three factors in case of polymers. They are (1) dissolution of molecules in polymer (following absorption at the surface), (2) diffusion of molecules through the material, and (3) desorption from the surface of the material (Crank and Park 1968; Kumins and Kwei 1968).

In case of polymers, mass transport of small molecules can take place, as there is intrinsic porosity in the polymer matrix. Even solid homogeneous polymers are likely to be porous to some degree owing to defects, inclusions and different phases, which leave pores, voids, and crazes capable of accommodating small molecules. For molecules to undergo transport within a polymer, they must dissolve in the solid polymer. If the molecules do not dissolve, in the polymer, then diffusion is irrelevant. The basic mechanism for diffusion is occupation of the free volume between the polymer chains. Dissolution is a thermodynamic process, where the solubility is determined by enthalpy change on dissolution of the molecule in the polymer matrix and the volume available. And diffusion is the net transport of matter in a system, which acts to nullify the potential differences in order to bring in a state of equilibrium. Here, the rate of diffusion is proportional to the concentration gradient of the diffusant.

The factors, which influence the permeability or mass transport, are the following: chemical composition of the polymer matrix and its free volume. In fact, crystallinity, molecular orientation, and physical aging in turn influence the free volume of a polymer matrix. In addition, porosity and voids, like free volume, offer sites into which molecules can absorb and are far less of a barrier to transport than solid polymer. Temperature also affects permeability and diffusion properties of small molecules in polymers. With increased temperature, the mobility of molecular chains (in polymer) increases and thermal expansion leads to reduced density; therefore, the free volume in the system will increase. External tensile stress applied is expected to increase free volume and open up internal voids or crazes, providing additional sites into which molecules can absorb. Of course, there may be unquantified internal residual stresses, arising from processing, present in the polymers. It is well established that the properties of materials

Fig. 10.65 HDPE–
polyamide-6 (20 wt%) blend.
Injection-molded flexural bar
in the skin zone as viewed
under SEM (Xavier and
Pendyala 2008)

near the interphase are different from those of the bulk material. Thus, the
diffusion properties in the interfacial region are likely to be different from those
of the bulk material.

10.10.2.2 Permeability and Polymer Blend Morphology
Morphology of HDPE-Polyamide-6 Compatibilized Blends
PE and PA-6 are incompatible with an unstable morphology when blended. To stabilize
PE/PA-6 blends, many compatibilizers have been used (Yeh et al. 1995; Chen et al.
1988; Kouloori et al. 1997; Gadekar et al. 1998; Raval et al. 1991; Willis and Favis
1988; Halldén et al. 2001), e.g., copolymers or adducts of maleic anhydride (Chen
et al. 1988; Gadekar et al. 1998), acrylate copolymers such as poly(ethylene-*g*-butyl
acrylate) (Raval et al. 1991) and ethylene/methacrylic acid/isobutyl acrylate terpoly-
mer (Willis and Favis 1988), poly(ethylene-*g*-ethylene oxide) and poly(ethylene-
co-acrylic acid) (Halldén, and Wesslen 1996; Serpe et al. 1988), and succinic anhydride
functional groups (Padwa 1992; Sánchez-Valdes et al. 1998; Kudva et al. 1999; Kelar
and Jurkowski 2000; Pan et al. 2001; Jurkowski et al. 2002; Filippi et al. 2002).

The morphology of the cryogenic fracture surfaces of HDPE blends with
polyamide-6 (PA-6) are presented in Figs. 10.65 and 10.66. PA-6 distributed in
a matrix of HDPE is clearly visible in Fig. 10.65. Here, as no compatibilizer was
engaged, the protruding strips of PA-6 do not show any interaction with the matrix
material. But when a compatibilizer, ethylene-methacrylic acid copolymer, was
engaged, the fracture morphology has altered (Fig. 10.66) and the PA-6 dispersion
is rather more uniform and does not show such protruding strips. The dispersion of
PA-6 (35 wt%) as viewed from optical microscope (Fig. 10.67) also exhibits good
dispersion of the same (Xavier and Pendyala 2008).

Morphology of HDPE-Polyamide-66 Compatibilized Blends
Poor interfacial interactions between polyamide-66 and matrix material are respon-
sible for considerable pulling out of the dispersed phase as revealed in Fig. 10.68.

Fig. 10.69 HDPE–polyamide-66 (23.75 wt%) with compatibilizer ethylene–methacrylic acid copolymer neutralized with metal ions (5 wt%). Injection-molded flexural bar in the core zone as viewed under SEM (Joshi et al. 2005)
Fig. 10.70 Lamellar morphology in fractured bottle wall of HDPE–polyamide-6 compatibilized blend with good barrier properties for diesel as viewed under SEM (Xavier and Pendyala 2008)
String and bead type of morphology is observed at many locations. However, as compatibilizer ethylene–methacrylic acid copolymer is introduced, the fracture has taken place in flat plane and no protrusions of polyamide-66 are observed (Joshi et al. 2005). The presence of the compatibilizer has altered the fracture propagation mechanism (Fig. 10.69).

The blow-molded bottle of HDPE blend with polyamide-6, after testing for permeability of diesel, was also tested for its morphology, using SEM. The bottle wall was cut into strips and the strip was fractured after soaking in liquid nitrogen. The morphology of the fractured surface revealed lamellae formed by the dispersed phase and oriented in the melt flow direction, parallel to the wall surface of the bottle (Fig. 10.70). These lamellae are responsible for restricting the permeation of diesel through the bottle. The wall of the bottle as well as the bottom of the cylindrical-shaped bottle was cut, and morphology
Fig. 10.71 PE–PA-6 bottle wall morphologies at different locations (Xavier and Pendyala 2008)

was studied at different locations. The lamellar morphology (as viewed in Fig. 10.70) was found to be present at all the locations of the bottle investigated (Fig. 10.71).

10.10.2.3 Permeability Tests for Diesel and Petrol

Permeation tests by pouring liquids in bottles and monitoring the weights of the bottles with regard to time have been practiced in many laboratories (Armstrong 1968a, b; Mesrobian et al. 1968; Subramanian 1983, 1984, 1985, 1987; Jen-Taut 1997; Xavier and Pendyala 2008).

Bottles of 250 ml capacity were prepared out of the dried granules of HDPE as well as compatibilized blend (with PA-6) having high mechanical properties; preferably with high notched Izod impact strength along with suitable melt flow characteristics. The injection molding was carried out in a Windsor Machine, SP-110, in a temperature range, 513–573 K, with injection pressure, 50–60 kg/cm^2, locking pressure around 70 t, injection time, 4.0–6.0 s, and cooling time, 5.0–7.0 s.
Fig. 10.72 Weight loss in bottles filled with Petrol and Diesel with regard to time in hours. Each point on the graph is an average weight of three bottles kept under investigation (Xavier and Pendyala 2008)

Diesel, as well as petrol, was poured separately into bottles of neat HDPE (control) and the selected blend bottles, at least three bottles for each case, covered with aluminum foil using a silicone sealant that cured at room temperature. It was further covered with molded plastic lid and was sealed with the same sealant. After the adhesive is cured, diesel/petrol permeation is tested and recorded at regular intervals by measuring the weight of each bottle.

Bottles with Petrol had shown a loss of 7 wt% in 25 days (600 h). Bottles filled with diesel had shown a marginal loss of 0.2 wt% in 25 days (600 h) or a weight loss of 0.8 g in about 1,000 h. See Fig. 10.72 (Xavier and Pendyala 2008).

10.10.3 Environmental Stress Cracking

Environmental stress cracking (ESC) in plastics means the failure of the plastic involved at about room temperature due to continuously acting external and/or internal stresses in the presence of surface-active substances (known as stress-cracking agents), which are normally liquids, such as alcohols, soaps, dyes, and agents containing moisture (Scheirs 2000; Wright 1996; Lagaron and Dixon 1998; Lagaron et al. 1999). ESC is a major problem in the long-term service behavior of plastic products. It can lead to quite expensive failures during warehouse storage, shipping, or during long-time applications. ESC of polymers is analogous to the stress corrosion problem in metals. It takes place after a certain period of time: the lower the stress, the longer the durability.

ESC occurs, in general, in amorphous polymers such as PC, PMMA, PS, PVC, SAN, and ABS as well as in semicrystalline thermoplastics like PE, PP, PA, and PB (Wright 1996). Amorphous polymers exhibit a higher tendency for this type of failure because their loose structure facilitates fluid permeation into the polymer. Amorphous polymers show enhanced sensitivity to ESC at temperatures close to

Fig. 10.73 Bent Strip ESCR Test (ASTM D1693-12)

"C" Shaped Bracket

IGEPAL® Solution

10 Notched Test Specimen in C Shaped Bracket
their T_g values due to the increased free volume as T_g is approached, which facilitates fluid permeation into the polymer. The solvent then becomes locally dissolved and promotes crazing which is a fore runner for cracking. Several molecular mechanisms have been proposed to explain ESC over the past few years (Lagaron et al. 2000). Lustiger and Ishikawa have proposed "interlamellar failure" as the controlling mechanism of ESC (Lustiger and Ishikawa 1991).

10.10.3.1 Test Methods for ESC
ASTM D 1693: Bent Strip ESC Test
This is a well-known original ESC test developed by Bell Labs in the late 1940s. Ten rectangular-shaped specimens are cut from a molded plaque prepared using standard methods. A controlled notch is cut horizontally across each specimen, which serves as a crack initiation point. The specimens are bent and inserted into a "C"-shaped bracket, creating a stress in the specimen. A diagram of this test method is shown in Fig. 10.73. The specimens and bracket are inserted into a tube filled with Igepal® solution. The tube is then placed into a heated environment

and monitored for cracking (failures). Solution concentration, environment temperature, and sample dimensions vary with the test condition mentioned in the method.

The various test conditions suggested in the method introduce different stresses and strains and allow testing of different polymers and still obtain results in a timely manner.

ASTM D 1693 is not used popularly, today, for it is not sufficiently aggressive towards modern resins. This test is a constant strain test, but polyethylene, like many polymers, relaxes when strained. This stress relaxation allows testing to run without failure for very long time periods ($>$1,500 h), even under severe conditions of temperature and *Igepal*[®] concentrations.

ASTM F 1248: Notched Pipe Ring ESCR Test

This method has been used in the United States for many years to measure ESC on finished pipe up to 12 in. diameter that is notched using a razor blade in a special notching device.

ASTM D 5397-99 Standard Test Method for Evaluation of Stress Crack Resistance of Polyolefin Geomembranes Using Notched Constant Tensile Load Test

This test is typically used in the United States to test Geomembrane materials. But other PE materials, including some pipe resins, have been tested to gauge slow crack growth performance. Typical test conditions are 50 °C in a 10 % *Igepal*[®] *solution*, and the applied load is 30 % of the sample's yield stress. The depth of the notch is 20 % of the thickness of the sample (ASTM D 5397-99).

The Full Notch Creep Test (FNCT)

This method is being accepted throughout Europe as the standard method to test PE pipe grade materials that exhibit very high environment stress crack resistance (ESCR) values. The FNCT test has been preferred in Europe, as it leads to shorter failure times, due to its particular specimen design and to the presence of a surface-active environment.

ASTM F 1473: The Polyethylene Notch Tensile (PENT) Test (Constant Load)

The PENT test is being used in the United States to test PE pipe grade materials that exhibit high ESCR values (ASTM F1473-11). A parallel test method is also being developed in Europe under the ISO protocol. Typical test conditions are 80 °C air and 2.4 MPa stress.

ISO 13479: Notch Pipe Pressure Test

This method is accepted as the standard method to test PE pipes throughout Europe. The specific performance levels are detailed in the respective pipe standards (i.e., ISO 4427 for water and ISO 4437 for gas). Typically a minimum of 165 h is set for PE pipe materials.

10.10.3.2 Factors Influencing ESC

The ESC behavior of a polymer is strongly influenced by (a) the concentration of the stress-cracking agent (liquid chemical), (b) exposure temperature, (c) exposure time, and, most of all, (d) the level of strain on/in the polymer.

The absorption of a stress-cracking agent into a micro-yielded or stress-dilated zone of a polymer ultimately leads to ESC. This process locally reduces yield strength of the polymer and leads to fracture. The fracture may be either ductile or brittle depending on stress and time considerations. Diffusion of detergent molecules into the polymer due to stress might result in increased chain mobility and therefore in a reduction of the activation energy (plasticizing effect) of the deformation process (Lagaron et al. 1999). Stress-cracking agents act to lower the cohesive forces which maintain the tie molecules in the crystallites, thus facilitating their "pullout" and disentanglement from the lamellae (Scheirs 2000). The stress-cracking agents accelerate the brittle-failure process. Any stress-cracking agent will lubricate the tie molecules and that will facilitate their pullout from the lamellae.

The effect of temperature is complex. It has been shown that the higher the test environment temperature, the faster the ESC onset. The transition to brittle behavior is accelerated to shorter times by increasing temperature, cyclic loading, dilational stress, and stress concentrations. Localized concentration of the stress due to local geometrical features as notches, voids, and inclusions will increase the stress and modify the nature of the stress field. Craze initiation is accelerated by stress fields with high dilational stress and retarded under hydrostatic pressure (Wright 1996).

In addition, there are critical polymer properties and variables which affect ESCR significantly. The higher the molar mass the longer the polymer chains, which results in more tie molecules and increased ESCR (Huang and Brown 1988). ESCR is directly influenced by the type, length, and complexity of chain branching. For polyethylenes, density is a convenient, if not wholly accurate, measure of short chain branching. As a general rule of thumb, as branching increases, so does ESCR. Thus, as density decreases, ESCR generally increases. ESCR appears to be particularly sensitive to subtle variations in crystal structure and thus to differences in short chain branching. ESCR decreases with increasing the degree of crystallinity (Huang and Brown 1988; Lagaron et al. 1998). Higher comonomer content and longer comonomer short chain branches (higher α–olefins) provide better ESCR of LLDPE (Lustiger 1998; Soares et al. 2000). Increased pigment content usually decreases the ESCR (Kendall and Sherliker 1980; Lustiger 1986). The thermal history of the material and the processing conditions are also important factors for the ESCR behavior of the polymers (Roe and Gieniewski 1975; Lu and Brown 1987; Wang et al. 2003).

10.10.3.3 ESC in Polymers and Blends: Examples
Polycarbonate
Polycarbonate is tough, strong, high-performance amorphous engineering thermoplastic which is finding widespread use in industry. It has applications where high

impact resistance and its ability to maintain its shape and size even under great stresses over a wide range of temperatures are desired. It is an ideal engineering plastic since it can be injection molded or extruded. Due to its excellent properties, it is often used in the appliance industry for vacuum cleaner bases, cord hooks, impellers and blender, and food processor housings. Motorcycle windshields, police shields, and headlight covers are other typical high stress applications that use polycarbonate.

A detailed investigation of environmental stress cracking was conducted with both monoethanolamine and surfactants. The detailed investigation (Faulkner 1985) included determinations of cracking strains for polycarbonate upon exposure to the fluid's components and several nonionic surfactants. Critical strain determinations for polycarbonate exposed to the liquid components indicate that both monoethanolamine and surfactants are stress-cracking agents for polycarbonate. Cracking strains were also determined for a polycarbonate/acrylic blend upon exposure to the same fluid and were shown to be significantly greater than those obtained for pure polycarbonate. However, both the materials stress crack in splash tests. Plastics with even moderate amounts of designed-in stress are at risk under prolonged exposure to certain chemicals, which makes design and manufacturing of such parts a challenge (Krishna and Berg 2011).

The synergistic effects of photodegradation on ESC of PC were also investigated. Injection-molded samples were exposed to the ultraviolet light for various times in the laboratory prior to solvent contact. The bars were then stressed with two different loads in a tensile testing machine under the presence of ethanol. During this period, the stress relaxation was monitored, and, after unloading, the ultimate properties were evaluated. The results indicated that ethanol causes significant modification in PC, with extensive surface crazing as well as reduction in mechanical properties. The synergist action of photodegradation and stress cracking in PC may be a consequence of the chemical changes caused by oxidation (Timoteo et al. 2008).

High-Density Polyethylene
Considering the fact that the slow crack resistance of polyethylene is usually assessed by tedious and time-consuming testing methods performed on the notched samples in contact with specific fluids, the findings of Kurelec et al. offer a possibility to assess the information on slow crack propagation in much simpler and faster way (Kurelec et al. 2005; Jansen 2004). It is shown that the average strain hardening slope <G> correlates with the data obtained by a classical accelerated ESCR test. The results provide experimental evidence for the existence of the unique strain–stress–strain rate surface by offering a simple way to predict long-term performance. The resistance to slow crack propagation in polyethylene can be predicted from a simple tensile measurement performed at 80 °C and for different types of polyethylene homopolymers and copolymers the slope of a tensile curve above its natural draw ratio (i.e., strain hardening) correlates well with the measured stress crack resistance.

The investigations confirm that the slow crack resistance in polyethylene is determined by the failure of the fibrils within the craze, which is shown to be determined by the strain hardening of a tensile curve. A material with a strong strain hardening will reduce the strain rate and consequently the time to failure will be strongly increased (ASTM D2561-12).

Polymethyl Methacrylate (PMMA)

The deterioration of polymer properties by ESC has been studied for several decades. But the actual mechanism is not certainly established (Hansen 2002). It is believed that in the presence of the stress, the active fluid causes local plasticization that generates crazes and eventually catastrophic cracks. The ultimate result in many cases is brittle fracture, even in normal ductile polymers like polyethylene, ABS, and polycarbonate. Since failure by ESC can be induced by environmental fluids like cleaning agents and lubricants and the mechanical stress can be the residual (molded-in) stresses, it was considered to be a "silent killer" (Sepe 1999).

The effects of environmental stress cracking in injection-molded PMMA samples were studied by Sousa et al. They used both γ-radiation and ethanol as stress-cracking agents. The combination of gamma degradation and the contact with ethanol intensifies the action of stress-cracking in PMMA (Sousa 2007).

Alex and Janice studied the resistance to crack and craze growth in PC and PMMA in the presence of several surface-active solvents including a component of the universal chemical warfare decontaminant, DS2 (Alex and Janice 1989). A static dead weight-loading apparatus is used for experimentation, and LEFM is used to interpret craze initiation and crack propagation via compact tension specimens. Results reflect relationships based on solubility parameters of the solvents and the polymers.

Acrylonitrile Butadiene Styrene (ABS)

The evaluation of the resistance of plastics to ESC is very important in material selection. ABS is widely used in a variety of fields owing to favorable cost/performance ratio. The advantages of ABS are its luster and resistance to impact. ABS is, therefore, used mainly for housings of appliances. However, ABS is vulnerable to certain chemical agents such as organic solvents and surfactants (Faulkner 1984; Woshinis 1994). ESC of ABS caused by a nonionic surfactant was investigated by creep tests and edge crack tension (ECT) tests. It was found that the results of the creep tests performed in the nonionic surfactant were very different from those conducted in air. The results showed that the change in the mechanism of fracture was attributable to the change of morphology at the crack tip (Kawaguchi et al. 2002).

An investigation was carried out by Wang et al. to determine the appropriate values of strain to be exerted in the test for environmental stress cracking of different kinds of polymeric materials (Wang et al. 2003). It was found that for

the brittle plastics the elastic region on the stress–strain curve is the best selection; for toughened plastics the strain should be selected in the plastic region; for polycarbonate, which can crack easily in a chemical medium, a strain below the yield point is Suitable.

10.10.3.4 Predicting ESC

The phenomenon of ESC has been known for several decades. And many researchers have been focusing their attention in understanding the phenomenon. However, research has not yet enabled prediction of this type of failure for all environments and for every type of polymer. Some scenarios are well known and documented and are able to be predicted. But there is no complete or comprehensive reference for all combinations of stress, polymer, and environment. The rate of ESC is dependent on many factors including the polymer's chemical structure, bonding, crystallinity, surface roughness, molecular weight, and residual stress. It also depends on the liquid reagent's chemical nature and concentration, the temperature of the system and the strain rate. Theoretical studies with computer-assisted modeling and practical confirmations may enable researchers to predict ESC with reasonable accuracy. And one may look forward for such attempts in research in years to come.

10.11 Outlook on the Future of Polymer Blends

This chapter is focused on the characteristic properties of polymer blends. Their measurements have reached a mature stage, both in terms of necessary theories and the methods of testing. However, efforts made in enhancing one property are often mitigated by the loss of another property. Intensive study of interrelations between processing, microstructure, and properties would certainly enable one to have a good control on performance of an ultimate product. Looking at the likely advances in understanding of these materials and their integration with developing technology, polymer blends will continue to receive increasing acceptance for a variety of applications.

TMOS Tetramethyl bisphenol A oligosulfones
UCST Upper critical solution temperature

Appendix 1

See Table 10.36.

Appendix 2

See Table 10.37.

Table 10.36 Definition of terms used in this chapter

Autoignition	Ignition caused solely by heat without application of a flame (also called self-ignition)
Autoignition temperature	The minimum temperature to which a substance must be heated, without application of a flame, in order to cause that substance to ignite
Burning behavior	The physical and chemical changes that take place when materials, products, or structures burn and/or exposed to fire
Char	Carbonaceous material formed by pyrolysis or incomplete combustion (ASTM E 176-81a)
Chemical resistance	The ability of a material to resist chemical attack (the attack is dependent on the method of test and its severity and is measured by determining the changes in physical properties (ASTM 1982)
Combustion	Reaction of a substance with oxygen with release of heat, generally accompanied by flaming and/or emission of smoke. Any chemical process that produces light and heat, either as glow or flame
Decomposition temperature	This is the temperature range associated with the decomposition of the polymer in the presence of oxygen
Dielectric breakdown voltage	The voltage at which electrical failure or breakdown of a dielectric occurs when energized between two electrodes under prescribed test conditions
Dielectric constant	For a given configuration of electrodes, the ratio of the capacitance with the material as the dielectric to the capacitance with vacuum
Dielectric strength	The average voltage gradient at which electric breakdown occurs under specific conditions of test
Dissipation factor	The ratio of the loss index to its relative permittivity, the tangent of its loss angle, δ or the cotangent of its phase angle, Θ
Elongation	The strain produced in the test specimen by a tensile stress, expressed as a percentage with respect to the gauge length
Elongation at break	The percentage elongation produced in the gauge length of the test specimen at the break point
Elongation at yield	The percentage elongation produced in the gauge length of the test specimen at the yield stress
Fatigue	The process of progressive localized permanent structural change occurring in a material subjected to conditions that produce fluctuating stresses and strains at some point or points that may culminate in cracks, complete fracture, or thermal softening after sufficient number of fluctuations (Borders et al. 1946)
Fatigue crack growth rate	Crack extension caused by constant amplitude fatigue loading and expressed in terms of crack extension per cycle of fatigue, da/dN (Borders et al. 1946)
Fire	A process of combustion characterized by the emission of heat, accompanied by smoke and/or flame (Mark et al. 1975)
Fire resistance	The property of a material or an assembly to withstand fire or give protection from it

(continued)

Table 10.36 (continued)

Fire retardant (flame retardant)	The quality of a substance of suppressing, reducing, or delaying markedly the combustion of certain materials. A fire retardant causes a material to resist burning when exposed to a high-energy source (Sanders 1978)
Flexural deflection	The distance over which the top or the bottom surface of the test piece at mid-span has deviated during flexure from its original position
Flexural stress (at conventional deflection)	The flexural stress at a deflection equal to 1.5 times the thickness of the test piece
Flexural stress at maximum load	The flexural stress developed when the load reaches the first maximum
Flexural stress at rupture	The flexural stress developed at the moment of rupture
Fracture	A break in the mechanical continuity of a material caused by stress exceeding the strength of the material, including joints and faults
Fracture toughness	A conventional fracture mechanics strength parameter indicating the resistance of a material to crack extension
Gauge length	The original length between two marks on the test piece over which the change in length is determined
Haze	Percentage of transmitted light that passes through the specimen deviates from the incident beam by forward scattering (ASTM D 1003)
Haze reflection	The scattering of reflected light in directions near that of specular reflection by a specimen having a glossy surface
Haze transmission	The scattering of light within a specimen or at its surface responsible for the cloudy appearance of objects observed through the specimen
Homogeneous specimen	A specimen in which every geometrically identical portion has the same apparent thermal conductivity
Impact strength	The property to resist physical breakdown when subjected to a rapidly increasing applied force (ASTM Standard Definitions 1982)
Layered specimen	A specimen that if sliced parallel to the faces has one or more slices with a significantly different apparent thermal conductivity than the other slices
Limiting oxygen index (LOI)	This is a measure of the minimum concentration of oxygen in an oxygen–nitrogen atmosphere that is necessary to support a flame for at least 3 min under specified test conditions (Mark et al. 1975)
Refraction	Change in the direction of propagation of radiation determined by change in the velocity of propagation in passing from one medium to another
Refractive index	The ratio of the velocity of light (of specified wavelength) in air to its velocity in the substance under examination
Rockwell hardness	A number derived from the net increase in the depth of impression as the load on a penetrator is increased from a fixed minor load to a major load and then returned to the minor load (ASTM D 785)

(continued)

Table 10.36 (continued)

Secant modulus	The ratio of stress to strain, in general, at any given point on the stress–strain curve
Smoldering	Combustion of a solid without flame. The combustion of a material without light being visible and generally evidenced by smoke and an increase in temperature (ASTM E 176-81a)
Specific heat	The heat capacity, C, per unit mass or per unit volume; usually the term refers to mass specific heat (Brown 1981)
Strain	The change in length per unit original length of the measured gauge length of the test specimen. It is expressed as a dimensionless ratio
Surface resistance (R_s)	Resistance between two electrodes that are on the surface of a specimen is the ratio of the direct voltage applied to the electrodes to that portion of the current between them which is primarily in a thin layer of moisture or other semiconducting material that may be deposited on the surface
Surface resistivity	The ratio of the potential gradient parallel to the current along its surface to the current per unit width of the surface
Tensile modulus (also elastic modulus in tension or Young's modulus)	The ratio of tensile stress to corresponding strain below the proportional limit. Many polymers/blends do not obey Hooke's law through out the elastic range but deviate therefrom even at stresses well below the yield stress. However, stress–strain curves almost always show a linear region at low stresses, and a straight line drawn tangent to this portion of the curve permits calculation of tensile modulus
Tensile strength (nominal)	The maximum tensile stress (nominal) sustained by a test piece during a tension test
Tensile stress (nominal)	The tensile force per unit area of the original cross section within the gauge length carried by the test piece at any given moment. The standard unit is mega-Pascal (MPa = MN/m)
Tensile stress at break	The tensile stress at which break of the test specimen occurs
Tensile stress at yield	The tensile stress at which the first marked inflection of the stress–strain curve occurs. Where any increase in strain occurs without any increase in stress, this point is taken as the tensile stress at yield or yield stress
Thermal conductance, (Γ)	The reciprocal of thermal resistance
Thermal Conductivity, (λ)	The heat flux per unit temperature gradient in the direction perpendicular to an isothermal surface, under steady-state conditions
Thermal resistance, R	The temperature difference required to produce a unit of heat flux through the specimens under steady state conditions (ASTM C 177)
Thermal resistivity (r)	The reciprocal of the thermal conductivity
Toughness	That property of a material by virtue of which it can absorb work

<div align="right">(continued)</div>

Table 10.36 (continued)

Toxicity	The amount of a substance that produces detrimental effects in an animal. It is expressed as a dose divided by the body weight of the animal, i.e., in mg/kg (Chamberlain 1978)
Transmittance (of light)	That fraction of the incident light of a given wavelength which is not reflected or absorbed, but passes through a substance
Volume resistance, (R_v)	The volume resistance between two electrodes that are in contact with or embedded in a specimen is the ratio of the direct voltage applied to the electrodes to that portion of the current between them that is distributed through the volume of the specimen (ASTM Standard Definitions 1982)
Volume resistivity	The volume resistance (in ohm-cm) between opposite faces of one centimeter cube of the material

ASTM D1525-91, *Test for Vicat Softening Point of Plastics* (Philadelphia, 1992)

ASTM D1637-61, *Test for Tensile Heat Distortion Temperature of Plastic Sheeting* (Philadelphia, 1970; discontinued in 1990)

ASTM D1693-12, *Standard Test Method for Environmental Stress-Cracking of Ethylene Plastics* (Philadelphia, 2012)

ASTM D2137-11, *Standard Test Methods for Rubber Property – Brittleness Point of Flexible Polymers and Coated Fabrics* (Philadelphia, 2011)

ASTM D256-00, *Impact Resistance of Plastics and Electrical Insulating Materials* (Philadelphia, 1993)

ASTM D2561-12, *Standard Test Method for Environmental Stress-Crack Resistance of Blow-Molded Polyethylene Containers* (Philadelphia, 2012)

ASTM D257-93, *Standard Test Method for D–C Resistance or Conductance of Insulating Materials* (Philadelphia, 1993)

ASTM D2583-95, *Standard Test Method for Indentation Hardness of Rigid Plastics by Means of a Barcol Impressor* (Philadelphia, 1996)

ASTM D3895-09, *Standard Test Method for Oxidative-Induction Time of Polyolefins by Differential Scanning Calorimetry* (American Society for Testing and Materials, Philadelphia, 2009)

ASTM D542-90, *Standard Test Methods for Index of Refraction of Transparent Organic Plastics* (Philadelphia, 1990)

ASTM D635-91, *Test Method for Rate of Burning and/or Extent of Burning of self-supporting Plastics in a Horizontal Position* (Philadelphia, 1991)

ASTM D638-95, *Standard Test Method for Tensile Properties of Plastics* (Philadelphia, 1996)

ASTM D648-82, *Deflection Temperature of Plastics Under Flexural Load* (Philadelphia, 1988)

ASTM D671-93, *Flexural Fatigue of Plastics by Constant Amplitude of Force* (Philadelphia, 1993)

ASTM D695-91, *Compressive Properties of Rigid Plastics* (Philadelphia, 1992)

ASTM D746-07, *Standard Test Method for Brittleness Temperature of Plastics and Elastomers by Impact* (Philadelphia, 2007)

ASTM D785-93, *Rockwell Hardness of Plastics and Electrical Insulating Materials* (Philadelphia, 1993)

ASTM D790-92, *Flexural Properties of Plastics and Electrical Insulating Materials* (Philadelphia, 1992)

ASTM E162-94, *Method for Surface Flammability of Materials Using a Radiant Heat Energy Source* (Philadelphia, 1994)

ASTM E399-90, *Standard Test Method for Plane-Strain Fracture Toughness of Metallic Materials* (Philadelphia, 1991)

ASTM E413-10, *Standard Classification for Rating Sound Insulation* (Phildelpheia, 2010)

ASTM E813, *Standard Test Method for J_{IC}, A Measure of Fracture Toughness*, in 1997 was replaced by E1737, which in turn was discontinued in 1998, Annual Book of ASTM Standards, Part 10 (American Society for Testing and Materials, Philadelphia, 1981)

ASTM E813-89, *Standard Test Method for J_c, a Measure of Fracture Toughness* (Philadelphia, 1990)

ASTM E90-09, *Standard Method for Laboratory Measurement of Airborne Sound Transmission* (Philadelphia, 2009)

ASTM F1473-11, *Standard Test Method for Notch Tensile Test to Measure the Resistance to Slow Crack Growth of Polyethylene Pipes and Resins* (Philadelphia, 2011)

ASTM, *Standard Definitions, Compilation of* (Philadelphia, 1982)

Abstract

Mechanical properties of polymer blends, including strength and toughness, are described in terms of morphology, resulting texture, and elementary deformation mechanisms and cavitation. Basic principles of toughening of blends based on glassy, crystalline, and thermoset polymers are described. Toughening strategies involving crazing, cavitation, crystal plasticity, and other micromechanisms involving energy dissipation are presented. Cavitation during deformation arising from mechanical mismatch between differently oriented stacks of lamellae in a semicrystalline polymer, decohesion at interfaces, as well as internal rubber cavitation contribute to the toughness by activation of other mechanisms of plastic deformation of the surrounding matter. Internal cavitation, although augmenting the toughness, greatly reduces the strength of the material. Micromechanisms that are engaged in rubber-toughened blends were characterized with significant attention. Matrix and dispersed-phase properties, as well as interfacial effects, were considered in the interpretation of structure–property relationship for incompatible and partially compatible polymer blends. The dispersion of the second component of the blend and its influence on stress concentrations around inclusions were discussed. The concept of easy deformation paths connected with interparticle distances and shear orientation was considered.

The function of the interfaces, including compatibilizers, in plastic response of polymer blends, is also analyzed.

11.1 Introduction

In polymer blends, the structure is more complicated than in homopolymers because usually there are three structure components: dispersed phase, continuous phase, and interface. Strong bonding between blend components assures that the applied force is transmitted into the dispersed inclusions. Therefore, modification of blends by introducing compatibilizers is a common practice. Compatibilized blends differ from blends of incompatible polymers, apart from more discrete dispersion of a minor component, mainly by the structure and properties of the interface between components. Usually, the achieved toughness of well compatibilized blends allows for their large plastic deformation. There are several simultaneous and synergistic phenomena which give a contribution to toughening of polymer blends. The important factors are the recovery of macromolecular chain mobility at interfaces connected with the change in morphology of interfacial layers and the shift of the brittle-to-ductile transition to a lower temperature. The modification of interfaces often removes the additional relaxation processes which can appear in the system containing unmodified interfaces. Therefore, the limitations to the mobility of kinetics elements at interfaces due to interactions between the inclusions and the matrix are also removed.

Nowadays plain homopolymers are rarely used. Instead, the use of polymer blends dominates in many applications. There are a great variety of blends, including a broad range of materials of a matrix as well as dispersed phase. They differ in compatibility of components, incompatibility, partial miscibility, and inclusion size and shape. A range of micromechanisms including crazing, shear yielding, cavitation of various kinds, and plasticity of polymer crystal are engaged in deformation of polymer blends. Dependencies on temperature, deformation rate, concentration of components, molecular characteristics of components, and other factors influence the brittle-to-ductile transition, morphology, and phase structure. Therefore, this chapter was divided into subsections in which the behavior and mechanical properties of most important cases, related phenomena, and features of mechanical performance of polymer blends are discussed.

11.2   Plastic Deformation and Damage Mechanisms in Polymers

There are a large variety of mechanical responses of solid polymers. The range spans from brittle fracture through highly ductile behavior to rubber elasticity. Deformation processes of both glassy and semicrystalline polymers have been extensively explored in the past. For an overview of these numerous studies, see, e.g., Argon 2013; Balta-Calleja and Michler 2005; Haward and Young 1997; Michler and Balta-Calleja 2012. Above the elastic region, deformation of polymers is usually nonhomogeneous, especially when observed in the microscale. This is not only the case of polymers with clear heterogeneous morphology, such as semicrystalline polymers, block copolymers, or phase-separated polymer blends but also of homogeneous materials as amorphous glassy polymers. Plastic deformation and/or fracture mechanisms start to operate locally above the elasticity limit. Depending on the polymer molecular characteristics, such as chain flexibility and chain entanglement density, as well as test conditions (specimen geometry, loading mode, strain rate, temperature), three types of heterogeneous deformation are observed in the microscale: crazes, shear bands, and shear deformation zones (Michler and Balta-Calleja 2012). Among parameters controlling deformation, under standardized testing conditions, the molecular characteristics of the polymer remain the predominant parameter affecting the deformation mechanism.

Crazes are crack-like sharply localized bands of plastically deformed material, initiated when an applied tensile stress causes microvoids to nucleate at points of high stress concentrations that are created by surface scratches, flaws, cracks, dust particles, or other heterogeneities (Bucknall 1977; Haward and Young 1997; Kinloch and Young 1983). In homogeneous glassy polymers, crazes are usually initiated from microscopic surface flaws or embedded heterogeneities, like dust particles. Dust is difficult to avoid in processing (injection molding, extrusion) because it begins with pellets that become statically charged and attract airborne particles. Typical surface defects are small random scratches introduced during processing, machining, and handling. When these flaws are removed, e.g., by

cautious polishing, there is a marked increase in the critical stress of craze initiation, sometimes to the point at which tensile shear yielding and ductile drawing are initiated in relatively brittle polymers such as PMMA and PS (Argon and Hannoosh 1977). Crazes form in planes normal to the direction of maximum (tensile) principal stress and consist of highly oriented polymer fibrils of approximately 5–15 nm in diameter, stretched out in the direction of loading, and separated by elongated nanovoids. Crazes develop and propagate by two processes: by craze tip advance that allows fibrils to be generated and by craze width growth. In contrast to crack, the craze (which is, in fact, a highly localized yielded region, consisting of a system of alternating oriented polymer fibrils and voids) is capable of transmitting load. However, crazes are frequent precursors of brittle fracture since with the growth of the craze the most elongated fibrils break, which usually leads to the development of microcrack in the center of the craze. Due to the presence of voids, deformation of crazes is dilatational – the volume increases markedly with strain (Haward and Young 1997; Kausch 1983, 1990).

On the other hand, the shear bands and deformation zones are the result of shear processes and do not contain voids so that deformation advances at nearly constant volume. Shear bands can be either localized or diffuse, but even for very localized bands, their interface with bulk material is much thicker than for crazes. Thick bands and deformation zones are usually made of coalescing micro-shear bands.

The basic mechanisms involved in plastic deformation of glassy polymers are crazing and shear yielding (Argon 2013; Bucknall 1977; Haward and Young 1997; Kausch 1983, 1990; Michler and Balta-Calleja 2012), giving rise to the formation of crazes or shear bands and zones, respectively. For polymer crystals, plastic shear is realized through crystallographic mechanisms, primarily by crystallographic slips along and transverses to the chain direction, which are supported by the shear in interlamellar amorphous layers (Argon 2013; Bartczak and Galeski 2010; Oleinik 2003). Their collective activity gives rise to the formation of shear bands or deformation zones, similar to shear yielding in glassy amorphous polymers.

Crazing requires the presence of dilatational component in the stress tensor and may be inhibited by hydrostatic pressure. On the other hand, it is enhanced by the presence of triaxial tensile stress (Kinloch and Young 1983). Unfortunately, such a stress state exists ahead of large flaws or notches in relative thick specimens (plane-strain conditions). Therefore, the presence of sharp cracks, notches, or defects in thick specimens will favor craze initiation leading to brittle fracture, which is opposite to a bulk shear yielding mechanism that leads usually to ductile behavior.

Even the most brittle polymers demonstrate some localized plastic deformation – in front of the crack tip, there exists a small plastic zone where stretching of chains, chain scission, and crack propagation appear in a small volume. The size of that plastic zone is too small to manifest in macroscopic plastic yielding and the crack propagates in a brittle manner. The relative low energy absorbed by the sample on its fracture is almost entirely that dissipated inside the small plastic zone.

11.2.1 Brittle and Pseudoductile Polymers

Under given experimental conditions, chemically different polymers behave differently. For example, in tensile test at a low rate polystyrene tends to craze and is brittle while polycarbonate tends to yield and shows ductile behavior. Based on that, polymers are classified frequently as brittle or pseudoductile (i.e., generally showing a ductile behavior but changing to brittle at more severe conditions, e.g., at a lower temperature). According to this classification, brittle polymers (e.g., PS or PMMA) tend to fail by crazing, have low crack initiation energy (low unnotched toughness), and low crack propagation energy (low notched toughness). Pseudoductile polymers (e.g., PC, PET, PA, or PE) tend to fail by yielding, have high energy of crack initiation (high unnotched toughness), and relatively low energy of crack propagation (notch sensitivity, low notched toughness). The brittle or ductile response depends not only on the polymer itself but also on many extrinsic variables as specimen geometry, loading mode, and test conditions, so frequently the same polymer may either craze (i.e., be brittle) or yield (ductile) depending on external conditions. Argon (Argon et al. 2000; Argon and Cohen 2003) argued that with the exception of only a small class of pure metals, all other solids, including all solid polymers, should be actually classified as intrinsically brittle. Intrinsically brittle polymers only can change their response from brittle to ductile at certain specific experimental conditions (see Sect. 11.4.2.3).

11.2.2 Basic Mechanisms of Deformation

The brittle or ductile behavior of polymer and the preferred mechanisms of deformation and failure are controlled principally by two molecular parameters – the entanglement density and chain flexibility, determining an initiation stress for crazing or shear yielding, respectively. Depending on these parameters, one of the two basic deformation mechanisms (crazing or shear yielding) is selected as the dominating mechanism, so they occur separately in most cases. However, they also can be active simultaneously at different proportion in some polymer systems. Moreover, even a small change in the test conditions can result in a change from shear yielding to crazing or reverse. Crazing and shear yielding are considered to be independent processes, and the mechanism that at given experimental conditions requires the lower stress is activated first and becomes the dominant deformation mechanism that leads ultimately to the failure of the material.

11.2.2.1 Crazing and Entanglement Density

Crazes, in contrast to cracks, are load-bearing features owing to highly stretched fibrils connecting the walls of what would otherwise be a crack. Multiple crazes are actually the main source of ductility in amorphous polymers modified by blending with elastomers. However, crazes have also a big drawback as they frequently appear precursors of brittle fracture. This is due to high localization of deformation in crazes – large plastic deformation and related local energy absorption are highly

localized and confined to a very small volume of the material. Craze can be considered as a thin layer of polymer in which elastic and plastic deformation in the direction of principal tensile stress has occurred without lateral contraction. The lack of lateral contraction is due to voids created between fibrils. These voids can constitute up to approximately 50–75% of the volume of the craze (Haward and Young 1997). The thickness of a craze at the tip is below 10 nm, while a body of the mature craze is much thicker, by 2–4 orders of magnitude. Such significant thickening of the craze proceeds mainly by involving more bulk polymer at the interface into the plastic deformation zone due to strain hardening of the craze matter. This keeps molecular stretch and the void content quite uniform within the craze.

In the literature, there are many theories and models describing nucleation, initiation, and growth of crazes. They were discussed in several reviews, see, e.g., Argon (2013), Donald (1997), Kausch (1983, 1990), Michler and Balta-Calleja (2012). A craze is nucleated by an event of local plastic deformation by shear occurring in the vicinity of a defect and leading to the buildup of significant lateral stresses. This is followed by nucleation of nanovoids, relieving the triaxial constraints, and then by growth of these voids and strain hardening of polymer nanofibrils between voids as molecular orientation advances (Kramer 1983). The nanovoid nucleation stage is considered as a critical one. In highly entangled polymers, the load is distributed over different entanglements and different chains, and, as a consequence, the probability of breaking chains and void formation is lower. It is thus expected that a high entanglement density is unfavorable for craze initiation. Once a craze is initiated, it must grow both in width and length. The general mechanism of craze tip advance has been known to be meniscus instability process (Argon and Salama 1977). Kramer and Berger (1990) derived a detailed model of the craze growth. The craze will grow only when the deformation energy associated with the applied stress is larger than the surface energy needed to create a new surface. This surface energy per unit area of the void surface (Γ) is (Kramer and Berger 1990)

$$\Gamma = \gamma + \frac{1}{4} d_e v_e U_{ch} \tag{11.1}$$

where γ is the van der Waals surface energy, d_e is the entanglement mesh size, v_e is the entanglement density and U_{ch} is the bond energy of the polymer chain. The second term is the energy cost of elimination of entanglements crossing the interface, for example, by chain scission. It appears weighty – in PS of relatively low entanglement density ($v_e \sim 3 \times 10^{25}$ m^{-3}) is about equal to the van der Waals term, both being around 0.04 J/m^2. Increasing the entanglement density of the molecular network leads to a significant increase in Γ and, therefore, to an increase of the craze initiation stress. For PC, which has v_e higher by one order of magnitude than PS ($v_e \sim 3 \times 10^{26}$ m^{-3}), the additional contribution to Γ is 0.2 J/m^2, and consequently much higher stress would be required to initiate a craze. This explains why polymers of high entanglement density, as PC, often deform without crazes but readily form shear bands, instead. The dependence of the craze initiation stress on

Fig. 11.1 Dependence of the craze initiation stress σ_e on the entanglement density v_e for various polymers and their miscible blends (From Wu (1990); reproduced with permission of Wiley)
entanglement density was confirmed by experimental data (Wu 1990, 1992). The following relationship holds for the stress of craze initiation σ_{craze} and the entanglement density v_e:

$$\sigma_{craze} \propto f_z v_e^{1/2} \tag{11.2}$$

where f_z is a parameter related to the free volume, reflecting the effects of the physical aging on the crazing stress. Craze initiation stress appears weakly dependent on temperature. A low entanglement density should result in low stress σ_{craze}, thus favoring crazing – see Fig. 11.1, illustrating the relationship of σ_{craze} and entanglement density v_e, for a series of homopolymers and miscible blends of polystyrene (PS) and polyphenylene oxide (PPO), obtained by Wu (1990, 1992). Crazing is initiated at very low stress in PS, which demonstrates the low entanglement density. Blending of PS with PPO results in a notable increase of entanglement density and hence the resistance to crazing – much higher stress is needed to initiate crazing in PPO-rich blends (e.g., in the blend containing 75 wt.% PPO) than in plain PS. On the other hand, polymers exhibiting high entanglement density, as. e.g., PC, tend to deform by shear yielding rather than crazing.

Brittle polymers, such as PS and PMMA, developing crazes at low strains below 1 %, can absorb a greater amount of energy if crazing involves a larger volume of the sample. This can be achieved by increasing the number of the crazes upon deformation due to appropriate structure modification, e.g., by introducing rubber particles. The resultant greatly increased the concentration of crazes is referred to as multiple crazing, which is now acknowledged to be the principal mechanism by which glassy crazable polymers modified with elastomer particles accommodate deformation (Bucknall 1977, 1997, 2000). The multiple crazing mechanism was demonstrated operational and highly effective in high-impact polystyrene (HIPS), ABS copolymer, rubber-toughened PMMA, and other similar systems (Bucknall 1977).

Fig. 11.2 Multiple crazing in HIPS: TEM micrograph of the ultrathin section of HIPS with salami particles of rubber and crazes at early stage of deformation. *Arrow* indicates tensile direction. Scale bar 1 μm (From Heckmann et al. (2005); reproduced with permission of Taylor and Francis)
The occurrence of multiple crazing was evidenced by optical and electron microscopy (Bucknall 1977; Michler and Balta-Calleja 2012) and by real-time small-angle X-ray scattering (Bubeck et al. 1991). In glassy polymers modified with elastomer particles (commonly called rubber-toughened polymers), the numerous crazes were found to be initiated near the equator of the cavitating rubber particle due to high stress concentration there (Bubeck et al. 1991; Bucknall 1977). Initiation of numerous crazes at rubber particles involves a relatively large volume of the glassy matrix into deformation, all dissipating energy, which results in a significant increase of toughness. Multiple crazing phenomenon is illustrated in Fig. 11.2.

11.2.2.2 Shear Yielding and Chain Flexibility

Bucknall (2000) depicted shear yielding as the process by which most of the ductile polymeric materials accommodate high strains. Shear yielding involves a displacement of matter during the deformation (molecules sliding past each other). In contrast to crazing, there is no change in the volume or density associated with shear yielding. As cohesion is not lost, no voids are created by shear yielding. Opposite to crazing, shear yielding is strongly temperature dependent. The dependence of the yield stress on temperature and strain rate can be described by the Eyring-type equation (Bauwens 1967; Roetling 1965). In this approach, a positive correlation is expected between chain mobility, yielding, and toughness. That correlation was verified experimentally by Wu (1990, 1992), who found dependence of the reduced normalized yield stress on chain stiffness, which can be defined by the following parameter:

$$C_\infty = \lim_{n \to \infty} \left(R_o^2 / n_v l^2 \right) \qquad (11.3)$$

where $R_o{}^2$ is the mean-square end-to-end distance of an unperturbed chain, n_v is the number of statistical skeletal units, and l^2 is the mean-square length of a statistical unit. Rigid chains. such as liquid crystalline polymers. will have a high C_∞,

Fig. 11.3 Normalized reduced yield stress $\sigma_{yr} = \sigma_y/[\delta^2(Tg - T)]$ versus characteristic chain stiffness, C_∞ (From Wu (1990); reproduced with permission of Wiley)
whereas flexible polymers, as, e.g., polyethylene, will demonstrate low values of C_∞. According to Wu (1990) C_∞ and v_e can be related by the equation:

$$v_e = \frac{\rho_a}{3M_v C_\infty^2} \tag{11.4}$$

where M_v is the molecular mass of a statistical skeletal unit and ρ_a is the density of an amorphous polymer.

The stress initiating the shear yielding σ_y depends strongly on temperature and is additionally proportional to two parameters: $\Delta T = T_g - T$ and to δ^2, where T_g and T are the glass transition temperature and the temperature of the test, respectively, while δ denotes the cohesive energy density. The reduced normalized yield stress was defined by:

$$\sigma_{yr} = \sigma_y/\left[\delta^2\left(T_g - T\right)\right] \tag{11.5}$$

The denominator $\delta^2(T_g - T)$ accounts actually for the interchain effects (friction between chains) on the yield stress. Thus, the reduced yield stress defined above by Eq. 11.5 should be only a function of an intrachain property, characterized by the chain stiffness (Wu 1990, 1992):

$$\sigma_{yr} \propto f_y C_\infty \tag{11.6}$$

where f_y is a parameter related to the free volume, reflecting the effects of the physical aging. The above relation implies that the higher the chain stiffness, the lower its mobility and, therefore, the higher the reduced normalized yield stress. Figure 11.3 presents a plot of σ_{yr} as a function of the stiffness ratio, C_∞, constructed by Wu (1992) for a series of polymers and miscible blends. This experimental dependence, confirmed for a number of glassy polymers, shows that the yield

initiation stress increases with increasing chain stiffness of the polymer and that the reduced yield stress for polymers that are known ductile is lower than for those known brittle, as, e.g., PC and PS, respectively. Chains of PC exhibit low stiffness, $C_\infty = 2.4$ (Wu 1992), and PC prefers to deform by shear yielding while PS demonstrates a high chain stiffness, $C_\infty = 10.8$, which results in a high initiation stress for shear yielding. As a consequence PS appears vulnerable to crazing, which can be initiated at stress lower than that needed for initiation of shear yielding.

11.2.2.3 Molecular Criterion for Craze/Yield Behavior from Chain Structure Parameters

The competition between crazing and shear yielding determines which mode of fracture will predominate, so that the transition between crazing (which leads to brittle behavior) and shear yielding deformation mechanism (leading to ductility) is one of the key phenomena for toughness modification. Shear yielding wins the competition with crazing when the yield initiation stress is simply lower than the stress needed for initiation of crazing. The combination of Eqs. 11.2, 11.4, 11.5, and 11.6 leads to the following relationship that expresses the molecular criterion for dominant deformation mode (Wu 1990, 1992):

$$\frac{\sigma_z}{\sigma_{yr}} \propto \frac{v_e^{1/2}}{C_\infty} \left[= \left(\frac{\rho_a}{3M_v} \right)^{1/2} C_\infty^{-2} = \left(\frac{3M_v}{\rho_a} \right)^{1/2} v_e \right] \qquad (11.7)$$

Henkee and Kramer (1984) evidenced the entanglement density to be a critical parameter determining whether the polymer will tend to deform by crazing or by shear yielding. A low entanglement density favors crazing, while the entanglement density rising above the critical value (roughly $v_e \sim 0.15$ mmol/cm^3 (Wu 1992)) results in a change from crazing to shear yielding. On the other hand, the flexibility of chains in thermoplastic polymers seems also to be likely an important parameter for this crazing/shear yielding transition, because when the pseudoductile polymer is cooled down below the temperature of its secondary relaxation process, it becomes brittle despite that entanglement density does not change at this temperature. Taking into account both entanglement density and chain stiffness parameters, the following classification was proposed:

1. Brittle polymers, for which $v_e < \sim 0.15$ mmol/cm^3 and $C_\infty > \sim 7.5$. They fracture by a dominant crazing mechanism and additionally exhibit a low crack initiation energy and a low crack propagation energy (resulting in low, both unnotched and notched, toughness). Examples are PS or PMMA.
2. Pseudoductile polymers, when $v_e > \sim 0.15$ mmol/cm^3 and $C_\infty < \sim 7.5$. They tend to deform by shear yielding mechanism prior to failure. They usually demonstrate a high crack initiation energy (resulting in high unnotched toughness) and a low crack propagation energy (low notched toughness). Examples are PC, polyesters (PBT, PET), or polyamides (PA6, PA6,6).

3. Intermediate class ($v_e \sim 0.15$ mmol/cm^3 and $C_\infty \sim 7.5$) demonstrating combined crazing/shear yielding deformation habit. Examples are some grades of PMMA, PVC, and POM.

   According to the Eq. 11.7 both v_e and C_∞ provide a consistent prediction of the deformation behavior. It seems, however, that the entanglement density v_e can be considered as the primary parameter which controls the crazing behavior, whereas the chain stiffness parameter C_∞ is predominant in controlling the shear yielding behavior.

11.2.3 Plastic Deformation of Semicrystalline Polymers

There are three, currently recognized, principal modes of deformation of the amorphous material in semicrystalline polymers: interlamellar slip, interlamellar separation, and lamellae stack rotation (Argon 2013; Bowden and Young 1971; Butler et al. 1998; Haudin 1982; Oleinik 2003). Interlamellar slip involves shear of the amorphous phase between lamellae. It is relatively easy mechanism of deformation for the material above T$_g$. The elastic part of the deformation can be nearly entirely attributed to the reversible interlamellar slip. Interlamellar separation is induced by a component of tension or compression perpendicular to the lamellar surface. This type of deformation is difficult since a change in the lamellae separation should be accompanied by a transverse contraction and the deformation must involve a change in volume. Stacks of lamellae are embedded in the amorphous matrix, and the stacks are free to rotate under the stress. When the possibility of further deformation of the amorphous phase is exhausted, the deformation of crystalline materials sets in. Any additional deformation of the amorphous phase requires a change in the crystalline lamellae. Crystalline component of polymeric materials is deformed by crystallographic mechanisms, mostly crystallographic slips (Bowden and Young 1974; Lin and Argon 1994; Oleinik 2003). The concept was initially proposed by Peterson (1966, 1968) and developed by Shadrake and Guiu (1976) and Young (1974, 1988): an emission of dislocations from the edges of the lamellae across their narrow faces and their travel across crystals via crystallographic slip mechanism. Many of such subtle slips contribute to a macroscopic strain. Much evidence for the correctness of that mechanism was found in the past (Kazmierczak et al. 2005; Lin and Argon 1994; Seguela 2007; Wilhelm et al. 2004; Young 1988). The model of thermal nucleation of screw dislocations (Peterson 1966, 1968; Young 1974, 1988) was demonstrated to account fairly well for the plastic behavior of many crystalline polymers (Argon et al. 2005; Brooks and Mukhtar 2000; Crist et al. 1989; Darras and Seguela 1993; Seguela 2002). Dislocation theory predicts the correct order of magnitude of the yield stress (O'Kane et al. 1995).

   It is commonly believed that the function of the amorphous phase, above the glass transition temperature, in yielding during tensile deformation of semicrystalline polymers is relatively small and is limited to transfer the stress between adjacent crystals (Seguela and Darras 1994). The stress is transmitted through

such elements as tie molecules, entanglements, etc., called "the tie-molecule fraction," An increase of the yield stress was observed with the increase in the tie-molecule fraction. Men et al. (2003) established that tie molecules are of lesser importance with respect to the deformation, while the entangled chains in amorphous phase play a decisive role.

Since all stress is transferred to crystals via amorphous layers, the amorphous phase appears nevertheless essential for load bearing of semicrystalline polymers, including yielding. Amorphous phase must be stressed at yield with a stress similar to plastically deformed crystals. On the other hand, when the stress in the amorphous phase exceeds its cohesive strength, it undergoes cavitation. Cavitation occurs in semicrystalline polymers, usually in tension. A triaxial local stress, contributing to negative pressure, is necessary for cavitation. If the plastic strength of crystals is low, then with an increase of the stress, it is easier to activate dislocation mechanisms of plastic deformation of lamellae rather than to disrupt the amorphous phase or the interface and create a cavity. In such a case, the deformation can proceed without cavitation. Opposite is the case when the breaking of an amorphous phase is easier than plastic deformation of crystals. Then cavities are generated in the amorphous phase during deformation prior to crystal yielding. However, the formation of voids changes rapidly the local stress state and by this can promote deformation of crystals. There are some ways of modification relations between strength of crystals and amorphous phase. First, it is by controlling the perfection, sizes, and number of crystals by crystallization process. Second, any modification of the amorphous component should result in changes of the material response to loading. Recently it was demonstrated that the amorphous phase can be subjected to various modifications without changing crystalline phase and morphology. Those modifications can greatly influence the yielding and deformation of semicrystalline polymers (Rozanski and Galeski 2013). The amorphous phase may be modified by removing of a low molecular weight fraction to increase its strength or by filling the free volume space with low molecular additives.

Many polymers cavitate during deformation at certain experimental conditions. The polymer morphology seems crucial for cavitation. It seems that the cavitation is generally easier in those semicrystalline polymers which are characterized by higher crystallinity and thicker, less defected crystals. However, it is difficult to separate the influence of crystallinity and crystal perfection. There is a kind of competition between two possible processes: cavitation of anamorphous phase and plastic deformation of crystals. If the crystals are defected and therefore become less resistant to plastic deformation, then their plastic deformation becomes relatively easy while the strength of the amorphous phase prevents for its cavitation. Conversely, if the crystals are thick and demonstrate a reduced number of defects giving rise to dislocations, the breaking of the amorphous phase may become easier and will occur first, prior to crystal yielding. Annealing causes some limited changes of crystal structure, including an increase of their thickness and perfection; however, it may cause also a significant change to amorphous phase and modify its cavitation ability. Average molecular weight and molecular weight distribution of polymers may also drastically change the yield cavitation stress (Kennedy et al. 1994). Also,

the deformation rate is an important factor: yields stress increases with deformation rate, and it becomes easier to initiate cavitation in the amorphous phase. Similar effect is due to lowering the temperature. If the cavitation occurs first, before significant deformation of crystals, then the stress at the apparent yield point is defined by cavitation, rather than by crystal plasticity.

Based on the facts presented above, the plastic deformation behavior of semi-crystalline polymer materials and the structural changes accompanying the deformation of such materials are controlled by the properties of both crystalline and amorphous phases.

The most significant contribution to toughness comes from the plastic deformation of a material, which is a complex phenomenon involving both the crystalline and amorphous phases. As discussed in Sect. 11.2, the ability to an extensive plastic deformation, called ductility, requires an adequate flexibility of polymer chain segments in order to ensure the plastic flow on a molecular level. It is long known that the macromolecular chain mobility is a critical factor deciding on either brittle or ductile behavior of a polymer (Ferry 1970; Galeski 2002). The increase in the yield stress of an amorphous polymer with a decrease of the temperature is caused by a decrease of chain mobility, and vice versa, the yield stress can serve as a qualitative measure of macromolecular mobility. It was shown that the temperature and strain rate dependencies of the yield stress are described in terms of relaxation processes, similarly as in linear viscoelasticity. Also, the kinetic elements taking part in yielding and viscoelastic response of a polymer are similar: segments of chains, part of crystallites, and fragments of an amorphous phase. On the other hand, in semicrystalline polymers tested above their glass transition temperature, the yield stress is determined by the stress required for crystal deformation and not by the amorphous phase, provided that there is no cavitation. The behavior of crystals differs from that of the amorphous phase because the possibilities of motion of macromolecular chains within the crystals are subjected to severe constraints. Since the mobility of kinetic elements taking part in plastic deformation (mobile dislocations in crystals and shear strain carriers in amorphous phase) is lower at a lower temperature, the energy dissipated increases and can lead to local rise of temperature and produce deformation instability. The rate of plastic deformation increases drastically in such local plastic events referred sometimes as micronecks, and the material may fracture quickly hereafter. At a higher temperature the mobility of kinetic elements is higher, so less energy is dissipated and the local temperature increase is smaller. As a result, the deformation zone is stable and tends to extend to the whole gauge length of the sample. The material shows then a tough behavior.

The necessary condition for high plastic deformation is the possibility of motions of kinetic elements in a time scale as it follows from the deformation rate. The relaxation times and the activation energies are the parameters describing the kinetics of the conformation motions of macromolecules and larger elements taking part in the deformation.

Both massive voiding and shear yielding dissipate energy; however, shear yielding is often favored over voiding, especially under uniaxial stress, elevated

temperature, or slow deformation. Shear yielding dissipates the energy more efficiently (Horst and Spoormaker 1996).

The deformation of polymeric materials starts usually at scratches, notches, or internal defects because they are sources of local stress concentration, frequently well above the applied stress. Toughening of polymeric materials is based on the activation of such plastic deformation mechanisms which are activated at a stress lower than that required for triggering the action of surface and internal defects. Consequently, one of the important means of toughening appears to be a significant lowering of the yield stress of the material.

11.3   Blends

The comprehensive introduction to polymer blends is given in ▶ Chap. 1, "Polymer Blends: Introduction," while ▶ Chaps. 5, "Reactive Compatibilization," ▶ 8, "Morphology of Polymer Blends," ▶ 10, "Properties and Performance of Polymer Blends," ▶ 18, "Polyethylenes and Their Blends," and ▶ 21, "Miscible Polymer Blends" of this handbook are devoted to various aspects and detailed description of the formulation, structure, and morphology of polymer blends. Here, the attention will be briefly turned to such features of polymer blends that directly influence or determine their mechanical properties. In polymer blends, the structure is more complicated than in homopolymers because usually they have three components: dispersed phase, continuous phase, and interface. The interface has a finite thickness; hence it is the third component of the system. Applied force is transmitted onto the dispersed inclusions from the matrix via the interface. Therefore, the properties of the interface play a vital role in force transmission and overall behavior of a blend. Strong bonding between blend components prevents for slip between a matrix and inclusions, while weak adhesion is not efficient in stress transfer, but it may cause a certain amount of friction and may originate decohesion. Modification of blends by introducing compatibilizers is a common practice; therefore, the third component is *explicit* present in blends. It follows then that when considering mechanical properties, the polymer blends should be considered as the systems containing at least three components and with complicated interactions among them.

Compatibilized blends differ from blends of incompatible polymers, apart from more discrete dispersion of a minor component, mainly by the structure and properties of the interface between components. Usually, the achieved toughness of well compatibilized blends allows for their large plastic deformation. In plain crystalline polymers, the elementary mechanisms of plastic deformation are crystallographic slips. However, in simple drawing, the cavitation obscures the real crystallographic mechanisms. The origin of cavitation is the mechanical misfit between stacks of crystalline lamellae. In polymer blends, the interfaces between components are the other source of cavitation. Cavitation creates new internal surfaces; however, the energy dissipated for the formation of cavities is rather low. It is not so for the energy needed for the reorganization of the surrounding matter to accommodate cavities.

These and other considerations concerning mechanical properties of polymer blends will be presented in the forthcoming sections. The survey of existing data and applications shows that the main purpose of polymer modification by blending with other polymers is to modify their mechanical performance and primarily increase toughness. Therefore, in the forthcoming sections we will focus on issues related to polymer toughening which can be achieved by blending with other polymers, mainly those demonstrating elastomeric properties. That method of toughness modification is known under the name of "rubber toughening," because of rather historical reasons. Nowadays it is well established that the toughness can be successfully improved by thoughtful blending not only with classic rubbers but also with various other elastomers, selected other polymers, ready-to-mix polymer particles with core–shell morphology, and even mineral filler particles.

11.3.1 Low Strain Rate Deformation of Polymer Blends

Blending of a polymer with other immiscible polymers can lead to a substantial improvement of drawability and impact strength without a reduction in T_g. Blends of miscible polymers show a single glass transition at a temperature that is in between glass transitions of components. The position of glass transition of a miscible blend on a temperature scale determines its mechanical properties.

When the material is subjected to loading, it responds with deformation. Polymeric materials exhibit two types of mechanical response in elasticity range: in a glassy state the energy is stored as free energy, while in a rubbery state, the energy is stored as a change of macromolecular chain configurational entropy. The first type of elasticity is called energy elasticity and the second entropy elasticity or just rubber elasticity. The physical response of polymeric materials to a small strain or stress is then different because of different sources and different temperature and pressure dependencies. The first is a characteristic of glassy polymers and all inorganic and organic crystals and arises from interatomic and intermolecular interactions, while the second is a characteristic of polymers in a rubbery state and amorphous phase of crystalline polymers and is created by reversible shear and relaxation processes. The latter are specific for different polymers and determine their viscoelastic properties. Similar characteristics of elastic reaction to a small strain or stress concern polymer blends and their components. When a blend is composed of immiscible or partially miscible polymers, most of the free energy of deformation is stored in its matrix, less in dispersed inclusions. For miscible blends, the elastic response depends on their glass transition temperature. The rule of linearity between strain and stress was discovered by Hooke in the seventeenth century, and uniaxial strain or stress experiments can be described as below:

$$\sigma = E_o\varepsilon \tag{11.8}$$

where σ stands for stress, while ε for strain. The elastic constant E_o is called Young's modulus and it should be always defined at zero strain or zero stress;

Fig. 11.4 Typical stress–strain curves for polypropylene blended with ethylene-propylene rubber (EPDM) at different rubber concentrations. Strain rate $10^{-2}\,s^{-1}$, room temperature. The plot illustrates the relation of modulus and strain presented in Eq. 11.9 (From Gaymans (2000); reproduced with permission of Wiley)
hence it is called the tangent modulus. As the strain increases, the stress–strain relationship becomes gradually nonlinear. It was shown by Rose for metals (Rose et al. 1983) that the elastic response is modified by bulk decohesion arising from binding energy in the material in the following form:

$$\sigma = E_o \varepsilon \exp(-\alpha\varepsilon) \tag{11.9}$$

where α is a nonzero constant related to uniaxial decohesion strain. Equation 11.9 suggests that the tangent modulus progressively decreases with increasing tensile uniaxial strain (Argon 2013). However, for uniaxial compression, the modulus tends to monotonically increase. Equation 11.9 can be transformed to modulus dependence on ε as follows:

$$E(\varepsilon) = \frac{d\sigma}{d\varepsilon} = E_o (1 - \alpha\varepsilon) \exp(-\alpha\varepsilon) \tag{11.10}$$

Similar relations apply for polymers and polymer blends except that the binding energy for polymeric material is lower than for metals and nonlinearity of modulus is even more pronounced.

From Eq. 11.10, it is seen that the modulus decreases with increasing strain from the initial value of E_o eventually to 0, for strain of $1/\alpha$. The stress reaches then a maximum which is called yield stress, and the processes responsible for the phenomenon are called yielding (Fig. 11.4).

From the above discussion, it follows that most isotropic materials including polymeric materials behave for small strains in a very similar way all according to Eq. 11.10, differing only in a single parameter α. However, yielding in polymeric materials is reached due to other factors that come to play at slightly larger strain and not exhibiting yielding at strain $1/\alpha$ which is related to the binding energy and bulk decohesion as defined by Rose et al. (1983).

11.3.2 Yielding

Yielding in polymer blends is a very complicated event and is usually composed of several micromechanisms that are activated at various stages of deformation depending on the deformation rate, the temperature, deformation mode, and blend morphology.

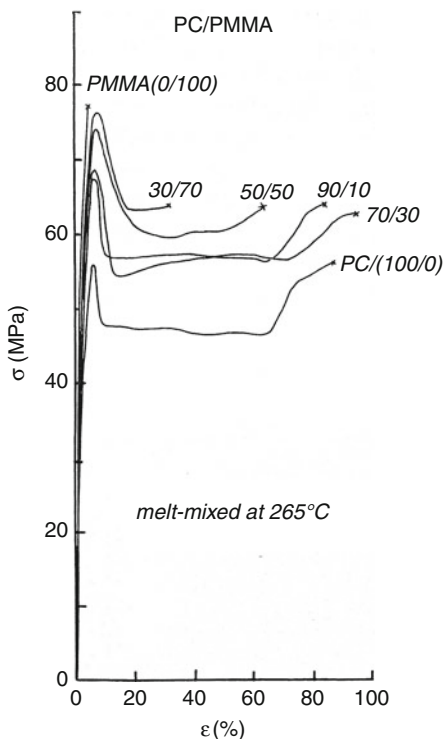
In glassy homogeneous polymer blends below T_g, their internal morphology plays only a secondary role, in contrast to the temperature, which is the major parameter governing the yielding, especially in compression, shear, and hardness measurements.

One of the few compatible polymer blends in a large concentration range is polystyrene–polyphenylene oxide system (PS/PPO) (Yee 1976). In tension, with increasing PPO content, the deformation habit changes from the formation of crazes, as in PS to homogeneous deformation bands and shear bands, characteristic for PPO (Berger 1990); *see* also the data of Figs. 11.1 and 11.3. There are other partially compatible blends, for instance, SAN/PMMA blends, when the acrylonitrile content in SAN is about 10–30 % (Fowler et al. 1987; Suess et al. 1987). Other examples are amorphous quenched blends of PMMA and polyvinylidene fluoride (PVDF), which are compatible at high temperatures (Nasef and Saidi 2006; Neuber and Schneider 2001). The blend PMMA/PVDF shows a remarkable agreement with the additivity rule of the two components for the yielding in microhardness measurements (Martinez-Salazar et al. 1991). The yielding behavior of the blend material is well correlated with glass transition temperature resulting from the equation of glass transition superposition of Gordon and Taylor (1952).

Immiscible blends have nonhomogeneous morphology and their tensile deformation at yield is much more complicated than miscible systems. There are several mechanisms that are activated at various stages of deformation depending on the deformation rate, the temperature, glass transition temperature of the components, deformation mode, and blend morphology.

Bubeck et al. (1991) showed that in high-impact polystyrene (HIPS), there are crazing and cavitation engaged. The complex mechanism of plastic deformation in the blends leading to improvement of ductility and toughness was revealed. They used real-time X-ray measurements during tensile deformation HIPS samples to show that cavitation of the rubber particles actually precedes crazing of the matrix under tensile impact conditions. Cavities formed within the rubber particles can thus be identified as nuclei for a craze growth, which occurs through the meniscus instability mechanism proposed by Argon and Salama (1977).

Another example of rubber-modified glassy polymer was given by the study of polylactide blends (Kowalczyk and Piorkowska 2012). Blending polylactide (PLA) with poly(1,4-*cis*-isoprene), which is immiscible with PLA, can lead to a substantial improvement of drawability and impact strength without a decrease in Tg. In contrast to HIPS reported by Bubeck et al. (1991), the rubbery particles initiated crazing in PLA matrix at the early stages of deformation. Crazing was accompanied by cavitation inside rubber particles, which further

Fig. 11.5 The tensile stress–strain curves of the two-phase PC/PMMA blends, obtained at room temperature. The plots illustrate a stepwise transition of yielding by crazing characteristic of PMMA, to shear banding, characteristic of PC (From Kyu et al. (1991); reprinted with permission of Hanser Verlag)


promoted shear deformation of PLA. All three elementary mechanisms acting in the sequence appeared responsible for surprisingly efficient toughening of PLA by blending with a small amount of poly (1,4-*cis*-isoprene) – a major component of natural rubber. In comparison, plain PLA not containing rubber particles deforms initially via crazing, stronger at higher deformation rate and lower temperature, and then shortly undergoes shear banding. Separate cavitation is not then observed. The yield stress depends on the deformation rate and temperature; however, yielding is triggered and then controlled by the micromechanism of deformation which is activated first, at the lowest stress under given experimental conditions, selected from crazing, shear yielding or cavitation.

In Fig. 11.5, the stress–strain plots are depicted for a series of two-phase PC/PMMA blends with various concentrations. The phase-separated morphology was obtained by melt mixing. The position of the yield point on the stress–strain curves illustrates the stepwise transition of micromechanism of tensile deformation, characteristic of PMMA, which is crazing, to the mechanism of deformation, characteristic of PC – shear yielding.

As an example, the tensile deformation of polycarbonate/polyethylene blends is similar for a range of concentrations except for the magnitude of the yield stresses (Yee 1977). In this blend polycarbonate matrix undergoes strong yield shearing, and the decisive factor is the shear resistance of polycarbonate.

11.3.3 Necking

Crazes always tend to be perpendicular to the tensile deformation direction. They are typical dilatational zones of deformation. Since most of deformation is located in fibrils spanning the edges of a craze, a polymeric material is elongated, but its transversal size is not much changed. Hence, the neck is not formed. Cavitation usually helps to generate crazes and also does not cause formation of a neck. Necking is always associated with shearing and formation of shear bands whenever they are formed as a basic micromechanism of deformation or when they are triggered by crazes or cavities.

The way in which polymer blends change the shape upon deformation is not very different from other polymeric materials. The decisive role is played by micromechanisms triggered or stimulated by the presence of other components of the blend. The other key parameters are the temperature and strain rate. One may induce or inhibit shear banding by changing those process parameters and in that way control necking.

11.4   Toughening

11.4.1 Overview

The toughness is the property of resisting a fracture by absorbing and dissipating energy during deformation prior to ultimate fracture (Bucknall 1997). Strength, on the other hand, is the ability of the material to resist high stresses. Strengthening is usually achieved by suppression of plastic deformation mechanisms, sometimes to the extent that the material becomes brittle under normal loading conditions. On the contrary, high toughness can be obtained by promotion of plastic deformation, although most frequently at some tolerated loss of stiffness, strength, and creep resistance. Some reduction of stiffness, as in the case of rubber toughening, is acceptable if accompanied by substantial increase of toughness. A simple measure of toughness is the area below the stress–strain curve. Three typical cases are illustrated in Fig. 11.6: (1) very high strength by avoiding all defects and suppressing of plastic deformation (e.g., highly oriented fibers); (2) very high elongation at break, but low stiffness and strength, obtained by significant softening of the material (e.g., by plasticization); and (3) good stiffness and strength with a higher elongation, which can be obtained only due to widespread plastic deformation. The optimum case in toughening is, of course, the combination of relatively high value of stiffness, strength, and possibly high ultimate strain (curve (3) of Fig. 11.6). This requires some suppression of large, critical defects producing high stress concentrations leading to brittle fracture and promotion of extensive plastic deformation proceeding in large volume of the material, initiated at relatively high yield stress in numerous small, localized yield events. Plastic deformation must be stabilized by strain hardening to prevent excessive strain localization and premature crack propagation.
    Retaining strength and increasing plastic deformation are generally opposed
requirements and are very hard to achieve simultaneously. In fact, the most popular
and efficient practice of toughening by modification with elastomers (rubbers)
suffers a drawback of a notable, sometimes serious, decrease in stiffness and
strength of modified material due to relatively large content of a soft rubber
(5–25 wt.%) (Bucknall 1977).

    Toughness is one of the most complex mechanical properties. As it is greatly
influenced by many morphological as well as micromechanical parameters, it is
very difficult to control. Toughening can be realized by a particular morphology
that permits lots of small local yielding events simultaneously in the entire volume
of the material. This practically cannot be achieved in a homogeneous morphology,
but only in heterogeneous one with specific morphology (e.g., small particles
dispersed in the matrix) modifying the structure and structure-related
micromechanical properties of the polymer at various scale levels. These modifi-
cations stimulate a large number of local plastic yielding and deformation processes
on a nano- and microscale, all absorbing energy. They appear together in a large
volume of the loaded material and result in large total energy absorption.

    While many polymers can dissipate considerable amounts of energy through
plastic deformation and appear tough at low deformation rate, they became brittle in
the presence of notches and in high-rate impact loading. Therefore, toughening
should be aimed not only to improve drawability at low rates but primarily to
enhance the fracture resistance at impact conditions, especially in the most severe
case when a notch is present in a thick sample. Consequently, the most
frequent basis for assessment of toughening is the notched Izod (or Charpy) impact
strength, determined in standardized impact tests of Izod or Charpy. This notched
impact strength indicates the energy dissipated during impact fracture of
relatively thick notched sample (according to the ISO 180 international standard
of the Izod test, sample thickness must be greater than 3.2 mm and the striker
speed v = 3.5 m/s).

11.4.2 Basic Principles of Toughening

11.4.2.1 Competition Between Plastic Deformation and a Terminal Process of Fracture

The toughness is administered by a competition between plastic deformation and a terminal process of fracture. The fracture is ultimately governed by stress and strain concentrations due to various structure imperfections like sharp notches, cracks, and other critical sized flaws or heterogeneities. Most commercial products made of polymers contain such imperfections. When the material is loaded, stresses become concentrated there, which results in high concentrations of strain and increase of the strain rate, all leading to very high localization of the deformation process. This localization can be high enough to trigger a brittle fracture. On the other hand, at some instances smaller, not critical, stress concentrations help also effectively to initiate the desired plastic deformation. Therefore, all these flaws and structure imperfections should be controlled precisely in quantity and size below critical in order to govern the fracture processes that limit material toughness. However, such a careful and precise control or management of the structure (flaws, imperfections) and surface (notches, scratches) of a product would be too difficult and expensive to be a practical solution for toughening, so that other measures to promote plastic deformation are necessary.

11.4.2.2 Intrinsic Brittleness

Argon (Argon et al. 2000; Argon and Cohen 2003) reasoned that with the exception of only a small class of pure metals, perhaps all other solids, including all unoriented solid polymers, are intrinsically brittle solids in the definition of Kelly et al. (1967) and will demonstrate brittle behavior at low temperatures and/or high strain rates, where a crack can propagate with little resistance, particularly in the presence of crack-like flaws and notches. While many polymers may appear quite tough at room temperature under low or moderate deformation rates, they became brittle at lower temperatures, in the presence of notches and in high-rate impact loading. Intrinsic brittleness denotes here that, in an otherwise flaw-free and homogeneous material, local tensile stress at the atomically sharp crack tip reaches the decohesion strength before local shear stresses concentrated at that crack tip initiate plastic flow (Kelly et al. 1967). Consequently, even the complete elimination of any notches, flaws, and other imperfection from the sample will not bring transformation of intrinsically brittle material to intrinsically ductile one, so that the approach seems of limited use for toughening. However, as already noted, intrinsically brittle polymers actually can exhibit a transition from brittle to ductile behavior at certain experimental conditions, e.g., higher temperature or lower deformation rate. That brittle-to-ductile transition is a crucial phenomenon in considering the toughness of polymers.

11.4.2.3 Brittle–Ductile Transition in Fracture

Stress–strain data collected for many rigid polymers deformed at various conditions revealed stronger dependence of the yield strength σ_y on temperature and strain rate

Fig. 11.7 Schematic
representation of brittle-to-
ductile transition in fracture
(Davidenkov plot)
than that of brittle fracture strength σ_B (Vincent 1971): the yield stress σ_y decreases
faster with increasing temperature T (typically by a factor of 10 between $-180°$C
and room temperature) than the brittle stress (decrease only by factor of less than 2).
The competition between the energy-absorbing plastic behavior characterized by
the yield strength, having significant temperature and strain rate dependence, and
the relatively temperature-independent brittle strength, governed by microstructural
flaws or extrinsic imperfections, is illustrated schematically in Fig. 11.7 in terms of
the well-known Ludwig–Davidenkov–Orowan criterion (Orowan 1949). This dia-
gram, generic to intrinsically brittle solids, shows that for a given strain rate, there
should be a transition from brittle to ductile behavior at a particular temperature
T_{BD}, defined by the intersection of both curves – when increasing the test temper-
ature above T_{BD}, the yield strength becomes lower than the brittle stress, $\sigma_y < \sigma_B$,
and the material changes its behavior from brittle to ductile. The dotted lines
represent a higher strain rate resulting in a shift to higher stress values and,
consequently, a shift of the brittle-to-ductile transition to a higher temperature
(Vincent 1971). The brittle-to-ductile transition temperature is very sensitive to
change in material parameters and test conditions, including specimen shape and
size, temperature, or the deformation rate. For example, while the brittle strength
relates to a tensile stress, the yield behavior responds only to a critical level of the
effective (deviatoric) stress, σ_e. In the presence of sharp notches or other flaws,
individual normal stress components can be substantially augmented by negative
pressure, while the effective stress producing plastic flow remains equal to σ_e. This
will result in a marked increase of the brittle-to-ductile transition temperature, as is
well known in the notch impact testing.

11.4.2.4 Strategies and Options for Toughening

One of the possibilities to obtain tough polymeric materials is of course synthesis of
new polymers, which would appear to be intrinsically ductile instead of intrinsically
brittle. However, this is perhaps fundamentally impossible, or at least such attempts

are not economically justified. Analysis of the Davidenkov plot of Fig. 11.7 demonstrates that the only possibility of improving toughness of an intrinsically brittle rigid polymer is then by moving the brittle-to-ductile transition temperature well below the temperature range of the expected application of that material. This can be done either by an increase of the brittle strength, without altering plastic deformation mechanisms, or by reduction of the yield strength which makes plastic deformation easier. The first alternative can be realized through careful modification in both synthesis technology and processing to exclude critical sized flaws and extrinsic imperfections, as, e.g., dust particles. When such structural imperfections are well controlled in quantity and size and are limited to only subcritical size comparing to the size of the imperfections that control ultimate stress σ_B, the brittle strength can increase above the level of the initial yield strength. As a consequence, such polymer sample will tend to deform plastically. Once plastic deformation is initiated, it will result in molecular alignment due to advancing deformation and in neutralization of some of the effects of small imperfections still present in the structure which can eventually elevate, even substantially, the fracture toughness across the extension direction. This approach is always an option, but often is either not possible or technologically not profitable (Argon and Cohen 2003; Lin and Argon 1994). In such a case, the only practical choice left is to decrease the global plastic resistance of the modified polymeric material and shift in this way the brittle-to-ductile transition temperature T_{BD} to a lower temperature, below the temperature range of the expected applications. As a result, toughness of the material can be improved, even substantially, but inevitably in expense of some loss of its strength, and perhaps also stiffness and creep resistance. However, that sacrifice of stiffness and strength is often tolerable. Actually most of the approaches to toughening have followed this route, which when wisely practiced can be very effective (Argon 2013; Argon and Cohen 2003).

The other general rule in polymer toughening is to take advantage of the deformation mechanisms already operating in a particular polymer and only stimulate its response to loading to procure an extensive deformation and therefore large energy dissipation. In many approaches to polymer toughening, it has been assumed that incorporation of compliant rubber particles might impart toughness to a brittle polymer by a notion arising from the simple rule of mixtures, i.e., hoping that very flexible rubber could alleviate the brittleness of the matrix. However, in nearly every instance, when such practices are adopted, the beneficial effect of improved toughness actually does not arise from the added modifier directly, but rather through its indirect stimulation of very effective matrix response (Argon 2013), such as, multiple crazing in glassy polymers, providing widespread dilatational plasticity or an extensive plastic deformation promoted by significantly lowered plastic resistance due to conversion of a continuous solid material into porous (cellular) solid as a result of particle internal cavitation or debonding at the particle–matrix interface. This transition not only relieves volumetric strain but also greatly modifies the yield conditions for the matrix material and facilitates extensive yielding and plastic deformation of the matrix. Another example is cavitation-induced modification of the stress state allowing deformation of

preferentially oriented crystals within ligaments of the semicrystalline matrix between particles, the orientation of which had been induced by the presence of matrix–particle interfaces or by processing.

Glassy Polymers

Glassy polymers are frequently capable of dissipating locally significant amounts of energy per unit volume through viscoelastic–plastic flow, most frequently, highly localized either in crazes or thin shear bands. Bucknall (2000) estimated for crazable polymers, like polystyrene, that locally, within the craze or thin deformation zone, energy absorption per unit volume of a glassy polymer is high, on the order of 100 MJ/m^3! However, the amount of the material involved in the deformation is very limited, roughly to the thickness of the craze, i.e., single micrometers, and fracture is, therefore, essentially brittle. Such a small amount of material involved in the process of energy absorption through the plastic deformation occurring within a craze is too small to give the material a satisfactory fracture resistance and toughness. The problem is the acutest when the specimen or structure contains sharp notches, surface scratches, cracks, voids, or other structural imperfections that could cause a severe localization of the deformation, frequently so strong to end up with the brittle-like fracture, even due to a single craze. Therefore, strategies of toughening should be directed primarily towards maximizing the volume of the material participating in such deformation by multiplication of deformation events like crazes or deformation bands. Concurrently, some reduction of overall deformation resistance is needed to ease craze nucleation or initiate yielding as well as to avoid premature fracture of crazes, since failure in crazable polymers is caused by fracture of the craze matter. Many effective procedures have been advanced to reach toughening by the reduction of overall deformation resistance to promote new crazes and avoid premature craze fracture (Argon 2013; Bucknall 1977, 2000; Kausch 1983, 1990; Michler and Balta-Calleja 2012).

There are several methods known to improve the toughness of glassy polymers, e.g., by co-polymerization, by mixing with another miscible polymer, or by incorporation of a second phase through the blending process, like particles of other thermoplastic polymers or rubbers, fine particles of inorganic materials, or even very small voids. By dispersion of particles of the second phase, the energy dissipating deformation processes that are native to the matrix (either crazing or shear yielding) can be notably intensified and stabilized. The selection of the active deformation mechanisms depends primarily on the details of the matrix chemistry, and the modification by incorporation of the second phase usually does not alter it.

For glassy brittle polymers prone to crazing, such as PS or PMMA, apart from blending with non-crazable polymers miscible with them in order to alter the entanglement density and hence increase the craze flow stress above the distortional plastic resistance (Wellinghoff and Beaer 1978), the majority of approaches to their toughening were based on the incorporation of compliant heterogeneities, like soft spherical elastomer particles. Such particles appeared very effective in increasing the craze concentration by promotion of craze nucleation at lowered overall plastic resistance, as, e.g., in high-impact polystyrene (HIPS) or ABS. The rubbery

particles not only initiate crazes but also participate in their stabilization and act as craze terminators. This approach to toughening has been well developed practically and was described in many fine books and reviews (Argon 2013; Balta-Calleja and Michler 2005; Bucknall 1977, 1997, 2000; Collyer 1994; Kinloch and Young 1983; Michler and Balta-Calleja 2012). Very similar methods of toughness modification by incorporation of rubber particles are also widely used for toughening of semiductile glassy polymers that tend to deform by shear yielding. A further approach to additional toughening of crazable polymers by lowering the craze resistance through "plasticization-on demand" by low molecular weight diluent accelerating craze plasticity, which was prepackaged in inclusions, was also explored (Brown et al. 1989; Gebizlioglu et al. 1990). This method while appearing quite effective in certain ranges turns ineffective at high strain rates, mainly due to limitations of the stress-enhanced processes of case II diffusion which govern the local plasticization process (Argon et al. 1999; Piorkowska et al. 1993; Qin et al. 1999).

Thermoset Polymers

Epoxies and other thermoset resins are used widely as matrix materials in composites reinforced with long and short fibers as well as with fine particles and in other bulk applications. Therefore, the problem of alleviating their brittleness has attracted much attention. Incorporation of soft compliant particles into epoxies, in order to achieve a toughening effect similar to HIPS, has basically failed (Sultan and McGarry 1973) because of elementary reasons that these thermosets demonstrate notably in high plastic resistances due to cross-linking, which leads to a dense and robust molecular network. Consequently, they do not form crazes as PS or other glassy polymers do. Nevertheless, incorporation of well dispersed, small and compliant particles has demonstrated to be effective in promoting cavitation of particles under stress localized in planar zones (Sue 1992; Sue and Yee 1996) which give rise to craze-like dilatational bands similar to those observed on crazing of glassy polymers (Lazzeri and Bucknall 1995), a response similar to the cavitational craze process found in spherical-domain block copolymers (Schwier et al. 1985). It was also shown that use of rigid particulate fillers can also be quite effective through the crack pinning mechanism (Shaw 1994).

Semicrystalline Polymers

Many semicrystalline polymers, such as high-density polyethylene (HDPE), polypropylene (PP), polyacetals (POM), or polyamides (PA), are generally known to be quite tough at usual conditions of deformation, i.e., away from low temperatures and at moderate rates. Unfortunately, they also appear notch brittle, particularly under impact loading and at low temperatures. These and other semicrystalline polymers have been, however, successfully toughened by incorporation of elastomeric particles which, when present at certain conditions, triggered an extensive plastic deformation of the semicrystalline matrix through common crystallographic slip and interlamellar shear mechanisms. The primary function of rubbery particles here is again to bring about reduction of plastic resistance of the matrix, based on the same deformation mechanism as these are active already in the plain polymer.

Much of the recent work has been concerned on toughening of polyamides (Borggreve and Gaymans 1989; Borggreve et al. 1987; Dijkstra et al. 1994a; Gaymans 1994, 2000; Muratoglu et al. 1995a, c, d; Wilbrink et al. 2001; Wu 1985, 1988). These studies highlighted the correlation between toughness improvement and the critical interparticle distance, found in such blends. This interparticle distance was tried to relate mechanistically to a specific form of preferential "edge-on" orientation of lamellar crystals around particles that was shown to reduce markedly the overall plastic resistance of the polymer matrix (Muratoglu et al. 1995a, c, d). It was postulated that such a preferential local orientation could be obtained at the matrix–particle interfaces, not only for rubbery particles but also for other particles, including stiff particles of a mineral filler (Bartczak et al. 1999a, b, c). Considerable work was carried out on isotactic polypropylene (iPP) using both elastomeric particles (Jiang et al. 2000; Martuscelli et al. 1996; Liang and Li 2000; Liu et al. 2013; Nitta et al. 1998, 2005) and mineral filler (Chan et al. 2002; Cioni and Lazzeri 2010; Gong et al. 2006; Lazzeri et al. 2004; Thio et al. 2002; Zuiderduin et al. 2003; Dubnikova et al. 2004; Lin et al. 2010; Weon et al. 2006). Toughening of high-density polyethylene with both elastomeric and stiff particles was also studied extensively (Bartczak et al. 1999b, c; Deshmane et al. 2007; Yuan et al. 2009), and the effect of the critical interparticle distance was explored here, too.

11.4.3 Rubber Toughening

The invention of rubber toughening is one of the milestones in the history of the plastic industry (Bucknall 1977). In the late 1940s, high-impact polystyrene (HIPS) and acrylonitrile-butadiene-styrene (ABS) were developed by compounding butadiene rubber into PS or SAN, respectively. Both HIPS and SAN demonstrate a heterophase morphology with compliant micron-sized particles dispersed in the rigid matrix. The success of these products has led not only to the formulation of their improved grades, but also to the idea that the principle of rubber toughening could be applied to all other types of plastics, not only to crazable glassy polymers. Since then modification of polymers by blending them with other polymers, mostly compliant elastomers, to create a continuous matrix-dispersed inclusion morphology, commonly referred to as rubber toughening (due to rather historical reasons), has been successfully applied to many amorphous polymers such as PS, SAN, or PC (Hourston and Lane 1994; Parker et al. 1990), as well as to semicrystalline ones, including polyamides (Abate et al. 1992; Billon and Haudin 1997; Borggreve and Gaymans 1988, 1989; Borggreve et al. 1987, 1988, 1989a, b, Bucknall et al. 1989; Cimmino et al. 1986; Dijkstra and Gaymans 1994a, b; Dijkstra et al. 1994a, b; Epstein 1979; Flexman 1979; Gaymans 1994, 2000; Gaymans et al. 1990; Gaymans and Dijkstra 1990; Gaymans and van der Werff 1994; Gonzales-Montiel et al. 1995a, b, c; Hobbs et al. 1983; Janik et al. 1995; Kayano et al. 1997; Lu et al. 1993, 1995, 1996; Majumdar et al. 1994a, b, c, d, e; Margolina and Wu 1988; Muratoglu et al. 1995c, d; Okada et al. 2000; Oshinski et al. 1992a, b, 1996a, b, c, d;

Ramsteiner and Heckmann 1985; Scott and Macosko 1995; Takeda et al. 1992; Takeda and Paul 1992; Wilbrink et al. 2001; Wu 1983, 1985, 1987, 1988, 1989), polypropylene (Gensler et al. 2000; Harrats and Groeninckx 2005; Jang et al. 1984, 1985; Jiang et al. 2000, 2004b; Liang and Li 2000; Liu et al. 2013; Martuscelli et al. 1996; Nitta et al. 1998, 2005; Tiwari and Paul 2011; Utracki and Dumoulin 1995; van Der Wal et al. 1998), polyacetal (Flexman 1988; Kloos 1985; Xie et al. 1997), and thermoplastic polyesters such as polyethylene terephthalate and polybutylene terephthalate (Abu-Isa et al. 1996; Arostegui and Nazabal 2003; Brady et al. 1994; Cecere et al. 1990; Hage et al. 1997; Hale et al. 1999a, b, c, d, e; Hert 1992; Hosti-Miettinen et al. 1995; Hourston and Lane 1994; Hourston et al. 1991, 1995; Kanai et al. 1994; Kang et al. 1997; Laurienzo et al. 1989; Loyens and Groeninckx 2002, 2003; Mouzakis et al. 2001; Neuray and Ott 1981; Okamoto et al. 1994; Park et al. 2000; Penco et al. 1995; Polato 1985; Sanchez-Solis et al. 2000; Tanrattanakul et al. 1997). Rubber-modified polyamide 6,6 was the first marketed super-tough engineering blend (Epstein 1979; Flexman 1979; Wu 1987) with more than tenfold improvement in toughness when compared to the pristine parent polymer. Brittle thermosets like epoxies have also been toughened by blending with elastomers (Shaw 1994; Yee et al. 2000).

It has been established that the fracture toughness could be increased significantly by adding a relative small amount (usually from 5 to 25 wt.%) of a suitable elastomer to the thermoplastic matrix. Optimum particle size appropriate to toughen satisfactorily a rigid polymer varies, depending on properties of the host polymer (matrix), primarily on its inherent fracture mechanism, but is commonly within the range of 0.1–5 μm. As a general rule, brittle glassy matrices that tend to craze benefit more from large rubber particles size, typically between 2 and 3 μm. On the other hand, matrices that can absorb energy via shear yielding are effectively toughened with relatively small particles, on the order of 0.5 μm or less. Very fine particles, as, e.g., those smaller than 0.05 μm in blends based on polyamide, do not take part in toughening process (Gaymans et al. 1990; Oshinski et al. 1992a, 1996b), since they need higher stress to cavitate. The immiscibility and phase separation appear very important as a rubber dissolving in the matrix acts merely as a plasticizer, which reduces the glass transition temperature and hence seriously affects the stiffness but with only limited influence on toughness. Optimum commercial rubber-toughened glassy polymers (phase-separated blends), such as HIPS and ABS, demonstrate toughness about one order higher than the unmodified matrix material (PS, SAN). Similar, impressive results were obtained for elastomer-toughened semicrystalline polymers. Toughness of several glassy and semicrystalline polymers toughened by elastomers is given in Table 11.1.

