The second setup corresponds to the model analyzed in [10]. Slot durations and frame spacings conform to the 802.11 standards [4] as indicated in Table 1. Network time is *slotted* with a resolution of $t_{\text{slot}} = 1\,\mu\text{s}$ as baseline. Typical parameters for radars operating in 3.5 and 5 GHz are included in Table 2 based on [1, 14, 17]. The radars transmit a series of equally spaced pulses called a pulse *burst* with low-duty cycles (often less than 1%) in a given direction (Directionality could be achieved through a phased array in place of mechanical rotation.), with peak transmit powers that can exceed 90 dBm. Accordingly, a simple link-budget analysis using an irregular terrain path-loss model (e.g., Fig. 5 in [15]) indicates that

Table 1 Wi-Fi timing parameters

Parameter	Description	Duration
t_{slot}	Timing slot	$1\,\mu\text{s}$
t_{bo}	Backoff	$9 \times t_{\text{slot}}$
t_{difs}	DIFS	$34 \times t_{\text{slot}}$ (5 GHz)
t_{sifs}	SIFS	$16 \times t_{\text{slot}}$ (5 GHz)
t_{ack}	ACK	$48 \times t_{\text{slot}}$
t_{payload}	Payload	up to $\approx 3000 \times t_{\text{slot}}$
$t_{\text{slot}} = 1$ slot $= 1\,\mu\text{s}$		

Table 2 Example radar parameters

Parameter	Values
Pulse repitition interval (t_{pri})	100 μs–5 ms
Pulse duration	0.8–50 μs
Pulses per burst	10–25
Peak power	up to 90 dBm
Antenna main beam gain	up to 40 dBi

radar interference power at a Wi-Fi AP can exceed −62 dBm at distances of tens of kilometers from the radar. As a result, energy detection schemes can be effective in the exclusion region for meeting the 5 GHz DFS latency requirements. It noteworthy that radar detection is conducted typically by the AP and any information (such as DFS triggering) disseminated via broadcast to all clients.

Challenges in Radar Pulse Detection

Performance of radar pulse detector by the secondary user (Wi-Fi) in order to limit interference (by either controlling its own in-band transmission or switching to a different unoccupied channel) is measured by the obvious metric:

- **Detection delay:** The interval from the instant the incumbent (radar) becomes active until its successful detection by the secondary network (Wi-Fi).

which is impacted by (a) radar pulse duration and (b) pulse repetition interval (PRI).

Typically, in other applications of the shared spectrum paradigm (e.g., wireless microphones), the incumbents transmit high-duty cycle signals; any Wi-Fi idle period will thus overlap with multiple incumbent transmissions with high probability allowing for effective detection. In contrast, radars with low-duty cycles pose a significant challenge. In this work, the detection delay of radar by Wi-Fi systems for various Wi-Fi/radar system parameters is presented to establish the conditions under which such a system can adequately protect radar and if the associated cost (loss of WLAN throughput) is acceptable.

Wi-Fi Basics

The Wi-Fi standard employs a CSMA/CA-based approach [4] within a distributed slotted medium access scheme.

A brief summary of the core algorithm follows: each node attempting transmission must first ensure that the medium has been idle for a duration labeled the DCF interframe spacing period (DIFS) which is typically in the range of 28–50 μs. Once the medium has remained idle for a DIFS period, the node selects a backoff counter uniformly at random in the range of $[0, 2^m W - 1]$ (Typical W values are 16, 32.)

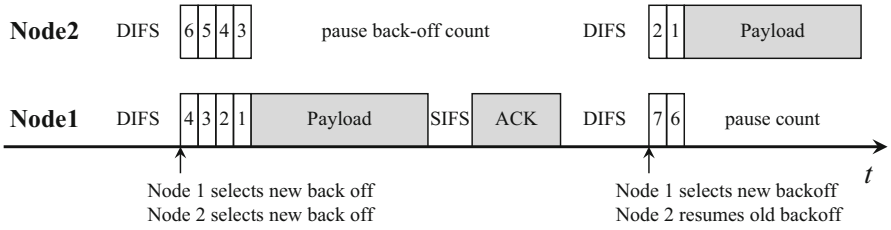

Fig. 3 This parallel timeline for two nodes contending for access to the same channel shows the role of the random backoff in reducing collisions

where the value of m is initialized to 0. The node then counts down from the selected backoff value in a slotted fashion (i.e., the node decrements the counter every t_{BO} microseconds corresponding to a backoff slot) as long as no other transmissions are detected. If during the countdown a transmission is detected, the counting is paused, and nodes continue to monitor the busy channel until it goes idle; thereafter the medium must remain idle for a further DIFS period before the backoff down-counting is resumed. Once the counter hits zero, the node transmits its payload (illustrated in Fig. 3). Any node that did not complete its countdown to zero in the previous transmission round resumes the countdown at the next opportunity without selecting a new backoff value.

A collision event occurs if and only if two nodes select the same backoff counter value at the end of a DIFS period. In case of a collision, the value of m (the backoff stage) is incremented by one (binary exponential backoff) such that the backoff counter is doubled for the next attempt, thereby reducing the probability that any two nodes select the same backoff counter repeatedly. Once a transmission has been completed successfully, the value of m is reset to 0. The value of m cannot exceed a maximum value $m_{\max}$ (typically values are 3–5).

Analytical Evaluation of Radar Detection in Wi-Fi Quiet Periods

Since no synchronization between the radar pulses and the Wi-Fi network is assumed, once the radar becomes active, the first pulse it transmits will arrive at random in relation to the Wi-Fi network state. From the alternating renewal theorem, it can be shown that if a pulse arrives at a random time instant, the Wi-Fi network will be in an idle state with probability P_{idle} (Fig. 4a, b) and in a busy state with probability P_{busy} (Fig. 4c) computed as below:

$$P_{\text{busy}} = \frac{\mathbb{E}[B_k]}{\mathbb{E}[B_k] + \mathbb{E}[I_k]} \tag{1}$$

$$P_{\text{idle}} = 1 - P_{\text{busy}} \tag{2}$$

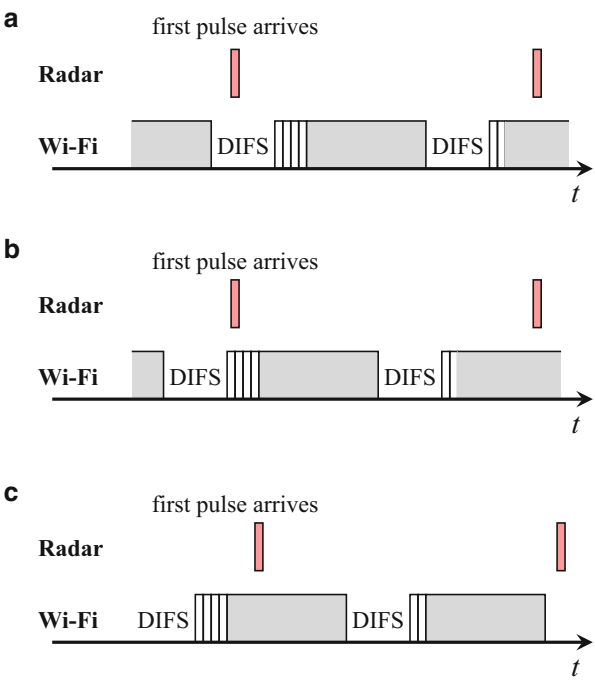

Fig. 4 (**a**) In this case, the first pulse arrives during a DIFS portion of the idle period. (**b**) In this case, the first pulse arrives during the backoff portion of the idle period. (**c**) In this case, the first pulse arrives during the busy period

where,

B_k The *random* duration of the busy period in the kth renewal cycle. Randomness is due to the success or failure of transmission.

I_k The *random* duration of the idle period in the kth renewal cycle. The randomness in the idle duration is due to the random backoff

Q_k The *random* number of backoff slots during idle period I_k. $Q_k \sim \text{Geo}(P_{\text{tr}})$ (P_{tr} is the probability that at least one node attempts transmission in a backoff slot)

It is assumed that for any radar pulse arriving during an idle period is detected perfectly (i.e., with probability 1, an approximation which is good for Wi-Fi nodes within the exclusion region for reasons stated earlier) and the (additional) processing delay for detection (post arrival) is negligible. Thus the detection delay is the interval measured from the first (reference) pulse, till the first time a pulse arrives during a Wi-Fi idle period, as shown in Fig. 5. Hence, if the first pulse arrives during an idle period, the detection delay is zero.

For the remainder of the analysis, the random variable B_k is replaced by a constant t_{busy} equal to expected duration of $E[B]$. This is reasonable for all *fixed packet length* scenarios since the ACK/SIFS durations are typically negligible compared to the payload duration (in the downlink-only case, this approximation is exact). Thus

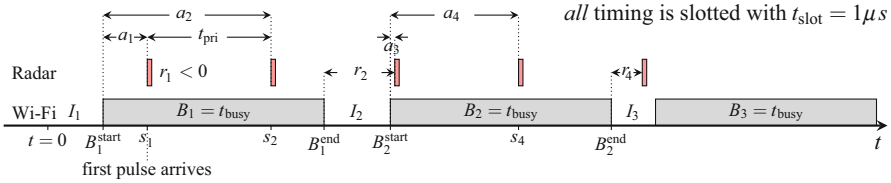

Fig. 5 Example timeline for a detection delay of 5 ($D = 5$) for $t_{pri} < t_{busy}$. The fifth pulse is the first that arrives during an idle period. Busy periods are of fixed duration t_{busy}, while idle periods are of a random duration

$$t_{busy} \triangleq \mathbb{E}[B] = t_{PAYLOAD} + P_s(t_{SIFS} + t_{ACK})$$

where P_s is the probability of successful packet transmission. Next, let us define:

S_i The *random* arrival time of the ith radar pulse. Since all timing is *slotted*, $S_i \in \mathbb{N}$ and clearly $S_i = S_{i-1} + t_{pri}$

N_i The index of the renewal period in which pulse i arrives (e.g., in Fig. 5, $N_1 = N_2 = 1$ since pulses 1 and 2 arrive during busy period 1, and $N_3 = N_4 = 2$)

A_i The *random offset* of the ith pulse inside the associated busy period. $A_i \in \{1, 2, \cdots, t_{busy}\}$. $A_i \triangleq S_i - B_{N_i}^{start}$

r_i The remaining time from the end of the busy period till the arrival of pulse $i+1$ as calculated in (4). A negative value for r_i signifies that a pair of pulses arrives in the same busy period (e.g., pulses 1 and 2 in Fig. 5)

D The random variable describing the detection delay in number of pulses where $D = 1$ signifies detection of the first arriving pulse. $D \in \{1, 2, \ldots\}$

d_{burst} The number of pulses in a radar pulse burst

For the radar to be detected with the first arriving pulse ($D = 1$), the network must be idle at arrival time which occurs with probability P_{idle} according to (2). For $D > 1$, the approach is to compute the detection delay distribution recursively; therefore, the derivation focuses on obtaining an expression for the following conditional probability:

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) \tag{3}$$

which denotes the probability that pulse $i + 1$ arrives at offset a_{i+1} in an upcoming busy period given that pulse i arrived at offset a_i in a busy period.

One key observation is that (3) *does not* depend on arrival values prior to i (e.g., A_{i-1}), a fact that is used to help simplify the analysis. Even so, two separate classes should be considered in the upcoming subsections:

1. $t_{pri} < t_{busy}$ (Fig. 5)
2. $t_{pri} \geq t_{busy}$ (Fig. 6)

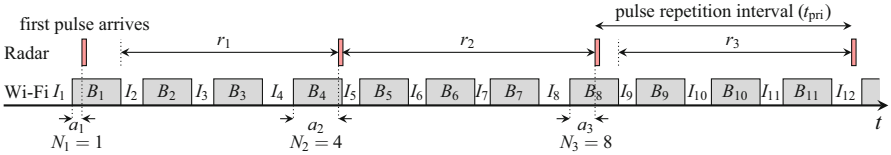

Fig. 6 Sample timeline for a detection delay of four pulses (i.e., $D = 4$) for $t_{\text{pri}} > t_{\text{busy}}$. Note that $N_i = n_i$ signifies that pulse i arrives during busy period B_{n_i}

Before doing so, let's define:

$$r_i \triangleq a_i + t_{\text{pri}} - t_{\text{busy}} \tag{4}$$

$t_{\text{Pri}} < t_{\text{Busy}}$

When $t_{\text{pri}} < t_{\text{busy}}$, multiple radar pulses can arrive within a single busy period (Fig. 5). An example of this coexistence class is when a radar with short PRI (e.g., 200 μs) is sharing spectrum with an 802.11 WLAN employing 3 ms aggregated frames.

Case 1: $r_i < 0$

This condition is satisfied if and only if both pulses fall within the same busy period. An example of this case can be observed with pulses 1 and 2 in Fig. 5. As shown, a_1 and a_2 differ by exactly t_{pri}. In this case, the trivial (deterministic) result is as

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) = \begin{cases} 1 & \text{when } a_{i+1} = a_i + t_{\text{pri}} \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

Case 2: $r_i \geq 0$

If pulse $i + 1$ falls within the next renewal cycle, it can be shown that

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) = \mathbf{P}(I_{N_i+1} = r_i - a_{i+1}) \tag{6}$$

Moreover,

$$I_{N_i+1} = Q_{N_i+1} \cdot t_{\text{bo}} + t_{\text{difs}};\ Q_{N_i+1} \in \mathbb{N}, \tag{7}$$

therefore, it can be written:

$$\mathbf{P}(I_{N_i+1} = r_i - a_{i+1}) = \mathbf{P}\left(Q_{N_i+1} = q_{N_i+1}\right), \tag{8}$$

where

$$q_{N_i+1} = \frac{r_i - a_{i+1} - t_{\text{difs}}}{t_{\text{bo}}}. \tag{9}$$

Hence,

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) = \begin{cases} \mathbf{P}(Q_{N_i+1} = q_{N_i+1}) & r_i \geq 0 \\ 1 & r_i < 0 \text{ and } a_{i+1} = a_i + t_{\text{pri}} \\ 0 & \text{otherwise} \end{cases}, \tag{10}$$

where $\mathbf{P}(Q_{N_i+1} = q_{N_i+1})$ for the uplink/downlink configuration is calculated as

$$\mathbf{P}(Q_{N_i+1} = q_{N_i+1}) = P_{tr}.(1 - P_{tr})^{q_{N_i+1}} \; q_{N_i+1} = 0, 1, \ldots \tag{11}$$

and for the downlink only there will be no collisions and therefore the success probability of any transmission equals 1. So,

$$\mathbf{P}(Q_{N_i+1} = q_{N_i+1}) = \frac{1}{W}, \; 0 \leq q_{N_i+1} < W. \tag{12}$$

$t_{\text{Pri}} \geq t_{\text{Busy}}$

For this class, it is possible for multiple busy periods to occur in a single PRI as would be the case for a long PRI radar coexisting with a WLAN not using frame aggregation. An example is shown in Fig. 6. It is straightforward to see that given some remainder time r_i, the next pulse cannot occur any later than busy period $N_i + K$, where

$$K = \left\lceil \frac{r_i}{t_{\text{busy}} + t_{\text{difs}}} \right\rceil, \tag{13}$$

therefore:

$$N_i < N_{i+1} \leq N_i + K. \tag{14}$$

Provided the value of r_i as calculated in (4), so

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) = 0 \;\text{ if } r_i - t_{\text{difs}} < 0, \tag{15}$$

Otherwise, if $r_i \geq 0$, for each $k = 1, \ldots, K$, it can be shown that

$$\mathbf{P}\left(\sum_{j=1}^{k} I_{N_i+j} = r_i - a_{i+1} - t_{\text{busy}}(k-1) \right) = \mathbf{P}\left(\sum_{j=1}^{k} Q_{N_i+j} = \hat{q} \right),$$

$$\text{where } \hat{q} = \frac{r_i - a_{i+1} - t_{\text{busy}}(k-1) - t_{\text{difs}} k}{t_{\text{bo}}}$$

$$r_i - t_{\text{difs}} \geq 0 \text{ and } \hat{q} = 0, 1, \ldots$$

The intuition behind this formulation is that for pulse $i+1$ to fall within busy period $N_i + k$, $k-1$ busy periods and k idle periods must have elapsed prior to B_{N_i+k}. Meanwhile, the quantity $\hat{q}$ is nothing, but the sum of all backoff slots that must be remained idle for this event to occur.

Now, depending on the network configuration of interest (uplink/downlink or downlink only), the distribution of Q_k will differ as will the distribution of the sum. When considering an uplink/downlink network, Q_k is distributed geometrically; hence, the sum can be computed using a negative binomial:

$$\mathbf{P}\left(\sum_{j=1}^{k} Q_{N_i+j} = \hat{q}\right) = \binom{k-1+\hat{q}}{k-1} P_{\text{tr}}^{k}(1-P_{\text{tr}})^{\hat{q}} \tag{16}$$

In contrast, in the downlink-only case, Q is discrete uniform and the sum distribution can be calculated as [24]

$$\mathbf{P}\left(\sum_{j=1}^{k} Q_{N_i+j} = \hat{q}\right) = \frac{k}{(W+1)^k} \times \sum_{u=0}^{\lfloor \hat{q}/W \rfloor} \frac{\Gamma(k+\hat{q}-u\cdot W)(-1)^u}{\Gamma(u+1)\Gamma(k-u+1)\Gamma(\hat{q}-u\cdot W+1)} \tag{17}$$

where $\Gamma(.)$ is the gamma function for integer arguments. As a final step, the sum over all possible values of k is as

$$\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i) = \sum_{k=1}^{K} \mathbf{P}\left(\sum_{j=1}^{k} Q_{N_i+j} = \hat{q}\right), \tag{18}$$

$$\text{where } \hat{q} = \frac{r_i - a_{i+1} - t_{\text{busy}}(k-1) - t_{\text{difs}}k}{t_{\text{bo}}}$$

$$r_i - t_{\text{difs}} \geq 0 \text{ and } \hat{q} = 0, 1, \ldots$$

Detection Delay

We gather and summarize the result for $\mathbf{P}(A_{i+1} = a_{i+1} | A_i = a_i)$ as follows:

$t_{\text{pri}} < t_{\text{busy}}$ and	uplink/downlink: Eq. 10, 11
$t_{\text{pri}} < t_{\text{busy}}$ and	downlink only: Eq. 10, 12
$t_{\text{pri}} \geq t_{\text{busy}}$ and	uplink/downlink: Eq. 16
$t_{\text{pri}} \geq t_{\text{busy}}$ and	downlink only: Eq. 18

With expressions in hand for the various network configurations and coexistence classes, the detection delay can be computed recursively. If the first pulse arrives at $a_1 = \alpha$, so

$$\mathbf{P}(D = 2|\alpha) = 1 - \sum_{\alpha'=1}^{t_{\text{busy}}} \mathbf{P}(A_{i+1} = \alpha' | A_i = \alpha), \tag{19}$$

then for $d > 2$,

$$\mathbf{P}(D = d|\alpha) = \sum_{\alpha'=1}^{t_{\text{busy}}} \mathbf{P}(A_{i+1} = \alpha' | A_i = \alpha)\mathbf{P}(D = d - 1|\alpha'), \tag{20}$$

and the full expression for the detection delay can be written as

$$\mathbf{P}(D = d) = \begin{cases} 1 - P_{\text{busy}} & \text{when } d = 1 \\ \frac{P_{\text{busy}}}{t_{\text{busy}}} \sum_{a_1=1}^{t_{\text{busy}}} \mathbf{P}(D = d|A_1 = a_1) & \text{otherwise} \end{cases}, \tag{21}$$

where

$$A_1 \sim \text{Unif}(1, t_{\text{busy}}). \tag{22}$$

Finally, the detection rate for a radar burst of d_{burst} pulses is as

$$P_d(d_{\text{burst}}) = \mathbf{P}(D < d_{\text{burst}}). \tag{23}$$

Simulation Results and Discussion

In this section, the results for several radar parameter sets are presented to gain some insight into suitability of the proposed sensing/detection as a coexistence mechanism. Later, using the analysis developed is considered as a guideline for selecting Wi-Fi parameters that allows to achieve some desired detection requirements.

The Impact of Wi-Fi and Radar Parameters

Figure 7 shows the dramatic affect of payload size on the detection delay when comparing corresponding results for the different payloads; increases in the payload duration negatively impact detection delay (by comparing a with b). In the worst case, it can take hundreds of pulses for detection when the secondary network's channel utilization is high. Thus increased payloads both reduce the frequency with which idle periods occur as well as the overall average idle time duration, making it less likely for the low-duty cycle radar signal to be detected.

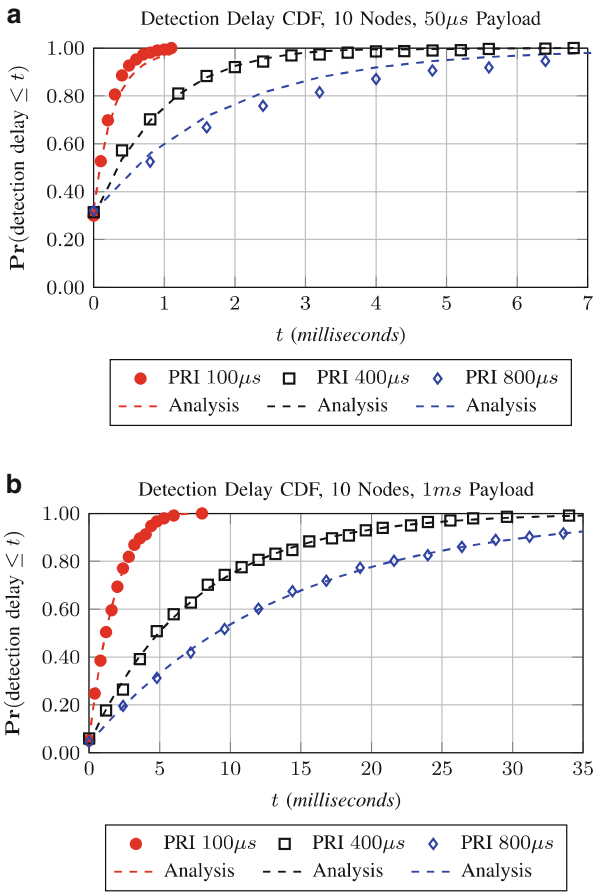

Fig. 7 Detection delay (in seconds) as a function of radar PRI for two fixed payloads. Aside from the PRI, all parameters match those in Table 3. (**a**) shows a ten-node saturated network with a fixed payload size of 50 μs. Wi-Fi throughput at this setting is 0.299. (**b**) shows the detection delay for a similar network but with a longer payload duration of 1 ms. Wi-Fi throughput at this setting is 0.725

The Detection Versus Throughput Trade-Off

The framework developed is now applied to achieving good WLAN throughput subject to the detection requirements, i.e., explore the detection-throughput trade-off. To do so, the length of the payload (busy period) and the DIFS (idle period) is tuned to achieve two goals:

1. Modifying the proportion of network idle time,
2. Adjusting the frequency with which idle periods occur.

From a secondary network throughput perspective, these constitute necessary overheads while they reduce detection delay. Note that any desired detection delay $D_{\text{des}} > 1$ can be trivially guaranteed by imposing the following conditions:

$$I^{\min} \geq t_{\text{pri}} \implies t_{\text{difs}} \geq t_{\text{pri}} \tag{24}$$

which ensures that every idle period is of sufficient duration to contain at least a single pulse arrival. The second condition ensures that at least one such idle period occurs by the desired detection delay (D_{des})

$$D_{\text{des}} t_{\text{pri}} \geq I^{\min} + B^{\max} \tag{25}$$

While feasible, this guarantee comes at a (potentially) heavy cost. In essence, by lengthening the inter-frame spacing which reduces throughput while simultaneously, the duration of the payload is decreased which compounds the effect. Such overheads impose a heavy penalty that would significantly degrade Wi-Fi throughput. However, by forgoing strict requirements and adopt statistical guarantees instead, one will be able to achieve far better network performance while maintaining acceptable protection for radars. Currently, the specific detection requirements available in the public literature are those applying to the 5 GHz band [14]. Hence, these numbers simply is considered as a benchmark.

The derivations in the previous section show that the distribution of detection delay is a function of the distributions of I and B. However, they cannot be considered as independent "knobs" used for tuning. Modifying either one affects both throughput and detection; in fact, adjusting the payload seems to be clearly sufficient.

Based on the calculations, WLAN parameters can be selected to achieve a particular in-service detection probability given particular radar characteristics. As an example, a radar with a PRI of 200 μs in line with [14] is considered. Table 3 shows the parameter sets that yield a 60% detection rate for a PRI of 200 μs. When the payload size is 3 ms (which is close to the maximum allowable by Wi-Fi), the throughput is maximized; however, $d_{\text{burst}} > 40$ pulses is needed before it can be detected with desired reliability. Reducing the payload size to 1 ms deceases the number of pulses required for detection by more than one half. Evidently, this improvement results in only a minimal loss of throughput (less than 10%) though additional improvements through further reductions of the payload size come at a much greater cost. It can be concluded that high throughput (by using 1 ms Wi-Fi payloads) and a 60% detection rate for bursts longer than 16 pulses can be obtained

Table 3 Simulation verification scenarios

Scenario:	1	2	3	4	5
t_{payload}	50 μs	150 μs	250 μs	1 ms	3 ms
Clients			10		
Radar pulse			4 μs		
Radar PRI			200 μs		
Energy detection			Ideal		
d_{burst} for $P_d = 0.6$	4	6	6	16	44
Throughput (Analysis)	0.299	0.571	0.599	0.718	0.7553
Throughput (Sim.)	0.3	0.58	0.61	0.725	0.75

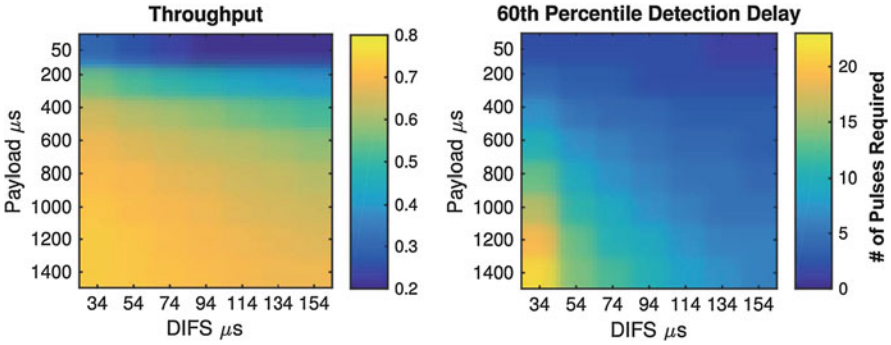

Fig. 8 For $t_{\text{pri}} = 200\,\mu\text{s}$, these figures illustrate the detection delay vs. throughput trade-off for various t_{difs} and t_{payload}

Table 4 DFS scenarios

PRI	250 μs	1429 μs	5000 μs
Pulse duration	1 μs	1 μs	5 μs
d_{burst}	25	18	10
Target burst P_d		0.6	
Clients		10	
Max throughput	0.7363	0.715	0.6470
Payload duration	1.5 ms	930 μs	400 μs

simultaneously; this is an indication that through careful selection of the appropriate parameters, a Wi-Fi network can achieve acceptable throughput while adequately protecting a radar.

Figure 8 shows a complete picture of the detection vs. throughput trade-off for a radar with a PRI of 200 μs as a function of payload and DIFS duration. As alluded to earlier, it is evident that for almost any desired pulse burst, the best throughput can be attained by simply adjusting the payload. To conclude, the results for a selection of other radar parameters indicated in [14] is presented, namely, those listed in Table 4. Evidently, radars that transmit less frequently (i.e., longer PRIs as well as fewer pulses per burst) are more difficult to detect reliably. Nevertheless, the key insight from this exercise points to the feasibility of achieving desired detection rates with latency budgets for specific radar parameter sets, while preserving a good throughput for the Wi-Fi network.

WLAN Modifications for Radar Interference Mitigation

In this section, the Wi-Fi networks outside the exclusion region is considered that have an opportunity to detect pulse interference during a packet transmission and subsequently mitigate it to preserve WLAN throughput. This section begins with

the description of a standard Wi-Fi transceiver chain and indicates the sort of modifications necessary for this purpose [21].

WLAN Generic System Architecture

A generic Wi-Fi link is illustrated in Fig. 9, where the blocks without red circles constitute the generic receiver and transmitter chain. The system has one transmit and two receive antennas and uses maximal ratio combining (MRC) in the receiver. There are two error correction coding options available in the 802.11 standard [3,5]: binary convolutional code (BCC) and low-density parity check (LDPC). The LDPC code with 1944 coded bits is chosen because of its superior performance in burst error circumstances. The LDPC decoder uses a sum-product algorithm-based soft-input decoder. The traditional symbol interleaver interleaves among a sequence of encoded data corresponding to each OFDM symbol. The constellation mapper takes a group of bits (depending on the modulation index and scheme) and maps them to a constellation point. After OFDM modulation of the payload, the framing block in Fig. 9a constructs a frame with preamble and payload (Fig. 11). Automatic gain control (AGC) block regulates the received signal power at the input prior to analog to digital conversion (ADC). The frame synchronization block achieves frame (timing) synch and pilot common phase error (CPE) estimator uses transmitted pilots to estimate the oscillator phase noise which causes rotation of all subcarriers and causes intercarrier interference (ICI). The standard soft demodulator passes an

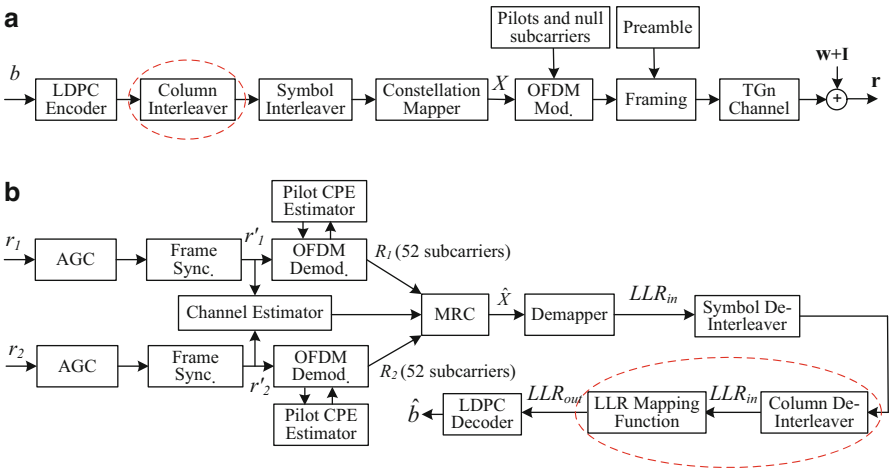

Fig. 9 The transmitter and receiver block diagrams of the Wi-Fi system. The blocks without *red circles* shows the generic Wi-Fi system receiver and transmitter chain. The blocks with *red circles* are the new components added to the genetic system that is the modified Wi-Fi system receiver and transmitter chain. (**a**) The transmitter block diagram of the Wi-Fi system, (**b**) The receiver block diagram of the Wi-Fi system

Table 5 Wi-Fi system parameters

BW	Pilots	Number of data subcarriers	Cyclic prefix	OFDM symbol duration
20 MHz	11, 25, 40, 54	52	16 Samples (0.8 μs)	80 Samples (4 μs)

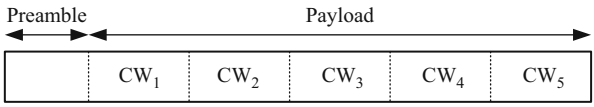

Fig. 11 The structure of a WLAN frame consisting of preamble data and several CWs

LLR value for each encoded bit to the LDPC soft input decoder. Finally, the blocks with red circles represent the new components to be added to the generic Wi-Fi system receiver and transmitter chain, and their role is explained in section "Wi-Fi System Modifications for Interference Mitigation".

Table 5 lists the Wi-Fi system parameters used in this work, consistent with 802.11ac WLAN: a 64 subcarrier OFDM with spacing of 312.5 KHz. The 20 MHz channel has 4(3) guard subcarriers at the left (right) band edge, and the DC (center) subcarrier that are unused. The remaining subcarriers as listed in Table 5 are pilot and data subcarriers. For simulations, the MATLAB 2015 WLAN toolbox [7] is used that implements the IEEE 802.11ac PHY layer, adapted for radar/Wi-Fi coexistence by (a) adding the new elements of the modified Wi-Fi system as described and (b) injecting a suitably modeled pulsed radar signal as additive interference at the Wi-Fi receiver input.

We consider linear frequency modulation (LFM) radar pulse as shown in Fig. 10 with $T_{PRI} = 200\,\mu s$ and pulse duration (T_p) of 4 μs. The LFM radar waveform has sweep frequency of $f_s = 4$ MHz and relative carrier frequency offset of $\Delta f_r = [-4, 4]$ MHz relative to the center of the Wi-Fi channel.

The baseband LFM radar waveform is given by

$$I(t) = Ae^{j(\pi \frac{f_s}{T_p} t + 2\pi \Delta f_r)t} \quad 0 \le t \le T_p. \tag{26}$$

The radar pulse arriving are assumed to hit the payload randomly (we ignore the small probability that it hits the preamble, which is much smaller than the payload as indicated in Fig. 11). The received OFDM symbol at the Wi-Fi receiver under the two hypothesis (radar pulse present or absent) can be written as

$$\begin{aligned} \mathscr{H}_0 &: \text{(W/O Interference) } \mathbf{r}(n) = x_s(n) * h(n) + \mathbf{w}(n) \\ \mathscr{H}_1 &: \text{(W/ Interference) } \mathbf{r}(n) = x_s(n) * h(n) + \mathbf{w}(n) + \mathbf{I}(n), \end{aligned} \tag{27}$$

where **r** is the received data vector at the Wi-Fi receiver input as indicated in Fig. 9b, h is the WLAN channel, **w** is the additive white Gaussian noise vector, **I** is the radar interference vector, x_s is the OFDM modulated signal and $*$ denotes convolution. The modulated signal and noise is assumed to the following the complex normal distribution, i.e.,

$$w \sim CN(0, \sigma_w^2), \qquad x_s \sim CN(0, \sigma_s^2). \tag{28}$$

Hence, the signal to noise ratio (SNR) at the receiver input is calculated as

$$\text{SNR} = 10 \log_{10} \left(\frac{\sigma_s^2}{\sigma_w^2} \right), \tag{29}$$

since the frequency selective channel $h(n)$ is assumed normalized (i.e. $\sum_n |h(n)|^2 = 1$), σ_s^2 is equal to the power of $x_s(n) * h(n)$ at the receiver. The interference to noise ratio (INR) seen at Wi-Fi receiver is thus

$$\text{INR} = 10 \log_{10} \left(\frac{A^2}{\sigma_w^2} \right), \tag{30}$$

where A is the radar signal magnitude.

Exclusion Region Calculation

The numerical results in [18] shows that for a single co-channel Wi-Fi network impacted by continuous wave pulse radar, the effective interference from radar to the Wi-Fi receiver can be calculated as

$$\text{INR}_{eff} = 10 \log_{10} \left(\frac{PWf_R P_T G_w G_{max} l(d)}{N_0 BW} \right), \tag{31}$$

$l(d) = k_0 d^{-\alpha}$ is the path loss model between radar and Wi-Fi receiver [18] and BW is the Wi-Fi channel bandwidth. The other parameters are defined in Table 6. Based on (31), the maximum INR_{eff} from radar to the Wi-Fi receiver at the border of exclusion region (the exclusion region range is 20 Km in the main lobe direction) is computed to be 43.8 dB.

Wi-Fi System Modifications for Interference Mitigation

Pulsed radar interference causes – in general – burst or consecutive error events at the Wi-Fi receiver. As explained in section "WLAN Generic System Architecture", the symbol interleaver just interleaves among the sequence of data corresponding to one OFDM symbol. If the radar pulse impacts the OFDM symbols, it is

Table 6 Wi-Fi and radar parameters for maximum interference calculation

Parameters	Descriptions	Values
PW	Radar pulse width	1.03 (μs)
f_R	Pulse repetition frequency	1115.5
P_T	Radar Tx power	1.32 (MW)
G_w	Wi-Fi antenna gain	2.15 (dBi)
$G_{\max}$	Radar maximum antenna gain	33.5 (dBi)
NF	Noise figure	8 (dB)
k_0	Path loss constant	259
α	Path loss constant	3.97

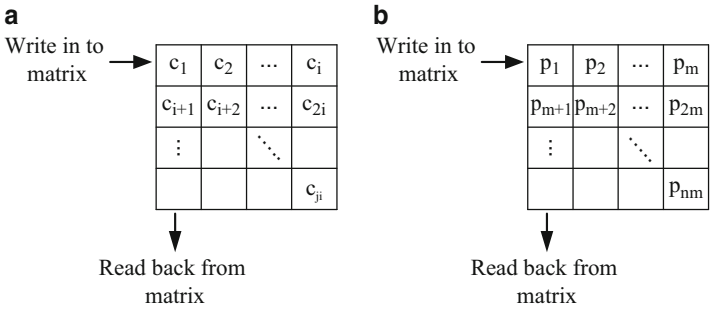

Fig. 12 (**a**) Column CW interleaver. (**b**) Column frame interleaver

typically lost, i.e., results in decoding failure. So a longer interleaver is needed (that interleaves among several OFDM symbols) to distribute the error burst through the frame and potentially mitigate the burst error event. To deal with this problem, a column interleaver/de-interleaver is added to the Wi-Fi transmitter/receiver as illustrated in Fig. 9.

Two types of column interleaving – (i) codeword (CW) interleaving and (ii) frame interleaving are proposed that both interleave over several OFDM symbols, as shown in Fig. 12. In CW interleaver, an LDPC CW is interleaved denoted by the sequence of $C = (c_1, c_2, \ldots, c_{ji})$ and length of $N_{cw} = j \times i$ as follows – it is written row by row into a matrix (N_{cw} = 1944, corresponding to $j = 9$ and $i = 216$) and read back column by column from the matrix as shown in Fig. 12a. To de-interleave, the identical process is conducted at the receiver.

In the frame interleaver, a frame of data is interleaved which consists of several CWs. For example, in the case of modulation and coding scheme (MCS) 4, a frame consists of 5 CWs with the length of 1944 followed by a small set of data to construct a standard size frame. A frame sequence of $P = (p_1, p_2, \ldots, p_{nm})$ and length of $N_p = n \times m$ is written row by row into a matrix (N_p in this case is 9776, n is 52 and m is 188) and read back column by column from the matrix as shown in Fig. 12b. To de-interleave, the same process is performed at the receiver. In CW interleaving, the objective is to distribute the symbols with interfered LLR among a CW so to remove the burst error effect (for MCS4, each CWs consists of almost nine payload

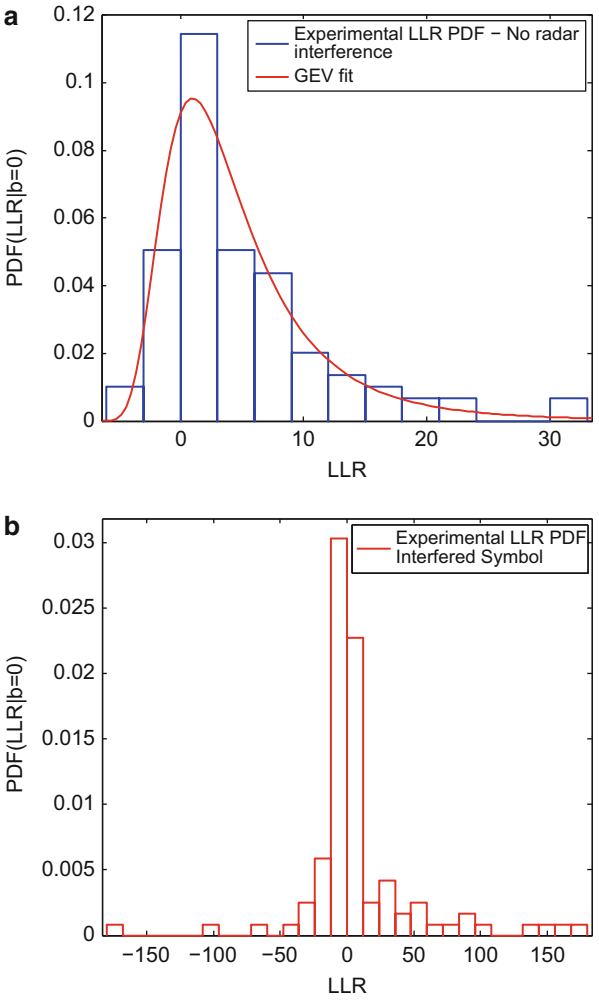

Fig. 13 Conditional LLR PDF of an OFDM symbol interfered by the radar pulse. For (a) the label is "No Radar interference" and for (b) the label is "Radar interference"

OFDM symbols). A frame consists of several CWs (Fig. 11), so frame interleaving distributes the symbols with interfered LLRs over the multiple CWs, and hence the decoder needs to correct for fewer interfered symbols per CW.

Figure 13 compares the conditional distribution of LLR_{in} at the output of demapper in Fig. 9b) for the cases of with and without radar pulse interference, at SNR=15 dB, INR=30 dB and MCS4. In the demapper implementation of MATLAB 2015 WLAN toolbox, the generic LLR calculation for BPSK modulation is done via

$$LLR_d = \log\left(\frac{P(b=0|\hat{X})}{P(b=1|\hat{X})}\right), \tag{32}$$

LLR_d is then multiplied by the channel gain inside the demapper to yield [27],

$$LLR_{in}(l) = |H_{k,l}|^2 LLR_d(l) \tag{33}$$

where $H_{k,l}$ is the (estimated) frequency-domain channel coefficient for kth OFDM symbol in a frame and lth subcarrier ($H_{k,l}$ is assumed constant for all OFDM symbols in a frame, i.e., for different k), $LLR_{in}(l)$ is the LLR for the lth subcarrier after weighting. The distribution of LLR_{in} corresponds to the multiplication of the channel gain represented by a Rayleigh-distributed random variable and LLR_d, represented by a Gaussian distribution. By fitting the experimental LLR_{in} histogram (as illustrated in Fig. 13a), it is observed that the generalized extreme value (GEV) distribution [13] achieves a good fit as can be seen in Fig. 13a. The GEV distribution is given by

$$f(x|k_v, \mu_v, \sigma_v) = \frac{1}{\sigma_v} \exp\left(-\left(1 + k_v \frac{(x-\mu_v)}{\sigma_v}\right)^{-\frac{1}{k_v}}\right)\left(1 + k_v \frac{(x-\mu_v)}{\sigma_v}\right)^{-1-\frac{1}{k_v}}, \tag{34}$$

where the GEV parameters in Fig. 13a are the following: $k_v = 0.2$, $\mu_v = 3.93$, and $\sigma_v = 1.69$.

Figure 13b shows the LLR_{in} for interference due to the radar pulse; most noticeably, it shows significantly larger LLR magnitudes compared with the no interference case. Hence, for a transmitted symbol that is interfered by the radar pulse, the constellation symbol value is superimposed with additive, random interference component with large magnitude. As a result, the LLR calculated in the demapper has a large value either to the left or right of the median in Fig. 13b. Since large LLR values (even if due to an external interference) imply high confidence about the correctness of the bit, the LDPC soft-in decoder cannot recover the transmitted CW as is.

To help the LDPC decoder to recover CW in the presence of large interference, a new LLR mapping function is proposed as shown in Fig. 14, given by

$$LLR_{out} = \begin{cases} Th_{out} \times sign(Th_{in}) & \text{if } |LLR_{in}| >= Th_{in} \\ \frac{Th_{out}}{Th_{in}} \times LLR_{in} & \text{if } |LLR_{in}| < Th_{in} \end{cases} \tag{35}$$

representing a thresholded linear function where Th_{in} – the input threshold – is determined by the *maximum LLR value in the noninterfered OFDM symbols*, i.e., $Th_{in} = th_1 \times \max(LLR)$, and $\max(LLR)$ is calculated based on the noninterfered OFDM symbol. Input LLRs with magnitude larger than Th_{in} map to Th_{out} where $Th_{out} = th_2 \times \max(LLR)$. The slope or gain of the linear region equals $\frac{th_2}{th_1}$, where th_1 and th_2 are selected by searching over a discretized set of values during training phase. Via the thresholding, the LLR to the LDPC decoder is desensitized to large LLR values and can detect instances where large LLRs result due to interference. Thus, smaller LLRs represent either noninterfered symbols or ones

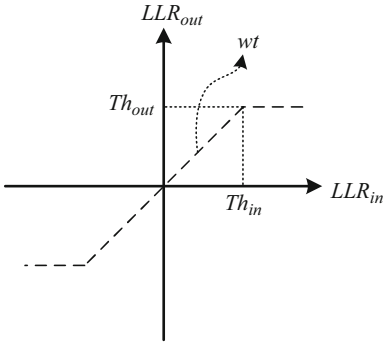

Fig. 14 The LLR mapping function

Table 7 LLR mapping function parameters for the frame interleaving cases

MCS	SNR	th_1, th_2, INR	th_1, th_2, INR
0	4	0.1, 0.001, [−5, 40]	–
0	8	0.05, 0.01, [−5, 40]	–
4	15	0.1, 0.05, [−5, 20]	0.1, 0.01, (20, 40]
4	20	0.01, 0.001, [−5, 40]	–
8	25	0.1, 0.01, [−5, 25]	0.05, 0.001, (25, 40]
8	30	0.01, 0.001, [−5, 40]	–

with small interference; by appropriately weighting them, the mapping function aids the decoding.

Simulation Results for Interference Mitigation

We simulate the modified Wi-Fi system under different MCSs. MCS0 uses BPSK modulation, whereas MCS4 uses 16QAM modulation and MCS8 uses 256QAM modulation. The LDPC code rate for MCS0 is $\frac{1}{2}$ and for the two other MCSs is $\frac{3}{4}$. The maximum number of LDPC decoder iteration is 50. The LDPC iteration is terminated when either the CW is detected or the maximum number of iteration is reached. For each frame error rate (FER) point in the figures, 2500 frames were used in simulation. The parameter values selected for the LLR mapping function (contained in Table 7) are chosen to yield low FER in the different scenarios; in general, the choice of (th_1, th_2) are seen to depend (mildly) on both the SNR and INR in some cases.

Figure 15 illustrates the performance of the Wi-Fi system interfered with the co-channel radar interference in comparison with the modified Wi-Fi system for MCS0. When the interference mitigation is not performed, the FER increases very rapidly as the INR increases even at high SNR case (e.g., SNR=8 dB). The modified Wi-Fi system shows a better FER performance compared with the no-mitigation system. In this figure, the FER performances of the system with CW interleaver and frame interleaver are almost the same and follow a flat curve under the no-mitigation

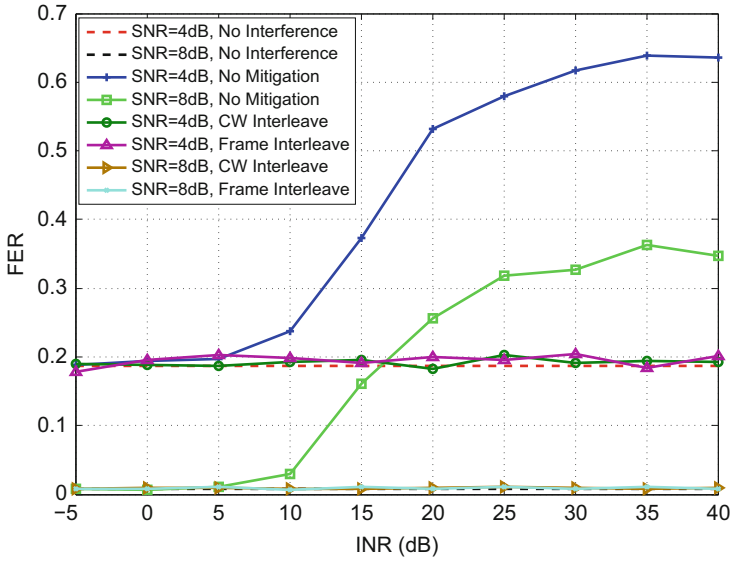

Fig. 15 FER comparison of the Wi-Fi system without interference mitigation and a modified Wi-Fi system for two different cases of CW interleave and frame interleave at MCS0

Wi-Fi system curve. In MCS0 the number of interfered coded bits is relatively small compared with the CW length because of the fewer number of bits in one OFDM symbol, so smaller column interleaver like CW interleaver is enough for mitigating the radar interference burst effect.

Figure 16 compares the performance of the Wi-Fi systems at MCS4. When the interference mitigation is not performed, the FER increases much faster in MCS4 compared with the MCS0. It implies that the radar interference has a greater (deteriorating) effect at higher MCSs. The modified receiver shows a very good FER performance compared with the no-mitigation system. When the total frame is interleaved, the FER curves remain below the no-mitigation curves for all of the INR values. In the CW interleave case, the FER is higher than the no-mitigation case for small INR values (especially at 15 dB SNR curve). Also, there is an (expected) FER gap between the CW interleave and frame interleave cases; by interleaving a frame, the incorrect interfered LLRs are distributed among multiple CWs, so the decoder needs to deal with fewer corrupted LLRs. At higher SNR, the gap between the CW interleave and frame interleave curves is smaller because fewer error happens anyway, so each LDPC CW has fewer corrupted LLRs for correction. The performance of the modified system compared with the system without interference mitigation for MCS8 is also illustrated in Fig. 17 as a benchmark. The FER curve for the modified system is flat (insensitive to INR) and very close to the "no-interference" curve, suggesting that the modified Wi-Fi receiver can completely mitigate the radar interference.

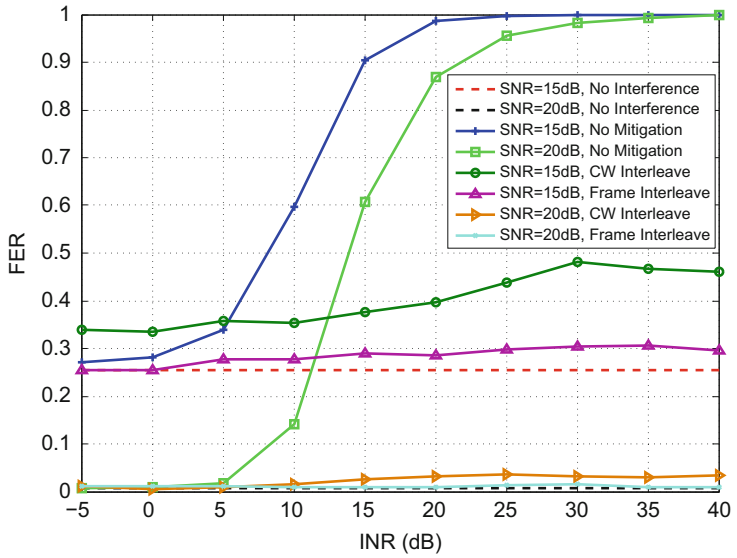

Fig. 16 FER comparison of the Wi-Fi system without interference mitigation and a modified Wi-Fi system for two different cases of CW interleave and frame interleave at MCS4

Radar Pulse Detection During Wi-Fi Transmission

Interference mitigation requires accurate radar pulse detection first. Generic approaches proposed in the literature include energy-based detection (that does not require any knowledge of the radar pulse shape) or some feature-based detection schemes such as cyclostationary and autocorrelation-based sensing [11, 20, 23]. Specifically for OFDM transmission, signal detectors using embedded pilots were proposed in [12]. In [11], cyclic prefix (CP)-based autocorrelation detection is considered, and cyclostationary-based detection proposed in [26]. Following the above, two detection approaches are proposed: (a) CP-based autocorrelation detector and (b) frequency domain data subcarrier detector.

(a) CP is inherent in 802.11 WLAN modulation in an OFDM symbol (by repeating the trailing samples as prefix data) to combat ISI for a frequency selective channel. Thus at the receiver, there is a high correlation between prefix data samples and those at the end of OFDM symbol. When a symbol is interfered by a radar pulse, it decreases the correlation between these two pieces of an OFDM symbol, which can be used as a criterion to detect the presence of radar interference.
(b) Spectral shape of the radar pulse in frequency domain may also be used for OFDM subcarrier based detector. The interference in the frequency domain is spectrally limited to subset of the OFDM subcarriers; thus, the energy concentrated in a portion of the impacted subcarriers compared to the rest provides another heuristic for improved radar pulse detection.

Conclusion and Future Directions

In this chapter, the statistical properties of randomly occurring quiet periods in Wi-Fi networks for the purposes of radar detection using DFS in a Wi-Fi/radar coexistence scenario was first studied. In many circumstances, these random quiet periods occur with sufficient frequency to provide some statistical guarantees for in-service radar detection, especially in the regions close to the radar that are designated as exclusion or no-transmit zones. An intelligent method to adjust Wi-Fi parameters is proposed in order to achieve the desired protection for the radar while attaining acceptable throughput. Lastly, it is shown that modifying the payload duration is the most effective adjustment for Wi-Fi to speedily detect radars and provide adequate in-service protection.

Next, the Wi-Fi transmitter/receiver chains were modified to enable the coexistence of WLAN and radar by mitigating the radar interference. The impact of radar interference on the generic Wi-Fi system and the modified Wi-Fi system was studied in terms of FER. The simulation results show that by a relatively small modification to the Wi-Fi system, the FER performance is significantly improved; the modified Wi-Fi system can perform at very high INR.

As a final step, it is clear that in order to mitigate radar interference, accurate radar (pulse) detector is required. This suggests a path for future extension of this work. Radar pulse detection has focused thus far on detecting a single pulse; however, in almost all cases, radar sources emit a pulse burst, which provides significant potential for further improvement if this property were to be suitably exploited.

Abstract

Wireless transmission using non-contiguous chunks of spectrum is becoming increasingly important due to a variety of scenarios such as secondary users avoiding incumbent users in TV white space, anticipated spectrum sharing between commercial and military systems, and spectrum sharing among uncoordinated interferers in unlicensed bands. multichannel multi-radio (MC-MR) platforms and non-contiguous orthogonal frequency division multiple access (NC-OFDMA) technology are the two commercially viable transmission choices to access these non-contiguous spectrum chunks. Fixed MC-MRs do not scale with increasing number of non-contiguous spectrum chunks due to their fixed set of supporting radio front ends. NC-OFDMA allows nodes to access these non-contiguous spectrum chunks and put null subcarriers in the remaining chunks. However, nulling subcarriers increases the sampling rate (spectrum span) which, in turn, increases the power consumption of radio front ends. Our work characterizes this trade-off from a cross-layer perspective, specifically by showing how the slope of ADC/DAC's power consumption versus sampling rate curve influences scheduling decisions in a multi-hop network. Specifically, we provide a branch and bound algorithm-based mixed integer linear programming solution that performs joint power control, spectrum span selection, scheduling, and routing in order to minimize the system power of multi-hop NC-OFDMA networks. We also provide a low-complexity ($O(E^2M^2)$) greedy algorithm where M and E denote the number of channels and links, respectively. Numerical simulations suggest that our approach reduces system power by 30% over classical transmit power minimization based cross-layer algorithms.

Introduction

Demand for wireless services is becoming much greater than the currently available spectrum [22]. FCC has already opened up 300 MHz in TV bands [6] and plans to open up an additional 500 MHz by 2020 [14] to meet this demand. Any radio can use these channels if it abides by FCC specifications [14]. If uncoordinated networks (e.g., different broadband wireless service providers) use these channels, they will adjust spectrum usage according to their individual traffic demands. Available spectrum will become partitioned into a set of non-contiguous segments. For some bands, like white space [6], available spectrum itself is non-contiguous.

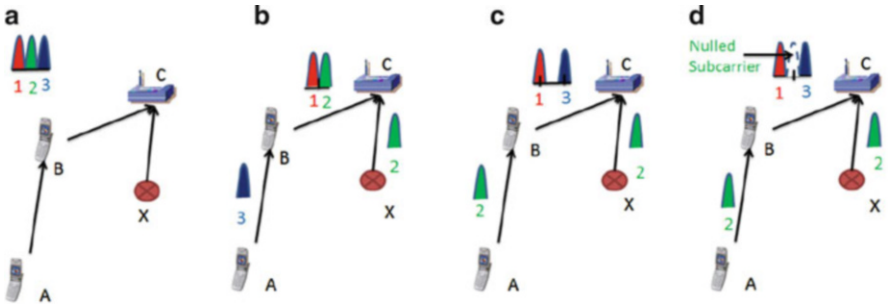

Fig. 1 Motivation of non-contiguous spectrum access. (**a**) Three node network. (**b**) Contiguous OFDMA implementation. (**c**) MC-MR implementation. (**d**) NC-OFDMA implementation

Multichannel multi-radio (MC-MR) technology allows nodes to simultaneously access multiple fragmented spectrum chunks [24, 25]. However, the number of non-contiguous spectrum chunks that fixed MC-MR can access is limited by the number of available radio front ends, which is often constrained due to the size and power limitations of the transmission device [16]. Software defined radio-based non-contiguous orthogonal frequency division multiple access (NC-OFDMA) technology allows nodes to transmit in these non-contiguous spectrum chunks with a single radio front end. Nodes can null interference-limited subcarriers and select better channels in NC-OFDMA-enabled networks. Hence, NC-OFDMA has grabbed a lot of attention in resource allocation [34–36], cooperative forwarding [21,38], and experimental research [39, 40]. However, nulling unwanted channels increases the spectrum span and the sampling rate of nodes.

Figure 1 illustrates the benefits and inherent challenges of NC-OFDMA using the example of a two-hop network. Figure 1a shows a two-hop network where node A transmits to node C via node B; node B relays node A's data and also transmits its own data to node C. Channel 1, 2, and 3 are available channels, and let us assume, without loss of generality, that transmission on any of these channels results in identical signal quality. Node X, an external and uncontrollable interferer, transmits in channel 2. If we want to minimize the maximum rate between node A and B and allocate channels accordingly, node B will require two channels and node A will require one channel. There are three possible techniques/configurations to allocate the three available channels as shown in Fig. 1b–d. Figure 1b shows contiguous OFDMA that suffers from interference in link BC at channel 2. Figure 1c shows MC-MR that requires two radio front ends to capture channels 1 and 3 in link BC. Figure 1d shows NC-OFDMA that uses only one radio front end, transmits at channels 1, and 3 and nulls channel 2. However, due to the nulling of channel 2, NC-OFDMA spans three channels, instead of two.

It is well known that the circuit power consumption of ADC and DAC increases linearly and exponentially with sampling rate and the number of quantization bits, respectively [3, 9]. As software defined radios continue to improve their higher quantization resolution, the ADC and DAC that are used in the radio circuits will

dominate the amount of power consumption. A comparison between Tables 1 and 2 shows that the power consumption of some commercial ADCs is more than 10 dB higher than the maximum allowed transmission power for portable devices in the 802.22 standard. On the one side, NC-OFDMA reduces transmission power by selecting channels with better link gains, while on the other side, this increased spectrum span increases circuit power consumption of the transceiver. In this chapter, we investigate this trade-off between transmission power reduction and circuit power increase in the context of cross-layer optimization of NC-OFDMA-based wireless networks.

Specifically, we ask the following question in this work: *How can single front-end radio-based nodes of a multi-hop network access non-contiguous spectrum chunks?* We investigate this question from a system power perspective and find that *scheduling a small subset of channels may outperform traditional transmit power minimization based approaches – which allocate power across all "good" channels – since it consumes less circuit power.* Our algorithm selects scheduling variables based on the slope of ADC and DAC power consumption versus sampling rate curves. Figure 2a, b the power consumption versus sampling rate curves of some commercial DACs and ADCs, respectively. These figures show that the slope of the

power consumption curve varies from device to device. We show two special subcases of our finding based on the slope of the curves. We find that if the curves are almost flat, our algorithm converges to the transmission power minimization-based scheduling algorithms. If the curves are very steep, our algorithm selects the channel with the highest link gain. For commercial ADC & DACs, whose slopes lie between these two extreme cases, our algorithm selects channels to minimize the summation of transmit and circuit powers of the network.

In general, we provide a branch and bound algorithm-based mixed integer linear programming solution that performs joint power control, spectrum span selection, scheduling, and routing and minimizes system power of multi-hop NC-OFDMA networks. We also provide a greedy algorithm that runs in $O(E^2M^2)$ time where E and M denote the number of links and channels, respectively. *To the best of our knowledge, ours is the first work that shows how the slope of ADC/DAC's power consumption curve influences the scheduling decisions of a multi-hop network*. Numerical simulations suggest that our approach reduces system power by 30% over classical transmission power minimization-based cross-layer algorithms.

Related Work

The authors of [24, 25] characterized the capacity region of an MC-MR-based multi-hop network. The authors of [34,36] focused on software-defined radio-based multi-hop networks and performed cross-layer optimization using a protocol and signal-to-interference-plus-noise-ratio model, respectively. Shi and Hou extended the work of [34] and provided a distributed algorithm in [35]. None of these works considered circuit power and addressed how non-contiguous spectrum access influences cross-layer decisions.

Consideration of system power has been gaining attention in energy-efficient wireless communication literature [27]. Cui et. al. focused on system energy constrained modulation optimization in [9]. Sahai et. al. investigated system power consumption – especially decoder power consumption – in [18]. Isheden and Fettweis assumed circuit power to be a linear function of the data rate [20]. All these works focused on single transceiver pair. Our approach differs from these works in the following way: in NC-OFDMA technology, ADC and DAC consume power not only for used channels (i.e., transmitted data) but also for nulled channels. Our work considers the power consumption related to spectrum span and investigates the performance of NC-OFDMA-based multi-hop networks.

The impact of hardware constraints on the performance of NC-OFDMA networks was previously raised in [5, 23]. The authors of [23] performed cross-layer resource allocation when each node's maximum spectrum span is limited by its ADC/DAC. The authors of [5] investigated how the size of the guard band, required to reduce cross-band interference, affects the performance of NC-OFDMA-based distributed transceiver pairs. Our work uses system power to investigate the performance of NC-OFDMA-based multi-hop networks.

Periodic nonuniform sampling (PNS) can recover a sparsely located non-contiguous signal with sub-Nyquist sampling rate [28] and potentially reduce the power consumption of the ADC circuits. However, PNS requires Nyquist rate circuitry at track-and-hold stages. PNS also needs compensation for imperfect production of the time delay elements. As a result, PNS is not widely used by industry to access non-contiguous spectrum [30]. Our work focuses on the system power minimization of an NC-OFDMA network that uses commercial ADCs and DACs with Nyquist sampling rate to access non-contiguous spectrum.

Time and frequency mismatch affect an NC-OFDMA network more severely due to its use of a large number of nulled subcarriers. Several researchers have implemented different techniques to reduce interference between unsynchronized NC-OFDMA nodes. The authors of [39] have used adaptive multibank stop-band filters to reduce interference of unwanted channels. The authors of [40] have used wider guard bands to reduce leakage power into neighboring channels. We do not focus on synchronization techniques and test bed implementation of NC-OFDMA nodes in our work. Interested readers are suggested to go through [19, 39–41] to understand the implementation and synchronization details of NC-OFDMA.

The remainder of the chapter is organized as follows: section "System Model" presents system power and multi-hop network model. Section "Branch-and-Bound Based Solution Overview" provides a branch and bound-based solution of the optimization problem. We present theoretical insights of our algorithm in section "Low-Complexity Algorithm Design" and a low-complexity algorithm in section "Polynomial Time Algorithm for a Multi-hop Networks." After showing numerical results in section "Simulation Results," we conclude in section "Conclusion."

System Model

System Power Model

We assume that baseband signal processing techniques like multiuser detection and iterative decoding are not employed in the system. In this context, power consumption in the baseband is negligible compared with that in the radio frequency (RF) circuitry [29]. Each radio node has two front ends: one for transmission and the other for reception. Nodes are half-duplex, i.e., they can simultaneously transmit and receive using these two front ends but not in the same channel.

Figure 3 shows signal level blocks in the transmitter and receiver. At the transmitter, the baseband digital signal goes through DAC, filters, mixer (where it gets multiplied by the local oscillator (LO)), and programmable amplifier (PA) before reaching transmitter antenna. The received signal at the antenna goes through low-noise amplifiers (LNA), filters, mixer, intermediate-frequency amplifier (IFA), and ADC to reach the baseband circuit [9].

Typically, transceiver circuits work on a multimode basis. When there is a signal to transmit, all RF circuits work in active mode; when there is no signal to transmit,

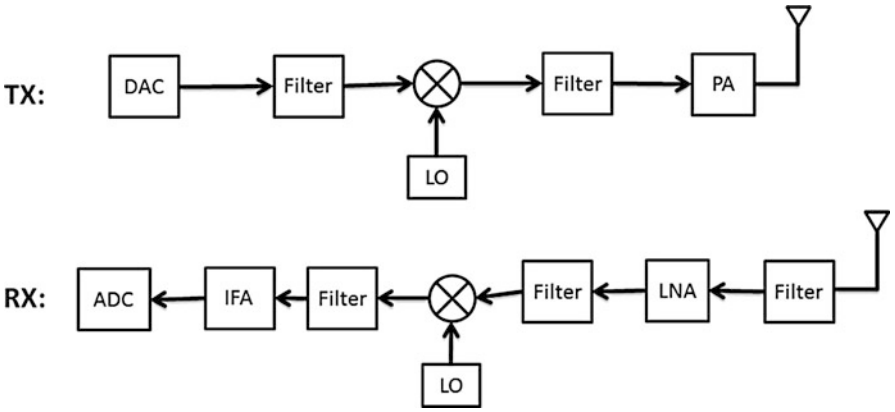

Fig. 3 Radio front-end circuit blocks (Reproduced from [9])

all RF circuits remain in sleep mode; circuits switch from sleep to active mode through transient mode [9]. Here, we focus on system power minimization of all RF circuits in the active mode. Let p_t, p_r and p denote active mode power consumption of transmitter and receiver and transmitter's emitted power at radio frequency, respectively. Now,

$$p_t = \frac{PAPR}{\eta} p + p_{tc}, \quad p_r = p_{rc}. \tag{1}$$

where $PAPR$ and η denote the peak-to-average-power ratio (PAPR) and drain efficiency of the programmable amplifier. $\frac{PAPR}{\eta} p$ denote the total power consumption of programmable amplifier [9]. Also, p_{tc} and p_{rc} are the circuit power consumption of transmitter (excluding programmable amplifier's power consumption) and receiver, respectively.

The power consumption at almost all blocks of the radio front end, except ADC and DAC, does not depend on sampling rate [9, 26]. The power consumption of ADC and DAC is affine functions of the sampling rate [3,9]. Denoting $k_{pa} = \frac{PAPR}{\eta}$, system power consumption in the transmitter and receiver front end become

$$p_t = \alpha_1 + \alpha_2 f_{st} + k_{pa} p. \tag{2}$$

$$p_r = \beta_1 + \beta_2 f_{sr}. \tag{3}$$

In the above, f_{st} and f_{sr} are the sampling rates of the transmitter and receiver path. α_1, α_2, β_1 and β_2 are constants that depend on the power consumption of different blocks. Appendix Power Consumption of Different Blocks in Transmitter and Receiver describes the power consumption of each block in details. Table 3 shows the list of notations that we have used throughout the chapter.

Table 3 List of notations

Notation	Description
$\mathscr{N}$	Set of nodes
N	Total number of nodes
$\mathscr{E}$	Set of edges
E	Total number of edges
$\mathscr{L}$	Set of sessions
L	Total number of sessions
$(s(l), d(l))$	Source and destination of session l
$r(l)$	Rate requirements of session l
W	Bandwidth of each channel
N_0	Noise spectral density
$f_{ij}^m(l)$	Flow on link ij in channel m for session l
c_{ij}^m	Capacity on link ij in channel m
s_{ij}^m	Signal-to-noise ratio on link ij in channel m
M	Total number of channels
$\mathscr{M}$	Set of all available channels across all nodes
$\mathscr{M}_i$	Set of available channels in node i
P_I	Interference threshold
$\mathscr{M}_{ij}$	Set of available channels between node i and j
M	Total number of available channels
g_{ij}^m	Link gain of ij in channel m
$p_{ij,m}$	Allocated power between i and j in channel m
x_{ij}^m	If link ij uses channel m
$x_i^{t,m}$	If node i uses channel m for transmission
$x_i^{r,m}$	If node i uses channel m for reception
$q_{t,i}$	Spectrum span of the transmitter path of node i
$q_{r,i}$	Spectrum span of the receiver path of node i
$f_{st,i}$	Sampling rate of node i's transmitter path
$f_{sr,i}$	Sampling rate of node i's receiver path
$f_{s,\max}$	Maximum allowed sampling rate of the nodes
$P_{s,\max}$	Maximum allowed system power consumption
A	An arbitrary large number

Multi-hop Cross-Layer Model

We consider a multi-hop network with a set of $\mathscr{N}$ cognitive radio nodes. Let $\mathscr{M}$ denote the set of all available channels. Bandwidth of each channel is W.

Power Control and Scheduling Constraints

The number of available channels may vary in different (spatial) parts of the network due to interference and other spectrum constraints such as primary users and systems. Hence, we focus on frequency scheduling. Denote the binary scheduling decision x_{ij}^m as follows:

$$x_{ij}^m = \begin{cases} 1, & \text{if node } i \text{ transmits to node } j \text{ using channel } m. \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

Due to self-interference, node i can use channel m only for receiving from node k or transmitting to node j. In other words:

$$\sum_{j \in \mathcal{N}, j \neq i} x_{ij}^m + \sum_{k \in \mathcal{N}, k \neq i} x_{ki}^m \leq 1 \quad \forall\, i \in \mathcal{N}\,,\ \forall\, m \in \mathcal{M}_i\,. \tag{5}$$

We use protocol interference model. Assume that node i transmits to node j in channel m, i.e., $x_{ij}^m = 1$. Let p_{ij}^m and g_{ij}^m denote the transmission power and channel gain in channel m of link ij. Let P_I denote the interference threshold. P_I should be chosen in such a way so that it is negligible compared to the noise power $N_0 W$ where N_0 is the noise spectral density. Another node k can transmit to node h in channel m if p_{kh}^m causes negligible interference in node j. Hence,

$$p_{kh}^m \leq \frac{P_I}{g_{kj}^m} x_{ij}^m \ \forall (k,h) \in \mathcal{N},\ k \neq i,\ h \neq j. \tag{6}$$

Also, a node can allocate power in a link only if it is scheduled, i.e.,

$$p_{ij}^m \leq A x_{ij}^m \ \forall\, (i\,,\, j\ \in \mathcal{N})\,,\ m \in \mathcal{M}\,. \tag{7}$$

Here, A is a big number that couples power control and scheduling variables.

Routing and Link Capacity Constraints

Let $\mathcal{L}$ be the set of active sessions and $|\mathcal{L}| = L$. Let $s(l)$, $d(l)$, and $r(l)$ denote the source node, destination node, and minimum rate requirements of session l. Let $f_{ij}^m(l)$ denote the flow from node i to node j in channel m for session l. If i is the source (destination) node of session l, the total outgoing (incoming) flow from (to) node i should exceed the minimum rate requirements of session l, i.e.,

$$\sum_{j \in \mathcal{N}} \sum_{m \in \mathcal{M}_{ij}} f_{ij}^m(l) \geq r(l) \quad (l \in \mathcal{L}\,,\ i = s(l)). \tag{8}$$

$$\sum_{k \in \mathcal{N}} \sum_{m \in \mathcal{M}_{ki}} f_{ki}^m(l) \geq r(l) \quad (l \in \mathcal{L}\,,\ i = d(l)). \tag{9}$$

The incoming flow of session l should match the outgoing flow in an intermediate node i:

$$\sum_{j \in \mathcal{N}}^{j \neq s(l)} \sum_{m \in \mathcal{M}_{ij}} f_{ij}^m(l) = \sum_{k \in \mathcal{N}}^{k \neq d(l)} \sum_{m \in \mathcal{M}_{ki}} f_{ki}^m(l) \ \forall\, (l \in \mathcal{L},\ i \in \mathcal{N},\ i \neq s(l), d(l)). \tag{10}$$

Additionally, the aggregated flows of all sessions in a particular link should not exceed the capacity of the link. Therefore,

$$\sum_{l\in\mathscr{L}}^{s(l)\neq j\,,\,d(l)\neq i} f_{ij}^{m}(l) \leq c_{ij}^{m}\ (i\,,\,j\ \in\mathscr{N}\,,\,i\neq j\,,\,\forall\, m\ \in\mathscr{M}_{ij}\,,\,\mathscr{M}_{ij}\neq\emptyset). \tag{11}$$

where

$$c_{ij}^{m} \leq W\log(1+s_{ij}^{m})\ \ (i\,,\,j\ \in\mathscr{N}\,,\,i\neq j), \tag{12}$$

$$s_{ij}^{m} = \frac{g_{ij}^{m}\,p_{ij}^{m}}{N_0 W},\ \ (i\,,\,j\ \in\mathscr{N}\,,\,i\neq j). \tag{13}$$

In the above, c_{ij}^{m} and s_{ij}^{m} denote the capacity and signal-to-noise ratio in link ij of channel m. The denominator of s_{ij}^{m} only contains $N_0 W$ because (6) ensures that the interference from other nodes is negligible compared to the noise power.

The constraints described above resemble previous works that focus on *transmission power* based cross-layer optimization (i.e., power control, scheduling and routing). The novelty of the work here is in relating the hardware constraints imposed by the radio front end to the above cross-layer optimization as we describe next.

System Power Constraints

Let $p_{t,i}$ and $p_{r,i}$ denote the system power consumption in the transmitter and receiver path of node i. The total system power consumption, P_{tot}, is:

$$P_{\text{tot}} = \sum_{i\in\mathscr{N}}\left(p_{t,i}+p_{r,i}\right). \tag{14}$$

Equations (2) and (3) show a radio node also contains a fixed amount of power (independent of sampling rate) if it transmits or receives in a channel. Denoting α_{1_i} and β_{1_i} as this fixed power consumption of node i's transmit and receive path respectively, we find,

$$\alpha_{1_i} \geq \alpha_1 x_{ij}^{m}\ \ \forall m\in\mathscr{M}_{ij},\ j\in\mathscr{N},\ i\in\mathscr{N}, \tag{15}$$

$$\beta_{1_i} \geq \beta_1 x_{ki}^{m}\ \ \forall m\in\mathscr{M}_{ij},\ k\in\mathscr{N}\ i\in\mathscr{N}. \tag{16}$$

Using (2), (3), (14), (15) and (16),

$$\sum_{i\in\mathscr{N}}\left(\alpha_{1_i}+\alpha_2 f_{st,i}+\sum_{j\in\mathscr{N}}\sum_{m\in\mathscr{M}_{ij}} k_{pa}\,p_{ij}^{m}+\beta_{1_i}+\beta_2 f_{sr,i}\right) = P_{\text{tot}}, \tag{17}$$

where $f_{st,i}$ and $f_{sr,i}$ denote the sampling rates in the transmitter and receiver of node i.

The constraints introduced so far involve channel scheduling decisions and sampling rate of different nodes. We now show how channel scheduling decisions influence the sampling rate of the nodes, which in turn influences the total system power.

Relation Between Channel Scheduling and System Power

The sampling rate of a transceiver depends on its spectrum span, which in turn is determined by the choice of channels selected for its intended transmission.

Let $x_i^{t,m}$ and $x_i^{r,m}$ denote the following:

$$x_i^{t,m} = \begin{cases} 1, & \text{if } i \text{ transmits to any node } j \in \mathcal{N} \text{ in channel } m. \\ 0, & \text{otherwise.} \end{cases}$$

$$x_i^{r,m} = \begin{cases} 1, & \text{if } i \text{ receives from any node } j \in \mathcal{N} \text{ in channel } m. \\ 0, & \text{otherwise.} \end{cases}$$

In other words,

$$\begin{aligned} x_i^{t,m} &\geq x_{ij}^m \ \forall\, j \in \mathcal{N}, \\ x_i^{r,m} &\geq x_{ki}^m \ \forall\, k \in \mathcal{N}, \end{aligned} \tag{18}$$

Using this notation, analog power equations of (15) and (16) are redefined as

$$\alpha_{1_i} \geq \alpha_1 x_i^{t,m}, \quad \beta_{1_i} \geq \beta_1 x_i^{r,m}, \ \forall m \in \mathcal{M}_i, \ \forall i \in \mathcal{N}. \tag{19}$$

We define spectrum span as the gap between the furthest edges of the used channels. Node i's uppermost used channel index in the transmitter path is

$$\max_{m \in \mathcal{M}_i} m \cdot x_i^{t,m}. \tag{20}$$

Node i's lowermost used channel index in the transmitter path is

$$\min_{m \in \mathcal{M}_i} \left(m \cdot x_i^{t,m} + |M| \cdot (1 - x_i^{t,m}) \right). \tag{21}$$

The second term of (21) ensures that we do not consider the index i's for which $x_i^{t,m} = 0$. Let $q_{t,i}$ and $q_{r,i}$ denote the spectrum spans of the transmitter and receiver path of node i. Now,

$$q_{t,i} = W \cdot \max\left(\left(\max_{m \in \mathcal{M}_i} \left(m \cdot x_i^{t,m} \right) - \min_{m \in \mathcal{M}_i} \left(m \cdot x_i^{t,m} + |M| \cdot (1 - x_i^{t,m}) \right) + 1 \right), 0 \right). \tag{22}$$

$$q_{r,i} = W \cdot \max\left(\left(\max_{m \in \mathcal{M}_i} \left(m \cdot x_i^{r,m} \right) - \min_{m \in \mathcal{M}_i} \left(m \cdot x_i^{r,m} + |M| \cdot (1 - x_i^{r,m}) \right) + 1 \right), 0 \right). \tag{23}$$

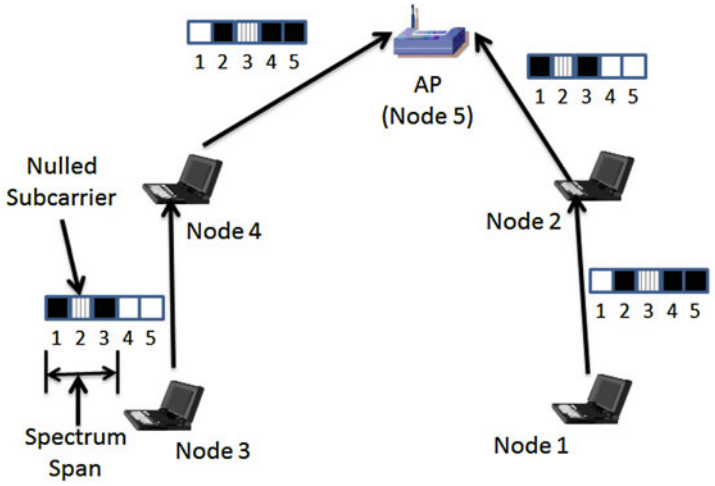

Fig. 4 Spectrum span, occupied, and nulled subcarrier in an NC-OFDMA-based multi-hop network. *Black solid, lined ash,* and *white boxes* denote occupied, nulled, and un-spanned subcarriers, respectively. Spectrum span is the summation of occupied and nulled subcarriers

Figure 4 illustrates the concept of spectrum span in a five node multi-hop network. We now verify (20), (21), (22) and (23) by focusing on the spectrum span of node 3 of Fig. 4. There are 5 available channels. Node 3 transmits in channels 1 and 3 and nulls channel 2. Node 3 does not receive in any channel from other nodes. Hence,

$$\mathscr{M} = \{1, 2, 3, 4, 5\}\,,\; x_3^{r,m} = 0\;\forall\, m \in \mathscr{M},$$

$$x_3^{t,m} = 1\;\forall m \in \{1, 3\}\,,\; x_3^{t,m} = 0\;\forall m \in \{2, 4, 5\}.$$

Using the values of $\mathscr{M}$, $x_3^{r,m}$ and $x_3^{t,m}$ in (22) and (23), $q_{r,3} = 0$ and $q_{t,3} = 3W$. Figure 4 shows that node 3 does not receive from any node and spans three channels while transmitting to node 4.

Now, using (19), (22) and (23), along with the fact that sampling rate of a transceiver should be at least twice its spectrum span, we convert (17) to the following:

$$\sum_{i\in\mathscr{N}}\left(\alpha_{1_i} + 2\alpha_2 q_{t,i} + \sum_{j\in\mathscr{N}}\sum_{m\in\mathscr{M}_{ij}} p_{ij}^m + \beta_{1_i} + 2\beta_2 q_{r,i}\right) = P_{\text{tot}}. \tag{24}$$

Equations (19), (22), (23), and (24) relate total system power to the scheduling variables.

In this work, our objective is to minimize the total system power subject to rate requirements. Using the above equations, we formulate our optimization problem and show it in (25).

$$\min \quad P_{\text{tot}} \tag{25a}$$

$$s.t. \sum_{j\in\mathcal{N}} \sum_{m\in\mathcal{M}_{ij}} f_{ij}^{m}(l) \geq r(l) \quad (l \in \mathcal{L}\,,\, i = s(l)) \,,\, \sum_{k\in\mathcal{N}} \sum_{m\in\mathcal{M}_{ki}} f_{ki}^{m}(l) \geq r(l)$$

$$(l \in \mathcal{L}\,,\, i = d(l)). \tag{25b}$$

$$\sum_{j\in\mathcal{N}}^{j\neq s(l)} \sum_{m\in\mathcal{M}_{ij}} f_{ij}^{m}(l) = \sum_{k\in\mathcal{N}}^{k\neq d(l)} \sum_{m\in\mathcal{M}_{ki}} f_{ki}^{m}(l) \;\; (l \in \mathcal{L},\, i \in \mathcal{N},\, i \neq s(l), d(l)). \tag{25c}$$

$$\sum_{l\in\mathcal{L}}^{s(l)\neq j\,,\, d(l)\neq i} f_{ij}^{m}(l) \leq c_{ij}^{m} \;\; (i\,,\, j \;\in \mathcal{N}\,,\, i \neq j\,,\, \mathcal{M}_{ij} \neq \emptyset). \tag{25d}$$

$$c_{ij}^{m} \leq W \log(1 + s_{ij}^{m}) \;\; (i\,,\, j \;\in \mathcal{N}\,,\, i \neq j) \,,\; s_{ij}^{m} = \frac{g_{ij}^{m} p_{ij}^{m}}{N_0 W},\; (i\,,\, j \;\in \mathcal{N}\,,\, i \neq j). \tag{25e}$$

$$p_{kh}^{m} \leq \frac{P_I}{g_{kj}} x_{ij}^{m} \;\forall\, k \in \mathcal{N},\, h \in \mathcal{N},\, k \neq h \;,\; p_{ij}^{m} \leq A x_{ij}^{m} \;\forall\, (i\,,\, j \;\in \mathcal{N})\,,\, m \in \mathcal{M}. \tag{25f}$$

$$q_{t,i} \geq W \cdot \Big(\max_{m\in\mathcal{M}_i} \big(m \cdot x_i^{t,m}\big) - \min_{m\in\mathcal{M}_i} \big(m \cdot x_i^{t,m} + |M| \cdot (1 - x_i^{t,m})\big) + 1\Big). \tag{25g}$$

$$q_{r,i} \geq W \cdot \Big(\max_{m\in\mathcal{M}_i} \big(m \cdot x_i^{r,m}\big) - \min_{m\in\mathcal{M}_i} \big(m \cdot x_i^{r,m} + |M| \cdot (1 - x_i^{r,m})\big) + 1\Big). \tag{25h}$$

$$\alpha_{1_i} \geq \alpha_1 x_i^{t,m} \,,\quad \beta_{1_i} \geq \beta_1 x_i^{r,m} \;\; \forall m \in \mathcal{M}_i \;\forall i \in \mathcal{N}. \tag{25i}$$

$$\sum_{j\in\mathcal{N}\,,j\neq i} x_{ij}^{m} + \sum_{k\in\mathcal{N}\,,k\neq i} x_{ki}^{m} \leq 1 \quad \forall\, i \in \mathcal{N}\,,\, \forall\, m \in \mathcal{M}_i. \tag{25j}$$

$$\sum_{i\in\mathcal{N}} \Big(\alpha_{1_i} + 2\alpha_2 q_{t,i} + \sum_{j\in\mathcal{N}} \sum_{m\in\mathcal{M}_{ij}} p_{ij}^{m} + \beta_{1_i} + 2\beta_2 q_{r,i}\Big) \leq P_{\text{tot}}. \tag{25k}$$

$$x_{ij}^{m} \in \{0, 1\}\,,\, s_{ij}^{m} \geq 0 \;\; (i, j \in \mathcal{N},\, i \neq j,\, m \in \mathcal{M}_{ij})\,,\; q_{t,i} \geq 0,\, q_{r,i} \geq 0 \;\forall i \in \mathcal{N}. \tag{25l}$$

$$P_{\text{tot}}\,,\, f_{ij}^{m}(l)$$

$$\geq 0 \,\big(l \in \mathcal{L}, m \in \mathcal{M}_{ij},\, i, j \in \mathcal{N},\, i \neq j,\, i \neq d(l),\; j \neq s(l),\, \mathcal{M}_{ij} \neq \emptyset\big). \tag{25m}$$

Next two sections provide solution methodologies of (25).

Branch-and-Bound Based Solution Overview

Linearization of the Optimization Problem

The optimization problem of (25) is a mixed integer nonlinear program (MINLP). The nonlinearity of (25) comes from the logarithm function of (25e) and max-min functions of (25g) and (25h).

The logarithmic function of the capacity term in (25e) can be linearized by reformulation linearization technique (RLT) [33]. RLT uses a number of tangential supports at different points of the logarithmic curve and generates a convex hull linear relaxation of the logarithmic function. We ask interested readers to go through [33] for the details of RLT.

The max-min equations of (22) and (23) can be rewritten in following linear forms:

$$\begin{aligned} & q_{t,i} + W\left(m_2 \cdot x_i^{t,m_2} + |M| \cdot (1 - x_i^{t,m_2})\right) \\ & \geq W\left(m_1 \cdot x_i^{t,m_1} + 1\right) \ \forall (m_1, m_2) \in \mathscr{M}_i \,, \ \forall i \in \mathscr{N}. \end{aligned} \tag{26}$$

$$\begin{aligned} & q_{r,i} + W\left(m_2 \cdot x_i^{r,m_2} + |M| \cdot (1 - x_i^{r,m_2})\right) \\ & \geq W\left(m_1 \cdot x_i^{r,m_1} + 1\right) \ \ \forall (m_1, m_2) \in \mathscr{M}_i \,, \ \forall i \in \mathscr{N}. \end{aligned} \tag{27}$$

$$q_{t,i} \geq 0 \,, \ q_{r,i} \geq 0 \ \ \forall i \in \mathscr{N}. \tag{28}$$

The optimization problem of (25) with the reformulated linear equations can be directly solved in CVX [10] (with MOSEK [31]) software. This problem is a MILP. CVX uses branch-and-bound algorithm [33] to solve this problem.

Feasible Solution

CVX outputs flow variables $f_{ij}^m(l)$, scheduling decisions x_{ij}^m and power variables $p_{ij}^m\big(l \in \mathscr{L}, m \in \mathscr{M}_{ij}, i, j \in \mathscr{N}, i \neq j,\big)$. Since we relaxed flow capacity equations to get this output, the resultant flow rates may exceed the capacity of the links. We keep flow variables and scheduling decisions unperturbed and increase power variables to get feasible solutions. We use the following set of equations for flows and powers:

$$\begin{aligned} & \sum_{i \in \mathscr{L}} f_{ij}^m(l) = W \log\left(1 + \frac{p_{ij}^m g_{ij}^m}{N_0 W}\right), \\ & p_{ij}^m = \frac{N_0 W}{g_{ij}^m}\left[\exp\left\{\frac{\sum_{i \in \mathscr{L}} f_{ij}^m(l)}{W}\right\} - 1\right] \ \ \forall m \in \mathscr{M}_{ij}, \, i, j \in \mathscr{N}, \, i \neq j. \end{aligned} \tag{29}$$

These power variables along with flow and scheduling decisions of the CVX output form a feasible solution. We refer to this solution as "BnBSysPowerMin." The resulting algorithm however suffers from exponential complexity in the worst-case scenario. Next section develops low-complexity algorithms to minimize system power in a multi-hop network, i.e., to solve the original optimization problem of (25).

Low-Complexity Algorithm Design

We first focus on the system power minimization of a point-to-point link. Thereafter, we use the insights obtained from this scenario to develop a low-complexity algorithm to minimize system power in a multi-hop network.

Theoretical Insights from Point-to-Point Link Case

In a point-to-point link, the optimization problem of (25) takes the following form:

$$\min \quad \sum_{m \in \mathscr{M}} p^m + \alpha_1 + 2\alpha_2 q + \beta + 2\beta_2 q, \tag{30a}$$

$$s.t. \;\; q \geq W \left(\max_{m \in \mathscr{M}} (m \cdot x^m) - \min_{m \in \mathscr{M}} (m \cdot x^m + |M|(1 - x^m)) + 1 \right),$$

$$x^m \in \{0, 1\}, \; \forall m \in \mathscr{M}, \; q \geq 0, \tag{30b}$$

$$\sum_{m \in \mathscr{M}} W \log_2 \left(1 + \frac{p^m g^m}{N_0 W} \right) \geq r \;, \;\; p^m \geq 0, \;\; \forall m \in \mathscr{M}, \tag{30c}$$

$$p^m \leq A x^m \;\; \forall m \in \mathscr{M}. \tag{30d}$$

In above equations, p^m and g^m denote the allotted power and link gain in channel m, respectively. Rate requirement and spectrum span are denoted by r and q, respectively. In the objective function, $\sum_{m \mathscr{M}} p^m$ denotes transmit power, and $\alpha_1 + 2\alpha_2 q + \beta + 2\beta_2 q$ denotes circuit power consumption.

The optimization problem of (30) is the combination of two separate optimization problems. The objective is to minimize the summation of transmit and circuit power. Equation (30b) denotes the constraints associated with circuit power minimization problem, and it only involves spectrum span and scheduling variables. Equation (30c) denotes the constraints associated with transmit power minimization problem, and it only involves power variables. Equation (30d) relates the power and scheduling variables and couples these two optimization problems.

The optimization problem of (30) has two sub-cases. These sub-cases depend on the values of α_2 and β_2, i.e., the slope of ADC and DAC's power consumption versus sampling rate curves

Case I: Transmit Power Minimization

When α_2 and β_2 are very small, i.e., ADC and DAC's power consumption versus sampling rate curves are very flat, the impact of spectrum span on system power becomes negligible. Scheduling decisions do not influence system power that much, and we can concentrate on minimizing transmit power. Then the optimization problem gets reduced to

$$\min \sum_{m \in \mathscr{M}} p^m, \tag{31a}$$

$$s.t. \sum_{m \in \mathscr{M}} W \log_2 \left(1 + \frac{p^m g^m}{N_0 W}\right) \geq r \ , \ p^m \leq A x^m \ , \ p^m \geq 0, \ x^m \in \{0, 1\} \ \forall m \in \mathscr{M}. \tag{31b}$$

Since x^m's are not present in the objective function, we can just solve the problem with p^m variables and then enforce $x^m = 1$ for every positive p^m.

The optimization problem of (31) is similar to the classical waterfilling [8] problem, which maximizes rate subject to a total power constraint. In the remainder of the chapter, we refer to the above problem "TxPowerMin." The solution to this problem selects the "good" channels in the network and spreads power across the whole spectrum [8].

Case II: Circuit Power Minimization

When α_2 and β_2 are very large, i.e., ADC and DAC's power consumption are very steep, circuit power consumption dominates system power. Transmit power variables do not influence circuit power that much, and we can just concentrate on minimizing circuit power. The optimization problem reduces to

$$\min \quad \alpha_1 + 2\alpha_2 q + \beta + 2\beta_2 q, \tag{32a}$$

$$s.t. \ \ q \geq W \left(\max_{m \in \mathscr{M}} (m \cdot x^m) - \min_{m \in \mathscr{M}} (m \cdot x^m + |M|(1 - x^m)) + 1 \right),$$

$$x^m \in \{0, 1\}, \ \forall m \in \mathscr{M}, \ q \geq 0, \tag{32b}$$

$$\sum_{m \in \mathscr{M}} W \log_2 \left(1 + \frac{p^m g^m}{N_0 W}\right) \geq r \ , \ p^m \geq 0, \ \forall m \in \mathscr{M} \ , \ p^m \leq A x^m \ \forall m \in \mathscr{M}. \tag{32c}$$

The objective of the optimization problem of (32) increases with spectrum span q. Minimum circuit power occurs if we schedule only one channel and allocate enough power in that channel so that it can meet rate requirement. Scheduling any single channel leads to same circuit power in the above optimization problem. Since the original system power minimization problem contains both transmit and

circuit powers, it is prudent to select the channel with the best link gain. This greedy selection requires less transmit power to meet rate requirement.

Trade-Off Between Transmit and Circuit Power Minimization

If ADC and DAC's power consumption versus sampling rate curves are very flat, our algorithm selects all good channels in the network. If ADC and DAC's power consumption vs. sampling rate curves are very steep, our algorithm selects the channel with the best link gain. In a practical setting with commercial ADCs and DAC, our algorithm trades off between transmit and circuit power.

Polynomial Time Algorithm for a Multi-hop Networks

The analysis from the point-to-point link case provides us insights to develop a low-complexity greedy algorithm to solve the optimization problem of (25). The algorithm minimizes the circuit power by using only one channel at the first step and then tries to minimize the system power, i.e., the combination of transmit and circuit power, by greedily selecting more and more channels in the subsequent steps. Our greedy algorithm can be explained simply as follows:

- Find the initial route between each sender and receiver using the shortest path algorithm [7].
- Assign the best channel to each link unless the current assignment interferes with previously assigned channels.
- For each active link, check if any other channel assignment reduces system power.
- Once channels are scheduled, determine power allocation and routing through a convex optimization program.

Our greedy system power minimization algorithm consists of the central program of Algorithm 1 and the subroutines of Algorithms 2 and 3. Next three subsections describe the central program and the subroutines. We analyze the complexity of our algorithm in section "Computational Complexity."

Central Program

Algorithm 1 shows the pseudocode of our greedy polynomial time algorithm. Operation 1 finds large-scale gains of all links by averaging small-scale fading in time or frequency domain. Operation 2 assigns weight to each link. Operation 3 finds the shortest path between each sender and forwarder based on the assigned weights of operation 2. Operation 5 finds the active links and operation 7 calculates the flow requirement among these links. Operation 8 initiates total power (P_{tot}), power allocation (p_{ij}^m), and scheduling (x_{ij}^m) variables to zero for the greedy channel scheduling algorithm. We initiate an outer loop in operation 9. Operations 11, 12, and 13 calls the subroutine of Algorithm 2 and checks if any link should be assigned a channel. The outer loop breaks if none of the active links becomes suitable to

Algorithm 1 Polynomial time algorithm to minimize system power in a multi-hop network

Input : $\mathscr{M}, s(l), d(l), r(l)\ \forall l \in \mathscr{L}, W, N_0, g_m\ \forall m \in \mathscr{M}$
. **Output**: $x_m,\ p_m \forall m \in \mathscr{M}$, P_{tot} , $f_{ij}^m(l)\ \forall m \in \mathscr{M},\ \forall l \in \mathscr{L},\ \forall (i,j)\ \in \mathscr{E}$
.

1: Denote g_{ij} as the average gain (e.g., path loss plus shadowing) of link ij.
2: Assign weight w_{ij} to each link, $w_{ij} = \frac{1}{g_{ij}}$.
3: Find shortest path between between source $(s(l))$ and destination $(d(l))$ of every session $l \in \mathscr{L}$ based on the link weight w.
4: $b_{ij}(l) = 1$ if link ij falls in the routing path of any session $l \in \mathscr{L}$.
5: A link is active if it falls in the routing path of any session, i.e., $x_{ij} = 1$ if $\exists l \in \mathscr{L}$ s.t. $b_{ij}(l) = 1$.
6: Define $\mathscr{A}$ to be set of active links.
7: Flow in each link, $f_{ij} = \sum_{l \in \mathscr{L}} b_{ij}(l) r(l)$.
8: $P_{\text{tot}} = \infty$, $x_{ij}^m = p_{ij}^m = 0\ \forall (i,j) \in \mathscr{E}$, $\forall m \in \mathscr{M}$, $x_i^{t,m} = x_i^{r,m} = 0$, $\alpha_{1_i} = \beta_{1_i} = 0, \forall i \in \mathscr{N}, \forall m \in \mathscr{M}$.
9: **while** True **do**
10: $flag = 0$.
11: **for** $(a,b) \in \mathscr{A}$ **do**
12: $\big(flag, x_{ij}^m, p_{ij}^m\ \forall m \in \mathscr{M}, (i,j) \in \mathscr{E}\big) =$ GreedyAlgo$\big(\mathscr{M}, (a,b), f_{ab}, r, W, N_0, flag, P_{\text{tot}}, \alpha_{1_i}, \beta_{1_i}, x_i^{t,m}, x_i^{r,m}, x_{ij}^m, p_{ij}^m, g_{ij}^m$ $\forall m \in \mathscr{M}, i \in \mathscr{N}, (i,j) \in \mathscr{E}\big)$.
13: **end for**
14: **if** $flag = |A|$ **then**
15: Break.
16: **end if**
17: **end while**
18: Solve the optimization problem of (25) where scheduling variables $(x_{ij}^m\ \forall m \in \mathscr{M}, \forall (i,j) \in \mathscr{E})$ are constants, not variables. Find power allocation, scheduling and routing variables, and total power, P_{tot}.

be assigned a channel. This outer loop determines the channel scheduling (x_{ij}^m) variables.

We obtain power allocation (p_{ij}^m) and routing path $(f_{ij}(l))$ variables from the optimization problem of (25) where scheduling variables (x_{ij}^m) are constants. Since we fix the integer variables of (25), the total power minimization problem becomes a convex optimization program and can be solved in polynomial time [4].

We assume one path (shortest path), i.e., no flow splitting, per session during the initial routing topology design of operations 1, 2, and 3. This allows us to easily calculate the flow requirement of each link which we later use in the greedy scheduling algorithm. We consider optimal flow splitting, based on the selected scheduling variables, in the final optimization of operation 18 of Algorithm 1.

Greedy Scheduling Algorithm

The greedy scheduling algorithm of Algorithm 2 is a subroutine that's called from operation 12 of the central program of Algorithm 1. The subroutine receives previously assigned scheduling and power allocation variables from the central

Algorithm 2 Greedy scheduling algorithm

Input : $\mathscr{M}$, Link (a,b), f_{ab}, r, W, N_0, $flag$, α_{1_i}, β_{1_i}, $x_i^{t,m}$, $x_i^{r,m}$, x_{ij}^m, p_{ij}^m, g_{ij}^m $\forall\,(i,j) \in \mathscr{E}$, $\forall\, i \in \mathscr{N}$, $\forall m \in \mathscr{M}$

. **Output**: $flag$, x_{ij}^m, $\forall\,(i,j) \in \mathscr{E}$, $\forall m \in \mathscr{M}$

.

1: $x_{\text{new},ij}^m = x_{ij}^m$, $p_{\text{new},ij}^m = p_{ij}^m$, $\forall\,(i,j) \in \mathscr{E}$, $\forall m \in \mathscr{M}$.

2: $f_{\text{new},ab}^m = \frac{f_{ab}}{\sum_{m\in\mathscr{M}} x_{\text{new},ab}^m + 1} \cdot x_{\text{new},ab}^m$, $p_{\text{new},ab}^m = \frac{N_0 W}{g_{ab}^m} \cdot \left(2^{\frac{f_{\text{new},ab}^m}{W}} - 1\right) x_{\text{new},ab}^m$ $\forall\, m \in \mathscr{M}$.

3: **for** $m \in \mathscr{M}$ where $x_{ab}^m \neq 1$. **do**

4: $x_{\text{new},ab}^m = 1$. $x_a^{t,m} = 1$. $x_b^{r,m} = 1$. $\alpha_{1_a} = \alpha_1$. $\beta_{1_b} = \beta_1$.

5: $q_{t,i} = W \cdot \left(\max_{m\in\mathscr{M}} \left(m \cdot x_i^{t,m}\right) - \min_{m\in\mathscr{M}} \left(m \cdot x_i^{t,m} + |M| \cdot (1 - x_i^{t,m})\right) + 1\right)$ $\forall\, i \in \mathscr{N}$.

6: $q_{r,i} = W \cdot \left(\max_{m\in\mathscr{M}_i} \left(m \cdot x_i^{r,m}\right) - \min_{m\in\mathscr{M}_i} \left(m \cdot x_i^{r,m} + |M| \cdot (1 - x_i^{r,m})\right) + 1\right)$ $\forall\, i \in \mathscr{N}$.

7: $f_{\text{new},ab}^m = \frac{f_{ab}}{\sum_{m\in\mathscr{M}} x_{\text{new},ab}^m} \cdot x_{\text{new},ab}^m$, $p_{\text{new},ab}^m = \frac{N_0 W}{g_{ab}^m} \cdot \left(2^{\frac{f_{\text{new},ab}^m}{W}} - 1\right) x_{\text{new},ab}^m$.

8: $IntFlag = \text{IntCheck}\left(x_{\text{new},ab}^m, p_{\text{new},ab}^m, \mathscr{M}, \mathscr{A}, W, N_0, x_{ij}^m, p_{ij}^m\ \forall\,(i,j) \in \mathscr{E}\right)$.

9: **if** IntCheck(·) = 1 **then**

10: $P_{\text{new,tot}}^m = \infty$.

11: **else**

12: $P_{\text{new,tot}}^m = \sum_{i\in\mathscr{N}} \left(\alpha_{1_i} + 2\alpha_2 q_{t,i} + \sum_{j\in\mathscr{N}} \sum_{m\in\mathscr{M}_{ij}} p_{\text{new},ij}^m + \beta_{1_i} + 2\beta_2 q_{r,i}\right)$.

13: **end if**

14: $x_a^{t,m} = 0$, $x_b^{r,m} = 0$.

15: **end for**

16: $P_{\text{tot,new}} = \min_{m\in\mathscr{M}} P_{\text{tot,new}}^m$. ind $= \arg\min_{m\in\mathscr{M}} P_{\text{tot,new}}^m$.

17: **if** $P_{\text{tot,new}} < P_{\text{tot}}$ **then**

18: $x_{ab}^{\text{ind}} = 1$.

19: $x_a^{t,\text{ind}} = 1$. $x_b^{r,\text{ind}} = 1$. $\alpha_{1_a} = \alpha_1$. $\beta_{1_b} = \beta_1$.

20: $f_{ab}^m = \frac{f_{ab}}{\sum_{m\in\mathscr{M}} x_{ab}^m} \cdot x_{ab}^m$, $p_{ab}^m = \frac{N_0 W}{g_{ab}^m} \cdot \left(2^{\frac{f}{W}} - 1\right) x_{ab}^m$ $\forall\, m \in \mathscr{M}$.

22: $flag = flag + 1$.

23: **end if**

24: **return**

program. The central controller also asks the subroutine to focus on a particular link (a,b). The subroutine iterates through all available channels and finds the best available channel for (a,b).

Operation 1 stores the global scheduling (x_{ij}^m) and power allocation (p_{ij}^m) variables in local dummy variables $x_{\text{new},ij}^m$ and $p_{\text{new},ij}^m$, respectively. Operation 3 of Algorithm 2 starts the iteration for all channels. Operation 4 assigns the current channel to the focus link (a,b). Operation 5 and 6 calculate the transmit span $(q_{t,i})$ and receiver span $(q_{r,i})$ for all nodes $i \in \mathscr{N}$. Operation 7 assumes equal flow allocation among the selected channels and finds the power allocation in link (a,b) to meet rate requirement. Operation 8 calls the subroutine of Algorithm 3 and checks if current channel assignment causes interference to other links. Operation 12 calculates total system power of the current iteration. Operation 15 comes out of the loop. Operation 16 finds the minimum system power $(P_{\text{tot,new}})$ among all possible channel allocations. Operations 17, 18, 19, 20, 21, 22, and 23 compare the achievable minimum system power $(P_{\text{tot,new}})$ with the stored global system power (P_{tot}) and update scheduling and power variables accordingly.

Algorithm 3 Primary and secondary interference checking algorithm

Input : $x^m_{\text{new},ab}$, $p^m_{\text{new},ab}$, $\mathscr{M}$, $\mathscr{A}$, W, N_0, x^m_{ij}, p^m_{ij} $\forall(i,j) \in \mathscr{A}$
Output: $Intflag$
1: $count = 0$. $Intflag = 0$.
2: **for** $(i,j) \in \mathscr{A}$, $i \neq a$, $j \neq b$ **do**
3: **if** $\left((p^m_{\text{new},ab} g^m_{aj} \geq 0.1 N_0 W x^m_{ij}) || (p^m_{ij} g^m_{ib} \geq 0.1 N_0 W x^m_{\text{new},ab})\right)$ **then**
4: $count = count + 1$.
5: **end if**
6: **if** $\left(x^m_{ia} + x^m_{ab} + x^m_{bj} > 0\right)$ **then**
7: $count = count + 1$.
8: **end if**
9: **end for**
10: **if** $count > 0$ **then**
11: $Intflag = 1$.
12: **end if**
13: **return**

We assume equal flow per channel in each link in operation 7 and 20 of Algorithm 2. This simplifies the calculation of transmission power per channel and avoids the computation of a convex optimization program in each loop. However, we consider optimal flow and power allocation in our final optimization problem of operation 18 of Algorithm 1.