The most important feature of rubber toughening is that the fracture of the toughened polymer is substantially postponed – material becomes ductile and undergoes extensive plastic deformation, usually according to the same mechanism as the pristine parent polymer, prior to reaching the failure limit – at the expense of a limited, yet usually tolerated reduction of stiffness, yield strength, and creep resistance (Bucknall 1977; Kinloch and Young 1983). This change from brittle to ductile behavior is possible due to the reduction of the overall plastic resistance of

Table 11.1 Toughness of selected polymers and their blends with rubbers

Matrix polymer	Predominant fracture mechanism	Typical notched Izod impact strength (J/m)	Polymer–rubber blend fracture mechanism	Optimum rubber diameter (μm)	Typical notched Izod impact strength of the blend (J/m)
PS	Crazing	21	Crazing	2.5	130
SAN	Crazing	16	Crazing and yielding	0.75	780
PMMA	Crazing	16	Crazing and yielding	0.25	80
POM	Yielding	110	Yielding	<0.5	910
PP	Yielding	20–40	Yielding	0.1–0.4	500–700
PA	Yielding	40–60	Yielding	0.1–0.4	1100

the matrix material below the brittle fracture strength. The desired changes in the deformation behavior and the balance of properties are achieved by a suitable dispersion of the soft elastomer or rubber in the polymer matrix, in the form of small spherical inclusions (particles). The dispersed particles can have a form of homogeneous or heterogeneous particles (as, e.g., "salami" particles in HIPS or core–shell particles (Cruz-Ramos 2000)).

It has been established that the use of phase-separated, well-dispersed elastomer with a suitable particle size allows to bring a large volume of the matrix into the process of plastic deformation, resulting in absorption of a significant amount of energy. Concurrently, rubbery particles frequently help to limit the growth and breakdown of voids and crazes and prevent in this way an initiation of a crack and premature failure. A number of quite different mechanisms of such toughening have been proposed in the past, but all of these rely on a dispersion of elastomer particles within a glassy or semicrystalline matrix. These have included energy absorption directly by rubber particles (Buchdahl and Nielsen 1950; Merz et al. 1956), energy dissipation upon rubber cavitation, or debonding at rubber–matrix interface (Sultan and McGarry 1973), matrix crazing (Bucknall 1977, 2000) or shear yielding (Newman 1978) or a combination of both (Bucknall 1977, 2000). The early hypothesis attributed toughness enhancement to dissipation of energy in the elastomeric phase either directly (Buchdahl and Nielsen 1950) or by the effect of bridging cracks by rubber particles (Merz et al. 1956). The amount of energy absorbed at impact was attributed to the sum of the energy to fracture the rigid matrix and the work to break the elastomeric particles encountered on the crack path. This hypothesis was dismissed soon since it was estimated that the total energy associated with the rubber deformation and break can account for only a small fraction of the observed enhanced impact energy (Bucknall 1978). Consequently, this mechanism can play only a minor role in toughening of rigid polymers. In the late 1960s Schmitt (1968) and Kesskulla (1970) proposed that the rubber particles can not only deflect or terminate cracks but can also act as stress concentrators, which efficiently initiate crazes in their very surroundings. Microscopic examination of deformed HIPS revealed formation of numerous crazes at

interfaces of rubber particles in their equatorial regions, which confirmed that hypothesis (Bucknall and Smith 1965). The role of rubber particles as stress concentrators, able to initiate extensive crazing, turned out crucial for toughening of the matrix. Bucknall proposed the mechanism of toughening by the so-called multiple crazing (Bucknall 1977), which became the basis of many toughening approaches developed later. It has been established and widely accepted that the deformation process involving crazing is initiated at surface of numerous elastomer particles, simultaneously in many sites of the matrix (Bucknall 1977, 2000; Collyer 1994). The primary function of elastomer particles is to modify the stress field in the surrounding matrix (stress concentrations, relief of the triaxial stress state upon cavitation), which can promote a widespread deformation of the matrix (Bucknall 2000). In rubber-modified crazable polymers, crazes are initiated under an applied tensile stress at points of maximum principal strain, which is typically near the equator of rubber particles (where maximum concentration of the stress is observed), and propagate outwards, normal to the direction of maximum tensile stress, although deviations may occur because of an interaction between the neighboring particle stress fields (Kinloch and Young 1983) (cf. Fig. 11.2). Craze propagation is terminated when another particle is encountered by a craze, which prevents the growth of very long crazes. As a result, a large number of small crazes are produced in polymer modified with rubber particles, in contrast to a small number of large crazes formed in the same polymer in the absence of elastomer. This mechanism is effective enough for absorption of large amounts of energy, which results in a substantial enhancement of impact strength of the material. Similar scenario of initiation of widespread plastic deformation at rubber particles (at points of maximum shear stress) holds also when the dominating deformation mechanism of the matrix is shear yielding rather than crazing.

The addition of rubber particles promotes energy absorption through the initiation of crazing or local yielding phenomena in the proximity of numerous particles, followed by an extensive plastic deformation that involves quite a large volume fraction of the sample. Such a toughening mechanism can be described by the following sequence (Bucknall 1977, 1997; Kim and Michler 1998b; Michler 2005; Michler and Balta-Calleja 2012):

1. **Stress concentration:** Tensile elastic deformation results in the generation of stress concentrations around the modifier particles, due to different stiffness of particles from the matrix. The stress concentration leads to the development of a triaxial stress in the rubber particles as well as in their surrounding within matrix.

2. **Voids formation:** Due to the stress concentration and/or thermal stress, a higher triaxial or hydrostatic stress builds up inside particles and gives rise to nano- or microvoids formation through cavitation inside particles or debonding at the particle–matrix interface which substantially modifies the local stress state (e.g., partially relieves triaxial stress in front of the crack tip) and matrix response to the stress (through a change of the sensitivity of the yield stress to mean stress). Due to void formation the volume strain is released and constraints imposed earlier by incompressible rubber particle on a neighboring matrix are relieved.

All of this can reduce the sensitivity of the material towards crazing and promote shear yielding.

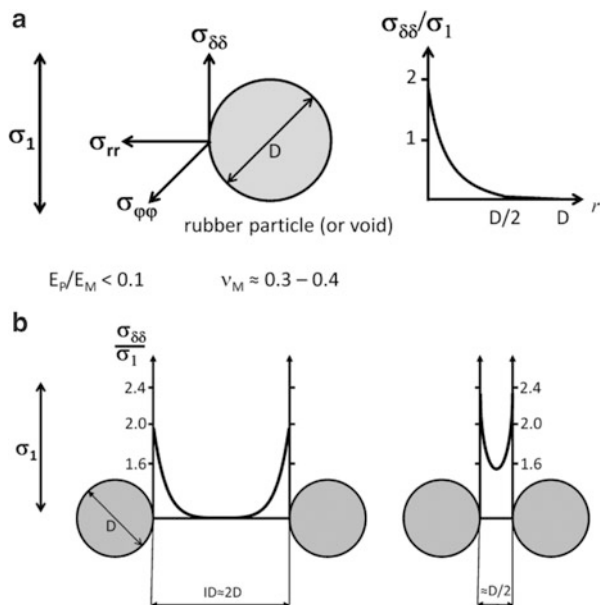
3. **Local yielding:** Initiation of local yielding of the matrix occurs in the points of the highest stress concentrations, usually around the equatorial zone of a particle (plastic strain softening). The mechanism of that local yielding of the matrix can be either multiple crazing (fibrillated or homogeneous crazes), extensive shear yielding, or some combination of both. In semicrystalline matrices, local shear yielding proceeds by shear of crystals (crystal plasticity involving primarily crystallographic slip mechanisms) and amorphous layers (interlamellar shear) (Argon 2013; Oleinik 2003). If the shear yielding mechanism is active, then weak shear bands become to develop in the matrix between the voided/debonded particles at an angle of around $45°$ to the direction of the maximum principal tensile stress, simultaneously with continuous growth of voids.

4. **Extensive deformation stabilized by strain hardening** of the yield zone, mostly due to increasing matrix deformation, although stretching of the rubber phase to high strains can make a significant contribution to this, especially when the rubber is well bonded to the matrix and its content is high. The strain hardening stabilizes deformation process and prevents its localization which could result in a generation of crack and premature fracture. This stabilization is especially important when multiple crazing is the dominating mechanism of deformation. In specimens containing sharp notches or cracks, rubber particles can cause also crack tip blunting and consequently crack stop.

The selection of the dominant deformation mechanism in the matrix depends not only on the properties of this matrix material but also on the test temperature, strain rate, as well as the size, shape, and internal morphology of the rubber particles (Bucknall 1977, 1997, 2000; Michler 2005; Michler and Balta-Calleja 2012; Michler and Starke 1996). The properties of the matrix material, defined by its chemical structure and composition, determine not only the type of the local yield zones and plastic deformation mechanisms active but also the critical parameters for toughening. In amorphous polymers which tend to form fibrillated crazes upon deformation, the particle diameter, D, is of primary importance. Several authors postulated that in some other amorphous and semicrystalline polymers with the dominant formation of dilatational shear bands or extensive shear yielding, the other critical parameter can be the interparticle distance (ID) (the thickness of the matrix ligaments between particles) rather than the particle diameter.

11.4.3.1 Stress Concentrations

Particles dispersed in the matrix (as elastomer or other polymer inclusions in polymer blends or block copolymers, filler particles in composites, impurities) similarly to small voids initiate stress concentrations in loaded material due to the difference in stiffness between particle and the matrix. These stress concentrations are highly localized – they decrease rapidly with distance from particle or void (as r^{-3}), and at a distance of particle radius (R = D/2), the stress concentration almost disappears (see Fig. 11.8a). The intensity of stress concentration at the particle–matrix interface depends on the properties of both materials, as shear

Fig. 11.8 (a) Stress components in the equatorial plane of the rubber particle under the remote tensile stress of σ_1 and the change of the tensile stress $\sigma_{\delta\delta}$ with the distance r from the interface. (**b**) Stress concentrations overlap between the close particles when the interparticle distance is about 2D (*left*) and D/2 (*right*) (Drawn after Michler and Balta-Calleja (2012))


moduli and Poisson's ratio of the particle and the matrix, respectively, while it does not depend on the particle diameter D. The elastic stress concentration at rubber particle–rigid matrix interface depends mainly on the ratio of the moduli of rubber and matrix G_R/G_M and reaches the maximum value of slightly above than 2 for $G_R/G_M < 0.001$ and is already near 2 for $G_R/G_M = 0.1$ (Oxborough and Bowden 1974). This indicates that $G_R/G_M < 0.1$ is practically enough for high stress concentrations that can lead to effective toughening. However, the absolute size of the stress concentration region increases with increasing particle diameter D – the size of the equatorial stress concentration zone is approximately D/2. An initiation of the local deformation (e.g., through initiation of crazes) should be the most effective, when the size of the stress concentration region correlates with the typical size of the plastic zone (note that typical craze thickness in PS is in the range $0.2 - 1\ \mu m$ and the most effective rubber particles in HIPS appear to be of similar size). If the particle diameter decreases, then the size of the stress concentration zone and also the size of initiated plastic zone decrease, too. The minimum size of the deformation zone, which is double the thickness of the typical transition layer between the plastically deformed material and its undeformed surrounding, determines roughly the smallest effective particle radius for craze initiation. The small rubber particles are, therefore, unable to initiate any plastic deformation of the matrix by crazing, although, as will be discussed in Sect. 11.5, it may appear effective in the promotion of the shear yielding.

The stress concentration fields of the neighboring particles overlap when the interparticle distance ID becomes small, approximately below the particle diameter. Rough estimations, assuming regular packing of uniform particles in cubic lattice,

demonstrate that average interparticle distance ID decreases to around D at the rubber volume concentration of $\phi \approx 10$ vol.% and to D/2 at $\phi \approx 15$ vol.% (Michler and Balta-Calleja 2012). The resultant stress field between particles can be estimated by simple superposition of stress concentration field of isolated particles, as illustrated in Fig. 11.8b. Due to that superposition the stress concentration at the equatorial plane of particles which are placed close enough (ID < D/2) is higher than for isolated particles, and the stress concentrations extend over the entire cross section of the matrix interparticle ligament.

An inevitable side effect of compliant elastomeric particles (or voids) dispersed in rigid polymer matrix is a reduction of the yield stress of the material. As a first approximation the Ishai–Cohen effective area model (Ishai and Cohen 1968), considering a unit cube with a spherical particle of radius R at its center, can be used for estimation of the reduction of the yield stress:

$$\frac{\sigma_y(\phi)}{\sigma_y(0)} = 1 - \pi R^2 = 1 - \pi \left(\frac{3\phi}{4\pi}\right)^{2/3} = 1 - 1.21\phi^{2/3} \qquad (11.11)$$

where $\sigma_y(\phi)$ is the yield stress of a blend containing a volume fraction ϕ of voids or compliant inclusions with the radius R, and $\sigma_y(0)$ is the yield stress of the pristine matrix. Another dependence was found experimentally for rubber-toughened PMMA deformed in compression (cavitation inhibited) (Gloagen et al. 1993):

$$\frac{\sigma_y(\phi)}{\sigma_y(0)} = 1 - 1.375\phi \qquad (11.12)$$

Although different, both Eqs. 11.11 and 11.12 demonstrate a clear dependence of the yield stress on volume fraction alone. The above equations apply to uniform distribution of particles. Significantly higher local stress concentrations, leading to a deeper reduction of the yield stress, and higher toughness can be expected when the rubber particles are not dispersed uniformly but form a pseudo-network morphology (Bucknall 2000).

When shear modulus of a rubber is much smaller than that of the matrix ($G_R/G_M < 0.1$), the high stress concentrations around rubber particles can additionally cause a significant increase of the deformation rate (Bucknall 2000), in addition to modification of the stress state reducing locally the yield stress.

At temperature below glass transition temperature of the elastomer, its modulus becomes similar to that of the matrix, i.e., $G_R/G_M \approx 1$. As a consequence, stress concentrations weaken substantially, and rubber particles are not able any more to reduce the yield stress enough to produce significant toughening. Additionally, the stress required to cavitate a particle that becomes glassy increases dramatically, which practically stops any internal cavitation of particles and also leads to the disappearance of the toughening effect. In impact tests, like Charpy or Izod, the minimum temperature at which any toughening can be observed is usually about 10 K higher than the actual T_g (Bergen 1968) due to relatively slow relaxation and
Fig. 11.9 Impact resistance of SAN of various compositions blended with PBA/SAN core-shell particle impact modifier (From Heckmann et al. (2005); reproduced with permission of Taylor and Francis)

high deformation rate. The effect is illustrated in Fig. 11.9 for different SAN copolymers toughened by blending with core–shell particles containing the poly (butylacrylate) (PBA) rubber core. One can observe here that toughness of the blends is enhanced only above the glass transition temperature of the rubber phase, which is below –40 °C, independently on properties of the matrix (the differences in toughening efficiency with changing composition of the matrix observed above T_g of the rubber are related primarily to the agglomeration habits of particles) (Heckmann et al. 2005).

In contrast to soft rubber particles, the stiff particles dispersed in a softer matrix (particles of stiff polymer or particulate filler, $G_R/G_M \geq 1$) respond on tensile loading with the concentration of the tensile stress in the polar regions ($\sigma_r/\sigma_o \approx 1.8$) and compressive stresses around particle equator. If the adhesion between the matrix and particles is poor, the concentration of tensile stress at the particle–matrix interface can result in debonding and formation of voids in polar region of particles. These voids become the source of new stress concentrations, similar to that around isolated void or rubber particle. Further elastic or plastic stretching of the matrix can lead to the expansion of these polar voids towards the equator and their eventual merging. This produces a single relatively large and elongated void around the particle. The voids created by debonding initiate stress concentrations, advantageous for matrix yield and deformation around the void equator. More frequently, however, due to other factors, the stiff particles debonded from the matrix initiate crack and followed by brittle fracture rather than yielding of the matrix.

In addition to the stress concentrations upon loading, which arise from a difference in stiffness of the matrix and elastomeric modifier, there are thermal stresses generated around particles due to the difference in thermal expansion

coefficient of the matrix and the elastomer. Upon cooling after melt processing, both the matrix and modifier phase contract, but with a different degree, which results in compressive or tensile radial stresses at particle–matrix interfaces. Elastomers shrink on cooling more than a glassy matrix, so that the tensile thermal stresses are produced, while, for stiff mineral fillers, which show expansion coefficient lower than the matrix, thermal stresses are compressive.

The thermal tensile stress developed in spherical rubber particle in the radial direction can be determined from the following relation (Beck et al. 1968):

$$\sigma_{rr} = \frac{2(\alpha_R - \alpha_M)E_R E_M \Delta T}{6(1 - 2v_R)E_R + 3E_M(1 - v_M)} \tag{11.13}$$

where α is coefficient of thermal expansion, v is Poisson's ratio, E is the Young's modulus, and the subscripts M and R refer to the matrix and rubber, respectively. It can be noted that similarly to intensity of stress concentrations, thermal stresses do not depend on the particle diameter. They depend strongly on Poisson's ratio, especially when the v_R approaches the value 0.5. Thermal stresses of 1.3 MPa and 9.6 MPa can be estimated for a glassy matrix, like PS, and rubber particles with the Poisson's ratio of $v_R = 0.49$ and 0.499, respectively (Michler and Balta-Calleja 2012). The thermal tensile stresses acting at a rubber particle–matrix interface together with the radial component of stress concentrations can induce debonding at interface when particles show poor interfacial strength. For well-bonded particles, an isotropic tension (negative hydrostatic pressure), which is produced inside particle, leads to their increased volume dilatation. This results in an increase of free volume and hence easier initiation of cavitation as well as reduction of the glass transition temperature. A significant reduction of T_g by 12–19 $^\circ$C was observed experimentally for polybutadiene inclusions dispersed in polystyrene (Bates et al. 1983).

Thermal stresses generated in the matrix around rubber particles have a radial tensile component and tangential compressive components. These tangential components reduce the effective stress concentration in the equatorial zone of the rubber particle.

11.4.3.2 Particle Cavitation

Rubber particle cavitation, i.e., formation of holes inside of rubber inclusions, is one of the most important ways in which toughened polymer can respond to tensile stress. Although recognized already in 1970s, this phenomenon was initially believed to be merely a secondary process, triggered by extensive shear yielding or crazing of the surrounding matrix, and not significant for toughening. With increasing experimental evidence, that opinion has gradually changed and there has been a growing understanding and acceptance of cavitation importance. Now it is widely accepted that cavitation within rubber particles is, in fact, a decisive step in toughening (Argon 2013; Argon and Cohen 2003; Bucknall 2000, 2007a, b; Bucknall and Paul 2009, 2013; Michler and Balta-Calleja 2012). Although

cavitation itself involves little energy absorption, it allows for the subsequent enhanced, sometimes massive, deformation of the matrix, which appears the primary source of the energy absorption.

In the middle of thick sample or in front of the crack tip, the stress state is triaxial (plane-strain conditions). It occurs also in front of the notch in Izod and Charpy notched samples. Such a stress state makes plastic deformation more difficult than the biaxial stress under plane-stress conditions and favors brittle fracture as the surrounding stressed material resists the lateral contraction which is needed to maintain a constant volume on deformation. The rubber particles respond to a high level of triaxial stresses produced by near plane-strain conditions with cavitation or sometimes with debonding, if the rubber–matrix interfacial adhesion is low. Both processes create voids either inside rubber particles or at their interfaces, respectively. Cavitation manifests with the easily observed stress whitening in the deformation zone (Ban et al. 1988; Gaymans et al. 1990). The volume strain experiments demonstrated that rubber cavitation begins at low strains (2–6 %) (Borggreve et al. 1989a; Bucknall et al. 1989) under triaxial stress when the matrix material is still in the elastic region.

The stress needed to initiate cavitation of an elastomer particle is a function of the cohesive energy density of that elastomer, chain entanglements, and presence of any inhomogeneities inside the elastomer particle (as, e.g., precavities, small crystallites, or foreign impurities) (Gent 1990; Kramer 1983; Wu 1989). The number of entanglements depends on the molecular weight and its distribution of the elastomer. Cavitation becomes easier for lower molecular weight and narrows its distribution (Brown and Ward 1983). Any defect or heterogeneity, if present inside the elastomer particle, can result in a significant reduction of the cavitation stress of that particle. The cavitation stress decreases further with an increasing inhomogeneity (defect) size to the micron-scale length (Gent 1990). However, it is frequently observed that rubber particles dispersed in the matrix, even those much smaller than 1 μm, cavitate quite easily under dilatational stress. This implies that there must be another mechanism for nucleation of nanovoids and cavitation, which is independent on the presence of occasional micron-scale defects and is inherent in the behavior of rubbers themselves, perhaps at the level of individual chain segments. Bucknall reasoned that since resistance to dilatation in rubbers arises almost entirely from weak van der Waals interactions, and shear occurs easily, it could be expected that under high triaxial tensile stresses, the distribution of polymer chains within the expanded volume of the elastomer become unstable, giving rise to nucleation of the nanovoid (Bucknall 1997). Calculations of Lazzeri and Bucknall (1993) and Bucknall et al. (1994) confirmed that hypothesis and demonstrated that even for particles as small as 0.2 μm in diameter, the energy barrier for cavitation is quite low and can be overcome easily with the aid of thermal energy.

Impact tests of pre-cavitated samples of rubber-toughened Nylon (pre-cavitation obtained by a slight tensile pre-straining at low deformation rate) demonstrated their impact behavior very similar to samples without initial cavities (Gaymans 1994). Similar results were reported by Dasari et al. (2010) for polypropylene and PP/CaCO$_3$ nanocomposites pre-cavitated during processing. They observed that the

voids in both plain iPP and composite acted in a similar way as the cavitating rubber particles in rubber-toughened polymer systems; i.e., the preexistent voids expanded at the early stage of the PP matrix deformation and subsequently triggered large plastic deformation of the surrounding matrix in the form of isolated and domain-like deformation zones (Dasari et al. 2010). The above findings demonstrate that the cavitation process itself, although crucial for toughening, is not a major energy-absorbing mechanism. It is rather the plastic deformation of the matrix, which follows the cavitation step.

Upon formation of voids, the constraints imposed on the matrix are locally eased, and the triaxiality of the stress is relieved, at least partially, around each cavitated elastomer particle ahead the notch or the running crack (Bucknall 1977; Donald 1994; Kinloch and Young 1983). Due to a notable reduction of constraints, the stress state around these particles, especially within thin matrix ligaments between neighboring cavitated particles, can be converted from a triaxial to a nearly biaxial one (plane-stress conditions). When the stress concentrations are present around voided particles (they actually become even slightly stronger than prior to internal particle cavitation), the change of the stress distribution from plane-strain to plane-stress conditions might be advanced enough to depress locally the yield strength and initiate plastic deformation. Shear yielding is favored by plane-stress, whereas crazing is preferred under plane-strain conditions (constraints reduced, yet not fully dismissed). Therefore, the primary effect of cavitation is usually an enhancement of shear yielding mechanism in the matrix (Bucknall 2000; Bucknall et al. 1989). Formation of cavities results in local decrease in the hydrostatic stress component and a corresponding increase in the deviatoric (shear) component, and a higher stress concentration factor (Bucknall et al. 1989). Another important result of cavitation is conversion of the material from a continuous solid to the porous (cellular) structure, which demonstrates modified sensitivity to the mean stress on yielding. Consequently, the matrix can yield easier, even at the plane-strain conditions ahead of the notch. This feature will be discussed further in Sect. 11.5.3.

Once the rubber particles have cavitated, the surrounding matrix is free to yield and stretch in a way it was previously impossible. The deforming shell of the matrix enclosing cavitated particle extends biaxially, which increases the volume of the cavitated particle. If the particle is isolated, that deformation of the adjacent matrix is limited by constraints imposed by yet undeformed surroundings. However, if particles are closely spaced, the thin matrix ligaments between them may become yielded fully across, which results in extensive plastic deformation in large volume of the sample and evolution of the shape of the cavitated rubber particle from spherical to ellipsoidal or sausage-like shape, elongated in the direction of local principal stretch due to high extension of the matrix ligaments around particle (Muratoglu et al. 1995d), as illustrated in Fig. 11.10.

It is sometimes suggested that rubber particles lose completely their ability to sustain a stress once they have cavitated. This is actually not true except only for a very few cases. First exception is when voids are formed along particle–matrix interfaces due to debonding (poor adhesion). Transfer of stress between the matrix

Fig. 11.10 SEM micrographs of cavitated tensile sample of polyamide 6,6 modified with 19 wt.% EPDM rubber: (**a**) stress-whitened zone outside the neck region and (**b**) stress-whitened zone inside the neck region. The scale bar represents 5 μm (From Muratoglu et al. (1995d); reproduced with permission of Elsevier)
and such debonded particles is very limited. The other case is when crazes formed away from rubber particle intercept it upon their growth. In such a case, a significant lateral contraction must accompany elongation of the particle in the applied stress direction. As this contraction proceeds, debonding at the particle/craze interface occurs, and the void is created. This void grows then under increasing load, which can lead to premature craze breakdown and subsequent crack initiation.

For homogeneous rubber particles with high interfacial strength (strong adhesion) to the matrix, their cavitation results in the formation of the void in the center of the particle. When a void is formed, the rubber particle transforms into a continuous thick spherical shell around the void, in which the stress and strain are no longer uniform. As the void grows, the rubber shell is expanded by biaxial tension. The strain is distributed in this shell nonuniformly: the inner face of the shell must deform most, close to the ultimate stretch, which results in substantial strain hardening, whereas the outer layer, contacting the matrix, deforms much less. The expanding rubber shell bonded to the matrix can transmit load and also contribute to strain hardening of the entire material with an advance deformation of the matrix and the rubber, initiated by its cavitation. However, further expansion

of the void can lead eventually to the rupture of the most strained rubber segments in the inner layer close to the void, and consequently the entire shell can fail by progressive tearing (Bucknall 2000).

In all cases, a premature rupture of the rubber will restrict extensive deformation of the matrix as it leads to the formation of voids larger than critical, resulting in fast crack initiation and propagation. When rubber rupture occurs later, after some advance of matrix deformation, the orientation-induced hardening of the matrix can alleviate to some extent the effect of such flaws and the material is allowed to deform further.

Frequently fibrils are formed inside the rubber particle, especially in cross-linked or heterogeneous particles, as, e.g., particles with stiffer sub-inclusions or core–shell morphology. These fibrils, anchored both sides at particle–matrix interfaces or bridging a particle stiff core/inclusion with the matrix matter at the interface, are clearly load-bearing elements of the structure, which make a major contribution to the strain hardening. The fibrillar morphology of cavitated particle is the most effective for stress transfer and contribution in strain hardening that prevents premature fracture since stress and strain across fibrils are uniform and can be high, simultaneously in all fibrils. The experimental evidence indicated that the stress in the fibrils formed in core–shell particle reached much more than 30 MPa (Starke et al. 1997). Bucknall (1997) claimed that a low-level cross-linking of the rubber is desirable for homogeneous rubber particles, as it allows a still early cavitation of the particles and high strains by fibrillation, while the fibrils would have high strength. Excessive cross-linking, also that caused by photodegradation effect (e.g., in outdoor applications), can lead, however, to a marked reduction or even loss of the impact strength due to stiffening of the rubber and impediment of cavitation.

Various morphologies of cavitating rubber particles were considered by Kim and Michler (Kim and Michler 1998a, b). Depending on the original morphology of the particle (homogeneous, heterogeneous with inclusions, core–shell) and adhesion between particle and the matrix, which can be modified broadly by addition of various compatibilizers, different modes of cavitation or debonding can be observed: from single-site cavity in the center of a homogeneous inclusion, through multiple internal cavitation, to multiple cavitation with formation of fibrils in the shell of the core–shell particle or around debonding particle which had been moderately bound to the matrix, cf. Fig. 11.11. The most favorite situation is when rubber forms fibrils rather than a single smooth shell around cavity since contrary to a single shell around void, fibrils are strained uniformly and therefore can transmit higher stress and participate effectively in strain hardening (in a similar manner as fibrils in a craze), which stabilizes advancing deformation of the matrix and prevents premature initiation of a crack. The presence of fibrils controls also the size of the microvoids and prevents expansion of the void to the overcritical size which could quickly end up in crack formation.

Observations of rubber cavitation and growth of the voids offer an additional explanation for the enhanced shear yielding of the matrix (Donald and Kramer 1982). The presence of many closely packed particles which can cavitate enables
Fig. 11.11 Various morphologies produced by cavitation and debonding: (**a**) single cavitation in homogeneous particles (e.g., PA/BA blend); (**b**) single cavitation in heterogeneous particles (blend PP/ethylene–propylene block copolymer with low content of ethylene); (**c**) fibrilized cavitation (PP/PA/SEBS-g-MA blend); (**d**) multiple cavitation in heterogeneous particles (PP/LLDPE/SEBS-g-MA blend); (**e**) single debonding (PP/ethylene–propylene random copolymer blend); and (**f**) fibrilized debonding at the interface (PP/EPDM blend). *I* – initial morphology, *II* – low strain, *III* – high strain (Adapted from Kim and Michler (1998b); with permission of Elsevier)

relief of the local buildup of hydrostatic tension produced by localized shear process (proceeding at constant volume). Thus, possibly soon after initiation of cavitation and the development of some initial shear yielding, the constrained conditions might be fully relieved by expansion of numerous cavities distributed densely over the process zone, which changes the structure of the material into cellular, in which thin cell walls are under plane-stress, so that even the relatively thick bulk specimens may behave as if the matrix were everywhere under plane-stress conditions. Shear deformation occurs more readily under biaxial rather than at triaxial stress state, and cavitation of the rubber particles therefore favors local shear yielding deformation. However, if the matrix does not shear readily, but like polystyrene is far more prone to crazing, then this mechanism is not available and rubber cavitation followed by expansion of created voids is more damaging.

11.4.4 Core–Shell Particles

A very effective way of toughening is the use of core–shell particles instead of homogeneous rubber particles. The core–shell particles were commercially introduced as PVC impact modifiers in 1958 and since that time, their use has continuously expanded into new toughening applications, which now include a wide variety of engineering polymers (Cruz-Ramos 2000). In contrast to other impact

modifiers, as homogeneous rubber particles, which are most frequently formed by high shear forces during blending of a molten matrix polymer with an elastomer, the core–shell particles are preformed by emulsion polymerization prior to mixing with the host polymer. This makes a major difference between core–shell particles and other types of impact modifiers: the size and size distribution of core–shell particles are set during the synthesis process and continue the same after they are introduced and dispersed in a matrix of a host polymer, whereas elastomer particles formed in the blending process have the final size depending heavily on processing conditions.

The typical architecture of core–shell particles consists of a soft core, made up of a rubbery polymer, surrounded by relatively thin shell of rigid polymer that is grafted to the core. The core in commercial materials is usually a cross-linked rubber based on poly(butyl acrylate) (PBA), poly(butyl acrylate-co-styrene), or poly(butadiene-*co*-styrene). It provides the soft second phase that induces toughening similarly to homogeneous rubber particles in conventional blends. The shell of the particles consists of a polymer that is chemically grafted onto the core and generally is much stiffer since it has a much higher glass transition temperature than rubber of the core. Typical polymers used for a shell in commercial products are homo- and copolymers of PMMA and styrene–acrylonitrile copolymers (SAN) (Cruz-Ramos 2000). Two basic functions of the shell are (1) to prevent adhering of particles from one to another during the drying after emulsion polymerization process and (2) to provide a good dispersion and compatibility of particles with the matrix of the host polymer – the shell gives the particle a layer that physically binds the rubber core to the surrounding matrix and prevents particle coalescence upon blending.

There are several advantages on the use of core–shell particles as impact modifiers. The main is a relatively easy control of the matrix–particle morphology of the final blend. The particles, preformed prior to blending, have defined size and narrow size distribution, and dispersing them within the matrix does not alter these, independently on the processing conditions. Good and uniform particle dispersion can be achieved relatively easy. The shell, grafted to the rubbery core, provides usually sufficient bonding between particles and the matrix. Due to versatility of the emulsion polymerization, the particles of various sizes can be produced and selected for blend formulation according to particular demands. All this allows for a relative easy modification and fine-tuning of the impact strength and other mechanical properties of the material. Furthermore, the small size with a narrow size distribution and the uniform spatial distribution in the matrix make possible formulation of transparent impact-modified blends. The mechanism of the toughness improvement is the same as in the case of materials modified by homogeneous rubber particles, although cavities in core–shell particles are frequently stabilized by the core–shell structure, and this prevents coalescence of voids of neighboring particles, in which coalescence would lead to critical flaw and crack initiation (Michler and Bucknall 2001).

Another type of the core–shell particles is by multilayer particles that consist of a glassy core, a thin intermediate rubber layer, and an outer glassy shell (Lovell and
Fig. 11.12 TEM micrograph of fibrillar cavitation of the core–shell multilayer particle in the SAN/PBA blend; tension direction vertical (From Starke et al. (1997); reproduced with permission of Springer)

El-Aaser 1997; Michler and Bucknall 2001; Shah 1988; Starke et al. 1997). An example is the particle with the core of cross-linked PMMA, ca. 180 nm in diameter, poly(butyl acrylate-*co*-styrene) (PBA) rubber shell of approx. 40 nm thickness, and an additional outer thin-grafted PMMA shell added for improved bonding with the matrix (Michler and Bucknall 2001; Starke et al. 1997). The overall particle diameter was approximately 260 nm. Compounding of particles with SAN results in acrylonitrile–styrene–acrylate copolymer. Due to rigid core and relative low amount of the rubber, such multilayer particles with rigid core allow for better balance between toughness and stiffness of the final toughened material. The other extremely important benefit is that cavitation of such particles proceeds via nucleation of many small nanovoids in thin intermediate rubber shell. With subsequent expansion of these voids, a quite regular fibrillar morphology develops within the rubber shell with elongated fibrils anchored well to the rigid core and the outer shell (rubber had been grafted to both core and the outer shell). The morphology of cavitated particles is shown in Fig. 11.12.

As discussed in the previous section, such extended fibrils are effective load-bearing elements of the structure, which make a major contribution to strain hardening. Multiple cavitation and formation of fibrils results in uniform stress and strain distribution in these fibrils, which prevents their premature fracture, stabilizes cavities, and allows for effective stress transfer across the rubber shell. All of this brings a significant contribution of particles in strain hardening and stabilization of the matrix material extensive deformation. The stretching of fibrils is very similar to drawing of fibrils from the walls of a craze and generates

substantial stress, which can be estimated even above 100 MPa at room temperature for highly elongated fibrils (Michler and Balta-Calleja 2012). The experimental evidence indicated the stress in the fibrils formed in core–shell particle exceeded well 30 MPa (Starke et al. 1997). Such a high stress transmitted to the hard polymer core can be high enough to involve its yielding, which if happen would provide an additional effective mechanism of energy absorption upon impact. The plastic deformation of the core of particles was indeed observed by Michler and Bucknall (2001).

Taking all above into account, the multilayer core–shell particles seem to be suited very well for toughening of rigid polymers, as they provide a relatively good balance between toughness and stiffness of the impact-modified material, in contrast to modification with homogenous rubber inclusions, which frequently leads to unacceptable deep reduction of stiffness of toughened material. However, to get full benefit of potential of modification with core–shell particles, these particles must be carefully designed (with respect to particle composition, layer thickness, overall diameter, selection, or adequate chemical modification of the outer layer to ensure good adhesion to the matrix) and custom made for a particular blend and its application.

It is well known that the particle size needed to toughen a rigid polymer depends on inherent fracture mechanism of the matrix. In general, brittle glassy matrices that tend to craze benefit more from large rubber particles, of diameter exceeding 1 μm. Smaller particles, below 0.5 μm diameter, are, in turn, effective in toughening matrices in which shear yielding is a main deformation mechanism. Since typical core–shell particles have a diameter well below 1 μm (usually in the range of 0.25–0.5 μm), they are used most frequently for toughening of non-crazable polymers, in which shear yielding is a dominant deformation mechanism. Core–shell particles were used as effective impact modifier in many polymers, including PC (Kayano et al. 1996; Lovell and El-Aaser 1997), PMMA (He et al. 1998; Laatsch et al. 1998; Lovell and El-Aaser 1997; Lovell et al. 1993; Shah 1988; Vazquez et al. 1996), PVC (Lutz and Dunkelberger 1992), PA (Aerdts et al. 1997; Kesskula and Paul 1994; Majumdar et al. 1994d), PBT, and PET (Brady et al. 1994; Hage et al. 1997). Preparation of larger particles by emulsion polymerization to be used for toughening of crazable polymers, like PS, received also some amount of attention (Cruz-Ramos 2000).

11.4.5 Rigid Particles (Fillers)

The idea of toughening with rigid particles instead of soft rubber particles has attracted great attention because incorporation of rigid particles would contribute to a greatly enhanced stiffness of the modified material in addition to possible toughness improvement, while modification with elastomers always leads to an inevitable reduction in modulus. The rigid particles can be either particles of a particulate filler or particles of another polymer, stiffer than the matrix polymer. The possibility of simultaneous enhancement of both toughness and stiffness would be a significant advantage of rigid particles over traditional rubber toughening.

   Stiff particles dispersed in the polymer matrix increase its modulus, and if there is strong adhesion between particles, they can also increase the yield strength. However, in the case of low or missing interfacial strength, debonding appears on loading readily while still in the elastic region as stiff particles are unable to deform to any significant degree. The microvoids created around particles due to debonding should not form immediately upon application of stress as this may reduce the elastic modulus. Ideally, debonding should occur at stress only slightly lower than the yield of the pristine matrix. As it is often the case, it prevents any increase of the yield strength of the system, unwanted for toughening. The microvoids created at interfaces act as stress concentrators, like cavitated elastomer particles. Widespread particle debonding in the deformation zone close to notch root or fracture surface transforms this zone into a porous solid and helps to relieve plastic constraints imposed earlier on the matrix by rigid and hardly deformable particles (Bartczak et al. 1999b, c; Muratoglu et al. 1995a, d; Thio et al. 2002; Tzika et al. 2000; Wilbrink et al. 2001) and make yield easier due to modification of yield sensitivity to the mean stress. The related change in the stress state can initiate local yielding process and consequently lead to an improved toughness. This however can be achieved only in the case of small, semi-equiaxed, and homogeneously distributed particles, since large particles create large voids when debonding, with the disadvantage of void coalescence and formation of cracks of overcritical length. On the other hand, very small particles, well dispersed in the matrix, require high mean stress for debonding, while agglomerates of such very small particles, which are difficult to destroy in processing, can rupture easily on loading and produce sharp cracks reaching quickly the critical length (Kim and Michler 1998a, b; Michler 2005; Michler and Balta-Calleja 2012). Clustering of rigid particles can also result in the formation of quite large unbounded inclusions, which, similarly to very large particles, upon separating from the matrix, can act as supercritical flaws that trigger a brittle response (Argon and Cohen 2003).

   In the case of filler particles in shape of fibers or platelets (as, e.g., organoclays), oriented randomly, the distribution of voids created at their interfaces on loading can be not homogeneous enough to produce a uniform porous structure needed for successful toughening. Therefore, toughening with anisotropic rigid particles seems more difficult than with semi-equiaxed ones.

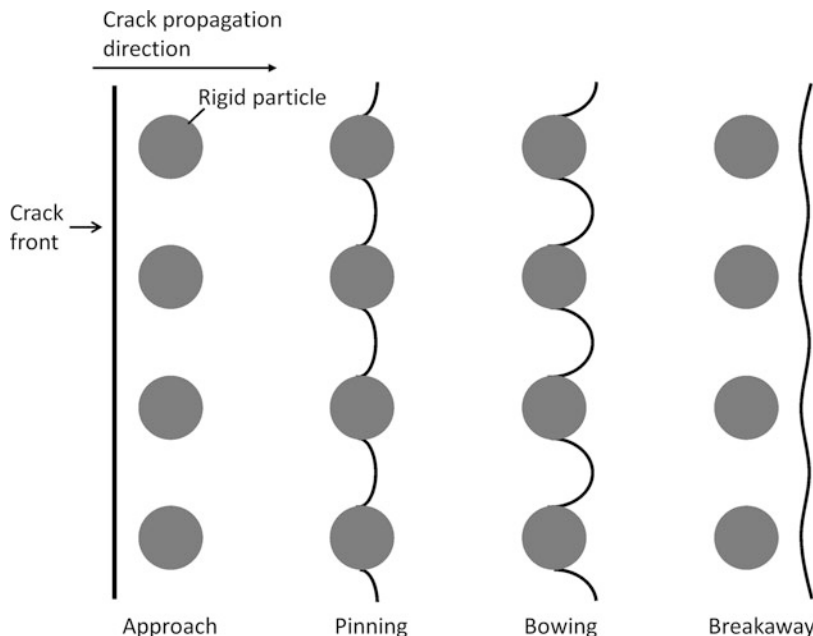
   It has been suggested (Bucknall 1978; Kinloch and Young 1983; Lavengood et al. 1973) that rigid particulate fillers might be used to increase the toughness of brittle glassy polymers by initiating multiple crazing. Under an applied stress, rigid particles do induce tensile stress concentrations in the matrix and debond from the matrix readily, which generate stress concentrations sufficient to initiate crazing, yet near the particle poles rather than the equator, as it was for rubber particles. On the other hand, due to limited adhesion between the rigid particulate filler and the matrix, the filler particles do not appear particularly as effective craze or crack terminators. To act as efficient terminators, the second phase has to be adequately bonded, while rigid particles when called to do this job may have already become debonded from the matrix. Consequently, rigid particles of particulate fillers debonding from the matrix prior to yield point demonstrate low ability to act as


Fig. 11.13 Schematic representation of the crack pinning mechanism (Drawn after Kinloch and Young (1983))

effective craze and crack terminators, which results in much poorer toughening performance when compared with well-bonded rubber particles.

Several investigations have demonstrated that incorporation of particulate fillers such as silica or alumina trihydrate can improve the toughness of thermosets, like cross-linked epoxies (Shaw 1994). The mechanism considered responsible for an increase of impact resistance is different than that of rubber particles effective in promoting cavitation under stress localized in planar zones (Sue 1992; Sue and Yee 1996), giving rise to craze-like dilatational bands (Lazzeri and Bucknall 1995). Particles of filler are expected to impose stress concentrations in epoxy matrix due to a substantial modulus difference between particle and the matrix. However, this is usually not considered as significant. Instead, a mechanism based essentially on the impeding characteristics of the particles was proposed (Evans 1972; Green et al. 1979; Lange 1970). The mechanism, called the crack pinning mechanism (Lange 1970), postulates that a propagating crack front, when encountering an inhomogeneity, as, e.g., well-bonded filler particle, becomes temporarily pinned at that point. An increase in load increases the degree of bowing between pinning points caused by adjacent particles, resulting in both a new fracture surface and an increase in the length of the crack front, as illustrated schematically in Fig. 11.13. These processes will absorb some amount of energy and therefore lead to an increase of the fracture toughness of the resin. Although incorporation of the filler can lead to a noticeable toughness improvement, this is generally much smaller than

Fig. 11.14 TEM micrograph of polyethylene thin film with a particle of CaCO$_3$ (seen as a continuous *black* region in the left-hand side). Crystalline lamellae seen as *black ribbons* when oriented edge on against interface (From Chacko et al. (1982); reproduced with permission of Wiley)
that obtained with cavitating elastomer particles. Thus, in the direct comparison, rubber modification would prevail, although a substantial stiffness increase accompanying toughness enhancement is a major advantage of rigid particle toughening and this method may be preferred for some applications.

Another possibility of improvement of impact strength with rigid particles was demonstrated for notch-sensitive semicrystalline polymers, like polyamides, polyethylene, or polypropylene. Many studies investigating toughening of polyamides with elastomer particles (Borggreve and Gaymans 1989; Borggreve et al. 1987; Dijkstra et al. 1994a; Gaymans 1994, 2000; Muratoglu et al. 1995a, c, d; Wilbrink et al. 2001; Wu 1985, 1988) emphasized the correlation between toughening and the critical interparticle distance. This distance was correlated with a specific form of preferential crystal orientation around particles (with crystalline lamellae oriented locally edge on with respect to the particle–matrix interface and with the low energy/low plastic shear resistance (001) crystallographic plane oriented parallel to that interface). Such an orientation was shown by Muratoglu et al. (Bartczak et al. 1999a, b, c; Muratoglu et al. 1995a, c, d) to reduce markedly the plastic resistance of the layer of polymer matrix around the particle due to possibility of activation of the easiest crystallographic slip system, (001) [010] of polyamide crystals (Lin and Argon 1992). Bartczak et al. (1999a, b, c) postulated that such a preferential local orientation can be obtained at the matrix–particle interfaces, not only in the system consisting of PA matrix and rubbery particles but also for other polymers and particles, including stiff particles of other polymers or mineral fillers. They demonstrated it for polyethylene modified with various elastomers and CaCO$_3$ particles of various sizes. Figure 11.14 presents the TEM micrograph illustrating an oriented layer formed in polyethylene around the particle of CaCO$_3$.

Bartczak et al. (1999a) proposed that the driving force for such a unique crystal orientation around particle is the secondary nucleation at the interface, enhanced

due to the difference in interfacial energy when lamella grows in bulk and in the edge-on contact with the substrate, here the particle surface. This energy difference results in faster growth of those lamellae which maintain contact with particle surface and are oriented edge on, and consequently in the formation of the preferred crystal orientation in a thin layer around particle. Thickness of this specially oriented layer of reduced shear plastic resistance is defined for a given polymer, while independent on the type and size of particles. It was determined approximately 150 nm for Nylon 6 (Muratoglu et al. 1995a) and around 300–400 nm for HDPE (Bartczak et al. 1999a). When the interparticle distance in the blend is reduced below double the oriented layer thickness (300 nm for PA or 800 nmm for PE, respectively), the matrix ligaments consist almost entirely of the oriented material of low plastic shear resistance. They create then easy deformation paths, which percolate the sample. Upon sample loading and particle debonding, the stress concentrations induced by microvoids initiate easily the plastic deformation of crystals within these ligaments just relieved from constraints by debonding of neighboring particles, massive formation of microvoids, and then conversion of the material within deformation zone into a cellular solid. Deformation of ligaments results in an extensive plastic deformation in a large volume of the sample and high energy absorption, exactly the same as in the case of toughening with cavitating rubber particles. It was demonstrated experimentally that a big jump of impact resistance (approximately one order of magnitude) occurred in blends of PE with various elastomers and PE filled with stiff $CaCO_3$ particles, in all systems for the same critical interparticle ligament thickness of approximately 800 nm (Bartczak et al. 1999b, c), which indicates that the same toughening mechanism has to be activated for rubber and rigid particle toughening.

Toughening with rigid particles has two significant advantages over rubber toughening: (a) First, it leads to simultaneous improvement of both toughness and stiffness, in contrast to rubber toughening, which always reduces material stiffness, as illustrated in Fig. 11.15. (b) The other benefit of toughening with rigid particles is its insensitivity to the test temperature (again in contrast to their rubber toughened counterparts). As mentioned earlier, in Sect. 11.4.3.1 at temperature below T_g of the elastomer used for toughening, the stress required to cavitate a particle which became glassy increases dramatically. This practically stops any internal particle cavitation and leads to disappearance of the toughening effect (rubber is usually well bonded and cannot debond from the matrix). In impact tests, the minimum temperature at which any toughening can be observed is usually even about 10 °C higher than actual T_g (Bergen 1968). This is not the case of rigid particles toughening as it relies on particle debonding which does not depend on temperature dramatically. As a result, semicrystalline polymers toughened with rigid particles remain tough in a wide range of temperatures down to around T_g of the matrix polymer (Bartczak et al. 1999c) – cf. Fig. 11.16. Therefore, for polymers with matrices of low glass transition temperature, toughening with stiff fillers has a clear advantages over rubber modification.

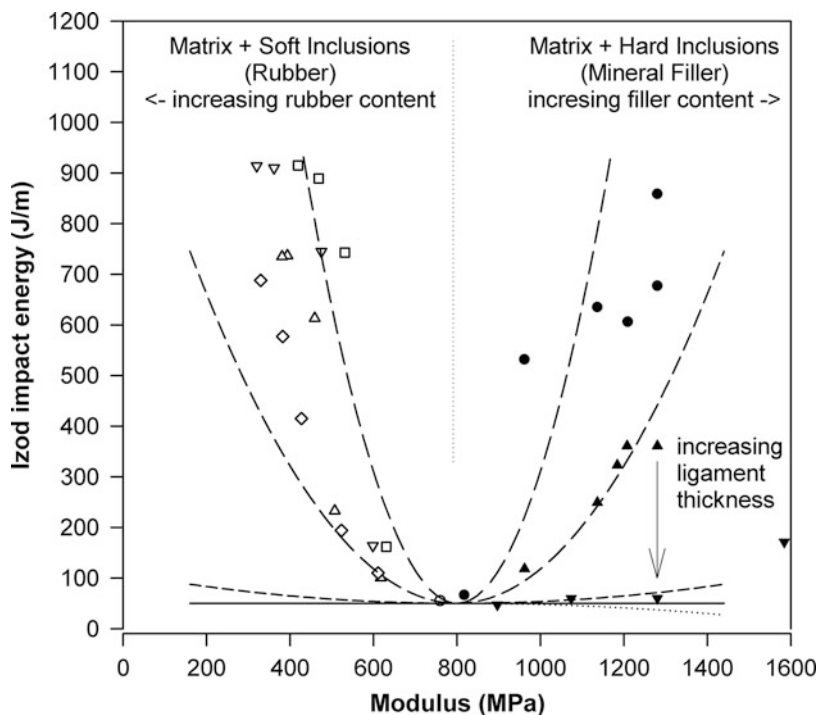
There are several prerequisites for successful toughening with rigid particles: particles must be small enough and with narrow size distribution in order to prevent


Fig. 11.15 Schematic plot of possible routes of toughening of semicrystalline polymers with soft particles (e.g., rubber, *left* branch) and hard particles (e.g., mineral filler, *right* branch) (From Bartczak et al. (1999c); reproduced with permission of Elsevier)

crack initiation at the microvoids of overcritical size formed around large particles due to their debonding, and particle dispersion must very good and their spatial distribution uniform to avoid clustering and to obtain an optimum interparticle distance, below the critical, set by matrix properties. The aspect ratio of particles should be close to unity to avoid very high stress concentrations (Zuiderduin et al. 2003). Moreover, adhesion between filler and the matrix must be kept as low as possible to allow easy particle debonding prior to matrix yielding. However, as the debonding stress increases with decreasing particle diameter, the filler particles cannot be too small since very small particles will not debond prior to the matrix yield and the mechanism will not work. Another negative consequence of very small particles is their tendency to form agglomerates or clusters. The composite suffers severely from clustering of rigid particles into quite large unbounded inclusions, which upon separating from the matrix often act as super-critical flaws, triggering a brittle response (Argon and Cohen 2003). Loose agglomerates can also rupture across, giving rise to the development of a sharp crack, cf. Fig. 11.17.

   All above show that there is only a limited range of average size and size distribution of particles to be used for toughening; moreover, particles must have
Fig. 11.16 The dependence of notched Izod impact energy on temperature for the HDPE/CaCO₃ (80:20vol./vol.) and HDPE/ethylene–octene rubber (78:22 vol./vol.) blends (From Bartczak et al. (1999c); reproduced with permission of Elsevier)

an appropriate surface treatment that promotes good dispersion but at the same time highly reduces or completely eliminates adhesion to the matrix. Furthermore, there is a strong need of optimum processing protocol, utilizing very high shear forces in order to obtain a very good and uniform particle dispersion, which is essential for toughening effect. A nonuniform dispersion causes some ligaments may become too thick to do deform easily. Particle clustering often results in supercritical flaws. All these effects can lead to material embrittlement instead of expected toughening. The method of toughening with rigid particles, with its potential and strong limitations, was analyzed in detail by Argon and Cohen (Argon and Cohen 2003).

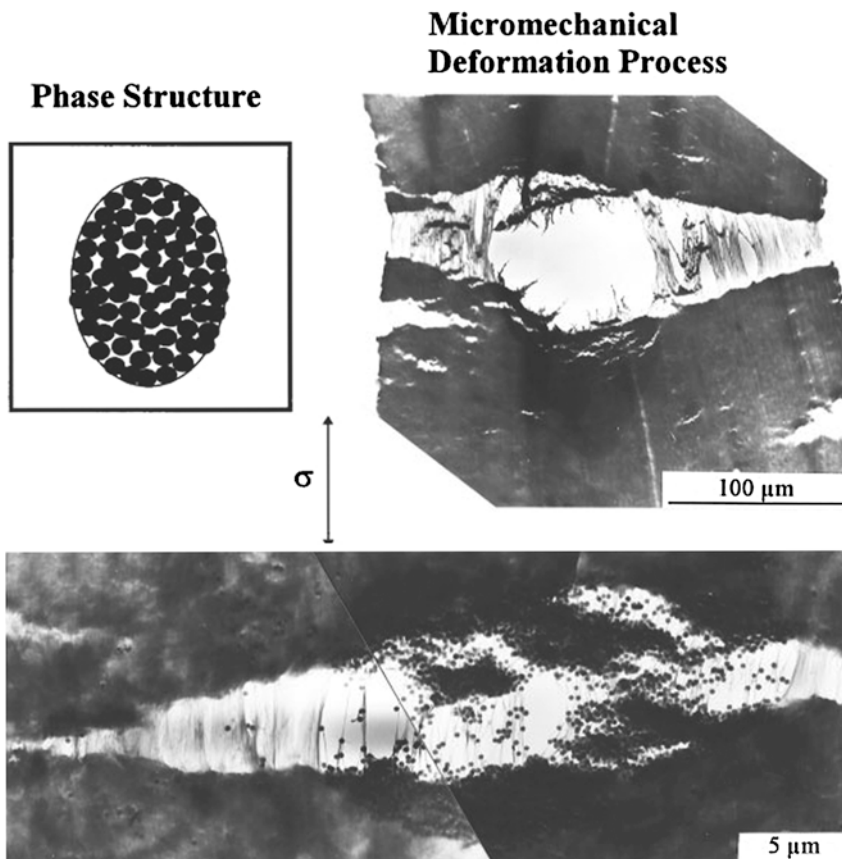
Successful toughening with rigid particles, mainly of CaCO₃, was reported for high-density polyethylene (Badran et al. 1982; Bartczak et al. 1999b, c; Deshmane et al. 2007; Fu et al. 1993; Lazzeri et al. 2005; Lei and Zhou 2000; Liu et al. 2002; Wang et al. 1997; Yuan et al. 2009), polypropylene (Bartczak 2002; Chan et al. 2002; Cioni and Lazzeri 2010; Gong et al. 2006; Kamal et al. 2012; Lazzeri et al. 2004; Lin et al. 2008, 2010, 2012; Thio et al. 2002; Weon et al. 2006; Yang et al. 2006, 2007, 2009; Zuiderduin et al. 2003), Nylon 6 (Ou et al. 1998; Wilbrink et al. 2001), POM (Bartczak 2002), and aliphatic polyketone (Zuiderduin et al. 2006). On the other hand, a need of fulfillment of all severe preconditions mentioned above makes toughening with rigid particles very difficult, which in turn


Fig. 11.17 Characteristic deformation structure depending on the phase structure of PP filled with SiO$_2$ particles demonstrating tendency to agglomeration (From Kim and Michler (1998a); reproduced with permission of Elsevier)

makes often the modification with rubbery particles more attractive in industrial practice.

The described above toughening mechanism of semicrystalline polymers proposed by Muratoglu was criticized by Hwang et al. (2006) who, on the basis of computer simulation, suggested that the observed preferred orientation of crystals which led to toughness improvement of studied samples might result from, or be significantly amplified by, oriented crystallization induced by shear during sample injection molding, possibly much enhanced within interparticle ligaments, rather than by interfacial energy differences postulated by Bartczak et al. (1999a, b, c). It was also questioned on other grounds by Bucknall and Paul (2009, 2013), who remarked inconsistency of the Muratoglu's hypothesis with recent work by Huang et al. which shows that the impact behavior of 80/20 rubber-toughened blends based on the amorphous polyamide (Zytel 330) is very similar to that of 80/20 blends

based on semicrystalline PA6 (Huang et al. 2006a, b; Huang and Paul 2006), which may suggest that crystalline structure and morphology of the matrix are inessential for toughening with particles.

11.5 Plastic Deformation Mechanisms in Toughened Polymer Blends

11.5.1 Overview of Micromechanical Behavior

As it was already discussed in Sect. 11.4.3, the modification of a rigid thermoplastic polymer with rubber particles promotes energy absorption through the initiation of local yielding in the close proximity of particles, followed by the extensive deformation involving large volume of the sample owing to dense arrangement of rubber particles. This deformation mechanism can be described by the following sequence (Bucknall 1977, 1997; Kim and Michler 1998b; Michler 2005; Michler and Balta-Calleja 2012):

- Buildup of stress concentrations around particles and negative pressure inside
- Generation of microvoids due to cavitation or debonding of rubber particles that alters the stress state in the surrounding and modifies matrix response by reducing locally the yield stress
- Initiation of local yielding by an accessible mechanism (crazing, shear yielding)
- Extensive plastic deformation stabilized by strain hardening, resulting in large energy absorption

The dominant mechanism of deformation depends mainly on the type and properties of the matrix polymer, but can vary also with the test temperature, the strain rate, and the morphology, shape, and size of the modifier particles (Bucknall 1977, 1997, 2000; Michler 2005; Michler and Balta-Calleja 2012; Michler and Starke 1996). Properties of the matrix determine not only the type of the local yield zones but also the critical parameters for toughening. In amorphous polymers with the dominant formation of crazes, the particle diameter, D, is of primary importance, while in some other amorphous and in semicrystalline polymers with the dominant formation of dilatational shear bands or intense shear yielding, the interparticle distance ID, i.e., the thickness of the matrix ligaments between particles, seems to be also an important parameter influencing the efficiency of toughening. This parameter can be adjusted by various combinations of modifier particle volume fraction and particle size.

It is now widely appreciated that independently on the actual mechanism of plastic deformation dominating the matrix response and brought about by modification with rubber particles, the critical step in toughening is generation of microvoids, common for all toughening mechanisms (Argon 2013; Argon and Cohen 2003; Bucknall 2000, 2007a, b; Bucknall and Paul 2009, 2013; Michler and Balta-Calleja 2012), not only in rubber toughening but also in toughening with rigid particles (Argon 2013). Cavitating or debonding particles facilitate the development of voids and then activation of dilatational yielding in the deformation zone

close to the fracture surface. The primary role of cavitating/debonding particles is to alter the stress state in the surrounding matrix. Such a change enables matrix to yield at moderate stress, even under plane-strain conditions (see Sect. 11.5.4) which initiate an extensive plastic deformation of the matrix (Bucknall 2000). This is possible because generation of microvoids by closely spaced cavitating/debonding particles converts the material in the deformation zone from continuous solid into a porous (cellular) solid, which is generally the most effective way to reduce plastic resistance of the material (Argon and Cohen 2003).

Depending on matrix characteristics and test conditions, its deformation, which has been triggered by the formation of microvoids, can proceed according to several mechanisms, including multiple crazing, shear yielding, or combination of both, or crystal plasticity mechanisms supported by shear of interlamellar amorphous layers, if the material is semicrystalline. It is not completely clear whether cavitation of rubber particles is the necessary precondition for multiple crazing. It seems that the triaxial stress at equatorial regions of rubber particles induced by stress concentrations may be alone sufficient to induce crazes. However, cavitation increases additionally the stress concentration (as the ratio of moduli of cavity and the surrounding, determining the stress concentration, falls to 0) and this must enhance craze initiation. Therefore, cavitation increases the efficiency of toughening by multiple crazing and perhaps allows to obtain the desired effect at lower rubber content. On the other hand, particle cavitation must certainly occur in order to induce the shear yielding of the matrix – prior to cavitation the extrinsic constraints and those imposed on the matrix deformation by well-bonded rubber particles do not allow for dilatation (as rubber is nearly incompressible), which in turn highly restricts deformation by shear, especially when sample is thick or in front of the notch or crack tip. The microvoids developed by cavitation help to alleviate these constraints and convert the stress state within interparticle ligaments from plane-strain towards plane-stress conditions, which corresponds to an increase in the shear component and thereby to reduction of the yield strength. Additionally, as the volume strain is released, the material sensitivity towards crazing is reduced. All of this might facilitate shear yielding in ligaments between particles, much less constrained now.

11.5.2 Criteria of Rubber Particle Cavitation

As discussed in the previous section, cavitation of rubber particles is practically necessary for toughening. In this section, some conditions important for cavitation to occur will be discussed.

The criteria for cavitation in polymers modified with rubbers were modeled by Lazzeri and Bucknall (Bucknall et al. 1994; Lazzeri and Bucknall 1993, 1995). They are based on energy release rate principles similar to those used in fracture mechanics. Void nucleation and expansion in elastomer particles are accompanied by the formation of a new surface, significant stretching of the surrounding layers of elastomer, and the stress relaxation in the adjacent matrix. All of these are driven by

the release of energy stored both in the particle itself and in the surrounding rigid matrix material. The model was simplified and did not account for any additional effects resulting in an energy barrier restricting void formation. The essential condition for void growth is that the volumetric strain energy release rate dU/dr must be greater than the rate at which energy is absorbed in increasing the surface area and stretching the adjacent layers of rubber. Considering the blend as an assembly of small volume elements, each consisting of a spherical elastomer particle of radius R which is surrounded by a rigid elastic shell of the outer radius Q (particle volume fraction is $\Phi_p = R^3/Q^3$), the total energy released upon cavitation can be calculated from the difference of potential energy of that element prior to and after cavitation (Lazzeri and Bucknall 1993). The simplified example in which a rubber particle of radius R is held at a fixed volume strain ε_v and forms a single void of radius r_{vd} can be described with the following equation:

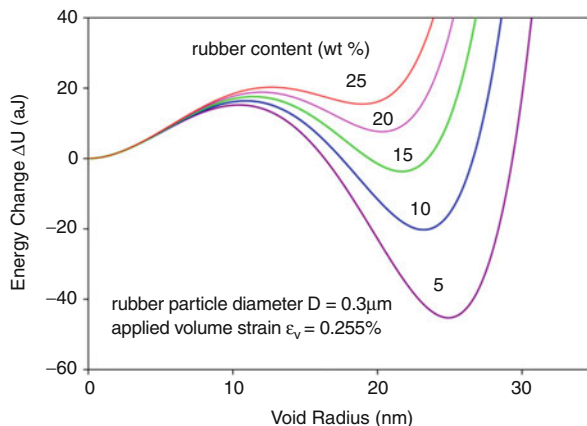
$$U_p(r_{vd}) = \frac{2}{3}\pi R^3 K_R\left(\varepsilon_v - \frac{r_{vd}^3}{R^3}\right)^2 + 4\pi r_{vd}^2 \Gamma_r + 4\pi r_{vd}^3 G_R f(\lambda_f) \qquad (11.14)$$

where $U_p(r_{vd})$ is the potential energy of the rubber particle; r_{vd} is the radius of the cavity in the center of the particle; ε_v is the current volume strain of the particle, including the void; R is the radius of the particle; G_R, K_R are the shear and bulk moduli of the rubber; Γ_r is surface energy of that rubber; and λ_f is the extension ratio of the rubber at fracture in biaxial tension. The function $f(\lambda_f)$, which typically has a value close to 1, represents energy lost in tearing the thin layer of rubber that is very close to the expanding void surface, where $\lambda > \lambda_f \approx 10$.

Calculations based on this model demonstrated that the main parameter controlling cavitation is the size of rubber particles – the critical volume strain at cavitation, $\varepsilon_v(cav)$, increases as the particle size is decreased, principally because the strain energy release rate depends on the size of the local volume element. The model predicts that when the shear modulus of the rubber is small, the relationship between logarithms of critical volume strain at cavitation $\varepsilon_v(cav)$ and the particle diameter D should be approximately linear (Bucknall 1997, 2000), which, in fact, was confirmed by experimental data of PVC blends reported by Dompas et al. (1994a). They demonstrated that a decrease of particle size caused an increase of critical strain to a maximum value $\varepsilon_v(cav) = 0.0128$, where the specimens did not cavitate any longer and yielded before any cavitation happened. The observed dependence of $\log(\varepsilon_v(cav))$ on $\log(D)$ was almost linear and could be fitted with a straight line calculated with Eq. 11.14, although an upward shift in experimental $\varepsilon_v(cav)$ was seen, related most probably to several simplifying assumptions used for model formulation (Bucknall 2000). There are strong indications that similar relationships between D and $\varepsilon_v(cav)$ to the described above, predicted by Eq. 11.14, apply to other polymer blends containing soft rubber particles ($G_R \approx 0.1$ MPa) (Bucknall and Paul 2009). Apart from size, the other important factors which affect cavitation are the surface energy Γ_r (energy needed to create a new surface inside the rubber particle) and the shear modulus of the rubber G_R,
Fig. 11.18 Map of cavitated zone in plane-strain region, showing dependence of zone boundary on the particle diameter when $K_I = 1$ MPa m$^{0.5}$. Critical mean stresses calculated with bulk modulus K = 3GPa and data of Dompas et al. (Dompas and Groeninckx 1994) (From Bucknall and Paul (2009); reproduced with permission of Elsevier)

determining the work done in biaxial extension of the rubber shell upon void expansion. On the other hand, any additional energy barrier restricting formation of cavities, which was not taken into account in model calculations, would additionally increase critical volume strain and corresponding stress.

Figure 11.18 illustrates the effects of particle size on cavitation around a crack tip, calculated by Bucknall and Paul (2009) using Eq. 11.14 with $K_I = 1.0$ MPam$^{1/2}$ and ε_v(cav) from the line fitting the data of Dompas et al. (1994a). For fine particles the cavitated zone is very small, yet with increasing particle diameter, D, this zone expands distinctly outwards from the crack tip. Such behavior helps to explain observations that very small particles are not effective in toughening (Gaymans et al. 1990; Oshinski et al. 1992a, 1996b), which was usually interpreted as a result of an inability of very fine particle to cavitate. The results of calculations of Bucknall and Paul presented in Fig. 11.18 show that the difference in efficiency of toughening by fine and large particles can be explained without making an assumption that very small particles are unable to cavitate. According to these authors, problems arise simply because critical volume strain ε_v(cav) and stress are very high for fine particles, which limits noticeably the size of the cavitated yielded zone, which raises the probability of brittle fracture. In the limit, ε_v(cav) becomes so high that the void-free blend would yield under plane-strain conditions at the very high shear stress, still before reaching the particle cavitation stress. However, as the stress needed for craze nucleation is lower than the stress needed for shear yielding and so reached first, a craze will develop from the notch tip instead of shear zone

Fig. 11.19 Energy curves for a cavitating rubber particle, calculated using Eq. 11.14 in blends with D = 0.3 μm, Γ_r = 35 mJ/m^2, and ε_v = 0.255 %, showing the effect of varying rubber particle concentration at a critical particle size. Energy in aJ (atto-Joule; 1 aJ = 10^{-18} J) (From Bucknall and Paul (2013); reproduced with permission of Elsevier)


and a crack will be initiated before a significant amount of energy has been absorbed in ductile deformation by shear (Bucknall and Paul 2009). For a typical blend (Young's modulus E = 2 GPa and Poisson's ratio of v = 0.4), a stress intensity factor K_{IC} of 1.0 MPam$^{1/2}$ corresponds to a fracture surface energy G_{IC} = 420 J/m^2, which is sufficient to form and rupture a single mature craze. By contrast, increasing D (above about 0.03 μm (Bucknall and Paul 2009)) enables the particles to cavitate before reaching the yield point and consequently reduces the shear yield stress, which at this stage becomes a function of the volume fraction of cavitated particles (see Sect. 11.5.4).

Further calculations made by Bucknall and Paul (2013) illustrate additionally the influence of rubber concentration on cavitation, which is shown in Fig. 11.19. This figure compares curves of calculated energy change upon cavitation for blends containing various weight fractions of rubber particles, all with diameters of D = 0.3 μm. A fixed applied strain ε_v = 0.255 % was chosen for illustrating the sensitivity of the energy balance to the change in rubber content. It is clear in this example that blends containing up to 15 wt.% of rubber can cavitate at the specified applied volume strain but blends with 20 % or 25 wt.% rubber cannot, as there is no net energy fall: $\Delta U = U_p(r_{vd}) - U_p(0) > 0$. For these high rubber concentrations, the volume strain ε_v has to be increased in order to induce cavitation. Taking into account that increasing rubber concentration reduces the yield stress, the volume strain required for cavitation of such particles could be not reached before the yield point. This may indicate that the range of particle size ready to cavitate narrows with increasing rubber content.

Summarizing, the extent of cavitation and hence the level of toughness which can be achieved depend mainly on the particle size, although also partially on rubber concentration and its properties, as, e.g., shear modulus or surface energy, as well as on test conditions (especially temperature and strain rate). Cavitation resistance increases when either the shear modulus or the surface energy of the rubber is increased, similarly to the effect of reduced particle size. Most notably, increasing the shear modulus of the rubber phase due to cross-linking, change of

chemical composition, or simply reduction of the test temperature increases critical volume strain for cavitation $\varepsilon_v(cav)$, which eventually results in a reduction, sometimes dramatic, of fracture resistance of the blend (Gaymans 2000). The same shear modulus term accounts also for the brittle–ductile transition observed in many toughened polymers near T_g of the rubber phase (already discussed in Sect. 11.4.3.1), where G_R changes dramatically.

11.5.3 Shear Yielding

Analysis of the stress field and deformation behavior in front of the tip of sharp notch or crack allows to calculate principal stresses and estimates the size of the plastic zone ahead of the crack tip. Under assumption that the material near the crack tip is an elastic–plastic continuum, the radius of the plastic zone on the crack plane can be expressed, according to Irwin (1964):

$$r_p = \frac{1}{2\pi}\left(\frac{K_I}{m_p\sigma_{1y}}\right)^2 \tag{11.15}$$

where K_I is the stress intensity factor, σ_{1y} is the first principal stress at yield, and m_p is the plastic constraint factor, which reflects the amount of constraint on the developing plastic zone, created by the surrounding elastic material. This increases the stress necessary for the yield to occur above that needed in uniaxial tension, i.e.,

$$m_p = \frac{\sigma_e}{\sigma_y} \tag{11.16}$$

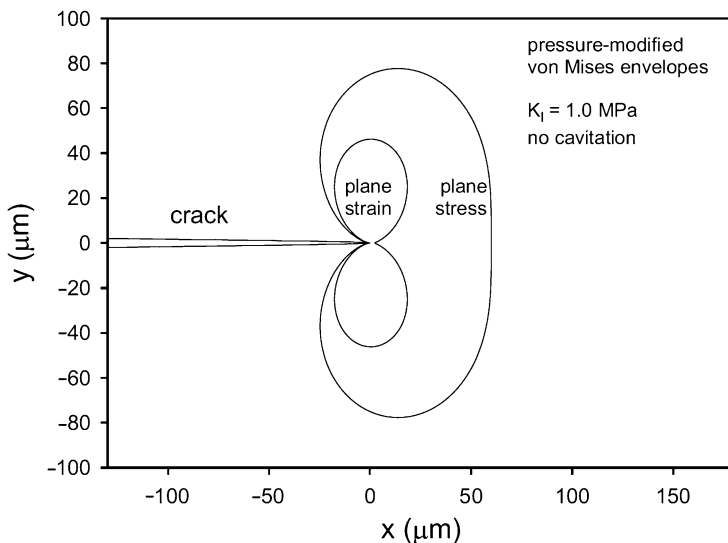
where σ_e and σ_y are the effective yield stress and the yield stress in uniaxial tension, respectively. The value of m_p depends upon the stress state around the crack tip. The value of $m_p = 1$ is for plane-stress conditions ($\sigma_3 = 0$), while according to Irwin and Paris (1971), the increased constraints in plane strain (where $\sigma_3 = v(\sigma_1 + \sigma_2)$ to the first approximation may be represented by assuming $m_p = \sqrt{3}$, which implies that the stress needed to yield in plane strain is higher than in uniaxial tension: σ_e (plane strain)$=\sqrt{3}\ \sigma_y$; thus, the radius of the plastic zone in plane strain is only one third or perhaps even less than that of plane stress. Another approach predicts the relation $m_p = 1/(1 - 2v)$, which for typical rigid polymer with the Poisson's ratio of $v = 0.4$ results in the size of the plastic zone under plane strain smaller than under plane stress by a factor of 25 (Bucknall and Paul 2009). The yield envelopes calculated for 80:20 PA6/rubber blend under the plane-stress and plane-strain conditions using the pressure-dependent von Mises criterion are shown in Fig. 11.20 (Bucknall and Paul 2009). The calculated sizes are probably underestimated because of simplified calculations, which have not allowed for stress redistribution sizes of real plastic zone in similar materials to be about double those shown in Fig. 11.20. Nevertheless, even after necessary adjustments, it appears clearly that the size of the yield


Fig. 11.20 Pressure-dependent von Mises yield envelopes under plane-stress and plane-strain condition of loading, calculated with $K_I = 1.0$ MPa m$^{0.5}$, for void-free 80:20 PA6/rubber blend with Poisson's ratio $v = 0.4$ and pressure coefficient $\mu = 0.36$ (From Bucknall and Paul (2009); reproduced with permission of Elsevier)

zone under plane strain is too small to enable a notched specimen to overcome its susceptibility to brittle fracture (Bucknall and Paul 2009).

Since a blend containing high concentration of cavitated rubber particles becomes cellular solid (porous) rather than continuous material, Eq. 11.15 does not apply to it any longer and any analysis of the plastic zone size must be based on yield criteria appropriate for the porous solid. Free from the constraints of continuum mechanics, the cavitated plastic zones formed in polymer blends are able to increase substantially in radius even under plane-strain conditions (Bucknall and Paul 2009).

The commonly used criterion for shear yielding in cavity-free rigid polymers is a pressure-modified von Mises criterion (Ward 1983):

$$\sigma_e \geq \sigma_{y0} + \mu P = \sigma_{y0} - \mu \sigma_m \qquad (11.17)$$

where σ_e is the effective stress, σ_{y0} is the yield stress in pure shear ($\sigma_m = 0$), μ is the pressure coefficient, P is pressure, and σ_m is the mean stress. The effective stress σ_e is given by

$$\sigma_e = \sqrt{\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}{2}} \qquad (11.18)$$

and the mean stress σ_m is defined as follows:

$$\sigma_m = -P = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3} = K\,\varepsilon_v \tag{11.19}$$

where K is bulk modulus and ε_v is the volume strain. Typical values of K at room temperature are 3.5 GPa for a glassy polymer and 2.0 GPa for a rubber.

The presence of voids increases markedly the pressure sensitivity of the material. Gurson (1977a, b) modified the von Mises criterion to be used for porous solid that contains well-distributed small voids. He applied a continuum treatment to a cavitated ductile material containing a volume fraction Φ_{vd} of voids and obtained the following yield criterion:

$$\sigma_e \geq \sigma_{yt}\sqrt{1 - 2\Phi_{vd}\cosh\left(\frac{3\sigma_m}{2\sigma_{yt}}\right) + \Phi_{vd}^2} \tag{11.20}$$

where σ_{yt} is tensile yield stress of the rigid polymer matrix and Φ_{vd} is the volume fraction of voids. His analysis leads to the conclusion that yielding occurs through the formation of dilatation bands, which allows the original voids to expand as plastic flow proceeds in the intervening ligaments between voids.

By further modification of this approach to account for pressure sensitivity of the initial material, Bucknall and Paul (2009) obtained the following equation for pressure-sensitive material containing small voids, which can be applied to the description of a polymer blend in which all rubber particles have already fully cavitated:

$$\sigma_e \geq (\sigma_{yo} - \mu\sigma_m)\sqrt{1 - 2\Phi_{vd}\cosh\left(\frac{1.5\sigma_m}{\sigma_{yo} - \mu\sigma_m}\right) + \Phi_{vd}^2} \tag{11.21}$$

where $\sigma_{yt} = \sigma_{y0} - \mu\sigma_m$ is tensile yield stress of the rigid polymer matrix (pressure sensitive) and Φ_{vd} is the volume fraction of voids. For pure shear conditions ($\sigma_m = 0$), the above Eq. 11.21 reduces to the simple rule of mixtures:

$$\sigma_e = \sigma_{y0}(\Phi_{vd}) = \sigma_{y0}(0)(1 - \Phi_{vd}) \tag{11.22}$$

It was postulated (Bucknall and Paul 2009) that the same equation can be used also for the approximation of yield in pure shear of rubber-toughened blends, which contain only void-free rubber particles or the combination of cavitated and void-free particles with the total volume fraction of intact and cavitated particles ϕ replacing Φ_{vd} (pure shear):

$$\sigma_e = \sigma_{y0}(0)\,(1 - \phi) \tag{11.23}$$

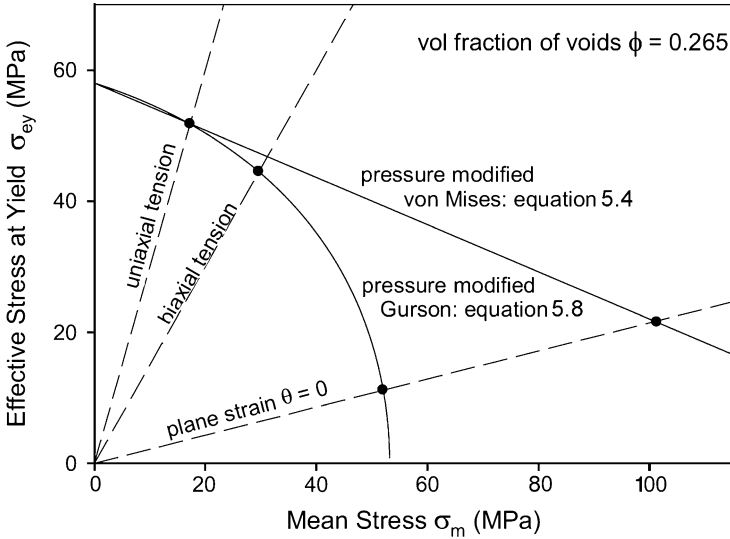
Of course, this equation cannot be considered as a universal relationship, applicable also to other deformation modes. Other dependencies of the yield stress


Fig. 11.21 Comparison between pressure-modified von Mises criterion for a void-free blend (Eq. 11.17 with $\mu = 0.36$) and the pressure-modified Gurson criterion for the same blend, now fully cavitated (Eq. 11.21) (From Bucknall and Paul (2009); reproduced with permission of Elsevier)

on concentration were presented in Sect. 11.4.3.1 (Eqs. 11.11 and 11.12) for uniaxial tension and compression and can be also considered in the context here. Both predict, however, a direct dependence of the yield stress on concentration as the Eq. 11.23 above.

Figure 11.21 illustrates the application of criteria of Eqs. 11.17 and 11.21 to shear yielding at the crack tip in a model blend of rigid polymer with 20 wt.% of soft rubber ($\phi = 0.265$) prior and after cavitation of the rubber particles, respectively. The plot was constructed by Bucknall and Paul (2009) with data of dry PA6 ($\nu = 0.4$, $\mu = 0.265$, $\sigma_{yt} = 70$ MPa) used for the matrix. Tensile stress of PA6 matrix $\sigma_{yt} = 70$ MPa corresponds to yield stress in pure shear of $\sigma_{yo} = 78.4$ MPa. Blending with the soft rubber reduces those to $\sigma_{yt} = 51.5$ MPa and $\sigma_{y0} = 57.6$ MPa, respectively. Under plane strain, the construction line meets the pressure-modified von Mises curve (calculated with Eq. 11.17 at a mean stress of $\sigma_m = 100.4$ MPa where $\sigma_1 = \sigma_2 = 107.6$ MPa and $\sigma_3 = \nu(\sigma_1 + \sigma_2) = 86.0$ MPa) and $\sigma_e = 21.5$ MPa). This shows that pressure sensitivity helps to alleviate the adverse effects of notch tip constraint on shear yielding. The lower curve in Fig. 11.21 calculated for the same blend but with all rubber particles cavitated (Eq. 11.21) demonstrates a significant departure from the curve of non-cavitated blend, but practically only in the plane-strain conditions. This means that differences between voids and well-bonded soft particles become prominent only when the material is subjected to large dilatational stresses as in the presence of triaxial stress (plane strain). The curve calculated for the fully cavitated blend intersects the plane-strain construction line at $\sigma_m = 52.1$ MPa and $\sigma_e = 11.1$ MPa (corresponding to the stress state of

$\sigma_1 = \sigma_2 = 55.8$ MPa, and $\sigma_3 = 44.7$ MPa), i.e., well below the yield stress for the same blend with non-cavitated, continuous rubber particles.

The results presented in Fig. 11.21 are very meaningful as they clarify some of the key issues concerning the contribution of void formation to toughness in polymer blends. It appears that the cavitation is extremely important in notched specimens because it allows the blend to yield under plane-strain conditions at still moderate stresses due to increased sensitivity to the mean stress. It implies that this modification of yielding does not result from eliminating geometrical constraints and converting a state of plane-strain to plane-stress state, as it has been frequently postulated in the past (Bucknall and Paul 2009).

Cavitation enables the plastic zone, including the plane-strain region in front of the notch or crack tip, to react to dilatational stresses by expansion in volume and an increase in radius. To get the maximum toughness, two conditions must be satisfied: a widespread cavitation ahead of the crack tip and extensive involvement of the matrix in plastic deformation. To engage the matrix fully in an energy absorption through deformation, shear yielding should be the dominant mechanism of deformation. The chains must be long enough to prevent premature failure and allow accommodation of high strain. Moreover, in most cases, participation of the rubber phase in the strain-hardening mechanism is also required. To achieve this, the rubber should be strongly bonded to the matrix and to any internal sub-inclusions, when particles have heterogeneous morphology. This implies that the formation of voids through internal cavitation, especially multiple, resulting in formation of fibrils inside particle, is more efficient in toughening than particle debonding, as internal cavitation allows for higher load transfer into particle and hence better stabilization of deformation owing participation of the elastomer phase in strain hardening. The range of cavitation and thereby the level of achieved toughness depends primarily on the particle size and additionally on the degree of cross-linking of the rubber phase, surface energy, and test conditions (temperature and strain rate).

11.5.4 Dilatation Bands

The mechanism for rubber toughening in non-crazing polymers has been explained by Lazzeri and Bucknall (1993, 1995, 2000) who demonstrated that rubber particles can facilitate formation of microvoids and activate dilatation yielding in the deformed zone close to the fracture surface. They concluded that yielding in the blend sample occurs through the formation of dilatation bands, containing cavitated rubber particles, which allows the original voids to expand as plastic flow develops in the band and to relieve the dilatational stress. There is broad evidence that rubber particle cavitation in several different polymers is indeed concentrated within band-like zones of high shear strain (Lazzeri and Bucknall 1995; Sue 1992). Similar cavitated yield zones have been reported in the literature concerning metals, where they have been referred to as "dilatation bands." Such dilatation bands form because when an element of material is restrained in two dimensions, the only

Fig. 11.22 (**a**) Transmission electron micrograph of an 0s0₄-stained ultrathin section from a fractured Charpy specimen of rubber-toughened PA6, showing a dilatation band. (**b**) Sketch showing the location of band in the broken Charpy bar and the strains within the band (From Lazzeri and Bucknall (1995); reproduced with permission of Elsevier)
modes of deformation compatible with the imposed constraints are simple shear parallel to the plane and volume dilatation normal to it. The presence of both results in formation of a dilatation band, as illustrated in Fig. 11.22.

The inclination angle Ψ of the band to the principal tensile axis depends on the sensitivity of the yield stress to the mean stress (pressure) – cf. Eq. 11.17. The following equation was obtained (Lazzeri and Bucknall 1993):

$$\cos 2\Psi = -\frac{2\mu}{3}\frac{(\sigma_o - \mu\sigma_m)}{(\sigma_1 - \sigma_2)} \tag{11.24}$$

where Ψ is the inclination angle of the band, μ = pressure sensitivity coefficient, $\sigma_m = -P$ is the mean stress, and σ_1 and σ_2 are principal stresses in the deformation plane. For anisotropic material not sensitive to pressure, $\mu = 0$, and containing no voids, the angle between the principal tensile axis and the normal to the band is $\Psi = 45°$. For polymers, in which yielding depends on pressure, Ψ is about $38°$. Introduction of voids into the shear bands through cavitation increases significantly the pressure dependence (see the Sect. 11.5.3) and leads to further reduction in Ψ, so that dilatation bands respond to stress by both increasing thickness and

undergoing shear in a plane. The inclination angle eventually falls to zero when the void volume fraction reaches 0.53 (Lazzeri and Bucknall 1993). This rotation of the band plane reduces resistance to crack tip opening; at the crack tip plane, $\Theta = 0^\circ$, yielding occurs entirely in response to tensile stresses applied normal to the bands, which in that respect may resemble crazes. Some examples of craze-like cavitated shear bands have been reported for rubber-toughened epoxy by Sue (1992).

11.5.5 Crazing

Multiple crazing is the basic deformation mechanism of all disperse systems with an amorphous brittle matrix prone to crazing, including rubber-toughened grades of PS, SAN, PMMA, and related glassy polymers. On the other hand, it does not seem to play a significant role in the process of energy absorption in the blends based on ductile glassy polymers (such as PC), semicrystalline polymers, or thermosetting resins. In the above mentioned blends of amorphous brittle polymers, the matrix is a brittle thermoplastic, which tends to form crazes at strains between 0.3 % and 1 % and fractures shortly afterwards. Although macroscopically brittle, these polymers appear ductile on the length scale below 1 μm, within a single craze, and would absorb a considerable amount of energy if this ductility could be extended over a large volume of the material. Multiple crazing, first observed in HIPS, is an extensive crazing in which individual crazes are nucleated by numerous rubber particles dispersed in the matrix. Those rubber particles are also able to terminate crazes. As a result, large number of short crazes is developed in the material, which engages much more of its volume in plastic deformation events, and consequently notably higher energy dissipation is observed.

The soft rubber particles dispersed in glassy matrix act as stress concentrators (see Sect. 11.4.3.1) and like microscopic surface scratches can constitute the sites of effective craze initiation. Bubeck et al. (1991) used real-time X-ray measurements on HIPS to show that crazing of the matrix under tensile impact conditions is actually preceded by cavitation of the rubber particles. Cavities formed within the rubber particles can thus be seen as the real nuclei for the craze growth, which occurs through the meniscus instability mechanism proposed by Argon and Salama (1977). Cavitated particles initiate crazes in the immediate matrix adjacent to their equatorial regions. The crazes propagate then outwards through the matrix perpendicularly to the direction of principal tensile stress until termination by other rubber particle encountered along the propagation path. This produces secondary cavitation within encountered particle and crazing around. At higher rubber concentration (above approximately 15 vol.%), the stress concentration fields of neighboring particles overlap, which results in stress concentrations higher than around isolated particles. In such interparticle zones, broader crazes and craze bands develop roughly perpendicularly to the principal tensile stress and propagate from one particle to the other, cf. Fig. 11.8 in Sect. 11.4.3.

One of the serious difficulties in developing a quantitative description of toughening with elastomer particles is the lack of a suitable criterion for craze initiation.

Several criteria were developed in the past by Sternstein and Ongchin (1969), Oxborough and Bowden (1973), and Argon and Hannoosh (Argon 2011; Argon and Hannoosh 1977) suffer from serious flaws (Bucknall 2007a). Recently Bucknall (2007a, b) demonstrated that the craze initiation can be considered as a frustrated fracture process which actually falls within the scope of linear elastic fracture mechanics (LEFM); therefore, the Griffith equation, modified accordingly, can be regarded as an appropriate criterion for craze initiation. It is evidenced that rubber particles can be effective craze initiation sites, e.g., microscopic surface scratches. In order to act as craze initiators, the elastomer particle must cavitate internally first to form rubber-reinforced spherical holes, in which the rubber provides significant reinforcement, but only when it becomes highly strained. Such a behavior pattern was confirmed experimentally (Bubeck et al. 1991). Using LEFM approach and treating cavitated rubber particles as isolated spherical voids embedded in a homogeneous matrix, the following equation of the critical stress for craze initiation by cavitated particle can be formulated:

$$\sigma_{1craze} = \sqrt{\frac{\pi E G_{\text{craze}}}{2(1 - v^2) D}} \qquad (13.25)$$

where σ_{1craze} is the critical tensile stress for craze initiation, E is the matrix Young's modulus, G_{craze} is the energy absorbed in forming unit area of a new craze, and D is the diameter of the cavitated particle. Typically, in well-prepared tensile specimens of glassy crazable polymer (plain, not modified), the critical stress $\sigma_{1craze} \approx 20$–50 MPa. It can be estimated that G_{craze} is small, between 0.1 and 1 J/m^2.

Equation 11.25 becomes inaccurate with increasing rubber concentration, ϕ, and the average stress in the matrix raising much above the applied tensile stress σ_1. A simple solution might be to apply the rule of mixtures and assume the crazing stress is proportional to $(1 - \phi)$. However, comparison with experimental data demonstrates that this method leads to a substantial overestimation of the yield stress for HIPS blends, where multiple crazing is the dominant mechanism of deformation. Bucknall and Paul (2013) found that much better fitting the data, for both HIPS (Bucknall et al. 1986) and ABS (Ricco et al. 1985), can be obtained by using the effective area model proposed by Ishai and Cohen (1968), who assumed that cracks and shear bands tend to follow paths of minimum resistance through heterogeneous or porous solids and formulated the dependence of stress on rubber concentration (cf. Eq. 11.11 in Sect. 11.4.3.1). Applying this model to materials in which multiple crazing is the dominant mechanism, the critical tensile stress can be obtained:

$$\sigma_{1craze}(\phi) = \left(1 - \pi \left(\frac{3\phi}{4\pi}\right)^{\frac{2}{3}}\right) \sigma_{1craze}(0) = \left(1 - 1.21\phi^{\frac{2}{3}}\right) \sqrt{\frac{\pi E G_{\text{craze}}}{2(1 - v^2) D}} \quad (11.26)$$

where $\sigma_{1craze}(\phi)$ is the stress at which crazes propagate and thicken in a blend containing volume fraction ϕ of rubber particles, and $\sigma_{1craze}(0)$ is the limiting crazing stress at very low rubber contents.
Fig. 11.23 Critical tensile stress for craze initiation as a function of (cavitated) rubber particle diameter, calculated using Eq. 11.26 with three different values of G_{craze}, the specific energy of craze initiation (From Bucknall and Paul (2009); reproduced with permission of Elsevier)

Equations 11.25 and 11.26 predict the proportionality of the critical craze initiation stress on the inverse square root of the particle diameter. It allows to estimate that σ_{1craze} decreases with increasing particle diameter from above 100 MPa to the level of below 20 MPa for large particles, exceeding 1 μm in diameter (typical values of E = 2.8GPa and v = 0.4 assumed for calculation) (Bucknall and Paul 2009); see Fig. 11.23 illustrating strong dependence of the critical stress for craze formation on particle size. That size dependence implies that for particles which are large enough, σ_{craze} must eventually decrease below the shear yield stress of the fully cavitated blend, which becomes independent of D after complete cavitation of particles (cf. Sect. 11.5.3). In this way, crazing can emerge as the dominating mechanism for large particles, in contrast to smaller particles which upon cavitation will initiate preferably the shear yielding in the same matrix. The process begins with primary cavitation of larger particles, which then initiate crazes that propagate outwards. These can induce secondary cavitation and crazing in other particles encountered by a propagating craze. Such a picture is supported by experimental evidence that in many blends tested at impact conditions, crazing is accompanied by dilatational shear yielding and that increasing particle size suppresses shear yielding while promoting crazing as an active mechanism (Bucknall 1977; Bucknall and Paul 2009). The exception is HIPS, which demonstrates almost no signs of ductility under tensile load.

Crazing is a mechanism of plastic deformation that is extremely localized. Even when the number of crazes in the sample is substantially increased, as in the case of multiple crazing in rubber-toughened blends, their early stages of development

engage much less of the matrix volume into plastic deformation than the shear yielding mechanism. Therefore, less energy is usually dissipated in crazing, and toughness improvement may appear below that demanded. Moreover, crazes, if have not been stabilized sufficiently, can quickly degrade to cracks, which inevitably leads to a premature failure. As a result, toughness of the blend which responds to load with crazing is usually lower compared to the blend responding with shear yielding. This explains the appearance of an upper ductile–brittle transition (see section "Rubber Concentration" and Figs. 11.26 and 11.27), observed for some blends, in which toughness falls down as the particle diameter increases. This transition is presumably a result of the change of active deformation mechanism from shear yielding, which is promoted by smaller particles, to crazing which is related to large particles present in the blend.

For effective performance of multiple crazing as the toughening mechanism, the craze growth must be controlled and stabilized. Crazes can be stabilized efficiently by rubber particles, provided these particles can transmit loads and consequently participate in strain hardening of the blend. The particles, especially large ones, tend to cavitate prior to craze initiation and their ability to transmit load depends strongly on their morphology after cavitation. From this point of view, the worst case is when particles are weakly bonded to the matrix and tend to debond from the matrix rather than cavitate internally. Debonding prevents any stress transfer from the matrix into the particles, which then cannot participate in the strain-hardening process and therefore are not able to stabilize craze. As a result, such material with particles debonded usually fractures shortly after craze initiation in nearly brittle fashion. The homogeneous particles, which are well bonded to the matrix, tend to cavitate internally in a single site and form a single void which is surrounded by the continuous rubber shell. Their ability to transfer stress is much higher than debonded particles, but participation in strain hardening is moderate, as the continuous rubber shell does not deform uniformly and eventually fails by progressive tearing with advance of the strain (Bucknall 2000). As a result, cracks can develop relatively early, and toughening effect may be unsatisfactory, especially when particles are large, e.g., few microns in diameter (which is just the optimum size for craze initiation). The most advantageous situation is when the particles are not only bonded well to the matrix but show additionally heterogeneous structure: either contain harder sub-inclusions dispersed inside or have a core–shell morphology. When the internal sub-inclusions or the core is bonded well with the surrounding rubbery phase, then cavitation is frequently followed by a stable fibrillation of the rubber. These fibrils, strongly bonded both to the core or sub-inclusion and to the surrounding matrix matter, can deform uniformly by stretching to high strains, close to the ultimate stretch of the rubber. This enables an effective participation of rubber in strain hardening which greatly helps to stabilize crazes. Consequently, properly formulated and balanced blends made with heterogeneous particles, which are ready to cavitate and form internal fibrils and thereby able to stabilize crazes, show frequently quite large elongations to break, sometimes up to above 50 %, and can even demonstrate a super-tough behavior at impact conditions.