Interference Checking Algorithm

The subroutine of Algorithm 3 gets called from operation 8 of the greedy scheduling algorithm of Algorithm 2. This subroutine checks if the scheduling and power allocation of link ab in channel m, calculated in Algorithm 2, interferes with other links. Operation 3 of Algorithm 3 checks if transmitted power in link ab causes interference to any nonadjacent link that uses channel m. Operation 6 checks if link ab maintains half-duplex relationships with its adjacent links. Operation 11 updates the interference flag and returns this value to the greedy scheduling subroutine of Algorithm 2.

Computational Complexity

Global system power minimization algorithm of Algorithm 1 contains three major parts: (1) Initial routing path selection (operations 1, 2, and 3) of Algorithm 1, (2) channel scheduling (operations 9, 10, 11, 12, 13, 14, 15, 16, and 17) of Algorithm 1 along with Algorithm 2 and Algorithm 3 , and (3) optimal power control and routing path design (operation 18 of Algorithm 1).

Initial routing path selection involves computing link weights ($O(E)$) and shortest path ($O(E + N \log N)$) for L sessions. Therefore, the overall complexity for this part is $O\big(L(E + N \log N)\big)$.

The greedy scheduling algorithm starts with a while loop. The while loop iterates through all active links ($O(E)$). Each link calls the subroutine of Algorithm 2, iterates through M channels. Inside each channel, the code calls the subroutine of Algorithm 3. Algorithm 3 checks if the current channel assignment interferes with

Table 4 Summary of algorithms

Algorithm index	Objective	Complexity
1	Minimize system power of the multi-hop network	$O(E^2M^2)$
2	Schedule channel for a given link of the multi-hop network	$O(EM)$
3	Check if current schedule interferes with other links of the multi-hop network	$O(E)$

other links ($O(E)$). The global while loop of Algorithm 1 can iterate at most $O(M)$ times since each iteration will either select a channel for a link or the loop will break. Therefore, the greedy scheduling algorithm runs in $O(E^2M^2)$ time.

The optimal power allocation and routing path selection problem of operation 18 of Algorithm 1 is a convex optimization program. Barrier method [4] can solve this in $O(R\log(R))$ steps where R is the number of inequality constraints. From (25), we find the complexity to be $O(EM\log(EM))$.

The greedy scheduling part dominates the overall complexity ($O(E^2M^2)$) of Algorithm 1. We term this algorithm "GreedySysPowerMin." We compare the performance of both "GreedySysPowerMin" and "BnBSysPowerMin" with that of "TxPowerMin" in section "Simulation Results."

Table 4 summarizes the objective and computational complexity of the three algorithms presented in the paper. As mentioned before, Algorithms 2 and 3 are subroutines of Algorithm 1, which is the greedy algorithm that solves the optimization problem of (25) with polynomial complexity. This greedy algorithm does not provide any optimality guarantee.

The number of channel M does not denote the number of subcarriers in a multi-hop network. It represents the number of wideband channels, e.g., 6 MHz TV channels in white space and 20 MHz channels in 5.8 GHz, in the network. This ensures that our overall complexity ($O(E^2M^2)$) remains reasonable for a moderately sized network.

Simulation Results

System Power Minimization in a Single Point-to-Point Link

We focus on an NC-OFDMA-based single transceiver pair. There is only one session in the network and minimum data rate requirement is 18 Mbps. There are 20 channels available for transmission. Each channel is 3 MHz wide. The left subplot of Fig. 5 shows the link gains across these channels. We designed the link gains so that every other channel has better link gain than its adjacent neighbors.

The second subplot (from the left) of Fig. 5 shows the power allocation and scheduling variables of TxPowerMin approach. This approach minimizes transmit power subject to the rate constraint. Similar to the concept of "waterfilling" algorithm [8], this approach spreads power across all ten "good" channels of the network.

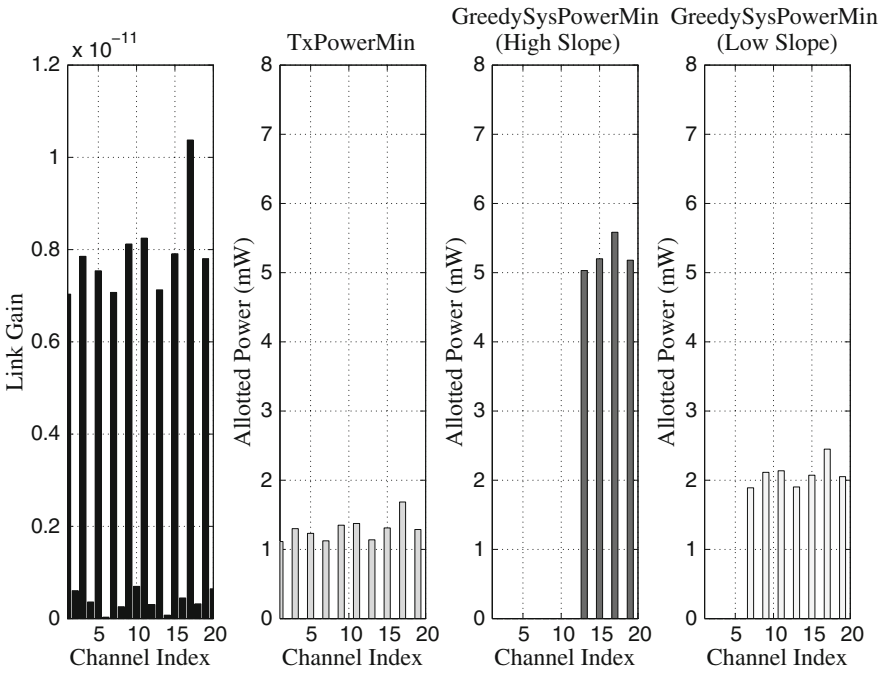

Fig. 5 Comparison of 'TxPowerMin' and our approach in power allocation and scheduling

The third and fourth subplot (from the left) of Fig. 5 shows the scheduling and power variables of our greedy algorithm (GreedySysMin). We use two different types of ADC and DAC models to investigate the influence of ADC/DAC slopes on our algorithm. We use the high-slope ADC and DAC models – ADC 9777 and ADS 62P4 (see Fig. 2a, b) – in the third subplot of Fig. 5 and the low-slope ADC and DAC model, DAC 3162 and ADS 4249 (see Fig. 2a, b), in the fourth subplot (the rightmost one) of Fig. 5. With high-slope ADC and DAC, our algorithm focuses more on minimizing circuit power and selects only four channels. With low-slope ADC and DAC, our approach finds a trade-off between transmit and circuit power and selects seven channels.

Figure 6 compares the performance of our algorithm with that of TxPowerMin approach in high ADC/DAC slope setting. "TxPowerMin" approach minimizes transmit power by spreading data across all "good" channels of the network. Both of our algorithms consume more transmit power than the "TxPowerMin" approach since selecting a subset of available good channels is a suboptimal policy in terms of transmit power. Our algorithms consume less circuit power due to the reduced spectrum span. Overall, our algorithms reduce system power – summation of transmit and circuit power – consumption by almost 30%.

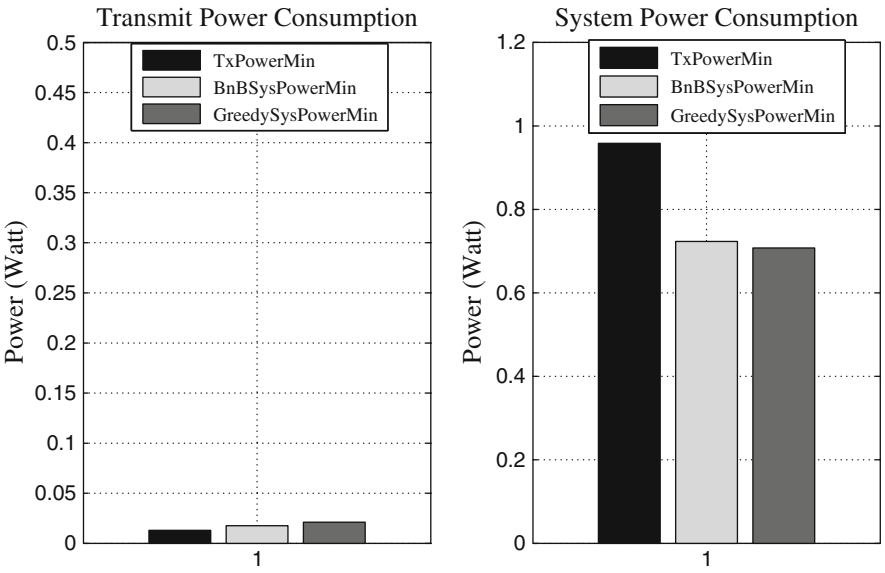

Fig. 6 Comparison of our algorithms with the "TxPowerMin" approach using the high-slope ADC/DAC's of Fig. 2a, b

Note that the lower bound of the system power consumption (obtained from the mixed integer linear programming relaxation) was 0.63 W in this scenario. Hence, both of our algorithms gave feasible results with roughly 15% optimality gap.

Figure 7 compares the performance of our algorithm with that of "TxPowerMin" approach in low ADC/DAC slope setting. We use the same link gain, bandwidth, and traffic demands of Fig. 6, but we use the low power consumption ADC and DAC's to generate these new figures. Our algorithm performs almost similar to the "TxPowerMin" approach here because the power consumption of these low power ADC & DAC is negligible compared to the transmit power requirement.

System Power Minimization in a Multi-hop Network

To illustrate the influence of system power minimization in a practical setting of non-contiguous spectrum access, we consider an exemplary scenario of multi-hop networking among fixed devices in the TV white space channels of Wichita, Kansas, USA. We use standard spectrum databases [37] to find the available TV channels in Wichita, Kansas. Figure 8 shows the locations of nodes. Nodes 1, 2, and 3 transmit to nodes 12, 11, and 10, respectively. Each session requires 10 Mbps data rate. Table 5 shows the available channel indexes. Each channel is 6 MHz wide. We consider both large-scale fading (with path loss exponent 3) and small-scale fading (with

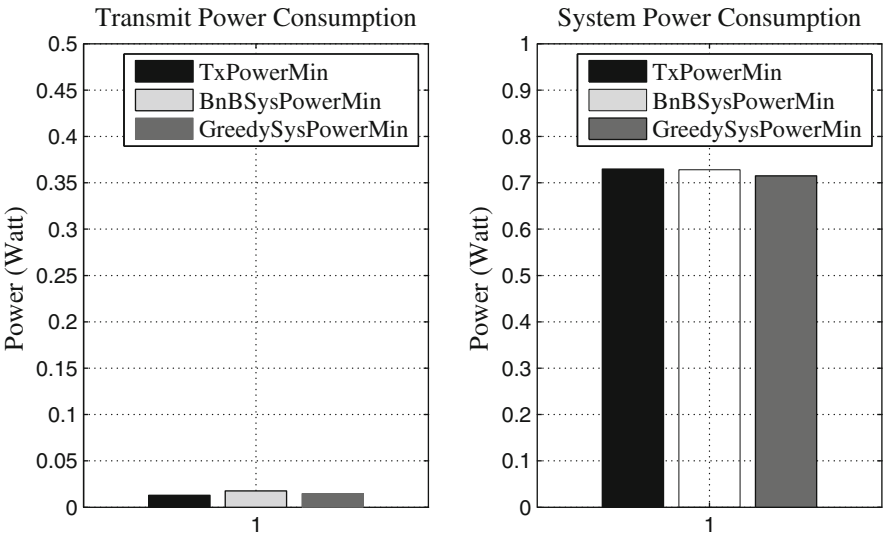

Fig. 7 Comparison of our algorithms with the "TxPowerMin" approach using the low-slope ADC/DAC's of Fig. 2a, b

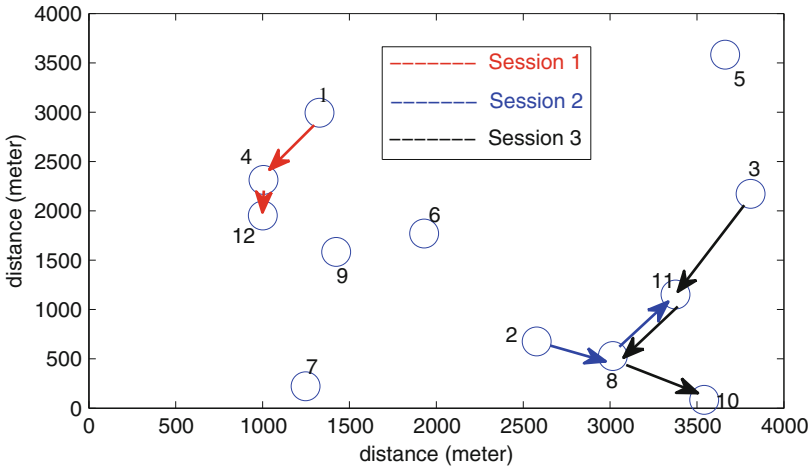

Fig. 8 Twelve-node three-session multi-hop network

12 dB random fluctuation) in each channel. Maximum allowed transmission power is 4 W [17].

Channel Indexing Notations in Optimization Formulation

The difference between channel's carrier frequencies in TV bands are not always proportional to the index differences. Channel 17's center frequency is $((23-17)*6)$

Table 5 Available TV channels for fixed devices in Wichita, Kansas

Channel index	2	5	6	17	23	24	47
Center freq. (MHz)	57	79	85	491	527	533	671

Table 6 Comparison between the spectrum span of "TxPowerMin" and our "BnBSysPowerMin" algorithm in the network of Fig. 8

Node	Mode	TxPowerMin		BnBSysPowerMin	
		Channel index	Spectrum span (MHz)	Channel index	Spectrum span (MHz)
1	Tx	{23, 47}	150	{17, 23}	42
	Rx	{Ø}	0	{Ø}	0
2	Tx	{17}	6	{23}	6
	Rx	{Ø}	0	{Ø}	0

	Rx	{Ø}	0	{Ø}	0
4	Tx	{17}	6	{6}	6
	Rx	{23, 47}	150	{17, 23}	42
8	Tx	{2, 23}	476	{2, 47}	620
	Rx	{5, 24}	460	{17, 23, 24}	48
10	Tx	{Ø}	0	{Ø}	0
	Rx	{23}	6	{47}	6
11	Tx	{5, 24}	460	{17, 24}	48
	Rx	{2, 6, 47}	620	{2, 5, 6}	34
12	Tx	{Ø}	0	{Ø}	0
	Rx	{17}	6	{6}	6

36 MHz far from that of channel 23 but not $((17 - 6) * 6)$ 66 MHz far from that of channel 6. The spectrum span calculation of our optimization formulations depends heavily on the coherence of channel indexing differences. Therefore, we use an index set of $\{9, 13, 14, 81, 87, 88, 111\}$ to denote the channel list of $\{2, 5, 6, 17, 23, 24, 47\}$ in the optimization formulations. We use the original channel list to show the numerical results.

Comparison of "Waterfilling" Algorithm and Our Approach

Here, we use the low-slope ADC and DAC models of Fig. 2b, a. We also use Hou and Shi's algorithm [34] to illustrate the scheduling and power control decisions of "TxPowerMin" approach.

Table 6 compares the channel scheduling decisions and spectrum spans of "TxPowerMin" approach and our algorithm. Although "TxPowerMin" minimizes transmit power by selecting channels with better quality, it increases radio front-end power by selecting channels that are too far apart. Our approach spans narrow spectrum and reduces circuit power consumption. Figure 9 shows that our algorithm reduces system power by 30%.

The 30% system power saving achieved here was obtained with the low-slope ADC and DAC models of Fig. 2b, a – termed as "ultralow-power ADC" and

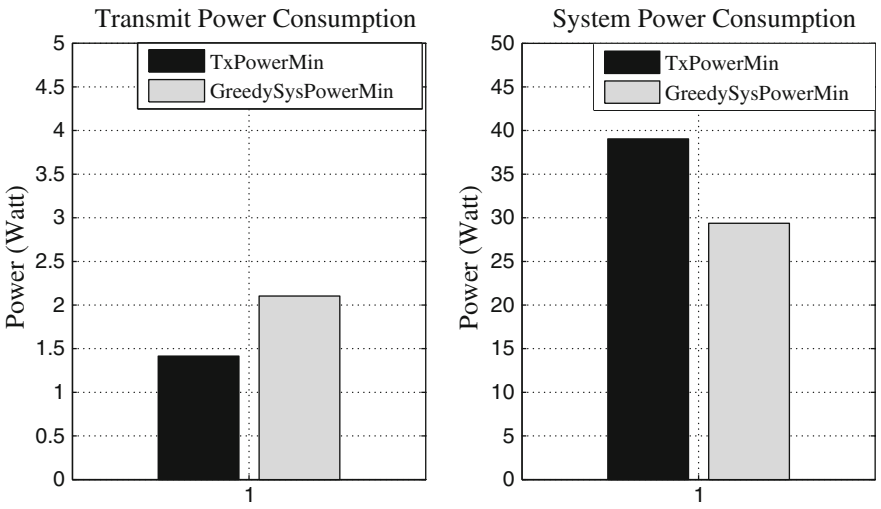

Fig. 9 Performance comparison of "TxPowerMin" approach and our algorithm in the network of Fig. 8, based on the low-slope ADC and DAC models of Fig. 2b, a

"low-power DAC" by their maker, Texas Instruments. Had we used the high-slope ADC and DAC models of Fig. 2b, a, our algorithm would have saved system power by a much higher amount in this simulation. In the future, even if the power consumption curves of ADC and DAC become flatter, our algorithm will reduce the system power considerably as long as the number of available channels is sparsely located – which is often the case in a cognitive radio network.

The lower bound of system power consumption is 24 W in this scenario. Our algorithm provides a feasible solution (29 W) with 20% optimality gap.

Conclusion

Wireless transmission using non-contiguous chunks of spectrum is becoming increasingly essential. MC-MR and NC-OFDMA are the two commercially viable choices to access these non-contiguous spectrum chunks. Fixed MC-MRs do not scale with increasing number of non-contiguous spectrum chunks. NC-OFDMA accesses non-contiguous spectrum chunks with a single front-end radio but increases circuit power consumption by spanning wider spectrum. Our approach characterized this trade-off and performed joint power control, channel scheduling, spectrum span selection, and routing to minimize system power consumption in an NC-OFDMA-based multi-hop network. Our algorithm showed how the slopes of ADC and DAC's power consumption versus sampling rate curves influence the scheduling decisions of a multi-hop network. Numerical results suggested that our algorithm can save 30% system power over classical

transmission power-based cross-layer algorithms in single front-end radios. We developed a branch-and-bound-based mixed integer linear programming model to optimize the cross-layer decisions of a general multi-hop network. Furthermore, we also provided a low-complexity ($O(E^2M^2)$) greedy algorithm.

The optimal fragmentation results presented here have only accounted for the radio front-end power and transmitters' emitted power. Future work will incorporate baseband power in the optimization formulation.

We focused on system power consumption of single front-end radio in this work. A multifront-end programmable radio can dynamically switch its multiple set of center frequencies and access several spectrum chunks in each radio front end with less spectrum span by using NC-OFDMA technology [15]. In the future, we will focus on optimal system power consumption of multifront-end radios.

Power Consumption of Different Blocks in Transmitter and Receiver

Based on Fig. 3, power consumption of transmitter and receiver are:

$$p_{tc} = p_{dac} + p_{tfilt} + p_{mix} + p_{pa}. \tag{33}$$

$$p_{rc} = p_{adc} + p_{rfilt} + p_{mix} + p_{ifa} + p_{lna}. \tag{34}$$

In the above, p_{dac}, p_{mix}, p_{pa}, p_{adc}, p_{ifa} and p_{lna} denote the circuit power consumption in the DAC, mixer, PA, ADC, IFA and LNA respectively. p_{tfilt} and p_{rfilt} represent the summation of circuit powers in the filters of transmitter and receiver respectively.

The power consumption in the mixer, LNA and IFA are constants with respect to the sampling rate [26]. Baseband filter power depends on sampling rate but we assume it to be constant due to its low power consumption [9]. Let us assume,

$$p_{tfilt} + p_{mix} = k_t\,,\ \ p_{rfilt} + p_{mix} + p_{ifa} + p_{lna} = k_r. \tag{35}$$

DAC and ADC power consumptions are affine functions of sampling rate [9]. Hence,

$$p_{dac} = k_1 + k_2 fs\,,\ \ p_{adc} = k_3 + k_4 fs. \tag{36}$$

Now, using(36) and (35) in (33) and (34).

$$p_{tc} = k_1 + k_2 fs + k_t = \alpha_1 + \alpha_2 fs\,,\ \ p_{rc} = k_3 + k_4 fs + k_r = \beta_1 + \beta_2 f. \tag{37}$$

In the above equation, $\alpha_1 = k_1 + k_t$, $\beta_1 = k_3 + k_r$, $\alpha_2 = k_2$ and $\beta_2 = k_4$.

We assume low power consumption at these blocks and use the following values [9]: $p_{tfilt} = 5\,\text{mW}$, $p_{mix} = 30.3\,\text{mW}$, $p_{rfilt} = 7.5\,\text{mW}$, $p_{ifa} = 3\,\text{mW}$, $p_{lna} = 20\,\text{mW}$.

Due to its dependence on transmit power, we do not include programmable amplifier's circuit power consumption term p_{pa} in the overall circuit power consumption equations of (33) and (34). Instead, we couple it with the transmit power consumption p and include it in the total power equations of (2) and (3).

Power Consumption of Programmable Amplifier

Power consumption of programmable amplifier is, $p_{pa} = \frac{PAPR}{\eta} p$. We assume a class-B or a higher class (C, D or E) amplifier with $\eta = 0.75$ [9].

We consider OFDM to be our modulation scheme. The authors of [32] have related the PAPR with the number of subcarriers in OFDM systems as:

$$\text{Prob}\{\text{PAPR} > \gamma\} \approx 1 - \exp\left\{-Ne^{-\gamma}\sqrt{\frac{\pi}{3}\gamma}\right\}, \tag{38}$$

where N is the number of subcarriers.

In the presence of large number of subcarriers, the statistical distribution of the PAPR does not remain sensitive to the increase of the number of subcarriers [32]. During the simulations, we consider the worst case PAPR by assuming maximum possible spectrum span and highest number of subcarriers. We plug the value of maximum number of possible subcarriers of TV white space in (38), and assume $\gamma = 0.005$ and a 3–4 dB reduction in PAPR. Based on these calculations, we find PAPR to be around 9 dB.

Power Consumption of ADC and DAC

Figure 2a plots the power consumption vs. sampling rate curve of AD 9777 [2] (DAC of USRP radio) and DAC 3162 [12]. Figure 2b plots the power consumption vs. sampling rate curve of ADS62P4 [11] (ADC of USRP radio) and ADS4249 [13]. We obtain specific values of k_1, k_2, k_3 and k_4 from these plots.

Abstract

Making judicious channel access and transmission scheduling decisions is essential for improving performance (delay, throughput, etc.) as well as energy and spectral efficiency in multichannel wireless systems. This problem has been a subject of extensive study in the past decade, and the resulting dynamic and opportunistic channel access schemes can bring potentially significant improvement over traditional schemes. In this chapter, a couple of classical settings and problems for this decision-making question in cognitive radio networks, namely, multiuser, single-channel model and single-user, multichannel model, as well as their solutions, will be surveyed first. Toward making such studies more practical, we point to a common and severe limitation of these dynamic schemes in that they almost always require some form of a priori knowledge of the channel statistics. On the other hand, what is often available to the decision-maker is a rather rich stream of network data that can jointly describe channel conditions.

Then a natural remedy is to consider a learning framework, which has also been extensively studied in the same context, but a typical learning algorithm in this literature seeks only the best static policy (i.e., to stay in the best channel), with performance measured by *weak regret*, rather than learning a good dynamic channel access policy. There is thus a clear disconnect between what an optimal channel access policy can achieve with known channel statistics that actively exploits temporal, spatial, and spectral diversity and what a typical existing learning algorithm aims for, which is the static use of a single-channel devoid of diversity gain.

In this chapter, this gap is bridged by designing learning algorithms that track known optimal or suboptimal dynamic channel access and transmission scheduling policies via using collected observations following the made decisions, thereby yielding performance measured by a form of *strong regret*, the accumulated difference between the reward returned by an optimal solution when a priori information is available and that by our online algorithm. We do so in the context of two specific algorithms that appeared in [1] and [2], respectively, the former for a multiuser single-channel setting and the latter for a single-user multichannel setting. In both cases we show that our algorithms achieve sublinear regret uniform in time and outperform the standard weak-regret learning algorithms.

Introduction

Making judicious channel access and transmission scheduling decisions is essential for improving performance (delay, throughput, etc.) as well as energy and spectral efficiency in wireless systems, especially those consisting of multiple users and multiple channels. Such decisions are often nontrivial because of the time-varying nature of the wireless channel condition, which further varies across different users and different spectrum bands. Such variations bring in diversities that can provide opportunities for a radio transceiver to exploit for performance gain, and the past decade has seen many research advances in this area. For instance, a transmitter can seek the best channel through channel sensing before transmission, see, e.g., [3–5] for such dynamic multichannel MAC schemes that allow transmitters to opportunistically switch between channels in search of good instantaneous channel conditions; if a transmitter consistently selects a channel with better instantaneous condition (e.g., higher instantaneous received SNR) from a set of channels, then over time it sees (potentially much) higher average rate [6–8]. Similarly, a transmitter can postpone transmission if the sensed instantaneous condition is poor in hopes of better condition later, see e.g., [1] for stopping rule-based sequential channel sensing policies, in the single-user multichannel and single-channel multiuser scenarios, respectively. Variations on the same theme include [9] where a distributed opportunistic scheduling problem under delay constraints is investigated and [2] where a generalized stopping rule is developed for the single-user multichannel setting.

These dynamic channel access schemes (both optimal and suboptimal) improve upon traditional schemes such as channel splitting [10, 11], multichannel CSMA [12], and multi-rate systems [13]. In this chapter, we first go through two representative models, namely, single-user, multichannel model and multiuser, single-channel model, and we revisit their solutions.

In these solutions, formally there are three types of diversity gains being commonly explored. The first is *temporal diversity*, where the natural temporal variation in the wireless channel causes a user to experience or perceive different transmission conditions over time even when it stays on the same channel, and the idea is to have the user access to the channel for data transmission when the condition is good, which may require and warrant a certain amount of waiting. Studies like [14] investigate the trade-off involved in waiting for a better condition and when is the best time to stop.

The second is *spectral diversity*, where different channels experience different temporal variations, so for a given user at any given time, a set of channels present different transmission conditions. The idea is then to have the user select a channel with the best condition at any given time for data transmission, which typically involves probing multiple channels to find out their conditions. Protocols like [15] does exactly this, and studies like [16, 17] further seek to identify the best sequential probing policies using a decision framework.

The third is *user diversity* or *spatial diversity*, where the same frequency band at the same time can offer different transmission qualities to different users due to their differences in transceiver design, geographic location, etc. The idea is to have the user with the best condition on a channel use it. This diversity gain can be obtained to some degree by using techniques like stopping rules whereby a user essentially judges for himself whether the condition is sufficiently good before transmitting, which comes as a by-product of utilizing temporal diversity.

Harnessing the above forms of diversities is studied in different scenarios. For instance, temporal diversity is studied in a multiuser setting but with a single channel in [1, 18]; spectral diversity is analyzed for a single user in [4], among others. More specifically, [1] developed optimal stopping policies for single-channel multiuser access. [18] considered a distributed opportunistic scheduling problem for ad hoc communications under delay constraints. In [4], authors exploited spectral diversity in OSA for a single user with sensing errors, where the multi-channel overhead is captured by a generic penalty on each channel switching. This becomes insufficient in a multiuser setting as such overhead will obviously depend on the level of congestion in the system that results in different amount of collision and the time it takes to regain access to a channel. In [15], an opportunistic auto rate multichannel MAC protocol MOAR is presented to exploit spectral diversity for a multichannel multi-rate IEEE 802.11-enabled wireless ad hoc network. However, this scheme does not allow parallel use of multiple channels by different users due to its reservation mechanism. Other works that study multichannel access by a single user include [14, 17, 19–22].

Toward making such studies more practical, we note a common and severe limitation of these dynamic schemes in that they almost always require some form of a priori knowledge of the channel statistics. For instance, a typical assumption is that the channel conditions evolve as an IID process and that its distribution for each channel is known to the transmitter/user, see, e.g., [1, 2, 5]. While in some limited setting, such information may be acquired with high accuracy and low latency, this assumption does not generally hold. Furthermore, the channel statistics may be time-varying, in which case such an assumption can only be justified if there exists a separate channel sampling process which keeps the assumed channel statistics information updated.

To relax such an assumption, it is therefore natural to cast the dynamic channel sensing and transmission scheduling problem in a learning context, where the user is not required to possess a priori channel statistics but will try to learn as actions are taken and observations are made. Within this context, the type of *online* learning or *regret* learning, also often referred to as the Multi-Armed Bandit (MAB) [23–25] framework, is particularly attractive, as it allows a user to optimize its performance throughout its learning process. For this reason, this learning framework has also been extensively studied within the context of multichannel dynamic spectrum access, see, e.g., [26] for single-user and [27, 28] for multiuser settings. However, in most of this literature, the purpose of the learning algorithm is for a transmitter to find the best channel in terms of its average condition and then use this channel for transmission most of the time. It follows that the performance of such learning

algorithms is measured by *weak regret*, the difference between a learning algorithm and the best single-action policy which in this context is to always use the channel with the best average condition. Accordingly, the key ingredient in these algorithms is to form accurate estimates on the average condition for each channel.

We therefore see a clear disconnect between what an optimal channel access policy can achieve with known channel statistics (e.g., by employing a stopping rule-based algorithm) that actively exploits temporal, spatial, and spectral diversity and what a typical existing learning algorithm aims for, i.e., essentially the static use of a single channel, which unfortunately completely eliminates the utilization of diversity gain. Note that some multiuser learning algorithms attempt to separate users into different channels, so to exploit to some degree the multiuser diversity gain, see, e.g., [29]. Further in practice, when such an algorithm is deployed for users to shoot for the single best channel, a load balancing issue will arise.

Our goal is to bridge this gap and seek to design learning algorithms that, instead of trying to track the best average-condition channel, attempt to track a known optimal or suboptimal channel access and transmission scheduling algorithm, thereby yielding performance measured by a form of *strong regret*. Our presentation and analysis strongly suggest that such learning algorithms may be constructed in a much broader context, i.e., they can be made to track any prescribed policy and not just those cited earlier or even limited to the dynamic spectrum access context. However, to make our discussion concrete, we shall present our results in the context of specific channel sensing and access algorithms.

Specifically, we present the general framework of such a learning algorithm, followed by the detailed instances designed to track the stopping rule policies given in [1] and [2], respectively. The choice of these two algorithms is not an arbitrary one. Our intention is to use two representatives to capture a fairly wide array of similar algorithms of this kind. The stopping rule algorithm in [1] is a relatively simple one, designed for multiple users competing for access to a single channel; it exploits temporal and spatial (multiuser) diversity, the idea being for a user to defer transmission if it perceives poor channel quality thereby giving the opportunity to another user with better condition. The stopping rule algorithm in [2], on the other hand, is much more complex in construction; it is designed for a single user with access to multiple channels by exploiting spectral and temporal diversity, with the idea being to find the channel with the best instantaneous condition. Both algorithms assume that channel qualities evolve in an IID fashion with known probability distributions, though different channels may have different statistics [2]; both are provably optimal (or near-optimal) under mild technical conditions. For other stopping rule-based policies, see also [3–5]. We show that in both cases our algorithms achieve a sublinear cumulative strong regret (against their respective reference algorithms from [1] and [2]), thus achieving zero-regret averaged over time (Table 1).

The rest of the chapter is organized as follows. Problem formulation is presented in section "Preliminaries" and the two reference optimal offline algorithms in section "Offline Solutions Revisited". We present the setting of our online learning algorithms in section "Goal of Online Learning" and their details in section "Design

Table 1 Our contribution. Weak regret is often used as the performance measure when targeting a single best option on average over time. On the other hand, strong regret is defined as the performance loss w.r.t. selecting the best option at any time step. So far results on strong regret have largely focused on the case when channel statistics are known (decision-maker's perspective)

Measure \ channel stat.	Available	Not available
Weak regret	Trivial	[25–28]: best average option; easier to achieve
Strong regret	[1–5]: harness temporal/spatial diversity at any time; harder to achieve	Our work: minimize strong regret w/o channel information

of Online Algorithms." We brief over their performance analysis in section "Regret Analysis". Numerical results are given in section "Simulation", and possible extensions to this work are discussed in section "Discussion". Section "Conclusion" concludes the chapter.

Preliminaries

In this section, we present two system models and their corresponding transmission scheduling problems. These two models are generally regarded as the most fundamental ones that are analytically tractable, yet powerful, in characterizing key properties of these decision-making settings. Also this lays the foundation for us to introduce the two offline optimal stopping rule policies from [1] and [2], respectively, in section "Offline Solutions Revisited"; these are the policies our learning algorithm presented in section "Design of Online Algorithms" aims to track.

Model I: Multiuser, Single-Channel

Under the first model (studied in [1]), there is a finite number of users/transmitters, indexed by the set $\mathscr{M} = \{1, 2, \ldots, M\}$, $M \geq 1$, and a single channel. The system works in discrete time slots indexed by $n = 1, 2, \cdots$. Denote the channel quality by $X(n)$, $n = 1, 2, \cdots$. This quantity measures how good a channel is; for example, $X(n)$ could model the Signal-Noise-Ratio (SNR) for the channel at time n. At time n, if no one is transmitting on the channel, a user $i \in \mathscr{M}$ attempts to access with probability $0 \leq p_i \leq 1$ by sending a carrier sensing packet. A carrier sensing period takes a constant amount of time denoted by ζ (slots). The contention resolution is done by random access, i.e., an access attempt is successful with probability $p_s = \sum_{i \in \mathscr{M}} p_i \cdot \prod_{j \neq i}(1 - p_i)$, when there is only one user attempting access. Denote the random contention time between two successful accesses by η; it follows that $E[\eta] = \zeta / p_s$ (slots). We assume the process $\{X(n_k)\}_{k=1,2,\ldots,}$ forms an IID process, where n_k is the time the k-th contention succeeds. That is, we assume the

samples collected at successful accesses are generated in an IID fashion (as assumed and argued in [1]). Upon a collision, the current slot will be abandoned, and users recompete in the next time slot. On the other hand, users keep silent if there is an active transmission on the channel. For simplicity, it is assumed that $X(n)$ stays unchanged during each transmission, which may be justified if transmission times are kept on a smaller time scale than channel coherence times [30]. Once a user gains access right (and sees the channel quality $X(n)$), it has two options:

- Access the channel right away for K time slots (*stop*)
- Give up the access opportunity and release the channel for all users to recompete (*continue*)

This can be more formally stated as an optimal stopping rule (OSR) problem: users decide at which time to stop the decision process and use the channel. There are a number of variations of this problem with slightly different model, see, e.g., [4]. The idea is when the channel quality is poor, a user would give up the transmission opportunity so that it is more likely that a user with better perceived channel quality will get to use it. Denote the stopping time by τ, then the objective is to design a stopping rule for all users so as to maximize the rate of return, which is the effective data rate for each successful access ([1])

$$J_I^* = \max_{\tau \in \Pi} J_I^\tau = \max_{\tau \in \Pi} E\left[\frac{X(\sum_{k=1}^{\tau} \eta_k) \cdot K}{K_\tau}\right] \underbrace{\longrightarrow}_{\text{Renewal theory}} \max_{\tau \in \Pi} \frac{E[X(\sum_{k=1}^{\tau} \eta_k) \cdot K]}{E[K_\tau]}, \tag{1}$$

where Π is the strategy space and η_k is the k-th contention time and $K_\tau = \sum_{k=1}^{\tau} \eta_k + K$ is the total amount of time spent for each successful transmission.

Model II: Single-User, Multichannel

Under the second model (studied in [2]), there is a finite number of channels, denoted and indexed by $\mathcal{O} = \{1, 2, \ldots, N\}$, each of which yields a non-negative reward when selected for transmission (e.g., throughput, delay, etc.). For any subset $S \subseteq \mathcal{O}$ we will use $\mathcal{O} - S$ to denote the set $\{j : j \in \mathcal{O} \ \& \ j \notin S\}$. There is one decision-maker (user/transmitter) within the system. The system again works in discrete time slots $n = 1, 2, \ldots, \tau \leq N$; these however are much smaller time units than those under Model I because they are used only for channel sensing and not transmission. The user sequentially chooses a set of channels to probe for their condition, stops at a stopping time τ using certain stopping rule, and selects a channel for transmission (over a period of time larger than a slot). The decision process thus consists of determining in which sequence to sense the channels, when to stop, and which channel to use for transmission when stopping.

For consistency we reuse the terminology *meta stage* to describe the above decision process between $n = 1$ and τ; this will be referred to as one *meta stage*. Each time a new meta stage starts, the clock is reset to $n = 1$. The meta stages are indexed by $t = 1, 2, \ldots, T$. There is a period of transmission between two successive meta stages. It is assumed that the channel condition remains constant within a single meta stage and forms an IID process over successive meta stages. This is modeled by a reward X_i (to generate $\{X_i(t)\}_t$) for the i-th channel given by a pdf $f_{X_i}(\cdot)$ and cdf $F_{X_i}(\cdot)$, respectively. Channels are independent of each other, i.e., a specific channel i's realization $X_i(t;\omega)$ does not reveal any information for channels in $\mathcal{O} - \{i\}$.

The transmitter is able to sense one channel (to observe X_i) at each decision step n with a finite and constant sensing cost $c_i \geq 0$ for each channel i. The system works in the following way at each n of meta stage t: The transmitter makes a decision between the following choices:

- Continues sensing. If this is the case, then furthermore decides which channel to probe next (*sense*).
- Stops sensing and proceeds to transmit (*access*). Under this case, there are two more options to choose from:
  - Access the channel with the best observed instantaneous condition (*access with recall*)
  - Access the best channel (with highest expected reward) from the unprobed set without sensing (*access with guess*)

For the offline problem, due to the IID assumption on the channel condition, the decision strategy at each meta stage t is the same. We thus suppress the time index t; the transmitter's objective is to choose the strategy that maximizes the collected reward minus the sum of probing costs:

$$J_{II}^* = \max_{\pi \in \Pi} J_{II}^{\pi} = \max_{\pi \in \Pi} E\left[X_{\pi(\tau)} - \sum_{n=1}^{\tau-1} c_{\pi(n)} \right], \tag{2}$$

where π denotes a probing strategy and τ the stopping time. From [2], it can be shown that for time slots $n = 1, 2, \ldots, \tau$ at any meta stage t, a sufficient information state is given by the pair $(x(n), S_n)$ where S_n is the unprobed channel set and $x(n)$ is the highest observed reward among the set of probed channels $\mathcal{O} - S_n$. Let $V(x, S)$ denote the value function, the maximum expected remaining reward given the system state is (x, S); the problem/decision process at the n-th decision step is equivalent to the following dynamic programming (DP) formulation

$$\begin{aligned} &V(x(n), S_n) \\ &= \max \left\{ \max_{j \in S_n} \{-c_j + E[V(\max\{x(n), X_j\}, S_n - j)]\}, x(n), \max_{j \in S_n} E[X_j] \right\}, \end{aligned}$$

where the three terms on the RHS correspond to the decision options sense, access with recall, and access with guess, respectively.

Offline Solutions Revisited

To be self-contained as well as to provide certain intuition for the design of the online algorithms, below we present the optimal offline solutions to the scheduling problems in Model I and Model II, respectively.

Algorithm Description: Model I

The solution for the scheduling problem in Model I is surprisingly clean and elegant and can be easily described as follows. Within each meta stage l, the optimal stopping rule is given by a threshold policy [1]:

$$\tau^* = \min\{n \geq 1 : X(n) \geq x^*\}\,, \tag{3}$$

where x^* is given by the solution for u in the following equation:

$$E[X(n) - u]^+ = \frac{u \cdot \zeta}{p_s \cdot K}\,. \tag{4}$$

Intuitively the LHS captures the potential room for gain, compared with the "reserve price" μ (if gave up the chance for access). While RHS captures the loss in the rate of return, if user is up to "continue" the decision-making procedure. The stopping time occurs exactly when the above two terms equal to each other.

The above equation is guaranteed to have a unique solution. This can be intuitively explained by observing that the LHS is decreasing in u, while the RHS is increasing w.r.t. it; thus the two sides intersect exactly once, which corresponds to the solution. Then the corresponding algorithm is straightforward – at each n when a user needs to make a decision:

- If $X(n) \geq x^*$, a user will transmit.
- Otherwise he will release the channel.

Intuitively this says that when the channel quality is sufficiently good (as compared to x^* which separates the decision regions for stop and continue), a user should transmit. This algorithm will be referred to as (Offline_MU) (MultiUser) in our subsequent discussion.

Such a stopping rule-based solution framework can be extended to slightly more complicated settings, such as when there are delay constraints for the access procedures.

Algorithm Description: Model II

The solution for Model II is much more involved; this is primarily due to it allowing *access with guess* as an option, which is very different from classical stopping time problems. In this sense this model presents a generalization. Particularly the optimal policy is shown to have three major steps in [2]: parameter calculation, sorting, and decision-making, as detailed below.

STEP 1: Parameter calculation for channels

Compute the following two parameters $\forall j \in \mathscr{O}$:

$$a_j = \min\{u : u \geq E[X_j], c_j \geq E[\max(X_j - u, 0)]\},$$
$$b_j = \max\{u : u \leq E[X_j], c_j \geq E[\max(u - X_j, 0)]\}.$$

STEP 1 is based on a threshold property for the optimal policy proved in [2]. The first term on the RHS is the maximum reward by continuing sensing. The second term corresponds to stop and access best sensed option while the last term corresponds to the action selecting the best option (highest expected reward) from the unsensed set w/o sensing to access. It could be easily established that $a_j \geq E[X_j] \geq b_j$ and $a_j = b_j$ if and only if we have $a_j = b_j = E[X_j], \forall j$. Intuitively speaking, a, b separates the decision region as follows. A state larger than a_j means further probing is not profitable, whereas a state below b_j suggests gain from continued sensing (Fig. 1).

First we prove the following proposition for a_j, b_j [31].

Proposition 1. $a_j, b_j > 0, \forall j \in \mathscr{O}$.

For STEP 2, we refer to each of its sub-steps **m** as STEP 2.**m** (we will reuse this numbering style in later discussions). The sorting process is straightforward: we start with the full set $\mathscr{O}$, and at each step, we first calculate $\mathscr{R}$, the set of channels

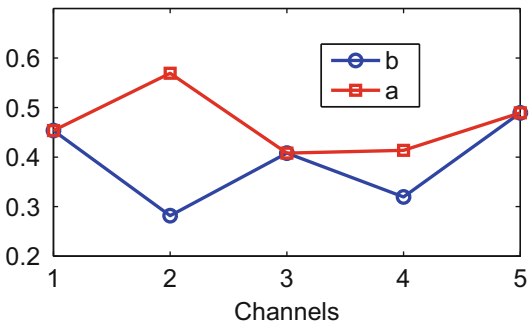

Fig. 1 Illustration of a, b

STEP 2: Channel sorting

1: Initialize $k = 1,\ S = \mathscr{O}$.

2: First compute $\mathscr{R} := \left\{ j \in S, a_j = \max_{i \in S} a_i \right\}$, and then j^*:

$$j^* = \text{argmax}_{j \in \mathscr{R}} \left\{ I_{b_j = a_j} \cdot E[X_j] + I_{a_j > b_j} \cdot \left[E[X_j | X_j \geq a_j] - \frac{c_j}{P(X_j \geq a_j)} \right] \right\}.$$

3: Let $o_k = j^*$ (randomly select one if multiple j^* exists) and set $k := k + 1$. $S = S - \{j^*\}$.

4: If $|S| \geq 1$, repeat **2**; o.w. return the sorted set $\{o_1, \ldots, o_N\}$.

5: Relabel the sorted set as $\{1, 2, \ldots, N\}$.

with the highest a_j. Then within $\mathscr{R}$, we further order the channels based on the one-step reward of probing channel j when $x(n) = a_j$ with j being the only remaining channel. The ordering repeats until all channels are in order.

The above two steps serve as processing steps toward the optimal decision-making. However as noted in [2], it is not easy to calculate the optimal solution in the last decision-making step which involves solving dynamic programming equations with exponentially growing (in N) state space. Instead of seeking the optimal solution, [2] gives out a suboptimal solution which has been shown (analytically and simulation-wise) to be performing well. The idea is, instead of iterating value functions over all remaining unprobed channels, we only consider the 1st & 2nd channels on the remaining options set S_n (ordered).

Given the current information state is $(x(n), S_n)$ at decision epoch n and denoting by d_s the solution to the following equation (solution is guaranteed to exist [2]):

$$V(0, S_n) = -c_1 + E[V(\max\{d_s, X_1\}, S_n - \{1\})],$$

where in above equation 1 denotes the first channel in the remaining channel set S_n (ordered). The decision-making process in STEP 3 can be intuitively explained as follows. First if the current observed maximum reward is larger than the remaining maximum a_j, we stop and access with recall. Otherwise if the current maximum reward $x(n)$ is below a_j but higher than d_s, we proceed to probe the 1st channel in S_n. When $x(n)$ is less than d_s, we further need to differentiate the decisions based on three conditions. Define

$$g_i(x) = -c_i + E[V(\max(X_i, x), -i + 3)],\ i = 1, 2,$$

then $g_1(x)$ is the expected reward of probing channel 1 facing information state $(x, \{1, 2\})$, while $g_2(x)$ is the reward for probing channel 2. $f_1(x)$ is the expected reward of probing 1 facing information state $(x, \{1, 2\})$, while $f_2(x)$ is the one for probing channel 2.

STEP 3: Decision-making step

1: If $x(n) \geq \max_{i \in S_n} a_i$, stop and access the best sensed channel.
2: Otherwise if $x(n) > d_s$, probe the first channel in S_n.
3: If $x(n) \leq d_s$ consider the following sub-cases
(1) : If $b_1 \geq a_2$, then access/guess 1st channel (in S_n, w/o sensing).
(2) : If $b_2 \geq b_1$ or $g_1(0) \geq \max\{E[X_1], g_2(0)\}$, probe 1 in S_n.
(3) : There exists a unique b_0, where $b_1 > b_0 > b_2$ and $g_1(b_0) = \max\{E[X_1], g_2(0)\}$:
– If $x(n) \geq b_0$: probe 1st channel.
– $x(n) < b_0$: guess channel 1 if $E[X_1] \geq g_2(0)$; probe channel 2 o.w.

We denote the algorithm consisting of (**STEP 1, STEP 2, STEP 3**) as (Offline_MC) (MultiChannel) and it serves as the offline benchmark solution for the multichannel scheduling problem.

Goal of Online Learning

Model I: Multiuser, Single-Channel

As can be readily seen from Eq. (4) and the whole procedures documented in (Offline_MC), in order to compute the optimal threshold access strategy x^*, users need to be fully aware of the distribution of channels' transmission qualities, i.e., the distribution of $X(n)$. In practice, such knowledge can only be collected gradually along with users' accesses.

In this model, we regard the decision process between two consecutive successful transmissions (note that no successful transmission occurs if a user who wins access forgoes the transmission opportunity) as one *meta stage*. Suppose there are all together H meta stages (thus H successful transmissions). We define the following *strong regret* performance measure,

$$R_I(H) = \sup_{\boldsymbol{\tau} \in \Pi^H} E^{\boldsymbol{\tau}}\left[\sum_{l=1}^{H} \frac{X(\sum_{k=1}^{\tau_l} \eta_k) \cdot K}{K_{\tau_l}}\right] - E^{\boldsymbol{\alpha}}\left[\sum_{l=1}^{H} \frac{X(\sum_{k=1}^{\alpha_l} \eta_k) \cdot K}{K_{\alpha_l}} | \mathscr{F}_{l-1}, \ldots, \mathscr{F}_0\right].$$

In the above formulation, since channel conditions are IID over time, for each meta stage we restart the clock, i.e., we always set the first time slot for each meta stage as $n = 1$. α_l is the stopping time for the l-th meta stage and $X(\sum_{k=1}^{\alpha_l} \eta_k)$ is the corresponding reward. Here we denote by the $\mathscr{F}_l := \cup_{j \in \mathscr{M}} \mathscr{F}_l^j$ the set of observations of channel qualities at meta stage l (with $\mathscr{F}_l^j$ for each user j).

Model II: Single-User, Multichannel

For this model, our goal is to design an online algorithm $\alpha_t, t = 1, 2, \ldots, T$ based on past observed history $\mathscr{F}_{t-1}, \ldots, \mathscr{F}_1$, so as to minimize the expected reward loss from the one-stage decision-making process. Or in other words, to minimize the following strong regret measure,

$$R_{II}(T) = \sup_{\boldsymbol{\pi} \in \Pi^T} E^{\boldsymbol{\pi}}\left[\sum_{t=1}^{T}(X_{\pi_t(\tau)}(t) - \sum_{n=1}^{\tau-1} c_{\pi_t(n)})\right] - E^{\boldsymbol{\alpha}}\left[\sum_{t=1}^{T}(X_{\alpha_t(\tau)}(t) - \sum_{n=1}^{\tau-1} c_{\alpha_t(n)})|\mathscr{F}_{t-1}, \ldots, \mathscr{F}_0\right], \tag{5}$$

where π_t is the optimal decision at meta stage t when the information on $\{X_i\}_{i\in\mathscr{O}}$ is known and τ the stopping time; $\pi_t(n), n = 1, 2, \ldots, \tau$ are the channels selected at decision step n of each meta stage t. α_t is the decision actually made at t by the user based on past observations when channel statistics is unknown.

For both problems, if an algorithm can achieve regret $\frac{R_I(H)}{H}$ (respectively, $\frac{R_{II}(T)}{T}$) $\to 0$ then it is called sublinear in total regret and zero-regret in time average.

Weak Regret

As mentioned earlier in the introduction, when the statistics for decision-making processes are missing, there is a large body of literature on online decision-making. Among all the solutions, Multi-Armed Bandit stands out as one of the most widely adopted solution, due to both its simple, elegant solution structure, as well as its very minor restriction on prior knowledge of models' statistics. However the distinct feature that sets our goal different from the existing one lies in that such policies try to minimize the notion of weak regret, a more commonly used objective as mentioned earlier. This is in contrast to *strong regret* that we are aiming to study.

Weak regret generally refers to the difference between an algorithm and the best single-action policy that always uses the option with the best average. For instance, under Model II, the weak regret is given by

$$R^{\text{weak}}(T) = T \cdot \max_i E[X_i] - E[\sum_{t=1}^{T} X_{\alpha_t}]\,. \tag{6}$$

This can be similarity defined for Model I, where $\max_i E[X_i]$ corresponds to always letting the "best user" (with the highest average access rate) use the channel.

The above weak regret minimization problem can be readily solved within the context of Multi-Armed Bandit, Existing online algorithms developed under this

category of studies can often help achieve a sublinearly growing $R^{\text{weak}}(T)$, that is, $R^{\text{weak}}(T) = o(T)$. For example, the celebrated UCB1 [25] algorithm:

Upper Confidence Bound 1 (UCB1) Auer et al. [25]

1: Initialization: for $t \leq N$, play arm/choice t, $t = t + 1$.
2: While $t > N$:

- For each choice k, calculate its sample mean:

$$\bar{X}_k(t) = \frac{X_k(1) + X_k(2) + \ldots + X_k(n_k(t))}{n_k(t)}$$

- Its index:

$$I_{k,t,n_k(t)} = X_k(t) + \sqrt{\frac{L \log t}{n_k(t)}}, \quad \forall k$$

- Play the arm with the highest index; $t = t + 1$

The algorithm executes the notion of exploration and exploitation implicitly. To be more specific, the sample mean term controls how often the learner exploits by favoring the arms that turned to be good empirically. The confidence terms regulate how often a user should *explore* by sampling less confident options.

The regret of running UCB1 is bounded at the order of $\log T$. Specifically, suppose $E[X_1] > E[X_2] > \ldots > E[X_N]$. Denote by $\Delta_k := E[X_1] - E[X_k]$

Theorem 1 ([25]). *$R^{\text{weak}}(T)$ when running UCB1 is bounded as follows:*

$$R^{\text{weak}}(T) \leq \sum_{k>1} \lceil \frac{8 \log T}{\Delta_i} \rceil + \text{const.} \tag{7}$$

Design of Online Algorithms

We detail our online learning algorithm in this section. To generalize the discussion we shall refer to the users in Model I and the channels in Model II as *units*. Then for a unifying framework of the online learning process, there are two main phases, *exploration* and *exploitation*, described as follows.

- Exploration: sample the units with sampling times less than $D_1(t) = L \cdot t^z \cdot \log t$ up to meta stage t, with $L > 0$, $0 < z < 1$ being constant parameters. Here L is a sufficiently large (we shall specify its bounds later alongside the analysis) *exploration* parameter. When the unit represents a channel, the sampling process

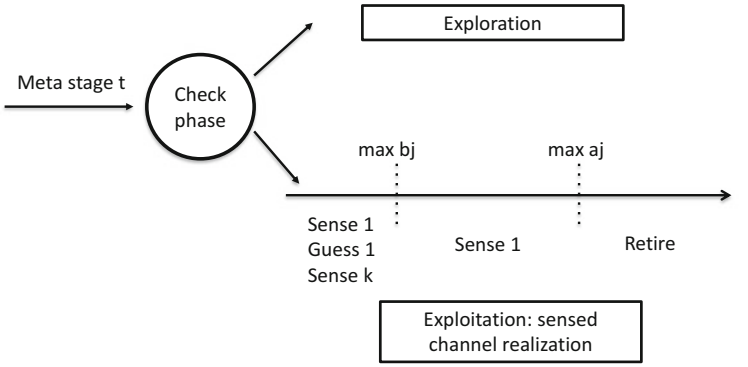

Fig. 2 Illustration of our online algorithm for Model II

is to probe the channel quality; when such a unit represents a user, the process corresponds to letting the user gain access to the channel to gather samples.

- Exploitation: execute the optimal scheduling policy using collected statistics as detailed in the offline solution, but with built-in tolerance for estimation errors as detailed below. The sensing results (possibly multiple) from exploitation phases will also be collected and utilized for training purpose.

The above steps are rather standard within the regret learning literature: when a unit has not been explored/sensed sufficiently (e.g., a user has not accessed a channel for a sufficient number of times in Model I or a channel has not been sampled sufficiently in Model II), the algorithm enters the exploration phase. Otherwise the algorithm mimics the procedures of calculating the optimal strategies as detailed in the offline solutions but with empirically estimated channel statistics. One notable difference here is that since the offline dynamic policies involve channel sensing as part of the decision process, effectively additional samples are collected during exploitation phases and used toward estimation. The general framework of this online approach is summarized as follows. We also illustrate above procedure with Model II in Fig. 2.

Online Solution: A unifying framework

1: *Initialization*: Initialize $L, z, t = 1$ and sample each unit at least once. Update the collection of sample as $\mathscr{F}_0$ and the number of samples for each unit j as $n_j(t)$.
2: *Exploration*: At stage t, if $\mathscr{E}(t) := \{j : n_j(t) < D_1(t)\} \neq \emptyset$, sense the set $\mathscr{E}(t)$ of units.
3: *Exploitation*: If $\mathscr{E}(t) = \emptyset$, calculate the optimal strategy according to steps in the corresponding offline algorithm (with relaxation) based on collected statistics $\{\mathscr{F}_{\hat{t}}\}_{\hat{t}=1}^{t-1}$.
4: *Update*: $t := t + 1$; update sample set and for sampled unit j update $n_j(t) := n_j(t) + 1$.

The exploitation phase is intended for the algorithm to compute and execute the optimal offline strategy using statistics collected during the exploration phase.

However, due to the estimation error, the executed version has to be error tolerant, e.g., by relaxing the conditions for the steps involving strict equalities. We show how this relaxation is done for the problem in Model II below.

(Online_MU) and (Online_MC)

We now detail the online counterparts for (Offline_MU) and (Offline_MC) by filling the details in above general framework. As a notational convention, we will denote by $\tilde{y}$ the estimated version of y, $t_j(k)$ the meta stage when the k-th sample is collected for channel j and $E[\tilde{X}]$ the sample mean of X.

Online_MU: Algorithm details

1: *Initialization*: Initialize $L, z, l = 1$ and let each user access the channel once. Denote the collected sample for user j at stage l as $\mathscr{F}_l^j$. Update $n_j(0) = 1$ and $\mathscr{F}_0^j$.
2: *Exploration*: At stage l, let

$$\mathscr{E}(l) := \{j : n_j(l) < D_1(l)\}.$$

At any decision epoch, if $\mathscr{E}(l) \neq \emptyset$ and let user $j \in \mathscr{E}(l)$ transmit right away. If multiple such j exist, a user is selected randomly from $\mathscr{E}(l)$.
3: *Exploitation*: Otherwise if $\mathscr{E}(l) = \emptyset$, calculate the optimal threshold $\tilde{x}^*$ according to Eq. (4) using collected statistics $\{\mathscr{F}_{\hat{l}}^j\}_{\hat{l}=0}^{l-1}$ for each user j and following the scheduling strategy detailed in (Offline_MU).
4: *Update*: $l := l + 1$; for user j who accessed the channel update $n_j(l) := n_j(l) + 1$ and its sample set $\{\mathscr{F}_{\hat{l}}^j\}_{\hat{l}=0}^{l}$.

In (Online_MC), besides the clear separation between exploration and exploitation phases, several relaxations are invoked and the relaxation term $\frac{1}{t^{z/2}}$ could be viewed as the tolerance/confidence region. This tolerance region decreases in time t and approaches 0 asymptotically as the estimation errors decrease as well. There is an inherent trade-off between exploration and the tolerance region. With more exploration steps (a larger z), a finer degree of tolerance region could be achieved. We shall further discuss the roles of z in the analysis.

Regret Analysis

In this section, we analyze performance of the online algorithm. We present the main results for both (Online_MU) and (Online_MC). Since (Online_MC) is a much more complex algorithm and its analysis can be easily adapted for (Online_MU), as well as for brevity, we will only provide details for (Online_MC).

Before formalizing the regret analysis for (Online_MC), we outline the key steps. The regret consists of two parts: that incurred during exploration phases and that during exploitation phases. For exploration regret, we will try to bound the

number of exploration steps that are needed. For the exploitation phase, the regret is determined by how accurate decisions are made using estimated values. Specifically, *Online.STEP 1* does not have a decision-making step as it is simply a calculation, though we will show later in the proof that the calculation of $\{a_j, b_j\}_{j\in\mathscr{O}}$ does play an important role in the sorting and decision-making process. In *Online.STEP 2*, if the sorting is done incorrectly, then this could lead to errors in *Online.STEP 3*, as all decision-making and sensing orders are based upon the ordering of the channels. *Online.STEP 3* has the following error: (1) error in computing a_j, b_js, (2) error in calculating d_s, and (3) error in calculating a set of value functions for sub-step 3.3.

Assumptions

We state a few mild technical assumptions. We will assume nontrivial channels, i.e., $E[X_j] > 0, \forall j \in \mathscr{O}$, so that they all have positive average rates. We will also assume all channel realizations are bounded, i.e., finite support over all channel condition, $0 \leq \sup_{j\in\mathscr{O},\omega} X_j(t;\omega) < \infty$, $\forall t$, with ω being an arbitrary channel realization. This is not a restrictive assumption since in reality the transmission rate is almost always nontrivial and bounded. Moreover denote

$$\Delta^* = \max_{t,i\neq j,\omega_i,\,\omega_j} |X_j(t;\omega_j) - X_i(t;\omega_i)| + \sum_{i\in\mathscr{O}} c_i \ .$$

Δ^* can be viewed as an upper bound for a one step loss when a suboptimal decision is made and $\Delta^* < +\infty$ (note c_is are finite). Finally, we assume the cdf of each channel i's condition satisfies the Lipschitz condition, i.e., there exists $\mathscr{L}$(note different from L), $\alpha > 0$ such that

$$|F_{X_i}(x+\delta) - F_{X_i}(x)| \leq \mathscr{L}\cdot|\delta|^\alpha, \forall i, x, \delta \ . \tag{8}$$

The Lipschitz condition has been observed to hold for various distributions, for example, the exponential distribution and uniform distribution [32].

Main Results for (Online_MC)

Full details can be found in [31]. We first separate the regret for different phases. We have the following simple upper bound on the regret $R_{II}(T)$,

$$R_{II}(T) = R_e(T) + R_s(T) \leq R_e(T) + \Big(R_2(T) + R_3(T)\Big) \ .$$

The first term $R_e(T)$ is the regret from exploration phases. $R_s(T)$ is the regret from exploitation which could be further upper bounded by the two terms from *Online.STEP 2&3* of (Online_MC), respectively: $R_2(T)$ comes from the sorting

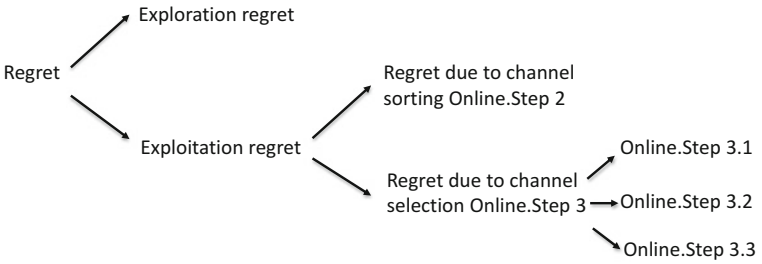

Fig. 3 Illustration of our regret analysis for (Online_MC)

procedure and $R_3(T)$ comes from the last step of decision-making. Notice for *Online.STEP 1* there is no direct regret incurred from parameter calculation: the errors in the calculation are reflected in *Online.STEP 2&3* later. The idea of upper bounding the regret by a union bound will be repeatedly utilized in the following analysis. For example, we can show that the regret in each step above can again be upper bounded by the sum of regrets of each of its sub-steps. This is illustrated in Fig. 3. Therefore we will not restate the details of the bounding for the rest of the proof. Denote the sum $s_p(T) := \sum_{t=1}^{T} \frac{1}{t^p}$. We have our main result for the regret analysis summarized as follows.

Theorem 2. *There exists a constant L s.t. the regret for (Online_MC) is bounded by*

$$R_{II}(T) \leq \Delta^* \left\{ NLT^z \log T + C_1 \cdot s_{\alpha \cdot z/2}(T) + C_2 \cdot s_2(T) \right\},$$

time uniformly, where $C_1, C_2 > 0$ are constants.

Here L is larger than a certain positive constant which we detail later. It is easy to notice since $T^z \log T$ and $s_{\alpha \cdot z/2}$ are both sublinear terms ($s_{\alpha \cdot z/2}$ is on the order of $1 - \frac{\alpha \cdot z}{2}$, while $s_2(\cdot)$ is bounded by a constant since $s_p(T) < \infty, \forall\, p > 1, T.$), $R_{II}(T)$ is also sublinear and asymptotically we achieve zero-regret on average ($\lim_{T \to \infty} R_{II}(T)/T = 0$). The first term $T^z \log T$ is due to the exploration while the term $s_{\alpha \cdot z/2}$ comes from exploitation. Clearly we see with a larger z (more exploration invoked), we will have a larger regret term from exploration phases; however the regret for exploitation will decrease. The balanced setting is achieved at $z = 1 - \frac{\alpha \cdot z}{2} \Rightarrow z = \frac{2}{2+\alpha}$.

Interesting to note when $\alpha \to \infty$, $z \to 0$, that is, similar to the weak regret results of MAB literature, our strong regret reduces from a sublinear order to the logarithmic one. What $\alpha \to \infty$ implies is that the Lipschitz condition becomes

$$|F_{X_i}(x + \delta) - F_{X_i}(x)| \leq \mathscr{L} \cdot |\delta|^{\alpha} = 0,$$

i.e., $F_{X_i}(x+\delta) - F_{X_i}(x) = 0$ when δ is small enough. This further implies when the channel quality state X_i is discrete, we are able to achieve a $O(\log T)$ strong regret, compared to a $O(T^z \log T)$ one.

Bounding the Exploration Regret

We start with bounding the exploration regret $R_e(T)$.

Lemma 1. *The exploration regret $R_e(T)$ is bounded as*

$$R_e(T) \leq D_1(T) \cdot N\Delta^*. \tag{9}$$

Proof. Note that since the exploration phase requires $D_1(T)$ samples for each channel up to time T, we know there are at most $N \cdot D_1(T)$ exploration phases being triggered. For each exploration phase, the regret is bounded by Δ^*, completing the proof. □

Bounding the Exploitation Regret

We next consider regret incurred during exploitation phases, that associated with the sorting (*Online.STEP 2*) and that associated with decision-making (*Online.STEP 3*), respectively. Main steps and sketches of the proofs are given below, while the details can be found in [31].

To bound the regret associated with the sorting step, we have the following result.

Lemma 2. *Regret $R_2(T)$ is bounded as follows, $R_2(T) \leq \Delta^* \cdot 2 \cdot N \sum_{t=1}^{T} \frac{2}{t^2}$.*

Proof. First of all, we could easily show the calculation of $E[X_j], a_j, b_j$ will fall into certain confidence region when the number of exploration steps are large enough (L). Moreover the estimation errors of a_j, b_j are proportional to the one for $E[X_j]$. Intuitively this is due to the calculation of a_j, b_j which relates to the calculation of $E[X_j]$ in a piece-wise linear way.

Lemma 3. *With sufficiently large $L(\geq \frac{1}{\varepsilon^2})$, $\forall j$ we have,*

$$P(|E[\tilde{X}_j] - E[X_j]| > \varepsilon) \leq \frac{2}{t^2}\ , \ \textit{and}$$

$$P(|\tilde{a}_j - a_j| > c_{1,j} \cdot \varepsilon) \leq \frac{2}{t^2},\ P(|\tilde{b}_j - b_j| > c_{2,j} \cdot \varepsilon) \leq \frac{2}{t^2}\ ,$$

where $\varepsilon, c_{1,j}, c_{2,j}$ are positive constants.

Accurate estimations of the parameters lead us to a small probability event of miscomputing $\mathscr{R}$:

Lemma 4. *At time t with sufficiently large L, and any iteration steps of the sorting procedure of Online.STEP 2, we have* $P(\mathscr{R} \neq \tilde{\mathscr{R}}) \leq N \cdot \frac{2}{t^2}$.

The above lemma helps us prove the following results for sorting S:

Lemma 5. *At t with sufficiently large L, the error for sorting set S is bounded as,*

$$P(\tilde{S} \neq S) \leq N \cdot \frac{2}{t^2} .$$

Putting up all terms and multiple by Δ^*, we have results claimed in Lemma 2. □

To bound the regret associated with decision-making (STEP 3), we have the following result.

Lemma 6. *Regret $R_3(T)$ is bounded as follows,*

$$R_3(T) \leq \Delta^* \cdot \left(C_1 \cdot s_{\alpha \cdot z/2}(T) + C_2^* \cdot s_2(T) \right),$$

where C_1, C_2^* are positive constants.

Proof. We sketch the key steps toward getting the claim.

Online.STEP 3.1

At first step of deciding whether $x(n) \geq a_1$ of *Online.STEP 3*, there will be no error when $x \leq \min\{\tilde{a}_1, a_1\}$ or $x \geq \max\{\tilde{a}_1, a_1\}$. Consider x falling in the middle. Make ε being small enough, $\varepsilon = \frac{1}{t^{z/2}}$. As we already proved $P(|\tilde{a}_1 - a_1| > c_{1,1} \cdot \varepsilon) < \frac{2}{t^2}$, and also due to the relaxation of $\mathscr{R}$, the difference between $\tilde{a}_1$ and the true a_1 is bounded away by at most $c_{1,1} \cdot \varepsilon + \varepsilon$. For $|\tilde{a}_1 - a_1| \leq (c_{1,1} + 1) \cdot \varepsilon$, the probability that x falls within the middle is bounded as

$$\begin{aligned} & P(\exists i \text{ s.t. } X_i(t) \in [\min\{\tilde{a}_1, a_1\}, \max\{\tilde{a}_1, a_1\}]) \\ & \leq \sum_i P(X_i(t) \in [\min\{\tilde{a}_1, a_1\}, \max\{\tilde{a}_1, a_1\}]) \\ & \leq N \cdot |F_{X_i}(\tilde{a}_1) - F_{X_i}(a_1)| \leq \frac{N \mathscr{L} \cdot (c_{1,1} + 1)^\alpha}{t^{\alpha \cdot z/2}} , \end{aligned}$$

by Lipschitz condition. Add up for all t we have a sublinear term.

Online.STEP 3.2

We first prove the following results:

Lemma 7. *With sufficiently large L, $\forall$ information state (x, S), we have at time t $\forall \varepsilon > 0$* $P(|\tilde{V}(x, \tilde{S}) - V(x, S)| > |S| \cdot \varepsilon) \leq \frac{2}{t^2}$.

This lemma bounds the difference in estimating the value function with enough samples. The proof is done by induction over the size S and relies heavily on the dynamic equations for $V(\cdot,\cdot)$. Based on above results, we prove that the estimation of d_s can be bounded by a confidence region, which we detail as follows:

Lemma 8. *With sufficiently large L and channel set S*

$$P(|\tilde{d}_s - d_s| > \frac{2|S|+3}{C_{d_s}} \cdot \varepsilon) \leq \frac{4}{t^2} ,$$

at time step t, $\forall \varepsilon > 0$, *where* $C_{d_s} = P(X_1 \leq d_s)$.
The proof is primarily done via analyzing the estimation errors from both sides of the equation

$$V(0, S_n) = -c_1 + E[V(\max\{d_s, X_1\}, S_n - \{1\})] ,$$

which decides d_s. For bounding the value functions, we repeatedly use Lemma 7. Taking $L \geq 4$ and $\varepsilon = \frac{1}{t^{z/2}}$ will lead to our bounds.

Remark 1. The above result invokes a constant $C_{d_s} = P(X_1 \leq d_s)$. If $P(X_1 \leq d_s) = 0$, i.e., $X_1(\omega) > d_s, \forall \omega$ our bound is not well defined. In fact under this case, what really matters is the overlapping between $[0, \tilde{d}_s]$ and $[\underline{X}_j, \overline{X}_j]$ (support of X_j). So long as the overlapping is bounded small enough, the decision error is again bounded.

Online.STEP 3.3

When $x(n) < d_s$, the optimal decision comes from one of three cases. For the first two cases, we have the following lemmas characterizing the regrets: for sub-steps *Online.STEP 3.3.1 and 3.3.2*, there are possibly three decisions to make and we have their error bounded as follows

Lemma 9. *With sufficiently large L, we have the following concentration results: (1). if* $b_1 \geq a_2$, $P(\tilde{b}_1 < \tilde{a}_2 - \frac{1}{t^{z/2}}) \leq \frac{2}{t^2}$. *(2). If* $b_2 \geq b_1$, $P(\tilde{b}_2 < \tilde{b}_1 - \frac{1}{t^{z/2}}) \leq \frac{2}{t^2}$. *(3). If* $g_1(0) \geq \max\{E[X_1], g_2(0)\}$, $P(\tilde{g}_1(0) < \max\{E[\tilde{X}_1], \tilde{g}_2(0)\} - \frac{2}{t^{z/2}}) \leq \frac{2}{t^2}$.

For error in b_1 in *Online.STEP 3.3.2*, the analysis is the same as for a_1 as in *Online.STEP 3.1* since we already established its estimation error bounds.

For the last case in *Online.STEP 3.3.3*, first notice if $E[X_1] = g_2(0)$, there is no error associated with the last step since guessing (access w/o sensing) the first channel and probing the second essentially return the same expected reward. Therefore we show the error analysis when $E[X_1] \neq g_2(0)$. We then bound the error of estimating b_0 (this is similar with proving the bound for d_s and we omit the details for proof): with C_{b_0} being certain constant, $P(|\tilde{b}_0 - b_0| > \frac{2\varepsilon}{C_{b_0}}) \leq \frac{2}{t^2}$. Moreover we have the following results: At time t

$$P(\mathbf{sign}(E[\tilde{X}_1] - \tilde{g}_2(0)) \neq \mathbf{sign}(E[X_1] - g_2(0))) \leq \frac{2}{t^2}.$$

These cover all parameters needed for the decision-making queries.

Putting up all terms we have results claimed in Lemma 6. □
Combining $R_e(T), R_2(T), and R_3(T)$ gives us the main result.

Discussion on Parameter *L*

In most of our proved results, we assumed L to be significantly large. We summarize the actual conditions on L below:

$$\textbf{(Condition 1):}\ L \geq \max\{4, 1/(\frac{\min_{a_{k_1} \neq a_{k_2}} |a_{k_1} - a_{k_2}|}{2 \max_j c_{1,j}})^2\}\ ,$$

$$\textbf{(Condition 2):}\ L \geq 1/\varepsilon_o^2\ ,$$

where $\{c_{1,j}\}_{j \in \mathscr{O}}$ is a set of positive constants and ε_o is a solution of ε for

$$C \cdot (\varepsilon + \mathscr{L} \cdot (c_{1,j} + 1)^\alpha \varepsilon^\alpha) \leq \frac{\min\{\varepsilon_3, \varepsilon_4\}}{2}\ ,$$

where C is a positive constant and

$$\varepsilon_3 = \min_{j \neq k} |E[X_j] - E[X_k]|,\ \varepsilon_4 = \min_{j \neq k} |\frac{E[X_j] - c_j}{P(X \geq a_j)} - \frac{E[X_k] - c_k}{P(X \geq a_k)}|$$

and for simplicity we assume $\varepsilon_3, \varepsilon_4 > 0$, that is, channels have different values in above two parameters.

From **(Condition 1)** we know when $\{a_i\}$s are closer to each other, L should be chosen to be larger. Also from **(Condition 2)** we know when channels' expected reward $E[X_j]$ and $\frac{E[X_j] - c_j}{P(X \geq a_j)}$ (can be viewed as potential term when sensed) are closer to each other, again L should be chosen to be larger. The intuition here is that in such cases a larger L can help achieve higher accuracy for the estimations to differentiate two channels that are similar.

The selection of L depends on a set of εs, which further depends on statistical information of X_js (though weaker as we only need to know a lower bound on them), but this is assumed unknown. Following a common technique [33], this assumption can be relaxed but with potentially larger regret. In particular, one can show that at any time t with L being a positive constant, the estimation error ε_t for any terms (e.g., a, b or $E[X_j]$) satisfies the following: $P(\varepsilon_t > \frac{1}{t^\theta}) \leq \frac{1}{t^\nu}$, with $\theta, \nu > 1$. Therefore with the error region ε_t being small enough, there would be no error associated with differentiating the channels of the algorithm. Thus there exists a constant T_0 such that $\varepsilon_t < \min \varepsilon, \forall t > T_0$. Consider the case $\varepsilon_t \leq \frac{1}{t^\theta}$. Since when the error happens under this case, two estimated terms (the suboptimal and optimal

one) are separated by at most $2\varepsilon_t$. The probability of the corresponding term falls into this region is bounded as $|F_{X_i}(x+\varepsilon_t) - F_{X_i}(x-\varepsilon_t)| \leq \mathscr{L} \cdot 2^{\alpha} \cdot \frac{1}{t^{\alpha \cdot \theta}}$ by the Lipschitz condition. Therefore we have the extra error bounded by $\sum_{t=1}^{T_0} \mathscr{L} \cdot 2^{\alpha} \cdot \frac{1}{t^{\alpha \cdot \theta}}$, which is a constant growing sublinearly up to time T_0.

Main Results for (Online_MU)

For (Online_MU) we can similarly prove the following result

Theorem 3. *There exists a constant L s.t. the regret for (Online_MU) is bounded by*

$$R_I(H) \leq \Delta^* \left\{ MLH^z \log H + \hat{C}_1 \cdot s_{\alpha \cdot z/2}(H) + \hat{C}_2 \cdot s_2(H) \right\},$$

time uniformly, where $\hat{C}_1, \hat{C}_2 > 0$ are constants.
Notice that though $R_I(H)$ looks similar to $R_{II}(T)$, they may have very different parameters for each term, i.e., $\hat{C}_1, \hat{C}_2$ may be quite different from C_1, C_2, as well as different constraints for L due to the different statistical structure of the two problems. Again the first term is coming from exploration phases, the second term is due to inaccurate calculations of x^*, and last term bounds the event that $\tilde{x}^*$ is too different from x^*.

Simulation

In this section we show a few examples of the performance of the proposed online algorithm via simulation. We measure the average *regret* rate $R_I(l)/l(R_{II}(t)/t)$ and compare our performance to the optimal offline algorithm, a static best single-channel policy, as well as that of a weak-regret algorithm.

For simplicity of demonstration, we assume channel qualities follow *exponential distribution* but with different parameters (We have similar observations for other distributions. The details are omitted for brevity.). The corresponding distributions' parameters are generated uniformly and randomly between $[0, 0.5]$. Users' attempt rates p_is are uniformly generated in the interval $[0, 0.5]$ (in Model I). The costs for sensing the channels (in Model II) are also randomly generated according to uniform distribution between $[0, 0.1]$. In the following simulation for Model I, we have $M = 5$ users, while for Model II, we have $N = 5$ channels. Simulation cycle is set to be $H = T = 4,000$. In the set of results for performance comparison with offline solutions, we set the exploration parameters as $L = 10, z = 1/5$. Later on we show the performance comparison w.r.t. different selection of L and z.

Comparison with Offline Solution

We first take the difference between the oracle ((Offline_MU)) and (Online_MU) at each step t and divide it by t (i.e., we plot $R_I(t)/t$). This regret rate is plotted in Fig. 4, and clearly we see a sublinear convergence rate. We repeat the experiment for (Online_MC), and the regret convergence is shown in Fig. 5, which validate our analytical results. To make the comparison more convincing, we compare the accumulated reward between (Online_MC), (Offline_MC), and the best single-channel (action) policy, which always selects the best channel in terms of its average rate (channel statistics is assumed to be known a priori) in Fig. 6. In particular, we see the accumulated rewards of (Online_MC) (red square) are close to the performance of the oracle (blue circle) who has all channel statistical information and follows the optimal decision process as we previously depicted in (Offline_MC). We observe that the dynamic policies clearly outperform the best single-channel policy.

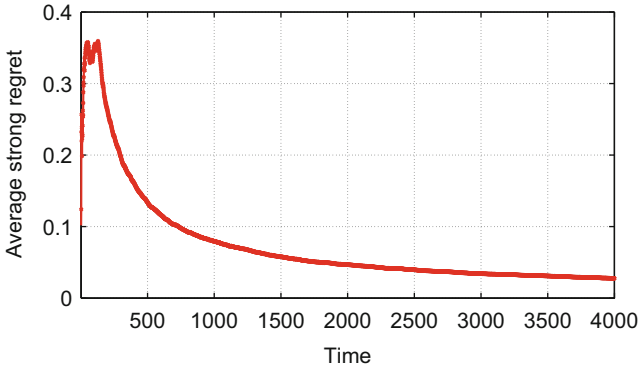

Fig. 5 Convergence of average regret: (Online_MC)

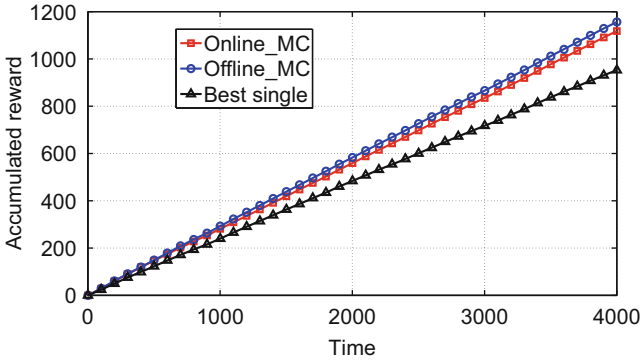

Fig. 6 (Online_MC) v.s. (Offline_MC) v.s. Best single

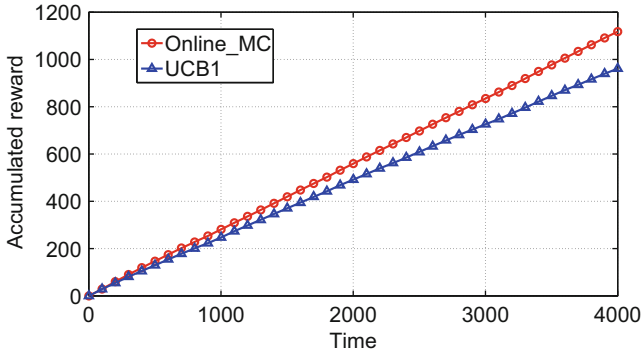

Fig. 7 (Online_MC) v.s. UCB1

Comparison with UCB1

We next demonstrate the advantages of our algorithm (Online_MC) by comparing it with UCB1, a classical online learning algorithm that achieves logarithmic weak regret for IID bandits [25]. The performance gain is quite clearly seen in Fig. 7. It is worth pointing out that there also exists extensive literature in reinforcement learning (RL), which is generally targeted at a broader set of learning problems in Markov Decision Processes (MDPs) [34]. Bandit problems constitute a special class of MDPs, for which the regret learning framework (using index policies) is generally viewed as more effective both in terms of convergence and computational complexity.

Effects of Parameter Selection

We next take a closer look at the effects of parameter selection, primarily with L and z. We demonstrate with (Online_MC). We repeat the above sets of experiment

Table 2 Average collected reward under different L (Avg. = 0.27 with random channel selection)

$L(z = 1/5)$	5	10	20	30	40
Average reward	0.3391	**0.3522**	0.3353	0.3183	0.3166

Table 3 Average collected reward under different z (Avg. = 0.27 with random channel selection)

$z(L = 10)$	1/6	1/5	1/4	1/3	1/2
Average reward	0.3411	0.3522	**0.3557**	0.3017	0.1949

w/ different L, z combinations and tabulate the average reward per time step. From Table 2, we observe the selection of L is not monotonic: a smaller L incurs less exploration steps, but more errors will be invoked at exploitation steps due to its less confidence in calculating the optimal strategy. On the other hand, a large L inevitably imposes higher burden on sampling and thus becomes less and less favorable with its increase. Similar observations hold for z since z controls the length of exploration phases jointly with L but with different scale. However it is indeed interesting to observe that when z grows large enough (e.g., $z = \frac{1}{2}$), the performance drops drastically: this is due to the fact in such a case more than enough efforts have been spent in sensing steps (Table 3).

Discussion

We discuss several possible extensions of existing results, concerning the relaxation of assumptions on channel properties. Note that our basic idea and method of tracking an offline optimal (or near-optimal) algorithm by estimating key parameters remain unchanged regardless of the assumptions on the channel model. However, two factors will be at play with more challenging models: (1) Different channel models may lead to only suboptimal offline solutions or approximations which may or may not have a performance guarantee; tracking such algorithms would lead to a "weakened" strong regret measure. (2) If the computation of an offline algorithm is complex either in terms of computation or in the amount of information it requires, then this could also affect the effectiveness of our learning procedure.

For instance, throughout the paper, we have assumed that the channel quality over time evolves as an IID process, though with unknown distributions. An immediate extension is to consider Markovian channel evolution, which leads to a restless bandit problem which does not have a known structured solution in general. In some special cases, optimal solutions can be derived and may take on a simple form, see, e.g., the greedy policy under the two-state channel model considered in [35, 36], or the LP relaxation approximation developed in [37]. Tracking these algorithms

requires the estimation of a set of two-state transition probability matrices and conceptually can be done and likely will not change the order of the regret bound; however, none of these algorithms are generally optimal so in some cases we could be tracking a target with poor performance. On the other hand, computing the optimal offline algorithm even with full-channel statistics is computationally intensive (restless bandit problems are known to be PSPACE complete [38], so tracking it becomes nontrivial).

Similarly, throughout this study, we have not considered interferences from multiple users; the channel quality perceived by a user is assumed to be entirely the result of factors like fading and shadowing but not interference. It would be an interesting extension to consider multiuser interference and investigate the effectiveness of our learning approach in tracking a certain offline multiuser algorithm. A natural way to design the learning procedure in this case is to combine stochastic bandit learning (for channel availability) with adversarial learning (for user interference). Possible candidates of target offline algorithms include, e.g., [39], which studied a capacity maximization problem in distributed wireless network under SINR interference model and showed a constant factor approximation bound compared to the global optimum is achievable, by using an adversarial model to capture the effects of interference, and [40] that proposed scheduling algorithms for a similar problem but under Rayleigh-fading interference models and showed a logarithmic order approximation.

Last but not least, the assumption that the channel statistics stay unchanged is needed only in deriving the bound under the current technique. It is however not needed for the learning algorithm to work as the exploration aspect of the algorithm is in principle designed to detect and adapt to changes in the underlying statistics. The challenge is in how to quantify the learning/adaptation performance when such changes are present. Some recent results may prove very helpful, see, e.g., [41] on a sharp bound (sublinear) for certain cases when such non-stationary statistical properties satisfy bounded variation [41].

Conclusion

In this chapter, we discuss several decision-making issues in channel switching and transmission scheduling in cognitive networks. We present a couple of classical results for single-user, multichannel model and multiuser, single channel model. We point out to a common limitation in all existing solutions in such decision-making solutions that often channel statistics are unknown a priori. Without knowing such information, we propose an online learning algorithm which helps collect samples of channel realization while making optimal scheduling decisions. We show our proposed learning algorithm (for both a multiuser and multichannel model) achieves sublinear regret uniform in time, which further gives us a zero-regret algorithm on average.

Abstract

The energy-efficient design for TDMA (time-division multiple access) MIMO (multiple-input multiple-output) cognitive radio (CR) networks can be treated as the joint optimization over both the time resource and the transmit precoding

matrices to minimize the overall energy consumption. Compared with the traditional MIMO networks, the challenge here is that the secondary users (SUs) may not be able to obtain the channel state information (CSI) to the primary receivers. The corresponding mathematical formulation turns out to be non-convex and thus of high complexity to solve in general. This chapter covers both the transmission choices for each SU: single-data-stream transmission and multiple-data-stream transmission. Fortunately, by applying a proper optimization decomposition, it can be shown that the optimal solution can be found in polynomial time in both cases. In practical wireless system, the time is usually allocated in the unit of slot. Moreover, by exploring the special structure of this particular problem, it can be shown that the optimal time slots allocation can be obtained in polynomial time with a simple greedy algorithm. Simulation results show that the energy-optimal transmission scheme adapts to the traffic load of the secondary system to create a win-win situation where the SUs are able to decrease the energy consumption and the PUs experience less interference from the secondary system. The effect is particularly pronounced when the secondary system is underutilized.

Cognitive radio networks · MIMO · Energy efficiency · Scheduling · Beamforming

Introduction

Background

Cognitive radio (CR), which allows secondary users (SUs) to opportunistically access the spectrum that is underutilized by the primary licensed users, is a promising approach to improve the spectrum efficiency [11, 17]. With the aid of multiple-input multiple-output (MIMO) techniques [9], the cognitive spectrum may efficiently work in the underlay mode, where the SUs transmit concurrently with the primary users (PUs) as long as the interferences from the SUs to the PUs are below a tolerable threshold [17]. Future wireless systems are evolving to support the exponentially increasing traffic demands, which, in most cases, are achieved at the expense of a higher energy consumption and a considerable impact on the environment. Energy-efficient transmission is of critical importance to reduce the carbon footprint and to prolong the battery lifetime of wireless devices [6–8, 12, 15, 16, 20, 27]. Performing energy-efficient transmissions among the SUs could also alleviate the interference to the primary system.

The key idea that enables the underlay mode in a CR network is that with multiple antennae, the SU can carefully design its precoding matrix so as to suppress the interference at the primary receivers. Such a technique normally requires channel state information (CSI), which can be assumed to be available in the traditional MIMO network setup. However, in a CR network, the PUs are usually not aware of the existence of the SUs. This has two effects: (1) the primary receivers may not

feed back the CSI to the SUs; (2) the primary receiver will not perform interference cancellation at the receiver side. In other words, the SUs are only able to do pre-interference suppression and may have to do this with only access to statistical CSI. This is the main challenge when designing energy-efficient transmission strategies for MIMO CR networks.

Related Works

Studies of energy-efficient transmissions of MIMO networks fall into two main classes: traditional MIMO networks [6, 8, 15, 16, 24, 27] and MIMO CR networks [12, 20]. For example, in the former class, [6] investigated the energy consumption of a single MIMO/SISO link by considering both the transmission energy and the circuit energy consumption. In [24], the authors considered the transmit power minimization through downlink transmit beamforming. In [8], the authors considered power minimization through downlink transmit beamforming and solved it with semidefinite programming (SDP) approach. In [15], the authors studied the energy efficiency of a MIMO-based TDMA cellular system. In particular, the authors proposed a cross-layer approach of joint rate selection and mode switching to save the system energy consumption. As discussed above, perfect CSI is typically assumed in traditional MIMO networks.

In the latter class, some recent papers, [12, 20, 34], considered the energy/power minimization problem in MIMO CR networks. When perfect CSI is not available to the secondary system, the deterministic interference constraints at the primary receivers cannot be satisfied and thus are not proper. A robust optimization framework is proposed in [12, 34], which requires the constraints to hold for every possible realization of the channel. Such an approach guarantees the worst-case performance and is thus overly conservative. In practice, many wireless applications can tolerate occasional outages without affecting users' QoS. Therefore, it is sufficient to consider a more realistic interference constraint which is to satisfy the interference constraints with high probability [28]. In [20], the authors considered the multicast precoding where a secondary transmitter communicates with multiple secondary receivers under statistical CSI. The problem was shown to be non-convex [24], and an SDP relaxation was proposed. Since there is only one secondary transmitter, it is sufficient to optimize the SU's precoding matrix only at the physical layer. This chapter focuses on the uplink transmission scenario involving multiple secondary transmitters. In this case, the scheduling and beamforming need to be jointly optimized in order to minimize the total energy consumption of all the SUs.

A closely related problem to energy minimization is rate maximization. Rate maximization in MIMO CR networks has been considered in [29–34]. In [31], Zhang et al. showed that rate maximization for a single secondary link under perfect CSI and no interference from the primary system to the secondary system is a convex optimization problem. Practical algorithms based on the singular-value decomposition of the SU's MIMO channel matrix were proposed. In [29], weighted sum-rate maximization of the multiple access channel in a MIMO CR network was

investigated and a capped multilevel water-filling algorithm was proposed. In [33], the authors considered maximizing the rate of a single secondary link under different levels of CSI availability of the channels from the SUs to the primary receivers. A unified homogeneous QCQP formulation was proposed, and an SDP relaxation was shown to produce the optimal solution in some special cases.

Summary

The joint design of physical and MAC layer techniques can further reduce the overall energy consumption of the secondary network with multiple SUs. With the aid of MIMO techniques, it is possible that multiple SUs send uplink traffic to the secondary base station (BS) simultaneously with spatial multiplexing. However, in a CR network, the interference power at each secondary receiver does not only come from the primary users but also from other SUs. The MIMO interference channel is well known to result in NP-hard problems [22]. Therefore, in order to avoid excessive interference among the SUs, the SUs send their traffic via TDMA. There is no interference among the SUs. However, the SUs share the same spectrum with some PUs, and thus the concurrent transmissions of SUs and PUs will cause interference to each other. Shannon's capacity formula implies that we can reduce the energy consumption for delivering a certain amount of traffic by increasing the transmission time [26]. However, in a TDMA network, the total transmission time is shared by multiple SUs. Increasing transmission time for one SU leads to the reduction of transmission time for others. Therefore, the energy consumptions of SUs trade off against each other. Meanwhile, each SU has a QoS requirement, measured as a target rate, to be satisfied. Therefore, the secondary BS needs to allocate the time resource and configure the beamforming patterns for the SUs in a way that could achieve the desirable balance between the SUs' target rates and the interference at the primary receivers.

The problem formulation involves jointly optimizing the time allocation and precoding for the SUs, with statistical CSI. As will be elaborated in section "Problem Formulations", the problem formulations are non-convex and thus can be expected to be hard to solve in general. This chapter covers a comprehensive investigation on this problem, under two different transmission choices for SUs: single-data-stream transmission and multiple-data-stream transmission. Quite surprisingly, it is possible to develop efficient algorithms that are guaranteed to find the optimal solutions in both cases. To tackle the non-convexity, the decomposition method that subdivides the overall problem into two separate problems is applied so that the problem can be solved efficiently. In particular, the optimal time allocation can be found by solving a convex optimization problem for each case. When each SU only transmits one data stream on all its transmit antennae, the transmit precoding matrix then reduces to a beamforming vector. This choice is more preferable in an interference-limited network to avoid excessive interference to other links [4, 18].Given the optimal time allocation, the optimal beamforming vector for each SU can be obtained efficiently through a simple matrix eigenvalue-eigenvector

computation. When each SU transmits multiple data streams, the SU further utilizes the multiplexing gain of MIMO systems. In this case, the number of data streams is also a system design variable, which is discrete by nature. In this case, given the optimal time allocation, the optimal precoding matrix can be found by "water-filling."

Furthermore, in practical wireless systems, a slot is the smallest unit during time allocation, which implies that there is additional integer constraint on the time variable. The overall problem formulation then becomes a mixed-integer non-convex optimization problem, which is typically even more complicated. By exploring the special structure of the time optimization problem, it can be shown that the optimal integer time allocation can be found in polynomial time with a simple greedy algorithm.

The remainder of this paper is organized as follows. Section "System Model" introduces the system model. Section "Problem Formulations" lays out the problem formulations in both the single-data-stream transmission case and the multiple-data-stream transmission case for each SU. Section "Single-Data-Stream Transmission: Problem Decomposition and Optimal Solution" is devoted to the optimization decomposition and the solution method when each SU transmits only one data stream on all its transmit antennae. Section "Multiple-Data-Stream Transmission: Problem Decomposition and Optimal Solution" covers the solution methods under the multiple-data-stream transmission case for each SU. Section "Simulation Results" is the simulation results. Section "Conclusion" concludes this chapter.

System Model

In a CR network with K SUs and J PUs, the primary links could potentially always be active and thus need to be protected at all times. The primary network is composed of J pairs of transmitters and receivers. The secondary system is a single-cell network, where the SUs send uplink traffic to the same secondary BS via TDMA. The uplink transmissions are synchronized by the secondary BS so that they are allocated different time slots for their transmissions and thus do not cause interference to each other.

Let S_k denote the kth SU. Let M_{S_k} denote the number of transmit antennas of S_k and N_{BS} denote the number of receive antennas at the secondary BS. Let $\mathbf{H}_{BS,S_k} \in \mathbb{C}^{N_{BS} \times M_{S_k}}$ denote the channel matrix from S_k to the secondary BS. There are J links in the primary network. Let P_j denote the jth primary transmitter-receiver pair. Let M_{P_j} and N_{P_j} denote the number of transmit antennas and the number of receive antennas of P_j, respectively. Let $\mathbf{H}_{P_i,P_j}$ denote the $N_{P_i} \times M_{P_j}$ channel matrix from the jth primary transmitter to the ith primary receiver. Since the SUs coexist with the PUs, their signals may interfere with each other. Let $\mathbf{H}_{P_j,S_k} \in \mathbb{C}^{N_{P_j} \times M_{S_k}}$ and $\mathbf{H}_{BS,P_j} \in \mathbb{C}^{N_{BS} \times M_{P_j}}$ denote the channel matrix from S_k to the receiver of P_j and the channel matrix from the transmitter of P_j to the secondary BS, respectively. The channel is assumed to be a frequency flat fading channel so that it is the same for the considered bandwidth. Furthermore,

the channel is assumed to be block fading channel, so that the channel matrices do not change during a TDMA frame, and the channel realizations in different frames are uncorrelated. This assumption is valid if the mobile user does not move very fast. In this case, the coherence time is long enough to cover the whole TDMA frame. In particular, it is assumed that the channel is Rayleigh fading channel in a rich scattering environment, so that the entries of the channel matrices are independently and identically distributed (i.i.d.) complex Gaussian random variables with a zero mean [21]. The variance of the complex Gaussian variables is half of the path loss from the corresponding transmitter to the corresponding receiver. Since the secondary system is centralized, the secondary BS can estimate $\mathbf{H}_{BS,S_k}$ and feed back it to each S_k with a separate control channel. Thus, it is reasonable to assume that $\mathbf{H}_{BS,S_k}$ is known to both S_k and the secondary BS.

Single-Data-Stream Transmission for Each SU

When each SU transmits the same data stream on all its transmit antennae, the transmit and receive beamforming can be defined on vector. Let $\mathbf{u}_{S_k} \in \mathbb{C}^{M_{S_k}\times 1}$ and $\mathbf{v}_{BS_k} \in \mathbb{C}^{N}_{BS} \times 1$ denote the transmit beamforming vector of S_k and the receive beamforming vector of the secondary BS when S_k is active, respectively. Let $\mathbf{u}_{P_j} \in \mathbb{C}^{M_{P_j}\times 1}$ and $\mathbf{v}_{P_j} \in \mathbb{C}^{N_{P_j}\times 1}$ denote the transmit beamforming vector and the receive beamforming vector of the primary link P_j, respectively. Without loss of generality, the receive beamforming vectors are normalized such that $\|\mathbf{v}_{BS_k}\|_2^2 = 1$ and $\|\mathbf{v}_{P_j}\|_2^2 = 1$. Let scalars x_{S_k} and x_{P_j} denote the transmit signals of S_k and P_j, respectively. Without loss of generality, it can be assumed that $\mathbb{E}[|x_{S_k}|^2] = 1$ and $\mathbb{E}[|x_{P_j}|^2] = 1$. The received signal of S_k after receive beamforming at the secondary BS is

$$y_{BS_k} = \mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}x_{S_k} + \sum_{j=1}^{J} \mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}x_{P_j} + \mathbf{v}_{BS_k}^H \mathbf{n}_{BS}, \quad k=1,\cdots,K.$$

The vector $\mathbf{n}_{BS} \in \mathbb{C}^{N_{BS}\times 1}$ is a circular complex additive Gaussian noise vector with a noise power of $N_0 w$ at the secondary BS, where $N_0/2$ is the noise power spectral density and w is the bandwidth used in the secondary system. The received signal-to-interference-plus-noise ratio (SINR) of S_k then becomes

$$\begin{aligned}\gamma_{BS_k} &= \frac{\mathbb{E}\left[\left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}x_{S_k}\right|^2\right]}{\mathbb{E}\left[\sum_{j=1}^{J}\left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}x_{P_j}\right|^2 + \left|\mathbf{v}_{BS_k}^H \mathbf{n}_{BS}\right|^2\right]} \\ &= \frac{\left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}\right|^2}{\sum_{j=1}^{J}\left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}\right|^2 + N_0 w}, \quad k=1,\cdots,K. \end{aligned} \tag{1}$$

According to the Shannon's capacity formula, the achievable transmission rate of S_k is

$$r_{S_k} = w \log\left(1 + \gamma_{BS_k}\right) = w \log\left(1 + \frac{\left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,S_k} \mathbf{u}_{S_k}\right|^2}{\sum_{j=1}^{J} \left|\mathbf{v}_{BS_k}{}^H \mathbf{H}_{BS,P_j} \mathbf{u}_{P_j}\right|^2 + N_0 w}\right).$$

The transmit power of S_k is $p_{S_k} = \|\mathbf{u}_{S_k}\|_2^2$, and S_k causes an interference to the jth primary receiver at the level of

$$q_{P_j S_k} = \left|\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k} \mathbf{u}_{S_k}\right|^2, \quad k = 1, \cdots, K, \quad j = 1, \cdots, J.$$

Multiple-Data-Stream Transmission for Each SU

To further explore the multiplexing gain of MIMO system, both the primary and secondary users can transmit multiple data streams. Let D_{S_k} and D_{P_j} denote the number of data streams of S_k and P_j, respectively. Let $\mathbf{x}_{S_k} \in \mathbb{C}^{M_{S_k} \times 1}$ and $\mathbf{x}_{P_j} \in \mathbb{C}^{M_{P_j} \times 1}$ denote the actual transmitted vectors of S_k and P_j, respectively. The covariance matrices of $\mathbf{x}_{S_k}$ and $\mathbf{x}_{P_j}$ are denoted by $\mathbf{Q}_{S_k}$ and $\mathbf{Q}_{P_j}$, which are Hermitian positive semidefinite matrices.

The received vector of S_k at the secondary BS is

$$\mathbf{y}_{BS_k} = \mathbf{H}_{BS,S_k} \mathbf{x}_{S_k} + \sum_{j=1}^{J} \mathbf{H}_{BS,P_j} \mathbf{x}_{P_j} + \mathbf{n}_{BS}, \; k = 1, \cdots, K.$$

The secondary BS treats the interference from the primary transmitters as noise, and there is no successive interference cancellation at the secondary BS. The interference-plus-noise covariance matrix at the secondary BS when S_k transmits is then

$$\mathbf{C}_{S_k} = \sum_{j=1}^{J} \mathbf{H}_{BS,P_j} \mathbf{Q}_{P_j} \mathbf{H}_{BS,P_j}^H + N_0 w \mathbf{I}_{N_{BS}},$$

which is an $N_{BS} \times N_{BS}$ Hermitian positive semidefinite matrix.

According to Shannon's capacity formula for a MIMO link [9,25], the achievable transmission rate of S_k is

$$r_{S_k} = w \log\left[\det\left(\mathbf{I} + \mathbf{H}_{BS,S_k} \mathbf{Q}_{S_k} \mathbf{H}_{BS,S_k}^H \mathbf{C}_{S_k}^{-1}\right)\right], k = 1, \cdots, K.$$

Here r_{S_k} is the instantaneous transmission rate (in nats/second) when S_k is active. The total transmit power of S_k on all its transmit antennas is $p_{S_k} = \mathrm{tr}\left(\mathbf{Q}_{S_k}\right)$, and S_k causes a total interference power to the jth primary receiver at the level of

$$q_{P_j,S_k} = \mathrm{tr}\left(\mathbf{H}_{P_j,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{P_j,S_k}^H\right),\ k = 1,\cdots,K, j = 1,\cdots,J.$$

Problem Formulations

The system target is to choose the proper time allocation and the transmit precoding design for each SU to minimize the total energy consumption of all the SUs while protecting the PUs and ensuring a minimum QoS for each SU. Specifically, the interference from each SU to each of the PUs needs to be below a certain threshold, and each SU has a rate requirement R_{S_k} to be satisfied. Here R_{S_k} (with the unit of nats/frame) is the number of nats that S_k needs to transmit in each time frame. Without loss of generality, the TDMA frame length of the secondary system is normalized to be 1. Each S_k is allocated a time fraction t_{S_k} $(0 \le t_{S_k} \le 1)$ to transmit its data. The instantaneous transmit power of S_k is limited by a maximum power of $p_{S_k,\max}$.

Problem Formulation for Single-Data-Stream Transmission

This problem can be mathematically formulated as follows:

$$\min_{t_{S_k},\mathbf{u}_{S_k},\mathbf{v}_{BS_k}} \quad \sum_{k=1}^{K} t_{S_k}\|\mathbf{u}_{S_k}\|_2^2$$

$$\text{s.t.} \quad t_{S_k} w \log\left(1 + \frac{\left|\mathbf{v}_{BS_k}{}^H\mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}\right|^2}{\sum_{j=1}^{J}\left|\mathbf{v}_{BS_k}{}^H\mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}\right|^2 + N_0 w}\right) \ge R_{S_k}, \quad \forall k, \tag{2a}$$

$$\sum_{k=1}^{K} t_{S_k} \le 1, \tag{2b}$$

$$\left|\mathbf{v}_{P_j}^H\mathbf{H}_{P_j,S_k}\mathbf{u}_{S_k}\right|^2 \le \phi_{P_j}, \quad \forall k, \quad \forall j, \tag{2c}$$

$$\|\mathbf{u}_{S_k}\|_2^2 \le p_{S_k,\max}, \quad \forall k, \tag{2d}$$

$$t_{S_k} \ge 0, \quad \forall k.$$

The objective function in (2) is the total energy consumption of all the SUs. Constraint (2a) guarantees each SU's rate requirement. Constraint (2b) states that the total time allocated to all the SUs is no larger than the TDMA frame length. Constraint (2c) ensures that the interference from each secondary transmitter to each primary receiver is no larger than a tolerable threshold ϕ_{P_j}. Constraint (2d) states that the SUs have limited transmission power. The variables in (2) are the time fraction variables t_{S_k}, the transmit beamforming vectors $\mathbf{u}_{S_k}$, and the receive beamforming vectors $\mathbf{v}_{BS_k}$ of the SUs.