11.5.6 Structure–Property Relationships

Important factors were found to affect the fracture behavior. These can be divided into three main groups related to:

- Matrix material:
  - Molecular weight
  - Entanglement density
  - Ability to crystallization and crystallinity
- Dispersed-phase material:
  - The type of the elastomer
  - Rubber modulus
  - Interfacial bonding
  - Concentration
  - Particle size/interparticle distance
- Sample and test parameters:
  - Sample shape and dimensions
  - Test method (deformation mode, presence of notch)
  - Test speed
  - Test temperature

Below, a short description of these parameters related to the properties of the matrix and the modifier dispersed in the matrix is presented. Sample and test parameters will be not addressed here.

11.5.6.1 Matrix Properties

Toughening of the polymer blend depends on the deformation mechanisms that dominate mechanical response of the host polymer (matrix), where most of energy is dissipated during deformation and fracture. These mechanisms are determined generally by the chemical structure of that polymer, including the repeat unit, chain architecture, molecular weight, and its distribution. Apart from crystal plasticity governing deformation of polymer crystals, the main deformation processes in polymers are shearing and crazing. Each of these mechanisms allows for different level of toughening, also because the starting level, i.e., the toughness of the pristine host polymer, is very different for brittle crazable polymers and quasi-ductile polymers which tend to deform by shear yielding. The selection of the active deformation mechanisms depends principally on details of the matrix chemistry (Bucknall 1977). As already discussed in Sect. 11.2, if the chains of the matrix polymer demonstrate low entanglement density and are stiff under the test conditions, like in PS, then crazing is promoted in tensile loading. On the other hand, if the chains are much more flexible and demonstrate higher entanglement density, then the shear deformation initiated by shear yielding is the dominant mechanism, as, e.g., in PC or PVC deformed at room temperature. These polymers exhibit secondary relaxation processes below their glass transition temperature. These relaxation transitions indicate some limited segmental mobility of the chain backbone which become allowed at temperature range between the lower, secondary relaxation and the glass transition temperature. These localized main-chain motions

facilitate parts of the macromolecules to slide past each other and initiate shear deformation when material is loaded. As a consequence, these polymers can exhibit ductile behavior already below their glass transition temperature. Temperature of the secondary relaxation determines then the brittle–ductile transition temperature (Kausch 1987). On the other hand, some of stiff glassy polymers like PS or SAN lack this type of secondary relaxation process below their T_g and consequently are not able to shear at the desired scale and deform at room temperature preferentially by crazing, instead. If this energy dissipating craze mechanism is not stabilized properly, e.g., by dispersed rubber particles, it leads shortly to crack formation and brittle fracture. PMMA, with a mobility of the side groups beginning near room temperature and also mobility of parts of the main chain slightly above room temperature (as indicated by the secondary relaxation process at 50°C), appears at room temperature to be in the intermediate range and can deform by shear yielding, by crazing, or by both mechanisms simultaneously, depending on particulate test conditions. Generally, crazing seems to dominate in tension at low temperatures and/or at high deformation rates, when the molecules have very limited time to rearrange under the stress, and also at conditions of triaxial tensile stress. In contrast to these situations resulting in brittleness, when enough time is given for possible chain rearrangement (e.g., at higher temperature, above the secondary relaxation temperature, and/or at low deformation rates), the polymer tends to yield in shear.

The details of the matrix chemistry determine not only the stiffness of the chain but also the tendency to form entanglements. Again, as discussed in Sect. 11.2, the density of chain entanglements, generally related to chain stiffness (cf. Eq. 11.4), influences markedly the choice of the deformation mechanism: low entanglement density promotes crazing, while polymers exhibiting high entanglement density tend to deform by shear yielding. Both the chain stiffness and entanglement density are intrinsic properties of the chains and therefore are difficult to modify by physical methods without interfering chain chemistry. The entanglement density can be increased, and thus vulnerability to crazing reduced, practically only by blending a polymer with another polymer, which is fully miscible with it and demonstrates higher flexibility. That blending leads to the formation of the uniform network consisting of stiff and flexible chains, and characterized by increased overall entanglement density. Such modification is possible for only a few polymer pairs that demonstrate complete miscibility, as, e.g., PS and PPO (cf. Fig. 11.1).

Polymers that deform preferentially by crazing demonstrate usually low fracture toughness. This toughness can be enhanced quite substantially by a suitable modification, e.g., by adding an elastomer, but the resulting toughness of the modified material, although much increased compared to the pristine polymer, can be still lower than the toughness of many quasi-ductile polymers that tend to deform by shear yielding rather than crazing. These quasi-ductile polymers, in general, demonstrate significantly higher initial toughness than brittle, crazable polymers and usually are also much more receptive for toughening. As a result, super-tough materials can be formulated on the basis of those polymers easier than using crazable polymers. Generally speaking, when a broad range of thermoplastic matrix

Fig. 11.24 Brittle-to-ductile transition temperature as a function of matrix molecular weight, 30 wt.% PP-CaCO$_3$ composites (From Zuiderduin et al. (2003); reproduced with permission of Elsevier)
polymers are examined, the observation is that the toughest rubber-modified materials will be those which possess the toughest matrices (Bucknall 1977).

Besides the stiffness of the chain and entanglement density, the molecular weight appears also an important factor (Kausch 1991) as it influences the properties of the molecular network, important for an initiation and development of both crazing and shear yielding. Moreover, polymers of high molecular weight demonstrate usually an increased fracture stress relative to the yield stress and the brittle-to-ductile transition shifted to a lower temperature. This relationship can be illustrated by an example of semicrystalline polypropylene (here modified with rigid particles) shown in Fig. 11.24. It can be observed there that an increasing molecular weight, depicted by decreasing melt flow index (MFI), results in the shift of the brittle–ductile transition towards lower temperature (Zuiderduin et al. 2003). Similar dependence of T_{BD} on molecular weight was observed also in various blends with elastomers (Dijkstra and Gaymans 1994b; Oshinski et al. 1996a, b, d; van Der Wal et al. 1998).

The chemical structure of the polymer, including the structure of the repeat unit, chain architecture, and molecular weight determine also the ability of the polymer to crystallization. The presence of crystalline phase influences deeply the toughness of the polymer as well as deformation mechanisms governing it, as the polymer crystals are allowed to absorb energy upon their deformation according to typical mechanisms of crystal plasticity. Moreover, they can facilitate additional relaxation modes of the amorphous phase which can simplify shear yielding of the amorphous component. The crystalline regions in semicrystalline polymers constitute the physical cross-links that stabilize and hold material together, particularly above its glass transition temperature. Above T_g, the modulus and the yield strength increase with increasing crystallinity of the matrix (Ward 1983). Below T_g, the effect of crystallinity on the modulus and yield strength is much smaller as the number of crystalline cross-links is small compared to the number of frozen (immobilized) entanglements, which act now similarly to permanent cross-links. Increasing crystallinity has a strong negative effect on the brittle-to-ductile transition, causing an increase of T_{BD} (van Der Wal et al. 1998).

The yield stress in a semicrystalline polymer increases with increasing crystallinity as well as with increasing lamellar thickness, which, in turn, is controlled by the temperature at which crystallization had occurred (Kazmierczak et al. 2005; Sirotkin and Brooks 2001; Ward 1983). Moreover, crystallization leads frequently to an increase of the entanglement density in the amorphous phase, as most of the entanglements were not resolved by crystallization but merely swept into amorphous interlamellar regions (Strobl 1997), especially when the molecular weight of polymer is high. For obtaining high toughness, the crystallinity level must be carefully balanced, since too high crystallinity can constrain excessively deformation of the amorphous component, which would manifest in an increase of T_{BD} and eventually lead to material embrittlement. On the other hand, the balance of all properties is of practical interest. Usually, it is demanded to have high ductility combined with a possibly high modulus and high yield strength. A highly crystalline polymer, demonstrating relative high modulus but being more brittle than its low crystallinity counterpart, can be successfully modified to obtain material that exhibits low temperature ductility by adding more rubber. In practice, the best balance of properties is obtained just with highly crystalline grades. As blending with a second polymer can in some cases modify significantly crystallization kinetic of the matrix as well as the resultant lamellar thickness and degree of crystallinity (Bartczak et al. 1995), this factor must be also taken into account when selecting the type and grade of the rubber to be used for toughening of a particular polymer. Also the processing conditions, especially the cooling rate, must be controlled to prevent an excessively high crystallinity. However, these effects are minor as compared to others, as, e.g., those related to the rubber content or its average particle size.

11.5.6.2 Dispersed-Phase Parameters
The Type of Elastomers
The function of the dispersed-phase material that in most instances is an elastomer is to induce an adequate toughening mechanism in order to shift the T_{BD} temperature down and increase notably the toughness of the material above T_{BD}. Therefore, it is expected that the choice of the elastomer type is important. It appears that the type of rubber may have a little influence on the notched Izod impact strength in the tough region, but give a strong effect on the temperature of brittle-to-ductile transition, T_{BD}, as it was observed by Borggreve et al. (1989b) in PA6 blended with various elastomers (Fig. 11.25).

A good correlation between T_{BD} and the modulus of an elastomer was found by Gaymans et al. (1990) in PA6 modified with olefinic rubbers: T_{BD} decreases steadily with rubber modulus (all at constant rubber concentration and average particle size). The volume strain experiments (Borggreve et al. 1989a; Bucknall et al. 1989) demonstrated that the blends with the highest impact resistance cavitated most easily. The correlation of T_{BD} and modulus is possibly due to both the cavitational stress and the tensile modulus being related to the cohesive energy density of the elastomer.

The type and grade of elastomer, through its chemical composition, molecular weight, and viscosity, determine miscibility with the matrix, the state of dispersion,

Fig. 11.25 Temperature of brittle–tough transition as a function of the weight-average particle size for blends of PA6 and 10 wt.% rubber, with different types of rubbers: ■, EPDM; +, EPR; ×, LDPE; ▲, Keltaflex®; ●, polyester TPE (From Borggreve et al. (1989b); reproduced with permission of Elsevier)
and the interfacial strength between rubber particles and the matrix, which in turn influence profoundly the impact behavior of the blend. The toughening effect is additionally dependent on the glass transition temperature of the rubber, as below T_g the cavitation stress increases drastically, so that rubber particles do not cavitate and consequently are not able to activate any toughening mechanism.

There are a great variety of elastomers applied to improve toughness of engineering polymers, including polyisoprene, butadiene elastomers (e.g., polybutadiene, styrene–butadiene, or butadiene–acrylonitrile copolymers), olefinic elastomers (e.g., ethylene–propylene, ethylene–octene-1 copolymers), styrene-butadiene-styrene (SBS), or styrene–ethylene–butene-1–styrene (SEBS) block copolymers, ionomers, polyurethanes, and many others, also functionalized with various groups, like maleic anhydride (MA) or glycidyl methacrylate (GMA), used for reactive extrusion. Elastomers used as toughness modifiers for various engineering polymers were reviewed, e.g., by Kesskula and Paul (1994). As an example, in Table 11.2 a survey of elastomers and compatibilization techniques tested for polyamides is presented (Akkapeddi 2001). Due to the polar nature of polyamides and apolar nature of elastomers, obtaining a very small rubber particles (0.2–0.4 μm in diameter) and their good dispersion, necessary for toughening of polyamides, is not easy and usually requires an adequate compatibilization, mainly through a reactive blending process, in order to produce blends containing appropriate small rubber particles.

Rubber Modulus

Because of very low stiffness, the rubber dispersed in the rigid matrix causes a decrease of the modulus and the yield strength of the blend. An extent of reduction depends, however, on the concentration of the rubber, rather than on its type or elastic properties (provided rubber is not highly cross-linked), since modulus of practically all elastomers above their glass transition is very much lower than modulus of the rigid matrix.

Table 11.2 Some common reactive rubbers and tougheners for polyamides (From Akkapeddi 2001)

Reactive rubber/toughener	Functionality	Reactivity	Other features
Maleic anhydride grafted ("maleated"), ethylene–propylene rubber (m-EPR)	Anhydride 0.3–0.9 % MA	High reactivity with the amine (NH_2) end group of PA	Amorphous rubber, low T_g leads to high-impact toughness down to –40 °C
Maleated, styrene–ethylene/butylene–styrene block copolymer rubber (m-SEBS)	Anhydride 0.5–2 % MA	High reactivity with the amine (NH_2) end group of PA	Amorphous rubber, low T_g leads to high-impact toughness down to –40 °C
Ethylene–ethyl acrylate–maleic anhydride (E-EA-MA) terpolymer	Anhydride 0.3–3 % MA	High reactivity with the amine (NH_2) end group of PA	Moderate T_g limits low-temperature toughness
Zinc neutralized, ethylene–methacrylic acid copolymer ionomer (E-MAA, Zn)	Zinc carboxylate, carboxylic acid	Low reactivity with amine but good polar interaction of Zn with amide and amine groups (interfacial complexation)	T_g and hardness limit low-temperature toughness; good solvent resistance
Zinc neutralized, ethylene–butyl acrylate–methacrylic acid terpolymer ionomer (E-BA-MAA, Zn)	Zinc carboxylate, carboxylic acid	Same as above	Low T_g and high-impact modification efficiency
Ethylene–glycidyl methacrylate copolymer (E-GMA)	Epoxide 3–8 % GMA	Moderate high reactivity with carboxyl group of PA	T_g and hardness limit achievable toughness; cross-linking tendency
Ethylene–ethyl acrylate–glycidyl methacrylate terpolymer (E-EA-GMA)	Epoxide 1–8 % GMA	Moderate high reactivity with carboxyl group of PA	Lower T_g, better impact; high viscosity
Acrylate core–shell rubber, functionalized	Carboxyl	Low reactivity with amine	Small rubber particle (<0.5 μm) aggregation
Ethylene–acrylic acid copolymers (E-AA)	Carboxyl	Low reactivity with amine	Not rubbery enough; modest impacts
Ethylene–ethyl acrylate or butyl acrylate copolymers (E-EA or E-BA)	Ester	No reactivity with amine	No impact improvement. Used only as codiluent

The stiffness of the rubber relative to the matrix determines the intensity of stress concentrations around rubber particles upon sample loading prior to their cavitation, as discussed in Sect. 11.4.3.1. The stress concentrations at the particle surface reach values very close to 2 already when G_R/G_M goes below 0.1 and are only slightly higher when G_R/G_M decreases below 0.01. That ratio of the moduli $G_R/G_M < 0.1$ facilitating high level of stress concentrations is easily reached for most of the rubber–matrix pairs at temperatures above T_g of the rubber. The situation changes when temperature decreases below T_g: the stress concentrations

diminish and additionally the stress required to induce cavitation in a glassy now particles increases dramatically, which practically inhibits any internal cavitation of particles and leads to the termination of the rubber toughening effect. Under impact loading conditions, the modulus is increased additionally due to high deformation rate and, therefore, the ductile-to-brittle transition is shifted to the "impact brittle point," which is about $10^{\circ}C$ above T_g (Bergen 1968). The impact strength can decrease then even below the level of unmodified material (see Sect. 11.4.3.1).

The modulus of the rubber can be increased notably also by cross-linking, either intentional or induced by material aging. It has long been known that some cross-linking is necessary to preserve the structure of the particles and avoid their coalescence at further stages of material processing (compression molding, injection molding, etc.). Bucknall (1977) reasoned that light cross-linking of the rubber, which does not increase significantly its modulus, is desirable also for other reasons: as during impact loading the rubber cavitates and then undergoes high strains, the light cross-linking would allow the rubber to reach high strains by fibrillation rather than of expansion of the shell around a single void in the center of the particle, and the fibrils would then participate more effectively in stabilization of the matrix deformation by strain hardening and help to avoid a premature fracture. On the other hand, excessive cross-linking impairs fracture resistance, notably by reducing notched impact strength. High levels of cross-linking shift T_g of the rubber highly upwards. Moreover, it results in a dense molecular network leading to a significant increase of the cavitation stress and serious reduction of the ultimate stretch. Therefore, a decrease of toughness of the blend with increasing cross-link density of the rubber can be expected: a heavy cross-linking should suppress substantially cavitation of rubber particles, and as a consequence, the impact strength would decrease either. Experimental results for PA6/SBS blends with different degree of rubber cross-linking, obtained by Suo et al. (1993), supported this view. The same, sometimes even dramatic, decrease of the impact strength can be a result of an excessive cross-linking which has occurred unwanted on improper processing or when material was exposed to prolonged sunshine during its outdoor use. It is known that HIPS and ABS can embrittle seriously if they have been processed too long or at too high temperatures, which leads to excessive thermal cross-linking of the rubbery phase. Embrittlement was also observed if the rubbery phase in the particles were intentionally cross-linked, either chemically or by radiation (Steenbrink et al. 1998; Suo et al. 1993). Similarly, these and other rubber-modified materials are known to turn brittle after long exposure to UV light or sunshine.

Structure of the Rubber Particles

Internal structure of the rubber particles is very important from the point of view of both initiation and stabilization of the matrix deformation. Generally, three types of rubber particles are used for toughening. In HIPS and solution ABS, salami particles obtained during polymerization process are preferred. These particles contain much occluded matrix so that the particles are sufficiently large for initiating crazing, while the rubber content is relatively low, which limits the

decrease of Young's modulus. The crazes are initiated near the equatorial region of the rubber particles, perpendicular to the tensile stress direction, as shown in Fig. 11.8. In this region, the normal stress component of the stress tensor is the highest.

Core–shell particles are used frequently with transparent polymer matrices. In this type of particle, the core is very often formed from a material similar or identical to the matrix and is covered with a relatively thin rubbery shell, which is grafted with an outer second shell of the polymer identical to the matrix. If the thickness of the rubber shell is small compared to the wavelength of light, then light scattering is reduced, and the final blend maintains some transparency (Heckmann et al. 2005). Due to the rigid core and relative low amount of the rubber, such multilayer particles with rigid core facilitate also a fairly good balance between toughness and stiffness of the toughened material. Core–shell particles are obtained by emulsion polymerization and their size as well as size distribution can be controlled precisely in a certain range, so that particles of the optimum size can be prepared for a particular blend. The only problem, rather minor, during compounding of such particles with the matrix polymer is in obtaining a good dispersion and avoiding agglomerates in the final blend. The other very important benefit of core–shell particles is that the cavitation of such particles proceeds usually via nucleation of many small nanovoids in the rubber intermediate shell (Michler and Bucknall 2001). With subsequent expansion of these voids, a fibrillar morphology develops easily within the rubber shell with many elongated fibrils very well bonded to a rigid core and the outer shell (cf. Fig. 11.12). Stress and strain are distributed uniformly in these fibrils, which prevents their premature fracture, stabilizes cavities, and allows for effective stress transfer across the rubber shell and eventually leads to a significant contribution of particles in strain hardening and stabilization of material extensive deformation. Consequently, a high impact strength can be reached (see Sect. 11.4.4).

The last group of rubber particles constitutes particles obtained by dispersion of an elastomer in the matrix by blending of molten polymers in the extruder. The size of particles and the state of dispersion depend on rheological properties of both constituents of the blend as well as parameters of the mixing process. Frequently, to obtain a blend with rubber particles of desired size and satisfactory dispersion, reactive rubbers or other components (e.g., compatibilizers) must be added to the blend. If the elastomer used was thermoplastic, then the small crystallites formed inside particles on cooling constitute heterogeneities that can act as nucleation sites for multiple nanovoids within particles. Such a multiple cavitation is followed by formation of fibrils rather than a single rubber shell, which fibrils then can participate effectively in strain hardening and stabilization of the deformation process. Rubber fibrillization on cavitation usually fosters enhanced impact strength. The same effect of fibrillization can be obtained also by using block copolymers in which small sub-inclusions can be formed inside the particles. Grafting particles to the matrix by using functionalized rubbers in the reactive extrusion process or using adequate compatibilizers can control the size and interfacial strength of the rubber particles.

Interfacial Effects

A low interfacial energy between components of the blend is essential for obtaining a fine elastomer particle dispersion, which in turn is necessary for effective toughening. This condition is relevant not only for dispersing of bulk rubber by melt blending but also for dispersing aggregated core–shell particles or rigid particles during compounding. A low interfacial tension can be obtained either by careful selection of a rubber suitable for modification of a given rigid polymer or through a grafting reaction at the interface or by adding selected third polymeric component as compatibilizer. Grafting at the interface or using compatibilizers reduces interfacial tension while increases the adhesion (interfacial strength) between elastomer particles and the matrix.

Wu (1985) studied the PA-EPR rubber blends with different levels of adhesion between components, prepared by reactive melt extrusion. He found that the minimum interfacial strength needed for toughening was around 10^3 J/m^2, which is about the tearing stress of a rubber. This level of an interfacial strength can be obtained already by van der Waals bonding (Gaymans 2000). When interfacial strength becomes higher, due to, e.g., compatibilization or grafting at interface, the rubber particles in the blend tend to fail by internal cavitation. Lower interfacial strength (weaker bonding) is usually not desirable since particle debonding at interfaces rather than internal cavitation can take place. Debonding is less favorable than cavitation since there is no stress transfer from the matrix to the debonded particles so that these particles practically do not deform and hence do not participate in the strain hardening as the deformation of the matrix in the plastic zone advances. Voids created by debonding, not stabilized by stretching rubber, may become quickly crack initiators that would lead to premature fracture resulting in relative low impact strength.

Borggreve and Gaymans (1989) studied the PA-EPR blends, in which the amount of maleic anhydride grafted on the rubber, used to bond rubber and the matrix, varied in the range of 0.1–0.7 wt.%. These blends had different particle size for a given PA/rubber composition but exhibited identical relationship between T_{BD} and average particle size. Thus, the interfacial strength, seriously modified by chemical bonding of the rubber and PA chains through MA groups, appeared to control the dispersion process and the final size of the rubber particles, but did not influence the impact behavior at the constant particle size, because in all blends studied, toughening was related to the same mechanism of particle cavitation initiating extensive shear deformation of the matrix. These results demonstrate the actual role of grafting and use of compatibilizers – their primary function is to reduce the average particle size to the desired level effective for toughening, and not to increase interfacial adhesion between particles and the matrix. The process of reactive compounding, during which rubber particles are formed by shear forces and grafted to the matrix, appears relatively simple and effective method of preparation of tough blends with controlled particle sizes.

The modification of the interfacial tension influences the particle size obtained in the blend, but does not influence yield stress and modulus, which both depend on rubber concentration rather than on particle size (Borggreve et al. 1987).

Rubber Concentration

Rubber concentration in the blend is a very important factor in deformation and fracture of all rubber-toughened polymer blends. The impact strength of ductile polymers was found to increase as a function of rubber content (Gaymans 1994; Harrats and Groeninckx 2005). The brittle–ductile transition, which is a crucial parameter in toughened polymers, shifts towards lower temperature as the rubber content is increased (Argon et al. 2000; Bucknall 1977; Michler and Balta-Calleja 2012). Unfortunately, this comes at a price of an inevitable reduction of the material stiffness (lowered modulus) and the yield strength. When the material is loaded, the particles of soft compliant rubber transfer the load to the stiffer matrix, thence set up stress concentrations and reduce in this way the modulus and the yield stress, as already discussed in Sect. 11.4.3.1. The reduction of the modulus or yield strength can be described with the simple theoretical "effective area" model of Ishai and Cohen (Ishai and Cohen 1968) (cf. Eq. 11.11) or with the empirical dependence found by Gloagen et al. (1993) for rubber-toughened PMMA:

$$\sigma_y(\phi) = (1 - 1.375\phi)\,\sigma_y(0) \qquad (11.27)$$

Both relationships show a dependence of the yield strength solely on the rubber volume concentration. The same holds for the modulus. It can be concluded then that in order to get an acceptable balance between toughness and stiffness of the modified material, the rubber content cannot be too high. The other reason for reducing the rubber content in the blend is related to the problems which may arise with appropriate rubber dispersion and particle size. When a bulk elastomer is dispersed in the matrix by high shear forces upon the melt compounding, a low rubber concentration is advantageous from the point of view of particle size and size distribution. Concentrations higher than 25–30 vol.% usually result in coalescence of inclusions already formed and consequently in an increase of the final average particle size and broad distribution of particle size, which in most cases appears negative for toughening. Similarly, when the ready particles of the core–shell type are used, their high concentration can bring on serious problems related to their dispersion, and particle agglomerates can survive the compounding process, which is also detrimental for toughening. Therefore, in most of the commercial formulations, the rubber concentration is kept usually rather low, in the range from 5 % to 20 % of the elastomer phase. Working within this concentration range usually allows to obtain a blend with sufficiently small rubber particles that are dispersed well enough in the matrix, which results in a tough material, while the unavoidable deterioration of its stiffness and yield strength is still at an acceptable level.

Particle Size and Interparticle Distance

It has been already well established that the impact resistance of rubber-toughened blends depends strongly not only on a concentration but also on size and size distribution of the rubber particles (Bucknall 1977). Generally, small particles (average diameter in the range 0.2–0.4 μm) are the most efficient in toughening

Fig. 11.26 Impact strength of PA-6/EPR blends as a function of particle size (26 vol.% of EPR rubber; notched Izod impact test at 20 °C): the different symbols refer to different manufacturing methods (From Gaymans (1994); reproduced with permission of Springer)
of these polymers for which shear yielding is the dominating mechanism of deformation and energy absorption. Significantly larger particles (D = 2–3 μm) appear, in turn, more effective when multiple crazing is the main mechanism of deformation.

It is now commonly recognized that the rubber particles play two major roles in the toughening of polymers: they generate a local stress concentrations (Bucknall 1977, 2000; Kausch 1983; Kausch 1987, 1990; Kinloch and Young 1983), and secondly, they modify the yield conditions for the matrix by altering significantly the stress state around cavitated particles and by increasing sensitivity of the yield to the mean stress, through transformation of the once continuous solid material into the porous (cellular) due to either particle cavitation or debonding (Bucknall and Paul 2009, 2013). The particles themselves should not initiate any fracture process; therefore, they should be sufficiently small to avoid excessive growth of voids up to the size of the critical flaw that can already cause crack initiation. On the other hand, in order to promote a necessary cavitation, they cannot be too small either (Bucknall 2000, 2007b; Bucknall and Paul 2009; Dompas and Groeninckx 1994; Lazzeri and Bucknall 1993). Numerous studies confirmed that for a given blend composition, optimum (high) toughness can be obtained only in certain, limited range of particle size. This size window was frequently found to be quite narrow. This feature can be illustrated by the results obtained for PA6/EPR blends of the constant overall compositions (26 vol.% of the rubber), in which the average particle size of the rubber was adjusted by variation in processing method or conditions, reported by Gaymans, Borggreve, and coworkers (Borggreve and Gaymans 1989; Borggreve et al. 1987, 1988, 1989a, b; Gaymans 2000; Gaymans et al. 1990) and presented in Fig. 11.26. They included in their study the blends with
Fig. 11.27 Relationship between particle size and impact behavior for a typical "super-tough" thermoplastic blend. Points *b* and *d* mark *lower* (●) and *upper* (o) ductile–brittle transitions. Schematic representation based broadly on data of Huang et al. (2006a) for a series of 80/20 rubber-toughened PA6 blends (From Bucknall and Paul (2009); reproduced with permission of Elsevier)

large, medium, but also very small particles and performed impact tests at various temperatures. The obtained results demonstrated that these PA6/EPR blends exhibited both a lower and an upper ductile–brittle (DB) transition with respect to the particle size and that the upper critical particle size appeared temperature dependent, varying continuously from 0.5 μm at T = −10 °C to 1.5 μm at T = 50 °C as found in blends containing 20 wt.% (26 vol.%) of grafted EPDM rubber. Further extensive work has confirmed the existence of a minimum particle size for effective toughening in other semicrystalline as well as amorphous blends containing a variety of different elastomers (Dompas and Groenickx 1994; Dompas et al. 1994a, b; Huang et al. 2006a, b; Majumdar et al. 1994d; Okada et al. 2000; Oshinski et al. 1996c). There is now a substantial collection of papers which evidenced the effects of particle size on impact behavior in a wide range of polyamide (Borggreve and Gaymans 1989; Borggreve et al. 1987, 1989a, b; Gaymans 1994, 2000; Gaymans et al. 1990; Hobbs et al. 1983; Majumdar et al. 1994a, b, c, d, e; Oshinski et al. 1992a, b, 1996c; Takeda and Paul 1992; Wu 1983, 1985), polyesters (Gaymans 2000; Hage et al. 1997, 1999a, b, c, d, e), and polypropylene blends (Jang et al. 1984, 1985; Jiang et al. 2000, 2004a, b; Liang and Li 2000).

On the basis of numerous experimental data, Bucknall and Paul (2009) have proposed a model general curve illustrating the dependence of impact strength on average particle size. That curve, shown in Fig. 11.27, was drawn to follow the

results obtained for a representative "super-tough" rubber-toughened PA6 blend (Huang et al. 2006a). Similar curves can be obtained with appropriate scaling for other rubber-toughened blends as well. As illustrated in Fig. 11.27, moving beyond the preferred size range (around the optimum marked by **c**) in either direction results in a ductile–brittle transition, where **b** and **d**, respectively, mark the lower and upper transitions. These points define lower and upper critical particle sizes.

In his pioneering work, Wu (1985) studied PA6,6 blends with 10–25 % of grafted polyolefin rubber and average particle sizes varying from 0.3 to 3.0 μm. He observed in these blends a ductile-to-brittle transition similar to that shown in section **c–e** of Fig. 11.27, as expected. He also found the critical average particle size D_{crit} increasing systematically with rubber content (see Fig. 11.28a), which seems against the prediction of the model curve in Fig. 11.27, which shows also a lower critical particle size while does not predict any dependence on the rubber concentration. This behavior is probably because only blends with particles larger than 0.3 μm were studied, i.e., still above the expected lower DB transition. The intriguing observation was, however, that when plotting impact strength against the calculated average interparticle distance ID, a single critical value, ID_{crit} was found. This critical interparticle distance was independent on rubber concentration and appeared to control exclusively the upper ductile–brittle transition, cf. Fig. 11.28b. On this basis, Wu concluded that the average particle size is not the primary parameter controlling the impact resistance. He proposed then to use the interparticle distance ID instead, which, in his opinion, is the principal parameter. The interparticle distance ID, which was defined as the distance between surfaces of two adjacent rubber particles, referred later to as the matrix ligament thickness is, according to Wu, the crucial morphological parameter which governs the toughening efficiency in rubber-modified blends.

Making two simplifying assumptions that all particles have the same diameter D and are packed in a regular array, Wu derived the following expression for ID (Wu 1992):

$$ID = D\left[k\left(\frac{\pi}{6\phi}\right)^{\frac{1}{3}} - 1\right] \tag{11.28}$$

where D is the particle diameter and k is a parameter dependent on lattice packing arrangement, with $k = 1$ for simple cubic lattice and $k = 1.12$ for face-centered cubic (fcc) or hexagonal closed packing (hcp). Margolina and Wu have introduced the term "matrix ligament thickness" to describe ID, in order to shift the focus from the rubber particles to the matrix material (Margolina and Wu 1988). To explain the dependence of BD transition on ligament thickness, they use the percolation concept (Margolina and Wu 1988; Wu 1992). If the particles cavitating internally are close enough, then the zones of yielded matrix around both particles come into contact, so that the thin matrix ligaments between particles become fully yielded across. For small ID, these ligaments become interconnected, and the yielding process percolates across the specimen, stimulating its ductile
Fig. 11.28 (**a**) Notched Izod impact strength versus rubber particle diameter in PA 6,6/reactive rubber blends (curve A, 10 wt.% rubber; curve B, 15 wt.%; curve C, 20 wt.% rubber). (**b**) The same Izod impact strength data plotted versus interparticle distance (From Wu (1985); reproduced with permission of Elsevier)

deformation behavior. This occurs when the thickness of the matrix ligaments falls below the critical thickness. Such a state can be achieved for a given rubber volume fraction by decreasing the particle size and enhancing their dispersion. These ideas have been elaborated over the years by other researchers (Jiang et al. 2000, 2004a, 2008; Liu et al. 1998a, b, 1999; Sjoerdsma 1989).

To explain the observed effect of the interparticle distance, Wu proposed first that a strong overlap of the stress fields around particles induces shear yielding in PA6,6 matrix, turning the blend ductile. Later, however, Wu recognized

Fig. 11.29 TEM micrograph of PA6 modified with EPDM-g-MA. The sample was negatively stained with phosphotungstic acid. The *dark lines* are the amorphous regions and the *white lines* are the lamellae. The rubber particles are not stained and appear white. The scale bars represents 100 nm (From Muratoglu et al. (1995d); reproduced with permission of Elsevier)
deficiencies of this model, since the local stress level depends on the ratio of the center-to-center distance ($L = D + ID$) to the diameter of the particle, L/D (Wu 1988). This ratio scales to volume fraction of particles and remains constant at a given volume fraction regardless of particle size, so that according to the stress field overlap model, toughening should be unaffected by the presence of large particles at any given L/D ratio. This, however, does not agree with the experimental results which demonstrate that small particles are certainly more effective in toughening than large ones (Borggreve et al. 1987; Bucknall and Paul 2009). A second proposed model was based on the transformation of the matrix material from a state of plane-strain to plane-stress when the volume fraction of cavitating rubber particles increases and the interparticle distance reduces below the critical size. This approach also fails because it attributes the embrittlement directly to the presence of high triaxial stresses. Those triaxial stresses in interparticle ligaments can be affected only by changing the geometrical ratios, but these ratios actually remain constant for a given volume fraction of the particles irrespective of their size.

To explain the sense of the ligament thickness parameter in semicrystalline polymers, Muratoglu et al. (1995d) proposed a model based on an specifically oriented crystalline layer of limited thickness ($\sim$0.15 μm for PA6,6 matrix) which forms upon matrix crystallization and extends radially from the surface of each rubber particle (Muratoglu et al. 1995a, b, c, d). This approach considered that in a tough blend where the rubber particles are closer than double the thickness of the oriented layer ($\sim$0.3 μm for PA6,6), the crystalline structure within the entire cross section of the interparticle ligament is well and specifically oriented. Crystalline lamellae oriented perpendicularly to the rubber–matrix interface were evidenced by TEM. Such a morphology surely induces a real anisotropy within the interparticle ligament zones, cf. Fig. 11.29. In these anisotropic zones, a considerable fraction of crystals is oriented with hydrogen-bonded (001) plane that appears as the plane of the easiest crystallographic slip, parallel to the rubber–matrix interface in the

interparticle ligament. As a result, the plastic shear resistance of ligaments is significantly reduced as compared to the isotropic matrix. Due to percolation effect, the entire deformation zone can deform extensively at the reduced stress, which eventually results in a super-tough material response. This approach was supported by microscopic observations of morphological features in the stress-whitened plastic process zones of tensile and Izod impact specimens, confirming the important role of the local orientation within ligaments. Similar local orientation behavior, leading to much enhanced impact strength, was postulated also for blends of polyethylene with various rubbers as well as those with stiff particles of $CaCO_3$ mineral filler (Bartczak et al. 1999a, b, c). In the latter case, debonding of stiff particles played the same role as rubber cavitation for yield initiation. Bucknall and Paul (2009) remarked critically that "the hypothesis of Muratoglu is not consistent with the strong relationship observed by Gaymans and co-workers (Borggreve and Gaymans 1989; Borggreve et al. 1988, 1989a, b; Gaymans 2000) between critical particle size and temperature, nor with recent work by Huang et al. which shows that the impact behavior of 80/20 rubber-toughened blends based on the amorphous polyamide Zytel 330 is very similar to that of 80/20 blends based on PA-6" (Huang et al. 2006a, b; Huang and Paul 2006).

Corte and Leibler (Corte et al. 2005; Corte and Leibler 2007) compared the characteristic lengths and deformation processes involved in toughening. On this basis they tried to explain a critical ligament thickness governing toughening of semicrystalline polymers by the existence of a characteristic confinement length that is governing the fracture behavior. They envisaged fracture of a semicrystalline polymer as a process in which a great number of very small nano- or submicron-sized cracks open in poorly cohesive amorphous layers and accumulate in the semicrystalline material long before its final rupture. A brittle fracture eventually occurs when these submicron cracks coalesce to form a flaw bigger than critical which happens at certain critical concentration, ρ^*, estimated on the order of 10^{14}–10^{16} cm^{-3} for semicrystalline polymers. This critical concentration implies the existence of a critical distance between nano- and submicron cracks $\xi^* \propto \rho^{*-1/3}$, estimated on the order of 100 nm. Analyzing the stress and strain state across the interparticle matrix ligament between cavitated particles, Corte and Leibler predicted that a small zone near particle equator should begin to yield due to high stress concentrations. Such yielded zones around neighboring particles would confine the elastically strained central part of the ligament between these particles. Now, if the width of this central part of the ligament is larger than the critical distance between nano- and microcracks ξ^* characteristic for a given polymer, then the discussed confinement by yielded zones does not affect crack coalescence, and a brittle fracture can propagate as in unmodified polymer. However, if this distance is smaller than ξ^*, the confinement can appear strong enough to shield interactions between microcracks and inhibit their coalescence. As a consequence, a brittle fracture does not develop. Instead, a plastic deformation can be activated, resulting in enhanced toughness. According to this approach, material becomes tough when the initial ligament thickness ID is smaller than a critical confinement length ID_{crit}, given by the equation (Corte and Leibler 2007):

$$\mathrm{ID}_{\mathrm{crit}} = \xi^* + \mathrm{D}\left(\frac{C\sigma_B}{\sigma_y}\right)^2 \tag{11.29}$$

where ξ^* is the critical distance between microcracks; D is the particle diameter; σ_B and σ_y are fracture and shear yield stress, respectively; and C is a dimensionless parameter depending on the ability of particles to release the stress and on the criterion for brittle stress. This equation suggests that $\mathrm{ID}_{\mathrm{crit}}$ depends not only on the matrix characteristics given by the critical distance ξ^*, σ_B, and σ_y but also directly on the particle diameter D. This model was applied to an interpretation of experimental data of polyamide-based blends and to demonstrate how the critical confinement length depends on material properties, temperature, and processing history. The model revealed an initially unexpected particle size effect: the critical interparticle distance $\mathrm{ID}_{\mathrm{crit}}$ varied linearly with the particle diameter and inversely with the square of the shear yield stress (Eq. 11.29). These findings demonstrate according to Bucknall and Paul that there is practically no advantage in using ID instead of D as a basis for comparisons of toughness data, especially as D is easier to measure experimentally, and ID is usually estimated indirectly (Bucknall and Paul 2009).

Bucknall and Paul (2009, 2013) reviewed and commented on the deficiencies of the interparticle spacing concept. They finally concluded that "there are sound reasons for abandoning the concept of interparticle spacing altogether. The alternative is to base all discussions of impact behavior on the size and volume fraction of rubber particles, which are known to affect fracture resistance in all polymer blends. From this perspective, any correlations involving interparticle spacings should be regarded as purely fortuitous" (Bucknall and Paul 2009). Consequently, they proposed an alternative approach, based on a new model for deformation and fracture of blends under the constraints imposed on the notch tip in Izod or Charpy specimens. This model is based on three stress criteria, which define critical conditions for rubber particle cavitation, dilational shear yielding, and craze initiation, respectively, described already in Sects. 11.5.2, 11.5.3, 11.5.4, and 11.5.5. The three criteria were used together with stress field equations to determine limits within which each of these mechanism can be activated in the notched or sample, and find in this way the sequence in which the various criteria are satisfied in a developing plane-strain deformation zone. This allowed to identify the mechanisms that govern fracture toughness under specific loading conditions in notched impact tests and to predict the relationships between rubber particle diameter and the impact strength.

Void formation plays a key role in this description of rubber toughening. At initial deformation stage, prior to rubber particle cavitation, very high constraints are imposed on the shear yielding in the plane-strain region of the notched sample, and therefore the local stress in the yield zone can increase rapidly up to the point of initiation of brittle fracture from the notch tip, which happens before any significant plastic deformation and energy dissipation has taken place. In order to obtain higher toughness, the blend must be capable of activating a widespread cavitation at

stresses still below the level required to generate shear yielding in a fully constrained, void-free material, the level of which under plane-strain conditions ahead of notch tip appears very high. This is possible only if the blend contains particles of average size above the critical minimum size (which is about 0.03 µm in blends of polyamides with elastomers). On the other hand, large particles tend to induce crazing upon the early stages of the test which leads to premature failure of the plastic zone and much lower energy absorption. Therefore, large particles, especially above approximately 1 µm in diameter, are not desirable. It appears that for many high-performance blends, the optimum particle size is about 0.3 µm.

The basic relationships between deformation behavior and the particle size are presented in Fig. 11.30. These plots were prepared by Bucknall and Paul to summarize their model of particle size dependence (Bucknall and Paul 2009, 2013). They indicate the ranges of the particle size in which the phenomena of particle cavitation, matrix shear yielding, and crazing, in sequence, control the maximum stress which can be supported by the blend under the plane-strain conditions, as, e.g., in notched impact tests. The basis for comparison is the critical major principal stress, σ_{1c}, which is an important parameter, controlling both the radius of the plastic zone and its susceptibility to fracture. Using this parameter enables to compare the critical stresses for cavitation, shear yielding, and craze initiation directly by means of a simple two-dimensional plot of σ_{1c} against log(D), although, in fact, cavitation is governed by the mean stress (pressure), shear yielding by the pressure-modified effective shear stress, and craze initiation by the applied tensile stress. For purposes of illustration, the plots in Fig. 11.30 are based on calculations done for a virtual series of idealized blends of dry PA6 with 20 wt.% of an olefin rubber which can be regarded as a representative case. Very similar charts can be calculated for other materials and/or test conditions as well.

Figure 11.30a shows how competition between the various deformation mechanisms affects the yield stress. The solid line denotes σ_{1c}, the critical value of σ_1 at the onset of shear yield, whether before (the first straight section, calculated with Eq. 11.17) or after cavitation. The cavitation stress curve was calculated with Eq. 11.14 scaled accordingly to fit experimental data of the real PA6/rubber blend. Finally, the craze initiation stress curve, similar to those shown in Fig. 11.23, was calculated with Eq. 11.25.

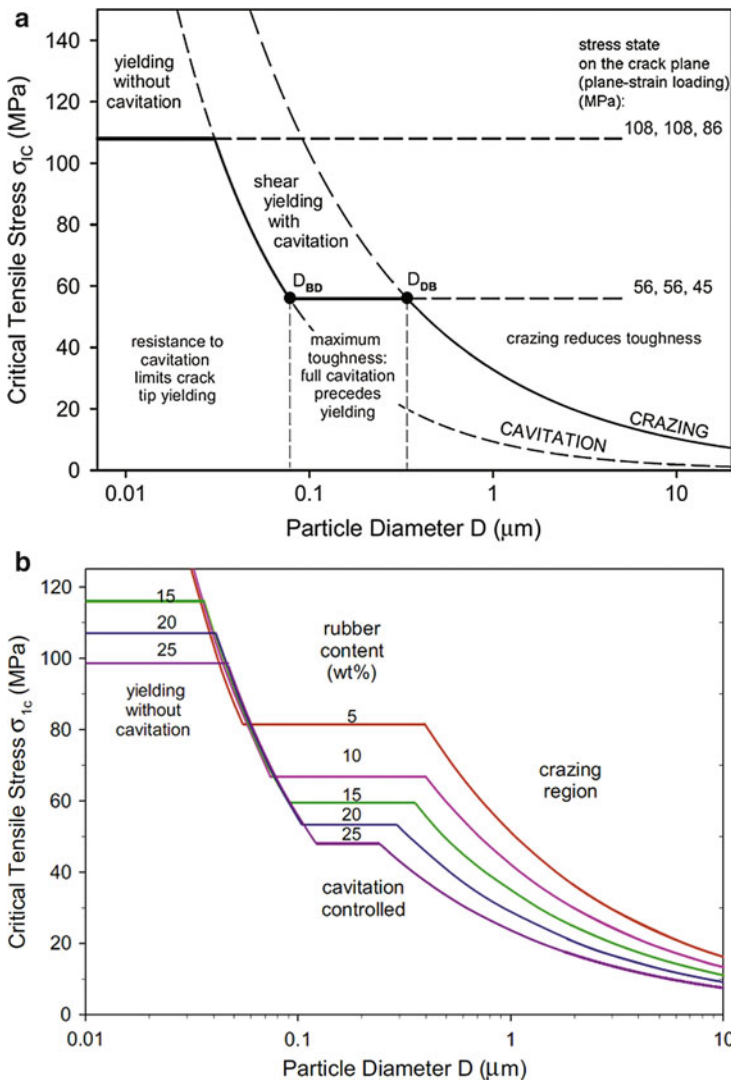
Under plane-strain loading conditions, the stresses (σ_1, σ_2, σ_3) on the crack plane are equal to ($\sigma,\sigma, 2v\sigma$). The highest calculated value of σ_{1c} is about 108 MPa, which corresponds to shear yielding of the void-free PA/rubber blend – cf. Fig. 11.21,which illustrates shear yielding of the non-cavitated blend under plane strain taking place when the mean stress $\sigma_m = 100$ MPa and the effective stress $\sigma_e = 21.5$ MPa, i.e., when stresses on the crack plane reach 108,108, 87 MPa. If the particles are very small, D < 0.03 µm, the cavitation stresses are higher than this σ_{1y}, so that the rubber does not cavitate, and constraints on shear yielding remain very high in the plane-strain region ahead of the notch. Yielding in a confined region close to the notch tip could take place


Fig. 11.30 (**a**) Critical stress map for PA6/rubber blends containing 20 % by weight (26.5 % by volume) of a lightly cross-linked olefin rubber, showing dependence of the critical major principal stress, on particle diameter. Craze line is calculated using Eq. 11.25 with E = 2.8 GPa and G_{craze} = 0.2 J/m^2. Shear yield stresses are calculated using Eq. 11.17, with pressure coefficient $\mu = 0.36$. *Solid line* defines critical stress for shear yielding, both with and without prior cavitation. Note that crazing and shear yielding can take place simultaneously in tough specimens containing relatively large particles (Adopted from Bucknall and Paul (2009); with permission of Elsevier). (**b**) Critical stress map for PA6/rubber blends containing various concentrations of rubber particles, showing the onset of rubber particle cavitation, shear yielding of cavitated blend, and crazing initiated by large particles (From Bucknall and Paul (2013); reproduced with permission of Elsevier)

without void formation, albeit at extremely high stresses (108,108, 87 MPa). Stresses of this magnitude do not develop in standard Izod or Charpy notched bars with rounded notch. Instead, local stresses increase quickly to the point of initiation of crack from the notch, leading to brittle fracture before reaching the high yield stress. By contrast, using the particle with size increasing above 0.03 μm enables the blend to cavitate before any fracture appears. Cavitation stress decreases with size, which causes a drop of the shear yield stress, down to $\sigma_{1c} = 56$ MPa (yield of the porous blend created by cavitation) at D ≈ 0.07 μm and to a significant increase of fracture toughness due to advancing plastic deformation. For even larger particles, the cavitation stress decreases below the shear yield stress of the fully cavitated blend; thus, the shear yield stress at plane strain is no longer a function of particle size. Consequently, an extensive dilatation shear yielding follows particle cavitation. This is the super-tough region, where K_I exceeds 3.5 MPam$^{0.5}$, and the radius of the plastic zone $r_p > 1$ mm. This dilatational shear yielding remains the dominating deformation mechanism until D ≈ 0.35 μm, the onset of the ductile–brittle transition, which occurs when the craze initiation curve crosses the line representing the shear yield. This crossing means that larger particles are likely to initiate crazes before the blend reaches its yield stress. Initiation and then propagation of crazes leads soon to failure of the plastic zone. As a result, impact strengths of the blend is reduced again. Summarizing, this chart explains the two brittle–ductile transitions, the lower brittle-to-ductile transition at $D_{BD} \approx 0.03$–0.08 μm, determined by the transition from brittle fracture in the absence of cavitation to dilatational shear yielding prompted by cavitation, and the upper ductile-to-brittle transition at $D_{DB} \approx 0.35$ μm, which is determined by the change from cavitation/yielding to crazing response. The optimum toughness is reached in the range of activity of cavitation and shear yielding, roughly at particle sizes between 0.1 and 0.3 μm.

Figure 11.30b is variant of Fig. 11.30a that illustrates the expected influence of the rubber concentration. It can be seen that critical stresses for yielding and for crazing tend to decrease with increasing concentration, but the same pattern of particle size dependence, discussed above, is valid for all composition. On the other hand, the range of particle size for which a super-tough behavior may be expected, limited by the upper ductile–brittle transition (transition from dilatational yield to crazing), drifts down with ϕ, which results in narrowing the size range optimum for toughening. What is more important, the yield stress goes down with increasing ϕ, which significantly reduces the probability of premature failure before the yield zone has fully developed. It must be noted, however, that once a high level of toughness has been achieved, any further increase of the rubber concentration becomes useless since the small expansion of the yield zone at the expense of a stronger reduction in the yield stress, so that total dissipated energy gradually decreases (Bucknall and Paul 2013).

The plots presented in Figs. 11.30a,b should be considered as diagrams which might appear useful in the interpretation of the notched impact toughness data, rather than a tool for predicting fracture resistance of any actual blend.

11.6   Concluding Remarks

Modification of polymers by blending with other polymers is known as an effective and economically justified method of enhancing their mechanical performance. Apart from modification of mechanical properties at low deformation rates, the most important target is the enhancement of toughness, especially at high deformation rates, including notched impact conditions.

Most of the amorphous glassy polymers tend to fracture in a brittle manner. Semicrystalline polymers, when unnotched, often fracture in a ductile manner, yet in the presence of a notch or other defects become brittle. Both amorphous and semicrystalline polymers can be made tougher by modification with particles of elastomers and in selected cases also with particles of other polymers or even stiff fillers. The change from brittle to ductile behavior is realized by promoting the deformation mechanism, either crazing or shear yielding, whichever is characteristic for a given polymer when in pristine form, in order to facilitate an extensive plastic deformation in possibly large volume of the sample that allows to dissipate large amounts of energy. The primary function of the particles is to cavitate (either internally or by debonding) and thereby produce changes in the local stress state in their adjacent vicinity that can facilitate the plastic response of the matrix. More importantly, cavitation transforms a continuous solid material into porous one, which demonstrates much higher sensitivity of the yield stress to the mean stress. This feature is crucial, especially in notched specimens, because it enables the blend to yield at moderate stresses still under plane-strain conditions found in front of the notch or crack tip. Recent studies indicate that the elimination of geometrical constraints and raising the state of plane-stress is not the primary role of cavitation, as some researchers have suggested in the past. Cavitation itself absorbs energy, but this is only a small fraction of the total fracture energy. The vast part of the impact energy is dissipated due to plastic deformation. Cavitation of the particles is, however, prerequisite for the enhanced ductile deformation.

The key to tough or super-tough impact behavior is the development of large and stable plastic zone, initially at the notch tip and then ahead of the propagating crack. One way of achieving this goal is to prepare the blend with high rubber contents (>25 % by volume), optimum particle sizes, and relatively low yield stresses. However, the high rubber content results also in a notably reduced material stiffness and therefore most frequently is not desirable. On the other hand, moderate yield stresses, obtained with the lower content of the rubber, and optimum particle sizes alone do not guarantee good toughening. Other material-related factors, including matrix chemistry and molecular weight, adhesion between particles and matrix, morphology of rubber particle shear modulus, and other properties of the rubber phase, are equally important in determining the total amount of energy absorbed and must be all taken into consideration when significant toughness improvement is demanded.

Average particle diameter of the rubber, D, and its volume fraction, ϕ, are among the most essential factors affecting the toughness of polymer blends. The concentration of the rubber must be well balanced in order to obtain material with

stiffness and strength, which are inevitably reduced, yet are still within acceptable limits. The optimum concentration of elastomer appears to be in the range from 5 to 20 wt.%. Regardless of the actual concentration, the average size of the rubber particles, together with its distribution, is the most important parameter. It is well known that there is an optimum range of particle sizes for which tough response in many systems may be expected, which is roughly from 0.1 to 0.5 μm for the majority of the blends, in which the shear yielding is the principal energy-absorbing deformation mechanism. To obtain tough materials on the basis of crazable polymers, larger particles, usually 2–3 μm in diameter, are necessary.

Broadband Dielectric Spectroscopy on Polymer Blends

12

Huajie Yin and Andreas Schönhals

Contents

Abstract

In this chapter broadband dielectric spectroscopy (BDS) is employed to polymeric blend systems. In its modern form BDS can cover an extraordinary broad frequency range from 10^{-4} to 10^{12} Hz. Therefore, molecular and collective dipolar fluctuations, charge transport, and polarization effects at inner phase boundaries can be investigated in detail including its temperature dependence.

H. Yin • A. Schönhals (✉)
BAM Federal Institute for Materials Research and Testing, Berlin, Germany
e-mail: huajie.yin@bam.de; Andreas.Schoenhals@bam.de

In the first part of the chapter, the theoretical basics of dielectric spectroscopy are briefly introduced covering both static and dynamic aspects. This section is followed by short description of the various experimental techniques to cover this broad frequency range. To provide the knowledge to understand the dielectric behavior of polymeric blend systems, the dielectric features of amorphous homopolymers are discussed in some detail. This concerns an introduction of the most important relaxation processes observed for these polymers (localized fluctuations, segmental dynamics related to the dynamic glass transition, chain relaxation), a brief introduction to the conductivity of disordered systems as well as polarization effects at phase boundaries. Theoretical models for each process are shortly discussed. In the last paragraph the dielectric behavior of polymer blends is reviewed where special attention is paid to binary systems for the sake of simplicity. In detail the dielectric behavior of binary miscible blends is described. The two most important experimental facts like the broadening of the dielectric relaxation spectra and the dynamic heterogeneity of the segmental dynamics are addressed in depth. Appropriate theoretical approaches like the temperature-driven concentration fluctuation model and the self-concentration idea are introduced.

12.1 Introduction

It was proved by many investigations that broadband dielectric spectroscopy (BDS) is a powerful technique to investigate the properties of polymeric systems (see, for instance, references McCrum et al. 1967; Hedvig 1977; Karasz 1972; Blythe 1979; Williams 1979, 1989, 1993; Runt and Fitzgerald 1997; Adachi and Kotaka 1993; Riande and Diaz-Calleja 2004; Kremer and Schönhals 2003; and references therein). This is mainly due to the fact that an extremely broad dynamical range from the millihertz to the terahertz region can be covered by dielectric spectroscopy in its modern form. A quite recent discussion of the basics and applications of this method can be found in reference Kremer and Schönhals (2003). This broad frequency range of BDS enables one to investigate motional processes which can take place in polymers on quite different length scales (localized fluctuations, segmental dynamics, and motions of the whole chain) by this method in broad range of frequencies and temperatures. This includes furthermore that the molecular motions in the different states of a polymeric material (i.e., the glassy or rubbery state) can be studied in detail from both points of view of basic and applied research. Moreover, the different motional processes as well as charge transport processes depend on the morphology of the system under consideration. Therefore, information on the structural state of the polymeric system under investigation can be indirectly extracted using molecular mobility and/or charge transport as probe for structure.

These considerations are absolutely relevant also for polymeric blends which have received much attention because materials with tailor-made and desired properties can be designed by the combination of polymers with different

properties. Therefore, the purpose of this chapter is to discuss the dielectric properties of polymers with special attention to polymeric blends. The motivation is both scientific and technological.

The literature about dielectric relaxation is rich. For instance, there are several recent reviews available for that field (Simon and Schönhals 2003; Runt 1997; Floudas et al. 2011; Colmenero and Arbe 2007). For instance, by application of dielectric spectroscopy to polymeric blends, the phase behavior of a system can be probed or the degree of miscibility of the blend components in the different phases can be discussed and estimated. This concerns also the question of the dynamic heterogeneity in miscible blend systems or confinement effects in dynamically asymmetric polymer blends (Colmenero and Arbe 2007).

The chapter is organized as follows. In the first part broadband dielectric spectroscopy is introduced. A brief review of the theoretical background of dielectric spectroscopy is provided. This will include the basics of dielectric spectroscopy, dielectric measurement techniques, and also data analysis. This section is followed by a discussion of the dielectric behavior of homopolymers to provide the basics to understand the dielectric properties of blends. In the second part of the chapter, the dielectric behavior of polymeric blends is reviewed where both miscible and immiscible systems are discussed. The chapter is restricted to binary systems.

12.2 Broadband Dielectric Spectroscopy

12.2.1 Fundamentals

Broadband dielectric spectroscopy deals with the interaction of electromagnetic fields with matter. The fundamental relationship between the electric field $\vec{E}$, the magnetic field strength $\vec{H}$, the dielectric displacement $\vec{D}$, the magnetic induction $\vec{B}$, the current density $\vec{j}$, and the density of charges ρ is given by the Maxwell equations (Maxwell 1865, 1868). In the linear case, this means for small electric field strengths, $\vec{D}$ can be expressed by

$$\vec{D} = \varepsilon^* \varepsilon_0 \, \vec{E} , \tag{12.1}$$

where ε_0 is the dielectric permittivity of vacuum ($\varepsilon_0 = 8.854 \ 10^{-12}$ As V^{-1} m^{-1}). The material properties are characterized by the complex dielectric function or dielectric permittivity ε^*. ε^* is time (or frequency) dependent if time-dependent processes take place within the sample. The molecular origin of the time dependence of ε^* will be discussed later during the course of this chapter.

In general, time-dependent processes within a material lead to a difference of the time dependencies of the outer electric field $\vec{E}$ (t) and the resulting dielectric

displacement $\vec{D}$ (t). In the simple case of a periodical field $E(t) = E_0 \exp(-i\,\omega\,t)$ (ω-radial frequency, $\omega = 2\pi f$, f-technical frequency, $i = \sqrt{-1}$ – imaginary unit) in the stationary state, the difference in the time dependence of $\vec{E}$ (t) and $\vec{D}$ (t) is a phase shift which can be described by the complex dielectric function

$$\varepsilon^*(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega), \tag{12.2}$$

where $\varepsilon'(\omega)$ is the real part and $\varepsilon''(\omega)$ the imaginary part of the complex dielectric function.

Equation 12.1 contains contribution to the dielectric displacement coming from the vacuum. The polarization $\vec{P}$ describes the dielectric displacement which originates from the response only of a material to an external field. It is defined as

$$\vec{P} = \vec{D} - \vec{D}_0 = (\varepsilon^* - 1)\,\varepsilon_0\ \vec{E} = \chi^*\varepsilon_0\ \vec{E}\ \text{ with } \chi^* = (\varepsilon^* - 1), \tag{12.3}$$

where χ^* is the dielectric susceptibility of the material under the influence of an outer electric field. For higher field strengths ($>10^6$ V/m, this order of magnitude will be valid for the most conventional polymeric systems), nonlinear effects may take place which can be described by a Taylor expansion of $\vec{P}$ with regard to $\vec{E}$ (t) where only odd powers will contribute. The corresponding coefficients are called hyperpolarizabilities. For more details, see, for instance, reference Schönhals and Kremer (2003c).

Analogous to Eq. 12.1, Ohm's law

$$\vec{j} = \sigma^* \vec{E} \tag{12.4}$$

gives the relationship between the electric field and the current density $\vec{j}$ (Ohm's law) where $\sigma^*(\omega) = \sigma'(\omega) + i\,\sigma''(\omega)$ is the complex conductivity where σ' and σ'' are the corresponding real and imaginary parts, respectively. In the case of absent magnetic fields, the current density and the time derivative of the dielectric displacement are equivalent quantities. It holds

$$\sigma^* = i\,\omega\,\varepsilon_0\,\varepsilon^*. \tag{12.5}$$

The time dependence of the dielectric properties of a material (expressed by ε^* or σ^*) under study can have different molecular origins. Resonance phenomena are due to atomic or molecular vibrations and can be analyzed by optical spectroscopy. The discussion of these processes is out of the scope of this chapter. Relaxation phenomena are related to molecular fluctuations of dipoles due to molecules or parts of them in a potential landscape. Moreover, drift motion of mobile charge carriers (electrons, ions, or charged defects) causes conductive contributions to the dielectric response. Moreover, the blocking of carriers at internal and external interfaces introduces further time-dependent processes which are known as Maxwell/Wagner/Sillars (Wagner 1914; Sillars 1937) or electrode polarization (see, for instance, Serghei et al. 2009).

Because $\vec{D}$ and $\vec{E}$ are vectors, $\varepsilon^*(\omega)$ and σ^* are in general tensors. This becomes important for anisotropic systems like liquid crystalline (Williams 1979) or crystalline materials. For the sake of simplicity, the tensorial character of the dielectric properties is neglected in the further discussion of this chapter.

In the following this chapter is organized as follows. In the first part the essential points of electrostatics are reviewed. That means the dielectric properties are discussed at an infinite time after an application of an outer electric field. In the second part, using the frame of linear response theory, the formalism of time-dependent dielectric processes is developed.

12.2.2 Electrostatics

12.2.2.1 Dipole Moments

The molecular origins of a macroscopic polarization P are dipole moments p_i. Hence, for molecules and/or particles in a volume V, the polarization can be calculated to

$$\vec{P} = \frac{1}{V}\sum \vec{p}_i, \tag{12.6}$$

where i counts all dipole moments in the system. Generally, a dipole moment is created if the electric centers of gravity of positive and negative charges do not collapse. In the simplest case a dipole moment is obtained if a positive and a negative charge q are separated by a distance. Then the dipole moment is $p = q * d$. This picture can be generalized to any distribution of charges (Schönhals and Kremer 2003c).

The microscopic dipole moments can have a permanent or an induced character. In the latter case the dipole moment is induced by the outer electric field itself which distorts a neutral distribution of charges. An example of induced polarization is the electronic polarization where the negative electron cloud of an atom (molecule) is shifted with respect to the positive nucleus. This process takes place at a time constant of 10^{-12} s because of the low mass of the electrons. A further example is atomic polarization which has a comparable time scale. Induced polarization effects can be abstracted in the induced polarization P_∞.

For molecules with a permanent dipole moment μ, charge separation is given by the structure of the chemical compound. Hence, for a system containing only one kind of dipoles, Eq. 12.6 simplifies to

$$\vec{P} = \frac{1}{V}\sum \vec{\mu}_i + \vec{P}_\infty = \frac{N}{V}\left\langle \vec{\mu} \right\rangle + \vec{P}_\infty, \tag{12.7}$$

where N denotes the whole number of dipoles in the system and $<\vec{\mu}>$ the mean dipole moment. If the system contains different kinds of dipoles, one has to sum up over all kinds. This is especially true for polymeric systems where dipole moments

can be related to molecular groups, to segments (repeating unit), or to the chain itself (Schönhals 2003). This will be discussed later during the course of this paragraph.

Permanent dipole moments can be oriented by an electric field. This is called orientation polarization. To calculate the mean dipole moment $<\vec{\mu}>$ under the influence of an electric field, several assumptions must be made. Generally, inertia effects contribute only to P_∞ because of the short time scale involved. Assuming further that the electric field at the locus of the dipole is equal to the outer electric field and that the dipoles do not interact with each other (isolated dipoles), then the mean dipole moment can be calculated in the framework of the Debye approach (Debye 1929). Under these assumptions the mean dipole moment is due to a counterbalance of the thermal energy k_BT (Boltzmann constant) and the interaction energy W of a dipole with the electric field given by $W = -\vec{\mu} \cdot \vec{E}$. Employing Boltzmann statistics and further reconsidering that the electrical interaction energy is small compared to the thermal energy, one obtains (Schönhals and Kremer 2003c)

$$\left\langle \vec{\mu} \right\rangle = \frac{\mu^2}{3\,k_B\,T}\ \vec{E}. \qquad (12.8)$$

The polarization can be calculated by inserting Eq. 12.8 into Eq. 12.7:

$$\vec{P} = \frac{\mu^2}{3\,k_B\,T}\ \frac{N}{V}\ \vec{E}. \qquad (14.9)$$

The change in the dielectric permittivity due to orientation polarization can be obtained by combining Eqs. 12.3 and 12.9. It holds

$$\Delta\varepsilon = \varepsilon_S - \varepsilon_\infty = \frac{1}{3\,\varepsilon_0}\,\frac{\mu^2}{k_B\,T}\,\frac{N}{V}, \qquad (12.10)$$

where $\varepsilon_S = \lim_{\omega\to 0} \varepsilon'(\omega)$. $\varepsilon_\infty = \lim_{\omega\to\infty} \varepsilon'(\omega)$ covers all contributions to the dielectric function which are due to induced polarization P_∞. In the following $\Delta\varepsilon$ is also called dielectric strength.

The fact that the electric field at the dipole is not exactly the same as the applied one results in shielding effects. These internal field effects were treated historically by Lorentz (1879), Clausius (1879), and Massotti (1847). A more general approach was developed by Onsager (1938) introducing the reaction field. Within this approach Eq. 12.10 is modified to

$$\varepsilon_S - \varepsilon_\infty = \frac{1}{3\varepsilon_0}F\frac{\mu^2}{k_B\,T}\,\frac{N}{V} \ \text{with} \ F = \frac{\varepsilon_S(\varepsilon_\infty + 2)^2}{3\,(2\varepsilon_S + \varepsilon_\infty)}. \qquad (12.11)$$

In general the Onsager factor F is an unspecific correction. A more detailed discussion can be found in reference Böttcher (1973).

In difference to the Onsager factor F, the interaction of dipoles plays an important role in condensed systems. This is especially true also for polymeric materials. Specific interactions between molecules and segments in the case of polymers can be caused, for instance, by hydrogen bonding, steric interactions, etc., and can lead to associations of molecules or segments.

The problem of the interaction of dipoles was treated by Kirkwood (1939, 1940, 1946) and Fröhlich (1958). Starting point is the statistical mechanics (Böttcher 1973; Landau and Lifschitz 1979) where the contribution of the orientation polarization to the dielectric permittivity is expressed by

$$\varepsilon_S - \varepsilon_\infty = \frac{1}{3\,k_B\,T\,\varepsilon_0}\,\frac{<\vec{P}(0)\;\vec{P}(0)>}{V} = \frac{1}{3\,k_B\,T\,\varepsilon_0}\,\frac{<\sum_i \vec{\mu}_i(0) \sum_j \vec{\mu}_j(0)>}{V},$$

(12.12)

where $<\vec{P}(0)\;\vec{P}(0)>$ is the static correlation function of polarization (dipole) fluctuations. The symbol (0) refers to an arbitrary time, for instance, $t = 0$. In the further consideration it is dropped for brevity. The brackets denote averaging which has to be carried out over the whole system considering all interactions. For complex systems including polymers, Eq. 12.12 is extremely difficult to analyze. Therefore, a correlation factor g was introduced by

$$g = \frac{<\sum_i \mu_i \sum_j \mu_j>}{N\mu^2} = 1 + \frac{<\sum_i \sum_{i<j} \mu_i \mu_j>}{N\mu^2} = \frac{\mu_{Interact.}^2}{\mu^2},$$

(12.13)

where μ^2 is the mean square dipole moment for noninteracting, isolated dipoles which can be measured, for instance, in diluted solutions. The value of g can be smaller or greater than 1 depending on the case if the segments have the tendency to orient antiparallel or parallel due to specific interaction as discussed above.

The calculation of g by Eq. 12.13 involves the same difficulties as estimations according to Eq. 12.12. Therefore, Kirkwood and Fröhlich (Kirkwood 1939, 1940, 1946; Fröhlich 1958) suggested to treat a given number of dipoles exactly where the remaining molecules/segments were considered like in the Onsager approach as an infinite continuum where the dielectric behavior is characterized by ε_S. Within this approach one obtains

$$\varepsilon_S - \varepsilon_\infty = \frac{1}{3\varepsilon_0}\,F\,g\,\frac{\mu^2}{k_B T}\,\frac{N}{V}.$$

(12.14)

In the simplest case only the nearest neighbors of a selected test dipole are considered. For that case g can be approximated by

$$g = 1 + z < \cos \Psi >, \tag{12.15}$$

where z is the coordination number and ψ is the angle between the test dipole and a neighbor (Böttcher 1973).

12.2.2.2 Dipole Moments of Polymers

For a macromolecule the polarization can be written as

$$\vec{P} = \frac{1}{V} \sum_{\text{chain}} \sum_{\text{repeating unit}} \vec{\mu}_i, \tag{12.16}$$

where $\vec{\mu}_i$ is the dipole moment of the repeating unit i. In difference to low-molecular-weight compounds where the dipole moment can be well represented by a rigid vector for long-chain molecules, there are different possibilities for the orientation of a molecular dipole vector with respect to the polymer backbone. A corresponding nomenclature was developed by Stockmayer (1967) (Stockmayer and Burke 1969). A macromolecule where the dipole moment is oriented parallel to the backbone is called type-A polymer. For these systems the dielectric strength is proportional to the mean square end-to-end vector of the chain (Adachi and Kotaka 1993). For type-B polymers the dipole moment is rigidly attached perpendicular to the chain skeleton. Therefore, for the dipole moment $\vec{P}_B$ of a type-B polymer $< \vec{P}_B \cdot \vec{r} > = 0$ holds, where $\vec{r}$ is the end-to-end vector of the chain, there is no correlation between the dipole moment and the chain contour (no long-range correlations of the dipole moments of different repeating units). Most of the synthetic polymers are of type B. Although there is no polymer which is solely of type-A, there are several examples of macromolecules like *cis*-1,4-polyisoprene (Adachi and Kotaka 1993) having components of the dipole moment parallel and perpendicular to the chain. These polymers are also called type-A or type-AB polymers. A more detailed discussion is given by Adachi (Adachi and Kotaka 1993).

Macromolecules having a flexible side chain carrying a dipole moment are called to be of type C (Block 1979). A typical example are poly(n-alkyl methacrylate)s. This definition is only appropriate under the condition that the side chain can fluctuate on a shorter time scale than the segmental dynamics of the macromolecule. Otherwise the polymer is of type B.

For a type-B polymer, the mean square dipole moment can be expressed by

$$<\mu^2> = \sum_{i=1}^{N} |\vec{\mu}_i|^2 + 2 \sum_{i=1}^{N} \sum_{j<i} |\vec{\mu}_i| \, |\vec{\mu}_j| < \cos \gamma_{ij} >, \tag{12.17}$$

where γ_{ij} is the angle between bonds i and j. $| \vec{\mu} | = m$ denotes the norm of the dipole moment perpendicular to the chain. $< \cos \gamma_{ij} > = 0$ holds for the freely joined

chain model (for definition see Flory (1989)). For real chains also short-range intramolecular correlations ($<\cos \gamma_{ij}> \neq 0$) contribute to the mean square dipole moment which can be described by the intramolecular dipolar correlation coefficient g_{intra} defined as

$$g_{intra} = \frac{<\mu^2>}{\sum\limits_{i=1}^{N} m_i^2} = 1 + 2 \sum\limits_{i=1}^{N} \sum\limits_{j<i} <\cos \gamma_{ij}>. \tag{12.18}$$

g_{intra} can be regarded as the Kirkwood/Fröhlich correlation factor for an isolated chain and is a measure for the correlations between dipole moments of neighbored repeating units. Calculations of g_{intra} were started by Debye and Bueche (1951). The rotational isomeric state model (Flory 1989; Volkenstein 1963) can be used to make more detailed estimations. A discussion can be found elsewhere (Riande and Saiz 1992).

12.2.3 Time-Dependent Dielectric Processes

For small electric field strength, the dielectric relaxation can be described in the framework of the linear response theory (Landau and Lifschitz 1979). The relevant materials equation which links the time-dependent polarization P(t) with the time-dependent electric field E(t) is given by (Schönhals and Kremer 2003c)

$$P(t) = P_\infty + \varepsilon_0 \int\limits_{-\infty}^{t} \varepsilon(t - t') \frac{dE(t')}{dt'} dt', \tag{12.19}$$

where P_∞ is the polarization for infinite time covering all contributions from induced polarization and $\varepsilon(t)$ is the time-dependent dielectric function. $\varepsilon(t)$ can be directly measured as response of the system caused by a steplike change of the outer electric field as it is shown in Fig. 12.1.

If the time dependence of the outer electric field is periodically $E^*(\omega) = E_0 \exp(-i\omega t)$, in the stationary case, Eq. 12.19 becomes

$$P^*(\omega) = \varepsilon_0 (\varepsilon^*(\omega) - 1) E^*(\omega), \tag{12.20}$$

where $\varepsilon^*(\omega)$ is the complex dielectric function defined above (see Eq. 12.2). The relationship between $P^*(\omega)$ and $E^*(\omega)$ on the one hand side and $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$ on the other side is sketched in Fig. 12.2. The tangent of the phase angle δ (see Fig. 12.2) is given by

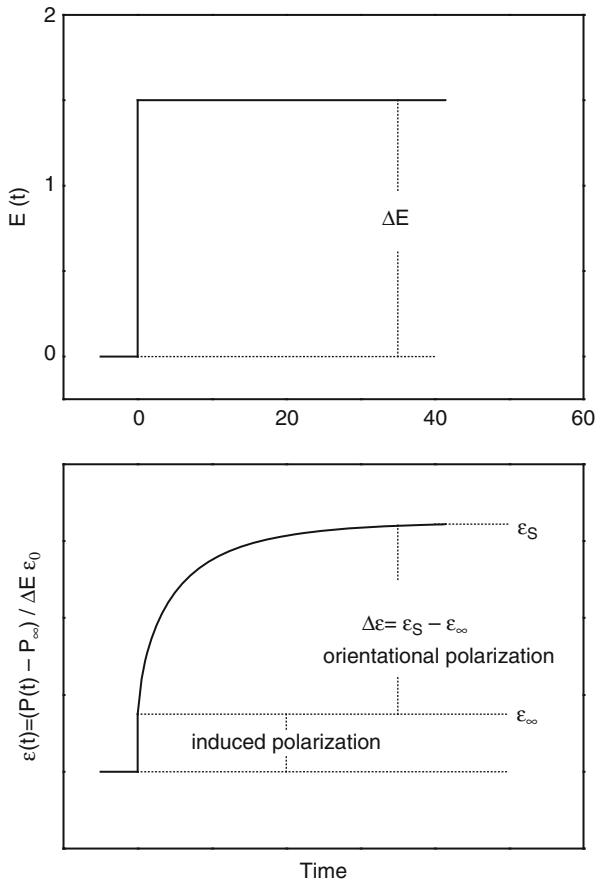
Fig. 12.1 Schematic relationship between the time dependence of the electric field ΔE (*upper panel*), the polarization P(t), and the time-dependent dielectric relaxation function ε(t) (*lower panel*). For the sake of simplicity, the vector sign is omitted in the figure


Fig. 12.2 (**a**) Phase shift between the electric field and dielectric displacement. (**b**) Relation between the complex dielectric function, its real part ε' and imaginary part ε'' as well as the phase angle δ

$$\tan \delta = \frac{\varepsilon''}{\varepsilon'}. \tag{12.21}$$

For scientific studies, however, the dielectric properties should be characterized by $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$ since they have a defined physical significance. In electrical engineering, the reciprocal value of $\tan \delta$ is termed the merit factor $Q = 1/\tan\delta$.

Equation 12.22 further provides the relationship between the time-dependent dielectric function $\varepsilon(t)$ and the complex dielectric function $\varepsilon^*(\omega)$:

$$\varepsilon^*(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega) = \varepsilon_\infty - \int_0^\infty \frac{d\varepsilon(t)}{dt} \exp(-i\omega t)\, dt. \tag{12.22}$$

The time dependence of the dielectric response can be due to different processes like the fluctuations of dipoles (relaxation processes), the drift motion of charge carriers (conduction processes), and the blocking of charge carriers at interfaces (Maxwell/Wagner/Sillars polarization). In the following subchapters these effects will be discussed from a theoretical point of view.

12.2.3.1 Dielectric Relaxation

Relaxation processes are due to molecular fluctuations of dipoles. For this case Eq. 12.12 can be generalized to time-dependent processes defining a correlation function $\Phi(\tau)$ by

$$\Phi(\tau) = \frac{<\Delta P(\tau)\,\Delta P(0)>}{<\Delta P^2>} \sim \frac{<\sum_i \vec{\mu}_i(0) \sum_j \vec{\mu}_j(\tau)>}{<\sum_i \mu_i \sum_j \mu_j>}, \tag{12.23}$$

where τ denotes a time variable. It holds $\Phi(0) = 1$ and $\Phi(\tau\rightarrow\infty) = 0$. Like Eq. 12.12 $\Phi(\tau)$ can be related to the fluctuations of microscopic dipole moments (right part of Eq. 12.23). For more details see references Williams (1979) and Schönhals and Kremer (2003). Equation 12.23 is difficult to handle from a microscopic point of view.

From a macroscopic point of view, the simplest approach to calculate the time dependence of the dielectric behavior is to assume that the change in polarization is proportional to its actual value (Debye 1929; Fröhlich 1958)

$$\frac{dP(t)}{dt} = -\frac{1}{\tau_D} P(t), \tag{12.24}$$

where τ_D is a characteristic relaxation time. The solution of this first-order differential equation leads to an exponential decay for $\Phi(\tau)$:

Fig. 12.3 Frequency
dependence of the real part ε'
and imaginary part ε'' of the
complex dielectric function
according to the Debye
function
$$P(t) \sim \varepsilon(t) \sim \Phi(\tau) = \exp\left[-\frac{t}{\tau_D}\right]. \tag{12.25}$$

According to Eq. 12.22 for the complex dielectric function, one obtains

$$\varepsilon^*(\omega) = \varepsilon_\infty + \frac{\Delta\varepsilon}{1 + i\omega\tau_D}; \ \varepsilon' = \varepsilon_\infty + \frac{\Delta\varepsilon}{1 + (\omega\tau_D)^2}; \ \varepsilon'' = \frac{\Delta\varepsilon\,\omega\tau_D}{1 + (\omega\tau_D)^2}. \tag{12.26}$$

Equation 12.26 is known as Debye equation. Figure 12.3 gives the frequency
dependence of the real and imaginary (loss) part of the Debye function. ε' shows
a steplike decay with increasing frequency where ε'' presents a symmetric peak
with a maximum $\omega_p = 2\pi f_p = 1/\tau_p$ and a half width of 1.14 decades. The Debye
equation can be justified by different molecular models like in the framework of
a simple double potential model or the rotational diffusion approach.

For polymeric systems in the most cases, the measured dielectric loss is much
broader and in addition the loss peak is asymmetric. This is called non-Debye or
nonideal relaxation behavior. Formally such a non-Debye-like behavior can be
described by a supposition of Debye functions

$$\varepsilon^*(\omega) - \varepsilon_\infty = \Delta\varepsilon \int_{-\infty}^{\infty} \frac{L(\tau)}{1 + i\omega\tau} d\ln\tau \qquad \int_{-\infty}^{\infty} L(\tau)\,d\ln\tau = 1, \tag{12.27}$$

where $L(\tau)$ is the dielectric relaxation time distribution. A modeling of a dielectric
relaxation process by Eq. 12.27 does not mean automatically that the underlying
molecular processes can be interpreted in terms of Eq. 12.26.

There were several attempts to generalize the Debye function like the Cole/Cole formula (Cole and Cole 1941) (symmetric broadened relaxation function), the Cole/Davidson equation (Davidson and Cole 1950, 1951), or the Fuoss/Kirkwood model (asymmetric broadened relaxation function) (Fuoss and Kirkwood 1941). The most general formula is the model function of Havriliak and Negami (HN function) (Havriliak and Negami 1966, 1967; Havriliak 1997) which reads

$$\varepsilon^*_{HN}(\omega) = \varepsilon_\infty + \frac{\Delta\varepsilon}{\left(1 + (i\omega\tau_{HN})^\beta\right)^\gamma}. \tag{12.28}$$

In Eq. 12.28 β and γ ($0 < \beta$, $\beta\gamma \leq 1$) are fractional shape parameters which describe the symmetric and asymmetric broadening of the complex dielectric function. τ_{HN} is characteristic relaxation time. The maximum position of the dielectric loss depends on the shape parameters according to (Diaz-Calleja 2000; Boersema et al. 1998; Schröter et al. 1998)

$$\omega_p = \frac{1}{\tau_{HN}} \left[\sin \frac{\beta\pi}{2 + 2\gamma}\right]^{\frac{1}{\beta}} \left[\sin \frac{\beta\gamma\pi}{2 + 2\gamma}\right]^{\frac{-1}{\beta}}. \tag{12.29}$$

The separation into real and loss part yield to

$$\varepsilon'(\omega) - \varepsilon_\infty = \Delta\varepsilon\, r(\omega) \cos(\gamma\Psi(\omega)); \quad \varepsilon'' = \Delta\varepsilon\, r(\omega) \sin(\gamma\Psi(\omega)) \tag{12.30}$$

with

$$r(\omega) = \left[1 + 2(\omega\tau_{HN})^\beta \ \cos\left(\frac{\beta\pi}{2}\right) + (\omega\tau_{HN})^{2\beta}\right]^{\frac{-\gamma}{2}} \tag{12.30a}$$

and

$$\psi(\omega) = \arctan\left[\frac{\sin\left(\frac{\beta\pi}{2}\right)}{(\omega\tau_{HN})^{-\beta} + \cos\left(\frac{\beta\pi}{2}\right)}\right]. \tag{12.30b}$$

Figure 12.4 compares the calculated dielectric loss for the Debye and the HN function for different shape parameters.

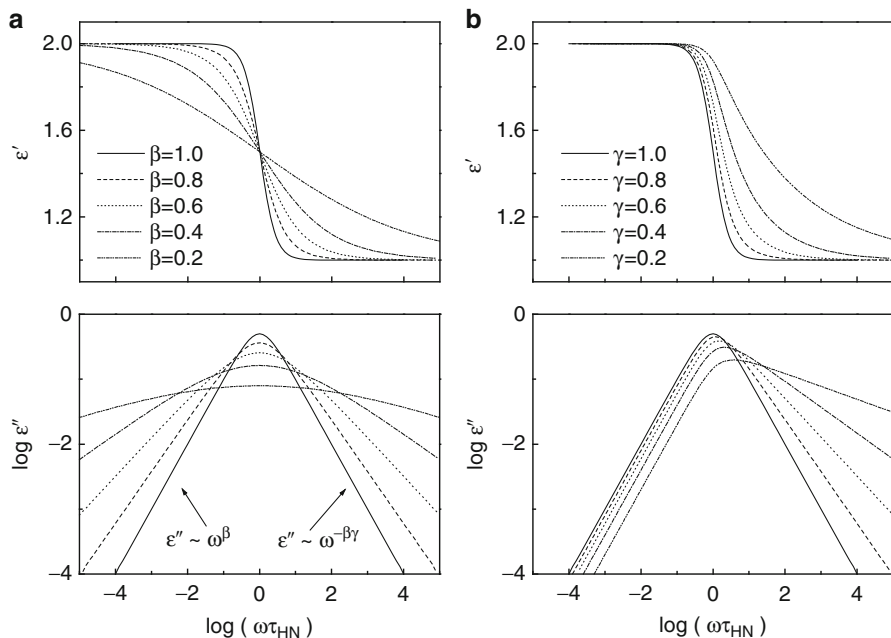
From the experimental point of view, all relevant parameters like the relaxation rate (or time), the dielectric strength, and the shape parameters can be estimated by fitting the HN function to the data (for details see references Schlosser and Schönhals 1989; Schönhals and Kremer 2003). As an example Fig. 12.5 gives the dielectric loss for poly(vinyl acetate) at the dynamic glass transition versus frequency at a temperature of T = 335.6 K. Only the HN function is able to describe the data correctly.


Fig. 12.4 Complex dielectric function according to the Havriliak/Negami function ($\tau_{HN} = 1$ s, $\Delta\varepsilon = 1$, $\varepsilon_\infty = 1$): (**a**) γ fixed to $\gamma = 1$, β varied. (**b**) β fixed to $\beta = 1$, γ varied

Fig. 12.5 Dielectric loss of poly(vinyl acetate) versus frequency at T = 335.6 K. The *dashed line* is a fit of the HN equation to the data including a conductivity contribution. The *solid line* represents the relaxational contribution according to the HN function. The *dashed-dotted line* represents the Debye function
12.2.3.2 Electrical Conduction

Equation 12.5 gives the relationship between the complex dielectric function and the complex conductivity. For semiconducting disordered materials like conducting polymers, the frequency dependence of the real part of the complex conductivity

$\sigma'(\omega)$ displays a kind of similar behavior (Dyre and Schroder 2000). (1) At temperatures where charge transport is enabled, $\sigma'(\omega)$ has a plateau σ_0 for frequencies ω smaller than a given crossover frequency ω_c. (2) For frequencies $\omega > \omega_c$ a gradual dispersion sets in the form of a power law $\sigma'(\omega) \sim \omega^s$, with $0.5 \leq s \leq 1$. The parameter s increases with decreasing temperature and increasing frequency. (3) In a good approximation a time-temperature superposition can be assumed by scaling the normalized conductivity $\sigma'(\omega)/\sigma'(0)$ with respect to a normalized frequency ω/ω_c. (4) Between $\sigma'(0)$ and ω_c the Barton-Nakajima-Namikawa (BNN) relationship $\sigma'(0) \sim \omega_c$ holds (Barton 1966; Nakajima 1971; Namikawa 1975).

A variety of models exist to explain these similarities on a microscopic level. The simplest of them is the random free energy barrier model developed by Dyre (1988). In this model hopping is assumed to be basic mechanism for conduction where hopping takes place over spatially varying energy barriers. Within the continuous time random walk approximation (Montroll and Weiss 1965), this model results in

$$\sigma^*(\omega) = \sigma(0) \left[\frac{i\omega\tau_e}{\ln(1 + i\omega\tau_e)} \right], \tag{12.31}$$

where $1/\tau_e$ is the attempt frequency to overcome the highest energy barrier determining the DC conductivity $\sigma(0)$. For the real $\sigma'(\omega)$ and imaginary part $\sigma''(\omega)$,

$$\sigma'(\omega) = \frac{\sigma(0)\,\omega\tau_e \arctan(\omega\tau_e)}{0.25\ln^2\left(1 + \omega^2\tau_e^2\right) + \arctan(\omega\tau_e)} \tag{12.32}$$

$$\sigma''(\omega) = \frac{\sigma(0)\,\omega\tau_e \ln(1 + \omega\tau_e)}{0.25\ln^2\left(1 + \omega^2\tau_e^2\right) + \arctan(\omega\tau_e)} \tag{12.33}$$

is delivered. For the exponent s one obtains $s = 1 - 2/\ln(\omega\tau_e)$ (Dyre 1988).

12.2.3.3 Interfacial Polarization

Interfacial polarization or Maxwell/Wagner/Sillars (MWS) polarization (Wagner 1914; Sillars 1937) is a phenomenon that is characteristic for phase-separated or multiphase systems like immiscible polymer blends. Precondition for the observation of a MWS polarization is that the different phases have nonidentical properties. As a result of this, for instance, accumulation of charges takes place at the interfaces of the different phases. Steeman and van Turnhout (2003) published a compilation concerning polymeric materials including polymer blends.

MWS polarization gives rise to a dielectric behavior that can be very difficult to be distinguished from dipole relaxation. All properties of the process related to MWS polarization like its position, its strength, and its shape depend strongly on

the complex permittivity, the geometry and conductivity of the dispersed phase, as well as the dielectric properties of the matrix. As an example, a dispersed phase is considered having the complex dielectric function $\varepsilon_f^*(\omega)$ with the volume fraction ϕ_f where the matrix exhibits a complex dielectric permittivity $\varepsilon_M^*(\omega)$. In a mean field approach, the complex dielectric function $\varepsilon_C^*(\omega)$ of the heterogeneous system can be calculated to (Steeman and van Turnhout 2003)

$$\varepsilon_C^*(\omega) = \varepsilon_M^*(\omega) \frac{\left[n\varepsilon_f^*(\omega) + (1-n)\varepsilon_M^*(\omega) \right] + (1-n)\left[\varepsilon_f^*(\omega) - \varepsilon_M^*(\omega)\phi_f \right]}{\left[n\varepsilon_f^*(\omega) + (1-n)\varepsilon_M^*(\omega) \right] - n\left[\varepsilon_f^*(\omega) - \varepsilon_M^*(\omega)\phi_f \right]}. \quad (12.34)$$

n $(0 \leq n \leq 1)$ is the shape factor of the dispersed phase in the direction of the electric field lines. For spheres the values n in three directions (a, b, c) are identical with $n_a = n_b = n_c = 1/3$. For rodlike phase $0 \leq n \leq 1/3$ holds with the limiting case of a needle $n_a = 0$ and $n_b = n_c = 1/2$. For a platelike particle $n_a = 1$ and $n_b = n_c = 0$ holds. For more details see reference van Beek (1967).

Considering these equations one has to keep in mind that the morphology of phase-separated polymer systems is often more complex or even not well defined. This makes a quantitative modeling quite difficult.

12.2.4 Dielectric Instrumentation

The complex dielectric function $\varepsilon^*(f)$ can be measured in the extremely broad frequency regime from 10^{-3} to 10^{12} Hz. To do so different methods based on different physical principles must be combined. A detailed overview can be found elsewhere (Kremer and Schönhals 2003).

For lower frequencies (10^{-3}–10^7 Hz), the sample is modeled as a parallel or serial circuit of an ideal capacitor and an ohmic resistor. The spatial extent of the sample on the distribution of the electric field is neglected. This is called lumped circuit approximation. For frequencies higher than 100 kHz, firstly, parasitic impedances caused by cables, connectors, etc., become important. Secondly, the wavelength of the electromagnetic field decreases to the order of magnitude of the sample dimension. This means the geometrical dimensions of the sample capacitor become more and more important limiting the application of the lumped circuit methods to about 10 MHz. For higher frequencies the so-called distributed circuit approach has to be applied. By the application of both waveguide and cavity techniques, complex propagation factor (in reflection or transmission) can be measured from which the complex dielectric function can be deduced in the frequency range from 10^7 to 10^{11} Hz. For even higher frequencies quasi-optical setups and Fourier transformation techniques can be employed. A detailed discussion of these methods is beyond the scope of this chapter.

The complex dielectric function is related to the complex capacity C* of a capacitor filled with a polymeric material under study by

$$\varepsilon^*(\omega) = \frac{C^*(\omega)}{C_0} = \frac{J^*(\omega)}{i\,\omega\,\varepsilon_0\,E^*(\omega)} = \frac{1}{i\,\omega\,Z^*(\omega)\,C_0}, \qquad (12.35)$$

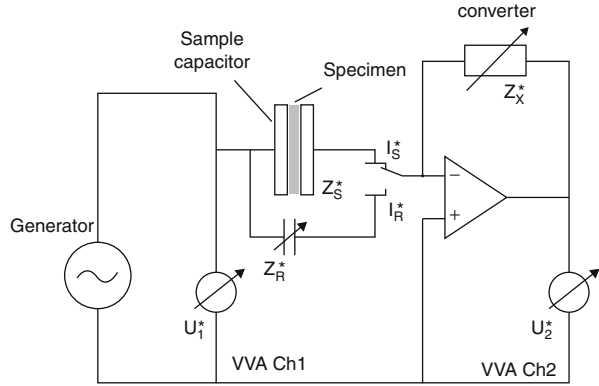
where C_0 is the (geometrical) capacitance of the unfilled sample capacitor. For a periodical field in the linear range with the angular frequency ω, the complex dielectric function can be expressed by measuring the complex impedance $Z^*(\omega)$ of the sample where $J^*(\omega)$ is the complex current density. Different experimental setups (Kremer and Schönhals 2003) like Fourier correlation analysis in combination with dielectric converters (10^{-6}–10^7 Hz) (Pugh and Ryan 1979; Schaumburg 1994, 1999), impedance analysis (10^1–10^7 Hz), RF reflectometry (10^6–10^9 Hz) (Böhmer et al 1989; Jiang et al. 1993), and network analysis (10^7–10^{11} Hz) (Collin 1966; Hewlett Packard 1985; Pelster 1995) are employed. In the following selected methods which have implications on polymeric blend systems are described in more detail.

12.2.4.1 Fourier Correlation Analysis in Combination with Dielectric Converters

The principle of the Fourier correlation analysis is given in Fig. 12.6. A generator provides a sinusoidal voltage $U_1(t)$ with angular frequency ω which causes a current $I_S(t)$ through the sample having an impedance $Z_S^*(\omega)$. The resistor R converts $I_S(t)$ into a voltage $U_2(t)$. Both voltages $U_1(t)$ and $U_2(t)$ are analyzed with respect to their amplitude and phase with regard to the base frequency ω by Fourier analysis. Technically this is carried out by employing two phase sensitive correlators providing the complex voltages $U_1^*(\omega)$ and $U_2^*(\omega)$. Hence, the sample impedance is given according to Ohm's law by

$$Z_S^*(\omega) = \frac{U_S^*(\omega)}{I_S^*(\omega)} = R\left(\frac{U_1^*(\omega)}{U_2^*(\omega)} - 1\right) \qquad (12.36a)$$

where for $U_j^*(\omega) = U_j'(\omega) + i\,U_j''(\omega)$ (j = 1,2),
Fig. 12.6 Circuit diagram of Fourier correlation analysis (*VVA* vector voltage analyzer)

Fig. 12.7 Circuit diagram of Fourier correlation analysis with a dielectric converter for the low-frequency range and a variable reference impedance $Z_R^*(\omega)$ (*VVA* vector voltage analyzer)


$$U_j'(\omega) = \frac{1}{NT} \int_0^{NT} U_j(t) \sin(\omega t)\, dt \quad \text{and} \tag{12.36b}$$

$$U_j''(\omega) = \frac{1}{NT} \int_0^{NT} U_j(t) \cos(\omega t)\, dt \tag{12.36c}$$

holds. N is the number of cycles with duration $T = 2\pi/\omega$, $U_S^*(\omega)$ is the complex voltage at the sample, and $I_S^*(\omega)$ is the complex current through the sample. Technically the Fourier analysis is done by frequency response analyzers or lock-in amplifiers which are state-of-the-art equipments. Digital components like filters are employed.