Since the secondary system is a centralized TDMA network, it is reasonable to assume that $\mathbf{H}_{BS,S_k}$ is known to both S_k and the secondary BS. As, in a CR network, the secondary system is usually aware of the existence of the primary system, it is also reasonable to assume that the secondary BS can overhear the transmissions on the primary links. At the secondary BS, the overheard signal of P_j is $\mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}$. Therefore, the secondary BS is able to estimate $\mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}$ for all PUs. However, in a CR network, the secondary system is usually transparent to the primary system. The primary system would not deliberately provide the CSI to the secondary system. Therefore, the secondary system may only know the statistics of coefficient vectors $\mathbf{v}_{P_j}^H\mathbf{H}_{P_j,S_k}$ in constraint (2c) (e.g., the type of distribution and $\mathbb{E}[\mathbf{v}_{P_j}^H\mathbf{H}_{P_j,S_k}\mathbf{H}_{P_j,S_k}^H\mathbf{v}_{P_j}]$). However, it does not know the precise realization of $\mathbf{v}_{P_j}^H\mathbf{H}_{P_j,S_k}$.

Notice that in formulation (2), the receive beamforming variables $\mathbf{v}_{BS_k}$ only appear in constraint (2a). These variables can be eliminated by exploring the optimal receive beamforming, which are the minimum-mean-square-error (MMSE) receivers [14]:

$$\mathbf{v}_{BS_k}^* = \theta_{S_k}\mathbf{B}_{S_k}^{-1}\mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}, \quad k = 1, \cdots, K, \tag{3}$$

where $\mathbf{B}_{S_k} = \sum_{j=1}^{J}\mathbf{H}_{BS,P_j}\mathbf{u}_{P_j}\mathbf{u}_{P_j}^H\mathbf{H}_{BS,P_j}^H + N_0 w\mathbf{I}$, and θ_{S_k} is the normalized factor given by $\theta_{S_k} = \frac{1}{\|\mathbf{B}_{S_k}^{-1}\mathbf{H}_{BS,S_k}\mathbf{u}_{S_k}\|_2}$, which ensures $\|\mathbf{v}_{BS_k}^*\|_2^2 = 1$. The maximum received SINR is then given by

$$\gamma_{BS_k} = \mathbf{u}_{S_k}^H\mathbf{A}_{S_k}\mathbf{u}_{S_k}, \quad k = 1, \cdots, K, \tag{4}$$

where $\mathbf{A}_{S_k} = \mathbf{H}_{BS,S_k}^H\mathbf{B}_{S_k}^{-1}\mathbf{H}_{BS,S_k}$, which is an $M_{S_k} \times M_{S_k}$ Hermitian matrix.

Substituting (4) into constraint (2a), formulation (2) can be simplified to

$$\min_{t_{S_k},\mathbf{u}_{S_k}} \quad \sum_{k=1}^{K} t_{S_k}\|\mathbf{u}_{S_k}\|_2^2$$

$$\text{s.t.} \quad t_{S_k} w \log\left(1 + \mathbf{u}_{S_k}^H\mathbf{A}_{S_k}\mathbf{u}_{S_k}\right) \geq R_{S_k}, \quad \forall k, \tag{5a}$$

$$\sum_{k=1}^{K} t_{S_k} \leq 1, \tag{5b}$$

$$\left|\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k} \mathbf{u}_{S_k}\right|^2 \leq \phi_{P_j}, \quad \forall k, \quad \forall j, \tag{5c}$$

$$\|\mathbf{u}_{S_k}\|_2^2 \leq p_{S_k,\max}, \quad \forall k, \tag{5d}$$

$$t_{S_k} \geq 0, \quad \forall k,$$

The receive beamforming vectors $\mathbf{v}_{BS_k}$ are removed, and the variables in formulation (5) are the time fraction variables t_{S_k} and the transmit beamforming vectors $\mathbf{u}_{S_k}$ of the SUs.

Since the secondary system does not know the precise realization of $\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k}$, the left-hand side of constraint (5c) is random for any given $\mathbf{u}_{S_k}$. The requirement of satisfying constraint (5c) would easily lead to suboptimal or infeasible solutions. Interestingly, many wireless applications (such as video streaming, voice over IP) can tolerate occasional outages without affecting users' QoS. Thus, in a more realistic requirement, it is sufficient to satisfy the interference constraints with a high probability. In other words, the CR network allows the interference from the secondary transmitters to the primary receivers to exceed the power threshold ϕ_{P_j} with a small outage probability δ_{P_j}. Constraint (5c) is then replaced by

$$\Pr_{\mathbf{H}_{P_j,S_k},\mathbf{v}_{P_j}} \left\{ \left|\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k} \mathbf{u}_{S_k}\right|^2 \leq \phi_{P_j} \right\} \geq 1 - \delta_{P_j}, \quad \forall k, \forall j, \tag{6}$$

where the probability is taken over both $\mathbf{H}_{P_j,S_k}$ and $\mathbf{v}_{P_j}$.

Under Rayleigh fading channel assumption, the entries of the channel matrix $\mathbf{H}_{P_j,S_k}$ are i.i.d. complex Gaussian random variables with a zero mean and a variance of $\frac{\beta_{P_j,S_k}}{2}$, where β_{P_j,S_k} denotes the path loss from S_k to the jth primary receiver. Furthermore, because $\mathbf{H}_{P_j,S_k}$ and $\mathbf{v}_{P_j}$ are independent of each other, $\left|\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k} \mathbf{u}_{S_k}\right|^2$ follows an exponential distribution with the parameter $\frac{1}{\beta_{P_j,S_k}\|\mathbf{u}_{S_k}\|_2^2}$ [33]. So we have

$$\Pr_{\mathbf{H}_{P_j,S_k},\mathbf{v}_{P_j}} \left\{ \left|\mathbf{v}_{P_j}^H \mathbf{H}_{P_j,S_k} \mathbf{u}_{S_k}\right|^2 \leq \phi_{P_j} \right\} = 1 - \exp\left(-\frac{\phi_{P_j}}{\beta_{P_j,S_k}\|\mathbf{u}_{S_k}\|_2^2} \right).$$

Therefore, the outage probability constraint (6) is equivalent to

$$\|\mathbf{u}_{S_k}\|_2^2 \leq \frac{-\phi_{P_j}}{\beta_{P_j,S_k} \log \delta_{P_j}}, \quad \forall k, \quad \forall j. \tag{7}$$

Furthermore, after converting the outage probability constraint to (7), it can be shown that (7) can be combined with the maximum transmission power

constraint (5d). Let $\rho_{S_k} = \min\left\{\frac{-\phi_{P_1}}{\beta_{P_1,S_k}\log\delta_{P_1}},\cdots,\frac{-\phi_{P_J}}{\beta_{P_J,S_k}\log\delta_{P_J}},p_{S_k,\max}\right\}$. Constraints (7) and (5d) are equivalent to

$$\|\mathbf{u}_{S_k}\|_2^2 \le \rho_{S_k}, \quad \forall k = 1,\cdots,K.$$

Therefore, problem (5) can be recast as follows:

$$\begin{aligned}
\min_{t_{S_k},\mathbf{u}_{S_k}} \quad & \sum_{k=1}^{K} t_{S_k}\|\mathbf{u}_{S_k}\|_2^2 \\
\text{s.t.} \quad & t_{S_k} w \log\left(1+\mathbf{u}_{S_k}^H \mathbf{A}_{S_k}\mathbf{u}_{S_k}\right) \ge R_{S_k}, \forall k, && \text{(8a)}\\
& \sum_{k=1}^{K} t_{S_k} \le 1, && \text{(8b)}\\
& \|\mathbf{u}_{S_k}\|_2^2 \le \rho_{S_k}, \quad \forall k, && \text{(8c)}\\
& t_{S_k} \ge 0, \quad \forall k.
\end{aligned}$$

Problem Formulation for Multiple-Data-Stream Transmission

When each SU transmits multiple data streams, the joint design of time allocation and the transmit precoding matrix to minimize the energy consumption of all the SUs can be mathematically formulated as follows:

$$\begin{aligned}
\min_{t_{S_k},\mathbf{Q}_{S_k}} \quad & \sum_{k=1}^{K} t_{S_k}\,\mathrm{tr}\left(\mathbf{Q}_{S_k}\right) \\
\text{s.t.} \quad & t_{S_k} w \log\left[\det\left(\mathbf{I}+\mathbf{H}_{BS,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{BS,S_k}^H\mathbf{C}_{S_k}^{-1}\right)\right] \ge R_{S_k}, \quad \forall k, && \text{(9a)}\\
& \sum_{k=1}^{K} t_{S_k} \le 1, && \text{(9b)}\\
& \mathrm{tr}\left(\mathbf{H}_{P_j,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{P_j,S_k}^H\right) \le \phi_{P_j}, \quad \forall k, \quad \forall j, && \text{(9c)}\\
& \mathrm{tr}\left(\mathbf{Q}_{S_k}\right) \le p_{S_k,\max}, \quad \forall k, && \text{(9d)}\\
& t_{S_k} \ge 0, \quad \forall k,\\
& \mathbf{Q}_{S_k} \succeq \mathbf{0}, \quad \forall k.
\end{aligned}$$

Problem (9) is non-convex due to both the objective function and Constraint (9a) and is thus in general difficult to solve. It can be shown that the rank of the optimal covariance matrix to Problem (9) is never higher than the corresponding channel, i.e., $\text{rank}(\mathbf{Q}_{S_k}^*) \leq \text{rank}(\mathbf{H}_{BS,S_k}^H \mathbf{C}_{S_k}^{-1} \mathbf{H}_{BS,S_k}) \leq \text{rank}(\mathbf{H}_{BS,S_k})$. Suppose there is one optimal $\mathbf{Q}_{S_k}^*$ with a higher rank than $\text{rank}(\mathbf{H}_{BS,S_k})$. It is easy to obtain a new solution of the transmit covariance matrix by projecting $\mathbf{Q}_{S_k}^*$ to the row space of $\mathbf{H}_{BS,S_k}^H \mathbf{C}_{S_k}^{-1} \mathbf{H}_{BS,S_k}$. The new solution obtained by the projection satisfies Constraints (9a) and (9c). Further, it reduces the LHS of Constraint (9d) and the objective function. This contradicts with that $\mathbf{Q}_{S_k}^*$ with a higher rank than $\text{rank}(\mathbf{H}_{BS,S_k})$ is the optimal solution. Therefore, we do not need to impose rank constraint on $\mathbf{Q}_{S_k}$ in Problem (9).

The secondary system only knows the statistics of $\mathbf{H}_{P_j,S_k}$ (e.g., the type of distribution and $\mathbb{E}[\mathbf{H}_{P_j,S_k} \mathbf{H}_{P_j,S_k}^H]$). It does not know the precise realization of $\mathbf{H}_{P_j,S_k}$. Similarly, under the probabilistic interference constraints, the CR network allows the interference from each secondary transmitter to each primary receiver to exceed the power threshold ϕ_{P_j} with a small outage probability δ_{P_j}. Constraint (9c) is then replaced by

$$\Pr_{\mathbf{H}_{P_j,S_k}} \left\{ \text{tr}\left(\mathbf{H}_{P_j,S_k} \mathbf{Q}_{S_k} \mathbf{H}_{P_j,S_k}^H \right) \leq \phi_{P_j} \right\} \geq 1 - \delta_{P_j}, \ \forall k, \ \forall j, \tag{10}$$

where the probability is taken over $\mathbf{H}_{P_j,S_k}$.

Given the Rayleigh distribution of the channels, $\text{tr}\left(\mathbf{H}_{P_j,S_k} \mathbf{Q}_{S_k} \mathbf{H}_{P_j,S_k}^H \right)$ follows an exponential distribution with the parameter $\frac{1}{\beta_{P_j,S_k} \text{tr}(\mathbf{Q}_{S_k})}$ [33]:

$$\Pr_{\mathbf{H}_{P_j,S_k}} \left\{ \text{tr}\left(\mathbf{H}_{P_j,S_k} \mathbf{Q}_{S_k} \mathbf{H}_{P_j,S_k}^H \right) \leq \phi_{P_j} \right\} = 1 - \exp\left(-\frac{\phi_{P_j}}{\beta_{P_j,S_k} \text{tr}\left(\mathbf{Q}_{S_k}\right)} \right).$$

Thus, the outage probability constraint (10) is equivalent to

$$\text{tr}\left(\mathbf{Q}_{S_k}\right) \leq \frac{-\phi_{P_j}}{\beta_{P_j,S_k} \log \delta_{P_j}}, \quad \forall k, \ \forall j. \tag{11}$$

Furthermore, (11) can be combined with Constraint (9d), which can be expressed by

$$\text{tr}\left(\mathbf{Q}_{S_k}\right) \leq \rho_{S_k}, \quad \forall k.$$

Therefore, the problem formulation can be recast as follows:

$$
\begin{aligned}
\min_{t_{S_k},\mathbf{Q}_{S_k}} \quad & \sum_{k=1}^{K} t_{S_k} \operatorname{tr}\left(\mathbf{Q}_{S_k}\right) \\
\text{s.t.} \quad & t_{S_k} w \log\left[\det\left(\mathbf{I}+\mathbf{H}_{BS,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{BS,S_k}^{H}\mathbf{C}_{S_k}^{-1}\right)\right] \geq R_{S_k}, \quad \forall k, && \text{(12a)} \\
& \sum_{k=1}^{K} t_{S_k} \leq 1, && \text{(12b)} \\
& \operatorname{tr}\left(\mathbf{Q}_{S_k}\right) \leq \rho_{S_k}, \quad \forall k, && \text{(12c)} \\
& t_{S_k} \geq 0, \quad \forall k, \\
& \mathbf{Q}_{S_k} \succeq \mathbf{0}, \quad \forall k.
\end{aligned}
$$

Note that similar to Problem (9), it does not need to add rank constraint on $\mathbf{Q}_{S_k}$ in Problem (12). Furthermore, Problem (12) is also a non-convex optimization problem. It is challenging to solve the non-convex Problems (8) and (12) directly. As can be seen in the subsequent sections, we will tackle this difficulty by finding a closed-form solution for $\mathbf{u}_{S_k}$ and $\mathbf{Q}_{S_k}$, respectively. Therefore, (8) and (12) can be further reduced to convex optimization problems in t_{S_k} only. As a result, the optimal solutions to both Problem (8) and Problem (12) can be found efficiently.

Feasibility

The feasible set in Problem (8) (or (12)) may not always be nonempty. For each S_k, its maximum feasible instantaneous transmission rate $r_{S_k,\max}$, with the unit of nats/second, depends on its maximum transmit power and the interference constraints at the primary receivers. In the single-data-stream transmission case, the maximum link rate for S_k can be computed by solving the following problem:

$$
\begin{aligned}
\max_{\mathbf{u}_{S_k}} \quad & w \log\left(1+\mathbf{u}_{S_k}^{H}\mathbf{A}_{S_k}\mathbf{u}_{S_k}\right) \\
\text{s.t.} \quad & \|\mathbf{u}_{S_k}\|_2^2 \leq \rho_{S_k}.
\end{aligned}
\tag{13}
$$

In the multiple-data-stream transmission case, the maximum link rate for S_k can be obtained by solving

$$
\begin{aligned}
\max_{\mathbf{Q}_{S_k}} \quad & w \log\left[\det\left(\mathbf{I}+\mathbf{H}_{BS,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{BS,S_k}^{H}\mathbf{C}_{S_k}^{-1}\right)\right] \\
\text{s.t.} \quad & \operatorname{tr}\left(\mathbf{Q}_{S_k}\right) \leq \rho_{S_k}, \\
& \mathbf{Q}_{S_k} \succeq \mathbf{0}.
\end{aligned}
\tag{14}
$$

Problem (14) can be solved with standard "water-filling" [9, 25].

The minimum time resource $t_{S_k,\min}$ that each S_k needs to satisfy its rate requirement is

$$t_{S_k,\min} = \frac{R_{S_k}}{r_{S_k,\max}}.$$

Problem (8) (or (12)) is feasible when the traffic load in the secondary system does not exceed its capacity, i.e.,

$$\sum_{k=1}^{K} t_{S_k,\min} \leq 1. \tag{15}$$

In section "Single-Data-Stream Transmission: Problem Decomposition and Optimal Solution", it can be shown that there is a closed-form feasibility condition in the single-data-stream transmission case. In the multiple-data-stream transmission case, first it is required to solve Problem (14) to obtain $r_{S_k,\max}$. Then the feasibility of Problem (12) can be guaranteed if Condition (15) is satisfied.

Single-Data-Stream Transmission: Problem Decomposition and Optimal Solution

It can be shown that there is a closed-form feasibility condition in the single-data-stream transmission case. Furthermore, the optimal time fractions and transmit beamforming vectors can be obtained efficiently through a proper decomposition. Therefore, the time fractions t_{S_k} and the transmit beamforming vectors $\mathbf{u}_{S_k}$ can be separately optimized without affecting the overall optimality.

Given any time fraction allocation $(t_{S_1}, \cdots, t_{S_K})$, Problem (8) reduces to K separate optimization problems among the SUs. For each S_k, the optimization problem is given by

$$\begin{aligned} \min_{\mathbf{u}_{S_k}} \quad & \|\mathbf{u}_{S_k}\|_2^2 \\ \text{s.t.} \quad & w \log\left(1 + \mathbf{u}_{S_k}^H \mathbf{A}_{S_k} \mathbf{u}_{S_k}\right) \geq \frac{R_{S_k}}{t_{S_k}}, && \text{(16a)} \\ & \|\mathbf{u}_{S_k}\|_2^2 \leq \rho_{S_k}. && \text{(16b)} \end{aligned}$$

It can be shown that the optimization problem (16) has a closed-form solution by a simple eigenvalue-eigenvector computation. Let $\pi_{S_k,1}, \pi_{S_k,2}, \cdots, \pi_{S_k,M_{S_k}}$ denote all the eigenvalues of matrix $\mathbf{A}_{S_k}$. Let $\mathbf{z}_{S_k,i}$ $(\|\mathbf{z}_{S_k,i}\|_2^2 = 1)$ denote the normalized eigenvector of $\mathbf{A}_{S_k}$ associated with eigenvalue $\pi_{S_k,i}, (1 \leq i \leq M_{S_k})$. Let $\pi_{S_k,\max}$ denote the largest eigenvalue of $\mathbf{A}_{S_k}$ and $\mathbf{z}_{S_k,\max}$ denote the normalized eigenvector

of $\mathbf{A}_{S_k}$ associated with $\pi_{S_k,\max}$. The closed-form solution to (16) is given in the following lemma.

Lemma 1. *The necessary and sufficient condition for optimization problem* (16) *to be feasible is*

$$t_{S_k} \geq \frac{R_{S_k}}{w \log\left(\rho_{S_k} \pi_{S_k,\max} + 1\right)}, \quad k = 1, \cdots, K. \tag{17}$$

When condition (17) *is satisfied, the optimal solution to* (16) *is*

$$\mathbf{u}_{S_k}^* = \sqrt{\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right) - 1}{\pi_{S_k,\max}}} \mathbf{z}_{S_k,\max}, \quad k = 1, \cdots, K. \tag{18}$$

Proof. Matrix $\mathbf{A}_{S_k}$ is a Hermitian matrix. Therefore $\mathbf{A}_{S_k}$ can be unitarily diagonalized as $\mathbf{A}_{S_k} = \mathbf{P}_{S_k} \mathbf{\Pi}_{S_k} \mathbf{P}_{S_k}^H$, where $\mathbf{P}_{S_k}$ is a unitary matrix and $\mathbf{\Pi}_{S_k}$ is a diagonal matrix containing all the eigenvalues of $\mathbf{A}_{S_k}$. So we have

$$\mathbf{u}_{S_k}^H \mathbf{A}_{S_k} \mathbf{u}_{S_k} = \mathbf{u}_{S_k}^H \mathbf{P}_{S_k} \mathbf{\Pi}_{S_k} \mathbf{P}_{S_k}^H \mathbf{u}_{S_k} = \left(\mathbf{P}_{S_k}^H \mathbf{u}_{S_k}\right)^H \mathbf{\Pi}_{S_k} \left(\mathbf{P}_{S_k}^H \mathbf{u}_{S_k}\right) \leq \pi_{S_k,\max} \|\mathbf{P}_{S_k}^H \mathbf{u}_{S_k}\|_2^2.$$

Since matrix $\mathbf{P}_{S_k}$ is unitary, we further know that $\|\mathbf{P}_{S_k}^H \mathbf{u}_{S_k}\|_2^2 = \|\mathbf{u}_{S_k}\|_2^2$. So we have

$$\mathbf{u}_{S_k}^H \mathbf{A}_{S_k} \mathbf{u}_{S_k} \leq \pi_{S_k,\max} \|\mathbf{u}_{S_k}\|_2^2, \tag{19}$$

where the equality is achieved when $\mathbf{u}_{S_k}$ is an eigenvector of $\mathbf{A}_{S_k}$ corresponding to $\pi_{S_k,\max}$.

On the other hand, constraint (16a) is equivalent to

$$\mathbf{u}_{S_k}^H \mathbf{A}_{S_k} \mathbf{u}_{S_k} \geq \exp\left(\frac{R_{S_k}}{wt_{S_k}}\right) - 1. \tag{20}$$

According to (19) and (20), we know that if we only consider constraint (16a) in optimizing Problem (16), the minimum value of the objective function in (16) is $\|\mathbf{u}_{S_k}^*\|_2^2 = \frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)-1}{\rho_{S_k,\max}}$, and the optimal solution is $\mathbf{u}_{S_k}^* = \sqrt{\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)-1}{\pi_{S_k,\max}}} \mathbf{z}_{S_k,\max}$. Since constraint (16b) only states that $\|\mathbf{u}_{S_k}\|_2^2$ should be no greater than ρ_{S_k}, therefore (16) is feasible if and only if the minimum value of $\|\mathbf{u}_{S_k}\|_2^2$ satisfies constraint (16b). That is,

$$\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right) - 1}{\pi_{S_k,\max}} \leq \rho_{S_k} \Rightarrow t_{S_k} \geq \frac{R_{S_k}}{w \log\left(\rho_{S_k} \pi_{S_k,\max} + 1\right)}. \quad \square$$

According to Lemma 1, the optimal transmit beamforming vectors are explicit functions of the time fraction allocation $(t_{S_1}, \cdots, t_{S_K})$. This enables us to solve optimization problem (8) through a proper decomposition.

Theorem 1. *In the single-data-stream transmission case, the necessary and sufficient condition for optimization problem* (8) *to be feasible is*

$$\sum_{k=1}^{K} \frac{R_{S_k}}{w \log\left(\rho_{S_k} \pi_{S_k,\max} + 1\right)} \leq 1. \tag{21}$$

Furthermore, problem (8) *can be solved in polynomial time. In particular, the optimal time fractions are the optimal solutions to the convex optimization*

$$\begin{aligned} \min_{t_{S_k}} \quad & \sum_{k=1}^{K} t_{S_k} \frac{\exp\left(\frac{R_{S_k}}{w t_{S_k}}\right) - 1}{\pi_{S_k,\max}} \\ \text{s. t.} \quad & \sum_{k=1}^{K} t_{S_k} \leq 1, \\ & t_{S_k} \geq \frac{R_{S_k}}{w \log\left(\rho_{S_k} \pi_{S_k,\max} + 1\right)}, \quad \forall k. \end{aligned} \tag{22}$$

The optimal transmit beamforming vectors are then given by the closed-form solution in (18).

Proof. Substituting (18) into Problem (8), then (8) becomes (22). The condition for the constraint set of (22) to be nonempty is $\sum_{k=1}^{K} \frac{R_{S_k}}{w \log\left(\rho_{S_k} \pi_{S_k,\max}+1\right)} \leq 1$.

Problem (22) is an optimization problem with the time fraction variables t_{S_k} only. The second order derivative of the objective function in (22) with respect to variable t_{S_k} is

$$\frac{R_{S_k}^2}{w^2 \pi_{S_k,\max} t_{S_k}^3} \exp\left(\frac{R_{S_k}}{w t_{S_k}}\right),$$

which is always positive for any nonnegative t_{S_k}. Thus, the objective function in (22) is a convex function. Furthermore, the constraints in (22) are linear. Therefore, (22) is a convex optimization problem, which can be solved in polynomial time with the standard interior-point method [5]. □

Two remarks are in order for Theorem 1:

1. In the single-data-stream transmission case, it is energy-optimal for each SU to scale its transmit beamforming vector with the eigenvector corresponding to the largest eigenvalue of its $\mathbf{A}_{S_k}$. The scaling factor depends on the time resource

for each SU. Furthermore, the energy-optimal time allocation can be found by solving convex optimization problem (22).

2. Finding the optimal solutions in the single-data-stream transmission case is straightforward. When a new SU sends transmission request to the secondary BS, the secondary BS first checks whether Condition (21) is satisfied. If yes, the secondary BS solves the convex optimization Problem (22) to obtain the optimal time fractions. Furthermore, the optimal transmit beamforming vectors are then computed by (18). After obtaining the optimal transmit beamforming vectors, the optimal receive beamforming vectors can be computed by (3). If Condition (21) is not satisfied, the rate requirements of all the SUs cannot be satisfied. In this case, the secondary BS performs call admission control to block the new SU.

Multiple-Data-Stream Transmission: Problem Decomposition and Optimal Solution

In the multiple-data-stream transmission case, the optimal solutions to the non-convex Problem (12) can be found in polynomial time by first optimizing the time fractions t_{S_k} and then the transmit covariance matrices $\mathbf{Q}_{S_k}$. Furthermore, it can be shown that the optimal time slot allocation (discrete time allocation) can be obtained with a polynomial-time algorithm.

Optimal Solution for Continuous Time Allocation

Given any feasible time allocation $(t_{S_1}, \cdots, t_{S_K})$, Problem (12) reduces to K separate transmit covariance matrix optimization problems, one for each S_k:

$$\min_{\mathbf{Q}_{S_k}} \quad \mathrm{tr}\left(\mathbf{Q}_{S_k}\right)$$

$$\text{s.t.} \quad w \log\left[\det\left(\mathbf{I} + \mathbf{H}_{BS,S_k}\mathbf{Q}_{S_k}\mathbf{H}_{BS,S_k}^H\mathbf{C}_{S_k}^{-1}\right)\right] \geq \frac{R_{S_k}}{t_{S_k}}, \tag{23a}$$

$$\mathrm{tr}\left(\mathbf{Q}_{S_k}\right) \leq \rho_{S_k}, \tag{23b}$$

$$\mathbf{Q}_{S_k} \succeq \mathbf{0}.$$

The optimal solution to Problem (23) can be computed by standard "water-filling" [9, 25]. Let $\mathbf{F}_{S_k}$ denote $\mathbf{H}_{BS,S_k}^H\mathbf{C}_{S_k}^{-1}\mathbf{H}_{BS,S_k}$, which is an $M_{S_k} \times M_{S_k}$ Hermitian positive semidefinite matrix. Let $W_{S_k} = \mathrm{rank}\left(\mathbf{F}_{S_k}\right)$ and $\lambda_{S_k,1} \geq \lambda_{S_k,2} \geq \cdots \geq \lambda_{S_k,W_{S_k}}$ denote all the nonnegative eigenvalues of matrix $\mathbf{F}_{S_k}$. Let $\mathbf{g}_{S_k,i}$ ($\|\mathbf{g}_{S_k,i}\|_2^2 = 1$) denote the normalized eigenvector of $\mathbf{F}_{S_k}$ associated with eigenvalue $\lambda_{S_k,i}$, $(1 \leq i \leq W_{S_k})$ and $\mathbf{G}_{S_k}$ be a matrix whose ith column is $\mathbf{g}_{S_k,i}$. The optimal solution to Problem (23) is given in the following lemma.

Lemma 2. *The necessary and sufficient condition for Problem (23) to be feasible is*

$$t_{S_k} \geq t_{S_k,\min}. \tag{24}$$

Furthmore, let $\tilde{\mathbf{Q}}^*_{S_k}$ *be a diagonal matrix with entries*

$$\tilde{Q}^*_{S_k,ii} = \left(\mu_{S_k} - \frac{1}{\lambda_{S_k,i}}\right)^+, \tag{25}$$

where $(x)^+ = \max\{x, 0\}$*, and the value of* μ_{S_k} *is chosen to sastisfy*

$$\prod_{i=1}^{W_{S_k}} \left(\lambda_{S_k,i}\mu_{S_k}\right)^+ = \exp\left(\frac{R_{S_k}}{wt_{S_k}}\right). \tag{26}$$

Then, when Condition (24) is satisfied, the optimal solution to Problem (23) is

$$\mathbf{Q}^*_{S_k} = \mathbf{G}_{S_k}\tilde{\mathbf{Q}}^*_{S_k}\mathbf{G}^H_{S_k}. \tag{27}$$

Proof. If we do not consider Constraint (23b) when solving Problem (23), the optimal solution is given by standard "water-filling." Constraint (23b) only states that the minimum objective value should be no greater than ρ_{S_k}. Since the MIMO link rate obtained from the water-filling is an increasing function in $\mathrm{tr}\left(\mathbf{Q}_{S_k}\right)$ [25], we can find that Constraint (23b) is satisfied if t_{S_k} satisfies Condition (24). □

The optimal transmit covariance matrices are functions of the time allocation $(t_{S_1}, \cdots, t_{S_K})$. Thus, the optimal number of data streams and the optimal energy consumption of each S_k are dependent on its time resource allocation. To simplify the notation, let

$$\tau_{S_k}\left(m_{S_k}\right) = \frac{R_{S_k}}{w\left(\left(\sum_{i=1}^{m_{S_k}} \log\lambda_{S_k,i}\right) - m_{S_k}\log\lambda_{S_k,(m_{S_k}+1)}\right)},$$

where $m_{S_k} \in \left\{1, \cdots, \left(W_{S_k} - 1\right)\right\}$. Observe that τ_{S_k} is a decreasing function of m_{S_k}. The optimal number of data streams $D^*_{S_k}$ is a stepwise function of t_{S_k}, given by

$$D^*_{S_k}\left(t_{S_k}\right) = \begin{cases} W_{S_k}, & 0 < t_{S_k} < \tau_{S_k}\left(W_{S_k} - 1\right), \\ m_{S_k}, & \tau_{S_k}\left(m_{S_k}\right) \leq t_{S_k} < \tau_{S_k}\left(m_{S_k} - 1\right), \\ 1, & t_{S_k} \geq \tau_{S_k}\left(1\right). \end{cases} \tag{28}$$

Furthermore, the optimal "water level" $\mu^*_{S_k}$ is a function of t_{S_k}, given by

$$\mu_{S_k}^* \left(t_{S_k}\right) = \left(\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)}{\prod_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)} \lambda_{S_k,i}} \right)^{\frac{1}{D_{S_k}^*\left(t_{S_k}\right)}}.$$

Therefore, the optimal energy consumption of S_k is a function of t_{S_k}, which can be computed according to

$$E_{S_k}\left(t_{S_k}\right) = t_{S_k} \left(D_{S_k}^*\left(t_{S_k}\right) \left(\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)}{\prod_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)} \lambda_{S_k,i}} \right)^{\frac{1}{D_{S_k}^*\left(t_{S_k}\right)}} - \sum_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)} \frac{1}{\lambda_{S_k,i}} \right), \tag{29}$$

Note that because the optimal number of data streams $D_{S_k}^*\left(t_{S_k}\right)$ is a stepwise function of t_{S_k}, $E_{S_k}\left(t_{S_k}\right)$ is a piecewise defined function of t_{S_k}. Here the piecewise defined function means that $E_{S_k}\left(t_{S_k}\right)$ takes on different forms for different intervals of t_{S_k}. As shown in Proposition 1, $E_{S_k}\left(t_{S_k}\right)$ is a continuous function in t_{S_k}. The following proposition establishes some key properties of the optimal energy consumption $E_{S_k}\left(t_{S_k}\right)$, which will be useful later when solving the time allocation problem among the SUs.

Proposition 1. *The optimal energy consumption $E_{S_k}\left(t_{S_k}\right)$ is a strictly convex, continuous, first-order differentiable, and monotonically decreasing function in t_{S_k}.*

Proof. The proof is in the Appendix. □

Substituting (24), (27), and (29) into Problem (12), it then becomes an optimization problem in the time fraction variables t_{S_k} only. Furthermore, as shown in Proposition 1, the energy consumption (29) is a monotonically decreasing function in t_{S_k}. Thus, the optimal solution could be achieved only when Constraint (12b) is satisfied with equality. Therefore, the time resource optimization problem among the SUs is given by

$$\begin{aligned} \min_{t_{S_k}} \quad & \sum_{k=1}^{K} E_{S_k}\left(t_{S_k}\right) \\ \text{s.t.} \quad & \sum_{k=1}^{K} t_{S_k} = 1, \\ & t_{S_k} \geq t_{S_k,\min}, \quad \forall k. \end{aligned} \tag{30}$$

The objective function $E_{S_k}\left(t_{S_k}\right)$ is convex as shown in Proposition 1, and the constraints in (30) are linear. Therefore, Problem (30) is a convex optimization problem. Problem (12) can be solved efficiently through the decomposition method.

Theorem 2. *In the multiple-data-stream transmission case, the optimal time allocation and the optimal transmit covariance matrices can be found separately. In particular, the optimal time allocation is the optimal solution to the convex optimization problem* (30)*. After obtaining the optimal* $t^*_{S_k}$*, the optimal transmit covariance matrix of each SU can then be computed by "water-filling," given in* (27)*.*

Proof. From Lemma 2, it can be shown that given any feasible time allocation, the optimal transmit covariance matrix is computed by "water-filling." Proposition 1 further shows that the energy consumption, based on the optimal covariance matrix, is a strictly convex function of t_{S_k}. Thus, the optimal solution to Problem (30) is the global optimal time allocation. Given this optimal $t^*_{S_k}$, the optimal transmit covariance matrix is then computed by "water-filling." □

Note that although the objective function in (30) is a piecewise defined function in t_{S_k}, it is continuous, and its first-order derivative is also continuous. However, it is not second-order differentiable. Thus, only first-order methods for convex optimization problems (such as the gradient methods) can be applied to solve Problem (30) [2, 5]. Here the spectral projected gradient (SPG) method [3], which is a variation of the projected gradient method, is a time-efficient algorithm for Problem (30). The SPG method makes two modifications. First, it incorporates the non-monotone line search scheme proposed in [10]. Second, the step size is chosen to be the one introduced in [1]. With these two modifications, the number of iterations can be significantly reduced. Thus, the SPG method has been shown to converge to the global optimal solution with a competitive convergence rate for convex optimization problems [3, 23].

The time complexity for the SPG method to solve Problem (30) is $O\left(K^2\right)$ in terms of iterations [3]. In each iteration, the gradient can be easily updated from an explicit function. The time complexity for each SU to obtain the optimal transmit covariance matrix by "water-filling" is $O\left(W^3_{S_k}\right)$, where $W_{S_k} = \min\{M_{S_k}, N_{BS}\}$ [19]. Therefore, the overall time complexity to obtain the optimal solution in multiple-data-stream transmission case is $O\left(K^2\right) + O\left(K W^3_{S_k}\right)$.

Optimal Solution for Discrete Time Allocation

In many wireless systems, the time frame is divided into a number of time slots. A slot is the smallest unit in the time allocation process. The time resource allocated to each S_k should be an integer indicating the number of time slots instead of a real number. With the additional integer constraint on the variable t_{S_k} in Problem (12), it then becomes a mixed-integer non-convex optimization problem, which is generally very difficult to solve. Fortunately, by exploring the special structure of Problem (12), optimal solutions can be obtained within polynomial time.

Without loss of generality, suppose each normalized frame has a total number of T time slots, the time resource optimization problem among the SUs is given by

$$\begin{aligned} \min_{t_{S_k}} \quad & \sum_{k=1}^{K} E_{S_k}\left(t_{S_k}\right) \\ \text{s. t.} \quad & \sum_{k=1}^{K} t_{S_k} = T, \\ & t_{S_k} \in \left\{t_{S_k,\min}^{(I)}, \left(t_{S_k,\min}^{(I)}+1\right), \cdots, T\right\}, \quad \forall k, \end{aligned} \tag{31}$$

where $t_{S_k,\min}^{(I)} = \lceil t_{S_k,\min} T \rceil$ is the minimum number of time slots that each S_k needs.

Problem (31) is an integer optimization problem, which is feasible if and only if

$$\sum_{k=1}^{K} t_{S_k,\min}^{(I)} \leq T.$$

The objective function of (31) is a separable sum of convex functions. With this special property, it is not difficult to find the optimal solution to (31) with a greedy algorithm [13]. Let $\Delta_k(t_{S_k})$ denote the change in the energy consumption when the number of time slots allocated to S_k is increased from $t_{S_k}-1$ to t_{S_k},

$$\Delta_k(t_{S_k}) = E_{S_k}\left(t_{S_k}\right) - E_{S_k}\left(t_{S_k}-1\right), \quad t_{S_k} \in \left\{\left(t_{S_k,\min}^{(I)}+1\right), \cdots, T\right\}.$$

The value of $\Delta_k(t_{S_k,\min}^{(I)})$ can be defined as $-\infty$.

As shown in Proposition 1, the energy consumption $E_{S_k}\left(t_{S_k}\right)$ is strictly convex and monotonically decreasing in t_{S_k}. We then have

$$\Delta_k(t_{S_k,\min}^{(I)}) \leq \Delta_k(t_{S_k,\min}^{(I)}+1) \leq, \cdots, \leq \Delta_k(T), \quad \forall k.$$

In the greedy algorithm, starting from the minimum slot allocation $\mathbf{t}_{\min}^{(I)} = \left(t_{S_1,\min}^{(I)}, \cdots, t_{S_K,\min}^{(I)}\right)$, one time slot is allocated at a time. A time slot is added to the S_k which has the minimum $\Delta_k(t_{S_k})$ among all the SUs. The algorithm stops when all the T time slots are allocated. The optimal solution to Problem (31) can be characterized by

$$\begin{cases} \Delta_k(t_{S_k}^*) \leq \varphi^*, & \forall k, \\ \Delta_k(t_{S_k}^*+1) \geq \varphi^*, & \forall k, \\ \sum_{k=1}^{K} t_{S_k}^* = T, & \\ t_{S_k}^* \in \left\{t_{S_k,\min}^{(I)}, \left(t_{S_k,\min}^{(I)}+1\right), \cdots, T\right\}, & \forall k. \end{cases}$$

In the allocation of one slot, the energy consumption can be easily computed from an explicit function. The time complexity for finding the minimum $\Delta_k(t_{S_k})$ among all the SUs is $O(K)$. Therefore, the overall time complexity to obtain the optimal discrete time allocation with the greedy algorithm is $O(KT)$.

Simulation Results

The performance of the proposed algorithms is evaluated in terms of energy consumption, interference to primary system, convergence, and optimality. In the simulation setup, there are two primary links with 10 m distance between the transmitter and corresponding receiver. The SUs are uniformly distributed in a square area of 200 m×200 m, with a minimum separation of 35 m from the primary receivers. An example CR network with 35 SUs is shown in Fig. 1. Each node in the network has 4 antennae. For each network setting, 1000 independent simulation runs are performed.

The frame length of the secondary system is 20 ms, and each SU has a rate requirement of 32 kbps. The carrier frequency is 1 GHz and the network bandwidth is 20 MHz. The wireless channel is assumed to be the i.i.d. Rayleigh fading channel with path loss exponent equal to 4. The PUs transmit at the maximum power of 20 dBm, while the maximum transmit power for each SU is 27.5 dBm. The noise power density is −174 dBm/Hz. The interference power threshold ϕ_{P_j} is set such that $\frac{\phi_{P_j}}{N_0 w}$ is 25 dB. The outage probability δ_{P_j} in the statistical CSI scenario is 1%.

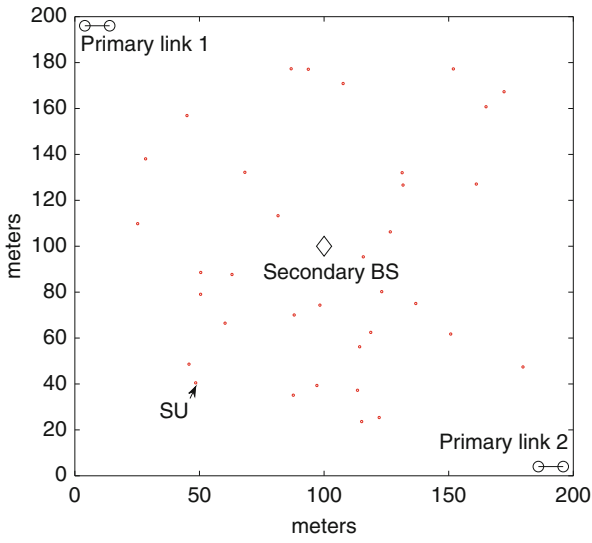

Fig. 1 A sample random CR network with 2 primary links and 35 secondary users

Energy Consumption

The energy consumptions per bit of the SUs, for both the single-data-stream transmission case and the multiple-data-stream transmission case, named "optimal time & single stream" and "optimal time & multiple streams," are shown in Fig. 2. For comparison, the energy consumption of the "max-rate" transmission schemes is shown. In the "max-rate" scheme, each SU uses the minimum time resource and the transmit covariance matrix of the solution to Problem (14).

Compared with the "max-rate" scheme, the energy consumption of both the "optimal time & single stream" and "optimal time & multiple streams" is reduced significantly. The energy consumption per bit roughly remains constant in the "max-rate" scheme. In the "optimal time & single stream" and "optimal time & multiple streams" schemes, there is a trade-off between the energy consumption and the system traffic load (i.e., the number of SUs). Taking the "max-rate" scheme as the baseline, the energy reduction of "optimal time & multiple streams" is up to 78% when the secondary system is underutilized. During simulations, it can be observed that when the secondary system is underutilized or when it experiences a strong interference from the primary system, the optimal way for each SU to perform transmit precoding is to do the single-data-stream transmission. This can be seen in Fig. 2: when the secondary system has less than 8 SUs, both the "optimal time & single stream" and "optimal time & multiple streams" produce the same result. As the traffic load further increases, the optimal number of data streams will increase to

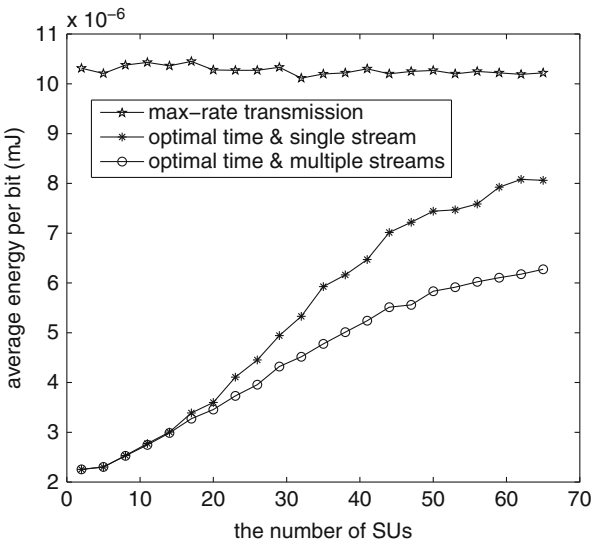

Fig. 2 Average energy consumption per bit of the secondary system

exploit the multiplexing gain and further reduce the energy consumption. Compared with the "optimal time & single stream" scheme, the energy consumption of the "optimal time & multiple streams" scheme is reduced by 23% when the secondary system has 65 users.

Interference to the Primary Receivers

Figure 3 shows the average interference power from the SUs to the primary receivers in the statistical CSI scenario, which is measured by the interference-to-noise ratio (in dB).

In the "max-rate" scheme, the average interference-to-noise ratio is smaller than the required 25 dB. This is because the secondary transmitter needs to satisfy the interference constraint at both primary receivers in each simulated network. Therefore, the interference-to-noise ratio at each primary receiver is smaller than 25 dB in many simulation runs. The interference to the primary system is also alleviated in the "optimal time & single stream" and "optimal time & multiple streams" schemes. The interference power to the primary system adapts to the traffic load of the secondary system. Moreover, it can be observed that in the "optimal time & multiple streams" scheme, the interference power increases slower compared with the "optimal time & single stream" scheme.

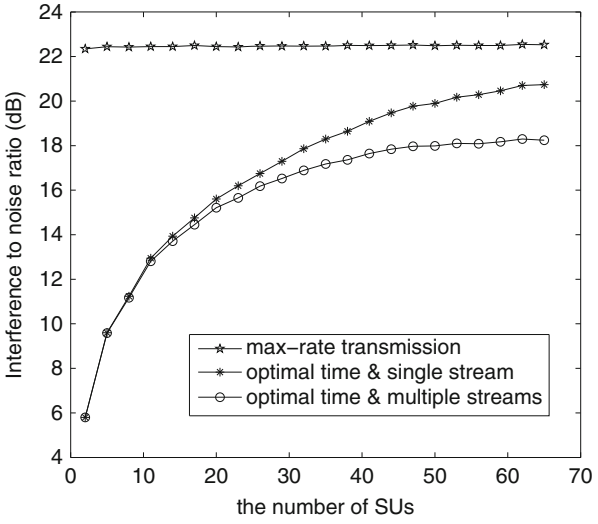

Fig. 3 Average interference power at primary receiver vs. the number of SUs

Convergence

As shown in section "Optimal Solution for Continuous Time Allocation", the SPG method is guaranteed to converge to the optimal time allocation in multiple-data-stream transmission case. Figure 4 shows the convergence performance for the sample random secondary network with 35 users, as shown in Fig. 1. It can be found that the objective function is reduced significantly during the first 10 iterations. Another observation is that the objective function in the SPG method may not monotonically decrease in every iteration, which has also been discussed in [23].

Figure 5 shows the convergence performance, plotted in terms of the average number of iterations. The stopping criterion is $\|\mathbf{t}^{(n+1)} - \mathbf{t}^{(n)}\|_\infty < 10^{-5}$. The number of iterations first increases and then decreases with the number of SUs and always stays below 85 iterations. This indicates that the SPG method has a good convergence rate even in a secondary system with many users. Note that in the perfect CSI scenario, the SPG method is also guaranteed to converge to the optimal solution with similar convergence performance when the secondary system is underutilized.

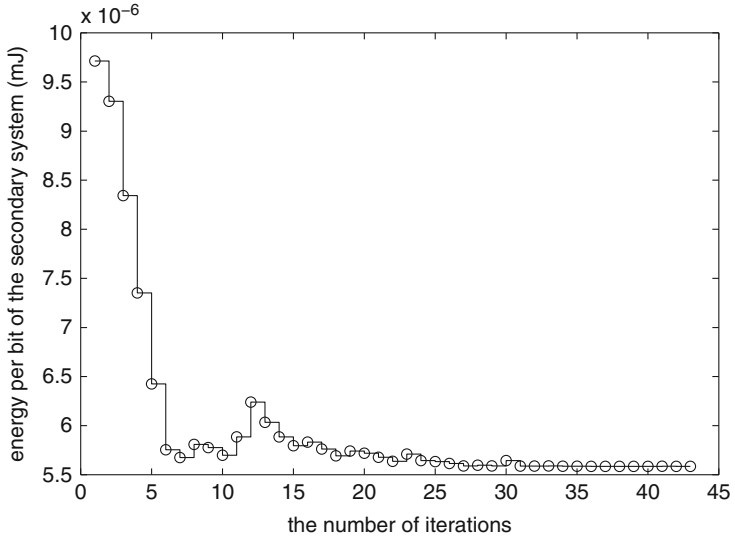

Fig. 4 The energy consumption of the secondary network as a function of the number of iterations in the multiple-data-stream transmission case. The secondary network has 35 users with the topology shown in Fig. 1

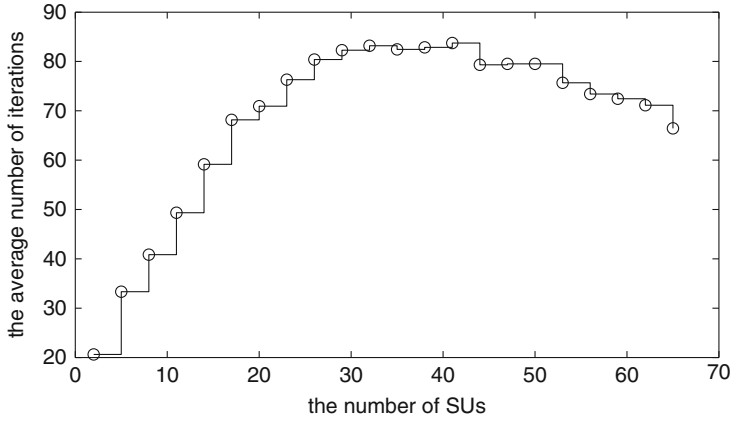

Fig. 5 Average number of iterations needed to converge to the optimal solution in the multiple-data-stream transmission case

Conclusion

This chapter discusses the jointly energy-optimal time allocation and precoding design in MIMO CR networks. In particular, it covers two transmission choices for each SU: single-data-stream transmission and multiple-data-stream transmission. The problem formulations turn out to be non-convex optimization problems. The non-convexity can be conquered by applying an optimization decomposition technique. As a result, in the single-data-stream transmission case, the global optimal time allocation can be found by solving a convex optimization problem. Furthermore, the optimal beamforming vector can be found by simple matrix eigenvalue-eigenvector computation.

In the multiple-data-stream transmission case, since the number of data streams in the transmit covariance matrix is discrete by nature, the energy consumption is a piecewise defined function in the time variable. In this case, the optimal energy consumption is shown to be continuous, first-order differentiable, strictly convex, and monotonically decreasing in the time variable. Thus the SPG algorithm can be applied to quickly find the optimal time allocation. In a slotted system, where time is a discrete variable, the optimal number of time slots can be found with a greedy algorithm. Given the optimal time allocation, the optimal transmit covariance matrix is obtained by water-filling.

Note that spectrum efficiency can be further improved if the SUs send simultaneous uplink transmissions with spatial multiplexing. However, in this case, the SUs will interfere with each other. Finding the optimal transmit covariance matrices for the SUs is more challenging. Considering the trade-off between the diversity gain and the spatial multiplexing gain for energy-efficient MIMO CR networks is an interesting yet challenging topic for future investigation.

Appendix

Proof of Proposition 1:

We first show that $E_{S_k}\left(t_{S_k}\right)$ is a continuous function in t_{S_k} by showing $\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})} E_{S_k}\left(t_{S_k}\right) = \lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})} E_{S_k}\left(t_{S_k}\right)$:

$$\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})} E_{S_k}\left(t_{S_k}\right) = \tau_{S_k}\left(m_{S_k}\right)\left(\left(m_{S_k}+1\right)\left(\frac{\exp\left(\frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)}{\prod_{i=1}^{m_{S_k}+1}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}+1}} - \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}\right)$$

$$= \tau_{S_k}\left(m_{S_k}\right)\left(\left(m_{S_k}+1\right)\left(\frac{\exp\left(\left(\sum_{i=1}^{m_{S_k}}\log\lambda_{S_k,i}\right) - m_{S_k}\log\lambda_{S_k,\left(m_{S_k}+1\right)}\right)}{\prod_{i=1}^{m_{S_k}+1}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}+1}} - \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}\right)$$

$$= \tau_{S_k}\left(m_{S_k}\right)\left(\left(m_{S_k}+1\right)\left(\frac{\prod_{i=1}^{m_{S_k}}\lambda_{S_k,i}}{\lambda_{S_k,\left(m_{S_k}+1\right)}^{m_{S_k}}\prod_{i=1}^{m_{S_k}+1}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}+1}} - \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}\right)$$

$$= \tau_{S_k}\left(m_{S_k}\right)\left(\frac{m_{S_k}}{\lambda_{S_k,\left(m_{S_k}+1\right)}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}\right),$$

and

$$\lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})} E_{S_k}\left(t_{S_k}\right) = \tau_{S_k}\left(m_{S_k}\right)\left(m_{S_k}\left(\frac{\exp\left(\frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)}{\prod_{i=1}^{m_{S_k}}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}\right)$$

$$= \tau_{S_k}\left(m_{S_k}\right)\left(m_{S_k}\left(\frac{\exp\left(\left(\sum_{i=1}^{m_{S_k}}\log\lambda_{S_k,i}\right) - m_{S_k}\log\lambda_{S_k,\left(m_{S_k}+1\right)}\right)}{\prod_{i=1}^{m_{S_k}}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}\right)$$

$$= \tau_{S_k}\left(m_{S_k}\right)\left(\frac{m_{S_k}}{\lambda_{S_k,\left(m_{S_k}+1\right)}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}\right).$$

Thus we have

$$\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})} E_{S_k}\left(t_{S_k}\right) = \lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})} E_{S_k}\left(t_{S_k}\right).$$

Therefore, $E_{S_k}\left(t_{S_k}\right)$ is a continuous function in t_{S_k}.

Next, we show that $\frac{dE_{S_k}}{dt_{S_k}}$ is a continuous function in t_{S_k} by showing $\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}} = \lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}}$. The first-order derivative of $E_{S_k}\left(t_{S_k}\right)$ with respect to t_{S_k} is

$$\frac{dE_{S_k}}{dt_{S_k}} = \left(D_{S_k}^{*}\left(t_{S_k}\right) - \frac{R_{S_k}}{wt_{S_k}}\right)\left(\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)}{\prod_{i=1}^{D_{S_k}^{*}\left(t_{S_k}\right)}\lambda_{S_k,i}}\right)^{\frac{1}{D_{S_k}^{*}\left(t_{S_k}\right)}} - \sum_{i=1}^{D_{S_k}^{*}\left(t_{S_k}\right)}\frac{1}{\lambda_{S_k,i}}.$$

It can be shown that

$$\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}} = \left(\left(m_{S_k}+1\right) - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\left(\frac{\exp\left(\frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)}{\prod_{i=1}^{m_{S_k}+1}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}+1}} - \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}$$

$$= \left(\left(m_{S_k}+1\right) - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\left(\frac{\exp\left(\left(\sum_{i=1}^{m_{S_k}}\log\lambda_{S_k,i}\right) - m_{S_k}\log\lambda_{S_k,(m_{S_k}+1)}\right)}{\prod_{i=1}^{m_{S_k}+1}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}+1}}$$

$$- \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}$$

$$= \left(\left(m_{S_k}+1\right) - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\frac{1}{\lambda_{S_k,(m_{S_k}+1)}} - \sum_{i=1}^{m_{S_k}+1}\frac{1}{\lambda_{S_k,i}}$$

$$= \left(m_{S_k} - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\frac{1}{\lambda_{S_k,(m_{S_k}+1)}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}},$$

and

$$\lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}} = \left(m_{S_k} - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\left(\frac{\exp\left(\frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)}{\prod_{i=1}^{m_{S_k}}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}$$

$$= \left(m_{S_k} - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\left(\frac{\exp\left(\left(\sum_{i=1}^{m_{S_k}}\log\lambda_{S_k,i}\right) - m_{S_k}\log\lambda_{S_k,(m_{S_k}+1)}\right)}{\prod_{i=1}^{m_{S_k}}\lambda_{S_k,i}}\right)^{\frac{1}{m_{S_k}}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}$$

$$= \left(m_{S_k} - \frac{R_{S_k}}{w\tau_{S_k}\left(m_{S_k}\right)}\right)\frac{1}{\lambda_{S_k,(m_{S_k}+1)}} - \sum_{i=1}^{m_{S_k}}\frac{1}{\lambda_{S_k,i}}.$$

Thus, we have

$$\lim_{t_{S_k}\to\tau_{S_k}^{-}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}}=\lim_{t_{S_k}\to\tau_{S_k}^{+}(m_{S_k})}\frac{dE_{S_k}}{dt_{S_k}}.$$

Therefore, $\frac{dE_{S_k}}{dt_{S_k}}$ is a continuous function in t_{S_k}.

The second-order derivative of $E_{S_k}\left(t_{S_k}\right)$ with respect to t_{S_k} is

$$\frac{d^2E_{S_k}}{dt_{S_k}^2}=\frac{R_{S_k}^2}{w^2t_{S_k}^3D_{S_k}^*\left(t_{S_k}\right)}\left(\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)}{\prod_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)}\lambda_{S_k,i}}\right)^{\frac{1}{D_{S_k}^*\left(t_{S_k}\right)}},$$

which is always positive for any positive t_{S_k}. However, it is not continuous in t_{S_k}, with the noncontinuous points at $t_{S_k}=\tau_{S_k}\left(m_{S_k}\right)$, $(m_{S_k}=\left\{1,\cdots,\left(W_{S_k}-1\right)\right\})$.

Next we show that $\frac{dE_{S_k}}{dt_{S_k}}$ is always negative for any positive t_{S_k}. Since $\frac{d^2E_{S_k}}{dt_{S_k}^2}$ is always positive, this means that $\frac{dE_{S_k}}{dt_{S_k}}$ is an increasing function in t_{S_k}. Thus, we have

$$\begin{aligned}\frac{dE_{S_k}}{dt_{S_k}}&<\lim_{t_{S_k}\to\infty}\left(\left(D_{S_k}^*\left(t_{S_k}\right)-\frac{R_{S_k}}{wt_{S_k}}\right)\left(\frac{\exp\left(\frac{R_{S_k}}{wt_{S_k}}\right)}{\prod_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)}\lambda_{S_k,i}}\right)^{\frac{1}{D_{S_k}^*\left(t_{S_k}\right)}}-\sum_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)}\frac{1}{\lambda_{S_k,i}}\right)\\&=\left(D_{S_k}^*\left(t_{S_k}\right)\left(\frac{1}{\prod_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)}\lambda_{S_k,i}}\right)^{\frac{1}{D_{S_k}^*\left(t_{S_k}\right)}}-\sum_{i=1}^{D_{S_k}^*\left(t_{S_k}\right)}\frac{1}{\lambda_{S_k,i}}\right)\Bigg|_{D_{S_k}^*\left(t_{S_k}\right)=1}=\frac{1}{\lambda_{S_k,1}}-\frac{1}{\lambda_{S_k,1}}=0.\end{aligned}\tag{32}$$

The second line of (32) follows from (28), which states that when t_{S_k} approaches infinity, the optimal number of data streams equals 1. Therefore, we can find that the optimal energy consumption $E_{S_k}\left(t_{S_k}\right)$ is a strictly convex, continuous, first-order differentiable, and monotonically decreasing function in t_{S_k}. □

Abstract

Spectrum trading is one of the most promising approaches to enabling dynamic spectrum access (DSA) in cognitive radio networks (CRNs). With this approach, unlicensed users (a.k.a. secondary users) offer licensed users (a.k.a. primary users) with monetary rewards or improved quality of services (QoSs) in exchange for spectrum access rights. In this chapter, we present a comprehensive introduction to spectrum trading. First, we provide a brief introduction to DSA and CRNs as the background and motivation for the spectrum trading. Then, we present various state-of-the-art spectrum trading mechanisms for spectrum sharing. Finally, by analyzing various design issues in these mechanisms, we introduce the concept of service-oriented spectrum trading and offer a novel collaborative network architecture, called a cognitive mesh assisted network, to effectively utilize unused licensed/unlicensed spectrums with high spectral efficiency. We expect that this chapter provides readers with basic understanding on spectrum trading technology and foster future research initiatives.

Introduction

In recent years, the popularity of smart devices, such as smartphones and tablets, and wireless services, such as mobile health (mHealth), online social networking, and mobile gaming, has led to the exponential growth in data traffic. According to the Cisco Visual Networking Index, mobile traffic has raised up to almost 400-million-fold over the past 15 years through the end of 2015 and will continue to grow by about eightfold between 2015 and 2020 [1]. This surge of data traffic will ultimately cause congestion over existing telecommunication systems, which calls for more spectrum resource. Nevertheless, current spectrum allocation adopted by Federal Communications Commission (FCC) is static and inefficient because spectrums are licensed to authorized users (a.k.a. licensed users) for long-term (often for 10 or more years with possible renewal) prespecified service provisioning

across a relatively large geographical region. Licensees cannot change the type of use or transfer the right to others, and thus the current spectrum allocation policy is commonly referred to as the static spectrum access (SSA) [2]. Obviously, the SSA scheme is inflexible and leads to low spectrum utilization because the right to access certain spectrum bands is only limited to license owners even if the band is temporally or spatially unoccupied. Experimental tests in academia and measurements conducted in industries both show that even in some big cities with dense populations, many licensed spectrum bands have surprisingly low utilization (e.g., less than 20% on average in Chicago city across all bands [3]). The conflicts between high demands for spectrum resources and inflexibility in SSA have spurred government to open the discussions on intelligently sharing licensed spectrums. As reported by the President's Council of Advisors on Science and Technology (PCAST) in July 2012, exclusive licensing is not the way to stepping forward, and advanced spectrum sharing should become the new paradigm, which has the potential to transform spectrum scarcity into abundancy [4]. In July 2016, US National Science Foundation (NSF) declared an investment of over $400 million to foster advanced wireless research, and dynamic spectrum sharing, also known as dynamic spectrum access (DSA), is regarded as a promising research direction [5].

Dynamic Spectrum Access

As defined in [6], DSA can be treated as the near-real-time adjustment of spectrum usage toward varying environments, operating states (e.g., operational modes, battery life, location, etc.), and external constraints (e.g., propagation characteristics, operational policies, etc.). In general, DSA schemes can be categorized into the following three models [7].

Spectrum Commons Model

In this model, also referred to as the open sharing model, spectrum resources are openly shared among different users. All users have equal rights to access a spectrum band once they obey certain operational rules. For example, unlicensed industrial, scientific, and medical (ISM) radio bands (e.g., WiFi) are used under this open sharing model. The phenomenal success of WiFi networks has motivated mobile operators to take advantage of the spectrum commons model for traffic offloading purpose. To be specific, instead of using their cellular networks, cellular operators can offload some broadband services to WiFi networks and save precious cellular bands for more QoS stringent services. In such a way, WiFi-offloading technique could help relieve high demands on cellular bands and mitigate congestion in cellular networks. However, it mainly targets at delay-tolerant services and the quality of service (QoS) cannot be guaranteed. Having in mind that cellular networks and WiFi networks adopt different spectrum access schemes, how to effectively manage interference among accessing users in such a heterogeneous network is one of the most important issues to address for this model. Otherwise,

packet collisions and retransmissions will seriously degrade the performance of these networks, particularly the WiFi networks, which will lead to low network throughput.

Hierarchical Access Model

In this model, users are classified into two types. One is the license owners, a.k.a. primary users (PUs), and the other is the unlicensed users, a.k.a. secondary users (SUs). Hierarchical access-based spectrum sharing allows SUs to access the PUs' spectrum with limited interference imposed on them, which is thus also referred to as the shared use model (note that, unlike the open sharing model, the users in this model have different priorities). Two approaches, i.e., the *underlay* and the *overlay* approaches, can be adopted by SUs when they access the PUs' spectrums [8].

In the underlay approach, SUs and PUs can transmit over the same spectrum simultaneously, but SUs should comply with restrictions on their transmit power so that the interference imposed on primary receivers does not exceed certain level (also known as interference temperature) [9]. Generally speaking, the optimal underlay spectrum sharing can be formulated as an optimization problem with a suitable objective function reflecting the performance of secondary network and a set of constraints with different considerations, such as fairness, quality of service (QoS), interference management, etc., which can be mathematically expressed as

$$\begin{aligned} &\text{Max} \quad f\left(R_1, \cdots, R_n\right) \\ &\text{s.t.} \quad R_i \geq R_{\text{th}}^i, \ \forall i \in \{1, \cdots, n\}; \quad \sum_{i=1}^{n} h_{ij} \cdot p_i \leq I_{\text{th}}^j, \ \forall j \in \{1, \cdots, m\}. \end{aligned} \tag{1}$$

Here, R_i, R_{th}^i, and p_i denote the achievable rate, the minimal guaranteed rate, and the transmit power of the i-th SU, respectively, h_{ij} is the channel gain from the i-th secondary transmitter to the j-th primary receiver, and I_{th}^j signifies the maximum tolerable interference level (threshold) on the j-th primary receiver. To satisfy the stringent limits on interferences for PUs, some sophisticated power control schemes for secondary transmitters can be adopted. Furthermore, if the constraints are too strict and/or the network load is too high, admission control mechanisms can be embedded as well to limit the number of admitted SUs. Moreover, beamforming techniques can also be jointly considered with power control to improve the performance of the secondary network. In addition to power control, SUs can also use spread-spectrum techniques (i.e., spread transmitted signals over a wide frequency band) to achieve short-range high-rate transmissions with extremely low power to avoid interference to the narrowband transmissions of the PUs.

In the overlay approach, there is no strict limits on SUs' transmission powers. Instead, SUs exploit spectrum white spaces (spectrum holes), i.e., spatially and/or temporally unoccupied parts of the spectrum, and access them opportunistically. Therefore, different from the interference control approach (underlay), to adopt the interference avoidance approach (overlay), SUs need to have the knowledge about spectrum holes so that they can ensure no interference caused to PUs. To gather the timely and accurate information about the usage of PUs' spectrum,

either noncooperative or cooperative way can be employed. In the former case, SUs must have the ability to perceive and analyze the surrounding radios by using various spectrum sensing methods. This could accomplish the noninterfering communications between PUs and SUs. In the latter case, the exclusive spectrum usage information is provided by PUs. Since PUs cannot get any benefit from sharing spectrum with SUs and thus usually have no motivation to participate in the spectrum sharing process, this approach mainly applies to the government-issued cases or the spectrum trading market where PUs lease/sell their unused spectrum resources to SUs in order to create additional revenue. A typical example of overlay spectrum sharing is the approval by FCC in November 2008 of the unlicensed use of the TV white spaces (TVWS) (54–72, 76–88, 174–216, and 470–806 MHz bands, which have superior radio propagation characteristics) based on spectrum sensing as well as consultation with an FCC-mandated database. In September 2010, FCC released new rules for the use of white space for unlicensed wireless devices, which removed the mandatory sensing requirements and facilitated the use of the spectrum with geolocation-based channel allocation. In the TVWS, the TV broadcasting stations and low-power wireless microphones are PUs, and the secondary systems such as the IEEE 802.22-based WRANs, the WiFi hot-spots, and home networks can coexist in an overlay sharing manner.

Dynamic Exclusive Use Model

This model is the closest to the current spectrum regulation policy (spectrum licenses are granted for exclusive use by the corresponding licensees) but in a more flexible way and at smaller time scale, which improves spectrum efficiency. Two approaches, namely, *spectrum property rights transfer* and *dynamic spectrum allocation*, have been proposed under this model. The former approach makes the spectrum property rights transferable from one licensee to another. In order to explore the most profitable use of the spectrum resource, economic market is adopted as an important method, which leads to spectrum trading. To be specific, in general, three factors, i.e., time, geographic area, and spectrum frequency, can be used to specify the spectrum property rights. Based on this approach, the spectrum licensees are allowed to flexibly sell or lease portions of their spectrums, such as the unused bands, to SUs and authorize them to use in certain geographic areas during certain time periods, which in turn creates revenue return for themselves. Note that spectrum trading is not limited to this model. For example, the shared-use-based spectrum trading model also exists, which is very practical because in some cases it is difficult for licensees to give up their precious spectrum rights considering the unpredictable demands in the future. Such a shared-use-based spectrum trading model has been implemented by FCC on 3.5 G band [2], which will be introduced in detail in section "The State-of-the-Art of Spectrum Trading". The latter approach is introduced by the European DRiVE project [10]. Such an approach aims to improve spectrum efficiency through dynamic spectrum assignment according to the spatial and temporal traffic statistics of different services. Similar to the current static spectrum licensing policy, this approach allocates spectrums to services for exclusive use, but the spectrum relocation occurs at a much smaller scale.

Cognitive Radios

With regard to the aforementioned DSA models, hierarchical access-based spectrum sharing has attracted increasing attention and been treated as a promising solution to the low spectrum utilization problem in the traditional SSA scheme. It allows unlicensed users to access a licensed spectrum under certain restrictions, which makes spectrum access more flexible. In such a way, spectrum efficiency can be improved significantly without losing the benefits associated with the traditional SSA scheme. However, legacy wireless devices were usually designed for a dedicated frequency band and incapable of spectrum sensing to identify spectrum holes, which makes them hardly utilize the improved flexibility provided by this sharing scheme. Cognitive radios (CRs), as smart radios, provide the adaptability and technologies for wireless transmissions and enable the spectrum sharing. Specifically, it can be regarded as a sophisticated radio device that mimics the human brain, perceives and learns the radio environment, and adjusts the transmission parameters accordingly (e.g., frequency band, modulation mode, transmission power, etc.) [8]. CR devices usually work collaboratively to form a network, a.k.a. the cognitive radio network (CRN). To achieve self-adaptive transmissions in a CRN, each CR device senses its local radio environment (distributed sensing), or a centralized sensing controller senses the whole network (centralized sensing). Then, the sensing results are processed either centrally or distributedly, which guide CR devices to control their transmission patterns, including modulation, transmission power, error control methods, etc., and establish communications accordingly.

Consequently, three main functionalities are associated with a CR device, namely, *spectrum sensing*, *spectrum management*, and *spectrum mobility* [8]. These three mechanisms can facilitate SUs to access the PUs' spectrum under the hierarchical access-based spectrum sharing. To be more specific, *spectrum sensing* can be employed to determine the status of PUs' spectrum bands. By periodically sensing PUs' activities on target spectrum bands, spectrum holes in temporal and/or spatial domain can be detected and thus leveraged by SUs (with CR devices) without causing too much interference. Then, based on the *spectrum management*, SUs can conduct their spectrum access and optimize their transmission parameters. By analyzing the sensed information, SUs can learn about spectrum access related information, such as interference estimation, available duration, collision probability, etc., and make spectrum access decisions, including frequency band, transmit power, time duration, etc., by optimizing their performance (e.g., achievable rate) under certain constraints (e.g., limited interference). When the PU returns or shifts to services with high QoS requirements, *spectrum mobility*, which is also called spectrum hand-off, plays an important role in making the SU switch to another idle spectrum band. Such a spectrum hand-off process must ensure that the parameters at different protocol layers can be adjusted to match the new frequency band so that the data transmissions of this SU can be continued.

In summary, the emergence of CR technologies makes the hierarchical access-based spectrum sharing possible. If the SU has CR ability, it can obtain and utilize the information on PUs' spectrums through spectrum sensing function, make

optimal decisions on spectrum access through spectrum management function, and change the operating frequency bands in order to continue data transmissions even in the context of the unpredictable return of PUs through spectrum mobility function.

Trading-Based Spectrum Sharing Mechanism

Although the emerging CR technology could provide a strong technical support for DSA and eliminate PUs' concerns on interference imposed by SUs if they open up their licensed bands, one key issue is why PUs are willing to share their preciously owned spectrums with others. To guarantee their QoSs, if there is no incentive, PUs might even prefer to transmit bogus data to keep spectrums occupied and deter SUs from using it. Therefore, it is essential to design proper mechanisms to provide incentives for PUs to share out their spectrum bands. From the economic aspect, spectrum trading, referring to the process of selling and buying spectrum resources, has been widely advocated as a promising mechanism for DSA and attracted a lot of attention. In spectrum trading, the spectrum owners (PUs) can sell their unused spectrum resources in certain geographic areas during certain time periods to unlicensed users (SUs) for monetary gains or performance improvements, and unlicensed users can purchase them to fulfill their desired communication goals at the monetary cost or resources (e.g., serving as relays for PUs). As a result, such a secondary spectrum market can realize the DSA with a win-win situation while generating high economic profits. In what follows, along with different directions, we will discuss various spectrum trading mechanisms proposed in the current literature.

Exclusive-Use Mode vs. Shared-Use Mode

As aforementioned, DSA can be implemented in an exclusive-use mode or a shared-use mode, which corresponds to two different spectrum trading operations. These two types of trading have different characteristics with different relevant problems, which, however, are ambiguous in many existing research works. To be specific, in the former case (exclusive-use), the spectrum access rights (including specific frequency bands, available regions, and time durations) are traded for exclusive use by SUs. In other words, within the leasing duration, the SUs who have purchased the access right turn to be the PUs and can exclusively use the purchased bands at the corresponding geographic areas. In turn, the original PUs cannot use them until the end of the leasing period. As for this mode, spectrum sensing and interference management are not critical issues anymore because the spectrum is exclusively used by either PUs or SUs. One key challenge here is on the seller side (PUs), namely, how to design an optimal selling/leasing strategy. Since the spectrum owners have to guarantee the QoS for their subscribed users, they have to reserve enough resource, and it is not an easy task to determine the access right for selling due to the unpredictable traffic in the future.

In the latter case (shared-use), if SUs want to use the purchased spectrum access right, they have to obey certain rules, rather than exclusively use it as PUs. In other words, the sold spectrum access right is utilized based on spectrum sharing among both PUs and SUs where PUs have higher priority. Generally speaking, overlay-based sharing has been widely adopted, where SUs have to monitor the PUs' activities and vacate the spectrum if PUs return even though they have purchased the access right. Actually, this mode can be treated as a hybrid mode with both exclusive-use and shared-use. Between PUs and SUs, it is based on shared-use to ensure PUs' QoS; and among SUs, it is based on exclusive-use that only the SUs who have purchased the access right can opportunistically access the spectrum. In fact, in comparison with the former mode, the shared-use mode is more practical because the rational spectrum owners are usually unwilling to totally give up their access right considering their unpredictable traffic demands. In the shared-use mode, one key challenge is on the buyer side (SUs), i.e., how to valuate the reward under the uncertain risk of purchasing certain access right. Due to the hierarchical sharing mode, it is important for SUs to capture the statistical features of the sold spectrums (e.g., by taking spectrum measurements) and determine an optimal buying strategy [11].

Monetary Reward vs. Resource Exchange

It is known that the radio spectrum resource is very valuable. In 2008, the auction of 700 MHz frequency band in the United States raised $19.59 billion for the US government. Therefore, as the traditional trading market in economics, currency, also referred to as money, is widely used as the payment in the spectrum trading market as well, i.e., in the so-called money-exchange trading model. Generally speaking, this model is most effective if PUs have redundant spectrum resource to sell because in this case, SUs are transparent to PUs and high monetary revenue can be gained, which is most interesting to PUs. However, if PUs' own traffic load is heavy or the primary channels' qualities are poor (e.g., due to the severe channel fading), there might be no extra spectrum resource left for sale. In this scenario, resource-exchange spectrum trading becomes an attractive option, where PUs could share spectrum with SUs in exchange for the performance improvement, such as increasing data rate or reducing probability of outage [12]. Under the barter-like trading rule, SUs provide communication resources for PUs in exchange for the access right to PUs' certain spectrum (also known as cooperative spectrum sharing).

Serving as relays is one typical way for SUs to obtain the spectrum access right in the resource-exchange trading model [13, 14]. To be specific, direct transmission of a primary session may be at a low data rate due to poor channel condition or long transmission distance. Thus, suitable SUs could be utilized as the cooperative relays for the PU's traffic to achieve a higher data rate accordingly. If the selected SUs join the cooperation and the primary session's data rate can be increased, the time occupied by this primary session on the licensed band can be decreased.

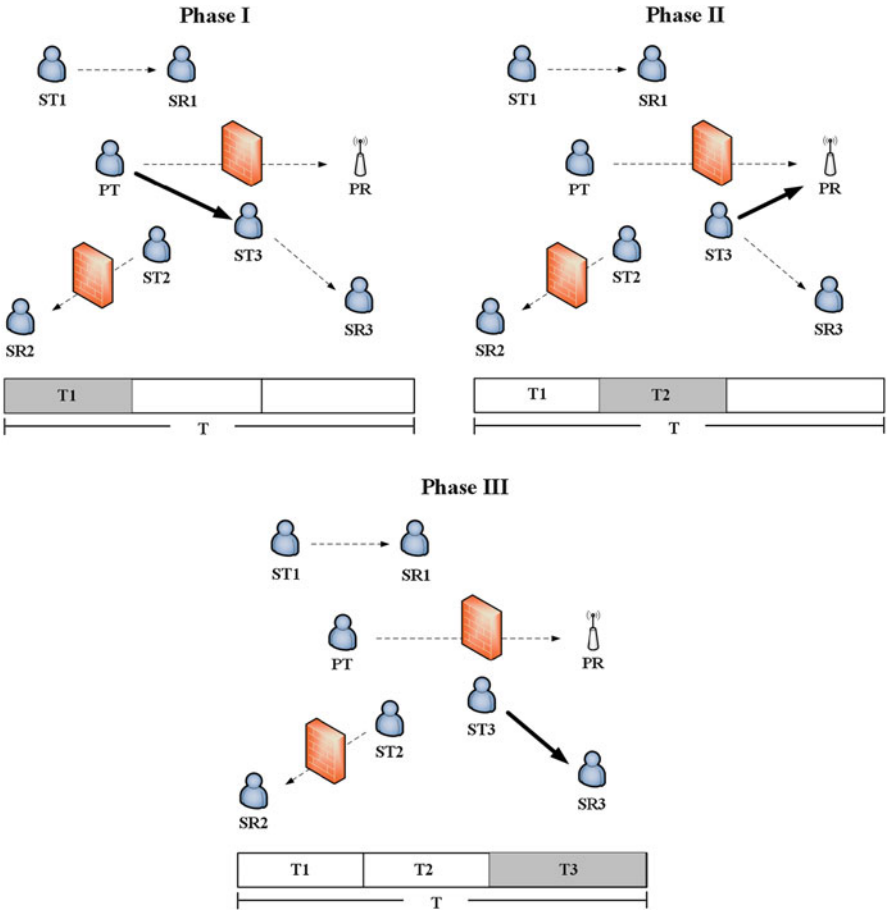

Fig. 1 A toy example of the relay-based resource-exchange spectrum trading

In return, the involved SUs could gain the access right for the remaining session period. Therefore, by exploiting relay-based cooperation between PUs and SUs as a resource-exchange trading mechanism, both sides can increase their own interests. Here, a toy example is presented as Fig. 1, where one primary transmission pair (PU) and three secondary transmission pairs (SU) coexist.

The PU has the exclusive access right to the licensed band with certain transmission task, but experiences a poor channel condition from its transmitter PT to its receiver PR, and the SUs have no right to use the spectrum for their transmissions unless explicitly permitted by the PU. Based on the resource-exchange trading, the PU employs some SUs to relay its traffic and allows involved SUs to use the spectrum after the primary session is completed. Suppose that the primary session is scheduled as T. In phase I, the primary transmitter PT broadcasts its data to the involved SUs who are willing to join the cooperation, by using T_1. In this

example, ST1 rejects the invitation because it is quite far away from PR, and ST2 rejects as well because of its poor channel condition between ST2 and SR2. The trading agreement can be reached by bargaining between the PU and SUs or adopting a contract-based approach in which the PU can claim different reward-effort combinations and design contracts for different SUs. In phase II, the involved SUs (ST3) relay the primary traffic to PR in either amplify-and-forward or decode-and-forward manner by using T_2. In phase III, the PU rewards the involved SUs (ST3) to use the spectrum within the remaining time period, i.e., $T - T_1 - T_2$ (if multiple SUs participate in the cooperation, they can share the spectrum by using TDMA with a dedicated time allocation managed by the PU).

Auction Market vs. Open Market

Auction Market

An auction is a process of procurement via competitive bidding. It is a traditional but efficient way to distribute commodities and especially suitable for the spectrum trading market because the price of a radio spectrum is difficult to be determined precisely in advance.

First, some basic terminologies in auction theory are introduced as follows [15]. (a) *Seller and bidder*: In auctions, a seller and a bidder (buyer) are the one who owns and wants to sell commodities and the one who wants to buy them, respectively. In the secondary spectrum market, the seller is usually the spectrum owner, and the bidder is usually a secondary user or a secondary service provider who wants to obtain the spectrum access right. (b) *Auctioneer*: An auctioneer works as an intermediate agent who receives bids/asks from both bidders and sellers and hosts and directs the auction process. In general, the auctioneer could be employed by the seller or certain third-party institution such as government agencies. (c) *Valuation:* In an auction, for each commodity, a bidder/seller has a reserved valuation in his mind, i.e., the monetary estimated value of it. Different players may value commodities with different valuations depending on their preferences. (d) *Clearing price*: According to the bids from bidders and asks from the seller, auctioneer will determine winners, charge them by certain price (so-called clearing price) and clear the market. Note that, for each winner, the charging price may not be equal to his bid. Generally, it is not higher/lower than the valuation of the bidder/seller on this commodity.

After introducing some basic definitions, we next present some typical auction types, which could be embedded in the spectrum trading market. (a) *Open-cry and sealed-bid auction*: In an open-cry auction, each buyer calls out his bid, i.e., the bidding strategy of each buyer is public. This type of auction is usually held in several rounds, and each buyer could adjust his bidding strategy according to others' calls which could reach a high revenue for the seller. However, generally, it is time-consuming and needs to make all bidders stay in one room. On the contrary, in a sealed-bid auction, buyers privately submit bids to the auctioneer without knowing others' bidding strategies, which is more suitable for the dynamic spectrum

trading. Specifically, first-price and second-price sealed-bid auctions are the two most important sealed-bid auctions. In both auctions, the winner is the buyer who submits the highest bid, but the charging prices are different. As for the first-price mechanism, the charging price is just his highest bid, but as for the second-price mechanism (also known as Vickrey auction), the charging price is equal to the second highest bid among all bidders. As a generalized Vickrey auction, Vickrey-Clarke-Groves (VCG) auction has attracted great attention because it can achieve the maximal social welfare due to its truthfulness property (introduced later), and many VCG-styled auction mechanisms have been proposed for the auction-based spectrum trading market. For an overview see section "The State-of-the-Art of Spectrum Trading". (b) *Single-sided and double-sided auction*: In the single-sided auction [16–19], the competition only happens on either seller side or buyer side, corresponding to the following two cases, one is that multiple sellers compete with each other to sell commodities to one buyer. In this case, Dutch auction (descending-bid auction) is usually adopted where each seller decreases the price from the initial setting ceiling price over time until the deal is completed. The other case is that multiple buyers compete for the commodity from one seller. Then English auction (ascending-bid auction) can be employed, in which the bids submitted by buyers increase monotonically until no higher bid comes out, and the buyer who offers the highest bid wins the auction. In practice, generally, multiple sellers and buyers coexist in the market, and thus double auction emerges to handle this scenario [20–23]. In a double auction, the auctioneer matches the asks from multiple sellers and bids from multiple buyers by allocating commodities from sellers to buyers and payments from buyers to sellers accordingly. (c) *Offline and online auction*: In an offline auction, the auctioneer will keep listening to asks from sellers and bids from buyers and determine the auction result at certain specified time points, i.e., the auction is based on a wait-and-clear procedure. Nevertheless, in an online auction [18, 22, 23], whenever the asks and the bids arrive, the market is cleared immediately, i.e., the auction is based on a real-time procedure. The online auction is more complicated than its offline counterpart but could reach a more flexible spectrum trading market, where the auction requests could be generated randomly and handled as soon as possible. (d) *Single-unit, multiunit, and combinatorial auction*: In single-unit auctions, each buyer bids for one commodity unit, while in multiunit auctions, each buyer bids for multiple commodities. The requested commodities may be partly or fully allocated to the buyers, and buyers can accept the case if only some of the requested commodities are received. However, in some cases, buyers may need a complete set of commodities. In other words, buyers bid for certain commodity bundles in an all-or-none mode, i.e., each bid for the whole bundle is either fully accepted or rejected. Such a scenario is common in spectrum trading market because a SU may need to use a set of bands within a large area to provide end-to-end services. To deal with such bidding requests, combinatorial auctions [24–26] can be applied. Since each buyer bids for certain bundles, the conflict relationships among different bidders will be more complicated and thus makes the optimal commodity allocation more difficult.

In general, an auction mechanism design mainly contains two components (no matter what type the auction is), namely, the winner determination and the pricing mechanism. There are many key issues to be considered.

(a) Winner determination: As for the winner determination process, social welfare maximum is usually adopted as the decision metric, which is defined as the sum of all auction participants' utilities, indicating the total profits produced in the market. By maximizing the social welfare, an auction could allocate each commodity to the buyer who values it the most, which is called allocation efficient or Pareto efficient. To be specific, for a buyer, if he wins the commodity, his utility is equal to the difference between his valuation and his payment (clearing price). For a seller who sells the commodity, his utility is the gap between the charging price and his valuation (reserved price). Then, for the auctioned commodity, the achieved social welfare is equal to the sum of all winners' valuations minus the reserved price of the sold commodity, and the optimal decision can be obtained by solving certain optimization problems. In addition to efficiency, fairness issue is also considered in some research works to ensure that different participants can benefit fairly in the auction, which could encourage buyers to join the auction. Different fairness levels can be developed, such as the basic level ensuring the equal chance for buyers to participate in an auction and the max-min fairness level to make each buyer at least receive a basic portion of commodities [27]. Generally speaking, in an auction market, efficiency and fairness cannot be achieved at the same time, and there should be trade-offs between these two metrics. Furthermore, different from the conventional auction, for the commodity which is not reusable, i.e., an auction in which commodity claimed by one buyer cannot be allocated again to others, in the spectrum auction, the radio resource can be allocated to many buyers simultaneously as long as they will not interfere with each other (e.g., sufficiently apart from each other). Such a special feature makes the winner determination process more complicated, and conflict graph model has been regarded as an effective way to handle the interference issue. Furthermore, the reusability also leads to some other interesting research works, such as the group-based auction [28] where multiple buyers targeting at the same radio resource group together as a virtual bidder and the corresponding profit sharing problem, i.e., how to share the profit among individual buyers in the same virtual bidder group [29].

(b) Pricing mechanism: With regard to the pricing mechanism design, the following three important economic properties are usually taken into account, namely, individual rationality (IR), budget balanced (BB), and incentive compatibility (IC, also known as truthfulness or strategy proof) [30, 37]. To be specific, IR property means that the charging price to certain winner cannot be higher than his bid. BB property indicates that the generated revenue of the trader should be nonnegative. These two properties are relatively easy to achieve. However, satisfying IC property, as an extremely important property to realize the maximal social welfare, is usually challenging for an auction design. In general, buyers in the market are selfish and may deceive others by submitting false information about their private valuations to gain more profit. In such a way, although some lying buyers may earn more profit, the social welfare may be impaired seriously. From this point of view, a

truthful auction design with IC feature can guarantee that each buyer will achieve the optimal utility only when he submits the truthful bid, reflecting his real valuation on the requested commodity. In other words, when IC property is satisfied, each buyer's dominant strategy (social choice) is to submit the true valuation no matter what other buyers' bidding strategies are. In such a way, the auctioneer can make the socially optimal winner determination just according to buyers' bids, which reflect their real valuations, and also prevent market manipulations. A simpler approach to achieve IC is referring to the existing auction mechanisms that have been proved to be IC, such as the typical VCG auction.

Open Market

Unlike the auction-based spectrum trading, instead of being controlled by an auctioneer, in an open market, PUs and SUs are allowed to sell and buy radio resources freely. Due to the flexibility in the open market, some new issues emerge accordingly, which lead to several interesting research directions. In the following, three popular marketing mechanisms are introduced, namely, pricing based, contract based, and bargaining based.

(a) Pricing-based mechanism: Different from the auction market, where the final price of the commodity is derived from buyers' bidding strategies (e.g., first-price or second-price mechanism), in the open market, the price of the commodity is designed by its corresponding seller. As the most important role in the open market, the pricing strategy of a seller will not only determine his revenue but also influence the decision of buyers, which usually stand on two opposite sides, e.g., a high price will increase the seller's revenue while reducing the satisfaction of the buyer. Due to the complicated relationships among different market participants, several factors will impact the price setting, such as the demand/supply of buyers/sellers, the competition among buyers/sellers, etc. Considering a typical scenario where multiple sellers and multiple buyers coexist, generally, three pricing models are involved, i.e., market-equilibrium model, competitive model, and cooperative model, corresponding to different levels of competition and cooperation among different sellers [31]. In the market-equilibrium pricing model, each seller is not aware of others, and the prices of commodities of each seller are natively set by himself according to the demand in the market. Specifically, since the price of commodities will influence the demand of buyers, the market-equilibrium price represents the price that makes the demand just equal to the supply in the market. Such a pricing strategy could ensure that there is no excess supply in the market and maximize both seller's profit and buyer's satisfaction. In general, demand function and supply function are considered in this model to derive the market-equilibrium-based solution. In the latter two models, sellers are aware of each other, and the prices are set in either a competitive or a cooperative manner. To be specific, in the competitive pricing model, each seller has its own interest to maximize his individual profit. Therefore, competition occurs in terms of pricing, and game theory can be used to deal with this situation. In general, a game formulation consists of three main components, i.e., players, actions, and corresponding payoffs. As for this situation, multiple sellers (i.e., players) offer prices (i.e., actions) to

sell commodities to buyers trying to maximize their profits (i.e., payoffs), and thus a noncooperative game can be adopted to model such a situation. The Nash equilibrium is usually considered as the solution to such a game model, where no seller can improve his payoff by deviating from the equilibrium, and the Nash equilibrium can be obtained by analyzing the best response function, i.e., the best strategy adopted by one player given others' strategies. Although more buyers could be attracted in the market through the competition among sellers, it may result in a low revenue for each seller. Therefore, instead of competing with each other, sellers may be willing to cooperate together to choose higher prices so that they can earn a higher profit than that in case of competition, i.e., the so-called cooperative pricing model. In addition to game theory (i.e., cooperative game), optimi zation approach could be employed as well in the cooperative pricing model, e.g., to achieve the highest total profit for all sellers.

(b) Contract-based mechanism: In some cases, precisely pricing commodities is inflexible or even hardly achievable for sellers (e.g., due to the limited knowledge about buyers' valuations). As a result, contract mechanism has been regarded as an effective approach in the open market [32–35]. To be specific, the seller can design a contract by offering different supply-price options to different buyers, such as different effort-reward combinations in resource-exchange market or different quality-price combinations in money-exchange market. Each buyer can choose to sign one of the contract items or reject. A typical example is the labor market, in which an employer offers a contract with several different items specifying different combinations of effort level and salary level. Each potential employee can select one of the contract items or refuse it to maximize his payoff according to his own capability and valuation. By means of the contract, buyers will gain enhanced satisfactions, and meanwhile sellers can optimally allocate their commodities to maximize own revenue or the social efficiency. Consequently, how to optimally specify the class of contracts so that both sellers and buyers are able to maximize their individual utilities is the most important issue for contract mechanism design.

(c) Bargaining-based mechanism: In the former two market mechanisms, the trading process is based on a monopoly market, in which the seller acts as a monopolist who sets prices or contracts for the sold commodities. Different from that, in the bargaining mechanism, the buyer and the seller can negotiate on the price and the requested commodities repeatedly until an acceptable solution for both sides is achieved (i.e., for certain commodity, the seller and the buyer take turns to offer and counteroffer until reaching an agreement). Such a bargaining mode is especially suitable for the multiplayer scenario, where each player prefers to reach an agreement rather than not, however, with conflicting interests. As a mathematical basis for modeling and analyzing interactive decision-making problems, game theory is commonly used for bargaining scheme design. For example, the Stackelberg game as a strategic game has attracted intensive attention, which contains two types of players, i.e., leader and followers. In the Stackelberg game, the leader moves first, and then the followers move subsequently. For the bargaining market, the seller acts as the leader, and the buyers acts as the followers, and the Nash equilibrium solution can be solved through backward induction, i.e., the leader makes the best decision

by predicting what the possible best response of the followers is and the follower moves according to the adopted strategy of the leader. In addition to the Stackelberg game, Bayesian game can also be used in the bargaining market when considering a common scenario that sellers and buyers do not have complete information about each other, in which probabilistic analysis plays an important role.

Summary

The aforementioned various classifications of spectrum trading along with different directions have been summarized as Fig. 2, including their categories, descriptions, features, and possible application scenarios.

The State-of-the-Art of Spectrum Trading

In this section, we present the state-of-the art of spectrum trading, including both practical initiatives implemented by the government and theoretical research works developed in the academic research community.

Auction-Based Spectrum Sharing Initiatives by Government

Although the dynamic spectrum trading market, where spectrum owners and unlicensed users can trade spectrum access right freely, is still in the draft, in practice, such an economic-based spectrum sharing mechanism has been implemented by the government to provide more spectrum for commercial use due to the booming growth on wireless services. In the United States, the radio spectrum is managed by two governmental agencies, namely, the Federal Communications Commission (FCC) and the National Telecommunications and Information Administration (NTIA). The former is responsible for managing the non-Federal use (e.g., commercial, private internal business, and personal use) and the latter for Federal use (e.g., used by the Army, the FAA, and the FBI) of the spectrum. In order to enable various wireless broadband technologies, the Presidential Memorandum in June 2010, "Unleashing the Wireless Broadband Revolution," called for the NTIA and the FCC to make 500 MHz of spectrum available for the wireless broadband use within 10 years [36]. Generally, the traditional way to make additional frequency bands available for commercial use is based on a clear-and-relocate process, i.e., clear the target spectrum (original users are moved to other bands) and relocate the cleared spectrum to new commercial users (e.g., by an auction). For example, in 2002, the NTIA and the FCC jointly reallocated the 1710–1755 MHz band from Federal use to non-Federal Advanced Wireless Service (AWS) use, also referred to as AWS-1. The spectrum relocation, although additional spectrum could be made available for commercial use as well, is extremely expensive and time-consuming. Take the case AWS-1 as an example, 12 Federal agencies representing 173 separate

	Categories		Descriptions	Features	Application Scenarios
Sharing Scheme	Exclusive-use		SUs can exclusively use the purchased spectrum access rights	Guaranteed QoS for SUs (higher selling price); No access by PUs; Selling strategies on spectrum owner side	Spectrum holes are determinant in both spatial and temporal domains, i.e., PUs have regular activities, e.g., TVWS
	Shared-use		SUs can use the purchased spectrum access rights only when PUs are inactive	Non-guaranteed QoS for SUs; Sharing mechanisms (PU protection); Buying strategies on SU-side (spectrum uncertainty)	Spectrum holes are unpredictable, e.g., 3.5GHz
Payment Mode	Monetary Reward		SUs pay money to spectrum owners for spectrum access rights	High monetary revenue gained by spectrum owners; Transparency of SUs for PUs	Spectrum holes exist
	Resource Exchange		SUs improve the QoS of PUs by using their own resources, e.g., as relays, to gain spectrum access rights in return	Improved QoS gained by PUs; Cooperation between SUs and PUs	No spectrum hole exists because of the heavy traffic of PUs or the primary channels' conditions are poor
Market Mechanism	Auction Market	Open-cry/Sealed-bid	SUs buy spectrum access rights through competitive bidding in an auction managed by an auctioneer	buyer-driven prices; Time-consuming (bidding decision-making, multi-round auction process, etc.); Two main steps: Winner Determination (social welfare maximum)+Pricing Mechanism (economic-robustness)	Difficult to pre-determine the selling price; Time scale is relatively large; A trusted auctioneer can be found to manage the auction process
		Single-sided/Double-sided			
		Offline/Online			
		Single-unit/Multi-unit/ Combinatorial			
	Open Market	Pricing-based Mechanism	SUs buy spectrum access rights directly from sellers based on their selling mechanisms	Specific price determined by the seller based on Market-equilibrium/Competive/Cooperation model	Sellers are willing to pre-determine the selling price; Time scale can be small because the trading process is flexible and simple without auctioneer as a controller
		Contract-based Mechanism		Multiple supply-price options offered by the seller	
		Bargaining-based Mechanism		Negotiation between buyers and sellers; Game theory	

Fig. 2 Summary of various spectrum trading classifications

systems with thousands of radio equipments in hundreds of locations have to move away from the 1710–1755 MHz band. Facing the serious drawback of the clear-and-relocate process, the NTIA and the FCC have been cooperating to develop advanced spectrum sharing schemes to fulfill the 500 MHz goal. Due to the high economic revenue of the spectrum resource, auction has been considered as an effective way to grant new licenses. As a result, many auction-based spectrum sharing actions on different frequency bands have been executed recently. Next, two concrete examples are presented, namely, AWS-3 and Citizens Broadband Radio Service (CBRS) at 3.5 GHz [2].

AWS-3

In March 2014, the Report and Order makes 65 MHz available for commercial use via auction (including 1695–1710, 1755–1780, and 2155–2180 MHz) and specifies some rules for sharing with incumbent Federal users (40 MHz to be shared). The incumbent Federal users will either relocate to other bands or share with the incoming commercial systems based on the establishment of certain geographic protection zones. In January 2015, the AWS-3 auction was conducted, which raised $41.3 billion in total with 31 winning bidders granted 1611 licenses. The new AWS-3 licensees must agree on the transmission rule where the incumbent Federal users within protection zones have higher priority for operation. In other words, the sharing is based on the underlay mode where the AWS-3 licensees within protect zones need to control their transmission power in order to avoid harmful interference imposed on incumbent Federal users. By using such an auction-based underlay spectrum sharing mechanism, high economic revenue has been generated, more spectrum has been made available to carriers, and meanwhile disruptions to Federal missions can be prevented.

CBRS at 3.5 GHz

In July 2012, the President's Council of Advisors on Science and Technology (PCAST) released its report "Realizing the Full Potential of Government-Held Spectrum to Spur Economic Growth," which claims that exclusive licensing is not the way to stepping forward and the advanced spectrum sharing should become the new paradigm [4]. The report proposes a new spectrum management mode by dividing the spectrum into large blocks, called spectrum superhighways, and allowing users with compatible services to dynamically share them on a priority basis. To be specific, users are classified into three tiers with different priorities, and all users are required to register in a database, called Spectrum Access System (SAS) database, which acts as the controller to manage the dynamic spectrum access. (a) The incumbent users, also called primary access users, are at the top tier with the highest access right. They would register their actual deployments in the SAS database and obtain the guaranteed protection against harmful interference in their deployment areas. (b) Secondary access users, also called priority access licensees, are at the secondary tier, who are issued short-term operating rights in certain specified geographic areas and would be protected from interference caused by the third tier users. However, they are required to vacate the spectrum when a

primary access user registers a conflicting deployment in the database. (c) General authorized access (GAA) users are at the third tier, who would be allowed to access the unoccupied spectrum opportunistically if there is no conflicting primary and secondary access users registering in the database. Particularly, the secondary access users and GAA users are required to query the SAS database to gain the permission to access certain spectrum. The implementation of CBRS at 3.5 GHz is just based on this three-tier sharing model proposed in the PCAST Spectrum Report, which enables incumbent Federal users, operating at the first tier, and CBRS users, operating at the second and third tier, to share spectrum via a dynamic spectrum access system, and the priority access licenses (PALs) at the secondary tier are allocated by an auction. Obviously, different from the AWS-3 case, the spectrum sharing for CBRS at 3.5 GHz is in an overlay sharing mode, and the auction for the PALs belongs to the shared-use trading model.

Spectrum Auction

The aforementioned spectrum auction, as a well-known economic-effective allocation mechanism, has been widely adopted for spectrum trading. Different auction models with different features have been embedded in the spectrum auction design.

VCG Auction

Vickrey-Clarke-Groves (VCG) auction is a type of truthful sealed-bid auction for multiple commodities. Such an auction allocates commodities in a socially optimal way (i.e., to maximize the total valuation of winners) based on the bidders' bids (equal to their true valuations) and charges each winner the harm he causes to other bidders. Suppose that there are $\mathscr{M} = \{c_1, \cdots, c_m\}$ commodities and $\mathscr{N} = \{k_1, \cdots, k_n\}$ bidders in the auction. For the bidder k_i, his bid for the commodity c_j is expressed as $b_i\left(c_j\right)$, which is equal to his valuation due to the guarantee of truthfulness in VCG auctions. Then, based on the VCG mechanism, the socially optimal allocation can be formulated as the following optimization problem

$$\begin{aligned} &\text{Max} \quad \sum_{j=1}^{m} \sum_{i=1}^{n} b_i\left(c_j\right) \cdot x_{ij} \\ &\text{s.t.} \quad \sum_{i=1}^{n} x_{ij} \leq 1, \ \forall j \in \mathscr{M}, \quad x_{ij} \in \{0,1\}, \end{aligned} \tag{2}$$

in which the integer x_{ij} indicates whether or not k_i wins c_j. In some cases, each bidder only allows to win one item, then, the constraint $\sum_{j=1}^{m} x_{ij} \leq 1, \forall i \in \mathscr{N}$ can be included as well. Denote the achievable social value of this VCG auction as $V_{\mathscr{N}}^{\mathscr{M}}$, i.e., $V_{\mathscr{N}}^{\mathscr{M}} = \sum_{j=1}^{m} \sum_{i=1}^{n} b_i\left(c_j\right) \cdot x_{ij}$, and use $\mathscr{A} \backslash \mathscr{B}$ to represent the set of elements of $\mathscr{A}$

which do not belong to $\mathscr{B}$. Assume that k_i wins c_j, i.e., $x_{ij} = 1$, then, the charging price to k_i for c_j can be calculated as $V^{\mathscr{M}}_{\mathscr{N}\setminus\{k_i\}} - V^{\mathscr{M}\setminus\{c_j\}}_{\mathscr{N}\setminus\{k_i\}}$. The first term represents the total valuation of others if the bidder i does not participate into the auction, and in the second term, the commodity c_j is excluded from the available commodity set due to the participation of the bidder i. Therefore, such a gap indicates the harm that the bidder i causes to others. A simple example is presented here for a better understanding. Assume that there are two bidders with bidding values $b_1(c_1) = 10$, $b_1(c_2) = 6$, $b_2(c_1) = 7$, $b_2(c_2) = 5$ for two commodities and each bidder is allowed to get only one commodity. Obviously, the socially optimal allocation is to let k_1 get c_1 and k_2 get c_2, achieving the maximal social value 15. According to the aforementioned pricing mechanism, the charging price to k_1 for c_1 should be $7 - 5 = 2$ and that to k_2 for c_2 should be $10 - 10 = 0$.

The VCG auction guarantees the most important truthfulness property, i.e., forces buyers to bid truthfully in the sense that bidding lower than the true valuation does not gain anything advantage, and thus achieves the maximal social welfare. Therefore, it has attracted great attention and inspired many truthful VCG-styled spectrum auction development. Due to the specific feature of radio resource, i.e., spectrum reusability in different regions, the truthful design on spectrum auction is different from (and much more difficult than) that in conventional auctions. Zhou et al. developed the first truthful and computationally efficient spectrum auction scheme, called VERITAS, in [16], which consists of a greedy spectrum allocation algorithm for winner determination and a VCG-styled pricing mechanism to charge winners. Take the scenario (conflict graph) in Fig. 3 as an example. Each vertex represents a bidder, i.e., there are totally five bidders in this auction. The edge between two vertices indicates that they conflict with each other, i.e., a spectrum band cannot be allocated to these two bidders at the same time. Suppose that there are two bands auctioned in this market denoted as f_1 and f_2 and each bidder bids for one (for each bidder, either f_1 or f_2 is acceptable). The bidding values of the five bidders are shown in Fig. 3 as $b_1 = 6, b_2 = 5, b_3 = 4, b_4 = 3$, and $b_5 = 1$. First, the greedy algorithm is adopted to allocate the two bands. Specifically, it sequentially allocates spectrums to bidders from the one with the highest bid to the one with the lowest bid, considering their conflicting relationships. For each bidder, the algorithm first checks whether or not there is an available band for him. If so, it assigns him one band with the lowest available index. Consequently, the allocation process can

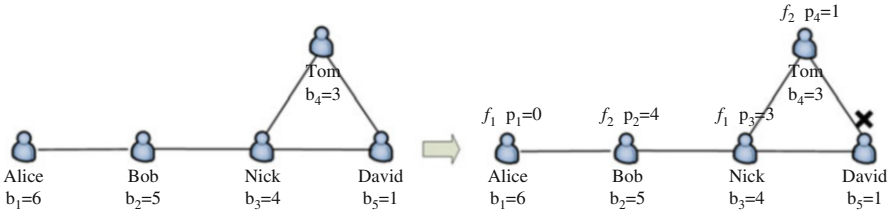

Fig. 3 An example of VERITAS scheme

be described as follows: (Alice gets f_1) → (Bob gets f_2) → (Nick gets f_1) → (Tom gets f_2) → (David gets nothing). After the greedy allocation, a VCG-styled pricing mechanism is applied on the winners to calculate their payments. To be specific, the charging price of each winner i is the bidding value of his critical neighbor (i.e., the one of the i's conflicting neighbors where if i bids lower than his, i will lose, and if i bids higher than his, i will win). Take Alice and Nick as an example. Alice does not have a critical neighbor because even if she bids lower than her neighbor Bob, e.g., 4.5, she can also win the auction with f_2, i.e., (Bob gets f_1) → (Alice gets f_2) → (Nick gets f_2) → (Tom gets f_1) → (David gets nothing). Therefore, the charging price to Alice is 0. Nick has three conflicting neighbors, i.e., Bob, Tom and David, and Tom is his critical neighbor because if he bids lower than Tom's bid 3, Tom will get f_1 based on the greedy algorithm and Nick will lose the auction. Therefore, the charging price to Nick is 3. Similarly, the charging price to Bob and Tom is 4 and 1, respectively. It is noteworthy that comparing with the aforementioned VCG pricing mechanism, the charging price to winner i in VERITAS can be denoted as $V^{\mathscr{M}}_{\mathscr{N}\setminus\{k_i\}} - \left(V^{\mathscr{M}}_{\mathscr{N}} - b_i\right)$, which can be treated as a special VCG mechanism due to the reusability of the auctioned commodity. Such an auction mechanism can be proved to be truthful, and detailed proof can be found in [16].

According to the VERITAS design, a key rule for truthful spectrum auction design is summarized here by satisfying the following two crucial factors: (a) The resource allocation process (winner determination) is monotonic, i.e., if a bidder could win/lose by certain bid, he could also win/lose if he bids higher/lower. (b) The charging price for a winner is the critical value (boundary value) of him, i.e., if he bids higher than that, he would win, otherwise, he would lose. Under different scenarios, the monotonic allocation and the critical value could be different, and readers could refer to such a design rule to develop different truthful spectrum auction schemes. For example, in [17], Li et al. considered the multi-hop scenario by modeling unlicensed users as secondary networks (SNs) with end-to-end routing service requests. A truthful heuristic auction scheme with the consideration of inter-SN interference and a truthful randomized auction framework based on primal-dual linear optimization were proposed. Also targeting at the multi-hop communication scenario, in [37], Li et al. proposed a novel economic-robust transmission opportunity auction scheme (TOA). Different from the case in [17], in [37], the bidders are the individual SUs with certain multi-hop data transmission tasks, rather than SNs, which are deployed by a secondary service provider working as a network operator. To support the multi-hop data traffic, instead of using spectrum bands as the auctioned commodities, in the TOA scheme, each SU bids for transmission opportunities (TOs), i.e., the permit of data transmission on a specific link using a certain band (link-band pair). Based on the sophisticated design on TO allocation, TO scheduling, and TO pricing, the developed TOA scheme can satisfy all the IC, IR, and BB properties. Similarly, to support the end-to-end service in multi-hop networks, Pan et al. developed a session-based spectrum trading system in [38] and [39] and further designed an economic-robust session-based auction scheme in [40] by following the aforementioned design rule. In [18], considering the dynamic CRN environment, Sodagari et al. developed a truthful online auction

for expiring spectrum sharing, where the SUs are allowed to arrive and participate in the auction with expiring spectrum bands at any time. The SUs are required to submit their valuations and arrival-departure time instances, which can be enforced to be truthful. In order to enable bidders' flexible strategies in terms of demands and valuations, in [19], Feng et al. designed a novel truthful auction mechanism called Flexauc, in which each bidder can bid for any amount of demands with different valuations and will be satisfied with any possible result.

Double Auction

Double auction is also a common auction model when multiple sellers are involved, in which buyers bid for resources and sellers compete for demands. As an extension of the single-sided truthful auction design in [16], in [20], Zhou et al. proposed a framework for truthful double auctions called TRUST. To be specific, based on the conflicting relationships, buyers are formed into many groups. Then, by comparing the sellers' asks with the buyer groups' bids, several matching seller/buyer-group pairs are selected as the auction winners, and payments are made from the winning buyers to the winning sellers. In [21], Chen et al. developed a truthful double auction mechanism with the consideration of the heterogeneity of spectrum, called TAMES, in which each buyer is allowed to submit a bidding profile to express his diversified valuations for different spectrum bands. Similarly, buyer grouping, matching allocation, and VCG-styled pricing are adopted by the TAMES. In [22], Wang et al. designed a truthful online double auction (TODA) scheme because the selling/buying requests from PUs/SUs often come in an online fashion. In the TODA, once the auctioneer receives spectrum requests, it will decide and match winning SUs and PUs immediately and also determine how much SUs should pay and PUs should get. By incorporating the buyers' location information into the auction mechanism design, a location-aware online truthful double auction scheme called LOTUS was proposed in [23], which has considered the sporadic nature of spectrum requests and the geographic feature of buyers.

Combinatorial Auction

Combinatorial auction has been regarded as a widely used model for spectrum auction as well because in general, to satisfy the end-to-end QoS, the SU may need to bid for a whole bundle of frequency bands covering certain regions during an extended time period in an all-or-none mode. In [24], Zheng et al. modeled the heterogeneous spectrum allocation as a combinatorial auction, named AEGIS, with the consideration of five features, i.e., strategic behaviors of unknown users, channel heterogeneity, preference diversity, channel spatial reusability, and social welfare maximization. Specifically, two mechanisms are developed, i.e., a direct revelation combinatorial spectrum auction mechanism for unknown single-minded users (AEGIS-SG) and an iterative ascending one for unknown multiple-minded users (AEGIS-MP). In [25], Dong et al. modeled the spectrum opportunity in a time-frequency division mode and proposed a truthful combinatorial auction with the consideration of time-frequency flexibility. It consists of a polynomial-time and near-optimal winner determination algorithm and a novel payment mechanism that

guarantees the truthfulness. Many-to-many matching theory was adopted in [26] to realize the combinatorial auction, in which buyers can freely express their preferences for different combinations of spectrum bands. Instead of achieving the maximal social welfare, the stable status is the main goal of the interference-free spectrum matching where both sellers and buyers are satisfied with the result.

In addition to the investigation of various auction models, there are also many other hot research directions for spectrum auction in the literature, such as the allocation objective design, the bidding strategy adaption, the multitier architecture development, etc. (a) With regard to the optimization objective for resource allocation (winner determination), in [41], Huang et al. proposed a flexible one that can be set to maximize either the overall social efficiency (social welfare) or the expected revenue. In order to prevent some bidders from starvation in the long run, in [27], Gopinathan et al. brought the fairness criterion into the objective to increase the diversity of the winners. In general, such an optimization problem involving interference-free scheduling is essentially an NP-hard graph coloring problem [15], which, therefore, attracts many research works to develop approximation algorithms. For example, in [41], a series of near-optimal mechanisms were proposed based on many approximation techniques, namely, linear programming (LP) relaxation, randomized and de-randomized rounding, monotone de-randomization, and Lavi-Swamy method. In [16] and [17], heuristic algorithms were employed to achieve the truthful auction based on the rule that combines the monotonic allocation and critical value-based pricing. In [25], a polynomial-time approximation algorithm that could reach the upper bound of the worst-case approximation ratio was developed. (b) Furthermore, as for the bidding strategy adaption, many interesting updating techniques have been proposed, which are usually based on the auction results in the past and other auction participants' statistical information. For example, in [42], Fu et al. proposed a best-response learning algorithm for bidders to improve their bidding policies based on the historical information on bidding and allocation, the current auction participants' statuses, and the estimated future auction results. In [43], Han et al. considered a repeated auction game and developed a Bayesian nonparametric belief update scheme based on the Dirichlet process. According to the proposed bidding learning algorithm, buyers can alter their bidding strategies optimally. (c) Moreover, to enable a more flexible auction market, the multitier auction framework has been studied as well. For example, in [44], Tang and Jain presented a hierarchical auction model where multiple auction markets are cascaded as multiple tiers to iteratively trade the spectrum resource. In [45], Lin et al. developed a three-stage auction framework, including an outer auction between secondary access point (SAP) and SUs and an inner auction between spectrum holder and SAPs.

Spectrum Trading in Open Market

Different from the auction market where the trading process is hosted by an auctioneer, the open market is more flexible where sellers and buyers could freely conclude the transactions with each other by reaching certain agreement, which

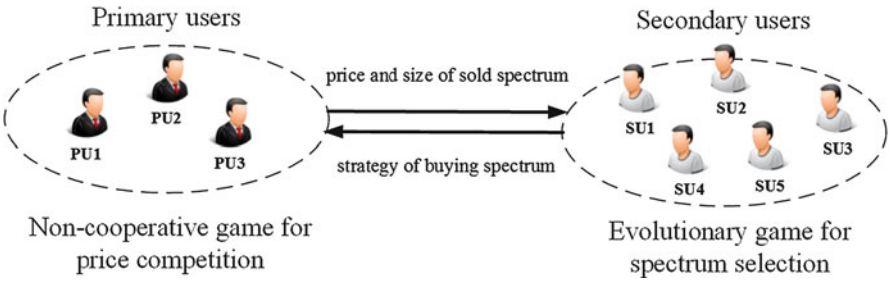

Fig. 4 A game-theoretic framework for spectrum trading in an open market

makes the relationship among the market participants more complicated. A typical open market with multiple PUs selling spectrum opportunities to multiple SUs was considered in [46], and the interactions among PUs and SUs were modeled by a game-theoretic framework. As shown in Fig. 4, in general, there are two levels of competition in such an open market. The first one happens among different PUs in terms of the size and the price on their sold spectrum bands. Denote the total bandwidth owned by PU i as B_i, the size for sale as b_i, and the number of SUs demanding that spectrum as n_i. Assume that all spectrum demanding SUs are allocated with the same size of the spectrum, i.e., b_i/n_i, and charged with the same price p_i. Then, the payoff, also called *net utility*, of PU i can be defined as

$$\gamma_i\left(\mathbf{b},\mathbf{p}\right)=\mathscr{U}\left(B_i-b_i\right)+p_i\cdot n_i\left(\mathbf{b},\mathbf{p}\right), \tag{3}$$

in which $\mathscr{U}(b)$ represents the utility function of a user when using the spectrum with bandwidth b, and it is usually defined as a logarithmic function, e.g., $\mathscr{U}(b)=u_1\log\left(u_2\cdot b\right)$ (u_1 and u_2 are constants that depend on the application type). $\mathbf{b}$ and $\mathbf{p}$ indicate the size and the price vectors, respectively, corresponding to all PUs, which will influence the demanded spectrum from SUs. In order to maximize its own payoff, each PU should set the size and the price carefully. If the size is small and/or the price is high, SUs may buy from other PUs. Conversely, if the size is large and/or the price is low, although many SUs may be attracted, the payoff may be low because of the low price and the poor utility of their usage. Such a competitive spectrum selling can be modeled as a noncooperative game, and the Nash equilibrium may provide an optimal solution. In this case, the Nash equilibrium can be obtained by using the best response function, i.e., the best strategy of one player given others' strategies, which can be described as

$$\{b_i^*,p_i^*\}=\arg\max_{b_i,p_i}\gamma_i\left(b_i,p_i,\mathbf{b}_{-i},\mathbf{p}_{-i}\right). \tag{4}$$

The other level of competition occurs among the SUs. The payoff of one SU, if he buys spectrum from PU i, can be expressed as

$$\phi_i=\mathscr{U}\left(b_i/n_i\right)-p_i. \tag{5}$$

Obviously, if many SUs choose to buy spectrum from the same PU, the spectrum may become overutilized, or the price may be increased, resulting in poor performance and low payoff for each SU. Consequently, the rational SUs will buy spectrum bands with low price while achieving reasonable performance, which can be modeled as an evolutionary game. Note that the evolutionary equilibrium, i.e., the final buying strategy of each SU, will in turn influence the selling strategies of PUs, which has been considered in the best response function to achieve the Nash equilibrium.

As for the spectrum trading in an open market, the pricing strategy of PUs is usually treated as the most important design issue because it influences the benefit of each trading participant. In [31], Niyato et al. investigated three typical pricing models for spectrum trading, namely, market-equilibrium, competitive, and cooperative pricing models, which aims at satisfying spectrum demands from SUs, maximizing individual profit, and maximizing total profit, respectively. In [47], Xing et al. explored the price dynamics in the market with multiple competitive sellers. A myopically optimal strategy was developed when full information is available to the sellers, and a stochastic learning-based strategy was studied when the information is limited. In [48], by considering different states of the primary channel (e.g., good or bad), Bajaj et al. investigated the optimal pricing that maximizes the PU's payoff under three scenarios, i.e., overlay-based spectrum sharing, relaying-based spectrum sharing, and underlay-based spectrum sharing.

In addition to the pricing mechanism, contract mechanism has also been regarded as an effective mechanism for spectrum trading, in which the seller could design several options with different supplies and prices as a contract or the items in one contract for different buyers by considering their different characteristics, and each buyer could choose one to sign or reject. For example, in [32], Gao et al. designed a monopolist-dominated quality-price contract, which is offered by the PU with a set of quality-price combinations corresponding to different consumer types, and further derived the optimal contract, which maximizes PU's utility. In [33], Gao et al. investigated a hybrid spectrum market, consisting of both future market with guaranteed contracts (including the price, the guaranteed supply, and the penalty if PU violates the contract) and spot market with spot transactions (where SUs buy spectrum in a real-time and on-demand mode). They focused on the PU's expected profit maximization and addressed the problem on how to optimally allocate the idle spectrum among contract users and spot market users. Similarly, a two-stage spectrum trading market, including a long-term market and a short-term market, was studied in [34]. In the long-term market, the PU designs a set of contracts for different types of SUs, and the optimal contract is developed. In the short-term market, SUs can buy some amount of spectrum in a real-time manner, and the interaction between the PU and SUs is modeled as a Stackelberg game. In [35], Jin et al. proposed a novel insurance mechanism for spectrum trading, in which the PUs serve as spectrum sellers as well as insurers. With the insurance contracts, SUs simply purchase the spectrum or sign an insurance contract with the PU to obtain insurance for the potential accident, i.e., transmission failure incurred by the excessively poor channel quality. Such a market game was modeled as a four-stage

Bayesian game characterized by the second-best Pareto optimal allocations and the perfect Bayesian equilibrium.

Instead of the preceding monopolistic market, in which sellers as monopolists to determine prices or contracts, in some cases, buyers are allowed to negotiate with sellers, which is called the bargaining-based market. Such a market mechanism could provide more incentives for buyers to participate because they could express their intentions in the market and thus more transactions could be achieved. In [49], a two-tier market was proposed for decentralized dynamic spectrum access. To be specific, in the tier-1 market, spectrum is traded from a PU to several SUs in a relatively large time scale, which is modeled by a Nash bargain game, and the equilibrium prices are derived. The tier-2 market is set up by SUs to redistribute channels among themselves in a small time scale, which is modeled by a strategic bargain game that SUs can exchange channels with low overhead through random matching, bilateral bargain, and the predetermined market equilibrium price. Actually, such a bargaining mode is especially suitable for the resource-exchange-based spectrum trading, also referred to as cooperative spectrum sharing/trading. For example, in [13], Yan et al. studied a cooperative spectrum sharing scenario with one PU and one SU where the SU was allowed to opportunistically use the licensed band if he relays the PU's traffic. By considering the incomplete information obtained by the PU, the dynamic bargaining process was modeled as a dynamic Bayesian game, and the equilibria was investigated under both single-slot and multi-slot bargaining models. In [14], Simeone et al. considered the cooperative spectrum sharing scenario with multiple SUs. The PU leases the spectrum for a fraction of time to a subset of SUs in exchange for the cooperation, i.e., relaying. On the one hand, the PU attempts to maximize his QoS in terms of either rate or probability of outage. On the other hand, the SUs compete with each other for transmission within the leased time period based on a distributed power control mechanism.

After reviewing the state-of-art of spectrum trading, in the next section, we will discuss some related practical issues and then present a novel flexible network architecture, called *cognitive mesh assisted network*, accordingly. Furthermore, we will demonstrate how to leverage the new network architecture to design an efficient service-oriented spectrum trading scheme.

Service-Oriented Spectrum Trading

Given all these spectrum trading schemes, natural questions to ask are how much cost do they have to pay to implement such schemes and how much end-users can benefit. To address these questions, we may have to revisit our prior research on cognitive radio networks [38, 39, 50–53], particularly on practical implementation consideration. In this section, we first discuss some of the practical issues, then present our flexible network architecture developed previously, followed by our recently proposed service-oriented spectrum trading (SOST) scheme to facilitate end-users to benefit from the spectrum trading [55].

Design Issues and Concerns for CRNs

In this subsection, we first discuss several issues when end-users are directly involved in spectrum trading processes.

Decision-Making for End-Users: End-users might lack necessary expertise and intelligence to join the spectrum trading processes. Similar to its counterpart in economics, spectrum trading requires buyers to specify desired commodities (i.e., spectrum bands) with certain valuations. In contrast, what end-users exactly know is just the service they want to acquire, such as downloading an HQ-video with 1.5 Gbits from Dropbox within 10 min. To join the spectrum trading processes, end-users must convert their service requests to desired bands and the corresponding valuations. Specifically, end-users should decide how much spectrum is needed to meet the QoS, which set of bands is the best choice, how to evaluate different bands, and so on. Clearly, it is not an easy task to make these decisions without specialized knowledge in telecommunications. Even with necessary knowledge, end-users might still not be able to specify their desired bands because of difficulties in gathering intelligence. How much each end-user can gain from purchased spectrum bands depends on PUs' activities, network topology, and the decisions of other end-users, particularly when destinations cannot be reached within one hop. When end-users look for extra spectrum resources for service delivery, they have already suffered from the lack of spectrum resources and might not have enough spectrum bands to collect necessary information for decision-making.

Implementation of Spectrum Markets: Considering the large number of end-users, it will cast a heavy burden on spectrum markets if these users directly join spectrum markets. On the one hand, spectrum markets should be able to interact with substantial number of end-users. To facilitate spectrum trading, spectrum markets need to exchange various kinds of information with end-users, including spectrum band availability, reserve price for each band, and end-users' desired bands and the corresponding valuations. This implies that some exclusive reliable bands/channels must be reserved for fast information exchange, but where do they come from? On the other hand, the extremely large number of end-users will impose considerable computational complexity on spectrum markets, which may become the bottleneck, even for some heuristic algorithms to achieve an approximate maximum of social welfare. For example, unlike traditional trading in economics, since one band can be shared among many nonconflicting users in spectrum trading, spectrum markets need to figure out the conflict relationships among different users' transmissions, which is a very daunting task.

Uncertain Spectrum Availability: Other than above issues, spectrum uncertainty is also an important factor for spectrum trading, which makes it challenging for end-users to directly participate in the spectrum trading processes. The basic premise of CRNs is to protect PUs from being interfered by SUs. In other words, despite end-users' payments for spectrum access, what they obtained is actually

the right to *opportunistically access* these licensed bands, rather than accessing them freely and unconditionally as PUs. End-users still need to obey the FCC ruling and immediately evacuate from the licensed band if the PU returns. This observation has two implications. First, end-users should consider potential risks (service interruptions due to the return of the PU) when purchasing a band. However, due to limited information, it is difficult for end-users to make the appropriate judgement on the potential risk. Second, end-users need to execute spectrum sensing to monitor PUs' activities when accessing licensed bands. These spectrum sensing may consume too power, imposing unbearable burdens on SUs' lightweight mobile devices in terms of energy consumptions.

Capabilities of End-Users' Devices: Even if the aforementioned issues could be well addressed and end-users could get what they need from the spectrum market, they might still not be interested in joining spectrum markets due to limitations of their communication devices. To trade and access licensed spectrum bands, end-users must have frequency-agile communication devices to search for unused licensed bands, reconfigure the RF front end, switch among a wide range of spectrum bands (e.g., from MHz bands such as TV bands to GHz bands such as 5 GHz unlicensed bands), and send and receive packets over potentially noncontiguous spectrum bands. According to [1], by 2020, nearly 50% of global devices and connections will be handheld smartphones which will account for more than four-fifths of mobile data traffic. Due to limited size, it is extremely difficult to embed cognitive radio capability into these lightweight handheld devices. Although some of the desired features could be implemented in these devices in the future, significant amount of time and efforts must be devoted to design more capable hardware devices as well as more efficient signal processing algorithms. Besides, even if it is possible to have lightweight handheld communication devices with CR capability, the prohibitively high price of these new fancy devices might discourage end-users, especially the economically disadvantaged ones, from joining the spectrum trading processes.

In view of above concerns, it would be ideal if there is a network to assist end-users to join spectrum markets, which is the theme of the next subsection.

Cognitive Mesh Assisted Network Architecture

In this subsection, we elaborate our formerly proposed flexible network architecture, called *cognitive mesh assisted network (CMAN)* or *cognitive capacity harvesting network (CCHN)*, as shown in Fig. 5, where an SSP is introduced to manage the services for end-users [38–40, 50, 53, 54]. Our CMAN consists of an SSP, a group of SUs, a set of base stations (BSs) and cognitive radio routers (CR routers), and a collection of licensed spectrum bands, i.e., *basic bands*. The SSP can be either an existing wireless service provider or an independent wireless service provider which is willing to provide better or new kinds of services to their customers. BSs are deployed by the SSP via, for example, leasing infrastructure (towers and cables)

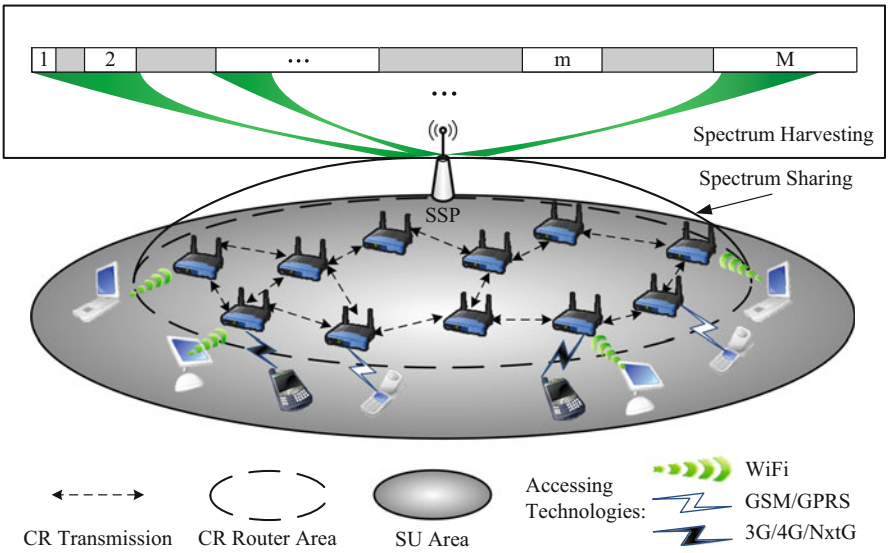

Fig. 5 The cognitive capacity harvesting network architecture for spectrum trading

from an existing cellular operator but with its own transceivers and spectrum bands to reduce initial deployment costs. BSs are interconnected via data networks and allow the SSP to gain access to data networks. The SSP employs BSs as an agent to exchange control signaling with CR routers and SUs as well as to provide basic coverage services. CR routers are deployed by the SSP to assist BSs in service provisioning. Specifically, under the supervision of the SSP, CR routers collectively form a cognitive radio mesh network (CMN) as a backhaul network between SUs and BSs for data transportation. It should be noted that BSs and CR routers are equipped with cognitive radios and communication interfaces, including the basic band interface. The basic band is mainly used for control message exchange between BSs and CR routers, user access related control signaling, and, if possible, data delivery in both the access network and the CMN. The cognitive radio interface is mainly used for data delivery in the CMN. Depending on SUs' locations, mobility, and service requests, they connect to either BSs or CR routers for services. If SUs have cognitive capability (i.e., equipped with cognitive radios), BSs and CR routers can deliver data services to these SUs via cognitive radio interfaces. If SUs do not have cognitive radio interfaces, BSs and CR routers can tune to the interfaces which SUs normally use for service delivery. CR routers collect SUs' traffic requests via basic bands and submit the aggregated traffic requests to the SSP. After receiving these data requests, the SSP make centralized network optimization by jointly considering link scheduling, flow routing, and resource allocation and sends the coordination decisions back to CR routers via BSs. According to these decisions, CR routers in the CMN collectively deliver data services to SUs. Since this may potentially reduce the transmission range for the last-hop communications

to the end SUs, the frequency reuse for the bands used for network access can be significantly increased with proper frequency planning, resulting in high spectral efficiency.

The CMAN architecture can help end-users interact with spectrum markets without knowing what the spectrum market is, which spectrum bands are needed, and how to complete their data transmissions. End-users only need to know their expected services and affordable monetary costs. They submit their service requests and their valuations of these services to the SSP, i.e., end-users bid for services from the SSP instead of spectrum resources from the spectrum markets. Once end-users' data requests are received, the SSP will search for appropriate spectrum resources in spectrum markets according to end-users' service requests and spatial distributions, prices of different bands and how these bands will be utilized, etc. As an operator, the SSP always attempts to maximize its own profits, and thus how much spectrum the SSP should purchase from spectrum markets is closely related to end-users' bids, which implies that end-users interact with spectrum markets via the CMAN. Such a spectrum trading scheme is referred to as the SOST scheme to emphasize the fact that end-users purchase services instead of directly purchasing spectrum bands in most existing research works.

Compared with end-user-based spectrum trading, the SOST scheme has many attractive features. First, in the SOST scheme, each end-user only needs to submit its service request and bidding allowance to the SSP, and the SSP will act as an agent to bid for bands that can support the requested services. This shifts the complexity from SUs' side to the operator which is more trustworthy and has more bargaining power and credibility. Second, as a network operator, the SSP can collect necessary network intelligence and make centralized optimization accordingly to determine which bands to purchase. Third, the number of SSPs will be much fewer than that of end-users, which not only reduces the complexity but also improves the efficiency of spectrum markets. Fourth, since services in the CMAN are carried over the CMN, end-users are not aware of the specific spectrum allocation across the whole session (i.e., from the source to the destination). Even if an SU overhears the bids of other SUs, it is not helpful since the SU is not sure who are his competitors for spectrum usage, which simplify the spectrum trading mechanism design. Finally, this SOST scheme does not pose any additional requirements on end-users' communication devices. Even for end-users without cognitive radio devices, they can still benefit from spectrum trading, which allows the SSP to extend its services and enhance the prosperity of spectrum markets.

CMAN-Based Two-Tier Service-Oriented Spectrum Auction

In this subsection, we introduce the basic operation process of the SOST scheme by taking the auction market as a concrete example. For illustration, we consider a secondary spectrum market with one primary service provider (PSP) and N infrastructure-based secondary service providers (SSPs). The PSP can share its licensed bands for economic profits, and SSPs can bid for them to support their own

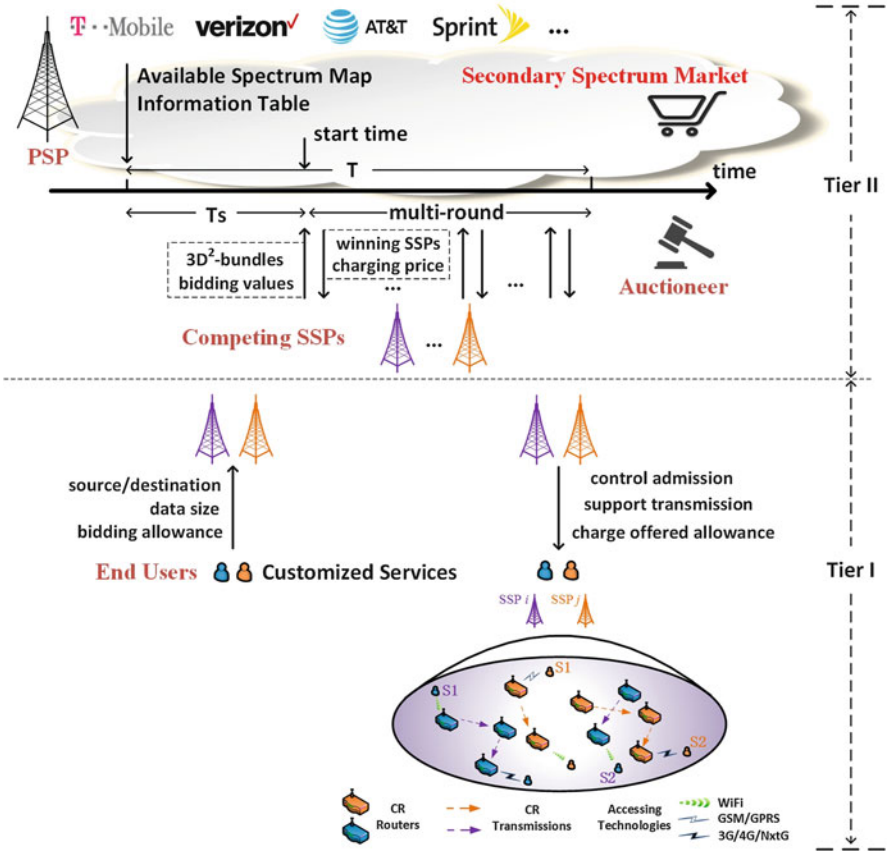

Fig. 6 Two-Tier framework for multi-round service-oriented combinatorial spectrum auction

wireless services. To be specific, a multi-round auction is held periodically in the market. At each period, the PSP constructs a fine-grained available spectrum map (ASM) and an information table (IT) to show which bands are idle within which regions in the next time period. Each SSP bids for needed bands within certain regions in an all-or-none mode, i.e., either fully obtained or rejected, according to users' service requests. Different from the traditional spectrum market, where end-users directly bid for specific bands, in this market, although the initiators are still the end-users, they only need to submit their service requests, and the buyers who truly participate in the auction are the SSPs. To be specific, such a market has a two-tier framework as shown in Fig. 6.

Mesh Network of an SSP in Tier I

Tier I is between SSPs and their end-users. End-users do not need to know what the spectrum market is, which spectrum bands are needed, and how to complete their

data transmissions, other than their expected services and affordable monetary costs. Each SSP acts as an admission controller, a bidding agent, and a service provider for end-users. Specifically, as shown in Fig. 6, each SSP deploys BSs and CR routers to deliver data services to end-users. Each BS serves as a central controller in its coverage area with some basic bands to provide reliable common control signaling to manage the network resources (both basic bands and harvested bands). The BS also manages a group of CR routers deployed in its coverage area, which have CR capability to operate over the purchased PSP's bands. These CR routers form a mesh network to relay data traffic between the BS and end-users. If possible, end-users can access CR routers through the SSP's basic bands using any available interfaces, e.g., Wi-Fi, GSM/GPRS, 3G/4G/NxtG, etc., without making any changes on their devices.

Two main functions are provided by the CR mesh network. One is aggregating information from its end-users. Assume that each end-user generates a specific service request, which will be submitted to the SSP through the closest CR router. Each service request includes its source/destination, data size, and bidding allowance, and each SSP aggregates end-users' service information through CR routers via basic bands. According to the aggregated information from end-users and available bands in the market, each SSP bids for needed bands during the auction. According to the results, each SSP broadcasts its admission decisions and charges each admitted end-user its bidding allowance via basic bands and, then, provides requested services to end-users with CR routers and purchased PSP's bands according to predetermined routing and scheduling decisions.

Auction-Based Spectrum Market in Tier II

In Tier II, a series of multi-round auctions are held by a third-party auctioneer every time period T for access rights to the opened bands in the next time period, where T is a controllable time parameter. As shown in Fig. 6, at the starting time of each auction period, the seller, the PSP, provides a fine-grained ASM and an IT to reveal available bands and regions in the next period T. An example of the fine-grained ASM is shown as Fig. 7. It has several overlapped zones, and each one represents an available region for an unoccupied band, which is further divided into many blocks with corresponding specific location coordinates. The bands in separated zones can be either different or the same. In the considered spectrum market, for certain band m, if certain SSP wants to bid for it, he has to specify which blocks he wants to get, i.e., he has to bid for a set corresponding to all needed blocks for this band. Therefore, while bidding for the band m, the SSP needs to specify both the band's index and the block's coordinates which form a spectrum bundle as $\{m, (x, y)\}$. All the requested spectrum bundles of an SSP is called a three-dimensional desired bundle ($3D^2$-bundle). Note that the $3D^2$-bundle is purchased in an all-or-none mode, i.e., only part of it is unacceptable.

IT is provided as the supplement to the ASM including multidimensional information of the sold bands. First, it contains the specific spectrum range with the bandwidth and the available blocks' coordinates. Second, for each band within certain available block, a reserved price required by the PSP is also included in

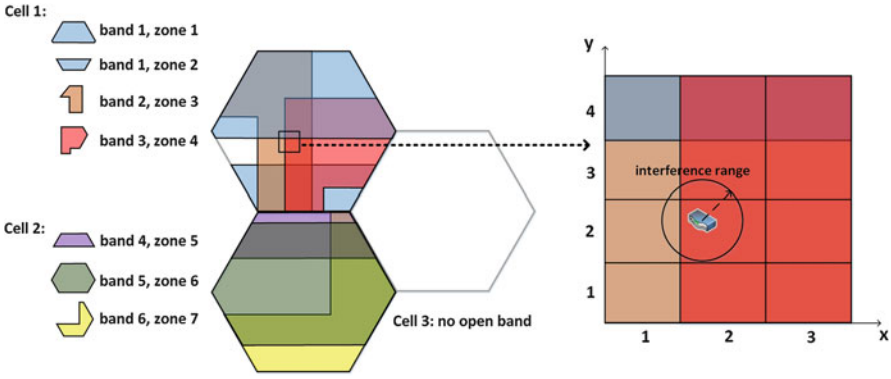

Fig. 7 An example of the fine-grained available spectrum map

the IT. Furthermore, it is noteworthy that PUs' activities are diverse in different areas during different time periods. Therefore, to capture the spatial variation in spectrum availability, the actual available bandwidth of certain band within certain available zone can be treated as a random variable. In order to help SSPs take such an uncertainty into consideration, in the IT, as a reference, historical usage data for each band is also provided (e.g., the average available bandwidth during the same time period everyday in previous several days collected via spectrum measurements).

The competing SSPs should submit their $3D^2$-bundles to the auctioneer before the auction starts, i.e., within the first T_s, in each period. Considering certain CR router, if its SSP wants to obtain certain band for its data transmissions, he has to claim an exclusive area, i.e., specify certain needed blocks. On the one hand, no other SSPs can use this band within this area if it has been claimed already. On the other hand, the CR router can transmit data using this band only within this area and will not cause interference to other areas. For certain transmit power, the exclusive area can be described as a circle, with the CR router as the center and the interference range as the radius, and the desired set of blocks corresponds to the minimal set of blocks covering this circle. A band is called an available band to certain CR router only if its SSP can find available blocks to cover the corresponding exclusive area.

Summary

After aggregating end-users' service requests, according to the available bands of each router, each SSP optimally schedules its network transmissions to obtain its needed $3D^2$-bundle which is submitted to the auctioneer along with certain bidding value. When the auction begins, the auctioneer determines winners and their charging prices. After that, the sold blocks of bands will be deleted from the ASM, and each losing SSP can reschedule its network transmissions according to the updated ASM and bids for desired spectrum bands during the next auction round. The auction continues multiple rounds until no available bands on ASM or no participating SSPs, or this auction period is over. In such a way, more transactions

are achievable in this market and thus generate higher revenue for both PSP and SSPs. It should be noted that many other mechanisms, such as other auction models or game-based open market, can also be adapted in the CCHN based SOST scheme to fulfill different design goals.

Case Study

Next, we present a one-shot experiment as a case study to illustrate the whole process of the SOST scheme. We consider a $1000 \times 600\,\mathrm{m}^2$ grid network with 3 SSPs owning 9 CR routers, respectively, as shown in Fig. 8.

SSP_1 has two end-users with request as ($7 \to 5$, $r_1^1 = 6\,\mathrm{Mbps}$, $p_1^1 = 20$) and ($1 \to 3$, $r_2^1 = 1.3\,\mathrm{Mbps}$, $p_2^1 = 10$), respectively. SSP_2 has three end-users with request as ($5 \to 1$, $r_1^2 = 6\,\mathrm{Mbps}$, $p_1^2 = 19$), ($5 \to 1$, $r_2^2 = 4\,\mathrm{Mbps}$, $p_2^2 = 7$), and ($5 \to 7$, $r_3^2 = 5\,\mathrm{Mbps}$, $p_3^2 = 17$), respectively. SSP_3 has one end-user with request as ($6 \to 4$, $r_1^3 = 7\,\mathrm{Mbps}$, $p_1^3 = 25$). Assume that four bands are opened by PSP and each one is available to all CR routers in all 15 blocks. The four numbers in each block in Fig. 8 represent the reserve price of the four unoccupied bands within this block, respectively, and some other information including bandwidth and 13 historical data is shown as Table 1. According to the bands' information and its own end-users' service requests, each SSP makes an optimal scheduling to determine a $3D^2$-bundle (the needed blocks outside this map are not considered). For the 3 SSPs, suppose that they have the same path loss factor $\beta = 4$, the antenna related parameter $\lambda = 4$, and the noise density power at each CR router $\eta = 10^{-16}\,\mathrm{W/Hz}$. The transmission power at each CR router on each band of each

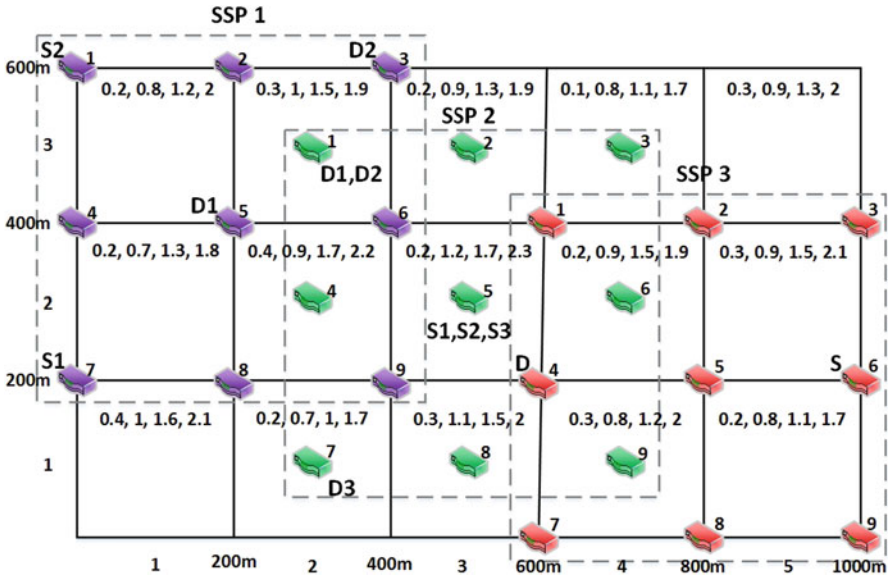

Fig. 8 Topology of the grid network for the case study

Table 1 Information of the four unoccupied bands

Band	Bandwidth (MHz)	Historical data (MHz)												
1	0.4	0.34	0.37	0.13	0.37	0.28	0.12	0.18	0.26	0.38	0.38	0.14	0.39	0.38
2	1.8	1.54	1.19	1.45	0.97	1.50	0.83	1.07	0.84	0.89	1.62	1.49	1.11	1.75
3	4.0	2.06	2.87	2.76	3.53	3.59	2.37	2.97	2.89	3.29	3.41	3.50	2.55	3.35
4	5.5	4.21	5.00	3.35	4.05	5.28	4.98	5.39	4.63	3.08	5.12	5.33	4.69	4.89

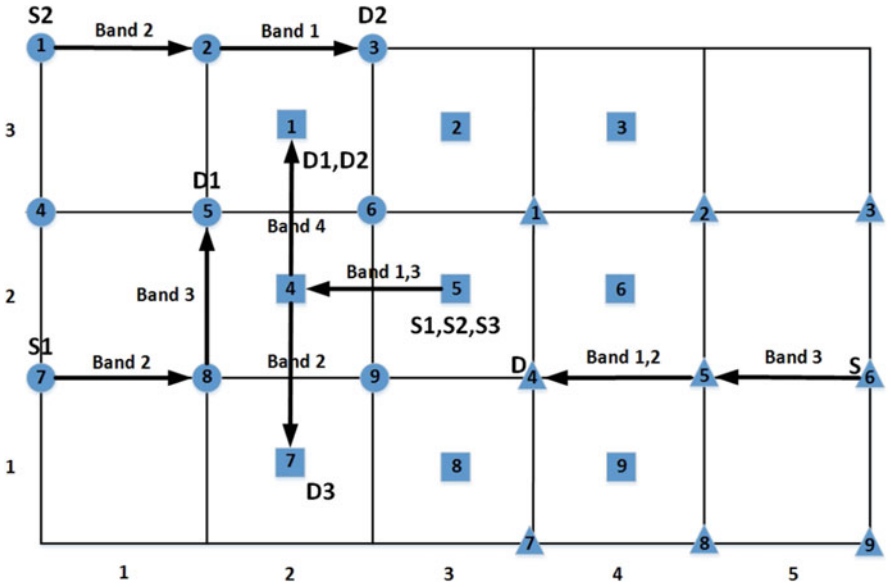

Fig. 9 The optimal transmission schedule of each SSP

SSP is assumed to be equal as 5 W with a transmission/interference range as 210 and 350 m, respectively, and the confidence level for probabilistic link capacity $\alpha = 0.8$. Then, through the optimal network scheduling, the transmission schedule of each SSP is shown as Fig. 9 (readers can refer to [55] for the details of the optimal network scheduling).

According to the optimal schedule, at the first round of the auction, SSP_1 has a $3D^2$-bundle as $\hat{\mathscr{B}}_1^1 = \{\{m, (x_m, y_m)\}\}$, $m = 1, 2, 3$, $x_1, y_2, x_3, y_3 = 1, 2, 3$, $y_1 = 2, 3$, $x_2 = 1, 2$, with a total reserve price as 18.4 and its bidding value $b_1^1 = v_1^1 = 30$, and SSP_2 has a $3D^2$-bundle as $\hat{\mathscr{B}}_1^2 = \{\{m, (x_m, y_m)\}\}$, $m = 1, 2, 3, 4$, $x_1, x_3 = 2, 3, 4$, $y_1, y_3, x_2, x_4, y_2, y_4 = 1, 2, 3$, with a total reserve price as 40.9 and its bidding value $b_1^2 = v_1^2 = 43$, and SSP_3 has a $3D^2$-bundle as $\hat{\mathscr{B}}_1^2 = \{\{m, (x_m, y_m)\}\}, m = 1, 2, 3, x_1, x_2 = 3, 4, 5, x_3 = 4, 5, y_1, y_2, y_3 = 1, 2, 3$, with a total reserve price as 18.2 and its bidding value $b_1^3 = v_1^3 = 25$. Obviously, three SSPs conflict with each other. By taking the social welfare maximum as the

metric to determine winners, since the bid of SSP_2 is the maximum, it becomes the winner. To guarantee the truthfulness property, the corresponding clearing price is set as its critical value, i.e., $\max(40.9, 30) = 40.9$. The auction only has one round because all bands within the middle region have been sold to SSP_2, and SSP_1 and SSP_3 cannot find any bundled remaining bands to support any service. More detailed mechanism design and performance evaluation can be found in [55].

Conclusion and Future Directions

Facing the dramatic increase of wireless data traffic, making more spectrum available is imperative. Consequently, dynamic spectrum sharing via spectrum trading, as one promising technique with the potential to transforming spectrum scarcity into abundancy, has attracted great attentions. In order to provide incentives for spectrum owners to open up their licensed spectrum, economic perspective has been embedded to burst the spectrum trading. In the spectrum trading market, the spectrum owners could sell/lease their radio resources for monetary revenue or performance improvement, and unlicensed users could buy/rent the spectrum access opportunities for their own services. Based on different characteristics, the spectrum trading market could be categorized into many different types, such as exclusive-use based and shared-use based, money exchange and resource exchange, and auction market and open market, which have been elaborated in this chapter. By referring to the overview of the state of the art, readers could acquire a broad view of the spectrum trading on both governmental issued mechanisms and those designed by the academic research community. Furthermore, some practical issues have been summarized, and a novel service-oriented spectrum trading scheme based on a newly developed network architecture has been presented as a promising solution. As the future research direction, spectrum trading market will become more and more flexible in spatial, temporal, and frequency dimensions, which still needs lots of research efforts, including the sophisticated market frameworks to enable such an extremely dynamic trading, the superior bidding languages with low overhead, the hybrid market mechanisms to satisfy different types of users, the privacy protection for users exposed in the public market, the computational-efficient advanced strategy adaptation designs on both seller and buyer sides, etc. We hope this chapter provides the needed background for spectrum trading and inspire more deep research on this topic.

Abstract

We have witnessed an explosion in wireless video traffic in recent years. Video applications are bandwidth intensive and delay sensitive and hence require efficient utilization of spectrum resources. Born to utilize wireless spectrum more efficiently, cognitive radio networks are promising candidates for deployment of wireless video applications. In this chapter, we introduce our recent advances in *foresighted resource allocation mechanisms* that enable multiuser wireless video applications over cognitive radio networks. The introduced resource allocation mechanisms are foresighted, in the sense that they optimize the *long-term* video quality of the wireless users. Due to the temporal coupling of delay-sensitive video applications, such foresighted mechanisms outperform mechanisms that maximize the short-term video quality. Moreover, the introduced resource allocation mechanisms allow wireless users to optimize while learning the unknown dynamics in the environment (e.g., incoming traffic, primary user activities). Finally, we introduce variations of the mechanisms that are suitable for networks with self-interested users. These mechanisms ensure efficient video resource allocation even when the users are self-interested and aim to maximize their individual video quality. The foresighted resource allocation mechanisms introduced in this chapter are built upon our theoretical advances in multiuser Markov decision processes, reinforcement learning, and dynamic mechanism design.

Introduction

Video applications, such as video streaming, videoconferencing, remote teaching, and surveillance, have become the major applications deployed over wireless networks. Video applications are bandwidth intensive and delay sensitive and hence require efficient allocation of spectrum resources among the users and efficient scheduling of each user's video packets based on its allocated resources.

One promising physical-layer technology to improve the spectrum efficiency is cognitive radio. In cognitive radio, secondary users (SUs) can utilize the idle spectrum when primary users (PUs) are inactive. Due to the potential of high spectrum efficiency, cognitive radio is a promising candidate for the physical-layer technology of video applications. Although cognitive radio is promising, there are several challenges in efficiently deploy video applications over cognitive radio networks.

First, video applications are delay-sensitive, namely, the video packets have to be received before strict deadlines for successful decoding. Therefore, video

applications require not only high spectrum efficiency but also efficient scheduling of video packets.

In addition, there is interdependency across video packets, which makes the issue of delay sensitivity more challenging. Specifically, the successful decoding of some video packets may depend on the successful decoding of others. In other word, even if a video packet is received before its deadline, it may not be decoded if some packets that it depends on were not received by deadlines. This interdependency results in temporal coupling of packet scheduling decisions. Therefore, we need *foresighted* video packet scheduling that aims at maximizing the *long-term* video quality, instead of instantaneous video quality.

Moreover, the delay sensitivity and interdependency mentioned above require not only efficient packet scheduling but also efficient allocation of spectrum resources. More specifically, we need *foresighted* resource allocation among the users in the network, in order to maximize the long-term video quality.

Furthermore, the unknown dynamic environment requires users to make resource allocation and packet scheduling decisions while *learning* the unknown dynamics. Here the unknown dynamics include incoming video traffic, the channel quality, and the PU activities.

Finally, the users in cognitive radio networks are autonomous and may aim to maximize their own video quality (i.e., they are *self-interested*). It is more challenging to design efficient resource allocation mechanism for self-interested users, because they may misreport their information (e.g., their video traffic and channel quality). In this case, the resource allocation mechanism has to be *strategy proof*.

In this chapter, we introduce our solutions to the aforementioned challenges in multiuser wireless video transmission over cognitive radio networks. Specifically, we introduce a framework to design foresighted resource allocation mechanisms and packet scheduling algorithms [1–7]. The introduced resource allocation mechanisms allow wireless users to optimize while learning the unknown dynamics in the environment (e.g., incoming traffic, channel quality, primary user activities). We also describe variations of the mechanisms that are suitable for self-interested users [1–5]. These mechanisms ensure efficient video resource allocation even when the users are self-interested and aim to maximize their individual video quality. The foresighted resource allocation mechanisms introduced in this chapter are built upon our theoretical advances in multiuser Markov decision processes, reinforcement learning, and dynamic mechanism design.

The rest of this chapter is organized as follows. We give a literature review in section "Related Work." We introduce the system model in section "General Model for Video Applications over Cognitive Radio" and then formulate the design problem in section "The Design Problem." We describe the introduced solutions in section "Optimal Foresighted Video Transmission." We also briefly describe the strategy-proof variations of the solutions in section "Strategy-Proof Resource Allocation Mechanisms." Finally, we conclude the chapter in section "Conclusion and Future Directions."

Related Work

Multimedia Applications over Cognitive Radio Networks

A plethora of recent works [1–14] propose distinct solutions to optimize the video quality. Some works [8–16] assume that the users are *myopic*, namely, they only maximize their *instantaneous* video quality over a given time interval without considering the impact of their actions on the *long-term* video quality. They cast the problem in a network utility maximization (NUM) framework to maximize the instantaneous joint video quality of all the users and apply the NUM framework repeatedly when the channel conditions or video traffic characteristics change. However, since the users are optimizing their transmission decisions myopically, their long-term average performance is inferior to the performance achieved when the users are *foresighted* [17]. Some of the works considering the foresighted decision of users focus solely on a *single* foresighted user making sequential transmission decisions (e.g., packet scheduling, retransmissions, etc.) [17]. However, these single-user solutions do not discuss how to allocate resources among multiple users as well as how this allocation is impacted by and impacts the foresighted scheduling decisions of individual users. Static allocations of resources, which are often assumed in the works studying the foresighted decisions of a single user, have been shown to be suboptimal compared to the solutions that dynamically allocate resources among multiple users [6].

In contrast, our introduced solutions, based on [1–7], make *foresighted* resource allocation and packet scheduling decisions over *multiple* video users.

Table 1 summarizes the above discussions. Note that the optimality shown in the last column of Table 1 indicates whether the solution is optimal for the long-term network utility (i.e., the joint long-term video quality of all the users in the network).

Last but not the least, there are a plethora of works that address other important issues in cognitive radio networks with multimedia applications, such as spectrum handoff [18], routing [19], spectrum sensing [20], and applications in smart grid [21]. These works are out of scope of this chapter.

Theoretical Frameworks

Single-user foresighted decision-making in a dynamically changing environment has been studied and formulated as Markov decision process (MDP). Foresighted

Table 1 Related works on video (the first two rows are works introduced in this chapter)

[6, 7]	Multiple	Yes	Yes	No	Yes
[8–16]	Multiple	No	No	Yes/No	No
[17]	Single	Yes	Yes	No	No

Table 2 Related theoretical frameworks (the first row is works introduced in this chapter)

	Decision makers	Foresighted	Learning	Optimal
MU-MDP [6, 7]	Multiple	Yes	Yes	Yes
MDP [17]	Single	Yes	Yes	No
Repeated NUM [16]	Multiple	No	No	No
Lyapunov optimization [22]	Single	Yes	Yes	No

decision-making in a dynamically changing environment can also be solved using the Lyapunov optimization framework [22]. However, the Lyapunov optimization framework is not able to make optimal decisions for video streaming since it disregards specific interdependency and distortion impact of video traffic [23].

Table 2 summarizes the above discussions about existing theoretical frameworks.

General Model for Video Applications over Cognitive Radio

We first present a general model for multiuser wireless video transmission in cognitive radio networks. Then we give an example of a commonly used model as in [6, 14, 17] as an instantiation of our general model.

The General Model

We consider a cognitive radio network with a network manager indexed by 0 and a set $\mathscr{I}$ of I wireless video users, indexed by $i = 1, \ldots, I$. Time is slotted at $t = 0, 1, 2, \ldots$. In the rest of the paper, we will put the user index in the superscript and the time index in the subscript of variables. The multiuser wireless video transmission system is described by the following features.

States

Each user i has a finite state space S^i, from which a state s^i is realized and revealed to user i at the beginning of each time slot. The state s^i may consist of several components, such as the video traffic state and the channel state. An example of a simplified video traffic state can be the types of video frames (I, P, or, B frame) available for transmission and the numbers of packets in each available video frame. Note that the video traffic in our model can come from video sequences that are either encoded in real time, or offline, and stored in the memory before the transmission. An example channel state can be the channel quality reported to the application layer by the lower layers. The network manager has a finite state space S^0 that describes the status of the resource in the network. An example resource state can be the available idle bandwidth.

Actions

At each state s^i, each user i chooses an action $a^i \in A^i(s^i)$. For example, an action can be how many packets within each available video frame should be transmitted. We allow the sets of actions taken under different states to be different, in order to incorporate the minimum video quality requirements that will be discussed.

Payoffs

Each user i has a payoff function $u^i : S^i \times A^i \rightarrow \mathbb{R}$. The payoff function u^i is concave in the action under any state. A typical payoff can be the distortion impact of the transmitted packets minus the cost of energy consumption in transmission.

State Transition

Each user i's state transition is Markovian and can be denoted by $p^i(s^{i\prime}|s^i, a^i) \in \Delta(S^i)$, where $\Delta(S^i)$ is the probability distribution over the set of states.

Resource Constraints

Given the status of the resource (i.e., the network manager's state s^0), we can write the (linear) resource constraint as

$$f(s^0, a^1, \ldots, a^I) \triangleq f^0(s^0) + \sum_{i=1}^{I} f^i(s^0) \cdot a^i \leq 0,$$

where $f^i(s^0)$ is the coefficient under state s^0. When a^i is a vector, $f^i(s^0)$ is a vector of the appropriate length, and $f^i(s^0) \cdot a^i$ is the inner product of the two vectors.

A variety of multiuser wireless video transmission systems can be modeled as special cases of our general model. Next, we present a packet-level video transmission model as an example.

An Example Packet-Level Video Transmission Model

Packet-level video transmission models have been proposed in a variety of related works, including [6–14]. In the following, we briefly describe the model based on [6–14] and refer interested readers to [6–14] for more details.

We first consider a specific video user i and hence drop the superscript before we describe the resource constraints. The video source data is encoded using an H.264 or MPEG video coder under a group of pictures (GOP) structure: the data is encoded into a series of GOPs, indexed by $g = 1, 2, \ldots$, where one GOP consists of N data units (DUs). Each DU $n \in \{1, \ldots, N\}$ in GOP g, denoted DU_n^g, is characterized by its size $l_n^g \in \mathbb{N}_+$ (i.e., the number of packets in it), distortion impact $q_n^g \in \mathbb{R}_+$, delay deadline $d_n^g \in \mathbb{N}_+$, and dependency on the other DUs in the same GOP. The dependency among the DUs in one GOP comes from encoding techniques such as motion estimation/compensation. In general, if DU_n^g depends on DU_m^g, we have $d_n^g \geq d_m^g$ and $q_n^g \leq q_m^g$, namely, DU_m^g should be decoded before DU_n^g and has a higher distortion impact than DU_n^g [17]. Note that in the case of scalable video coding, there is no dependency among the DUs, and the following representation of

the model can be greatly simplified. We will keep the dependency for generality in our exposition.

Among the above characteristics, the distortion impact q_n^g, delay deadline d_n^g, and the dependency are deterministic and fixed for the same DUs across different GOPs (e.g., $q_n^g = q_n^{g+1}$) [6, 17]. As in [6], the sizes of all the DUs are independent random variables and that the sizes of the nth DUs in different GOPs have the same distribution.

States

Each user's state consists of the traffic state T_t and the channel state h_t. We describe the traffic state T_t first. At time slot t, as in [6, 14, 17], we assume that the wireless user will only consider for transmission the DUs with delay deadlines in the range of $[t, t+W)$, where W is referred to as the scheduling time window (STW). Following the model in [6, 17], at time slot t, we introduce *context* to represent the set of DUs that are considered for transmission, i.e., whose delay deadlines are within the range of $[t, t+W)$. We denote the context by $C_t = \left\{DU_j^g | d_j^g \in [t, t+W)\right\}$. Since the GOP structure is fixed, the transition from context C_t to C_{t+1} is deterministic. An illustration of the context is given in Fig. 1.

Given the current context C_t, we let $x_{t,DU}$ denote the number of packets in the buffer associated with a DU in C_t. We denote the buffer state of the DUs in C_t by $x_t = \{x_{t,DU} | DU \in C_t\}$. The traffic state T_t at time slot t is then $T_t = (C_t, x_t)$, where the context C_t represents which DUs are available for transmission, and the buffer state x_t represents how many packets each available DU has left in the buffer.

Next we describe the channel state h_t. At each time slot t, the wireless user experiences a channel condition $h_t \in \mathscr{H}$, where $\mathscr{H}$ is the finite set of possible channel conditions. We assume that the wireless channel is slow fading (i.e., remains the same in one time slot) and that the channel condition h_t can be modeled as a finite-state Markov chain [24].

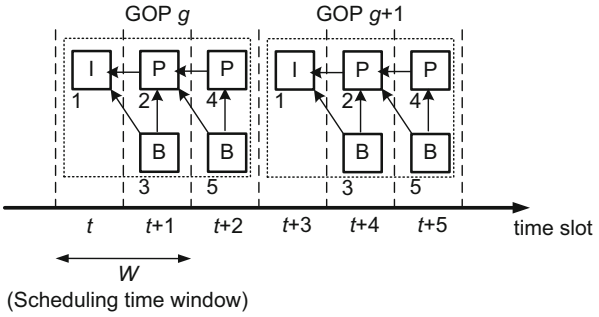

Fig. 1 Illustration of group of pictures (GOP), data unit (DU), and the context. Since the scheduling time window is $W = 2$, the contexts in different time slots are $C_t = \{DU_1^g, DU_2^g, DU_3^g\}$, $C_{t+1} = \{DU_2^g, DU_3^g, DU_4^g, DU_5^g\}$, $C_{t+2} = \{DU_4^g, DU_5^g, DU_1^{g+1}\}$, $C_{t+3} = \{DU_1^{g+1}, DU_2^{g+1}, DU_3^{g+1}\}$, and so on

In summary, the state of a user at each time slot t is $s_t = (C_t, x_t, h_t)$, which includes the current context, buffer state, and channel state.

(Packet Scheduling) Actions
At each time slot t, the user decides how many packets should be transmitted from each DU in the current context. The decision is represented by $a_t(s_t) = \{y_{t,DU} | DU \in C_t, y_{t,DU} \in [0, x_{t,DU}]\}$, where $y_{t,DU}$ is the amount of packets transmitted from the DU.

Payoffs
As in [17], we consider the following *instantaneous payoff* at each time slot t: (The payoff function can be easily extended within our framework to include additional features in the model. For example, when there are packet losses, we can modify the first term to be the expected distortion reduction given the packet loss rate or modify the second term to consider the additional energy consumption associated with packet retransmission.)

$$u(s_t, a_t) = \sum_{DU \in C_t} q_{DU}\, y_{t,DU} - \beta \cdot \rho\left(h_t, \|a_t\|_1\right), \tag{1}$$

where the first term $\sum_{DU \in C_t} q_{DU}\, y_{t,DU}$ is the *instantaneous video quality*, namely, the distortion reduction obtained by transmitting the packets from the DUs in the current context, and the second term $\beta \cdot \rho\left(h_t, \|a_t\|_1\right)$ represents the disutility of the energy consumption by transmitting the packets. Since the packet scheduling action a_t is a vector with nonnegative components, we have $\|a_t\|_1 = \sum_{DU \in C_t} y_{t,DU}$, namely, $\|a_t\|_1$ is the total number of transmitted packets. As in [17], the energy consumption function $\rho(h, \|a\|_1)$ is assumed to be convex in the total number of transmitted packets $\|a\|_1$ given the channel condition h. An example of such a function can be $\rho(h, \|a\|_1) = \sigma^2(e^{2\|a\|_1 b} - 1)/h$, where b is the number of bits in one packet [25]. The payoff function is a trade-off between the distortion reduction and the energy consumption, where the relative importance of energy consumption compared to distortion reduction is characterized by the trade-off parameter $\beta > 0$. In the simulation, we will set different values for β to illustrate the trade-off between the distortion reduction and energy consumption.

The Resource Constraint
Suppose that the users access the channels in a frequency-division multiple access (FDMA) manner. The total bandwidth B is shared by the users. We assume that each user i uses adaptive modulation and coding (AMC) based on its channel condition. In other words, each user i chooses a data rate r_t^i under the channel state h_t^i. Note that the rate selection is done by the physical layer and is not a decision variable in our framework. Then as in [8], we have the following resource constraint:

$$\sum_{i=1}^{I} \frac{\|a_t^i\|_1 b}{r_t^i(h_t^i)} \leq B, \tag{2}$$

where $\frac{\|a_t^i\|_1 \cdot b}{r_t^i(h_t^i)}$ is the bandwidth needed for transmitting the amount $\|a_t^i\|_1 \cdot b$ of bits given the data rate $r_t^i(h_t^i)$.

In this model, the network manager's state s^0 is then the collection of channel states, namely, $s^0 = (h^1, \ldots, h^I)$. The information about the channel states is fed back from the users to the network manager. We can write the constraint compactly as the linear constraint $f(s_t^0, a_t^1, \ldots, a_t^N) \leq 0$ with $f^i(s_t^0) = \frac{b}{r_t^i(h_t^i)}, i = 1, \ldots, I$ and $f^0(s_t^0) = -B$.

The Design Problem

Each user makes decisions based on its state s_t. Hence, each user i's strategy can be defined as a mapping $\pi^i : S^i \to \cup_{s^i} A^i(s^i)$, where $A^i(s^i)$ is the set of actions available under state s^i. We allow the set of available actions to depend on the state, in order to capture the minimum video quality guarantee. For example, at any time, user i has a minimum distortion impact reduction requirement D^i, formulated as

$$A^i(s_t^i) = \left\{ a_t^i : \sum_{DU \in C_t^i} q_{DU} \cdot y_{t,DU}^i \geq D^i \right\}.$$

The users aim to maximize their expected long-term payoff. Given its initial state s_0^i, each user i's strategy π^i induces a probability distribution over the sequences of states $s_1^i, s_2^i, \ldots$, and hence a probability distribution over the sequences of instantaneous payoffs $u_0^i, u_1^i, \ldots$. Taking expectation with respect to the sequences of payoffs, we have user i's *long-term payoff* given the initial state as

$$U^i(\pi^i | s_0^i) = \mathbb{E}\left\{ (1-\delta) \sum_{t=0}^{\infty} \left(\delta^t \cdot u_t^i \right) \right\}, \tag{3}$$

where $\delta \in [0, 1)$ is the discount factor.

The design problem can be formulated as

$$\begin{aligned} \max_{\pi^1, \ldots, \pi^I} \quad & \sum_{s_0^1, \ldots, s_0^I} \sum_{i=1}^{I} U^i(\pi^i | s_0^i) \\ s.t. \quad & \text{minimum video quality guarantee:} \\ & \pi^i(s^i) \in A^i(s^i), \ \forall i, s^i, \\ & \text{resource constraint:} \\ & f(s^0, \pi^1(s^1), \ldots, \pi^I(s^I)) \leq 0, \ \forall s^0. \end{aligned} \tag{4}$$

Note that the design problem (4) is a weakly coupled MU-MDP as defined by [26]. It is a MU-MDP because there are multiple users making foresighted decisions. The MU-MDP is coupled, because the users influence each other through the resource constraints (namely, the choice of one user's action depends on the choices of the other users). However, it is weakly coupled, because the coupling is through the

resource constraints only and because one user's *instantaneous* payoff $u^i(s^i, a^i)$ is not affected by the other users' actions a^j. It is this weak coupling that enables us to decompose the multiuser problem into multiple single-user problems through prices. Such a decomposition of weakly coupled MU-MDPs has been studied in a general setting [26] and in wireless video transmission [6], both adopting a dual decomposition approach based on *uniform* price (i.e., the same Lagrangian multiplier for the resource constraints under all the states).

Note also that we sum up the network utility $\sum_{i=1}^{I} U^i(\pi^i|s_0^i)$ under all the initial states $(s_0^1, \ldots, s_0^I)$. This can be interpreted as the expected network utility when the initial state is uniformly distributed. The optimal stationary strategy profile that maximizes this expected network utility will also maximize the network utility given any initial state.

The design problem (4) is very challenging and has never been solved optimally. To better understand this, let us assume that a central controller would exist which knows the complete information of the system (i.e., the states, the state transitions, the payoff functions) at each time step. Then, this central controller can solve the above problem (4) as a centralized single-user MDP (e.g., using well-known value iteration or policy iteration methods) and obtain the solution to the design problem $\boldsymbol{\pi}^\star$ and the optimal value function $U^\star$. However, the multiuser wireless video system we discussed is inherently informationally decentralized, and there is no entity in the network that possesses the complete information. Moreover, the computational complexity of solving (4) by a single entity is prohibitively high. Hence, our goal is to develop an optimal decentralized algorithm that converges to the optimal solution.

Optimal Foresighted Video Transmission

In this section, we show how to determine the optimal foresighted video transmission policies. We propose an algorithm that allows each entity to make decisions based on its local information and the limited information exchange between the BS and the users. Specifically, in each time slot, the BS sends resource prices to each user, and the users send their total numbers of packets to transmit to the BS. The BS keeps updating the resource prices based on the resource usage by the users and obtains the optimal resource prices based on which the users' optimal individual decisions achieve the optimal network utility.

Decoupling of The Users' Decision Problems

Each user aims to maximize its own long-term payoff $U^i(\pi^i|s_0^i)$ subject to the constraints. Specifically, given the other users' strategies $\boldsymbol{\pi}^{-i} = (\pi^1, \ldots, \pi^{i-1}, \pi^{i+1}, \ldots, \pi^I)$ and states $\boldsymbol{s}^{-i} = (s^1, \ldots, s^{i-1}, s^{i+1}, \ldots, s^I)$, each user i solves the following long-term payoff maximization problem:

$$\pi^i = \arg\max_{\tilde{\pi}^i} U_i(\tilde{\pi}^i|s_0^i) \quad (5)$$
$$s.t. \quad \tilde{\pi}^i(s^i) \in A^i(s^i), \ \forall s^i,$$
$$f(s^0, \tilde{\pi}^i(s^i), \boldsymbol{\pi}^{-i}(\boldsymbol{s}^{-i})) \leq 0.$$

Assuming that the user knows all the information (i.e., the other users' strategies $\boldsymbol{\pi}^{-i}$ and states $\boldsymbol{s}^{-i}$), user i's optimal value function should satisfy the following:

$$V(s^i) = \max_{a^i \in A^i(s^i)} (1-\delta)u^i(s^i, a^i) + \delta \sum_{s^{i\prime}} p^i(s^{i\prime}|s^i, a^i)V(s^{i\prime})$$
$$s.t. \quad f(s^0, a^i, \boldsymbol{\pi}^{-i}(\boldsymbol{s}^{-i})) \leq 0. \quad (6)$$

Note that the above equations would be the Bellman equation, if user i knew the other users' strategies $\boldsymbol{\pi}^{-i}$ and states $\boldsymbol{s}^{-i}$ and the BS' state s^0 (i.e., the channel states of all the users). However, such information is never known to a particular user. Without such information, one user cannot solve the decision problem above because the resource constraint contains unknown variables. Hence, we need to separate the influence of the other users' decisions from each user's decision problem.

One way to decouple the interaction among the users is to remove the resource constraint and add it as a penalty to the objective function. Denote the Lagrangian multiplier (i.e., the "price") associated with the constraint under state s^0 as $\lambda^0(s^0)$. Then the penalty at state s^0 is

$$-\lambda^0(s^0) \cdot f(s^0, a^1, \ldots, a^I) = -\lambda^0(s^0) \cdot \textstyle\sum_{i=1}^I f^i(s^0) \cdot a^i.$$

Since the term $-\lambda^0(s^0) \cdot \sum_{j \neq i} f^j(s^0) \cdot a^j$ is a constant for user i, we only need to add $-\lambda^0(s^0) \cdot f^i(s^0) \cdot a^i$ to each user i's objective function. We define $\lambda^i(s^0) \triangleq \lambda^0(s^0) \cdot f^i(s^0)$. Then we can rewrite user i's decision problem as

$$\tilde{V}^{\lambda^i(s^0)}(s^i) = \max_{a^i \in A^i(s^i)} (1-\delta)\left[u^i(s^i, a^i) - \lambda^i(s^0) \cdot a^i\right]$$
$$+\delta \cdot \textstyle\sum_{s_i'} \left[p^i(s^{i\prime}|s^i, a^i)\tilde{V}^{\lambda^i(s^0)}(s^{i\prime})\right]. \quad (7)$$

By contrasting (7) with (6), we can see that given the price λ^i, each user can make decisions based only on its local information since the resource constraint is eliminated. Note, importantly, that the above decision problem (7) for each user i is different from that in [6] with uniform price. This can be seen from the term $\lambda^i(s^0) \cdot a^i$ in (7), where the price $\lambda^i(s^0)$ is user specific and depends on the state, while the uniform price in [6] is a constant λ. The decision problem (7) is also different from the subproblem resulting from dual decomposition in NUM, because

it is a foresighted optimization problem that aims to maximize the long-term payoff. This requires a different method to calculate the optimal Lagrangian multiplier $\lambda^i(s^0)$ than that in NUM.

Optimal Decentralized Video Transmission Strategy

For the general model described in section "General Model for Video Applications over Cognitive Radio"-A, we propose an algorithm used by the BS to iteratively update the prices and by the users to update their optimal strategies. The algorithm will converge to the optimal prices and the optimal strategy profile that achieves the minimum total system payoff $U^\star$. The algorithm is described in Table 3.

Theorem 1. *The algorithm in Table 3 converges to the optimal strategy profile, namely,*

$$\lim_{t,k\to\infty} \left| \sum_{s_t^1,\ldots,s_t^I} \sum_{i=1}^{I} U_i(\pi^{i,\lambda_k^i}|s_t^i) - U^\star \right| = 0\,.$$

Proof. See the appendix in [7].

We illustrate the BS's and users' updates and their information exchange in one time slot in Fig. 2. At the beginning of each time slot t, the BS and the users exchange information to compute the optimal resource price and the optimal actions to take. Specifically, in each iteration k, the BS updates the resource price λ_k^0. Then based on the user-specific resource price λ_k^i, each user i solves for the optimal individual strategy π^{i,λ_k^i} and sends the BS its resource request $f^i \cdot \pi^{i,\lambda_k^i}(s_t^i)$. Then the BS updates the prices based on the users' resource requests using the stochastic subgradient method, which can be performed easily. The difference from the dual decomposition in NUM is that each user's decision problem in our work is a foresighted optimization problem aiming to maximize the long-term, instead of instantaneous, payoff. Our algorithm is also different from the algorithm in [6] in that we have different prices under different states.

Table 3 Distributed algorithm to compute the optimal strategy at time t

Input: Performance loss tolerance ϵ
Initialization: Set $k = 0$, $\lambda_k^0 = 0$.
Each user i observes s_t^i, the BS observes s_t^0
repeat
Each user i solves the decoupled decision problem (7) to obtain π^{i,λ_k^i}
Each user i submits its resource request $f^i(s_t^0) \cdot \pi^{i,\lambda_k^i}(s_t^i)$
The BS updates the prices (stochastic subgradient update):
$\lambda_{k+1}^i(s_t^0) = \lambda_k^i(s_t^0) + \frac{1}{k+1} f(s_t^0, \pi^{1,\lambda_k^1}(s_t^1), \cdots, \pi^{I,\lambda_k^I}(s_t^I))$
until $\|\lambda_{k+1}^i(s_t^0) - \lambda_k^i(s_t^0)\| \le \epsilon$
Output: optimal price λ_k^0, optimal strategies $\{\pi^{i,\lambda_k^i}\}_{i=1}^I$

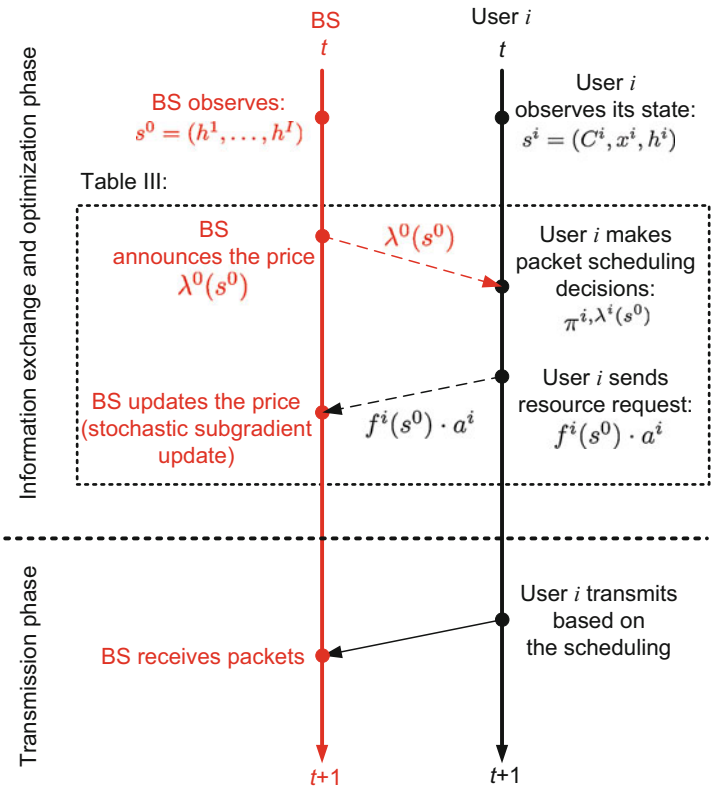

Fig. 2 Illustration of the interaction between the BS and user i (i.e., their decision-making and information exchange) in one period

From Fig. 2, we can clearly see what information (namely, resource prices λ_k^0 and resource requests $f^i \cdot \pi^{i,\lambda_k^i}(s_t^i)$) is exchanged. The amount of information exchange is small ($O(I)$), compared to the amount of information required by each user to solve the decision problem (6) directly ($\prod_{j \neq i} |S_i|$ states plus the strategies $\boldsymbol{\pi}_{-i}$). In other words, the algorithm enables the entities to exchange a small amount ($O(I)$) of information and reach the optimal video transmission strategy that achieves the same performance as when each entity knows the complete information (i.e., the states and the strategies of all the entities) about the system.

Optimal Packet Scheduling

In the previous subsection, we propose an algorithm of optimal foresighted resource allocation and packet scheduling for the general video transmission model described in section "General Model for Video Applications over Cognitive Radio"-A. In

the algorithm, each user's packet scheduling decision is obtained by solving the Bellman equation (7) (see Table 3). The Bellman equation (7) can be solved by a variety of standard techniques such as value iteration. However, the computational complexity of directly applying value iteration may be high, because each user's state contains the information of all DUs, and thus each user's state space can be very large. In the following, we show that for the specific model described in section "General Model for Video Applications over Cognitive Radio"-B, we can greatly simplify the packet scheduling decision problem. The key simplification comes from the decomposition of each user's packet scheduling problem with multiple DUs into multiple packet scheduling problems with single DU. In this way, we can greatly reduce the number of states in each single-DU packet scheduling problem, such that the total complexity of packet scheduling grows linearly, instead of exponentially without decomposition, with the number of DUs.

The decomposition closely follows the decomposition of multiple-DU packet scheduling problems proposed in [17]. The only difference is that the decision problem (7) in our work has an additional term $-\lambda^i(s^0)\cdot a^i$ due to the price, while such a term does not exist in [17] because the *single*-user packet scheduling problem is considered in [17].

Lemma 1 (Structural Result). *Suppose $DU_1 \in C_t$ and $DU_2 \in C_t$. If DU_2 depends on DU_1, we should schedule the packets of DU_1 before scheduling the packets of DU_2.*

Although Lemma 1 is straightforward, it greatly simplifies the scheduling problem because we can now take advantage of the partial ordering of the DUs. However, this still does not solve the scheduling decision for the DUs that are not dependent on each other. Next, we provide the algorithm of optimal packet scheduling in Table 4. The algorithm decomposes the multiple-DU packet scheduling problem into a sequence of single-DU packet scheduling problems and determines how many packets to transmit for each DU sequentially. This greatly reduces the total computational complexity (which is linear in the number of DUs) compared to

Table 4 The optimal packet scheduling algorithm

Input: Directed acyclic graph given the current context: $DAG(C_t)$
Initialization: Set $DAG_1 = DAG(C_t)$.
For $k = 1, \ldots, \lvert C_t \rvert$
$DU_k = \arg \max_{DU \in root(DAG_k)} \max_{0 \le y \le x_{t,DU}} (1-\delta)\left[q_{DU}\cdot y - \lambda_k^i(s^0)\cdot y\right]$
$+ \delta \cdot \sum_{s^{i\prime}} \left[p^i(s^{i\prime} \lvert s^i, a_{f,t}) \tilde{V}^{i,\lambda^{i,(k)}(s^0)}(s^{i\prime}) \right]$
$y^*_{t,DU_k} = \arg \max_{0 \le y \le x_{t,DU_k}} (1-\delta)\left[q_{DU_k}\cdot y - \lambda_k^i(s^0)\cdot y\right]$
$+ \delta \cdot \sum_{s^{i\prime}} \left[p^i(s^{i\prime} \lvert s^i, a_{f,t}) \tilde{V}^{i,\lambda^{i,(k)}(s^0)}(s^{i\prime}) \right]$
$DAG_{k+1} = DAG_k \setminus \{DU_k\}$
End for

solving the multiple-DU packet scheduling problem directly (in which the number of states grows exponentially withe the number of DUs). The algorithm is similar to [17, Algorithm 2]. The only difference is the term $-\lambda^i(s^0)\cdot a^i$.

Learning Unknown Dynamics

In practice, each entity may not know the dynamics of its own states (i.e., its own state transition probabilities) or even the set of its own states. When the state dynamics are not known a priori, each entity cannot solve their decision problems using the distributed algorithm in Table 3. In this case, we can adapt the online learning algorithm based on post-decision state (PDS) in [17], which was originally proposed for single-user wireless video transmission, to the considered deployment scenario.

The main idea of the PDS-based online learning is to learn the post-decision value function, instead of the value function. Each user i's post-decision value function is defined as $\tilde{U}^i(\tilde{x}^i,\tilde{h}^i)$, where $(\tilde{x}^i,\tilde{h}^i)$ is the post-decision state. The difference from the normal state is that the PDS $(\tilde{x}^i,\tilde{h}^i)$ describes the status of the system *after* the scheduling action is made but before the DUs in the next period arrive. Hence, the relationship between the PDS and the normal state is

$$\tilde{x}^i = x^i - a^i,\ \tilde{h}^i = h^i.$$

Then the post-decision value function can be expressed in terms of the value function as follows:

$$\tilde{U}^i(\tilde{x}^i,\tilde{h}^i) = \sum_{x^{i\prime},h^{i\prime}} p^i(x^{i\prime},h^{i\prime}|\tilde{x}^i + a^i,\tilde{h}^i)\cdot \tilde{V}^i(x^{i\prime},\tilde{h}^i).$$

In PDS-based online learning, the normal value function and the post-decision value function are updated in the following way:

$$\begin{aligned} V^i_{k+1}(x^i_k,h^i_k) &= \max_{a^i}\ (1-\delta)\cdot u^i(x^i_k,h^i_k,a^i) \\ &\quad + \delta\cdot U^i_k(x^i_k+(a^i-l^i_k),h^i_k), \\ U^i_{k+1}(x^i_k,h^i_k) &= (1-\frac{1}{k})U^i_k(x^i_k,h^i_k) \\ &\quad + \frac{1}{k}\cdot V^i_k(x^i_k-(a^i-l^i_k),h^i_k). \end{aligned}$$

We can see that the above updates do not require any knowledge about the state dynamics. In particular, we propose the decomposed optimal packet scheduling with PDS-based learning in Table 5. Note that the difference between the learning algorithm in Table 5 with the algorithm assuming statistic knowledge in Table 4

Table 5 The optimal decomposed packet scheduling algorithm with PDS-based learning

Input: Directed acyclic graph given the current context: $DAG(C_t)$
Initialization: Set $DAG_1 = DAG(C_t)$.
For $k = 1, \ldots, \lvert C_t \rvert$
$DU_k = \arg \max_{DU \in root(DAG_k)} \max_{0 \le y \le x_{t,DU}} (1-\delta)\left[q_{DU} \cdot y - \lambda_k^i(s^0) \cdot y\right] + \delta \cdot U_{DU}(C_t, x_{t,DU} - y, h_t)$
$y^*_{t,DU_k} = \arg\max_{0 \le y \le x_{t,DU}} (1-\delta)\left[q_{DU} \cdot y - \lambda_k^i(s^0) \cdot y\right] + \delta \cdot U_{DU}(C_t, x_{t,DU} - y, h_t)$
$DAG_{k+1} = DAG_k \setminus \{DU_k\}$
End for

is that we use the post-decision state value function instead of the normal value function. It is proved in [17] that the PDS-based online learning will converge to the optimal value function. Hence, the distributed packet scheduling and resource allocation solution in Table 3 can be modified by letting each user perform the packet scheduling using the PDS-based learning in Table 5.

Strategy-Proof Resource Allocation Mechanisms

When the users are self-interested, they may not follow the solutions introduced in section "Optimal Foresighted Video Transmission". In particular, they may not be truthful in the message exchange with the network manager. There are several ways of designing strategy-proof resource allocation mechanisms, based on pricing [3] and mechanism design [1–5]. In this section, we describe a representative framework based on auctions [4, 5].

The auction-based resource allocation mechanism is illustrated in Fig. 3. The basic procedure at each time slot is described as follows:

1. The network manager announces the total amount of available resources (e.g., state s^0).
2. The SUs submit bids of how much resources they are willing to get.
3. Based on SUs' bids, the network manager determines the resource allocation and the payments required from SUs.
4. Based on the allocated resources, the SUs schedule their video packets.

As we can see, most elements (e.g., states, rewards) in auction-based mechanisms are the same as in the general model in section "General Model for Video Applications over Cognitive Radio". Here we list some key features of the auction-based mechanism.

- In the auction-based mechanism, the SUs' actions consist of two types of actions, internal actions and external actions. The internal actions, denoted by b_i^t in

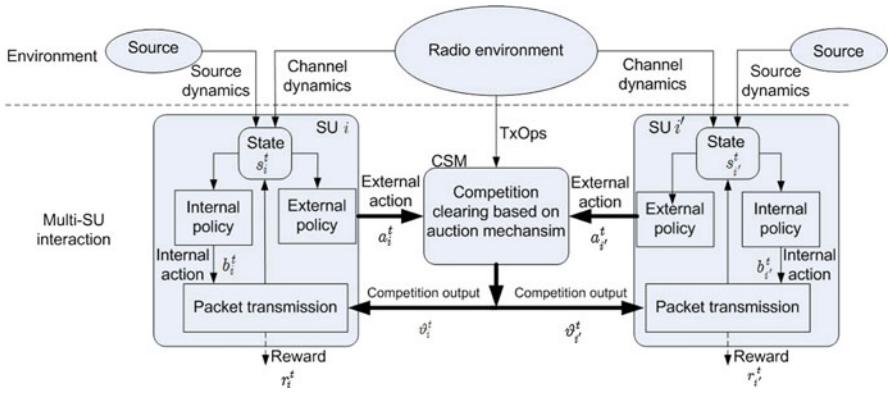

Fig. 3 Illustration of strategy-proof resource allocation mechanism based on auctions

Fig. 3, are the packet scheduling actions described in section "General Model for Video Applications over Cognitive Radio". The external actions are unique in the auction-based mechanism. Specifically, the external action is the amount of resources each SU wants to get (i.e., their bids).

- In the auction-based mechanism, the network manager directly allocates the resources to the SUs and announces the payments required from the SUs. This is different from the mechanism in section "General Model for Video Applications over Cognitive Radio", where the network manager announces the prices and the SUs determine the resource allocation based on the prices.

We refer interested readers to [4, 5] for detailed descriptions and theoretical results of the auction-based mechanisms.

Conclusion and Future Directions

In this chapter, we introduce the optimal foresighted resource allocation and packet scheduling for multiuser wireless video transmission over cognitive radio networks. The introduced solution achieves the optimal long-term video quality subject to each user's minimum video quality guarantee, by dynamically allocating resources among the users and dynamically scheduling the users' packets while taking into account the dynamics of the video traffic and channel states. We develop a low-complexity algorithm that can be implemented by the network manager and the users in an informationally decentralized manner and converges to the optimal solution. We also introduce strategy-proof variations of our solutions for self-interested users.

There are many important future research directions. First, we have focused on the cases where users have orthogonal spectrum access. One interesting direction is to allow non-orthogonal spectrum access through power control. This will further

complicate the coupling among the users. This is because orthogonal spectrum access results in resource allocation constraints as linear inequality, while non-orthogonal spectrum access will destroy the linearity. Theoretically, the resulting problems are *strongly coupled* multiuser MDPs, instead of *weakly coupled* multiuser MDPs in this chapter.

Second, in the scenarios where users are self-interested, theoretical analysis of the efficiency at the equilibrium is yet missing. There are existing works in computer science and economics literature that analyze the Price of Anarchy (PoA) and efficiency of learning in games. However, most of these works focus on one-shot games (i.e., when users are myopic). When the users are foresighted, the problem is more challenging and calls for novel analytical frameworks.

Abstract

Cognitive radio (CR) and multiple-input multiple-output (MIMO) are two independent physical layer technologies that have made significant impact on wireless networks. In particular, CR operates on the channel level to exploit efficiency across spectrum dimension, while MIMO operates within the same channel to exploit efficiency across spatial dimension. In this chapter, we explore MIMO-empowered CR technique to enhance spectrum access in wireless networks. Specially, we study how to apply MIMO-empowered CR for both interweave and underlay paradigms in multi-hop network environment. With MIMO interference cancelation (IC) capability, we first show how multiple secondary links achieve simultaneous transmission on the same channel under the interweave paradigm. Next, we show how secondary networks achieve simultaneously transmission with the primary network on same channel to achieve transparent coexistence under the underlay paradigm. Through rigorous mathematical modeling, problem formulation, and extensive simulation results, we find that MIMO-empowered CR can offer significant improvement in terms of spectrum access and throughput performance under both interweave and underlay paradigms.

Keywords

Cognitive radio · MIMO · Interference cancelation · Spectrum sharing · Coexistence · Interweave · Underlay · Multi-hop network

Introduction

Since its inception, cognitive radio (CR) has quickly been accepted as the enabling radiotechnology for next-generation wireless communications [8, 22]. A CR promises unprecedented flexibility in radio functionalities via programmability at the lowest layer, which was once done in hardware. Due to its spectrum sensing, learning, and adaptation capabilities, CR has the potential to address the heart of the problem associated with spectrum scarcity (via dynamic spectrum access (DSA)) and interoperability (via channel switching). Already, CR or its predecessor, software-defined radio (SDR), has been implemented for cellular communications [20], the military [10], and public safety communications [13]. It is envisioned that CR will be employed as a general radio platform upon which numerous wireless applications can be implemented.

In parallel to the development of CR, MIMO [2, 19] has already been widely implemented in commercial wireless products to increase capacity. The goal of

MIMO and how it operates are largely independent of and orthogonal to CR. Instead of exploiting idle channels for wireless communications, MIMO attempts to increase capacity within the same channel via space-time processing [6]. In particular, by employing multiple antennas at both the transmit and receive nodes, wireless channel capacity can scale almost linearly with the number of antennas (via spatial multiplexing) [4, 18]. Further, with zero-forcing beamforming (ZFBF) [3, 21], a node may use its degrees of freedom (DoFs) to cancel interference from other nodes or its own interference to other nodes.

In this chapter, we explore MIMO in CR-based secondary networks in both interweave (i.e., interference avoidance or DSA) and underlay paradigms [7] to enhance spectrum efficiency and spatial reuse. In interweave paradigm, to avoid interference to primary network, the secondary networks can only operate on spectrum holes. However, with MIMO IC capability, secondary nodes are allowed to be active simultaneously on the same band in the secondary network. If we assume that each node in a cognitive radio network (CRN) is equipped with A_{MIMO} antennas, then one would expect at least A_{MIMO}-fold capacity increase when compared to a CRN with only a single antenna at each node, due to spatial multiplexing gain from MIMO. Now observing that CR and MIMO handle interference differently (with CR on the channel level and MIMO within a channel), we ask the following fundamental question: *Will joint optimization of CR (via channel assignment) and MIMO (via DoF allocation) offer more than A_{MIMO}-fold in capacity?*

In underlay paradigm, we explore the potential of *simultaneous activation* of a secondary network with the primary network, as long as the interference produced by the secondary nodes can be properly "controlled" (e.g., canceled) by secondary nodes. In other words, secondary nodes are allowed to access the spectrum as long as they can cancel their interference to the primary nodes in such a way that primary nodes do not feel the presence of secondary nodes. In other words, activities by the secondary nodes are made transparent (or "invisible") to the primary nodes. We call this *transparent coexistence*. Although the idea of the transparent coexistence has been explored in the information theory (IT) community, results from the IT and communication (COMM) communities have mainly limited to very simple network settings, e.g., several nodes or link pairs, all for *single-hop* communications [1, 5, 11, 23, 24]. The more interesting problem of how transparent coexistence can be achieved in a *multi-hop* secondary network remains open. As shown in [9, 14], the problem complexity associated with multi-hop CR networks is much higher than single-hop CR networks.

The remainder of this chapter is organized as follows. In sections "MIMO-Based Secondary Network in Interweave Paradigm" and "MIMO-Based Secondary Network in Transparent-Coexistence Paradigm", we explore MIMO-empowered CR for a multi-hop secondary network under the interweave and underlay paradigms, respectively. Through case studies, we demonstrate that MIMO-empowered secondary networks can significantly improve spectrum efficiency and spatial reuse under both interweave and underlay paradigms. Section "Summary and Future Directions" summarizes this chapter.

MIMO-Based Secondary Network in Interweave Paradigm

In this section, we study MIMO-based secondary multi-hop network in interweave paradigm. Our discussion consists of two levels: The first is on channel level, i.e., how does a secondary network exploit available spectrum and handle interference via the use of different channels. The second is within a channel, i.e., how does MIMO mitigate co-channel interference via ZFBF (i.e., using DoF). A thorough understanding of these interference avoidance/cancelation techniques across/within channels is critical to mathematical modeling and ultimately fully exploit the potential of MIMO and CR. Based on this background, we then develop a rigorous mathematical model and study a throughput maximization problem to exploit the potential benefit of MIMO-based secondary network.

Co-channel Interference Cancelation with MIMO DoFs

The total number of antennas at a node is called *degrees of freedom* (or DoFs) [12] at the node. A node can use some or all of its DoFs for either spatial multiplexing (SM) (to achieve multiple concurrent data streams over a link) or co-channel IC (to enable multiple links on the same band), as long as the number of DoFs being used does not exceed the number of antennas at the node.

The allocation of DoFs at a node for SM and IC can be based on an ordering of all nodes in the network [16]. For a given ordered node list, the DoFs at a node can be allocated as follows.

- *DoF Allocation at A Transmit Node.* First, the transmit node needs to allocate DoFs for SM. The number of DoFs to be allocated equals to the number of data streams to be transmitted. Then, for IC, this transmit node must ensure that its transmission does not interfere with those receive nodes that are before this node in the ordered list. To cancel its interference to these receive nodes, this node needs to allocate a number of DoFs that are equal to the received data streams by those nodes. This transmit node does not need to allocate any of its DoFs to null potential interference to those receive nodes that are after itself in the ordered node list.
- *DoF Allocation at A Receive Node.* First, the receive node needs to allocate DoFs for data reception (SM). The number of DoFs to be allocated equals to the number of data streams to be received. Then, for IC, this node must ensure that its reception is not interfered by those transmit nodes that are ordered before this node in the list. To cancel the interference from these transmit nodes, this node needs to allocate a number of DoFs that are equal to the transmitted data streams by those nodes. This receive node does not need to allocate any of its DoFs to null potential interference from those transmit nodes that are after itself in the ordered node list.

An example is given in Fig. 1, where there are four nodes, each equipped with 4 antennas. All nodes operate on the same channel, and there are two mutually

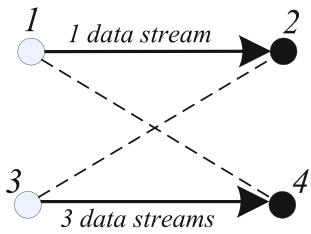

Fig. 1 Simultaneous activation of two secondary links with IC

interfering links in the network: $1 \rightarrow 2$ and $3 \rightarrow 4$. Suppose the ordered node list for DoF allocation is 1, 2, 3, and 4. Further, node 1 is transmitting 1 data stream to node 2 and node 3 is transmitting 3 DoF to node 4 . Now we show how the DoFs at each node are allocated for interference cancelation and spatial multiplexing:

- Starting with node 1, it is the first node in the list and it is a transmit node. Then it allocates 1 DoF for its transmission with 1 data stream. It does not need to allocate any DoF to cancel potential interference to other receive nodes that are after itself in the ordered node list, i.e., node 4.
- The next node in the list is node 2. As a receive node, it allocates 1 DoF for receiving 1 data stream from node 1. It does not need to consider allocating any DoF to cancel interference from other transmit nodes that are after itself in the ordered node list, i.e., node 3.
- The next node in the list is node 3. As a transmit node, it needs to ensure that its transmission does not interfere with any receive node before itself in the list, i.e., node 2. Thus, node 3 uses 1 DoF (equals to the number of received data streams by node 2) to cancel its interference to node 2. Now it has 3 remaining DoFs, which can all be used to transmit data streams (up to 3) to node 4.
- The last node in the list is node 4. As a receive node, node 4 needs to allocate 3 of its DoFs for receiving 3 data streams from node 3. Node 4 also needs to use its remaining 1 DoF (equals to the number of transmitted data streams by node 1) to cancel interference from node 1. This completes the DoF allocation at each node.

Mathematical Modeling

We consider a secondary multi-hop network consisting of a set of $\mathcal{N}$ nodes. At each node $i \in \mathcal{N}$, there is a set of $\mathcal{B}_i$ available frequency bands that can be used for communications. As discussed, $\mathcal{B}_i$ may represent the set of bands that are unused by the primary users and may be different at each node due to geographical difference. Denote the set of commonly available bands between nodes i and j as $\mathcal{B}_{ij} = \mathcal{B}_i \bigcap \mathcal{B}_j$. Also, denote A_i as the number of antennas at node i. Suppose there are multiple sessions in this network. Denote $\mathcal{Q}$ the set of sessions in the network. For a session $q \in \mathcal{Q}$, denote $s(q)$ the source node, $d(q)$ the destination node, and $f(q)$ the flow rate (in b/s). Table 1 lists all notation used in the interweave paradigm.

Table 1 Notation in interweave paradigm

Symbol	Definition
A_i	The number of antennas at node $i \in \mathcal{N}$
A_{MIMO}	The number of antennas at each node
$\mathcal{B}_i$	The set of available bands at node $i \in \mathcal{N}$
$\mathcal{B}_{ij}$	The set of common available bands at nodes $i, j \in \mathcal{N}$
c	The capacity when 1 DoF is used for data transmission on a band over a link
$d(q)$	Destination node of session q
$f(q)$	The rate of session q
g_i^b	A binary indicator. g_i^b is 1 if node i is transmitting or 0 otherwise
h_i^b	A binary indicator. h_i^b is 1 if node i is receiving or 0 otherwise
$\mathcal{I}_i^b$	The set of nodes in the interference range of node i on band b
$\mathcal{L}_{i,b}^{\text{Out}}$	The set of outgoing links on band b at node i
$\mathcal{L}_{i,b}^{\text{In}}$	The set of incoming links on band b at node i
$\mathcal{L}_{\text{Active}}$	The set of links used for routing
$\mathcal{N}$	The set of all nodes in the network
$\mathcal{Q}$	The set of active sessions in the network
$\text{Rx}(l)$	Receiving node of link l
$s(q)$	Source node of session q
$\text{Tx}(l)$	Transmitting node of link l
z_l^b	The number of data streams over link l on band b
θ_{ji}^b	Binary indicator showing the relationship between nodes i and j in the ordered list on band b
λ_{ji}^b	The number of DoFs on band b used by transmitting node i to cancel its interference to node j
μ_{ji}^b	The number of DoFs on band b used by receiving node i to cancel the interference from node j

Half-Duplex Constraint. To model the half-duplex nature of each node in a band, we use two binary variables g_i^b and h_i^b to indicate node i's transmission/reception status on band b, i.e.,

$$g_i^b = \begin{cases} 1 & \text{if node } i \text{ is transmitting on band } b, \\ 0 & \text{otherwise.} \end{cases}$$

$$h_i^b = \begin{cases} 1 & \text{if node } i \text{ is receiving on band } b, \\ 0 & \text{otherwise.} \end{cases}$$

where $i \in \mathcal{N}, b \in \mathcal{B}_i$. Then the half-duplex constraint (i.e., a node cannot transmit and receive at the same time in the same band) can be represented as follows:

$$g_i^b + h_i^b \leq 1, \quad (i \in \mathcal{N}, b \in \mathcal{B}_i). \tag{1}$$

Node Ordering for IC. As discussed in section "Co-channel Interference Cancelation with MIMO DoFs", the DoF allocation (for SM and IC) at each node is determined sequentially based on an ordered node list. This ordering determines DoF allocation behavior in the final solution and should be part of the optimization problem. We point out that such a node ordering approach for DoF allocation is the most efficient approach among all existing DoF models that can guarantee feasibility. As pointed out in [16], an optimal ordering of secondary nodes can be found by inserting a formulation of the ordering relationship into the specific optimization problem.

Denote π^b as an ordered list of the nodes in the secondary network on channel $b \in \mathscr{B}$, and denote π_i^b as the position of node $i \in \mathscr{S}$ in π^b. Therefore, $1 \le \pi_i^b \le S$, where $S = |\mathscr{S}|$. For example, if $\pi_i^b = 3$, then it means that node i is in the third position in the list π^b.

To model the relative ordering between any two secondary nodes i and j in π^b, we define a binary indication variable $\theta_{j,i}^b$ and define it as follows:

$$\theta_{j,i}^b = \begin{cases} 1 \text{ if node } j \text{ is before node } i \text{ in } \pi^b \text{ on channel } b; \\ 0 \text{ otherwise.} \end{cases}$$

It was shown in [16] that the following relationships hold:

$$\pi_i^b - S \cdot \theta_{j,i}^b + 1 \le \pi_j^b \le \pi_i^b - S \cdot \theta_{j,i}^b + S - 1 \,, \quad (i, j \in \mathscr{S}, b \in \mathscr{B}). \tag{2}$$

Transmitter DoF Constraint. Now we consider DoF allocation at a node, which includes DoFs allocated for SM and DoFs allocated for IC.

For transmission and reception, the number of required DoFs is $\sum_{l \in \mathscr{L}_{i,b}^{\text{Out}}} z_l^b$ for a transmit node i and $\sum_{m \in \mathscr{L}_{j,b}^{\text{In}}} z_m^b$ for a receive node j, respectively. As we discussed in section "Co-channel Interference Cancelation with MIMO DoFs", in any given band, the total number of data streams for transmission or reception at a node is limited by its number of antennas. Denote l as a directional link in the network and z_l^b as the number of data streams over link l in band b. Then we have the following two constraints:

$$g_i^b \le \sum_{l \in \mathscr{L}_{i,b}^{\text{Out}}} z_l^b \le g_i^b A_i \qquad (i \in \mathscr{N}, b \in \mathscr{B}_i) \,, \tag{3}$$

$$h_i^b \le \sum_{l \in \mathscr{L}_{i,b}^{\text{In}}} z_l^b \le h_i^b A_i \qquad (i \in \mathscr{N}, b \in \mathscr{B}_i) \,, \tag{4}$$

where $\mathscr{L}_{i,b}^{\text{Out}}$ and $\mathscr{L}_{i,b}^{\text{In}}$ represent the sets of outgoing and incoming links at node i in band b, respectively.

For IC, as discussed in section "Co-channel Interference Cancelation with MIMO DoFs", a transmit node needs to allocate its DoFs to cancel its interference to all receive nodes before itself in the ordered node list. Denote $\mathscr{I}_i^b$ as the set of nodes to which node i can interfere within band b. Then the number of DoFs that node i allocates for IC can be computed as $\sum_{j\in\mathscr{I}_i^b}(\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b)$, where the inner summation $\sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b$ gives the number of data streams for a given receive node j, while the outer summation is taken only over those receive nodes that are before node i in the ordered node list. Now considering both the DoFs at a node allocated for SM and IC, we have the following constraint:

$$\sum_{l\in\mathscr{L}_{i,b}^{\text{Out}}} z_l^b + \sum_{j\in\mathscr{I}_i^b}\left(\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b\right) \leq A_i g_i^b + (1-g_i^b)M, \tag{5}$$

where $i \in \mathscr{N}, b \in \mathscr{B}_i$, and M is a sufficiently large number to ensure the constraint holds when node i is not a transmitnode (e.g., we can set $M = \sum_{j\in\mathscr{I}_i^b} A_j$).

Receiver DoF Constraint. Similarly, if node i is a receive node, we have the following constraint for its DoF allocation:

$$\sum_{l\in\mathscr{L}_{i,b}^{\text{In}}} z_l^b + \sum_{j\in\mathscr{I}_i^b}\left(\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{Out}}}^{\text{Rx}(m)\neq i} z_m^b\right) \leq A_i h_i^b + (1-h_i^b)M, \tag{6}$$

where $i \in \mathscr{N}, b \in \mathscr{B}_i$.

For a given route for each session, we can identify the set of links on this route. Denote $\mathscr{L}_{\text{Active}}$ as the set of links that are used by all these routes in the network. Then we have the following capacity constraint on link $l \in \mathscr{L}_{\text{Active}}$.

$$\sum_{q\in\mathscr{Q}}^{l \text{ is traversed by } q} f(q) \leq c \sum_{b\in\mathscr{B}_{\text{Tx}(l),\text{Rx}(l)}} z_l^b \quad (l \in \mathscr{L}_{\text{Active}}), \tag{7}$$

where $f(q)$ is the flow rate of session $q \in \mathscr{Q}$ and c is the capacity when 1 DoF is used for data transmission on a band over link l.

Problem Formulation

Based on the above mathematical model, various problems can be formulated. In this chapter, we study a throughput optimization problem with the objective of maximizing the minimum session rate among all secondary sessions. The optimization problem can be written as follows:

$$
\begin{aligned}
\text{OPT}\ \max\ & f_{\min} \\
\text{s.t}\ & f_{\min} \le f(q) \quad (q \in \mathscr{Q}); \\
& \text{Half-duplex constraints: (1);} \\
& \text{Node ordering constraints: (2);} \\
& \text{Transmitter DoF constraints: (3), (5);} \\
& \text{Receiver DoF constraints: (4), (6);} \\
& \text{Link capacity constraints: (7).}
\end{aligned}
$$

In this formulation, $f_{\min}$, $f(q)$, g_i^b, h_i^b, z_l^b, and θ_{ji}^b are optimization variables and A_i, M, and c are given constants. Due to the nonlinear product term $\sum_{j\in\mathscr{I}_i^b}(\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b)$ in (5), $\sum_{j\in\mathscr{I}_i^b}(\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{Out}}}^{\text{Rx}(m)\neq i} z_m^b)$ in (6), and integer variables, the problem is in the form of mixed-integer nonlinear programming (MINLP).

Mathematical Reformulation

Note that the constraints in (5) and (6) have nonlinear terms (product of variables), which bring in extra complexity in problem formulation. We now show how these nonlinear terms can be removed via linearization. For the nonlinear term in (5), we define a new variable λ_{ji}^b as follows:

$$
\lambda_{ji}^b = \theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b \qquad (i \in \mathscr{N}, b \in \mathscr{B}_i, j \in \mathscr{I}_i^b), \tag{8}
$$

which is the number of DoFs that transmit node i uses to cancel the interference to receive node j. With λ_{ji}^b, (5) can be rewritten as:

$$
\sum_{l\in\mathscr{L}_{i,b}^{\text{Out}}} z_l^b + \sum_{j\in\mathscr{I}_i^b} \lambda_{ji}^b \le A_i g_i^b + (1 - g_i^b)M, \tag{9}
$$

where $i \in \mathscr{N}, b \in \mathscr{B}_i$. Now, we need to add some constraints for λ_{ji}^b. This can be done by examining the definition of λ_{ji}^b in (8). For binary variable θ_{ji}^b, we have the following relaxed constraints: $\theta_{ji}^b \ge 0$, $1 - \theta_{ji}^b \ge 0$. For $\sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b$, we have $\sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b \ge 0$, $A_j - \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b \ge 0$. Multiplying each constraint involving θ_{ji}^b by one of the two constraints involving $\sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b$, and replacing the product term $\theta_{ji}^b \cdot \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b$ with the new variable λ_{ji}^b, we obtain the following four constraints:

$$
\lambda_{ji}^b \ge 0 \tag{10}
$$

$$
\lambda_{ji}^b \le \sum_{m\in\mathscr{L}_{j,b}^{\text{In}}}^{\text{Tx}(m)\neq i} z_m^b \tag{11}
$$

$$\lambda_{ji}^{b} \leq A_j \cdot \theta_{ji}^{b} \tag{12}$$

$$\lambda_{ji}^{b} \geq A_j \cdot \theta_{ji}^{b} - A_j + \sum_{m \in \mathscr{L}_{j,b}^{\mathrm{In}}}^{\mathrm{Tx}(m) \neq i} z_m^b \tag{13}$$

where $i \in \mathscr{N}, b \in \mathscr{B}_i, j \in \mathscr{I}_i^b$. Note that due to the relaxation of integer variable θ_{ji}^b, $\sum_{m \in \mathscr{L}_{j,b}^{\mathrm{In}}}^{\mathrm{Tx}(m) \neq i} z_m^b$, and product operations, the above four constraints for λ_{ji}^b might be looser than (8). However, for the special case when θ_{ji}^b is a binary variable, it can be easily verified that (8) is equivalent to the four constraints in (10), (11), (12), and (13). Therefore, it is sufficient to have linear constraints (9), (10), (11), (12), and (13) to replace (5).