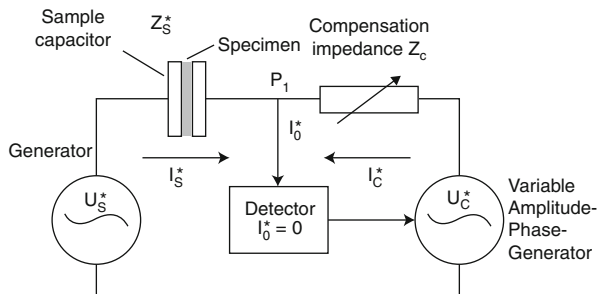
A fixed resistor R especially for low frequencies f suffers several limitations. Therefore, the resistor R is replaced by an amplifier with a variable gain according to Fig. 12.7. This results in a variable impedance $Z_X^*(\omega)$ which can be adjusted to the impedance of the sample $Z_S^*(\omega)$. For the sample impedance, then

$$Z_S^*(\omega) = \frac{U_{1S}^*(\omega)}{I_S^*(\omega)} = -\frac{U_{1S}^*(\omega)}{U_{2S}^*(\omega)} Z_X^*(\omega) \tag{12.37}$$

holds. The accurateness in the determination of $Z_S^*(\omega)$ is limited by phase and amplitude errors in the amplifier and correlators as well as by the contribution of the cables. These errors can be minimized by measuring a known impedance $Z_R^*(\omega)$ under the same condition as the sample. Analogous to Eq. 12.37

$$Z_R^*(\omega) = \frac{U_{1R}^*(\omega)}{I_R^*(\omega)} = -\frac{U_{1R}^*(\omega)}{U_{2R}^*(\omega)} Z_X^*(\omega) \tag{12.38a}$$

holds. By combining Eqs. 12.37 and 12.38a, one obtains for the impedance of the sample

Fig. 12.8 Circuit diagram of an impedance bridge


$$Z_S^*(\omega) = \frac{U_{1S}^*(\omega)}{U_{2S}^*(\omega)} \frac{U_{2R}^*(\omega)}{U_{1R}^*(\omega)} Z_R^*(\omega). \tag{12.38b}$$

12.2.4.2 Impedance Bridges

In principle impedance bridges are the extensions of the Wheatstone resistance bridge to complex resistances (impedances). Historically one has to consider the Schering bridge or the bridge according to Giebe und Zickner (see, for instance, McCrum et al. 1967).

The principle of modern impedance bridges is given in Fig. 12.8. In the sample branch a generator generates the sinusoidal voltage $U_S^*(\omega)$ with an angular frequency ω. This voltage causes a current $I_S^*(\omega)$ through the sample with the impedance $Z_S^*(\omega)$ at point P1. In the comparison branch a second generator generates a voltage which can be varied with regard to both its phase and its amplitude. This voltage is adjusted in that way that it drives a current $I_C^*(\omega)$ through a compensation impedance $Z_C^*(\omega)$ which is equal to $-I_S^*(\omega)$. Hence, in the balanced state at P1 $I_0^* = I_S^* - I_C^* = 0$ is valid and for the sample impedance

$$Z_S^*(\omega) = \frac{U_S^*(\omega)}{I_S^*(\omega)} = -\frac{U_S^*(\omega)}{U_C^*(\omega)} Z_C^*(\omega) \tag{12.39}$$

is obtained.

12.2.4.3 High-Frequency Methods

For frequencies higher than 10^6 Hz, the electromagnetic waves have to be guided in coaxial waveguides because the use of cables will lead to parasitic losses mainly due to inductivities. Moreover, standing waves may arise at frequencies higher than 10^7 Hz. A modern approach to measure the dielectric properties in the frequency range from 10^6 to 10^9 Hz is coaxial reflectometry (Böhmer et al. 1989; Jiang et al. 1993; Agilent Technologies 2000). By this approach the sample is modeled as a part of the inner conductor of a coaxial short. The principle of this technique is illustrated in Fig. 12.9. The impedance of the specimen is estimated from a complex reflection coefficient Γ^* defined by the ratio of the complex voltages of the incident (U_{Inc}^*) and reflected (U_{Ref}^*) waves:
Fig. 12.9 Scheme of a coaxial line reflectometer with sample head

$$\Gamma^* = \Gamma_x - i\,\Gamma_y = \frac{U^*_{Ref}}{U^*_{Inc}} \quad Z^* = Z_0\,\frac{1 + \Gamma^*}{1 - \Gamma^*}. \tag{12.40}$$

Z_0 is the wave resistance of the coaxial line.

To derive Eq. 12.40 ideal coaxial lines have to be assumed which is not the case in practice. Therefore, calibration procedures have to be applied. First, the influence of the measuring cell has to be obtained and considered during the calculation of the sample impedance. Second, the direction-dependent resistance of the line has to be measured by a second calibration procedure because it cannot be obtained by an equivalent circuit diagram.

At frequencies above 1 GHz, network analysis might be applied where both the reflected and the transmission of the signal through the sample are analyzed with respect to phase and amplitude (Kremer and Schönhals 2003).

An example for a broadband dielectric measurement is given in Fig. 12.10, where the dielectric loss versus frequency is given for poly(propylene glycol) ($M = 200\ \mathrm{g\ mol^{-1}}$). The data were obtained by a combination of Fourier correlation analysis and coaxial line reflectometry.

12.2.4.4 Thermostimulated Currents

The dielectric properties of a polymeric system can be also investigated in the temperature domain by the method of thermally stimulated currents (TSC) developed by Bucci et al. (1966). This method was broadly applied to polymers by van Turnhout (1975), Lacabanne (Larvergne and Lacabanne 1993), and Teyssedre (Teyssedre et al. 1997) (see also the references given therein). In principle the method is based on the temperature dependence of the relaxation times and the fact that a given value of the relaxation time corresponds to an experimental time scale

Fig. 12.10 Dielectric loss ε'' versus frequency for poly (propylene glycol) (M = 2,000 g mol^{-1}) at the given temperatures. The peak at lower frequencies corresponds to the normal mode process, whereas the peak at higher frequencies is due to the α-relaxation. The data were obtained by a combination of Fourier correlation analysis and coaxial line reflectometry
(heating rate) at a certain temperature. In the simplest approach assuming a Debye-like response (see Eq. 12.24), the sample is polarized by a field E_P for a given time at a polarization temperature T_P. After that, the sample is cooled down to a temperature T_S with applied electric field. T_S should be low enough that $\tau(T_S)$ is long enough to prevent any depolarization of the sample at the experimental time scale. The frozen-in polarization P_0 is estimated to $P_0 = \frac{N\mu^2}{3k_B T_P V} E_P$. A subsequent heating of the specimen with a heating rate $\kappa = dT/dt$ leads to a depolarization current or depolarization current density J(T). By measuring the current density as function of time, a peak is observed when groups or segments become mobile and frozen-in polarization can be released. According to Eq. 12.24 the temperature dependence of the polarization can be described theoretically by

$$P(T) = P_0 \exp\left(-\int_{T_S}^{T} \frac{dT'}{\kappa \tau(T')}\right). \tag{12.41}$$

Experimentally the temperature dependence of the polarization can be obtained by integrating J(T) between T and a temperature T_f at which J(T) becomes zero:

$$P(T) = \frac{1}{\kappa} \int_{T}^{T_f} J(T') \, dT'. \tag{12.42}$$

Depending on the heating rate, a TSD measurement corresponds to a conventional dielectric measurement carried out at a low frequency of 10^{-4}

to 10^{-3} Hz. For this reason a TSC curve can be also directly compared to a corresponding differential scanning calorimetry (DSC) measurement.

A relaxation time can be calculated from the measurements according to (Teyssedre et al. 1997)

$$\tau(T) = -\frac{P(T)}{dP/dT} \tag{12.43}$$

without any further hypothesis.

In addition to these general considerations, methods have been developed considering also a distribution of relaxation times based on partial heating techniques or the fractional depolarization approach (Teyssedre et al. 1997).

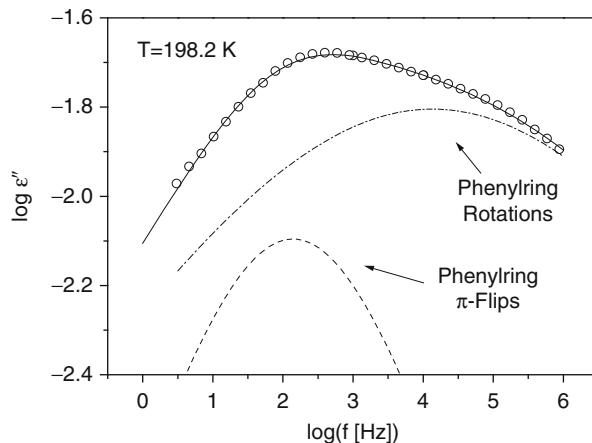
Because currents can be measured with a high accuracy, the TCS method is a quick and sensitive method to investigate the dielectric properties of polymers. But it should be noted that, for instance, in the glass transition range, the data depends on the experimental conditions like heating and cooling rates which make the quantitative analysis of these measurements more difficult (Kubon et al. 1988; Schrader and Schönhals 1989).

The application of the TSC method to miscible blends is discussed below (see Sect. 12.4.2). Some further discussion can be found in references Vanderschueren et al. (1980), Topic et al. (1987), Migahed and Fahmy (1994), Topic and Veksli (1993), Sauer et al. (1997), Sauer and Hsiao (1993), and Sauer et al. (1992).

12.3 Dielectric Relaxation of Amorphous Homopolymers

In the following section the essential properties of amorphous polymer systems in the bulk will be discussed briefly. In general, for dense polymers one has to consider that the fluctuations of segments or whole chains are influenced not only by intramolecular but also by intermolecular correlations. In order to calculate the mean square dipole moment (see Eq. 12.16) or the corresponding correlation function, one has to sum up over all chains in the system (Schönhals 2003).

The most amorphous polymers have two relaxation regions. At low temperature (or high frequencies) a so-called β-relaxation is observed as a broad peak in the dielectric loss. At higher temperatures or lower frequencies than the β-process, the α-relaxation is observed which is also called principal relaxation or dynamic glass transition. For type-A polymers (see Sect. 12.2.2.2) having a component of the dipole in the direction of the chain backbone at frequencies lower than that of the α-relaxation, a further dielectric active process is observed which is called α'- or normal mode relaxation related to the overall chain dynamics. As an example for the last two processes, Fig. 12.10 depicts the dielectric loss for poly(propylene glycol) (M = 2,000 g mol^{-1}) as a type-A polymer in the frequency range from 10^{-4} to 10^9 Hz. The relaxation processes are indicated as peaks in the dielectric loss. The process at higher frequencies is the α-relaxation which is related to the dynamic

Fig. 12.11 Dielectric loss versus frequency for the β-relaxation of polycarbonate. At a temperature of T = 198.2 K. The *solid line* is a fit of two HN functions to the data where the *dashed* and the *dashed-dotted lines* represent the individual contribution (The figure was adopted from reference Yin et al. (2012))


glass transition, whereas the peak at lower frequencies corresponds to the normal mode process. In the following the characteristic properties of the β-, α-, and the normal mode relaxation of amorphous polymers are briefly discussed. Apart from these processes amorphous polymers can also exhibit further dielectrically active relaxation processes.

12.3.1 β-Relaxation

There is a general agreement that the dielectric β-relaxation of amorphous polymers arises from localized rotational fluctuations of the dipole vector. There are two different approaches to discuss the β-relaxation on a molecular level. At the one hand side, Heijboer (1978) developed a nomenclature for the molecular mechanisms which can be responsible for this process. According to this picture, fluctuations of localized parts of the main chain and the rotational fluctuations of side groups or parts of them can be discussed. There are studies on model systems which seem to support this approach (Buerger and Boyd 1989; Katana et al. 1993; Corezzi et al. 1999; Tetsutani et al. 1982a, b). Moreover, detailed investigations on poly(n-alkyl methacrylate)s in dependence on the length of the alkyl side chain seem to favor this idea also (Tetsutani et al. 1982a, b; Gomes Ribelles and Diaz Calleja 1985; Garwe et al. 1996; Zeeb et al. 1997). Regarding the latter class of materials, one has to keep in mind that the relaxation behavior of the poly(n-alkyl methacrylate)s is quite unusual compared to other polymers. Also a degeneration of the calorimetric glass transition with increasing length of the side chains (Hempel et al. 1996) and indications for a nanophase separation (Beiner and Huth 2003) are detected. Moreover, the β-peak can consist of different relaxation processes. This is demonstrated by Fig. 12.11 where the β-peak of poly(bisphenol A carbonate) is deconvoluted in to two processes (Yin et al. 2012) in agreement also with the literature (Alegría et al. 2006; Arrese-Igor et al. 2008).

The second approach to assign the β-relaxation on a molecular level was outlined by Goldstein and Johari (1970; Johari 1973). In their approach the β-relaxation is a generic feature of the glass transition and the amorphous state. The main argument is that such β-relaxation processes could be observed besides for polymeric systems for a great variety of glass-forming materials like low-molecular-weight glass-forming liquids and rigid molecular glasses (Johari 1973). Also for polymers in which the dipoles are rigidly attached to the main chain, the dielectric β-relaxation was well known. Recently the β-relaxation is intensively discussed because it is supposed that the investigation of this process can help to understand the nature of the dynamic glass transition which is a topical problem of soft matter physics (Anderson 1995; Angell 1995). As a general conclusion one can state that the β-relaxation can be of intra- and/or intermolecular nature.

In the following the properties of the β-relaxation are briefly given in terms of its relaxation rate, its dielectric strength, and the shape of the relaxation function.

12.3.1.1 Relaxation Rate $f_{p,\beta}$

In general the temperature dependence of the relaxation rate of the β-relaxation follows the Arrhenius equation:

$$f_{p,\beta} = f_{\infty\beta} \exp\left[-\frac{E_A}{k_B T}\right]. \tag{12.44}$$

$f_{p\infty}$ is the preexponential factor which should be in the order of 10^{12}–10^{13} Hz. The activation energy E_A depends on both the internal rotational barriers and the environment of a fluctuating unit. Typical values for E_A are 20–50 kJ mol^{-1}.

12.3.1.2 Dielectric Strength $\Delta\varepsilon_\beta$

For most of the polymers for the relaxation strength of the β-relaxation, $\Delta\varepsilon_\beta << \Delta\varepsilon_\alpha$ holds. Here $\Delta\varepsilon_\alpha$ is the dielectric strength of the α-relaxation. This is true for such polymers like polycarbonate (Katana et al. 1993), poly(vinyl chloride) (Matsuo et al. 1965; Colmenero et al. 1993), poly(propylene glycol) (Schönhals and Kremer 1994), or poly(chloroprene) (Matsuo et al. 1965), just to mention a few. This is also the case for semicrystalline polymers poly(ethylene terephthalate) (Coburn and Boyd 1986; Hofmann et al. 1993) or poly(ethylene 2,6 naphthalene dicarboxylate) (Hardy et al. 2001). For some polymers containing flexible side groups like poly(n-alkyl acrylate)s (Kremer et al. 1992; Williams and Watts 1971), $\Delta\varepsilon_\beta \leq \Delta\varepsilon_\alpha$ is valid. The exceptions of these rules are the poly(n-alkyl methacrylate)s for which $\Delta\varepsilon_\beta > \Delta\varepsilon_\alpha$ is measured (McCrum et al. 1967; Garwe et al. 1996; Williams and Edwards 1966; Sasabe and Saito 1968). Untill now the molecular reason for this behavior is not clear. NMR measurements show that the motions of the main and the side chain are coupled (Kulik et al. 1994). This might be a molecular reason for this exception.

12.3.1.3 Shape of the Relaxation Function

The peak related to the β-relaxation is rather broad and symmetric. Using the half-height width of the loss peak, it can be four to six decades wide. With increasing temperature, the width of the β-peak decreases. Quite often the width of the β-relaxation is modeled by both a distribution of the activation energy and the preexponential factor (in the sense of Eq. 12.27) which might be related to a distribution of molecular environments of the relaxing dipole. In most cases it is difficult to extract information on the basic mechanisms of molecular motion. In other cases the broadness of the β-peak can be also due to the overlapping of different relaxation processes as demonstrated for polycarbonate (see Fig. 12.11).

12.3.2 α-Relaxation (Dynamic Glass Transition)

Untill today the dynamic glass transition (α-relaxation) which is related to the thermal glass transition is a topical problem of soft matter research (Anderson 1995; Angell 1995; Schönhals and Kremer 2012). For polymers the dynamic glass transition is related to segmental dynamics which is related to conformational changes. These changes are not independent from each other and many degrees of freedom are involved in such a process. A variety of models have been developed for such a process. Examples for such models are the Shatzki crankshaft (Shatzki 1962) and the so-called three-bond motion (Valeur et al. 1975a, b) which are critically discussed in reference Hall and Helfand (1982). Today, the understanding of the segmental dynamics in an isolated chain is based on ideas of Helfand et al. (Hall and Helfand 1982) and/or Skolnik et al. (Skolnik and Yaris 1982). They describe the segmental motion as a damped diffusion of conformational states along the chain. A conformational transition can occur spontaneously and isolated, but due to the disturbed bond lengths and also the angles, the probability that in a neighbored segment also a conformational transition will take place is enhanced. For this reason a conformational state seems to diffuse along the backbone. At some point this process will stop because of the fact that the probability for a conformation change in a neighbored segment is smaller than one. This means not each conformational change in a segment will lead automatically to a conformational transition in the neighbored unit. So the diffusion of conformational states along the chain is damped.

The model developed for isolated chains in solutions should be also applied in the dense state. But for bulk systems besides the intermolecular interactions, also the intramolecular interactions have to be taken into account. This can be done, for instance, by considering a test segment which fluctuates in the environment of other fluctuating segments (Schönhals and Schlosser 1989).

12.3.2.1 Relaxation Rate $f_{p,\alpha}$

It is well known that the temperature dependence of the relaxation rate of the α-relaxation does not follow the Arrhenius law. Very often close to the thermal

glass transition temperature T_g, it can be described by the Vogel/Fulcher/Tammann/Hesse (VFT) formula (Vogel 1921; Fulcher 1925; Tammann and Hesse 1926):

$$\log f_{p\alpha} = \log f_{\infty\alpha} - \frac{A}{T - T_0}. \tag{12.45}$$

$\log f_{\alpha\infty}$ ($f_{\alpha\infty} \approx 10^{10}$–$10^{12}$ Hz) and A are constants where T_0 is the so-called Vogel temperature which is found to be 30–70 K below T_g. Empirically and also by temperature-modulated DSC (Schick 2012), it was shown that the glass transition temperature corresponds to relaxation rates of 10^{-3}–10^{-2} Hz. Therefore, a dielectric glass transition temperature T_g^{Diel} can be defined by $T_g^{Diel} = T$ ($f_{p\alpha} \approx 10^{-3}...10^{-2}$ Hz).

An analogous representation for the temperature dependence of the relaxation rate of the α-relaxation is the Williams/Landel/Ferry (WLF) relation (Ferry 1980):

$$\log a_T(T) = \log \frac{f_{p\alpha}(T)}{f_{p\alpha}(T_{Ref})} = -\frac{C_1(T - T_{Ref})}{C_2 + T - T_{Ref}}, \tag{12.46}$$

where $a_T(T)$ is the so-called shift factor, T_{Ref} is a reference temperature and $f_{p\alpha}(T_{Ref})$ is the relaxation rate at this temperature. C_1 and $C_2 = T_{Ref} - T_0$ are the WLF parameters. Equations 12.45 and 12.46 are mathematically equivalent. Moreover, it has been discussed that the WLF parameters should have universal material-independent values if $T_{Ref} = T_g$ is chosen (Ferry 1980). However, it was found experimentally that these estimates are only rough approximations.

$a_T(T)$ is often used to construct master curves in the framework of the time-temperature superposition (TTS) principle (Ferry 1980).

The VFT equation can be used to describe the temperature dependence of the relaxation rate close to the glass transition temperature. For higher temperatures ($T = T_g + 80 \ldots 100$ K) deviations are observed. It is discussed in the literature whether the data at higher temperature have to be described by a second VFT law with different parameters or by an Arrhenius equation.

There are several models to understand the strong temperature dependence of the relaxation rate of the dynamic glass transition. Besides mode coupling theory (see, for instance, Götze 2009), one of them is the free volume approach discussed in detail in reference Schönhals and Kremer (2012). The cooperativity approach was pioneered by Adam and Gibbs (1965). They introduced the cooperatively rearranging region (CRR) which is defined as the smallest volume which can change its configuration independently from the neighboring regions. If z(T) is the number of segments per CRR, the relaxation rate can be expressed as

$$\frac{1}{\tau} \sim f_p \sim \exp\left(-\frac{z(T)\,\Delta E}{k_B\,T}\right) \sim \exp\left(-\frac{s^*\Delta E}{k_B\,T\,S_C}\right) \sim \exp\left(-\frac{C}{T\,S_C}\right). \qquad (14.47)$$

ΔE is a free energy barrier for a conformational change of a segment, S_C is the total configurational entropy, and s^* is the configurational entropy related to such a rearrangement. The right-hand part of Eq. 12.47 corresponds to the original formulation of Adam and Gibbs theory (Adam and Gibbs 1965). The configurational entropy S_C can be related to the change of the specific heat capacity Δc_p at T_g by

$$S_c(T) = \int_{T_2}^{T} \frac{\Delta c_p}{T}\, dT. \qquad (12.48)$$

With $T_2 = T_0$ and $\Delta c_p \sim 1/T$, the VFT equation is obtained. At the Vogel temperature the configurational entropy vanishes, $z(T)$ diverges like $z(T) \sim (T - T_0)^{-1}$, but no information about the absolute size of a CRR can be obtained. The approach of Adam and Gibbs was extended by Donth (1992, 2001) to obtain the size of a CRR. Within a fluctuation model a formula was developed which allows to calculate a correlation length ξ (or volume V_{CRR}) from the height of the step in c_p and the temperature fluctuation δT of a CRR at T_g as

$$\xi^3 = V_{CRR} = \frac{k_B\, T_g^2 \Delta\left(1/c_p\right)}{\rho\,\delta T^2}, \qquad (12.49)$$

where ρ is the density and $\Delta(1/c_p)$ the step of the reciprocal specific heat capacity at the glass transition where $c_V \approx c_p$ was assumed. δT can be extracted experimentally from the width of the glass transition (Donth 1982; Schneider et al. 1981; Donth et al. 2001a, b). Within that approach the size of a CRR was estimated for several polymers to be in the range of 1 to 3 nm in accord with the above estimation. This corresponds to 10–200 segments (Hempel et al. 2000; Beiner et al. 1998b; Kahle et al. 1997).

12.3.2.2 Dielectric strength $\Delta\varepsilon_\alpha$

Generally, for the α-relaxation $\Delta\varepsilon_\alpha$ decreases with increasing temperature. This seems in accord with Eq. 12.11, but the experimental results show that the dependence is much stronger than predicted. Especially close to T_g the increase of $\Delta\varepsilon_\alpha$ with decreasing temperature is quite strong. It is clear that this increase of $\Delta\varepsilon_\alpha$ with decreasing temperature cannot be explained by the increase of the density with decreasing temperature. Also its modeling by a temperature-dependent g-factor remains formal because g was introduced to describe static correlations between dipoles like association. Apart from polymer a similar temperature dependence of $\Delta\varepsilon_\alpha$ was also observed for low-molecular-weight glass-forming materials (Schönhals 2001). It can be argued that this temperature dependence results from

Fig. 12.12 Dielectric loss versus temperature at fixed frequency of 10^4 Hz for *cis*-1,4-polyisoprene. The molecular weights are as follows: *circles*, 1,400 g mol^{-1}; *squares*, 3,830 g mol^{-1}; and *triangles*, 8,400 g mol^{-1}. *Lines* are guides for the eyes (The figure was adapted from Schönhals (1993))
an increasing influence of (intermolecular) cross-correlation terms to μ^2 with decreasing temperature. In other words the reorientation of a test dipole is influenced increasingly by its environment with decreasing temperature. This is in agreement with the cooperativity approach to the glass transition as discussed above.

12.3.2.3 Shape of the Relaxation Function

In general the α-process shows in the frequency domain a broad (the width ranges from two up to six decades depending on structure) and asymmetric peak. Generally, it is assumed that in contradiction to the β-process, the shape of the relaxation function of the dynamic glass transition is not related to a distribution of relaxation times due to local spatial heterogeneities. Rather this broad, asymmetric loss peak is an intrinsic feature of the dynamics of glass-forming systems.

12.3.3 Normal Mode Process

A dielectric normal mode process is observed only for polymers having a dipole moment in parallel to the chain backbone, the so-called type-A polymers like *cis*-1,4-polyisoprene or poly(propylene glycol). The resulting dipole moment is proportional to the end-to-end vector of the chain. Therefore, the normal mode relaxation is directly related to the overall chain dynamics. Figure 12.10 shows that the corresponding relaxation rate $f_{p,n}$ is always located at frequencies lower than that characteristic for the α-relaxation. $f_{p,n}$ depends strongly on the molecular weight of the polymer chain. Figure 12.12 shows the dielectric loss versus temperature at a fixed frequency for *cis*-1,4-polyisoprene for different molecular weights. While the low-temperature (high-frequency) α-relaxation shows only a weak dependence on the molecular weight M, the high-temperature peak caused by the normal mode process depends strongly on M.

Fig. 12.13 Relaxation rate versus inverse temperature for poly(propylene glycol) (M = 4,000 g/mol): *stars*, β-relaxation; *spheres*, α-relaxation; *squares*, normal mode relaxation. The *dashed line* is a fit of the Arrhenius equation to the data of the β-relaxation. The *solid lines* are fits of the VFT equation to the corresponding data
The temperature dependence of the relaxation rate for the normal mode process follows in a wide temperature range the VFT equation but with different parameters than for the α-relaxation.

For chains with a low molecular weight (unentangled case), the Rouse theory (Adachi and Kotaka 1993; Rouse 1953) can be employed to describe it because excluded volume effects and hydrodynamic interactions are screened out (de Gennes 1979).

For higher molecular weights (entangled case), in principle the reputation theory (de Gennes 1979; Doi and Edwards 1986) and its generalization (contour length fluctuations and/or constrained release) have to be used (Milner and McLeish 1998; Likhtman and McLeish 2002; Liu et al. 2006; Zamponi et al. 2006; Chávez and Saalwächter 2010). A more detailed discussion of the normal mode process is beyond this chapter. The reader is referred to the relevant literature (Adachi and Kotaka 1993; Schönhals 1993; Gainaru and Böhmer 2009; Abou Elfadl et al. 2010).

To conclude this section Fig. 12.13 gives the relaxation map where the relaxation rates for the different processes are plotted versus inverse temperature for poly (propylene glycol) with a molecular weight of 4,000 g mol^{-1}. While the temperature dependence of the β-relaxation follows the Arrhenius equation, the relaxation rates for both the α-process and the normal mode process are curved when plotted 1/T.

12.4   Dielectric Relaxation of Polymer Blends

12.4.1 General Consideration

The blend miscibility is governed by the free energy of mixing:

$$\Delta G_M = \Delta H_M - T\Delta S_M, \qquad (12.50)$$

where ΔG_M is the change in the Gibbs free energy of mixing. ΔH_M and ΔS_M denote the excess enthalpy and the mixing entropy. Mixing will take place for $\Delta G_M < 0$.

For polymers the contribution of the entropy of mixing ΔS_M to the free enthalpy of mixing ΔG_M is small. According to the lattice model of Flory/Huggins (Sperling 1986), ΔG_M is assumed to be

$$\Delta G_M = -k_B T \Delta S_M + \kappa \Phi_1 \Phi_2. \tag{12.51}$$

Here Φ_i are the volume fractions, N_i are the degrees of polymerization, and κ denotes the Flory/Huggins interaction parameter. For the entropy of mixing ΔS_M,

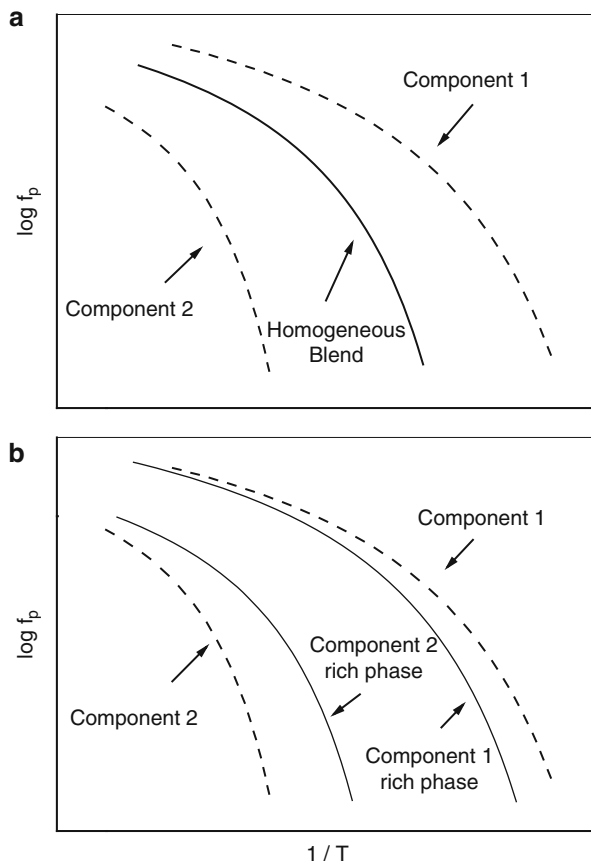
$$\Delta S_M = -\left[\frac{\Phi_1}{N_1}\ln\Phi_1 + \frac{\Phi_2}{N_2}\ln\Phi_2\right] \tag{12.52}$$

is assumed. Based on the principle of thermodynamics, the conditions for miscibility, the critical (solution) temperature for phase separation T_C, or the binodals can be calculated from Eqs. 12.51 and 12.52. In general the Flory/Huggins theory can be used to describe systems with an upper critical solution temperature. This means at temperatures above T_C, the two components are miscible on a molecular level, whereas below T_C phase separation occurs. The composition of these phases follows the binodal. That means even in the phase-separated state, a certain degree of mixing (depending on κ and on N_i) is observed which leads to a component 1 and to a component 2 rich phase. Systems with a lower critical solution temperature cannot be described by the Flory/Huggins theory.

Because for most systems the entropy of mixing is small, attractive interactions between both components are needed to obtain a homogeneous mixed state. In the opposite case miscible polymer blends for which $\kappa \approx 0$ (no or weak interactions) are called athermal blends.

In general the β-, the α-, and even the normal mode process will be modified in the case of miscible blends or in systems with partial miscibility. Only for completely phase-separated materials (as the limiting case), the relaxational characteristic of both compounds is fully maintained. The most sensitive process with regard to blending is the α-relaxation. Figure 12.14a shows the expected relaxation map for a miscible system. From the theoretical point of view, a single α-process should be observed which is located – depending on the composition – in between the traces obtained for each component. There are several models like the Flory/Fox or the Gordon/Taylor equation for the dependence of the glass transition temperature on the composition for a homogeneous blend which can be found in standard textbooks of polymer science (Sperling 1986; Strobl 1996). For more theoretical discussion see, for instance, reference Lu and Weiss (1992). A recent comparison is given in reference Brostow et al. (2008). Discussions in the frame of the self-concentration model (for a detailed discussion see below) are given in Lodge and McLeish (2000). This concerns also the Brekner equation (Brekner et al. 1988).

For a phase-separated blend with a partial miscibility, two α-processes will be observed where the location of both processes depends on the composition of both

Fig. 12.14 Schematic representation (relaxation map) of the temperature dependence of the rate of the α-relaxation for a binary polymeric blend: (**a**) theoretical expectation for a molecular miscible blend. (**b**) A blend with a partial miscibility of the two components


phases (see Fig. 12.14b). Therefore, dielectric spectroscopy is expected to provide valuable information on the local fluctuations of concentrations and on the local miscibility.

Therefore, dielectric spectroscopy can be used to detect and to define criteria of miscibility on a molecular level (Zetsche et al. 1990) by studying the dynamic glass transition. Moreover, both components of a blend will have different polarities in general. One component can be dielectrically more visible than the other one. In the limiting case one component can be dielectrically invisible (Zetsche et al. 1990). Extending this idea by blending a type-A and a type-B polymer, the overall chain dynamics can be studied only for the polymer of type A employing dielectric spectroscopy. Taking advantage from the fact that the chain dynamics of type-B polymer is dielectrically invisible, one can raise the question how the chain motion of the type-A polymer is influenced by the second component. The normal mode relaxation senses a larger length scale than the segmental one, so information about composition fluctuations on different length scales can be deduced. This was discussed, for instance, for blends of polybutadiene and *cis*-1,4-polyisoprene

(Adachi and Kotaka 1993; Adachi et al. 1995; Poh et al. 1996), polystyrene and *cis*-1,4-polyisoprene (Se et al. 1997), *cis*-1,4-polyisoprene and poly(vinyl ethylene) (PVE) (Hirose et al. 2003), or poly(n-butyl acrylate) and poly(propylene glycol) (Hayakawa and Adachi 2000a, b).

Concerning the localized β-relaxation, it was found if the interaction of the two components are weak (athermal blends) the effect of blending on this relaxation process is small (see, for instance, Schartel and Wendorff 1995; Pathmanathan et al. 1986; Cendoya et al. 1999; Urakawa et al. 2001; Dionissio et al. 2000). These dielectric results are also in agreement with quasielastic neutron scattering investigations (Arbe et al. 1999) and are probably a consequence of the rather small length scale (localized fluctuations) of motions involved in these processes. This is further discussed also in reference Fischer et al. (1985).

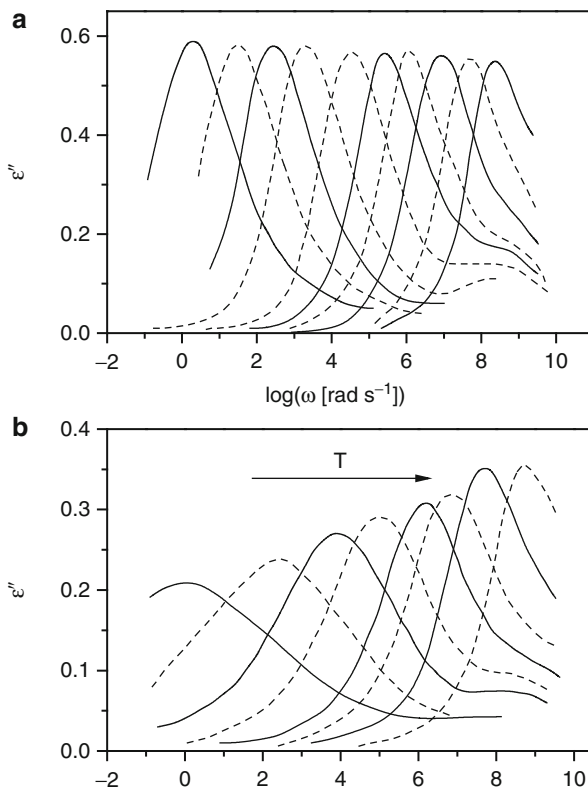
12.4.2 Miscible Polymeric Blends

12.4.2.1 Dynamic Glass Transition: Experimental

There is a considerable large literature body concerning the dielectric relaxation of binary polymer blends especially in the temperature range of the dynamic glass transition (see, for instance, Floudas et al. 2011; Colmenero and Arbe 2007; Zetsche et al. 1990; Adachi et al. 1995; Poh et al. 1996; Se et al. 1997; Hirose et al. 2003; Schartel and Wendorff 1995; Dionissio et al. 2000; Arbe et al. 1999; Wetton et al. 1978; Alexandrovich et al. 1980; Miura et al. 2001; Rellick and Runt 1986a, b, 1988; Angeli and Runt 1990; Alvarez et al. 1997; Hoffman et al. 2002; Cangialosi et al. 2005, 2006; Alegria et al. 2002; Leroy et al. 2002, 2003; Lorthioir et al. 2003; Schwartz et al. 2007a, b; Jin et al. 2004; Ngai and Roland 2004; Watanabe et al. 1991, 1996; Urakawa et al. 1993a, b, 2006; Katana et al. 1995, 1993, 1992; Zetsche and Fischer 1994; Karatasos et al. 1998; Sy and Mijovic 2000; Roland et al. 2006; Zhang et al. 2005; Mpoukouvalas et al. 2005; Pathak et al. 1999; Krygier et al. 2005).

Broadening of the Relaxation Spectrum

It is known for a long time (Wetton et al. 1978) that the relaxation function measured for a miscible blend is considerably broadened compared to the spectra of the pure polymers (Colmenero and Arbe 2007). To be more precise the broadening is more or less symmetric. As an example this is shown for a miscible blend of polystyrene (PS) and poly(vinyl methylether) (PVME) in Fig. 12.15 (Colmenero and Arbe 2007; Katana et al. 1992; Zetsche and Fischer 1994). Compared to PVME the dipole moment of PS is weak, and therefore, the contribution of PS to the dielectric loss of the blend is negligible. In other words the fluctuations of PVME are selectively monitored by dielectric spectroscopy, whereas the fluctuations of the PS segments are dielectrically invisible. For the blend (see Fig. 12.15b), the loss peak is much broader than that for the single component PVME (see Fig. 12.15a). Moreover, the loss peak narrows as temperature increases. For the PVME/PS blend system, it was proven by a combination

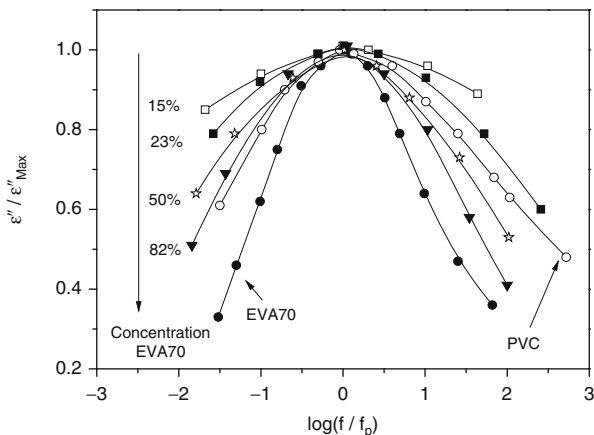
Fig. 12.15 Dielectric loss for the PVME/PS blend at a composition of 65 % PVME/35 % PS. (**a**) Dielectric loss versus frequency for pure PVME: (T = 253 K, 258 K, 263 K, 268 K, 278 K, 288 K, 298 K, 308 K, 328 K, 348 K). (**b**) Dielectric loss versus frequency for PVME/PS blend: (T = 263 K, 273 K, 283 K, 293 K, 308 K, 318 K, 338 K, 368 K) (Data were taken from reference Cendoya et al. (1999))


of dielectric, NMR, and quasielastic neutron scattering investigations using deuterated polystyrene that the shape of the relaxation function is similar to that of the corresponding homopolymer at high temperatures (Colmenero and Arbe 2007).

The broadening of the dielectric spectra for miscible polymer blends is not only observed for the PS/PVME system. This further demonstrated by Fig. 12.16 where the normalized dielectric loss is plotted for a blend poly(ethylene-co-vinyl acetate) (EVA70, 70 % vinyl acetate) with poly(vinyl chloride) (PVC). With increasing concentration of PVC in the blend, the loss peak systematically broadens in comparison to that of both components (Rellick and Runt 1988).

The broadening of the dielectric spectra has to be considered as an intrinsic feature of the dielectric properties of miscible blends. Moreover, the broadening of the α-relaxation increases with the difference of the glass transition temperatures.

A phenomenological treatment is most simple if one component is dielectrically more or less invisible as it is the case for polystyrene. In this case the broadening of the loss peak can be described by a distribution function $\widetilde{c}$ in the sense of Eq. 12.27:

Fig. 12.16 Normalized
dielectric loss versus
normalized frequency for the
blend system
EVA70/PVC. Parameter is
the concentration of EVA70
in the blend as indicated.
Lines are guides for the eyes
(Data were taken from
reference Rellick and Runt
(1986b))


$$\varepsilon''_{\text{Blend}}(\omega) = \int_0^\infty \widetilde{c}(\tau)\, \varepsilon''_{\text{Vis}}(\omega\tau)\, d\tau. \tag{12.53}$$

$\varepsilon''_{\text{Vis}}(\omega)$ is the relaxation function of the dielectrically visible component of the blend. Clearly $\widetilde{c}$ should be related to the molecular structure of the miscible blend. Equation 12.53 is derived under the assumption that the "live time" of $\widetilde{c}$ is much longer than the longest relaxation time for the α-relaxation. Often $\widetilde{c}$ is assigned on a molecular level to temperature-driven composition fluctuations (Katana et al. 1995; Zetsche and Fischer 1994) which will be discussed in detail later.

Adachi et al. (Hayakawa and Adachi 2000b) suggest the following formula for the complex dielectric function of a miscible blend:

$$\varepsilon*_{\text{Blend}}(\omega) = \Phi_1 \varepsilon*_1 \left(\frac{\zeta_{\text{Blend}}}{\zeta_1}\omega \right) + \Phi_2 \varepsilon*_2 \left(\frac{\zeta_{\text{Blend}}}{\zeta_2}\omega \right), \tag{12.54}$$

where $\varepsilon*_i$ are the complex dielectric function of pure components and ζ_i the corresponding monomeric friction coefficients (for definition see Ferry 1980; Sperling 1986; Strobl 1996). This formula is firstly based on the idea that the dipole moment of the mixture is a weighted sum of the dipole moments of each component. Secondly, the segmental mobility in the blend can be described by a common friction coefficient ζ_{Blend}. According to this assumption the segmental relaxation time τ_i for the pure component i has to be changed to $\tau_i \frac{\zeta_{\text{Blend}}}{\zeta_i}$. For the friction coefficient of the blend ζ_{Blend},

$$\ln \zeta_{\text{Blend}} = \Phi_1 \ln \zeta_1 + \Phi_2 \ln \zeta_2 + k\Phi_1\Phi_2 \tag{12.55}$$

was suggested. k is a parameter which characterizes the interaction between the two components. Please note that the k parameter can be different from the Flory/Huggins interaction parameter. This model can also qualitatively describe experimental results (Hayakawa and Adachi 2000a, b).

Fig. 12.17 Dielectric loss versus frequency at 270 K for the PVE/PI blend at a composition of 50 % PVE/50 % PI. *Circles*, pure PVE; *squares*, pure PI; *stars*, blend PVE/PI. *Lines* are estimated contributions of the dynamic glass transition (Data were taken from reference Arbe et al. (1999))
Dynamic Heterogeneity

For the simple theoretical approach outlined in Fig. 12.14a, one should expect that for a blend which is fully miscible on a molecular level, only a single relaxation process with a single average relaxation rate (or time) should be observed. In other words this would correspond to a single average $<T_g>$ measured by DSC. Figure 12.17 gives the dielectric spectra of poly(vinyl ether) (PVE) and *cis*-1,4-polyisoprene (PI) together with results for the blend PVE/PI (50 %/50 %) according to reference Arbe et al. (1999). For the PVE/PI system both components are dielectrically visible. For the blend a two peak structure is observed. It is worth to point out that this double peak structure is observed independently of the already discussed broadening of the α-relaxation peak. That was proven by quasielastic neutron scattering investigations where both components of the blend were selectively deuterated (Hoffman et al. 2000). This effect observed for a variety of miscible binary polymer blends and is called "dynamic heterogeneity."

Further evidence for the dynamical heterogeneity in miscible polymer blend was provided by a combination of DSC and TSC measurements. While DSC is sensitive to the molecular dynamics of the whole blend, TSC monitors selectively the molecular fluctuations of the polar component. Figure 12.18 compares the temperature dependence of specific heat capacity with that of the depolarization current for the blend system PVME/PS (Leroy et al. 2002). For the polar component PVME, the peak in the TSC curve collapses with the midpoint of the steplike change of the specific heat capacity usually taken as thermal glass transition temperature. This indicates that both methods sense the same process which is the molecular fluctuation of PVME segments responsible for the glass transition. For the blend a broad DSC trace is observed but with a single step in the specific heat capacity indicating miscibility. In difference to the thermal data, the TSC peak is observed at essential lower temperatures. This means the effective ("local") $T_{g,eff}$ due to the polar PVME segments is observed at much lower temperatures than the overall T_g ($<T_g>$) of the blend and proves that an $T_{g,eff}$ different from $<T_g>$ exists (Leroy et al. 2002).

Fig. 12.18 Comparison of DSC and TSC measurements for pure PVME (*dashed lines*) and a PVME/PS (*solid lines*) at a composition of 50 % PVME/50 % PS. *Dotted vertical lines* indicate the glass transition temperatures (Data were taken from reference Leroy et al. (2002))
In reference Leroy et al. (2002), this was investigated for three different blend systems. Also Lodge and coworkers evidenced the existence of two different glass transitions in miscible blends by DSC measurements alone (Lodge et al. 2006) or by a combination of DSC and TSC investigations (Herrera et al. 2005). A similar conclusion was provided by a combination of dielectric spectroscopy with adiabatic calorimetry (Sakaguchi et al. 2005) or employing temperature-modulated DSC (Miwa et al. 2005). Results provided in reference Schwartz et al. 2007b can be discussed in the same direction. In conclusion, besides the broadening of the relaxation spectrum, the dynamic heterogeneity must be considered as the second main feature of the (dielectric) properties of miscible blends.

Kirkwood/Fröhlich Correlation Factor

In Sect. 12.2.2.1 the Kirkwood/Fröhlich correlation factor g as a measure of static correlations between dipoles is introduced and discussed (see Eq. 12.14). It seems to be an interesting question in which way g is changed in miscible blends. Data are provided, for instance, in references Wetton et al. (1978), Alexandrovich et al. (1980), and Malik and Prud'homme (1984) using Eq. 12.14. As a result it was observed that the g parameter is only weakly affected by blending

(Alexandrovich et al. 1980; Rellick and Runt 1986b) in the whole considered concentration range. This means the conformation of segments was not significantly changed in the blend. Runt et al. (Rellick and Runt 1986b) derived an equation to assess the effect on blending on the g-factor relative to the unblended state:

$$g_{Blend} = 9\varepsilon_0 k_B T \, \frac{\frac{\Delta\varepsilon \, (2\varepsilon_s + \varepsilon_\infty)}{n\,\varepsilon_S}}{g_1 n_1 \mu_1^2 \left(\varepsilon_\infty^1 + 2\right)^2 + g_2 n_2 \mu_2^2 \left(\varepsilon_\infty^2 + 2\right)^2}, \qquad (12.56)$$

where subscript i indicates the component, n the overall dipole density in the blend, and n_i the mole fraction of the component i in the blend. The numerator is the effective squared dipole moment in the blend where the denominator was obtained by a linear combination of the dielectric properties of the blend. Then g_{Blend} is a measure of the polarization of the blend with respect to an unblended environment (Rellick and Runt 1986b; Angeli and Runt 1989).

12.4.2.2 Dynamic Glass Transition: Theoretical Models

Most researchers will agree that the molecular fluctuations of a segment i of a polymer "A" in binary blend are controlled by the local composition ϕ_i in some volume around that segment. This local concentration which is different from the macroscopic blend composition will give rise to a relaxation time τ_i which is different from the mean relaxation time. In general we have a distribution of different environments having different compositions ϕ_i which will lead to a distribution of relaxation times and hence results in a broadening in the loss curve. A further consequence of this distribution at a segment i is a distribution of local T_g.

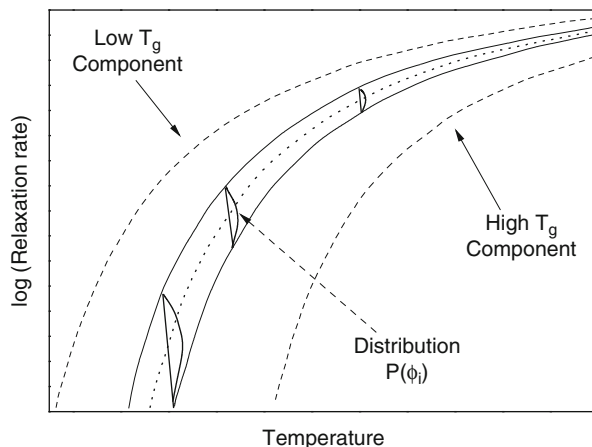
One approach to model this effect is based on the coupling scheme of Ngai et al. (Roland and Ngai 1991, 1992a, b). In this scheme a so-called coupling parameter determines the shape of the relaxation function. In its application to blends, the local concentrations ϕ_i lead to a distribution of the coupling parameter which will consequently cause a broadening of the relaxation function.

Besides the coupling model two other groups of model have been developed during the last 15 years: the model of "temperature-driven composition fluctuations" at the one side and the idea of "self-concentration" on the other side.

Temperature-Driven Concentration Fluctuations (TCF)

The idea of temperature-driven concentration or composition fluctuation traces back to Karazs et al. (Wetton et al. 1978). One of the first models was developed by Fischer et al. (Katana et al. 1995; Zetsche and Fischer 1994). This work was further extended in several directions by Kumar and Colby et al. (Salaniwal et al. 2002; Kamath et al. 2003a, b, 1999; Kumar et al. 1996, 1999; Kant et al. 2003).

The temperature-driven concentration fluctuation approach is based on the following assumptions (see Fig. 12.19):

Fig. 12.19 Scheme of the temperature-driven concentration fluctuation approach to binary miscible blends


1. The sample is divided into i subcells of the volume V having a composition ϕ_i and thus a local glass transition temperature $T_g^i(\phi_i)$.
2. A distribution $P(\phi_i)$ of the composition ϕ_i is introduced. This will lead to a distribution of relaxation times and also a distribution of the local glass transition temperatures $T_g^i(\phi_i)$. In the approach by Fischer et al. (Katana et al. 1995; Zetsche and Fischer 1994), $P(\phi_i)$ was assumed to be Gaussian with a variance $<(\delta\phi)^2>$. In this model $<(\delta\phi)^2>$ is the only adjustable parameter. Extending this model non-Gaussian distributions have been also discussed, for instance, by Kumar (Kumar et al. 1996).
3. The system is incompressible which means that density fluctuations do not exist.
4. The lifetime of the composition fluctuations is much longer than the longest relaxation time for the α-relaxation.

One open point in the discussion untill now is the size of the volume V. Usually it is assumed that V is related to the cooperatively rearranging region (CRR, $V \sim V_{CRR}$, see discussions above) characteristic for the glass transition. It can be estimated taking advantage from the fact that for a Gaussian distribution $P(\phi_i)$ V should be inversely proportional to $< (\delta\phi)^2 >$ ($V \sim < (\delta\phi)^2 >^{-1}$). A quantification can be done by assuming the CRR to be spherical and relating $<(\delta\phi)^2>$ to the static structure factor S(Q) in the same way as it was proposed by Ruland for density fluctuations (Ruland 1957). This approach is based on the random phase approximation (de Gennes 1979). In reference Katana et al. (1995), a comparison is made between the values estimated from that approach and the V_{CRR} calculated from the fluctuation approach by Donth (see Eq. 12.49). The data are in the same order of magnitude but do not agree quantitatively.

The TCF models are able to describe the broadening of the relaxation function as temperature approaches the average glass transition temperature $<T_g>$. It can be also seen from Fig. 12.19 that the extra-broadening due to blending decreases with increasing temperature. The main problem of that approach is the fact that these

models have no explanation for the heterogeneous behavior. Moreover, the estimated length scales for glass transition $\xi \sim V_{CRR}^{1/3}$ grow too strongly as temperature decreases towards $<T_g>$ and can become larger than 10–20 nm. This is much too large than expected for the glass transition. A more detailed discussion can be found, for instance, in reference Colmenero and Arbe (2007).

Self-Concentration Models (SC)

The idea of self-concentration in polymer blends was mainly developed by Lodge and McLeish (2000) based also on earlier works of Kornfield et al. (Chung et al. 1994a, b). For reviews in relation to dielectric spectroscopy, see, for instance, references Colmenero and Arbe (2007) and Maranas (2007). The basic idea is that due to chain connectivity the average composition in local environment around any selected segment is enriched in the same kind of segments (correlation hole effect). In consequence this will lead to different average relaxation times for the segment of the two components in the blend and hence each component will sense its own glass transition temperature which is of course composition dependent. For this reason the self-concentration can account for the heterogeneity effects in the dynamic of polymer blends.

In the formulation of Lodge and McLeish (2000) (LM model) for a binary blend with the components i (i = 1,2), the effective concentration is

$$\phi_{eff}^i = \phi_{self}^i + \left(1 - \phi_{self}^i\right) < \phi > , \qquad (12.57)$$

where $<\phi>$ is the overall macroscopic composition of the blend. Because of the chain connectivity, the relevant intramolecular length scale to estimate the self-concentration is the Kuhn segment length l_k (Strobl 1996) which is only weakly temperature dependent. The self-concentration can be estimated from the volume fraction due to monomers in a volume spanned by the Kuhn length $(V_k \sim l_k^3)$ as

$$\phi_{self} = \frac{C_\infty M_0}{k \rho N_A V_K}, \qquad (12.58)$$

where C_∞ is the characteristic ratio, ρ density, M_0 the molar mass of the repeating unit, N_A Avogadro number, and k counts the number of backbone per repeating unit. The effective glass transition temperature is defined as

$$T_{g,eff}^i = <T_g> \left(\phi = \phi_{eff}^i\right). \qquad (12.59)$$

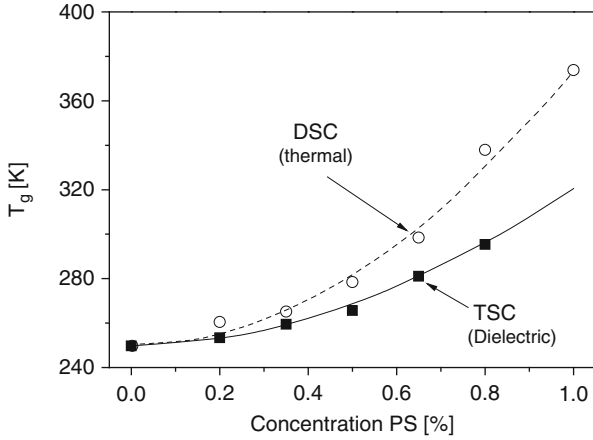
Besides the self-concentration the Lodge and McLeish model assumes further that the composition of the volume V is similar to the macroscopic one. Basically this means that one distribution of relaxation times (or T_g) is involved. The LM model treats in contradiction to the TCF approach only mean values. But it is interesting to note that also self-concentration effects decreases with increasing temperature.


Fig. 12.20 Glass transition temperatures for the blend system PVME/PS versus the concentration of PS. The *open spheres* are data measured by DSC indicating the macroscopic T_g of the sample. The *solid squares* are data measured by TSC for the dielectrically visible component PVME. The *dashed line* is a fit of the Brekner equation to the DCS data. The *solid line* corresponds to the prediction of the LM model according to Eq. 12.61 (Data were taken from reference Rellick and Runt (1986))

In Fig. 12.20 the DSC and TSC data for the blend system PVME/PS discussed in Fig. 12.18 are analyzed in the framework of the LM model (for details see reference Leroy et al. 2002). The glass transition temperature of the blend measured by DSC is described by the Brekner formula (Brekner et al. 1988):

$$T_g(\phi^2) = T_g^1 + \left(T_g^2 - T_g^1\right)\left[(1 + K_1)\phi^2 - (K_1 + K_2)(\phi^2)^2 + K_2(\phi^2)^3\right].$$
(12.60)

ϕ^2 is the blend concentration of the polymer with the higher T_g value, and T_g^i (i = 1,2) are the glass transition temperatures of the pure polymers. K_1 and K_2 are fitting constants. By combining Eqs. 12.57, 12.59, and 12.60 according to Lodge and McLeish (2000), the glass transition temperature for the individual components can be estimated. For the component with the higher T_g^2, one obtains

$$T_{g,\,eff}^2(\phi^2) = T_g^1 + \left(T_g^2 - T_g^1\right)\left[(1 + K_1)\phi_{eff}^2 - (K_1 + K_2)(\phi_{eff}^2)^2 + K_2(\phi_{eff}^2)^3\right].$$
(12.61)

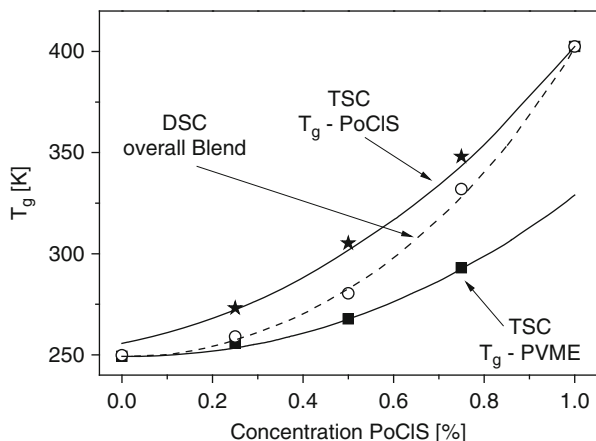
An analogous equation can be obtained for T_g^1. For details see reference Leroy et al. (2002). Figure 12.20 reveals a remarkably good agreement between the experimental data and the predictions of the LM model.


Fig. 12.21 Glass transition temperatures for the blend system PVME/PoClS versus the concentration of PoClS. The *open spheres* are data measured by DSC indicating the macroscopic T_g of the sample. The *solid squares* are data measured by TSC for PVME, whereas the stars are TSC data measured for PoClS. The *dashed line* is a fit of the Brekner equation to the DCS data. The *solid line* corresponds to the prediction of the LM model for both the low and the high glass transition temperature component (Data were taken from reference Leroy et al. (2002))

The same approach was also applied by Colmenero et al. to poly (vinyl methylether) blended with poly(o-chlorostyrene) (PoClS) (Leroy et al. 2002). The difference to the PVME/PS is that in the case of PVME/PoClS system, both components are polar and therefore dielectrically visible. Figure 12.21 shows the results for this system also obtained by a combination of DSC and TSC investigations. Again a good agreement with the LM model is obtained.

The self-concentration model by Lodge and McLeish can be also employed to describe the relaxation map of a miscible blend system. In reference Mpoukouvalas and Floudas (2008), Floudas et al. report dielectric data for the miscible blend poly (methyl methacrylate) (PMMA) and poly(ethylene oxide) (PEO) (see Fig. 12.22). As expected, with increasing concentration of PEO the relaxation rates shifts to lower temperatures. The data can be modeled by assuming the Vogel temperature T_0 in the VFT equation (see Eq. 12.45) to be dependent on the effective concentration according to Eq. 12.57:

$$-\log f_p^i = \log \tau^i(\phi_{eff}, T) = \log \tau_\infty^i + \frac{A^i}{T - T_0^i(\phi_{eff})}, \qquad (12.62)$$

where A^i and τ_∞^i are the VFT parameters for the two components. In this approach only the Vogel temperature depends on composition according to
Fig. 12.22 Temperature dependence of the relaxation times of the segmental dynamics (α-relaxation) for the blend system PMMA/PEO at the indicated concentrations: *solid squares*, PMMA; *solid circles*, PEO. The *solid lines* correspond to fits of the VFT equation to the data of the pure polymers. The *dashed lines* are due to fits of the LM model with the Kuhn lengths for PMMA as adjustable parameter ($l_k = 1.62$ nm, theoretical value 1.38 nm) (Data were taken from reference Mpoukouvalas and Floudas (2008). The concentration dependence of the whole blend was described by the Fox/Flory equations. For details see also reference Mpoukouvalas and Floudas (2008))

$$T_0^i(\phi_{eff}) = T_0^i + \left[T_g^i(\phi_{eff}) - T_g^i \right], \tag{12.63}$$

where T_0^i are the Vogel temperatures of the pure polymers and $T_0^i(\phi_{eff})$ the value of the Vogel temperature for the polymer i in the blend. As Fig. 12.22 shows this approach can reasonably describe the segmental dynamics of PMMA in the blend PMMA/PEO under the condition that l_k is adjusted to 1.62 nm which is larger than the theoretical value of 1.38 nm (Mpoukouvalas and Floudas 2008). This means, the self-concentration approach covers some intrinsic features of the molecular dynamics in polymer blends. A better agreement can be obtained by adjusting l_k for each blend composition.

As discussed above the self-concentration idea is able to describe one essential experimental fact of the molecular dynamics of polymer blends, the dynamic heterogeneity. But nevertheless there are some strong problems of this approach which are discussed in detail in reference Colmenero and Arbe (2007). Here only the main arguments are summarized:

1. The most important drawback of the self-concentration approach is the fact that the model cannot describe the broadening of the relaxation function induced by blending. Attempts to combine the self-concentration idea with that of temperature-driven composition fluctuations are discussed, for instance, in reference Leroy et al. (2003) and more recently in Shenogin et al. (2007).

2. In the original version of the LM model, ϕ_{self}^i is assumed to be independent of temperature that is found in some cases. But in other cases the data can be only described allowing ϕ_{self}^i to be temperature dependent. This concerns also the relevant length scale ξ, which is in the LM approach the Kuhn length known to be only weakly temperature dependent. Experimentally it was motivated that ξ could be dependent on temperature (Colmenero and Arbe 2007) as well as on pressure (Mpoukouvalas and Floudas 2008). This length scale can be also dependent on the composition and the components (Lutz et al. 2005; He et al. 2003).

Combination of the Self-Concentration Approach with the Adam/Gibbs Theory

In the framework of the Adam and Gibbs theory, the temperature-dependent size of a CRR is related to the spatial extent of cooperative segmental fluctuations at the dynamic glass transition. For polymer blends the effect of chain connectivity depends on temperature and can be less or more pronounced. Therefore, the assumption of a temperature-dependent CRR has some consequences for the relevant length scale responsible for glassy dynamics. Recently the approach of self-concentration was combined with the theory of Adam and Gibbs to the glass transition (Cangialosi et al. 2005). Two essential assumptions are made. Firstly, the systems should behave athermal – this means that thermodynamic quantities are additive according to the composition. Secondly, both the configurational entropy S_C and the constant C (see Eq. 12.47) are assumed to be depend on the effective concentration according to Eq. 12.57:

$$S_C^{1/Blend} = \phi_{eff}^1 S_C^1 + \left(1 - \phi_{eff}^1\right)S_C^2; \quad C^{1/Blend} = \phi_{eff}^1 C^1 + \left(1 - \phi_{eff}^1\right)C^2. \quad (12.64)$$

It is worth to note that $S_C^{1/Blend}$ and $C^{1/Blend}$ are related to a region (radius r_C) centered around a segment of the polymer 1 relevant to the dynamics of the α-relaxation. (Similar equations can be written down for polymer 2).

Depending on the value of r_C with respect to the Kuhn length l_k, the self-concentration can be estimated using simple geometrical arguments to

$$\phi_{self} = \frac{l_k l_P}{2\pi r_C^2} \quad \text{for } r_C < l_k \quad \text{and} \quad \phi_{self} = \frac{3l_P}{2\pi r_C} \quad \text{for } r_C > l_k. \quad (12.65)$$

l_P is a packing density. In the Adam/Gibbs approach, the number of correlated segments is proportional to S_C^{-1}. Therefore, r_C can be related to the configurational entropy by $r_C = \alpha S_C^{-1/3}$ where α is a constant which can be obtained in principle by fitting experimental data. With that the self-concentration can be expressed by the configurational entropy:
Fig. 12.23 Relaxation time versus temperature for the blend system PS/PoClS: *open circles*, pure PS (molecular weight 700 g/mol); *triangles*, 25 % PoClS; *squares*, 50 % PoClS; *stars*, 75 % PoClS; *open squares*, pure PoClS. The *solid lines* are fits of the combined Adam/Gibbs – self-concentration approach as described in the text. The *dashed lines* are fits of the Adam and Gibbs model to the data of the pure components. For details see reference (Data were taken from reference Cangialosi et al. (2005))

$$\phi_{\text{self}} = \frac{l_k \, l_P}{2\pi \, \alpha^2} S_C^{2/3} \quad \text{for } r_C < l_k \quad \text{and} \quad \phi_{\text{self}} = \frac{3 l_p}{2\pi \, \alpha} S_C^{1/3} \text{ for } r_C > l_k. \tag{12.66}$$

To apply this approach to experimental data, several further assumptions have to be made: (1) the prefactor for the temperature dependence of the relaxation times or rates of the blends is similar to that of the pure components, (2) the configurational entropy S_C is expressed by the excess entropy $S_C \sim S_{\text{Ex}} = S^{\text{Melt}} - S^{\text{Crys}}$ where Eq. 12.64 applies also for S_{Ex}, and (3) the contribution of the vibrations to the excess entropy is similar for the two components in the blend. Under these assumptions the temperature dependence of the relaxation times for the blends can be described for several systems. This is demonstrated in Fig. 12.23 for the blend system PS/PoClS (Cangialosi et al. 2005).

This approach was further extended in reference Cangialosi et al. (2007) to estimate the absolute size of a CRR. Therefore, the parameter α has to be obtained quantitatively. As a result for a variety of polymers, the size of a CRR was found to be between 1 nm and 3 nm at the glass transition. These numbers are in agreement with the fluctuation approach by Donth (Donth et al. 2001b; Hempel et al. 2000; Beiner et al. 1998; Kahle et al. 1997) as well as with more recent theories using approximations of higher order correlation functions (Berthier et al. 2005; Dalle-Ferrier et al. 2007).

Fig. 12.24 Scheme of the dynamics of dynamic asymmetric blends
12.4.2.3 Dynamically Asymmetric Polymer Blends: Confinement Effects

Besides the dynamic heterogeneity discussed above, binary miscible polymer blends can be considered as dynamically asymmetric if the two components have a large difference in the glass transition temperatures. Usually the dynamic asymmetry is defined by $\Delta = \tau^{1/Blend}/\tau^{2/Blend}$ where $\tau^{i/Blend}$ is the relaxation time of the component i in the blend and 1 is the polymer with the higher glass transition temperature (Colmenero and Arbe 2007). It becomes clear from Fig. 12.19 that the dynamic asymmetry decreases with increasing temperature.

Figure 12.24 gives schematically the relaxation map for the α-relaxation of a polymer blend where the two components have a large difference in their glass transition temperatures. The solid lines indicate the behavior of the pure polymers where the dashed lines correspond to the heterogeneous dynamics of miscible blends which can be estimated by the LM model. It becomes clear from Fig. 12.24 that the dynamic asymmetry Δ is small and both blend components behave as expected. With decreasing temperature Δ increases strongly and the segmental dynamics of the polymer 1 (component in the blend with the higher T_g) slows more and more down. This will have some implications onto the dynamics of the component 2 having a lower T_g. These segments have to fluctuate in a kind of more and more frozen environment built by the segments of the component 1 which will act as a rigid confinement. As it is known for low-molecular-weight glass formers and polymers confined to nanoporous glasses (Zorn et al. 2002; Schönhals et al. 2005), polymer segments embed between liquid crystalline structures (Turky et al. 2012), as well as water intercalated in the intergalleries of clays (Swenson et al. 2001) or in pores (Gallo 2000), such a confinement will lead to a crossover from a VFT behavior at high-temperature behavior to an Arrhenius-like dependence at low temperatures because of the fact that the molecular fluctuations become localized due to the confinement relative to that what is expected for the confined state. According to Fig. 12.24 this is also expected for dynamically asymmetric blends.

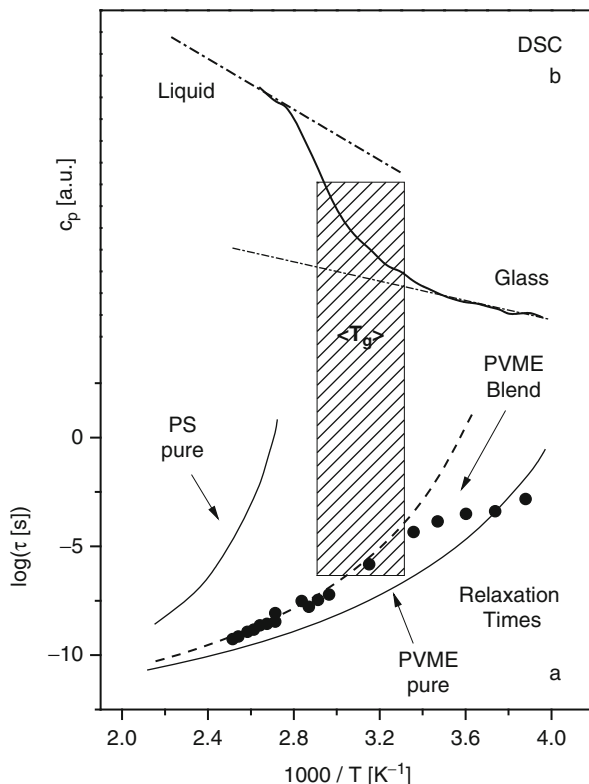
Fig. 12.25 Result for the dynamic asymmetric blend PS/PVME at a composition 80 %/20 %. *Lower panel*: *solid spheres*, dielectric data; *dashed line*, temperature dependence of the relaxation times expected for PVME in the blend; *solid lines* indicate the temperature dependence of the relaxation times for the pure components. *Upper panel*: temperature dependence of the heat capacity measured by DSC (All data were taken from reference Cendoya et al. (1999))


Figure 12.25a shows dielectric results for the blend system PVME (T_g = 249 K)/PS (T_g = 373 K) at a composition of 20 % PVME/80 % PS which is rich in the component with the higher T_g PS (see reference Cendoya et al. 1999). Due to the low dipole moment of PS, it is dielectrically invisible in the blend and only the segmental dynamics of the low T_g component PVME is dielectrically monitored. It is evident from Fig. 12.25a that the temperature dependence of the PVME segments in the blend is curved and follows the VFT equation. In the broad range of the glass transition of the whole blend measured by DSC (see Fig. 12.25b), this VFT temperature dependence crosses over to an Arrhenius-like behavior which is fully developed at even lower temperatures. Because of the fact that the blend is rich in PS, the DSC measurement monitors mainly the glass transition of polystyrene. This fact implies that the crossover in the temperature dependence of PVME is really due to the freezing of the PS segments. In the same temperature range also characteristic deviations in the temperature dependence of the forward scattering intensity S(Q→0) obtained from small angle neutron scattering from the predictions of the random phase approximation are observed for the same system (Koizumi 2004). These deviations are consistent with the formation of a gel-like structure due to the freezing of the PS segments.

Similar results have been also reported by Adachi et al. (Urakawa et al. 2002) for PVME/PS, for the blend PMMA/PEO (Maranas 2007), or for blends of PVDF/PMMA (Sy and Mijovic 2000). Besides dielectric spectroscopy quasielastic neutron scattering is found to be quite useful to investigate the molecular dynamics of dynamic asymmetric polymer blends because spatial information is provided by this technique (see, for instance, Tyagi et al. 2006, 2007). For a more detailed discussion, the reader is referred to the literature (Colmenero and Arbe 2007).

Besides of the segmental dynamics also the chain dynamics in blends is affected by the dynamical asymmetry (Brodeck et al. 2010). Recently a generalized Langevin approach was presented to calculate the chain (Rouse dynamics) for dynamically asymmetric blends (Colmenero 2013). A further discussion is beyond the scope of this chapter.

12.4.2.4 Dielectric Relaxation of Blends Under Pressure

Besides temperature pressure is an important quantity. Moreover, from the applicative point of view, pressure has a direct implication in processing. From the point of basic research, the properties and the thermodynamics of polymer blends are often discussed assuming incompressibility (properties are unaffected of pressure) like in the random phase approximation (de Gennes 1979; Binder 1994) or in the approach of temperature-driven concentration fluctuations (Katana et al. 1995). The effect of pressure on the dielectric properties of blends has been intensively discussed by Floudas et al. (Floudas et al. 2011; Floudas 2003) and is also reviewed in reference Roland et al. (2005). On the one hand as a general result, the assumption of incompressibility seems to be in contradiction to the results obtained by dielectric spectroscopy under pressure (Floudas et al. 2011) as it was also found by other methods in reference Beiner et al. (1998a). Moreover, pressure can increase or decrease miscibility. But one has also to consider that the number of dielectric relaxation studies under pressure is quite limited and different (partly contradictory) results have been found (see discussion in reference Roland et al. 2005). From the experimental point of view, this indicates that the influence of pressure on the molecular dynamics is complex and that more experimental studies should be carried out. Theoretical approaches have been pioneered by Rabeony et al. (Rabeony et al. 1998), by Kumar (Kumar 2000), and by Lipson et al. (lattice-based equation of state) (Lipson et al. 2003, 1998; Tambasco et al. 2006). Recently Colmenero et al. (Schwartz et al. 2007) combined the approach of Adam and Gibbs with the idea of self-concentration as described above by considering also pressure. For the PVME/PS blend system, this approach can describe the temperature dependence of the dielectric relaxation times measured under the different pressures (Schwartz et al. 2007).

12.4.3 Immiscible Blends

Immiscible blends are inhomogeneous systems. For dielectric spectroscopy this fact – like for semicrystalline polymers – has several implications: Firstly,

appropriate mixing rules for the dielectric permittivity have to be applied. For a completely phase-separated structure and if the two components having approximately the same dipole moment in the most simplest case, one can write for the dielectric function of the blend to

$$\varepsilon*_{Blend}(\omega) = \Phi_1 \varepsilon_i^*(\omega) + \Phi_2 \varepsilon_2^*(\omega). \qquad (12.67)$$

However, in most cases a limited miscibility (depending on N_i and κ) (see Eq. 12.52) is observed leading to two phases enriched in one component which can be described by a concentration C_i. In principle the concepts developed in Sect. 12.4.2 can be employed to model the dielectric properties of each phase. In principle by analyzing the frequency position of the α-relaxation and its dielectric strength, the unknown concentration of each component can be estimated assuming appropriate mixing rules. In practical work this can be difficult. Of special interest is again the case where one component is dielectrically invisible as also discussed in Sect. 12.4.2.

12.4.3.1 Blends with a Semicrystalline Component

Miscible blends where one component of the blend is a semicrystalline polymer and the other one are typical examples for two or more phase systems. In such a system in the amorphous state, both components are miscible, whereas the crystallites appear as a second phase. As a first fact of course, the crystallinity measured, for instance, by DSC or by wide angle X-ray diffraction might be changed by blending. This further implies that the volume fraction of dipoles in the amorphous phase which can become mobile at the glass transition will decrease with increasing crystallinity. This will result in a decrease in the dielectric relaxation strengths. Secondly, the frequency (or temperature) position of the glass transition will shift to lower frequencies (higher temperatures) with increasing crystallinity.

Even for semicrystalline homopolymers it is well-known fact that its morphology cannot be described by a simple two-phase model. A characteristic feature of semicrystalline homopolymers is the so-called rigid amorphous fraction (RAF) (Wunderlich 2003). The RAF is phase which is amorphous in structure but immobilized at the dynamic glass transition of the amorphous phase. Therefore, the steplike change of the heat capacity at the glass transition is smaller than expected. Probably the RAF is located between the crystals and the mobile amorphous regions. Besides DSC the rigid amorphous phase can be also investigated by dielectric spectroscopy (Schlosser and Schönhals 1989; Huo and Cebe 1992a, b, 1993; Cebe and Huo 1994; Kalika and Krishnaswamy 1993). Like for the thermal measurements, the dielectric strength is found to be smaller than expected.

For miscible blends an even more complex behavior is observed as discussed in reference Runt et al. (1991) with regard to interphases. As discussed (Runt et al. 1991) interphases can be consists on the one hand side of segments of the

Fig. 12.26 Temperature dependence of dielectric tan δ at a frequency of 2 kHz for melt crystallized PCL/PVC blends at the indicated concentrations (Data were taken from reference Runt et al. (1991))
semicrystalline polymer. Examples for that are blends of poly(vinylidene fluoride) with PMMA or blends of poly(ethylene oxide) also with PMMA. On the other side the interphase can contain segments of both polymers. This is, for instance, the case for blends of poly(butylene terephthalate) with polyarylate or poly(ε-carpolactone) (PLA) mixed with poly(vinyl chloride). As an example for the latter system, Fig. 12.26 depicts the temperature dependence of tan δ for the blend system PLA/PVC at a frequency of 2 kHz. Two relaxation processes are indicated by peaks in tan δ. The process located at lower temperatures is assigned to the discussed interphase where the peak at higher temperatures is related to the segmental fluctuations in the blended PLA/PVC amorphous phase. The interphase process shifts a bit to higher temperatures with increasing concentration of PVC. For concentration greater than 15 % of PVC, the interphase peak disappears.

The discussed situation can become even more complex for cases where a variety of different morphologies have been observed like for blends of polyimides (Hudson et al. 1992; Sauer and Hsiao 1993; Hsiao und Sauer 1993; Li and Kim 1997). This includes the observation of multiple glass transitions (Bristow and Kalika 1997). In this connection one has to note that the existence of a given morphology will depend on the thermal history of a sample like for instance crystallization rates.

12.4.3.2 Interfacial Polarization

Due to the phase-separated structure of immiscible polymer blends including phase boundaries in the corresponding dielectric spectra, Maxwell/Wagner polarization process can be observed especially at low frequencies. As discussed in Sect. 12.2.3.3, the theoretical equations are complex and hard to solve. For certain model systems like inclusion in poly(carbonate filled) with poly(ethylene oxide) (Hayward et al. 1992), it could be shown that for low concentrations the most important quantities are the volume fraction, the geometry of the dispersed phase

(expressed by the shape factor n), and its conductivity as well as the permittivity of the matrix. Also for model systems it was early shown that the shape factor n extracted from the dielectric measurements is in good agreement with the observed morphology using electron microscopy (Steeman et al. 1994). This suggests that from a careful analysis of the dielectric spectra, quantitative conclusions about the morphology of immiscible polymeric blends can be drawn. That also includes the detection of the first stages of a phase-separated structure (Dionisio et al. 1996). Higher concentrations of the dispersed phase were considered, for instance, in reference Banhegyi (1986, 1991).

The most complete theoretical treatment of Maxwell/Wagner polarization process in polymer blends was done by Steeman and coworkers (Steeman and van Turnhout 2003) especially also for higher concentrations of the dispersed phase and multicomponent polymer blends (Steeman et al. 1994; Steeman and Maurer 1990, 1992). Quantitative conclusions about the phase structure of the different systems can be drawn including the modeling also of interfaces. This has also some impact on blend compatibilization by grafted copolymers (Eklind et al. 1997).

12.5   Conclusions

Broadband dielectric spectroscopy is a powerful method to investigate the molecular dynamics of polymeric blend systems. This is particularly due to the fact that an extraordinary broad dynamic range can be covered by this technique in its modern form. Different dielectric active processes can be observed in this extended frequency range like relaxation processes due to the fluctuation of molecular dipole moments, charge transport related to the drift motion of charge carriers, or polarization effects due to the presence of both interfaces and interphases. In this chapter broadband dielectric spectroscopy is discussed in relationship to polymer blends where mainly binary blends are considered. The impact of blending on the different relaxation processes is discussed where special attention is paid on the dynamic glass transition related to segmental dynamics. The main features of miscible binary polymeric blends like broadening of the relaxation function as well as dynamic heterogeneity are discussed in detail. The experimental results are related to theoretical approaches like temperature-driven concentration fluctuations and the self-concentration phenomenon characteristic for chain molecules. Immiscible polymeric blends are briefly reviewed.

Physical Aging of Polymer Blends

13

J. M. G. Cowie and V. Arrighi

Contents

Abstract

The selection of polymers and polymer blends for use as specific materials requires the consideration of how these will withstand the environmental

---

J. M. G. Cowie: Deceased.

J.M.G. Cowie • V. Arrighi (✉)
Institute of Chemical Sciences, School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, Scotland, UK
e-mail: V.Arrighi@hw.ac.uk

conditions to which these will be subjected. The long-term stability of a polymer will depend on its aging characteristics both physical and chemical.

Physical aging is the term used to describe the observed changes in properties of glassy materials as a function of storage time, at a temperature below the glass transition, T_g. This phenomenon is important mainly when the materials have a substantial amorphous content. For these materials, a quench from above T_g into the glassy state introduces a nonequilibrium structure which, on annealing at constant temperature, approaches an equilibrium state via small-scale relaxation processes in the glassy state. The aging process can be detected through the time evolution of thermodynamic properties such as the specific volume or enthalpy or mechanical methods such as creep, stress-relaxation, and dynamic mechanical measurements. Here, the fundamental principles of physical aging will be described, and models that quantitatively describe the aging process are briefly described.

Physical aging effects have practical implications and need to be considered when assessing the long-term stability of polymers and polymer–polymer mixtures. This chapter focuses on a discussion of the effect of blending on physical aging and gives a review of the different experimental methods that can be used to compare aging rates in blends to those of the individual components.

13.1   Introduction

The long-term stability of polymeric materials is a matter of considerable importance, both to materials scientists and to engineers. Two types of aging occur that result in changes in the properties of polymers: chemical and physical. Chemical aging normally leads to modification of the polymer chain and may involve chain scission, oxidation, dehalogenation, loss of pendant groups, hydrolysis, and cross-linking, all of which are nonreversible chemical reactions. Physical aging is a manifestation of small-scale relaxation processes that take place predominantly in the amorphous regions of a glassy polymer, causing volume contraction and densification of the sample. Thus, while both are time and temperature dependent, the chemical aging results in an alteration of the chemistry of the polymer and usually leads to degradation with a concurrent deterioration of the properties (e.g., discoloration, embrittlement, loss of tensile strength). This type of aging will not be considered here.

During physical aging more subtle changes take place which do not involve chemical modification: the polymer structure remains unchanged, but the local packing of the chains alters due to the slow structural relaxation of the glass. This leads to dimensional changes and alteration of physical properties such as density, brittleness, tensile strength, and the glass transition temperature, T_g. Unlike chemical aging, physical aging is a reversible process.

In practice, aging tends to render the material more brittle and this may impair any long-term applications. A wide range of materials may be affected by physical aging and extensive studies have been carried out on homopolymers and copolymers. Contrary to this, less attention has been devoted to physical aging of polymer

blends, and there are still important aspects of the aging process, e.g., the role of intermolecular interactions that are not fully understood. This is somewhat surprising given the commercial importance of polymer blends, but it is likely related to our incomplete understanding of the molecular processes that govern physical aging even in the case of relatively simple homopolymers. Extending our current knowledge to complex systems such as blends, composites, and nanocomposites is not trivial. However, a detailed knowledge of the glassy state of polymeric materials is necessary if we are to measure and model the aging process and then use the results to design more stable materials.

In the following sections, aging data for blend systems will be reviewed.

13.2   Thermodynamics of the Glass Transition

Polymers behave as liquids as long as temperature changes occur at a slower rate than that required by the molecules to readjust to their new equilibrium condition. As the annealing temperature, T_a, approaches T_g [i.e., as $(T_g - T_a)$ increases], the aging process slows down. A temperature is eventually reached at which the characteristic rate of motion is too slow compared to the rate of temperature changes: molecular conformations are fixed, and the material is no longer able to attain structural equilibrium, i.e., it behaves as a glass.

Below T_g the glass that is formed is not in equilibrium with its surroundings, and, on annealing at a given temperature, T_a, there will be a driving force to reduce excess thermodynamic quantities such as volume and enthalpy to their equilibrium values at that temperature. The continuous, slow, relaxation of the glass from the initial nonequilibrium state toward a final thermodynamic equilibrium state produces time-dependent changes in the physical properties of the polymer. This slow structural reorganization of the glass is termed *physical aging*.

Chain mobility is rather limited below T_g and so structural changes can only result from limited segmental relaxation processes. Therefore, it is believed that aging should occur within a limited temperature range, $T_\beta < T < T_g$, where T_β is the temperature of the first secondary relaxation process that can take place in the glassy state (Struik 1978). This restricted temperature range is disputed (Johari 1982; McCrum 1992), and it is believed that aging is a phenomenon affecting all viscoelastic relaxation processes.

13.3   Experimental Determination of Aging

As the annealing temperatures T_a drop further away from T_g, the aging process slows down and the time scales involved become quite long. Consequently many studies are carried out under thermally accelerated conditions. The relaxation of the enthalpy and volume of the glass are convenient parameters to follow when monitoring the physical aging process, as are the time-dependent small strain mechanical properties. Spectroscopic and scattering methods can also be employed

in some cases. A brief description of the techniques is given in the following sections. A more comprehensive review has been given by Hutchinson (Hutchinson 1992).

13.4   Enthalpy Relaxation

Calorimetry has been one of the most commonly used techniques to follow the enthalpic relaxation during aging. Measurements are readily carried out at temperatures below T_g using a differential scanning calorimeter (DSC), a convenient and widely available instrument.

To obtain meaningful results, it is important to define a reproducible thermal history for the sample. The principles underpinning the measurements are summarized in the schematic diagrams of Fig. 13.1a, b. The first step is to ensure that the influence of any previous thermal history is erased by annealing the sample at a temperature in excess of $T_g + 50\ °C$, i.e., at the point A in Fig. 13.1. The polymer is then cooled from the melt at temperature T_2, (A), at a rate q_1, into the glass at temperature T_a, (B). The distance of the sample from its "equilibrium state" at T_a will depend on the rate of cooling of the sample, and so this thermal treatment should remain unchanged for all measurements that are to be compared. Annealing the sample at temperature T_a, for a specified time t_a, results in an enthalpy loss $H_B - H_C$ (along the lines B-C), the extent of which depends on the magnitude of t_a. When measurements are carried out using DSC, the sample is then quenched from T_a after t_a, and on reheating the polymer at a rate q_2, the enthalpy overshoots the equilibrium curve, as shown in Fig. 13.1 by an amount proportional to that lost during the aging process. This is represented by the line (C-A). The enthalpy difference $(H_B - H_C)$ is then given by

$$(H_B - H_C) = \Delta H(t_a, T_a) = \int_{T\alpha}^{T\beta} \left\{ C_p(\text{aged}) - C_p(\text{unaged}) \right\} dT \qquad (13.1)$$

and it is equivalent to the area (A-B) in Fig. 13.2.

As DSC measures the specific heat, C_p, and $C_p = (\partial H / \partial T)_p$, the enthalpy change can be obtained by integration of the DSC curves. From a practical point of view, the aging temperatures T_a are normally close to T_g because the greater $(T_g - T_a)$, the slower the aging processes become and the time scales for the relaxation events are too long for accurate measurement. It is necessary to carry out accelerated aging at temperatures close to T_g, so that measurements can be made over periods of a few hours up to several days at the most.

The majority of models developed to describe the physical aging process are based on the idea of free volume in the polymer. Some only attempt to model the

Fig. 13.1 (**a**) Schematic diagram of the time–temperature profile used in enthalpy relaxation experiments and (**b**) schematic representation of cooling, aging, and heating cycles using the time–temperature profile in (**a**)
observed behavior, while others take a more holistic approach and try to understand the relationship between the molecular relaxation events and the distribution of free volume in the sample.

13.4.1 The Multiparameter Phenomenological Models

A number of theoretical treatments have been developed that attempt to model the aging process in organic and inorganic glasses. Notable examples are the phenomenological models of Narayanaswamy (1971), Moynihan et al. (1976), Hodge et al. (Hodge and Berens 1981; Hodge and Berens 1982; Hodge and Huvard 1983), Gomez-Ribelles and Monleon-Pradas (1995), and Gomez-Ribelles et al. (1995).

Fig. 13.2 Schematic diagram of DSC curves for an aged (full line) and unaged (broken line) polymer sample (top diagram) before and after (bottom diagram) subtraction
As the relaxation processes in the glassy state and glass transition region are non-exponential and nonlinear, the theories must take account of the thermal history of glass formation and the asymmetry of the relaxations, which depend on how the system departs from equilibrium.

To account for the nonlinearity of the relaxation use is made of the convenient concept of a "fictive" temperature, T_f, first proposed by Tool (1946). This is defined as the temperature at which the nonequilibrium value of a macroscopic property of the system would be an equilibrium one. As shown in Fig. 13.3, the enthalpy difference $H(T_2) - H(T)$ can be expressed in one of the two equivalent ways:

$$H(T_2) - H(T) = \int_T^{T_2} \left\{ C_p\left(T'\right) \right\} dT' \tag{13.2}$$

$$H(T_2) - H(T) = \int_T^{T_f} \left\{ C_{p,\,\text{glass}}\left(T'\right) \right\} dT + \int_{T_f}^{T_2} \left\{ C_{p,\,\text{liquid}}\left(T'\right) \right\} dT' \tag{13.3}$$

where T' is a dummy variable. Equating the two terms and rearranging leads finally to

$$\int_T^{T_f} \left\{ C_p\left(T'\right) - C_{p,\,\text{glass}}\left(T'\right) \right\} dT - \int_{T_f}^{T_2} \left\{ C_{p,\,\text{liquid}}\left(T'\right) - C_p\left(T'\right) \right\} dT' = 0 \tag{13.4}$$

From this a normalized heat capacity can be formulated in terms of experimental quantities as

Fig. 13.3 Representation of how the fictive temperature is defined (Reproduced with permission from Cowie and Ferguson (1993))
When the heat capacities of the glass and the liquid are defined by linear functions of temperature, the value of T_f can be calculated from numerical integration of the DSC curves to obtain $H(T_2) - H(T)$.

The concept was developed further by Narayanaswamy (1971) and Moynihan et al. (1976) who treated the kinetics of the aging processes by describing the relaxation toward an equilibrium state in terms of a nonequilibrium decay function. As this depended on the departure from equilibrium, the kinetics are also nonlinear. To allow for this, the average relaxation time, τ, was made a function of both temperature and structure and expressed as

$$\tau\left(T, T_f\right) = \tau_o \exp\left[\frac{x\Delta h^*}{RT} + \frac{(1-x)\Delta h^*}{RT_f}\right] \tag{13.6}$$

where τ_o is the relaxation time at equilibrium ($T_f = T$) at high temperatures, x is the structural or nonlinearity parameter which defines the relative contribution of structure and temperature to the relaxation time ($0 < x \leq 1$), and Δh^* is the effective activation energy for the relaxation processes, assumed to display an Arrhenius temperature dependence.

Equation 13.6 is referred to as the Tool–Narayanaswamy–Moynihan (TNM) equation to acknowledge the contributions of different authors to the theoretical model. Both Δh^* and x have no clear physical meaning. However, in their treatment of the glassy state, Gibbs and DiMarzio (1958) (GD) postulated that a second thermodynamic transition T_2 existed below T_g at which the configurational entropy S_c is zero. The concept of a temperature at which $S_c = 0$ was introduced by

Kauzmann in 1948 and further developed in the Adam–Gibbs theory (Adam and Gibbs 1965), which introduces the idea of a "cooperative rearranging region," where the configurational entropy changes may occur without affecting the surrounding. At T_2 only one-chain configuration is possible; thus $S_c = 0$. Hodge (1987) used the GD theory to show that $x = (T_f'/T_2)$ where T_f' is the value of the fictive temperature in the glass and T_2 is the "equilibrium" T_g.

As discussed previously, the annealing of the glass at the aging temperature T_a results in a relaxation of the enthalpy toward the equilibrium value ΔH_∞. The relaxation function, $\phi(t)$, describes the progression of a system to equilibrium and is defined by

$$\phi(t) = \frac{\Delta H_t - \Delta H_\infty}{\Delta H_0 - \Delta H_\infty} \tag{13.7}$$

where ΔH_0, ΔH_t, and ΔH_∞ are the enthalpy values at the initial time, at time t, and at equilibrium, respectively.

The relaxation function, $\phi(t)$, can also be expressed in terms of a semiempirical function introduced originally by Kohlrausch (1897) and revived by Williams and Watts (1970), abbreviated as the KWW equation:

$$\phi(t) = \exp\left[-\left(\frac{t}{\tau}\right)^\beta\right] \tag{13.8}$$

Equation 13.8 expresses the non-exponentiality of the recovery process during isothermal aging in terms of the parameter β which is related to the breadth of the distribution of relaxation times and has values $0 < \beta < 1$. A value of $\beta = 1$ would imply an infinitely sharp distribution with only one relaxation time. The latter parameter is represented by τ and the effects of physical aging are then analyzed in terms of β and τ. Equation 13.8 has been shown to describe the relaxation process well for small temperature jumps, but it is reported to fail for temperature jumps higher than 1 K. As a result, the relaxation function does not scale linearly with the extent of the departure from equilibrium meaning that the responses cannot be superimposed to form a single master curve by a linear transformation in time.

Gomez-Ribelles and Monleon-Pradas (1995) and Gomez-Ribelles et al. (1995) did not use the fictive temperature, but considered instead the temporal evolution of the configurational entropy, S_c. This provides an improved correlation between the theory and experimental heat capacity data during aging, allowing for the direct use of C_p from experiment without having to normalize the data and removing the restriction of having to calculate the limiting C_p of a fully aged glassy polymer from a linear extrapolation of the liquid C_p curve. In other words the authors recognized that because of the physical restrictions imposed by chain entanglements and inefficient chain packing, the glass may be unable to attain the limiting value derived from a simple linear extrapolation procedure. This concept had been adopted earlier by Cowie and Ferguson (1986, 1989).

Alternative analytical methods are the KAHR isothermal single relaxation time model (Kovacs et al. 1979) and the peak shifting technique (Hutchinson 1992).

13.4.2 Predictive Models for Long-Term Aging

The Petrie–Marshall (P-M) (Petrie and Marshall 1975) or the Cowie–Ferguson (C-F) (1986, 1989) models have been developed in order to facilitate predictions of long-term aging. In both, the enthalpy lost on aging is given by

$$\Delta H(t_a, T_a) = \Delta H(\infty, T_a)[1 - \phi(t_a)] \tag{13.9}$$

where the P-M approach uses Eq. 13.9 to define $\phi(t_a)$ with $\beta = 1$, but C-F express this relaxation function as

$$\phi(t_a) = \exp\left[-\left(\frac{t}{t_c}\right)^{\beta}\right] \tag{13.10}$$

where t_c is a characteristic time, such that $t_a = t_c$ when the polymer glass has aged to 63.2 % of the fully aged glass. The method of determining $\Delta H(\infty, T_a)$ also differs. In the P-M model, this is estimated by a linear extrapolation of the heat capacity (liquid) into the glassy state. The relaxation time is then related to the departure from equilibrium of the enthalpy (δH) by

$$\frac{1}{\tau} = \frac{1}{t_a}\ln\left[1 - \frac{\Delta H(t_a, T_a)}{\Delta H(\infty, T_a)}\right] \tag{13.11}$$

where $\delta H = \Delta H(\infty, T_a) - \Delta H(t_a, T_a)$.

The C-F approach treats $\Delta H(\infty, T_a)$ as an adjustable parameter as it is considered that the linear C_p extrapolation is inaccurate. The data are analyzed by curve fitting plots of $\Delta H(t_a, T_a)$ against log t_a, to assess the thermodynamic aspects from the $\Delta H(\infty, T_a)$ parameter, and the kinetic aspects, embodied in $\phi(t_a)$, both of which are obtainable from this approach. Also considered in the C-F approach is the prediction of t_e, which is the time to reach 99.9 % of the thermodynamic equilibrium state of the infinitely aged glass, from accelerated aging experiments.

The C-F model has been extensively used to compare the aging behavior of polymer blends to that of the corresponding homopolymers, because of its simplicity. However, it should be noted that this model does not adequately describe all of the phenomenology associated with the glass transition, namely, its nonlinear character. The consequences of this when describing the physical aging process have been recently discussed in the literature (Li and Simon 2006; Hutchinson and Kumar 2002).