Similarly, to remove the nonlinear term in (6), we define μ_{ji}^b as the number of DoFs that receive node i uses to cancel the interference from transmit node j. Following the same token, (6) can be replaced by the following linear constraints:

$$\sum_{l \in \mathscr{L}_{i,b}^{\mathrm{In}}} z_l^b + \sum_{j \in \mathscr{I}_i^b} \mu_{ji}^b \leq A_i h_i^b + (1 - h_i^b) M \tag{14}$$

$$\mu_{ji}^b \geq 0 \tag{15}$$

$$\mu_{ji}^b \leq \sum_{m \in \mathscr{L}_{j,b}^{\mathrm{Out}}}^{\mathrm{Rx}(m) \neq i} z_m^b \tag{16}$$

$$\mu_{ji}^b \leq A_j \cdot \theta_{ji}^b \tag{17}$$

$$\mu_{ji}^b \geq A_j \cdot \theta_{ji}^b - A_j + \sum_{m \in \mathscr{L}_{j,b}^{\mathrm{Out}}}^{\mathrm{Rx}(m) \neq i} z_m^b \tag{18}$$

where $i \in \mathscr{N}, b \in \mathscr{B}_i, j \in \mathscr{I}_i^b$.

With the above linearization, we have a revised optimization problem formulation (denoted as OPT-R).

OPT-R max $f_{\min}$
s.t $f_{\min} \leq f(q) \quad (q \in \mathscr{Q})$;
Half-duplex constraints: (1);
Node ordering constraints: (2);
Transmitter DoF constraints: (3), (10), (11), (12), and (13);
Receiver DoF constraints: (4), (14), (15), (16), (17), and (18);
Link capacity constraints: (7).

In this formulation, $f_{\min}$, $f(q)$, g_i^b, h_i^b, z_l^b, θ_{ji}^b, λ_{ji}^b, and μ_{ji}^b are optimization variables and A_i, M, and c are constants. The problem is now in the form of mixed-integer linear programming (MILP), which is NP-hard in general. The computation complexity of MILP is exponential, but fortunately, the branch-and-cut based solution procedure used by a commercial solver such as CPLEX is very efficient. Therefore, we will use CPLEX to solve our MILP problems, which turns out to be very successful for all practical purposes.

Anticipated Results

Before we present numerical results, we offer the following discussion on the possible solution to our problem. Consider a CRN with only a single transmit/receive antenna at each node (i.e., $A_i = 1, i \in \mathcal{N}$). Denote f_{CRN} as the optimal objective value for this CRN with our problem formulation. Now consider a CRN$^{\text{MIMO}}$ with the same topology as the above CRN but now with A_{MIMO} transmit/receive antennas at each node. This CRN$^{\text{MIMO}}$ is a special case of our CRN$^{\text{MIMO}}$ network with all $A_i = A_{\text{MIMO}}, i \in \mathcal{N}$. Denote $f_{\text{CRN}^{\text{MIMO}}}$ as the optimal objective value for this CRN$^{\text{MIMO}}$ under our problem formulation. Comparing $f_{\text{CRN}^{\text{MIMO}}}$ with f_{CRN}, we have the following observation:

$$f_{\text{CRN}^{\text{MIMO}}} \geq A_{\text{MIMO}} \times f_{\text{CRN}} \tag{19}$$

The equality part in (19) can be easily explained by exploiting SM, i.e., constructing the same solution in CRN$^{\text{MIMO}}$ as that in the CRN but with A_{MIMO} data streams on each link.

However, we are more interested in the possible *inequality* part in (19), i.e., with joint channel level (via CR) and co-channel level (via MIMO DoF) optimization within a CRN$^{\text{MIMO}}$, we should anticipate more than A_{MIMO}-fold increase in the optimal solution. The greater the gap is in this inequality, the more potential in the joint CR and MIMO that can be exploited. We shall look into this potential gain via numerical results on various networks in the next section.

A Case Study

In this section, we present some numerical results for various network configurations. We consider randomly generated secondary networks with $|\mathcal{N}| = 30$ nodes in an 100×100 area. For ease of scalability and generality, we normalize all units for distance, bandwidth, and rate with appropriate dimensions. In this case study, we assume there are four sessions in the network with the source node and destination node for each session which are randomly selected. There are $|\mathcal{B}| = 15$ frequency bands available in the network. The set of available bands at each node is being

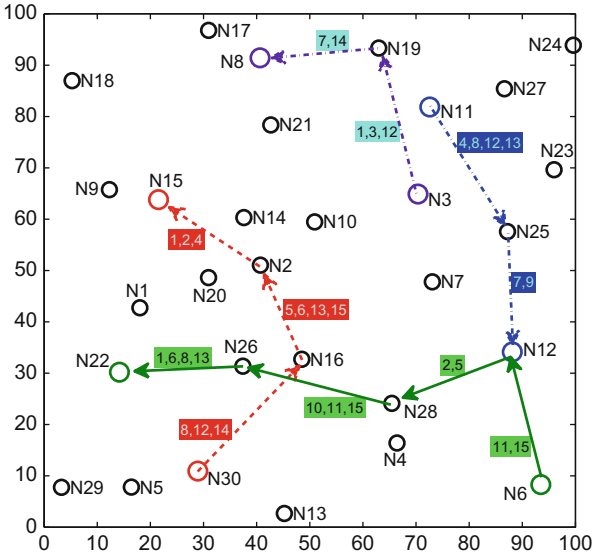

Fig. 2 Assigned bands on each link for the 30-node secondary network

randomly selected from the 15-band pool. The capacity achieved by one band and 1 DoF is normalized to 1. We assume that the transmission range is 30 and the interference range is 60.

Results Before we present results to validate for all 30-node network instance, we select one network instance and explain the details of its optimal solution. This will offer us thorough understanding on what is behind MIMO-based CRN.

The particular network configuration that we will examine is shown in Fig. 2. The location and available bands for each node are listed in Table 2. Table 3 specifies the source and destination nodes for each session. For MIMO, we assume each node in the network is equipped with 4 antennas. We assume minimum-hop routing is used in the network.

Using CPLEX, we can obtain optimal solution to the OPT-R problem. The optimal objective value for this secondary network is 6, which means each session can send at least 6 data streams from its source to its destination.

In addition to the optimal objective value, we show channel level and co-channel level solution to achieve this objective. Figure 2 shows the optimal band assignment to each link for each session. The bands assigned on each link are shown in shaded boxes. This result is also shown in Table 4 (first 3 columns). Also shown in column 4 of Table 4 is the capacity on each band under the optimal solution. In column 5, we show the capacity (in terms of sum of capacity on each band) over each link. Note that this capacity is at least 6, thus guaranteeing each session can transport at least 6 data streams.

Table 2 Each node's location and available frequency bands for the 30-node CRN^{MIMO}

Node	Location	Available bands	Node	Location	Available bands
N1	(18.0, 42.7)	1,2,4,5,6,8,9,10,11,12,13,14	N16	(48.5, 32.7)	2,4,5,6,8,10,11,12,13, 14,15
N2	(40.7, 51.0)	1,2,4,5,6,7,8,9,10,11,13,14,15	N17	(31.0, 96.8)	4,6,7,12,15
N3	(70.4, 64.9)	1,2,3,4,5,7,8,9,12,13,14,15	N18	(5.3, 87.0)	6,7,15
N4	(66.4, 16.4)	2,7,10	N19	(63.0, 93.3)	1,3,4,7,12,14
N5	(16.4, 7.8)	5,6,9,10,12,13,14	N20	(30.9, 48.6)	1,2,4,6,8,9,10,11,12, 13,14
N6	(93.5, 8.3)	11,15	N21	(42.7, 78.4)	1,3,4,7,12,14
N7	(73.1, 47.8)	1,2,3,4,5,7,8,9,13,15	N22	(14.2, 30.2)	1,2,5,6,8,9,10,11,12, 13,14
N8	(40.6, 91.4)	4,6,7,12,14	N23	(99.0, 69.6)	1,2,3,4,7,9,12,13,15
N9	(12.3, 65.8)	1,2,7,14	N24	(99.6, 93.9)	3,9,12
N10	(50.9, 59.5)	1,2,3,4,5,6,7,8,11,14,15	N25	(87.2, 57.6)	1,2,4,5,7,8,9,12,13,15
N11	(72.6, 81.9)	1,2,3,4,5,7,8,9,12,13,14,15	N26	(37.4, 31.4)	1,2,4,5,6,8,9,10,11, 12,13,14,15
N12	(88.1, 34.1)	2,5,7,9,11,15	N27	(86.6, 85.4)	1,2,3,4,7,9,12,13
N13	(45.2, 2.7)	10,12,13,14	N28	(65.5, 24.1)	2,5,7,10,11,15
N14	(37.6, 60.3)	1,2,4,5,6,7,8,10,11,13,14,15	N29	(3.3, 7.8)	5,6,9,13
N15	(21.5, 63.8)	1,2,4,7,8,10,14	N30	(28.9, 10.9)	5,6,8,9,10,11,12,13,14

Table 3 Source and destination nodes of each session in the 30-node CRN^{MIMO}

Session q	Source node $s(q)$	Destination node $d(q)$
1	N30	N15
2	N6	N22
3	N11	N12
4	N3	N8

We now examine co-channel DoF allocation in the optimal solution. Recall that DoF allocation is performed within the same band. Given that we have a total of 15 bands in the network, we shall have DoF allocation within each of the 15 bands. Let's first show DoF allocation in one particular band, say band 1. Note that band 1 is used by links N2 → N15, N3 → N19, N26 → N22 in Fig. 2. The DoF allocation on these 6 nodes are given in Fig. 3 and Table 5. As shown in Fig. 3, there are 2 data streams in each of these 3 links on band 1. The dashed lines in Fig. 3 show the interference relationship among the nodes, i.e., node N2 interferes with N19 and N22, node N3 interferes with N15, and node N26 interferes with N15. These transmission links and interference relationships are also listed in Table 5 (row 1), where "N2 → N15 (N19, N22)" denotes N2 transmits to N15 and interferes with N19, N22, etc. Also shown in the first column of Table 5 is the optimal order for the 6 nodes for DoF allocation in the optimal solution, i.e., N2, N3, N15, N19, N26, and N22. Based on this order, the DoFs at each node are allocated as follows (also see Fig. 3):

Table 4 Details of band assignment, capacity on each band, and capacity on each link in the 30-node CRN^{MIMO}

Session q	Link	Assigned band	Capacity on band	Link capacity
1	N30 → N16	8	1	6
		12	1	
		14	4	
	N16 → N2	5	1	6
		6	3	
		13	1	
		15	1	
	N2 → N15	1	2	6
		2	1	
		4	3	
2	N6 → N12	11	3	6
		15	3	
	N12 → N28	2	3	6
		5	3	
	N28 → N26	10	4	6
		11	1	
		15	1	
	N26 → N22	1	2	7
		6	1	
		8	1	
		13	3	
3	N11 → N25	4	1	6
		8	2	
		12	2	
		13	1	
	N25 → N12	7	2	6
		9	4	
4	N3 → N19	1	2	7
		3	4	
		12	1	
	N19 → N8	7	2	6
		14	4	

- Starting with node N2, it is the first node in the ordered node list and it is a transmit node. Then it allocates 2 DoFs to transmit 2 data streams to node N15. It does not need to allocate any DoF to cancel potential interference to other receive nodes after itself in the node list, i.e., nodes N19 and N22.
- The next node in the list is N3. As a transmit node, it allocates 2 DoFs to transmit 2 data streams to node N19. It does not need to allocate any DoF to cancel potential interference to receive node N15, which is after itself in the ordered node list.

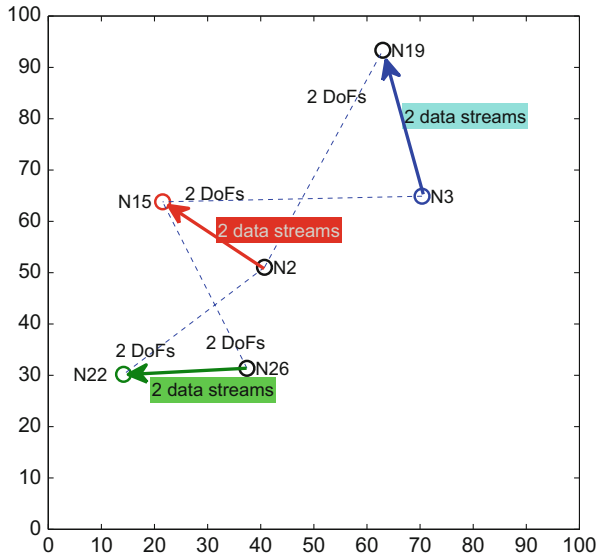

Fig. 3 The DoF allocation in the optimal solution in band 1 for the 30-node CRN^{MIMO} example

Table 5 The DoF allocation in band 1 in the 30-node CRN^{MIMO} example

Transmission and interference	N2 → N15 (N19, N22), N3 → N19 (N15), N26 → N22 (N15)	
Ordered node list	Interference cancelation (# of DoFs, to/from, node)	Spatial multiplexing (# of DoFs, transmit/receive, node)
N2		(2, Transmit, N15)
N3		(2, Transmit, N19)
N15	(2, From, N3)	(2, Receive, N2)
N19	(2, From, N2)	(2, Receive, N3)
N26	(2, To, N15)	(2, Transmit, N22)
N22	(2, To, N2)	(2, Receive, N26)

- The next node in the list is N15. As a receive node, it needs to allocate 2 DoFs to receive 2 data streams from node N2. In addition, it must ensure that its reception is not interfered with by any transmit node before itself in the list, i.e., N3. Thus it allocates the remaining 2 DoFs to cancel the interference from node N3.
- The next node in the list is N19. As a receive node, it allocates 2 DoFs for receiving 2 data streams from node N3. In addition, it allocates the remaining 2 DoFs to cancel interference from transmit node N2 which is before itself in the list.
- The next node in the list is N26. As a transmit node, it needs to ensure that its transmission does not interfere with any receive node before itself in the list, i.e., N15. For this purpose, it allocates 2 DoFs to cancel its interference to node N15. Then it allocates the remaining 2 DoFs to transmit 2 data streams to node N22.

- The last node in the list is N22. As a receive node, it allocates 2 DoFs to receiving 2 data streams from node N22. In addition, it must ensure that its reception is not interfered with by any transmit node before itself in the list, i.e., N2. Thus, it allocates the remaining 2 DoFs to cancel the interference from node N2.

This completes the DoF allocation for each node in the list in band 1. The DoF allocation for the 6 nodes is also listed in Table 5, where we employ the following two abbreviated notations:

- We use the tuple (# of DoFs, From/To, Node) to denote the IC relationship between the nodes. For example, (2, From, N3) denotes current node (in the first column of the same row) allocates 2 DoFs to cancel the interference from N3, whereas (2, To, N15) denotes current node allocates 2 DoFs to cancel its interference to N15.
- We use the tuple (# of DoFs, Transmit/Receive, Node) to denote data transmission relationship between the nodes. For example, (2, Transmit, N15) denotes the current node (in the first column of the same row) allocates 2 DoFs to transmit data streams to N15, whereas (2, Receive, N2) denotes the current node uses 2 DoFs to receive data streams from N2.

Discussions in bands 2 to 15 are similar and are omitted to conserve space.

$$f_{\text{CRN}^{\text{MIMO}}} vs. A_{\text{MIMO}} \times f_{\text{CRN}}$$

The results above show an optimal solution for a 30-node secondary network with $A_{\text{MIMO}} = 4$ antennas at each node. We now validate the result in (19) under different number of antennas at each node. Figure 4 shows the optimal objective values under different number of antennas for the same 30-node network discussed in the last section. Also shown in this figure is a dashed line with a slope of f_{CRN}.

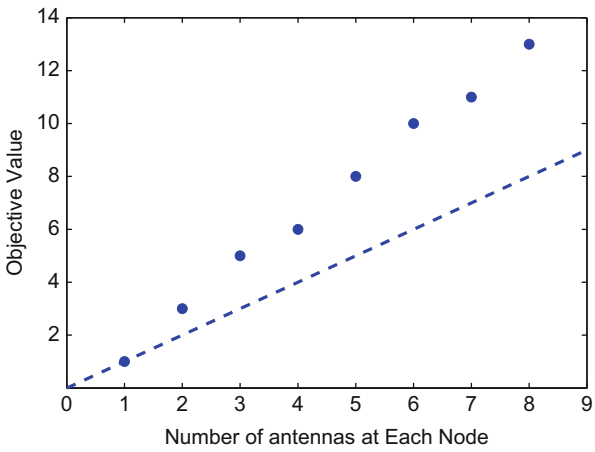

Fig. 4 Objective value under different antennas for the 30-node CRN^{MIMO}

Note that the equality in (19) only coincides for the first point, i.e., single antenna at each node. When the number of antennas at each node is greater than 1, we have an inequality, i.e., $f_{\text{CRN}^{\text{MIMO}}} > A_{\text{MIMO}} \times f_{\text{CRN}}$. That is, with joint channel level (via CR) and co-channel level (via MIMO DoF) optimization within a CRN^{MIMO} network, we have more than A_{MIMO}-fold increase in the optimal solution.

MIMO-Based Secondary Network in Transparent-Coexistence Paradigm

In section "MIMO-Based Secondary Network in Interweave Paradigm", we have studied how multi-hop secondary CR network achieve simultaneous transmission on the same channel among secondary nodes with MIMO-empowered CR under the interweave paradigm. In this section, we study how a multi-hop secondary CR network can coexist with a primary network transparently. A MIMO node's ability to use a subset of its DoFs to cancel interference while using the remaining subset of DoFs for data transmission allows the possibility of simultaneous activation of the secondary nodes with the primary nodes. For a set of channels owned by the primary networks, the primary nodes may use them in whatever manner to suit their needs. On the other hand, the secondary nodes are only allowed to use these channels if they can cancel their interference to the primary nodes. Further, to ensure successful transmission among the secondary nodes, the secondary nodes also need to perform IC to/from the primary nodes as well as potential interference among the secondary nodes. Simply put, all IC burden should rest solely on the secondary nodes and remain invisible to the primary nodes.

It is important to realize that we strive to put all IC burden on the secondary node side. Specifically, the transmitter of a secondary node needs to cancel its interference to all neighboring primary receive nodes who are interfered with by this secondary transmitter; the receiver of a secondary node needs to cancel interference from all neighboring primary transmit nodes who interfere with this secondary receiver. To achieve transparency to primary nodes, it is important for the secondary nodes to have accurate channel state information (CSI). The problem here is: how can a secondary node obtain the CSI between itself and its neighboring primary nodes while remaining transparent to the primary nodes? We propose the following solution to resolve this problem. For each primary node, it typically sends out a pilot sequence (training sequence) to its neighboring primary nodes such that those primary nodes can estimate the CSI for communication. This is the practice for current cellular networks, and we assume such a mechanism is available for a primary network. Then, the secondary nodes can *overhear* the pilot sequence signal from the primary node while staying transparent. Suppose the pilot sequence from the primary nodes is publicly available (as in cellular networks) and is thus known to the secondary nodes. Then the secondary nodes can use this information and the actual received pilot sequence signal from the primary node for channel estimation. Based on the reciprocity property of a wireless channel [17], the

estimated CSI can also be used as CSIT (channel state information at transmitter side). Therefore, a secondary node can obtain complete CSI between itself and a primary node.

Problem Scope

Although the new coexistence paradigm has been explored at the physical layer, its application to a multi-hop network environment is far from trivial. Consider a primary multi-hop ad hoc network $\mathscr{P}$ shown in Fig. 5, which is colocated with a secondary multi-hop network $\mathscr{S}$ in the same geographical region. Suppose that there is a set of channels $\mathscr{B}$ available to the primary network. The primary nodes can use this set of frequency channels freely as if they were the only nodes in the network. The primary nodes do not need to be MIMO-capable. The secondary nodes, however, are allowed to use a channel in $\mathscr{B}$ only if their interference to the primary nodes is canceled properly, with complete transparency to the primary nodes. As discussed, the secondary nodes are assumed to be equipped with MIMO. In this context, we have a number of challenges for the secondary network.

- **Channel Selection** In a secondary network, an intermediate relay node is both a transmitter and a receiver. Due to half-duplex, a node cannot transmit and receive on the same channel at the same time. Therefore, scheduling (either in time slot or channel) is needed. In this chapter, we assume scheduling is performed in the form of channel assignment. Therefore, a secondary relay node needs to select different channels for transmission and reception. Note that scheduling transmission and reception of a secondary node will lead to a different interference relationship among the primary and secondary nodes in the network. This brings in considerable complexity to the mathematical modeling of interference relationship.
- **IC to/from Primary Network** A secondary transmitter needs to cancel its interference to its neighboring primary receivers, while a secondary receiver

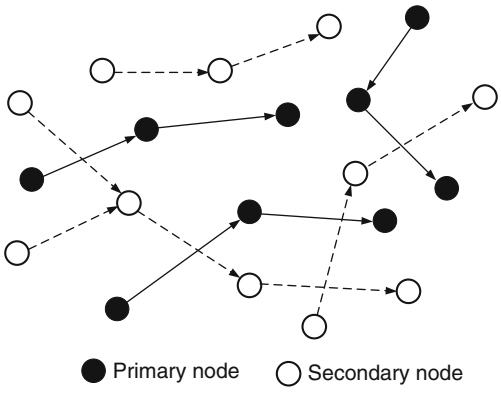

Fig. 5 A multi-hop secondary network colocated with a multi-hop primary network

needs to cancel the interference from its neighboring primary transmitters. Such challenge magnifies when the secondary network is a multi-hop network.

- **IC Within Secondary Network** In addition to interference between the primary and secondary nodes, interference from a secondary node may also interfere another secondary node within their own network. Such interference must also be canceled properly (either by a secondary transmitter or the secondary receiver that is being interfered with) to ensure successful data communications inside the secondary network. Resource allocation to account for such IC is clearly not a trivial problem.

It is important to realize that the above three challenges are not independent, but rather deeply intertwined with each other. In particular, channel selection at a secondary node is directly tied to the interference relationship between primary and secondary nodes as well as interference among the secondary nodes within each channel. Further, the combined channel resource and total DoFs at each node determine a complete resource space in the network: an optimal DoF allocation and channel selection at each secondary node for both IC to/from the primary nodes and within the secondary nodes are critical to achieve the desired network performance objective. A modeling and formulation of transparent-coexistence paradigm would call for a joint consideration of all these components.

Mathematical Modeling

In this section, we develop a mathematical model for the transparent-coexistence paradigm where a multi-hop secondary network shares the same spectrum as a primary network (see Fig. 5).

Referring to Fig. 5, we consider a secondary multi-hop network consisting of a set of nodes $\mathscr{S}$, which is colocated with a primary multi-hop network consisting of a set of nodes $\mathscr{P}$. Suppose that there is a set of channels $\mathscr{B}$ available to the primary network. For the primary network, there is no special node requirement, and we assume that each primary node is a traditional single-antenna node. A primary node may transmit and receive on the same channel but in different time slots or transmit and receive on different channels. We consider the latter in this chapter. Consider a set of multi-hop sessions $\tilde{\mathscr{F}}$ among the primary nodes. For a given routing for each session, denote $\tilde{\mathscr{L}}$ the set of active links in the primary network (shown in solid arrow lines in Fig. 5). Denote $\tilde{z}^b(\tilde{l})$ as the number of data streams over primary link $\tilde{l} \in \tilde{\mathscr{L}}$ on channel b. Then due to single antenna on each primary node, $\tilde{z}^b(\tilde{l}) = 1$ if link $\tilde{l}$ is active on channel b and 0 otherwise.

For the secondary network, we assume MIMO's capability at each node. Denote A_i as the number of antennas on a secondary node $i \in \mathscr{S}$. Suppose there is a set of multi-hop sessions $\mathscr{F}$ in $\mathscr{S}$. For a given routing for each session, denote $\mathscr{L}$ as the set of secondary links (shown in dashed arrow line in Fig. 5). Denote $r(f)$ as the rate of session $f \in \mathscr{F}$. A general goal of throughput maximization is to maximize a function of $r(f)$, $f \in \mathscr{F}$. Table 6 lists all notations used in the underlay paradigm.

Table 6 Notation in underlay paradigm

Primary network	
$\tilde{\mathscr{P}}$	The set of nodes in the primary network
T	The number of time slots in a frame
$\tilde{\mathscr{B}}$	The sets of channels owned by the primary network
B	The number of channels in set $\tilde{\mathscr{B}}$, $B = \lvert\tilde{\mathscr{B}}\rvert$
$\tilde{\mathscr{F}}$	The set of sessions in the primary network
$\tilde{\mathscr{I}}_i$	The set of primary nodes within the interference range of secondary node i
$\tilde{\mathscr{L}}_i^{\text{In}}$	The set of incoming links (from other primary nodes) at node $i \in \tilde{\mathscr{P}}$
$\tilde{\mathscr{L}}_i^{\text{Out}}$	The set of outgoing links (to other primary nodes) at node $i \in \tilde{\mathscr{P}}$
$\tilde{\mathscr{L}}$	The set of links in the primary network
$\tilde{z}_{(\tilde{l})}^b$	The number of data streams over primary link $\tilde{l}$ on channel b
Secondary network	
$\mathscr{S}$	The set of nodes in the secondary network
S	The number of secondary nodes in the network, $S = \lvert\mathscr{S}\rvert$
A_i	The number of antennas at secondary node $i \in \mathscr{S}$
c	The minimum data rate carried by a data stream
$\mathscr{F}$	The set of sessions in the secondary network
$\mathscr{I}_i$	The set of node in $\mathscr{S}$ that are within the interference range of secondary node i
$\mathscr{L}_i^{\text{In}}$	The set of incoming links (from other secondary nodes) at node $i \in \mathscr{S}$
$\mathscr{L}_i^{\text{Out}}$	The set of outgoing links (to other secondary nodes) at node $i \in \mathscr{S}$
$\mathscr{L}$	The set of secondary links
$r(f)$	The data rate of the session $f \in \mathscr{F}$
$r_{\min}$	The minimum data rate among all secondary sessions
$\text{Rx}(l)$	The receiver of link $l \in \mathscr{L}$
$\text{Tx}(l)$	The transmitter of link $l \in \mathscr{L}$
x_i^b	$= 1$ if node $i \in \mathscr{S}$ is a transmitter on channel b and is 0 otherwise
y_i^b	$= 1$ if node $i \in \mathscr{S}$ is a receiver on channel b and is 0 otherwise
$z_{(l)}^b$	The number of data streams over link $l \in \mathscr{L}$ on channel b
$\lambda_{j,i}^b$	The number of DoFs used by transmit node $i \in \mathscr{S}$ to cancel its interference to receive node $j \in \mathscr{S}$ on channel b
$\mu_{j,i}^b$	The number of DoFs used by receive node $i \in \mathscr{S}$ to cancel the interference from transmit node $j \in \mathscr{S}$ on channel b
$\theta_{j,i}^b$	Binary indicator showing the relationship between nodes i and j in ordered list on channel b, $i, j \in \mathscr{S}$
π^b	An ordering for IC among the secondary nodes on channel b
π_i^b	The position of node $i \in \mathscr{S}$ in π^b

Channel Selection. To model channel use behavior at a secondary node for transmission or reception, we denote x_i^b and y_i^b ($i \in \mathscr{S}$ and $b \in \mathscr{B}$) as whether node i selects channel b for transmission or reception, respectively. We have

$$x_i^b = \begin{cases} 1 & \text{if node } i \text{ uses channel } b \text{ for transmission;} \\ 0 & \text{otherwise.} \end{cases}$$

$$y_i^b = \begin{cases} 1 \text{ if node } i \text{ uses channel } b \text{ for reception;} \\ 0 \text{ otherwise.} \end{cases}$$

To consider half-duplex (a node cannot transmit and receive on the same channel at the same time), we have the following constraint on x_i^b and y_i^b:

$$x_i^b + y_i^b \leq 1 \qquad (i \in \mathscr{S}, b \in \mathscr{B}). \tag{20}$$

DoF Allocation at a Secondary Transmitter. Recall that the secondary network is solely responsible for IC to/from the primary network as well as IC within itself. At a secondary transmitter, it needs to expend DoFs for SM, IC to primary receivers, and IC to other secondary receivers:

- For SM, denote $z^b(l)$ and $\mathscr{L}_{i,\text{Out}}^b$ as the number of data streams over link $l \in \mathscr{L}$ and the set of outgoing links from secondary node i on channel b. Then the number of DoFs at secondary node $i \in \mathscr{S}$ for SM on channel b is $\sum_{l \in \mathscr{L}_{i,\text{Out}}^b} z^b(l)$.
- For IC to primary receivers, recall $\tilde{z}^b(\tilde{l})$ is the number of data streams over primary link $\tilde{l}$ on channel b. For a primary node $p \in \tilde{\mathscr{P}}$, denote $\tilde{\mathscr{L}}_{p,\text{In}}^b$ as the set of incoming primary links on channel b. Denote $\tilde{\mathscr{I}}_i$ as the set of neighboring primary nodes that are located within the interference range of secondary transmitter i. Then at node i, the number of DoFs required for IC to primary receivers is $\left(\sum_{p \in \tilde{\mathscr{I}}_i} \sum_{\tilde{l} \in \tilde{\mathscr{L}}_{p,\text{In}}^b} \tilde{z}^b(\tilde{l})\right)$ on channel b.
- For IC to secondary receivers, as discussed earlier, a secondary transmitter i only needs to cancel its interference to those nodes that are before itself in the ordered list. For a secondary node $j \in \mathscr{S}$, denote $\mathscr{L}_{j,\text{In}}^b$ as the set of incoming secondary links. Denote $\mathscr{I}_i$ as the set of neighboring secondary nodes that are located within the interference range of secondary transmitter i. Then at node i, the number of DoFs required for IC to secondary receivers is $\sum_{j \in \mathscr{I}_i} \left(\theta_{j,i}^b \cdot \sum_{k \in \mathscr{L}_{j,\text{In}}^b}^{\text{Tx}(k) \neq i} z^b(k)\right)$ in channel b, and $\text{Tx}(k)$ represents the transmitter of link k.

Putting all three DoF consumptions together at a secondary transmitter i, we have the following constraints:

$$x_i^b \leq \sum_{l \in \mathscr{L}_{i,\text{Out}}^b} z^b(l) + \left[\left(\sum_{p \in \tilde{\mathscr{I}}_i} \sum_{\tilde{l} \in \tilde{\mathscr{L}}_{p,\text{In}}^b} \tilde{z}^b(\tilde{l})\right) + \sum_{j \in \mathscr{I}_i} \left(\theta_{j,i}^b \cdot \sum_{k \in \mathscr{L}_{j,\text{In}}^b}^{\text{Tx}(k) \neq i} z^b(k)\right)\right] \cdot x_i^b \leq x_i^b A_i, \tag{21}$$

which means that if node i is transmitting, its DoF consumptions cannot exceed the total number of DoFs at node i; if node i is not transmitting, there is no

DoF consumption for transmissions, and $\sum_{l\in\mathscr{L}^b_{i,\mathrm{Out}}} z^b(l) = 0$. By introducing a large constant M, which is an upper bound of $\left[\left(\sum_{p\in\tilde{\mathscr{I}}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{In}}}\tilde{z}^b(\tilde{l})\right) + \sum_{j\in\mathscr{I}_i}\left(\theta^b_{j,i}\cdot\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)\right)\right]$ (e.g., $M = \sum_{j\in\mathscr{I}_i} A_j + \sum_{p\in\tilde{I}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{In}}}\tilde{z}^b(\tilde{l})$), we can use the following two sets of constraints to replace (21):

$$x^b_i \le \sum_{l\in\mathscr{L}^b_{i,\mathrm{Out}}} z^b(l) + \left(\sum_{p\in\tilde{\mathscr{I}}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{In}}}\tilde{z}^b(\tilde{l})\right) + \sum_{j\in\mathscr{I}_i}\left(\theta^b_{j,i}\cdot\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)\right) \le A_i x^b_i + (1-x^b_i)M, \tag{22}$$

$$\sum_{l\in\mathscr{L}^b_{i,\mathrm{Out}}} z^b(l) \le x^b_i A_i. \tag{23}$$

We can see that when node i is transmitting (i.e., $x^b_i = 1$), (22) becomes (21) and (23) holds trivially; if node i is not transmitting (i.e., $x^b_i = 0$), (23) and (21) are equivalent, which is $\sum_{l\in\mathscr{L}^b_{i,\mathrm{Out}}} z^b(l) = 0$, and (22) holds trivially.

Since (22) has a nonlinear term $\left(\theta^b_{j,i}\cdot\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)\right)$, we can use *reformulation-linearization technique* (RLT) [15] to reformulate this nonlinear term as several linear terms. We define a new variable $\lambda^b_{j,i}$ as follows:

$$\lambda^b_{j,i} = \theta^b_{j,i}\cdot\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)\,, \qquad (i\in\mathscr{S}, j\in\mathscr{I}_i, b\in\mathscr{B}).$$

For binary variable $\theta^b_{j,i}$, we have the following related constraints: $\theta^b_{j,i} \ge 0, (1-\theta^b_{j,i}) \ge 0$. For $\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)$, we have $\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k) \ge 0$ and $A_j - \sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k) \ge 0$. We can multiply each constraint involving $\theta^b_{j,i}$ by one of the two constraints involving $\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)$, replacing the product term $\left(\theta^b_{j,i}\cdot\sum^{\mathrm{Tx}(k)\neq i}_{k\in\mathscr{L}^b_{j,\mathrm{In}}} z^b(k)\right)$ with a new variable $\lambda^b_{j,i}$. Then (22) can be replaced by the following linear constraints:

$$\begin{aligned} x^b_i &\le \sum_{l\in\mathscr{L}^b_{i,\mathrm{Out}}} z^b(l) + \left(\sum_{p\in\tilde{\mathscr{I}}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{In}}}\tilde{z}^b(\tilde{l})\right) + \sum_{j\in\mathscr{I}_i}\lambda^b_{j,i} \\ &\le A_i x^b_i + (1-x^b_i)M \quad (i\in\mathscr{S}, b\in\mathscr{B}), \end{aligned} \tag{24}$$

$$\lambda_{j,i}^{b} \geq 0 \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{25}$$

$$\lambda_{j,i}^{b} \leq \sum_{k \in \mathscr{L}_{j,\mathrm{In}}^{b}}^{\mathrm{Tx}(k) \neq i} z^{b}(k) \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{26}$$

$$\lambda_{j,i}^{b} \leq A_j \cdot \theta_{j,i}^{b} \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{27}$$

$$\lambda_{j,i}^{b} \geq A_j \cdot \theta_{j,i}^{b} - A_j + \sum_{k \in \mathscr{L}_{j,\mathrm{In}}^{b}}^{\mathrm{Tx}(k) \neq i} z^{b}(k) \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}). \tag{28}$$

DoF Allocation at a Secondary Receiver. At a secondary receiver, it needs to expend DoFs for SM, for IC from primary transmitters, and for IC from other secondary transmitters. For a primary node $p \in \mathscr{P}$, denote $\tilde{\mathscr{L}}_{p,\mathrm{Out}}^{b}$ as the set of outgoing primary links. Following the same token as our discussion for a secondary transmitter, we can put all DoF consumption at a secondary receiver as follows:

$$y_i^b \leq \sum_{k \in \mathscr{L}_{i,\mathrm{In}}^{b}} z^{b}(k) + \left(\sum_{p \in \tilde{\mathscr{I}}_i} \sum_{\tilde{l} \in \tilde{\mathscr{L}}_{p,\mathrm{Out}}^{b}} \tilde{z}^{b}(\tilde{l}) \right) + \sum_{j \in \mathscr{I}_i} \left(\theta_{j,i}^{b} \cdot \sum_{l \in \mathscr{L}_{j,\mathrm{Out}}^{b}}^{\mathrm{Rx}(l) \neq i} z^{b}(l) \right) \leq A_i y_i^b + (1 - y_i^b) N, \tag{29}$$

$$\sum_{k \in \mathscr{L}_{i,\mathrm{In}}^{b}} z^{b}(k) \leq y_i^b A_i, \tag{30}$$

where $\sum_{k \in \mathscr{L}_{i,\mathrm{In}}^{b}} z^{b}(k)$ represents the number of DoFs used for SM, $\left(\sum_{p \in \tilde{\mathscr{I}}_i} \sum_{\tilde{l} \in \tilde{\mathscr{L}}_{p,\mathrm{Out}}^{b}} \tilde{z}^{b}(\tilde{l}) \right)$ represents the number of DoFs used for suppressing interference from primary transmitters, and $\sum_{j \in \mathscr{I}_i} \left(\theta_{j,i}^{b} \cdot \sum_{l \in \mathscr{L}_{j,\mathrm{Out}}^{b}}^{\mathrm{Rx}(l) \neq i} z^{b}(l) \right)$ represents the number of DoFs consumed for canceling interference from other secondary transmitters, and N represents a large constant, and $\mathrm{Rx}(l)$ represents the receiver of link l.

Again, we can use RLT to linearize the nonlinear term $\left(\theta_{j,i}^{b} \cdot \sum_{l \in \mathscr{L}_{j,\mathrm{Out}}^{b}}^{\mathrm{Rx}(l) \neq i} z^{b}(l) \right)$ in (29). Denote $\mu_{j,i}^{b}$ as $\left(\theta_{j,i}^{b} \cdot \sum_{l \in \mathscr{L}_{j,\mathrm{Out}}^{b}}^{\mathrm{Rx}(l) \neq i} z^{b}(l) \right)$. Then (29) can be replaced by the following linear constraints:

$$y_i^b \leq \sum_{k \in \mathscr{L}_{i,\mathrm{In}}^{b}} z^{b}(k) + \left(\sum_{p \in \tilde{\mathscr{I}}_i} \sum_{\tilde{l} \in \mathscr{L}_{p,\mathrm{Out}}^{b}} \tilde{z}^{b}(\tilde{l}) \right) + \sum_{j \in \mathscr{I}_i} \mu_{j,i}^{b} \leq A_i y_i^b + (1 - y_i^b) N \qquad (i \in \mathscr{S}, b \in \mathscr{B}), \tag{31}$$

$$\mu_{j,i}^{b} \geq 0 \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{32}$$

$$\mu_{j,i}^{b} \leq \sum_{l \in \mathscr{L}_{j,\text{Out}}^{b}}^{\text{Rx}(l) \neq i} z^{b}(l) \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{33}$$

$$\mu_{j,i}^{b} \leq A_j \cdot \theta_{j,i}^{b} \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}), \tag{34}$$

$$\mu_{j,i}^{b} \geq A_j \cdot \theta_{j,i}^{b} - A_j + \sum_{l \in \mathscr{L}_{j,\text{Out}}^{b}}^{\text{Rx}(l) \neq i} z^{b}(l) \qquad (i \in \mathscr{S}, j \in \mathscr{I}_i, b \in \mathscr{B}). \tag{35}$$

Link Capacity Constraint. For link $l \in \mathscr{L}$, we have the following link capacity constraint:

$$\sum_{f \in \mathscr{F}}^{f \text{ traversing } l} r(f) \leq c \cdot \sum_{b \in \mathscr{B}} z^{b}(l) \qquad (l \in \mathscr{L}), \tag{36}$$

where c is the data rate carried by a data stream.

Formulation

Based on the above mathematical model, various problems can be formulated. In this chapter, we study a throughput optimization problem with the objective of maximizing the minimum session rate among all secondary sessions. The optimization problem can be written as follows:

OPT
max $r_{\min}$
s.t $r_{\min} \leq r(f) \qquad (f \in \mathscr{F})$;
Half-duplex constraints: (20);
Node ordering constraints: (2);
Transmitter DoF constraints: (23), (22), (24), (25), (26), (27), and (28);
Receiver DoF constraints: (30), (31), (32), (33), (34), and (35);
Link capacity constraints: (36).

In this formulation, $r_{\min}, r(f), x_i^b, y_i^b, z^b(l), \pi_i^b, \lambda_{j,i}^b, \mu_{j,i}^b$ and $\theta_{j,i}^b$ are optimization variables, and $A_i, M, N, \tilde{z}^b(\tilde{l})$ and c are given constants. This optimization problem is in the form of a mixed-integer linear program (MILP), which is NP-hard in general. The computation complexity of MILP is exponential but can be solved efficiently by CPLEX solver.

A Case Study

The goal of this section is twofold. First, we want to use numerical results to demonstrate how a secondary network can operate simultaneously with the primary network while being transparent to the primary network. Second, we will show the tremendous benefits in terms of throughput gain under the transparent-coexistent paradigm.

Consider a 20-node primary network and a 30-node secondary network randomly deployed in the same 100×100 area (see Fig. 6). For the ease of scalability and generality, we normalize all units for distance, bandwidth, and throughput with appropriate dimensions. As discussed in section "Mathematical Modeling", the primary nodes are traditional single-antenna device, while the secondary nodes are equipped with MIMO. We assume there are 4 antennas for transmission or reception on each secondary node. Further, we assume all nodes' transmission range and interference range are 30 and 50, respectively, on all channels. There are $|\mathscr{B}| = 10$ channels available in the network. For simplicity, we assume the achievable rate of 1 DoF on a channel is 1 unit. In this case study, we assume there are three active sessions in the primary network and four active sessions in the secondary network and that minimum-hop routing is used for each primary and secondary session. Further, the channel allocation on each hop for a primary session is known a priori (see Fig. 6).

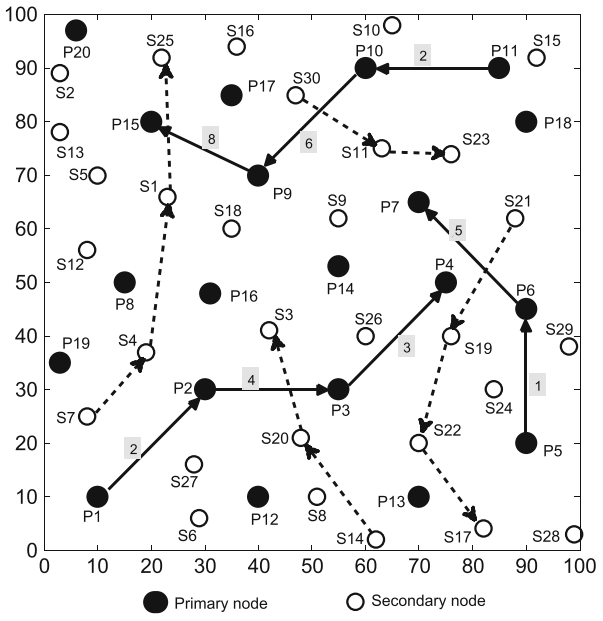

Fig. 6 Active sessons in the primary and secondary networks

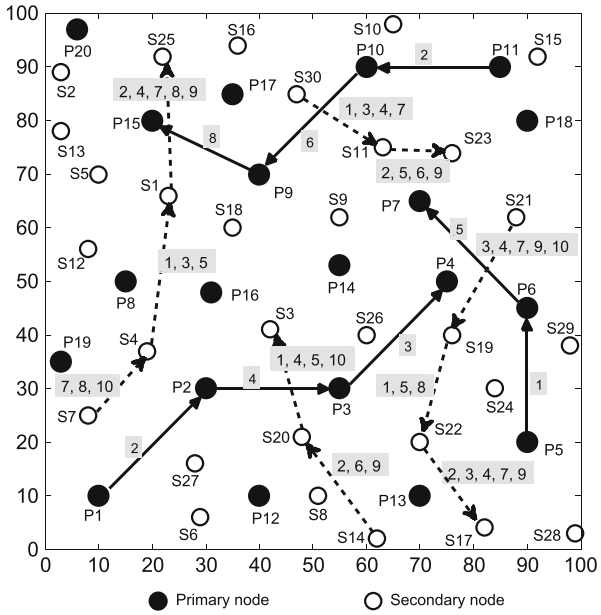

Fig. 7 Channel allocation on each link for the secondary sessions. Channel allocation on each link for the primary sessions is given a priori

For this network setting for the primary and secondary networks, the obtained objective value is 7. The channel allocation on each link for each secondary session is shown in Fig. 7. The details of DoFs used for SM on each channel at each link are shown in Table 7. The achievable rate (i.e., total number of DoFs used for SM) on a link is also shown in this table.

To see how links in the primary and secondary networks can be active in the same channel at the same time, consider channel 2 in Fig. 7. For channel 2, it is active on $P_1 \rightarrow P_2$ and $P_{11} \rightarrow P_{10}$ in the primary network and $S_{14} \rightarrow S_{20}$, $S_{22} \rightarrow S_{17}$, $S_1 \rightarrow S_{25}$ and $S_{11} \rightarrow S_{23}$ in the secondary network. The interference relationships among these 6 links are shown in Fig. 8, where the dotted arrow lines show the interference relationships among them. The 2 primary links $P_1 \rightarrow P_2$ and $P_{11} \rightarrow P_{10}$ do not interfere with each other as the receiver of each link is outside the interference range of the other link's transmitter. But each of these two primary links is within the interference range of its neighboring secondary links. Now consider link $P_1 \rightarrow P_2$:

- To cancel interference from secondary nodes (S_1, S_{14}, and S_{22}) to primary node P_2, secondary transmitters S_1, S_{14}, and S_{22} use 1 DoF to cancel their interference to primary receiver P_2. Consequently, the transmissions on $S_1 \rightarrow S_{25}$, $S_{14} \rightarrow S_{20}$, and $S_{22} \rightarrow S_{17}$ will be transparent to primary node P_2.

Table 7 Channel allocation on each link, DoF allocation on each channel for SM, and achievable data streams on each link for the secondary sessions

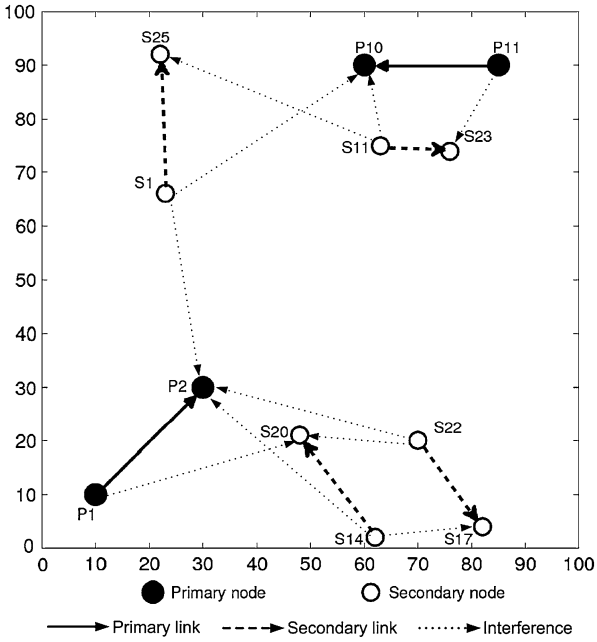

Fig. 8 Illustration of interference relationships among the primary and secondary links on channel 2 in the case study

- To cancel interference from primary node P_1 to secondary receive node S_{20}, S_{20} uses 1 DoF to cancel this interference.
- Among the secondary links, $S_{14} \rightarrow S_{20}$ and $S_{22} \rightarrow S_{17}$ interfere with each other since the receiver of each link falls within the interference range of the transmitter of the other link. To cancel its interference to S_{17}, transmitter S_{14} uses 1 DoF to cancel this interference. On the other hand, to cancel the interference from S_{22}, receiver S_{20} uses 1 DoF to cancel this interference. After IC, nodes S_{14} and S_{20} can use the remaining 2 DoFs for SM (on both transmitter and receiver sides), while nodes S_{22} and S_{17} can only use 1 DoF for SM to meet IC constraints (24) and (31).

The discussion for primary link $P_{11} \rightarrow P_{10}$ is similar and is omitted to conserve space. In addition to channel 2, other channels that exhibit transparent coexistence between the primary and secondary links include channels 1, 3, 4, 5, 6, and 8.

Comparison to Interference-Avoidance Paradigm To see the benefits of transparent-coexistence paradigm, we compare to the interference-avoidance paradigm. Under the interference-avoidance paradigm, a secondary node is not allowed to transmit (receive) on a channel when a nearby primary receiver (transmitter) is using the same channel. Therefore, the set of available channels

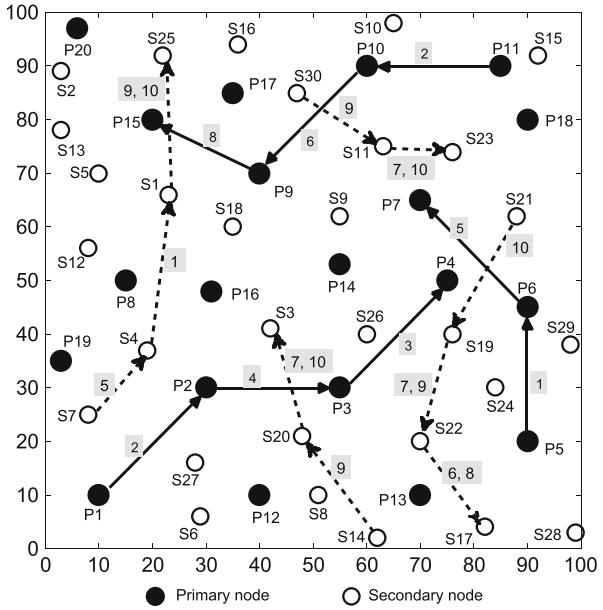

Fig. 9 Channel allocation on each link under the interference-avoidance paradigm

that can be used for secondary nodes is smaller. The problem formulation for this paradigm is simpler (although somewhat similar) than OPT and was presented in section "Mathematical Modeling". In particular, we can remove the second term ($\sum_{p\in\tilde{\mathscr{I}}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{In}}}\tilde{z}^b(\tilde{l})$ and $\sum_{p\in\tilde{\mathscr{I}}_i}\sum_{\tilde{l}\in\tilde{\mathscr{L}}^b_{p,\mathrm{Out}}}\tilde{z}^b(\tilde{l})$) in constraints (24) and (31) in OPT that are used for secondary nodes to cancel interference to/from the primary nodes.

Following the same setting as in the case study above, we solve the above optimization problem under the interference-avoidance paradigm. The obtained objective value is 3 (compared to 7 in transparent-coexistence paradigm). The channel allocation on each link for each secondary session is shown in Fig. 9. Comparing Figs. 7 with 9, we find that the set of channels used on each secondary link under interference-avoidance paradigm is smaller than that under transparent-coexistence paradigm.

Summary and Future Directions

In this chapter, we explore MIMO-empowered CR in multi-hop networks for efficient spectrum sharing. Specially, we study joint optimization of CR and MIMO under both interweave and underlay paradigms in multi-hop ad hoc

network environment. In the interweave paradigm, by exploiting CR's behavior at channel level and MIMO's capability within a channel, we showed that we can have much bigger design space to mitigate interference in the network. In the underlay paradigm, by employing the MIMO IC capability, we can achieve simultaneous transmission of primary and secondary networks in the same channel. Under both paradigms, we offer the systematic mathematical modeling, problem formulation, and performance evaluation. The extensive simulation results show that the MIMO-empowered secondary networks offer significant improvement in spectrum efficiency and throughput performance.

Much work remains to be done to transition the ideas in this paper into reality. In particular, the focus of this paper has been on exploring performance gain under idealized network setting (by ignoring many details that may arise from practical operations). We briefly discuss some of the practical issues that must be addressed to apply the MIMO-empowered CR in interweave and underlay paradigms in the real world. First, to perform IC, we assume each secondary node could obtain the accurate CSI based on channel reciprocity. But in reality, the communication channel not only consists of the physical channel but also the antennas, RF mixers, filters, A/D converters, etc., which are not necessarily identical on all the nodes. Therefore, complex calibration among the nodes is needed to achieve channel reciprocity. Such calibration is not a simple task even for a pair of transmitter and receiver and certainly is more complicated among a network of nodes. Second, zero-forcing based IC may not be perfect even if we have perfect CSI. A consequence of non-perfect IC is interference leakage, which is undesirable for both primary and secondary receivers. How to mitigate such interference leakage to a minimal acceptable level should be a key consideration when deploying MIMO-empowered CR technique into secondary network for real applications. Third, the IC and DoF allocation algorithm that we designed for the secondary network is a centralized one. Such a centralized solution serves our purpose of introducing new concepts. It bears similar pros and cons of other centralized algorithm for a wireless network. If a centralized solution is adopted in practice, those issues must be carefully addressed. On the other hand, if a distributed solution is desired, then a different set of issues need to be addressed. These issues include partial network knowledge, limited information sharing, communication overheard, and ensuring IC feasibility at each secondary node, among others. Regardless centralized or distributed solution, flow dynamics (new session initiation, existing session termination) will add additional complexity on information update and algorithm execution. Clearly, there is a large landscape for further research on these practical operation issues. We expect to see more follow-up research in this area in the near future.

(CRNs). This chapter considers a CRN with multiple primary users (PUs) and multiple secondary users (SUs) and presents two cooperative spectrum sensing and access (CSSA) schemes. The first CSSA scheme allows each SU to sense one channel and is formulated as a hedonic coalition formation game, where each coalition is composed of the SUs that sense on the same channel. The value function of each coalition and the utility function take into account both the sensing accuracy and the energy consumption. The algorithms for decision node selection in each coalition and SU decision-making are proposed to obtain a final network partition, which is proved to be both Nash stable and individually stable. This chapter then focuses on a more general scenario, where each SU can simultaneously sense multiple channels based on its traffic demand. The traffic demand-based CSSA scheme is formulated as a nontransferable utility (NTU) overlapping coalitional game, where each SU implements a cooperation strategy based on its expected payoff. Two algorithms, namely overlapping coalition formation (OCF) and sequential coalition formation (SCF), are proposed to obtain a coalition structure. The OCF algorithm guarantees the stability of the coalition structure, while the SCF algorithm reduces the computational complexity and information exchange. Simulation results show that the proposed algorithms significantly enhance the network throughput.

Introduction

Driven by the rapidly increasing number of connected devices and the popularity of data intensive applications, the global mobile data traffic explosion is expected to continue according to Cisco's forecast [1]. Due to the scarcity of the spectrum resources, the radio spectrum should be efficiently utilized to meet the huge amount of data traffic demand. However, the scarce spectrum is assigned to the licensed users by the Federal Communications Commission (FCC) over a long period of time. Such a static spectrum allocation strategy leads to a large portion of the assigned spectrum being underutilized [2]. This motivates the concept of cognitive radio (CR), which allows the unlicensed users to dynamically and opportunistically access the temporarily unused licensed spectrum that has been allocated to the licensed users.

The FCC defines the CR as follows: "Cognitive radio: A radio or system that senses its operational electromagnetic environment and can dynamically and autonomously adjust its radio operating parameters to modify system operation, such as maximize throughput, mitigate interference, facilitate interoperability, access secondary markets." [3]. Based on this definition, in order to enhance the

spectrum efficiency, a CR user should have the capability to monitor the licensed spectrum and accurately identify the temporarily unoccupied spectrum.

A cognitive radio network (CRN) consists of a primary network and a secondary network. The users of the primary and secondary networks are referred to as the primary users (PUs) and secondary users (SUs), respectively. Generally, the SUs can operate on the licensed spectrum using either spectrum overlay or spectrum underlay. In particular, in an overlay system, the SUs are only allowed to utilize the unoccupied spectrum. On the other hand, spectrum underlay allows the SUs to operate on the occupied spectrum under the condition that the SUs do not cause harmful interference to the PUs.

In order to protect the transmissions of the PUs, local spectrum sensing should be performed by each SU to detect the availability of the spectrum within its operating range before accessing it. However, the local spectrum sensing is susceptible to sensing errors due to shadowing, path loss, or receiver uncertainty [4]. In order to enhance the performance of spectrum sensing, multiple SUs can sense the spectrum cooperatively to exploit the spatial diversity from the observations of spatially located SUs [4–6]. In centralized cooperative spectrum sensing, a central unit is required to collect the sensing results of the cooperative SUs. Based on the received sensing results, the central unit makes the final decision on the availability of the sensed spectrum and sends the final decision to all SUs. After that, the available channels are shared among the SUs that participate in spectrum sensing.

Cooperative spectrum sensing has the potential to enhance the sensing accuracy and network throughput, at the cost of consuming more energy for spectrum sensing. Note that a CRN generally consists of multiple PUs (i.e., multiple licensed channels) and multiple SUs. Hence, it is important to determine the channel for each SU to sense and access while taking into account the sensing accuracy, throughput, and energy efficiency. Many cooperative spectrum sensing strategies have been proposed to achieve high network throughput or improve energy efficiency, as discussed in the following.

- Enhancing network throughput: the SUs are offered the opportunities to access the licensed channel by participating in spectrum sensing. There exists a trade-off between the sensing performance and the network throughput [6]. By optimizing the sensing parameters (e.g., the detection threshold and the sensing duration), the efficient cooperative spectrum sensing scheduling methods can be developed to balance the sensing performance and the network throughput [7, 8]. An adaptive and cooperative spectrum sensing method is proposed in [9], and the impact of cooperative spectrum sensing on the performance of the proposed optimal spectrum sensing scheme is studied. A periodic sensing opportunistic spectrum access scheme is proposed in [10], where the constrained Markov decision processes are utilized to maximize the channel utilization.
- Enhancing energy efficiency: performing spectrum sensing consumes energy, and more SUs participating in spectrum sensing leads to more energy consumption. By allocating spectrum resources to the SUs based on the channel states and the traffic demand, developing efficient scheduling algorithms to assign available

channels to different SUs can improve the energy efficiency [11,12]. The system energy efficiency can also be maximized by optimizing the sensing time, the energy detection threshold, and the number of the SUs [13]. In addition, the constraints of both the transmission power and the sensing performance should be considered to protect the transmission of the PUs [14,15].

Game theory has been widely applied in CRNs to study the cooperative spectrum sensing. The problem of cooperative spectrum sensing in CRNs with multiple channels can be formulated as an evolutionary game, where each SU makes its own decision on whether to sense the spectrum, and an entropy-based coalition formation algorithm is proposed to select the channel for the SUs [16]. To achieve better performance of cooperative sensing and efficiently allocate the spectrum resources among the SUs, coalitional game is also applied in the cooperation strategy design [17], in which Bayesian learning is used to estimate the channel states and Markov chain decision process is applied to make channel access decisions for the SUs. In addition, there exists a trade-off between spectrum sensing and spectrum access [18]. Such a problem can be formulated as a disjoint coalition formation (DCF) game, where each SU joins one coalition to maximize the utility. Note that a collection of coalitions is referred to as a coalition structure. The SUs can serve as cooperative relays of the PUs and obtain channel access in return. It is shown in [19] that the SUs can form the grand coalition structure to maximize the system utility.

Although many studies have been conducted for cooperative spectrum sensing, there are still several issues that should be addressed.

- The traffic demand of the SUs should be taken into account when investigating the cooperative spectrum sensing and channel access in CRNs. Most of the existing works assume that the SUs always have data to transmit, and the channels are always fully utilized if they are assigned to the SUs. However, in practice, the traffic demand of the SUs may change over time, and the amount of data to be transmitted depends on the applications. For instance, an SU that monitors the environment and aims to report the temperature changes does not transmit periodically, while an SU with a video streaming application has higher traffic demand than an SU running a best-effort application. Although the traffic demand of the SUs are considered in [11,20], they focus on spectrum resource allocation rather than spectrum sensing. Besides, they aim to maximize the aggregate system utility instead of developing a cooperation strategy from the perspective of each individual SU.
- Both the energy efficiency and the traffic demand should be taken into account when each SU makes its own decision on whether to participate in the cooperative spectrum sensing. Most of the existing works assume that all SUs in the system participate in cooperative spectrum sensing as in [12,21,22]. However, an energy-constrained SU having no data to transmit within a certain amount of time may prefer to stay in idle to reduce the energy consumption.
- By allowing each SU to join multiple coalitions, each SU can contribute to spectrum sensing for multiple channels at the same time so as to increase the probability of channel access. Most of the existing works assume that each SU

can join only one coalition to perform cooperative spectrum sensing, formulate the problem as a DCF game, and find a nonoverlapping coalition structure. Such an assumption restricts the cooperation opportunities of the SUs. By exploiting the advantage of simultaneously sensing multiple channels, the overlapping coalitional game theory is required. One exception is [23], in which the problem of cooperative spectrum sensing is formulated as an overlapping coalitional game, and a distributed algorithm is proposed to find a stable coalition structure. However, the spectrum resource allocation and additional energy consumption due to joining coalitions are not taken into account.

In the following two sections, two coalitional games for cooperative spectrum sensing and access in CRNs are described to address the aforementioned issues. Section "Hedonic Coalition Game for Cooperative Spectrum Sensing and Channel Access" presents a cooperative spectrum sensing and access (CSSA) scheme for the SUs and formulates the multichannel CSSA problem as a hedonic coalition formation game. The algorithms for decision node selection and SU decision-making are proposed. Section "Overlapping Coalitional Game for Cooperative Spectrum Sensing and Access" proposes a traffic demand-based cooperation strategy for the SUs and formulates it as a nontransferable utility (NTU) overlapping coalitional game. The overlapping coalition formation (OCF) and sequential coalition formation (SCF) algorithms are proposed to solve the problem.

Hedonic Coalition Game for Cooperative Spectrum Sensing and Channel Access

System Model and CSSA Scheme

Consider a CRN consisting of one base station, $|M|$ PUs, and $|N|$ secondary transmitter-receiver (ST-SR) pairs. As the ST performs spectrum sensing and data transmission, the terms SU and ST are used interchangeably. The sets of PUs and STs are denoted as M and N, respectively. Each $PU_i, i \in M$ transmits data to the base station through its own licensed channel with bandwidth B_i. Hence, there are $|M|$ nonoverlapped channels in the system. On the other hand, each ST_j is assumed to always have data to transmit and seeks to exploit possible transmission opportunities over one of the $|M|$ licensed channels.

Consider a frame structure for periodic spectrum sensing, where each time frame has the same frame duration, denoted as T. Each time frame is composed of one sensing subframe and one data transmission subframe. All SUs have the same spectrum sensing duration, denoted as $\delta \in (0, T]$. Hence, the data transmission duration is $T - \delta$. Note that the time duration required for sensing results collection and data fusion is negligible as it is much shorter than the time required for spectrum sensing and data transmission. Each $ST_j, j \in N$ samples the received signal intended for the PU with sampling frequency f_s. Both δ and T are assumed to be a multiple of $1/f_s$.

Each SU senses one channel in each time frame and determines the probabilities of detection and false alarm. The hypotheses that $PU_i, i \in M$ is active and inactive are denoted as $H_{1,i}$ and $H_{0,i}$, respectively. The probability of detection is the probability that the presence of PU_i is correctly detected under hypothesis $H_{1,i}$ (i.e., a busy channel is detected as busy), while the probability of false alarm is the probability of falsely declaring the presence of the primary signal under hypothesis $H_{0,i}$ (i.e., an idle channel is detected as busy).

The noise in the channel of $PU_i, i \in M$ is assumed to be an independent and identically distributed (i.i.d.) random variable with zero mean and variance $\sigma_{n,i}^2 = N_0 B_i$, where N_0 denotes the power spectral density. The signals of the primary users are i.i.d. random variables with zero mean and variance $\sigma_{s,i}^2, i \in M$. Hence, the received signal-to-noise ratio (SNR) of PU_i, $i \in M$ measured at ST_j, $j \in N$ under the hypothesis $H_{1,i}$ is $\gamma_{i,j} = |g_{i,j}|^2 \sigma_{s,i}^2 / \sigma_{n,i}^2$, where $|g_{i,j}|$ denotes the average channel gain of the link between PU_i and ST_j in channel i. Complex phase shift keying (PSK) modulated primary signals and circularly symmetric complex Gaussian (CSCG) noise are considered. By using energy detection [4, 24], the probability of false alarm [6] in channel $i \in M$ by ST_j under hypothesis $H_{0,i}$ is given by

$$\begin{aligned} P_{f,i,j}(\varepsilon, \delta, \sigma_{n,i}^2) &= \Pr(y_{j,i} > \varepsilon \mid H_{0,i}) \\ &= Q\left(\left(\frac{\varepsilon}{\sigma_{n,i}^2} - 1\right)\sqrt{\delta f_s}\right), \end{aligned} \tag{1}$$

where ε denotes the detection threshold for all STs, $y_{j,i}$ denotes the test statistic for the energy detector of ST_j in channel i, and Q denotes the complementary distribution function of the standard Gaussian. If all PUs have the same bandwidth, then $P_{f,i,j}(\varepsilon, \delta, \sigma_{n,i}^2)$ are the same with $\forall\, i \in M$, $\forall\, j \in N$. On the other hand, the probability of detection in channel $i \in M$ by ST_j under hypothesis $H_{1,i}$ is given by

$$\begin{aligned} P_{d,i,j}(\varepsilon, \delta, \sigma_{n,i}^2, \gamma_{i,j}) &= \Pr(y_{j,i} > \varepsilon \mid H_{1,i}) \\ &= Q\left(\left(\frac{\varepsilon}{\sigma_{n,i}^2} - \gamma_{i,j} - 1\right)\sqrt{\frac{\delta f_s}{2\gamma_{i,j} + 1}}\right). \end{aligned} \tag{2}$$

The performance of local spectrum sensing can be degraded by many factors, including the hidden node problem, deep fading, and shadowing [4]. Cooperative spectrum sensing as an effective technique for realizing spatial diversity has been proposed to enhance the detection performance. In particular, each SU senses the channel independently and reports the sensing result to the decision node (DN) when sensing time δ expires. The selection of DN for each channel will be presented in the next subsection. Based on the sensing results from the SUs that sense channel i, DN_i determines the status (i.e., busy or idle) of channel i.

The DN makes the spectrum sensing decision based on the k-out-of-n rule [25]. In particular, a busy channel is determined if k or more SUs individually detect the

presence of primary activity. For $k = 1$, $k = n$, and $k \geq n/2$, k-out-of-n rule becomes the "or" rule, "and" rule, and majority rule, respectively [4]. The local decisions made by the SUs in the same channel are assumed to be independent. Let S_i denote the set of SUs sensing channel i. As each SU can sense only one channel in each time frame, the constraints $S_i \subseteq N$, $\forall\, i \in M$, $\bigcup_{i \in M} S_i = N$, and $S_i \cap S_l = \emptyset$, $\forall\, i, l \in M, i \neq l$ should be satisfied. When $k = 1$, the probability of false alarm under hypothesis $H_{0,i}$ and the probability of detection under hypothesis $H_{1,i}$ in channel $i \in M$ can, respectively, be expressed as

$$P_{f,i} = 1 - \prod_{j \in S_i} \left(1 - P_{f,i,j}\left(\varepsilon,\, \delta,\, \sigma_{n,i}^2\right)\right), \tag{3}$$

$$P_{d,i} = 1 - \prod_{j \in S_i} \left(1 - P_{d,i,j}\left(\varepsilon,\, \delta,\, \sigma_{n,i}^2,\, \gamma_{i,j}\right)\right). \tag{4}$$

For channel $i \in M$, the probabilities that PU_i is active and silent are denoted as $P_{H_{1,i}}$ and $P_{H_{0,i}}$, respectively, and $P_{H_{1,i}} + P_{H_{0,i}} = 1$. If DN_i declares that channel i is busy, then ST_j, $\forall\, j \in S_i$ cannot transmit during the data transmission subframe. On the other hand, if DN_i declares that channel i is idle, then each ST_j, $j \in S_i$ can access channel i with equal probability (i.e., $1/|S_i|$) and only one SU in S_i can be selected to transmit data, where $|S_i|$ denotes the number of the SUs sensing channel i. If channel i is declared to be idle and PU_i is actually silent, then the secondary data transmission in channel i is successful. However, if channel i is declared to be idle but PU_i is actually active (i.e., a missed detection), then the secondary data transmission in channel i interferes with the transmission of PU_i. In this case, if the collision is detected by the base station, then the SUs will be charged $\varphi > 0$ by the base station as a penalty. The value of φ can be selected to map the level of the performance degradation of the PU to the penalty value of the SUs. Hence, it is important to decide which channel each SU should sense and access so as to optimize the performance.

Hedonic Coalition Formation Game

In this subsection, the multichannel energy-efficient cooperative spectrum sensing and access problem is formulated as a hedonic coalition formation game, in which the switch rule is utilized to decide whether the SUs join or leave a coalition. In addition, the formulated hedonic coalition formation game is proved to always converge to the Nash-stable and individually stable partition.

Value Function and Utility Function

To fully exploit the possible transmission opportunities, each SU should carefully decide which channel to sense and access during each time frame. Both the sensing accuracy and the energy consumption should be considered when making the decisions. In particular, the sensing accuracy affects the amount of data transmitted

by the SUs and the penalty charged for interfering with the PUs' transmissions. The energy consumption of the SUs is a critical criterion for spectrum sensing and data transmission in practice.

There are four scenarios in the proposed CSSA scheme, depending on the activity of the PU_i and the decision of DN_i in channel $i \in M$. The payoff of set S_i is defined as the reward (i.e., the amount of data transmitted by the SUs in S_i) minus the penalty (i.e., the payment charged for interfering with PU_i's transmission) during the data transmission subframe. The payoff, the energy consumption, and the probability that each scenario occurs are discussed as follows:

Scenario 1: PU_i is silent, and the decision made by DN_i is not a false alarm. In this scenario, ST_j, $\forall\, j \in S_i$ transmits data within the data transmission subframe. The transmission rate $R_{j,i}$ of ST_j can be expressed as [26]

$$R_{j,i} = B_i \log_2 \left(1 + |h_{j,i}|^2 \frac{P_t}{\sigma_{n,i}^2}\right), \tag{5}$$

where P_t denotes the signal transmission power and $|h_{j,i}|$ denotes the average channel gain of the link between ST-SR pairs j in channel i.

In this scenario, the payoff of set S_i is $v_{0|0,D}(S_i) = \frac{\sum_{j\in S_i} R_{j,i}}{|S_i|}(T-\delta)$, as the transmission of the SUs is successful and the penalty is zero. By denoting the sensing power of ST_j, $\forall\, j \in N$ as P_s, the energy consumption of set S_i is given by $v_{0|0,E}(S_i) = P_s|S_i|\delta + P_t(T-\delta)$, where $P_s|S_i|\delta$ and $P_t(T-\delta)$ represent the energy consumption due to spectrum sensing and data transmission, respectively. The probability that this scenario occurs is $P_{0|0,i} = P_{H_{0,i}}(1 - P_{f,i})$.

Scenario 2: PU_i is silent, and the decision made by DN_i is a false alarm. In this scenario, as no SU transmits during the data transmission subframe and interfere with the PU, the payoff of set S_i is $v_{1|0,D}(S_i) = 0$, and the energy consumption of set S_i is $v_{1|0,E}(S_i) = P_s|S_i|\delta$. The probability that this scenario occurs is $P_{1|0,i} = P_{H_{0,i}} P_{f,i}$.

Scenario 3: PU_i is active, and DN_i detects the presence of PU_i. In this scenario, no SU transmits data during the data transmission subframe. The payoff of set S_i is $v_{1|1,D}(S_i) = 0$, as both the reward and the penalty are zero. In addition, the energy consumption of set S_i is $v_{1|1,E}(S_i) = P_s|S_i|\delta$, and the probability that this scenario occurs is $P_{1|1,i} = P_{H_{1,i}} P_{d,i}$.

Scenario 4: PU_i is active, and DN_i fails to detect the presence of PU_i. In this scenario, both PU_i and $ST_j, j \in S_i$ transmit data during the data transmission subframe. Due to co-channel interference, it is assumed that both transmitted packets are corrupted. The payoff of set S_i is $v_{0|1,D}(S_i) = -\varphi(T-\delta)$, where the reward is zero. The energy consumption of set S_i is $v_{0|1,E}(S_i) = P_s|S_i|\delta + P_t(T-\delta)$. The probability that this scenario occurs is $P_{0|1,i} = P_{H_{1,i}}(1 - P_{d,i})$.

Based on the above discussions, the expected payoff for set S_i over each time frame is given by

$$\begin{aligned} v_D(S_i) &= \sum_{a=0}^{1}\sum_{b=0}^{1} P_{a|b,i}\, v_{a|b,D}(S_i) \\ &= P_{0|0,i}\frac{\sum\limits_{j\in S_i} R_{j,i}}{|S_i|}(T-\delta) - P_{0|1,i}\varphi(T-\delta). \end{aligned} \tag{6}$$

The expected energy consumption for set S_i in each time frame of duration T is

$$\begin{aligned} v_E(S_i) &= \sum_{a=0}^{1}\sum_{b=0}^{1} P_{a|b,i}\, v_{a|b,E}(S_i) \\ &= P_s|S_i|\delta + (P_{0|0,i} + P_{0|1,i})P_t(T-\delta). \end{aligned} \tag{7}$$

The value function of set S_i is defined as the ratio of $v_D(S_i)$ to $v_E(S_i)$, which represents the expected payoff per unit of energy consumed in set S_i:

$$\begin{aligned} v(S_i) &= \frac{v_D(S_i)}{v_E(S_i)} \\ &= \frac{P_{0|0,i}\sum_{j\in S_i} R_{j,i}(T-\delta) - |S_i|P_{0|1,i}\varphi(T-\delta)}{|S_i|\big(P_s|S_i|\delta + (P_{0|0,i} + P_{0|1,i})P_t(T-\delta)\big)}. \end{aligned} \tag{8}$$

The trade-off between the energy efficiency and the protection of the PUs' transmission depends on the value of φ. Specifically, when $\varphi = 0$, $v(S_i)$ equals to the energy efficiency (i.e., the expected amount of data transmitted by the SUs divided by the expected energy consumption) of the CSSA scheme. When φ is large, a higher priority is given to protect the PU from the interference of the SUs. According to (8), the value function takes into account the sensing accuracy by considering the sensing results related to false alarm (i.e., $P_{0|0,i}$ is related to $P_{f,i}$), and detection (i.e., $P_{0|1,i}$ is related to $P_{d,i}$). The value of $v(\emptyset)$ is chosen such that $v(S_i) > v(\emptyset)$, $\forall\, S_i \subseteq N$, and $S_i \neq \emptyset$.

As all SUs that in set S_i perform spectrum sensing have the same probability to access channel i, they receive the same utility. Hence, the utility function of ST_j, $\forall\, j \in S_i$ can be expressed as

$$x_j^{S_i} = \frac{v(S_i)}{|S_i|}. \tag{9}$$

The utility defined in (9) can be used as a performance metric to affect the decision of each SU on which channel to sense and access during each time frame. Note that the utility does not correspond to a physical quantity that can be divided among the SUs in a coalition.

Hedonic Coalition Formation Analysis

In order to formulate the multichannel cooperative spectrum sensing and channel access problem as a coalition formation game with transferable utility (TU) [27], the following basic elements need to be introduced:

- *Players*: the players of the coalition formation game are the $|N|$ SUs (i.e., ST_j, $\forall\ j \in N$).
- *Strategies*: the strategy of each SU is the licensed channel it chooses to sense and access (i.e., ST_j chooses a licensed channel $i \in M$).
- *Utilities*: the utility of each SU depends on which coalition it belongs to, and it is defined in (9) (i.e., the utility of ST_j in coalition S_i is $x_j^{S_i}$).

Based on coalitional game theory, set S_i is referred to as coalition i. Hence, $|M|$ coalitions can be formed in the system, and each SU joins one coalition. By restricting one coalition per channel, different coalitions operate in different nonoverlapping channels. Hence, the SUs of different coalitions do not interfere with each other. The SUs autonomously form coalitions to achieve higher utilities. This game is a hedonic coalition formation game [28], which will be shown later. Before presenting its definition, some basic definitions used in the coalition formation games are introduced as follows.

Definition 1. The set $S = \{S_1, \ldots, S_{|M|}\}$ is a partition (or coalition structure) of N if $S_i \cap S_l = \emptyset$, $\forall\, i, l \in M, i \neq l$ and $\bigcup_{i \in M} S_i = N$.

Definition 2. For any player $j \in N$, a preference relation $\succeq_j$ is defined as a complete, reflexive and transitive binary relation over the set of all coalitions that player j can possibly form [28].

Based on Definition 2, given two coalitions $S_1 \subseteq N$ and $S_2 \subseteq N$, $S_1 \succeq_j S_2$ indicates that player $j \in N$ prefers to be a member of coalition S_1 over to be a member of coalition S_2, or at least, player j prefers both coalitions equally. Similarly, $S_1 \succ_j S_2$ indicates that player j strictly prefers being a member of coalition S_1 over being a member of coalition S_2. The preference function $U_j(S_i)$, $j \in S_i$ is defined as

$$U_j(S_i) = \begin{cases} x_j^{S_i}, & S_i \notin h(j), \\ -\infty, & \text{otherwise}, \end{cases} \tag{10}$$

where $h(j)$ is the history set of ST_j. Note that the preference over different coalitions for ST_j, $\forall\ j \in N$ depends on its utility function defined in (9). The following operation is defined to evaluate the preferences of ST_j, $\forall\ j \in N$:

$$S_1 \succ_j S_2 \Leftrightarrow U_j(S_1) > U_j(S_2), \tag{11}$$

where $S_1 \subseteq N$ and $S_2 \subseteq N$ are any two coalitions containing ST_j.

Based on the above discussions, ST_j, $\forall\ j \in N$ prefers to join a new coalition, which ST_j has never been a member of, if and only if ST_j can obtain a higher utility in this new coalition than ever before. Given the set of players N and a preference relation $\succ_j$ for each player $j \in N$, a hedonic coalition formation game is defined as follows:

Definition 3. A hedonic coalition formation game is a coalitional game that satisfies the following two conditions: (1) The utility of any player depends solely on the members of the coalition to which the player belongs; (2) the coalitions form as a result of the preferences of the players over their possible coalition set. Therefore, a hedonic coalition formation game is defined by the pair $(N, \succ)$, where N is the set of players and $\succ$ is a profile of preferences defined for each player in N.

The formulated game satisfies the conditions of a hedonic coalition formation game. In particular, the utility function of ST_j, $\forall\ j \in S_i$ defined in (9) only depends on the SUs in coalition S_i, $i \in M$, and the preference function of each SU is given in (10). The switch rule for coalition formation is defined as follows.

Definition 4. (Switch rule) Given a partition $S = \{S_1, \ldots, S_{|M|}\}$, ST_j, $j \in S_i$ decides to leave its current coalition S_i and joins another coalition S_l, where $i \neq l$, if and only if $S_l \bigcup \{j\} \succ_j S_i$.

Based on the switch rule, an SU leaves its current coalition and joins another coalition if the new coalition is strictly preferred over the current coalition. Each player makes a selfish decision and moves from the current coalition to a new coalition, regardless the effect of its move on other players. All SUs make decisions to automatically form coalitions based on the switch rule. Hence, the partition of the $(N, \succ)$ hedonic coalition formation game may change in each time frame. The initial partition of the hedonic coalition formation game is denoted as $S^{(0)} = \{S_1^{(0)}, \ldots, S_{|M|}^{(0)}\}$, and the partition at the r-th time frame is denoted as $S^{(r)} = \{S_1^{(r)}, \ldots, S_{|M|}^{(r)}\}$. The history set $h(j)$ of ST_j is defined as follows:

Definition 5. At the r-th time frame, the history set for $ST_j, j \in N$ is given by $h(j) = \{S_{i_0}^{(0)}, \ldots, S_{i_{r-1}}^{(r-1)}\}$, where $i_z \in M$ and $j \in S_{i_z}$ hold at any time frame index $z \in \{0, 1, \ldots, r-1\}$. At the end of the r-th time frame, ST_j will update its history set $h(j)$ by including a new element $S_{i_r}^{(r)}$, where $i_r \in M$ and $j \in S_{i_r}$.

Proposition 1. *If ST_j performs the switch rule in the r-th time frame, in which it leaves its previous coalition S_i (denoted as $S_{i_{r-1}}^{(r-1)}$) and joins another coalition S_l with $i \neq l$, the newly formed coalition $S_l \bigcup \{j\}$ (denoted as $S_{i_r}^{(r)}$) cannot be the same with the previous coalition members in the history set $h(j)$. That is, $S_l \bigcup \{j\} \notin h(j)$ holds before the update of $h(j)$ at the end of the r-th time frame.*

Proof. Please refer to [29].

Before proving that there exists a stable partition in this hedonic coalition formation game, the definitions of Nash-stable and individually stable partitions [30] are presented as follows.

Algorithm 1 Decision node DN_i selection algorithm in channel $i \in M$. The algorithm is executed by ST_j, $\forall\, j \in S_i$

1: **for** iteration $r := 1$ to MAX **do**
2: ST_j broadcasts its measured SNR information $\gamma_{i,j}^{(r)}$ and transmission rate $R_{j,i}$ to other secondary transmitters ST_k, $\forall\, k \in S_i^{(r)} \backslash \{j\}$
3: ST_j receives the measured SNR information $\gamma_{i,k}^{(r)}$ and transmission rate $R_{k,i}$ from other ST_k, $\forall\, k \in S_i^{(r)} \backslash \{j\}$
4: $q := \arg\max_{p \in S_i^{(r)}} \gamma_{i,p}^{(r)}$
5: $DN_i^{(r)} := ST_q$
6: **end for**

Definition 6. A partition $S = \{S_1, \ldots, S_{|M|}\}$ is Nash stable if $\forall\, j \in S_i$ with $\forall\, i \in M$, $S_i \succeq_j S_l \bigcup \{j\}$, $\forall\, l \in M$.

Definition 7. A partition $S = \{S_1, \ldots, S_{|M|}\}$ is individually stable if there does not exist $j \in S_i$ with $i \in M$, and a coalition S_l $(l \neq i)$ such that $S_l \bigcup \{j\} \succ_j S_i$, and $S_l \bigcup \{j\} \succeq_k S_l$ for all $k \in S_l$.

Hence, a coalition partition S is Nash stable if no player has an incentive to move from its current coalition to another coalition (i.e., no player can obtain a higher utility by performing the switch rule). When a partition is Nash stable, it implies that it is individually stable [30] that there does not exist any coalition, where a player strictly prefers to join, while the other players in that coalition do not get hurt by the formation of this new coalition.

Theorem 1. *Starting from any initial partition $S^{(0)}$, all the SUs will always converge to a final partition $S^* = \{S_1^*, \ldots, S_{|M|}^*\}$, which is both Nash stable and individually stable.*

Proof. Please refer to [29].

Note that if the history sets are not used, the partition still converges to stability, but a longer convergence time is required.

Algorithms for Coalition Formation

In this subsection, the implementations of the proposed CSSA scheme and the hedonic coalition formation game are described. Besides, a DN selection algorithm and a coalition formation algorithm based on the switch rule are proposed.

The hedonic coalition formation game has two stages. In stage one, the base station gathers necessary information, including the number of the PUs, the operating frequency, bandwidth B_i of PU_i, $\forall\, i \in M$, the locations of the PUs, the transmit power of the PUs $\sigma_{s,i}^2$, $\forall\, i \in M$, and the channel models. Assuming that the base station does not know exactly when the PUs will be active. The base station sets and broadcasts the initial partition $S^{(0)}$ to all SUs. The initial partition

is set as $S_1^{(0)} = N$ and $S_l^{(0)} = \emptyset$, $\forall\, l \in M \backslash \{1\}$. In stage two, all SUs perform the switch operations until the CRN converges to the final Nash-stable partition S^*. The total number of iterations required to converge is denoted as MAX. Based on Theorem 1, the CRN can always converge to the final Nash-stable partition S^* if the value of MAX is large enough. Note that at each time frame, only one SU can leave its current coalition and move to another coalition to increase its utility. The selection of DN_i, $\forall\, i \in M$ and the switch operations in coalition formation are illustrated in Algorithm 1 and Algorithm 2, respectively. After the final Nash-stable partition S^* is reached, the SUs stay in their current coalitions to sense and access the channels based on the proposed CSSA scheme.

In order to avoid the corruption of the sensing results due to transmission error between ST_j, $j \in S_i$ and DN_i, the SU with the highest detection probability in coalition S_i is selected as DN_i. By selecting the SU with the highest detection probability as the DN, the most reliable sensing result can be directly used in the decision fusion without experiencing any corruption. Hence, the primary data transmission can be protected if PU_i is active. In the r-th iteration of Algorithm 1, ST_j, $\forall\, j \in S_i$ selects $DN_i^{(r)}$ for channel $i \in M$. All SUs in coalition $S_i^{(r)}$ exchange their measured SNR and transmission rate $R_{j,i}$ via a dedicated error-free control channel [31] (lines 2–3). Finally, the SU with the highest measured SNR is selected as $DN_i^{(r)}$ (lines 4–5). As $P_{d,i,j}(\varepsilon, \delta, \sigma_{n,i}^2, \gamma_{i,j})$ is an increasing function of $\gamma_{i,j}$, the following proposition holds.

Proposition 2. *The DN_i selected by Algorithm 1 has the highest detection probability in S_i.*

The r-th iteration of Algorithm 2 consists of two phases: phase one (lines 3–8) and phase two (lines 9–25). In phase one, each SU randomly generates a number (line 4) and broadcasts in the dedicated control channel (lines 6–7). The SU with the largest random number is selected (line 8) to perform the switch operation in phase two. Without the loss of generality, user $ST_j \in S_i^{(r)}$ and channel $\alpha_j \in M$, where $\alpha_j \neq i$ (line 5), are assumed to be selected. In phase two, ST_j is temporarily switched from its current coalition $S_i^{(r)}$ to another coalition $S_{\alpha_j}^{(r)}$ (lines 11–13). Subsequently, ST_j obtains the information of $S_{\alpha_j}^{(r)}$ from $DN_{\alpha_j}^{(r)}$, which include data rates R_{k,α_j} ($\forall\, k \in S_{\alpha_j}^{(r)}$), coalition size $|S_{\alpha_j}^{(r)}|$, and statistics P_{d,α_j}, P_{f,α_j}, and $P_{H_{0,\alpha_j}}$ (line 12). If ST_j has already joined $S_{\alpha_j}^{(r)}$ before (lines 14–17) or its achieved utility is reduced (i.e., $x_j^{S_{\alpha_j}^{(r)}} \leq x_j^{S_i^{(r)}}$) (lines 19–22), then ST_j moves back to its original coalition $S_i^{(r)}$. Otherwise, ST_j remains in coalition $S_{\alpha_j}^{(r)}$. Finally, ST_j updates its history set $h(j)$ (line 25).

The proposed algorithms can adapt to the network changes. Specifically, if new PUs and SUs are deployed, existing PUs and SUs are removed, or the wireless channel conditions are changed, both stages will be performed again to find the new Nash-stable partition. In practice, these two stages can be periodically performed for the CRN to handle occasional changes of network settings. Note that the proposed algorithms can be directly applied to a more general scenario, which is not restricted

Algorithm 2 Coalition formation algorithm based on the switch rule. It is executed by ST_j, $\forall\ j \in N$

Initialization: $S_1^{(0)} := N$; $S_l^{(0)} := \emptyset$, $\forall\ l \in M \backslash \{1\}$
for iteration $r := 1$ to MAX **do**

  ST_j generates θ_j, which is a Gaussian random variable with mean 0 and variance 1
  ST_j randomly selects another licensed channel α_j such that $\alpha_j \in M$, $\alpha_j \neq i$
  ST_j broadcasts the information of θ_j to other ST_k, $\forall\ k \in N$, $k \neq j$
  ST_j receives the information of θ_k from other ST_k, $\forall\ k \in N$, $k \neq j$
  $m := \arg\max_w \theta_w$, $\forall\ w \in N$
  if $ST_j = ST_m$ **then**
    ST_j computes $x_j^{S_i^{(r)}} := v(S_i^{(r)})/|S_i^{(r)}|$
    $S_i^{(r)} := S_i^{(r)} \backslash \{j\}$
    ST_j requests and obtains the information of $S_{\alpha_j}^{(r)}$ from $DN_{\alpha_j}^{(r)}$
    $S_{\alpha_j}^{(r)} := S_{\alpha_j}^{(r)} \bigcup \{j\}$
    if $S_{\alpha_j}^{(r)} \in h(j)$ **then**
      $S_{\alpha_j}^{(r)} := S_{\alpha_j}^{(r)} \backslash \{j\}$
      $S_i^{(r)} := S_i^{(r)} \bigcup \{j\}$
    else
      ST_j computes $x_j^{S_{\alpha_j}^{(r)}} := v(S_{\alpha_j}^{(r)})/|S_{\alpha_j}^{(r)}|$
      if $x_j^{S_{\alpha_j}^{(r)}} \leq x_j^{S_i^{(r)}}$ **then**
        $S_{\alpha_j}^{(r)} := S_{\alpha_j}^{(r)} \backslash \{j\}$
        $S_i^{(r)} := S_i^{(r)} \bigcup \{j\}$
      end if
    end if
  end if
  ST_j updates $h(j)$ by adding its current coalition at the end of $h(j)$
end for

to using the PSK-modulated signal for transmission and the OR rule for data fusion. In [29], the proposed model is further extended to consider the coalition formation game under the NTU framework.

Performance Evaluation

In this subsection, the performance gain of the proposed CSSA scheme is evaluated and compared with the closest PU (CPU) scheme and the noncooperative spectrum sensing and access (NSSA) scheme. In the CPU scheme, each SU senses the closest PU and joins that coalition to perform cooperative sensing, while the SUs in the NSSA scheme only perform local spectrum sensing. Unless specified otherwise, there are one base station, $|M| = 5$ PUs, and $|N| = 10$ ST-SR pairs. All nodes are randomly placed in a square region of 100×100 m. The average channel gain of the link between PU_i and ST_j is $|g_{i,j}|^2 = 1/d_{i,j}^{\gamma}$, where $d_{i,j}$ denotes the distance

between PU_i and ST_j, and $\gamma = 2$ denotes the path loss exponent. Similarly, the average channel gain of the link between ST_j and SR_j is $|h_{j,i}|^2 = 1/d_{j,i}^{\gamma}$, where $d_{j,i}$ denotes the distance between ST_j and SR_j. The bandwidth of the primary channel B_i is 10 MHz, $\forall\, i \in M$. Other parameters are set as follows: the duration of one time frame T is 100 ms; the sampling frequency f_s is 1 kHz; the transmit power of each ST P_t is 10 mW; the sensing power of each ST P_s is 10 mW; the detection threshold ε is 0.2 mW; the noise power $\sigma_{n,i}^2$ is 0.1 mW for all $i \in M$. The probability that $PU_i, i \in M$ is active is $P_{H_{1,i}} = P_{H_1} = 0.8$, $\forall\, i \in M$. The sensing duration δ and the unit penalty per second φ are to be 5 ms and 100, respectively. The OR rule is used for the data fusion.

Figure 1 shows the average utility of the SUs versus the number of the PUs $|M|$ in the CRN when $|N|$ is equal to 10. It can be observed that the performance of CSSA is better than those of CPU and NSSA. For all schemes, the average utility of the SUs first increases with $|M|$, as more spectrum can be utilized by the SUs. The performance of CPU is worse than that of CSSA, as the SUs in the CPU scheme choose to sense the closest PU, which leads to crowded coalition. When $|M| < 10$ and $|N| > |M|$, CSSA performs better than NSSA due to the cooperative gain of cooperative spectrum sensing. When $|M| \geq 10$, each SU can sense and access a different channel under CSSA and NSSA. Hence, the average utilities of the SUs for both the CSSA scheme and the NSSA scheme are the same. When $|M| \geq 10$, the average utility of the SUs still increases with $|M|$, as each SU may select a better channel when there are more channels available in the CRN. When $|M|$ is large, increasing $|M|$ further will not improve the spectrum utilization, as the number of the SUs is limited and the additional spectrum cannot be utilized by the SUs.

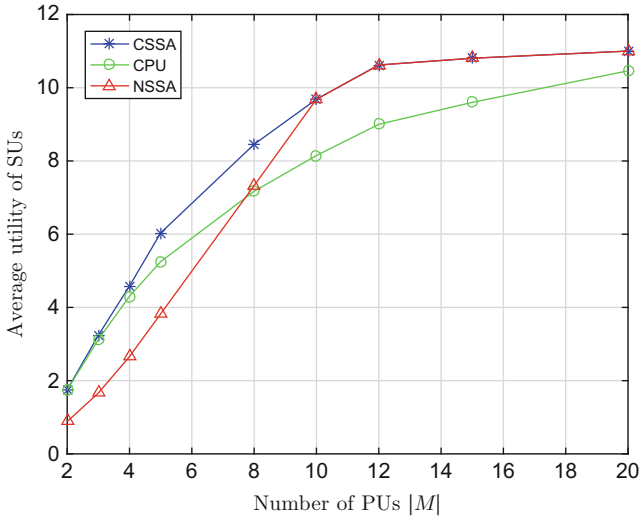

Fig. 1 The average utility of the SUs versus the number of PUs $|M|$ ($|N| = 10$) (Reproduced with permission from the IEEE)

Figure 2 shows the average utility of the SUs versus the probability that the PUs being active P_{H_1}. It can be observed that CSSA outperforms both CPU and NSSA. The performance gap between CSSA and CPU does not change too much with P_{H_1}, but the performance gap between CSSA and NSSA increases with P_{H_1}. When P_{H_1} is small, the improved sensing accuracy due to cooperative spectrum sensing is not

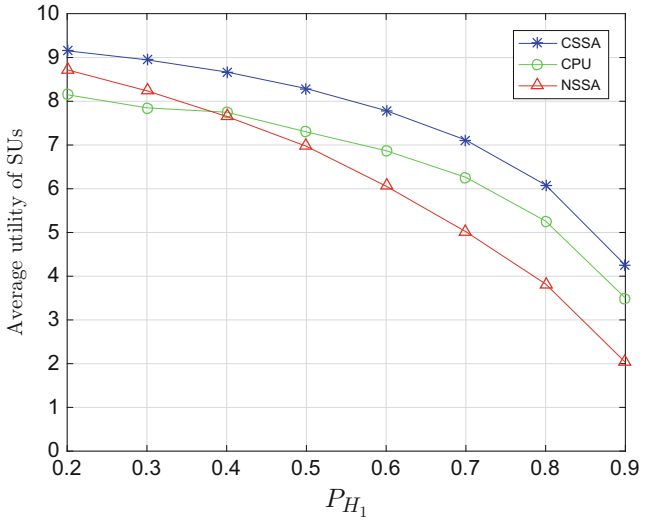

Fig. 2 The average utility of the SUs versus the probability for PUs being active P_{H_1} ($|M| = 5$, $|N| = 10$) (Reproduced with permission from the IEEE)

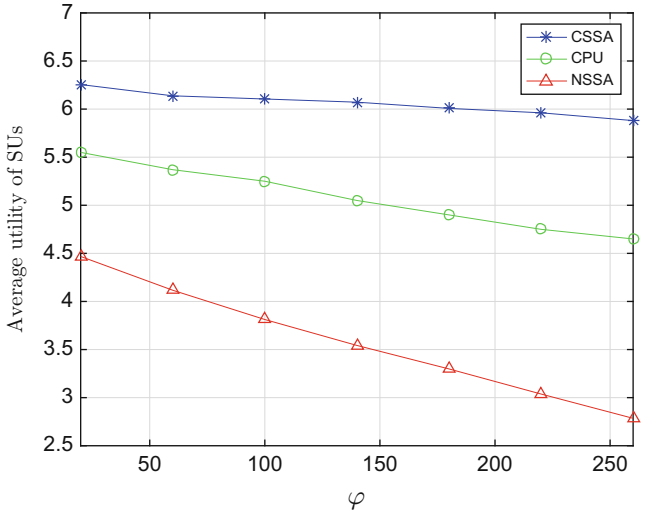

Fig. 3 The average utility of the SUs versus the unit penalty per second φ ($|M| = 5$, $|N| = 10$) (Reproduced with permission from the IEEE)

significant because the channels are vacant for most of the time. With the increase of P_{H_1}, the PUs occupy the channels more frequently. Due to the improved sensing accuracy, the SUs pay less penalty for interfering the PUs' transmissions and makes an effective use of the energy that has been consumed for sensing.

Figure 3 illustrates the average utility of the SUs versus the unit penalty φ. The results show that the performance of CSSA is better than those of CPU and NSSA. The average utility of the SUs decreases with the value of φ. However, the average utility of CSSA decreases much slower. The reason is that when φ is large, each SU is charged a larger penalty if there is a missed detection. Since the probability of detection of CSSA is higher than those of CPU and NSSA, the average utility of the SUs for CSSA does not decrease as significantly as CPU and NSSA when φ is increased.

Overlapping Coalitional Game for Cooperative Spectrum Sensing and Access

In the previous section, the multichannel cooperative spectrum sensing and access problem is formulated as a hedonic coalition formation game, where each SU can only sense one channel at a time and is assumed to always have data to transmit. By relaxing these two assumptions, in this section, a traffic demand-based cooperation strategy is proposed, and this problem is formulated as an NTU overlapping coalitional game. Comparing with the DCF game, the overlapping coalitional game can achieve better performance at the expense of a higher computational complexity.

System Model

As in the previous section, a CRN consisting of one base station, $|M|$ PUs (i.e., $|M|$ licensed channels), and $|N|$ SUs, is considered. Recall that $M = \{1, \ldots, |M|\}$ and $N = \{1, \ldots, |N|\}$ denote the sets of PUs and SUs, respectively, T denotes the frame duration, δ denotes the length of the spectrum sensing period, and S_i denotes the set of SUs choosing to sense and access channel $i \in M$. Assuming that each SU has multiple energy detectors and can sense multiple channels in a sensing period, but each SU can access at most one channel during one time slot [32]. A group refers to all the SUs that sense the same channel, and there are multiple groups in the system. The base station allocates a channel that is detected as idle to a group member. To avoid interference between different SUs, an idle channel can only be allocated to one SU at a time. Different SUs have different amount of data in their buffer waiting to be transmitted. An idle channel can only be assigned to the SU that is participating in sensing. Hence, each SU decides whether or not to participate in cooperative sensing based on the traffic demand and the channel capacity. As the individual sensing result may not be accurate due to path loss and shadowing, the SUs perform cooperative sensing in this work. The base station, which also serves as a fusion center, collects the sensing results from the SUs, and uses the OR rule to

decide the status of each channel. The detection probability of the set of the SUs S_i that sense channel $i \in M$ is given in (4). The false alarm probability of SU $j \in N$ after sensing channel $i \in M$, denoted as $P_{f,i,j}$, is given by

$$P_{f,i,j}\left(P_{d,i,j}, \gamma_{i,j}\right) = Q\left(\sqrt{2\gamma_{i,j}+1}Q^{-1}\left(P_{d,i,j}\right) + \sqrt{N_s}\gamma_{i,j}\right), \tag{12}$$

where N_s denotes the number of sensing samples during the sensing period in a time frame.

To protect the transmission of PU i, the cooperative sensing performance needs to satisfy a target value, denoted as $\bar{P}_{d,i}$ for SUs in set S_i. Hence, the individual target detection probability of SU $j \in S_i$ is given by [33]

$$\bar{P}_{d,i,j} = 1 - (1 - \bar{P}_{d,i})^{\frac{1}{|S_i|}}, \tag{13}$$

where $|S_i|$ denotes the number of SUs sensing channel i.

By substituting (13) into (12), the value of $P_{f,i,j}$ can be obtained. According to the OR rule, the false alarm probability at channel i is given by

$$P_{f,i} = 1 - \prod_{j \in S_i}\left(1 - P_{f,i,j}\right). \tag{14}$$

The transmission rate achieved by SU j over channel i can be expressed as

$$R'_{i,j} = B_i \log_2\left(1 + |g_j|^2 \frac{W_{t,i,j}}{\sigma^2_{n,i}}\right), \tag{15}$$

where $W_{t,i,j}$ denotes the transmit power of SU j when it performs transmission on channel i, and g_j denotes the channel gain of the transmission link of SU j.

The probability that channel i is correctly detected as idle is $P_{I,i}\left(1 - P_{f,i}\right)$, where $P_{I,i}$ denotes the probability that channel i is idle. When a channel is detected as idle, each member in the same coalition has the same probability $\left(\text{i.e., } \frac{1}{|S_i|}\right)$ to access the channel. The base station assigns an idle channel to only one SU that participates in cooperative sensing. Thus, the probability that SU j is allowed to transmit over channel i without interfering the transmission of the PU is given by

$$P^U_{i,j} = P_{I,i}\left(1 - P_{f,i}\right)\frac{1}{|S_i|}. \tag{16}$$

The number of the information bits in the buffer of SU j is denoted by D_j, which is a constant during one time slot. SU j cannot transmit more than the number of the information bits in its buffer. When an idle channel i is assigned to SU j, the

transmission time, denoted as $t_{i,j}$, is given by

$$t_{i,j} = \min\left\{\frac{D_j}{R'_{i,j}}, T-\delta\right\}. \tag{17}$$

Thus, the throughput that SU j can achieve in the time slot is

$$U_{i,j} = \frac{R'_{i,j}t_{i,j}}{T}. \tag{18}$$

An SU can transmit over channel $i \in M$ when the following two cases happen. The first case is that channel i is detected as idle, and it is indeed idle, which occurs with probability $P_{I,i}\left(1-P_{f,i}\right)$. The second case is that channel i is detected as idle but actually it is busy, which occurs with probability $(1-P_{I,i})(1-P_{d,i})$. Based on these two cases, the probability that SU j is assigned channel i and transmits data is

$$P^E_{i,j} = \left((1-P_{I,i})(1-P_{d,i}) + P_{I,i}(1-P_{f,i})\right)\frac{1}{|S_i|}. \tag{19}$$

By participating in multiple coalitions, the SUs can sense multiple channels during the sensing period, and the set of channels that SU j chooses to sense is denoted as A_j. Let K denote a subset of A_j which contains the channels assigned to SU j. The probability that set $K \subseteq A_j$ is obtained on SU j is given by $\prod_{i\in K}\left(P^E_{i,j}\right)\prod_{i\in A_j\setminus K}\left(1-P^E_{i,j}\right)$. Among these $|K|$ channels, SU j selects the channel that can maximize its throughput (i.e., $\max_{i\in K}\{U_{i,j}\}$). Due to mis-detection, the transmission of SU j in channel $\arg\max_{i\in K}\{U_{i,j}\}$ may not always be successful. Hence, the expected throughput of SU j is given by

$$U_j(A_j) = \sum_{K\subseteq A_j}\left(\left(\prod_{i\in K}P^E_{i,j}\prod_{i\in A_j\setminus K}\left(1-P^E_{i,j}\right)\right)\times\frac{P^U_{j,\,\mathrm{argmax}_{i\in K}\{U_{i,j}\}}}{P^E_{j,\,\mathrm{argmax}_{i\in K}\{U_{i,j}\}}}\max_{i\in K}\{U_{i,j}\}\right). \tag{20}$$

where $P^U_{j,\,\mathrm{argmax}_{i\in K}\{U_{i,j}\}}/P^E_{j,\,\mathrm{argmax}_{i\in K}\{U_{i,j}\}}$ denotes the probability that SU j can successfully transmit data over this channel. Note that the expected throughput of SU j increases with the cardinality of set A_j.

An energy-constrained SU should limit the energy spent on sensing and save its energy for data transmission. The power consumption consists of the sensing power consumption and the data transmission power consumption. The energy that SU j spends to sense channel i is $E^s_{i,j} = W_{s,i,j}\delta$, where $W_{s,i,j}$ denotes the sensing power of SU j to channel i. Similarly, the energy spent by SU j on data transmission over channel i is $E^t_{i,j} = W_{t,i,j}t_{i,j}$, where $W_{t,i,j}$ is the transmission power of SU j on

channel i. As a result, the expected power consumption of SU j is a function of the set of channels A_j that it prefers to sense, which is given by

$$E_j\left(A_j\right) = \frac{1}{T}\Bigg(\sum_{K\subseteq A_j}\Bigg(\Big(\prod_{i\in K} P_{i,j}^{E}\prod_{i\in A_j\setminus K}\left(1-P_{i,j}^{E}\right)\Big) \times E^{t}_{j,\,\mathrm{argmax}_{i\in K}\{U_{i,j}\}}\Bigg) + \sum_{i\in A_j} E_{i,j}^{s}\Bigg). \tag{21}$$

Energy efficiency is used as a metric to evaluate an SUs' decision on cooperation. The expected energy efficiency of SU j is defined as [34]

$$\eta_j\left(A_j\right) = \frac{U_j\left(A_j\right)}{E_j\left(A_j\right)}. \tag{22}$$

Each SU aims to maximize its throughput subject to an energy efficiency constraint. When the traffic demand of an energy-constrained SU is low, it may prefer not to participate in the cooperative sensing, as the cost of participating in the cooperation outweighs the payoff. The energy saved can be used to transmit data when there are enough information bits in the buffer. Hence, the problem that how each SU should cooperate with other SUs to sense the channels needs to be addressed.

Overlapping Coalitional Game for Cooperation Strategy

In this subsection, the CSSA problem is formulated as an NTU overlapping coalitional game. Each SU makes its own decision on coalition formation based on the move rules, which take into account both social welfare and individual payoff. An OCF algorithm is proposed to enable SUs to form a stable coalition structure, and a SCF algorithm is proposed to reduce the number of iterations and information exchange among the SUs.