13.4.3 Molecular Models

The majority of the models developed are based on the idea that significant free volume exists in the glass state of a polymer. Some only attempt to model the consequences of the reduction in this free volume during aging, while others try to understand the relationship between the molecular relaxation processes which are responsible for the change in free volume, and the distribution of this free volume in the aging sample. The latter approach is much more desirable if a deeper understanding of the glassy state is to be achieved. This philosophy underpins the approach of Simha, Robertson, and coworkers.

Simha et al. have used the "hole" theory of Simha–Somcynsky (S-S) (Simha and Somcynsky 1969) as a starting point to develop further the idea of free volume. In their vacant cells or "holes" in a polymer lattice constitute the free volume arising from inefficient chain packing. An equation of state was developed to calculate the fraction of occupied lattice sites and hence the fractional free volume.

This approach has been expanded by Robertson (1979) who examined the relationship between molecular relaxation events that occur via small, simple trans, and gauche conformational changes in the chains and the free volume distribution. The former are assumed to be coupled with the free volume environment which will also be subject to thermal fluctuations.

Making use of these ideas and the S-S theory, Robertson and coworkers (Robertson et al. 1984) have described the structural relaxation in terms of the free volume reduction via the diffusion of vacant holes, in response to molecular relaxation events along the polymer chains. Other models have been proposed by Ngai (1979) and Kubat et al. (1999, 2000).

In the coupling model of Ngai (1979), account is made for the influence of the strength of molecular relaxation on the relaxation times. It was suggested that a "primary relaxing species," such as an α-relaxation, can be described by a time-independent relaxation state $W_o = \tau_o^{-1}$. However, this can be affected by low energy excitations in the glass which modifies W_o to a time-dependent rate $W(t)$. This leads to an expression for a coupled relaxation time:

$$\tau^* = \left[(1-n)\,\omega_c^n\,\tau_o \right]^{\frac{1}{(1-n)}} \tag{13.12}$$

where ω_c is a critical frequency and $(1-n)$ is the equivalent of β in the KWW function. As n depends on temperature and structure, it may vary during the relaxation process. This means that the system is no longer considered to be thermorheologically simple.

A coupling model has also been developed by Kubat et al. (1999, 2000). In it, the authors proposed that, while single relaxation events are most likely to occur, a cluster of these relaxations can also take place. Thus, in addition to single elementary transitions, double, triple, and higher transitions may occur with decreasing relaxation times ($\tau, \tau/2, \tau/3, \ldots$). While the available free volume still

imposes a limitation on the motion of the molecular units, the authors assumed that the activation energy of one unit will facilitate the simultaneous molecular rearrangement of other units in the vicinity of the first. Calculation of the size of the distribution of these clusters shows that the simple relaxing units are the most numerous and that the clustering tendency decreases with time.

13.4.4 Enthalpic Relaxation in Polymer Blends

The phenomenon of physical aging in polymers has received considerable attention, but relative few studies of physical aging in polymer/polymer mixtures have appeared in the literature. Most of these have made use of differential scanning calorimetry and enthalpic data to assess physical aging behavior in blends. Tables 13.1 and 13.2 provide a list of the most important systems investigated to date.

13.4.5 Aging as a Means of Detecting Phase Behavior

One of the most commonly used criteria for establishing the phase behavior in amorphous binary polymer blends is the presence of one or more T_gs. If the blend is one phase, a single T_g lying between the values for each component is detected and characterizes the mixture. If the blend is two phase, then two T_gs are observed close to or matching those of the two components.

It was initially believed that thermoanalytical methods such as DSC could not to be used to study blend systems whose constituent polymers had T_gs in close proximity to each other, namely, 10–20 degrees apart, due to the difficulty of discriminating between the presence of one or two T_gs at normal scan rates. However, both Bosma et al. (1988) and Jorda and Wilkes (1988) demonstrated that the use of isothermal aging experiments could overcome this problem. These authors argued that in a homogeneous, one-phase, blend, the kinetics of the aging process would be an average representing the blend and as such would exhibit only one enthalpy recovery peak. Early enthalpy relaxation studies of poly(methyl methacrylate) (PMMA)/poly(styrene-co-acrylonitrile) (SAN) blends carried out by Naito et al. (1978) had confirmed this point as a single endothermic aging peak was observed for the 50/50 blend and the pure components. In this case, no measurable changes on the magnitude of the enthalpy relaxation peak after blending were detected and the authors concluded that this was a result of a weak interaction between the two polymers.

Isothermal aging experiments have been used to determine phase behavior in several systems. Blends of poly(vinyl chloride), PVC, ($T_g = 80$ °C) and poly (isopropyl methacrylate), PiPMA, ($T_g = 82.5$ °C), are believed to be immiscible, but because of the closeness of the T_g values, this is difficult to confirm. A 50/50 blend was annealed first at 195 °C, to erase previous thermal history, then quenched to 60 °C, i.e., ($T_g - T_a$) ~20 °C, and aged for various times t_a (Bosma et al. 1988).

CCS-PS core cross-linked star PS

The thermograms shown in Fig. 13.4a demonstrate clearly the development of two distinct enthalpy recovery peaks that increase with increasing aging time t_a. Good separation of the peak maxima is obtained as T_{max} tends to increase with aging time for both components but at different rates. This indicates that phase separation has occurred and the enthalpy recovery peaks are characteristic of each distinct phase in the mixture. A miscible blend of PVC and atactic PMMA was also treated in a similar fashion, but only one enthalpy recovery peak could be detected (Fig. 13.4b) indicating a single-phase system.

This work was extended by Grooten and ten Brinke (1989) to include the immiscible blend of polystyrene, PS, with poly(2-vinyl pyridine), P2VP. The authors concluded that the most appropriate range of aging temperature for this type of experiment was T_g to $\sim (T_g - 20\ °C)$. The same method was applied to distinguish the two-phase nature of PS-P2VP diblock copolymers (ten Brinke and Grooten 1989).

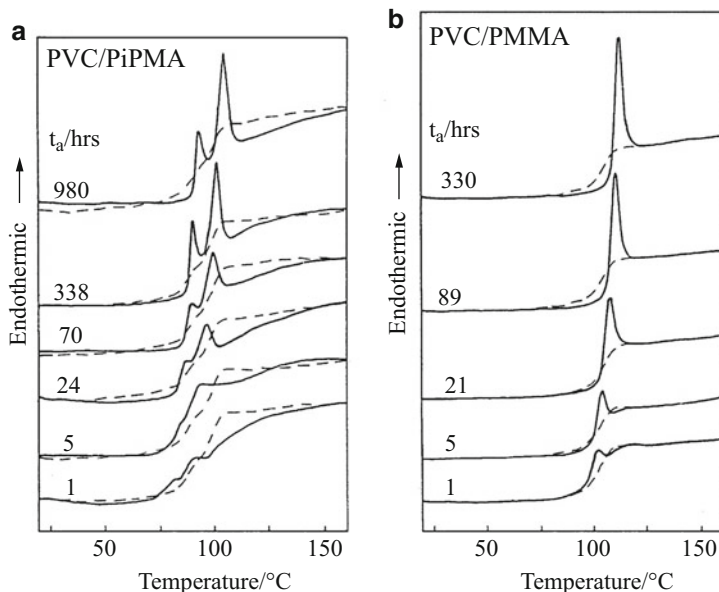
The sensitivity of this method was demonstrated by Jorda and Wilkes (1988) who showed, after aging, that blends of racemic polylactide and its optically active L-form were two phase, a convincing demonstration that two stereo-regular forms of a polymer may be immiscible.


Fig. 13.4 (**a**) DSC thermograms for aged polymer blends (**a**) poly(vinyl chloride)//poly(isopropyl methacrylate), immiscible blend, aged at a temperature of 60 °C, and (**b**) poly(vinyl chloride)//poly(methyl methacrylate), miscible blend, aged at 80 °C. Time of aging, t_a in hours, is shown alongside each curve. Broken lines represent the unaged samples for comparison (Adapted from Bosma et al. (1988))

It was noted that it is the difference in the enthalpy relaxation of the single components that is crucial when investigating polymer–polymer miscibility. As pointed out by ten Brinke et al. (1994), the ability to distinguish between one- and two-phase systems as the T_g values approach one another depends on the effective aging times, t_{eff}:

$$t_{eff} = \frac{t_a}{\tau} \tag{13.13}$$

Since the relaxation time τ is related to x, $\Delta E,^*$ and τ_o (Eq. 13.6), even if the two blend components have a similar T_g, when these kinetic parameters differ so will the enthalpy relaxation at T_a.

Analysis of the kinetics of the recovery process in terms of T_{max}, T_{on} (see Fig. 13.2) provides a further means to quantitatively assess phase behavior (Ellis 1990; Hong et al. 1998). The structural dependence of these parameters has made it possible to investigate the phase behavior of blends containing aromatic polyamides (Ellis 1990). Despite the similarity in structure of the blend components and therefore the close proximity of the glass transition temperatures, Ellis was able to confirm the immiscibility behavior predicted using the mean field binary interaction model (ten Brinke et al. 1983; Paul and Barlow 1984).

Fig. 13.5 Curves of calorimetric overshoots at various T_a for a PB/SBR blend (at 0.5 volume fraction). Inset: amplitudes of peaks as a function of aging temperature (Reproduced with permission from Shi et al. 2013)
The effect of annealing temperature on aging has been well demonstrated by Shi et al. (2013) who investigated blends of polybutadiene (PB) and styrene butadiene rubber (SBR). Starting from the idea that a blend can be viewed as an ensemble of different domains each exhibiting its own glass transition, these authors carried out a range of annealing experiments and showed that annealing affects only a region of the relaxation spectrum, specifically the one that has a relaxation time close to the annealing time at T_a. This is shown in Fig. 13.5 where a 50/50 PB/SBR blend's response to annealing is plotted. The assumption that annealing at a given T_a is selective toward the blend's response was confirmed by consecutively annealing samples at very different temperatures and observing that this results in two distinct annealing peaks. Interestingly, the envelope of all contributions determined by the aging experiments was exploited to predict quantitatively the viscoelastic spectrum of the PB/SBR blends.

Similar effects have been observed in interpenetrating networks (IPN) characterized by an exceptionally wide distribution of relaxation times, with $\beta \rightarrow 0$. For example, the DSC traces of an IPN consisting of 25 % polyurethane and 75 % PMMA measured by Sartor et al. (1994) did not provide evidence of a step-like change that could be attributed to the T_g. However, aging experiments revealed aging peaks with onset close to the aging temperature, an effect that was attributed to the existence of a very broad distribution of relaxation times.

13.4.6 Enthalpy Relaxation: Quantitative Treatment

The first comprehensive study of physical aging in a miscible blend system using enthalpy relaxation was reported by Cowie and Ferguson (1989) who followed the enthalpic relaxation in a series of blends of PS and poly(vinyl methyl ether), PVME. Comparison of the blend behavior with that of the two components by analyzing the data on the basis of both the P-M and C-F models led to the conclusions that the blends aged more slowly than PVME when aging was carried

Table 13.3 Physical aging parameters derived from Petrie model for PS/PVME blends (Cowie and Ferguson 1989)

[a]50 wt% PVME

out at a comparable temperature below T_g; hence the component with the lower T_g, i.e., the more mobile component in the blend, PVME, was responsible for most of the aging effects seen in this blend (see Tables 13.3 and 13.4). The PS component did not appear to contribute significantly to the total aging because the relaxation processes were much slower than PVME at the aging temperature. This suggests that even though the blend can be regarded as a miscible, one-phase system, the components can largely relax independently although the relative rates of each will be influenced by the second component. In the PS/PVME blends, the T_gs of the two components are quite different and the blends can be regarded as comprising a flexible polymer (PVME) mixed with a relatively stiff polymer (PS), a situation which is not favored thermodynamically. It is interesting to note that if an even more rigid analogue poly(α-methyl styrene) replaces PS in the blend, a two-phase system is obtained.

The PS/PVME blend is unlikely to be representative of a typical miscible system; its glass transition region is quite broad, spanning up to 23 K. Thus, aging close to the enthalpic T_g might impinge on the onset region of the glass transition process, and this may result in accelerated aging of the more flexible component. As shown in Fig. 13.6, these conclusions are supported by a comparison of the C-F parameters of a 50/50 wt% blend and those of the pure polymers. In the case of
random mixing, one may expect ΔH_∞ for a blend to have intermediate values
between those of the two pure components. This is not the case for this system and
in fact ΔH_∞ for the blend lies below the PVME values (Fig. 13.6).

However, an alternative explanation may be found in the "Sequential Aging
Theory" proposed by Chai and McCrum (1980). The authors postulated that at
a given T_a and t_a, the viscoelastic elements with relaxation times equivalent to t_a
will be aging, but that elements with $\tau < t_a$ will already have reached equilibrium
and those with $\tau > t_a$ will not yet have begun to move toward equilibrium. Thus, in
the PVME/PS case, the more flexible PVME, which at T_a will also be closer to its
own T_g, will possess more elements with shorter relaxation times than the
PS. Consequently the PVME relaxation spectrum will tend to move more rapidly
toward equilibrium than the PS and so would age more rapidly. In fact this blend is
known to be dynamically heterogeneous in the molten state (Zhang et al. 2004) with
the PVME relaxing much faster (by ca. three decades) than the PS segments at
temperature close to the blend T_g.

Values of the β parameter (Table 13.4) are relatively large for PVME com-
pared to those measured for the blend and PS. This suggests that, while aging is
dominated by the faster PVME component, blending causes a broadening of the
distribution of relaxation times. The dielectric studies of PS/PVME blends of
Roland and Ngai (1992) indicate that the coupling parameter n defined by

Eq. 13.12 is 0.67 in a blend (60 % PVME content) substantially larger than $n = 0.56$ for PVME. Bearing in mind the relationship between coupling and β parameter, the aging behavior seems to follow the dynamic changes arising from the distribution of environments experienced by the relaxing units in a blend. As shown by data in Table 13.4, the degree of intermolecular coupling of the PVME segments substantially increased in the blend (average $n = 0.41$ for PVME vs. average $n = 0.60$ for the blend).

The work of Oudhuis and ten Brinke (1992) on the aging of blends of PS with poly(2,6-dimethyl-1,4-phenylene oxide), PPO, provides an interesting comparison with the PS/PVME system. In PS/PPO blends, both components are relatively rigid, although there is still about 100 °C difference between the T_g values. While the amount of enthalpy relaxation observed in these blends was lower than that for either component, there was no evidence for faster relaxation by the component with the lower T_g, viz., PS (Table 13.5). This observation has been confirmed by Cowie and Elliot (1990). Oudhuis and ten Brinke suggested that since the enthalpic definition of T_g was used as proposed by Cowie and Ferguson (1989) and the blend showed a broad glass transition region covering about 23 °C, the use of the onset T_g instead of the mid-range temperature might be a more accurate reference for selection of the aging temperatures. This would partially overcome some of the problems associated with accelerated aging studies where the precise location of T_g for a weakly miscible blend may be difficult to define.

Blends of PMMA and poly(styrene-*stat*-acrylonitrile), SAN, have been studied by several authors (Naito et al. 1978; Mijovic et al. 1989; Mijovic et al. 1990; Cowie et al. 1991; Cowie et al. 1998; Robertson and Wilkes 2001). Mijovic et al. have investigated blends of PMMA with a commercial SAN sample containing 25 wt% AN, using enthalpy (Mijovic et al. 1989) and stress-relaxation (Mijovic et al. 1990) measurements. Data are shown in Tables 13.5 and 13.6. The authors observed, in common with all other workers, that aging is faster at higher temperatures. No comparison was made with the component polymers, but it was observed that blends rich in SAN relaxed faster than PMMA- rich blends. The aging times used in that work were no more than 150 min.

A more comprehensive study of this system has been carried out by Cowie and Ferguson (1991) who studied a series of blends with SAN compositions spanning the miscibility window, i.e., from 13.3 to 30 wt% AN, using enthalpy and stress relaxation. In agreement with findings of Mijovic et al. (1989), temperature was reported to affect the enthalpic relaxation behavior: at $(T_g - T_a) = 10$ °C blends were found to relax faster than either of the components, but aging was intermediate to both components at $(T_g - T_a) = 20$ °C. Examples of $\Delta H(t_a, T_a)$ versus log t_a plots are shown in Fig. 13.7 together with fits obtained using the P-M and C-F models. It is evident that the C-F model provides a better estimate of the long-term aging effects, whereas overestimates of the time taken to reach equilibrium are made when using the P-M model. The parameters derived from each analysis are shown in Table 13.6 for PMMA/SAN (26.6 wt% AN) at $T_a = (T_g - 10\ °C)$.

Several models are available to quantitatively describe the aging process and practically all of these have been applied to blends as indicated in Table 13.2.

Table 13.6 Aging parameters calculated from the C-F and P-M analysis of data obtained from PMMA, SAN (26.6 wt% AN), and their (50/50) blend PMMA/SAN at $T_a = (T_g - 10$ K)

Polymer	C-F model				P-M model	
	$\Delta H(\infty)$	$\log t_c$	β	$\log t_e$	$\Delta H(\infty)$	$\log t_e$
PMMA	0.820	1.780	0.290	4.678	2.381	11.479
SAN (26.6 wt% AN)	2.365	1.864	0.422	3.853	3.386	4.697
PMMA/SAN (50/50)	1.766	1.678	0.498	3.362	4.142	6.008

For example, Cameron et al. (2002) have employed the G-M model (Gomez-Ribelles and Monleon-Padras 1995) to describe the aging in blends of PMMA and SAN copolymers. The temperature dependence of the equilibrium relaxation time, τ^{eq}, that can be extracted from the enthalpic data is particularly informative. As shown in Fig. 13.8, log τ^{eq} versus $T_{g,100}/T$ (where $T_{g,100}$ is the temperature at which the relaxation time in equilibrium is 100 s) blends that are far from the upper limit of miscibility (i.e., containing SAN13 and SAN17) have nearly identical behavior, whereas PMMA/SAN26 has a significantly lower slope. This has been attributed to microheterogeneity and the blend being close to the miscibility limit. This is reflected in a distribution of glass transition temperatures, broader than in pure polymers. Such an effect which is evident in the enthalpy relaxation studies cannot be observed by conventional DSC measurements, nor does it manifest itself in the enthalpic aging data which display a single aging peak (Fig. 13.8).

The G-M theoretical approach has also been used to reproduce the enthalpic relaxation of PS/PPO blends, and in agreement with other studies, the results show that the distribution of relaxation times is broader in the blends than in the individual components (Brunacci et al. 1997a, b). Considering the Angell (1991) concept of "fragile-strong" classification of materials, this suggests that blends are "stronger" than the individual components.

a $\Delta H\,(t_a, T_a)\,/\,\mathrm{Jg}^{-1}$

b $\Delta H\,(t_a, T_a)\,/\,\mathrm{Jg}^{-1}$

c $\Delta H\,(t_a, T_a)\,/\,\mathrm{Jg}^{-1}$

(1991))

Enthalpy relaxation studies have also been used to assess the aging of polyether ether ketone blends with polyetherimide, PEEK/PEI = 50/50 (Hay 1992). The preparation of the blend produced an amorphous system with T_g ~215 °C, but crystallization of the PEEK occurred after raising the temperature above T_g. Data could only be collected in the temperature range T_g to ($T_g - 50$) and no aging could be detected at temperatures below 150 °C (Table 13.7). The enthalpic relaxation data were analyzed using the C-F model and fits yielded values of β = 0.4, intermediate between those of the pure polymers. It was noted that values of β were higher than those obtained from dielectric relaxation measurements (0.1–0.22). This technique probes the dipole relaxation spectrum, and the lower

values of the shape parameter could be a result of heterogeneity at the molecular level caused by the crystallization of the PEEK component.

Polyethersulfone, PES, can be blended with epoxy resins in certain combinations that do not lead to phase-separated systems, and Breach et al. (1992) have investigated the aging characteristics of Epikote 828 (Shell) and Victrex 5003P. Comparison of aged and unaged samples allowed the enthalpy relaxation to be calculated from the peak areas. Data in Table 13.8 show once that the blends age at a faster rate than the components and that this increases with increasing PES content. In this case, β also increases and these effects can be explained by considering that the incorporation of PES loosen the epoxy resin network thereby increasing the free volume. As this would change the size distribution of the free volume "holes," the presence of larger holes would accelerate the relaxation process and narrow the relaxation time distribution.

Table 13.8 C-F parameters extracted from enthalpy relaxation data of epoxy resin blends with polyethersulfone (Breach et al. 1992)

It follows from the discussion so far that the kinetics of the structural relaxation in miscible polymer blends can show significant differences with respect to the pure components. Aging experiments on well-investigated blend systems, such as PS/PVME and PS/PPO, suggest that blending causes a reduction of the enthalpic changes compared to the pure components, at similar undercoolings. However, blending may affect the rate of aging in different ways, depending on the specific system under study, even for systems having equally large differences between the T_gs of the components (as is the case for PS/PVME and PS/PPO). One possible reason for this is that blends may display different levels of microheterogeneity and therefore unequal distribution of relaxation times. In some cases, the presence of secondary relaxations (e.g., β process) may need to be considered as it will be discussed later, PMMA/SAN blends (Robertson and Wilkes 2001).

One would also expect polymer–polymer interactions to play a major role in the physical aging process, particularly when the blend components can interact strongly, e.g., via hydrogen bonding. To date, very few studies have considered the effect of hydrogen bonding and other secondary interactions on the physical aging of polymer blends. The most investigated systems are blends of poly (4-hydroxystyrene) (PHS) with PVME (Arrighi et al. 2006) and PMMA (Cowie et al. 2005). The hydroxyl group in PHS can act as a proton donor and acceptor, forming self-associated hydrogen bonds between either two PHS repeat units of the same chain (intra-chains) or two adjacent ones (interchain). When blended with a proton acceptor such as PVME or PMMA, intermolecular hydrogen bonds are formed with PHS through the ether or carbonyl linkages of PVME and PMMA, respectively. The presence of strong interactions leads to a considerable increase in glass transition temperature of the PS/PVME blends compared to that of pure PVME. The presence of intermolecular hydrogen bonds retards the aging process as shown in Fig. 13.9 where the average relaxation time, $\langle t_c \rangle$ for the KWW distribution:

$$\langle t_c \rangle = t_c \ \Gamma(1 + 1/\beta) \tag{13.14}$$

of blends and pure polymers are compared.

The rate of aging of PHS is comparable to that of PVME and PS/PVME, thus indicating that, at similar undercoolings, the presence of inter- and intra-H-bonding has little effect on the aging rate of the pure polymer.

(Replotted from data reported
by Arrighi et al. (2006))
However, intermolecular hydrogen bonding between PHS and PVME strongly affects the enthalpic relaxation (Fig. 13.9). PALS measurements have indicated that at an optimum 59:41 mol% PHS/PVME composition, the free volume is at a minimum compared to the pure components. As illustrated in Fig. 13.9, this blend aged more slowly than any of the other systems investigated, suggesting that an optimum strength of the interaction is realized at approximately equimolar composition. At compositions where intermolecular hydroxyl–ether interactions are greatest, the C-F enthalpy parameters for PHS/PVME blends were found to be higher than those of the PHS/PMMA blends, reflecting the higher strength of the former interactions compared to the hydroxyl–carbonyl interactions.

The effect of hydrogen bond strength on physical aging has also been examined, but it was noted that differences in aging behavior could not simply be accounted for by the strength of the hydrogen bonding (Cowie et al. 2005). Other factors such as structural differences between the polymeric components are likely to affect the aging properties, and this makes it difficult to establish a simple structure–property relationship in hydrogen-bonded blends.

13.5   Volume Relaxation

During physical aging, short-chain segments relax into the free volume available, and this causes reduction in the total volume upon aging results of the relaxation of short chain, a process that leads to improved chain packing and a denser material. Dilatometry can be used to monitor the time dependence of the volume change on aging. The material is either cooled from an equilibrium state above (T_g) to the aging temperature T_a (down-jump) and the isothermal volume contraction (*volume relaxation*) is measured (Greiner and Schwarzl 1984) or the sample is heated in the glassy state (up-jump) in which case an expansion follows (Adachi and Kotaka 1982).

The simplest volume recovery experiment is the down-jump. Volumetric data collected at a series of aging temperatures are normalized in order to examine the relative departure from equilibrium δ which is defined as

$$\delta = \frac{V - V_\infty}{V_\infty} \qquad (13.15)$$

where V represents the volume at a specific aging time and V_∞ is the equilibrium volume. Volume relaxation can be quantitatively described in terms of the volume relaxation rate, b_V (Struik 1978):

$$b_V = -\frac{1}{V} \frac{dV}{d\log t_a} \qquad (13.16)$$

which is valid for isothermal volume relaxation following a fast quench (or down-jump) into the glassy state from the equilibrium liquid state. This parameter can be used to follow changes with blend composition and aging temperature (Robertson and Wilkes 2000, 2001). One should note that the volume changes during isothermal volume recovery are small, typically of the order of 1 % or less, and require high precision measurements.

Compared to aging studies using enthalpy relaxation, very few reports have appeared in the literature where volume changes have been exploited to monitor aging in polymer–polymer mixtures. For PS/PPO blends, negative deviations from simple additivity have been observed, for small undercoolings which seem to disappear upon aging at temperatures deep in the glassy state (Robertson and Wilkes 2000). To verify whether this behavior was to be attributed to concentration fluctuations and the breadth of the glass transition as suggested by Oudhuis and ten Brinke (1992), Robertson and Wilkes (2000) scaled the volume relaxation rates by the onset temperature, T_{onset} and T_g, and found similar trends. Therefore, the authors concluded that the volume data provided no evidence of concentration fluctuations being responsible for the trends in volume relaxation rate. Measurements of specific volume suggested that the blends have better packing in the glassy state compared to expected values based on the densities of the pure polymers. The existence of interactions between the PS and PPO components was considered to be the more likely cause of the observed slower aging of the blends.

To assess how the presence of specific interactions affects the physical aging behavior, Robertson and Wilkes carried out volume relaxation measurements on PMMA/SAN blends as a function of blend composition (Robertson and Wilkes 2001). In this system, there are no attractive interactions between the components, and miscibility is a result of the so-called copolymer repulsion effect. The dependence of the volume relaxation rate on blend composition was found to be consistent with the enthalpic measurements of Mijovic et al. (1989) on the same system: both values of volume and enthalpy relaxation rates were intermediate for the blends compared to the pure components and composition dependent except for $T_g - 45\,^\circ\text{C}$. In contrast to the PS/PPO system that displayed deviations from simple additivity, PMMA/SAN showed a linear dependence of b_V upon blend composition. As discussed by Robertson and Wilkes (2000, 2001), the volume relaxation properties of these blend systems are related to the different density, secondary relaxation, and fragility characteristics of PMMA/SAN and PS/PPO.

Fig. 13.10 Relaxed enthalpy versus relaxed volume for blends PMMA (○) and PMMA/PEO blends with (△) 3 vol%, (□)6 vol%, (◇)10 vol%, and (▽)14 vol% of PEO (Reproduced with permission from (Slobodian et al. 2006)
One of the blends whose aging properties have been extensively studied is PMMA/PEO (Shimada and Isogai 1996; Vernel et al. 1999; Slobodian et al. 2006a, b; Riha et al. 2007). The blend consists of a fully amorphous polymer (PMMA) and a crystallizable component (PEO). Miscibility in the melt state occurs when the PMMA content is above 70–80 %, but phase separation in the glassy state has been reported as indicated by the appearance of heterogeneous structures with domain sizes of 20–70 nm.

Slobodian et al. (2004) have shown that addition of PEO to atactic PMMA causes a significant increase in volume relaxation rate. For example, annealing at about 28 degrees below T_g causes β_V to increase by approximately 37 % when the blend contains 14 vol% PEO, compared to pure PMMA. Further studies by Slobodian et al. have provided insight into the relationship between enthalpy and volume relaxation in PMMA/PEO (Slobodian et al. 2004, 2006). These authors found that both volume and enthalpy changes, following a temperature down-jump of 15 degrees, varied linearly with the logarithm of annealing time for all miscible PMMA/PEO blends containing up to 14 vol% PEO. As shown in Fig. 13.10, the measured volume and enthalpy changes are linearly related to each other. These graphs were used to calculate an aging bulk modulus K_a defined as the slope of the relaxed enthalpy versus volume curves, i.e., $(dh/dv)_T$, whose dimensions equal those of a modulus. Values of K_a (2 GPa) are similar in magnitude to the bulk modulus and therefore consistent with the inverse of the isothermal compressibility.

13.6   Mechanical Relaxation

The effect of thermal and chemical aging on the mechanical properties of polymers including blends is of primary concern to assess the service lifetime and long-term

Fig. 13.11 Schematic representation of temperature, strain, and stress program for a single aging time test (Reproduced with permission from reference (Bernatz et al. 1999)
performance of these materials (Sanchez 2007; McKenna 2012). Since the visco-elastic relaxation spectrum shifts to longer times as aging progresses, aging can be followed using stress-relaxation, creep, or volume relaxation measurements. It has been shown that momentary creep curves have a universal shape and a master curve can be constructed using either time–aging time (t–t_a) or time–temperature (t–T) superposition (Kovacs et al. 1979; Struik 1978).

A schematic representation of a creep experiment is given in Fig. 13.11. Similar to enthalpic relaxation measurements, in a creep test the sample is quenched from above T_g to the annealing temperature T_a. A series of short (typically less than 10 % of the aging time t_a) load–unload tests are performed. As shown in Fig. 13.11, the applied stress, σ_o, is constant and the time-dependent response, the strain, is measured following both load and unload steps. Because times t_e during which creep response is measured are kept deliberately short, the creep response gives a "snapshot" of the viscoelastic properties of the material at a particular aging time.

The momentary creep compliance, $D(t)$, can be calculated:

$$D(t) = \frac{\varepsilon(t) - \varepsilon_{\text{unload}}(t)}{\sigma_o} \qquad (13.17)$$

where ε is the measured strain value and $\varepsilon_{\text{unload}}(t)$ is the extrapolated strain from the previous unload step. The momentary creep compliance curves can be described in terms of the KWW function using a relationship originally proposed by Struik (1978):

$$D(t) = D_o e^{(t/\tau)^{\beta}} \qquad (13.18)$$

where D_o is the compliance at zero time, τ is the relaxation time, and β is the usual shape parameter. Stress-relaxation measurements are carried out in a similar way,

but in this case small strains rather than small stresses are applied to the specimen. The stress-relaxation modulus can be expressed in a manner similar to Eq. 13.18:

$$G(t) = G_o \exp\left[-\left(\frac{t}{\tau}\right)^{\beta}\right] \tag{15.19}$$

where G_o and $G(t)$ are the stress-relaxation moduli at zero time and time t, respectively. Hence a relaxation function can be defined as $\phi(t) = G(t)/G_o$.

Momentary creep or stress-relaxation curves usually have a universal shape: a master curve can be constructed using either time–aging time $(t–t_a)$ or time–temperature $(t–T)$ superposition. A small vertical shift is sometime needed to overlap the data. Both time–temperature and time–aging time superposition are a feature of systems displaying structural–rheological simplicity; superposition rests on the idea of a constant distribution of relaxation times. Thus, provided that the measuring time is short compared to the relaxation or retardation times, the aging process can be studied effectively. For small values of an applied deformation, the shift factors needed to superimpose the isothermal data depend on aging time according to

$$\mu = \frac{d(\log \tau)}{d(\log t_a)} \tag{13.20}$$

where $\log \tau$ is the shift along the logarithmic relaxation time necessary to superimpose compliance or modulus data determined at increasing aging times, t_a. It follows that the shift factor μ can be viewed as a measure of the rate of aging and can be used to predict long-term behavior.

Mechanical relaxation techniques have been used to investigate aging in single component systems and blends. Measurements of the effect of aging on the viscoelastic properties of PMMA/SAN blends have been reported by different research groups. For example, Ho et al. (1991) have carried out short-term stress-relaxation tests on blends of PMMA/SAN and PS/PPO. By analyzing their data using the KWW equation, they were able to show that the stress-relaxation time, τ, depended on blend composition according to

$$\ln \tau = A + C_T \ln\left(T_g - T_a\right) + C_t \ln t_a \tag{13.21}$$

where A is a function of the weight fraction of one of the components in the blend, while C_T and C_t are adjustable temperature and time coefficients, respectively. Fitting parameters for PMMA/SAN and PS/PPO are reported in Table 13.9. Values of the shape parameter β were found to be centered within a narrow range around 0.41. While this, as well as many other reports, suggests β does not vary significantly during aging, there is not common agreement. In fact, by analogy to other relaxations, one might expect β to be an increasing function of $(T_g - T_a)$, reaching a plateau at temperatures well below the glass transition.

[a]w_2 = weight % first homopolymer component in blend

In some cases, when one blend component is in excess of the other, the aging of the blend appears to match that of the major component. Stress-relaxation measurements carried out by Cowie et al. (1998) have shown that the aging rate of a (50/50) PMMA/SAN blend was similar to that of PMMA rather than being intermediate between the two components. This was attributed to the PMMA component being more responsive to the mechanical stresses than SAN, a conclusion that is consistent with spectroscopic measurements of stressed blends indicating that PMMA is more oriented than the SAN component (Oultache et al. 1994).

Chang et al. have compared the stress-relaxation behavior of three miscible blend systems, PS/PPO, PS/PVME, and PMMA/PEO (Chang et al. 1997), for compositions in which one of the components was always in excess. For PS/PPO and PS/PVME, the stress-relaxation rates were found to be faster for the blends in comparison with PS alone, whereas the opposite was true for a PMMA/PEO blend when compared with pure PMMA. Two main effects were discussed: packing density and concentration fluctuations. It was noted that for PS/PPO and PS/PVME, addition of the second component leads to a decrease in the packing density of the blend but this is not the case for PMMA/PEO. Concentration fluctuations in the blend, detected via changes in width of the stress-relaxation time distribution, may also be responsible for differences in mechanical response, and their contribution appeared to be particularly significant in the PS/PVME system.

While the creep and stress-relaxation data of many pure polymers and blends have been reported to obey time–aging time superposition, failure to achieve this has been observed in some cases. For example, Robertson et al. have questioned the applicability of time–aging time superposition to the creep data of PMMA and PMMA/SAN blends (Robertson and Wilkes 2001). These authors argued that

apparent failure to produce a fully superimposed master curve by horizontal and vertical shifting of the creep data was due to overlapping, for the PMMA component, of primary and secondary mechanical relaxations. Thus, when two distinct relaxation processes overlap in the time and temperature regions of the mechanical measurements, the system is expected to display thermorheological complexity.

An attempt to correlate the results of enthalpic and viscoelastic measurements was made by Mijovic and Ho (1993) who reported comparable enthalpy and stress-relaxation times. This suggests that it should be possible to establish correlations between calorimetric and viscoelastic changes during aging, despite the fundamental difference between these two types of measurements. However, one should note that these are empirical correlations and should be tested for each system. Differences in response between enthalpic and mechanical tests have been often observed. For example, Brunacci et al. (1997a, b; 1998) noted that free volume arguments were not sufficient to explain discrepancies between enthalpic and mechanical data of polystyrene and substituted polystyrenes and suggested that dipole interactions while not affecting enthalpic aging could become active during mechanical relaxation.

Novel mechanical tests are being developed and shown to be useful tools to investigate thermal and structural relaxation. These include the modulated-temperature–thermomechanometry technique (mT-TM) which has been recently employed to investigate blends of core cross-linked (CCS) PS and PMMA (Spoljaric et al. 2011) and nanomechanical thermal analysis. By using silicon microcantilever deflection measurements, the latter technique can provide a measure of temperature-dependent thermal stresses and therefore investigate the influence of physical aging (Yun et al. 2011).

13.7   Positron Annihilation Lifetime Spectroscopy

The decrease in volume that accompanies the physical aging process can be related to a change of the distribution of free volume holes. Since the size and concentration of free volume holes in amorphous polymers is closely linked to the thermal expansion, direct measurements of the free volume can be used to monitor the aging processes.

Positron Annihilation Lifetime Spectroscopy (PALS) provides a measure of free volume "holes" or "voids," free volume, and free volume distribution, at an atomic scale. The technique exploits the fact that the positively charged positron (e^+), the antiparticle to the electron, preferentially samples regions of low positive charge density. When injected in a polymer matrix, thermalized positrons can combine with an electron to form a bound state, known as positronium (Ps). This species can only exist in a void and it rapidly annihilates on contact with the electron cloud of a molecule. For polymer studies using PALS, it is ortho-positronium (oPs, a triplet state) which is of interest. The oPs spin exchanges with electrons of opposite spin on the walls of the cavity and it is annihilated. Thus, the oPs lifetime, τ_3, gives a measure of the mean free volume cavity radius, whereas the relative intensity of

the oPs component, I_3, can be related to the number of cavities. A semiempirical equation has been derived that correlates τ_3 with the cavity radius, r (Eldrup et al. 1981):

$$\tau_3 = \frac{1}{2}\left[1 - \frac{r}{r + \Delta r} + \frac{1}{2\pi}\sin\left(\frac{2\pi r}{r + \Delta r}\right)\right]^{-1} \qquad (13.22)$$

which was obtained by using a spherical potential of radius r_o with an electron layer of thickness $(r - r_0) = 1.656$ Å.

As aging tends to be accompanied by changes in the packing density of the system, PALS can provide a qualitative estimate of the free volume in the system and its changes due to blending. For PS/PPO blends, PALS measurements were found to be in qualitative with stress-relaxation data. As discussed in the previous sections, Chang et al. (1997) found that PS/PPO and PS/PVME blends were less dense than PS, while PMMA/PEO was denser than PMMA, thereby making chain relaxation easier in the former and more difficult in the latter, a result that could explain the stress-relaxation behavior.

PALS has been used to examine the effect of intermolecular interactions on aging in copolymers and blends. The technique has proven to be particularly useful when attempting to correlate physical aging data of a series of hydrogen-bonded blends (Cowie et al. 2001; McGonigle et al. 2005). The PALS data of blends of poly (vinylacetate-*co*-vinylalcohol) (PVAc-*co*-VA) with poly(vinylpyrrolidone) (PVP) have revealed a particularly interesting behavior. As discussed by Cowie et al. (2001), for this system, low levels of hydrogen bonding give rise to open structures with increased free volume, but as the hydrogen bond concentration increases, a dramatic "collapse" in the free volume is observed (Fig. 13.12). This dramatic change which should greatly affect the physical aging properties has not been observed for similar blends with strong interactions between components.

13.8   Phase-Separated Blends

The behavior of the two-phase systems is complex and responses on aging can be affected by the thermal history and aging temperature. This is well illustrated by a series of investigations, the two-phase blend of acrylonitrile–butadiene–styrene copolymer (ABS, $T_g = 110$ °C) and polycarbonate of bisphenol-A (BPAPC, $T_g = 151$ °C). Due to the phase-separated structure of the blend, two enthalpy recovery peaks are detected by enthalpy relaxation and attributed to the two components (Tang and Lee-Sullivan 2008). However, aging appears to have little effect on the ABS component even at temperatures close to the ABS glass transition.

Using stress relaxation, Maurer et al. (1985) have observed four regimes of behavior for BPAPC/ABS blends. Below 70 °C both time–temperature and time–ta superpositions were possible, because the two components had similar aging
Fig. 13.12 Positron annihilation lifetimes at 303 K for poly(vinylacetate-*co*-vinylalcohol) (PVAc-*co*-VOH) copolymers (**b**) and blends of these copolymers with poly(vinylpyrrolidone) (PVP) (Reproduced with permission from Cowie et al. (2001))

rates, μ. Between 70 °C and 100 °C, only time–ta superposition was achieved. However, close to the T_g of the ABS component, and between the T_gs of both components, neither were valid. While Eq. 13.19 has been used by other workers, Booij and Palmen (1978) proposed a modified form:

$$G(t) = G_o \left(\frac{t}{\tau}\right)^\alpha \exp\left[-\left(\frac{t}{\tau}\right)^\beta\right] \qquad (13.23)$$

where β was kept constant to 0.4 (although this might be structure dependent) and α was normally a very small number. Equation 13.23 was used to analyze the ABS/PC blend data.

Aging may affect the mechanical performance of both miscible and phase-separated blends. For example, polycarbonate has been found to lose its toughness when aged at temperatures below T_g. This has been recently confirmed by Suzuki et al. (2012) who showed that the Izod impact strength decreased suddenly in the very early stage of physical aging and suggested that annealing may trigger a ductile-to-brittle transition in BPAPC.

Impact modifiers are often added to BPAPC to counteract this effect (Cheng et al. 1992; Tan et al. 2005) and a few studies have been conducted to investigate the effect of thermal annealing on the mechanical performance of BPAPC. For example, blends of BPAPC with several core–shell methacrylate–butadiene–styrene impact modifiers have been studied after aging at 125 °C, 130 °C, and 135 °C (Cheng et al. 1992).

Although changes in impact strength, tensile strength, dynamic mechanical response, and fracture morphology were complicated by the simultaneous chemical degradation of the samples when aged in air, it was reported that the modifiers did slow down the sample embrittlement caused by physical aging. More recent studies have shown that when blending BPAPC with a hydrogenated styrene–butadiene–styrene block copolymer (SEBS), aging of the polycarbonate component proceeded at the same rate as in the pure polymer, but the Izod impact strength did not decrease. This thermal aging resistance was attributed to the negative pressure effect of the SEBS particles leading to enhanced local segment dynamics of BPAPC (Suzuki et al. 2012).

As shown by the early work of Cheng et al. (1992), both chemical and physical effects may be responsible for changes in mechanical properties during aging. In this respect the work of Haghighi-Yazdi·and Lee-Sullivan (2013) has highlighted the competing effects of physical aging and moisture absorption on the stress-relaxation behavior of a BPAPC/ABS blends subjected to both thermal and hygrothermal aging. Short-term tests were carried out and master curves generated by applying time–t_a and time–moisture superposition. The relaxation times were found to increase in the order $\tau_{\text{thermally aged}} > \tau_{\text{hygrothermally aged}} > \tau_{\text{unaged}}$, for the same temperature levels. The authors concluded that relaxation was more affected by physical aging than absorbed moisture effects, meaning that the former provides the dominant mechanism affecting the relaxation behavior of this blend even in the presence of relatively high levels of absorbed moisture.

13.9   Summary and Conclusions

Physical aging is a universal phenomenon displayed by amorphous glasses, including blends and composites. As discussed in this chapter, aging over an extended time period results in changes in many physical properties and strongly affects the performance of polymeric materials. A great deal of effort has been expended by both theoreticians and experimentalists in attempting to understand the phenomenon and provide a sound theoretical description of the vitreous state and the aging process.

On a simplistic level, one might expect that the physical aging properties of blends could be predicted from those of the constituent polymers on an additive basis. This is clearly not the case and examination of the available data suggests that several other factors can influence the response of a blend to thermal annealing.

In weakly interacting systems, the differences in chain stiffness, reflected in the T_g values, can determine the aging characteristics of a blend. This can be quite variable, however, and, at our present level of knowledge, each blend needs to be viewed as a unique system with its own unique aging behavior. This is determined by a combination of the relative flexibility of the component polymers and the extent and strength of the intermolecular interactions between them.

Recent investigations show considerable changes in the rate of aging for blends where there is significant intermolecular H-bonding. For these systems, it may be

argued that molecular relaxation processes are either impeded or retarded due to formation of the reversible cross-links originating from the hydrogen-bonded network structure. Comparable results have been obtained in some heterogeneous nanocomposites, particularly in systems where the additive can interact with the polymer through secondary bonding. Generally, materials that are stabilized by effective intermolecular interactions appear to show reduced physical aging effects, and their properties are less likely to alter significantly over time.

Degradation, Stabilization, and Flammability of Polymer Blends

14

Zvonimir Matusinovic and Charles A. Wilkie

Contents

Abstract

The thermal degradation and fire retardancy of polymer blends is covered in this chapter. Blends of PVC, polystyrenes, polyolefins, and polyamides are covered. The component parts of the blend may have the same stability as does its homopolymer or it may be less or more thermally stable. In some cases the relative amounts of the polymers may cause a change from a less thermally

stable polymer to one which is more thermally stable. Thus, one can only determine through experimentation how making a blend will affect the thermal stability of its constituent parts.

14.1   Introduction

It has been generally accepted that new polymers are not always necessary to meet the need for new materials. Blending of existing commodity or engineering polymers often can be implemented more rapidly and can be a less expensive alternative than the development of new polymers (Koning et al. 1998).

Polymer blending has a developed scientific basis (Folkes and Hope 1993; Utracki 1997), and the impressive increase in commercialization of blends is one of the most prominent and rapidly growing features of the contemporary polymer industry. Polymer blends are intimate mixtures of different commercially available polymers with no covalent bonds between individual component polymers (La Mantia 1994). They can be formed by melt mixing or solution blending and/or by coprecipitation or co-coagulation of systems arising from polymerization of a monomer in a latex medium. Properties of the resulting materials may be tailored to meet requirements of customers or expectations of specific new applications with satisfactory balance of a wide range of material properties and costs (La Mantia 1992). In most cases, each component polymer contributes in a specific manner to the overall property profile. The final materials are mostly characterized by combinations of the useful properties of the components of the polymer blend, superior to those of single polymers. Synergy in material properties is obtained (Koning et al. 1998; Utracki 1997; La Mantia 1992).

Blending substantially improves the properties of commodity plastics, such as polyolefins, styrenics, or poly(vinyl chloride) (PVC). Encouraging commercial results were obtained with blends containing engineering and specialty plastics, such as polyamides (PA), polycarbonates (PC), poly(phenylene oxide) (PPO), or electroconducting polymers, like polyaniline, polythiophene, polypyrrole, or polyacetylene. The main goal of blending is modification of mechanical properties, improvement of impact strength at low temperatures, in particular abrasion resistance and improvement of processability (Billingham et al. 1997). Moreover, blending of recycled and virgin plastics is a promising technique in plastic waste management.

Important material properties are miscibility and compatibility of component polymers. Polymer blends may be homogeneous or heterogeneous on a microscopic scale, but should not exhibit any obvious inhomogeneity on the macroscopic scale (Fox and Allen 1991). The terms "compatible" or "incompatible" refer to the degree of intimacy in blends. A blend that is heterogeneous on the macroscopic level and exhibits symptoms of polymer segregation is considered incompatible. Heterogeneous blends appear in a variety of morphologies. These include most frequently dispersion of one polymer in the matrix of the other and/or a co-continuous two-phase morphology (Koning et al. 1998). The blend morphology and character of interfaces influence co-reactivity in degrading blends.

A low degree of compatibility is a serious problem encountered in polymer blends. Consequently, there is a strong effort to enhance compatibility by using additives (compatibilizers). They reduce the dimensions of dispersed particles and prevent undesirable processes such as separation of phases, delamination, agglomeration or skinning, and ultimate physical failure (Koning et al. 1998; Bonner and Hope 1993). While compatibilizers certainly contribute to the material properties of polymer blends, they are also an impurity and could have a negative influence on the lifetime of blends, which has probably been underestimated (Pospisil et al. 1999).

Unfortunately, all polymers, including polymer blends, undergo degradation, and thus the purpose of this chapter is to address this degradation.

14.2   General Aspects of Polymer Degradation

The term degradation of polymers must include all changes in both the chemical structure and physical properties of polymers which occur due to external chemical or physical action and will lead to materials with properties, both chemical and physical, that are different from those of the starting material (La Mantia 1994). Usually this means poorer properties. Organic polymers can be changed by the environment, due to both chemical reaction and physical stresses (heat, mechanical forces, radiation). According to the lifetime stages of polymers, these may be classified as melt degradation, long-term heat aging, and weathering. Thermomechanical, thermal, catalytic, and radiation-induced oxidations and environmental biodegradation may be involved (Pospisil and Klemchuk 1990).

In addition to the regular structure of a polymer, there may also be low amounts of polymeric inhomogeneities (e.g., unsaturation, oxygenated structures, weak links) and non-polymeric impurities, including metallic contaminants and photoactive pigments, and each of these may be affected by various degradation processes (Pospisil et al. 1998). The concentration of active impurities (catalysts or sensitizers) increases over the polymer lifetime. The knowledge of degradation mechanisms of homopolymers and copolymers is helpful only to some extent in elucidation of the degradation of polymer blends as individual components of a blend may behave rather differently from their behavior as isolated polymers (La Mantia 1992; Wypych 1992). This may affect the degradation resistance of the blend in a positive or a negative manner. Consequently, the degradation behavior of blends is not predictable without experimentation (La Mantia 1992), due to co-reaction phenomena at the interfaces of the blended polymers, controlled by morphology. The processes are complicated by the reactivity of compatibilizers (Chiantore et al. 1998). The heterogeneous character of the system, reaction in the bulk and at the boundaries of individual phases, and involvement of macromolecular and low-molecular-weight degradation products, increase the complexity of reactions in blends (La Mantia 1992, 1994; Chiantore et al. 1998; McNeill 1977; McNeill et al. 1978). Thus, improvements of mechanical properties by blending are sometimes at the expense of stability (Chiantore et al. 1998). Structural changes,

due to aging, produce an effect on various physical properties. The practical service lifetime of blends in general and blends containing recycled materials can be different in terms of resistance to degradation. Accordingly, performance characteristics of blends are of major commercial importance.

14.3 Thermal Degradation

The processes described in this part proceed in polymer blends stressed in an inert atmosphere by a single agent – heat. The effect of thermal degradation on blends containing vinyls, styrenics, polyolefins, acrylics, and rubber elastomeric blends are herein described. Most of the experimental data were obtained by dynamic or isothermal differential scanning calorimetry (DSC) and thermogravimetry (TG) or thermal volatilization analysis (TVA). Infrared (IR) and nuclear magnetic resonance (NMR) spectrometry, chromatographic methods, and conductometric measurements were used for analysis of volatile and condensable products of thermolysis. Interactions are observed between the components in the polymer bulk with low-molecular-weight molecules or free-radical products, arising by thermolysis of any of the component polymers and migrating across the phase boundaries from one polymer to another (McNeill et al. 1978; McNeil 1989). Ultimately, the products of thermolysis either trigger degradation of the blend (destabilizing effect) or act as stabilizing species for any of the component polymers (Wypych 1992; McNeil 1989). The final effect may depend on the ratio of components or the temperature. Systems where the ultimate degradation rates are reduced or the decomposition temperatures of all component polymers are shifted to higher values have the optimum behavior. The thermal behavior of polymer blends shows some similarities with graft copolymers, but differs from those of random copolymers (McNeill 1977).

14.4 Vinyl Blends

14.4.1 PVC

Much attention has been paid to blends containing PVC. Blending with other polymers improves the properties of this commodity polymer and increases possible applications (Braun and Böhringer 1989). Knowledge of the thermal behavior of different blends containing PVC is of commercial importance.

Thermal dehydrochlorination of unstabilized PVC occurs at about 100 °C and is also an undesired process in stabilized PVC at processing temperatures (180/200 °C) (Braun 1981). Dehydrochlorination accounts for the formation of conjugated double bonds (Scheme 14.1) and leads to allylic activation in degrading PVC. Hydrogen atoms of the methylene group in the allylic moiety are able to form hydrogen bonds with functional groups (e.g., $>C=O$) in the component of the blend (Lizymol et al. 1997). Sequences of conjugated double bonds may participate in PVC cross-linking (McNeil 1989).
Scheme 14.1 Degradation of PVC

The low thermal stability of PVC requires effective stabilization (Braun 1981). It was realized that performance of tin stabilizers was enhanced in some blends of PVC in comparison with pure PVC (Braun and Böhringer 1989).

A detailed elucidation of dehydrochlorination rates of PVC blends with HIPS containing 16 % non-grafted PS, poly(styrene-*co*-acrylonitrile) (SAN), and acrylonitrile–butadiene–styrene terpolymer (ABS) containing 27 % non-grafted SAN in inert atmosphere at 180 °C revealed accelerated degradaon of the PVC component (Braun et al. 1994).

14.4.2 PVC/PMMA

The influence of PMMA in the PVC matrix on the thermal stability of blends has been investigated by dynamic TGA (Ahmad et al. 2008). The thermal degradation of PVC proceeds in two distinct stages in an inert atmosphere (Owen 1984; Ahmad and Mahmood 1996; Marongiu et al. 2003). In the first stage, the most abundant volatile product is HCl. At low temperature molecular dehydrochlorination plays a fundamental role, whereas at higher temperature a radical mechanism becomes relevant. The initiation reaction can involve $C-C$, $C-H$, and $C-Cl$ bond cleavage, the last being the weakest and consequently the most probable initiation step. The $Cl^{\cdot}$ radicals can initially abstract a H atom from a repeating unit and form HCl. The HCl further catalyzes the degradation process releasing more HCl with the formation of polyenes.

The typical species involved in the first degradation stage are H_2, Cl_2, and HCl. After the loss of HCl, the allylic chlorine is more reactive, and its unzipping leads to the polyene linkage; the conjugated structure is stabilized by resonance. The decomposition temperature in the first step of dehydrochlorination, which starts around 220 °C, increases as the heating rates increases (Ahmad et al. 2008).

The polyene linkages above 360 °C may undergo aromatization through intermolecular cyclization leading to volatile aromatics, e.g., benzene, naphthalene, and anthracene, or through intermolecular cross-linking reaction leading to alkyl aromatics and char above 500 °C.

As the heating rate increases, the thermal decomposition temperature of the second step of degradation also increases (Ahmad et al. 2008), since there is less time available for the degradation. The fraction of residue at 600 °C also increases at high heating rates. In the cyclization process taking place around 450 °C, the polyene linkages not only cyclize but cross-link as well (Nagi et al. 1980; Varma and Sharma 2003). The cross-linked structure, however, decomposes with difficulty (Yanborisov et al. 2003) as seen by the mass retained in the thermograms.

The details of the PMMA degradation process have been studied by Manring (Manring 1988, 1991; Manring et al. 1989) and Kashiwagi (Kashiwagi et al. 1986). PMMA generally degrades by end-chain scission at 360 °C and by random scission around 400 °C giving monomer as the product. Random scission produces both primary and tertiary radicals. The tertiary radical degrades by unzipping to give monomer and a new tertiary radical. The primary radical may form a methallyl-terminated species which leads to a new tertiary radical. The detailed analysis and DTA show that a part of PMMA begins to degrade around 140 °C. Nearly 2 % weight loss is evident from the TGA curves. In the second degradation stage, which starts around 220 °C, nearly 3 % weight loss occurs. PMMA polymerized by free-radical polymerization may contain some head-to-head linkages and early decomposition, which takes place around 140–150 °C, is due to breakage at these linkages as the bond dissociation energy of such bonds is less than the C–C bonds, mainly due to steric and inductive effects of vicinal ester groups. The second degradation stage, which occurs around 230–255 °C, is likely due to the unsaturated chain ends resulting from the termination by disproportionation. The thermal decomposition in both the first and second stage results in a weight loss of nearly 4–5 %; the main degradation process involving random scission starts in the third stage around 360 °C (Ahmad et al. 2008). Thermal decomposition temperatures in all cases increase with an increase in the heating rates, though with higher heating rates the initial step is not that visible (Ahmad et al. 2008).

The thermal degradation of PVC/PMMA blends containing between 2.5 and 20 wt% PMMA in PVC were studied at various heating rates (Ahmad et al. 2008). For 10 wt% PMMA in PVC at 2.5 °C min^{-1}, the first degradation step, which in pristine PVC is at 280 °C, increases to 300 °C. At 20 wt% PMMA content, the first degradation is at 287 °C. The thermal decomposition temperature increases with higher heating rates in all cases. Blends with 10 wt% PMMA again show the maximum increase from 319 °C in case of pure PVC to 352 °C, whereas at higher PMMA content it decreases, but always remains above the thermal decomposition temperature of pristine PVC. More mass is retained above 600 °C in blends containing 10 wt% PMMA. The relative decrease of the thermal decomposition temperature with higher content (15 wt% or more) of PMMA in blends was less in the case of higher heating rates. The thermal decomposition temperature in the second degradation step in PVC also increases and shows a maximum value for 10 wt% PMMA in PVC; the decrease is larger compared to the first decomposition step (Ahmad et al. 2008).

The PMMA/PVC blends, as observed through SEM studies, seem heterogeneous, particularly at higher PMMA content where the two polymers may

predominantly degrade in their phase-separated regions. However, they may give rise to some cross products formed by small radicals or molecules migrating across the phase boundaries. The reaction of a macroradical of one component with the macroradical of the other component may take place at the phase boundaries, but there is more probability for the reaction of a microradical of one polymer with the macroradical of the other. As shown already, some weak links in PMMA, e.g., head-to-head linkages, decompose earlier, at 140–200 °C. These will produce primary radicals, which then can further degrade. Free radicals thus produced may combine with macroradicals of the matrix. This can act as a catch or block for further unzipping in PVC. The first degradation step, the dehydrochlorination process in PVC, is therefore delayed as the chain is stabilized. It was observed through dehydrochlorination and UV–Vis spectroscopic studies that the size of polyene linkage in PVC increases with heating in the presence of a destabilizer such as metal chlorides (Manzoor et al. 1996; Khan and Ahmad 1996), whereas Aouachria and Belhaneche-Bensemra have recently observed relatively shorter polyene linkages produced in degradation of rigid and plasticized PVC/PMMA blends (Aouachria and Belhaneche-Bensemra 2006). This observation supports a mechanism where the reaction of free radicals produced in PMMA degradation combine with the unzipping PVC chain, thus stabilizing it.

In PMMA, random degradation occurs around the same temperature where the second stage of degradation of PVC begins. The combination of the free radicals from both components may produce some cross-linked structures, which are slightly more difficult to degrade. This is evident by the larger amount of weight retained above 600 °C with blends having 10 wt% PMMA in the PVC matrix (Ahmad et al. 2008). The slight decrease in the thermal degradation temperatures at higher concentration of PMMA, 15 % or more, seems due to phase aggregation tendencies of the components in blends, which is confirmed by SEM micrographs. This may result in less interaction between the degrading products from the two polymers thus reducing the mutual stabilization.

The activation energies for the thermal decomposition of PVC and its various blends with different concentrations of PMMA can be calculated using dynamic TGA data obtained at different heating rates and methods by Flynn, Friedman, and Ozawa (Flynn and Wall 1983; Friedman 1965; Ozawa and Bull 1965). The apparent activation energy of decomposition for pure PVC is 138.8 kJ mol^{-1}. Bockhorn et al. (Bockhorn et al. 1999) have discussed the mechanism and kinetics of thermal decomposition of PVC and reported the value of activation energy of the first step to be 140 kJ mol^{-1}, which agrees with the value obtained in the work of Ahmad et al., who showed that the activation energy of the degradation in blends varies with an increase in the PMMA content. The activation energy increases for up to 10 wt% of PMMA in the matrix and then falls sharply. The maximum value of activation energy measured in these blends is 149.9 kJ mol^{-1}. The higher value of activation energy for the blends confirms the stability of all the blends as compared to the pure polymer, however, the optimum amount of PMMA was found to be 10 % by weight in PVC.

14.4.3 PVC/CPE

Chlorinated polyethylene (CPE) is a commonly used impact modifier of PVC, and its compatibility depends upon the chlorine content and the distribution of the chlorine atoms on the polyethylene (PE) backbone. As the chlorine content in CPE increases, first the regularity of the polyethylene structure breaks up, reducing and then eliminating crystallinity, then converting a rigid polymer into a flexible, rubbery material. When the rubbery phase is semi-compatible with PVC, it disperses as small discrete domains in the PVC matrix and serves as an impact modifier for rigid PVC. A continuous increase in the chlorine content of CPE increases its polarity, making it more miscible in PVC and can improve melt processability. At high concentrations of chlorine, it can act as a polymeric plasticizer. In all these functions, the saturated structure of CPE makes it more weather resistant than butadiene polymers, and its high molecular weight makes it a much more permanent plasticizer than the conventional liquid monomeric ones (Deanin and Chuang 1987). CPE with 36 % chlorine is the optimum composition for obtaining the necessary features of impact, processing, and strength (Walsh and Higgis 1985). The morphology of the polymer blend has a significant effect on the impact behavior of the material. At a concentration less than 13 mass % CPE in the PVC/CPE blend, PVC is the continuous phase, while CPE is the noncontinuous phase. Increasing the CPE concentration above 13 mass % reverses the phase distribution (Chen et al. 1995).

It is well established that blending may greatly influence the thermal stability of the individual polymers (McNeil 1977; McNeil and Gorman 1991; Goh 1993). Under degradation conditions, considerable interactions may occur between components in the blend and/or their degradation products. The type of interaction will depend on the degree of miscibility of the components, as well as on their ratio in the blend.

Differential scanning calorimetry results showed that amorphous PVC and partly crystalline CPE are immiscible for all the investigated compositions of the blends in the temperature range 30–150 °C, that is, PVC/CPE blends are heterogeneous, and the glass transitions of both PVC (83 °C) and CPE (115 °C) are observed (Klarić et al. 2000). The TGA curves at higher heating rates (5, 10, 20, and 40 °C) are shifted to higher temperatures. Both pure polymers undergo two degradation steps. In the first stage, the dehydrochlorination of the polymer occurs, and in the second, the degradation of the dehydrochlorinated residue and the formation of compounds of low molecular mass take place. The maximal rate of PVC dehydrochlorination is about six times greater than the maximal rate of CPE. Dehydrochlorination of PVC occurs with a peak temperature between 250 °C and 290 °C, while in CPE this is at about 330 °C. The maximal rate of PVC dehydrochlorination in the blends decreases by one-half for each 20 % addition of CPE, and the corresponding peak temperature is shifted to higher values.

When the experimental TG curves of the blend were compared with the curves predicted on the basis of the TG curves of the unblended components (Fig. 14.1), the additivity rule indicates interactions in the blends (Goh 1993; Moscala and Lee 1989). Klarić et al. found that in the heterogeneous blend, PVC/CPE 50/50,

Fig. 14.1 TGA curves for (*1*) PVC, (*2*) CPE, (*3*) PVC/CPE 50/50 blend, and (*4*) predicted TGA curve for PVC/CPE 50/50 blend; heating rate 2.5 °C min^{-1} (Reproduced with permission from John Wiley and Sons, from I. Klarić, N. Stipanelov-Vrandečić, U. Roje, J. App. Polym. Sci. **78**, 166 (2000))
interactions do occur between the polymers. In the temperature range about 240–370 °C (the first degradation step), the blend is more stable than calculated according to the additivity rule. For example, at 300 °C, the blend has lost approximately 10 % mass less than predicted. At temperatures over 370 °C, the blend shows less stability. The values $\Delta\alpha = (\alpha_{exp} - \alpha_{calc})/\alpha_{calc}$ were also calculated (Kovačić et al. 1993) for all blend compositions at a heating rate 2.5 °C min (Moscala and Lee 1989). The PVC/CPE blends are thermally more stable in the temperature range for which $\alpha_{calc} > \alpha_{exp}$, that is, $\Delta\alpha < 0$. If $\Delta\alpha > 0$, the PVC/CPE blends are less stable than would be predicted from the behavior of the pure polymers (Fig. 14.2).

The main degradation reaction of PVC at moderate temperatures is dehydrochlorination, which is also the dominant reaction in CPE degradation. While dehydrochlorination of PVC is an autocatalytic reaction, the dehydrochlorination of CPE is statistical (Jimenez 1993; Stoeva et al. 2000).

The addition of heat stabilizers improves the thermal stability of polymers. One group of commercially available PVC heat stabilizers are Ca/Zn stabilizers. According to the Frye–Horst mechanism (Thomas 1993), the zinc fatty acid salt reacts with PVC by an esterifying displacement of chlorine. Stabilization arises from substitution of labile chlorine atoms with more stable carboxylate groups (Scheme 14.2):

The progressive dehydrochlorination reaction is prevented in this way, but the zinc chloride, produced as a result of the esterification reaction, will cause further rapid degradation. This problem is solved by the synergistic effect of combining alkaline earth (Ca) carboxylates with the covalent metal carboxylates. Alkaline earth carboxylates undergo ester exchange reactions with covalent metal chlorides, regenerating the covalent metal carboxylates:

$$ZnCl_2 + Ca(OOCR)_2 \rightarrow Zn(OOCR)_2 + CaCl_2$$
Alkaline earth chlorides do not promote dehydroxylation, thus the alkaline earth carboxylates are not primary stabilizers of PVC resin but serve to

Fig. 14.2 Dependence of the interaction $\Delta\alpha$ on the degradation temperature for PVC/CPE blends of different compositions; heating rate 2.5 °C min^{-1} (Reproduced with permission from John Wiley and Sons, from I. regenerate the active stabilizer and remove the potentially destructive effect of the covalent metal chloride.

Thermal degradation of stabilized and unstabilized PVC/CPE was studied by Stipanelov Vrandečić et al. (Stipanelov Vrandečić et al. 2001). Dynamic TGA was performed for the thermal degradation of PVC/CPE blends between 50 °C and 600 °C at a heating rate 2.5 °C min^{-1}. It was found that the thermal degradation of the "pure" unstabilized and stabilized polymers, as well as the PVC/CPE blends, occurs in two degradation steps: dehydroclorination of PVC or/and CPE and the degradation of the dehydrochlorinated residues.

The maximum rate of autocatalytic PVC dehydrochlorination is considerably higher than the maximum rate of statistical dehydrochlorination of CPE, and it decreases as the ratio of CPE increases from 0 % to 50 %. In the PVC/CPE 30/70 blend, the maximum dehydrochlorination rate of CPE is higher than that of PVC. In the second degradation step, the dehydrochlorination rate of CPE is the highest, but it is lowered by increasing the ratio of PVC in the blends.

In the first degradation step of the stabilized PVC/CPE blends, there are two maxima in the TGA curves for 90/10 and 80/20 blends, while for other blends those maxima become one. By comparing the DTG curves of the stabilized and unstabilized blends, it can be concluded that the Ca/Zn stabilizer

increases the maximum dehydrochlorination rate of "pure" PVC and decreases the corresponding rate of "pure" CPE.

Although they are chemically similar, CPE has superior thermal stability to PVC, which can be explained by difference in microregularity of the corresponding polymer chains. The mutual location of the monomer segments in PVC corresponds to "head-to-tail" pattern. PVC releases HCl more readily on dehydrochlorination, since the chloroallylic fragments of the relatively weak C–Cl bond are formed. CPE has non-regular location of chlorine atoms along the polymer chain associated with certain "blockwise" structures involving "head-to-tail," "tail-to-tail," and other patterns of connection of the chain segments. The dehydrochlorination results in the formation of "vinyl" structure of much stronger C–Cl bonds. The degradation of CPE with the same chlorine content in PVC occurs more slowly than that of PVC; dehydrochlorination of CPE is slow random HCl elimination as opposed to the rapid dehydrochlorination of PVC (Stoeva et al. 2000).

In immiscible polymer blends, one polymer is dispersed in the form of domains in the continuous phase of the other. The degree of dispersion depends upon the mixing ability of the polymers, which decreases with an increase in concentration of the other polymer in the blend. Therefore, the quantity of domains and the degree of dispersion in PVC/CPE blends determine the progress of the degradation. The evolved HCl partially lags in the bulk sample, due to inefficient diffusion and, consequentially, has a catalytic effect on dehydorchlorination at low level of dehydrochlorination, as well as on the secondary reactions of polyene residues (Mahmood and Quadeer 1994).

To evaluate the thermal stability of the blends, the characteristics of the first degradation step were determined from the TGA and DTG curves: the onset temperature, $T_1(o)$ (the intersection of the extrapolated baseline with the inflection tangent); the temperature at the maximum rate of PVC degradation, $T_1(m)$; the degree of conversion at the corresponding maximum rate, $\alpha_1(m)$; and the mass loss at the end of the first degradation step, Δm_1.

The $T_1(o)$ and $T_1(m)$ of unstabilized blends shift towards higher values with increasing CPE ratio. With the addition of stabilizer, the blends containing up to 30 % CPE have higher $T_1(o)$ than the corresponding unstabilized blends, the addition of stabilizer does not change the $T_1(o)$ of the blend with 50 % of CPE, while in the 30/70 and 0/100 blends, it decreases. The temperature $T_1(m)$, at which the dehydrochlorination rate of stabilized blends is maximum, is higher than for the corresponding unstabilized blends, with the exception of the 0/100 blend.

The conversion value $\alpha_1(m)$, at the maximum dehydrochlorination rate of PVC, is 19–20 % for 100/0, 90/0, and 80/20 blends. With an additional increase in the CPE content, $\alpha_1(m)$ decreases, and for the 30/70 blend it amounts to 9 %, though it is 25 % for the "pure" CPE. The maximum dehydrochlorination rates of stabilized PVC/CPE blends are achieved at higher conversion in comparison with unstabilized blends, with the exception of the 0/100 blend.

During degradation of either unstabilized or stabilized blends, the Δm_1 mass losses depend on the blend composition, and, by increasing the amount of CPE in the blend, Δm_1 decreases. The values of Δm_1 for stabilized blends are somewhat

lower than for the corresponding unstabilized blends. In the investigated temperature range, the unstabilized PVC loses 61 % of its mass in the first degradation step. This mass loss is a bit higher than the stoichiometric quantity of chlorine contained in PVC and corresponds to total PVC dehydrochlorination. The difference of several percent is attributed to the formation of benzene (Jimenez 1993; McNeill et al. 1995). The mass loss of 43 % of the unstabilized CPE in the first degradation step is also a bit higher than the chlorine content in CPE, so the dehydrochlorination of CPE is total. At the end of the first degradation step, the stabilized PVC and stabilized CPE have lost 60 % and 42 %, respectively.

To estimate the thermal stability of unstabilized and stabilized blends, besides the abovementioned indicators, temperatures $T_{1\%}$ and $T_{5\%}$, at which the mass loss (conversion) of 1 and 5 % was achieved, are determined. The $T_1(o)$ temperature is considered to be an inadequate indicator of thermal stability as it depends on experimental conditions during recording of the TG curve. The $T_{1\%}$ temperatures of stabilized blends are, on average, about 20 % lower than the $T_{1\%}$ of unstabilized blends of the same composition. The $T_{5\%}$ temperatures for the stabilized blends containing up to 20 % of CPE are higher than the $T_{5\%}$ of unstabilized blends; for the blends with 30 % of modifier, these temperatures are equal. For the stabilized blends with 50 % and 70 % of modifier, $T_{5\%}$ is lower than for the corresponding unstabilized blends. The increase of mass ratio of CPE in the stabilized blends has a destabilizing effect. The destructive effect of $ZnCl_2$ seems to be the probable explanation for this behavior (Prospect Dow CPE Resins for Impact Modification of Rigid PVC. Dow Chemical 1993).

The thermal stability of a particular polymer in the blend depends on possible interactions of the blend components and their degradation products. In immiscible blends, as PVC/CPE, the type of interaction depends on the ratio of the components in the blend and their mixing ability. The interactions of PVC and CPE are confirmed by comparison of experimental TGA curves and TGA curves calculated using the additivity rule. In the temperature range which corresponds to the first degradation step (240–370 °C), PVC/CPE blends were more stable than was calculated (Klarić et al. 2000).

14.4.4 PVC/PS

Polystyrene (PS) is considered an excellent polymer suitable for various commercial and domestic applications. PVC and PS stand second and third in the world, respectively, as far as the consumption of polymers is concerned. The structure and composition of various products formed during the degradation process and their mutual interactions in the ultimate degradation mechanism depends on the compatibility of polymeric components in the blends. PS/PVC blends with different compositions have been prepared (Ahmad et al. 2007) in the forms of film and powder. Thermal degradation was studied at various heating rates in an inert atmosphere. Pure PS degrades in one step between 300 °C and 400 °C, producing monomer, dimer (2,4-diphenyl-1-butene), trimer(2,4,6-triphenyl-1-hexane),

benzene, and toluene as volatile products (Faravelli et al. 2001; Ohtani et al. 1990; Kruse et al. 2002; Swistek et al. 1996) and a residue above 430 °C which may consist of some condensed products. The thermal decomposition temperatures at different heating rates were obtained from the DTG curves. The thermal decomposition temperature of PS increases at higher heating rates, due to less exposure to heat as the degradation time is reduced. At low heating rates, some cross-linked products are evident at temperature around 400–500 °C, but at higher heating rates the volatile products may not have sufficient time in the matrix to react.

A small weight loss, 1–1.5 %, occurs around 200 °C in all blends, which is likely due to the presence of moisture or residual solvent. The TDT of the blends increases as the amount of PVC increases in the blend then it slightly decreases for higher amounts of PVC. At this heating rate, the mutual stabilizing effect of these polymers is higher for relatively low PVC loadings, which may be due to more interfacial interaction due to homogenous distribution compared to the higher PVC loadings.

Two different concentrations of PVC, i.e., 2.5 and 20 wt% in PS, were examined at 2.5 °C min^{-1} heating rate. Only one DTA peak at 378 °C is observed, showing that the thermal degradation temperature of PS has increased from 352 °C to 378 °C. But with higher PVC amounts (20 wt%), three DTA peaks are observed, and it seems that the phase-separated PVC component decomposes earlier than PS. The first degradation step in high PVC content blends is the dehydrochlorination reaction in the temperature range of 280–350 °C. The second DTA peak at 370 °C is due to PS degradation. In these blends, the first-step degradation of PVC is not affected by PS, whereas the degradation of PS is affected by the degraded components of PVC. The third DTA peak around 500 °C is due to second-step degradation of PVC where the polyene sequence formed as a result of dehydrochlorination further splits up into small polyene linkages ultimately giving volatile aromatic products. Blends with high PVC loading degrade predominantly within their phase-separated regions. As the phase boundaries, where mutual interactions occur, are dominant in the blends with lower PVC loading, a higher stabilization effect is observed. From the DMTA and SEM studies, there is a tendency towards phase aggregation (leading ultimately to phase separation) with higher PVC content in the matrix. The SEM micrographs of the films with prolonged heating also show that at higher temperature this tendency further increases due to the viscous properties of the polymer matrix. The slow heating rate (and thus longer heating times) increases the phase aggregation tendencies in blends in particular with higher PVC contents. The interfacial interaction between the polymeric components with 20 wt% PVC in PS therefore is greatly reduced with a tendency for the polymer to degrade independently which causes a smaller increase in TDT as compared to lower amounts of PVC in the matrix.

For higher heating rates, the increase in the concentration of PVC has a different effect on the TGA curves than at low heating rates (Ahmad et al. 2007). The thermal decomposition temperature of the blends with higher PVC contents shows a continuous increase in contrast to that observed for low heating rates. When the polymer blends are degraded at higher heating rates (giving less time for

degradation), phase segregation, which depends upon diffusion, does not takes place to the same extent as in case of low heating rates.

The degradation reactions involved in PS include random scission (which reduces the molecular weight of the polymer), depolymerization (which yields monomer), intramolecular transfer reaction (which produces dimer, trimer, etc.), and intermolecular transfer reaction which reduces the molecular weight of the polymer. The initial degradation products from PVC are Cl radicals and HCl (Owen 1984; Ahmad and Mahmood 1996). The structure and composition of PVC and PS and the interaction of various products formed may give rise to some cross products formed from the radicals or molecules which migrate across these phase boundaries and can play an important role in the degradation of blends.

In such blends, the loading of PVC in the blend cannot impose diffusion restrictions on PS to reduce the possibility of PS degradation by intramolecular reaction. It has already been shown in programmed-heating experiments on the degradation of PS using thin films (McNeill and Mohammed 1972) that the production of styrene is delayed by as much as 60 °C. The matrix in this can be considered as a two-dimensional structure, and this was interpreted due to reduction of intermolecular transfer reaction in PS which gives rise to more active centers. Interference with the intermolecular transfer process in PS due to the presence of PVC may also possibly be one factor affecting PS stability.

It is expected that the Cl radical produced from the degradation of PVC (Scheme 14.3) can either combine with a tertiary hydrogen atom from PS or abstract hydrogen from PVC to produce HCl. The macroradical produced when the abstraction is from PS can combine with the radical from PVC, leading to cross-linking, thus mutually annihilating free radicals; zip elimination of the polymer chain stops and requires renewed initiation. The PVC chain, however, may also continue unzipping due to further abstraction of hydrogen by chlorine or by the catalytic action of HCl producing double bonds which can cross-link with PS products. When TGA curves were compared in the temperature range 400–500 °C, it was found that cross-linked products are formed through the cross-reaction.

Flammability of PVC/PS blends were investigated by cone calorimetry (Yao and Wilkie 2001). Cone calorimetry is the most effective method for the laboratory evaluation of the fire performance of polymers. The parameters obtained are total heat released (THR); average specific extinction area (ASEA), a measure of smoke; average mass loss rate (AMLR); and the time to ignition (t_{ig}); the most important is the heat release rate (HRR) and especially its peak value (PHRR) which gives information about the size of the fire and can be viewed as the "driving force" of the fire. Although there is modulation of the 90/10 PVC/PS curve, which may be caused by the action of HCl on the combustion of PS, the trend for the blends is similar to that of virgin PVC. As a matter of fact, the extinction area (total smoke) shows very similar values for PVC and 90/10 PVC/PS. If one excludes the specific extinction area contributed by PS, one finds that PVC in 90/10 PVC/PS is not significantly different from pure PVC. This conclusion holds true for most of the cone parameters. Because the specific extinction area is related to the production of aromatic
Scheme 14.3 Cross-linked products formed for PVC/PS blends

compounds, which, in the case of PVC, are produced by the intra- or intermolecular cyclization of polyenes, the similarity in the curves and values indicates that the combustion of PVC is unaffected by the presence of PS, which means that there is a little chemical interaction between PVC and PS.

14.5 Polyolefin Blends

Polyolefins are synthetic polymers of olefinic monomers. They may be classified based on their monomeric unit and chain structures as ethylene-based polyolefins (contain mostly ethylene units), propylene-based polyolefins (contain mostly propylene units), higher polyolefins (contain mostly higher olefin units), and polyolefin elastomers (Gahleitner 2001).

Ethylene-based polyolefins are normally produced either under low pressure conditions using transition metal catalysts resulting in predominantly linear chain

structure or under high pressure conditions using oxygen or peroxide initiators resulting in predominantly branched chain structures of various densities and crystallinities.

Propylene-based polyolefins are normally produced with transition metal catalysts resulting in linear chain structures with stereospecific arrangement of the propylene units or special stereoblock structures from a single-site catalyst. Higher polyolefins are normally produced using transition metal catalysts resulting in linear and stereospecific chain structures. Polyolefin elastomers, based mainly on a combination of ethylene and propylene, may be produced using metal or single-site catalysts with or without the inclusion of dienes (for cross-linking) and are mostly amorphous with high molecular weights and heterogeneous phase structures. A given polyolefin may be a homopolymer, copolymer, or terpolymer depending on the number of monomers used in making the polyolefin, crystalline, or amorphous depending on their chain conformation, configuration, and processing conditions.

Polyolefin homopolymers, copolymers, and terpolymers are foundation materials for polyolefin blends. They may be obtained via radical or ionic chain growth polymerization of alkenes using conventional free radicals (e.g., from peroxides) and organometallic complexes (Ziegler–Natta and metallocenes) catalyst systems. Polyolefin polymerization technologies and novel catalyst systems have enabled the rapid development of polyolefins with a wide range of molecular chain structures, morphologies, properties, and particle size and shape. Polyolefin homopolymers include polyethylene (PE), polypropylene (PP), polybutene-1 (PB), polymethylpentene-1 (PMP), and higher polyolefins. PE and PP are the largest by amount produced yearly by the global polyolefin companies. PE comes in various forms differing in chain structures, crystallinities, and densities. These are high-density polyethylene (HDPE), low-density polyethylene (LDPE), linear low-density polyethylene (LLDPE), ultralow-density polyethylene (ULDPE), and ultrahigh-molecular-weight polyethylene (UHMWPE). PP and higher polyolefins come in three stereospecific forms of varying densities: isotactic, syndiotactic, and atactic forms.

14.5.1 PP/PE

Although both polyethylene and polypropylene have similarities in properties (Brydson 1975), the two polymers are immiscible and incompatible in general. The terms "immiscible" and "incompatible" have been adopted here in line with the definition by Utracki (Utracki 1989), where immiscible is defined thermodynamically as the case when the Gibbs free energy of mixing ΔG_m is greater than 0, whereas incompatible means that the blend gives properties inferior to those of both the original constituents or neat polymers. Addition of a small amount of polyethylene or ethylene–propylene copolymer to polypropylene improves the impact performance of polypropylene (Brydson 1975; Utracki 1989), whereas the addition of a small amount of polypropylene to polyethylene enhances the

transparency of solid polyethylene (Last 1959), at the expense of environmental stress cracking resistance.

The effects of an organoclay and alumina trihydrate (ATH) and/or magnesium dihydroxide (MDH) on the fire retardancy of a ethylene–vinyl acetate (EVA) and low-density polyethylene (LDPE) blend were assessed by TGA and the cone calorimeter (Zhang et al. 2009).

The profiles of the polymer blend (PB) and polymer blend/nanoclay (PB/NC) in nitrogen are similar; both curves show two-step thermal degradation depicting two-stage degradation processes. The first step occurs between 300 °C and 400 °C and likely corresponds to the loss of acetic acid (Camino et al. 2000; Allen et al. 2000), while the second step involves the thermal decomposition of the resulting backbone by further radical scission (Beyer 2001). The presence of nanoclay accelerates the deacetylation of EVA (Zhang et al. 2009, 2001). On the other hand, the inclusion of a flame retardant reduces the onset degradation temperature to around 200–350 °C due to liberation of water in the flame retardant (Beyer 2001); ATH gives the greatest shift, since it has lower thermal stability, compared with magnesium dihydroxide. The second weight loss step is also affected by the presence of the clay; the onset of the second weight loss step for PB/NC is lower compared to PB, possibly related to a catalytic cracking of polymer induced by the clay (Zhang et al. 2009), in agreement with results reported in the literature for PE and PP (Manos et al. 2001; Tartaglione et al. 2008). Interestingly, this effect is particularly significant for PB/NC/ATH compared with PB/ATH and for PB/NC/MH compared with PB/MH.

When heated in air, the same two main weight loss stages are found, although the profiles of the weight loss curves are more complex due to the presence of oxygen, which promotes additional degradation pathways compared to the degradation in inert atmosphere. The presence of nanoclay promotes thermo-oxidative stabilization of PB, resulting in an overall decreased weight loss, whereas light destabilization is observed for PB/NC/ATH compared to PB/ATH, and no significant differences are seen for PB/NC/MH compared with PB/MH. The onset temperatures of PB/NC are slightly lower than those of PB, whereas those of the Fire Retardant Clay Materials (FRCMs) are significantly lower due to release of water at lower temperatures. In particular, PB/ATH and PB/NC/ATH reduce the onset temperature by more than 50 °C. In both nitrogen and air, PB pyrolyzes completely whereas about 4 % (in nitrogen) and 6 % (in air) residues were found for PB/NC, which are approximately the same as its initial concentration of 5 %, implying that NC remains after pyrolysis. It should be noted that the residual inorganic clay results from degradation of the organic compatibilizer of the organoclay, which reduces the initial weight of clay from 5 % to 4 %. For the FRCMs, it is worth noting that the final residues are slightly lower (4–7 %) than the theoretical ones calculated from the weight loss contributions of the individual components in the formulation. This may reflect an experimental error resulting from compounding of very highly filled formulations, but chemical interactions between the polymers and the hydroxide to produce a higher amount of volatile products cannot be excluded at this stage.

Once the PB ignited, extensive bubbling was observed having the appearance of liquid-like foam. The other formulations behave more like solids with only minor bubbling but with large deformations. No cracks were found for PB/NC and ATH-containing materials, whereas cracks were found for MH-containing materials. At heat fluxes below 40 kW m^{-2}, deformation (especially severe for PB/NC/ ATH and PB/NC/MH) caused the samples to move towards the igniter. This upward movement has two effects on the test results: (i) it causes the actual imposed heat flux to be higher than the nominal one, affecting the accuracy of the test results (Schartel and Hull 2007; Babrauskas 1992) and (ii) in some cases the experiment had to be stopped prior to ignition to avoid contact between the igniter and the sample. No ignition (within 10 min) was observed for all the formulations at 15 kW m^{-2}, and for PB/NC/ATH and PB/NP/MH, no ignition occurred at 20 and 30 kW m^{-2}. At low heat fluxes (15 and 20 kW m^{-2}), a carbonaceous layer was observed to form on the surface prior to ignition, which poses uncertainties in measuring the ignition time (there are relatively large differences between the measurements in duplicated tests). At higher heat fluxes (30 kW m^{-2} and above), the ignition times of the PB and PB/NC are similar, indicating again that NC does not alter the thermal properties of polymers. In contrast, all the FRCMs (ATH or MH) increase the ignition time. This should not be considered contradictory to the TGA results that the FRCMs decrease the onset degradation temperature, because (i) the water released from the FRs hinders ignition and (ii) ATH or MH is completely transformed into oxides (endothermic reaction) before ignition during heating, and therefore the temperature of the substrate is lowered, increasing the ignition time (Bourbigot et al. 1999).

The results at other heat fluxes show similar patterns. Although PB/NC has the same first peak HRR as the PB, the second peak for the PB is completely removed by the addition of 5 wt% nanoclay. This may be attributed to a surface layer formed during pyrolysis of nanocomposites, reducing the transfer of heat into unpyrolyzed material and increasing the surface radiation heat loss (Kashiwagi et al. 2004a, b; Wilkie 2002; Zanetti et al. 2001). For the FRCMs, the reduction is more substantial; even the first peak HRR is reduced by a factor of 2–3 compared to the PB with PB/NC/ATH achieving the lowest HRR. However, one should note that the reduction of the HRR by the FRCM is also due to the fact that there is less polymer in the FRCMs. Comparing the results of PB/ATH to PB/NC/ATH and PB/MH to PB/NC/ MH indicates that the effect of NC is not significant, and there is no clear indication of a synergistic effect between NC and FRs.

Since the HRR is proportional to the mass loss rate (MLR) (the proportionality factor is the heat of combustion), the MLR results have similar trends as the HRR.

The effective heat of combustion (EHC) is calculated as the ratio of the total heat released over the total mass loss (for the FRCMs, the mass loss of water (35 % for ATH and 32 for MH) was subtracted from the total mass loss). The average value for the PB is about 32 kJ g^{-1}, which is similar to the one reported for pure EVA by Lyon (Lyon and Janssens 2005). PB/NC has a similar but slightly lower value, implying that though it takes longer for PB/NC to burn, it burns completely. As for the FRCMs, the EHC is actually higher than the PB and PB/NC. To explain this,

it must be noted that the combustion efficiency of EVA (Lyon and Janssens 2005) is only about 0.8, and the water released due to degradation of FRs appears to assist combustion by increasing the mixing efficiency, as commonly used in combustion engines.

The mass loss (%) is essentially the same in the TGA and the cone. For the FRCMs, there are some differences between the residual weights obtained and the theoretical values, and these differences might also relate to the higher EHC discussed above.

As observed very recently (Shah and Paul 2006; Cervantes et al. 2007; Leszczynska et al. 2007), the products of the degradation of the organic modifier may interact with the matrix, and their solubility in the matrix would play a vital role in the process. In particular, the α-olefins produced by the Hoffman reaction, due to their affinity with the polyolefin phase, will disperse quickly into polyethylene (Frankowski et al. 2007). Likely, this diffusion is slower when the affinity is lower, as for PA6. In this latter case, as already observed for another system (Frankowski et al. 2007), the final effect would be a sort of swelling of the tactoid caused by the permanence of the degradation products between the clay layers. This was confirmed in separate investigations (Scaffaro et al. 2008) performed on PA6 and HDPE nanocomposites (5 % clay, extruded under the same conditions as the other blends). The interlayer distance in the clay is 3.15 nm, while in PA6 it is 3.57 nm and in HDPE it is 2.54 nm; a significant degradation of the clay modifier occurs during preparation.

In the HDPE phase, the reduction of the interlayer distance can be explained by a rapid diffusion of the degradation products from the clay galleries towards the HDPE phase and, as a consequence, the collapse of the tactoid and the reduction of the interlayer distance.

In addition, the slight increase of the interlayer distance in the PA6 phase can be ascribed, beyond some intercalation of the polymer, also to the permanence of the degradation products in the clay galleries. In this case, these products are less prone to diffuse into the PA6 matrix, and the final effect is the expansion of the tactoids.

Of course, the interactions of the degradation products with the matrix can contribute, together with the decrease of the crystalline fraction, to the decrease of the mechanical properties.

14.6   Styrenic Blends

The thermal degradation of polystyrene proceeds by a random scission process (Cullis and Hirschler 1981); the production of benzene, toluene, styrene, and styrene oligomers begins at about 350 °C (Suzuki and Wilkie 1995). A graft copolymer has been produced by the addition of acrylonitrile onto polystyrene using an anionic copolymerization process (Xue and Wilkie 1997a, b). In order to offer thermal protection by a graft copolymerization process, it is necessary that the graft layer degrades first and forms a char which can protect the underlying layer. From a TGA/FTIR study, the first product one observes is ammonia which arises

from the degradation of polyacrylonitrile. For virgin polyacrylonitrile, ammonia evolution begins at about 290 °C, while in this graft copolymer ammonia evolution does not commence until 350 °C, and the evolution of aromatics, which is the signature of polystyrene degradation, does not begin until 420 °C which is 70 °C higher than in virgin polystyrene. Both graft copolymers and blends of polystyrene with polyacrylonitrile show similar behavior. There are two observations of significance here: the degradation of polystyrene begins at higher temperature and the degradation of acrylonitrile begins at higher temperature; each of these will be examined separately.

The higher temperature for the evolution of aromatics indicates enhanced thermal stability for the graft copolymer (Wilkie 1999). Since the graft layer does degrade initially, it will form a char layer, i.e., a thermal barrier, which protects the underlying polystyrene. A similar degradation pathway is seen in blends, which implies that it is not necessary that the char be formed at the surface of the polymer, it is just important that char be formed. From TGA/FTIR, the graft copolymerization of acrylonitrile onto polystyrene does enhance the thermal stability of polystyrene. While from cone calorimetry, this is not observed, and the graft copolymer and the blends have a lower thermal stability than virgin polystyrene. This leads to an apparent contradiction. The graft copolymerization of sodium methacrylate onto ABS, SBS, and K-resin gives a good correlation between TGA/FTIR studies in an inert atmosphere and cone calorimetric studies in air, while for poly(styrene-graft-acrylonitrile) there is no correlation. The difference is due to the kind of graft layer. When the graft layer is inorganic, it cannot burn and one would not expect a difference between nitrogen and air; this is the case for the graft copolymerization of sodium methacrylate. When the graft layer is largely carbonific, it must burn, and a correlation between studies in air and in an inert atmosphere may not be observed.

In order to understand why the presence of polystyrene should raise the temperature at which polyacrylonitrile begins to degrade, a detailed investigation of the degradation of polyacrylonitrile, PAN (Xue et al. 1997), was undertaken. It was realized that TGA/FTIR studies do not enable a complete understanding of a degradation pathway, and the solid residues which are produced in the course of the thermolysis were also examined. The solid residues were obtained at temperatures which corresponded to some change in the TGA curve or the appearance of the infrared spectrum of gaseous products and at other temperatures based upon these results. The solids were characterized both by elemental analysis and by infrared spectroscopy. From the analysis of the solid residues, one can determine that PAN undergoes a cyclization reaction without any mass loss and that the loss of ammonia occurs from this cyclized product. A complete degradation pathway has been mapped out for PAN based on these results. Cyclization occurs through the ends groups of the PAN chain, and this is then followed by tautomerization and aromatization with the elimination of ammonia and hydrogen.

The application of this degradation pathway to poly(styrene-graft-acrylonitrile) permits one to understand the stabilization of the acrylonitrile fragments in the graft copolymer. Degradation of PAN is initiated at the chain ends; the graft copolymer is prepared via an anionic route so the chain ends will be saturated and will not contain

functionalities, and thus the initiation of cyclization will be more difficult and the degradation will occur at higher temperatures.

The above leads one to believe that a material which gives an inorganic char should be more efficacious than an organic char. Accordingly, other monomers which have the potential for graft copolymerization have been examined; these include sodium styrenesulfonate, sodium vinylsulfonate, vinylsulfonic acid, and vinylphosphonic acid (Jiang et al. 1999). All of these materials show a significant volume expansion during degradation. This intumescent behavior may be of advantage for the stabilization of some polymers. One of the more significant observations in this study is that the TGA curve is essentially the same in either air or an inert atmosphere. As noted above, this is likely due to the production of a largely inorganic residue and lends further credence to the assertion made above on the nature of the residue.

14.6.1 Acrylonitrile–Butadiene–Styrene (ABS)

Acrylonitrile–butadiene–styrene terpolymer (ABS), as well as its fiber reinforced composites and blends, is a very important and widely used engineering material. The demand for and production of this family of materials increase year by year; however, there is only little work on the thermal degradation of ABS terpolymer (Dong et al. 2001; Luda di Cortemiglia et al. 1985; Suzuki and Wilkie 1995).

A thermal degradation process was performed upon ABS by heating ABS (200 mg) to 350 °C at the rate of 50 °C min^{-1} and keeping it at 350 °C (Dong et al. 2001). The evolution of butadiene commenced at 340 °C and styrene at 350 °C, while the evolution of monomeric acrylonitrile began at 400 °C. The evolution of volatile substances, butadiene and aromatics, e.g., styrene and benzene, is observed throughout the process. The residue dissolves in tetrahydrofuran (THF); no cross-linked product was formed throughout the whole process, but the resulting solution darkened as the reaction time increased.

The ABS residues were investigated by GPC; the average molecular weight of ABS decreases rapidly. The molecular weight distribution curve suggests that larger fragments of ABS chains are generated due to random scission. The low-molecular-weight peaks are attributed to a combination of monomers (butadiene, styrene) and small molecular weight oligomers (dimer, trimer) due to specific scission, i.e., end-chain scission. However, most of monomers volatilized, therefore the peaks for monomers in GPC curve are not strong but detectable. No evidence for repolymerization or cross-linking reaction was observed. Apparently, the nonvolatile degradation product contains monomers, oligomers (dimer, trimer), and larger fragments of ABS chain. The results suggest that both random and specific scissions occur during the degradation procedure of ABS at 350 °C.