NTU Overlapping Coalitional Game Formation

In this cooperative spectrum sensing and access strategy, the SUs can choose multiple channels and contribute to multiple coalitions, so as to maximize their expected throughput while satisfying the energy efficiency requirements. The SUs that participate in sensing, the same channel forms a coalition. If the channel is detected as idle, the SUs in the coalition share the spectrum resource. Thus, it can be formulated as an overlapping coalitional game where an SU is allowed to join multiple coalitions, and each coalition is formed on one channel that the SU prefers to sense. As the payoff of an SU in one coalition is constrained by its traffic demand,

the utility obtained by an SU in an overlapping coalition game cannot be transferred to other SUs. As a result, this overlapping coalitional game is an NTU game. The NTU overlapping coalitional game [35] is defined as follows:

Definition 8. An NTU overlapping coalitional game $G = (N, v)$ is given by a set of players $N = \{1, \ldots, |N|\}$ and a function $v : S \rightarrow \mathbb{R}^{|S|}$, where $S \subseteq N$ denotes a coalition formed by players and $v(\emptyset) = \mathbf{0}$.

The players of this game are $|N|$ SUs, and they form different coalitions to sense and access different channels. The coalition value is defined as the expected payoff that each SU can obtain in the coalition. Hence, $v(S_i) = (x_j(S_i), \forall j \in S_i)$, where value function v maps each coalition $S \subseteq N$ to an $|S|$-dimensional vector and $x_j(S_i) = P_{i,j}^U U_{i,j}$ is the payoff of SU j in coalition S_i. In a DCF game, a coalition structure is a partition of N [36]. The SUs in an overlapping coalitional game can join multiple coalitions at the same time. The definition of the coalition structure Π in an overlapping coalitional game [37] is given as follows:

Definition 9. An overlapping coalition structure Π over a player set N is defined as a set $\Pi = \{S_1, \ldots, S_{|K|}\}$, where $|K|$ is the number of coalitions. $\forall\ 1 \leq i \leq |K|$, $S_i \subseteq N$ and $\cup_{i=1}^{|K|} S_i = N$. Since coalitions can be overlapped, $\exists\ S_i, S_k \in \Pi, i \neq k$ such that $S_i \cap S_k \neq \emptyset$.

The SUs that choose to sense and access channel $i \in M$ form coalition S_i. On the other hand, the SUs with low-traffic demand may choose to stay in idle to save energy, and they form coalition $S_{|M|+1}$. Hence, the number of the coalitions $|K|$ in the system is equal to $|M| + 1$. Although more than one channel may be available for an SU in a time slot, the SU can only transmit data over one channel. Hence, the total payoff of an SU cannot be calculated by summing up its payoffs from all coalitions that it belongs to. The total payoff of SU j is defined as

$$p_j(\Pi) = \begin{cases} U_j(A_j), & \text{if } \eta_j(A_j) \geq \eta_{\min}, \\ -\infty, & \text{otherwise.} \end{cases} \tag{23}$$

The total payoff of SU j is equal to the expected throughput that it can obtain by choosing channel set A_j to sense, when the expected energy efficiency of SU j is greater than energy efficiency threshold $\eta_{\min}$. Otherwise, it is equal to negative infinity. This payoff definition guarantees that the expected energy efficiency of the SUs during the coalition formation process is not lower than threshold $\eta_{\min}$. The payoff of each SU in set $S_{|M|+1}$ is defined as zero. Each SU that belongs to set $S_{|M|+1}$ does not sense and access any channel and cannot join set $S_i, \forall\ i \in M$. Hence, $S_{|M|+1}$ is an isolated coalition, which does not overlap with any other coalitions.

The proposed preference order of the SUs takes into account both social welfare and individual payoff, which helps SUs compare two coalition structures and select the one that can provide more social welfare and individual payoff at the same time. The social welfare $u(\Pi)$ of a coalition structure Π is the value of coalition structure

Π, which is the sum of the payoff of each individual player. Hence,

$$u(\Pi) = \sum_{j \in N} p_j(\Pi). \tag{24}$$

The social welfare $u(\Pi)$ also represents the expected overall throughput of the SUs when the energy efficiency constraints are met. The preference order of the coalition structures is defined as follows, which takes into account both individual payoff and social welfare.

Definition 10. In an overlapping coalitional game $G = (N, v)$, given two coalition structures Π_p and Π_q over N, Π_p is j-preferred over Π_q, where $j \in N$ is equivalent to $p_j(\Pi_p) > p_j(\Pi_q)$ and $u(\Pi_p) > u(\Pi_q)$. This preference order is represented as

$$\Pi_p \succ_j \Pi_q \Leftrightarrow p_j(\Pi_p) > p_j(\Pi_q) \text{ and } u(\Pi_p) > u(\Pi_q). \tag{25}$$

Based on Definition 10, an SU prefers a coalition structure over another if and only if both the total payoff of the coalition structure and the individual payoff of the SU are increased. Such an preference order not only guarantees the increase of social welfare during the coalition formation but also keeps the spectrum efficiency above a certain level.

Coalition Formation Algorithms

During the process of overlapping coalition formation, each SU makes its own decision to join or leave a coalition based on the proposed preference order. Three move rules for the possible moves of each SU are defined as follows. First, the SU joins a new coalition that it does not belong to. Second, the SU leaves one of its current coalitions. Third, the SU switches from one of its current coalitions to a new coalition. The following three definitions provide the mechanisms for the SUs to form different coalitions by performing these moves.

Definition 11. *Join rule*: consider a coalition structure Π_p over a set of players N, where coalition $S_i \in \Pi_p$ and SU $j \in N \setminus S_i$. A new coalition structure is defined as $\Pi_q = \{\Pi_p \setminus S_i\} \cup \{S_i \cup \{j\}\}$. If $\Pi_q \succ_j \Pi_p$, SU j joins coalition S_i and coalition structure Π_p changes into coalition structure Π_q.

Based on Definitions 10 and 11, SU j in coalition structure Π_p, which does not belong to coalition S_i, joins coalition S_i in new coalition structure Π_q, if coalition structure Π_q is preferred by SU j over coalition structure Π_p. The join rule takes into account both the individual payoff and social welfare. An SU joins a new coalition if and only if both its payoff and the coalition structure value are improved by its move. Hence, SU j does not act selfishly without considering the effects of its move on other SUs.

Definition 12. *Quit rule* [29]: consider a coalition structure Π_p over a set of players N, where coalition $S_i \in \Pi_p$ and SU $j \in N \cap S_i$. A new coalition structure is defined as $\Pi_q = \{\Pi_p \setminus S_i\} \cup \{S_i \setminus \{j\}\}$. If $\Pi_q \succ_j \Pi_p$, then SU j leaves coalition S_i, and coalition structure Π_p changes into coalition structure Π_q.

Based on Definition 12, SU j leaves one of its current coalitions S_i and Π_p changes into Π_q if the newly formed coalition structure is preferred by SU j over the current one. SU j may prefer to leave coalition S_i to avoid a negative payoff in the following two situations. One is that there are too many SUs in coalition S_i to sense channel i, which leads to a low chance of assigning this channel to SU j. The other is that SU j has only several information bits to be transmitted in a time slot.

Definition 13. *Switch rule*: consider a coalition structure Π_p over a set of players N, where coalitions $S_i, S_k \in \Pi_p$ and SU $j \in N$ satisfy $j \in S_i$ and $j \notin S_k$. A new coalition structure is defined as $\Pi_q = \{\Pi_p \setminus \{S_i, S_k\}\} \cup \{S_i \setminus \{j\}\} \cup \{S_k \cup \{j\}\}$. If $\Pi_q \succ_j \Pi_p$, then SU j switches from coalition S_i to coalition S_k, and coalition structure Π_p changes into coalition structure Π_q.

Based on Definition 13, SU j switches from one of its coalitions to a new coalition when the new coalition structure is preferred over the current one. During the coalition structure formation, some channels may be chosen by many SUs, while some other channels are selected by few ones. An SU performs the switch move, when it notices that its payoff can be increased by switching from the coalition chosen by many SUs to another coalition selected by few SUs. As a result, the SUs autonomously distribute their contributions to different coalitions. In this way, the switch rule balances the size of different coalitions and improves the spectrum efficiency. The stability of an overlapping coalition structure is defined as follows:

Definition 14. An overlapping coalition structure Π over a set of players N is stable if any SU $j \in N$ such that $j \in S_i$ and $j \notin S_k$ for coalitions $S_i, S_k \in \Pi$, SU j will not deviate from coalition S_i or join coalition S_k.

Based on Definition 14, each SU $j \in N$ in a stable coalition structure will not leave any of its coalitions or join any new coalition. Therefore, all SUs do not make any change and stay in the current coalitions.

(1) Overlapping Coalition Formation (OCF) Algorithm

Algorithm 3 shows the proposed OCF algorithm, which can reach a stable coalition structure. The proposed algorithm is distributed and executed by each SU $j \in N$.

In Algorithm 3, all SUs are initialized to join quit sensing coalition $S_{|M|+1}$ (line 1). Then SU j exchanges the traffic demand information with other SUs by invoking functions j.broadcast() and j.receive() via a dedicated control channel (lines 2–3). At the beginning of each iteration, SU j randomly selects a coalition that it currently belongs to, denoted as S_k, and a new coalition it does not belong to, denoted as S_i (lines 5–10). SU j calculates its resulted payoff if it leaves coalition S_k and the value of newly formed coalition structure Π_{Quit} according to Eqs. (22), (23) and (24) (lines 6–7). Similarly, SU j calculates its payoffs in potential new coalition structures Π_{Join} and Π_{Switch} due to join move and switch move, and the values of

27: **end if**

the coalition structures by Eqs. (22), (23) and (24) (lines 9–11), respectively. If the quit move improves the coalition structure, the coalition structure is updated (line 13). Otherwise, SU j considers join move (line 14) and switch move (line 16). After that, SU j updates the coalition structure and its value and exchanges the updated information with other SUs (lines 19–20). All the updated coalition structure information form a set T_{info} (line 21). The coalition structure with the greatest value is selected as the new coalition structure (line 22). The coalition formation process is repeated until all SUs do not deviate from their current coalitions or join other new coalitions (line 23). After the process converges to a stable coalition structure, SU j cooperatively senses the channels with other SUs in corresponding coalitions by invoking function j.sense(Π). During the spectrum access stage, if SU j is allocated a channel, it calculates the optimal transmission power $W_{t,i,j}^{opt}$ to minimize the energy consumption spent on data transmission. Finally, SU j transmits data with the optimal transmission power (line 26). In [38], an adaptive transmission power control scheme is proposed to calculate the optimal transmission power for each SU that has been assigned a channel.

The following theorem guarantees the convergence of the proposed OCF algorithm.

Theorem 2. *The proposed OCF algorithm converges to a stable overlapping coalition structure after a finite number of iterations.*

Proof. Please refer to [38].

According to Algorithm 3, each SUs seeks to increase both its individual utility and the value of the coalition structure in each iteration. Hence, the total payoff for SUs is always increased when the coalition structure Π changes. In addition, the proposed algorithm adapts to network changes (e.g., number of SUs, channel states). Specifically, the SUs adaptively change their cooperation strategies and form a stable coalition structure, when new SUs join in the network, more channels are available, or channel states vary.

(2) Sequential Coalition Formation (SCF) Algorithm

Although Algorithm 3 always converges, the number of iterations required to converge grows exponentially with the number of SUs. As a result, the SCF algorithm is proposed, which reduces the computational complexity and exchanges less information among SUs to form an overlapping coalition structure.

In a sequential game of coalition formation, the coalition structure is formed step by step. In each step, only one player can update the coalition structure according to the rule of order h. Once a player joins a coalition, it remains in the coalition. In the proposed SCF algorithm, the rule of order h depends the traffic demands of SUs. Specifically, the SU that has the highest traffic demand moves first. The active SU makes a decision to join multiple coalitions based on the current coalition structure. The active SU remains in these coalition once it has joined them.

Algorithm 4 shows the proposed SCF algorithm, where the SUs make distributed decisions on coalition formation. However, the behaviors of the SUs are coordinated by a central coordinator. First, each SU reports its traffic demand information to the central coordinator by invoking function j.broadcast() (line 2). The traffic demand information of different SUs forms vector D (line 4). A sorting function $H(X)$ is defined, which maps a vector X to a $|X|$-dimensional vector, and returns a vector with each element representing the sorted index of each X's element in a descending order. The coordinator calculates the rule of order ρ using function $H(D)$ and broadcasts the information of ρ to all SUs (line 5). Then, the coalition formation decision is made by SUs one by one based on ρ. In particular, SU $\rho(1)$ makes the first decision as it has the highest traffic demand and initializes the coalition structure by setting all SUs in quit sensing coalition $S_{|M|+1}$ (line 8). The active SU receives the updated information of Π from previously active SU by invoking function j.receive() (line 10). During the coalition formation process, each active SU checks all channels one by one to find new coalition. For a new channel i, the active SU can join coalition i or switch to coalition i if SU prefers to sense channel i. Assuming an active SU joins coalition S_i (line 13), the SU calculates the payoff and the value of the newly resulted coalition structure based on Eqs. (22), (23) and (24) (line 14). In addition, assuming the active SU switches from a randomly selected

coalition that it belongs (line 15) to coalition S_i (line 16), the SU calculates SU's new payoff and the value of the potential new coalition structure resulting from switch move (line 17). If the resulted coalition structure due to join move Π_{Join} is preferred over the current coalition structure Π, the coalition structure is updated (line 19). On the other hand, if the join move cannot improve the coalition structure, the resulted structure by switch move Π_{Switch} is considered (line 20). After checking all new coalitions, the currently active SU $\rho(j)$ reports the updated information of Π to the next active SU $\rho(j+1)$ by invoking function j.send() (line 27). The last active SU broadcasts the final coalition structure to other SUs (line 25). After the coalition formation process, the SUs perform cooperative sensing in each coalition

according to the final coalition structure. During the transmission stage, the SUs transmit data with the optimal transmission power (lines 34–36).

Although the stability of the final coalition structure is not guaranteed in the SCF algorithm, it can achieve the same aggregate throughput as the OCF algorithm. In addition, the computational complexity of the SCF algorithm is lower than that of the OCF algorithm. As the active SU in the SCF algorithm checks each potential channel only once and makes one move, at most $|M||N|$ iterations are required when running the SCF algorithm. However, in the OCF algorithm, the formation of a coalition structure takes place every time when a new coalition structure is preferred over the current coalition structure. Hence, the number of possible overlapping coalition structures in the OCF algorithm is $2^{|M||N|}$, which is much larger than the number of iterations required in the SCF algorithm. Moreover, as each SU only needs to send the updated coalition structure to the next active SU, less information exchange is required by the SCF algorithm.

Performance Evaluation

In this subsection, the aggregate throughput of the proposed OCF and SCF algorithms is evaluated and compared to the DCF algorithm. In the DCF algorithm, each SU can only join at most one coalition. The base station is placed at the center of a 100 ×100 m square region, in which the SUs are randomly placed. The channel gain of the link between SU j and the base station is modeled as $|g_j|^2 = 1/d_j^n$, where d_j denotes the distance between SU j and the base station, and $n = 2$ is the path loss exponent. The number of packets generated by each SU within one time slot follows the Poisson distribution with rate $\lambda = 0.5$ packet per time slot. The number of sensing samples during the sensing period in one time slot is $N_s = 5000$. The probability of each channel being idle is randomly chosen between $[0.5, 1]$. The bandwidth of channel i, B_i, and noise power, $\sigma_{n,i}^2$, are set to be 100 kHz and 0.01 mW, respectively. A list of simulation parameters is summarized in Table 1.

Table 1 List of Simulation Parameters

Parameter	Value
Number of PUs (licensed channels) $\|M\|$	6
Number of SUs $\|N\|$	10
Target detection probability $\bar{P}_{d,i,j}$	0.99
Received SNR at each SU during the sensing stage $\gamma_{i,j}$	−15 dB
Sensing power of SU j on channel i $W_{s,i,j}$	50 mW
Slot duration T	100 ms
Sensing duration δ	5 ms
Packet size	20 kbit
Buffer size of each SU	200 kbit
Lower bound of the energy efficiency η_{min}	500 kbit/Joule

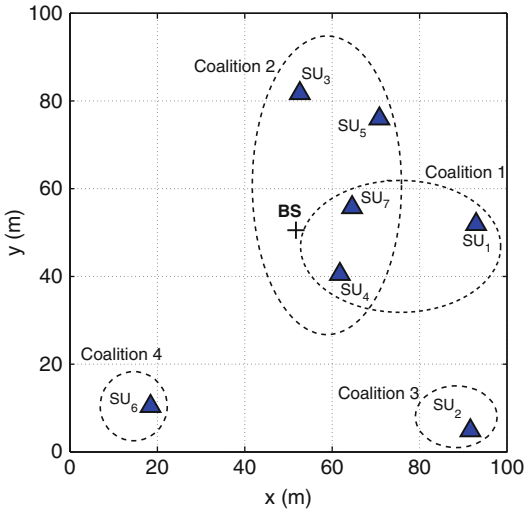

Fig. 4 An example of the stable overlapping coalition structure ($|M| = 3, |N| = 7$) by the OCF algorithm (Reproduced with permission from the IEEE)

Figure 4 shows a snapshot of a stable overlapping coalition structure obtained by using the proposed OCF algorithm, when there are 3 PUs and 7 SUs. The SUs within the same ellipse form a coalition. SUs 1, 4, and 7 form coalition 1 in channel 1. Similarly, SUs 3, 4, 5, and 7 form coalition 2 to sense and access channel 2. SU 2 forms a singleton coalition 3 to sense and access channel 3. SU 6 joins the coalition 4, which is the quit sensing coalition. Hence, the overlapping coalition structure can be expressed as $\Pi = \{\{1, 4, 7\}_1, \{3, 4, 5, 7\}_2, \{2\}_3, \{6\}_4\}$, in which coalitions 1 and 2 overlap with each other, and SUs 4 and 7 belong to both coalitions at the same time. Besides, SU 6 chooses not to cooperate with other SUs and joins the quit sensing coalition due to its low traffic demand.

Figure 5 illustrates the impact of the number of SUs $|N|$ on the aggregate throughput of SUs. Both the OCF and SCF algorithms outperform the DCF algorithm, as the chance of each SU to be assigned a channel is increased by allowing each SU to join multiple coalitions. However, in the DCF algorithm, an SU can only join one coalition and share one channel with other SUs, which limits the chance of being assigned a channel. Moreover, the performance of the SCF algorithm is slightly better than that of the OCF algorithm. This is because the SCF algorithm gives higher priorities to the SUs with greater traffic demands to join coalitions. As a result, these SUs have a higher chance to transmit data than those SUs with lower traffic demands.

Figure 6 shows the impact of the number of PUs $|M|$ (i.e., the number of channels) on the aggregate throughput of the SUs. The SCF algorithm obtains a slightly higher aggregate throughput than the OCF algorithm. The performance gap between the DCF algorithm and the proposed algorithm is small when $|M|$ is small and increases with $|M|$. This is because the SUs in the proposed OCF

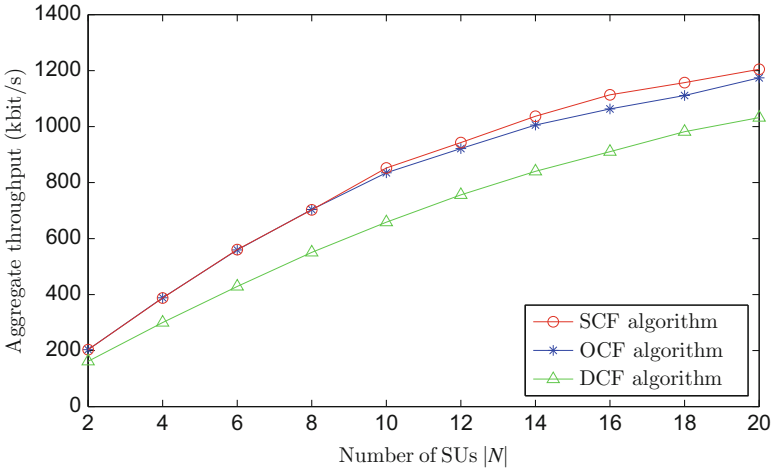

Fig. 5 Aggregate throughput versus the number of SUs in CRN for $|M| = 6$ (Reproduced with permission from the IEEE)

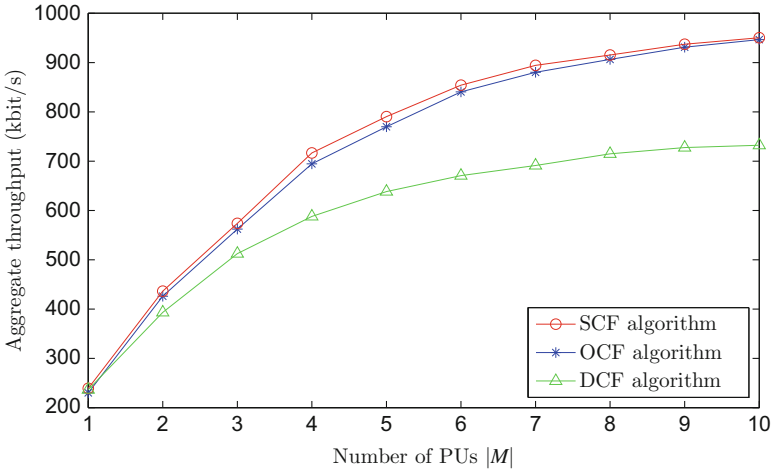

Fig. 6 Aggregate throughput versus the number of PUs in CRN for $|N| = 10$ (Reproduced with permission from the IEEE)

or SCF algorithm can obtain higher throughput when more channels are available by joining multiple coalitions. However, the SUs in the DCF algorithm obtain limited throughput improvement as each SU can sense and access at most one channel.

Conclusion and Future Directions

This chapter has studied cooperative spectrum sensing and access in a CRN with multiple licensed channels. A CSSA scheme has been proposed and formulated as a hedonic coalition formation game, in which the sensing accuracy and energy consumption are taken into account. The algorithm to find Nash-stable partition has been proposed. Simulation results showed that the proposed CSSA scheme outperforms the CPU and NSSA schemes. In addition, this chapter has proposed a traffic demand-based cooperative spectrum sensing and access scheme to achieve high throughput without degrading the energy efficiency. To solve this problem, an overlapping coalition game was formulated, where each SU is allowed to sense multiple channels. An OCF algorithm was proposed to find a stable coalition structure, which takes into account the individual payoff and social welfare. An SCF algorithm was also proposed to reduce the computational complexity and information exchange. Simulation results showed that the proposed OCF and SCF algorithms outperform the DCF algorithm in terms of the aggregate throughput.

In this chapter, all SUs are assumed to have the same sensing duration and sensing power. An extension to a more general setting is interesting but challenging, in which each SU can choose its sensing duration and sensing power as part of its strategy based on the network settings.

Abstract

Secondary spectrum trading is a promising solution to address the economic incentive issue in dynamic spectrum access, by allowing primary users (PUs) to sell the underutilized spectrum to secondary users (SUs) for the temporary access. This chapter studies a *monopoly* secondary spectrum market with a single PU (seller) and multiple heterogeneous SUs (buyers), where SUs have different preferences for spectrum access quality. The key focus is to study the optimal trading mechanism for the PU (that maximizes his profit) under information symmetry or asymmetry, depending on whether the preference of each SU is public information (hence can be observed by the PU) or private information (hence cannot be observed by the PU). The key solution idea to this PU-profit maximization problem is a contract-based spectrum trading mechanism, in which the PU offers a list of quality-price combinations (called a *contract*) for SUs, and each SU chooses the proper quality and price according to his (private or public) preference information. The optimal design for this contract-based trading mechanism consists of two steps: (i) analyze the incentive compatibility (IC) and individual rationality (IR) for feasible contracts, which guarantee the truthful information disclosure of SUs, and (ii) derive the optimal contract that maximizes the PU's profit under each information scenario, based on the IC and IR analysis in the first step. Simulations show that the optimal contract can increase the PU's payoff significantly.

Introduction

Nowadays, wireless spectrum resource is becoming more and more scarce with the explosive growth of wireless services and mobile devices [1]. On the other hand, however, many licensed spectrum bands are often in a low utilization rate (efficiency) due to the temporal and spatial variation of licensed users' behaviors. Taking the VHF/UHF band (licensed for broadcast television services) as an example, it is largely unused during midnight to morning, and the average utilization rate is lower than 40% in many countries [2]. Therefore, it is highly desirable to open the underutilized licensed spectrum for the secondary utilization of unlicensed users who are starving for spectrum. As a consequence, FCC in the USA and Ofcom in UK have approved the license-exempt use of the *unused* or *underutilized* spectrum in the VHF/UHF band (called TV white space [3]) to support new wireless

applications [4, 5]. However, without a proper incentive mechanism, the licensed users may not be willing to open and share their spectrum with others due to the potential interference they may suffer from. This motivates the study of incentive mechanism and secondary spectrum trading in this chapter.

Motivations

Cognitive radio-based dynamic spectrum access (DSA) [6–8] has been recognized as a promising technology for improving the spectrum efficiency and alleviating the spectrum scarcity, by allowing unlicensed secondary users (SUs) access the under-utilized spectrum of licensed primary users (PUs) opportunistically. Obviously, the successful implementation of DSA requires to solve many technical challenges (e.g., how to explore and exploit the idle licensed spectrum efficiently and how to avoid the harmful interference to PUs) as well as economic challenges (e.g., how to incentivize PUs to share their idle spectrum with SUs).

While most of the existing works focused on the technical issues of DSA (e.g., spectrum sensing [9], allocation [10–12], and sharing [13]), this chapter focuses on the economic incentive issue in DSA. In particular, how to incentivize PUs to open their idle licensed spectrum for the secondary access of SUs. Some recent studies have been devoted to the incentive issue in DSA and proposed various incentive mechanisms, including cooperative spectrum sharing [14–18] and secondary spectrum trading [19–29].

In [14–18], authors proposed a *cooperative spectrum sharing* mechanism, in which SUs relay the traffic of PUs in exchange for the opportunities to access the PUs' licensed spectrum. With the cooperative spectrum sharing, PUs can increase their service qualities through the cooperative relay of SUs, and SUs can obtain the opportunities of accessing the PUs' licensed spectrum. Hence, PUs can obtain the necessary incentive to open their spectrum for SUs under a proper mechanism design. However, this mechanism needs to exchange a large amount of control signals between PUs and SUs (e.g., to formulate the cooperative PU-SU pair and to determine their cooperation details) and hence will introduce a large communication overhead. Moreover, it requires strict time synchronization between a pair of cooperative PU and SU. Both limit the use of this mechanism in practice.

In [19–25], authors proposed a *secondary spectrum trading* market, in which PUs directly lease the unused or underutilized licensed spectrum to SUs for the temporary access. Inspired by the classic market theory and numerous maths tools in economics, they proposed various trading mechanisms (e.g., auction, wholesale pricing, and usage-based pricing) for different market scenarios ranging from monopoly market to competitive market. With the secondary spectrum trading, PUs can achieve additional profit directly from the unused or underutilized spectrum, and meanwhile the total spectrum efficiency can be improved. In [26–29], authors further studied the secondary spectrum trading market for TV white space networks. However, the above works considered neither the quality and/or price discrimination in the trading of spectrum nor the information asymmetry between PUs and SUs.

Contributions

This chapter studies a *monopoly* secondary spectrum market with a single PU selling his idle (licensed) spectrum to multiple heterogeneous SUs for the temporary access, where SUs have different efficiencies in accessing spectrum, hence different preferences for spectrum quality. Such a spectrum access efficiency or quality preference is referred to as the *type* of SU. The *quality* of spectrum denotes the constraints (for SUs) of using the spectrum: a higher quality implies a looser constraint. The PU can sell the spectrum to different SUs in different qualities and prices, leading to the *quality and price discrimination spectrum trading*. Our focus is to study the optimal trading mechanisms for the PU (maximizing his profit) under both information symmetry and asymmetry (between the PU and SUs).

Under *information symmetry*, the preference information (i.e., type) of each SU is public information and can be observed by the PU directly. In this case, the PU can derive the best quality and price for each SU (with a particular type) directly, while each SU can only decide whether to accept the quality and price assigned to him. Hence, the optimal trading mechanism that maximizes the PU's profit can be derived by solving the best quality and price for each SU separately.

Under *information asymmetry*, however, the preference information (i.e., type) of each SU is his private information and cannot be observed by the PU. In this case, the PU cannot derive the best quality and price for each SU directly, due to the lack of the SU's preference information. To solve this problem, the *contract theory* [30], a Nobel Prize (in Economics) awarded theory in 2016, is introduced for eliciting the private information of each SU. More specifically, the key solution idea is to propose a contract-based spectrum trading mechanism, in which the PU offers a list of quality-price combinations (called a *contract*) for SUs, each intended for one type of SUs; and each SU chooses the proper quality and price (which can be different from those intended for his type) according to his private preference information. A contract is *incentive compatible* (IC), if each SU can achieve the maximum payoff when choosing the quality and price designed for his type. A contract is *individually rational* (IR), if each SU can achieve a non-negative payoff when choosing the quality and price designed for his type. Obviously, only under a feasible contract that satisfies IC and IR, each SU will choose the quality and price designed for his type. Hence, IC and IR guarantee the acceptance and truthful information disclosure of SUs. This chapter will first design the feasible contracts that satisfy IC and IR and then derive the optimal (and feasible) contract that maximizes the PU's profit.

In summary, the key results and contributions of this chapter are as follows:

- *Model and Solution Novelty:* Study a general monopoly secondary spectrum market, taking the user heterogeneity and information asymmetry into consideration. Contract theory, a Nobel Prize awarded theory, is introduced to solve the PU's profit maximization problem under information asymmetry.

- *Multiple Information Scenarios:* Study the optimal contract design under two typical information scenarios: information symmetry and information asymmetry, depending on whether the PU can observe the type of each SU. Hence, the analysis can be applied to a wide range of situations.
- *Optimal Contract Design:* Design the optimal contract systematically. First, the feasible contracts satisfying IC and IR are designed (to guarantee the truthful information disclosure of SUs). Then, within the feasible contract set, the optimal (and feasible) contract is derived (to maximize the PU's profit).
- *Performance Evaluation:* Simulations show that the optimal contract under information asymmetry can increase the PU's payoff significantly and can achieve 60% $\sim$ 70% of the optimal performance under information symmetry.

The rest of this chapter is organized as follows. Section "System Model and Contract Formulation" provides the system model. Section "Contract Formulation" provides the contract formulation. Sections "Optimal Contract Under Information Symmetry" and "Optimal Contract Under Information Asymmetry" study the optimal contract designs under information symmetry and asymmetry, respectively. Section "Contract Design in Continuous SU-Type Model" extends the discrete SU-type model to the continuous SU-type model. Section "Simulation Results" presents the simulation results, and Section "Conclusion" concludes this work.

System Model and Contract Formulation

Consider a cognitive radio network with a single PU and multiple SUs, where the PU shares the underutilized licensed spectrum with SUs for the temporary access. The PU can be a licensed potable device (e.g., a smartphone), a licensed infrastructure (e.g., a base station) serving multiple subscribers in a small area or even a primary network consisting of multiple infrastructures and serving many subscribers in a wide area. Each SU can be an unlicensed potable device (e.g., a laptop) or infrastructure (e.g., an unlicensed access point) serving multiple unlicensed subscribers. The PU owns some licensed spectrum bands (called *channels*) but not fully utilizes them, while SUs are starving for spectrum but do not have any licensed spectrum channel. Hence, the PU can potentially sell the unused or underutilized channels to SUs for the temporary access, leading to a *monopoly* secondary spectrum market, where the PU is the *monopolist* in the market.

The licensed channels of the PU are *homogeneous*, in the sense that they are in the same frequency band with the same bandwidth and time length. Different channels are orthogonal, and hence the transmissions on different channels do not interfere with each other. Each SU desires for one channel for his service, and multiple SUs can operate on the same channel without mutual interference if they are far enough from each other. Moreover, the PU has sufficient idle channels for SUs such that each SU can get one channel without interference with any other SU.

PU Model

To protect the quality of service (QoS) of the PU, SUs can only access the PU's channels with the specific constraints specified by the PU, such as the maximum transmission power (as required by FCC [4] and Ofcom [5]) and the fast backoff mechanism (to avoid collision with the PU when the PU reoccupies a channel). Obviously, a looser constraint imposed on a channel implies a higher quality of the channel for SUs, as they have more freedom to use the channel. Without loss of generality, in this chapter the *quality* of a channel is defined as the *maximum allowable transmission power of SUs on that channel*. In this sense, a higher-quality channel implies that SUs can transmit with a larger power on that channel. Note that the whole analysis can be applied to a general quality definition.

As the monopolist in the market, the PU can specify the quality $q \geq 0$ and price $\pi \geq 0$ of the channels to be sold to SUs, while SUs decide whether to buy a channel. For the quality q, it further satisfies: $0 \leq q \leq Q_{\max}$, where $Q_{\max}$ is the maximum achievable transmission power of SUs' devices. Moreover, a zero quality $q = 0$ implies that the SU cannot use the channel. Hence, if an SU chooses a zero quality $q = 0$, it is equivalent to say that he decides *not* to buy a channel.

When selling a channel with a quality q to an SU at a price π, the PU's profit (defined as *payoff*) can be computed as follows:

$$R(q, \pi) = \pi - C(q), \tag{1}$$

where π and $C(q)$ are the PU's revenue and cost when selling a channel with quality q to an SU. Here the cost $C(q) \geq 0$ captures the QoS degradation of the PU due to the potential interference and collision of the SU.

It is easy to see that when selling a channel with a higher-quality q to an SU, the PU will incur a higher QoS degradation or cost $C(q)$ potentially. This is because a higher-channel quality implies that the SU can use the channel with less constraint (e.g., larger transmission power), hence imposing a higher interference or collision to the PU potentially. Thus, it is reasonable to assume that:

- $C(q)$ is non-negative and monotonically increases with q.

To facilitate the analysis, we further assume that

- $C(q)$ is a convex function of q.

This implies that $C(q)$ tends to grow faster with the increasing of q. Suppose $C(q)$ is twice differentiable. Let $C'(q) \triangleq \frac{\partial C(q)}{\partial q}$ and $C''(q) \triangleq \frac{\partial^2 C(q)}{\partial q^2}$ denote the first- and second-order derivatives of $C(q)$ with respect to q. Then, the above assumptions can be formally written as: $C'(q) > 0$ and $C''(q) \geq 0$, for all $q \in [0, Q_{\max}]$.

SU Model

When an SU gets a licensed channel from the PU, he can achieve a certain benefit from using that channel. Such a benefit mainly depends on the amount of data that the SU can transmit on that channel, which is highly related to the data rate or channel capacity that the SU can achieve. Moreover, when using a channel with quality q, the maximum channel capacity that an SU can achieve (when transmitting with the maximum allowable transmission power q) is

$$\Phi(\theta, q) = \log(1 + q \cdot \theta) \tag{2}$$

where $\theta \triangleq \frac{1}{|L|} \cdot \frac{1}{|I|+\sigma^2}$ is the SU's signal-to-noise ratio (SNR) under a unit transmission power, called the *efficiency factor*. Here the channel bandwidth is normalized to be one; σ^2 is the average background noise power, which is identical for all SUs on all channels; $|I|$ is the aggregate interference, which may come from the PU, other SUs, or even outside systems operating on the same frequency band; $|L|$ is the average path loss (signal attenuation) of the SU, which depends on both the transmission range and the antenna technology. For example, an SU transmitting a longer distance often has a larger path loss than transmitting a shorter distance; an SU using a directional antenna with an advanced beamforming technology often has a smaller path loss than using an omnidirectional antenna.

Due to the channel homogeneity, each SU has the same pass loss factor L and aggregate interference I on different channels and hence has the same efficiency factor θ on all channels. It is worth noting that different SUs may have different efficiency factors θ, due to the different path loss factors L and/or aggregate interferences I. Such an efficiency factor θ captures not only the SU's efficiency in accessing spectrum but also his *preference* for spectrum access quality. For example, an SU with a higher efficiency θ has a stronger preference for high quality, as he can achieve a higher capacity gain from a quality improvement.

For convenience, the efficiency factor θ of an SU is also referred to as his *type*. SUs are categorized into different classes according to their efficiency factors or types. Namely, the SUs in the same class have the same efficiency factor or type θ, while the SUs in different classes have different efficiency factors or types. Let Θ denote the set of all SU types, and $|\Theta|$ denote the number of types. Let $f_\theta, \forall \theta \in \Theta$, denote the percentage of type-θ SUs among all SUs, where $0 \leq f_\theta \leq 1$ and $\sum_{\theta \in \Theta} f_\theta = 1$. Then, the number of type-θ SUs can be computed by

$$N_\theta = N \cdot f_\theta, \quad \forall \theta \in \Theta,$$

where N is the total number of SUs and $\sum_{\theta \in \Theta} N_\theta = N$. It is easy to see that this is a discrete SU-type model, where each SU's type is chosen from a discrete set Θ. Later section "Contract Design in Continuous SU-Type Model" will extend the above discrete SU-type model to the continuous SU-type model, where the SU-type set Θ is a continuous region.

The *utility* of a type-θ SU from a channel with quality q, denoted by $U(\theta, q)$, is the benefit that he can achieve from using that channel, which can be defined as a strictly increasing function of channel capacity $\Phi(\theta, q)$. Without loss of generality, the utility $U(\theta, q)$ is defined as a linear function of capacity $\Phi(\theta, q)$ as follows:

$$U(\theta, q) = w \cdot \Phi(\theta, q) = w \cdot \log(1 + q \cdot \theta), \tag{3}$$

where $w > 0$ is a constant evaluation factor, indicating the benefit for SUs from one unit of channel capacity. Note that w is a predefined parameter and identical for all SUs. In the rest of this chapter, w will be normalized to be one, i.e., $w = 1$.

The *payoff* of a type-θ SU achieved from purchasing a channel with quality q at price π, denoted by $V(\theta, q, \pi)$, is defined as the difference between the achieved utility and the payment for the channel, i.e.,

$$V(\theta, q, \pi) = U(\theta, q) - \pi = w \cdot \log(1 + q \cdot \theta) - \pi. \tag{4}$$

It is easy to see that the utility $U(\theta, q)$ of SUs increases with the channel quality q, and the increase rate tends to be smaller with the increasing of q. That is,

- $U(\theta, q)$ is a non-negative, concave, and increasing function of q.

Suppose $U(\theta, q)$ is twice differentiable. Let $U'(\theta, q) \triangleq \frac{\partial U(\theta, q)}{\partial q}$ and $U''(\theta, q) \triangleq \frac{\partial^2 U(\theta, q)}{\partial q^2}$ denote the first- and second-order derivatives of $U(\theta, q)$ with respect to q. Then, the above observation can be formally written as $U'(\theta, q) > 0$ and $U''(\theta, q) \leq 0$, for all $q \in [0, Q_{\max}]$.

Social Welfare

The *social welfare* is defined as the aggregate payoff of all involved players, including the PU and all SUs. Specifically, when selling a channel with a quality q to a type-θ SU at a price π, the total generated social welfare is:

$$W(\theta, q) = R(q, \pi) + V(\theta, q, \pi) = U(\theta, q) - C(q), \tag{5}$$

where the price π in both payoff functions cancels each other out.

It is easy to see that $W''(\theta, q) \leq 0, \forall q \in [0, Q_{\max}]$, since $U''(\theta, q) \leq 0$ and $C''(q) \geq 0$, where $W''(\theta, q) \triangleq \frac{\partial^2 W(\theta, q)}{\partial q^2}$ is the second-order derivatives of $W(\theta, q)$ with respect to q. That is, the social welfare $S(\theta, q)$ is a concave function of q. Thus, the socially optimal quality for a type-θ SU, i.e., that maximizes the social welfare $W(\theta, q)$, can be solved by the following first-order condition:

$$U'(\theta, q) - C'(q) = 0.$$

Let $q^\circ(\theta)$ denote the socially optimal quality for a type-θ SU derived by the above first-order condition, and $W^\circ(\theta) = W(\theta, q^\circ(\theta))$ denote the corresponding optimal social welfare generated by a type-θ SU. It is easy to check that both $q^\circ(\theta)$ and $W^\circ(\theta)$ monotonically increase with θ. In other words, from a social perspective, the optimal qualities for SUs with different types are different: a higher type (efficiency) SU will be assigned with a higher-quality channel. This implies that offering different qualities for different types of SUs (i.e., *quality discrimination*) is desired from a social perspective.

Problem Description

As mentioned previously, the PU's decision is to specify the quality and price of the channels to be sold to SUs, and moreover, the quality discrimination is desired from a social perspective. Specifically, with the *quality discrimination* spectrum trading, the PU can offer multiple quality and price choices to SUs, and each SU decides not only whether to buy a channel but also which quality and price he would like to choose (when deciding to buy a channel).

The focus of this chapter is to design the optimal trading mechanism (i.e., the sets of quality and price choices to be offered to SUs) for the PU that maximizes his payoff (profit). The problem is challenging, especially under *information asymmetry*, where the type of each SU is his private information and cannot be observed by the PU. We will study the PU's profit maximization problem under both information symmetry (in section "Optimal Contract Under Information Symmetry") and information asymmetry (in section "Optimal Contract Under Information Asymmetry"), by using the *contract theory* [30]. Contract theory is a widely used theoretic tool in economics and often studies how economic actors can and do construct contractual arrangements, generally in the presence of asymmetric information. Recently, contract theory has also been introduced to solve various wireless communication and networking problems, e.g., cooperative spectrum sharing [14], secondary spectrum trading [23–25], TV white space networking [29], and WiFi community networking [31].

Contract Formulation

As mentioned early, with the *quality discrimination* spectrum trading, the PU can offer multiple quality and price choices to SUs, while each SU decides whether to buy a channel, and if so, which quality and price he would like to choose.

Notice that the SUs in the same class (i.e., those with the same type θ) are homogeneous, in the sense that they have the same preference, decision, utility/payoff functions, and social impact. This implies that it is sufficient for the PU to design one quality and one price for *each class of SUs* (with the same type), instead of for each SU. Let $q(\theta)$ and $\pi(\theta)$ denote the quality and price designed for

the type θ SUs. The set of all quality and price combinations (each for one type of SUs) is called a *contract*, denoted by

$$\Psi \triangleq \{(q(\theta), \pi(\theta)),\ \theta \in \Theta\}, \tag{6}$$

where each quality and price combination $(q(\theta), \pi(\theta))$ is called a *contract item* (for type θ SUs). The aim of the PU (and also the focus of this chapter) is to design the optimal contract that maximizes his profit.

It is important to note that without a proper contract design, a type-θ SU may not be willing to accept a contract item $(q(\theta), \pi(\theta))$ designed for his type θ. For example, if a contract item $(q(\theta), \pi(\theta))$ brings a negative payoff for a type-θ SU, then none of the type-θ SUs are willing to accept it; if a contract item $(q(\theta), \pi(\theta))$ has a higher quality and lower price than another one $(q(\theta'), \pi(\theta'))$, i.e., $q(\theta) > q(\theta')$ and $\pi(\theta) < \pi(\theta')$, then none of the type-$\theta'$ SUs are willing to choose the contract item $(q(\theta'), \pi(\theta'))$. Therefore, a joint design of $q(\theta)$ and $\pi(\theta)$ for all $\theta \in \Theta$ is necessary. This leads to the important concept of *feasible contract*.

Definition 1 (Feasibility). A contract $\Psi = \{(q(\theta), \pi(\theta)), \theta \in \Theta\}$ is feasible, if each SU of type θ is willing to choose the contract item $(q(\theta), \pi(\theta))$ designed for his type θ (hence truthfully reveal his type information).

Note that the feasibility constraint is different under different information scenarios. Specifically, under information symmetry, the PU can observe the type of each SU and hence can assign a specific contract item to each type of SUs. Thus, the feasibility constraint can be satisfied, if each SU of type θ can achieve a non-negative payoff under the contract item $(q(\theta), \pi(\theta))$ assigned to him. This condition is often referred to as the *individual rationality* (IR) [30]. Formally,

Definition 2 (Individual Rationality – IR [30]). A contract $\Psi = \{(q(\theta), \pi(\theta)), \theta \in \Theta\}$ is individually rational, if for all $\theta \in \Theta$,

$$V(\theta, q(\theta), \pi(\theta)) \geq 0. \tag{7}$$

Under information asymmetry, the PU cannot observe the type of each SU and hence cannot assign a specific contract item to each type of SUs. Instead, the PU can only offer all contract items for all SUs, while let SUs choose the best contract items according to their private-type information. Thus, the feasibility constraint can be satisfied, if each SU of type θ can achieve not only the non-negative payoff (IR condition) but also the best payoff among all contract items, under the contract item $(q(\theta), \pi(\theta))$ designed for his type. The latter condition is often referred to as the *incentive compatibility* (IC) [30]. Formally,

Definition 3 (Individual Compatibility – IC [30]). A contract $\Psi = \{(q(\theta), \pi(\theta)), \theta \in \Theta\}$ is incentive compatible, if for all $\theta \in \Theta$,

$$V(\theta, q(\theta), \pi(\theta)) \geq V(\theta, q(\theta'), \pi(\theta')), \quad \forall \theta' \in \Theta, \theta' \neq \theta. \tag{8}$$

Intuitively, under information symmetry, a contract is feasible if it satisfies the IR condition, while under information asymmetry, a contract is feasible only if it satisfies both the IR and IC conditions. Under a feasible contract Ψ, the payoff of the PU can be computed as follows:

$$R(\Psi) = \sum_{\theta \in \Theta} N_\theta \cdot R(q(\theta), \pi(\theta)) = \sum_{\theta \in \Theta} N_\theta \cdot (\pi(\theta) - C(q(\theta))), \tag{9}$$

where N_θ is the number of type-θ SUs. Note that (9) is only available under a feasible contract, where each type-θ SU chooses the contract item $(q(\theta), \pi(\theta))$ designed for his type θ. For an arbitrary contract, however, the PU payoff may not be the form of (9), due to the uncertainty of SUs' choices. This introduces an additional challenge in finding the optimal contract for the PU.

One effective way to resolve this challenge is the *revelation principle* [32], a fundamental principle in mechanism design. Specifically, revelation principle states that for an arbitrary mechanism, the designer can always find a feasible mechanism (where users truthfully report their types) that achieves the same outcome and payoff. By the revelation principle, the PU can restrict his search within the feasible contracts, in which every SU will choose the contract item designed for his type. In other words, the PU can focus on the optimal contract within the feasible contract set, which can achieve the same outcome as a globally optimal contract.

Definition 4 (Optimality). A contract $\Psi = \{(q(\theta), \pi(\theta)), \theta \in \Theta\}$ is optimal, if it is feasible, and meanwhile maximizes the PU payoff given in (9).

Let $\Psi^* = \{(q^*(\theta), \pi^*(\theta)), \theta \in \Theta\}$ denote the optimal contract (within the feasible contract set). Then, it can be formally derived as follows:

$$\begin{aligned} \max_{\Psi} \quad & R(\Psi) = \sum_{\theta \in \Theta} N_\theta \cdot (\pi(\theta) - C(q(\theta))) \\ \text{s.t.} \quad & \Psi \text{ is feasible.} \end{aligned} \tag{10}$$

The feasibility constraint guarantees that each SU is willing to choose the contract item designed for his type; hence the PU payoff can be written as $R(\Psi)$ in (9). As mentioned previously, under information symmetry, it can be satisfied if the IR condition holds, while under information asymmetry, it can be satisfied only if both the IR and IC conditions hold.

Optimal Contract Under Information Symmetry

This section studies the optimal contract design under information symmetry, where the type of each SU is public information and can be observed by the PU. In this case, the PU can assign a specific contract item to each type of SUs, and each SU can only decide whether to accept the quality and price designed for his type. Thus, the

feasibility constraint can be satisfied if each SU can achieved a non-negative payoff under the contract item assigned to him (IR condition); and the optimal contract can be derived by solving the best contract item for each type of SUs separately.

Feasibility of Contract

Under information symmetry, the feasibility of contract can be achieved if the IR condition holds. That is, each SU of type θ can achieve a non-negative payoff under the contract item $(q(\theta), \pi(\theta))$ assigned to him.

Lemma 1. *A contract $\Psi = \{(q(\theta), \pi(\theta)), \theta \in \Theta\}$ is feasible under information symmetry, if and only if the following IR conditions hold:*

$$U(\theta, q(\theta)) - \pi(\theta) \geq 0, \quad \forall \theta \in \Theta.$$

where $U(\theta, q(\theta)) = w \cdot \log(1 + q(\theta) \cdot \theta)$ is the utility of SU defined in (3).

Intuitively, under information symmetry, each SU has only two choices: accept or reject the contract item assigned to him. The latter choice implies that the SU decides not to buy a channel, leading to a zero payoff for the SU. Thus, each SU is willing to accept a contract item if it brings a non-negative payoff for the SU.

Optimality of Contract

The optimal contract can be derived by solving the best quality and price for each type of SUs separately. Formally, for a type-θ SU, the best quality and price, denoted by $q^\dagger(\theta)$ and $\pi^\dagger(\theta)$, can be derived as follows:

$$\begin{aligned} \max_{\{q(\theta), \pi(\theta)\}} \quad & R(q(\theta), \pi(\theta)) = \pi(\theta) - C(q(\theta)) \\ s.t. \quad & U(\theta, q(\theta)) - \pi(\theta) \geq 0; \\ & \pi(\theta) \geq 0, \quad Q_{\max} \geq q(\theta) \geq 0. \end{aligned} \tag{11}$$

Here $U(\theta, q(\theta)) - \pi(\theta) \geq 0$ is the IR condition, which guarantees the feasibility of contract. Let $R^\dagger(\theta) \triangleq R(q^\dagger(\theta), \pi^\dagger(\theta))$ denote the solution of (11), i.e., the maximum payoff that the PU can achieved from a type-θ SU.

To solve (11), it is notable that given any feasible quality $q(\theta)$, the best price strategy for the PU is to charge a price as high as the SU's utility $U(\theta, q(\theta))$, i.e., $\pi^\dagger(\theta) = U(\theta, q(\theta))$. Substitute the above best price into (11), the best quality $q^\dagger(\theta)$ can be solved in the following way:

$$\begin{aligned} \max_{\{q(\theta)\}} \quad & U(\theta, q(\theta)) - C(q(\theta)) \\ s.t. \quad & Q_{\max} \geq q(\theta) \geq 0. \end{aligned} \tag{12}$$

Note that $U(\theta, q(\theta)) - C(q(\theta))$ is exactly the social welfare defined in (5). Thus, the above (12) is exactly the social welfare maximization problem, and the best quality $q^\dagger(\theta)$ is equivalent to the corresponding socially optimal quality $q^\circ(\theta)$. Formally,

Lemma 2. *The optimal contract* $\Psi^\dagger = \{(q^\dagger(\theta), \pi^\dagger(\theta)), \theta \in \Theta\}$ *under information symmetry is given by*

$$q^\dagger(\theta) = q^\circ(\theta) \ \text{ and } \ \pi^\dagger(\theta) = U(\theta, q^\circ(\theta)), \quad \forall \theta \in \Theta.$$

where $q^\circ(\theta)$ *is the socially optimal quality for a type-*θ *SU.*

Intuitively, when the PU can observe the type information of SUs, he can design such an optimal contract, which assigns each SU the corresponding socially optimal quality (hence generates as much social welfare as possible) and charges each SU as high as possible (up to the SU's achieved utility). Thus, the maximum payoff $R^\dagger(\theta)$ that the PU can achieved from a type-θ SU is exactly the maximum social welfare $W^\circ(\theta)$ that can be achieved from a type-θ SU, i.e., $R^\dagger(\theta) = W^\circ(\theta)$.

Optimal Contract Under Information Asymmetry

This section studies the optimal contract design under information asymmetry, where the type of each SU is his private information and cannot be observed by the PU. In this case, the PU cannot assign a specific contract item to each SU; instead, he can only offer all contract items for all SUs, while let SUs choose the best contract items according to their private-type information. Thus, the feasibility constraint can be satisfied if each SU can achieve not only a non-negative payoff (IR condition) but also the best payoff among all contract items (IC condition), under the contract item designed for his type. Accordingly, the optimal contract needs to solve the best contract items for all SU types jointly.

Suppose there is a total of T SU classes (types), with θ_t denoting the type of SUs in the t-th class. Then, the set of SU types can be written as $\Theta = \{\theta_1, \cdots, \theta_T\}$. Assume that $\theta_1 < \theta_2 < \cdots < \theta_T$ without loss of generality. For notational convenience, denote $f_t = f_{\theta_t}$ and $N_t = N_{\theta_t}$ as the percentage and the number of type-θ_t SUs (in the t-th class), respectively, and $q_t = q(\theta_t)$ and $\pi_t = \pi(\theta_t)$ as the quality and price designed for type θ_t SUs, respectively. Then, a contract can be rewritten as

$$\Psi \triangleq \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}.$$

Accordingly, the contract optimization problem (10) can be rewritten as

$$\max_{\Psi} \ R(\Psi) = \sum_{t=1}^{T} N_t \cdot (\pi_t - C(q_t)) \qquad (13)$$

$$\text{s.t. IR and IC conditions.}$$

Before discussing the feasibility and optimality of contract, we first introduce the following important property for the utility model: when increasing a quality with a

given value, the utility improvement for a higher-type user is greater than that for a lower-type user. This property is refereed as the *increasing preference* (IP).

Definition 5 (Increasing Preference – IP). Let $u(\theta, q)$ denote the utility of a type-θ user for quality q. Then, the utility model satisfies the property of increasing preference (IP), if for any $\theta > \theta'$ and $q > q'$, the following conditions hold:

$$u(\theta, q) - u(\theta, q') > u(\theta', q) - u(\theta', q'). \tag{14}$$

That is, a higher-type user can achieve a larger utility gain from a given quality improvement than a lower-type user.

It is easy to see that the SU's utility $U(\theta, q)$ defined in (3) satisfied the above IP property. Namely, when increasing the quality with a given value, a higher-type SU (who has a higher efficiency factor) can achieve a larger utility gain than a lower type SU (who has a lower efficiency factor).

In what follows, we will first provide the necessary and sufficient conditions for feasible contracts and then find the optimal contract within the feasible contract set.

Feasibility of Contract

Under information asymmetry, the feasibility of contract can be achieved only if both IR and IC conditions hold. That is, each SU of type θ can achieve not only a non-negative payoff but also the best payoff among all contract items, under the contract item $(q(\theta), \pi(\theta))$ assigned to him.

First, we show the necessary conditions for a contract to be feasible.

Lemma 3. *If a contract* $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$ *is feasible under information asymmetry, then the following necessary conditions hold:*

$$q_i > q_j \quad \textit{if and only if} \quad \pi_i > \pi_j, \quad \forall i, j \in \{1, \cdots, T\},\ i \neq j.$$

Proof. Notice that if a contract is feasible under information asymmetry, it must satisfy the IR and IC conditions defined in (7) and (8).

$\rightarrow$: In this direction, we will show: if $q_i > q_j$, then $\pi_i > \pi_j$. By the IC condition defined in (8), the following condition holds for each type-θ_j SU:

$$U(\theta_j, q_j) - \pi_j \geq U(\theta_j, q_i) - \pi_i,$$

or equivalently,

$$\pi_i - \pi_j \geq U(\theta_j, q_i) - U(\theta_j, q_j) > 0,$$

where the second inequality follows because $U(\theta, q)$ strictly increases with q.

$\leftarrow$: In this direction, we will show: if $\pi_i > \pi_j$, then $q_i > q_j$. By the IC condition defined in (8), the following condition holds for each type-θ_i SU:

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_j) - \pi_j,$$

or equivalently,

$$U(\theta_i, q_i) - U(\theta_i, q_j) \geq \pi_i - \pi_j > 0,$$

which implies that $q_i > q_j$, as $U(\theta, q)$ strictly increases with q. □

Lemma 3 provides an important property of a feasible contract: *a higher quality must be associated with a higher price*. This lemma also implies that if there exist two qualities (or prices) with the same value, then the associated prices (or qualities) are also the same value. Formally,

Corollary 1. *For any feasible contract* $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$ *under information asymmetry, the following conditions hold:*

$$q_i = q_j \quad \textit{if and only if} \quad \pi_i = \pi_j, \quad \forall i, j \in \{1, \cdots, T\},\ i \neq j.$$

Lemma 4. *If a contract* $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$ *is feasible under information asymmetry, then the following necessary conditions hold:*

$$\textit{if} \quad \theta_i > \theta_j, \quad \textit{then} \quad q_i \geq q_j \quad \forall i, j \in \{1, \cdots, T\},\ i \neq j.$$

Proof. Assume, to the contrary, that there exist $\theta_i > \theta_j$ and $q_i < q_j$. Then, by the IP property defined in (14), the following condition holds:

$$U(\theta_i, q_j) - U(\theta_i, q_i) > U(\theta_j, q_j) - U(\theta_j, q_i)$$

By the IC condition in (8), the following condition holds for each type-θ_i SU,

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_j) - \pi_j,$$

and for each type-θ_j SU,

$$U(\theta_j, q_j) - \pi_j \geq U(\theta_j, q_i) - \pi_i.$$

Combine the above two IC conditions, we obtain:

$$U(\theta_i, q_j) - U(\theta_i, q_i) \leq U(\theta_j, q_j) - U(\theta_j, q_i),$$

which violates the IP property given above. □

Lemma 4 provides another important property of a feasible contract: *a higher-type SU must be assigned with a higher quality (and also a higher price by Lemma 3)*. Recall that the type of an SU reflects the SU's transmission efficiency, and the quality of a channel reflects the constraint on using the channel. Thus, this lemma implies that the SUs with a higher efficiency can use the channels with a less constraint, which coincides with the social expectation.

Recall that $\theta_1 < \theta_2 < \cdots < \theta_T$. According to Lemmas 3 and 4, a feasible contract $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$ has the following structure:

$$q_1 \leq q_2 \leq \ldots \leq q_T \quad \text{and} \quad \pi_1 \leq \pi_2 \leq \ldots \leq \pi_T, \tag{15}$$

with $q_t = q_{t+1}$ if and only if $\pi_t = \pi_{t+1}$.

Next, we show the sufficient conditions for a contract to be feasible.

Lemma 5. *A contract $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$ is feasible under information asymmetry, if the following sufficient conditions hold:*

$$0 \leq q_1 \leq \cdots \leq q_T \leq Q_{\max} \tag{16}$$

and

$$\begin{cases} 0 \leq \pi_t \leq U(\theta_1, q_1), & t = 1 \\ \pi_{t-1} + A \leq \pi_t \leq \pi_{t-1} + B, & t = 2, \cdots, T \end{cases} \tag{17}$$

where $A \triangleq U(\theta_{t-1}, q_t) - U(\theta_{t-1}, q_{t-1})$ and $B \triangleq U(\theta_t, q_t) - U(\theta_t, q_{t-1})$.

Proof. Prove the lemma by induction. Define a new contract

$$\Psi_{(k)} \triangleq \{(q_t, \pi_t),\ t \in \{1, \ldots, k\}\},$$

which consists of the first k contract items in the original contract Ψ, for the first k types of SUs in the system. Obviously, $\Psi_{(T)} = \Psi$. By induction, the contract Ψ or $\Psi_{(T)}$ is feasible, if the following two conditions hold: (a) $\Psi_{(1)}$ is feasible, and (b) If $\Psi_{(k)}$ is feasible, then $\Psi_{(k+1)}$ is also feasible, for all $k = 1, \cdots, T-1$.

Proof for (a): $\Psi_{(1)}$ is feasible. Since there is only one contract item (q_1, π_1) in $\Psi_{(1)}$ and one SU type θ_1, the sufficient condition for the contract $\Psi_{(1)}$ to be feasible is only the IR condition in (7). By (16) and (17), it is easy to see that: $V(\theta_1, q_1, \pi_1) = U(\theta_1, q_1) - \pi_1 \geq 0$, that is, the IR condition holds, hence $\Psi_{(1)}$ is feasible.

Proof for (b): if $\Psi_{(k)}$ is feasible, then $\Psi_{(k+1)}$ is also feasible, for all $k = 1, \cdots, T-1$. Notice that $\Psi_{(k)}$ consists of the first k contract items in Ψ for the first k types of SUs, while $\Psi_{(k+1)}$ consists of the first $k+1$ contract items in Ψ for the first $k+1$ types of SUs. Thus, to prove that $\Psi_{(k+1)}$ is feasible, we need to show:

- (b.1) For the newly joined SUs with type θ_{k+1}, the IR and IC conditions hold:

$$\begin{aligned} &U(\theta_{k+1}, q_{k+1}) - \pi_{k+1} \geq 0, \\ &U(\theta_{k+1}, q_{k+1}) - \pi_{k+1} \geq U(\theta_{k+1}, q_i) - \pi_i, \quad \forall i = 1, \cdots, k. \end{aligned} \tag{18}$$

- (b.2) For the existing SUs with types $\theta_1, \cdots, \theta_k$, the IC conditions hold:

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_{k+1}) - \pi_{k+1}, \quad \forall i = 1, \cdots, k. \tag{19}$$

  Note that the IR conditions for the exiting SUs are naturally satisfied by the feasibility of $\Psi_{(k)}$.

Proof for (b.1): the IC and IR conditions for the new SUs with type θ_{k+1}. Since $\Psi_{(k)}$ is feasible, the following IC conditions must hold for the type-θ_k SUs:

$$U(\theta_k, q_k) - \pi_k \geq U(\theta_k, q_i) - \pi_i, \quad \forall i = 1, \cdots, k.$$

According to (17), i.e., $\pi_{k+1} \leq \pi_k + U(\theta_{k+1}, q_{k+1}) - U(\theta_{k+1}, q_k)$, we have:

$$U(\theta_k, q_k) + U(\theta_{k+1}, q_{k+1}) - U(\theta_{k+1}, q_k) \geq U(\theta_k, q_i) - \pi_i + \pi_{k+1}, \ \forall i = 1, \cdots, k.$$

With simple transformation, the above condition can be written as:

$$U(\theta_{k+1}, q_{k+1}) - \pi_{k+1} \geq U(\theta_k, q_i) - U(\theta_k, q_k) + U(\theta_{k+1}, q_k) - \pi_i, \ \forall i = 1, \cdots, k.$$

Notice that $\theta_{k+1} > \theta_k$ and $q_k \geq \cdots \geq q_1$. By the IP property, we have:

$$U(\theta_k, q_i) - U(\theta_k, q_k) + U(\theta_{k+1}, q_k) \geq U(\theta_{k+1}, q_i), \ \forall i = 1, \cdots, k.$$

Based on the above, we can prove the IC conditions for the new type θ_{k+1}:

$$U(\theta_{k+1}, q_{k+1}) - \pi_{k+1} \geq U(\theta_{k+1}, q_i) - \pi_i, \ \forall i = 1, \cdots, k.$$

Notice that $U(\theta_{k+1}, q_i) - \pi_i \geq U(\theta_i, q_i) - \pi_i$ for any $i \leq k$ and $U(\theta_i, q_i) - \pi_i \geq 0$ by the feasibility of $\Psi_{(k)}$. Then, using the above IC conditions, we can prove the IR conditions for the new type θ_{k+1}:

$$U(\theta_{k+1}, q_{k+1}) - \pi_{k+1} \geq 0.$$

Proof for (b.2): the IC conditions for the exiting SUs with types $\theta_1, \cdots, \theta_k$ under the new contract $\Psi_{(k+1)}$. Since $\Psi_{(k)}$ is feasible, the following IC conditions must hold for all the existing SUs with types $\theta_1, \cdots, \theta_k$:

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_k) - \pi_k, \quad \forall i = 1, \cdots, k.$$

According to (17), i.e., $\pi_k + U(\theta_k, q_{k+1}) - U(\theta_k, q_k) \leq \pi_{k+1}$, we have:

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_k) + U(\theta_k, q_{k+1}) - U(\theta_k, q_k) - \pi_{k+1}, \quad \forall i = 1, \cdots, k.$$

Notice that $\theta_{k+1} > \theta_k > \cdots > \theta_1$ and $q_{k+1} \geq q_k \geq \cdots \geq q_1$. By IP property, we have:

$$U(\theta_i, q_k) + U(\theta_k, q_{k+1}) - U(\theta_k, q_k) \geq U(\theta_i, q_{k+1}), \quad \forall i = 1, \cdots, k.$$

Based on the above, we can prove the IC conditions for the existing types $\theta_1, \cdots, \theta_k$:

$$U(\theta_i, q_i) - \pi_i \geq U(\theta_i, q_{k+1}) - \pi_{k+1}, \quad \forall i = 1, \cdots, k.$$

Up to now, we have proved that (a) $\Psi_{(1)}$ is feasible, and (b) If $\Psi_{(k)}$ is feasible, then $\Psi_{(k+1)}$ is also feasible. By induction, the contract $\Psi_{(T)}$ or Ψ is feasible. □

It is important to note that the sufficient conditions in Lemma 5 are also necessary for a feasible contract: the necessity of (16) can be proved by Lemma 4, and the necessity of (17) can be proved by the IC and IR conditions directly. Moreover, the conditions in Lemma 5 satisfy the feasible structure in (15). First, $q_k \geq q_{k-1}$ by (16); second, $\pi_k \geq \pi_{k-1}$ as $A \geq 0$; third, if $q_k = q_{k-1}$, then $A = B = 0$ and $\pi_k = \pi_{k-1}$ as $\pi_{k-1} \leq \pi_k \leq \pi_{k-1}$; and forth, if $\pi_k = \pi_{k-1}$, then $A \leq 0 \leq B$, which implies that $q_k \leq q_{k-1}$ and $q_k \geq q_{k-1}$; hence $q_k = q_{k-1}$. In fact, Lemma 5 provides more strict and tight necessary conditions for a feasible contract.

Optimality of Contract

To derive the optimal contract, we first derive the best price set under a given (feasible) quality set and then derive the best quality set. For notational convenience, let $\mathsf{Q} \triangleq \{q_t,\ t \in \{1, \cdots, T\}\}$ and $\mathsf{P} \triangleq \{\pi_t,\ t \in \{1, \cdots, T\}\}$ denote the quality set and the price set of a contract $\Psi = \{(q_t, \pi_t),\ t \in \{1, \cdots, T\}\}$, respectively. Then, a contract can also be written as $\Psi = \{\mathsf{Q},\ \mathsf{P}\}$.

By Lemma 5, a quality set Q is feasible, if and only if $0 \leq q_1 \leq \cdots q_T \leq Q_{\max}$ Let $R^*_{(\mathsf{Q})}$ denote the maximum payoff that the PU can achieve under a given feasible quality set Q, by optimizing the price set P solely. Let $\mathsf{P}^*_{(\mathsf{Q})} \triangleq \{\pi^*_t,\ t \in \{1, \cdots, T\}\}$ denote the best price set given the feasible quality set Q. Formally, the best price set $\mathsf{P}^*_{(\mathsf{Q})}$ and the maximum payoff $R^*_{(\mathsf{Q})}$ can be derived by

$$\begin{aligned} \max_{\mathsf{P}} \ & \sum_{t=1}^{T} N_t \cdot (\pi_t - C(q_t)) \\ \text{s.t.} \ & \text{The Conditions in (17).} \end{aligned} \tag{20}$$

The conditions in (17) are used to guarantee the feasibility of contract.

Lemma 6. *Given a feasible quality set* Q *with* $0 \le q_1 \le \cdots q_T \le Q_{\max}$, *the unique best price set* $\mathsf{P}^* \triangleq \{\pi_t^*,\ t \in \{1, \cdots, T\}\}$ *for problem* (20) *is given by*

$$\begin{cases} \pi_t^* = U(\theta_1, q_1), & t = 1; \\ \pi_t^* = \pi_{t-1}^* + U(\theta_t, q_t) - U(\theta_t, q_{t-1}), & t = 2, \cdots, T. \end{cases} \tag{21}$$

Proof. It is easy to check that the price set in (21) is a feasible price set, and thus the achieved contract (with the given quality set and the derived price set) is feasible. Note that this feasibility is necessary for the optimality.

Next we prove the optimality of the price set in (21). Notice that, given a feasible quality set $\mathsf{Q} = \{q_t,\ t \in \{1, \cdots, T\}\}$, the total cost $\sum_{t=1}^{T} N_t \cdot C(q_t)$ of the PU is a constant. Thus, the PU's profit maximization problem (20) can be transferred into the following revenue maximization problem (22):

$$\max_{\mathsf{P}} \sum_{t=1}^{T} N_t \cdot \pi_t \tag{22}$$
$$\text{s.t. The Conditions in (17).}$$

Assume, to the contrary, that there exists another feasible price set $\mathsf{P}' = \{\pi_t',\ t \in \{1, \cdots, T\}\}$, which is different from P^* in (21) and achieves $\sum_{t=1}^{T} N_t \pi_t' > \sum_{t=1}^{T} N_t \pi_t^*$. Then, there exists at least one price in P' larger than the corresponding price in P^*. Suppose $\pi_k' > \pi_k^*$ without loss of generality. By (17), the following condition must hold for π_k' (in order to guarantee the feasibility of contract):

$$\pi_k' \le \pi_{k-1}' + U(\theta_k, q_k) - U(\theta_k, q_{k-1}).$$

By (21), we have: $\pi_k^* - \pi_{k-1}^* = U(\theta_k, q_k) - U(\theta_k, q_{k-1})$. Thus,

$$\pi_k' \le \pi_{k-1}' + \pi_k^* - \pi_{k-1}^*,$$

or equivalently,

$$\pi_{k-1}' - \pi_{k-1}^* \ge \pi_k' - \pi_k^* > 0.$$

Continue the above process, we can finally reach $\pi_1' - \pi_1^* > 0$, which violates the IR condition for the type-θ_1 SUs. Namely, with a price $\pi_1' > \pi_1^* = U(\theta_1, q_1)$, a type-$\theta_1$ SU will not accept the price contract item (q_1, π_1') assigned to him. Therefore, there does *not* exist another feasible price set $\mathsf{P}' \ne \mathsf{P}^*$ such that $\sum_{t=1}^{T} N_t \pi_t' > \sum_{t=1}^{T} N_t \pi_t^*$, which implies that P^* is the best price set.

Then we prove that P^* in (21) is the unique best price set for (20). Assume, to the contrary, that there exists another feasible price set $\mathsf{P}' = \{\pi_t',\ t \in \{1, \cdots, T\}\}$, which is different from P^* in (21) and achieves the same maximum revenue, i.e., $\sum_{t=1}^{T} N_t \pi_t' = \sum_{t=1}^{T} N_t \pi_t^*$. Since $\mathsf{P}' \ne \mathsf{P}^*$, there exists at least one price in P'

different from the corresponding price in P^*. Suppose $\pi'_k \neq \pi^*_k$ without loss of generality. If $\pi'_k > \pi^*_k$, then we will finally reach $\pi'_1 - \pi^*_1 > 0$, using the similar analysis in the above. If $\pi'_k < \pi^*_k$, then there must exist another price $\pi'_j > \pi^*_j$ since $\sum_{t=1}^{T} N_t \pi'_t = \sum_{t=1}^{T} N_t \pi^*_t$. Similarly, we will finally reach $\pi'_1 - \pi^*_1 > 0$. Therefore, there does *not* exist another feasible price set $\mathsf{P}' \neq \mathsf{P}^*$ such that $\sum_{t=1}^{T} N_t \pi'_t = \sum_{t=1}^{T} N_t \pi^*_t$, which implies that P^* is the unique best price set. □

Lemma 6 states that, given any feasible quality set Q, the best price set P^* is unique and given by (21). By substituting the best price set P^* into (20), the best quality set $\mathsf{Q}^* \triangleq \{q^*_t,\ t \in \{1, \cdots, T\}\}$ can be derived as follows:

$$\max_{\mathsf{Q}} \ R^*_{(\mathsf{Q})} \triangleq \sum_{t=1}^{T} N_t \cdot (\pi^*_t - C(q_t)) \qquad \text{s.t. The Conditions in (16).} \tag{23}$$

The conditions in (16), i.e., $0 \leq q_1 \leq \cdots \leq q_T \leq Q_{\max}$, are used to guarantee the feasibility of contract.

Introduce the notations: $\Delta_1 = 0$ and $\Delta_t = U(\theta_t, q_t) - U(\theta_t, q_{t-1}), \forall t = 2, \ldots, T$. Then, the best price set P^* given in (21) can be rewritten as

$$\pi^*_t = U(\theta_1, q_1) + \sum_{k=1}^{t} \Delta_k, \quad \forall t = 1, \ldots, T. \tag{24}$$

Substitute (24) into (23), the PU's payoff $R^*_{(\mathsf{Q})}$ can be written as follows:

$$R^*_{(\mathsf{Q})} = \sum_{t=1}^{T} N_t \cdot \left(U(\theta_1, q_1) + \sum_{k=1}^{t} \Delta_k - C(q_t) \right), \tag{25}$$

where $\Delta_1 = 0$ and $\Delta_k = U(\theta_k, q_k) - U(\theta_k, q_{k-1}), \forall k = 2, \ldots, T$ as defined above. Rearranging the above equation by putting the terms associated with the same quality together, the PU's payoff $R^*_{(\mathsf{Q})}$ can be rewritten as follows:

$$R^*_{(\mathsf{Q})} = \sum_{t=1}^{T} \left(N_t \cdot U(\theta_t, q_t) - N_t \cdot C(q_t) + \Lambda_t \cdot \sum_{k=t+1}^{T} N_k \right) \tag{26}$$

where $\Lambda_t = U(\theta_t, q_t) - U(\theta_{t+1}, q_t), \forall t = 1, \cdots, T-1$, and $\Lambda_T = 0$. Introduce

$$G_t(q_t) \triangleq N_t \cdot U(\theta_t, q_t) - N_t \cdot C(q_t) + \Lambda_t \cdot \sum_{k=t+1}^{T} N_k.$$

Then, the PU's payoff $R^*_{(\mathsf{Q})}$ can be rewritten as $R^*_{(\mathsf{Q})} = \sum_{t=1}^{T} G_t(q_t)$. Accordingly, the optimization problem (23) can be rewritten as follows:

$$\begin{aligned} \max_{\mathsf{Q}} \quad & \sum_{t=1}^{T} G_t(q_t) \\ \text{s.t.} \quad & \text{The Conditions in (16).} \end{aligned} \tag{27}$$

It is worth noting that $G_t(q_t)$ depends only on the quality q_t, while independent of all other qualities $q_k, \forall k \neq t$. This implies that the optimization problem (27) can be solved by optimizing the quality q_t for each $G_t(q_t)$ separately. Let $\tilde{q}_t^*$, $t = 1, \cdots, T$, denote the quality that maximizes $G_t(q_t)$. That is,

$$\begin{aligned} \tilde{q}_t^* \triangleq \arg\max_{q_t} \quad & G_t(q_t) \\ \text{s.t.} \quad & 0 \leq q_t \leq Q_{\max}. \end{aligned} \tag{28}$$

Note that if the quality set $\widetilde{\mathsf{Q}}^* \triangleq \{\tilde{q}_t^*, \ t = 1, \cdots, T\}$ derived by (28) is a feasible quality set, i.e., satisfying the conditions in (16), then it is exactly the optimal solution of (23). This condition holds for a wide range of SU distributions. For example, with the uniform distribution, i.e., $N_1 = \cdots = N_T$ and $\theta_t - \theta_{t-1} = \delta, \forall t = 2, \cdots, T$, the quality set $\widetilde{\mathsf{Q}}^*$ derived by (28) satisfies the conditions in (16) and hence is the best quality set for the problem (23). Formally,

Theorem 1. *Suppose* $\widetilde{\mathsf{Q}}^* \triangleq \{\tilde{q}_t^*, \ t = 1, \cdots, T\}$ *derived by* (28) *is a feasible quality set satisfying the conditions in* (16)*. Then, the optimal contract* $\Psi^* = \{(q_t^*, \pi_t^*), \ t \in \{1, \cdots, T\}\}$ *under information asymmetry is given by*

$$q_t^* = \tilde{q}_t^* \quad \textit{and} \quad \pi_t^* = U(\theta_1, q_1^*) + \sum_{k=1}^{t} \Delta_k, \quad \forall t = 1, \ldots, T.$$

where $\Delta_1 = 0$ *and* $\Delta_k = U(\theta_k, q_k^*) - U(\theta_k, q_{k-1}^*), \forall k = 2, \ldots, T$.

In a general case, however, the quality set $\widetilde{\mathsf{Q}}^*$ derived by (28) may not satisfy the conditions in (16), hence not feasible. That is, there may exist two qualities $\tilde{q}_t^*$ and $\tilde{q}_{t-1}^*$ such that $\tilde{q}_t^* < \tilde{q}_{t-1}^*$. In this case, similar as in [25], an iterative algorithm can be used to adjust the quality set $\widetilde{\mathsf{Q}}^*$ such that it is feasible. The key idea is to optimize q_t and q_{t-1} together with the constraint $q_t \geq q_{t-1}$. Specifically, any infeasible qualities $\tilde{q}_t^*$ and $\tilde{q}_{t-1}^*$ with $\tilde{q}_t^* < \tilde{q}_{t-1}^*$ will be adjusted in the following way:

$$\begin{aligned} \{\tilde{q}_t^*, \tilde{q}_{t-1}^*\} \triangleq \arg\max_{\{q_t, q_{t-1}\}} \quad & G_t(q_t) + G_{t-1}(q_{t-1}) \\ \text{s.t.} \quad & 0 \leq q_{t-1} \leq q_t \leq Q_{\max}. \end{aligned} \tag{29}$$

Eventually, the feasible quality set $\widetilde{\mathbb{Q}}^*$ can be obtained, by repeating the above process to remove any infeasible quality bundle.

Contract Design in Continuous SU-Type Model

The previous sections study the optimal contract design in the discrete SU-type model with a finite set of SU types $\Theta = \{\theta_1, \cdots, \theta_T\}$. This section will extend such a discrete SU-type model to the continuous one, where the set of SU types Θ is a continuous region $[\theta_{\min}, \theta_{\max}]$. Note that the optimal contract design under information symmetry in the continuous SU-type model is totally same as that in the discrete model (section "Optimal Contract Under Information Symmetry"). Thus, this section will focus on the optimal contract design under information asymmetry in the continuous SU-type model.

Let $f(\theta)$ denote the probability distribution function (pdf) of θ in $\Theta = [\theta_{\min}, \theta_{\max}]$. With the continuous SU types in $\Theta = [\theta_{\min}, \theta_{\max}]$, a contract can be defined as

$$\Psi \triangleq \{(q(\theta), \pi(\theta)),\ \theta \in \Theta\}, \tag{30}$$

where $q(\theta)$ and $\pi(\theta)$ are continuous functions of θ in Θ. Under a feasible contract Ψ, the expected payoff (9) of the PU can be rewritten as

$$\begin{aligned} R(\Psi) &= \int_{\theta\in\Theta} R(q(\theta), \pi(\theta)) \cdot f(\theta) \mathrm{d}\theta \\ &= \int_{\theta\in\Theta} (\pi(\theta) - C(q(\theta))) \cdot f(\theta) \mathrm{d}\theta. \end{aligned} \tag{31}$$

Accordingly, the contract optimization problem (10) can be rewritten as

$$\begin{aligned} \max_{\Psi}\ & R(\Psi) = \int_{\theta\in\Theta} (\pi(\theta) - C(q(\theta))) \cdot f(\theta) \mathrm{d}\theta \\ \text{s.t.}\ & \Psi \text{ is feasible.} \end{aligned} \tag{32}$$

Following the structure of section "Optimal Contract Under Information Asymmetry", in what follows, we will first provide the necessary and sufficient conditions for feasible contracts and then find the optimal contract within the feasible contract set.

Feasibility of Contract

Intuitively, the continuous SU-type model can be achieved from a discrete model with an infinite number of types (i.e., $T \to \infty$) and an infinitesimal gap between any two successive types (i.e., $\theta_{t+1} - \theta_t \to 0$). Thus, the conditions in Lemmas 3, 4,

and 5 for the discrete SU-type model are also applicable to the continuous SU-type model, but with different forms.

Suppose that $q(\theta)$ and $\pi(\theta)$ are continuous and differentiable in Θ. Let $q'(\theta) \triangleq \frac{\partial q(\theta)}{\partial \theta}$ and $\pi'(\theta) \triangleq \frac{\partial \pi(\theta)}{\partial \theta}$ denote the first-order derivatives of $q(\theta)$ and $\pi(\theta)$ with respect to θ, respectively. Then, Lemmas 3, 4, and 5 can be rewritten as follows:

Lemma 7. *If a contract* $\{(q(\theta), \pi(\theta)),\ \theta \in \Theta\}$ *is feasible under information asymmetry, then the following necessary conditions hold:*

$$q'(\theta) > 0 \quad \textit{if and only if} \quad \pi'(\theta) > 0, \quad \forall \theta \in \Theta.$$

Lemma 8. *If a contract* $\{(q(\theta), \pi(\theta)),\ \theta \in \Theta\}$ *is feasible under information asymmetry, then the following necessary conditions hold:*

$$q'(\theta) \geq 0, \quad \forall \theta \in \Theta.$$

By Lemmas 7 and 8, the feasible contract structure in (15) can be rewritten as

$$q'(\theta) \geq 0 \quad \text{and} \quad \pi'(\theta) \geq 0, \quad \forall \theta \in \Theta, \tag{33}$$

with $q'(\theta) = 0$ if and only if $\pi'(\theta) = 0$.

Lemma 9. *A contract* $\{(q(\theta), \pi(\theta)),\ \theta \in \Theta\}$ *is feasible under information asymmetry, if and only if the following conditions hold:*

$$q'(\theta) \geq 0, \quad \forall \theta \in \Theta \tag{34}$$

and

$$\begin{cases} 0 \leq \pi(\theta_{\min}) \leq U(\theta_{\min}, q(\theta_{\min})) \\ \pi'(\theta) = U'(\theta, q(\theta)) \cdot q'(\theta), \quad \forall \theta \in \Theta \end{cases} \tag{35}$$

where $U'(\theta, q(\theta)) = \frac{\partial U(\theta, q)}{\partial q}|_{q=q(\theta)}$ *and* $q'(\theta) \triangleq \frac{\partial q(\theta)}{\partial \theta}$.

Proof. The first two conditions can be easily derived from the corresponding conditions in Lemma 5 for the discrete SU-type model. Therefore, we focus on proving the last condition, i.e., $\pi'(\theta) = U'(\theta, q(\theta)) \cdot q'(\theta),\ \forall \theta \in \Theta$.

As mentioned previously, the continuous SU-type model can be viewed as a discrete model with an infinitesimal gap between any two successive types, i.e., $\theta_t = \theta_{t-1} + \sigma$ where $\sigma \to 0$. Substitute the above θ_t and $\theta_{t-1} = \theta_t - \sigma$ into the third condition in Lemma 5, we can obtain the following condition:

$$\pi(\theta_t - \sigma) + A \leq \pi(\theta_t) \leq \pi(\theta_t - \sigma) + B, \tag{36}$$

where $A \triangleq U(\theta_t - \sigma, q(\theta_t)) - U(\theta_t - \sigma, q(\theta_t - \sigma))$ and $B \triangleq U(\theta_t, q(\theta_t)) - U(\theta_t, q(\theta_t - \sigma))$. From the right inequality of (36), we have:

$$\begin{aligned}\pi'(\theta_t) &= \lim_{\sigma \to 0} \frac{\pi(\theta_t) - \pi(\theta_t - \sigma)}{\sigma} \\ &\leq \lim_{\sigma \to 0} \frac{U(\theta_t, q(\theta_t)) - U(\theta_t, q(\theta_t - \sigma))}{\sigma} \\ &= \lim_{\sigma \to 0} \frac{U(\theta_t, q(\theta_t)) - U(\theta_t, q(\theta_t - \sigma))}{q(\theta_t) - q(\theta_t - \sigma)} \cdot \frac{q(\theta_t) - q(\theta_t - \sigma)}{\sigma} \\ &= U'(\theta_t, q(\theta_t)) \cdot q'(\theta_t).\end{aligned} \tag{37}$$

Similarly, from the left inequality of (36), we have:

$$\pi'(\theta_t) \geq U'(\theta_t - \sigma, q(\theta_t)) \cdot q'(\theta_t) = U'(\theta_t, q(\theta_t)) \cdot q'(\theta_t). \tag{38}$$

Combining the above two inequalities, we have:

$$\pi'(\theta_t) = U'(\theta_t, q(\theta_t)) \cdot q'(\theta_t), \quad \forall \theta_t \in \Theta.$$

Thus, we complete the proof by using the results in the discrete SU-type model. □

Note that Lemma 9 provides the feasible price function $\pi(\theta)$ with the first-order derivative indirectly. The explicit form of the feasible price function can be derived by using the integral calculus. Formally, for any $x \in \Theta$,

$$\begin{aligned}\pi(x) &= \int_{\theta_{\min}}^{x} \pi'(\theta) \mathrm{d}\theta + \pi(\theta_{\min}) \\ &= \int_{\theta_{\min}}^{x} U'(\theta, q(\theta)) \cdot q'(\theta) \mathrm{d}\theta + \pi(\theta_{\min}).\end{aligned} \tag{39}$$

The full derivative of $U(\theta, q(\theta))$ with respect to θ is:

$$\begin{aligned}\frac{\mathrm{d}U(\theta, q(\theta))}{\mathrm{d}\theta} &= \frac{\partial U(\theta, q(\theta))}{\partial \theta} + \frac{\partial U(\theta, q(\theta))}{\partial q(\theta)} \cdot \frac{\partial q(\theta)}{\partial \theta} \\ &= \frac{\partial U(\theta, q(\theta))}{\partial \theta} + U'(\theta, q(\theta)) \cdot q'(\theta).\end{aligned} \tag{40}$$

Substitute the above full derivative into (39), we have: for any $x \in \Theta$,

$$\begin{aligned}\pi(x) &= \int_{\theta_{\min}}^{x} \frac{\mathrm{d}U(\theta, q(\theta))}{\mathrm{d}\theta} - \frac{\partial U(\theta, q(\theta))}{\partial \theta}\mathrm{d}\theta + \pi(\theta_{\min}) \\ &= U(x, q(x)) - U(\theta_{\min}, q(\theta_{\min})) - \int_{\theta_{\min}}^{x} \frac{\partial U(\theta, q(\theta))}{\partial \theta}\mathrm{d}\theta + \pi(\theta_{\min}) \\ &= U(x, q(x)) - U(\theta_{\min}, q(\theta_{\min})) - \int_{\theta_{\min}}^{x} \frac{q(\theta)}{1 + q(\theta)\cdot\theta}\mathrm{d}\theta + \pi(\theta_{\min}),\end{aligned} \tag{41}$$

where the last line follows because $\frac{\partial U(\theta,q)}{\partial \theta} = \frac{\partial \log(1+q\cdot\theta)}{\partial \theta} = \frac{q}{1+q\cdot\theta}$.

Optimality of Contract

Similar as in section "Optimality of Contract", to derive the optimal contract, we first derive the best price function under a given (feasible) quality function and then derive the best quality function. Specifically, given a feasible quality function $q(\theta)$, the best price function $\pi^*(\theta)$ and the maximum payoff $R^*_{q(\theta)}$ can be derived by

$$\begin{aligned}\max_{\pi(\theta)} \quad & \int_{\theta\in\Theta} (\pi(\theta) - C(q(\theta)))\cdot f(\theta)\mathrm{d}\theta \\ \text{s.t.} \quad & \text{The Conditions in (35).}\end{aligned} \tag{42}$$

Similar as Lemma 6, the unique best price function $\pi^*(\theta)$ is given below.

Lemma 10. *Given a feasible quality function $q(\theta)$ with $q'(\theta) \geq 0, \forall\theta \in \Theta$, the unique best price function $\pi^*(\theta)$ for problem (42) is given by*

$$\pi^*(\theta) = U(\theta, q(\theta)) - \int_{\theta_{\min}}^{\theta} \frac{q(x)}{1 + q(x)\cdot x}\mathrm{d}x, \quad \forall\theta \in \Theta. \tag{43}$$

Lemma 10 states that, given any feasible quality function $q(\theta)$, the best price function $\pi^*(\theta)$ is unique and given by (43). By substituting the best price function $\pi^*(\theta)$ into (42), the best quality function $q^*(\theta)$ can be derived as follows:

$$\begin{aligned}\max_{q(\theta)} \quad & R^*_{q(\theta)} \triangleq \int_{\theta\in\Theta} (\pi^*(\theta) - C(q(\theta)))\cdot f(\theta)\mathrm{d}\theta \\ \text{s.t.} \quad & \text{The Conditions in (34).}\end{aligned} \tag{44}$$

Substitute the best price function $\pi^*(\theta)$ in (43) into Lemma (44), the PU's maximum payoff $R^*_{q(\theta)}$ under a given quality function $q(\theta)$ can be written as

$$R^*_{q(\theta)} \triangleq \int_{\theta\in\Theta} \left(U(\theta, q(\theta)) - \int_{\theta_{\min}}^{\theta} \frac{q(x)}{1 + q(x)\cdot x}\mathrm{d}x - C(q(\theta)) \right)\cdot f(\theta)\mathrm{d}\theta \tag{45}$$

Using integration by parts, we have:

$$\begin{aligned}
&\int_{\theta\in\Theta}\left(\int_{\theta_{\min}}^{\theta}\frac{q(x)}{1+q(x)\cdot x}\mathrm{d}x\right)\cdot f(\theta)\mathrm{d}\theta \\
&= F(\theta)\int_{\theta_{\min}}^{\theta}\frac{q(x)}{1+q(x)\cdot x}\mathrm{d}x\Big|_{\theta_{\min}}^{\theta_{\max}} - \int_{\theta\in\Theta}F(\theta)\frac{q(\theta)}{1+\theta q(\theta)}\mathrm{d}\theta \\
&= \int_{\theta\in\Theta}(1-F(\theta))\cdot\frac{q(\theta)}{1+q(\theta)\cdot\theta}\mathrm{d}\theta,
\end{aligned} \tag{46}$$

where $F(\theta)$ is the cumulative distribution function (cdf) of θ. The last line follows because $F(\theta_{\min})=0$ and $F(\theta_{\max})=1$. Thus, we can rewrite (45) as follows:

$$R^*_{q(\theta)} \triangleq \int_{\theta\in\Theta}\left(U(\theta,q(\theta)) - C(q(\theta)) - \frac{1-F(\theta)}{f(\theta)}\cdot\frac{q(\theta)}{1+q(\theta)\cdot\theta}\right)\cdot f(\theta)\mathrm{d}\theta. \tag{47}$$

It is easy to see that (47) has the similar structure as (26) in the discrete SU-type model. Similar as in (26), we introduce:

$$G(\theta,q(\theta)) \triangleq U(\theta,q(\theta)) - C(q(\theta)) - \frac{1-F(\theta)}{f(\theta)}\cdot\frac{q(\theta)}{1+q(\theta)\cdot\theta}.$$

Then, the PU's payoff $R^*_{q(\theta)}$ in (47) can be rewritten as $R^*_{q(\theta)} \triangleq \int_{\theta\in\Theta} G(\theta,q(\theta))\cdot f(\theta)\mathrm{d}\theta$. Accordingly, the optimization problem (44) can be rewritten as follows:

$$\begin{aligned}
&\max_{q(\theta)} \quad R^*_{q(\theta)} \triangleq \int_{\theta\in\Theta} G(\theta,q(\theta))\cdot f(\theta)\mathrm{d}\theta \\
&\text{s.t.} \quad \text{The Conditions in (34).}
\end{aligned} \tag{48}$$

Similar as $G_t(q_t)$ in the discrete SU-type model, here $G(\theta,q(\theta))$ depends only on the quality $q(\theta)$ for type θ while independent of the quality $q(\theta')$ for any other type $\theta' \neq \theta$. This implies that the optimization problem (48) can be solved by optimizing the quality $q(\theta)$ for each $G(\theta,q(\theta))$ separately. Let $\tilde{q}^*(\theta)$ denote the quality that maximizes $G(\theta,q(\theta))$. That is,

$$\begin{aligned}
&\tilde{q}^*(\theta) \triangleq \arg\max_{q} \quad G(\theta,q) \\
&\text{s.t.} \quad 0 \le q \le Q_{\max}.
\end{aligned} \tag{49}$$

If the quality function $\tilde{q}^*(\theta), \forall\theta \in \Theta$, derived by (49) is a feasible quality function, i.e., satisfying the conditions in (34), then it is exactly the optimal solution of (44). In a general case, however, the quality function $\tilde{q}^*(\theta)$ derived by (49)

may not be feasible. A similar iterative algorithm can be used to adjust the quality function $\tilde{q}^*(\theta)$ such that it is feasible. Formally,

Theorem 2. *Suppose* $\tilde{q}^*(\theta), \forall\theta \in \Theta$, *derived by* (49) *is a feasible quality function satisfying the conditions in* (34). *Then, the optimal contract* $\Psi^* = \{(q^*(\theta), \pi^*(\theta)),\ \theta \in \Theta\}$ *under information asymmetry is given by:*

$$q^*(\theta) = \tilde{q}^*(\theta), \quad \forall\theta \in \Theta,$$

and

$$\pi^*(\theta) = U(\theta, q^*(\theta)) - \int_{\theta_{\min}}^{\theta} \frac{q^*(x)}{1 + q^*(x) \cdot x} \mathrm{d}x, \quad \forall\theta \in \Theta.$$

Simulation Results

We evaluate the performance of the proposed optimal contract in a network with $T = 20$ types of SUs. The type of k-th SUs is $\theta_k = k$, and hence the set of all types is $\Theta = \{1, 2, \cdots, 20\}$. The cost function of the PU is defined as $C(q) = c_0 + a \cdot q^b$ where $c_0 = 0.01$, $a = 2$ and $b = 1.2$. The upper-bound of quality is $Q_{\max} = 1$. We study the optimal contracts in three different network scenarios, which differ from each other in the distribution of SU types. In case (a), the percentage of higher-type SUs is larger than that of lower-type SUs; In case (c), the percentage of higher-type SUs is smaller than that of lower-type SUs; and In case (b), the percentage of higher-type SUs is same as that of lower-type SUs. Without loss of generality, we set: (a) $N_k = N \cdot \frac{\theta_k}{\sum_{t=1}^{T} \theta_t}$, (b) $N_k = N \cdot \frac{1}{T}$, and (c) $N_k = N \cdot \frac{\theta_{T-k+1}}{\sum_{t=1}^{T} \theta_t}$.

Figure 1 presents the best quality set and price set under the optimal contracts in three different network scenarios (under information asymmetry). The dark blue bar (SO) denotes the socially optimal quality set (which maximizes the social welfare) and the associated best price set given by Lemma 6. From Fig. 1, we can see that the best qualities in three optimal contracts (under information asymmetry) are smaller than the socially optimal qualities. The quality gap is smaller for a higher type. This implies that in order to elicit the private information of SUs, there will be certain social welfare loss. We can further see that in the network with more higher-type SUs, i.e., case (a), the optimal contract tends to sell channels to less SUs with higher types and charge them higher prices.

Figure 2 presents the PU's payoff achieved by the optimal contracts under information symmetry and information asymmetry. For an illustrative purpose, we also provide the PU's payoff achieved by an non-optimal contract (under information asymmetry) with the socially optimal qualities and the associated prices, i.e., the SO in Fig. 1. Comparing the optimal contracts under information symmetry and asymmetry, we can see that under information asymmetry, the PU can achieve 60% $\sim$ 70% of the maximum payoff under information symmetry.

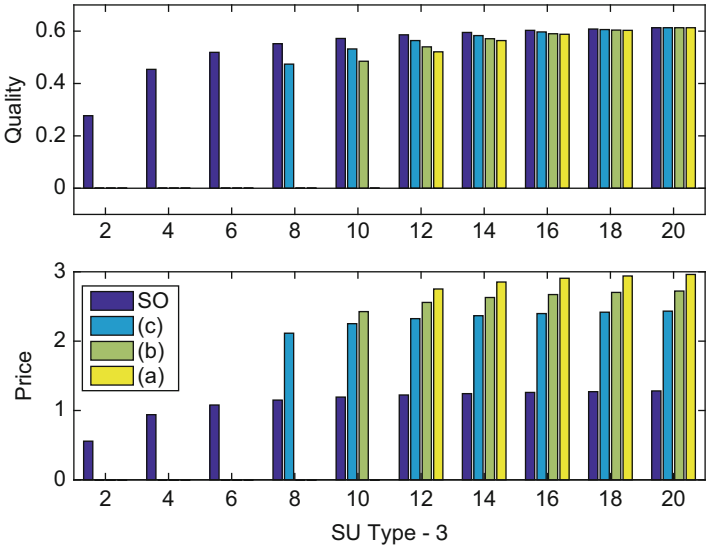

Fig. 1 The best quality assignments and price assignments under the optimal contracts

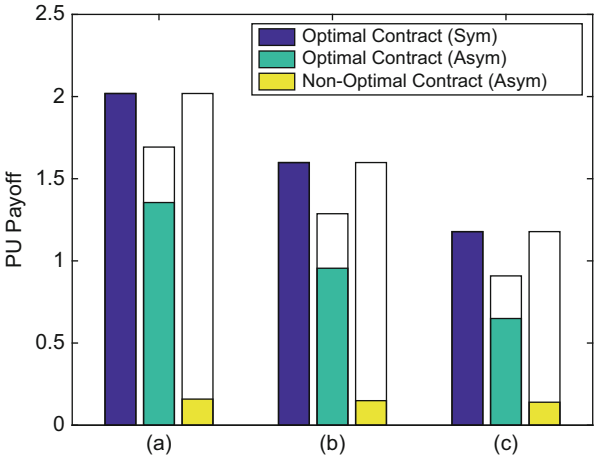

Fig. 2 The social surplus and the revenues of the PO in the optimal contracts

Comparing the optimal and non-optimal contracts under information asymmetry, we can see that by using the optimal contract, the PU can increase his payoff by $400\% \sim 700\%$.

Conclusion

This chapter proposes contract-based spectrum trading mechanism for a monopoly secondary spectrum market with a single PU (seller) and multiple SUs (buyers).

In the proposed mechanism, the PU offers a list of quality-price combinations (contract) for SUs, and each SU chooses the proper quality and price according to his public/private preference information. The necessary and sufficient conditions for feasible contracts (that guarantee the truthful information disclosure of SUs) are proved analytically, and then the optimal (feasible) contract (that maximizes the PU's payoff) is derived under both information symmetry and information asymmetry. This chapter further extends the optimal contract design to the continuous SU-type model. Simulations show that the optimal contract under information asymmetry can increase the PU's payoff significantly and can achieve $60\% \sim 70\%$ of the optimal performance under information symmetry.

In terms of the future extensions, it is important (also challenging) to study the optimal contract design under the more general model with multidimension private information, where each SU's private information consists of multiple dimension parameters (e.g., preferences on both quality and payment). Some recent works (e.g., [31]) have started to consider this issue under some simplified cases, while the complete analysis for the general case is still open. It is also important to study the contract design under the practical constraint of limited price and quality discrimination, where a limited number (often smaller than the number of SU types) of different prices and qualities can be selected in the designed contract. This is important for the implementation of the designed contract in practice. In [33], Li *et al.* have considered this problem and obtained some interesting preliminary results. However, the complete analysis and results are still open.

Machine learning · Cognitive radio · Supervised learning · Unsupervised learning · Reinforcement learning

Introduction

Cognitive radio users are equipped with capabilities of sensing (spectrum sensing), thinking (powerful computing devices), and talking (communications). Hence, a cognitive radio can be considered as an intelligent device, which is also endowed the capability of learning. Due to the changing environment (e.g., the dynamically changing frequency spectrum, fast fading channel, and mobile communication network), learning is a necessary requirement for the adaptivity to the environment. Therefore, it is of key importance to study the learning issues in cognitive radio.

This chapter will first provide a brief introduction to the area of machine learning, which consists of supervised, unsupervised, and semi-supervised learning. In particular, it will focus on the reinforcement learning, which is of particular importance in cognitive radio networks, since usually there is no explicit supervision in cognitive radio networks while each learner does receive rewards which can be used to train the decision maker. Comprehensive introductions to machine learning can be found in [15, 22].

Then, this chapter will provide several case studies on the application of machine learning in cognitive radio scenarios. The discussion will focus on the applications of reinforcement learning and multiarmed bandit learning for channel selection and routing. Both the single-user and multiple-user cases will be discussed. The introduction will focus on the general principles, instead of discussing the details and providing a comprehensive survey of works in this area.

Basics of Learning

This section provides a brief introduction to machine learning to make this chapter self-contained and will first introduce the dichotomy of learning and then explain each type of learning techniques. Since reinforcement learning is very useful in cognitive radio, this chapter will use an independent section to introduce its details.

Essence and Dichotomy of Learning

In a machine-learning problem, one is provided a series of samples $\{X_i\}_{i=1,\ldots,N}$ (which is called the training set) with a distribution P_X. Usually the distribution P_X is unknown. The goal of machine learning is to learn a function c, mapping from a given X (which may be beyond the training set) to a Y. Here Y is the outcome of the mapping, which can be considered as a label to the sample X. When Y is discrete, the learning can be considered as a classification problem (namely, assigning a label to a given sample); when Y is continuous, the output means a certain property of the sample X. The procedure is illustrated in Fig. 1. Hence, essentially machine learning is a function approximation problem, where both the true function and the sample distribution are unknown.

There are many possible dichotomies for machine learning. Below are several typical ones, as illustrated in Fig. 2:

- Supervised or not: In the training set, in many cases, the label of each sample is also provided. Hence, the tuples $\{(X_i, Y_i)\}_{i=1,\ldots,N}$ are used in the training. One calls this case the supervised learning. When labels are not available, it is called unsupervised learning. When only a fraction of the labels are available, it is called semi-supervised learning.

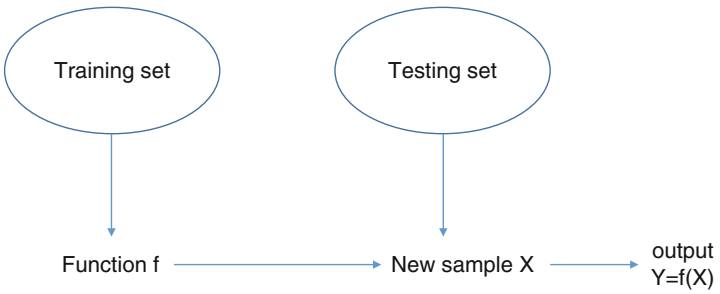

Fig. 1 Illustration of learning problem

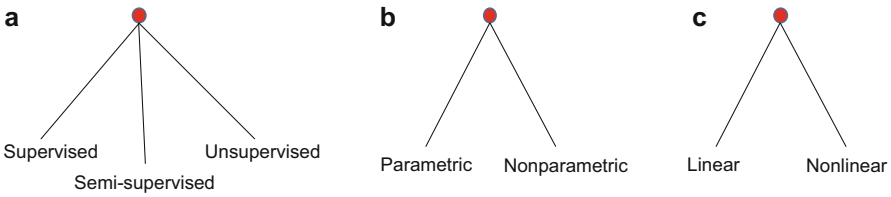

Fig. 2 Dichotomy of machine learning. (**a**) Classification according to the availability of labeled samples. (**b**) Classification the availability of parameterized expressions. (**c**) Classification the application of linear functions

- Parameterized or not: The mapping f could be parameterized or not, thus resulting in parametric and nonparametric ones, respectively.
- Linear or not: The function f, or an intermediate function, could be linear or nonlinear. For example, in classification problems, one may apply a linear function g such that $c(X) = 1(g(X) \geq 0)$, where the characteristic function $1(E)$ equals 1 if the corresponding event E is true and 0 otherwise. Although f itself is not linear (it cannot be linear since the output Y is discrete), the classifier is still called a linear one, since g is linear.

In the following discussion, this chapter follows the dichotomy of supervised/unsupervised/semi-supervised learning.

Supervised Learning

As has been explained, in supervised learning, labeled samples are provided for the training procedure, in which $Y_n = c(X_n)$, $n = 1, \ldots, N$. Since c, usually called concept in the community of machine learning, is actually unknown, the goal is to learn an estimation of c, denoted by h and called hypothesis, such that h can well approximate c and can be well generalized to samples not observed in the training set.

For cognitive radio networks, supervised learning is mainly used in classifications, e.g., how to recognize the modulation and coding schemes of primary users [23]. The learning procedure can be accomplished by training the classifiers using signal with known modulation and coding schemes.

Learning Criterion and Generalization

To find an optimal approximation h to the concept c, one first needs to identify a class of functions for h, which is denoted by $\mathcal{H}$ and is called the hypothesis set. Then, one defines a risk function for each hypothesis h as

$$R(h) = E[r(h(X), c(X))], \tag{1}$$

where the expectation $E[\cdot]$ is over the randomness of sample X and r is the risk of h when the sample is X. Take the binary classification problem for example: the risk r is defined as $1(h(X) \neq c(X))$, namely, whether the classification result is wrong or not. Hence, for this example, one has

$$R_c(h) = E[1(h(X) \neq c(X))] = P(h(X) \neq c(X)), \tag{2}$$

namely the error probability of classification. Then, the optimal selection of hypothesis is given by

$$h_{\text{opt}} = \arg\min_h R(h). \tag{3}$$

Unfortunately, the calculation of h_{opt} in (3) is infeasible, since the expectation in (1) cannot be calculated due to the lack of information on the sample distribution P_X. Hence, a feasible approach is to approximate the expectation using the empirical average, namely

$$R(h) \approx \hat{R}(h) = \frac{1}{N} \sum_{n=1}^{N} r(h(X_n), c(X_n)). \tag{4}$$

Hence, the supervised learning is to minimize the empirical risk, namely

$$h_{\text{emp}} = \arg\min_{h} \sum_{n=1}^{N} r(h(X_n), c(X_n)). \tag{5}$$

When a new sample that is not observed in the training set is given, the gap between the risk for the empirically optimal hypothesis, namely, $r_{\text{rmp}}()$, and the minimum risk can be written as

$$R(h_{\text{rmp}}) - R^* = \underbrace{R(h_{\text{rmp}}) - R(h_{\text{opt}})}_{\text{estimation}} + \underbrace{R(h_{\text{opt}}) - R^*}_{\text{approximation}}, \tag{6}$$

where $R^* = R(c)$ is the minimum risk incurred by the true concept. The two terms in (6) have the following meanings:

- Estimation: The term $R(h_{\text{rmp}}) - R(h_{\text{opt}})$ means that the performance gap between the empirically optimal hypothesis and the optimal hypothesis (both in the hypothesis set $\mathcal{H}$) is due to the limited number of samples. The gap can be reduced by taking more samples such that the empirical average can better approximate the expectation.
- Approximation: The term $R(h_{\text{opt}}) - R^*$ is the performance gap between the optimal hypothesis in $\mathcal{H}$ and the true concept. If $c \in \mathcal{H}$, the gap will be zero. However, since c is unknown, it is impossible to know whether c has been incorporated in $\mathcal{H}$. Therefore, a larger $\mathcal{H}$ can reduce this approximation error. However, a larger (or more complex) $\mathcal{H}$ may increase the estimation error when the number of samples is fixed.

Based on the above two terms of errors, when one designs a learning algorithm, one needs to consider the following two aspects of the hypothesis set $\mathcal{H}$:

- If the cardinality of $\mathcal{H}$ is too small, it cannot well approximate the true concept c even if there are sufficiently many samples (i.e., term of the approximation error will be large).

- If the cardinality of $\mathcal{H}$ is too large, the optimal solution can well approximate the concept c. However, it requires more samples to find a near-optimal hypothesis in $\mathcal{H}$.

Linear Classifier

A simple but effective hypothesis set is the linear functions. Take the classification task for instance. Suppose that the samples are d-dimensional vectors $\mathbf{x}$. A vector $\mathbf{w}$ and an offset b are trained, such that the decision of classification is given by

$$h(\mathbf{x}) = \begin{cases} 1, & \mathbf{w}^T\mathbf{x} + b \geq 0 \\ 0, & \mathbf{w}^T\mathbf{x} + b < 0 \end{cases}. \tag{7}$$

The linear classifier is illustrated in Fig. 3a, where the boundary of the two classes is generated by $\mathbf{w}$ and b. It is possible that the linear classifier cannot achieve perfect performance even in the training set. Hence, it is necessary to introduce nonlinear classifiers, such as support vector machine [15, 22], as illustrated in Fig. 3b. This chapter will introduce a few in the subsequent discussions.

Support Vector Machine

Support vector machine (SVM) is one of the most useful approaches to exploit linear classifiers and nonlinear features. Again, one uses classification task as the example. The discussion begins from the linearly separable case and estimates the weighting coefficient vector $\mathbf{w}$ and offset b. When the two classes of training samples are linearly separable, usually there are many possible choices for $\mathbf{w}$ and b. An example is illustrated in Fig. 4, where both linear boundaries can separate the two classes of samples. However, the boundary in (a) is better since the minimum distance from training samples to the boundary, which is called the margin, is larger. A larger margin means a safer classification, because it can better tolerate a new sample close to the boundary, as illustrated in Fig. 4.

It has been shown that the margin, whose detailed definition is given in [15,22], is equal to $\frac{1}{\|\mathbf{w}\|}$. Hence, the following optimization problem is employed to maximize the margin:

$$\min_{\mathbf{w},b} \frac{1}{2}\|\mathbf{w}\|^2 \tag{8}$$

$$s.t. \quad y_i(\mathbf{w} \cdot \mathbf{x}_i + b) \geq 1, \qquad \forall i = 1, \ldots, m, \tag{9}$$

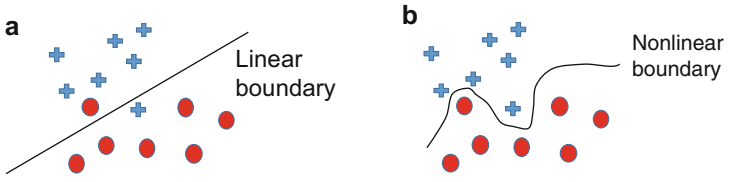

Fig. 3 Illustration of linear and nonlinear classifiers. (**a**) Linear classifier. (**b**) Nonlinear classifier

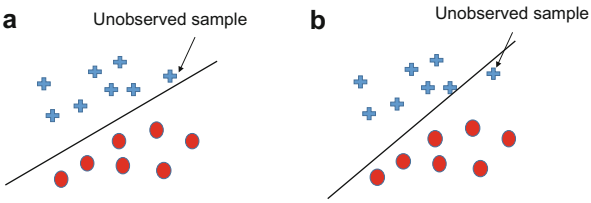

Fig. 4 Illustration of margin in linearly separable case. (**a**) Larger margin. (**b**) Smaller margin

where m is the number of samples. The inequalities in the constraints are used to guarantee the correctness of classification. Using the Lagrange factor method, the above optimization problem can be rewritten as

$$\min_{\mathbf{w},b} \frac{1}{2}\|\mathbf{w}\|^2 - \sum_{i=1}^{m} \alpha_i \left[y_i(\mathbf{w}\cdot\mathbf{x}_i + b) - 1\right], \tag{10}$$

where $\alpha = (\alpha_1, .., \alpha_m)$ is the vector consisting of the Lagrange factors. Using the KKT condition of constrained optimization, one can obtain the following conclusions for the optimization in (10):

$$\begin{cases} \mathbf{w} = \sum_{i=1}^{m} \alpha_i y_i \mathbf{x}_i \\ \alpha_i = 0, \text{ or } y_i(\mathbf{w}^T\mathbf{x}_i + b) = 1 \end{cases}. \tag{11}$$

Hence, one can see that the optimal weighting coefficient vector $\mathbf{w}$ is determined by those samples $\mathbf{x}_i$ with $\alpha_i \neq 0$. These vectors are called the support vectors. Taking the dual form of (10), the optimization problem is converted to

$$\max_{\alpha} \sum_{i=1}^{m} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{m} \alpha_i \alpha_j y_i y_j \mathbf{x}_i^T \mathbf{x}_j \tag{12}$$

$$s.t. \quad 0 \leq \alpha_i \leq C \tag{13}$$

$$\sum_{i=1}^{m} \alpha_i y_i = 0. \tag{14}$$

Although SVM is originally designed for linear models, it can also be extended to nonlinear cases. One can design a nonlinear mapping h, which maps $\mathbf{x}$ to a higher dimension. Then, one can apply the SVM approach to the new vector $h(\mathbf{x})$ and thus result in the following nonlinear function:

$$f(\mathbf{x}) = \mathbf{w}^T h(\mathbf{x}) + b. \tag{15}$$

This discussion will come back to this point later when one discusses the kernel method.

Boosting

An effective nonlinear learning algorithm, called boosting [27], is to train multiple weak learners using simple hypothesis sets and then combine these weak classifiers to obtain a strong classifier. By weak learner, it means hypothesis set $\mathcal{H}$ such that there exist an algorithm of learning and parameters γ and that for any $\delta > 0$, one can always find a sample size m and thus train a hypothesis h satisfying

$$P\left(R(h) \leq \frac{1}{2} - \gamma\right) \geq 1 - \delta. \tag{16}$$

Intuitively speaking, a weak leaner can guarantee a certain performance (an error rate better than random guess) but cannot guarantee to reach one regardless of the training sample size.

A detailed introduction to the procedure of boosting can be found in [27]. The rough procedure of the most typical boosting algorithm, named AdaBoost [27], is given as follows:

- Given m samples, the sampling probability of each sample is set to be identical.
- A weak classifier is learned and the corresponding error probability is evaluated.
- The sampling probability of each sample is reevaluated according to the error rate.
- One repeats the procedure of updating the sampling probability and training new weak classifiers using the new probability.
- After a given number of iterations, a strong classifier is obtained by combining the trained weak learners.

Note that, although the weak learners could be linear, the final resulting classifier of the boosting procedure is nonlinear, thus being more powerful than linear classifiers.

Neural Networks

Another typical nonlinear model for machine learning is neural networks [2, 14], which is motivated by the study on neural systems. In a neural network, there is an input layer which accepts the vector sample $\mathbf{x}$. The output layer outputs $\mathbf{y}$, which could be either vector or scalar. There is also one or multiple hidden layers, linking the input and output layers, as illustrated in Fig. 5. In each layer, there are multiple nodes, accepting the inputs from a lower layer. Consider a node whose output is z_o and input is $\mathbf{z}^i = (z_1^i, \ldots, z_n^i)$. Then, the input-output relationship is given by

$$z_o = g(\mathbf{w}^T \mathbf{z}^i), \tag{17}$$

where $\mathbf{w}$ is the linear coefficients obtained from the training process and g is a nonlinear function such as sigmoid function or max operation. It has been shown that, even when there is only a single hidden layer (called shallow networks), a neural network can approximate functions with arbitrarily small errors, given sufficiently many nodes in the network. The research in recent years has shown that a deep network with many hidden layers can achieve much better performances

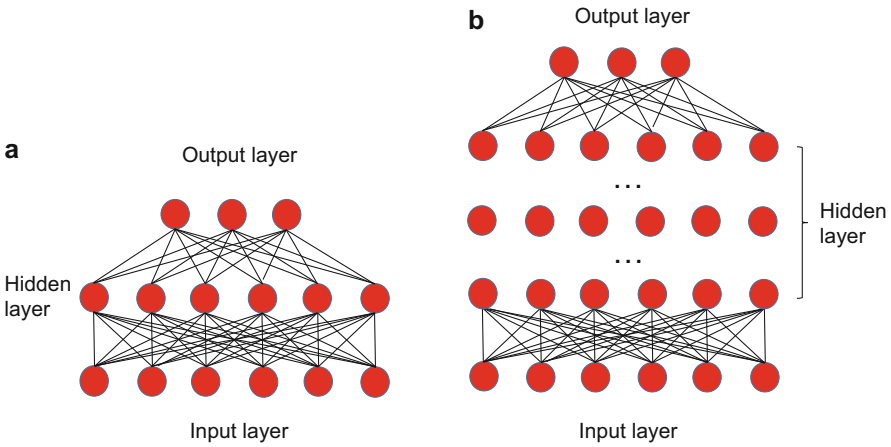

Fig. 5 Illustration of neural networks. (**a**) Shallow networks. (**b**) Deep networks

than the shallow ones and has gained substantial successes in many areas such as artificial intelligence, image processing and speech processing [14]. The training of the neural network can be accomplished by using the famous back propagation (BP) algorithm [14].

Kernel Method

Kernel method is a family of nonlinear models, which has been widely used in machine learning [28]. One calls a two-argument real function $K(x, x')$ a kernel, where $x, x' \in \mathcal{X}$. One wants to define a kernel K such that there exists a mapping $\Phi : \mathcal{X} \to \mathbb{H}$, where $\mathbb{H}$ is a Hilbert space, such that

$$K(x, x') =< \Phi(x), \Phi(x') >, \qquad \forall x, x' \in \mathcal{X}, \tag{18}$$

where $< \cdot, \cdot >$ is the inner product in the Hilbert space $\mathbb{H}$. Here $\mathbb{H}$ is called the feature space. Hence, the mapping Φ maps the original sample $\mathbf{x}$ to a feature of it, which facilitates the further processing. Another typical requirement on the kernel K is to make the matrix $\mathbf{K} = (K(x_i, x_j))_{i,j}$ symmetric and nonnegative definite for any $(x_1, \ldots, x_m) \subset \mathcal{X}$. One calls such kernels positive definite symmetric (PDS) kernels.

To guarantee the existence of Φ, one needs some constraint on the kernel K, which is stated in the following Mercer's condition:

Theorem 1. *Consider a compact set $\mathcal{X} \subset \mathbb{R}^N$ and a continuous and symmetric kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. K can be written as*

$$K(x, x') = \sum_{n=0}^{\infty} a_n \phi_n(x) \phi(x'), \tag{19}$$

if and only if the following Mercer's condition holds:

$$\int\int_{\mathcal{X}\times\mathcal{X}} c(x)c(x')K(x,x')dxdx' \geq 0, \tag{20}$$

for any square-integrable function c.

Obviously, the condition in (20) guarantees the nonnegativity of the inner product. A typical kernel is the Gaussian kernel, which is given by

$$K(\mathbf{x},\mathbf{x}') = \exp\left(-\frac{\|\mathbf{x}-\mathbf{x}'\|^2}{2\sigma^2}\right), \tag{21}$$

for a certain positive σ^2.

The following conclusion is of key importance for the kernel methods.

Theorem 2. *Consider a PDS kernel K. Then there is a Hilbert space* $\mathbb{H}$ *and a mapping* $\Phi : \mathcal{X} \to \mathbb{H}$ *such that*

$$K(x,x') =< \Phi(x), \Phi(x') >, \qquad \forall x, x' \in \mathcal{X}. \tag{22}$$

Moreover, the Hilbert space $\mathbb{H}$ *satisfies the following reproducing property:*

$$h(x) =< h, K(x,\cdot) >, \qquad \forall h \in \mathbb{H}, x \in \mathcal{X}. \tag{23}$$

Here the Hilbert space $\mathcal{H}$ is called the reproducing kernel Hilbert space associated to K.

When a kernel K is fixed, it can be applied to machine learning. For example, for the context of SVM, one can use Φ, associated to the kernel K, to map the sample to a higher-dimensional space, thus resulting in the following SVM optimization:

$$\max_{\alpha} \sum_{i=1}^{m} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{m} \alpha_i \alpha_j y_i y_j \Phi^T(\mathbf{x}_i)\Phi(\mathbf{x}_j) \tag{24}$$

$$s.t.\ \ 0 \leq \alpha_i \leq C \tag{25}$$

$$\sum_{i=1}^{m} \alpha_i y_i = 0. \tag{26}$$

where the maximization can also be written as

$$\max_{\alpha} \sum_{i=1}^{m} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{m} \alpha_i \alpha_j y_i y_j K(\mathbf{x}_i, \mathbf{x}_j). \tag{27}$$

Since K and ϕ are nonlinear, the resulting classifier is also nonlinear. The advantage of changing (24), (25), (26), and (27) is that the computation of $\Phi(\mathbf{x})$ and the subsequent inner product will be very difficult since $\Phi(\mathbf{x})$ is usually of high dimension, while the calculation of the kernel K is straightforward. This is called the kernel trick.

Unsupervised Learning

In unsupervised learning, there is no "teacher"; i.e., the samples are not labeled. What the learner sees is only the samples $\{X_i\}_{i=1,\ldots,N}$, without the Y component. Hence, the learner has to find the inherent pattern of the samples without the direction of the teacher. The following approaches can be used to find the pattern of the samples:

- Density estimation [8]: One can estimate the probability density of X from finitely many samples. It is well known that the density estimation is very challenging, especially when the dimension of X is high.
- Cluster analysis: It is desirable to group the samples into multiple clusters, each of which forms a convex region. Then, the density can be approximated by a mixture of the clusters. Examples of 1-dimensional and 2-dimensional cases are illustrated in Fig. 6.

Below the discussion provides a simple introduction to the clustering. A most popular approach to divide the samples into multiple clusters is the k-means algorithm, which follows the following steps:

1. Set the number of clusters. Randomly initialize the center of each cluster.
2. For each sample, find the closest center and associate it to the corresponding cluster.
3. Calculate the centers by calculating the averages of the samples in the clusters.
4. Go back to step 2 and repeat the procedure until it converges or reaches a maximum number of steps.

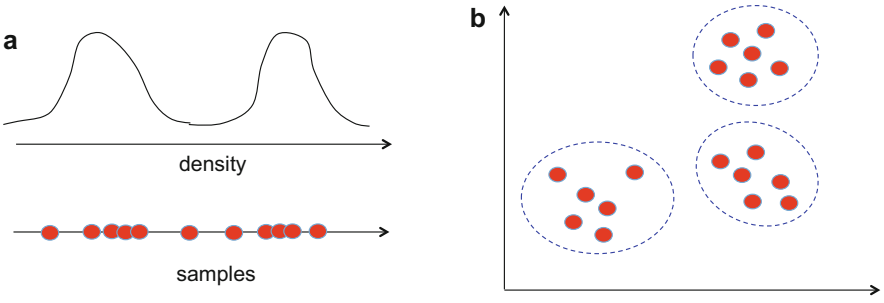

Fig. 6 Examples of 1-dimensional and 2-dimensional cases

Unsupervised learning is not very widely used in cognitive radio. One useful application is to divide the spectrum-sensing outcomes into clusters, each of which is considered as a primary user or an operation mode of primary user [24, 30]. The above k-means clustering algorithm has been used for the cluster analysis.

Semi-supervised Learning

In semi-supervised learning, there are a small set of labeled samples and a large set of unlabeled samples. The challenge is how to incorporate the unlabeled samples into the training procedure. One approach is to regard the missing labels as unobserved data. Then, the standard expectation maximization (EM) algorithm can be applied to handle the unobserved data. More details can be found in [7].

Reinforcement Learning

Introduction

Reinforcement learning [29, 32] has been widely used in cognitive radio. It is different from both supervised and unsupervised learning techniques in the following aspects:

- In unsupervised learning, what the learner sees is only the unlabeled sample; hence, the learning has no standard answer. In reinforcement learning, the learner can receive feedback of reward which may be delayed. Hence, one can say that reinforcement learning does have supervision which is implicit.
- In supervised learning, the learner has labeled samples. Although reinforcement learning does receive feedback through system rewards, the feedback is not labeled; instead it is quantified. It is possible that the feedback could be substantially delayed and be implicit (when you receive a large reward, you may not know which action taken before triggers it).
- In both supervised and unsupervised learning, the training is usually carried out in an offline manner; i.e., the learner first obtains a set of training samples and then apply the learned mapping to testing samples. In reinforcement learning, the training and testing are carried out simultaneously. When a new sample arrives, the reinforcement learning tests its performance and updates its strategy using the feedback of the outcome. Hence, reinforcement learning is in an online manner.

Essentially, supervised and unsupervised learnings are function approximations of input-output mapping, while reinforcement learning is a decision-making problem which determines the action given the current system state and observation. Hence, reinforcement learning is essentially different from the learning tasks introduced in the previous section. However, the strategy, namely, the mapping from system state to the action, can be considered as an input-output relationship; hence,

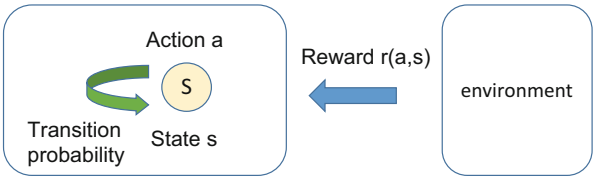

Fig. 7 Illustration of Q-learning

one can also consider reinforcement learning as approximating the optimal strategy. Hence, many techniques in supervised/unsupervised learning can also be applied in the context of reinforcement learning.

There are several types of reinforcement learning. This chapter will introduce them in the subsequent discussion. Note that one considers only the reinforcement learning of a single learner. The learning of multiple learners will be introduced in the next section.

Q-Learning

As a typical reinforcement learning, Q-learning is deeply related to dynamic programming (DP) [5]. A DP problem has the following key elements:

- System state: The learner has N system states, $s_1, \ldots, s_N$, characterizing the current status of the learner.
- Control action: The learner has M possible actions, $a_1, \ldots, a_M$, which is determined by the system state; i.e., there exists a mapping (also called the control strategy) π such that $a = \pi(s)$.
- State transition: The state dynamics of the learner can be considered as a Markov chain. The transition probability is given by $P_a(s_i|s_j)$, which means the probability that the learner transits from state s_j to s_i when the control action is a.
- Reward: When the learner takes an action a when the current system state is s, it receives a reward $r(s, a)$, as a function of s and a.

The goal of DP is to find the optimal strategy π such that the following total reward is maximized:

$$\max_{\pi} E\left[\sum_{t=1}^{T} \alpha^t r(s(t), a(t))\right], \tag{28}$$

where $0 < \alpha < 1$ is a discounting factor and T could be either finite or infinite.

In the context of Q-learning [31], the learner knows the set of system states. However, it does not know the reward function and the transition probability.

The learner has to learn its strategy using its experience. Basically, it needs to achieve a good tradeoff between the exploitation and exploration:

- Exploitation: For each state s, the learner may have found a good action incurring more reward. Hence, it is desirable to take this action more frequently.
- Exploration: It is also important to try actions that have not been considered or have been rarely tried. If the learner uses only the good actions that have been demonstrated, it may miss possibly better actions. Hence, the learner should also explore the actions that have not or have been rarely tested.

To accomplish the tradeoff of exploration and exploitation, Watkins proposed the Q-learning approach, in which the learner keeps a Q-value for each pair of state and action (s, a), which is denoted by $Q(s, a)$. The value of $Q(s, a)$ means the estimated total reward (with discount) in the future after using the action a at state s. These Q-values can be initialized as zeros or random numbers. During the operation, the Q-values are updated using the following rule:

$$\begin{aligned} Q(s(t), a(t)) \leftarrow\ & Q(s(t), a(t)) \\ & + \beta \left(r(t) + \alpha \max_a Q(s(t+1), a) - Q(s(t), a(t)) \right), \end{aligned} \tag{29}$$

where $s(t)$ and $a(t)$ are the state and action of the learner at time t, $r(t)$ is the received reward, and β is a coefficient controlling the learning rate. The term $\alpha \max_a Q(s(t+1), a)$ is an estimation of the future total reward when the state transits to $s(t+1)$. The gap $r(t) + \alpha \max_a Q(s(t+1), a) - Q(s(t), a(t))$, which can be considered as an estimation of the Q-value error, is used to update the new Q-value.

There is still one problem to be solved: how to choose the control action a given the state s, in order to achieve the tradeoff between the exploitation and exploration. One popular approach is to use the Boltzmann distribution; i.e., the probability of taking action a, when the system state is s, is given by

$$P(a|s) = \frac{\exp\left(\frac{Q(s,a)}{T_0}\right)}{\sum_{a'} \exp\left(\frac{Q(s,a')}{T_0}\right)}, \tag{30}$$

where T_0 is called the temperature, which controls the tradeoff between exploitation and exploration: when T_0 is large (hotter), the learner is more inclined to exploration; when T_0 is small (cooler), the learner is more inclined to exploitation. The two extreme cases are:

- When $T_0 \to 0$, the leaner will fix on the action having the highest Q-value.
- When $T_0 \to \infty$, the learner will choose the action in a uniform manner.

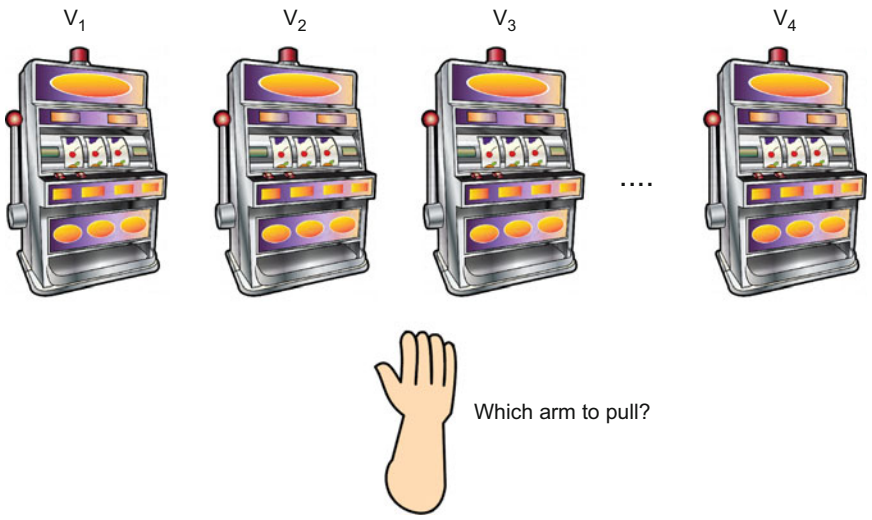

Fig. 8 Illustration of multi-armed bandit problem

It has been shown that the Q-learning can finally converge to the optimal strategy, although the convergence rate is difficult to analyze (Fig. 8).

Multiarmed Bandit

Another setup of reinforcement learning is as follows: at each time, the learner can choose an action a from the set $\{a_1, \ldots, a_n\}$ and receive a random reward r satisfying distribution ν_a. The goal of the learner is to maximize the expected reward. Obviously, when the distribution ν is known, the solution is straightforward: one simply chooses the action having the highest expected reward, namely,

$$a_{\text{opt}} = \arg\max_a E_{\nu_a}[r]. \tag{31}$$

However, the problem is how to make the decision when the distribution $\{\nu_i\}_{i=1,\ldots,n}$ is unknown. This is coined the multiarmed bandit problem [12, 25], which is different from the Q-learning in the following aspect: there is no state at the learner in the multiarmed bandit problem; hence, the learner does not need to consider the explicit impact of the current action on the future rewards, while the Q-learning needs to consider the state transition besides the current reward. The similarity is that both the Q-learning and the multiarmed bandit problem need to address the tradeoff between exploitation and exploration. Hence, the learner should also pull the arms that have not been pulled or have been seldom pulled.

One defines the cost function of the multiarmed bandit problem as the cumulative regret:

$$R_n = n \max_i \{v_i\} - \sum_{t=1}^{n} r(t), \tag{32}$$

where R_n is the regret until time n. Obviously, this is the gap between the optimal reward and the real reward. The learner desires to minimize the regret R_n.

There have been many proposed approaches to handle the multiarmed bandit problem. This chapter will introduce one approach in a subsequent section discussing single-user channel selection.

Multiagent Learning

When multiple agents have coupled dynamics and learn their strategies, the problem is much more complicated than the single-agent learning. It is because, for a certain agent, the behaviors of other agents are part of its environment. However, the behaviors of other agents are changing. Hence, the learning agent is experiencing a changing environment, which is different from the single-agent learning where one assumes that the environment does not change. Hence, it is possible that the dynamics of learning will oscillate and never converge.

Take the channel selection in cognitive radio, for instance. Suppose that many secondary users choose from two channels. Consider the following procedure:

1. All users choose channel 1, and then channel 1 becomes crowded.
2. The users find that channel 1 is congested, and all switch to channel 2.
3. Then channel 2 becomes congested; hence, the users switch to channel 1 again.

The above procedure may repeat and never converge. Hence, it is important to design algorithms that converge for a stable performance. In this section, one introduces two types of multiagent learnings, namely, fictitious play and multiagent reinforcement learning.

Another possibility of multiagent learning is that the rewards of the agents are not coupled. However, the agents can share information with each other, such that they can accelerate the learning process. The discussion will introduce this type of learning by taking the collaborative filtering [1] as the example.

Fictitious Play

For simplicity, one considers the case of two agents. In fictitious play, both agents take simultaneous moves and receive rewards. Suppose that, in each move, the two agents can take actions $a_1 \in \mathcal{A}_1$ and $a_2 \in \mathcal{A}_2$, where $\mathcal{A}_1$ and $\mathcal{A}_2$ are the sets of actions. The rewards are given by $r_1(a_1, a_2)$ and $r_2(a_1, a_2)$, respectively. This is illustrated in Fig. 9

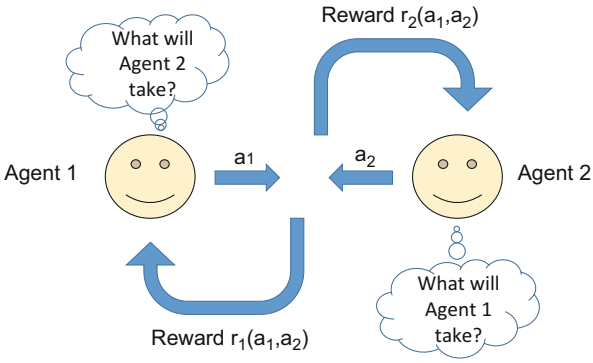

Fig. 9 Illustration of fictitious play

The strategies of both agents are to consider the opponent as having stationary probabilities. Hence, each agent calculates the frequencies of different actions taken by the opponent. Take agent 1, for instance. At round t, it updates the counter for each action, denoted by $\{c_2(a)\}_{a\in\mathcal{A}_2}$, namely,

$$c_2^t(a) = c_2^{t-1}(a) + \begin{cases} 1, \text{ if } a_2(t) = a \\ 0, \text{ if } a_2(t) \neq a \end{cases}. \tag{33}$$

Then, agent 1 updates the frequencies as follows:

$$f_2^t(a) = \frac{c_2^t(a)}{\sum_{a'} c_2^t(a')}. \tag{34}$$

This frequency update can be fit into the Bayesian framework: when more actions of the opponent are observed, the belief of the action distribution is updated. Then, the agent can take actions according to the estimated frequency. For example, it can take the action that maximizes the expected reward if the estimated frequency is true:

$$a_1(t+1) = \arg\max_{a'} f_2^t(a) r(a', a). \tag{35}$$

The analysis of the learning dynamics is complicated. One can consider the counters $\{c_1^t(a)\}_{a\in\mathcal{A}_1}$ and $\{c_2^t(a)\}_{a\in\mathcal{A}_2}$. It is easy to verify that the learning dynamics is nonlinear, which makes the analysis of converge challenging. For such nonlinear dynamics, a most useful approach is the Lyapunov method. For a generic dynamics given by

$$\frac{d\mathbf{x}(t)}{dt} = g(\mathbf{x}(t)), \tag{36}$$

one can try to find a Lyapunov function V, in terms of the system state $\mathbf{x}$, satisfying the following conditions:

- $V : \mathbb{R}^n \to \mathbb{R}$ is continuous.
- V has continuous derivatives and is positive definite.
- The gradient ∇V is nonpositive definite.

One can consider such a Lyapunov function as the energy of the system. Then, if one can prove that,

$$\frac{dV(\mathbf{x}(t))}{dt} < 0, \qquad \forall \mathbf{x} \in \mathbb{R}^n - \{0\}, \tag{37}$$

then, the dynamics is stable and will converge as time evolves. Unfortunately, there is no systematic approach to find such a Lyapunov function.

Multiagent Reinforcement Learning

The fictitious learning does not consider the evolution of system states. When the agents have internal system states, they can employ the reinforcement learning. Since every agent is updating its strategy during the learning procedure, the convergence becomes a major concern. In this chapter, one assumes that every agent employs the Q-learning. A comprehensive survey on multiagent reinforcement learning can be found in [6]. In this chapter, one provides a brief introduction to the basic model, concept, and method.

First, the multiagent reinforcement learning can be formulated as a stochastic game with n agents represented by a tuple $(X, U_1, \ldots, U_n, f, \rho_1, \ldots, \rho_n)$, where the components are illustrated in Fig. 10 and are explained as follows:

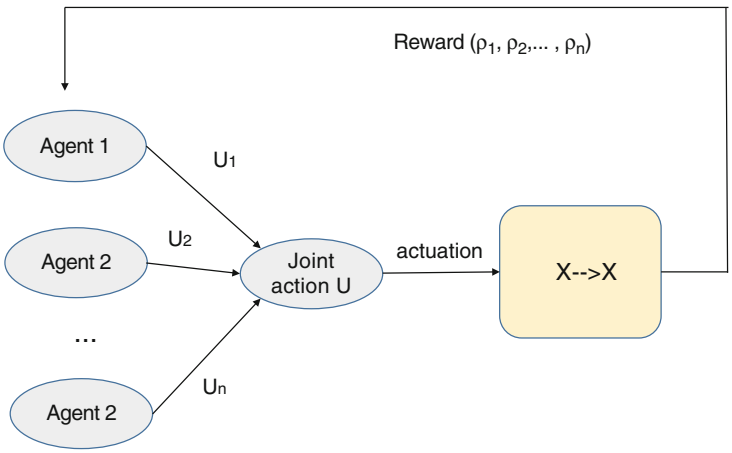

Fig. 10 Illustration of multiagent reinforcement learning

- X is the environment state, which is assumed to be discrete.
- $U_i, i = 1, \ldots, n$ is the action taken by agent n. One defines the joint action as $\mathbf{U} = (U_1, \ldots, U_n)$.
- f is the transition probability of the environment given different joint actions. One can write it as $f_U(X(t+1)|X(t))$.
- $\rho_i, i = 1, \ldots, n$ is the reward of agent i, which can be written as $\rho_i(X(t+1), X(t), U(t))$.

It is assumed that each agent can observe the system state X and choose a random action according to distribution $\pi_i(U|X)$, where π_i is called the policy of agent i. The goal of reinforcement learning is to optimize ρ_i for a larger expectation of reward. Since the reward is dependent on the joint action, the expected reward will also be dependent on the policies of other agents. Therefore, the learning dynamics of the agents are coupled with each other. In the subsequent discussion, several cases of the rewards will be discussed.

Fully Cooperative Tasks

When $\rho_1 = \ldots = \rho_n = \rho$, the agents have the same benefit. Hence, they need to fully cooperate to improve the common reward ρ. Then, each agent can apply the Q-learning by updating the Q-values $Q(X, U_k)$:

$$Q_{t+1}(X_t, \mathbf{U}_t) = Q_t(X_t, \mathbf{U}_{t+1}) + \beta \left[r_{t+1} + \alpha \max_{U'} Q_t(X_{t+1}, \mathbf{U}') - Q_t(X_t, \mathbf{U}_t) \right]. \tag{38}$$

Given the Q-value, the agent needs to choose a good action upon the current system state X. Since the task is fully cooperative, the agent can imagine that all the other agents have similar Q-values and are also trying to maximize the reward. Hence, one can define a Q-value for each local action U_i as follows:

$$Q_i'(X, U_i) = \max_{U_1, \ldots, U_{i-1}, U_{i+1}, \ldots, U_n} Q_i(X, \mathbf{U}), \tag{39}$$

namely, choosing the action that can maximize the reward given the full support of all other agents. Using this Q-value, the agent can choose the corresponding action given the environment state X, e.g., using the Boltzmann distribution.

Fully Competitive Tasks

Suppose that there are two agents, namely, $n = 2$. One assumes that $\rho_1 = -\rho_2$, thus forming a zero-sum game. In this case, if all the information (especially the reward functions) is known, the two agents will form a maxmin equilibrium, according to game theory [10]. Hence, the maxmin principle can also be applied in the learning

procedure. In [20], the maxmin-Q algorithm is proposed, in which each agent learns the rewards of different combinations of actions under different environment states. Hence, the agents will learn the Q-values in the following manner:

$$Q_{t+1}(X(t), U_1(t), U_2(t)) = Q_t(X(t), U_1(t), U_2(t)) + \beta \left[\rho_1(t+1) + \alpha m_1(Q(t), X(t+1)) - Q_{t+1}(X(t), U_1(t), U_2(t))\right], \quad (40)$$

where m_1 is the maxmin reward, which is given by

$$m_1(Q, X) = \max_{\pi_1} \min_{U_2} \sum_{U_1} \pi_1(X, U_1) Q(X, U_1, U_2), \quad (41)$$

namely, the optimal probability of different actions subject to the most detrimental action taken by agent 2. Once the Q-value is updated, the optimal strategy of agent 1 is given by

$$\pi_1(Q, X) = \arg\max_{\pi} \min_{U_2} \sum_{U_1} \pi(X, U_1) Q(X, U_1, U_2). \quad (42)$$

It is complicated to analyze whether the learning procedure can achieve the Nash equilibrium.

Collaborative Filtering

Collaborative filtering has a longer history than cognitive radio systems. It originated from the study of Tapestry system, which helps users to scan a list of documents and select desired ones [13]. Collaborative filtering is proposed to let people collaboratively filter the document list according to their shared interest. Since then, multiple approaches have been proposed. People considered the preferences of all users as a matrix and converted the collaborative filtering into a mathematical problem called matrix completion, i.e., predicting missing entries in a matrix according to some a priori information about the matrix. Quite often, the matrix is singular or near singular due to the similarities among different rows if the preference of each user is considered as a row in the matrix. Then, singular value decomposition (SVD) is applied to reconstruct the matrix by recovering the sparse spectrum of the matrix [3].

Since the beginning of this century, collaborative filtering has been widely applied in e-commercial recommendation systems, which is a popular research topic in computer science. Recommendation systems help users to leverage the experience of other people to achieve a more oriented purchase; i.e., users can purchase goods that have been experienced and recommended by other users, provided that they have similar flavors. Practical systems include eBay's reputation

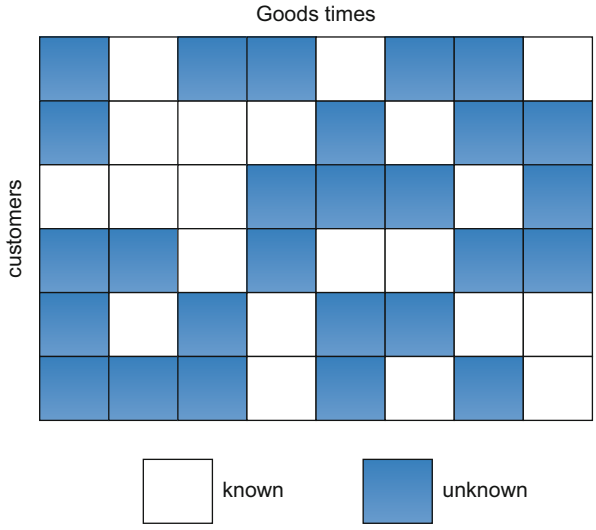

Fig. 11 Illustration of collaborative filtering in terms of matrix completion

system and Amazon's customer review system. Collaborative filtering is a natural and powerful tool to recover the preferences of users (thus completing the matrix) based on the similarities among users. The SVD approach is applied for identifying groups with similar flavors in [9]. In [4], the preference matrix is divided into multiple domains for enhancing the collaborative filtering in websites. When users are distributed, it is difficult to apply the centralized approaches such as SVD or nuclear norm optimization. Therefore, linear predictions are applied to estimate the preferences according to the estimation of Pearson's correlation among different users.

The collaborative filtering can also be considered as a matrix completion. One can consider the customer index as one dimension while the goods item as the second dimension, thus forming a matrix, as illustrated in Fig. 11. Each element corresponding to customer-goods pair is the fondness of the customer to the goods. The simplest case is whether the customer likes or dislikes the goods, thus forming a binary value. However, many elements in the matrix are unknown, because the customer may not know the goods (thus, the fondness is also unknown). However, one believes that the elements in this matrix are not mutually independent because of the similarity of the rows (namely, the similarity of customers) and the similarity of the columns (namely, the similarities of the goods). Hence, the goal of the collaborative filtering is to guess the values of the unknown elements and thus complete the matrix.

A comprehensive introduction to collaborative filtering can be found in [1]. Here an outline of the dichotomy of various collaborative filtering techniques is provided.

Neighborhood-Based Collaborative Filtering

Suppose that there is a set of purchase record for M customers. The set of goods purchased by customer m is denoted by $\mathcal{I}_m$. Obviously, a customer cannot purchase all goods. Hence, it is important to predict the preference of each customer and make recommendations. There are two approaches for the prediction from two different aspects:

- Customer based: One measures the similarity between different customers. Two customers are similar if they purchase similar goods. However, it is tricky to measure the similarity. Many approaches can be found in [1]. Once one detects two customers A and B, one can send recommendations to B about the goods that A has purchased while B has not.
- Goods based: One measures the similarity between two goods. Two goods are similar if they are purchased by similar customers. Again, it is important to devise measures for the similarity between two goods. Once two similar goods A and B have been found, one can send recommendations to the customers that have purchased A but have not purchased B (and vice versa).

Model-Based Collaborative Filtering

The neighborhood-based collaborative filtering can be considered as the method based on raw data, similarly to the k-nearest neighbor classifiers. If structures can be identified from the data, one can first build a model for the data and then use the model to predict unknown elements (Fig. 12).

One possible selection of model is the decision tree, in which multiple attributes are used to judge the path selection in the tree, while each leaf of the tree means a decision. Hence, one can design a decision tree for each goods, while the attributes are the fondness of other goods. When one needs to predict the fondness of one customer for a certain goods, the decision tree can be used to make the decision by using the fondness of the customer for other goods. The missing elements in the matrix incur two challenges for this decision-based approach: (a) how to train

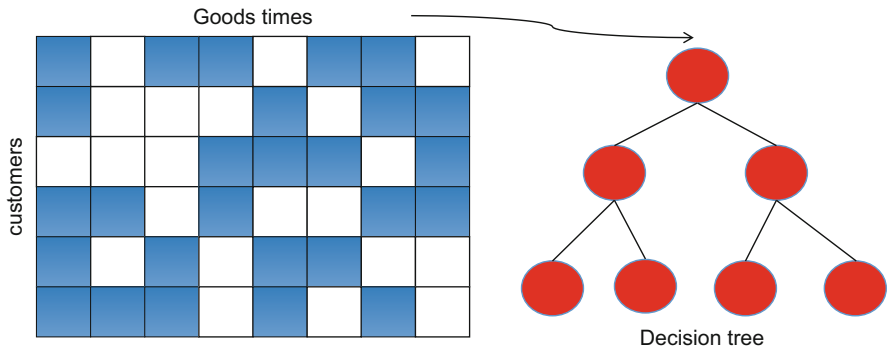

Fig. 12 Illustration of model based collaborative filtering

the decision tree when some of the attributes are missing and (b) given a decision tree, how to make the decision when some attributes are not available. There are systematic approaches to handle them (see Chapter 3 of [1]).

Knowledge-Based Collaborative Filtering

The above approaches do not exploit the domain knowledge of the task; they simply mine the raw data. If there is domain knowledge to be exploited, one can improve the efficiency of the collaborative filtering. The application of knowledge-based collaborative filtering is highly task specific. It is discussed for several scenarios in Chapter 5 of [1]. In the context of cognitive radio, it is intuitive that nearby secondary users are more likely to observe similar spectrum activities. Hence, the distance between two secondary users can also be incorporated into the similarity metric.

Applications in Cognitive Radio

In this section, some illustrative examples will be provided for the applications of learning in cognitive radio networks. One mainly focuses on the reinforcement learning without an explicit supervision and the applications in the channel selection in MAC layer, as well as routing in the network layer.

Channel Selection Using Multiarmed Bandit

In this subsection, one follows the discussion in [17] to introduce the channel selection in the MAC layer.

Channel Model

One considers N communication channels with synchronized timing. At each time slot t, the status of channel i is represented by a Bernoulli random variable $Z_i(t)$, which is equal to 1 (which means that the channel is idle and can be used by secondary user) with probability θ_i and is equal to 0 (which means that the channel is being used by a primary user) with probability $1 - \theta_i$. One assumes that $Z_i(t)$ is independent for different i and different t. This is illustrated in Fig. 13.

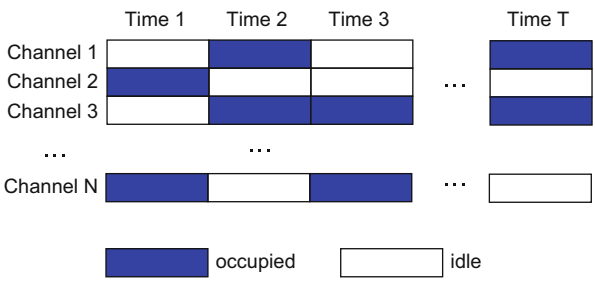

Fig. 13 Channel model for cognitive radio

Problem Formulation

Suppose that the secondary user chooses channel $S(t)$ at time t. Then, the total number of bandwidth it can access in T time slots is given by

$$W = \sum_{t=1}^{T} Z_{S(t)}(t), \tag{43}$$

where one assumes a unit bandwidth for each channel. The goal of the secondary user is to maximize the expected bandwidth given by

$$W = \sum_{t=1}^{T} E[Z_{S(t)}(t)]. \tag{44}$$

If the probabilities $\{\theta_i\}_{i=1,\ldots,N}$ are known, the secondary user can simply choose the channel having the largest probability, namely, $\arg\max_i \theta_i$. However, these probabilities are unknown. Hence, the secondary user needs to determine the selection of channel according to the outcomes of the previous trials.

Multiarmed Bandit Learning

One can consider each communication channel as an arm, thus forming a multi-armed bandit problem. In this chapter, one assumes that the secondary user can sense only one channel, namely, pulling one arm. In [17], the case of simultaneously sensing multiple channels is also discussed.

Multiple approaches can be used to solve the problem:

- Bayesian approach: In this approach, one updates the knowledge about the system parameter $\theta = (\theta_1, \ldots, \theta_N)$. One assumes that θ is a random variable, whose prior probability density function (pdf) is given by $f(\theta)$. When a new decision has been made and the spectrum sensing result is available, the prior pdf f can be updated:

$$f^{t+1}(\theta) = \frac{z_{s(t)}(t)\theta_{s(t)} f^t(\theta) + (1 - z_{s(t)}(t))(1 - \theta_{s(t)}) f^t(\theta)}{z_{s(t)}(t) \int \xi_{s(t)} f^t(\xi) d\xi + (1 - z_{s(t)}(t)) \int (1 - \xi_{s(t)}) f^t(\xi) d\xi} \tag{45}$$

  Based on this Bayesian updating rule for f, the problem can be solved by using DP [5], as illustrated in Fig. 14. One denotes by $V^*(f, T)$ the optimal reward between time 1 and T when the pdf of θ is f. Then, this optimal reward satisfies the following Bellman equation:

$$V^*(f, T) = \max_s E_f\{Z_s + V^*(f_s, T - 1)\}, \tag{46}$$

  where f_s is the possible pdf of θ after the updating step according to the outcome Z_s when the channel selection is s. Then, the optimal channel selection is given by

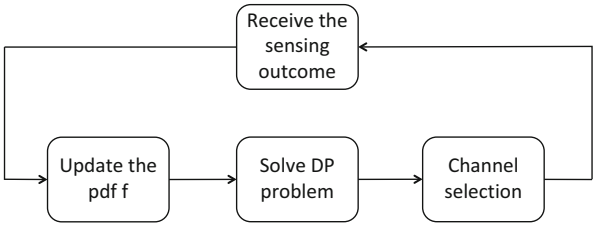

Fig. 14 Bayesian solution to bandit problem

$$s^*(f, T) = \arg\max_s E_f\{Z_s + V^*(f_s, T-1)\}. \tag{47}$$

These equation can be solved in a recurrent manner since, when $T = 1$, one simply chooses the channel with the maximum expected probability $\theta^* = \max_i f(\theta_i)$. However, the challenge is that V^* is a functional in terms of f (since f is a function). Hence, a precise solution to (46) is prohibitively difficult except for some special cases. One possible approach is to discretize the space of f, thus turning V to a vector. Another possible solution is to parameterize the functional V and discretize f.

- Non-Bayesian methods with loss $O(T)$: When the parameter θ is not considered as random variables, there are several approaches for the decision-making of channel selection. One simple approach is simply choose a channel randomly; another simple one is the myopic strategy, namely, choosing the channel having the largest probability estimation (hence, only exploitation; no exploration). In [17], a more intelligent approach is called the strategy of staying with the winner and switching from the loser. The rule is simple. The secondary user begins with a random channel selection. If the channel turns out to be idle, it will sense this channel again in the next time slot. If the channel is busy, then the secondary user will randomly choose one from the remaining channels. It is shown in [17] that the performance loss, which is defined as

$$L(\theta) = \sum_{j=1}^{T} \theta_{i^*} - \sum_{j=1}^{T} \sum_{i=1}^{N} Pr(S(j) = i), \tag{48}$$

where i^* is the index of the optimal channel, is of order $O(T)$. It has been shown in [17] that there exist better algorithms that achieves $O(\log T)$.

- Non-Bayesian methods with loss $O(\log T)$: It has been found in [17] that several approaches can achieve a performance loss defined in (48) of order $O(\log T)$. For example, the order-optimal single-index strategy can achieve the loss $O(\log T)$. In this approach, the secondary user maintains two vector $\mathbf{x}$ and $\mathbf{y}$. Here x_i means the number of times in which the secondary user finds channel i to be idle, while y_i means the times that the secondary user has sensed channel i. The secondary user begins from sensing each channel for one time, such that $\mathbf{y} = (1, 1, 1, \ldots, 1, 1)$. Then, at each time slot, the secondary user updates the probability estimation by

$$\hat{\theta}_i(t) = \frac{x_i(t)}{y_i(t)}, \tag{49}$$

and then assign an index to channel i:

$$\Lambda_i(t) = \hat{\theta}_i(t) - \sqrt{\frac{2\log t}{y_i(t)}}. \tag{50}$$

Then, the secondary user will choose the index having the largest index. As long as y_i increases as fast as $O(\log T)$, the index will converge to the true probability and thus the secondary user will finally keep using the best channel. On the other hand, if a channel has not been sufficiently sensed, the corresponding value of y_i will be small, thus making the index Λ_i large and the secondary user sense this channel. Hence, this mechanism forces the secondary user to sense channels rarely sensed for exploration.

Routing Using *Q*-Learning

Reinforcement learning algorithms usually address problems of a single objective, when scalar rewards are received. Different from the traditional reinforcement learning algorithms, multi-objective reinforcement learning (MORL) introduced by Gabor [11] employs reinforcement learning in problems having multiple objectives, thus forming vector rewards. Note that multiple objectives do exist in wireless communication networks, such as expected delay and packet drop rate, which may conflict with each other. Thus MORL is applicable in the routing of cognitive radio networks to meet the multiple performance goals.

In this chapter, one considers the task of routing with two objectives, whose value functions are represented by $V^{\pi,1}(s)$ and $V^{\pi,2}(s)$, respectively [33]. To handle the two conflicting objectives, one sets a hard constraint on one objective and then optimizes the other one. Then, one has the following optimization problem:

$$\max V^{\pi,1}(s) \tag{51}$$

$$s.t.\ \ V^{\pi,2}(s) \leq R_{\text{constr}}, \tag{52}$$

where R_{constr} is the hard constraint on the second objective. One will use the following assumptions for the cognitive radio under study:

- There exist multiple licensed channels.
- The activities of primary users can be modeled as Markov processes.

- In each time slot, each primary user can be either active or idle. If a primary user is active, it will occupy a fraction of the licensed channels. Before SUs start transmitting packets, they must perform spectrum sensing first.
- One only considers the packet loss due to transmission failures, which is dependent on the link condition.

In this chapter, one focuses on two typical metrics in wireless communication networks, namely, the transmission delay and packet drop rate [33]. When one formulates the algorithm design as an optimization problem, there could be the following two choices:

- One minimizes the transmission delay subject to a constraint of packet drop rate. This is suitable for the scenario of best effort applications.
- One minimizes the packet drop rate subject to a constraint of transmission delay. This is proper for the scenario of real-time applications.

In the MORL-based routing, one will adopt the first one. It is also straightforward to implement the second one within the proposed framework. Meanwhile, in order to simplify the MORL procedure, two Q-value tables will be used in the learning and routing algorithm, one for the transmission delay and the other one for the packet loss rate. Similarly to the standard Q-learning procedure, each Q-value table stores the accumulated reward given the state and corresponding action. Thus the first Q-value table (for transmission delay) uses the negative of one hop transmission delay as the immediate reward, while the second Q-value table uses the negative of the accumulated packet loss rate as the immediate reward. The action is to find the forwarding node for the next hop in order to maximize the Q-values.

An MORL algorithm is proposed for the routing procedure, which is summarized in Procedure 1. Simulations have shown that the proposed learning algorithm can achieve a good performance for the routing task.

Procedure 1 Procedure of MORL routing [33]

```
Initialize all the Q-value tables of all nodes
for Each time slot do
    for Each node forwarding a packet do
        Choose the forwarding node from the local Q-value table. The action should minimize
        the Q-value table for the transmission delay, while maintaining the corresponding value
        of the Q-value table for packet loss rate under a specific constraint.
        Sense the channel. If the channel is occupied by PU, then randomly choose another
        channel.
        if ACK is received then
            Update the Q-value tables.
        end if
    end for
end for
```

Multiple User Learning

In the previous discussion, the discussion focused on the learning procedure of a single secondary user. However, in many cases, multiple secondary users need to compete for limited resources. Hence, it is also important to study the learning procedures of multiple users and examine their interactions. In this subsection, one uses the channel selection for instances.

Multiagent Reinforcement Learning

Here one applies the multiagent reinforcement learning for channel selection [18]. For simplicity, one considers only two secondary users, denoted by A and B, and two channels, denoted by 1 and 2. The reward to secondary user i, $i = A, B$, of channel j, $j = 1, 2$, is R_{ij} if secondary user succeeds in transmitting data over channel j (which is not interrupted by primary user or the other secondary user). Otherwise the reward received by the secondary user is 0. For simplicity, one denotes by j^- the other user (channel) different from user (channel) j.

One has the following assumptions for the system:

- The rewards $\{R_{ij}\}$ are unknown to both secondary users, whereas they are fixed throughout the game.
- Both secondary users can sense both channels simultaneously. However, they can choose only one channel for data transmission.
- One considers only the case that both channels are available. Otherwise the actions that the secondary users can take are obvious (transmit over the only available channel or not transmit if no channel is available).
- There is no direct communication between the two secondary users.

The above channel selection game is a 2×2 one, in which the payoff matrices for player A and B are shown in Fig. 15. The actions, denoted by $a_i(t)$ for user i at time t, in the game are the channel selections. The diagonal elements in the

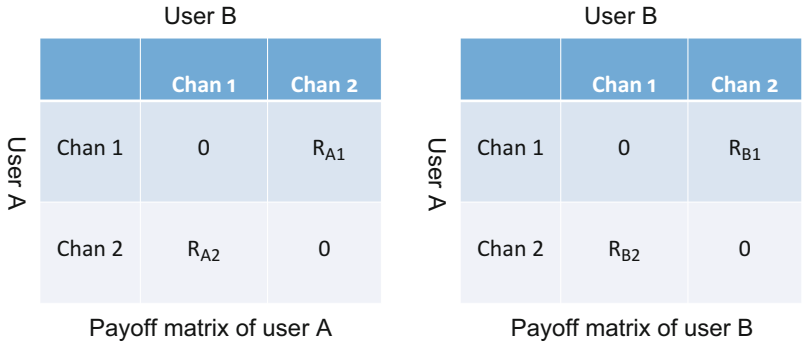

Fig. 15 Payoff matrices in the game of channel selection

payoff matrices are all zero since transmission conflict incurs zero reward. There are two Nash equilibria in the channel selection game, namely, the strategies such that unilaterally changing strategy incurs performance degradation. Both equilibria are pure; i.e. $a_A = 1, a_B = 2$ and $a_A = 2, a_B = 1$ (namely the orthogonal transmission without interference).

Since both channels are available without the interruption of primary users, the system is state-less. Therefore, the Q-value of each player is simply the expected reward of each action; i.e.

$$Q(a) = E[R(a)], \tag{53}$$

where a is the action, R is the reward corresponding to the action while the expectation is over the randomness of the other user's action. Since the action is the channel selection, one denotes by Q_{ij} the value of selecting channel j by secondary user i. The actions in the Q-learning are stochastic for possible exploration. One considers the standard Boltzmann distribution for exploration [29]; i.e.

$$P(\text{user } i \text{ chooses channel } j) = \frac{e^{Q_{ij}/T}}{e^{Q_{ij}/T} + e^{Q_{ij^-}/T}}, \tag{54}$$

where T is the temperature.

When secondary user i selects channel j, the expected reward is given by

$$E[R_i(j)] = \frac{R_{ij} e^{Q_{i^-j^-}/\gamma}}{e^{Q_{i^-j}/\gamma} + e^{Q_{i^-j^-}/\gamma}}, \tag{55}$$

since secondary user i^- chooses channel j with probability $\frac{e^{Q_{i^-j}/\gamma}}{e^{Q_{i^-j}/\gamma}+e^{Q_{i^-j^-}/\gamma}}$ (namely, collision occurs and secondary user i receives no reward) and channel j^- with probability $\frac{e^{Q_{i^-j^-}/\gamma}}{e^{Q_{i^-j}/\gamma}+e^{Q_{i^-j^-}/\gamma}}$ (the transmissions are orthogonal; thus, secondary user i receives reward R_{ij}).

During the operation of the system, the Q-values are updated right after each spectrum access using the following rule:

$$Q_{ij}(t+1) = (1-\alpha_{ij})Q_{ij}(t) + \alpha_{ij}(t) r_i(t) I(a_i(t) = j), \tag{56}$$

where $0 < \alpha_{ij}(t) < 1$ is a step factor (when channel j is not selected by user i, $\alpha_{ij}(t) = 0$) and $r_i(t)$ is the reward that secondary user i receives at time slot t, and I is characteristic function for the event that channel j is selected.

Next, one checks whether the updating rule of Q functions in (56) converges to a point close to the Nash equilibrium if the step factor α satisfies certain conditions. One first provides an intuitive explanation for the convergence using the geometric argument proposed in [21], and illustrated in Fig. 16 (which is called it *Metrick-Polak plot* since it was originally proposed by A. Metrick and B. Polak in [21]). Here the axes represent $\mu_A = \frac{Q_{A1}}{Q_{A2}}$ and $\mu_B = \frac{Q_{B1}}{Q_{B2}}$, respectively. The plane is divided into

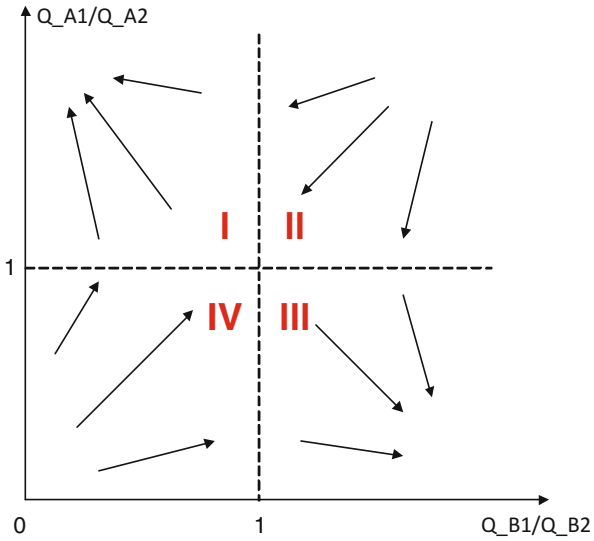

Fig. 16 Illustration of the dynamics in the Q-learning

four regions by two lines $\mu_A = 1$ and $\mu_B = 1$, in which the dynamics of Q-learning follows different patterns. The following four regions are discussed separately:

- Region I: In this region, $Q_{A1} > Q_{A2}$, which means that secondary user A prefers visiting channel 1. Meanwhile, secondary user B prefers to access channel 2 since $Q_{B1} > Q_{B2}$. Then, with a large probability, the strategies of both players will converge to the Nash equilibrium point in which secondary users A and B access channels 1 and 2, respectively.
- Region II: In this region, both secondary users prefer to access channel 1, thus causing collisions. Therefore, both Q_{A1} and Q_{B1} will be reduced until entering either region I or region III.
- Region III: similar to region I.
- Region IV: similar to region II.

The points in regions II and IV are unstable and will move into region I or III with a large probability. In regions I and III, the strategy will move close to the Nash equilibrium points with a large probability. Therefore, regardless of where the initial point is, the updating rule in (56) will yield a stationary equilibrium point with a large probability.

In order to prove the convergence rigorous, one first finds the equivalence between the updating rule in (56) and the celebrated Robbins-Monro iteration [26], which is used to solve equations with unknown expressions. Then, one can apply the conclusion in the theory of stochastic approximation [16] to relate the iteration with an ordinary differential equation (ODE) and thus prove the convergence.

The updating rule of Q-learning is equivalent to the following four equations:

$$Q_{ij} = \frac{R_{ij} e^{Q_{i-j}-/\gamma}}{e^{Q_{i-j}/\gamma} + e^{Q_{i-j}-/\gamma}}, \qquad i = A, B, \ j = 1, 2. \tag{57}$$

Then, one defines $\mathbf{q} = (Q_{A1}, Q_{A2}, Q_{B1}, Q_{B2})^T$, which makes (57) equal to

$$\mathbf{g}(\mathbf{q}) = \mathbf{A}(\mathbf{q})\mathbf{r} - \mathbf{q} = 0, \tag{58}$$

where $\mathbf{r} = (R_{A1}, R_{A2}, R_{B1}, R_{B2})^T$ and the matrix $\mathbf{A}$ is given by

$$\mathbf{A}_{ij} = \begin{cases} \frac{e^{Q_{i-j}-/\gamma}}{e^{Q_{i-j}/\gamma} + e^{Q_{i-j}-/\gamma}}, & \text{if } i = j \\ 0, & \text{if } i \neq j \end{cases}. \tag{59}$$

Then, the iteration in (56) is equivalent to solving the equation in (58). However, the expression of the equation is unknown in advance, since the rewards, as well as the strategy of the other user, are unknown. Hence, one can use the Robbins-Monro algorithm [16], which is given by

$$\mathbf{q}(t+1) = \mathbf{q}(t) + \alpha(t)\mathbf{Y}(t), \tag{60}$$

where $\mathbf{Y}(t)$ is a random and noisy observation on function g; i.e.

$$\begin{aligned} \mathbf{Y}(t) &= \mathbf{r}(t) - \mathbf{q}(t) \\ &= \bar{\mathbf{r}}(t) - \mathbf{q}(t) + \mathbf{r}(t) - \bar{\mathbf{r}}(t) \\ &= \mathbf{g}(\mathbf{q}(t)) + \delta M(t), \end{aligned} \tag{61}$$

where $\mathbf{g}(\mathbf{q}(t)) = \bar{\mathbf{r}}(t) - \mathbf{q}(t)$, $\delta M(t) = \mathbf{r}(t) - \bar{\mathbf{r}}(t)$ is noise for estimating $\bar{\mathbf{r}}(t)$ and $\bar{\mathbf{r}}(t)$ is the expectation of reward, which is given by

$$\bar{\mathbf{r}}(t) = \mathbf{A}(\mathbf{q}(t))\mathbf{r}. \tag{62}$$

As has been shown above, the procedure of using the Robbins-Monro algorithm is the stochastic approximation of the equation solution. It has been shown that the convergence of such a procedure can be determined by an ODE. Since the noise $\delta M(t)$ in (61) is a Martingale difference, it is easy to verify the conditions in Theorem 12.3.5 in [16] and thus obtain the following proposition:

Proposition 1. *With probability 1, the sequence* $\mathbf{q}(t)$ *converges to some limit set of the ODE*

$$\dot{\mathbf{q}} = \mathbf{g}(\mathbf{q}). \tag{63}$$

What remains is to analyze the convergence of the ODE in (63). With a nontrivial proof in [18], the following proposition is obtained for the convergence of the learning procedure:

Proposition 2. *The solution of ODE* (63) *converges to the stationary point determined by* (58).

Multiagent Bandit

The multiarmed bandit algorithm can also be extended to the case of multiple users. Suppose that there are K secondary users in the cognitive radio system [17]. Then, these secondary users need to avoid the interruptions from primary users and interference from other secondary users. The model for the channels can be found in the single user case discussed above.

In this chapter, one assumes that each secondary user can sense and transmit over only one channel. One assumes that the secondary users sharing the same channel use the carrier sense multiple access/collision avoidance (CSMA/CA) protocol to avoid collisions. One denotes by $\mathcal{K}_i(j)$ the set of secondary users sensing channel i at time slot j. Hence, if at time slot j secondary user k finds that channel i is free of primary users, it generates a random number $t_k(j)$ according to a predetermined distribution g. Then, it will wait for a time duration $t_k(j)$, and sense the channel at the end of the waiting period. If the channel is free, the secondary user goes ahead to transmit; otherwise it gives up the transmission. One assumes that the transmission of a packet will span the whole time slot. Hence, only the secondary user having the smallest waiting time will obtain the chance to transmit. Therefore, the throughput of secondary user k within one time slot is given by

$$W_k = \sum_{j=1}^{T} Z_{S_k(j)}(j) I\left\{k = \arg \min_{q \in \mathcal{K}_{S_k(j)}(j)} t_q(j)\right\}, \tag{64}$$

In the setup of multiple secondary users, even if the probabilities θ are known to the secondary users, the strategy for channel selection and accessing is still nontrivial. Different from the single-user case, it is not a good idea to always choose the channel having the least primary user activities, since there will be a congestion among the secondary users if all the secondary users select the idlest channel. Hence, the secondary users should "spread" their selections over more channels in a random manner. It is shown in [17] that the optimal strategy in the multiple user case is given by

$$p_i^* = \begin{cases} \left[1 - \left(\frac{\lambda^*}{K\theta_i}\right)^{\frac{1}{K-1}}\right], & \text{if } \theta_i > 0 \\ 0, & \text{otherwise} \end{cases}, \tag{65}$$

where λ^* is the Lagrange factor to make $\sum_{i=1}^{N} p_i^* = 1$ and $\{x\}^+$ is equal to $\max\{0, x\}$.

When the idle probability θ is unknown, the following rule is adopted in [17]:

1. Initialization: Similarly to the single-user case, each secondary user k maintains two N-vectors: $\mathbf{x}_k$ and $\mathbf{y}_k$, whose meanings are the same as those of the single-user case.
2. At the beginning of each time slot, the secondary user updates the values of $\mathbf{x}_k$ and $\mathbf{y}_k$, according to the sensing result.
3. At the beginning of each time slot j, user k updates the estimation of θ_i using

$$\hat{\theta}_i(j) = \frac{X_{k,i}(j)}{Y_{k,i}(j)}. \tag{66}$$

4. Then, the secondary user will choose channel i using the following probability

$$p_i(j) = \frac{\hat{\theta}_i(j)}{\sum_{i=1}^{N} \hat{\theta}_i(j)}. \tag{67}$$

It is shown that, if K is sufficiently large, the above rule will converge to the Nash equilibrium in probability, as T tends to infinity.

Collaborative Filtering

As has been explained in the previous section, collaborative filtering can be used to find similar users or items such that recommendations can be made for users having not accessed certain items. The recommendation could be positive (namely, this channel is good for you) or negative (namely, this channel is harmful for you). In this discussion, one follows the study in [19] and consider a cognitive radio network having N secondary users. One can use an undirected graph to use to represent the network, where each vertex is a secondary user and each edge means that the corresponding two secondary users can directly communicate with each other. One denotes by $\mathcal{N}_i$ the set of neighbors that can communicate directly to secondary user i. These secondary users are allowed to access M licensed channels, which may be dynamically used by primary users. One considers the following assumptions:

- The system timing is slotted, as illustrated in Fig. 17. In each time slot, each secondary user can choose a channel and sense the spectrum. At the end of each time slot, the secondary user exchanges information for collaborative learning.

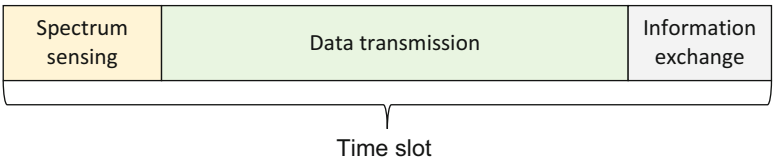

Fig. 17 An illustration of the timing structure

Due to the limited capability of spectrum sensing, each secondary user can sense only one channel in each time slot. It is straightforward to extend the algorithm to the case of sensing multiple channels simultaneously.

- The spectrum sensing result is always correct. This is reasonable when the signal-to-noise ratio (SNR) is good. The study is focused on the competition, instead of low SNR.
- In each time slot, a secondary user can communicate with only one neighbor, due to the limited communication capability. The communication fails with a small probability P_c. The packet containing the information for collaborative learning is protected by parity check bits, such that the receiver can detect possible decoding errors.
- The secondary users have no knowledge about the locations, transmission time and transmit power of primary users. The spectrum activities are independent in different time slots and for different primary users. Different primary users can share the same channel, e.g., using code division multiple access (CDMA).

The activity of each channel can be modeled as a Bernoulli random variable: 0 means that the channel has been occupied by primary users, while 1 means that the channel is usable by secondary users. The Bernoulli assumption is reasonable if each time slot is sufficiently large, such that the time correlation of spectrum occupancy vanishes. One denotes by μ_{ij} the probability that channel j cannot be used by secondary user i. Since μ_{ij} is unknown, it is considered as a random variable in the Bayesian framework. μ_{ij} has a conjugate a priori beta distribution with parameters α and β, which is denoted by beta(α, β). One assumes that α and β are common for all μ_{ij}. The expression of the pdf of $\mu$is thus given by

$$f(\mu; \alpha, \beta) = \frac{\mu^{\alpha-1}(1-\mu)^{\beta-1}}{\int_0^1 q^{\alpha-1}(1-q)^{\beta-1}dq}. \tag{68}$$

Now, the collaborative filtering is discussed. One begins from the simplest case, in which there is only one secondary user. Consider secondary user i. It can use the following unbiased estimation for μ_i:

$$\hat{\mu}_{ii} = \frac{1}{n_i} \sum_{j \in I_{i1}} x_{ij}, \tag{69}$$

where x_{ij} is the observation, 1 or 0, of secondary user i at time slot j.

Then, one considers two neighboring secondary users carrying out the collaborative filtering. One uses the estimation of secondary user 1 to predict the parameter of secondary user 2. Suppose that the estimation of secondary user 1 is given by μ_1. Then, the linear prediction is given by

$$\hat{\mu}_2 = a\mu_1 + b. \tag{70}$$

In the MMSE linear prediction, the optimal coefficients a and b are given by

$$a = \rho_{12}\frac{\sigma_2}{\sigma_1}, \tag{71}$$

and

$$b = E[\mu_2] - aE[\mu_1]. \tag{72}$$

Note that σ_1 and σ_2 are variances of μ_1 and μ_2, respectively. ρ_{12} is the correlation factor of μ_1 and μ_2, which is defined as

$$\rho_{12} = \frac{E[(\mu_1 - E[\mu_1])(\mu_2 - E[\mu_2])]}{\sqrt{\sigma_1}\sqrt{\sigma_2}}. \tag{73}$$

The above estimation can be easily extended to the case of multiple neighbors.

The above calculation assumes that the correlation factor ρ_{12} between secondary users 1 and 2 is known. However, this information is unknown to secondary users in advance. Therefore, each secondary user needs to estimate ρ_{ij} from the history of spectrum sensing in the following procedure:

1. Consider secondary user i, $i = 1, 2$. Each estimates its own expectation and variance using the following equations:

$$\hat{\mu}_{ii} = \frac{1}{T}\sum_{t=1}^{T} x_{it}, \tag{74}$$

and

$$\hat{\mu}_{iim} = \frac{1}{n_{im}}\sum_{t\in I_m}^{T} x_{it}, \forall n_{im} > 0, \tag{75}$$

and

$$\hat{\sigma}_{ii} = \frac{1}{|Z_i|}\sum_{m\in Z_i}(\hat{\mu}_{iim} - \hat{\mu}_{ii})^2. \tag{76}$$

These statistics are obtained from the channels probed by secondary user i before. Secondary user j also carries out the same procedure.

2. The correlation between secondary users i and j is computed using

$$\hat{\rho}_{ij} = \frac{1}{|Z_i \cap Z_j|}\frac{\sum_{m\in Z_i, m\in Z_j}(\hat{\mu}_{iim} - \hat{\mu}_{ii})(\hat{\mu}_{jjm} - \hat{\mu}_{jj})}{\sqrt{\hat{\sigma}_{ii}}\sqrt{\hat{\sigma}_{jj}}}. \tag{77}$$

Once the correlations and expectations have been estimated, the secondary users need to carry out the channel selection. Consider two secondary users 1 and 2. Assume that channel j has been probed by secondary user i for n_{ij} times. When applying the linear prediction proposed in the previous discussion, each secondary user faces the following tradeoff between exploration and exploitation:

- Exploitation: Consider a certain secondary user n. If the availability probability of channel i has been well estimated by another secondary user, say m, secondary user n should exploit the estimation of secondary user m and does not probe channel i, given that the channel availability probabilities of secondary users m and n are similar.
- Exploration: Secondary user n should probe channels that are rarely probed by itself in order to better assess the similarity to other secondary users.

One approach is to borrow the idea of Boltzmann distribution from reinforcement learning. One can adjust the temperature to tune the tradeoff between exploitation and exploration.

One remaining problem is the user selection, namely, how to choose a neighbor to consult about the spectrum situation. Since it is very difficult to derive a theoretically optimal rule, one proposes heuristic algorithms for the information request motivated by the exploration rule used in reinforcement learning. One assumes that, in each time slot, each secondary user can exchange information with at most one neighbor, and it needs to choose a neighbor to request the information of spectrum statistics. It is desirable for a secondary user to exchange information with a neighbor that is more similar to itself. The similarity can be measured by the correlation factor ρ. Therefore, the secondary user can choose a neighbor having the largest correlation factor. However, this approach focuses too much on the exploitation and thus may lose chances of finding better channels. Suppose that one considers the user selection of a generic secondary user i. Then, the considerations of exploration and rejection are discussed as follows:

- Exploration: Since the estimated correlation factors are never precise, it is possible that another secondary user having a smaller estimation of the correlation factor actually has a larger correlation factor. If secondary user i insists on the neighbor currently having the largest correlation factor estimation, it may lose the opportunity to find a neighbor that is actually more similar. Therefore, secondary user i should also explore neighbors other than the one having the largest correlation factor estimation.
- Rejection: Even if a neighbor, say secondary user j, has the largest true correlation, it may not respond to the request of secondary user i. It is possible that user j may have a more similar neighbor, say secondary user k, and thus will communicate to secondary user k, instead of user i. Therefore, secondary user i should try to contact other neighbors if its request is declined by secondary user j for several times.

Based on the above reasons, one approach is to use the Boltzmann distribution to alleviate the tradeoff between exploration and exploitation. Consider secondary user i. The probability that it chooses secondary user j, which is a neighbor of secondary user i, is given by

$$p_i^j = \frac{e^{\frac{\tilde{\rho}_{ij}}{T}}}{\sum_{k \in \mathcal{N}_i} e^{\frac{\tilde{\rho}_{ik}}{T}}}, \tag{78}$$

where T is the temperature, which controls the balance between the exploration and exploitation. To address the problem of possible rejection by the requested secondary user, one can use an exponentially decreasing correlation factor in (78), which is given by

$$\tilde{\rho}_{ij} = \beta^{r_{ij}} \hat{\rho}_{ij}, \tag{79}$$

where $\hat{\rho}_{ij}$ is the estimated correlation obtained from (77), $0 < \beta < 1$ is a decaying factor and r_{ij} is the number of times that the request from secondary user i to secondary user j is rejected, which is reset to 0 once secondary user j grants the request from secondary user i.

Conclusions and Future Directions

Machine learning has widely been applied in the area of cognitive radio networks and will be a promising direction of research. The following techniques in machine learning could be of particular value in cognitive radio networks:

- Deep reinforcement learning: With the substantial success of deep learning, it is prospective to employ deep learning techniques in cognitive radio networks, due to the capability of universal learning of neural networks. Deep reinforcement learning has integrated both deep learning and reinforcement learning, which can be used in the scheduling and routing of cognitive radio networks.
- Distributed learning: The learning procedure in cognitive radio networks is often carried out in a distributed manner. Hence, it is of substantial importance to consider the communication complexity in distributed learning since the efficiency can be improved when the communication overhead can be minimized.

Abstract

A key feature of wireless communications is the spatial reuse of wireless resources. However, such a spatial aspect is relatively less understood for the purpose of designing efficient spectrum sharing mechanisms. In this chapter, we propose a framework of spatial spectrum access games, where we model fairly general spatial interference relationships among users as directed interference graphs. We show that a pure Nash equilibrium exists for the two classes of games: (1) any spatial spectrum access games on directed acyclic graphs and (2) any games satisfying the congestion property on directed trees and directed forests. We identify the graphical structures under which the spatial spectrum access games have pure Nash equilibria and further show that under mild conditions, the spatial spectrum access games with random backoff and Aloha channel contention mechanisms on undirected graphs are potential games and have pure Nash equilibria as well. We also quantify the price of anarchy of the general spatial spectrum access game. We then propose a distributed learning algorithm, which only utilizes users' local observations to adaptively adjust the spectrum access strategies. We show that the distributed learning algorithm can converge to an approximate mixed strategy Nash equilibrium for any spatial spectrum access games. We further generalize the spatial spectrum access game framework to accommodate the physical interference model. Numerical results demonstrate that the distributed learning algorithm achieves significant performance improvement over the benchmark algorithms.

Introduction

Cognitive radio is envisioned as a promising technology to alleviate the problem of spectrum underutilization [2]. It enables unlicensed wireless users (secondary users) to opportunistically access the licensed channels owned by legacy spectrum holders (primary users) and, hence, can significantly improve the spectrum efficiency [2].

A key challenge of the cognitive radio technology is how to resolve the resource competition by selfish secondary users in a decentralized fashion. If multiple secondary users transmit over the same channel simultaneously, severe interferences or collisions might occur, and the individual as well as total data rates of all users may get reduced. This highlights the importance of designing efficient spectrum sharing mechanisms for cognitive radio networks.

The competitions among secondary users for common spectrum have often been studied as a noncooperative game (e.g., [3–7] and the references therein). A common assumption of many existing studies is that secondary users are close-by and interfere with each other when they transmit on the same channel simultaneously. However, a unique feature of wireless communication is spatial reuse. If users who transmit simultaneously are located sufficiently far away, then simultaneous transmissions over the same channel may not cause any performance degradation to the users. Such spatial effect on spectrum sharing is less understood than many other aspects in the existing literature [8].

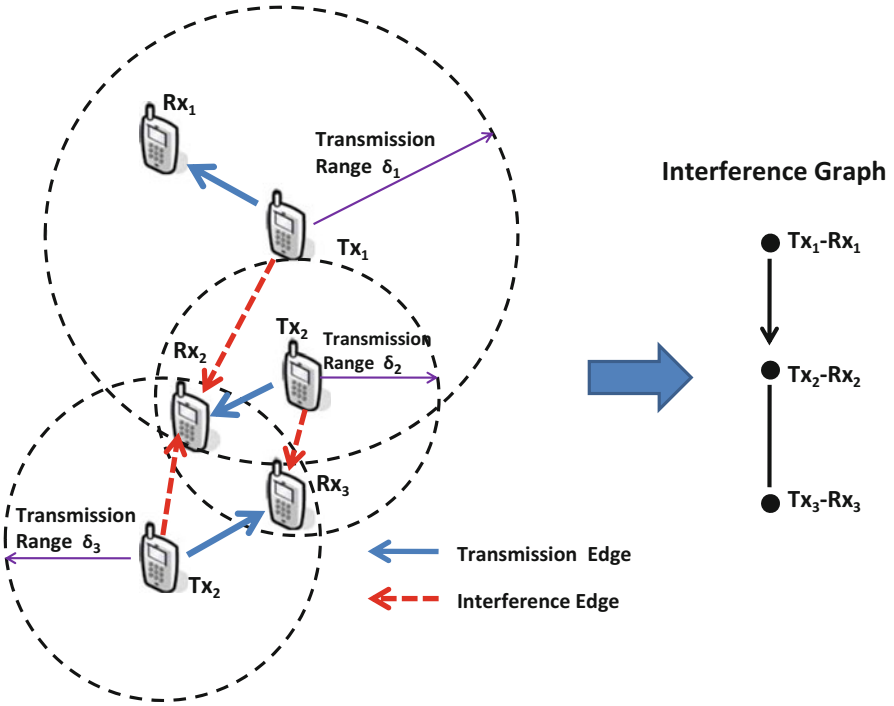

Fig. 1 Illustration of distributed spectrum access with spatial reuse under the protocol interference model. Each user n is represented by a transmitter Tx_n and receiver Rx_n pair. Users 2 and 3 cannot generate interference to user 1, since user 1's receiver Rx_1 is far from user 2 and 3's transmitters. On the other hand, user 1 can generate interference to user 2, since user 2's receiver Rx_2 is within the transmission range of user 1's transmitter Tx_1. Similarly, user 2 and user 3 can generate interferences to each other

Motivated by this, in this chapter, we describe a novel spatial spectrum access game framework to take spatial relationship into account. As illustrated in Fig. 1, the interference relationship among the secondary users can be asymmetric due to the heterogeneous transmission powers and locations of the users. We hence propose a general framework of spatial spectrum access game where secondary users interact over the directed interference graphs, which allows us to model users' heterogeneous resource competition capabilities and asymmetric interference relationship. Moreover, we design a practical distributed algorithm for achieving the equilibria of the spatial spectrum access game. The main results and contributions of this chapter are as follows:

- *General game formulation*: We formulate the distributed spectrum access problem as a spatial spectrum access game on directed interference graphs, with user-specific channel data rates and channel contention capabilities.

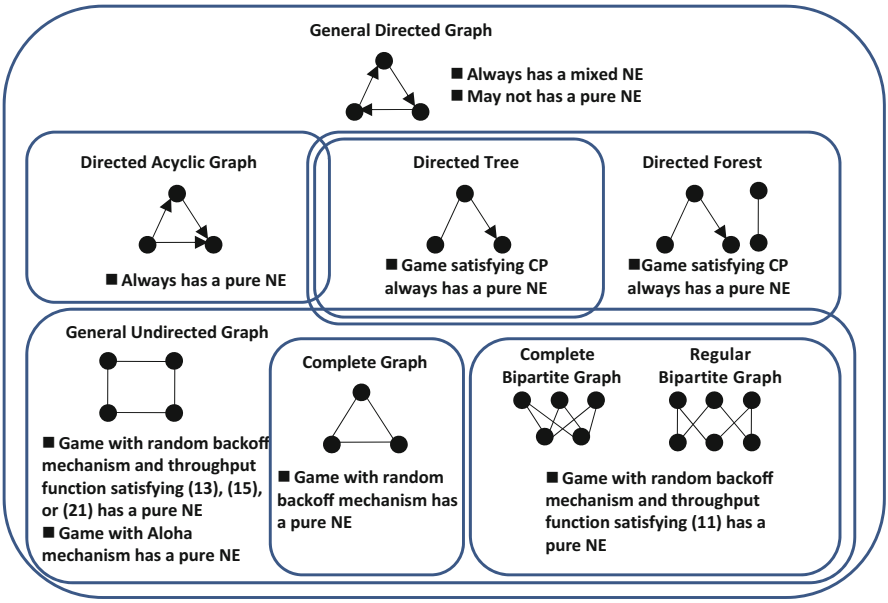

Fig. 2 Summary of the results on the existence of both mixed and pure Nash equilibrium (NE) of spatial spectrum access games. Here CP means congestion property (see section "Existence of Nash Equilibria")

- *Existence of Nash equilibria*: As summarized in Fig. 2, we systematically investigate the existence of Nash equilibrium. Specifically, we show by counter examples that a general spatial spectrum access game may not have a pure Nash equilibrium. We also show that a pure strategy equilibrium exists in the following two classes of games: (1) any spatial spectrum access games on directed acyclic graphs and (2) any games satisfying the congestion property on directed trees and directed forests. We identify the graphical structures under which the spatial spectrum access games have pure Nash equilibria and further show that under mild conditions, the spatial spectrum access games with random backoff and Aloha channel contention mechanisms on undirected graphs are potential games and have pure Nash equilibria as well. We also quantify the price of anarchy of the spatial spectrum access game.
- *Distributed learning for achieving an approximate Nash equilibrium*: We develop a maximum likelihood estimation approach for estimating user expected throughput based on local observations. Based on such local estimations, we then propose a distributed learning algorithm that can converge to an approximate mixed Nash equilibrium for any spatial spectrum access games. Numerical results demonstrate that the distributed learning algorithm achieves significant performance improvement over the random access algorithm.

The rest of the chapter is organized as follows. We first introduce the related work in section "Related Research" and present the system model in section "System

Model". We then present the spatial spectrum access game framework in section "Spatial Spectrum Access Game" and explore the existence of Nash equilibrium in section "Existence of Nash Equilibria". We analyze the price of anarchy and propose the distributed reinforcement learning algorithm in sections "Price of Anarchy and Distributed Learning for Spatial Spectrum Access Game", respectively. We discuss the extension of the spatial spectrum access game in section "Extension to Physical Interference Model", present the numerical results in section "Numerical Results", and finally conclude the chapter in section "Conclusion".

Related Research

A common modeling approach for distributed spectrum access is to consider selfish secondary users and model their interactions as noncooperative games. There is a vast literature along this line, and here we will briefly outline some representative ones. Nie et al. in [9] designed a self-enforcing distributed spectrum access mechanism based on potential games. Niyato and Hossain in [3] proposed a dynamic game approach for analyzing the competition among secondary users for spectrum access. Flegyhzi et al. in [4] proposed a two-tier game framework for cognitive radio medium access control (MAC) mechanism design. Yang et al. in [5] studied a price-based spectrum access mechanism for competitive secondary users. Li et al. in [6] proposed a game theoretic framework to achieve incentive compatible multiband sharing among the secondary users. Law et al. in [7] studied the system performance degradation due to the competition of secondary users in distributed spectrum access game.

When not knowing the spectrum information such as channel availability, secondary users need to learn the network environment and adapt the spectrum access decisions accordingly. Han et al. in [10] and Maskery et al. in [11] used no-regret learning to solve this problem, assuming that the users' channel selections are common information. The learning converges to a correlated equilibrium [12], wherein the common observed history serves as a signal to coordinate all users' channel selections. When users' channel selections are not observable, authors in [13–15] designed a multi-agent multiarmed bandit learning algorithm to minimize the expected performance loss of distributed spectrum access. Li [16] applied reinforcement learning to analyze Aloha-type spectrum access by relying on each individual secondary user's local adaption and experience.

As mentioned above, a commonly adopted assumption of many existing studies is that secondary users are close-by and interfere with each other when they transmit on the same channel simultaneously. Only a few efforts have been made to investigate the spatial reuse feature of distributed spectrum access. In a recent work, Tekin et al. in [17] proposed a novel spatial congestion game framework to take spatial relationship into account. The key idea is to extend the classical congestion game upon an *undirected* graph, by assuming that the interferences among the players are symmetric and a player's throughput depends on the number of players in its neighborhood that choose the same resource. However, as discussed

above the interference relationship among the secondary users can be asymmetric due to the heterogeneous transmission powers and locations of the users. Hence we propose a more general framework of spatial spectrum access game on *directed* interference graphs in this chapter. The congestion game on directed graphs has also been studied in [18], with the assumption that players have linear and homogeneous payoff functions. The game model in this chapter is more general and allows both linear and nonlinear player-specific payoff functions.

System Model

We consider a cognitive radio network with a set $\mathscr{M} = \{1, 2, \ldots, M\}$ of independent and stochastically heterogeneous primary channels. A set $\mathscr{N} = \{1, 2, \ldots, N\}$ of secondary users try to access these channels distributively when the channels are not occupied by primary (licensed) transmissions. Here we assume that each secondary user is a dedicated transmitter-receiver pair.

To take users' spatial relationship into account, we denote $\boldsymbol{d}_n = (d_{Tx_n}, d_{Rx_n})$ as the **location vector** of secondary user n, where d_{Tx_n} and d_{Rx_n} denote the locations of the transmitter and the receiver, respectively. Each secondary user n has a **interference range** ν_n. Then given the location vectors of all secondary users, we can obtain the **interference graph** $G = \{\mathscr{N}, \mathscr{E}\}$ to describe the interference relationship among the users. Here the vertex set $\mathscr{N}$ is the same as the secondary user set. The edge set is defined as $\mathscr{E} = \{(i, j) : ||d_{Tx_i}, d_{Rx_j}|| \leq \nu_i, \forall i, j \neq i \in \mathscr{N}\}$, where $||d_{Tx_i}, d_{Rx_j}||$ is the distance between the transmitter of user i and the receiver of user j. In general, an interference edge can be directed or undirected. If an interference edge is directed from secondary user i to user j, then user j's data transmission will be affected by user i's transmission on the same channel, but user i will not be affected by user j. If the interference edge is undirected (Here the edge is actually bi-directed. We follow the conventions in [17] and ignore the directions on the edge.) between user i and user j, then the two users can affect each other. Note that a generic directed interference graph can consist of a mixture of directed and undirected edges. In the sequel, we call an interference graph undirected, if and only if all the edges of the graph are undirected. We also denote the set of users that can cause interference to user n as $\mathscr{N}_n = \{i : (i, n) \in \mathscr{E}, i \in \mathscr{N}\}$.

Based on the interference model above, we describe the cognitive radio network with a slotted transmission structure as follows:

- *Channel State*: the channel state for a channel m during time slot t is $S_m(t) = 0$ if channel m is occupied by primary transmissions, and $S_m(t) = 1$ otherwise.
- *Channel State Transition*: for a channel m, the channel state $S_m(t)$ is a random variable with a probability density function as ψ_m. In the following, we denote the channel idle probability θ_m as the mean of $S_m(t)$, i.e., $\theta_m = E_{\psi_m}[S_m(t)]$. For example, the state of a channel changes according to a two-state Markovian process. We denote the channel state probability vector of channel m at time t as

$\boldsymbol{q}_m(t) \triangleq (Pr\{S_m(t) = 0\}, Pr\{S_m(t) = 1\})$, which forms a Markov chain as $\boldsymbol{q}_m(t) = \boldsymbol{q}_m(t-1)\Gamma_m, \forall t \geq 1$, with the transition matrix

$$\Gamma_m = \begin{bmatrix} 1-\varepsilon_m & \varepsilon_m \\ \xi_m & 1-\xi_m \end{bmatrix}.$$

Furthermore, the long-run statistical channel availability $\theta_m \in (0, 1)$ of a channel m can be obtained from the stationary distribution of the Markov chain, i.e.,

$$\theta_m = \frac{\varepsilon_m}{\varepsilon_m + \xi_m}. \tag{1}$$

As another example, we can also use the channel idle probability θ_m to indicate the spectrum availability for white-space spectrum access. Due to the fact that the activities of primary users on TV channels typically change very slowly, the most recent FCC ruling requires white-space devices (i.e., secondary users of TV channels) to determine the spectrum availability via a database [19]. In this case, we can set that $\theta_m = 1$ if the TV channel m is vacant for secondary users and $\theta_m = 0$ otherwise.

- *User-Specific Channel Throughput*: for each secondary user n, its realized data rate $b_m^n(t)$ on an idle channel m in each time slot evolves according to a random process with a mean B_m^n, due to users' heterogeneous transmission technologies and the local environmental effects such as fading. For example, we can compute the data rate $b_m^n(t)$ according to the Shannon capacity as

$$b_m^n(t) = W \log_2 \left(1 + \frac{\eta_n z_m^n(t)}{\omega_m^n}\right), \tag{2}$$

where W is the channel bandwidth, η_n is the fixed transmission power adopted by user n according to the requirements such as the primary user protection, ω_m^n denotes the background noise power, and $z_m^n(t)$ is the channel gain. In a Rayleigh fading channel environment, the channel gain $z_m^n(t)$ is a realization of a random variable that follows the exponential distribution.

- *Time Slot Structure*: each secondary user n executes the following stages synchronously during each time slot:
  - *Channel Sensing*: sense one of the channels based on the channel selection decision made at the end of previous time slot.
  - *Channel Contention*: Let a_n be the channel selected by user n and $\boldsymbol{a} = (a_1, \ldots, a_N)$ be the channel selection profile of all users. The probability that user n can grab the chosen idle channel a_n during a time slot is $g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})) \in (0, 1)$, which depends on the subset of user n's interfering users that choose the same channel $\mathcal{N}_n^{a_n}(\boldsymbol{a}) \triangleq \{i \in \mathcal{N}_n : a_i = a_n\}$. Here are two examples:

1. *Random backoff mechanism*: the contention stage of a time slot is divided into $\lambda_{\max}$ mini-slots (The contention window size $\lambda_{\max}$ plays an important role for optimizing the system performance. If $\lambda_{\max}$ is too small, it would increase the collision probability among users and hence negatively affect the system performance. In general, if $\lambda_{\max}$ is too large, it would reduce the spectrum access time and hence reduce the system throughput. To optimize the system performance, we can adopt the approach in [20] to determine the optimal contention window size.). Each contending user n first counts down according to a randomly and uniformly generated integer backoff time counter (number of mini-slots) λ_n between 1 and $\lambda_{\max}$. If there is no active transmissions till the countdown timer expires, the user monitors the channel and transmits RTS/CTS messages on that channel. If multiple users choose the same backoff counter, a collision will occur, and no users can grab the channel successfully. After a user successfully grabs the channel, he starts to transmit its data packet. In this case, we have

$$\begin{aligned} g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})) &= Pr\{\lambda_n < \min_{i \in \mathcal{N}_n : a_i = a_n} \{\lambda_i\}\} \\ &= \sum_{\lambda=1}^{\lambda_{\max}} Pr\{\lambda_n = \lambda\} Pr\{\lambda_n < \min_{i \in \mathcal{N}_n : a_i = a_n} \{\lambda_i\} | \lambda_n = \lambda\} \\ &= \sum_{\lambda=1}^{\lambda_{\max}} \frac{1}{\lambda_{\max}} \left(\frac{\lambda_{\max} - \lambda}{\lambda_{\max}} \right)^{K_n^{a_n}(\boldsymbol{a})}, \end{aligned} \tag{3}$$

   where $K_n^{a_n}(\boldsymbol{a}) = |\mathcal{N}_n^{a_n}(\boldsymbol{a})| = \sum_{i \in \mathcal{N}_n} I_{\{a_i = a_n\}}$ denotes the number of user n's interfering users choosing the same channel as user n.
2. *Aloha mechanism*: user n contends for an idle channel with a probability $p_n \in (0, 1)$ in a time slot. If multiple interfering users contend for the same channel, a collision occurs, and no user can grab the channel for data transmission. In this case, we have

$$g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})) = p_n \prod_{i \in \mathcal{N}_n^{a_n}(\boldsymbol{a})} (1 - p_i). \tag{4}$$

– *Data Transmission*: transmit data packets if the user successfully grabs the channel.
– *Channel Selection*: choose a channel to access during next time slot according to the distributed learning algorithm in section "Distributed Learning for Spatial Spectrum Access Game".

Under a fixed channel selection profile $\boldsymbol{a}$, the long-run average throughput of a secondary user n choosing channel a_n can be computed as

$$U_n(\boldsymbol{a}) = \theta_{a_n} B_{a_n}^n g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})). \tag{5}$$

Note that in practices, due to hardware constraint, each secondary user typically cannot observe the channel states of all the channels in each time slot. In this case, one possible modeling approach is to formulate the distributed spectrum access problem as a partial-observation dynamic game, such that the game state is defined as the channel states $\{S_m(t)\}_{m=1}^M$ in the current time slot and each secondary user has a partial observation of the game state in each time slot. However, it is well known that such a partial-observation dynamic game is very difficult to analyze and is computationally intractable due to the curse of dimensionality. To enable tractable analysis and achieve an efficient spectrum access, we hence study the distributed spectrum access problem from the long-run average perspective and utilize the statistical channel availability information (i.e., channel idle probability θ_m) to aid secondary users' decision-makings. This is due to the fact that the statistical channel availability information can be learned from the history of a secondary user's local observations, via the maximum likelihood estimation approach described in section "Distributed Learning for Spatial Spectrum Access Game". Moreover, the spatial spectrum access game solution in this chapter can help us solve the complete information dynamic game, where each secondary user is able to globally observe the channel state realization $\{S_m(t)\}_{m=1}^M$ of all the channels in each time slot. Since the secondary users cannot control the transition of channel states, we can easily derive the solution of the complete information dynamic game as follows: for each time slot t, we solve the corresponding stage spatial spectrum access game using the algorithm proposed in this chapter, with the channel idle probabilities $\{\theta_m\}_{m=1}^M$ of the stage game replaced by the channel state realization $\{S_m(t)\}_{m=1}^M$ of time slot t. Since our analysis is from the secondary users' perspective, we will use the terms "secondary user" and "user" interchangeably.

Spatial Spectrum Access Game

We now consider the problem that each user tries to maximize its own throughput by choosing a proper channel in a distributed fashion. Let $a_{-n} = \{a_1, \ldots, a_{n-1}, a_{n+1}, \ldots, a_N\}$ be the channels chosen by all users except user n. Given other users' channel selections a_{-n}, the problem faced by a user n is

$$\max_{a_n \in \mathscr{M}} U(a_n, a_{-n}), \forall n \in \mathscr{N}. \tag{6}$$

We thus formulate the distributed channel selection problem on an interference graph G as a **spatial spectrum access game** $\Gamma = (\mathscr{N}, \mathscr{M}, G, \{U_n\}_{n \in \mathscr{N}})$, where $\mathscr{N}$ is the set of players, $\mathscr{M}$ is the set of strategies, G describes the interference relationship among the players, and U_n is the payoff function of player n.

The distributed nature of the channel selection problem naturally leads to a formulation based on the game theory, such that users can self-organize into a mutually acceptable channel selection, which is defined as follows.

Definition 1 (Pure Nash Equilibrium [21]). A strategy profile $\boldsymbol{a}^* = (a_1^*, a_2^*, \ldots, a_N^*)$ is a pure Nash equilibrium if and only if

$$a_n^* = \arg\max_{a_n \in \mathscr{M}} U(a_n, a_{-n}^*), \forall n \in \mathscr{N}. \tag{7}$$

It is known that not every finite strategic game possesses a pure Nash equilibrium [21]. We then introduce the more general concept of mixed Nash equilibrium. Let $\boldsymbol{\sigma}_n \triangleq (\sigma_1^n, \ldots, \sigma_M^n)$ denote the mixed strategy of user n, where $0 \leq \sigma_m^n \leq 1$ is the probability of user n choosing channel m and $\sum_{m=1}^{M} \sigma_m^n = 1$. For simplicity, we use the same payoff notation $U_n(\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_N)$ to denote the expected throughput of user n under the mixed strategy profile $(\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_N)$, and it can be computed as

$$U_n(\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_N) = \sum_{a_1=1}^{M} \sigma_{a_1}^1 \ldots \sum_{a_N=1}^{M} \sigma_{a_N}^N U_n(a_1, \ldots, a_N). \tag{8}$$

Similarly to the pure Nash equilibrium, the mixed Nash equilibrium is defined as:

Definition 2 (Mixed Nash Equilibrium [21]). The mixed strategy profile $\boldsymbol{\sigma}^* = (\boldsymbol{\sigma}_1^*, \ldots, \boldsymbol{\sigma}_N^*)$ is a mixed Nash equilibrium, if for every user $n \in \mathscr{N}$, we have

$$U_n(\boldsymbol{\sigma}_n^*, \boldsymbol{\sigma}_{-n}^*) \geq U_n(\boldsymbol{\sigma}_n, \boldsymbol{\sigma}_{-n}^*), \forall \boldsymbol{\sigma}_n \neq \boldsymbol{\sigma}_n^*,$$

where $\boldsymbol{\sigma}_{-n}^*$ denotes the mixed strategy choices of all other users except user n.

In the spatial spectrum access game, each secondary user takes both the primary activity levels on different channels and the competition with other secondary users into consideration, in order to improve its long-run average throughput. Nash equilibrium is the natural solution concept for the spatial spectrum access game. At a Nash equilibrium, secondary users are mutually satisfied with their long-run average throughputs, and no user can improve by changing its channel unilaterally. One important property of the mixed Nash equilibrium is that if a user assigns positive probabilities of some actions, then the expected payoff of these actions should be the same at the equilibrium. Otherwise, the user can improve by increasing the probability of the action with a higher expected payoff.

In the following sections, we will study the existence of both mixed and pure Nash equilibria based on the global network information and then discuss how to achieve the Nash equilibria based on the local user observations only.

Existence of Nash Equilibria

In this part, we study the existence of Nash equilibria in a spatial spectrum access game. Since a spatial spectrum access game is a finite strategic game (i.e., with a finite number of players and a finite number of channels), we know that it always admits a mixed Nash equilibrium according to [21].

On the other hand, not every finite strategic game possesses a pure Nash equilibrium [21]. Compared with the mixed Nash equilibrium, a pure Nash equilibrium can achieve the mutually satisfactory spectrum sharing solution without requiring the frequent channel switching and hence helps reduce the system overhead such as energy consumption of frequent channel switching. This motivates us to further investigate the existence of pure Nash equilibria of the spatial spectrum access games.

Existence of Pure Nash Equilibria on Directed Interference Graphs

We first study the existence of pure Nash equilibria on directed interference graphs. First of all, we can construct a game which does not have a pure Nash equilibrium.

Theorem 1. *There exists a spatial spectrum access game on a directed interference graph not admitting any pure Nash equilibrium.*

Figure 3 shows such an example. It is easy to verify that for all eight possible channel selection profiles, there always exists one user (out of these three users) having an incentive to change its channel selection unilaterally to improve its throughput.

We then focus on identifying the conditions under which the game admits a pure Nash equilibrium. To proceed, we first introduce the following lemma (the proof is given in the appendix at the end of the chapter).

Lemma 1. *Assume that any spatial spectrum access game with N users on a given directed interference graph G has a pure Nash equilibrium. Then we can construct a new spatial spectrum access game by adding a new player, who cannot generate interference to any player in the original game and may receive interference from one or multiple players in the original game. The new game with $N + 1$ users also has a pure Nash equilibrium.*

We know that any directed acyclic graph (i.e., a directed graph contains no directed cycles) can be given a topological sort (i.e., an ordering of the nodes), such that if node $i < j$, then there are no edges directed from the node j to node i in the ordering [22]. This is due to that any spatial spectrum access game with $N = 1$

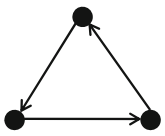

Fig. 3 An example of spatial spectrum access game without a pure Nash equilibrium. There are two channels available and the throughput of a user n is $U_n(\boldsymbol{a}) = p\prod_{i\in\mathcal{N}_n^{a_n}(\boldsymbol{a})}(1-p)$. If all three players (nodes) choose channel 1, then each player has the incentive of unilaterally changing its choice to channel 2 to improve its throughput, assuming that the other two players do not change their channel choices. We can show that such derivation will happen for all eight possible strategy profiles $\boldsymbol{a} = (a_1, a_2, a_3)$, where $a_i \in \{1, 2\}$ for $i \in \{1, 2, 3\}$

user always has a pure Nash equilibrium. By the induction argument, we know from Lemma 1 that

Corollary 1. *Any spatial spectrum access game on a directed acyclic graph has a pure Nash equilibrium.*

To obtain more insightful results, we next impose the following property on the spatial spectrum access games:

Definition 3 (Congestion Property – CP). User n's channel grabbing probability $g_n\left(\mathcal{N}_n^{a_n}(\boldsymbol{a})\right)$ satisfies the congestion property if for any $\tilde{\mathcal{N}}_n^{a_n}(\boldsymbol{a}) \subseteq \mathcal{N}_n^{a_n}(\boldsymbol{a})$, we have

$$g_n(\tilde{\mathcal{N}}_n^{a_n}(\boldsymbol{a})) \geq g_n\left(\mathcal{N}_n^{a_n}(\boldsymbol{a})\right). \tag{9}$$

Furthermore, a spatial spectrum access game satisfies the congestion property if (9) holds for all users $n \in \mathcal{N}$.

The congestion property (CP) means that the more contending users exist, the less chance a user can grab the channel. Such a property is natural for practical wireless systems such as the random backoff and Aloha systems. We can show that the following result (the proof is given in the appendix in the separate supplemental file).

Lemma 2. *Assume that any spatial spectrum access game with N users satisfying the congestion property on a given directed interference graph G has a pure Nash equilibrium. Then we can construct a new spatial spectrum access game by adding a new player, whose channel grabbing probability satisfies the congestion property and who has an interference relationship with at most one player $n \in \mathcal{N}$ in the original game. The new game with $N+1$ users also has a pure Nash equilibrium.*

Definition 4 (Directed Tree [22]). A directed graph is called a directed tree if the corresponding undirected graph obtained by ignoring the edge directions is a tree.

Note that a (undirected) tree is a special case of directed trees. Since any spatial spectrum access game over a single node always has a pure Nash equilibrium, we can then construct the directed tree recursively by introducing a new node and adding an (directed or undirected) edge between this node and one existing node. By using Lemma 2 and the induction argument, we have

Corollary 2. *Any spatial spectrum access game satisfying the congestion property on a directed tree has a pure Nash equilibrium.*

Definition 5 (Directed Forest [22]). A directed graph is called a directed forest if it consists of a disjoint union of directed trees.

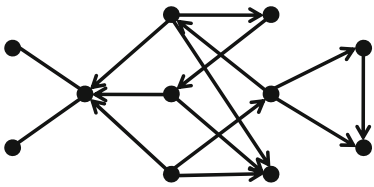

Fig. 4 An interference graph that consists of directed acyclic graphs and directed trees

Similarly, we can obtain from Lemma 2 that

Corollary 3. *Any spatial spectrum access game satisfying the congestion property on a directed forest has a pure Nash equilibrium.*

Note that the directed acyclic graph and directed tree structures are widely observed in many wireless networking systems such as wireless ad hoc and sensor networks [23]. For example, the star topology with sink/hub nodes in wireless sensor networks is a special case of directed tree. Based on Lemmas 1 and 2, we can construct more general directed interference graphs over which a spatial spectrum access game satisfying the congestion property has a pure Nash equilibrium. Figure 4 illustrates such an example.