From the infrared spectra of the nonvolatiles residues, one learns that aromatics increase and nitrile decreases and new bands corresponding to C=C and C=N appear (Fochler et al. 1985; Conley 1972) (C=C stretching, 1,590–1,670 cm^{-1}; C=N stretching, 1,580–1,620 cm^{-1}). Some nitrile groups are converted as a result

of the cyclization reaction. Furthermore, coloration as the reaction proceeds confirms that conjugation increases. Extensive work concerning thermal degradation behavior of polyacrylonitrile has demonstrated that new structures result from the polymerization or oligomerization of sequences of adjacent nitrile groups by a radical process (Grassie and Scott 1985; Coleman and Sivy 1981; Grassie and McGuchan 1970; Xue et al. 1997). However, acrylonitrile is only one component of ABS, so the conjugated nitrile sequence is of very short length and linked by unchanged segments, which is one of the reasons why the residues are soluble in THF. Some spectra exhibit absorption in the 1,680–1,750 cm^{-1} region. This group of peaks is generally assigned to a composite absorbance in which aldehydes (1,735 cm^{-1}) and ketones (1,720 cm^{-1}) are the main species formed during the early stages of degradation, but carboxylic acids (1,710 cm^{-1}) predominate in the later stages. Undoubtedly, oxygen in the air participated in the thermal degradation reaction at high temperature and led to the formation of the carbonyl groups. In fact, ABS is particularly sensitive to oxidation due to the presence of polybutadiene which is an oxidation sensitizer and leads to the formation of carboxylic acids (Grassie and Scott 1985). Additionally, it is reasonable that the formation of carboxylic acids can also result from the oxidation of some (isolated) nitrile groups.

Specific microstructural aspects of a polymer often facilitate thermal oxidation. In the case of ABS, hydrogen abstraction by oxygen is thermodynamically favorable due to the presence of tertiary substituted carbon atoms in the PB phase. The presence of sufficient thermal energy activates hydrogen abstraction to initiate oxidation and accelerates the overall process of degradation. After periods of exposure to heat and oxygen, the mechanical properties of ABS, impact strength and elongation to break, deteriorate as a consequence of polymer degradation, inducing premature failure (Wolkowicz and Gaggar 1981). The literature cites various explanations for the degradation of ABS due to heat aging. Several researchers state that thermo-oxidative degradation of ABS is confined to the rubbery PB phase, while others propose that property degradation is due to a combination of physical aging in the SAN phase and oxidation of the PB phase (Gesner 1965; Shimada and Kabuki 1968; Wyzgoski 1976; Salman 1991). Shimada and Kabuki (Shimada and Kabuki 1968) proposed that thermo-oxidative degradation occurs in the rubber phase of unstabilized ABS film, leading to the formation of hydroperoxides. Degradation was thought to occur by hydrogen abstraction from the carbon next to the *trans*-1,4 and *trans*-1,2 unsaturations in the PB phase, producing hydroperoxide radicals. The rate of this reaction was said to follow Arrhenius-type kinetics, with rate constants and reaction orders determined from the formation rate of carbonyl and hydroxyl products, as monitored by Fourier transform infrared (FTIR) spectroscopy. In contrast, Wyzgoski (Wyzgoski 1976) states that annealing ABS below the glass transition temperature (T_g) of its SAN phase (physical aging) produces molecular conformations which embrittle the polymer, significantly decreasing tensile elongation properties. Below its glass transition temperature, the SAN microstructure adopts an energetically unfavorable state driving towards equilibrium via molecular motion (Simha et al. 1984). The transformation between a glass and an amorphous polymer involves a kinetic

process of polymer molecular mobility. By providing thermal energy during the physical aging (annealing) process, a glass tends to equilibrate its polymer micro-structure (Wyzgoski 1976; Qi et al. 1993). When heating annealed polymers, as the temperature increases towards T_g, the rate of the kinetic process is retarded in comparison to unannealed polymers (Simha et al. 1984), and thus, in comparison, the rate of change in tan δ decreases as T_g is approached. On a macro level, this physical aging process increases stiffness and yield stress – in fact, yield stress is increased above craze stress such that brittle fracture is favored over yielding.

If one compares the degradation of ABS with that of its constituent parts (Suzuki and Wilkie 1995), one notes that the evolution of butadiene begins 50 °C higher for ABS than for PBD. Grafting SAN onto PBD stabilizes the PBD structure. Since SAN is directly bonded to butadiene units, the liberation of butadiene should be less facile. In SAN, the evolution of aromatics is first noted at 370 °C while in ABS, aromatics are first seen at lower temperature, 350 °C. These results are the same as reported by Camino (Luda di Cortemiglia et al. 1985). Apparently SAN is destabilized by the presence of butadiene. The formation of acrylonitrile is not reported by Camino; in SAN, it is first observed at 405 °C, and in ABS the evolution of acrylonitrile begins at about 400 °C. Since the thermocouple is not directly at the sample, these are considered to be the same temperature.

The degradation of ABS may be considered to be essentially the same as that of its constituents. It begins in the butadiene region of the polymer then proceeds to the SAN portion. The presence of SAN stabilizes the PBD while SAN is destabilized by the presence of PBD. Less acrylonitrile is obtained from ABS than from SAN. The amount of residue that is produced is directly related to the butadiene content of the sample.

The common flame retardants for ABS are halogen-containing compounds. Bromine-containing compounds such as decabromodiphenyl oxide (DB), tetrabro-mobisphenol (TBBPA), and 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPOE) have been regarded as very good flame retardants for ABS resin (Brebu et al. 2004).

The first halogenated flame retardant examined, aiming at the reduction of nanocomposite ignitability, was DB combined with antimony trioxide (AO). Metal oxides, such as AO, are added to halogenated compounds as synergists, since their interaction contributes to flame retardancy probably through the gener-ation of antimony halides (Mack 2004; Levchik and Weil 2000). The DB–AO system was employed by Hu and his colleagues (Wang et al. 2004) to prepare flame-retardant ABS/OMMT nanocomposites which could be rated by the UL94 protocol. Accordingly, the same type of clay (5 wt%) was well dispersed in ABS along with 15 wt% DB and 3 wt% AO using a twin-roll mill, and the fire properties of the resulting mixture were thoroughly studied. In contrast to neat ABS and its nanocomposite, the sample containing both the clay filler and the flame-retardant system obtained a V-0 rating and an increased LOI value (27.5 vol.%). Further-more, the performance in cone calorimeter was greatly improved, 78 % reduction in PHRR of the flame-retarded nanocomposite relative to pure ABS.

The challenge to enhance the thermal stability of ABS nanocomposites along with their resistance to ignite was faced by Ma et al. (Ma et al. 2006), substituting

DB with a brominated epoxy resin (BER). BER is a high molecular weight gas-phase flame retardant with 53 wt% bromine content based on tetrabromobisphenol A, which is commonly used in ABS or PC/ABS blends with AO as synergist. With small amount of the halogenated compound (12 wt% BER + 4wt%AO), the LOI of ABS containing 2 wt% clay increased from 20.5 to 31.4 vol.%, which is far beyond 24 vol.%, the LOI value usually required for a material to obtain a V-0 rating (Weil et al. 1992).). The combustion process and the synergistic effect of clay and BER–AO are presented schematically in Fig. 14.3. Similar to the OMMT–DB–AO system, the synergy between OMMT–BER–AO derived from silicates forming barriers that hindered BER pyrolysis and reactions between BER–AO at lower temperatures. Consequently, continuous flame retardancy in the vapor phase could be attained throughout combustion. Moreover, it was suggested that the alkylammonium cations residing in the interlayer decomposed, at around 200 °C, to fragments which could volatilize and expand clay layers promoting dispersion. Exfoliated structures, exhibiting better barrier properties than their intercalated analogues, could efficiently delay mass and heat transport. On the other hand, the reaction between the surfactant decomposition products and DB–AO, occurring at high temperatures, resulted in the formation of radical scavengers.

Although halogen-containing flame retardants show remarkable efficiency, they lead to environmental problems by generating great quantities of toxic and corrosive fumes during combustion which restricts their application. Organic phosphates, halogen-free flame retardants, are known to be good candidates to replace halogens. Among the various phosphorus-based flame retardants, triphenyl phosphate (TPP) (Kim et al. 2003; Lee et al. 2002; Costa et al. 1998) and tetra-2,6-dimethylphenyl resorcinol diphosphate (DMP-RDP) (Lee et al. 2003) are employed as the flame retardants for ABS resin with various novolac phenol resins (NP) and epoxy compounds (EP). TPP/NP, TPP/EP, and DMP-RDP/NP mixtures are effective in enhancing the thermal stability of ABS. TPP itself generates phosphoric acid during thermal degradation, and the reaction among phosphoric acids takes place and leads to pyrophosphoric acid, which acts as heat transfer barrier in the condensed phase (Green 2000; Hastie and McBee 1975). However, the evaporation temperatures of TPP and its analogues are lower than the processing temperature of ABS, which lead to TPP and its analogues partially decomposing/evaporating during processing (Costa et al. 1998). To utilize the mixtures of TPP with other polymers in order to overcome evaporation, mixtures of TPP with novolac phenols are the most intensively studied, and the evaporation of TPP is effectively suppressed due to the interaction between TPP and phenol, elevating the evaporation temperature of TPP (Costa et al. 1998; Fyfe et al. 1983; Chetan et al. 1993; Jackson and Conley 1964; Boscoletto et al. 1994). Polycondensates are produced from rearrangements of phenol formaldehyde in the main thermal degradation routes, and they act as char-forming agents and flame-retarding effects are observed (Costa et al. 1997; Jackson and Conley 1964; Morterra and Low 1985; Serio et al. 1991; Jha et al. 1989; Peters et al. 1980). On the other hand, the epoxide ring can be converted into carboxylic acid during thermal oxidation (Malinovski 1965). Consequently, enhancement in thermal stabilization may be expected if
Fig. 14.3 Schematic presentation of the synergistic effects between clay and BER–AO incorporated in ABS (Reproduced with permission from Elsevier, from H. Ma, Z. Fang, L. Tong, Polym. Degrad. Stab. **91**, 1972 (2006))

reaction between TPP and the generated carboxylic acids can take place during thermal oxidation. Mixtures of TPP and epoxy were incorporated into ABS and investigated to determine if there is any synergistic effect of epoxy addition on the thermal stability of ABS (Lee et al. 2002). The initial weight loss observed at 200–400 °C, which is mainly caused by TPP evaporation, is greatly reduced for the

compound containing epoxy resin. TGA results (Lee et al. 2002) show that epoxy resin delays evaporation of TPP in the initial thermal degradation, and, during further thermal degradation, more thermally stable char is formed through some reaction, which is not clear at this time, between TPP and epoxy resin. However, the earlier results are enough to claim that epoxy can be a very efficient synergistic co-flame retardant for ABS. Furthermore, most phosphorus-based flame retardants used for ABS are liquids, which are not convenient to use in the manufacturing of flame-retarded products.

Intumescent flame retardants (IFR) that contains phosphorus are also used in halogen-free flame-retardant systems. Most reported IFRs are mixtures of the three ingredients, an acid source, a polyol, and a nitrogen-containing compound (Halpern et al. 1984). Since processing of ABS resin requires that the additives withstand temperatures in excess of 200 °C, the commonly used intumescent system, ammonium polyphosphate, pentaerythritol, and melamine, which do not have sufficient thermal stability, cannot be incorporated into ABS resin under normal processing conditions; they are usually used in polyolefins.

A phosphorous–nitrogen-containing intumescent flame retardant, poly (diaminodiphenyl methane spirocyclic pentaerythritol bisphosphonate) (PDSPB), was synthesized and investigated by TGA and DTG. Only one step decomposition around 350–500 °C is found for pure ABS under nitrogen, leaving negligible char above 500 °C. Both T_{onset} and T_{max} in TGA curve of PDSPB in N_2 are lower than those of ABS resin, which means PDSPB degrades early. For ABS/PDSPB samples, T_{onset} of PDSPB-containing samples is lower than that of the pristine material, due to the earlier degradation of PDSPB; however, T_{max} of the major degradation step increases for the PDSPB-containing samples, indicating the thermal-enhancing effect of PDSPB. The amount of residue improves greatly with the increase of PDSPB addition.

TGA and DTG thermograms showed that the addition of PDSPB reduces the initial degradation temperature but enhances the thermal stability at high temperature. There must be a difference between the initial degradation temperature of the polymer and the intumescent flame retardant, since phosphoric and polyphosphoric acids have to be produced in the beginning of combustion to accelerate esterification and carbonization (but the T_{onset} of flame retardants should not be lower than the processing temperature) (Wang 2005).

The LOI value of ABS resin is 19.1 indicating its inherent flammability. As the amount of PDSPB increases, the LOI increases, indicating that the flame retardancy of the treated ABS composites is improved; at the same time, there is less tendency for dripping. PDSPB is an effective flame retardant for ABS resin.

Pure ABS resin burns rapidly after ignition and a sharp PHRR appears at 930 kW m^{-2}. In the case of the ABS/PDSPB system, both the PHRR and average HRR are reduced significantly. The PHRR is reduced by 52 % and 58 % for ABS/20 % PDSPB and ABS/30 % PDSPB samples, respectively, relative to pure ABS resin. The THR is reduced by 25 % and 33 % for the two PDSPB contained samples. The reduction of PHRR and THR becomes smaller as the PDSPB concentration increases. The reduction of PHRR indicates that a cohesive char

layer is formed during combustion which acts as an insulating barrier between the fire and ABS resin. Meanwhile, the ASEA and AMLR are also reduced. However, the ignition time of ABS/PDSPB samples is lower than that of pure ABS. This may be due to the earlier decomposition of PDSPB, producing some small volatile molecules. PDSPB cannot only reduce the HRR but also can suppress the emission of smoke.

A novel intumescent flame-retardant (IFR) system composed of a phosphorous–nitrogen (PSPTR)-containing spiro triazine structure and phenol formaldehyde resin (PF) was investigated by Hu et al. (Hu et al. 2012).

PSPTR shows four weight loss stages. The first stage is due to the scission of the methoxy group around 222 °C, while the second at around 290 °C is due to the pyrolysis of the P–N bond. The third is attributed to the decomposition of P–O–C and the triazine structure at around 337 °C (Chen and Jiao 2008). Meanwhile, a new substance, 2,4-diamino-1,3,5-triazine polyphosphate, is formed in this step. N-2-(4-amino-1,3,5-triazin-2-yl)-1,3,5-triazine-2,4-diamine polyphosphonate and ammonium polyphosphate groups could be formed from 2,4-diamino-1,3,5-triazine polyphosphate at high temperature. The last stage is attributed to the cracking of N-2-(4-amino-1,3,5-triazin-2-yl)-1,3,5-triazine-2,4-diamine polyphosphonate forming a complex P–N mixture at around 506 °C. Two simple thermal degradation processes are found in PF. The first weight loss stage is due to the condensation reaction at around 360 °C and the formation of diphenyl ether linkages (Costa et al. 1997). The diphenyl ether linkages will generate a polyaromatic system at about 450 °C. The second stage can be assigned to the thermal degradation of the polyaromatic system at around 548 °C.

What is more, the IFR has a high-residue char of 50.2 wt% at 700 °C and three weight loss stages. The first degradation stage occurs at 200−420 °C, which is the most important stage for intumescent char formation. The formation of polyphosphoric acid could catalyze PF to form diphenyl ether linkages. The second weight loss stage around 420–510 °C can be attributed to the thermal decomposition of the diphenyl ether linkages which leads to the formation of the polyaromatic system at high temperature. The third step around 546 °C is attributed to the thermal degradation of the polyaromatic system. In addition, a new DTG peak is observed at 420–510 °C, which does not appear in the DTG curve of either PSPTR or PF. It is thought that polyphosphoric acid, formed from PSPTR, can react with PF to form more diphenyl ether linkages during the heating process. The thermal decomposition of a large amount of diphenyl ether linkages at 420−510 °C will help in the formation of the char which can improve the flame retardancy of ABS. The catalytic char formation is also the reason for the observed synergistic flame-retardant action of PSPTR and PF. Furthermore, pure ABS starts to decompose at 383 °C and has a negligible char (1.6 wt%) at 700 °C. The onsets of degradation (5 wt% mass loss) of the PSPTR and PF occur at about 249 °C and 216 °C, which are lower than pure ABS resin, but higher residues, 40.3 wt% and 42.6 wt% at 700 °C, respectively, are obtained. The addition of IFR decreases the onset of degradation but enhances the thermal stability at high temperature. The char yield of the composite can reach 16.4 wt% at 700 °C. This could be the result of the

thermal degradation of PSPTR and PF at the lower temperature and formation of intact char layer which can protect the remaining polymer from heat and limit the access of oxygen to the polymer.

It was found that a possible synergistic chemical interaction may occur between PSPTR and PF during the thermal process. In order to investigate this further, the calculated and experimental TG curves of IFR system (PSPTR/PF = 1:1, wt %) were compared. It is unambiguously found that the char residue yield is higher than the calculated value above 346 °C and an improvement of 8.8 wt% at 700 °C is noted, indicating PF plays a synergistic role in the thermal degradation and acts as carbon source to participate in the formation of char. This result is favorable for the protection of the inner polymeric material from fire and oxygen.

14.6.1.1 Polyamides

Polyamides are a very attractive class of engineering polymers, used for numerous engineering applications because of their excellent tensile properties, chemical and abrasion resistance, high melting point, and fatigue resistance. However, polyamides are very notch sensitive and brittle at low temperatures (Keskkula and Paul 1995; Flexman 1979; Gayman 1994). Blends of polyamide with rubber have been extensively studied in order to obtain new materials with good impact properties (Van Duin and Borggreve 1997; Wu 1987, 1988; Borggreve et al. 1987, 1989; Oshinski et al. 1992, 1996; Cimmino et al. 1984, 1986; D'Orazio et al. 1988; Modic and Pottick 1993; Lu et al. 1995). Some requirements to achieve toughening include (i) an appropriate range of rubber particle size and interparticle distance and (ii) a uniform distribution of the rubber particles. Both requisites can be obtained by controlling the level of interfacial adhesion between the phases (Lu et al. 1995). To fulfill those requirements, existing rubbers can be chemically and/or physically modified prior to blending with polyamide. Maleated rubbers are a successful example of these modifications. The maleic anhydride (MA) groups can react with polyamide amine end group and form a graft copolymer at the rubber–matrix interface, reducing interfacial tension and retarding particle coalescence during mixing (Scheme 14.4). The resulting particles have suitable sizes uniformly distributed for effective toughening (Van Duin and Borggreve 1997; Wu 1987, 1988; Borggreve et al. 1987, 1989).

For non-functionalized rubbers, addition of a compatibilizer can be an alternative to improve toughness (Oshinski et al. 1992, 1996; Cimmino et al. 1984, 1986; D'Orazio et al. 1988; Modic and Pottick 1993; Lu et al. 1995), because it can react with one phase and physically interact with the other improving the adhesion between the rubber and polyamide phases.

Investigation of an effective method to compatibilize rubber–polyamide blends has been carried out (Carone et al. 2000). The rubber particles are formed from natural rubber (NR) and the matrix is polyamide 6. Compatibilization occurs by adding MA to the rubber in a roll mill at room temperature, prior to blending with polyamide 6. During processing at high temperature (240 °C), two different reactions can occur (Subramaniam 1986; Pinazzi et al. 1962, 1963; Nakayama 1973; Le Bras and Compagnon 1947). The first is the grafting of the MA

Maleic Anhydride (MA)
Scheme 14.4 Possible reactions between MA, NR, and PA6

onto NR chains as shown in Scheme 14.4. This reaction occurs only at temperatures above 200 °C, even in the absence of any free-radical initiator. Addition of peroxides increases the efficiency; however, a high degree of reticulation can be obtained (Subramaniam 1986). The other possible reaction is the formation of the graft copolymer between NR and polyamide 6 (NR-g-PA6), through the reaction between already maleated NR and polyamide. The question of interest in this work is whether this graft copolymer (NR-g-PA6) was generated during processing.

All of the polyamide-containing materials showed a weight loss of approximately 3 wt% at around 100 °C due to loss of water, and MA-containing materials showed weight loss due to free MA anhydride sublimation at approximately 200 °C. Natural rubber (with or without MA) showed weight loss due to degradation at around 400 °C, whereas all polyamide-containing materials showed weight loss at higher temperatures (around 500 °C).

It is interesting to note that after polymer degradation (above 500 °C), only MA-containing materials showed residual material up to 800 °C. This evidence indicates that reactions take place during processing and cause the formation of both gel and graft copolymer. Gel material is formed during processing of NR with MA as can be seen in the literature (Subramaniam 1986; Pinazzi et al. 1962, 1963; Nakayama 1973; Le Bras and Compagnon 1947). In the blend of polyamide 6/(NR 3 wt% MA), rubber reticulation also takes place; however, the 15 wt% rubber blend showed the same residual mass as neat NR with 3 wt% MA. This allows one to conclude that besides rubber cross-linking, the NR-g-PA6 graft copolymer is also formed, since the same amount of residual material was obtained.

It was shown that incorporating APP in PA6 enables the fire properties of interest to be obtained. Moreover, using PA6 as a carbonization agent in association with APP was shown to be successful in polypropylene (PP) (Bourbigot and Le Bras 2000). However, the stability of the APP/PA6 blends obtained by direct mixing of APP in melted PA6 is low: migration of the mineral (Le Bras et al. 2000) occurs during solidification of the melt and over time in the solid. The use of an interfacial agent is required. EVA compounds, which are known to be very efficient interfacial agents (Davis et al. 2001; Liu and Baker 1992), have been used as compatibilizers in the intumescent PP/APP/PA6 system. It was shown using oxygen consumption calorimetry that using EVA19 as a compatibilizer in the PP/APP/PA6 intumescent system gives fire properties of interest (Almeras et al. 2002a).

In addition, using the cone calorimeter a sharp reduction in the mass loss rate is demonstrated compared with pure PP (Almeras et al. 2002b). The virgin polymer degrades rapidly within 150 s whereas the PP/APP/PA6/EVA19 intumescent blend shows an initially reduced mass loss rate, which rapidly decreases, corresponding to the development of the intumescent structure. After 300 s, the second step of degradation is observed, which corresponds to the degradation of the protective shield.

From TGA in both air and nitrogen, PP degradation involves the scission of the polymer chain and occurs between 250 °C and 400 °C in air and 300 °C and 440 °C in nitrogen.

The mechanisms of thermal and thermo-oxidative degradations of PA6 were investigated by Dabrowski et al. (Dabrowski et al. 2000). In air, the major stage of weight loss occurs between 310 °C and 440 °C and is assigned to the main-chain breakdown, releasing water, ammonia, and carbon oxides. Above 460 °C, a charred residue (aromatic structure) stable up to 800 °C is formed. In nitrogen, the major stage of weight loss (about 90 wt%) occurs above 400 °C and may be assigned to the main-chain breakdown releasing water, ammonia, carbon monoxide and dioxide, and hydrocarbon fragments (Bourbigot et al. 1993), leading to the formation of a charred residue (about 3 wt%).

The thermal and thermo-oxidative degradations of APP have been reported (Hornsby et al. 1996; Camino et al. 1984; Zhang et al. 1993); they are similar and consist of two steps. The degradation begins around 300 °C with the elimination of NH_3, leading to the formation of a highly cross-linked polyphosphoric acid, whereas the second step above 550 °C corresponds to polyphosphoric acid evaporation and/or dehydration to P_4O_{10} which sublimes.

Incorporating APP in PA6 leads to the destabilization of PA6. Indeed the (APP/PA6) blend begins to degrade at a temperature 50 °C lower than virgin PA6. This can be explained by the attack induced by the phosphoric acid species (formed from the degradation of APP; Camino et al. 1985) on alkylamide bonds of PA6, which leads to the formation of a phosphate ester and primary amide chain ends and then elimination of ε-caprolactam (Levchik et al. 1992). A residue (about 35 wt% in air and about 25 wt% in nitrogen) with a low degradation rate between 400 °C and 500 °C in nitrogen and between 400 °C and 550 °C in air is then formed. Its degradation in air around 600 °C (in nitrogen around 550 °C) leads to the formation of a stable 2 wt% residue (10 wt% in nitrogen).

The thermo-oxidative degradation and the pyrolysis of the intumescent blend PP/PA6/APP/EVA19 occur in a three-step process. In air, the first step occurs at about 250 °C, and a carbonaceous material is formed in the temperature range 300–430 °C. Its degradation rate is low in the temperature range 410–540 °C. Finally, it degrades rapidly in the higher temperature range to give a residue about 4 wt% at 800 °C.

In nitrogen, the first stage (about 20 wt%) loss occurs at about 300 °C. Then the major weight loss takes place leading, above 500 °C, to the formation of a carbonaceous residue with a low degradation rate.

Oxygen plays a major role in the degradation process of the intumescent blend (as already put forward for the APP/PA6 blend). In particular, it must be noted that an oxidative atmosphere favors the charring process, increasing the residual weight after the second step from about 17 to 30 wt%. It is assumed that the two first steps correspond to the reaction between APP and PA6 and to the PP degradation. However, the order in which these steps occur is controversial.

14.7   Conclusions

Polymer blends, like all organic polymers, will undergo degradation by a variety of processes, including thermal degradation, photolytic degradation, biodegradation, and mechanical degradation. In this chapter, only thermal degradation and its close relative, fire retardancy, are covered. The starting point for the degradation of a blend is always the degradation of the constituent parts of the blend. In some cases, the components have an unchanged thermal stability, while in other cases they may be either more or less stable. One cannot predict how the stability may change, and it also can depend upon the relative amounts.

Abstract

This chapter builds on the information contained on the same subject in Chap. 13 of the first edition of the *Polymer Blends Handbook* by providing an overview of current applications of polymer blends and alloys with an outlook towards developing areas. A dual approach employed herein to portray the field covers both a description of polymer blend technologies directed toward solving application issues related to societal megatrends, as well as the generic performance/ testing specifications required for products in broad areas of commerce amenable to polymer blend applications.

15.1 Introduction

The blending and alloying of polymers is an important component of approaches for providing materials to address sustainable solutions to global needs, such as those associated with population growth and aging, urbanization, climate change, and energy demand. For example, according to Roland Hingmann of BASF Advanced Materials and Systems Research in an address to the Polymer Engineering Department of The University of Akron on March 20, 2013, the earth's current population of seven billion will increase to nine billion by the year 2050, 50 % more energy will be needed by 2030, 67 % of the world population will live in cities by 2025, and there will be 1.2 billion cars on the roads by only 2020. These megatrends open up opportunities for new polymeric products to address needs for lightweight vehicles, renewable and biodegradable materials in packaging and other applications, energy efficiency, safety, lifestyle comforts, medical instruments and supplies, and components for the food industry.

Polymers are ideal materials to meet developing societal needs due to their broad performance profiles, economical shape forming ability and generally low density. They thus can provide valuable properties in a cost-effective manner. The blending and alloying of various types of polymers, along with the compounding in of other ingredients such as fillers, plasticizers, stabilizers, colorants and reinforcements, extend their reach by providing a means to economically generate polymer systems with broader performance spectra than possible from individual polymer components.

While some commercial blends are marketed for wide-ranging applications deriving from their generally beneficial mechanical, electrical, thermal, chemical, or flow properties, as the technology matures, it focuses more on new blends and alloys having unique or critical properties or property mixes for specific applications. Other wide-ranging applications comprise the major subject matter of this chapter.

The chapter is organized by two complementary views of polymer blend applications. In Part 1, the focus is placed on describing important and emerging polymer blend technologies and their fit in applications that help solve issues related to current megatrends. In Part 2, the focus is placed on specific application areas, where requirements are described independent of blend system. This "outside-in" approach from market needs to performance requirements not only will be applicable to polymer blends on the market today but can aid in the design of new blend systems, which may incorporate the technologies highlighted in Part 1.

It is hoped that the approach outlined above provides a fresh view on polymer blend applications that builds on, and complements the presentation on the same subject in Chap. 13 of the first edition of the Polymer Blends Handbook.

15.2   Part 1: Polymer Blend Developments for Developing Opportunities

There are some newer application areas and polymer blend products targeted to fit those new opportunities. The latter include such combinations as PVC and PS blended with PP, HDPE, and each other; metallocene-polymerized nanoscale blends of polyolefins with more polar polymer partners; and, for high-temperature/high-performance applications, PPS blended with PSF, PEI, and polyamides as well as blends incorporating poly(aryl ketones), polyimides, and poly(amide-imides) (Thomas et al. 2006).

While the polyketone terpolymer derived from carbon monoxide, ethylene, and propylene is economical with some attractive properties, such as heat, chemical, permeation, and abrasion resistance, it suffers from low-impact strength. One cost-effective approach to overcoming this shortcoming and upgrading its performance profile for automotive applications such as wheel covers, wheel caps, fuel filter necks, fuel tanks, fuel tubes, center fascias, door handles, roof rack covers, gears, junction boxes, connectors, and seat backs, as well as electric/electronic components and durable household items involves blending with polyamides including a rubber modification (Lee et al. 2013).

Isotactic polypropylene can be blended with its random copolymers to enhance toughness. This can be accomplished without loss of stiffness and impact strength by nucleating beta form crystallization for applications such as in cables, pipes, and fittings (Machl et al. 2012).

Transparent blends having good properties can be made from suitable formulations containing sufficiently compatible components that the phase domains remain too small to scatter light (Hong et al. 2012).

The superior properties of semi-crystalline thermoplastics make them desirable for high-performance applications. While they can be suitably molded, their low elongational viscosity at forming temperature makes for difficult sheet processing such as by thermoforming. This limitation can be overcome by blending with other polymers, such as ABS, or by inducing cross-linking, e.g., by exposure to high-energy radiation (Seefried et al. 2012).

Improved impact strength with lower melt viscosity for better processability can be obtained by blending a thermoplastic polyester such as PTT with an ethylene copolymer. Including a nucleating agent increases crystallinity and impact strength (Talkowski et al. 2012).

Co-continuous blend structures find industrial application in selective, reverse osmosis and ion exchange membranes requiring specific functional properties. For example, PA/polyester blends could be appropriate for hydrophilic microporous separation and filtration membranes when the phases form a co-continuous structure with domain sizes ranging from 0.01 to 10.0 μm (Harrats and Makhlef 2006a).

15.2.1 Polymer Blends from Renewable Resources for Biodegradable Applications

The usage of naturally sourced polymers has increased in recent years in response to environmental threats, such as expanding landfills and carbon dioxide emissions, along with the rising prices of hydrocarbon raw materials. Three types of polymers considered to be derived from renewable resources are truly natural polymers (e.g., natural rubber, starch, protein, and cellulose), polymers synthesized from natural monomers (e.g., polylactic acid), and those produced by microbial fermentation (the PHA polyhydroxyalkanoates). The limiting properties of some natural polymers having a generally hydrophilic nature (including brittleness, narrow processing window, low heat resistance, and rapid degradation rate especially in wet environments) and the generally high cost of biosynthesis make blending of these with commodity synthetic polymers or other types of renewably resourced polymers attractive. It is preferable to limit blend components to biodegradable polymers in order to preserve full biodegradability. For example, 1,4-transpolyisoprene can be blended with gelatinized starch for food packaging or biomedical applications. Natural rubber can be dispersed in a blend with thermoplastic starch to reduce brittleness. Blends of cellulose and water-soluble starch can be formulated over a range of properties for applications in bone cements, drug delivery carriers, and tissue scaffolds (Yu et al. 2006).

Degradable aliphatic polyesters include both PLA and the PHAs. PLA, being biodegradable and compostable with low toxicity and high mechanical properties, is becoming a strong alternative to conventional plastic packaging materials in specialized markets. But it has insufficient thermal stability for many potential applications and is high in cost. Biodegradation in landfills can be enhanced by blending such biodegradable polyesters with starch and a transesterification catalyst (Changping 2012).

Poly(3-hydroxybutyrate) (PHB) as well as the more general class of PHAs produced by bacterial fermentation, being both biodegradable and biocompatible, are ideally suitable as materials for tissue engineering. The PHA biodegradable polyesters, however, tend to be brittle and thermally unstable in their neat state. Blending with other biopolymers can alleviate these problems along with reducing production cost. The PLA and PHB polymers can be blended together to provide a range of physical properties with improved processability. PLA can also be blended with starch to reduce its cost while maintaining biodegradable properties. Since these materials are thermodynamically incompatible due to the PLA being relatively hydrophobic and the natural starch polymer hydrophilic, various additives are required as compatibilizers.

Chitosan, a natural polymer derived from chitin, has application in edible coatings or films for packaging foodstuffs, but its use is limited by its high sensitivity to moisture. Its ability to form a water barrier can be improved by blending with a more hydrophobic polymer also derived from natural resources, such as PLA. Blends of starch with PCL can be reinforced with nanoscale platelets derived from smectic clay to significantly increase film ductility and barrier properties.

Despite the likely loss of some biodegradability, "green" materials of growing interest for environmental protection are nevertheless blended with synthetic polymers to manipulate their degradation rate and boost their relatively poor mechanical, physical, and formability properties. The shortcomings of the common bio-renewable resin polylactic acid can be addressed through blending of its D- and L-isomers along with poly(ethylene–alkyl acrylate–glycidyl methacrylate) terpolymer to improve heat resistance, impact strength, and tensile strength for applications in automotive parts (Hong and Han 2013). A balanced PLA/PC alloy (compatibilized blend) is still environmentally friendly with improved appearance, weldability, impact strength, and heat resistance over neat PLA (Chung et al. 2012). Similarly to the methyl methacrylate-butadiene-styrene terpolymer used for PC toughening, PLA can be blended with soft polyolefins or with a bio-based impact modifier to improve its toughness, flexibility, and processability. Enhanced mechanical strength and heat resistance may be achievable by blending with harder polyolefin resins like PP for applications in vehicles and building construction, as well as for films and heat-shrinkable labels (Ikeda and Taniguchi 2012; Hong and Han 2012). Compatibilization would be required.

Bio-based PHAs (polyhydroxyalkanoates) show improved mechanical and environmental performance over PVC. Since some versions may be miscible with PVC, it is possible to produce blends that have superior plasticization, impact strength, and processability. Acting as a plasticizer in the PVC, the PHA provides low migration and extractability, volatile loss, and staining. Toughness can exceed that afforded by traditional MBS core/shell impact modifiers without compromising transparency or UV stability (Anon 2013a).

Synthetic and natural biodegradable polymers may be difficult to process, as the high required molding temperature requirements may lead to degradation. Blending with a pliable synthetic resin as a continuous phase allows forming under the more gentle conditions characteristic of the additive without losing the character of the renewable component (Wang et al. 2012). Thus, PLA blended with PP can be extrusion cast or injection molded (Li et al. 2012).

15.2.2 Electrically Conducting Polymer Blends

Expensive conductive polymers can be blended with a commodity polymer major phase to produce a more economical and easily processed blend. The materials may be either both thermoplastic (e.g., PES), or one may be a thermoset (e.g., a phenolic). Another approach employs blending a rubber phase (EPR or urethane) with a commodity thermoplastic resin like PP, LDPE, or even polyesters or polyamides, to form a co-continuous phase structure in which incorporated carbon black resides either at the interface or within one of the phases. A similar approach, incorporating, for example, PC and PET along with an impact modifier, could be employed to produce conductive automotive body parts that are amenable to electrostatic painting (Harrats and Makhilef 2006b).

The increased electrical conductivity achieved by incorporating carbon nanotubes (CNTs) into a polymer would find application, for example, in the cathodes of lithium-ion batteries. Improved static charge dissipation could be achieved at lower CNT loadings than those conventionally used for carbon black in electrical component enclosures, thus avoiding detrimental filler effects on other properties. Furthermore, confining the incorporation to one phase, probably that having a continuous morphology, in an incompatible blend would concentrate the inclusions, leading to more efficient usage. Carbon black present at the interface in PS/PE blends provides a percolation threshold at 0.4 wt% (Thomas et al. 2006).

15.2.3 Molecular Composites

Blends of liquid-crystalline or other rigid-rod polymers, such as polybenzoxazoles, usually in a non-thermotropic high-performance plastic matrix, comprise this category of self-reinforced materials if they are molecularly dispersed in the host polymer. The dispersed network polymer would act as a reinforcement to enhance the load-bearing properties of the continuous polymer, which would in turn produce toughness by relieving stresses and could even provide a self-healing capability. A larger microfibrillar network phase structure produced, for example, when LCPs are blended with PPS would also provide synergistic properties suitable for automotive applications (Harrats and Makhilef 2006c).

15.2.4 Hard Phase–Soft Phase Polymer Blends: Thermoplastic Elastomers

Thermoplastic elastomers (TPEs) combine the physical properties of vulcanized rubber with the ease and economy of conventional thermoplastic processing. They are also well suited to reprocessing and recycling and minimize toxicity issues. Many types of thermoplastic elastomers are polymer blends comprising a thermoplastic continuous phase in combination with a discontinuous vulcanized or unvulcanized elastomeric phase, which in the latter case could also be co-continuous.

Global demand for all TPEs is forecasted to grow 6.3 % annually to 5.6 million metric tons by the year 2015. Since many applications (around 30 %) of these materials fall in the automotive sector, where they are replacing metal, conventional rubber and, for trim and interior applications, traditional thermoplastics like PVC and ABS, this improved growth rate can be attributed to recovery of motor vehicle production in the western world as well as its continuing emphasis on weight reduction. There is about a 60 % weight reduction for each metal part replaced with a polymer or its composite. Projected fuel savings due to reduced weight according to new fuel standards in year 2025 would amount to $1.7 trillion. New applications supplanting more traditional materials are also prevalent, for example, in appliances and housewares, especially in developing countries. Entirely new applications are appearing in medical products and packaging, though

these are currently of small volume. Some traditional application areas, such as footwear, however, are beginning to mature. Over the longer term, TPE demand will shift from the West to developing regions around the globe (Anon 2011).

The wide range of hardness properties achievable through blend compounding allows a wealth of specific applications across a wide spectrum of industries, including (Rader et al. 1986):

Appliances: boots, bumpers, casters, couplings, diaphragms, feet, gaskets, gears, grommets, handles, hose, seals, tubing, and wheels

Underhood automotive: air ducts, bushings, cable covers, hose, protective boots, shock mounts, tubing

Building/construction: door seals, drain seals, glazing seals, cover bases, pipe gaskets, plumbing fixtures, roof flashing, weather stripping

Electronic and electrical: battery blankets, flexible cord, coil cord, wire/cable insulation and jacketing, pad membranes, mining cable, motor shaft mounts, splicing tape, terminal plugs, transformer housings

Machinery and tools: bumpers, casters, rollers, welding hose connectors, welding rod handles, wheels, step pads

Medical devices: closures, gaskets, stoppers, plunger tips

Sporting goods: bat grips, rifle stock cushions, scuba diving equipment, ski pole handles.

"Super-TPVs" are replacing higher-cost thermoset rubbers in underhood, appliance, and industrial molded parts subject to higher temperatures and aggressive environments, for example, truck air-brake hoses and ignition-coil boots. Examples include cross-linked silicone rubber enveloped by a polyamide or TPU continuous phase. These can find application in consumer goods such as communication and medical devices that require high-temperature resistance, low-temperature flexibility, abrasion resistance, weathering resistance, colorability, and soft touch along with easy processability and bondability. A moderate performing cousin of conventional EPDM–PP TPVs at only moderately increased cost uses a styrenic rubber (SBR or hydrogenated styrenic block copolymer) for improved compression set, oil resistance, and adhesion that postures these materials for overmolded grips, seals, bellows, tubing, and diaphragms. A modified ethylene–acrylate rubber in combination with a polyamide or copolyester matrix exhibits superior oil resistance at elevated temperature, as needed in CVJ and spark plug boots as well as other underhood seals, hose, and ducting where temperatures are increasing due to stricter electrical and vapor-emission standards (Leaversuch 2004).

High-performance thermoplastic vulcanizates (TPVs), such as a dynamically vulcanized polyacrylate thermoset elastomer particulate dispersed in a continuous thermoplastic polyamide matrix, have more recently been finding greater under-the-hood automotive applications due to their improved heat and oil resistance. The presence of polar components would also allow adhesion to condensation polymer in-mold substrates to form soft overlays. This technology allows reduction of part complexity in previously multiple-component pieces, for example, high-temperature air intake and turbo engine ducts, by forming soft overmolded cuffs on a polyamide or copolyester core (Harber et al. 2005). Polyamide-bondable TPV

alloys now available in various colors over a range of hardness grades are said to offer thermal resistance up to 135 °C, excellent chemical resistance and better compression set than comparable styrenic-based TPEs (Anon 2013b).

Film and sheeting applications for soft TPV grades include surgical drapes, dental dams, and elastic tapes for wound care in the medical and healthcare arena; waist band tapes for clothing; and elastic geomembranes in building and construction (Mapleston 2007).

Hard grades of thermoplastic elastomers such as thermoplastic vulcanizates find applications as living hinges (useful in electronic products, toys, tools, and cases).

15.2.5 Reinforced Blends

15.2.5.1 Fiber-Reinforced Hard–Hard Polymer Blends

A synergistic interaction between the properties generated by polymer blending and polymer reinforcement with either micro- or nanoscale inclusions can be realized by introducing the reinforcing agents into a preformed blend of two hard plastics or into one or both of the components of the blend prior to the blending operation. The resulting reinforced blend shows higher toughness than either the unreinforced blend or fiber reinforcement of one of the plastic components acting alone, due to enhanced cavitation followed by local shear deformation and ductility.

A prime example is the glass fiber reinforcement of blends of ABS with notch-sensitive polymers such as polyamide or polycarbonate (Nair et al. 1997). The toughness of the reinforced blend can be greater than that of a corresponding polymer composite formed either with polymer of the blend or even with them in the neat state, as evidenced by the critical J-integral toughness parameter. Even the unreinforced blend can be tougher than either neat polymer component, but unlike the case for the reinforced blend, there could be a region of embrittlement. In that range, the reinforced blend would be tougher than its corresponding unreinforced composition. Such materials could find use in structural applications where additional toughness is required without loss of rigidity.

15.2.5.2 Nanocomposite Blends

Blends can also be reinforced with nanoscale inclusions, primarily for stiffening, as elongation to break usually suffers. However, that does not have to be the case. The identity of the phase containing the nanoparticle as well as its continuity in the blend are of prime importance to property development in the blend, as found for PP–EPDM blends reinforced with montmorillonite clay (Lee and Goettler 2004).

Besides mechanical performance, the introduction of nanoclay to the proper location and with the proper phase morphology can also be utilized to enhance the permeation properties of polymer blends in barrier film applications. The high aspect ratio and platelike shape of impermeable montmorillonite inclusions allow them to disrupt the diffusion of permeants through a polymer, thereby increasing the tortuosity of the path through the film and reducing its permeability. The component polymers comprising blends are often selected for reasons other than

their inherent permeability, for example, for mechanical integrity or sealability. In the case of a polymer blend, the nanoclay can be situated at a higher concentration in one phase of a selected polymer pair to maximize the overall barrier resistance of the blend. For example, it could augment the phase of least permeation resistance in order to diminish its deleterious effect on the overall permeability of the blend.

Adding nanoclay to the polar polyamide phase of a PA/PE blend will reduce its water vapor transmission rate significantly, even when the polyamide phase is discontinuous. Such nanoscale reinforcement can also operate by changing the phase morphology of the blend, through changes to the relative viscosity levels of the two polymer phases. The polyamide phase of the above example could be changed from being co-continuous with the polyethylene to becoming discontinuous, where its high water vapor permeability would be far less deleterious, through inclusion of nanoclay (Bhuva and Goettler 2014).

15.2.6 Recycling of Post-consumer and Postindustrial Waste

Recycling is critical to extending the life cycle of polymeric products and diminishing environmental impact by reducing waste, thereby allowing cost reduction. Automotive vehicles are a prime example of increased recycling requirements that envelop the entire package. These include polymer components, which must either all be of similar nature, separated, or compatibilized to form useful alloys.

Another, though older, example of alloying in recycling is compounding post-consumer nylon carpet (including the backing) with coupling agent to produce a compatibilized blend containing major components of nylon and polypropylene and having competitive properties to polypropylene. Its mechanical performance could be upgraded by adding fiberglass and/or rubber to allow partial nylon or polypropylene replacement in automotive applications (Hagberg and Dickerson 1996).

Polystyrene, including foams, can be recycled without degradation by blending with virgin polystyrene to improve tensile strength. Alternately, styrene monomer can be added and polymerized in situ, resulting in improved melt flow (Grossetete et al. 2012).

Nanoscale inclusions, such as nanoclays and nanopowders, could upgrade if not compatibilize mixed plastic post-consumer and postindustrial recycle streams to improve their processability, mechanical properties, thermal resistance, and stability.

15.3   Part 2: Application Areas for Polymer Blends

15.3.1 Healthcare

15.3.1.1 Recent Trends
The healthcare industry has seen rapid expansion in recent years with growth in virtually all segments. These segments include a breadth of applications from IV therapy, drug delivery, and surgical instruments to monitoring, diagnostics, and medical lighting. Within these applications, some trends include a need for higher

autoclave temperatures as well as enhanced compatibility with proteins and blood. Additionally, large part processing is becoming more critical. The regulatory and compliance arena is seeing constant change to stricter standards.

15.3.1.2 Performance Requirements

As autoclave temperatures increase, so do the needs for materials to be used in a wide variety of sterilization environments including gamma, E-beam, and ethylene oxide sterilization. In terms of more general physical properties, color and clarity are critical for visual identification of contents, and for this reason, blend systems which are typically opaque, are not a fit. However, requirements for impact resistance, extreme temperature resistance (both high and low), and good dimensional stability and creep resistance are frequently applicable to blends. Secondary operations and processing are also important and include capability for ultrasonic welding, adhesive and solvent compatibility, high flow for complex part geometries, and thin-wall moldability.

Chemical compatibility/resistance is of particular importance to medical applications. Disinfectants represent one class of chemicals that includes Betadine™, glutaraldehyde-based disinfectants, sodium hypochlorite solution (5 %), ethyl alcohol, isopropyl alcohol, hydrogen peroxide (3 %), and ammonium chloride-based disinfectant. Additionally, resistance to methyl ethyl ketone, saline solution, lipid-based compounds, and fatty acids is important.

15.3.1.3 Regulatory and Compliance Requirements

Generally speaking, applications that contain power supplies or that are electrical in nature require flame retardance in compliance with Underwriters Laboratory standards and test protocols that include UL-94 HB, V2, V1, V0, 5VA, and 5VB ratings. Environmental standards require no bromine or chlorine in accordance with TCO-99 and Blue Angel.

Biocompatibility involves adherence to ISO 10993 "Biological Evaluation of Medical Devices" or USP Class VI standards, hemocompatibility, platelet retention, and reduced protein binding. Moreover, food contact standards are typically applied to healthcare applications. The US Food and Drug Administration oversees adherence to the standards of the US Food, Drug, and Cosmetics Act. In Europe, the European Union Directive 2002/72/EC is applicable.

End-of-use requirements have evolved and the healthcare industry is not an exception to the newer standards. These include Waste Electrical and Electronic Equipment (WEEE) Directive 1002/96/EC that is in place in the European Union. In this standard, OEMs are required to be responsible for collection and treatment of materials at end of life.

15.3.1.4 Specific Applications

One of the more significant segments in the healthcare industry involves the handling and management of fluids. This segment includes blood handling during surgery, general blood collection and blood oxygenation. The segment also includes membrane and filter applications such as leukocyte filters, arterial filters, and kidney dialysis. In addition to blood handling, intravenous (IV) and

gastrointestinal fluid delivery systems often involve bottles, bags, pumps, and tubes. Blood handling typically requires clarity and transparency, but applications such as IV fluid handling are more applicable to blend systems that have impact resistance and chemical resistance. Polyester blends and PC/ABS blends have seen penetration into some of these applications.

There are additional applications with similar requirements which can be a fit for PPE/PS blends. Clinical diagnostics and labware applications such as connectors, fittings, and filtration housings require radiation/autoclave sterilizability and chemical resistance.

One of the application segments that is commonly associated with polymer blends is that of surgical instruments. As surgical techniques have proliferated, so has the need for increasingly specialized instruments. The drive toward minimally invasive surgeries has created the need for miniaturization, which in turn drives the need for smaller components with sufficient strength and durability. Access devices that are appropriate for polymer blends include trocars, retractors, and speculums. Hand instruments include staplers and forceps. Thermal ablation and electrosurgical techniques require powered instruments.

Drug delivery is a growing area of healthcare technology. Needleless injection techniques and inhalation are specific modes of delivery that are fueling this growth, driven largely by elevated requirements for patient comfort. As with blood handling applications, biocompatibility and sterilizability are key requirements. However, impact and wear resistance are also important. Some of the blends used in these applications include PC/PBT and PC/ABS.

Sleep therapy and respiratory care represent an additional class of applications in healthcare. Respirators, ventilators, and positive-pressure devices to allow airways to function properly are specific examples and require biocompatibilty. Respiratory masks and valves require chemical resistance and impact performance. PC-based blends are commonly used in applications in this space.

There are also many healthcare applications that have a more indirect connection to the patient. Medical trays that are used to transport, store, and sterilize surgical instruments require autoclave sterilizability, chemical resistance, and biocompatibility. Additionally, good mechanical performance such as high-impact resistance, as well as colorability, is required. PPE/PS blends are frequently positioned for these applications where this combination of properties is needed. Polymer blends provide other significant benefit in these applications. Many other materials in use such as metals or fiberglass have a significant deficiency relative to polymer blends since repeated use can cause creation of metallic, resin, and glass particles.

Monitoring, imaging, and medical lighting represent a broad set of applications that can range from relatively small component parts in blood glucose meter and pulse oximeters to large luminaire housings in a surgical theater and stationary equipment such as CT, MRI, and PET imaging machines. These applications require flame retardance and may require EMI/RFI shielding. Resistance to cleaners and chemicals may also be required. Impact and high-temperature performance are additional needs for lighting. Blend systems positioned for these applications include PPE/PS, PC/ABS, and ASA.

A series of thermoplastic vulcanizate elastomers available in a wide range of hardness values and displaying low compression set, high fatigue resistance, and long flex life along with good high-temperature and abrasion resistance are targeted for medical applications like syringe stoppers, peristaltic tubes, collection and drainage tubes, caps, plugs, seals, handles, valves, diaphragms, and vial gaskets. Their advantage is high purity and resilience with easy processability, offering high design freedom and recyclability. They are certified to pass ISO 10993-5 and are non-hygroscopic. Their lower oxygen permeability imparted by dynamic vulcanzation makes them well suited for vial seals and gaskets. They can be sterilized in steam, autoclave, or gamma radiation processes (Anon 2013c).

In tissue engineering, two biodegradable polymers can be blended to form a scaffold with a co-continuous structure, perhaps in the presence of an active drug to be dispensed by controlled release into the body. For example, hydroxyapatite can be combined with PLA and PMMA via melt extrusion processing to form a tissue scaffold or alternately be used in prosthetics. Blends of PP with SBR or SEBS can also be formulated to achieve the necessary body weight support and movement for the latter application (Harrats and Makhilef 2006a).

15.3.2 Aerospace

15.3.2.1 Recent Trends
Trends in the aerospace industry parallel those in the overall transportation-related market segments. Lighter weight for decreased fuel consumption and enhanced safety are trends that immediately come to mind. In addition to these, reduced cabin noise, and reduction of maintenance/extension of lifetime are important as well.

15.3.2.2 Performance Requirements
One of the most critical attributes of polymer blends in the aerospace segment is related to how the material performs in a fire. An industry standard test utilizes the Ohio State University heat release methodology as described in ASTM E906 as well as FAR25.853. In this test, the rate of heat and smoke release are calculated per unit area of exposed surface. Heat release is dependent on the mode of ignition, gas phase, or point ignition. This is a common test in the development of new materials. Smoke release is determined by the measured change in transmitted light caused by combustion products. Flammability can be evaluated for vertical burn performance according to Boeing standard BSS7330 and $60°$ flammability according to FAR25.853. In addition to flame and smoke generation behavior, the potential generation of toxic components is also a concern. Some tested for toxicity, which include BSS7239, Airbus standard ABD0031, and Bombardier standard SMP800C. Commonly measured combustion by-products include HF, HCl, NOx, SO2, HCN, and CO. Halogen-free flame retardant technology is an additional attribute that is desired for these applications.

15.3.2.3 Specific Applications

Traditional injection molding allows significant design flexibility and can allow for part consolidation and simplicity in aerospace interiors. Applications including arm and foot rests, overhead bins, tray arms, and structural supports all require weight reduction relative to traditional materials; high modulus and strength; aesthetic appeal; as well as flame, smoke, and toxicity compliance. Applications for lavatories and galleys require many of the attributes already mentioned but add requirements for chemical resistance and low moisture uptake.

There are many applications for opaque materials based on thermoforming. These include signage, window covers, seat components including seat backs, and semi-structural panels. Film products include safety labels commonly seen on seat backs.

Melt-spun or solvent-spun fibers can be converted into fabrics for use in textile applications. These can include wall coverings, kick-panels, and seating.

Foams, honeycomb structures, and composites are all viable routes to utilizing polymer blends to reduce weight. Many of the structural components in aircraft utilize composite and/or honeycomb structures as a way to reduce weight, reduce noise, and provide design flexibility relative to thermoset pre-preg-based systems.

15.3.3 Consumer Electronics

15.3.3.1 Recent Trends

Several trends are clearly evident in consumer electronics. Firstly, miniaturization continues to drive much of the portable electronics segment. As size and weight decrease for mobile phones, for example, the need for higher flow blends that maintain stiffness and ductility are important. Furthermore, as the industry moves to higher power processors, batteries with greater capacity, and the consolidation of functions into a single device, the need for higher-temperature capability becomes more critical. Aesthetics have become an element of branding, where specific colors and/or effects have become part of the OEM's marketing efforts.

In addition to the trends mentioned above, wireless technology is expanding. Radio frequency interference and electromagnetic interference attenuation are becoming more important attributes. This can be achieved through conductive filler technology. Electrostatic discharge behavior can also be achieved.

Radio frequency identification (RFID) is growing rapidly in multiple end use segments such as transportation, security, and asset/inventory management. Polymer blends can be used in the housings, internals, and plastic films containing passive tags.

Flame retardance is another critical attribute. As the industry continues to evolve, Underwriters Laboratory recognition continues to be essential. In addition to this, China Compulsory Compliance (CCC) is becoming more important due to the growth of the consumer electronics industry in the Pacific region. The China Quality Certification Center is responsible for defining products to meet CCC as well as managing the process to apply for registration.

15.3.3.2 Specific Applications

The display industry has evolved considerably over recent years. Just over a decade ago, most displays were based on cathode ray tube (CRT) technology. Liquid-crystal display (LCD) technology was just starting to displace CRTs and was based on cold-cathode fluorescent (CCFL) tube light sources. Plasma displays were also competing strongly, but have since taken a minor role relative to LCD. The LCD technology has also evolved, with light emitting diode (LED) light sources replacing CCFL in the interest of lower-energy usage, lower environmental impact, and reduced heat generation.

For display enclosures, WEEE/RoHS (Restriction of Hazardous Substance) standards have driven blend formulations to avoid flame retardants that contain chlorine and/or bromine. Given the move toward flat panel displays, the overall amount of plastic components has decreased relative to CRTs for similar sized displays. However, as the size of the average display increased, so does the opportunity for polymer blends in bezels, stands, and display backs.

Bezels are demanding in terms of aesthetic performance. High gloss, scratch resistance, and molded-in colors to replace painted surfaces are important. Also, films for in-mold decoration (IMD) can be used. For display backs, high strength and modulus are needed to replace metals, as well as EMI shielding. Speaker components benefit from sound and vibration absorption and moveable stands benefit from abrasion and wear resistance. Within the display, the deflection yoke application of CRTs has been supplanted by LCD components, such as the back-light frame, which typically requires high flow for thin-wall molding.

Beyond the display space, there are several other consumer segments that are seeing the trends noted earlier. For portable devices like mobile phones, the housings needed allow design flexibility such that the phones can be smaller and lighter which means thin-wall moldability is important while maintaining good surface aesthetics. ABS/polycarbonate blends impart lightweight and impact/chemical resistance along with good processing for molded cases incorporating portable electronics such as cell phones. Soft elastoplastics can also be molded against and bonded to the hard blend for gripping and aesthetics.

In laptop and desktop computers, internal components need good heat dissipation and static/shock protection. For housings, good aesthetics and mechanical robustness to drops and impacts are key. Home entertainment and networking are similar to the above. For printers and scanners, moving parts are involved, so for gear applications, wear resistance and lubricity are critical.

15.3.4 Electrical

15.3.4.1 Recent Trends

Electrical applications are experiencing increasingly strict standards. European standards such as EN, which are maintained largely by the European Committee for Standardization (CEN), are replacing other national standards as well as IEC (International Electrotechnical Commission).

Environmental trends are having an impact on electrical applications. Waste legislation includes WEEE (Waste of Electrical and Electronic Equipment) directive 2002/96/EC which holds producers responsible for collection and recovery of materials at end of life. Additionally, materials that contain bromine-based flame retardants must be removed from the waste and handled separately. In restrictions on use of hazardous substances (ROHS) directive 2002/95/EC, the use of various hazardous materials is restricted. These include lead, mercury, cadmium, hexavalent chromium, polybrominated biphenyls, and polybrominated diphenyl ether. Since the introduction of Blue Angel in Germany in 1978, several other eco-labels have been implemented. These include TCO (Sweden), Nordic Swan, Milieukeur (Netherlands), and the EU Ecolabel. The general purpose of these labels is to provide consumers with information relating to the environmental impact of the products they purchase.

15.3.4.2 Performance Requirements

Flammability testing is perhaps the most common requirement for materials that go into electrical applications. Underwriters Laboratories (UL) UL94 test standard is typically used to evaluate the material performance in molded test bars, which is not to be confused with application testing. It is equivalent to EN60695-11-10 and EN60695-11-20. There are several possible ratings for this test for materials used in enclosures, structural parts, and insulators. These include the horizontal burn test (HB), the vertical burn test (V0, V1, V2), as well as 5VA and 5VB ratings. Another standard, the glow wire test (GWT) is widely used in Europe (EN60695-2010,11,12,13) in conjunction with the needle flame test (9EN60695-11-5). Temperatures in the glow wire test can vary from $650\,^{\circ}\text{C}$ up to $960\,^{\circ}\text{C}$. Limited oxygen index (LOI, ISO 4589) is a measure of the minimum amount of oxygen that will support combustion. A higher LOI indicates a greater threshold for burning, i.e., a LOI greater than 21 % indicates the material will not burn in atmospheric conditions.

Another test that is critical for electrical applications is the comparative tracking index (CTI, UL746A, and IEC 60112). This test is used to determine the breakdown voltage of an insulating material. The voltage at which a conductive path, or breakdown due to carbonization, is quantified. Performance level categories (PLC) correlate inversely with the tracking voltage.

Flammability and electrical performance are the two categories of performance most unique to electrical application, which is not to say that other common performance criteria such as thermal, mechanical, and weathering behavior are unimportant.

The overall trend for enclosures is toward materials that have low-temperature performance, UV resistance, chemical resistance, and contain non-halogen flame retardants. Housing for fuse boxes typically requires good impact and tracking resistance, as well as consistent electrical performance in humid conditions. Power tool housings, on the other hand, require good impact and chemical resistance. Common UL electrical tests for this segment are covered under UL746C and include hot wire ignition, high-current arc ignition, and comparative tracking index tests.

Materials for plugs and sockets for household purposes are tested in accordance with IEC60884. For industrial plugs and sockets, standard EN60309 applies. Low-voltage connecting devices for household circuits are covered by EN 60998. Many of these applications also require weatherability and enhanced UV stability.

Conduit and installations are tested in accordance to IEC 60614 and EN 61386-1 as well as flame testing and glow wire. Applications for channels and pipes require extrudability.

Switchers and breakers require resistance to tracking, arcing, and elevated temperatures. For circuit breakers, high temperatures of 200 °C and high forces can be experienced.

The connectors segment is broad. Each subsegment has a rather unique set of requirements. Automotive connectors, for example, require chemical resistance and high heat. Flexible hinge connectors require high melt flow for small parts in intricate geometries, good chemical resistance, and exceptional ductility and elongation. In large connectors, good dimensional stability, warp resistance, and heat resistance or chemical resistance are vital. Fiber-optic connectors are particularly demanding for dimensional stability, where low CTE is critical.

Flammability requirements are stringent for electrical meters and are covered by EN 62053. Capacitor housings require good thermal resistance and dimensional stability. Additionally, both meters and capacitor housings are frequently laser marked, so materials that are compatible with laser marking processes have an advantage. Materials for transformers and insulation systems are tested in accordance with UL 1446 and EN 60085.

15.3.4.3 Specific Applications

One of the largest segments within the electrical application space is for lighting. Depending on the specific application, various degrees of heat performance and impact resistance may be required. EN 60598 covers requirements for flammability CTI and GWT.

For light reflectors, inherent reflectivity (i.e., 90 % or more) or ability to be metalized are important. For lamp holders, either fluorescent or incandescent, materials are categorized according to the temperature class of the holder according to EN 60238.

Other applications in the lighting segment include housings, which require high heat distortion temperature and weatherability. Examples of housings include street lamps which require mechanical strength and lightweight, spotlights, emergency lights, and traffic lights.

Recent demands for energy efficiency, longer life, and decreased environmental issues related to waste have created tremendous growth in the LED lighting segment. This growth is further fueled by increasing legislation mandating the phaseout of more traditional lighting such as incandescent bulbs. In general, materials going into LED applications require flame resistance without halogen or phosphorous and heat and impact resistance and may require direct metallization, reflectivity, thermal conductivity, and electrical conductivity.

Even though LEDs produce light more efficiently relative to incandescent bulbs, they must still convert input energy into heat. The lifetime of an LED is determined, in part, by its ability to manage heat. Blends with enhanced thermal conductivity can provide an advance over traditional heat sinks such as aluminum due to the design flexibility afforded by injection molding. Also, for housings and reflectors, high heat distortion and continuous use temperature are important.

Enhanced thermal conductivity useful in advanced packaging of electronic components could be achieved through selective dispersion of conductive high aspect ratio nanofillers into a polymer blend where they could segregate to form self-assembled conducting pathways. Mechanical properties could similarly benefit (Xu et al. 2013).

15.3.5 Automotive

15.3.5.1 Recent Trends

Lightweighting, fuel efficiency, reduction of emissions, enhanced safety, green sourcing, and recycling are a few of the more recent needs articulated by today's consumers that have translated directly into the design of plastic parts for automotive applications.

Thus, alloys employing plastics compatibilized to PP, which could be derived from recycled interior scrap, would be attractive. Properties could be enhanced as needed by further blending with virgin polymer or through reinforcement with micro- or nanoscale fillers.

Plastics find increasing use in "mobility" applications for weight savings (especially important in the new electric cars that need extended range between charging of their heavy batteries), increased durability, and improved appearance. Automotive plastics payload is expected to increase from 15 % today to 25 % by 2020. Both bodywork and interior component applications will benefit. Blending is an important route to providing property balances needed for these applications (Anon 2013d). For example, heat distortion and impact resistance are enhanced in blends of PVC with polyester or TPU with ABS for automotive applications (Harrats and Makhilef 2006c).

15.3.5.2 Exterior Automotive

Rigid–rigid blends of notch-sensitive plastics with ABS or PPO, like the commercial Noryl GTX™ blend of PA66 and PPO, are superior to rubber-toughened counterparts of the single components in their retention of stiffness and high-temperature performance. The GTX™ 979 blend of PA with a modified PPO makes an ideal replacement for steel in exterior body panels such as fenders. It provides good impact strength along with sufficient electrical conductivity for electrostatic painting. The Pulse GX PC/ABS blend targets interior automotive applications, for which it is optimally formulated to provide sufficient heat resistance along with low-temperature ductility to meet safety requirements (Toensmeier 2012).

One recent application for exterior body panels utilizes a hybrid polymer blend composite technology. It is currently being positioned for large horizontal body panels such as roof modules, hoods, and deck lids [IXIS®, Azdel, Inc]. The composite structure can comprise blends of PC/Polyester with unidirectional glass fiber orientation of 0/90 and 90/0, with a core of chopped glass mat-reinforced thermoplastic. The structure can be formed using aluminum tooling, which provides reduced capital cost relative to tooling to stamp steel body panels.

For some time, the designers of vertical body panel polymer blends have sought to achieve high modulus without sacrificing impact and toughness, with the greatest possible dimensional stability and ability to withstand temperatures of paint bake ovens [PC/ABS]. For painted body panels, it is critical for the material to withstand automotive online paint oven temperatures, which can be in excess of 200 °C. PA/PPE is suited for these extremes. For off-line painting, where the temperature requirements are significantly less, PC/PBT and PC/ABS can be used. Additionally, PC/PBT is commonly used for paint-free applications where in-mold color capability is leveraged. Fender and tailgate applications also see the use of PA/PPE and PC/PBT.

Film technology has been developed that makes use of a multilayer coextruded structure comprising a highly weatherable, glossy transparent surface layer above a colorable blend substrate layer [LEXAN ™ SLX]. Such a structure was designed to avoid the use of paint altogether by using an in-mold decoration process, whereby the multilayer film replaces the traditional clear coat and color coat layers of paint systems. Coextruded films are thermoformed into the shape of the final part and are subsequently back molded to create a roof module structure. Benefits of this technology include system cost reduction, lower emissions, and reduced weight when compared to steel roof structures.

15.3.5.3 Underhood and Powertrain

As automobiles become more reliant on microprocessors and electrical power, the application of polymer blends to housings for electronic components continues to increase. Key requirements for these applications can include electromagnetic shielding and electrostatic discharge.

For the foreseeable future, the automobile industry will continue to manufacture at least a portion of the overall car build with internal combustion engines. Fuel system components require extreme chemical resistance and heat resistance, while providing a balance of mechanical performance that includes such properties as dimensional stability, impact, and stiffness.

Gears require wear resistance and lubricity. Brackets for engines and gear boxes require toughness and stiffness across a wide range of temperatures.

15.3.5.4 Interior Trim/Accessories

EPDM–PP thermoplastic vulcanizates (TPVs) provide cost-effective durable sealing performance, with resistance to UV light, ozone, heat, and chemical

exposure. Being about 30 % lighter than traditional thermoset rubber formulations for weight savings and fuel economy, they can be used to produce weatherseal systems with aging resistance, balanced hardness, good extrudability, and low coefficient of friction, allowing the glass to slide easily. Moreover, part consolidation can be achieved through tri-extrusion processes that combine the lip, foot, and slip coat components of the glass run channel sealing system (Anon 2013e).

An application outside of packaging for nanoscale platelets to impart barrier resistance to a polymer blend is in preventing undesirable small molecule (plasticizer) migration to the surface. As in all applications, the clay particles should be dispersed to the highest degree possible without losing aspect ratio, even if it means only including them in one phase of the blend.

In some instances, existing polymer blends or alloys could be replaced by higher performance or less expensive neat polymers. LEXAN™ FST 3403 copolymer with high resistance to flame, smoke, and toxicity can augment or replace PC/ABS polymer blends in automotive seat back shells and side covers. It delivers high flow properties for injection molding of large parts with excellent appearance and impact strength, in compliance with new European safety standards (Anon 2012).

15.3.5.5 Automotive Safety

Within the last decade, pedestrian impact requirements have begun to play a visible role in automotive design. The front and hood portion of cars has effectively grown in volume to allow for deformable zones to absorb impact from pedestrians based on lower leg, upper leg, torso, and head impacts.

The front fascia serves multiple functions which are obvious by visual inspection. These include aesthetics, aerodynamics, and to house functional elements such as fog lights and air inlets. What is not obvious is the energy absorber systems that sit behind the fascia. Material properties such as impact strength and flexural modulus must be considered over a wide range of ambient temperatures. When these properties are combined with part design, an overall system can be produced that is light and space efficient and allows for macroscopic deformation to allow vehicles to meet FMVSS, CMVSS, IIHS, and ECE 42 requirements.

Polymer blends can play a role in airbag systems. Robust airbag deployment at down to $-40\,°C$ is critical to avoid material fragmentation. Frontal impact requirements include FMVSS201/208, CMVSS 201/208, ECE R49, and TRIAS 47.

15.3.5.6 Automotive Lighting

As automotive lighting systems become more advanced, there is an overall trend toward solid state lighting. There are two applications, in particular, that are well suited to polymer blends. These include bezels and reflectors. As with other injection molding applications, use of blends as bezel materials allows for part consolidation, lightweight, and design freedom. For reflectors, extreme heat performance at temperatures up to $230\,°C$ is required. Additionally, direct metallization is required.

15.3.5.7 Tires

Blends of two or more unsaturated elastomers (rubber–rubber blends) have traditionally found application in various components of the commercial and automotive tire. Specific applications are (Hess et al. 1993):

Component	Blend in passenger tires	Blend in commercial tires
Tread	SBR–BR	NR–BR or SBR–BR
Belt	NR	NR
Carcass	NR–SBR–BR	NR–BR
Sidewall	NR–BR or NR–SBR	NR–BR
Liner	NR–SBR–IIR	NR–IIR

Blends of saturated with unsaturated rubbers, e.g., EPDM–NR and BIMS–NR, find application in the tire sidewall, where the saturated component could aid in environmental resistance. Compatibilization is likely required to form a stable blend morphology from such dissimilar components.

Now dynamically vulcanized rubber–plastic blends are poised to enter the realm of automobile tires. A TPV comprising a PA thermoplastic phase with isobutylene-co-*p*-methylstyrene (BIMSM) rubber can be used as an innerliner, outperforming either historical butyl rubber or the more classical halobutyl and its blend with natural rubber. These and future developments are targeting down-gauging of the barrier film thickness to simultaneously reduce both tire weight and reduced air permeation. A five-to-tenfold reduction in the latter is claimed to be feasible along with improved tire performance (Tsou 2007).

15.3.6 Miscellaneous Applications

15.3.6.1 Packaging

A blend of HDPE and thermoplastic starch finds application in blow-molded bottles, especially for cosmetics, pharmaceuticals, and household chemicals due to its high permeation barrier and chemical resistance while enhancing sustainability due to significantly reduced greenhouse gas emissions during manufacture. Produced by extrusion blending with excess water to convert the starch to a thermoplastic form, the compound containing a minor dispersed starch phase can be employed in various layered combinations with HDPE depending on the application and contacting substances (Anderson 2012).

Blends of rubber modified SMA and PBT could be used to produce ductile blow-molded containers suitable for low-temperature environments (Harrats and Makhlef 2006c).

The numerous parameters defining polymer blends provide flexibility for tailoring their permeability for numerous applications as barrier films in the packaging, automotive, and medical industries through control of morphology and component

interactions. Newer high barrier components for such applications include liquid-crystalline polymers, ethylene–carbon monoxide-based copolymers, and syndiotactic polystyrene.

Co-continuous blends, e.g., of thermoplastic polyester with hydrogenated block copolymers can exhibit gas permeation barrier properties with good chemical, water, and heat resistance (Harrats and Makhilef 2006c). The degree of mixing becomes a critical parameter defining blend permeation performance when the barrier polymer is in a discontinuous morphology (Fetell 1985). Experimentally, essentially equal synergistic permeation decrease occurs with increase of barrier resin content in biaxially oriented blended versus coextruded films, both of which outperform the linear change characteristic of the cast blend (Watanabe 1986).

15.3.6.2 Fluid Engineering

One specialized application area for polymer blends involves water contact for such parts as water meters, pump housings, covers, and impellers. Traditionally, these parts have been manufactured using metal, but corrosion has been a long-standing issue that polymer blends can mitigate. At the top of the list of requirements is hydrolytic stability, where property retention after long exposure is needed. Low water absorption is another relatively obvious requirement which translates into dimensional stability. Since many of these applications are pressurized, high burst strength is needed. High modulus at elevated temperature may be required for hot water applications. Chemical resistance could be important, depending on the particular fluid in contact with the parts. Additionally, for components in contact with drinking water, NSF 61 compliance is needed.

15.3.6.3 Motorcycle and Scooter

Many of the requirements for motorcycles and scooters mirror those of the automotive industry. Metal replacement for lightweighting has become more important not only as a means to improve fuel efficiency but also for better handling and performance. Paint elimination is another benefit of using polymer blends. Through molded-in color, aesthetic needs can be met while eliminating the paint processes that add cost and can emit volatile organic compounds. In-mold decoration technology can also be applied to injection molded parts and provide enhanced manufacturing efficiency by eliminating or reducing the need for masking and point and/or decal application. Conductive plastics enable no-prime painting and can therefore reduce VOC emission and provide simpler operations.

15.4 Outlook: Evolution of Polymer Blends

The blending and alloying of new and existing polymer components is expected to continue adding value to the ongoing creation and development of polymer technologies. Prime focus among the application areas delineated in the above sections would be in those providing greatest impact on current societal concerns, such as sustainability via recycling, energy conservation, and green/renewable resourcing.

Indeed, while the market niche for bio-based polymers today is still less than 1 %, and only 3 % of that derive from new synthetic materials, the overall growth rate is about 13 % per year (Smith 2013). Drivers include consumer concerns and demands, as well as environmental, political, and economic considerations. Significant productivity increases in historical and projected corn yields will help to provide agricultural feedstock to fuel some of these developments.

Opportunities exist for multicomponent polymer systems utilizing new polymers and/or production/forming technologies in unique sophisticated applications, such as smart and high-performance materials for medical, aerospace, and military applications. Highway infrastructure and military needs for heavy-load bridges are being addressed by new developments in plastic lumber comprising blends of HDPE with either PS or reclaimed automotive bumper scrap (Giordano 2013).

Even conventional polymer blends can find new or expanded applications under evolving codes and performance requirements. For example, white roofing membranes of PP/EPR thermoplastic olefin elastomer having high reflectance result in reduced cooling costs (Giordano 2013), while blending polystyrene for foam insulation with an olefinic polymer can enhance its elastic strength and toughness against fracture during installation.

15.5   Summary

This chapter has reviewed applications for polymer blends from the dual perspectives of material development and application requirements. It indicates the viability of various types of polymer blends for current markets and emerging opportunities.

High Performance Polymer Alloys and Blends for Special Applications

16

Mark T. DeMeuse

Contents

Abstract

This chapter discusses blends that are based on the use of high performance polymers. Both miscible and immiscible mixtures of such polymers are discussed and advantages that are provided by both types of blends are highlighted. It is pointed out that due primarily to the molecular conformation of high performance polymers the criteria for obtaining miscible mixtures of these type of polymers are different than for more flexible type polymers

M.T. DeMeuse

e-mail: kumquats88@aol.com

and the influence of the entropic energy of mixing is emphasized. The continued need for in-depth structure–property studies of blends that contain high performance polymers is stressed so that a better understanding of the molecular features that lead to miscibility can be obtained. In addition, the requirement of improved theoretical models that explicitly consider the molecular conformation of the two polymers in a mixture is discussed in detail.

16.1   Introduction to High Performance Polymers

Polymer blends are being used in an increasing number of applications. Industrial sectors that range from the automotive to the aircraft industry have material requirements for specific applications that can be satisfied by blends. In fact, for some time, research in blends has been one of the biggest areas of polymer research, both in the industrial and academic world.

Recently, requirements for materials in certain areas have become increasingly severe. Temperatures that are in excess of 200 °C for times of hundreds of hours have become typical stated requirements for some materials. Particularly severe in this regard are needs for the aircraft industry where high service temperatures for long periods of time are often normal.

One approach to meet those performance requirements is to synthesize totally new polymers. Another method to tailor the properties of materials is through the blending of two polymers. In that particular approach, the goal is to highlight the positive features of both materials in the mixture while attempting to reduce or even eliminate the negative features.

This chapter will address various aspects of high temperature polymers and highlight the advantages of producing blends that involve those polymers. For purposes of these discussions, a high temperature polymer is generally defined as a material that has a service temperature in the neighborhood of 175 °C. This definition is obviously somewhat arbitrary in nature and is largely governed by the fact this is the temperature range that is specified in many high performance applications. Similarly, high temperature polymer blends are defined by the same use temperature. It should be noted that amorphous polymers that have a service temperature of 175 °C in general have glass transition temperatures or T_g's in the range of about 200 °C, approximately 25 °C higher than the actual service temperature. On the other hand, semicrystalline polymers have service temperatures that are largely defined by their melting points or T_m's.

Most high temperature polymers are amorphous in nature but several are semicrystalline. In the case of semicrystalline polymers, polymers with melting points that are less than about 400 °C are desirable. Above that temperature, degradation becomes significant and can become a competitive process with the melting.

16.2   Historical Development of High Performance Polymers (HPP)

16.2.1 Single-Phase, Single Component HPP

Much of the developmental work that has been done on high performance polymers has been based on needs of various branches of the U.S. federal government. An example of one such polymer is poly (benzimidazole) or PBI, the chemical structure of which is shown in Fig. 16.1. In the late 1950s, Carl Marvel first synthesized PBI while studying the creation of high-temperature stable polymers for the U.S. Air Force (Vogel and Marvel 1961). In 1961, PBI was further developed by Marvel and Herward Vogel, correctly anticipating that the polymer would have exceptional thermal and oxidative stability. In 1963, NASA and the Air Force Materials Laboratory sponsored considerable work with PBI for aerospace and defense applications as a non-flammable and thermally stable textile fiber.

After the tragedy of Apollo 1, NASA intensified its focus on advanced fire-resistant materials and one of the first alternatives considered was PBI. NASA contracted with Celanese Corporation to develop a line of PBI textiles for use in space suits and vehicles. Heat and flame resistant PBI fabric based on the fiber for high-temperature applications was developed. The fibers developed from the PBI polymer showed a number of highly desirable features, such as inflammability, no melting point, and retention of both strength and flexibility after exposure to flames. The stiff fibers also maintained their integrity when exposed to high temperatures and were mildew, abrasion and chemical resistant.

Poly (etheretherketone) or PEEK, the structure of which is shown in Fig. 16.2, was originally developed primarily for composite applications. It is produced by the step-growth polymerization process of dialkylation of bisphenolate salts. PEEK is a semicrystalline thermoplastic with excellent mechanical and chemical resistance properties that are retained at high temperatures. It has a glass transition temperature or T_g at about 143 °C and melts around 343 °C. It is highly resistant to thermal

Fig. 16.1 Chemical structure of PBI polymer
Fig. 16.2 Chemical structure of PEEK
Fig. 16.3 General chemical
structure of polyimides
degradation as well as attack by both organic and aqueous environments. Due to its
robustness, PEEK is also used in demanding applications such as bearings, piston
parts and pumps. Also, it is considered an advanced biomaterial used in medical
implants.

Liquid crystal polymers or LCP's are a class of aromatic polyester polymers.
They are present in melted/liquid or solid form (Callister 2007). Processing of
LCP's from liquid-crystal phases, or mesophases, gives rise to fibers and injection
molded materials having high mechanical properties as a results of the self-
reinforcing properties that are derived from the macromolecular orientation that
is present in the mesophase. They can be melt-processed on conventional equip-
ment at high speeds with excellent replication of mold details. The high ease of
forming of LCP's is an important competitive advantage against other plastics,
partially offsetting high raw material costs.

Typically, LCP's have a high mechanical strength at high temperature, extreme
chemical resistance, inherent flame retardancy, and good weather ability features.
They come in a variety of forms from sinterable high temperature compounds to
injection moldable formulations. Due to their various properties, LCP's are useful
for electrical and mechanical parts, food containers, and other applications that
require chemical inertness and high strength. They are particularly attractive for
microwave frequency electronic uses due to their low relative dielectric constants,
low dissipation features, and commercial availability of laminates.

Polyimides have the general chemical structure that is shown in Fig. 16.3. They
have been in mass production since 1955. Typical monomers used in their produc-
tion include pyromelitic dianhyride and 4,4′-oxydianiline. Polyimides can be either
thermoplastic or thermosetting in nature.

Polyimide materials are lightweight, flexible, and resistant to heat and
chemicals. Due to these properties, they are often used in the electronics industry
as flexible cables, as insulating film on magnet wire and in medical tubing appli-
cations. The semiconductor industry uses polyimides as a high temperature adhe-
sive material. Molded polyimide parts and laminates have very good heat resistance
that facilitates their use as bushings, bearings, sockets or constructive parts in
demanding applications. A further use of polyimide resin is as an insulating and
passivation layer in the manufacturing of digital semiconductors. The polyimides
have excellent elongation and tensile strength, which aids in the adhesion between
the polyimide layers or between the polyimide layer and the deposited metal layer.
The minimum interaction between the gold film and the polyimide film, coupled
with the high temperature stability of the polyimide film, leads to a system that
provides reliable insulation when subjected to various types of environmental
stresses.

There are other high performance polymers, such as polysulfone (PSF) and polyphenylene sulfide (PPS) that will briefly be discussed later in regards to blends. This section of the chapter is certainly not meant to be an exhaustive review of high performance blends. In fact, a single book (DeMeuse 2014) has already been devoted to that topic in detail. It has been the purpose of this brief historical review to provide some information on the classes of polymers that will be the main topics of discussion in the blends results that are later described.

16.2.2 Miscible Blends

There have been several miscible high temperature polymer pairs that have been identified in both the patent and open literature. The term thermodynamics invariably brings to mind miscibility. The aim of this section is to discuss the thermodynamic features of polymer blends and highlight studies that have focused on a determination of the features that lead to miscibility.

Since most high temperature polymers contain some form of heterocyclic units, they often have some restricted motion in their backbone. It is exactly that restricted motion that often leads to the high glass transition temperature that is observed in high temperature polymers, such as polyimides. Thus, most high temperature polymers can be regarded as rigid, or at least, semi-rigid in overall molecular conformation. An adequate theoretical model is still to be developed for the mixing of such polymers that have a molecular conformation between random coils and rigid rods.

It should be noted that there have been attempts to produce molecular modeling results and simulations of high temperature polymer blends. The most extensive of these efforts was published by Jacobson et al. (1992). Those workers used a short chain molecular model that incorporates the effects of both inter- and intra-molecular interactions. Using that model, estimates of the net interaction energies for a series of high temperature polymer blends were calculated and used to predict miscibility. The results were in general agreement with experiments and were used to focus the direction of additional experimental work.

Several of the polymer pairs that have been found to be miscible have been formed in solution and cast films have been produced. However, when processing of this same mixture is attempted in the melt state, immiscibility often results. These results suggest that the blends phase separate when heated above their glass transition temperature. Also, kinetic factors along with thermodynamic effects seem to be relevant for the observed miscibility. The general role of the solvent needs to be better understood in the overall scheme of the miscibility that is observed. It may be that the presence of the solvent produces a kinetically favorable situation for miscibility but, upon attainment of thermodynamic equilibrium, that situation no longer exists. One of the challenges for many of the systems that will be discussed is to broaden the temperature range between the blend glass transition temperature and its phase separation temperature. Such an
Fig. 16.4 Chemical structure of Ultem polyetherimide

effect will allow for the initially miscible blends to be processed in the melt state, thus eliminating the need for processing and handling of solvents in the fabrication of products from the blends.

PBI is one of the most highly studied high temperature polymers in miscible blends. The fundamental reason for the observation of miscibility in PBI-based systems is the presence of the N-H functional group that can interact with the functional groups which are present on the backbone of other polymers. Thus, miscibility in these type of systems is an example of a specific interaction that leads to a negative enthalpy of mixing, a requirement for forming miscible mixtures.

The most extensively studied PBI blend system that has been studied is PBI blended with a polyetherimide originally available from GE, Ultem (Takekoshi 1980). The chemical structure of Ultem is shown in Fig. 16.4.

The early work on that blend system lead to the phase diagram shown in Fig. 16.5.

That figure shows that a melt processing window exists for blends that contain in excess of 75 % PBI. In this case, a processing window is defined as those temperatures between T_g and the blend phase separation temperature. For a 85/15 PBI/Ultem blend ratio, the glass transition temperature is about 400 °C and the processing window is 25 °C.

Infrared (IR) studies of these blends showed that hydrogen bonding exists between the N-H groups of PBI and the carbonyl groups of the Ultem (Guerra et al. 1988) and that the hydrogen bonding relaxes during the thermal treatment phase separation (Musto et al. 1991; Choe et al. 1990). In subsequent studies (Foldes et al. 2000), a direct relationship was determined to exist between the strength of the hyrdogen bonding of the two component polymers, the glass transition temperature of the blends and the solvent diffusion rate of both water and 1,2,4-trichlorobenzene. These latter studies concluded that there is partial miscibility between the two polymers and that phase inversion occurs between 0.4 and 0.6 Ultem content.

The phase behavior observed with the PBI/Ultem blends is to be contrasted with the phase separation that was observed in blends of PBI with another polyimide, XU218 from Ciba Geigy (Choe et al. 1991). That system showed phase separation only above 400 °C. The actual phase separation temperatures are determined by the blend composition. Thus, the phase behavior that is observed in PBI/polyimide blends is dependent both on the type of polyimide and the thermal history of the blends.

Fig. 16.5 Phase separation diagram for PBI/Ultem blends

$$-CF_3-C-CF_3-$$
Fig. 16.6 6F chemical moiety

In further investigations of PBI blends, Jaffe et al. (1992a, b) showed that PBI is miscible with certain polyimides that contain the hexafluoroisopropylidene or 6F moiety, shown in Fig. 16.6. The miscibility and phase behavior in these blend systems is dependent on the $-CF_3-C-CF_3$ content and the overall structure of the polyimide. In addition, the amount of the 6F chemical group affects the T_g of the polyimide itself as well as the T_g of any miscible blends.

Those initial studies of blends of PBI with various polyimides were subsequently extended to include other polymers. For example, it was shown that PBI and polysulfone form immiscible mixtures (Chung et al. 1993). However, it was later shown (Deimede et al. 2000a) that the introduction of functional groups, such as sulfonate groups, into the polysulfone polymer chain resulted in the formation of miscible blends with PBI. It was shown that the sulfonation level as well as the blend composition controls the observed miscibility. FT-IR analysis confirmed the presence of specific interactions between the PBI N-H group and the sulfonate groups on the polysulfone.

There are other high temperature polymers that have been shown to form miscible mixtures as well. Several polyimides (PI's) have already been discussed in blends with PBI. Other miscible PI blends have been reported with PEEK (Kong et al. 1998), polyethersulfone (Liang et al. 1992) and sulfonated PEEK (Karcha and Porter 1989). Although the mechanism for miscibility of PBI/PI mixtures was demonstrated to be related to hydrogen bonding between the chains of the two components, the mechanism for miscibility of these other systems was not so clear.

In order to better understand miscibility in polyimide-based systems, Sun et al. (1991) prepared pairs of polyimide blends with different molecular structures by two ways, mixing of the polyamic acid precursors with subsequent imidization and direct solution mixing of the polyimides. Dynamic mechanical analysis (DMA) techniques showed that all of the blends prepared in the two different ways were miscible, as evidenced by the existence of only one T_g for all of the blends. It was proposed that the miscibility of these polyimide/polyimide blends is a result of the strong intermolecular charge-transfer interaction between the chains of the blend components.

Another polymer that has been investigated in several miscible polymer blends is polysulfone (PSF). Blends made from polyamide 11 (PA11) and sulfonated polysulfone (SPSF) were prepared by solution casting from dimethyl formamide (DMF) (Deimede et al. 2000b). In that work, differential scanning calorimetry (DSC) showed a melting point depression of the equilibrium melting point of the PA11. With lower degrees of sulfonation, less interaction between the two polymers was observed. FT-IR and FT-Raman spectroscopic techniques were used to confirm the nature of the specific interactions involved.

In EP07708077A3 (Dabou et al. 1996), gas separation polymer membranes were prepared from mixtures of a polysulfone, Udel P-1700 and an aromatic polyimide, Matrimid 5218. The two polymers were proven to be completely miscible as confirmed by optical microscopy, glass transition temperature values and spectroscopy analysis of the prepared mixtures. This complete miscibility allowed for the preparation of both symmetric and asymmetric blend membranes in any proportion from 1 to 99 wt% of polysulfone and polyimide. The blend membranes showed significant permeability improvements, compared to the pure polyimides, with a minor change in the selectivity. Blend membranes were also considerably more resistant to plasticization compared with pure polyimides. This work showed the use of polysulfone-polyimide polymer blends for the preparation of gas separation membranes for applications in the separation of industrial gases.

In another development focused on membranes, miscibility in blends of polysulfone with poly (1-vinylpyrrolidone-co-styrene) (P (VP-S)) copolymers containing various amounts of 1-vinylpyrrolidone (VP) was examined (Kim et al. 2002). Copolymers that contained VP from 68 to 88 wt% were used in that work and were found to be miscible with polysulfone. On the other hand, polysulfone blends with P (VP-S) copolymers containing 65 wt% VP and those with the P (VP-S) copolymers containing 90 wt% VP showed two Tg's, indicating that phase separation had occurred. In terms of membrane performance, the solute rejection examined with membranes made from miscible blends was similar to that

of a pure polysulfone membrane while the solute rejection examined with the membranes fabricated from the immiscible blends was lower than that of polysulfone membranes.

Overall, then, the high temperature polymer blends that have been discussed thus far display some type of well-defined specific interaction that leads to the observed miscibility. In the case of PBI blends, it is hydrogen bonding that occurs through the N-H group that is present in the PBI backbone. For PI blends, there appears to be a charge-transfer interaction that leads to miscibility in mixtures. In both cases, it is clearly the enthalpic part of the free energy of mixing that leads to miscible blends.

Such is not the case in blends of two liquid crystal polymers or LCP's that were first extensively studied by DeMeuse and Jaffe. In their initial study (DeMeuse and Jaffe 1988), they examined blends of LCP's that contain copolymers of *p*-hydroxybenzoic acid (HBA) and 6-hydroxy-2-naphthoic acid (HNA) of different copolymer ratios. It was surmised that miscibility in the melt state depended on the difference in copolymer ratios between the two component polymers. However, miscibility in the solid state seemed to be present for all blends that were studied. This is an interesting contrast to the systems previously mentioned because there is no obvious enthalpic interaction that is occurring between the two blend components.

In further studies by these same workers (DeMeuse and Jaffe 1989, 1990), efforts were extended to include LCP's that contained other monomers such as terephthalic acid (TA) and hydroquinone (HQ). In some cases, miscible systems were defined (DeMeuse and Jaffe 1989) and sometimes immiscible blends were observed (DeMeuse and Jaffe 1990). For all cases, however, there was not a well-defined specific interaction that could be ascribed to the observed miscibility. It appears that the entropy of mixing is important in defining miscibility in these type of blend systems.

Thus, we have two different types of behavior in blends of high temperature polymers. The first situation is exemplified by the PBI blends in which specific interactions through the N-H group of the PBI are responsible for the observed miscibility. The other situation is displayed by the mixtures of two LCP's in which entropic effects are important for the miscibility. These types of behavior are the extreme case of behavior. This also suggests that there are blend systems of high temperature polymers in which both enthalpic and entropic effects should be important factors in the miscibility.

This concept was explored by Lee and DiBenedetto (1992) who introduced a second LCP as a compatibilizing agent in order to improve the interfacial adhesion and dispersion between components of incompatible LCP/thermoplastic blends. The primary reason that the LCP and thermoplastic polymers are immiscible is due to molecular conformation differences or entropy effects. The concept for using a second LCP in such blends is that the two LCP's will be miscible due to entropy effects and the second LCP and the thermoplastic polymer will adhere due to specific interactions. The LCP coupling agent used in this work was a copolymer of PET and HBA known as PHB60. Blends of an LCP with both polycarbonate (PC) and PET were prepared with and without the addition of the second LCP

coupling phase. Morphological evidence indicated that the LCP reinforcing phase in the ternary systems exhibited improved adhesion and dispersion on a much finer scale than in binary blends that were produced using the same processing conditions.

This approach was further explored by Hakemi (2000) who prepared blends that contain both a wholly aromatic and an aromatic-aliphatic LCP that are miscible with each other. The ultimate goal of this approach was to develop multi-component blends that have components of thermoplastics. The miscible LCP blends could be useful as reinforcing agents for the thermoplastic matrix polymer and, due to the fact that the LCP's contain some of the components of the thermoplastic polymer, there is expected to be improved adhesion between the LCP portion and the matrix portion of the mixture. This is another example of an attempt to balance the phase separation that is inherent in high temperature polymer blends due to molecular conformation differences by strengthening the enthalpic interaction between the two polymers.

Before leaving the topic of LCP/LCP blends, one additional point needs to be stressed. Low molecular weight liquid crystals (LMWLC's) of the same mesophasic class often show miscibility (Gray and Windsor 1974). On the other hand, TLCP's that form the same mesophase, usually nematic, do not necessarily exhibit complete miscibility. Thus, in order to be able to implement the ideas of the last several paragraphs, caution must be exercised in choosing the two LCP's to form the miscible blend.

16.2.3 Immiscible Blends Based on HPP

This section of the chapter will focus on two applications of immiscible blends that contain high performance polymers. The first will be on the use of LCP's as processing aids and reinforcements of thermoplastics. There has been a great deal of both open literature and patents devoted to that topic. The second focus area will be on the use of polysulfone to enhance the fracture toughness of other thermoplastics. In that case, immiscibility is the desired phase structure for the observed effect.

In LCP/thermoplastic type blends, the size, shape and distribution of the LCP phase depends on many factors such as the blend composition, the processing conditions, the viscosity ratio of the component polymers at the shear rate that is being used in the processing, and the rheological features of the thermoplastic matrix polymer. This observation is prevalent in the work of Acierno et al. (1987) who demonstrated that different morphologies could be observed in the same LCP/polycarbonate blend simply by varying the processing temperature. The observed morphological differences were attributed solely to different viscosity ratios at the different processing temperatures.

Several reports have appeared in the literature which discuss the lowering of the viscosity of a thermoplastic polymer with the addition of a small amount of an LCP component. These studies have been performed on a variety of polymers

including polyamide (Siegmann et al. 1985), poly(etherimide) (Swaninathan and Isayev 1987), poly(ethersulfone) (James et al. 1987; Froix and Park 1984a; Froix et al. 1984b) and polycarbonate (Isayev and Modic 1987a; Malik et al. 1989; Kohli et al. 1989). All of the studies have reported a lowering of the viscosity of the traditional thermoplastic polymer with the addition of various small amounts of an LCP. The results are interpreted as being due to a lubricating effect of the LCP on the melt. This is due to the fact that the groups of LCP molecules, called domains, slide past each other.

This lowering of the melt viscosity allows the LCP to act as a processing aid for the conventional thermoplastic. Cogswell et al. (1983, 1984a, b) concluded that, in order for this effect to be realized, the temperature range at which the conventional polymers are melt-processed should overlap the temperature range in which the LCP forms an anisotropic melt. In that work, as in the other previously reported studies, the melts had lower viscosities than the pure thermoplastic polymer and, therefore, the processing temperature would be lower. The advantages of the subsequent reduction in the processing temperatures include reduced energy consumption and less degradation of polymers that are sensitive to high temperatures. Also, a lowering of the melt viscosity allows for easier filling of large and complex molds in injection molding applications.

The other principal effect that has been observed in blends of LCP's with thermoplastic polymers is the utilization of the LCP as a reinforcement for the more flexible polymer. A detailed discussion of the mechanical properties that are obtained will be provided later in this chapter. Here, just a brief introduction to the topic is made.

In numerous studies reported in the literature (Chung 1987a, b; Weiss et al. 1987a, b, c, d; Kiss 1987; Blizzard and Baird 1987; Weiss et al. 1988, 1990; Kohli et al. 1989; Wellmann et al. 1980; Nehme et al. 1988; Joseph et al. 1984; Ramanathan et al. 1987; Amano and Nakagawa 1987a, b), improved mechanical properties in blends that contain LCP's have been reported. Most of those studies have attempted to explain the changes in properties in terms of the morphology of the LCP domains in the blends. The most widely used experimental technique to study the blend morphology has been scanning electron microscopy or SEM.

One of the main drawbacks of using LCP's as a reinforcement is the poor adhesion to the matrix polymer. This lack of adhesion between two immiscible polymers is a quite general phenomenon and appears to be a concern for many blends that contain LCP's. A unique approach to address that problem has been proposed by Akkapeddi et al. (1986). They suggested blending thermoplastic oligomers and isotropic polymers in the presence of a particulate material such as talc or silica. The purpose of the particulate is twofold. First, it appears to reduce the phase separation between the thermotropic oligomer and the matrix polymer. Second, its presence helps improve the dispersion of the oligomer in the polymer. The final blend has an increased tensile modulus, tensile strength and abrasion resistance compared to blends in which the particulate was not used.

The second topic to be discussed is the use of polysulfone in blends with other thermoplastics as a way to increase the material toughness. The same technology

can be applied to thermoset polymer matrices. It will be discussed later in a section on semi-interpenetrating networks.

Kohlman and Petrie (1995) produced blends of 5 %, 10 % and 20 % by weight of polysulfone in polycarbonate by melt blending. The average impact strength and the percent of ductile failures decreased with increasing amount of polysulfone. The ballistic testing results that were reported showed a linear relationship exists between the percent of polysulfone in the blend and the critical velocity for complete penetration.

In a similar study, Garcia et al. (2004) produced blends of polysulfone with a liquid crystalline copolyester, Rodrun 5000, by processing methods of direct injection molding and extrusion followed by subsequent injection molding. The blends were immiscible and showed two pure polymer phases. There is an improvement in the notched impact strength of the polysulfone with the addition of small amounts of LCP that indicates a reduction in its notch sensitivity. The behavior of the tensile strength was close to linear with respect to the blend composition, except a 20/80 blend that showed synergistic behavior. This combination of behaviors is reminiscent of what has been observed previously in rubber-toughened blends.

Ramiro et al. (2004) studied the behavior of injection molded specimens based on blends of poly (ether imide) (PEI) and polysulfone. The impact strength was higher than that of the poly (ether imide) alone. On the other hand, the tensile strength and elongation at break were almost additive. The reported behavior is indicative of rubber-modified blends.

In terms of optimizing the fracture toughness enhancements that have been observed with these blends, immiscibility of the two polymers is the desired phase structure. However, control of the phase separation is required to be able to take full advantage of the observed effects. In other words, there is more to the effect than simply blending the two polymers together but an understanding of the mixing parameters on the resulting blend morphology needs to be obtained. More discussion of this point will be provided later in the Recommendation section of this Chapter.

16.2.4 Molecular Composites

Abe and Flory (1978) and Flory (1978) first proposed the concept of molecular composites that are systems based on the mixing of a rigid rod polymer and a random coil polymer, vastly different molecular conformations. The theoretical prediction was made that phase separation is easily induced in such mixtures. The predicted phase separation is based solely on entropic effects that arise from the conformation differences of the two component polymers.

Initial experimental work on molecular composites focused on attempting to kinetically delay the phase separation with a desirable morphology before the thermodynamics leads to complete immiscibility of the two polymers in the

mixture. Most of this initial work was performed as part of a program sponsored by the United States Air Force. For example, poly(*p*-phenylene terephtalamide) (PPTA) and poly(*p*-phenylene benzobisthiazole) (PBT) were successfully dispersed in a polyamide 66 matrix (Takayanagi et al. 1978, 1983; Takayanagi 1983; Takayanagi and Gotta 1985; Hwang and Wiff 1986). Kyu et al. (1989) reported that there are specific interactions present in a PPTA and polyamide six system and that phase separation can be thermally induced in molecular composites based on those two polymers. Thermally induced phase separation has also been observed in the PBT/PA six system when the melting temperature of the PA component is reached. Finally, Moore and Mathias (1986) reported a unique method for the preparation of molecular composites using an in-situ polymerization in which the anion of the PPTA molecule was used as the initiator for the anionic polymerization of acrylamide in the formation of a PA three matrix.

In order to improve the adhesion between the two components in the molecular composite, ionic bonds were utilized to produce miscibility (Parker et al. 1996a, b; Eisenbach et al. 1994; Weiss et al. 1992). Ionic bonds are stronger and more thermally stable than hydrogen bonds and, thus, are deemed to be more effective at promoting miscibility. Those initial studies focused primarily on molecular composites that were cast from solution.

One of the major challenges for this approach is the identification of a proper solvent that can be used. In addition, the majority of the solvents that are suitable are quite corrosive in nature. That fact, as well as the control of the phase separation and, hence, the final properties have largely limited widespread industrial development of these materials.

Recently, studies have also focused on the development of melt-processable molecular composites. Such mixtures were produced by dispersing a rigid rod polymer, such as ionic versions of Kevlar, poly(*p*-phenylene terephthalamide) (PPTA), in a matrix of a flexible coil polymer such as poly(4-vinyl pyridine) (PVP) (Hara and Parker 1992; Parker and Hara 1997a, b). Relatively low additions of a PPTA anion, that contains the ionic groups directly attached to the backbone chains, in the PVP matrix led to miscibility and to a good dispersion of the rigid rods in the matrix. These miscibility effects were attributed to the presence of ionic interactions between the ionic groups of the modified PPTA and the polar groups of the vinyl pyridine units.

This work represents another attempt of overcoming the inherent phase separation in mixtures of polymers of vastly different molecular conformations through the use of specific molecular interactions. That seems to be an effective approach for interrupting the phase separation. The general application to the development of specific high temperature blends is still to be realized, however. Also, it needs to be better understood how the chemical modifications of the rigid rod component in a molecular composite to increase molecular interactions alters its molecular conformation, if at all, towards more of a semi-rigid polymer. This could also contribute to enhanced miscibility with other high temperature polymers.

16.3   Properties and Performance of High Performance Polymers

16.3.1 Miscible HPP Blends

One of the properties that is affected by the production of miscible blends is the glass transition temperature or T_g. The T_g of miscible blends has been modeled using several different approaches in the literature (Wood 1958; Couchman and Karasz 1978). The simplest of these is the Flory-Fox equation:

$$T_{gBlend} = w_1 T_{g1} + w_2 T_{g2} \tag{16.1}$$

in which w_1 is the weight fraction of component 1 in the blend, T_{g1} is the glass transition temperature of component 1 and w_2 and T_{g2} are the same respective parameters for component 2 in the blend. Equation 16.1 predicts a monotonic change in a blend T_g between the respective T_g values of the two blend component values. It should be noted that Eq. 16.1 predicts an increase in the T_g when a higher T_g polymer is mixed with a lower T_g material.

The free volume of thermoplastic miscible blends has also been determined as a function of blend composition (Zhou et al. 2003; Campbell et al. 1997; Roland and Ngai 1991). Those studies have shown that the degree of blend miscibility alters the free volume behavior as a function of blend composition. On the other hand, Hsieh et al. (2000) have studied a number of blends containing only thermotropic liquid crystalline polymers TLCP's as the only components. That work showed that regardless of their various miscibilities, TLCP blends tend to display smaller, fewer free volume sites than expected from a weighted average. This observation has been ascribed to the intrinsic affinity of nematic TLCP's.

These observations are relevant to the work of Kenig et al. (1991) who studied blends containing two wholly aromatic, naphthalene-based liquid crystalline polymers. They observed synergistic behavior in the tensile and flexural properties of injection-molded specimens. A detailed analysis indicated that in the composition range where synergistic effects are observed in mechanical properties, only one glass transition temperature is detected. This suggests that miscibility is desirable for obtaining the maximum properties in these blend systems.

A similar synergistic effect in the physical properties of blends was observed by Cho et al. (2000) who studies novel blends of nitro-substituted poly(benzimidazole) ($NO_2 - PBI$) and poly(etherimide) (PEI) in a cosolvent. The blends possess tractable processability owing to the enhanced solubility of $NO_2 - PBI$. Miscilbility was observed and attributed to hydrogen bonding between the N-H groups of the NO_2-PBI and the carbonyl groups in the PEI.

These two examples, then represent cases of synergies being observed in the mechanical properties of miscible blends. These effects are likely due to improved packing of the polymer chains, as observed in the case of LCP/LCP blends.

Also, hydrogen bonding, as observed in PBI-based blends, is also expected to lead to efficient packing of the blend components. This improved packing effect leads to enhanced physical properties.

16.3.2 Immiscible Blends Based on HPP's

Often times, the performance of immiscible blends is worse than that of either of the component polymers. This is true of the strength and modulus of the immiscible polymer blends. In terms of temperature performance, it is largely dictated by the temperature behavior of the lower T_g component. This is because, in the case of immiscible blends, the T_g's of the two component polymers are observed at the same location as in the case of the unblended materials.

One exception to the above mentioned trend in physical properties of immiscible blends is in the utilization of liquid crystal polymers as a reinforcement for a more flexible thermoplastic polymer. The fact that LCP's can act as reinforcing agents in a blend has led some workers to model the mechanical behavior of the blends using theories of composites. Thus, Dutta et al. (1990) showed that the moduli values of highly drawn melts that contain liquid crystal polymers can be treated effectively by a simple rule of mixtures. That is, the modulus of a blend is given by

$$M_{Blend} = v_1 M_1 + v_2 M_2 \qquad (16.2)$$

where v_1 and v_2 are the volume fraction of the two components in the blend and M_1 and M_2 are the corresponding modulus values of the two polymers. These same workers showed that the moduli values of samples in which the LCP forms spherical particles can be treated using an inverse rule of mixtures.

The biggest technical issue that has prevented more widespread use of these type of blends is the lack of adhesion between the LCP and the matrix polymer. Additional work needs to be focused on solving that problem before the full potential of these blends can be realized. Effective ways to compatibilize the two polymers in the immiscible blends need to be further developed.

Another blend that consists of two immiscible polymers and has attracted recent attention is Victrex T (Victrex website 2013), which is a mixture of PBI and PEEK. The melt processability of the blend could bring the heat performance that is provided by PBI to a broader range of applications. In the blend, PBI gains processability but gives up some of its physical properties. PEEK boosts its strength, hardness and resistance to wear and creep. The blend's coefficient of thermal expansion approaches that of PBI, among the lowest of all commercial polymers.

One of the most important features of Victrex T is its heat resistance. It retains excellent mechanical properties up to 300 °C, 40 °C higher than glass-filled PEEK alone. Unfilled Victrex T has about three times the flexural modulus of conventional unfilled PEEK at 250 °C. It does even better when filled with either glass or

chopped carbon fiber. The blend is used in markets where PEEK does not quite meet the temperature targets. These markets include molded bearings, bushings and anything that faces mechanical loads and aggressive temperatures and chemicals.

16.3.3 Molecular Composites, Theory and Examples

Much of the theory behind molecular composites has already been elaborated in Sect. 16.2.4 of this chapter. Briefly, the idea is to disperse a rigid rod polymer into a more flexible random coil polymer to use the reinforcing effect of the rigid rod to increase the mechanical properties of the random coil matrix component. It is expected that the reinforcing effect that is observed will be dependent on the level of dispersion that is achieved for the rigid rod. This section of the chapter will focus explicitly on the mechanical properties that are achieved in molecular composite materials.

The early work on properties of molecular composites was done by Hwang et al. (1983a, b). They performed experimental studies of solution processing of films based on poly(p-phenylene benzobisthiazole) with both poly(2,5 (6′) benz-imidazole (ABPBI) and poly(2,5 (6′) benzothiazole) (ABPBT). The films were shown to possess very high modulus and strength values, which improve upon heat treatment. The uniaxial modulus of highly oriented molecular composites was shown to follow the linear rule of mixtures.

Tsou et al. (1996) prepared molecular composites by dispersing rigid-rod molecules of ionically-modified poly(p-phenylene terephtalamide) in a polar poly (4-vinyl pyridine) (PVP) matrix. The mechanical properties of the molecular composite were found to increase with concentration and to attain maximum values at about 5 wt% of the PPTA anion. When specific interactions are not present, as in composites with non-anionic PPTA, the properties are significantly reduced compared to those of the PPTA anion/PVP composites.

The mechanical properties of molecular composites have also been analyzed theoretically. A theory by Halpin and Tsai relates the composite modulus to the individual moduli of the components (Halpin and Tsai 1973; Halpin and Kardos 1976). In the limiting case where the reinforcing fiber aspect ratio approaches infinity, the composite modulus and tensile strength are predicted to follow a linear rule of mixtures. That is, the composite properties are a linear function of the fiber and the matrix properties and volume fraction. This ultimate rule of mixture reinforcement behavior was achieved for composites of PBT in aromatic, heterocyclic matrix polymers (Krause et al. 1986, 1988; Hwang et al. 1983) and work was also done to achieve that same effect with thermoplastic matrix materials (Wickcliffe 1986; Tsai and Arnold 1982).

16.3.4 Thermoplastic Blends with Liquid Crystal Polymers

An introduction to these types of blends has already been briefly provided in previous sections of this chapter. They have been categorized in the literature as

self-reinforced polymer composites. This section will specifically focus on the physical properties of these materials and the factors that affect the attainment of those property profiles.

A number of studies have considered the effect of LCP concentration on the mechanical properties and morphology of blends. Ko and Wilkes (Ko et al. 1989) reported that the modulus of blends of HNA/HBA and PET increased only at high LCP content of 80 % and higher. However, when this same LCP was blended with an amorphous polyamide, the mechanical properties increased monotonically with increasing LCP content (Zheng et al. 2003). For blends of another LCP with PET, Bhattacharya et al. (1987) found that the initial modulus and tenacity of melt-spun fibers increased with increasing LCP content, while elongation to break decreased. As the LCP content was increased, the fiber mode of failure changed from brittle to ductile.

Zhuang et al. (1988) found that adding small amounts of 40 PET/60 PHB to PET, PC or PS increased the modulus and tensile strength of compression molded films, extrudates, and melt spun filaments. Froix and Park (1984) also showed that the mechanical properties of PC were improved by incorporation of melt-processable, wholly aromatic liquid crystalline polyesters. Amano and Nakagawa (1987) studied the drawing behavior of blends of PET and a 40 PET/60 PHB copolyester using conventional and microwave heating methods. The optimum drawing tension, drawing temperature, and draw ratio for attaining an optimum modulus decreased with increasing LCP concentration.

Isayev and Modic (1987b) reported that injection molded and extruded blends of an HBA/HNA LCP and PC containing greater than 25 wt% LCP had spherical LCP domains dispersed in the PC matrix. However, blends with 10 % LCP had a fibrillar morphology. Pracella et al. (1987) reported a similar observation when they examined the morphology of blends of PBT with another LCP. The fracture surfaces of blends that contain up to 50 wt% LCP revealed the presence of rod-like structures of the LCP component oriented perpendicular to the fracture plane. For blends that contain more than 50 wt% LCP, the morphology was homogeneous and LCP domains were not observed.

Skin/core morphologies are common in blends of LCP's and thermoplastic polymers and they play a significant role in defining the properties of both extruded and injection molded samples. Usually, LCP's in the skin have a higher degree of orientation than in the core when the blends are extruded or injection molded (Husman et al. 1980; Hedmark et al. 1989; Lee 1988). Baird et al. (Baird and Mehta 1989; Baird and Sukhadia 1993) observed a skin/core morphology in blends of PA 66 with HBA/HNA and 40 PET/60 PHB and 20 PET/80 HBA copolyesters. More LCP fibers were present in the skin than in the core for both systems. Isayev and Swaninathan (1994) also reported shell-core structure in the fracture surfaces of injection molded blends of HNA/HBA liquid crystalline copolyesters and poly (etherimide).

In summary, then, a suitable processing history that includes extensional flow can yield a reinforcing, microfibrillar morphology of the dispersed LCP phase. Modulus values that are similar to those of short glass fiber-reinforced plastics can

be achieved. One major issue with these blends is poor interface adhesion, which limits the overall strength of the material. It is also quite difficult to prepare samples that possess other than a unidirectional microfibrillar orientation. This currently limits the applications of these blends to those requiring high mechanical anisotropy. Future work in this area needs to be focused on addressing these issues.

16.3.5 Semi-Interpenetrating Networks

The idea behind semi-interpenetrating networks (semi-IPN's) is to combine the processabiity of thermoplastics with the high temperature performance of crosslinked thermosetting materials. Such mixtures should possess the desirable features of both types of materials. The majority of semi-IPN's contain continuous phases and the components are immiscible at the molecular level.

St. Clair et al. (Hanky and St. Clair 1985; Egli et al. 1986) used the concept of sequential semi-IPN's to produce two unique IPN's that are based on acetylene-terminated imide oligomers and thermoplastic polyimides, particularly a material designated LARC-TPI. Pater and others (Pater and Morgan 1988; Pater 1988; Pater and Morgan 1988) used the concept of simultaneous semi-IPN's to make materials that are based on PMR-15 mixed with such materials as LARC-TPI, NR-150B2 and thermid 600 polyimides. Other examples of semi-IPN's that fit into the category of high temperature materials include thermoplastic modified bismaleimides (BMI). As one example, BMI has been mixed with condensation poly (aryl ether ketone) oligomers (Steiner et al. 1987). The observed miscibility that is based on thermoplastic BMI's was found to be further improved when a BMI and a thermoplastic, both prepared from aromatic diamines were blended (Arnold et al. 1988; Olabishi et al. 1979).

It is well recognized that phase separation is a necessary condition for improving the fracture toughness in thermoplastic-modified thermosetting matrixes (Bucknall and Partridge 1983; Hay et al. 1996). For a particular thermoplastic-modified thermosetting matrix, two primary properties control the final morphology and, hence, ultimate properties of the mixtures: thermodynamics and the kinetics of phase separation during the curing process itself. Both of these factors can be modified by changing the thermoplastic content in the mixture and/or by varying the cure conditions.

Martinez et al. (2000) performed such a study of polysulfone-modified diaminodiphenylmethane-cured diglycidyl ether of bisphenol-A epoxy mixtures. The immiscibility for the mixtures was proven for various polysulfone contents and as a function of the curing conditions that were used. It was found that the control of the generated morphologies can be performed only by varying the processing temperature. For a particular thermoplastic amount, it was discovered that immiscibility lowers the rigidity and strength but increases the fracture toughness of the mixtures. The properties, including the fracture toughness, are also dependent upon the percentage of thermoplastic and the subsequent morphology. The higher values of fracture toughness are achieved for a bicontinuous morphology.

Fig. 16.7 Chemical structure
of bisphenol A dicyanate
Hwang et al. (1997) have investigated mixtures of polysulfone with bisphenol A dicyanate, the structure of which is shown in Fig. 16.7.

When mixtures with less than 10 wt% were cured isothermally, they were phase separated due to a nucleation and growth mechanism. On the other hand, with more than 20 wt% polysulfone, the blends were phase separated by spinodal decomposition. These different mechanisms are important because in thermoset/thermoplastic blending, the fracture toughness is determined by the morphology that is formed as a consequence of the phase separation.

Those studies were extended to include the addition of an organic montmorillonite nanoscale filler to the polysulfone/dicyanate mixture (Mondragon et al. 2006). The primary reason for the introduction of the filler is the significant improvement in properties that can be obtained at low clay contents. The exfoliated configuration for the clay is of particular interest in that regard because it maximizes the interactions, making the entire surface of the clay layers available for interactions with the polymer matrix. This should lead to dramatic changes in both mechanical and physical properties.

In the quoted study, it was found that the polysulfone was initially miscible with the cyanate prepolymer and phase separates into spherical domains during the course of the cyanate polymerization process. The flexural modulus was not significantly modified by the thermoplastic/organoclay addition. On the other hand, the fracture toughness was slightly improved with the addition of polysulfone and clay to the cyanate.

All of these studies highlight the importance of obtaining the proper morphology in the polysulfone/thermoset mixtures in order to maximize the fracture toughness improvement that is observed. The mixtures often begin as miscible blends and upon curing of the thermoset component, phase separation occurs. It is control of the phase separation process that ultimately leads to the attainment of a particular physical property profile. Variables that can affect the phase separation process include the mixture composition as well as the curing temperature of the thermoset component in the mixture. Amont the blend composition variables, the molecular weight of the two components is very significant due to its effect on the overall mixture viscosity, an important factor in controlling the phase separation kinetics.

These conclusions imply that fundamental studies of the phase separation process in polysulfone/thermoset mixtures are needed to better understand the kinetics of the situation. General conclusions about the range of variables that allow for the development of a desirable morphology compared to others are needed to be able to take full advantage of the fracture toughness enhancements

that have been observed in polysulfone/thermoset mixtures. It is through such an understanding that the optimum polysulfone/thermoset mixtures can be defined and developed.

Variables that should be examined include the molecular weights of the two component materials, both the thermoplastic and thermoset component. It should be defined if these both affect the overall mixture viscosity in similar ways, or if it is not the overall viscosity that affects the phase separation kinetics but how that overall viscosity is indeed obtained. These studies should be performed on a single chemical system as a function of the curing temperature and a complete understanding of the resultant morphologies should be obtained. Having obtained that basic understanding on a single system, the goal is to apply that knowledge to be able to design other systems. That way, systems with particular and specific property profiles can be designed and fabricated.

16.4   Summary, Outlook and Conclusions

Much of the work that has been done up to this point on high temperature polymer blends is the definition of miscible blend polymer pairs and an understanding of the features that lead to that miscibility. The development of miscible blends often leads to the ability to tailor the properties, including the T_g of mixtures. Such a tailoring is an alternative to the development of entirely new polymeric materials with the desired property profile. One of the advantages of the blend approach is that it is generally faster and less expensive than the synthesis and scale-up of an entirely new polymer. The downside of the blend approach is that it is difficult to define miscible pairs and miscibility is often the situation that is not observed with polymer mixtures.

As has already been discussed earlier in this chapter, one of the most common ways to achieve miscibility in high temperature polymer blends is through the introduction of specific interactions between the two components in the mixture. This is not surprising, as this is also an often-used approach to develop miscibility in other types of blend systems as well. The one exception to this pattern is the case of blends of two liquid crystal polymers in which miscibility has been determined in systems in which there is no well-defined specific interaction. In those systems, miscibility appears to occur based primarily on similarities in molecular conformation between the two blend components. These results suggest that entropic effects play a significant role in defining the phase behavior of mixtures that contain high performance polymers.

This phenomenon is most clearly displayed in molecular composites, mixtures of rigid rods and random coils. In those systems, phase separation has been theoretically predicted and experimentally verified, based solely on the molecular conformation differences of the two polymers in the mixture. Thus, immiscibility can be observed without the implicit consideration of enthalpic interactions. In fact, one of the approaches that has been examined in the published literature to delay or interrupt phase separation in molecular composite systems is to provide favorable

specific interactions between the two polymer components to use favorable enthalpic interactions to overcome the inherent entropic molecular differences.

An area of work that needs to be further explored is a better quantitative definition of the interplay between the enthalpy and entropy energies of mixing for blends of high temperature polymers. As just discussed, molecular composites are largely controlled in their phase behavior by entropic effects while in the case of random coil/random coil mixing, enthalpy is assumed to dominate the situation. These observations, when taken together, imply that there are certain molecular conformations of polymer mixtures for which both the enthalpic and entropic portions of the free energy of mixing are significant. This region of behavior falls under the category of semi-rigid polymers, for which many high temperature polymers fall. This suggests that the class of high temperature polymers offers the possibility to manipulate the phase behavior of mixtures through a balance of the polymer conformation and interactions between the component materials.

Better theoretical models need to be developed that explicitly incorporate the conformational features of the polymers in a mixture. Such models need to deal with behaviors that range from the limits of rigid rods to random coils in a systematic way. In particular, semi-rigid polymers, that are common to high temperature polymers, need to be studied. In addition to the conformation of the two polymers, an explicit way of incorporating specific enthalpic interactions needs to be defined. The development of the proposed model will allow for a theoretical examination of the relative importance of entropic and enthalpic effects to the phase behavior and miscibility.

From an experimental perspective, systematic structure–property relationship studies of high performance polymer blends are needed to completely define the polymer features that lead to miscible mixtures. One of the primary focuses of those studies should be continued quantification of the molecular features, both entropic and enthalpic in nature, responsible for miscibility. Such quantitative input can, then, be used as information in theoretical developments. The entire process should be regarded as highly iterative in nature in the sense that theoretical predictions can be made, tested experimentally, and the results of the experimental work should lead to revised models that can make additional predictions.

In the case of immiscible blends, additional understanding needs to be obtained of the effect of various processing conditions on the final blend morphology. This is true of not only mixtures in which both components are thermoplastic in nature but also of semi-interpenetrating blends that are mixtures of thermoset materials with thermoplastic polymers. It is especially true of blends that are based on liquid crystal polymer with more traditional thermoplastic polymers. For example, different mechanical property profiles have been observed in such blends through changes in the processing conditions. Additional efforts need to be completed in that area to completely understand the effect of the different processing temperatures and conditions on the blend morphology and final properties. Much of the work that has appeared in the published literature has largely been of a trial-and-error variety. While many interesting property enhancements have been observed in numerous of those studies, a full realization of the benefits has still not been

obtained. Systematic studies are needed to take full advantage of the unique features that are provided by these types of mixtures.

Many of the features of high performance polymer blends that have been highlighted as requiring additional work are quite similar in nature to issues that need to be addressed with polymer blends in general. However, one of the somewhat unique features that high performance polymers have is the fact that many of them have molecular conformations that can be described as semi-rigid in nature. That feature modifies the miscibility criteria for mixtures that contain such polymers from usual random coil mixing. Since miscibility or at least some form of compatibility is generally believed to influence the physical properties of polymer mixtures, it can be inferred that the molecular conformation of high performance polymers has a direct bearing on the performance that is observed in blends.

Since many of the applications for high performance polymer blends are specialized in nature, these mixtures can often command a premium price. Due to that fact, efforts can be expended to optimize the performance to meet specific requirements. Sometimes that optimization can be done through the incorporation of chemical functionalities to take advantage of specific interactions. The overall key is to be able to define polymer features that allow for the attainment of the ever-increasing needs for high performance polymers and blends made from them.

Contents

Abstract

This chapter discusses the role of various nanoparticles in immiscible polymer blends for control of the size of the dispersed polymer phase particles, phase inversion and rheological behavior, impact strength, and mechanical performance. Various issues such as the effect of nanoparticle dimensions on the polymer particle size and properties, blending sequence, location of nanoparticles in the blend components, mechanism behind improvement in

properties, individual effect of various fillers on the blend properties, and future trends are also discussed in detail. Since the literature on polymer nanocomposites is vast and the utilization of nanoparticles in blends has significantly increased in recent years, this chapter is designed to review the current state of knowledge in this area. To do so, various examples of polymer blends and nanofillers relevant to the abovementioned factors are discussed.

17.1 Introduction

Polymer blends potentially offer materials with an attractive combination or balance of properties often not available in a single polymer; however, most polymer pairs are thermodynamically immiscible, and they often exhibit an unstable phase morphology during melt processing resulting in poor mechanical performance (Barlow and Paul 1981; Wu 1982; Brown 1989; Utracki 1989; Folkes and Hope 1993; Utracki 1998; Paul and Bucknall 2000a, b; Robeson 2007). There are significant numbers of polymer–polymer pairs, in spite of being immiscible, that can still provide a useful combination of properties desired for various commercial application purposes. The immiscibility arises from the fact that the mixing between the segments of two polymers is energetically unfavorable and the entropy of mixing is too small to achieve sufficient driving force for miscibility (Paul 1996). Incompatibility is caused to some extent by nonpolarity, low interfacial adhesion, specific group interactions, and molecular weight differences between two polymers (Tiwari and Paul 2011a). The thermodynamics of polymer mixing is well known and thoroughly reviewed in various scientific reports on polymer blends (Paul and Barlow 1980; Barlow and Paul 1981; Anastasiadis et al. 1988; Utracki 1989; Sundararaj and Macosko 1995; Paul 1996; Utracki 1998; Paul and Bucknall 2000a; Ophir et al. 2009).

The addition of copolymers that have block or graft segments chemically identical to the respective phases of immiscible polymers is commonly used to improve adhesion between polymer pairs, and since they solve the problem of "mechanical incompatibility" in blends, they are generally referred to as "compatibilizers" (Paul 1996). The appropriate selection of a compatibilizer can promote a stable and fine distribution of the dispersed phase within the matrix by reducing the interfacial tension between the blend components. The addition of functional groups to the minor phase that can react chemically with the major phase may form block or graft structures that can retard the coalescence of the dispersed phase by steric interaction and improve adhesion between immiscible polymer pairs; this approach is referred to as "reactive compatibilization" (Wu 1985, 1987; Oshinski et al. 1992a, b; Sundararaj and Macosko 1995; Oshinski et al. 1996a, b, c; Majumdar et al. 1997; Wildes et al. 1999; Paul and Bucknall 2000a, b). The purpose of using either approach is to obtain a fine and stable morphology along with improvement in the properties of the blend. However, the application of block copolymers or in situ reactive processing is sometimes not

a viable option, and there is a need to look for alternate routes that can lead to compatibilization of polymer blends.

In the last three decades, polymer composites based on nanofillers have shown remarkable improvements in material properties usually achieved at low filler content. Such composites are referred to as "nanocomposites." Nanocomposites are particle-filled polymer matrices where at least one dimension of the dispersed particles is in the nanometer range (Giannelis 1996; LeBaron 1999; Ray and Okamoto 2003; Paul and Robeson 2008). Among various nanofillers, layered silicate-based nanocomposites have attracted great interest from industry and academia because they often exhibit remarkable improvement in material properties when compared to the bulk polymer phase or conventional micro- and macro-composites. These improvements can include high moduli, increased tensile strength and heat resistance, decreased gas permeability and flammability, and increased biodegradability of biodegradable polymers (Giannelis 1996; Giannelis et al. 1999; Gilman 1999; Lagaly 1999; LeBaron 1999; Alexandre and Dubois 2000; Ishida et al. 2000; Bharadwaj 2001; Schmidt et al. 2002; Ray and Okamoto 2003; Jordan et al. 2005; Zeng et al. 2005; Okada and Usuki 2006; Tjong 2006; Crosby and Lee 2007; Goettler et al. 2007; Pavlidou and Papaspyrides 2008). Today, efforts are being conducted globally, using almost all types of known polymers.

In the past few years, the number of studies involving the use of organoclays to reduce dispersed phase particle size in immiscible blends has increased significantly (Li et al. 2002; Chow et al. 2003; Gelfer et al. 2003; Wang et al. 2003; Chow et al. 2004; Khatua et al. 2004; Lee and Kim 2004; Li and Shimizu 2004; Mehta et al. 2004; Ray et al. 2004; Gahleitner et al. 2005; González et al. 2005; Lee et al. 2005; Mishra et al. 2005; Austin and Kontopoulou 2006; González et al. 2006a, b; Hong et al. 2006b; Kelnar et al. 2006; Lai et al. 2006; Lee et al. 2006a; Si et al. 2006; Wu et al. 2006; Xu et al. 2006b; Kelnar et al. 2007; Kim et al. 2007b; Ray et al. 2007; Vo and Giannelis 2007; Zou et al. 2007; González et al. 2008; Kelnar et al. 2008; Kim et al. 2008; Rosales et al. 2008; Kelnar et al. 2009; Martin et al. 2009; As'habi et al. 2010; Moghbelli et al. 2010; Yoo et al. 2010a, b; Tiwari and Paul 2011a, b, c; Ojijo et al. 2012; Tiwari et al. 2012; Tiwari and Paul 2012; Vuluga et al. 2012; Tiwari et al. 2013); however, very few studies have focused on the usefulness of this strategy to achieve a balance of properties required for commercial applications. In immiscible polymer blends, organoclays have been shown to effectively reduce the dispersed phase particle size by locating either at the domain interface or in the continuous phase. When clay particles are completely dispersed in the matrix phase, it is believed that montmorillonite, MMT, particles act as a barrier to coalescence of the dispersed phase leading to a decrease in the dispersed phase particle size.

The presence of clay particles at the interface in a blend can occur when the interfacial energies are appropriate, and this will result in improved interfacial adhesion between the two polymer phases and a decrease in the dispersed phase domain size. The final morphology in the blend is also affected by the viscosity ratio of the dispersed and continuous phases and has been known to significantly

influence the deformability and breakup of droplets and might affect phase conti-
nuity. Hence, apart from the compatibilization and barrier effects of clay, any
change in the viscosity ratio also influences the final blend morphology (Khatua
et al. 2004; Vo and Giannelis 2007; Filippone et al. 2010b; Tiwari and Paul 2011b).
Similarly, kinetic effects during mixing affect the final filler dispersion and its
location in the polymer blend in addition to equilibrium effects expected from
a surface energy analysis (Yoo et al. 2010b; Tiwari and Paul 2011a). Nonetheless,
the presence of clay in blends can result in property trade-offs, e.g., stiffness
increases while toughness decreases which limits their use when both properties
are required. An optimum performance in blends can be achieved with proper
selection of materials and design of experiments (Chow et al. 2003; Gelfer
et al. 2003; Chow et al. 2004; Mehta et al. 2004; Kelnar et al. 2006, 2007, 2008;
Filippone et al. 2010a; Yoo et al. 2010b; Chen and Evans 2011; Martín et al. 2011;
Tiwari and Paul 2011a, b, c, 2012).

The decrease in the dispersed phase particle size using organoclay can be quite
beneficial in rubber toughening of rigid thermoplastics since elastomer particle
size is critical for improving toughness (Majumdar et al. 1994a, b; Oshinski
et al. 1996a, b, c; Majumdar et al. 1997; Zhou et al. 2005; Ahn and Paul 2006;
Huang et al. 2006b; Tiwari and Paul 2011b, c; Tiwari et al. 2012). Similarly, the
presence of organoclay in the blend can provide a stable morphology upon
annealing; however, the location of organoclay in the polymer blend has
a significant role on stability during annealing (Khatua et al. 2004; Moghbelli
et al. 2010; Tiwari and Paul 2011a). The major objective of this chapter is to
provide some understanding on the role of organoclay on the dispersed phase
particle size and their effects on the mechanical performance of immiscible poly-
mer blends. The effects of polymer properties such as molecular weight, rheology,
and clay content on the dispersed phase particle size and mechanical performance
are discussed in detail with several examples of polymer blends of commercial
interest. The effect of other nanofillers on the blend properties is also highlighted;
however, the major portion of this chapter is devoted to the role of organoclay filler
on the blend morphology and properties.

17.2   Role of Organoclay in Immiscible Polymer Blends

17.2.1 Polypropylene (PP)–Polystyrene (PS) Blends

Polypropylene (PP) and polystyrene (PS) are important commodity polymers;
however, blends of PP and PS are immiscible and several reports describe the use
of commercial block copolymers such as styrene–butadiene–styrene (SBS),
styrene–ethylene–butadiene–styrene (SEBS), styrene–ethylene–propylene (SEP),
and styrene–isoprene–styrene (SIS) as nonreactive compatibilizers to achieve
a finer morphology and improved performance in their blends (Bartlett
et al. 1981; Radonjič et al. 1998; Hlavatá et al. 1999; Raghu et al. 2003). However,
the block copolymers may tend to form micelles due to their high molecular weight

rather than residing at the interface, and often the synthesis of desirable block copolymers makes them rather expensive (Hung et al. 2008). On the other hand, organoclays are relatively cheap and easy to modify and, therefore, provide an economical route to prepare compatibilized polymer blends.

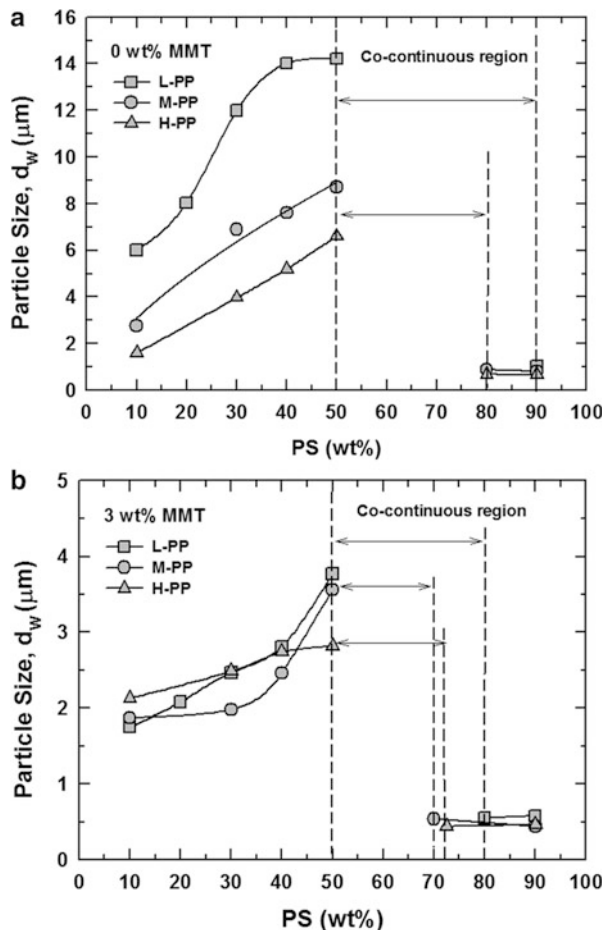
Wang et al. (2003) has observed a significant decrease in the dispersed phase PS particle size when clay is present in the dispersed PS phase and at the interface in the PP/PS (70/30) blend. The PS particle size decreased from ∼3 μm for PP/PS blend to ∼1 μm with the addition of ∼10 wt% organoclay in the blend. This was attributed to the decrease in coalescence of PS particles due to increase in viscosity ratio of blend components and enhanced compatibility due to intercalation of PP and PS chains in clay galleries. Later Zhu et al. (2008a, b) showed that the location of clay can be switched from one phase to another in PP/PS blends by tailoring the polarity of PP with the addition of PP grafted maleic anhydride, PP-g-MA, or by addition of sulfonate groups to PS; this promotes migration of clay particles from less polar to high-polarity blend components due to increased interfacial interactions between clay and the more polar component of PP/PS blends. It has been also proposed that organoclay platelets act like a "knife" thereby reducing dispersed PS domain size due to shear stress generated during mixing (Zhu et al. 2008a). Ray et al. (2004) observed higher mechanical properties for blends of PP-g-MA/PS/ C20A compared to PP/PS/C20A blends due to the better compatibilization effect of clay in the presence of polar anhydride groups. Although the literature on blend nanocomposites is growing, there is a lack of systematic and in-depth studies to better understand the effects of clay on the morphology development, their stability, and property improvements.

Recently, Tiwari and Paul (2011a) carried out detailed studies on the effect of PP viscosity on the dispersed phase particle size, stability of dispersed phase morphology upon annealing, phase inversion behavior, and changes in the mechanical properties of PP/PP-g-MA/MMT/PS nanocomposites prepared with different molecular weight grades of PP. PP-g-MA was added to PP to facilitate dispersion of organoclay in the nonpolar PP; moreover, it also provides better reinforcement effect when PP forms the continuous phase.

The location of clay particles in blend nanocomposites has a significant effect on the blend properties; hence, it is important to elucidate the location of clay particles in the blend. Figure 17.1 shows the dispersed phase morphology for PP/PP-g-MA/ MMT/PS nanocomposites before and after phase inversion. At 30 wt% PS in a PP/PP-g-MA/MMT/PS blend where PS forms the dispersed phase, the MMT particles are located in the PP matrix as well as at the PP/PS interface which confirms the decrease in the interfacial adhesion between PP and PS in the presence of clay. The PS particles are circular in low molecular weight PP (L-PP)- and medium molecular weight PP (M-PP)-based PP/PP-g-MA/MMT/PS nanocomposites and become elongated in the high molecular weight PP (H-PP)-based nanocomposites due to the high shear stress exerted by the H-PP on the dispersed phase during injection molding. To confirm the injection molding effects on the PS particle shape in H-PP blends, Tiwari and Paul showed TEM images of extruded H-PP blends with and without MMT and observed that PS particles are
Fig. 17.1 TEM micrographs showing the location of the MMT particles in PP/PP-g-MA/MMT/
PS blends containing 30 wt% PS (*top row*) and 90 wt% PS (*bottom row*). The blends were prepared
with different molecular weight grades of PP: L-PP (**a** and **d**), M-PP (**b** and **e**), and H-PP (**c** and **f**).
Images were taken from the core and viewed perpendicular to the flow direction (FD) (Tiwari and
Paul 2011a)

globular in shape as opposed to the elongated morphology seen for injection-
molded specimens. Such molding effects arise from the various flow fields gener-
ated during the mold filling process in addition to the effect of the matrix viscosity.
Moldenaers and coworkers have also observed elongated PS particles in blends of
high molecular weight PP and PS (Omonov et al. 2007). Above the phase inversion
composition, i.e., for 90 wt% PS in PP/PP-g-MA/MMT/PS blends, PP particles are
dispersed in the PS matrix and MMT particles are still located in the PP phase as
well at the interface (see Fig. 17.1d–f).

Figure 17.2 shows the combined effects of PS composition and PP viscosity
(influenced by the PP molecular weight and presence of clay) on the dispersed
phase particle size and co-continuous region of blends with and without MMT. The
dispersed phase particle size is significantly reduced in the presence of organoclay;
this decrease is more prominent when clay is present in the continuous PP phase and
envelope PS particles, i.e., below 50 wt% of PS in a PP/PP-g-MA/MMT/PS blend.
The effect of PP viscosity on the PS particle size is less prominent in the presence of
MMT compared to blends without MMT. At higher PS compositions, i.e., above
phase inversion, the PP viscosity has negligible effect on the dispersed PP particle
size. The increase in PS particle size with increased PS composition in the
blend results from the higher rate of coalescence during mixing finally resulting
in formation of co-continuous structures followed by phase inversion

Fig. 17.2 Effect of PS
content and PP melt viscosity
on the dispersed phase
particle size for (**a**) blends
without MMT and (**b**) blends
with MMT. PS is the
dispersed phase when the PS
content is below 50 wt%
while the matrix is PP/PP-g-
MA or PP/PP-g-MA/
MMT. The wt% MMT is
based on the MMT content in
PP/PP-g-MA/MMT. The
dashed line represents the
co-continuous region as
observed from TEM images
for blends prepared with
various grades of PP. The
L-PP, M-PP, and H-PP
represent low, medium, and
high molecular weight grades
of PP, respectively (Tiwari
and Paul 2011a)


(Fortelný and Živný 1995; Sundararaj and Macosko 1995; Wildes et al. 1999; Paul
and Bucknall 2000a). The phase inversion composition can be predicted based on
the empirical model developed by Paul and Barlow as given by $\phi_1/\phi_2 = \eta_1/\eta_2$
where ϕ and η represent volume fraction and viscosity of polymer components in
blend (Paul and Barlow 1980). According to this relation, the phase inversion
composition ϕ_1 decreases as the viscosity ratio η_1/η_2 decreases; the blends with
PS and PP/PP-g-MA/MMT show phase inversion at lower PS contents than blends
without MMT as the viscosity ratio of PS phase to PP phase decreases in the
presence of MMT (Tiwari and Paul 2011a). The onset of co-continuity did not
change when clay is present in the major PP phase, whereas the presence of clay in
the dispersed phase has been known to increase the co-continuity as observed in
HDPE/PA 6/MMT blends where organoclay is present in the dispersed PA 6 phase
(Filippone et al. 2008, 2010b).

17.2.1.1 Effects of MMT and Matrix Molecular Weight on Dispersed Phase Particle Size

The final morphology of a blend is a result of competing effects of droplet breakup and coalescence during blending that depends on several factors including the viscosity ratio of the dispersed phase to matrix phase (Barlow and Paul 1981; Favis and Chalifoux 1987; Wu 1987; Sundararaj et al. 1992; Sundararaj and Macosko 1995). The lower ratio defines the higher matrix viscosity which increases the breakup of dispersed particles due to high shear stresses and reduces the dispersed phase particle size in the blend. The high matrix viscosity also creates a more immobile interface thereby reducing coalescence of dispersed particles. It has been reported for PP/PP-g-MA/MMT/PS blend nanocomposites that for nearly similar viscosity ratios of the dispersed to continuous phase, i.e., for $\eta_{PS}/\eta_{(L-PP/PP-g-MA/MMT)} = 2.75$ and $\eta_{PS}/\eta_{(M-PP/PP-g-MA)} = 2.56$, the PS particle size in the L-PP-based blend with MMT is 2.47 μm compared to PS particle size of 6.9 μm observed for M-PP-based blends without MMT. Similarly, in H-PP-based blends containing 30 wt% PS, although the viscosity ratio of two phases did not change much with the addition of MMT, the PS particle size is reduced from 3.82 μm for the blend without MMT to 2.49 μm for a blend with MMT (Tiwari and Paul 2011a). This suggests that although rheology is a factor in decreasing particle size of dispersed phase, the decrease in coalescence of PS particles in the presence of MMT is an additional factor which helps to reduce the PS particle size to a much greater extent in blends with MMT than in blends without MMT.

17.2.1.2 Effect of MMT on Dispersed Phase Morphology Stability

For incompatible blends a low shear processing can lead to the coalescence of the dispersed phase particles and reduce their performance. An increase in the phase stability in the melt state extends the possibility of commercial applications for blends at high temperatures. Not many studies have explored the effect of annealing on dispersed phase particle size and shape in blends with organoclay (Khatua et al. 2004; Moghbelli et al. 2010; Tiwari and Paul 2011a). It is expected that polymer blends compatibilized with organoclay should lead to a more stable morphology; however, the location of organoclay in such blends can have a significant effect on the morphology stability. Well-dispersed clay particles in the continuous phase of immiscible blends can lead to improved phase stability of dispersed particles in the melt state as seen for the PA 6/ethylene–propylene rubber (EPR) (80/20) blends where organoclay resides in the PA 6 continuous phase. A poor stability of the dispersed phase in the melt is observed when MMT particles are located in the dispersed PS phase in PP/PS (70/30) blends (Khatua et al. 2004). The clay particles located in the continuous phase and at the interface in immiscible blends can also lead to significant improvement in phase stability upon annealing. Figures 17.3 and 17.4 show the morphology of dispersed PS particles in PP/PP-g-MA/PS blends with and without MMT after being subjected to annealing in a quiescent state at 210 °C for 2 h (Tiwari and Paul 2011a). The phase stability is significantly higher in blends with MMT compared to blends without MMT where the PS particle sizes increased by ∼10 times for the H-PP/PP-g-MA/PS blend.
Fig. 17.3 SEM images of PP/PP-g-MA/PS blends containing 30 wt% PS. *Top row* shows images for as-molded samples, while the *bottom row* shows images for annealed samples at 210 °C for 2 h. The blends were prepared with different PP grades: L-PP (**a** and **d**), M-PP (**b** and **e**), and H-PP (**c** and **f**) (Tiwari and Paul 2011a)
Fig. 17.4 SEM images of PP/PP-g-MA/MMT/PS blends containing 30 wt% PS. *Top row* shows images for as-molded samples, while *bottom row* shows images for annealed samples at 210 °C for 2 h. The blends were prepared with different PP grades: L-PP (**a** and **d**), M-PP (**b** and **e**), and H-PP (**c** and **f**) (Tiwari and Paul 2011a)

Table 17.1 Viscosity ratio and weight average PS particle size ($\overline{d}_w$) in PP/PP-g-MA/PS blends with and without MMT. The PS composition in blend is 30 wt% (Data taken from Tiwari and Paul 2011a)

Matrix	MMT wt% in matrix[a]	η_d/η_c[b]	$\overline{d}_w$(μm) As molded	After 2 h in melt at 210 °C
L-PP[c]	0	4.25	12.0	60.5
	3	2.75	2.47	2.66
M-PP[c]	0	2.56	6.9	72.3
	3	1.87	1.98	2.38
H-PP[c]	0	1.24	3.82	44.5
	3	0.97	2.49	2.71

[a]The PP/PP-g-MA or PP/PP-g-MA/MMT was used as a matrix to prepare blends at 30 wt% PS. The MMT wt% is based on MMT content in PP/PP-g-MA/MMT. The PP-g-MA/organoclay ratio is 1.0
[b]η_d is viscosity of dispersed phase PS; η_c is the viscosity of continuous phase PP/PP-g-MA (0 wt% MMT) and PP/PP-g-MA/MMT (3 wt% MMT). The viscosity ratio for the two phases is assumed for blends where PS forms the dispersed phase
[c]The various PP represent viscosities for PP/PP-g-MA (0 wt% MMT) and PP/PP-g-MA/MMT (3 wt% MMT)

The presence of MMT at the interface and in the PP matrix for PP/PP-g-MA/MMT/PS blends has a significant effect on morphology stability. The presence of clay at the interface effectively acts as a compatibilizer leading to smaller dispersed phase particles and morphology stability in the quiescent melt (Moghbelli et al. 2010; Tiwari and Paul 2011a). The increase in dispersed phase stability in the melt state for blends with clay correlates well with the stable morphology observed for reactive-compatibilized PP and amino-terminated PS blend (Omonov et al. 2007). Table 17.1 shows changes in PS particle size after annealing PP/PP-g-MA/PS and PP/PP-g-MA/MMT/PS blends.

17.2.2 Polypropylene (PP)–Elastomer Blends

Polypropylene is a semicrystalline thermoplastic with major application in diverse areas due to its excellent processability, low density, high thermal stability, good chemical resistance, and low cost; however, its low impact properties limit many practical applications (Karian 2003; Holden and Hansen 2004). Elastomers such as EPR, ethylene–propylene–diene terpolymer (EPDM), and SEBS have been used to improve toughness of PP (Yang et al. 1984; Chou et al. 1988a, b; Mighri et al. 2001; Bassani and Pessan 2002; Yazdani-Pedram et al. 2003; Abreu et al. 2005; Öksüz and Eroğlu 2005; Matsuda et al. 2006; Naderi et al. 2008; Bai et al. 2009). However, the recent development of metallocene catalyst technology has led to new ethylene-co-octene copolymer rubbers (EOR) with controlled levels of chain branching, narrow molecular weight distribution (MWD) that provides improved rheological properties, such as better shear thinning behavior, melt elasticity, and melt processability; EOR materials have shown better efficiency of impact modification of

Fig. 17.5 Comparison of
relative modulus as a function
of filler content formed from
melt mixing with MMT and
with talc (Lee et al. 2005)
PP compared to other elastomers (Reddy and Sivaram 1995; Bensason et al. 1996;
Carriere and Silvis 1997; Keating and Lee 1999; Da Silva et al. 2000a, b; Premphet
and Horanont 2000; Da Silva et al. 2001; Marquardt et al. 2001; Premphet and
Paecharoenchai 2001; Yu 2001; Da Silva et al. 2002; Ling et al. 2002; McNally
et al. 2002; Premphet and Paecharoenchai 2002; Prieto et al. 2002; Qiu et al. 2002;
Zhang et al. 2002; Rabinovitch et al. 2003; Yang et al. 2003; Arzondo et al. 2004;
Ono et al. 2005; Lim et al. 2006; Meng et al. 2006; Xu et al. 2006a; Lee et al. 2007;
Fasce et al. 2008; Svoboda et al. 2009; Zhu et al. 2009). Such blends of polyolefin
with elastomers are referred to as a "thermoplastic olefin" or TPO.

   Toughness of PP is usually obtained at the cost of stiffness due to the presence of
the soft elastomer particles; however, a major issue for some applications is to
achieve an optimum balance of stiffness and toughness. To address this issue,
conventional fillers such as calcium carbonate ($CaCO_3$), talc, short glass fiber, or
kaolin are generally added to PP/elastomer blends to improve their stiffness;
however, due to the low aspect ratio of conventional fillers, large loadings are
required to significantly increase stiffness which can result in poor processability,
lower ductility, and rough surface finish of the final product (Stamhuis 1984,
1988a, b; Pukánszky et al. 1990; Kolařík and Jančář 1992; Schaefer et al. 1993;
Premphet and Horanont 2000; Lee et al. 2005; Ma et al. 2010). Replacing such
fillers with high-aspect-ratio nanofillers such as organoclays could potentially
alleviate these issues, assuming good levels of clay dispersion can be achieved.
As seen in Fig. 17.5, the addition of ∼5 wt% MMT in TPO provides an equivalent
improvement in modulus as 20 wt% of talc (Lee et al. 2005, 2006a).

   TPO can be prepared either by melt mixing PP and elastomer in an extruder or by
copolymerization of olefins in a series of reactors to give a blocklike structure. The
reactor-made TPO produces a fine and stable morphology due to controlled reaction
parameters; however, they have an elastomer composition fixed by the polymeri-
zation process. On the other hand, extruder-made TPOs provide wide flexibility in

terms of changing material composition and properties to explore and understand their effects on elastomer phase morphology and mechanical performance (Carriere and Silvis 1997; Da Silva et al. 2000b; Premphet and Paecharoenchai 2002; Lee et al. 2005, 2006a; Lim et al. 2006; Tiwari and Paul 2011b, c; Tiwari et al. 2012; Tiwari and Paul 2012; Tiwari et al. 2013). This also forms a convenient route for formulating TPOs in terms of particle size control and properties based on end use applications. The purpose here is to focus on the role of organoclay to achieve a good balance of stiffness and toughness in extruder-made TPO nanocomposites. Deshmane et al. (2007) reported up to 10 % increases in the room temperature impact strength for reactor-made TPO nanocomposite with 4 wt% clay. On the contrary, Mehta et al. (2004) observed a decrease in the notched impact strength with clay content for TPO nanocomposites prepared from commercial TPO having 30 wt% EPR. Later, Paul and coworkers reported extensive work on the extruder-made TPO nanocomposites and systematically studied the effect of the molecular weight of PP, melt flow index of elastomers, elastomer octene content, and MMT content on the elastomer particle shape and size, toughness, ductile–brittle transition temperature, and thermal expansion behavior (Lee et al. 2005, 2006a; Tiwari and Paul 2011b, c; Tiwari et al. 2012; Tiwari and Paul 2012; Tiwari et al. 2013). The understanding of the role of nanofillers on blend morphology and properties is still evolving; however, the following provides a summary of the current state of this approach.

17.2.2.1 Effect of PP-g-MA Content

The nonpolar nature of PP is an impediment to a high level of dispersion of organoclays unlike polar polyamide nanocomposites, wherein clay can be efficiently exfoliated using appropriate melt processing techniques (Fornes et al. 2001). Addition of small amounts of PP-g-MA to a PP matrix can increase polarity of PP leading to improved affinity for the silicate surface to achieve better dispersion of the MMT particles in the PP matrix and, as a consequence, improved stiffness of PP nanocomposites can be obtained (Hasegawa et al. 2000; Nam et al. 2001; Okamoto et al. 2001; Reichert et al. 2001; Marchant and Jayaraman 2002; Zhang et al. 2003). Increasing PP-g-MA content in the PP results in significant improvement in the level of exfoliation of MMT particles in a PP matrix which in turn increases the stiffness and the thermal expansion behavior of PP/PP-g-MA/MMT nanocomposites (Kim et al. 2007a). The addition of an elastomer to PP nanocomposites can lead to "super-tough" materials at elastomer contents of ∼30 wt% and 3 wt% MMT as seen in Fig. 17.6. The masterbatch used here contains an equal amount of PP-g-MA and organoclay. The addition of PP-g-MA to the PP matrix facilitates the dispersion of MMT particles which in turn decreases elastomer particle size by retarding coalescence and, then, leading to increased toughness (Lee et al. 2005). Figure 17.7 shows the weight average elastomer particle size decreases from 2.8 μm for PP/EOR blend without MMT to 0.8 μm in the presence of 7 wt% MMT at 30 wt% elastomer content. The impact strength does not change much with further increase in MMT content beyond the onset from the brittle–ductile transition (Lee et al. 2005). In another study, the effect of

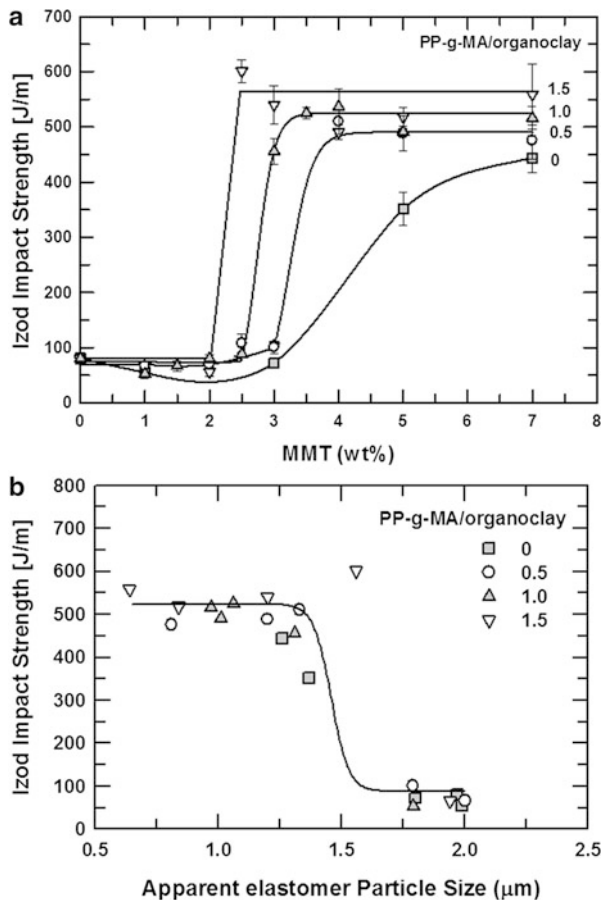
nanocomposites containing
various amounts of
elastomers. The masterbatch
contains equal amount of
PP-g-MA and organoclay
(Lee et al. 2005)
Fig. 17.7 The effect of MMT levels on the number and weight average apparent elastomer particle sizes (filled symbols) and interparticle distance (open symbol) of PP/elastomer/masterbatch nanocomposites containing 30 wt% elastomer. The masterbatch contains equal amount of PP-g-MA and organoclay (Lee et al. 2005)

PP-g-MA/organoclay ratio and MMT content on the toughness of extruder-made PP/PP-g-MA/MMT/EOR nanocomposites was determined by Tiwari et al. (2012). The elastomer content in this work was fixed at 30 wt% following the work done by Lee et al. (2005) where elastomer content >30 wt% showed a decrease in the tensile properties. Figure 17.8 shows the effect of MMT content and PP-g-MA/organoclay ratio on the notched impact strength of PP/PP-g-MA/MMT/EOR nanocomposites. A sharp brittle–ductile transition is observed in the presence of PP-g-MA in the nanocomposite; the onset of the transition shifts to lower MMT contents along with an increase in the plateau impact strength as the PP-g-MA/organoclay ratio is

Fig. 17.8 Notched impact strength of PP/PP-g-MA/ MMT/EOR nanocomposites. (**a**) Effect of MMT content and PP-g-MA/organoclay ratio, (**b**) effect of elastomer particle size (Tiwari et al. 2012)


increased. In the case of reactor-made "super-tough" TPO, the impact strength decreases with the addition of the PP-g-MA and MMT; the ductile–brittle failure is more prominent at a PP-g-MA/organoclay ratio of 2.0 as reported by Kim et al. (2007b). This reduced impact strength results from the decreased matrix ductility of reactor-made TPO in the presence of MMT; however, other factors such as differences in the TPO preparation methods (extrusion vs. reactor-made), molecular weight of PP and elastomer, matrix crystallinity, and elastomer type can also affect the performance of reactor-made TPO nanocomposites. The plot of elastomer particle size versus impact strength for extruder-made PP/PP-g-MA/ MMT/EOR nanocomposites shows the onset of toughness occurs at ∼1.6 μm followed by a plateau at lower elastomer particle size down to ∼0.6 μm (see Fig. 17.8b). The elastomer particle size at onset is specific to the matrix molecular weight, elastomer type, and content and can be easily tailored by varying these properties which is discussed in detail in next section. Except for impact strength,

the extruder-made and reactor-made TPO nanocomposites show similar trends in other properties where filler effects are dominant; such nanocomposites show increases in stiffness and yield strength and decrease in elongation at break as the MMT dispersion and MMT content are increased (Lee et al. 2005, 2006a; Kim et al. 2007b, 2008; Tiwari et al. 2012).

17.2.2.2 Effect of PP Molecular Weight and Elastomer MFI

The matrix molecular weight has a significant effect on the mechanical properties and toughness of elastomer-toughened blends; this is due to inherent ductility of the matrix and its response to toughening for different elastomers (Bucknall 1977; Wu 1985, 1987; Dijkstra and Gaymans 1994; Dijkstra et al. 1994; Majumdar et al. 1994a; Oshinski et al. 1996a, b; van der Wal et al. 1998, 1999). Tiwari and Paul (2011c) reported the effects of PP molecular weight, elastomer type, and MMT content on the elastomer particle size and toughness. Tables 17.2 and 17.3 lists the properties and designations of various PP and EOR used to prepare PP/PP-g-MA/MMT/EOR nanocomposites reported in this section. The elastomers designated as EOR 8150 and EOR 8150N are the same grade of Engage® 8150; however, based on the rheological measurements, EOR 8150N is reported to have high molecular weight than EOR 8150. PP/PP-g-MA/MMT/EOR nanocomposites were prepared with different molecular weight grades of PP and elastomer MFI at a fixed elastomer content of 30 wt% and PP-g-MA/organoclay ratio of 1.0. As seen in Fig. 17.9, the MMT particles in PP/PP-g-MA/MMT/EOR nanocomposites are exclusively located in the PP phase, irrespective of the PP molecular weight. The dark domains are the elastomer phase stained with ruthenium tetroxide.

The decrease in the elastomer particle size of PP/PP-g-MA/MMT/EOR nanocomposites is believed to result from the "barrier" effect of clay which retards the coalescence of elastomer particles. The dispersion of MMT particles has a significant effect on the extent of decrease in coalescence of dispersed phase; hence, it is important to understand the dispersion behavior of MMT particles as a function of matrix molecular weight. It is known that in partially exfoliated nanocomposites, the MMT particles are mostly skewed and randomly distributed in the low molecular weight matrix but become more well dispersed and aligned in the flow direction as the molecular weight of the matrix increases. The increased shear viscosity associated with increased molecular weight of the matrix improves MMT dispersion and aligns the particles along the flow direction (Fornes et al. 2001; Tiwari and Paul 2011a, b). Figure 17.10 shows the aspect ratio of the MMT particles as a function of elastomer MFI and octene content for PP/PP-g-MA/MMT/EOR nanocomposites prepared with various molecular weight grades of PP at a fixed MMT content of 5 wt%. A maximum MMT aspect ratio is observed for nanocomposites containing elastomers with MFI in the range of 0.5–1.0. For a given elastomer MFI, the aspect ratio of MMT ranks in the order: H-PP > M-PP > L-PP. The difference in the octene content of elastomers does not affect the aspect ratio of MMT particles in PP/PP-g-MA/MMT/EOR nanocomposites, even though they are reported to have different viscosities (see Table 17.3).

Table 17.2 Properties and designations of polypropylene (Tiwari and Paul 2011b)

Grade	Designation[a]	MFI g/10 min at 190 °C/2.16 kg	Viscosity (Pa. s) η_0	$\eta_{at250\ rad/s}$	ΔH_{fusion} (J/g^{-1})[b]	$T_m(°C)$[b]	Izod impact (J/m)	Tensile modulus (GPa)	Yield strength (MPa)	Elongation at break (%)

Fig. 17.9 TEM micrographs of PP/PP-g-MA/MMT/EOR 8100 nanocomposite prepared from L-PP (**a**) and H-PP (**b**) showing the location of the elastomer and the MMT particles. The elastomer content is 30 wt% and MMT content is 5 wt% based on total nanocomposite. All images viewed parallel to TD; clay particles are oriented parallel to FD (Tiwari and Paul 2011b)

The effect of MMT content and PP molecular weight on the elastomer morphology in PP/PP-g-MA/MMT/EOR nanocomposites is shown in Fig. 17.11. The elastomer particles are large with a mixture of spherical and elongated shapes in L-PP/EOR blend or mostly spherical shapes in the H-PP/EOR blend without MMT and become small and mostly elongated in the presence of MMT in both L-PP- and H-PP-based nanocomposites. The nonspherical nature of elastomer particles is

Fig. 17.10 The effect of elastomer MFI on MMT particle aspect ratio of PP/PP-g-MA/MMT/EOR nanocomposite prepared from various molecular weight PP. *Gray-* and *black-* filled symbol represents nanocomposites containing elastomers having 39 and 28 wt% octene content, respectively. The EOR and MMT content is based on the total nanocomposite weight (Tiwari and Paul 2011b)
related to the deformation that occurs during injection molding, whereas a decrease in the elastomer particle size and an increase in elastomer particle density are observed as the molecular weight of PP and MMT content increases. This is related to the effects of increased PP viscosity caused by MMT and the "barrier" effect of clay that retards the coalescence of elastomer particles as explained in various reports on blend nanocomposites (Gelfer et al. 2003; Khatua et al. 2004; Lee et al. 2005; Vo and Giannelis 2007; Yoo et al. 2010a, b). The percent decrease in the elastomer particle size in the presence of clay is higher for nanocomposites prepared from L-PP; however, the nanocomposites based on H-PP always have a smaller elastomer particle size than L-PP. For example, in the case of PP/PP-g-MA/MMT/EOR 8100 nanocomposites, L-PP is reported to be more effective in reducing elastomer particle size by 59 % at 3 wt% MMT compared to 41 % for M-PP and 16 % for H-PP-based nanocomposites at 3 wt% MMT; however, the elastomer particle size for L-PP nanocomposites is higher than the H-PP-based nanocomposite at any fixed MMT content, and this trend is the same for other elastomers (Tiwari and Paul 2011b, c, 2012). The elastomer with an MFI in the range of 0.5–1.0 gives maximum decrease in the elastomer particle size in PP/PP-g-MA/MMT/EOR nanocomposites irrespective of the PP molecular weight. The effect of elastomer MFI range on the properties cannot be generalized for blends of elastomer with other thermoplastics and may depend on several factors such as interaction between matrix and elastomer in addition to the viscosity ratio of elastomer to matrix.

17.2.2.3 Correlation Between Impact Strength and Elastomer Particle Size

Notched impact specimens fail in three different modes based on the ability to absorb impact energy: a hinged break for tough samples, a complete break into two pieces for brittle samples, and a mixed mode, either a hinged or a complete break, for samples near the ductile–brittle transition composition. These three failure
Fig. 17.11 AFM images of PP/PP-g-MA/MMT/EOR nanocomposites showing elastomer particle morphology as a function of MMT content and PP molecular weight grade. The PP-g-MA/organoclay ratio is 1.0 and elastomer content is 30 wt%. All images were taken from the core of the injection-molded sample and viewed parallel to TD; elastomer particles are oriented parallel to FD (Tiwari and Paul 2011b)
Fig. 17.12 Image representing failure modes in impact specimen. (**a**) A complete break into two pieces for brittle sample, (**b**) a mixed mode with hinged or a complete break for samples near brittle–ductile transition, and (**c**) a hinged break for tough samples (Tiwari and Paul 2011c)

modes for elastomer-toughened PP nanocomposites are shown in Fig. 17.12 (Tiwari and Paul 2012). Paul and coworkers have reported that elastomers with MFI in the range of 0.5–1.0 provide maximum improvement in the toughness in the case of L-PP/PP-g-MA/MMT/EOR nanocomposites. However, the effect of elastomer MFI becomes less significant as the PP molecular weight is increased, i.e., in the H-PP-based system; all nanocomposites maintain super-toughness, and no significant change in the impact strength is observed with MMT content and elastomer MFI (Tiwari and Paul 2011c). Figure 17.13 shows the effects of elastomer MFI and MMT content on the impact strength of extruder-made TPO nanocomposites prepared from different molecular weight grades of PP.

The elastomer particle size and size distribution plus elastomer content significantly affect the toughness of elastomer/thermoplastic blends (Oshinski et al. 1996a, b, c; Majumdar et al. 1997; Huang et al. 2006b; Bucknall and Paul 2009; Tiwari and Paul 2011b, c, 2012). It has been observed that small particles (weight average particle diameter, $\overline{d}_w \sim 0.2 - 0.4$ μm) provide toughness when shear yielding dominates the toughening mechanism, whereas larger particles ($\overline{d}_w \sim 2 - 3$ μm) are more effective when crazes contribute to energy absorption. It is also known that for most elastomer-toughened thermoplastics, the maximum toughness is restricted to a limited range of particle sizes, which is often quite narrow (Oshinski et al. 1996a, b, c; Majumdar et al. 1997; Huang et al. 2004, 2006a, b; Huang and Paul 2006; Bucknall and Paul 2009; Tiwari and Paul 2011b, c, 2012). It is believed that any deviation beyond the preferred range in either direction results in a ductile–brittle transition, as illustrated in Fig. 17.14, where b and d respectively mark the midpoints of the lower and upper transitions and thus define critical particle sizes. The curve represents the elastomer particle size for the blend of PA 6 and reactive-compatibilized elastomer; however, with appropriate scaling of particle size and peak height, similar curves could be drawn for almost any well-made rubber-toughened polymer blend provided elastomer particle size with lowest limit are obtained (Bucknall and Paul 2009). Not much is known about the elastomer particle size limits on the toughening of PP/elastomer blends and

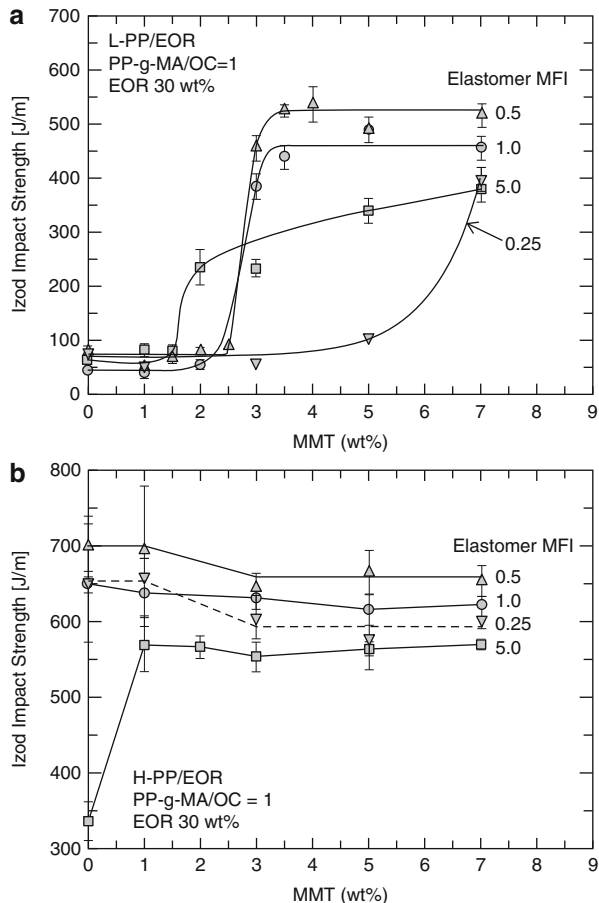
2011c)


nanocomposites (Jiang et al. 1995; Liang and Li 2000). The results on the effect
of various parameters such as PP molecular weight, elastomer and MMT content
on the elastomer particle size, and toughness in extruder-made TPO
nanocomposites can provide knowledge about elastomer particle size limits in
elastomer-toughened PP.

Figure 17.15 shows the effect of elastomer particle sizes on the room tempera-
ture impact strength for blends and nanocomposites prepared by varying elastomer
MFI and MMT content for L-PP, M-PP, and H-PP nanocomposites. The general
behavior is that the critical elastomer particle size below which the nanocomposite
shows tough behavior appears to decrease as the PP molecular weight increases; the
H-PP materials did not show any critical elastomer particle size irrespective of
elastomer octene content. The nanocomposites based on elastomers with high
octene content have higher impact strength, and the onset of toughness occurs at
a larger elastomer particle size compared to nanocomposites based on elastomers
with low octene content (see Fig. 17.15a). This relates to the higher crystallinity and
Fig. 17.14 Relationship between particle size and impact behavior for a typical "super-tough" thermoplastic blend. Points b and d mark *lower* (●) and *upper* (○) ductile–brittle transitions. Schematic representation based broadly on data of Huang et al. (2006b) for a series of 80/20 RTPA6 blends (Bucknall and Paul 2009)

higher modulus of the low octene content elastomer which limits its tendency to undergo cavitation desired for toughness; however, this effect of elastomer crystallinity and modulus on the onset of toughness and impact strength diminishes with the increase in the PP molecular weight especially for H-PP-based nanocomposite. Tiwari and Paul (2011c) have observed that for nearly similar elastomer particle sizes, the impact strength varies in the order H-PP > M-PP > L-PP indicating PP molecular weight has a significant effect on the toughness of PP/PP-g-MA/MMT/EOR nanocomposites other than elastomer particle size. The effect of matrix molecular weight on the toughness as seen in elastomer-toughened blends without MMT seems to be valid in the case of a matrix with clay particles (Bucknall 1977; Wu 1985, 1987; Dijkstra and Gaymans 1994; Dijkstra et al. 1994; Majumdar et al. 1994a; Oshinski et al. 1996a, b; van der Wal et al. 1998, 1999; Liang and Li 2000).

17.2.2.4 Toughening Mechanism and Ductile–Brittle (D-B) Transition Temperature

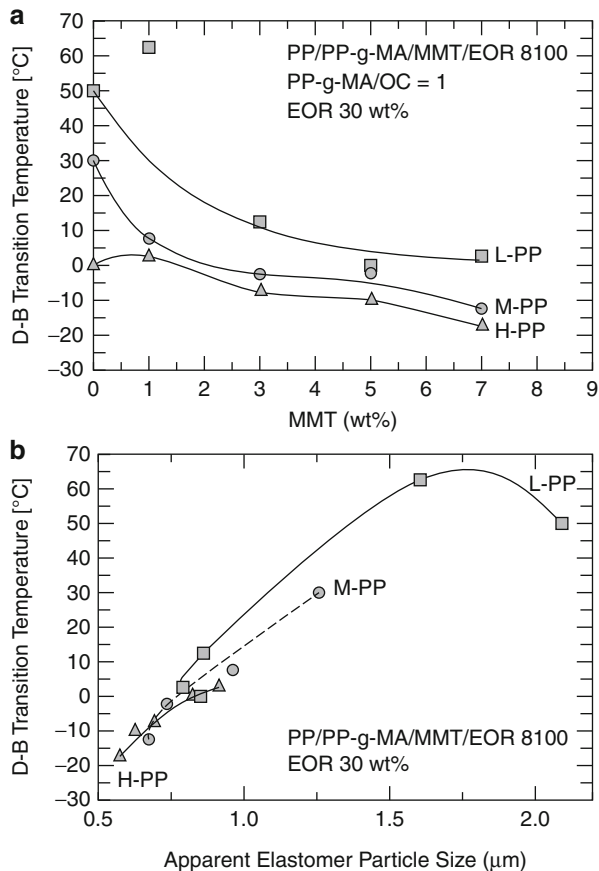
The ductile–brittle (D-B) transition temperature provides information about the performance limit below which the material fails in a brittle manner. The D-B transition temperature is generally defined as the midpoint in the steplike change in impact strength recorded as a function of temperature. The matrix and elastomer properties and elastomer particle size have a significant effect on the D-B transition temperature. Although, the understanding of the role of elastomer particle size and shape in the toughening process is still evolving, the two toughening mechanisms prominent in elastomer-toughened blends are (1) the stress concentration effect of

Fig. 17.15 Effect of the weight average apparent elastomer particle size on the notched impact strength of PP/PP-g-MA/MMT/EOR nanocomposites prepared from (**a**) L-PP, (**b**) M-PP, (**c**) H-PP, and elastomers with different MFI. Elastomer content is 30 wt% and PP-g-MA/organoclay ratio is 1.0 (Tiwari and Paul 2011c)
the low modulus elastomer particles in a more rigid matrix to initiate and terminate crazes and (2) rubber particle cavitation thereby relieving triaxial stress leading to shear yielding of pseudo-ductile matrices such as PP and nylon (Goodier 1933; Oxborough and Bowden 1974; Epstein 1979a, b; Lazzeri and Bucknall 1993;

Fig. 17.16 Modulus ratio of PP or PP/PP-g-MA/MMT and the elastomer as a function of temperature. The total MMT content in the PP/PP-g-MA/MMT is equivalent to 3 wt% MMT in the PP/PP-g-MA/MMT/EOR nanocomposites. Note that MMT is exclusively located in the PP phase in TPO nanocomposites (Tiwari and Paul 2012)
Bucknall et al. 1994; Dompas and Groeninckx 1994; Liang and Li 2000). The elastomer properties such as elastomer glass transition temperature, T_g, and modulus also put limits on the D-B transition temperature since it ceases to be elastomeric below T_g thereby reducing the stress concentration and the ability to undergo cavitation which are the important aspects of the toughening mechanism. The temperature at which the ratio of matrix to elastomer moduli falls below about 10 provides an empirical lower limit for the D-B transition temperature for rubber-toughened materials based on prior observations for rubber-toughened blends (Keskkula and Paul 1995; Oshinski et al. 1996c; Tiwari and Paul 2012).

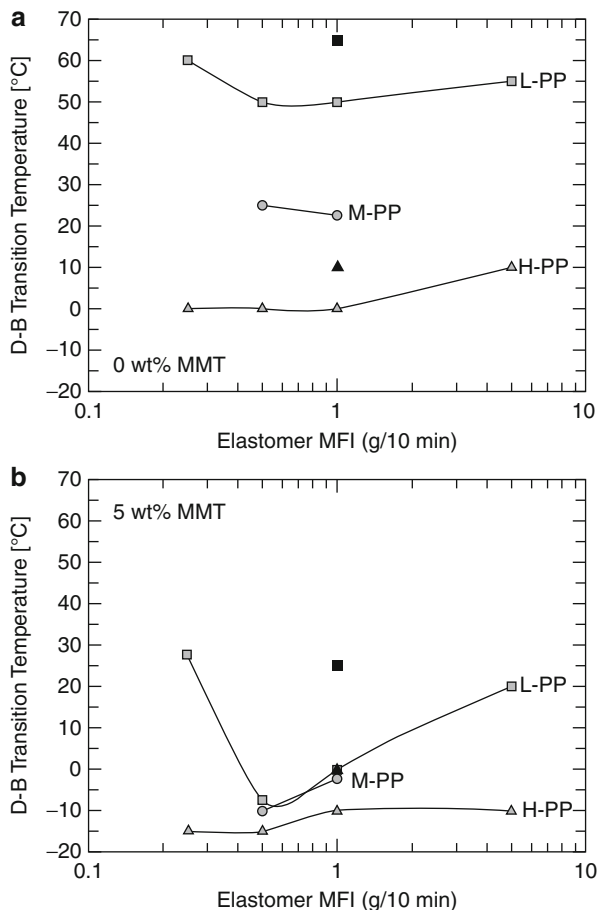
According to Lim et al. (2007, 2010), cavitation of elastomer particles followed by extensive shear yielding of PA 6 matrix accompanied by delamination of intercalated clay particles is a major cause of toughening in PA 6/elastomer/MMT nanocomposites. The delamination of clay particles in the matrix is an additional contributing factor to the toughening; however, no crazing was observed in the PA 6 matrix unlike in PA 6/EOR grafted maleic anhydride (EOR-g-MA) blends as reported by Huang and Paul (2006). More fundamental studies are required to elucidate toughening mechanisms in other elastomer-containing nanocomposites.

Figure 17.16 shows the modulus ratio of PP or PP/PP-g-MA/MMT and the elastomer as a function of temperature for PP/PP-g-MA/MMT/EOR nanocomposites. As seen in Fig. 17.16, the empirical matrix to elastomer modulus ratio of 10 when used as a criteria to define the lower limit of D-B transition temperature is obtained at approx. $-44\,°C$ and approx. $-30\,°C$ for nanocomposites containing elastomers with 39 wt% octene content and 28 wt% octene content, respectively. These temperatures are significantly lower than the lowest D-B temperatures observed with these elastomers, viz., $-17.5\,°C$ and $0\,°C$, respectively (Tiwari and Paul 2012). It is known that the elastomer properties, such as T_g and modulus, set the lower limit for the D-B temperature; however, elastomer particle

Fig. 17.17 Effect of MMT content (**a**) and weight average apparent elastomer particle size (**b**) on the ductile–brittle transition temperature of PP/PP-g-MA/ MMT/EOR 8100 nanocomposites prepared from three different molecular weight grades of PP. Elastomer content is 30 wt% and PP-g-MA/ organoclay ratio is 1.0 (Tiwari and Paul 2012)


size must be optimized to approach such a limit. The presence of MMT particles in the PP matrix might alter the applicability of this empirical rule of thumb based on the modulus ratio.

In the elastomer particle size range where toughness is expected, the D-B transition temperature is known to decrease with increased matrix molecular weight; however, little is known about this behavior in the presence of clay. In a recent study on the effect of PP molecular weight and elastomer MFI on the properties of extruder-made TPO nanocomposites, a significant drop in the D-B transition temperature is reported for the nanocomposites (Tiwari and Paul 2012). As seen in Fig. 17.17, the D-B transition temperature decreases with increased MMT content of PP/PP-g-MA/MMT/EOR nanocomposites. At a fixed MMT content, the D-B transition temperature decreases with increased PP molecular weight. The D-B transition temperature generally correlates with elastomer particle size with a smaller effect of PP molecular weight in the order of H-PP < M-PP < L-PP, and the trend becomes less significant for elastomer particle sizes smaller than ∼0.75 μm. The increase in the PP molecular weight reduces the

Fig. 17.18 Effect of elastomer MFI on the ductile–brittle transition temperature of (**a**) PP/EOR blend and (**b**) PP/PP-g-MA/MMT/EOR nanocomposites. *Gray*- and *black*-filled symbol represents nanocomposites containing elastomers having 39 and 28 wt% octene content, respectively. The total MMT content in the nanocomposites is 5 wt%. Elastomer content is 30 wt% and PP-g-MA/organoclay ratio is 1.0 (Tiwari and Paul 2012)


D-B transition temperature, and the effect of elastomer MFI on the D-B transition temperature becomes less prominent with the increased PP molecular weight as seen in Fig. 17.18. The nanocomposites based on the high-octene-content elastomer (~39 wt%) also lead to a lower D-B transition temperature compared with nanocomposites based on the elastomer with low octene content (~28 wt%). The toughening mechanism was not explored for this system; a more detailed study in this area would further enhance the understanding of the role of organoclay in elastomer-toughened nanocomposites with partially exfoliated clay particles.

17.2.2.5 Thermal Expansion Behavior

Recently, polymers have found a significant utilization in the automotive industry mainly due to their low density, ease of processing and molding into desired parts, and the ability to tailor properties based on the end application (Garcés et al. 2000; Hussain and Gorga 2006; Okada and Usuki 2006; Goettler et al. 2007). Among these, thermoplastic olefins are widely used due to their high toughness and low

Fig. 17.19 Typical thermal
expansion behavior of

composition is 30 wt%
elastomer and ∼3 wt%
MMT. The masterbatch
contains equal amount of
PP-g-MA and organoclay
(Lee et al. 2006a)
density. However, most polymers have significantly higher coefficients of linear
thermal expansion (CTE) than most metals within a temperature range suitable for
application purposes. For example, the CTE for PP is $\sim 10^{-4}$ mm/mm $^\circ$C compared
to CTE for metals $\sim 10^{-5}$ mm/mm $^\circ$C; this limits utilization of lightweight plastic
parts in various automotive applications (Kim et al. 2008). Layered silicates have
high modulus and low CTE; therefore, well-dispersed and appropriately oriented
clay particles can significantly reduce the CTE of thermoplastic olefins by simple
mechanical restraints imposed on expansion of the soft elastomer particles. More-
over, the small absolute size of filler particles gives a better surface finish of the
final product than that expected for conventional composites based on talc or glass
fibers. The nonuniform shape of the elastomer particle in the blend can lead to
anisotropic thermal expansion behavior; this issue is more complicated upon
addition of filler as the thermal expansion behavior is strongly influenced by the
nature of dispersion and orientation of the filler (Ono et al. 2005; Lee et al. 2006a;
Kim et al. 2008). Yoon et al. (2002) observed anisotropic thermal expansion
behavior in the flow direction (FD) and transverse direction (TD) of injection-
molded nanocomposite specimens; the CTE in the FD is significantly lower than
that in the TD due to the lower degree of alignment of the exfoliated clay platelets in
the TD compared to the FD as indicated by TEM images. Their work evaluates the
effect of angle of orientation of clay platelet and MMT dispersion on CTE in
various orthogonal directions of the injection-molded specimen.

Figure 17.19 shows typical thermal expansion behavior of a PP/PP-g-MA/MMT/
elastomer nanocomposite from the first and second heating; the thermal expansion
is a nonlinear function of temperature when viewed over the wide range of −40 $^\circ$C
to 125 $^\circ$C; hence, CTE is reported in the temperature range of 0–30 $^\circ$C so it can be
related to the mechanical properties determined at room temperature (Lee
et al. 2006a). For both extruder-made and reactor-made TPO nanocomposites, the
CTE along the FD and the TD decreases, whereas CTE along the normal direction
(ND) increases as the MMT content is increased. The increase in CTE in the ND is

related to the reduced thermal expansion in the FD and the TD in the presence of MMT. However, it is interesting to note from Fig. 17.20 that the initial CTE for the PP/EOR blend in the ND is higher than in the FD and the TD. This is ascribed to effects of elastomer shape and size plus elastomer deformation in the flow direction along with the polymer crystallite orientation (Lee et al. 2006a; Kim et al. 2008). The differences among CTE in the FD, TD, and ND are related to the anisotropic dispersion of MMT and elastomer in the injection-molded specimen. The MMT particles in TPO nanocomposites are more aligned in the FD than in the TD which results in more mechanical constraint imposed in the elastomer particles in the FD than in TD resulting into larger decrease in the CTE along FD than TD. Tiwari et al. (2011b, 2013) showed AFM images of elastomer particles in three orthogonal directions of injection-molded specimen of PP/PP-g-MA/MMT/ EOR nanocomposites and projected elastomer particle as a prolate ellipsoid as seen in Fig. 17.21.

17.2.3 Polyamide Blend Nanocomposites

17.2.3.1 Elastomer Particle Size, Impact Strength, and Fracture Behavior

Polyamides are widely used commercially due to their high stiffness and strength, excellent chemical resistance, low coefficient of friction, and toughness. However, their poor low-temperature impact strength and extreme sensitivity to notch failure put limits on some applications (Keskkula and Paul 1995). Rubber toughening of polyamides has been extensively studied where the effect of elastomer type and elastomer content and nature of reactive/functionalized groups on the elastomer morphology and elastomer particle size and toughness has been reported (Wu 1985, 1987; Oshinski et al. 1996a, b, c; Majumdar et al. 1997; Yu et al. 1998; Huang et al. 2004; Okada et al. 2004; Huang et al. 2006a, b; Huang and Paul 2006). Due to the amine end group of polyamides, they can react with elastomers functionalized with anhydride, acid, or other functional groups, and this grafting leads to reduced elastomer particle size along with improvement in the notched impact strength and a lower ductile–brittle transition temperature (Oshinski et al. 1996a, b, c).

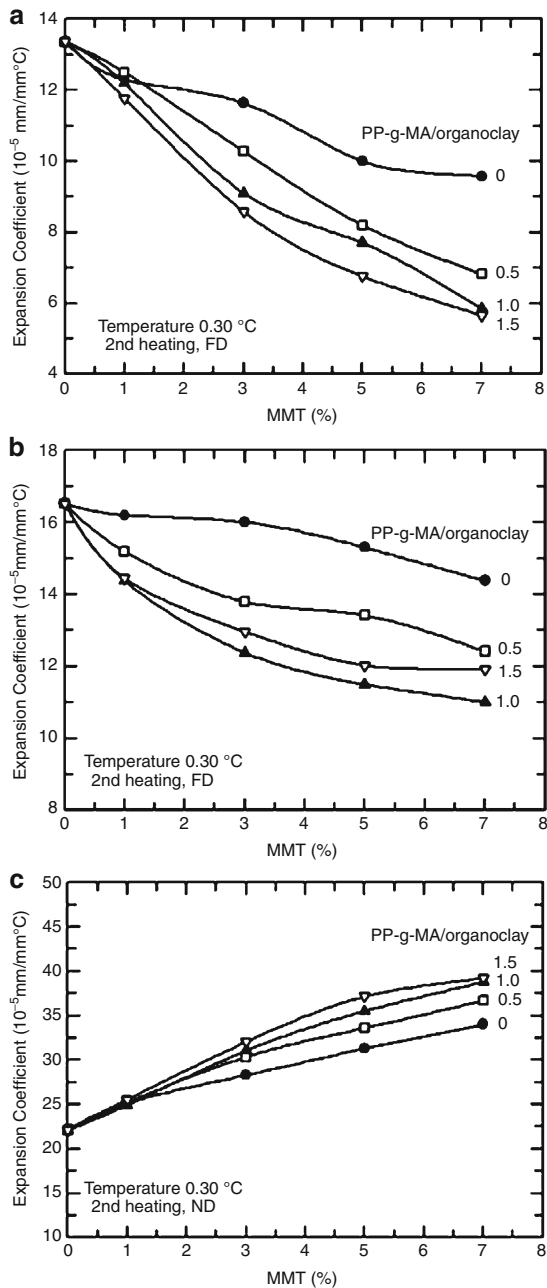
Blends of semicrystalline and amorphous polyamides with the reactive and nonreactive elastomers and with other thermoplastics have been extensively studied in the polymer blend nanocomposite literature (Chow et al. 2003, 2004; Khatua et al. 2004; Li and Shimizu 2004; Chiu et al. 2005; Dasari et al. 2005; González et al. 2005; Kelnar et al. 2005; Lai et al. 2005; Li and Shimizu 2005; Tjong and Bao 2005; Ahn and Paul 2006; González et al. 2006a, b; Kelnar et al. 2006; Lai et al. 2006; Wahit et al. 2006c; Wahit et al. 2006a, b; Kelnar et al. 2007; Lim et al. 2007; Vo and Giannelis 2007; Filippone et al. 2008; Goitisolo et al. 2008; González et al. 2008; Kelnar et al. 2008, 2009; As'habi et al. 2010; Filippone et al. 2010a, b; Lim et al. 2010; Motamedi and Bagheri 2010; Yang et al. 2010; Yoo et al. 2010a, b; González et al. 2012). The polar nature of polyamide facilitates dispersion of clay particles in it while the location of the clay particles at the


Fig. 17.20 (continued)
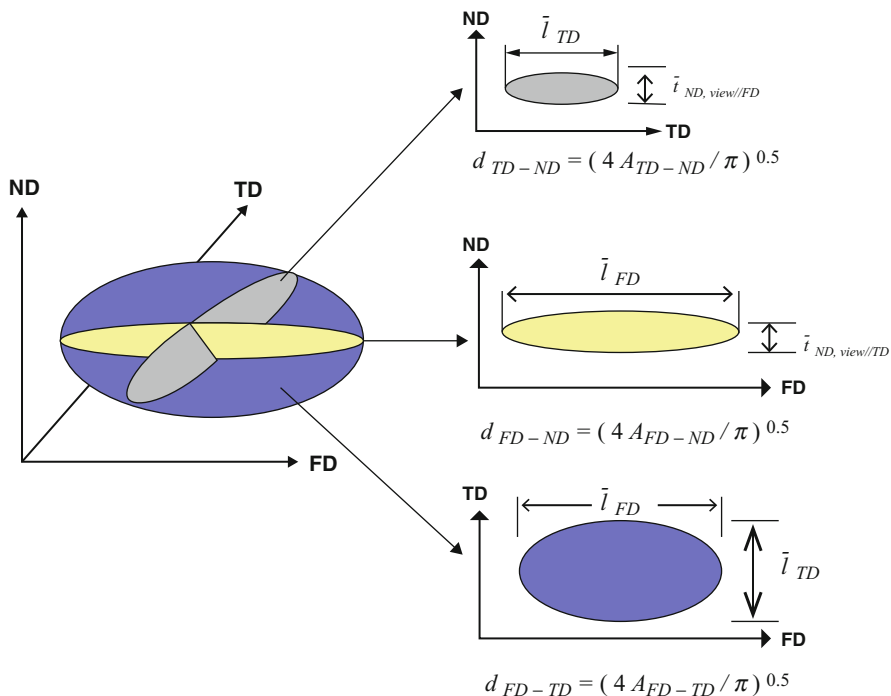
Fig. 17.20 Coefficient of linear thermal expansion (CTE) for PP/PP-g-MA/MMT/EOR nanocomposites as a function of MMT content for (**a**) FD, (**b**) TD, (**c**) ND, and (**d**) bulk expansion coefficients (Tiwari et al. 2013)


Fig. 17.21 Illustration of elastomer phase morphology of PP/PP-g-MA/MMT/EOR nanocomposites based on the AFM imaging in three orthogonal directions of the injection-molded Izod bar (Tiwari et al. 2013)

interface depends largely on the interfacial interaction of clay with other blend components. Khatua et al. (2004) reported significant decreases in the elastomer particle size with the addition of clay in PA 6/EPR (80/20) blend; the elastomer particle sizes in blend nanocomposites were similar to those obtained for PA 6/EPR grafted maleic anhydride (EPR-g-MA) (80/20) blend. The presence of clay particles in the PA 6 matrix retards the coalescence of EPR particles and thereby reduces their size similar to steric stabilization by maleated EPR; moreover, the EPR particles are more stable upon annealing when clay is present in the PA 6 phase. On the contrary, when clay particles are located exclusively in the dispersed phase, they can transform matrix-domain morphology into a co-continuous structure as observed for blends of polyamide with acrylonitrile–butadiene–styrene (ABS), polyphenylene oxide (PPO), low-density polyethylene (LDPE), and high-density polyethylene (HDPE) (Li and Shimizu 2004, 2005; Filippone et al. 2008; Filippone et al. 2010a; Filippone et al. 2010b). The increase in the viscosity ratio of dispersed to continuous phase with the addition of clay promotes co-continuity at lower dispersed phase content in these blends. The co-continuous morphology leads to the better combination of properties; hence, there is considerable interest in understanding the effect of nanoparticles in promoting co-continuity and their properties (Sundararaj and Macosko 1995; Pötschke and Paul 2003a; Pötschke and Paul 2003b; Li and Shimizu 2004, 2005; Wu et al. 2006; Ray et al. 2007; Zou et al. 2007; Filippone et al. 2008; Filippone et al. 2010a, b). Figure 17.22 shows TEM images and a schematic of co-continuous blend morphology observed for PA 6/ABS (40/60) nanocomposites where the clay particles are exclusively located in the dispersed PA 6 phase. The thermomechanical properties such as storage modulus are reported to increase by 205 % at 180 °C with the addition of 4 wt% clay in the blend. The co-continuous blend morphology becomes more finer as the clay content is increased (Li and Shimizu 2004, 2005).

Unlike PP/elastomer blends, a decrease in the elastomer size does not always lead to the increase in the impact strength of polyamide/elastomer blend containing organoclays. Figure 17.23 shows the effect of elastomer particle size on the notched impact strength for amorphous polyamide (a-PA) blends based on EOR and EOR-g-MA. The elastomer content in the blend is 20 wt%. The impact strength for a-PA/EOR-g-MA (80/20) blend reduced from 1,000 J/m for blend without clay to 20 J/m in the presence of 7 wt% MMT even though the elastomer particle sizes were within the range where toughness is expected. In the case of the a-PA/EOR (80/20) blend, the elastomer particle size decreased from 2 to 0.3 μm with addition of clay; however, no improvement in toughness was observed. The high T_g of a-PA and highly exfoliated clay particles makes a-PA brittle enough to contribute to the toughening mechanism. In general, for polyamide/maleated elastomer nanocomposites, the elastomer particle size either slightly increased or did not change with the addition of clay; this has been ascribed to the chemical interactions between the maleic anhydride group of the elastomer and the surfactant of the organoclay that may hinder the compatibilizing effect of elastomer resulting in a higher elastomer particle size as reported in Table 17.4 (González et al. 2006a).
Fig. 17.22 TEM micrographs of ABS/PA6 nanocomposite with 4 % clay. (**a**) Low-magnification image, (**b**) high-magnification image, (**c**) schematic diagram for the co-continuous ABS/PA6 blend nanocomposite. The *white* part is the SAN phase, the *gray* part is the PA6 phase, the *black* particles are the butadiene rubber phase, and the *dark line* in the PA phase is the organoclay platelet in (**a**) and (**b**) (Li and Shimizu 2005)

In another study on PA 6/MMT/EPR-g-MA blend nanocomposites where clay particles are exclusively located in the PA 6 phase, the impact strength was reported to decrease as the MMT content in the blend increases; a significant improvement in the toughness was observed for 25 parts per hundred (pph) of elastomer content in

Fig. 17.23 Effect of weight average elastomer particle sizes on the notched impact strength of a-PA/elastomer blend (80/20) nanocomposites containing (**a**) EOR and (**b**) EOR-*g*-MA. Data for a-PA/EOR (−*g*-MA) blend without organoclay are from Huang et al. (2006b) (Yoo et al. 2010a)
Table 17.4 Weight average dispersed elastomer particle size ($\overline{d}_w$) in PA 6/SEBS-g-MA blend nanocomposites as a function of maleic anhydride (MA) content in SEBS-g-MA. The elastomer content in blend is 15 wt% (González et al. 2006b)

1.5	0.08	0.36

the blend nanocomposites. The D-B transition temperature increased with the addition of clay at fixed elastomer content and further decreased with the addition of elastomer at fixed MMT content (Ahn and Paul 2006). The toughening mechanism for PA 6-based blend nanocomposites has not been extensively studied; however, it is reported that the toughening in elastomer-containing PA 6 nanocomposites arises from the cavitation of elastomer particles followed by extensive shear yielding of PA 6 matrix accompanied by delamination of intercalated clay particles (Lim et al. 2010). However, no crazing was observed within the matrix as previously observed in the case of PA 6/EOR-g-MA blend without clay (Huang and Paul 2006). Figure 17.24 shows the TEM images of the fractured surface of the PA 6/EOR-g-MA/MMT nanocomposites at various distances from the crack tip location (Lim et al. 2010). As seen in Fig. 17.24a, the voids are due to the delamination of the intercalated clay stacks at ∼100 μm away from the crack tip location in schematic. At position (b), i.e., closer to the crack tip, the elastomer particles have undergone significant cavitation even in the presence of organoclay in the PA 6 matrix followed by the extensive shear yielding of the PA 6 observed around the crack tip as seen from extensive deformation and coalescence of the elastomer particles at position (c). The voids generated by delamination of clay
Fig. 17.24 TEM micrographs of nylon 6/organoclay/EOR-g-MA (76/4/20) ternary nanocomposite showing (**a**) submicron and nano-voids which are associated with intra-gallery delamination of some organoclay layers (note that the section is not selectively stained in order to clearly reveal delaminations of clay layers), (**b**) cavitation of EOR-g-MA particles which preferentially starts from the larger particles as indicated by *arrows*, and (**c**) extensive matrix shear yielding at the arrested crack tip which in turn causes the EOR-g-MA particles and delaminated clay layers to collapse within the matrix. A schematic of the arrested crack tip illustrating different locations from where TEM micrographs (**a–c**) were taken is also shown. Note that the schematic is not to scale (Lim et al. 2010)

stacks are arrested and do not turn into micro-cracks; this contributes to toughening. More studies in this area including toughening mechanisms on other elastomer-toughened blend nanocomposites are required to further elucidate toughening mechanisms in blends with nanoparticles.

It is clear from the literature that PA 6/maleated elastomer/MMT nanocomposites show a decrease in the impact strength in the presence of clay compared to the pure blend; this decrease in the impact strength depends on several factors including clay content, elastomer type, location of clay in blend, and crystallinity of the matrix and elastomer in the presence of MMT. No clear understanding about this behavior is available; perhaps the low impact strength arises from the high aspect ratio of clay particles in the polyamide matrix that reduces their ability to contribute to toughening.

Kelnar et al. (2005, 2006, 2007) reported on morphology and properties of PA 6 nanocomposites prepared with various reactive and nonreactive elastomers and various organoclays. They concluded that in the PA 6/elastomer blend nanocomposites having nonreactive elastomer, the "core-shell" structures where clay particles form a shell around the elastomer particles provide improvement in the toughness. Later it was reported that combination of two clays where the elastomer is pre-blended with a less polar clay followed by blending the elastomer nanocomposite with PA 6 and more polar clay provides high reinforcement, better compatibilization, and favorable "core-shell" structure with balance of toughness and mechanical properties (Kelnar et al. 2007). This is an interesting observation that departs from usual behavior since the clay particles in a soft elastomer particle should reduce their ability to undergo cavitation; hence, further studies are needed to gain a better understanding about the practical applicability of this approach. Observations on other blends containing clay are listed in Table 17.5.

17.2.3.2 Effect of Blending Sequence

The mixing sequence is known to have a significant effect on the elastomer particle size, toughness, and mechanical properties of blends; in the case of blend nanocomposites, this can affect the dispersion and location of clay particles in the blend and dispersed phase particle size (Li et al. 2002; Dasari et al. 2005; García-López et al. 2007; Vo and Giannelis 2007; Wang et al. 2007; Gallego et al. 2008; González et al. 2008; Yoo et al. 2010b; Zhai et al. 2010; Chen and Evans 2011). Vo and Giannelis (2007) compared the effect of two organoclays, Cloisite® 30B and Cloisite® 20A, and simultaneous and sequential extrusions on the properties of polyvinylidene fluoride (PVDF)/PA 6 (30/70) blends. They demonstrated that the blend containing Cloisite® 30B prepared by simultaneous extrusion had good dispersion of organoclay, lower PVDF domain size, and exhibited the best mechanical properties. The majority of organoclay is dispersed in the PA 6 matrix, and some of the organoclays were observed at the PVDF/PA 6 interface. In another report on blending PA 66 with Cloisite® 30B, followed by mixing with SEBS-*g*-MA, led to maximum notched impact strength (Dasari et al. 2005). In the case of PA 6/EPDM-*g*-MA/organoclay nanocomposites, blending sequence had less influence on the mechanical properties, and simultaneous blending was selected as the simplest way to prepare nanocomposites. A two-step blending approach where the polyamide is mixed with organoclay followed by blending with elastomer leads to higher notched impact strength (Dasari et al. 2005; García-López et al. 2007) although other mixing routes such as blending the polyamide and elastomer

Table 17.5 Observations on immiscible polymer blends containing organoclays

Blend	Composition/content	Filler	Filler location	Observations	Reference
PA 6/ABS	40/60	Cloisite® 30B	PA 6 phase	Morphology changes from dispersed phase to co-continuous structure in the presence of organoclay. Co-continuity leads to significant improvement in dynamic storage modulus of the nanocomposites compared to pure blend	Li and Shimizu 2004, 2005
Nylon 6/EPR	80/20	Cloisite® 20A	Nylon 6 phase	Decrease in the dispersed elastomer particle size in the presence of clay and increase in the phase stability of elastomer particles on annealing	Khatua et al. 2004
PA 6/EOR-g-MA	90/10	Cloisite® 30B	PA 6 and EOR-g-MA phases	Tensile modulus and strength increased while elongation at break and impact strength decreased in the presence of MMT	Chiu et al. 2005
PP/EPDM/PP-g-MA	25 wt% PP	Cloisite® 20A	EPDM	Improvement in the tensile modulus and strength and decrease in the elongation at break in the presence of organoclay. Addition of PP-g-MA leads to a higher improvement in the properties compared to nanocomposites without PP-g-MA	Mishra et al. 2005
Nylon 66/SEBS-g-MA	84/16	Cloisite® 30B	Nylon 66 phase	Flexural modulus and strength increases while impact strength decreases in the presence of organoclay	Dasari et al. 2005

PA 6/elastomer Elastomers: EPR-g-MA, SBS-g-MA, VP701, EPR, E-MA-GMA, PE-GMA, PP-g-MA	95/5	Cloisite® 30B	PA 6 phase	Reactive elastomers, mainly EPR-g-MA and SBS-g-MA, result in better improvement in toughness compared to other elastomers. A tensile property increases in the presence of organoclay	Kelnar et al. 2005, 2006
Nylon 6/EPR-g-MA	EPR-g-MA: 0–25 wt%	Cloisite® 30B	Nylon 6 phase	Impact strength increased with the addition of elastomer at a fixed MMT content. Ductile–brittle transition temperature decreased with the addition of elastomer and with the decrease in the MMT content	Ahn and Paul 2006
PBT/HDPE	PBT: 1 to 90 wt%	Nanofil® 919	PBT phase and interface based on blend composition	The MMT particles located at the blend interface reduce the interfacial tension between blend components. The addition of organoclay also increases the thermal stabilization of blend morphology	Hong et al. 2006a, b
PPS/PA 66	60/40	OMMT	PA 66 phase	Morphology changes from dispersed phase to co-continuous and lamellar structure with the addition of clay. Tensile strength and impact strength increased with clay content. Increase in anti-wear property	Zou et al. 2007
PVDF/nylon 6	30/70	Cloisite® 30B	Nylon 6 and interface	Improvement in the tensile modulus, strength, and elongation at break of blend in the presence of organoclay	Vo and Giannelis 2007
PVDF/nylon 6	30/70	Cloisite® 20A	Interface		

HDPE/PA 6	75/25	Cloisite® 15A	PA 6 phase	Formation of co-continuous structure in the presence of MMT in PA 6 phase. Increase in the tensile modulus and strength and slight decrease in the elongation at break observed in the presence of clay	Filippone et al. 2008
PA 6/SEBS-g-MA	70/30	Nanomer® I.30TC	PA 6 phase	Modulus and yield strength increases and tensile ductility decreases with the increase in clay content. Higher rubber content is required to achieve toughness as clay content increases	González et al. 2008
Nylon 66/PP/PP-g-MA	70/20/10	OMMT	Nylon 66 phase and interface	Increase in the tensile modulus and strength and the flexural modulus and strength. Impact strength decreases with the addition of clay	Yang et al. 2010
PP/PP-g-MA/PS	70/30	Cloisite® 20A	PP/PP-g-MA phase and interface	Improvement in the phase stability, tensile modulus, and strength in the presence of clay	Tiwari and Paul 2011a
PP/PP-g-MA/EOR	70/30	Cloisite® 20A	PP/PP-g-MA phase	Improvement in the toughness, modulus, and yield strength in the presence of clay. CTE decreases in the presence of clay. CTE decreases in the FD and the TD in the presence of clay	Tiwari et al. 2012, 2013
Fig. 17.25 Effect of weight average elastomer particle sizes on the Izod impact strength of a-PA/ EOR (80/20) blends. The shadowed part refers to the "super-tough region" from Huang et al. (2006b) (Yoo et al. 2010b)

followed by mixing with organoclay have also resulted into high toughness and high ductility of nanocomposites (González et al. 2008). Wahit et al. (2006a) reported a three-step mixing for PA 6/PP/PP-g-MA/MMT/EOR nanocomposites where PP/PP-g-MA/EOR and PA 6/MMT were blended separately and then mixed together; this blend resulted in significant improvement in toughness compared to other mixing routes such as simultaneous mixing. Recently Yoo et al. (2010b) demonstrated that the mixing protocol where organoclay is first blended with a-PA followed by mixing a-PA nanocomposite with EOR results in much lower elasto- mer particle size and slightly better mechanical properties compared to an approach where a-PA/EOR/MMT masterbatch is further diluted with a-PA to give a ternary nanocomposite. Irrespective of the mixing sequence, the elastomer particle sizes were similar and in the range where "super-toughness" is expected for a-PA/EOR blends; however, all blends break in a brittle manner on impact test. Increased elastomer content does not lead to any improvement in the notched impact strength. Figure 17.25 shows a plot of impact strength as a function of weight average elastomer particle size. The shaded area shows the optimum elastomer particle size within the range of 0.15–0.8 μm that leads to super-toughness as observed for a-PA/EOR-g-MA (80/20) blends, whereas the a-PA/EOR/MMT blends with elas- tomer particle sizes in the shaded area ("super-tough" region) do not exhibit improved toughness. In fact, the toughness decreases as the elastomer particles become smaller in the presence of MMT. This is correlated to the increased stress

level of the nanocomposite as observed from the decrease in the extent of plastic deformation; however, the extent of plastic deformation as determined by elongation at break and area under the stress–strain or force–displacement curve does not always correlate well with the impact strength as has also been pointed out in various reports (Bucknall and Paul 2009; Yoo et al. 2010a; Tiwari and Paul 2011c). In fact, the toughening response is a complex process where yield strength, viscoelastic behavior, and other matrix effects in addition to blend morphology all play some role (Huang et al. 2006b; Yoo et al. 2010a).

17.3   Role of Other Nanofillers in Immiscible Polymer Blends

17.3.1   Polymer Blends Containing Nanometals (Metal and Metal Oxides)

The stabilization of immiscible polymer blends by nanoparticles at the blend interface can be considered similar to stabilization of low-viscosity emulsions by colloidal particles as in "Pickering emulsions" (Ramsden 1903; Pickering 1907). There have been several reports on the effect of the use of solid particles for stabilization of the morphology of immiscible polymer blends (Tambe and Sharma 1994; Yan and Masliyah 1995; Midmore 1998; Binks and Lumsdon 1999; Lagaly et al. 1999; Binks and Lumsdon 2000; Karim et al. 2000; Binks and Kirkland 2002; Aveyard et al. 2003; Vermant et al. 2004; Binks et al. 2005; Thareja and Velankar 2006; Elias et al. 2008b). The addition of fumed silica in a polydimethylsiloxane (PDMS)/polyisobutylene (PIB) (70/30) blend has resulted in decreased coalescence of PIB particles leading to a more stable blend morphology as reported by Vermant et al. (2004). Later a "particle bridging" mechanism was proposed for this blend based on the gel-like behavior observed at the low frequency (Thareja and Velankar 2006). In a separate study on the effect of hydrophilic and hydrophobic silica on the morphology of PP/PS (70/30) blend, both types of silica gave a similar decrease in the PS particle size from 3 μm in a blend without silica to 1 μm in a blend with silica (Elias et al. 2007). The hydrophilic silica is located exclusively in the PS phase, while hydrophobic silica is located in the PP phase and at the PP/PS interface. The effect of mixing protocols such as pre-blending silica with PP followed by mixing PP/silica with PS or simultaneously mixing PP, PS, and silica does not affect the final location of the silica particles based on the interfacial interactions although kinetic issues may preclude obtaining an equilibrium state for silica particles in the blend. The hydrophilic silica in the PS dispersed phase stabilizes morphology due to reduction in interfacial tension, whereas hydrophobic silica in PP matrix stabilizes the morphology by reducing coalescence of dispersed PS particles. The migration of nanoparticles from one phase to another is known to be affected by the interfacial interactions between the polymers and the filler along with kinetic effects (see Table 17.6) (Fowler et al. 1989; Cheng et al. 1992; Elias et al. 2007, 2008a). In the case of PP/EVA/silica nanocomposites, a significant drop in the dispersed EVA particle size is observed with the addition of 3 wt% silica in blend.

Table 17.6 Estimate of the equilibrium localization of fillers in polymer blends by calculation of a wetting coefficient, ω_a, from Young's equation. Here, 1 and 2 are two polymer components in blend and p represents solid filler

Young's equation	$\omega_a < -1$	$-1 < \omega_a < 1$	$\omega_a > 1$
$\omega_a = \frac{\gamma_{1p} - \gamma_{2p}}{\gamma_{12}}$	Filler p will reside in phase 1	Filler p will reside at interface	Filler p will reside in phase 2

When silica is pre-blended with PP, the hydrophilic silica particles migrate from the PP to the EVA phase on mixing. The effective interfacial tension determined using the Palierne model showed a decrease in the interfacial tension between PP and EVA in the presence of hydrophilic silica; however, a similar drop in the EVA particle size in the presence of hydrophobic silica indicated that decrease in interfacial tension alone is not responsible for the reduction in EVA size; other effects such as viscosity and structure of different phases should be considered to predict the final blend morphology of such systems (Elias et al. 2008b). In another study on PP/PS/silica nanocomposites, the addition of nanosilica particles showed a significant drop in the dispersed PS particle size when silica particles are located at the PP/PS interface; however, with the increase of mixing time, silica particles migrate back to the PP phase from the interface resulting in increased PS particle size. It was concluded that the compatibilization in PP/PS blends by nanosilica particles is controlled by kinetics rather than thermodynamics (Zhang et al. 2004). Observations on various blends containing nanoparticles are also reported in Table 17.7.

As discussed earlier in Sect. 17.2.3.2, blending sequence has a significant effect on the final dispersion of nanoparticles in the blend components, dispersed phase particle size, and impact behavior. A two-step processing method, wherein elastomer and filler is blended first and then mixed with PP or PP-g-MA, led to significant improvement in the toughness of PP (or PP-g-MA)/EPDM (80/20)/silica nanocomposites containing hydrophilic silica (Yang et al. 2006, 2007). The migration of hydrophilic silica from the elastomer phase to PP (or PP-g-MA) phase forms a filler-network-like structure wherein a large amount of silica particles agglomerate around EPDM particles and resides in the PP (or PP-g-MA) matrix as seen in SEM images of PP (or PP-g-MA)/EPDM/silica nanocomposites (see Fig. 17.26). The relative impact strength of PP/EPDM/silica or PP-g-MA/EPDM/silica nanocomposites prepared using nanosilica is increased by 1.6 and 2.7 times respectively in the presence of 5 wt% silica as seen in Fig. 17.27. The remarkable increase in the impact strength is attributed to the overlap of the stress volume between EPDM and silica particles due to the formation of the silica particles network around EPDM particles.

Kontopoulou and coworkers reported that addition of nanosilica to a PP/PP-g-MA/EOR (50/50) co-continuous blend resulted in refinement of the co-continuous structure followed by formation of dispersed elongated elastomer particles as the silica content is increased. This leads to improvement in the toughness with silica content as seen in Fig. 17.28 (Lee et al. 2010). Moreover, the dispersed elastomer

Table 17.7 Observations on immiscible polymer blends containing various nanoparticles

Blend	Composition/content	Filler	Filler location	Observations	Reference
LCP/PP	30/70	Hydrophobic nanosilica	PP phase	Morphology revealed deformation of LCP particles in the presence of nanosilica due to increase in the matrix viscosity and higher shear rates, resulting in a larger aspect ratio of the LCP particles	Lee et al. 2006b
PP/SBS	92/8	Nano-$CaCO_3$	PP phase	$CaCO_3$ particles located in the PP phase reduce SBS particle size resulting in a higher toughness, flexural modulus, and tensile strength of the nanocomposites. On contrary, the addition of micro-$CaCO_3$ particles into SBS/PP blends reduces toughness	Yu et al. 2007a
PP/PS	70/30	Aerosil® A200 (hydrophilic nanosilica)	PS phase	Decrease in the interfacial tension and dispersed PS particle size in the presence of nanosilica	Elias et al. 2007
PP/PS	70/30	Aerosil® R805 (hydrophobic nanosilica)	PP phase and interface	Hydrophilic silica resides in EPDM phase and forms aggregate, whereas hydrophobic silica is located in EPDM phase and at the interface	
PP/EPDM	EPDM: 10–50 wt%	nanosilica	Hydrophilic silica resides in EPDM phase and forms aggregate, whereas hydrophobic silica is located in EPDM phase and at the interface	The strain recovery profile for nanocomposites improved in the presence of nanosilica in blend; the addition of hydrophobic silica showed improvement in instantaneous and long-term strain recoveries compared to double-step recovery profile observed for	Martin et al. 2009

Table 17.7 (continued)

Blend	Composition/ content	Filler	Filler location	Observations	Reference
				hydrophilic silica resulting in poor elastic properties	
PLLA/PS	PS: 20–80 vol%	Hydrophilic nanosilica	PLLA phase	The coalescence rate is reduced and morphology stability of blend improved in the presence of silica. The incorporation of hydrophilic silica resulted in broad co-continuous PS/PLLA blends and refinement of morphology	Zhang et al. 2012
PP/PP-g-MA/ EOR	EOR: 30–50 wt%	Nanosilica	PP/PP-g-MA phase	The presence of nanosilica in PP/PP-g-MA phase significantly reduces dispersed phase EOR particle size and improved phase stability on annealing. The reinforcing effect of silica resulted in higher tensile and flexural strength and modulus, whereas impact strength did not change	Lee et al. 2012
PS/PA 6	PA 6: 20–40 wt%	Titanium dioxide (TiO$_2$)	PA 6 phase	TiO$_2$ particles are preferentially located in the PA 6 phase and reduce the coalescence of the dispersed phase; however, phase transformation was observed on annealing. At higher content, the nanoparticles agglomerate in the dispersed phase which reduces formation of co-continuous phase but slightly increases PA 6 domain size	Cai et al. 2012

PA 6/ABS	ABS: 0–100 wt%	Hydrophobic nanosilica	At interface when ABS forms the dispersed phase. In ABS phase when ABS is a continuous phase	The change in matrix and dispersed phase viscosity ratio shifts the phase inversion at higher ABS composition in the presence of nanosilica. The phase inversion composition was determined by various characterization techniques such as DSC, DMA, rheological behavior, and solvent extraction method	Liu et al. 2013
PA6/PP	80/20	Hydrophobic and hydrophilic nanosilica	Hydrophilic silica resides in PA 6 phase, whereas hydrophobic silica is located in PP phase and at the interface	Significant decrease in the PP particle size is observed when silica is located at the interface. Tensile modulus and yield strength increase in the presence of silica irrespective of the silica polarity; however, nanocomposites based on the hydrophobic silica showed higher elongation at break compared to pure blend	Laoutid et al. 2013
LLDPE/EVA	75/25	Hydrophobic nanosilica	LLDPE, EVA, and interface	The addition of nanosilica resulted in an increase in the tensile modulus, strength, and elongation at break; maximum improvement was observed at 10 wt% silica content. Interestingly, elongation at break did not decrease significantly in the presence of nanosilica	Heidary et al. 2013
Fig. 17.26 SEM images of PP/EPDM/SiO$_2$ ((80/20/3) (**a** and **b**) and PP-g-MA/EPDM/SiO$_2$ (80/20/3) (**c** and **d**) ternary composites prepared using hydrophilic silica: (**a** and **c**) one-step simultaneous mixing and (**b** and **d**) two-step mixing (elastomer and the filler were mixed by means of a two-roll mill at room temperature for 10 min to get masterbatch first, and then the masterbatch was melt blended with pure PP or PP-g-MA) (Yang et al. 2007)

phase is much more stable when silica is present in the continuous phase compared to the blend without silica. The silica particles localized in the PP matrix also provides a reinforcement effect leading to increased tensile and flexural modulus and yield strength. The addition of nanoparticles into a thermoplastic olefin is similar to what has been observed for clay-containing blends; however, the relative increase in the properties especially impact strength of PP/EOR blend is significantly higher for clay-containing nanocomposites. The efficiency of spherical particles as a barrier to coalescence is much smaller than organoclay due to their low aspect ratio and poor dispersion compared to MMT particles. In another approach where either PP-g-MA was added or the silica was functionalized to improve dispersion in the PP matrix of PP/EOR (70/30) blend, the impact strength did not change much with the addition of silica although mechanical properties were found to increase (Liu and Kontopoulou 2006; Bailly and Kontopoulou 2009). The effect of silica on toughness improvement is more effective at higher elastomer contents in PP/EOR blends.

The addition of nanoparticles to an immiscible blend greatly influences the viscosity ratio of the dispersed to continuous phase which in turn changes the phase inversion composition. When hydrophobic silica particles were added to
Fig. 17.27 Relative impact strength for PP/EPDM/SiO$_2$ and PP-g-MA/EPDM/SiO$_2$ nanocomposites as a function of SiO$_2$ content for composites prepared using hydrophilic silica and two-step processing method in which the elastomer and the filler were mixed by means of a two-roll mill at room temperature for 10 min to get masterbatch first and then the masterbatch was melt blended with pure PP. The weight ratio of PP/EPDM or PP-g-MA/EPDM was fixed at 80/20. Data taken from Yang et al. (2006, 2007)
Fig. 17.28 Notched Izod impact strength for (PP/PP-g-MA 90/10)/EOR (50/50) blend as a function of silica content. Error bars represent the standard deviation. TEM images in inset show change in blend morphology from co-continuous structure to elongated dispersed elastomer particles in the presence of silica. Dark domains represent the stained elastomer phase (Lee et al. 2010)

PA 6/ABS blends, the phase inversion was observed to shift towards higher ABS content due to increase in the viscosity ratio of ABS/PA 6 resulting from migration of silica particles from PA 6/ABS interface to ABS phase at higher ABS compositions in the blend (Liu et al. 2013).

Ou and Li (2009) showed that the dispersed PA 6 particle size was reduced from 4 to 1 μm in PP/PP-g-MA/PA 6 (70/30) blends with addition of 2 wt% functionalized TiO_2 nanoparticles. The addition of PP-g-MA did not influence blend morphology but significantly improved dispersion of TiO_2 nanoparticles in the PA 6 matrix as observed from much finer and uniform distribution of PA 6 particle size. In the case of HDPE/EVA/$CaCO_3$ blend obtained from HDPE/$CaCO_3$ masterbatch, the EVA particles encapsulate the $CaCO_3$ nanoparticles along with separate dispersion of $CaCO_3$ nanoparticles observed in an HDPE matrix. A surface energy analysis predicts the complete encapsulation of $CaCO_3$ by EVA due to lower interfacial tension (γ) of EVA/$CaCO_3$ than HDPE/$CaCO_3$; however, kinetic effects preclude the complete encapsulation of $CaCO_3$ by EVA as also observed in several other blends (see Table 17.6) (Fowler et al. 1989; Cheng et al. 1992; Yoo et al. 2010a; Ali et al. 2011; Tiwari and Paul 2011a). In addition to thermodynamic factors, kinetic factors almost always have some effect on the final blend morphology, location, and distribution of filler in blend nanocomposites.

17.3.2 Polymer Blends Containing Carbon Nanotubes (CNTs)

Addition of CNTs to polymers has been shown to improve electrical conductivity and mechanical properties of the polymer matrix (Pötschke et al. 2003; Ruan et al. 2003; Gorga and Cohen 2004; Meincke et al. 2004; Pötschke et al. 2004; Coleman et al. 2006; Dondero and Gorga 2006; Moniruzzaman and Winey 2006; Zou et al. 2006; Pötschke et al. 2007; Zhang and Zhang 2007; Zhao et al. 2007; Li and Shimizu 2008; Pötschke et al. 2008; Bose et al. 2009; Dasari et al. 2009; Liu et al. 2009; Wu et al. 2009; Grady 2010; Liu et al. 2010; Spitalsky et al. 2010; Baudouin et al. 2011; Li et al. 2011; Tao et al. 2011; Zonder et al. 2011; Göldel et al. 2012; Shi et al. 2012; Wode et al. 2012; Xiang et al. 2012; Chen et al. 2013); however, strong van der Waals interaction between nanotubes inhibits their dispersion in the polymer leading to a weak percolation network and low mechanical properties (Breuer and Sundararaj 2004; Zhao et al. 2007; Pötschke et al. 2008; Grady 2010; Spitalsky et al. 2010; Li et al. 2011; Tao et al. 2011). The covalent and non-covalent modifications of nanotube surfaces have been utilized to improve CNT dispersion in the polymer matrix (Breuer and Sundararaj 2004; Moniruzzaman and Winey 2006). Apart from improvement in the chemical affinity of CNTs for the polymer, the various modification strategies also assist in effective processing to form polymer–CNT nanocomposites with enhanced mechanical and electrical properties (see Table 17.8). The addition of CNTs into immiscible polymer blends results in higher electrical conductivity compared to single polymer filled with nanotubes at the same loading (Gorga and Cohen 2004; Meincke et al. 2004; Pötschke et al. 2004; Moniruzzaman and Winey 2006;

Table 17.8 Observations on immiscible polymer blends containing carbon nanotubes

Blend	Composition/ content	Filler	Filler location	Observations	Reference
PA 6/ABS	45/55	MWCNT masterbatch	PA 6 phase	Co-continuous structure. Tensile modulus increases, while elongation at break and impact strength decrease with the addition of CNT. The onset of electrical conductivity was observed at 2–3 wt% CNT	Meincke et al. 2004
PPS/PA66	60/40	Acid-treated MWCNT	PA 66 phase	At low content, CNTs are dispersed evenly in PA 66 phase and blend exhibits co-continuous structure. At high loading, the CNTs aggregate to give dispersed PA 66 phase	Zou et al. 2006
PVDF/PA6	50/50	MWCNT	PA 6 phase	Improvement in electrical conductivity, modulus, and ductility	Li and Shimizu 2008
PCL/PLA	70/30	MWCNT and carboxylic MWCNT	PCL phase and interface	Unfunctionalized MWCNT is located exclusively in the PCL phase, while carboxylic MWCNT is located in the PCL phase and at the interface. The reinforcing and compatibilization effect of nanotubes results in a higher improvement in electrical conductivity and mechanical properties compared to pure blend. Improved phase stability and lower rheological and electrical conductivity percolation threshold were observed	Wu et al. 2009
PA 6/PP	20/80 and 50/50	MWCNT	PA 6 phase	In PA6/PP (20/80) blend nanocomposites, nanotubes are dispersed in the PA6 phase and form the conductive network resulting in a higher electrical conductivity than the PA6/PP (50/50) nanocomposites	Zhang et al. 2009

(continued)

Table 17.8 (continued)

Blend	Composition/content	Filler	Filler location	Observations	Reference
PP/EVA	80/20 and 64/40	Acid-treated MWCNT	Mostly in EVA phase and tend to migrate in PP phase at higher CNT loading leading to bridge effect	The formation of co-continuous morphology results in significant improvement in the electrical conductivity and fracture toughness compared to disperse phase structure in the presence of nanotubes. A "dual-network structure" of MWCNTs and EVA phase exists in PP/EVA (60/40) system which accounts for the largely improved fracture toughness of the composites as opposed to "single-network" structure observed in PP/EVA (80/20) blend	Liu et al. 2009
PC/SAN	60/40	C150HP MWCNT	PC phase	Irrespective of mixing protocols, even for pre-dispersing the nanotubes in SAN, all CNTs are located in the PC phase. The formation of double percolation network resulted in lower electrical resistivity	Göldel et al. 2009
EA/PA 6/12	90/10	Nanocyl®-7000	Interface	Increase in the phase stability	Baudouin et al. 2011
PE/PA6	PA 6: 20–37 wt%	MWCNT	PA 6 phase	Co-continuous structures were obtained by blending PE with PA6-CNT masterbatch. Nanocomposites showed solvent resistance, improvement in tensile modulus, and increase in the tensile strength as the PA 6 and CNT content increase	Périé et al. 2012
PA 6/ABS	70/30 and 50/50	MWCNT	PA 6 phase	ABS particle size decreased from 22 μm to ~2–4 μm in the presence of MWCNT in PA6/ABS (70/30 wt) blends. PA6/ABS (50/50 wt) blends show refinement of	Liu et al. 2012

				co-continuous morphology in the presence of MWCNT. Significant improvement in the yield strength and flexural modulus was obtained for both blends in the presence of MWCNTs, irrespective of the blend morphology	
PP/PS	70/30 and 50/50	Nanocyl NC 7000	PS phase and interface	Improvement in electrical conductivity and onset of thermal degradation in the presence of nanotubes. In all cases, nanocomposites prepared from PP masterbatch and having co-continuous structure have shown higher improvement in properties	Hwang et al. 2012
PPC/PLA	70/30	MWCNT	PPC	MWCNT is located in the PPC phase due to the lower interfacial tension between PPC and nanotubes. Blend nanocomposites exhibit higher electrical conductivity than homopolymer nanocomposites, whereas blend properties are in between those of PPC and PLA nanocomposites	Park et al. 2012
PET/LDPE	LDPE 0–100 wt %	Nanocyl NC7000	PET phase and interface at higher CNT loadings	Increase in the electrical conductivity observed for co-continuous structure and when PET forms the continuous phase	Cardinaud and McNally 2013
PC/SAN	90/10	Nanocyl NC7000	SAN phase	Significant increase in the electrical conductivity with lower percolation threshold observed at 0.18 wt% MWCNT. Thermal and dynamic properties of nanocomposites are higher in the presence of CNT	Maiti et al. 2013

Zou et al. 2006; Bose et al. 2007; Pötschke et al. 2007; Li and Shimizu 2008; Pötschke et al. 2008; Liu et al. 2009; Wu et al. 2009; Baudouin et al. 2010b; Liu et al. 2010; Li et al. 2011; Xiang et al. 2011; Zonder et al. 2011; Shi et al. 2012; Xiang et al. 2012; Chen et al. 2013). The concept of a double percolation network, observed for carbon black-filled polymer blends, where conducting carbon black filler is located in one of the polymer phases or at the interface, reduces the percolation threshold composition and provides higher electrical conductivity; this has also been observed in blends containing CNTs depending on the location of the nanotubes in the blend and its morphology (Sumita et al. 1991; Gubbels et al. 1995; Zhang et al. 1998).

Pötschke and coworkers have shown that electrical conductivity in co-continuous blends of polycarbonate (PC) and high-density polyethylene (HDPE) is significantly higher in the presence of multiwalled carbon nanotubes (MWCNTs). The MWCNTs are located in the PC phase and at the PC/HDPE interface; this results in a stable blend morphology and broad co-continuous region. Increased mixing time leads to attrition of the nanotubes and a decrease in conductivity (Pötschke et al. 2003, 2004). In another blend of PC-2 wt% MWCNT and PP-3 wt% MMT, the nanotubes are located in the PC phase while MMT particles migrate from the PP phase to the PP/PC interface and encapsulate the PC-2 wt% MWCNT. This hinders the migration of MWCNTs into the nonconductive PE phase and results in higher conductivity values for this blend compared to a PC-2 wt% MWCNT/HDPE blend without MMT (Pötschke et al. 2007). In the case of polyamide 12 (PA12)/HDPE/MWCNT blend nanocomposites prepared from three different mixing procedures, it was reported that when nanotubes are located at the interface surrounding the dispersed HDPE particles, the electrical resistivity decreases by at least four orders of magnitude. The formation of surface and volume percolating networks, where the CNTs envelope HDPE particles and interconnect through the interphase to the few CNTs dispersed throughout the volume of the PA phase, leads to a significant decrease in the electrical resistivity (Zonder et al. 2011).

The presence of CNTs at the interface alters the region of co-continuous morphology and can lead to improvement in electrical conductivity at much lower CNT content (Meincke et al. 2004; Bose et al. 2007, 2009). The CNTs have a tendency to preferentially locate in the more polar component of immiscible blends as seen from the location of the nanotubes in the polyamide phase of PVDF/ PA 66, PA 6/ABS, and PPS/PA 66 blends when nanotubes are pre-blended with the polyamide matrix (Meincke et al. 2004; Zou et al. 2006; Li and Shimizu 2008; Zonder et al. 2011). It is reported that nanotubes are likely to migrate from the less polar to the more polar polymer phase even when the differences between the surface energies of the two are small. Bailly and coworkers reported that nanotubes are located at the interface and envelope the minor polyamide phase in blends with ethylene–acrylate (EA) copolymers resulting in a more stable blend morphology and narrow particle size distribution (Baudouin et al. 2010a, b, 2011; Tao et al. 2011). The presence of nanotubes at the interface significantly reduces the coalescence of dispersed phase droplets as seen in other nanoparticles containing
Fig. 17.29 Schematic representation of the PPS/PA66 (60/40 w/w)/MWCNT nanocomposites morphology changing: (**a**) low load MWCNTs (<0.5 phr) disperse evenly and form a percolating network, and (**b**) high load MWCNTs (>0.5 phr) aggregate like clews (Zou et al. 2006)

blends (Elias et al. 2007; Tiwari and Paul 2011a). Carbon nanotubes behave similar to other nanoparticles in immiscible blends, i.e., they promote co-continuity when completely located in the dispersed phase; however, at higher concentrations they tend to aggregate and can transform a co-continuous structure into a dispersed phase morphology (Zou et al. 2006). Figure 17.29 schematically shows the change from co-continuous to dispersed morphology as a function of nanotube content in poly (*p*-phenylene sulfide) (PPS)/polyamide 66 blends.

The addition of nanoparticles in immiscible blends leads to stabilization of blend morphology and a decrease in the dispersed phase particle size; the smaller dispersed phase particle size, particularly for elastomers, can lead to improvement in toughness of the blend. The decrease in the dispersed phase particle size is influenced by the filler dimension, their dispersion, and interfacial interactions with different polymer phases in blend. In a few studies on polymer–CNT nanocomposites, it is reported that good orientation and dispersion of nanotubes are required for improvement in tensile toughness. The nanotubes oriented in the flow direction can act as a bridge to crazes and cracks in tensile specimens resulting in a higher strain at break; moreover, the higher load-carrying capacity of nanotubes and ability to undergo deformation may also contribute to the improvement in ductility (Qian et al. 2000; Zhao et al. 2007; Liu et al. 2009; Li et al. 2011). Liu et al. (2009) reported a significant increase in the toughness of PP/EVA (60/40) blend nanocomposites from 102 to 632 J/m in the presence of 2 wt% MWCNT in the blend. The toughness is observed for co-continuous morphology where nanotubes are located at the interface and form a bridge between the two phases resulting in "super-tough" blends. The functionalization of CNT is important for

(Chen et al. 2013)
improving dispersion; however, some functionalization processes such as acid
treatment reduce the length of CNT with some loss of bridging effect (Liu
et al. 2009, 2010). Figure 17.30 shows the schematic of the possible fracture
mechanism of immiscible polymer blends containing functionalized MWCNTs at
the interface. Under the load, the initiation of a crack first occurs at the interface
because of the smaller entanglement density compared with the bulk polymer
which is followed by crazing of the polymer usually observed at the crack tip due
to high stress concentration. Crazing is also known to cause brittle fracture; it is
usually related to the fibrillation and the volume expansion of polymer, contributing
to the major part of energy dissipation (Bucknall 1977). When MWCNTs are
selectively distributed at the interface, the fibrillation of polymer chain segments
promotes the orientation of nanotubes perpendicularly to the interface plane and
facilitates further energy absorption. During initiation and propagation of cracks
along the interface, some nanotubes are oriented and few are pulled out of the
matrix. The oriented nanotubes that bridge the crack face prevent further propaga-
tion. Specifically when the interfacial adhesion between the CNT and polymer
matrix is strong enough, one can also see the breakage of MWCNTs; however, this
favors the energy absorption during the fracture process (Qian et al. 2000; Gorga
and Cohen 2004; Zhang and Zhang 2007; Zhao et al. 2007; Chen et al. 2013). The
co-continuous morphology has been extensively studied for CNT-containing blends
and has shown significant improvement in electrical conductivity and toughness
with double percolation effects (Bose et al. 2009; Liu et al. 2009, 2010; Xiang
et al. 2011). The various mixing sequences such as pre-blending versus simulta-
neous mixing, functionalization of carbon nanotubes, mixing time, and blend
composition all have a significant effect on the overall improvement of properties.
Although, CNTs are not as efficient for size reduction as MMT, CNTs are stiffer
and stronger plus their high aspect ratio and tubular structure provide a better load-
bearing capacity compared to other fillers provided there is an adequate interfacial
interaction.

17.4   Rheology of Blend Nanocomposites

The melt rheological behavior provides fundamental insights about the flow properties of materials and is important to optimize processing conditions for polymers, their blends, and composites. In the case of polymer blends, the flow behavior is much more complex and influenced by several factors such as composition, the viscoelastic properties of the blend components, and their interfacial interactions. The presence of solid filler particles in the blend further complicates the interpretation of the rheological behavior. The melt rheology of blends in the presence of nanoparticles such as organoclays, silica, and carbon nanotubes has been extensively studied to understand their effect on the interfacial interactions between the blend components, blend morphology, and phase inversion composition (Kontopoulou et al. 2003; Vermant et al. 2004; Austin and Kontopoulou 2006; Thareja and Velankar 2006; Elias et al. 2007; Vermant et al. 2007; Elias et al. 2008b; Pötschke et al. 2008; Vermant et al. 2008; Bailly and Kontopoulou 2009; Madivala et al. 2009a, b; Lee et al. 2010; Tiwari and Paul 2011a; Zonder et al. 2011; Liu et al. 2013).

17.4.1 Blends Containing Silica

Vermant et al. (2004) reported the rheological behavior of PDMS/PIB (70/30) blends in the presence of silica and observed no change in the G' behavior for the blend nanocomposite samples pre-sheared at various shear rates before rheological measurements. This confirmed the stable morphology of the blend in the presence of silica; moreover, the change in the interfacial properties obtained by fitting experimental data to the Palierne model also confirmed the compatibilizing effect of silica resulting in decreased coalescence of PIB particles. The general use of the Palierne model in immiscible blends is to determine the volume average dispersed particle radius, R, from the dynamic modulus provided the interfacial tension values are readily available from an independent measurement. However, for filled polymer blends, the interfacial tension is not usually known and cannot be determined by any direct method. Vermant et al. (2004) found that fitting the Palierne model to the experimental data for filled polymer blends is difficult even after introducing additional fitting parameters; therefore, they used the ratio R/γ_{12} (volume average dispersed particle radius over interfacial tension) in the Palierne model to avoid any ambiguity concerning the interfacial tension. The ratio R/γ_{12} was calculated from the following relation (Palierne 1990; Vermant et al. 2004):

$$\tau = \frac{R\eta}{4\gamma_{12}} \frac{(19p+16)(2p+3-2\phi(p-1))}{10(p+1)-2\phi(5p+2)} \tag{17.1}$$

where η is the viscosity of the matrix phase, p is the viscosity ratio, ϕ is the volume fraction of the dispersed phase, and τ is the dispersed phase relaxation time obtained from the crossover frequency between $G'(\omega)$ and $G''(\omega)$. Cassagnau and coworkers

have observed that the peaks corresponding to relaxation processes are complicated and difficult to follow; in some cases the dispersed phase relaxation time may be similar to one of the matrices which can lead to inaccurate determination of relaxation time (Elias et al. 2008b; Fenouillot et al. 2009). It was suggested that the ratio R/γ_{12} can be easily determined by isolating the dispersed phase contribution from the complex relaxation modulus using a modified Palierne model equation:

$$G'_{\text{Palierne}} = G^*_{\text{Composition}} + G^*_{\text{Dispersed}} \tag{17.2}$$

where $G^*_{\text{Composition}}$ is the complex shear modulus of the blend without any interfacial effects and $G^*_{\text{Dispersed}}$ captures the interfacial effects. The storage part of complex shear modulus, G', for a blend of two viscoelastic fluids can be expressed as follows:

$$G'_{\text{Palierne}}\left(\gamma_{12}, G^*_m, G^*_d\right) = G'_{\text{Palierne}}\left(0, G^*_m, G^*_d\right) + G'_{\text{Palierne}}\left(\gamma_{12}, \eta^*_m, \eta^*_d\right) \tag{17.3}$$

where G^* and η are the complex modulus and Newtonian viscosity, respectively, and subscripts m and d represent the matrix and dispersed phase, respectively. From the above equations, Eqs. 17.2 and 17.3, the contribution of the dispersed phase relaxation, which only depends on the interfacial tension, γ, can be easily determined by subtracting the composition effects to the experimental data of G^*. The modified approach was used to determine the effective interfacial tension between PP/EVA (80/20) blends in the presence of silica, and it was observed that the effective interfacial tension decreased from 0.75 to 0.25 mN/m when the silica particles are located in the dispersed phase. (Elias et al. 2008b).

17.4.2 Blends Containing MMT

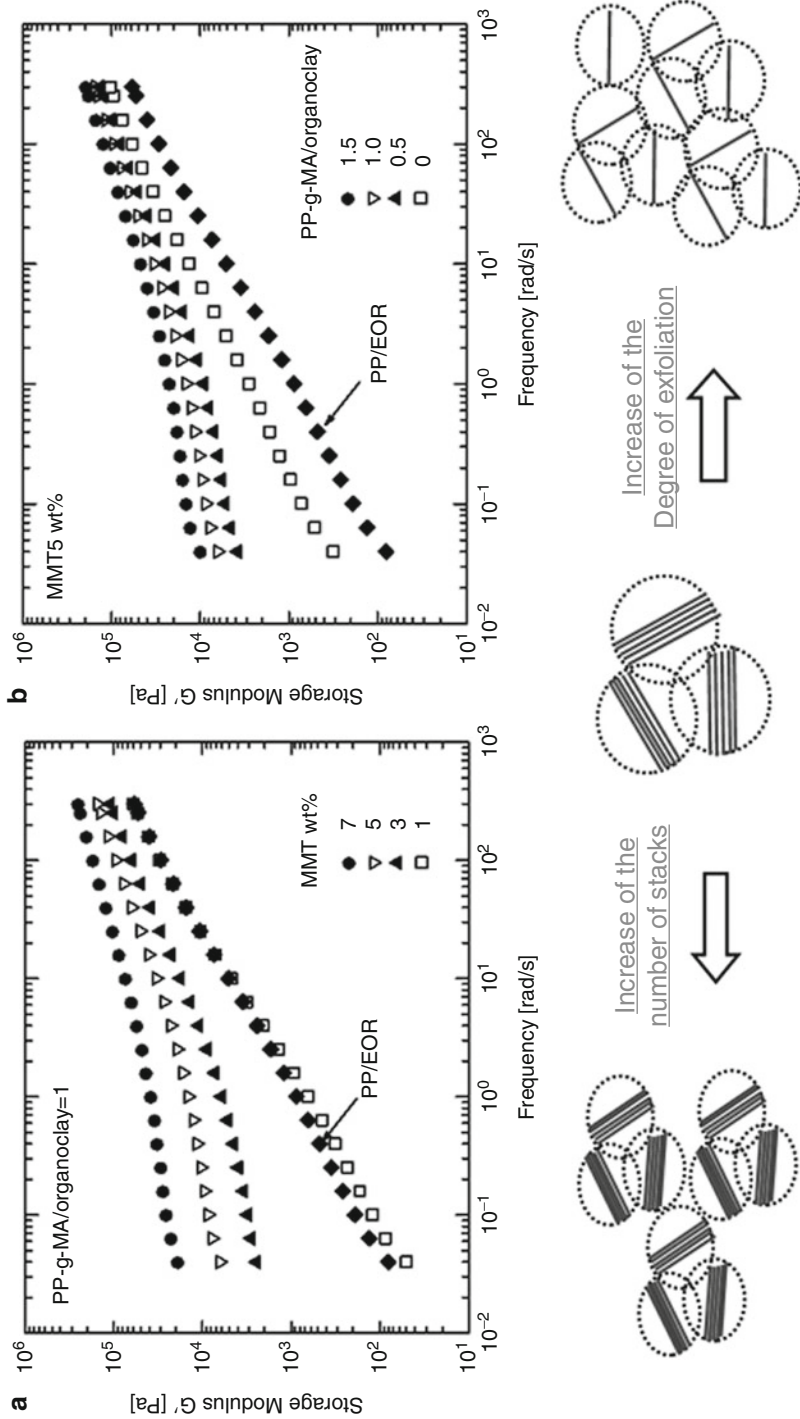
In clay-based polymer nanocomposites, a part of the enhancement of rheological properties is due to the formation of percolated networks of clay platelets. Figure 17.31 shows the storage modulus, G', plots as a function of frequency, ω, for PP/PP-g-MA/MMT/EOR nanocomposites containing different amount of MMT and various PP-g-MA/organoclay ratios. As seen in Fig. 17.31, a significant increase in the storage modulus is observed with the addition of MMT ≥ 3 wt% at fixed PP-g-MA/organoclay ratio of 1.0. Similar effects are seen with increasing PP-g-MA/organoclay ratio ≥ 0.5 at a fixed MMT content of 5 wt%. The decrease in the G' slope in the terminal zone ($\omega < 1$ rad/s) with increasing MMT and PP-g-MA/ organoclay ratios is due to the formation of a percolated network of clay particles resulting in solid-like behavior of nanocomposites at low frequency. The formation of a percolation network is facilitated either by increasing the number of clay stacks with increase in the amount of clay at fixed PP-g-MA content or by increasing the degree of exfoliation of clay platelets with increase of PP-g-MA content at fixed


Fig. 17.31 Storage modulus of PP/PP-g-MA/MMT/EOR nanocomposites (**a**) as a function of MMT content at fixed PP-g-MA/organoclay ratio of 1.0 and (**b**) as a function of PP-g-MA content at fixed MMT content of 5 wt%. All measurements were done at 190 °C (Tiwari et al. 2012)

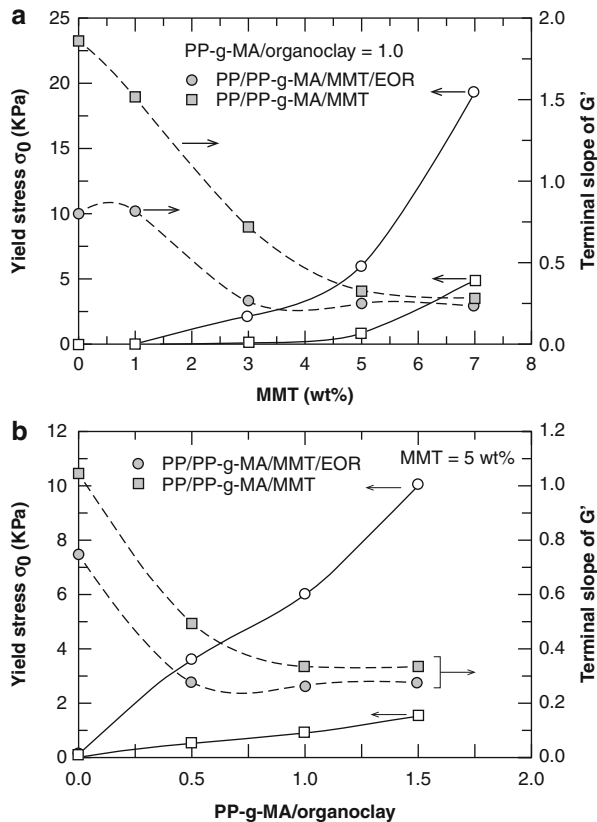
clay content as seen in schematic in Fig. 17.31. However, it is difficult to distinguish the effect of the minor phase on the rheological behavior from that of clay platelets in blend nanocomposites. To address this issue quantitatively, Paul and coworkers used a modified Carreau-Yasuda model to separate out effects of addition of elastomer in PP/PP-g-MA/MMT nanocomposites using the following relation:

$$\eta(\omega) = \frac{\sigma_0}{\omega} + \eta_0 [1 + (\lambda\omega)^a]^{\frac{(n-1)}{a}} \qquad (17.4)$$

where σ_0 is the melt yield stress, η_0 is the zero shear viscosity, λ is the time constant, a is the Yasuda parameter, and n is the power law index (Lertwimolnun and Vergnes 2005; Kim et al. 2007a). This approach is more appropriate for the systems where clay particles are exclusively located in the matrix phase such as in the case of PP/PP-g-MA/MMT/EOR nanocomposites (Tiwari and Paul 2011b). The melt yield stresses and terminal zone slope for PP/PP-g-MA/MMT and PP/PP-g-MA/MMT/EOR nanocomposites obtained from the best fit of the experimental data are compared in Fig. 17.32a, b. The melt yield stress increases with increase in the MMT content and with PP-g-MA/organoclay ratio; however, the PP/PP-g-MA/MMT/EOR nanocomposites have a higher value than for the PP/PP-g-MA/MMT nanocomposites and show a sharp increase beyond 3 wt% MMT and with increased PP-g-MA/organoclay ratio. The terminal slope of G' versus ω or $(d \ln G'/d \ln \omega)_{\omega \to 0}$ decreases with increasing MMT content and PP-g-MA/organoclay ratios due to the presence of MMT particles forming a percolated network leading to a solid-like behavior. This is because the elastomer phase in PP/PP-g-MA/MMT nanocomposite suppresses the dispersion of MMT particles and forms a percolated network at lower MMT content.

17.4.3 Blends Containing CNTs

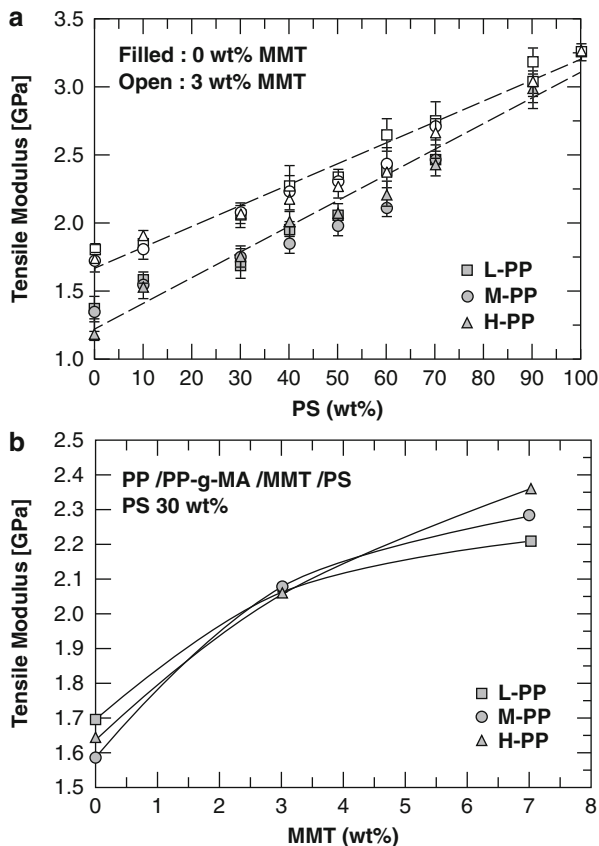
Pötschke et al. (2002) first reported rheological behavior of polycarbonate (PC)/CNT nanocomposites prepared by diluting a masterbatch containing 15 wt% MWCNT using a twin-screw extruder. They observed significant increase in the low-frequency melt viscosity for nanocomposites having greater than 2 wt% MWCNT. The non-Newtonian behavior was ascribed to the rheological threshold obtained at lower CNT loading due to its high aspect ratio which also correlates well with the electrical conductivity percolation threshold observed between 1 and 2 wt% nanotubes in blend. Several later papers have described correlation between the percolation threshold obtained from the rheological behavior and the electrical properties for immiscible blend containing carbon nanotubes (Gubbels et al. 1995; Li and Shimizu 2008; Bose et al. 2009; Tao et al. 2011; Wode et al. 2012). Zonder et al. (2011) studied the effect of three different mixing procedures on the rheological behavior of polyamide 12 (PA12)/HDPE blends containing 0.75 wt% MWCNT. The addition of carbon nanotubes resulted in higher dynamic storage modulus, G', values for all blend nanocomposites, irrespective of the blend

Fig. 17.32 Comparison of melt yield stress and terminal slope of G′ for PP/PP-g-MA/MMT/EOR and PP/PP-g-MA/MMT nanocomposites as a function of (**a**) MMT content and (**b**) PP-g-MA/organoclay ratio. Data for PP/PP-g-MA/MMT taken from Kim et al. (2007a) (Tiwari et al. 2012)


compositions; however, the effect of blending sequence was evident in PA12/HDPE (75/25) and PA12/HDPE (25/75) blend nanocomposites. In the case where PA 12 forms the continuous phase, the G' is significantly higher than the pure blend and shows a solid-like behavior at low frequency; this is attributed to the well-dispersed CNTs in the PA 12 matrix and formation of network structure. Among various blending sequences, the PA 12/HDPE (75/25) nanocomposite prepared from HDPE masterbatch has a slightly higher G' value in the low-frequency region as well as decreased frequency dependence compared to nanocomposites obtained from simultaneous mixing and PA 12 masterbatch. Based on SEM images, it was suggested that the kinetic parameters such as higher HDPE viscosity than PA 12 trap some nanotubes at the interface during migration from HDPE to PA 12 phase which delays relaxation of the dispersed HDPE particles. As carbon nanotubes do not have a significant effect on the rheology of HDPE, it is assumed that the nanotubes at the interface promote blend elasticity by either increasing the compatibility between HDPE and PA 12 or affecting the interfacial relaxation processes. The location of CNTs in blend is influenced by the mixing protocol and has a significant effect on the blend morphology, rheology, percolation threshold, and electrical conductivity.

17.5 Mechanical Properties of Blend Nanocomposites

The mechanical properties of blends are important factors for performance in most applications. The addition of high modulus fillers into polymers always increases the tensile modulus; however, tensile strength is very dependent on the interfacial adhesion between blend components (Bigg 1987; Ward and Sweeney 2013). Nonetheless, the addition of solid fillers reduces the elongation at break in nanocomposites. Figure 17.33 shows the effect of PP molecular weight and PS composition on the tensile modulus for PP/PP-g-MA/MMT/PS blend with and without MMT. The addition of PS to PP/PP-g-MA or PP/PP-g-MA/MMT substantially increases the modulus although the PP molecular weight has little effect on blend modulus. The addition of MMT increases blend modulus with the greatest increase observed at low PS contents <30 wt%. The contribution of MMT on blend modulus decreases as the PS content increases due to the increasing PS contribution to the blend modulus. The tensile modulus also increases with the increase in the MMT content at fixed PS composition in blend; however, no significant difference observed among PP with different molecular weight grades (Tiwari and Paul 2011a). The tensile strength at yield was usually found to increase for elastomer-toughened blends such as thermoplastic olefin nanocomposites (Tiwari et al. 2012). Kontopoulou and coworkers also observed increases in blend modulus and decreases in the elongation at break with the addition of nanosilica in PP/EOR blend nanocomposites containing 10–30 wt% of elastomer and 0–5 wt% silica content (Liu and Kontopoulou 2006). Meincke et al. (2004) reported significant increases in the modulus of PA 6/ABS blends in the presence of carbon nanotubes; however, the elongation at break and notched impact strength for the nanocomposites were lower than for the pure blend. The improvement in modulus was higher for blends containing carbon nanotubes than those containing carbon black. In another study on HDPE/PA 6/MWCNT (80/20/2) blend prepared from functionalized MWCNT, the blend nanocomposites prepared from a HDPE/MWCNT masterbatch showed excellent tensile strength and toughness simultaneously. The nanotubes migrate from the HDPE phase to the HDPE/PA 6 interface and provide a nano-bridge effect that prevents crack initiation and propagation along the interfaces and results in higher ductility of blend. Other blending sequences, where nanocomposites were obtained from a PA 6 masterbatch with the nanotubes located in the PA 6 phase, resulted in lower improvement in properties (Xiang et al. 2011). Though nanoparticles seem to provide reinforcement effects in blends, tensile strength or elongation at break may or may not be similarly improved. There is interest in modeling tensile modulus of blends and nanocomposites and to correlate the experimental data with composite models (Brune and Bicerano 2002; Fornes and Paul 2003; Chavarria and Paul 2004; Sheng et al. 2004; Stretz et al. 2005; Kim et al. 2007a; Shah et al. 2007; Clifford and Wan 2010; Wang et al. 2010). Paul and coworkers successfully used the Halpin–Tsai and Mori–Tanaka composite theories to predict the modulus trends for polymer nanocomposites (Hill 1965; Wu 1966; Halpin 1969; Mori and Tanaka 1973; Halpin and Kardos 1976; Fornes and Paul 2003; Chavarria and Paul 2004;

Fig. 17.33 (**a**) Tensile modulus for blends with and without MMT at various PS compositions and (**b**) effect of MMT content on tensile modulus of blends prepared with different molecular weight grades of PP having 30 wt% PS. The MMT wt% is based on the PP/PP-g-MA/MMT phase in blend (Tiwari and Paul 2011a)


Shah et al. 2007; Spencer et al. 2010). They have also modified the Mori–Tanaka model using a two-population approach to predict modulus of ternary systems such as polymer blend nanocomposites and polymer composites containing two different fillers. More details can be found in papers describing the extensive modeling work by Paul and coworkers (Spencer and Paul 2011; Yoo et al. 2011; Tiwari et al. 2012). Other composite models such as the Christensen model has been also used to predict modulus of PS/PP/PP-g-MA/MMT nanocomposites where PP particles form the dispersed phase (Istrate et al. 2012).

17.6   Future Trends

Polymer blends containing nanoparticles provide a route to balance the properties when prepared using an appropriate mixing protocol. Nonetheless, the improvement in the blend properties is very specific to the blend components and type of nanoparticle. For example, organoclays and silica reduce elongation at break, while functionalized carbon nanotubes have been shown to increase the tensile ductility

of blends in tensile tests (Liu and Kontopoulou 2006; Tiwari and Paul 2011a; Xiang et al. 2011). On the other hand, organoclay is much more beneficial in reducing dispersed phase particle size compared to other nanoparticles (Liu and Kontopoulou 2006; Elias et al. 2007; Kelnar et al. 2007; Vo and Giannelis 2007; Elias et al. 2008b; Fenouillot et al. 2009; Wu et al. 2009; Baudouin et al. 2011; Tiwari and Paul 2011a). The combination of two nanofillers such as MMT and CNTs in (PC/CNT)/(HDPE/MMT) blend has shown significant improvement in electrical conductivity than nanotube alone (Pötschke et al. 2007). Although there have been very few reports on utilization of multiple nanofillers in polymer blends, this concept is more frequently used in polymer nanocomposites (Liu and Grunlan 2007; Rattanasom et al. 2007; Yu et al. 2007b; Sumfleth et al. 2008; Tang et al. 2008; Wang et al. 2009). Polymer blend nanocomposites can offer a balance of properties such as combination of toughness and stiffness, increase in electrical conductivity, lightweight, and increased weatherability. The combination of high-aspect-ratio clay particles and conductive carbon nanotubes can provide improvement in toughness and electrical conductivity of elastomer-toughened thermoplastics. Recently, graphene has gained significant interest as a next-generation nanofiller for polymer nanocomposites due to the advantages of lower mass density compared to clay and, low cost and comparable mechanical properties, electrical and thermally conductivity than carbon nanotubes. However, there are challenges and difficulties associated with the production of high quality exfoliated monolayer graphene, poor dispersion of graphene in the polymer matrix, impurities and damaged edges after reduction of graphene oxide. The addition of graphene into a polymer matrix results in higher improvement in mechanical properties such as tensile modulus and strength and higher electrical conductivity depending on surface modification of graphene and processing method (Jang and Zhamu 2008; Kim et al. 2010; Li and Zhong 2011; Potts et al. 2011). The combination of graphene with carbon fibers has also been utilized to improve network formation; this resulted in higher electrical conductivity at low concentration of fillers (King et al. 2008). The application of graphene as a compatibilizer in PA 6/PPO blend showed a decrease in dispersed PPO particle size by an order of magnitude (Cao et al. 2011). Based on the exceptional properties of graphene it is expected to be the next-generation high performance material; however, many challenges exist in fundamental understanding and applicability to produce nanocomposites with excellent properties. More efforts to understand the effect of graphene on the dispersed particle size, blend morphology and stability, and mechanical properties are required to enhance knowledge and find new avenues for application of graphene in immiscible polymer blends.

17.7 Conclusions

This chapter discusses the role of nanofillers as a compatibilizer for immiscible blends when located at the blend interface or as an aid to reduce coalescence of dispersed particles when located in the continuous phase of blends. The presence of

a nanofiller in a blend can lead to significant decreases in the dispersed phase particle size; however, the extent of the decrease in size depends on the dimension of the filler, the state of dispersion, and location in blend. The nanofiller located in the minor component of blend results in an increase of dispersed phase particle size. The reinforcement effect of nanofiller provides higher mechanical properties in comparison to a pure blend; moreover, the dispersed particle size distribution is narrow, and a stable blend morphology can be observed during thermal annealing. In many blend nanocomposites, it was reported that kinetic effects contribute to the location of the filler in the blend in addition to that predicted from a surface energy analysis. In general, addition of a nanofiller increases tensile modulus and strength while elongation at break is usually mostly reduced; however, functionalized nanotubes have shown improvement in tensile ductility in some cases.

In the majority of papers, only a few compositions are studied, and details on the phase inversion behavior in the presence of nanofiller and its content, morphology stability, and possible application of those materials are not provided. The most promising advantage of using nanofillers is improvement in toughness and stiffness as observed for several elastomer-containing blends; however, this depends largely on the polymer blend system, interfacial interactions between polymer and filler, type of filler, and its location in the blend components. The presence of nanofiller in a soft elastomer particle can also act as stress concentrator reducing toughness; however, in elastomer-containing polyamide nanocomposites, the presence of organoclay in the elastomer and polyamide phase has shown improvement in toughness and other mechanical properties. The commercial viability of such approaches remains to be determined.

The extent of nanofiller dispersion and matrix properties have a significant effect on the overall blend properties, for example, highly exfoliated MMT particles in the polyamide matrix can make it brittle, whereas partially exfoliated clay particles in extruder-made thermoplastic olefin nanocomposites can lead to significant improvements in impact strength depending on the PP molecular weight and elastomer MFI.

The nanofillers discussed in this chapter have their own unique properties, e.g., organoclays with high surface area and platelet-like structure are more beneficial in reducing dispersed phase particle size compared to spherical nanosilica or tubular carbon nanotubes. However, addition of nanosilica in co-continuous blends can convert this structure into a dispersed phase structure with a stable morphology, whereas carbon nanotubes provide higher electrical conductivity in the blend and can improve tensile ductility acting as bridge to arrest propagation of cracks and crazes. The utilization of two fillers to encapsulate one of the phases to restrict migration of other filler and to promote network structure has also shown significant improvement in the electrical conductivity of blend nanocomposites.

Other than the thermodynamic effects, the mixing time can significantly affect the equilibrium location of filler; in fact, the additional processing time can even lead to migration of filler particles from its equilibrium position as predicted from the surface energy analysis. Future work on polymer blends containing nanoparticles should combine the basic and applied research that has been done

to date with additional considerations of the processing issues and experimental designs to prepare materials with better combinations of properties for commercial applications. The combination of experiments, computational modeling, and theory can be a powerful tool for optimizing properties of commercially valuable polymer blends. This chapter should provide a platform for building knowledge about fundamental issues and applications.

Abstract

Several books offer information on various aspects of polyolefin (PO) synthesis, technology, performance, as well as on the preparation, fundamentals, and degradability and recyclates of polymer alloys and blends (PAB) [Utracki and Weiss, *Multiphase Polymers: Blends and Ionomers.* ACS Symposium Series, vol. 395 (Washington, DC, 1989); Utracki *Polymer Alloys and Blends* (Hanser, Munich, 1989); J. Rheol. **35**(8), 1615–1637, 1991; *Encyclopaedic Dictionary of Commercial Polymer Blends* (Chem Tec Pub., Toronto, 1994); Makromol. Chem. Macromol. Symp. **118**, 335–345, 1997, *Commercial Polymer Blends* (Chapman & Hall, London, 1998); Zweifel, *Stabilization of Polymeric Materials* (Springer, Berlin, 1998); Moeller, *Progress in Polymer Degradation and Stability Research* (Nova Sci. Publ., New York, 2008); Anand (ed.), *National Seminar on Emerging Trends in Plastic Recycling Technologies and Waste Management* (Goa, India, 1995); *Recycling and Plastics Waste Management, Proceedings of National Seminar* (CIPET, Chennai, 1997); Akovali et al., *Reprocessing of Commingled Polymers and Recycling of Polymer Blends.* NATO ASI, vol. 351 (Kluwer, Dordrecht, 1998)]. There are also encyclopedic editions on PAB, e.g., Utracki [*Encyclopaedic Dictionary of Commercial Polymer Blends* (Chem Tec Pub., Toronto, 1994, 2013); Isayev (*Encyclopedia of Polymer Blends* (Wiley-VCH, Weinheim, 2010–2014)].

The first patent on PAB was granted to Parkes in 1846 for two natural polymers co-vulcanized during blending in the presence of CS_2, i.e., a natural rubber (NR = amorphous *cis*-polyisoprene, IR) with gutta-percha (GP = semi-crystalline *trans*-polyisoprene, IR). Thus, rubber PAB predates that of synthetic polymers by ca. 80 years (PMA/PVAc 1929). Notably, while the early plastics were bio-based, their usage fell to <5 wt% nowadays slowly recovering from the absolute dominance of synthetic, petroleum-based plastics.

PO is a part of the commodity resin category, where the continuous use temperature (CUT) $\leq 75\ ^{\circ}C$. Specifically, to this category belong polyethylenes (PE), polypropylenes (PP), styrenics (PS), acrylics (PMMA), and vinyls, such as poly(vinyl chloride) (PVC). The relative importance of commodity resin is evident from the data displayed in Fig. 18.1.

In the 1900s, world plastic production was about 30 kt, increasing to 300 Mt
by the year 2010. Figure 18.1 shows the growth after 1960, extrapolated
to 2020. Accordingly to Pardos Marketing [Pardos Marketing] plastic
consumption is dominated by the commodity resins to the extent that the total
consumption of plastics on the plot is indistinguishable from that of commodity
resin. Notably, within the commodity resin category, PE contribution is
45–55 wt%.

The 75th anniversary of the invention of the first commercial PE seemed to be
an appropriate occasion for summarizing in a (relatively) short chapter the
factors that create such a vast spectrum of materials often having unexpected
properties. Considering the character of the Polymer Blends Handbook – 2
(PBH-2), the Chapter provides concise, fundamental information in a historical
perspective, starting with single PE resins before addressing PE blends. It also
offers extensive tabulated data, useful for readers.

The chapter is divided into 19 parts, including classification of PE resin, their
discovery and historical evolution, and methods and equipment of PE charac-
terization, and then PE blends preceded by greatly abbreviated fundamentals
and followed by description of various mixtures. In view of the importance of
miscibility for processability and performance of PE blends, this aspect is
particularly stressed.

18.1   Introduction: 75 Years of Polyethylenes and Their Blends

Polyethylene (PE) is a product of ethene polymerization in a radical, anionic-
addition, ion-coordination, or cationic-addition reaction. These reactions
result in polyethylenes having different composition, molecular weight (MW)
branching type (short and long, SCB and LCB), branching distribution (SCBD),

and density (ρ) dependent on the structure regularity, thus crystallinity. Accordingly, PE is classified as:

- Cross-linked polyethylene (PEX or XLPE)
- High-density cross-linked polyethylene (HDXLPE)
- High-density polyethylene (HDPE)
- High-molecular-weight polyethylene (HMWPE)
- Linear low-density polyethylene (LLDPE)
- Low-density polyethylene (LDPE)
- Medium-density polyethylene (MDPE)
- Ultrahigh-molecular-weight polyethylene (UHMWPE)
- Ultralow-density polyethylene (ULDPE)
- Ultralow-molecular-weight polyethylene (ULMWPE or PE-WAX)
- Very low density polyethylene (VLDPE)

Process ability and properties of PE blends depend on the composition, the molecular structure, and the MW. The typical values of density, melting temperature, and crystallinity are listed in Table 18.1; there is a linear relation:

$$T_{\mathrm{m}}(^{\circ}C) = 171.9 + 1763 \cdot \log(\rho); r^2 = 0.925.$$

The first highly crystalline polymethylenes, $(CH_2)_n$ (melting point, $T_{\mathrm{m}} = 137\,^{\circ}\mathrm{C}$), were obtained fortuitously by thermal decomposition of diazomethane. In 1930, Carothers and his colleagues at du Pont de Nemours produced polydispersed polymethylenes by condensation of decamethylene bromide: $(CH_2)_{10}Br_2 + Na = H(CH_2)_nH$. After fractionation, the polymerization degrees were determined as $n = 40, 50, 60, 70, \ldots$. At about the same time, at IG Farbenindustrie, the polymerization of ethylene in the presence of BF was carried out under high pressure (Hofmann and Otto 1931).

Industrial polymerization or copolymerization of olefins started in 1936, thus a year after the Faraday Society meeting where Fawcett described Perrin's discovery of ethylene polymerization, dismissed by Herman Mark who stated that *ethylene does not polymerize* (Kennedy 1986). During the elapsed, 75 years or so, ethylene polymerization went through several stages, incorporating new technologies without abandoning the old ones:

1935–1936: Free radical polymerization of ethylene solution at high temperature $T > 180\,^{\circ}\mathrm{C}$ and pressure $P = 120$–300 MPa, facilitated by the presence of oxygen or peroxides producing **LDPE**.

1950: Catalytic polymerization of ethylene under mild conditions, e.g., $T = 100$–$250\,^{\circ}\mathrm{C}$ and $P = 1$–8 MPa, in the presence of a metal oxide, e.g., Cr_2O_3 or NiO on carbon black and Mo_2O_3 or $CoMoO_4$ on alumina; product **LLDPE** or **HDPE**.

1953: Disclosure of the Ziegler catalyst, used for industrial production of **HDPE** since 1954–1955. The Ziegler–Natta (Z-N) catalyst is mainly a binary mixture of a titanium halide and an organoaluminum compound producing mainly LLDPE copolymer with a broad MW distribution (MWD). Academic and industrial modifications of the Z-N catalyst started right away, e.g., by Elston in DuPont

Table 18.1   Typical range of PE properties

Acronym	Density range ρ (g mL^{-1})	Melting range point, T_m (°C)	Crystallinity range X (wt%)	Year of introduction
LDPE	0.910–0.940	100–115	40–60	1935
HDPE	0.940–0.965	125–135	65–80	1955
LLDPE	0.915–0.940	110–125	40–80	1975
VLDPE	0.885–0.910	100–120	25–40	1983

Canada who developed *Sclaire* catalyst based on vanadium (V) instead of titanium (Ti). A majority of commercial polyolefins (POs) are still produced with heterogeneous, multi-sited, modified Z-N catalysts, e.g., TiCl$_4$ on MgCl$_2$ support.

1975: Discovery of the metallocene catalyst by Kaminsky and Sinn. The catalyst is composed of a metallocene (Cp$_2$MCl$_2$, i.e., it has two Cp (cyclopentadienyl) ligands; M is Zr, Ti, or Hf) and a linear or cyclic methylaluminoxane (MAO) – both soluble in organic solvents. The metallocene polymers are produced under mild polymerization conditions (e.g., $T = 100$ °C and $P = 1$ MPa), producing **m-LLDPE** with narrow MWD and homogeneously distributed short-chain branches (SCB). The mono-Cp catalysts are known as single sited or pseudo metallocene.

1997: Beginning of the post-metallocene catalysis – the new ones often have imine ligand, but not Cp. They are characterized by high activity, a possibility of adjusting polymer MW and MWD as well as copolymerization of olefins with polar monomeric and macromeric species. A wide spectrum of catalysts based on light and heavy transition metals have been published in open literature and patents. There are also several types of catalysts with intermediate structure – pseudo metallocene with a post-metallocene imine ligand. Unfortunately, the product shows poor thermal stability and is not ready for commercialization.

More details on the historical evolution of PE and PE blend technology are tabulated in Appendix and Nomenclature.

18.2   Types of PE

18.2.1 LDPE

LDPE has a high degree of short-chain branching (SCB) and long-chain branching (LCB), which reduce macromolecular crystallization. Thus, since the intermolecular forces are weaker, so is the modulus and strength, accompanied by increased ductility. LDPE is a product of free radical polymerization. Owing to the LCB, molten LDPE in extensional flow shows the strain-hardening effects, which stabilize the bubble during the film-blowing operation. In consequence, LDPE is frequently used in PO blends for easing process ability of, e.g., LLDPE.

LDPE is being manufactured using either an autoclave reactor (AR as in ICI process) or a tubular reactor (TR process of IG Farbenindustrie, now BASF). The high-strength tubes are $L = 0.5–2$ km long with inner/outer diameters ID/OD = 70/180 mm; thus, L/OD = 3,000–11,000. Since the operating conditions in AR and TR are different ($T = 180–330$ and 140–340 °C and $P = 100–250$ and 200–350 MPa, respectively), the polymers have different properties.

18.2.2 HDPE

HDPE has a low degree of branching and thus higher crystallinity, modulus, and tensile strength. HDPE has been produced in several catalytic processes, viz., Zletz used molybdena-alumina, Hogan and Banks claimed CrO_3 on silica, and Ziegler et al. employed $TiCl_4$ with trialkyl aluminum (e.g., triethyl: $AlEt_3$). The lack of branching is ensured by the catalyst and reaction conditions. HDPE is produced either in suspension, gas phase, solution, or their combinations, using a variety of reactor type and polymerization media, viz., a continuously stirred tank (CSTR), loop, reactor, or fluidized bed reactor (FBR). There are single and multi-reactor production lines; there is a diversity of hydrocarbon solvents or suspending liquids and of catalysts and operating conditions, which leads to great performance diversity of HDPE available on the market.

18.2.3 UHMWPE

UHMWPE is HDPE with MW = 3.1–5.67 Mg mol^{-1}. The high molecular weight makes it tough and less crystalline than the lower-MW HDPE (e.g., $\rho = 930–935$ kg m^{-3}). UHMWPE can be made using any catalyst, but Ziegler type is common. Because of its outstanding toughness and its cut, wear, and chemical resistance, UHMWPE is used for moving machine parts, bearings, gears, artificial joints, edge protection on ice rinks, and butchers' chopping boards. More recently, through gel spinning and stretching, UHMWPE has been formed into highly oriented crystalline fibers, which under the trade names Spectra™ and Dyneema™ compete and complement aramids in bulletproof vests and helmets used in implants for hip and knee replacements.

18.2.4 LLDPE

LLDPE is a substantially linear polymer with numerous short branches, primarily made by copolymerization of ethylene (C_2) with short-chain alpha-olefins (e.g., 1-butene, 1-hexene, or 1-octene, i.e., C_4, C_6, or C_8). LLDPE is more difficult to process than LDPE, but it has higher modulus, strength, impact, and puncture resistance than LDPE and better environmental stress cracking resistance (ESCR). Thinner films of LLDPE replace those of LDPE in packaging applications.

Table 18.2 Operating conditions for the production of LLDPE in the solution and gas-phase reactors

Process	Solution	Gas-phase
Operating temperature (T °C)	>100	80–105
Operating pressure (MPa)	2–20	0.7–2
Polymer content in reactor (wt%)	10–30	(not applicable)
Residence time in reactor (min)	5–30	60–180
Hydrocarbon solvent	C_6–C_9	C_5–C_7
Comonomer	C_3, C_{10}	C_4, C_6
Catalyst	Z-N or metallocene	Ziegler or metallocene
Ref.	CA Pat. 660,869	U.S. Patent 4,302,566

The work on Z-N-type catalysts in DuPont Canada in Kingston resulted in a low-pressure solution technology, *SCLAIRTECH™*, based on a new coordination catalyst (Elston 1972, filed 1968). The process made it possible to copolymerize C_2 with 10–20 mol% of C_4, C_6, or C_8 olefins. The *SCLAIRTECH™* provides greater variety of PE properties than the standard Z-N-type process, ranging from HDPE to that of LLDPE. The density and crystallinity depend on the type, amount, and sequence of placement of a comonomer. Owing to excellent performance parameters, these resins are used for films and fibers as well as for gas pipelines. A full-scale production facility near Sarnia, ON, was built in the early 1960s (Lank and Williams 1982).

In 1968, Union Carbide introduced the gas-phase FBR low-pressure *UNIPOL™* process. The first large-volume production unit started in 1970 in Sweden and later in the USA and 13 other countries. Initially the *UNIPOL™* process used Z-N catalyst and after 1980 the metallocene single-site catalyst. In the early 1990s LLDPE constituted 25 % of the world production of PEs (Fraser et al. 1997; Univation Technol. 2007). A summary of conditions used in the solution- and gas-phase processes is presented in Table 18.2.

The conventional Z-N–LLDPE contains a major fraction of a "copolymer" with the desired MW, a large PE "homopolymer" fraction with broad molecular weight distribution (MWD) and a small amount of a very low density copolymer. Such heterogeneity leads to several problems: (1) organoleptic caused by the low-MW wax; (2) suboptimal impact strengths caused by the crystallinity of the homopolymer fraction; and (3) processability – the resins were difficult to process on LDPE lines. The development of the *m*-LLDPE resins has mitigated these disadvantages (Huang et al. 2002). However, the *m*-LLDPE has narrow MWD again causing processability problems, usually solved by blending (Brown et al. 2009; U.S. Patent **6777509**, 2004).

Numerous articles and patents were published on diverse methods of **LLDPE** blending with other POs and elastomers, e.g., *m*-LLDPE, LDPE variety of ethylene copolymers, thermoplastic elastomers, TPO, EPDM, EPR, EVAc, maleated polypropylene, and PP-MA (Haas and Raviola 1982; Hughes 1982; Cowan 1983; Jager et al. 1983; Turtle 1983; Fukui et al. 1983; Haas 1983; Hert 1983).

catalyst
18.2.4.1 m-LLDPE

The metallocene-type LLDPE (*m*-LLDPE) has been produced using the **single-site metallocene catalysts**. This technology started the production of high-quality PO, with controlled MW, MWD, comonomer placement, and density or crystallinity. As shown in Fig. 18.2, there is a significant difference in the melting point versus composition dependence for LLDPE and m-LLDPE. The difference originates in the regularity of the comonomers' placement, which controls the size of the crystallizing chain segments. Such regularity may be obtained using metallocene, but not Z-N catalysts.

In 1975, Mitsui Petrochemicals introduced metallocene *TAFMER*™ polyolefins, the m-LLDPO, with strictly controlled comonomer distribution. The resins had rather low MW. Eight years later, Polysar disclosed bimetallic metallocene alumoxane catalyst used in polymerization of olefins into elastomeric ethylene-α-olefin copolymer or ethylene-α-olefin-*non* conjugated diolefin (Davis 1994). Also in 1983, Exxon Chemical filed a patent application (granted 11 years later!) for polymerization of C_2 in the presence or absence of a comonomer into PE of controlled MW and density. The metallocene catalysts were cyclopentadienyl derivatives (Cp) of the general formula: R′s(Cp)$_2$MQ [M is a metal from Group 4b, 5b, or 6b (preferably Zr); R′ is a C_1–C_4 radical; Q is an alkylidene radical]. The catalyst was used in combination with alumoxanes (Welborn and Ewen 1994). Four years later, Exxon with Mitsui Petrochem. jointly developed *Exxpol*™ – a single-site metallocene catalyst for PO (co)polymerization in a solution, gas, or slurry phase. The metallocene catalyst had *at least one* substituted Cp ring facilitating production of PEs with less regular structure, beneficial for process ability (Jejelowo 1994). *Exxpol*™ from Exxon–Mitsui and *INSITE*™ from Dow showed better process ability, clarity, and mechanical properties than those obtained using Z-N catalysts. The first commercial metallocene-made PE was introduced by Exxon in 1991 as a *Plastomer*™ (Leaversuch 1991; Lai et al. 1993, 1994).

18.2.4.2 MDPE

MDPE can be produced by chromium/silica, Z-N, or metallocene catalysts. The polymer has good shock and drop resistance properties; it is less notch sensitive and has higher stress cracking resistance than HDPE. It is typically used in gas pipes and fittings, sacks, shrink film, packaging film, carrier bags, and screw closures.

18.2.4.3 VLDPE and ULDPE

In the 1980s, new catalysts $Mg_rAl_sTi_t(OR)_uCl_v$ (the subscripts are positive integers) were developed for gas-phase or solution polymerization at $T = 70–11\,°C$ and $P = 0.5–2\,MPa$ (Cady 1987) for the production of **VLDPE** with density of $\rho = 900–915\,kg\,m^{-3}$ and its homologue, **ULDPE** ($\rho = 855–900\,kg\,m^{-3}$). The latter copolymer was commercialized by Mitsui Toatsu in 1986 and has low crystallinity and $T_m = 40–85\,°C$. As a result, it shows properties intermediate between those of PE and an elastomer (Kim et al. 1992). The VLDPE and ULDPE are substantially linear metallocene copolymers of C_2 with α-olefins (e.g., $C_{4–8}$).

With development of VLDPE and ULDPE, the distinction between thermoplastic PE and olefinic rubbers became less apparent. By 1992, *Exact™ PE*, a VLDPE made using metallocene or "single-site" catalyst, was introduced by Exxon Chem. The main use of ULDPE is in blends of LDPE, HDPE, or PP (Utracki 1989b; Kohyama and Yamada 1991; Leaversuch 1992). While the extent of blending varies from one country to the next, the general advantages of blending are widely recognized. Blends with PP have attracted much commercial interest (Utracki and Dumoulin 1995). Since these polymers are immiscible (see Fig. 18.3), copolymers such as EPR or EPDM are frequently used. Compatibilization can also be achieved by reactive blending, "dynamic vulcanization," or post-blending cross-linking using peroxides, electron beam, or γ-radiation. Both factors, the reactive compatibilization and irradiation, lower the crystallinity. Thus, the micromorphological character of PP/PE blends can be controlled by composition, presence of the nucleating agents, type of compatibilizer, and thermal or radiative treatment (Nadkarni and Jog 1991).

18.2.4.4 PEX

PEX is a medium- to high-density PE containing cross-links. Cross-linking reduces its flow and increases the continuous use temperature (CUT) and chemical resistance. Because tubes made of the material can be expanded to fit over a metal nipple and then slowly return to its original shape, forming a permanent, watertight connection PEX is used in potable water plumbing systems.

In summary, as presented in Table 18.3, the current world production of PEs is close to 100 million metric tons (equivalent to a sphere with 1.3 km diameter), with ca. 45 % of this mass being HDPE, than LLDPE and the old LDPE keeping about 20 % of the market.
Fig. 18.3 PP with 65 wt% elastomer (from the LHS): morphology in pellets, in blown film, and in blown film in PP copolymerized with 3 mol% C_2 – effect of compatibilization (Montell Impact Copolymer Polypropylene, commercial information 2012)

Table 18.3 PE production/consumption in four regions 2008–2015

Region	LDPE (%PE)	HDPE (%PE)	LLDPE (%PE)	Total (Mton)
Asia Pacific	19	47	34	42.0
South and Central America	20	44	36	14.6
North America	18	44	38	20.8
Europe	34.4	49.7	15.9	22.1

18.3 PE Discovery and Evolution

18.3.1 High-Pressure Polymerization of LDPE

In March 1933, as a part of ICI studies of high-pressure reactions, Fawcett and Gibson observed the formation of a waxy white powder (later identified as polymethylene) in a reactor filled with C_2 and benzaldehyde T $\approx$ 170 °C and $P = 190$ MPa. It took 2 years for Perrin and Swallow to establish that polymerization was radical, initiated

by traces of O_2 or peroxide. The discovery was presented during the 1935 meeting of the Faraday Society (Kennedy 1986). A year later, a provisional British patent was filed. It described polymerization of ethylene at $T = 100$–$300\ ^\circ$C and $P = 50$–300 MPa into polymers with density $\rho = 910$–920 kg m^{-3} and melting point $T_m = 115\ ^\circ$C. In 1937, the first *Telcothene*™, a blend of PE and polyisobutylene (PIB), was produced for submarine cables, and in 1939, a large plant with 100 t year^{-1} capacity started the production of *Alketh*™ (Seymour and Cheng 1985; Ballard 1986). The following year a tenfold larger plant was commissioned.

The LDPE technology continues evolving. In the USA, the first PE was produced by Union Carbide in a tubular reactor in 1940. The ICI-developed **LDPE** technology was licensed to du Pont de Nemours, Arco, Eastman, and several other companies. Configurational studies indicated the presence of two types of branching: LCB and SCB, caused by intermolecular and intramolecular hydrogen transfer, respectively; LCB depends on the monomer/polymer ratio and mainly affects melt flow, whereas SCB is related to the polymerization temperature via formation of a 6-member ring that forms a C_4 pendant group, which influences the solid-state properties, viz., crystallinity and density ($\rho = 0.89$–0.97 g mL^{-1}). On the weight basis, the estimated branching density for LCB and SCB is, respectively, 8–10 and ≤ 50 per macromolecule (Roedel 1953).

18.3.2 Early Stage of Catalysis

In 1951, the first patent for low-pressure ($P = 1$–10 MPa) catalytic polymerization of ethylene into **HDPE** ($\rho = 920$–980 kg m^{-3}) was deposited by Standard Oil of Indiana (Zletz 1954; Nowlin 1985). The document described formation of a rubbery polymer with high MW. Similar discovery was announced by Phillips Petroleum Co. (Hogan and Banks 1955) and then by Ziegler et al. (1960, 1966). In 1953, Karl Ziegler, using a catalyst based on transition metal compounds suspended in organic solvent, polymerized ethylene at pressures slightly above ambient into linear HDPE, as well as propylene and butylene to isotactic polymers, PP and *i*-PB. Similar discoveries were published by Giulio Natta, who focused on the ability of the new catalyst to produce stereospecific poly-α-olefins. In 1963, Ziegler and Natta shared the Nobel Prize in chemistry. The organometallic compounds (e.g., $AlEt_3 + TiCl_4$) are known as the Z-N catalysts.

Z-N catalysts are based either on $TiCl_4$, VCl_5, or $CoCl_3$ mixed with $Al(C_2H_5)_3$ or $Al(C_2H_5)_2Cl$ in an inert solvent. Both the crystalline solid and highly colored supernatant solution can initiate polymerization, but only the former leads to stereospecific polymer. The crystalline catalyst has many active sites initiating different reactions – e.g., four types postulated by Floyd et al. (1987, 1990). Thus, the Z-N catalysts lead to polymers with a wide range of polydispersity, composition, and limited stereospecificity.

In 1954 Hoechst was the first manufacturer of HDPE by Ziegler process, followed by Hüls, Rührchemie, Montecatini, Shell, Mitsui, Dow, Esso, Gulf, Hercules, Koppers, Monsanto, and Union Carbide. In 1957, Hercules introduced

the Z-N-catalyzed **UHMWPE**. The industrial production of HDPE using Phillips technology started in 1956, which by that date was already licensed to nine companies in seven countries.

The comonomer distribution between LLDPE molecules produced using a multi-sited catalyst is not random. Their distribution is heterogeneous, where the copolymer molecules do not have the same ethylene/comonomer ratio. These copolymers are differentiated for the type of the degree of heterogeneity and the MW-dependent ethylene/comonomer ratio. In the heterogeneous copolymer type I, the ethylene/comonomer ratio is independent of MW; individual macromolecules have comonomer content above or below the average. Heterogeneous copolymers type II and III have the ethylene/comonomer ratio increasing and decreasing with MW, respectively. Combinations of types I, II, and III are also possible (Elston 1965, 1972).

This situation observed in Z-N PE may be compared to the homogeneous metallocene copolymers in which not only the comonomer is randomly distributed within a given macromolecule, but also all the copolymer molecules have the same ethylene/comonomer ratio. Homogeneous copolymers of narrow MWD exhibit a reduced haze in films, higher impact strength, reduced tendency toward delamination, and better (than heterogeneous ones) balance of physical properties in the machine (MD) and transverse (TD) direction of the blown films. It is interesting that blends of these two LLDPE types, heterogeneous and homogeneous, lead to films with improved impact and tensile properties (Chum et al. 1998, 2006).

18.3.3 Metallocene Catalysts

To improve selectivity of the catalyst, two routes were taken: (i) additives have been used to "poison" some of the sites, e.g., by injection of H_2 (Vanderberg 1962), and (ii) ligands have been incorporated forcing the monomer to a unique molecular orientation when approaching the active site. The latter strategy resulted in development of new class of metallocene catalysts discovered in 1976 by Kaminsky and Sinn for a slurry process. A metallocene or sandwich compound consists of two cyclopentadienyl anions ($Cp = C_5H_5^-$) bound to a metal (M) in the oxidation state II. The compounds are usually miscible in organic solvents.

Metallocene catalysts have well-defined single catalytic site and well-understood molecular structures consisting of a transition metal atom sandwiched between ring structures to form a sterically hindered site (Thayer 1995). The oligomeric co-catalyst is alumoxane, $[Al(CH_3)-O]_n$. The stereoselective catalytic sites polymerize almost any monomers into a polymer with well-defined MW and MWD, comonomer distribution and content, and tacticity. The two Cp rings may not be identical. Monocyclopentadienyl structures also exist in which one ring has been replaced by a heteroatom (often N). The transition metal, M, usually is from Group 4b (Zr, Ti, Hf). For example, the Dow Chem. *INSITE*™ metallocene catalyst contains $[C_5Me_4(SiMe_2N\text{-}Bu)]TiMe_2$ (where C_5Me_4 is a tetramethylcyclopentadienyl group), with two co-catalysts tris(pentafluorophenyl)borane and modified

methylaluminoxanes (ratios: B:Ti = 2:1; Al:Ti = 4:1), all soluble in saturated hydrocarbons, C_{8-10}.