Existence of Pure Nash Equilibria on Undirected Interference Graphs

We now study the case where the interference graph is undirected. This is a good approximation of reality if the transmitter of each user is close to its receiver and all users' interference ranges are roughly the same. For example, in 802.11 systems, undirected interference graph is widely used to approximate the interference relationships, since the access points are typically close to their associated clients and the carrier sensing ranges are similar.

When an undirected interference graph is a tree, according to Corollary 2, any spatial spectrum access game satisfying the congestion property has a pure Nash equilibrium. However, for those non-tree undirected graphs without a topological sort, the existence of a pure Nash equilibrium cannot be proved following the results in section "Existence of Pure Nash Equilibria on Directed Interference Graphs". This motivates us to further study the existence of pure Nash equilibria on generic undirected interference graphs.

First of all, [24] showed that a 3-players and 3-resources congestion game with user-specific congestion weights may not have a pure Nash equilibrium. Such a congestion game can be considered as a spatial spectrum access game on a complete undirected interference graph (by regarding the resources as channels). When all users have homogeneous channel contention capabilities and all channels have the same mean data rates, [17] showed that the spatial spectrum access game on any undirected interference graphs has a pure Nash equilibrium. Clearly, the applicability of such a channel-homogeneous model is quite limited, since the channel throughputs in practical wireless networks are often heterogeneous. Hence

we will focus on exploring the random backoff and Aloha systems with user-specific data rates, which provide useful insights for the user-homogeneous and user-heterogeneous channel contention mechanisms, respectively.

Our following analysis will rely on the properties of potential game (Note that it is much more difficult to find a proper potential function to take into account users' asymmetric relationships (i.e., directions of edges on graph) when the interference graph is directed. Hence in this study, we only apply the tool of potential game in the undirected case.), defined as follows:

Definition 6 (Potential Game [25]). A game is called a potential game if it admits a potential function $\Phi(\boldsymbol{a})$ such that for every $n \in \mathcal{N}$ and $a_{-n} \in \mathcal{M}^{N-1}$,

$$\operatorname{sgn}\left(\Phi(a_n^{'}, a_{-n}) - \Phi(a_n, a_{-n})\right) = \operatorname{sgn}\left(U_n(a_n^{'}, a_{-n}) - U_n(a_n, a_{-n})\right),$$

where $\operatorname{sgn}(\cdot)$ is the sign function.

Definition 7 (Better Response Update [25]). The event where a player n changes to an action $a_n^{'}$ from the action a_n is a better response update if and only if $U_n(a_n^{'}, a_{-n}) > U_n(a_n, a_{-n})$.

An appealing property of the potential game is that it always admits a pure Nash equilibrium. Furthermore, it enjoys the finite improvement property, which is defined as

Definition 8 (Finite Improvement Property [25]). A game has the finite improvement property if any asynchronous better response update process (i.e., no more than one player updates the strategy at any given time) terminates at a pure Nash equilibrium within a finite number of updates.

Based on the potential game theory, we first study the random backoff mechanism. We show in Theorem 2 that when the undirected interference graph is complete, there exists indeed a pure Nash equilibrium.

Theorem 2. *Any spatial spectrum access game on a complete undirected interference graph with the random backoff mechanism is a potential game with the potential function*

$$\Phi(\boldsymbol{a}) = \prod_{n=1}^{N} \theta_{a_n} B_{a_n}^{n} \prod_{m=1}^{M} \prod_{c=0}^{K_m(\boldsymbol{a})} \sum_{\lambda=1}^{\lambda_{\max}} \frac{1}{\lambda_{\max}} \left(\frac{\lambda_{\max} - \lambda}{\lambda_{\max}}\right)^{c}, \tag{10}$$

where $K_m(\boldsymbol{a})$ is the number of users choosing channel m under the strategy profile $\boldsymbol{a}$ and hence has a pure Nash equilibrium.

The proof is similar to that in [26] and hence is omitted here. We then consider the spatial spectrum access game with the random backoff mechanism on bipartite graphs.

Definition 9 (Bipartite Graph [22]). An undirected graph is called a bipartite graph if the set of its nodes can be decomposed into two disjoint sets, such that no two nodes within the same set are connected by an edge.

Definition 10 (Complete Bipartite Graph [22]). An undirected graph is called a complete bipartite graph if it is a bipartite graph and any two nodes selected from the two disjoint sets, respectively, are connected by an edge.

Definition 11 (Regular Bipartite Graph [22]). An undirected graph is called a regular bipartite graph if it is a bipartite graph and each node is connected by the same number of edges.

Note that a complete bipartite graph that has the same number of vertices in the two disjoint sets is also a regular bipartite graph. Many well-known graphs such as star graphs, circulant graphs, cycle graphs with even number of vertexes, hypercubes, and rectangular lattices are either complete bipartite graphs or regular bipartite graphs. We consider the user-specific throughput as

$$U_n(a_n, a_{-n}) = h_n \theta_{a_n} B_{a_n} g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})), \tag{11}$$

where h_n represents a user-specific transmission gain. We can show that

Theorem 3. *Any spatial spectrum access game on either a complete bipartite interference graph or a regular bipartite interference graph with user-specific transmission gains and the random backoff mechanism has a pure Nash equilibrium.*

The proof is given in the appendix in the separate supplemental file. We then consider the random backoff mechanism in the asymptotic case that $\lambda_{\max}$ goes to infinity. This can be a good approximation of reality when the number of backoff mini-slots is much greater than the number of interfering users and collision rarely occurs. In this case, we have

$$\begin{aligned} g_n(\mathcal{N}_n^{a_n}(\boldsymbol{a})) &= \lim_{\lambda_{\max}\to\infty} \sum_{\lambda=1}^{\lambda_{\max}} \frac{1}{\lambda_{\max}} \left(\frac{\lambda_{\max}-\lambda}{\lambda_{\max}}\right)^{K_n^{a_n}(\boldsymbol{a})} \\ &= \int_0^1 x^{K_n^{a_n}(\boldsymbol{a})} dx = \frac{1}{1+K_n^{a_n}(\boldsymbol{a})}, \end{aligned} \tag{12}$$

here $K_n^{a_n}(\boldsymbol{a})$ denotes the number of users that choose channel a_n and can interfere with user n. Equation (12) implies that the channel opportunity is equally shared among $1 + K_n^{a_n}(\boldsymbol{a})$ contending users (including user n). This can also apply in TDMA channel access mechanism. We consider the user-specific throughput as

$$U_n(a_n, a_{-n}) = h_n \theta_{a_n} B_{a_n} \frac{1}{1+K_n^{a_n}(\boldsymbol{a})}, \tag{13}$$

We show that

Theorem 4. *Any spatial spectrum access game on any undirected interference graph with user-specific transmission gains and the random backoff mechanism in the asymptotic case is a potential game with the potential function*

$$\Phi(\boldsymbol{a}) = -\sum_{n=1}^{N}\left(\frac{1+\frac{1}{2}K_n^{a_n}(\boldsymbol{a})}{\theta_{a_n}B_{a_n}}\right), \tag{14}$$

and hence has a pure Nash equilibrium.

Theorem 4 is a direct consequence of the more general result Theorem 5. More specifically, we generalize the throughput function in (13) as

$$U_n(a_n, a_{-n}) = h_n\theta_{a_n}B_{a_n}\frac{w_n}{w_n + \sum_{i\in\mathcal{N}_n^{a_n}(\boldsymbol{a})} w_i}, \tag{15}$$

where $w_n > 0$ denotes user-specific channel sharing weight. When $w_n = 1$, the throughput function in (15) degenerates to the equal-sharing case in (13). The physical meaning of (15) is that the channel is shared among the contending users according to their weights. We refer this to the spatial spectrum access game with user-specific sharing weights. Such a proportional channel sharing scheme has been widely used to model the heterogeneous channel access priority assignment for heterogeneous users of different QoS requirements in wireless networks [27]. We show that

Theorem 5. *Any spatial spectrum access game with user-specific sharing weights on any undirected interference graph is a potential game with the potential function as*

$$\Phi(\boldsymbol{a}) = -\sum_{n=1}^{N}\left(\frac{w_n^2 + \frac{1}{2}\sum_{i\in\mathcal{N}_n^{a_n}(\boldsymbol{a})} w_n w_i}{\theta_{a_n}B_{a_n}}\right), \tag{16}$$

and hence has a pure Nash equilibrium.

The proof is given in the appendix in the separate supplemental file. We then consider the random access mechanism under the scenario where all channels are homogeneous to each user (i.e., $\theta_m = \theta$ and $B_m = B$ for all $m \in \mathcal{M}$). This models the case where a licensed spectrum band of a large bandwidth (e.g., TV channel) is divided into equal width logical channels for secondary usage with interleaving technology at the physical layer (e.g., the IEEE 802.16d/e standard), such that all channels exhibit the same primary occupancy and have the same channel gain to the same user (but still different channel gains for different users). In this case, the user throughput function is given as

$$U_n(\boldsymbol{a}) = h_n\theta B g(\mathcal{N}_n^{a_n}(\boldsymbol{a})). \tag{17}$$

We can show that the following result (the proof is given in the appendix in the separate supplemental file).

Theorem 6. *Any spatial spectrum access game on any undirected interference graph with homogeneous channels, user-specific transmission gains, and the random backoff mechanism is a potential game with the potential function*

$$\Phi(\boldsymbol{a}) = \sum_{n=1}^{N} \left(\frac{1 + K_n^{a_n}(\boldsymbol{a})}{\theta B} \right)$$

and hence has a pure Nash equilibrium.

We now consider the Aloha mechanism. According to (4), we have the user throughput function as

$$U_n(\boldsymbol{a}) = \theta_{a_n} B_{a_n}^n p_n \prod_{i \in \mathcal{N}_n^{a_n}(\boldsymbol{a})} (1 - p_i). \tag{18}$$

We can show that the following result (the proof is given in the appendix in the separate supplemental file).

Theorem 7. *Any spatial spectrum access game on any undirected interference graph with the Aloha mechanism is a potential game with the potential function*

$$\Phi(\boldsymbol{a}) = \sum_{i=1}^{N} -\log(1 - p_i) \times \left(\frac{1}{2} \sum_{j \in \mathcal{N}_i^{a_i}(\boldsymbol{a})} \log(1 - p_j) + \log\left(\theta_{a_i} B_{a_i}^i p_i\right) \right)$$

and hence has a pure Nash equilibrium.

As a summary, we depict the results on the existence of pure Nash equilibria of spatial spectrum access games in Fig. 2.

Price of Anarchy

In previous sections, we have considered the existence of Nash equilibrium of spatial spectrum access games. We will further explore the efficiency of the Nash equilibrium.

Following the definition of price of anarchy (PoA) in game theory [28], we will quantify the efficiency ratio of the worst-case Nash equilibrium over the centralized optimal solution. Let $\mathcal{Z}$ be the set of Nash equilibria of a given spatial spectrum access game. Then the PoA is defined as

$$\text{PoA} = \frac{\min_{\boldsymbol{a} \in \mathcal{Z}} \sum_{n \in \mathcal{N}} U_n(\boldsymbol{a})}{\max_{\boldsymbol{a} \in \mathcal{M}^N} \sum_{n \in \mathcal{N}} U_n(\boldsymbol{a})},$$

which is always not greater than 1. A larger PoA implies that the set of Nash equilibrium is more efficient (in the worst-case sense) using the centralized optimum as a benchmark. Let $V_n = \max_{m \in \mathcal{M}} \{\theta_m B_m^n\}$. For a general spatial spectrum access game, we have the following result.

Theorem 8. *The PoA of a spatial spectrum access game* $\Gamma = (\mathcal{N}, \mathcal{M}, G, \{U_n\}_{n \in \mathcal{N}})$ *is at least* $\frac{\min_{n \in \mathcal{N}} \{V_n g_n(\mathcal{N}_n)\}}{\max_{n \in \mathcal{N}} V_n}$.

The proof is given in the appendix in the separate supplemental file. Intuitively, Theorem 8 indicates that we can increase the efficiency of spectrum sharing by better utilizing the gain of spatial reuse (i.e., reducing the interference edges $\mathcal{N}_n$ on the interference graph).

Distributed Learning for Spatial Spectrum Access Game

As mentioned in section "Spatial Spectrum Access Game", both pure and mixed Nash equilibria are important equilibrium concepts for spatial spectrum access games, characterizing system states where secondary users achieve a mutually satisfactory spectrum sharing solution. We hence consider how to achieve the Nash equilibrium for the spatial spectrum access games in this section.

As shown in section "Existence of Nash Equilibria", a generic spatial spectrum access game does not necessarily have a pure Nash equilibrium, and thus it is impossible to design a mechanism that is guaranteed to reach a pure Nash equilibrium in general. However, when the spatial spectrum access game is a potential game, a pure Nash equilibrium exists. In this case, we can apply the Safe Experimentation algorithm in [29] for achieving the pure Nash equilibrium. The key idea is to explore the pure strategy space based on the finite improvement property of the potential game. From the practical application's perspective, we can apply the results obtained in section "Existence of Nash Equilibria" to identify whether the spectrum sharing system satisfies the potential game property. We can then apply the Safe Experimentation algorithm to achieve the pure Nash equilibrium when the system possesses the potential game property.

Since any spatial spectrum access game always admits a mixed Nash equilibrium, we next target on approaching the mixed Nash equilibria. From a practical point of view, if the spectrum sharing system is complex and it is difficult to verify the existence of pure Nash equilibrium, we can consider to achieve a mutually satisfactory spectrum sharing solution by allowing users to choose mixed strategies. Govindan and Wilson in [30] proposed a global Newton method to compute the mixed Nash equilibria for any finite strategic games. This method hence can be applied to find the mixed Nash equilibria for the spatial spectrum access games. However, such an approach is a centralized optimization, which requires each user to have the complete information of other users and compute the solution accordingly. This is often infeasible in a cognitive radio network, since acquiring complete information requires heavy information exchange among the users and setting up

and maintaining a common control channel for message broadcasting demands high system overheads [2]. Moreover, this approach is not incentive compatible since some users may not be willing to share their local information due to the energy consumption of information broadcasting. We thus propose a distributed learning algorithm for any spatial spectrum access games, and the algorithm does not require any information exchange among users. Each user only learns to adjust its channel selection strategy adaptively based on its local throughput observations. We show that the distributed learning algorithm can converge to a mixed Nash equilibrium approximately.

Expected Throughput Estimation

For the distributed learning algorithm, we assume that each user does not have the complete network information and can only estimate its expected throughput locally. Similarly to the approaches in [31] and [32], we can divide the spectrum access time into a sequence of *decision periods* indexed by $T(=1,2,\ldots)$, where each decision period consists of $t_{\max}$ time slots. During a single decision period, a user accesses the *same* channel in all $t_{\max}$ time slots in order to better understand the environment. At the end of each decision period T, a user observes $S_n(T,t)$, $I_n(T,t)$ and $b_n(T,t)$. Here $S_n(T,t)$ denotes the state of the chosen channel (i.e., whether occupied by the primary traffic), $I_n(T,t)$ indicates whether the user has successfully grabbed the channel, i.e.,

$$I_n(T,t) = \begin{cases} 1, & \text{if user } n \text{ successfully grabs the channel,} \\ 0, & \text{otherwise,} \end{cases}$$

and $b_n(T,t)$ is the received data rate on the chosen channel by user n at time slot t. Note that if $S_n(T,t) = 0$ (i.e., the channel is occupied by the primary traffic), we set $I_n(T,t)$ and $b_n(T,t)$ to be 0. At the end of each decision period T, each user n will have a set of local observations $\Omega_n(T) = \{S_n(T,t), I_n(T,t), b_n(T,t)\}_{t=1}^{t_{\max}}$. Based on these observations, each user can then apply the Maximum Likelihood Estimation (MLE) method to estimate its expected throughput U_n. As an example, we next consider the MLE of user expected throughput in the Markovian channel environment introduced in section "System Model".

We first consider the estimation of the channel idle probability θ_m. From the observation set $\Omega_n(T)$ at period T, user n can observe a sequence of channel state transitions as

$$\mathscr{S}_n(T) = \left((S_n(T,1), S_n(T,2)), \ldots, (S_n(T,t_{\max}-1), S_n(T,t_{\max}))\right).$$

Here there are four different transition types between adjacent time slots t and t+1: $(0,0)$, $(0,1)$, $(1,0)$, and $(1,1)$. We denote $C_{00}(T)$, $C_{01}(T)$, $C_{10}(T)$, and $C_{11}(T)$ as the number of occurrences of the four state transitions types in $\mathscr{S}_n(T)$, respectively.

According to the principle of MLE, user n can then compute the likelihood function in terms of channel state transition parameters (ε_m, ξ_m) as

$$\begin{aligned}
&\mathscr{L}[\Omega_n(T)|\varepsilon_m, \xi_m] \\
&\quad = Pr\{\mathscr{S}_n(T)|\varepsilon_m, \xi_m\} \\
&\quad = Pr\{S_n(T,1)|\varepsilon_m, \xi_m\} \times \prod_{t=1}^{t_{\max}-1} Pr\{S_n(T,t+1)|S_n(T,t), \varepsilon_m, \xi_m\} \\
&\quad = Pr\{S_n(T,1)|\varepsilon_m, \xi_m\} \times (1-\varepsilon_m)^{C_{00}(T)} \varepsilon_m^{C_{01}(T)} (1-\xi_m)^{C_{11}(T)} \xi_m^{C_{10}(T)}.
\end{aligned}$$

Then MLE of (ε_m, ξ_m) can be computed by maximizing the log-likelihood function $\ln \mathscr{L}[\Omega_n(T)|\varepsilon_m, \xi_m]$, i.e., $\max_{\varepsilon_m, \xi_m} \ln \mathscr{L}[\Omega_n(T)|\varepsilon_m, \xi_m]$. By the first order condition, we obtain the optimal solution as

$$\begin{aligned}
\tilde{\varepsilon}_m &= \frac{C_{01}(T)}{C_{00}(T) + C_{01}(T)}, \\
\tilde{\xi}_m &= \frac{C_{10}(T)}{C_{11}(T) + C_{10}(T)}.
\end{aligned}$$

According to (1), we can then estimate the channel idle probability θ_m as

$$\tilde{\theta}_m = \frac{\tilde{\varepsilon}_m}{\tilde{\varepsilon}_m + \tilde{\xi}_m}.$$

We then consider the estimation of channel grabbing probability $g_n(T)$. When a channel is idle (i.e., no primary traffic), a user n will contend for the channel and can successfully grab the channel with a probability $g_n(T)$. Since there are a total of $\sum_{t=1}^{t_{\max}} S_n(T,t)$ rounds of channel contentions in the period T and each round is independent, the total number of successful channel captures $\sum_{t=1}^{t_{\max}} I_n(T,t)$ by user n follows the Binomial distribution. User n then computes the likelihood of $g_n(T)$ as

$$\begin{aligned}
\mathscr{L}[\Omega_n(T)|g_n(T)] = &\left(\begin{matrix} \sum_{t=1}^{t_{\max}} S_n(T,t) \\ \sum_{t=1}^{t_{\max}} I_n(T,t) \end{matrix} \right) g_m(T)^{\sum_{t=1}^{t_{\max}} I_n(T,t)} \\
&\times (1-g_m(T))^{\sum_{t=1}^{t_{\max}} S_n(T,t) - \sum_{t=1}^{t_{\max}} I_n(T,t)}.
\end{aligned}$$

Then MLE of $g_n(T)$ can be computed by maximizing the log-likelihood function $\ln \mathscr{L}[\Omega_n(T)|g_n(T)]$, i.e., $\max_{g_n(T)} \ln \mathscr{L}[\Omega_n(T)|g_n(T)]$. By the first-order condition, we obtain the optimal solution as

$$\tilde{g}_n(T) = \frac{\sum_{t=1}^{t_{\max}} I_n(T,t)}{\sum_{t=1}^{t_{\max}} S_n(T,t)}.$$

We finally consider the estimation of mean data rate B_m^n. Since the received data rate $b_n(T,t)$ is also i.i.d. over different time slots, similar to the MLE of the channel grabbing probability $g_n(T)$, we can obtain the MLE of mean data rate B_m^n as

$$\tilde{B}_m^n = \frac{\sum_{t=1}^{t_{\max}} b_n(T,t)}{\sum_{t=1}^{t_{\max}} I_n(T,t)}.$$

By the MLE above, we can then estimate the true expected throughput $U_n(T)$ as $\tilde{U}_n(T) = \tilde{\theta}_m \tilde{B}_m^n \tilde{g}_n(T)$. In the following analysis of distributed learning algorithm, we consider a general setting where the estimated expected throughput $\tilde{U}_n(T)$ of user n can be noisy. More precisely, we assume that $\tilde{U}_n(T) = U_n(T) + w_n$ where $w_n \in (\underline{w}, \overline{w})$ is the random estimation noise with a probability density function $f_n(w_n)$ satisfying $E[w_n] = \int_{\underline{w}}^{\overline{w}} w_n f_n(w_n) dw_n = 0$.

Distributed Learning Algorithm

Based on the expected throughput estimation, we then propose the distributed learning algorithm for spatial spectrum access games. The idea is to extend the principle of single-agent reinforcement learning to a multi-agent setting. Such multi-agent reinforcement learning algorithm has also been applied to the classical congestion games on complete interference graphs [33, 34] by assuming that users are homogeneous (i.e., user's payoff only depends on the number of users choosing the same resource). Here we extend the learning algorithm to the generalized spatial congestion games on any generic interference graphs with heterogeneous users, which lead to significant differences in analysis. For example, we show that the convergence condition for the learning algorithm depends on the structure of spatial reuse, which is different from those results in [33, 34].

More specifically, at the beginning of each period T, a user $n \in \mathcal{N}$ chooses a channel $a_n(T) \in \mathcal{M}$ to access according to its mixed strategy $\boldsymbol{\sigma}_n(T) = (\sigma_m^n(T), \forall m \in \mathcal{M})$, where $\sigma_m^n(T)$ is the probability of choosing channel m. The mixed strategy is generated according to $\boldsymbol{P}_n(T) = (P_m^n(T), \forall m \in \mathcal{M})$, which represents its *perceptions* of the payoff performance of choosing different channels based on local estimations. Perceptions are based on local observations in the past and may not accurately reflect the expected payoff. For example, if a user n has not accessed a channel m for many decision intervals, then perception $P_m^n(T)$ can be out of date. The key challenge for the learning algorithm is to update the perceptions with proper parameters such that perceptions equal to expected payoffs at the equilibrium.

Similarly to the single-agent learning, we choose the Boltzmann distribution as the mapping from perceptions to mixed strategies, i.e.,

$$\sigma_m^n(T) = \frac{e^{\gamma P_m^n(T)}}{\sum_{i=1}^{M} e^{\gamma P_i^n(T)}}, \forall m \in \mathcal{M}, \tag{19}$$

Algorithm 1 Distributed learning algorithm for spatial spectrum access game

1: **initialization:**
2: **set** the temperature γ.
3: **set** the initial perception values $P_m^n(0) = \frac{1}{M}$ for each user $n \in \mathcal{N}$.
4: **end initialization**

5: **loop** for each decision period T and each user $n \in \mathcal{N}$ in parallel:
6: **select** a channel $m \in \mathcal{M}$ according to (19).
7: **estimate** the expected throughput $\tilde{U}_n(\boldsymbol{a}(T))$.
8: **update** the perceptions value $\boldsymbol{P}_n(T)$ according to (20).
9: **end loop**

where γ is the temperature that controls the randomness of channel selections. When $\gamma \to 0$, each user will choose to access channels uniformly at random. When $\gamma \to \infty$, user n always chooses the channel with the largest perception value $P_m^n(T)$ among all channel $m \in \mathcal{M}$. We will show later on that the choice of γ trades off convergence and performance of the learning algorithm.

At the end of a decision period T, a user n estimates its expected throughput as $\tilde{U}_n(\boldsymbol{a}(T))$ and adjusts its perceptions as

$$P_m^n(T+1) = \begin{cases} (1-\mu_T)P_m^n(T) + \mu_T \tilde{U}_n(\boldsymbol{a}(T)), & \text{if } a_n(T) = m, \\ P_m^n(T), & \text{otherwise,} \end{cases} \tag{20}$$

where $(\mu_T \in (0,1), \forall T)$ are the smoothing factors. A user only changes the perception of the channel just accessed in the current decision period and keeps the perceptions of other channels unchanged.

Algorithm 1 summarizes the distributed learning algorithm. We then analyze the complexity of the distributed learning algorithm. In each iteration, Line 6 involves the arithmetic operations over M channels and hence has a complexity of $\mathcal{O}(M)$. The expected throughput estimation in Line 7 typically involves the arithmetic operations based on the observations of the chosen channel in $t_{\max}$ time slots of the decision period and hence has a complexity of $\mathcal{O}(t_{\max})$. In Line 8, the perception value update is only carried out in the chosen channel and hence has a complexity of $\mathcal{O}(1)$. Suppose that it takes K iterations for the algorithm to converge. Then total computational complexity of the algorithm is at most $\mathcal{O}(K(M + t_{\max}))$.

Convergence of Distributed Learning Algorithm

We now study the convergence of the proposed distributed learning algorithm based on the theory of stochastic approximation [35].

First, the perception value update in (20) can be written in the following equivalent form,

$$P_m^n(T+1) - P_m^n(T) = \mu_T[Z_m^n(T) - P_m^n(T)], \forall n \in \mathcal{N}, m \in \mathcal{M}, \tag{21}$$

where $Z_m^n(T)$ is the update value defined as

$$Z_m^n(T) = \begin{cases} \tilde{U}_n(\boldsymbol{a}(T)), & \text{if } a_n(T) = m, \\ P_m^n(T), & \text{otherwise.} \end{cases} \tag{22}$$

For the sake of brevity, we denote the perception values, update values, and mixed strategies of all the users as $\boldsymbol{P}(T) \triangleq \left(P_m^n(T), \forall m \in \mathcal{M}, n \in \mathcal{N}\right)$, $\boldsymbol{Z}(T) \triangleq (Z_m^n(T), \forall m \in \mathcal{M}, n \in \mathcal{N})$, and $\boldsymbol{\sigma}(T) \triangleq (\sigma_m^n(T), \forall m \in \mathcal{M}, n \in \mathcal{N})$, respectively.

Let $Pr\{\mathcal{N}_n^m(\boldsymbol{a}(T))|\boldsymbol{P}(T), a_n(T) = m\}$ denote the conditional probability that, given that the users' perceptions are $\boldsymbol{P}(T)$ and user n chooses channel m, the set of users that choose the same channel m in user n's neighborhood $\mathcal{N}_n$ is $\mathcal{N}_n^m(\boldsymbol{a}(T)) \subseteq \mathcal{N}_n$. Since each user independently chooses a channel according to its mixed strategy $\boldsymbol{\sigma}_n(T)$, then the random set $\mathcal{N}_n^m(\boldsymbol{a}(T))$ follows the Binomial distribution of $|\mathcal{N}_n|$ independent nonhomogeneous Bernoulli trials with the probability mass function as

$$\begin{aligned} &Pr\{\mathcal{N}_n^m(\boldsymbol{a}(T))|\boldsymbol{P}(T), a_n(T) = m\} \\ &\quad = \prod_{i \in \mathcal{N}_n^m(\boldsymbol{a}(T))} (\sigma_m^i(T)) \prod_{i \in \mathcal{N}_n \setminus \mathcal{N}_n^m(\boldsymbol{a}(T))} (1 - \sigma_m^i(T)) \\ &\quad = \prod_{i \in \mathcal{N}_n} (\sigma_m^i(T))^{I_{\{a_i(T)=m\}}} (1 - \sigma_m^i(T))^{1 - I_{\{a_i(T)=m\}}}, \end{aligned} \tag{23}$$

where $I_{\{a_i(T)=m\}} = 1$ if user i chooses channel m and $I_{\{a_i(T)=m\}} = 0$ otherwise.

Since the update value $Z_m^n(T)$ depends on user n's estimated throughput $\tilde{U}_n(\boldsymbol{a}(T))$ (which in turn depends on $\mathcal{N}_n^m(\boldsymbol{a}(T))$), thus $Z_m^n(T)$ is also a random variable. The equations in (21) are hence stochastic difference equations, which are difficult to analyze directly. We thus focus on the analysis of its *mean dynamics* [35]. To proceed, we define the mapping from the perceptions $\boldsymbol{P}(T)$ to the expected throughput of user n choosing channel m as $Q_m^n(\boldsymbol{P}(T)) \triangleq E[U_n(\boldsymbol{a}(T))|\boldsymbol{P}(T), a_n(T) = m]$. Here the expectation $E[\cdot]$ is taken with respective to the mixed strategies $\boldsymbol{\sigma}(T)$ of all users (i.e., the perceptions $\boldsymbol{P}(T)$ of all users due to (19)). We show that

Lemma 3. *For the distributed learning algorithm, the mapping from the perceptions to the expected throughput* $Q(\boldsymbol{P}(T)) \triangleq \left(Q_m^n(\boldsymbol{P}(T)), m \in \mathcal{M}, n \in \mathcal{N}\right)$ *forms a maximum-norm contraction if the temperature satisfies*

$$\gamma < \frac{1}{2 \max_{m \in \mathcal{M}, n \in \mathcal{N}} \{\theta_m B_m^n\} \max_{n \in \mathcal{N}} \{|\mathcal{N}_n|\}}, . \tag{24}$$

The proof is given in the appendix in the separate supplemental file. Lemma 3 implies that when the interference among users becomes more severe (i.e., the maximum degree $\max_{n\in\mathcal{N}}\{|\mathcal{N}_n|\}$ of the interference graph becomes larger), a smaller γ is needed to guarantee the convergence. This is because that interference relationship among users becomes more complicated and users should put more weight to explore the environment. Note that the condition (24) is a sufficient condition to form a contraction mapping, which in turn is a sufficient condition for convergence. Simulation results show that a slightly larger γ may also lead to the convergence of the mapping. Based on the property of contraction mapping, there exists a fixed point $\boldsymbol{P}^*$ such that $Q(\boldsymbol{P}^*) = \boldsymbol{P}^*$. By the theory of stochastic approximations [35], the distributed learning algorithm will also converge to the same limit point $\boldsymbol{P}^*$.

Theorem 9. *For the distributed learning algorithm, if the temperature γ satisfies (24), $\sum_T \mu_T = \infty$ and $\sum_T \mu_T^2 < \infty$, then the sequence $\{\boldsymbol{P}(T), \forall T \geq 0\}$ converges to the unique limit point $\boldsymbol{P}^* \triangleq (P_m^{n*}, \forall m \in \mathcal{M}, n \in \mathcal{N})$ satisfying that*

$$Q_m^n(\boldsymbol{P}^*) = P_m^{n*}, \forall m \in \mathcal{M}, n \in \mathcal{N}. \tag{25}$$

We next explore the property of the equilibrium $\boldsymbol{P}^*$ of the distributed learning algorithm. From Theorem 9, we see that

$$Q_m^n(\boldsymbol{P}^*) = E[U_n(\boldsymbol{a}(T))|\boldsymbol{P}^*, a_n(T) = m] = P_m^{n*}. \tag{26}$$

It means that the perception value P_m^{n*} is an accurate estimation of the expected throughput in the equilibrium. Moreover, we show that the mixed strategy $\boldsymbol{\sigma}^*$ is an approximate Nash equilibrium.

Definition 12 (Approximate Nash Equilibrium [36]). A mixed strategy profile $\bar{\boldsymbol{\sigma}} = (\bar{\boldsymbol{\sigma}}_1, \ldots, \bar{\boldsymbol{\sigma}}_N)$ is a δ-approximate Nash equilibrium if

$$U_n(\bar{\boldsymbol{\sigma}}_n, \bar{\boldsymbol{\sigma}}_{-n}) \geq \max_{\boldsymbol{\sigma}_n} U_n(\boldsymbol{\sigma}_n, \bar{\boldsymbol{\sigma}}_{-n}) - \delta, \forall n \in \mathcal{N},$$

where $U_n(\bar{\boldsymbol{\sigma}}_n, \bar{\boldsymbol{\sigma}}_{-n})$ denotes the expected throughput of player n under mixed strategy $\bar{\boldsymbol{\sigma}}$ and $\bar{\boldsymbol{\sigma}}_{-n}$ denotes the mixed strategy profile of other users except player n. Here $\delta \geq 0$ is the gap from a (precise) mixed Nash equilibrium. For the distributed learning algorithm, we show that

Theorem 10. *For the distributed learning algorithm, the mixed strategy $\boldsymbol{\sigma}^*$ in the equilibrium $\boldsymbol{P}^*$ is a δ-approximate Nash equilibrium, with $\delta = \max_{n\in\mathcal{N}}\{-\frac{1}{\gamma}\sum_{m=1}^{M}\sigma_m^{n*}\ln\sigma_m^{n*}\}$.*

The proof is given in the appendix in the separate supplemental file. The gap δ can be interpreted as the *weighted entropy*, which describes the randomness of

the learning exploration. A larger δ means a worse learning performance. When each user adopts the uniformly random access, the gap δ reaches the maximum value and results in the worst learning performance. In this case, we can obtain the upper-bound of the gap δ as $-\frac{1}{\gamma}\sum_{m=1}^{M}\frac{1}{M}\ln\frac{1}{M} = \frac{1}{\gamma}\ln M$. Theorems 9 and 10 together illustrate the trade-off between the exploration and exploitation through the choice of γ. A small enough γ is required to explore the environment (so that users will not put too many weights on exploitation and get stuck in channels with the *current* best throughputs) and guarantee the convergence of distributed learning to the approximate mixed Nash equilibrium. If γ is too small, however, then the performance gap δ is large due to over-exploration. Numerical results in section "Numerical Results" demonstrate that, by a proper choice of the temperature γ, the performance loss of the approximate mixed Nash equilibrium obtained by distributed learning is at most 10% compared with the exact mixed Nash equilibrium.

Extension to Physical Interference Model

In previous sections, we have focused on studying the spatial spectrum access game under the protocol interference model, which has been widely adopted in wireless network research literature [37, 38]. The protocol interference model uses the interference graph to describe the pair-wide interference relationships among users, i.e., two users can interfere with each other if they are within each other's interference range. This is useful for modeling the data transmission confliction when some random access MAC protocol is adopted. For example, in 802.11 networks, we can construct the interference graph by setting the carrier sensing range as the interference range. Moreover, by carefully constructing the interference edges via the reality check approach in [37] or the measurement-calibrated propagation scheme in [38], the protocol interference model can provide a good approximation to the physical interference model that captures the continuous nature of interference and takes into account the accumulated interference from multiple concurrent transmitters [39, 40].

We next study the spatial spectrum access game under the setting of physical interference model. According to [39], we can compute the data rate of user n under the physical interference model as

$$U_n(\boldsymbol{a}) = \theta_m W \log_2\left(1 + \frac{\eta_n d_n^{-\alpha}}{\omega_0 + \omega_{a_n}^n + \sum_{i\in\mathcal{N}/\{n\}:a_i=a_n}\eta_i d_{in}^{-\alpha}}\right). \tag{27}$$

Here W is the channel bandwidth, η_i is the transmission power of user n, α is the path loss factor, and $d_n^{-\alpha}$ denotes the channel gain between the transmitter and the receiver of user n due to free-space attenuation [39]. Furthermore, ω_0 denotes the background noise, $\omega_{a_n}^n$ denotes the interference from primary users to secondary user n on channel a_n, $\eta_i d_{in}^{-\alpha}$ denotes the interference generated by user i to user n,

and $\sum_{i\in\mathcal{N}\setminus\{n\}:a_i=a_n}\eta_i d_{in}^{-\alpha}$ denotes the accumulated interference from other second users to user n. Similarly to the setting of protocol interference model, we can model the distributed spectrum access problem among users under the physical interference model as a spatial spectrum access game with the payoff function given as in (27). We can show the following result for the case that the channel availability θ_m of all channels are homogeneous, i.e., $\theta_m = \theta$ for any $m \in \mathcal{M}$.

Theorem 11. *When the channel availabilities of all channels are homogeneous, the spatial spectrum access game under the physical interference model is a potential game, with the potential function given as*

$$\Phi(\boldsymbol{a}) = -\sum_i \sum_{j\neq i} \eta_i \eta_j d_{ij}^{-\alpha} I_{\{a_i=a_j\}} - 2\sum_{n=1}^{N} \eta_n \left(\omega_{a_n}^n + \omega_0\right)$$

and hence has a pure Nash equilibrium.

The proof is given in the appendix in the separate supplemental file. Since the spatial spectrum access game is a potential game, we can then apply the Safe Experimentation algorithm in [29] for achieving the pure Nash equilibrium. For the general case that the channel availabilities are heterogeneous, the analysis of spatial spectrum access game is much more challenging and can be an interesting future research direction.

Numerical Results

We now evaluate the proposed distributed learning algorithm by simulations. We consider a Rayleigh fading channel environment. The data rate of user n on an idle channel m is given according to the Shannon capacity, i.e., $b_m^n(t) = W \log_2\left(1 + \frac{\eta_n z_m^n(t)}{\omega_m^n}\right)$. We consider the Rayleigh fading channel environment where channel gain $z_m^n(t)$ is a random variable that follows the exponential distribution with the mean $\bar{z}_m^n$. In the following simulations, we set $W = 10\,\text{MHz}$, $\omega_m^n = -100\,\text{dBm}$, and $\eta_n = 100\,\text{mW}$. By choosing different mean channel gains $\bar{z}_m^n$, we have different mean data rates $B_m^n = E[b_m^n(t)]$ for different channels and users. We set the channel idle probability $\theta_m = 0.5$.

We consider a network of $M = 5$ channels and $N = 9$ users with four different interference graphs (see Fig. 5). Graphs (a) and (b) are undirected, and Graphs (c) and (d) are directed. Let $\boldsymbol{B}_n = \{B_1^n, \ldots, B_M^n\}$ be the mean data rate vector of user n. We set $\boldsymbol{B}_1 = \boldsymbol{B}_2 = \boldsymbol{B}_3 = \{2, 6, 16, 20, 30\}$ Mbps, $\boldsymbol{B}_4 = \boldsymbol{B}_5 = \boldsymbol{B}_6 = \{4, 12, 32, 40, 60\}$ Mbps, and $\boldsymbol{B}_7 = \boldsymbol{B}_8 = \boldsymbol{B}_9 = \{10, 30, 80, 100, 150\}$ Mbps. We implement both the random backoff and Aloha mechanisms for channel contention. For the random backoff mechanism, we set the number of backoff mini-slots in a time slot $\lambda_{\max} = 10$. For the Aloha mechanism, the channel contention probabilities of the users are randomly assigned from the set $\{0.3, 0.5, 0.7\}$. Notice that in this study, we focus on channel choices instead of the adjustment of contention

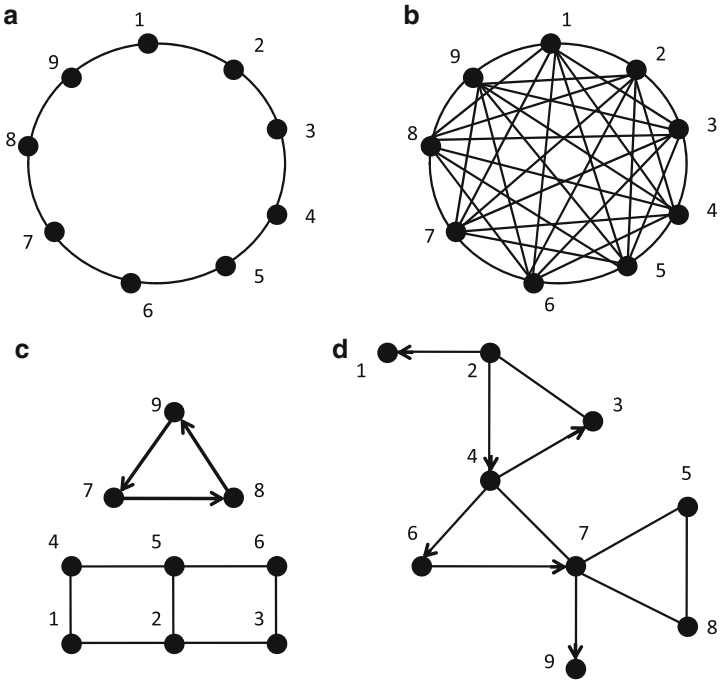

Fig. 5 Interference graphs

probabilities. For the distributed learning algorithm initialization, we set the smooth factor $\mu_T = \frac{1}{T}$, which satisfies the condition $\sum_T \mu_T = \infty$ and $\sum_T \mu_T^2 < \infty$.

We first evaluate the distributed learning algorithm with different choices of temperature γ on the interference graph (d) in Fig. 5. We run the learning algorithm sufficiently long until the time average system throughput does not change. The result in Fig. 6 shows the system performance with different γ and demonstrates that a proper temperature γ can achieve a balance between exploration and exploitation and offer the best performance. When γ is small, the users tend to select the channels randomly (i.e., over-exploration), and the performance gap δ can be large. When γ is very large, the algorithm focuses on exploitation and may get stuck in local optimum, and the performance is again negatively affected. In the following simulations, we set $\gamma = 5.0$ since it achieves good system performance in both random backoff and Aloha mechanisms as in Fig. 6.

We then evaluate the convergence of the distributed learning algorithm. In Fig. 7, we show the number of iterations for the convergence of distributed learning algorithm with random backoff and Aloha mechanisms. We see that as the interference graph becomes more dense (e.g., graph (b)), the convergence time becomes longer. The reason is that when the interference graph becomes more dense and a user can generate interference to more users, the environment becomes more complex, and it hence takes more time overhead to explore. We also observe that the convergence

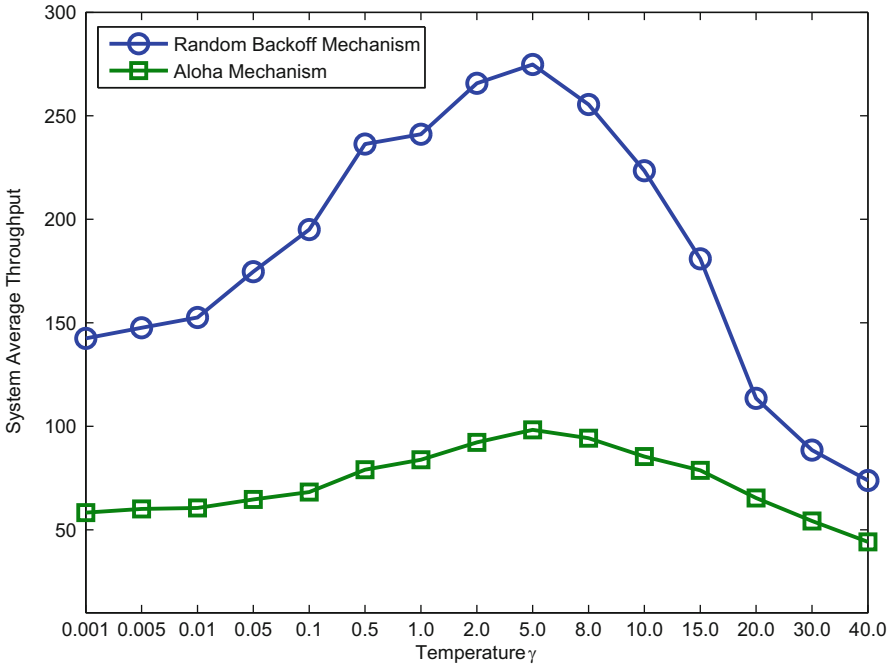

Fig. 6 The system performance of the distributed learning algorithm with different temperature γ

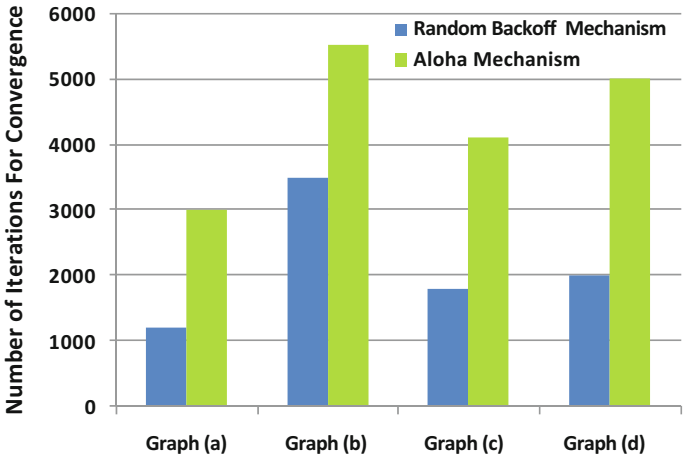

Fig. 7 Convergence time of distributed learning algorithm on different graphs

time of Aloha mechanism is longer than that of random backoff mechanism. This is due to the fact that in Aloha mechanism, users are heterogeneous in terms of channel contention capability; hence the system environment becomes more complicated.

We further compare distributed learning with the solutions obtained by the following benchmark algorithms:

- Random Access: each user chooses a channel to access purely randomly.
- Multiarmed Bandit: we implement the multiarmed bandit solution for distributed spectrum access in [41].
- Mixed NE: we compute the exact mixed Nash equilibrium of the spatial spectrum access game, based on statistical network information using the global Newton method [30].
- Dynamic Game: we compute the solution of the complete information dynamic game for spectrum access, by solving the corresponding stage spatial spectrum access game (using the global Newton method) for each time slot t, with the channel idle probabilities $\{\theta_m\}_{m=1}^{M}$ of the stage game replaced by the channel state realization $\{S_m(t)\}_{m=1}^{M}$ of time slot t.
- Centralized Optimization: the solution obtained by solving the centralized global optimization of $\max_{\boldsymbol{a}} \sum_{n\in\mathcal{N}} U_n(\boldsymbol{a})$.

We implement these algorithms together with the distributed learning algorithm on the four types of interference graphs in Fig. 5. The results are shown in Figs. 8 and 9. We see that the exact mixed Nash equilibrium of spatial spectrum access game based on statistical network information is quite efficient, with an average of less than 8% performance loss compared with the dynamic game solution. This is

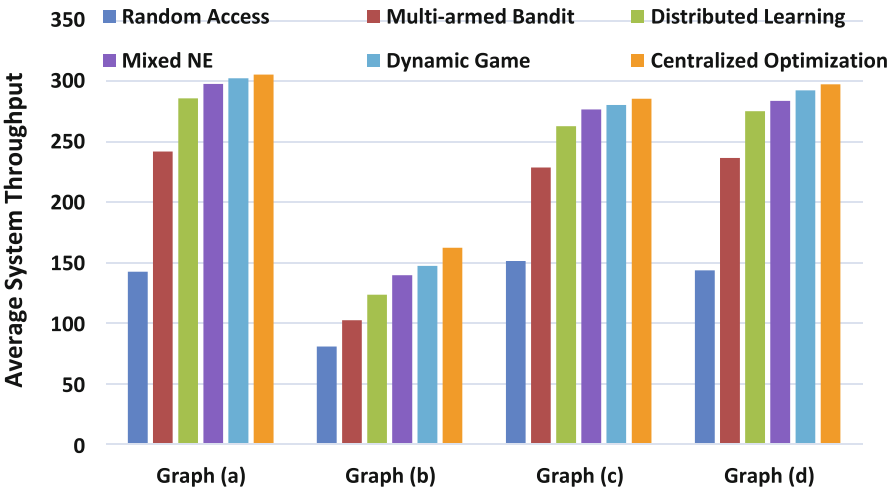

Fig. 8 Comparison of distributed learning, random access, global Newton, and centralized optimization with the random backoff mechanism

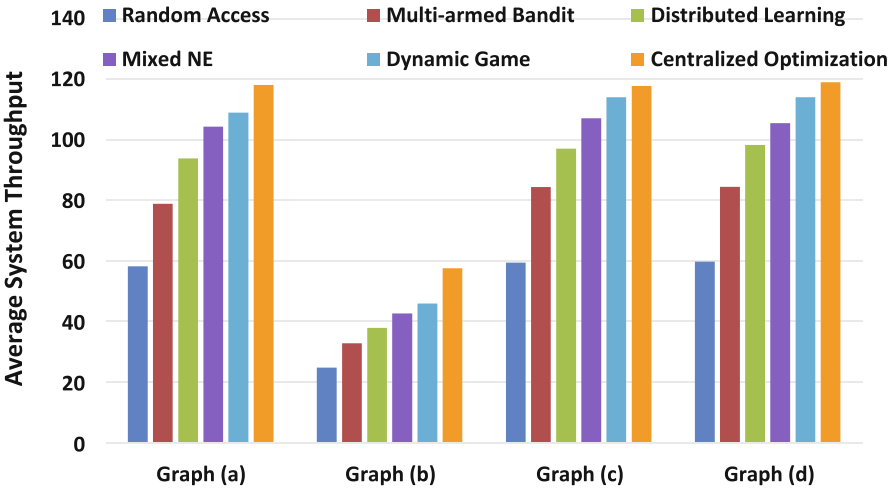

Fig. 9 Comparison of distributed learning, random access, global Newton, and centralized optimization with the Aloha mechanism

due to the fact that in the proposed spatial spectrum access game, each secondary user takes both the primary activity levels on different channels and the competition with other secondary users into consideration. This can help mitigate the congestion within secondary users and exploit the channels of high transmission opportunities. Moreover, the performance gap δ of the approximate mixed Nash equilibrium by distributed learning from the exact mixed Nash equilibrium is small, with a less than 10% performance loss in all cases. For the random backoff (Aloha, respectively) mechanism, we see that the distributed learning algorithm achieves up to 100% (65%, respectively) performance improvement over the random access algorithm. Moreover, we observe that the distributed learning algorithm can achieve a better performance than the multiarmed bandit scheme, with a performance gain of up to 15%. This is because that the design of multiarmed bandit scheme does not take the spatial reuse effect in account. Compared with the centralized optimal solution, the performance loss of the distributed learning in the full-interference graph (b) is 28% (34%, respectively). Such a performance loss is not due to the algorithm design; instead it is due to the selfish nature of the users (i.e., competition in distributed spectrum sharing). In the partial-interference graphs (a), (c), and (d), the performance loss can be further reduced to less than 10% (17%, respectively). This shows that the negative impact of users' selfish behavior is smaller when users can share the spectrum more efficiently through spatial reuse.

Conclusion

In this chapter, we explored the spatial aspect of distributed spectrum sharing and proposed a framework of spatial spectrum access game on directed interference graphs. We investigated the critical issue of the existence of pure Nash equilibria and developed a distributed learning algorithm converging to an approximate mixed Nash equilibrium for any spatial spectrum access games. We further discussed how to extend the framework to the setting of physical interference model. Numerical results showed that the algorithm is efficient and achieves a significant performance gain over a random access algorithm that does not consider the spatial effect.

For the future work, one interesting direction is to design distributed spectrum access mechanisms that can converge to pure Nash equilibria, for those spatial spectrum games which are not potential games but admit pure Nash equilibria. Another important direction is to study the general spatial spectrum access game under the physical interference model. It would be very challenging to show the existence of Nash equilibrium and extend the distributed learning algorithm under such a general physical interference setting.

Abstract

Many wireless standards for cellular networks (e.g., IEEE 802.11af and IEEE 802.22) have been developed or are currently being developed for enabling opportunistic access to spectrum using cognitive radio (CR) technology. When heterogeneous cellular networks that are based on different wireless standards operate in the same spectrum band, coexistence issues can potentially cause major problems. Enabling coexistence via direct coordination between heterogeneous cellular networks is very challenging due to incompatible MAC/PHY designs of coexisting networks, the conflict of interest issues, as well as customer privacy concerns. This chapter introduces a number of research problems that may arise in the context of coexistence of heterogeneous cellular networks, namely, the hidden terminal problem, the multichannel broadcast problem, the spectrum sharing problem, and the channel contention problem. This chapter also identifies the major challenges for addressing these problems, proposes the guidelines for devising potential solutions, and provides results of performance evaluation on the proposed solutions.

Introduction

Industry and research stakeholders have launched standardization efforts to enable the secondary networks' utilization of unused spectrum by leveraging *cognitive radio* (CR) technology. These efforts include IEEE 802.22 wireless regional area networks (WRAN) [22], IEEE 802.16h Cognitive WiMax, IEEE 802.11af (WiFi over TV white space) [20], ECMA 392 (WPAN over TV white space) [8], etc. All of these standards rely on CR technology to overcome the challenging *vertical* or *incumbent* coexistence problem between primary and secondary networks as well as the *horizontal* coexistence problem between secondary networks.

Heterogeneous vs. homogeneous coexistence: There exists a significant body of work on vertical coexistence [5, 6], and it has been attracting significant interest from academia and industry. In contrast, horizontal coexistence has garnered less attention thus far. Horizontal coexistence can be further categorized into:

- *Heterogeneous* coexistence that refers to the coexistence of networks that employ different wireless technologies (e.g., the coexistence between WiFi and Bluetooth [19, 50], the coexistence of heterogeneous wireless networks over TV white space [21]);

- *Homogeneous* coexistence (aka self-coexistence) that refers to the coexistence of networks that employ the same wireless technology (e.g., neighboring CR networks of the same type [3, 31], or neighboring 802.11 hotspots [30]).

This chapter has a focus on the heterogeneous coexistence between secondary cellular networks that employ different wireless technologies and uses the term "cellular network" to denote a CR-enabled cellular network operating over TV white space.

Existing coexistence schemes: The coexistence schemes for wireless networks can be broadly classified into two categories.

- A *noncollaborative* coexistence scheme is the only feasible approach when there are no means of coordination between the coexisting networks, such as the coexistence of WiFi and ZigBee networks [19, 50].
- A *collaborative* coexistence scheme can be employed when coexisting networks can directly coordinate their operations, such as the self-coexistence schemes for 802.22 networks [3, 31].

Major challenges: Existing coexistence schemes fail to adequately address the heterogeneous coexistence problem in TVWS for a number of technical and policy reasons. Noncollaborative schemes cannot facilitate the coexistence among heterogeneous networks due to their incompatible MAC strategies. Collaborative strategies may require the exchange of potentially sensitive information (e.g., traffic load, bandwidth requirements) across different networks to negotiate the spectrum partitioning [47, 48], which could raise conflict-of-interest issues and customer privacy concerns for competing wireless networks or service providers. Moreover, it is difficult to find a third party that can serve as a global or centralized decision-maker that supervise all heterogeneous networks and allocate spectrum them.

Problems in focus: This chapter studies a few challenging problems that are related to the medium access control (MAC) layer protocol design for coexistence of heterogeneous coexistence of cellular networks.

- *Hidden terminal problem* can be potentially exacerbated by the heterogeneity of the PHY/MAC designs of the coexisting cellular networks, especially when TDM-based cellular networks coexist with CSMA-based networks.
- *Broadcast failure* problem may arise over a single broadcast channel when the broadcast channel is reclaimed by a primary (or licensed) user that has a higher priority of accessing the spectrum, or when secondary users in coexisting cellular networks moves into a region where the co-channel interference is caused.
- *Spectrum sharing* among coexisting heterogeneous cellular networks is very challenging via direct coordination, while a *mediator* system is able to establish an *indirect* coordination mechanism for spectrum sharing between networks.

- *Channel contention* is a distributed inter-network coordination process that enables a CR network in need of more spectrum resources to acquire channels from neighboring networks by exchanging control messages via a local controller.

The following sections discuss each problem and its corresponding solution respectively.

Hidden Terminal Problem

In wireless networks, when more than one transmitter-receiver pairs share a channel, the *hidden terminal problem* can occur. This problem occurs when a transmitter is visible from a receiver node, but hidden from (or out of the sensing range of) another transmitter that is visible from the same receiver. This leads to packet collisions at the receiver when the two transmitters send packets simultaneously. The hidden terminal problem in single-channel environments has been widely studied. In single-channel systems employing CSMA/CA, a handshaking procedure (i.e., using RTS/CTS control packets [29]) has been adopted to address the problem. For handling the hidden terminal problem in *multi*channel wireless networks, some have proposed the use of a fixed control channel to facilitate a handshake procedure between two transceivers [40].

Unfortunately, the aforementioned handshaking procedures do *not* work when the hidden terminal problem is caused by heterogeneous coexistence. This is because the hidden terminal problem in heterogeneous coexistence is different from those mentioned above and is due to the fact that the coexisting networks *cannot understand each others' control messages* because they use different air interfaces (i.e., PHY/MAC stacks). An example is shown in Fig. 1 in which: an 802.22 network is coexisting with an 802.11af network. The 802.22's MAC protocol is TDM (time-division multiplexing) based with PHY resources allocated using OFDMA, while 802.11af relies on a contention-based CSMA protocol. Because the 802.22 base station (BS) and the 802.11af access point (AP) are hidden from each other, packets sent by the BS and the AP may collide at the 802.11af receiver node. Previous works have shown that enabling fair and efficient spectrum sharing is challenging in scenarios where a network with a contention-based MAC protocol (e.g., 802.11af) coexists with a network with a tightly scheduled TDM-based MAC

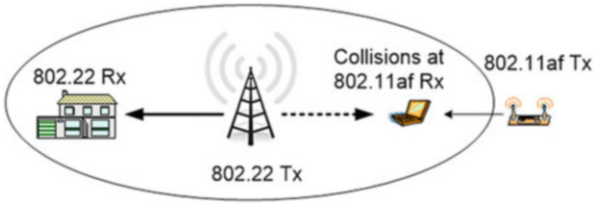

Fig. 1 An example of the hidden terminal problem caused by heterogeneous coexistence

protocol (e.g., 802.22 or 802.16h) [10, 11, 13, 27, 39, 44]. IEEE 802.22 is the first worldwide wireless standard based on CR technology for utilizing TVWS in rural areas. The 802.22 standard prescribes incumbent protection techniques necessary for secondary users to operate in licensed TV bands, while 802.16 does not. It is assumed that the TDM device can distinguish a packet sent by a CSMA device from the background noise. This section focuses on the particular type of heterogeneous coexistence between TDM and CSMA networks.

The hidden terminal problem in this heterogeneous coexistence scenario induces two types of packet collisions:

1. Collisions at the receivers of a TDM MAC network that are caused by hidden transmitters of a CSMA MAC network
2. Collisions at the receivers of a CSMA MAC network that are caused by hidden transmitters of a TDM MAC network

This section presents a coexistence scheme that mitigates the packet collisions caused by the hidden terminal problem in a particular type of heterogeneous coexistence scenario – viz., coexistence of TDM and CSMA MAC networks (e.g., 802.22 and 802.11af networks).

- To mitigate the first type of collisions, a *beacon transmission* mechanism is introduced to enable the receivers in a TDM MAC network to send beacon signals to prevent the hidden CSMA devices from accessing the shared channel, while transmitters of the TDM MAC network occupy the channel.
- To mitigate the second type of collisions, a *dynamic quiet period* mechanism is presented for the TDM MAC networks. This mechanism requires a TDM transmitter to dynamically determine the end point of its current quiet period (QP) in order to reduce the probability of packet collisions. The length of the quiet period is dynamically adjusted in order to maintain long-term weighted fairness in channel access between the coexisting TDM and CSMA networks.

Two Types of Collisions

Type 1: Collisions at the TDM Network Receiver

This type of collisions occur when a TDM receiver is located within the transmission ranges of both the TDM and CSMA transmitters, but the two transmitters are hidden from each other. To reduce this type of collisions, the TDM network has to prevent the CSMA transmitter from transmitting while the TDM transmitter is transmitting.

A straightforward solution to mitigate packet collisions in this scenario is to require the TDM receiver to emit *beacon signals* during a small time fraction at the beginning of every time slot. This time fraction is called the *beaconing fraction* of a time slot. Here, it is assumed that the TDM receiver is within the CSMA transmitter's sensing range – i.e., the CSMA transmitter can sense the

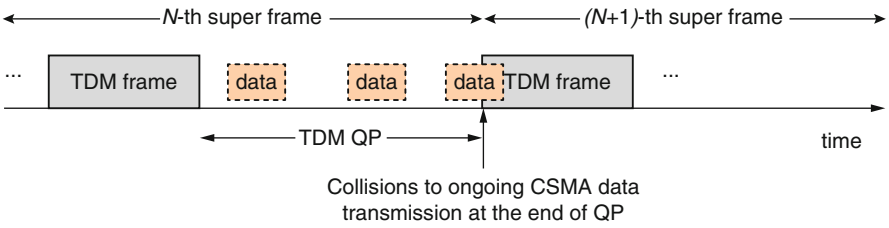

Fig. 2 Collisions at the end of the N-th frame's QP. *Dotted-line rectangles* represent the CSMA data packets

TDM receiver's beacon signals. The beacon signal's presence in the channel will cause the CSMA transmitter to suspend transmissions. It is reasonable to assume that the coexistence enabling system (e.g., 802.19.1 system) mandates the use of beacon signals by the TDM receivers to facilitate coexistence, since the TDM MAC networks are registered.

During the beaconing fraction of a time slot, the TDM transmitter stops transmitting, and the TDM receiver emits beacon signals such that the coexisting CSMA transmitter can detect the beacons and refrain from transmitting in the channel. As a result, the collision-free receptions at the TDM receivers can be guaranteed. Requiring the TDM receiver to transmit beacons can be a costly overhead and thus should be required only when its benefits outweigh the costs.

Type 2: Collisions at the CSMA Network Receiver

This type of collisions occur when the CSMA receiver is located within the transmission ranges of both the TDM and CSMA transmitters, but the two transmitters are hidden from each other. In this scenario, packet collisions occur because the TDM transmitter initiates transmission before the CSMA transmitter has finished transmitting its data packets.

A specific example of this scenario is shown in example in Fig. 2. In the figure, the first TDM frame transmitted by the TDM transmitter in the $(N + 1)$-th superframe collides with the CSMA transmitter's ongoing packet transmissions which started in the QP of the N-th superframe and has continued on past the QP. In this situation, requiring the CSMA receivers to use beacons is not a plausible solution, because they are not under the control of the 802.19.1 system.

During a QP, a TDM transmitter suspends its transmission, and it terminates the QP at the scheduled end time point by transmitting a prescribed number of beacons. After transmitting a prescribed number of beacons, the TDM transmitter terminates the current QP and starts the TDM frame of the next superframe. Note that the TDM transmitter simply terminates the QP at the scheduled time point, and it will not wait until the ongoing transmission for CSMA data and/or ACK packets to be finished.

Beacon Transmission by TDM Receiver

Consider an 802.22 WRAN co-located with an 802.11af WLAN, both sharing the same TV white space channel. To mitigate the first type of collisions, it is recommended to support two modes at the TDM receiver: beaconing and non-beaconing modes. It can switch from one mode to the other depending on the channel conditions, and this procedure of switching contains two steps:

1. First, the network entity performs channel evaluation to determine when to switch from one mode to the other. The TDM receiver measures the received SIR, estimates the channel capacity in the two modes, and makes a decision of which mode to operate in.
2. Then, the TDM receiver will notify the TDM transmitter if it decides to switch to the beaconing mode. In the beaconing mode, the TDM transmitter has to stop transmitting in the beaconing duration.

Beaconing by TDM receivers will incur additional overhead and waste the channel time. That is why a dynamic switch is needed between the two modes to balance the tradeoff between the performance loss due to interference caused by CSMA packets, and the beaconing overhead.

First, calculate the channel capacity in each of the two modes. By estimating the channel access time and packet error rate, the capacity of the shared channel, C, is:

$$C = \left(1 - \frac{u}{t}\right) \cdot (1 - \varepsilon), \tag{1}$$

where t is the length of a time slot, u is the duration of beaconing in a time slot, and ε denotes the packet error rate on the shared channel at the TDM receiver. In (1), $\left(1 - \frac{u}{t}\right)$ represents the ratio of channel access time used for non-beaconing transmission and the length of a time slot and $(1 - \varepsilon)$ shows the rate of successful packet reception given possible packet errors. The packet error can be caused by a few factors, such as noise, interference, fading, etc.

The reduction of channel capacity can be caused by two factors in the considered scenarios of heterogeneous coexistence, namely, the beaconing duration, and the inter-network interference. In the beaconing mode, the beaconing duration, u, is the major cost that may lower the channel capacity, and the inter-network interference can lead to a high packet error rate (i.e., a low channel capacity according to (1)) in the non-beaconing mode. The effect of fading may vary with time, geo-locations, or frequency, and it is independent of whether the beaconing mode is used.

Let γ denote the maximum achievable SIR perceived by the TDM receiver on the shared channel. In [38], Shellhammer describes a way of estimating ε based on γ: the symbol error rate (SER), ρ, can be estimated based on γ; then, ε can be calculated based on the SER. If the modulation is BPSK, the SER $\rho = Q[\sqrt{2\gamma}]$, where the function $Q(\cdot)$ is the integral of the tail of a normalized Gaussian

probability density function [37]. The packet error rate in a packet of m symbols is the probability that at least one symbol is incorrect,

$$\varepsilon = 1 - (1 - \rho)^m.$$

Channel capacity in beaconing mode: To avoid the first type of collisions, the TDM receiver is allowed to block the medium by emitting beacon signals in every time slot. The capacity of the shared channel in this mode can be expressed as

$$C_b = \left(1 - \frac{u}{t}\right) \cdot (1 - \varepsilon).$$

The CSMA transmitter could sense an idle channel during a time period of $(t - u)$ in every TDM time slot. To successfully block the medium, the TDM receiver needs to guarantee that the value of $(t - u)$ is less than the time for channel clear assessment (CCA) in CSMA networks. The time for CCA in WiFi networks is 28 μs [25].

Assume the noise source is additive white Gaussian noise (AWGN) N_0, and the signal-to-noise ratio is represented as E_s/N_0, where E_s denotes the signal energy in a symbol. That is,

$$\gamma = \frac{E_s}{N_0}.$$

Given the modulation, the TDM MAC network is able to estimate C_b using γ.

Channel capacity in non-beaconing mode: If the feature of beacons is disabled, the TDM receiver may experience the first type of collision when there is a nearby CSMA transmitter that is hidden from the TDM transmitter. The channel capacity in the non-beaconing mode can be expressed as

$$C_n = \left(1 - \frac{u}{t}\right) \cdot (1 - \varepsilon) = 1 - \varepsilon.$$

The fundamental principal of this approach in the non-beaconing mode is to equate the interference power at the TDM receiver, after the receive filter, to the equivalent noise power after the receive filter.

Given the AWGN N_0, the signal energy in a symbol of period T is related with the symbol power $P_s = \frac{E_s}{T}$. Let B denote the noise equivalent bandwidth of the receive filter for a symbol period of T, and $B = \frac{1}{T}$. The noise power after the receiver filter is given by $P_n = \frac{N_0}{B}$. The ratio E_S/N_0 can be expressed in terms of the signal power and the noise power after the receiver,

$$\frac{E_s}{N_0} = \frac{P_s T}{P_n T} = \frac{P_s}{P_n},$$

Since the TDM receiver has the same TVWS channel model as the interferer (CSMA transmitter), the noise power after the receive filter is equal to the value of the interference signal, P_I^r, after the receive filter [38], i.e., $P_n = P_I^r$. Therefore,

$$\gamma = \frac{E_s}{N_0} = \frac{P_s}{P_I^r},$$

and C_n can be accordingly estimated.

An approach of switching between two modes: In the proposed approach, the non-beaconing mode over the shared mode is attempted first. If the maximum achievable SIR on the channel is not sufficiently high, it is prescribed that the beaconing mode for TDM networks will block the medium and prevent CSMA devices' access to the channel. One possible approach is introduced here for determining when to enable the beaconing mode.

The network determines which mode for the the TDM receiver to operate in, for a given channel, by comparing γ with the required SIR threshold parameter γ^*. To obtain the value of γ^*, first solve for ε in the equation $C_b = C_n$ and then find the SIR value corresponding to the solved ε, which is used as the value of γ^*.

1. If $\gamma \geq \gamma^*$, the TDM receiver operates in the non-beaconing mode. The benefits of non-beaconing mode (e.g., low control overhead) outweigh the benefits of beaconing (e.g., no collisions).
2. If $\gamma < \gamma^*$, the TDM receiver operates in the beaconing mode. The benefits of beaconing mode outweigh the benefits of non-beaconing mode.

Dynamic Quiet Period at TDM Transmitter

In the proposed approach, the TDM transmitter chooses the appropriate starting time point for TDM transmission in order to avoid overlapped TDM and CSMA transmissions, and it starts occupying the channel immediately after the transmission of a whole CSMA packet and before the transmission of the next CSMA packet.

Quiet Period

In TDM MAC networks, channel access occurs in scheduled blocks of time slots; in CSMA MAC networks, channel access is contention based, and there is no predetermined schedule for channel access. A "universal" superframe structure is representative in TDM MAC networks with coexistence mechanisms (e.g., 802.22 or 802.16 networks). Time is divided into *superframes*, each superframe is divided into *frames*, and each frame contains a number of f time slots.

In 802.16h, a quiet period (QP) that contains an integer number of frames is periodically scheduled [22,36]. During a QP, the BS suspends its data transmissions to provide channel access opportunities for CSMA networks. Similarly, a QP is

scheduled at the end of every superframe, and non-QP frames are considered as *data frames*.

Let q denote the number of frames contained in a QP, and let d denote the number of data frames contained in a superframe. Thus, the number of frames in a superframe is $d + q$, and the number of time slots in a superframe is $(d + q) f$. A TDM network starts transmitting data immediately after the end of a QP (i.e., end of a superframe). The value of q quantifies the number of frames that TDM networks can share with CSMA networks during a superframe. The values of d and q are predetermined collectively by the coexisting TDM MAC networks or determined by the coexistence mediator. During a TDM QP, the CSMA networks sense an idle channel and start to transmit CSMA packets.

The proposed approach is built on top of the superframe structure of TDM MAC networks, and it adopts an innovative way of dynamically determining the length of the quiet period, which reduces the second type of collisions as well as maintains the weighted fairness for the TDM MAC network in channel access. It employs the following algorithms to achieve these objectives.

- *Collision avoidance algorithm*. The TDM transmitter monitors the data traffic during the QP and captures the ACK packets emitted by CSMA networks. To avoid collisions, the TDM transmitter is allowed to terminate the QP immediately after detecting an ACK packet. This will lead to a shortened QP in the current superframe and an advanced frame in the next superframe, which hurts the short-term weighted fairness for the TDM MAC network.
- *Weighted fairness maintenance algorithm*. By counting the number of time slots lost in previous shortened QPs, the TDM transmitter is able to determine whether it needs to increase the length of the next QP such that the long-term fairness can be maintained.

Collision avoidance: In either saturated or unsaturated WLANs, the aggregated traffic pattern (the inter-arrival time between WLAN packets) approximates a Poisson distribution [7, 49]. The experimental results in [19] show that the inter-arrival time of WLAN frame clusters fits a *Pareto* model. It is assumed that the packet arrival of the WLAN follows a Poisson distribution. Let λ denote the WLAN data packets' arrival rate, and thus the mean inter-arrival time is $1/\lambda$.

Definition 1. When the TDM network enters a scheduled QP,

- The *elapsed QP* is the time duration from the start of the QP to the current time point.
- The *residual QP* is the time duration from the current time point to the expected end of the QP.

Figure 3 illustrates the elapsed QP and residual QP.

To avoid collisions to the potential hidden CSMA receiver at the end of the QP (defined as the second type of collisions), the TDM MAC network (or TDM

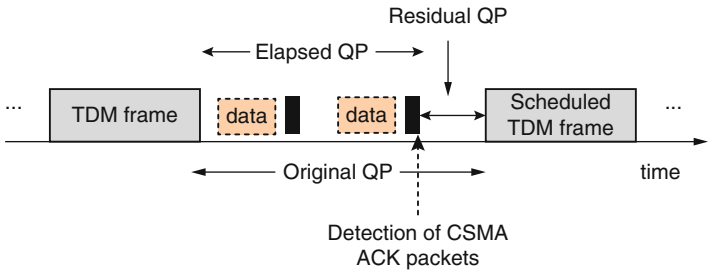

Fig. 3 Illustration of the elapsed QP and residual QP in a superframe of the TDM MAC network

transmitter) has to make a decision upon detecting a CSMA ACK packet: *Is the residual QP long enough for completing another CSMA packet transmission?*

1. If the answer is "yes," the TDM network will keep silent and wait for the next CSMA packet arrival (i.e., the next detected ACK).
2. If the answer is "no," the TDM network should terminate the QP by immediately starting TDM transmissions (or beacon transmissions) such that the CSMA receiver would refrain from operating in the channel.

As a result, it enables the TDM MAC network to autonomously terminate the QP at an "appropriate" time point.

Let e_i denote the duration of the elapsed QP and r_i denote the duration of the residual QP, in the i-th superframe, both of which are on a time slot basis. Let l_d and l_a denote the mean length of WLAN's data packets and the length of ACK packet, respectively. Recall that the number of time slots in a frame is f. Let p denote the probability that the next CSMA packet transmission can be finished in the residual QP, r_i. Upon detection of an ACK packet, the length of the residual QP is r_i, and the TDM network calculates the probability p.

- When $r_i < l_d$, the residual QP is smaller than the mean length of a WLAN data packet, and thus $p = 0$.
- When $r_i \geq l_d$, the residual QP is longer than the mean length of a WLAN data packet, and the next CSMA packet transmission can be finished in the residual QP, only if the packet arrives in next $(r_i - l_d)$ slots.

$$\begin{aligned} p &= \mathbb{P}\{\text{CSMA pkt arrival in next } (r_i - l_d) \text{ slots}\} \\ &= 1 - \mathbb{P}\{\text{no CSMA pkt arrival in next } (r_i - l_d) \text{ slots}\} \\ &= 1 - e^{-\lambda(r_i - l_d)}. \end{aligned} \tag{2}$$

Decision rule of dynamic QP mechanism: Based on the calculated value of p, the TDM network is able to decide whether to terminate the QP upon detection of

CSMA ACK packets, using the following decision rule, in which q_i denotes the *length of QP* (on a frame basis) in the i-th superframe, and the initial value $q_1 = q$. How to dynamically update the value of q_i will be described later.

1. When $e_i < q_i f$, the QP of the current superframe has not finished. Upon the detection of a CSMA ACK packet,
   a. The TDM network predicts that the residual QP is insufficiently long for completing a next CSMA packet transmission if $p < \tau$. Then, it terminates the QP by immediately transmitting beacons;
   b. The TDM network predicts that the residual QP is long enough for completing a next CSMA packet transmission if $p \geq \tau$. Thus, the TDM transmitter waits for the next ACK packet without sending any beacons.

   τ denotes the threshold that represents the *expected probability that the next CSMA packet transmission can be finished in the residual QP*.
2. When $e_i = q_i f$ (i.e., the residual QP $r_i = 0$), it means that the elapsed QP length exceeds the original length of QP in the i-th superframe, and the TDM network has to terminate the QP immediately even without detecting any ACK packet. In unsaturated CSMA networks, the waiting time before a CSMA packet arrival might be very long, which degrades the channel utilization. This step prevents the case that the waiting time is longer than the length of the current QP.

Simulation

This section compares the proposed approach with the fixed QP (FQP) mechanism, and considers a heterogeneous coexistence scenario between TDM networks (e.g., 802.22 networks) and CSMA networks (e.g., 802.11 networks). In each TDM network, there is one BS and multiple user devices, and the BSs of TDM networks are synchronized. Each CSMA network is placed at a location such that the AP is hidden from the BS. All coexisting networks are able to identify available TVWS channels by making queries to the TVWS database or leveraging the spectrum sensing techniques.

A synchronized superframe structure is simulated for all coexisting TDM networks to share the same channel. In each data frame, the TDM receiver is required to adopts the beacon transmission mechanism to prevent the collisions to the TDM packet reception when necessary. In each quiet period, the TDM transmitters suspend their traffic and observe the possible CSMA transmission over the channel to carry out the dynamic QP mechanism. The decision-making threshold $\tau = 0.5$, which implies that in the residual QP, the probability of the next complete CSMA packet transmission is required to be greater than the probability of an incomplete transmission. The length of QP is counted by the number of frames, and each frame contains ten time slots. The CSMA packet duration consists of multiple time slots. The CSMA packet arrival rate quantifies the probability that the CSMA packet arrives in a time slot. In the CS-based spectrum access scheme, $\frac{s}{f} = \frac{1}{5}$, which is the fraction of time a device spends on spectrum sensing in every time slot.

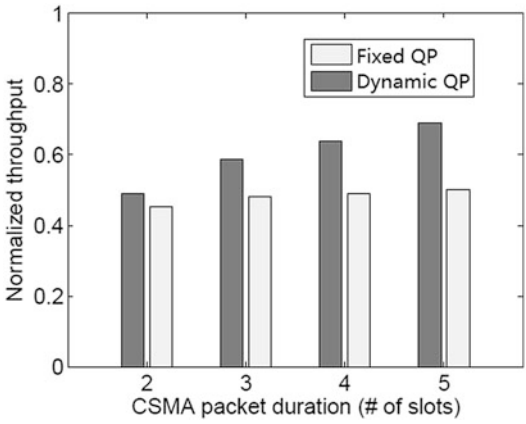

Fig. 4 Normalized throughput under the hidden terminal situation, when varying the basic QP length, $l_d = 2$ and $\lambda = 0.5$

The simulation parameter values were chosen to be consistent with those used by the 802.22 working group [23, 24].

Normalized Throughput in the Quiet Period

In a quiet period-based approach, the packet collision due to the hidden terminals only happens at the end of a QP.

Define the *normalized throughput in the QP* as the ratio between the number of time slots for transmitting CSMA packets without collisions during a QP and the total number of time slots in the QP. In general, Figs. 4 and 5 show that the performance of the dynamic QP approach is better than that of the FQP scheme in all cases.

As shown in Fig. 4, the gap between SHARE and FQP in terms of the normalized throughput narrows as the length of the QP increases. In contrary, the throughput gap between SHARE and FQP becomes wider when the CSMA packet duration l_d increases, as shown in Fig. 5. The reason has been explained above: with an increased CSMA packet duration, the collision probability increases in every QP, which decreases the normalized throughput.

The purpose of this set of simulations is to investigate how much is the performance gain that can be obtained from the proposed protocol.

- In Fig. 4, the performance gain is approximately 20% when the length of the quiet period is as small as the half of a frame length;
- As Fig. 5 shows, the longer the CSMA packet is, the more performance gain can be obtained (approximately 40% when the CSMA packet length is five slots).

Thus, the proposed protocol has a significant performance gain when a CMSA network that has a long packet length coexists with a TDM network that has a small QP length. Meanwhile, it has no significant performance gain given various packet arrival rates.

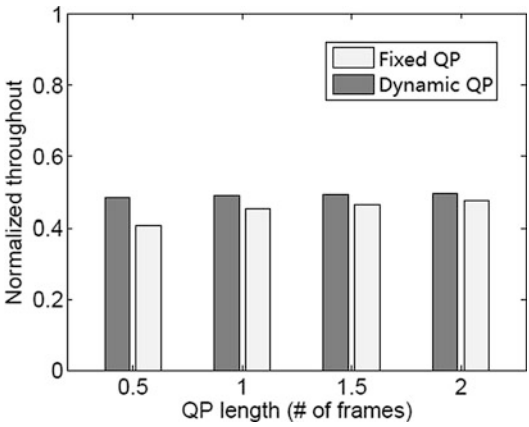

Fig. 5 Normalized throughput when varying the CSMA packet duration, $q = 1$ and $\lambda = 0.5$

Multichannel Broadcast Problem

Broadcast in cellular networks is typically offered as a push-type service for distributing important control information from the base station to a group of users that share radio resources. Moreover, broadcast enables the low-cost delivery of large volumes of popular content (e.g., multimedia content) to users in a cell. There are many existing solutions to broadcast in the market, including mobile TV broadcasting (DVB-H) [32], audio casting, massive software updates, content delivery over WiMax [28], and broadcast (or multicast) service offered by 3GPP in LTE cellular networks [15].

A single channel, referred to as a *broadcast channel*, is usually used by a base station to distribute the same content to a group of users that subscribe to the same service [9]. Meanwhile, a base station may employ multiple broadcast channels for delivering different contents to groups of users that subscribe to different services. A user or a content subscriber is able to successfully receive the broadcasted content when (1) the broadcast channel is available and (2) the user is located within the transmission range of the base station.

In dynamic spectrum access, the *broadcast failure problem* can occur due to the temporal and spatial variations in channel availability. Specifically, the primary users (PU, or licensed users) may reclaim the spectrum band where broadcast channels reside and the unlicensed users have to vacate this channel according to the requirement for protection of licensed users in CR networks. On the other hand, a secondary user is likely to move into a region where the interference is caused by coexisting cellular networks. In either case, the broadcast channel becomes unavailable thereby leading to unsuccessful deliveries of broadcasts.

A vast majority of existing work has focused on tackling this problem in *multi-hop or ad hoc* CR networks. Instead of relying on a single broadcast channel, the control information is transmitted over a preselected set of broadcast channels, which can be derived based on the neighbor graphs [33]. To determine the minimum broadcast schedule length for a CR network, two heuristics are presented and they

can produce schedules that have either optimal or near-optimal lengths [2]. In [26], a mixed broadcast scheduling algorithm is proposed under the unit disk graph (UDG) model, which combines the uni-cast and broadcast collaboratively in order to obtain a small broadcast latency. To broadcast over multiple channels, the channel hopping technique is used by cognitive radios without requiring the knowledge of global network topology or the requirement of time synchronization information [41–43].

This section focuses on the broadcast failure problem in the context of coexisting cellular networks, i.e., *infrastructure-based* CR networks. To guarantee the successful broadcast, a base station has to employ a *multichannel broadcast protocol* – i.e., it delivers contents over multiple broadcast channels using broadcast radios, so as to reduce the chance of colliding with primary users' transmissions or coexisting networks in the spatial or temporal domain.

This section presents a multichannel broadcast protocol, called *Mc-Broadcast*, for delivering contents to secondary users that are located in coexisting cellular networks. Every broadcast radio at a base station selectively transmit over a number of channels via a channel hopping process. The channel hopping sequence is generated using a mathematical construct called *Langford pairing*, such that Mc-Broadcast can only incur a small broadcast latency and guarantee a high successful delivery ratio.

Definition of Langford Pairing (LP)

Given an integer n, Langford pairing is a sequence of length $2n$ that consists of two 1s, two 2s, ..., and two ns and satisfies that there are exactly one number between the two 1's, exactly two numbers between the two 2's, ..., and exactly n numbers between the two n's.

Formally, A *Langford pairing*, $\{l_i\}_{0\le i\le 2n-1}$ of order n, also called a *Langford sequence*, is a permutation of the sequence of $2n$ integers $\{1, 1, 2, 2, 3, 3, \ldots, n, n\}$, and it satisfies the *Langford property*: if $l_i = l_j, 0 \le i < j \le 2n-1$, then $j - i = l_i + 1$.

For example, the sequence $l = \{3, 1, 2, 1, 3, 2\}$ is a Langford pairing of order $n = 3$. There is only one number (that is, 2) between the two 1s, two numbers (they are 1 and 3) between the two 2s and three numbers (they are 1, 2 and 1) between the two 3s. Given $i = 0$ and $j = 4$, then $l_0 = l_4 = 3$, and $j - i = 3 + 1$; given other combinations of i and j, the sequence l also satisfies the Langford property.

Slightly different from LP, an *extended Langford pairing* (ELP) is defined to contain two 0s (note that an LP does not contain any 0s) and that these two 0s be neighboring. Formally, an ELP, $\{l'_i\}_{0\le i\le 2(n+1)-1}$ of order n, which is a permutation of the sequence of $2(n+1)$ integers:

$$\{0, 0, 1, 1, 2, 2, \ldots, n, n\}.$$

The sequence satisfies the Langford property, i.e., if $l_i = l_j, 0 \le i < j \le 2(n+1)-1$, then $j - i = l_i + 1$. For example, the sequence

$$l' = \{0, 0, 3, 1, 2, 1, 3, 2\},$$

is an extended Langford pairing (ELP) of order $n = 3$.

Multichannel Broadcast Process

In a cellular network, the BS and the users in the BS's service area are secondary users, and they are equipped with CRs operating over broadcast channels. Due to PU's activities or interference from coexisting networks, a broadcast channel may become unavailable at any time. Therefore, the BS has to broadcast the content over multiple channels to ensure the successful delivery to users, and such a process is called a *multichannel broadcast* process.

Suppose there are N broadcast channels, labeled as $0, 1, 2, \ldots, N-1$. The BS is equipped with multiple broadcast radios, labeled as $r_1, r_2, \ldots, r_R$, where R is the total number of the BS's broadcast radios. There are U users $s_1, s_2, \ldots, s_U$ in the service area. Every user is equipped with a single radio interface.

Broadcast via Channel Hopping (CH)

To implement the multi-channel broadcast protocol, a BS's broadcast radio or a user's radio can hop across multiple broadcast channels to deliver or to receive the broadcast content. Thus, the channel hopping (CH) sequence is chosen to define the order with which a BS's broadcast radio (or a user's radio) visits the set of broadcast channels.

Consider a time-slotted communication system, where a global system clock exists. The local clock of each node may be synchronized to the global clock or may differ with the global clock by a certain amount of clock drift. A radio is assumed to be capable of hopping between different channels according to a channel hopping sequence and its local clock. A packet can be exchanged between two radios if they hop onto the same channel in the same time slot.

Then, a CH sequence u of period T can be represented as a sequence of channel indices:

$$u = \{u_0, u_1, u_2, \ldots, u_i, \ldots, u_{T-1}\},$$

where $u_i \in [0, N-1]$ represents the channel index of the ith time slot of CH sequence u. If $u_i = u_j, \forall i, j \in [0, T-1]$, the radio using u as its CH sequence stays on the same channel and does not hop.

Given two CH sequences of period T, u and v, if there exists $i \in [0, T-1]$ such that $u_i = v_i = h$, where $h \in [0, N-1]$, we say that a *broadcast delivery* occurs between u and v in the ith time slot on broadcast channel h. The ith time slot is called a *delivery slot* and channel h is called a *delivery channel* between u and v.

Given N channels, let $\mathscr{C}(u, v)$ denote the *set of delivery channels* between two CH sequences u and v. The cardinality of $\mathscr{C}(u, v)$ is called the *number of broadcast delivery channels*, denoted by $|\mathscr{C}(u, v)|$, and $|\mathscr{C}(u, v)| \in [0, N]$. The number of

broadcast delivery channels measures the number of channels in which successful broadcast delivery occurs, i.e., the diversity of broadcast delivery channels.

Let $\mathscr{T}(u, v)$ denote the *set of delivery slots* between two CH sequences u and v, and $|\mathscr{T}(u, v)| \in [0, T]$. The cardinality of $\mathscr{T}(u, v)$ reflects the number of times lots in which successful broadcast delivery occurs within a period.

Broadcast by Multiple Radios

To reduce the broadcast latency, the BS is allowed to use a set of broadcast radios, denoted by $\mathscr{B} = \{r_1, r_2, r_3, \ldots, r_R\}$. Since the BS has multiple radios, the broadcast delivery occurs between the BS and a user s if the broadcast delivery occurs between one of the BS's broadcast radios and the user s's radio – i.e., the broadcast delivery occurs between a radio set $\mathscr{B}$ and a user s if there exists a radio $r_i \in \mathscr{B}$ such that a broadcast delivery occurs between the CH sequences of radios r_i and s. To simplify the notation, it is recommended to use r_i to denote the CH sequence of the BS's broadcast radio $r_i \in \mathscr{B}$ and use s to denote the CH sequence of user s's radio.

The *set of broadcast delivery channels* between the BS with its set of broadcast radios $\mathscr{B}$ and a user s is the union of the sets of broadcast delivery channels between each broadcast radio of the BS and the user s's radio, i.e., let $\mathscr{C}(\mathscr{B}, s) = \bigcup_{r \in \mathscr{B}} \mathscr{C}(r, s)$ denote the set of broadcast delivery channels between the BS with its set of broadcast radios $\mathscr{B}$ and the user s's radio, and the cardinality of $\mathscr{C}(\mathscr{B}, s)$ is called the *number of delivery channels*, denoted by $|\mathscr{C}(\mathscr{B}, s)|$, and $|\mathscr{C}(\mathscr{B}, s)| \in [0, N]$.

Similarly, the *set of delivery slots* between the BS with its set of broadcast radios $\mathscr{B}$ and a user s is the union of the sets of delivery slots between each broadcast radio of the BS and the user s's radio, i.e., let $\mathscr{T}(\mathscr{B}, s) \triangleq \bigcup_{r \in \mathscr{B}} \mathscr{T}(r, s)$ denote the *set of delivery slots* between the BS with its set of broadcast radios $\mathscr{B}$ and the user s's radio, and $|\mathscr{T}(\mathscr{B}, s)| \in [0, T]$.

An Asynchronous Multichannel Broadcast System

Given a CH sequence u, use $rotate(u, k)$ to denote a *cyclic rotation* of CH sequence u by k time slots, i.e.,

$$rotate(u, k) = \{v_0, \ldots, v_j, \ldots v_{T-1}\},$$

where $v_j = u_{(j+k) \bmod T}$, $j \in [0, T-1]$. For example, given $u = \{0, 1, 2\}$ and $T = 3$, $rotate(u, 2) = rotate(u, -1) = \{2, 0, 1\}$.

Define an *asynchronous multichannel broadcast (AMB)* system $\mathscr{M}$ with CH period T as an ordered pair $(\mathscr{B}, \mathscr{U})$:

- $\mathscr{B}$ is the set of CH sequences of period T used by broadcast radios of the BS. Suppose $\mathscr{B} = \{r_1, r_2, r_3, \ldots, r_R\}$, where R is the number of the BS's broadcast radios, and the BS's broadcast radio r_i uses the CH sequence r_i in $\mathscr{B}$.

- $\mathscr{U}$ is the set of CH sequences of period T used by the users. Suppose $\mathscr{U} = \{s_1, s_2, s_3, \ldots, s_U\}$, where U is the number of users, and the user s_j's radio uses the CH sequence s_j in $\mathscr{U}$.

An AMB system must satisfy the *rotation closure property*: $\forall k, l \in [0, T-1]$, $\forall s \in \mathscr{U}$, there exists $r \in \mathscr{B}$ such that $|\mathscr{C}(rotate(s,k), rotate(r,l))| \geq 1$. And thus the design problem of CH sequences of the BS's broadcast radios and users' radios is mapped to the design problem of an AMB system with rotation closure property. And the rotation closure property implies that for all possible clock drifts between the BS and users, every user can have successful broadcast delivery with the BS, i.e., with one of the BS's broadcast radios.

In other words, in an AMB system, the BS, with each broadcast radio using CH sequences in $\mathscr{B}$, can deliver broadcast messages to all users using CH sequences in $\mathscr{U}$ via a channel hopping process for all possible clock drifts.

Performance Metrics

Given an AMB system $\mathscr{M} = (\mathscr{B}, \mathscr{U})$, the following metrics are defined to evaluate its performance.

- **Delivery channel diversity**. The delivery channel diversity for an AMB system measures the lower bound of the number of delivery channels between the BS and an arbitrarily given user for all possible clock drifts. The delivery channel diversity, denoted by $DIV(\mathscr{M})$, is the minimum number of delivery channels $|\mathscr{C}(\mathscr{B}, rotate(s,k))|$ for every $s \in \mathscr{U}$ and every $k \in \mathbb{Z}$, i.e.,

$$\begin{aligned} DIV(\mathscr{M}) &= \min_{s \in \mathscr{U}, k \in \mathbb{Z}} |\mathscr{C}(\mathscr{B}, rotate(s,k))| \\ &= \min_{s \in \mathscr{U}, k \in \mathbb{Z}} |\bigcup_{r \in \mathscr{B}} \mathscr{C}(r, rotate(s,k))|. \end{aligned}$$

- **Broadcast latency**. To quantify the broadcast latency, we define the maximum broadcast latency for a given AMB system as the upper bound of the latency before the first successful broadcast delivery between the BS and an arbitrary user on at least one channel for all possible clock drifts, which can be computed by

$$\max_{s \in \mathscr{U}, k \in \mathbb{Z}} [\min \mathscr{T}(\mathscr{B}, rotate(s,k))].$$

- **Delivery ratio**. To measure the proportion of delivery slots in a period, first it is needed to define the delivery ratio for a CH sequence pair. The delivery ratio for a CH sequence pair r and s, denoted by $\rho(r,s)$, is

$$\min_{k,l \in \mathbb{Z}} (|\mathscr{T}(rotate(r,k), rotate(s,l))|/T).$$

And then introduce the delivery ratio for an AMB system $\mathscr{M} = (\mathscr{B}, \mathscr{U})$, which measures the minimum proportion of delivery slots in all time slots. To be precise, the delivery ratio is

$$\rho(\mathscr{M}) \triangleq \min_{s\in\mathscr{U},k,l\in\mathbb{Z}} \frac{\sum_{r\in\mathscr{B}} |\mathscr{T}(rotate(r,k), rotate(s,l))|}{|\mathscr{B}|T}.$$

Extended Langford Pairing-Based Broadcast Protocols

An AMB system $\mathscr{M} = (\mathscr{B}, \mathscr{U})$ is constructed based on the extended Langford pairing (ELP). To illustrate the design of the ELP-based AMB system, it is better to first investigate a simple scenario in which the BS has a single radio, i.e., $|\mathscr{B}| = 1$, and there is only a single user, i.e., $|\mathscr{U}| = 1$. Then, the problem in a general scenario will be addressed where $|\mathscr{B}|$ and $|\mathscr{U}|$ are generally greater than 1.

CH Sequence Generation

In the ELP-based channel hopping protocol for AMB systems with a single radio pair, $\mathscr{M} = (\{r\}, \{s\})$, where r is the only BS radio and s is the only user.

First look at the simple scenario where $|\mathscr{B}| = |\mathscr{U}| = 1$, i.e., $\mathscr{B} = \{r\}$ and $\mathscr{U} = \{s\}$.

Consider the original Langford pairing (LP). If N is congruent to 0 or 3 modulo 4, there exists an LP $\{l_i\}_{0\le i\le 2N-1}$ of order N. Suppose both r and s use the CH sequence $\{l_i - 1\}_{0\le i\le 2N-1}$ of period $2N$. If s is one time slot ahead, the broadcast delivery cannot occur between r and s. For example, suppose the channel number $N = 3 \equiv 3 \pmod 4$ and $\{3, 1, 2, 1, 3, 2\}$ is an LP of order 3. Both r and s use the CH sequence $\{2, 0, 1, 0, 2, 1\}$ of period 6. If s is one time slot ahead, the broadcast delivery cannot occur between r and s , i.e., $|\mathscr{C}(r, rotate(s, 1))| = 0$.

However, an AMB system can be constructed by using ELP. If the channel number N is congruent to 0 or 1 modulo 4, then $N - 1$ is congruent to 0 or 3, there exists an ELP $\{l'_i\}_{0\le i\le 2N-1}$ of order $N - 1$. For example, when $N = 4$, the ELP-based CH sequence is

$$u = \{0, 0, 3, 1, 2, 1, 3, 2\}.$$

When $N \not\equiv 0, 1 \pmod 4$, easily use the *downsizing scheme* or the *padding scheme* to transform it into an AMB system design problem with the channel number N' congruent to 0 or 1 modulo 4.

Downsizing scheme. Suppose the channel number $N \not\equiv 0, 1 \pmod 4$, let N' be $\max\{N' \le N : N' \equiv 0, 1 \pmod 4\}$. It is easy to see that $|N - N'| \le 2$. The donwsizing scheme will limit the set of broadcast channels to a N'-element subset of the original broadcast channel set, e.g., $\{0, 1, 2, \ldots, N' - 1\}$ is used as the new broadcast channel set.

Padding scheme. Suppose the channel number $N \not\equiv 0, 1 \pmod 4$, let N' be $\min\{N' \geq N : N' \equiv 0, 1 \pmod 4\}$. It is easy to see that $|N - N'| \leq 2$. In contrast with the downsizing scheme, the padding scheme introduces $N' - N$ more channels but maps them to the original broadcast channels in $\{0, 1, 2, \ldots, N-1\}$. For example, suppose $N = 7$ and then $N' = 8$. Now add one more channel, i.e., channel 7, and adjoin channel 7 to the original broadcast channel set $\{0, 1, 2, \ldots, 6\}$, but channel 7 is an alias of channel 0 – i.e., it is mapped to channel 0.

For instance, if $N \equiv 2 \pmod 4$, use the downsizing scheme and $|N - N'| = 1$; if $N \equiv 3 \pmod 4$, use the padding scheme and $|N - N'| = 1$. And this will only lead to a very mild degradation of performance since $|N - N'| = 1$.

With the aid of the downsizing scheme and the padding scheme, the problem in focus becomes the AMB design problem with the channel number N' congruent to 0 or 1 modulo 4.

A Simple Broadcast (S-Broadcast) Scheme for a Single CH Sequence Pair

This section presents a simple broadcast scheme, called *S-Broadcast*, for the simple scenario of the AMB system ($\mathscr{M} = (\{r\}, \{s\})$) design problem.

Motivation. If the broadcast radio r and the user radio s both use the same ELP $u = \{l'_i\}_{0 \leq i \leq 2N'-1}$, the successful broadcast delivery between them is guaranteed; however, the delivery channel diversity is not ensured. If the broadcast radio uses cyclic rotated copies of u and the user radio uses periodically extended u, the delivery channel diversity will be increased.

To be precise, the CH sequences for the broadcast and user radios can be generated as follows:

1. The broadcast radio generates its CH sequence

$$r = \prod_{f=1}^{F} rotate(u, o_f),$$

   where $\{o_f\}_{1 \leq f \leq F}$ is a sequence of integers that are used to deliberately manipulate the clock drift and $\prod_{f=1}^{F} \theta_f$ denotes the concatenation of strings $\theta_1, \theta_2, \theta_3, \ldots, \theta_F$, i.e., $\prod_{f=1}^{F} \theta_f = \theta_1 \parallel \theta_2 \parallel \theta_3 \parallel \cdots \parallel \theta_F$.
2. The user radio generates its CH sequence as $s = \prod_{f=1}^{F} u$, which is the periodic extension of u.

The *delivery channel determination function* is defined as

$$\delta : \mathbb{Z} \to \mathbb{Z}.$$

For $k \in \mathbb{Z}$, $k \equiv g \pmod{2N'}$ where $|g| \leq N'$, then $\delta(k) = |g| - 1$. For example, when $N' = 4$, $\delta(1) = 0$, $\delta(2) = 1$, $\delta(3) = 2$, $\delta(4) = 3$, $\delta(5) = 2$, $\delta(6) = 1$, $\delta(7) = 0$, and in particular $\delta(0) = -1$.

S-Broadcast. The proposed broadcast protocol for the simple scenario of the AMB system ($\mathscr{M} = (\{r\}, \{s\})$) design problem, S-Broadcast, is an asynchronous CH-based channel broadcast protocol that achieves the broadcast latency at most $2N' - 1$, the delivery ratio $\rho = \frac{1}{N'}$ and full diversity. According to the design of S-Broadcast,

- $r = \prod_{f=1}^{2N'} rotate(u, f-1)$.
- $s = \prod_{f=1}^{2N'} u$.

Two examples illustrating the CH sequences of S-Broadcast when $N' = 4$ are shown in Fig. 6.

A Multichannel Broadcast (Mc-Broadcast) Scheme for Multiple CH Sequence Pairs

In the general AMB system design problem, $|\mathscr{B}|$ and $|\mathscr{U}|$ are generally greater than 1, i.e., $\mathscr{B} = \{r_1, r_2, r_3, \ldots, r_R\}$, $\mathscr{U} = \{s_1, s_2, s_3, \ldots, s_U\}$, $R, U \geq 1$. This section presents two ELP-based CH protocols, *A-Broadcast* and *L-Broadcast*, for the case $R \geq 2N'$ and the case $R < 2N'$, respectively.

Then, a multichannel broadcast protocol, called *Mc-Broadcast*, is the hybrid of the two above ELP-based CH protocols – i.e., it adopts A-Broadcast if $R \geq 2N'$ and it adopts L-Broadcast if $R < 2N'$.

Suppose $u = \{l'_i\}_{0 \leq i \leq 2N'-1}$ is an ELP of order $N' - 1$. The roadcast delivery can occur between any two cyclic rotation copies of u, say, between $rotate(u, k)$ and $rotate(u, l)$ – i.e., if $\forall 1 \leq i \leq R$, $r_i = rotate(u, o_i)$, and $\forall 1 \leq j \leq U$, $s_j = u$, $\mathscr{M} = (\mathscr{B}, \mathscr{U})$ is an AMB system. However, full delivery channel diversity ($DIV(\mathscr{M}) = N'$) is not necessarily guaranteed, and it is expected to reduce the broadcast latency. To take the advantage of multiple broadcast radios of the BS, it would be beneficial to select o_i's properly so as to achieve full delivery channel diversity, reduce the broadcast latency down to zero and guarantee successful broadcast delivery in every time slot.

Define the *balance sequences* as

$$\psi_i^{n,k} (0 \leq i < \mathrm{lcm}(n,k)/k),$$

where $\psi_i^{n,k}$ is a sequence of k elements and $\mathrm{lcm}(n,k)$ is the least common multiple of n and k. Denote the j-th element in $\psi_i^{n,k}$ by $\psi_{i,j}^{n,k}$, where $0 \leq j < k$. And let

$$\psi_{i,j}^{n,k} \triangleq (ik + j) \bmod n \in [0, n-1].$$

It is easy to see that $\{ik + j | 0 \leq i < \mathrm{lcm}(n,k)/k, 0 \leq j < k\} = \{0, 1, 2, 3, \ldots \mathrm{lcm}(n,k) - 1\}$. Hence $\forall n_0 \in [0, n-1]$, there exist exactly $\frac{\mathrm{lcm}(n,k)}{n}(i, j)$-pairs such that $\psi_{i,j}^{n,k} = (ik + j) \bmod n = n_0$.

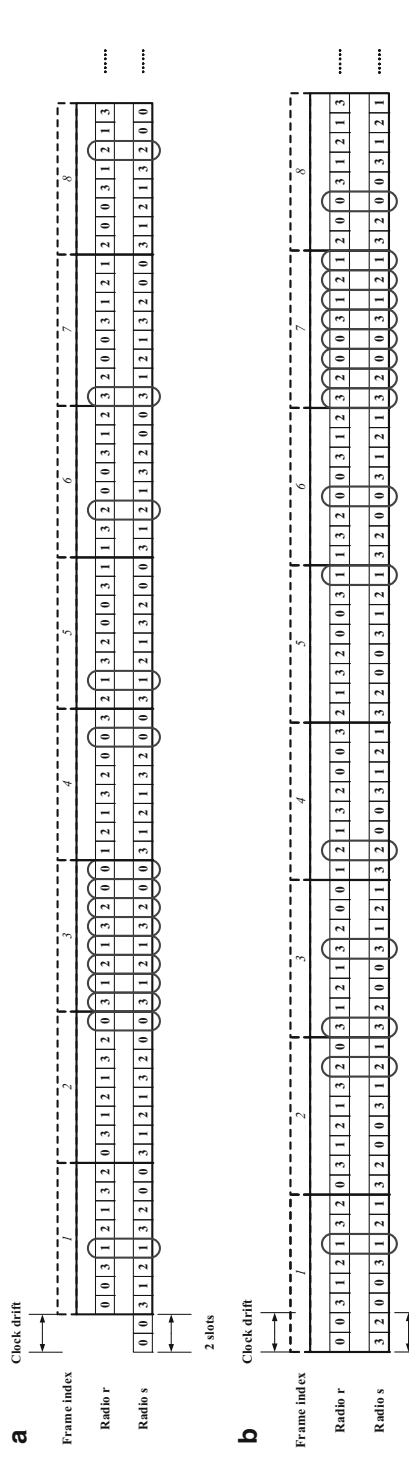

Fig. 6 Example illustrating the CH sequences of S-Broadcast when $N' = 4$. Radio r is the BS's broadcast radio, and there is only one user, i.e., radio s. The CH sequences of the two radios can achieve full diversity within a period of $4N'^2 = 64$ time slots, given a clock drift of two slots either forwards or backwards. The delivery latency in (**a**) and (**b**) is 3 and 5 time slots, respectively, both less than $2N' - 1 = 7$. And the delivery ratios in these two figures are both $\frac{1}{N'} = \frac{1}{4}$

As a result, $\forall n_0 \in [0, n-1]$, there exist exactly $\frac{\text{lcm}(n,k)}{n}$ (i, j)-pairs such that $\psi_{i,j}^{n,k} = (ik + j) \bmod n = n_0$.

A-Broadcast when $R \geq 2N'$: If the BS has a large number of broadcast radios, i.e., $R \geq 2N'$, the AMB system can be designed to have guaranteed successful broadcast delivery in every time slot and full delivery channel diversity. Suppose $R = 2qN' + w$, where $q = \lfloor \frac{R}{2N'} \rfloor \geq 1$ and $0 \leq w < 2N'$. A-Broadcast is designed as follows:

- $\forall 1 \leq i \leq 2qN', r_i = rotate(u, (i-1) \bmod 2N')$.
- $\forall 1 \leq i \leq w$, from time slot $\lfloor \frac{t_B}{2N'} \rfloor$ to time slot $\lfloor \frac{t_B}{2N'} \rfloor + (2N' - 1)$, radio $r_{2qN'+i}$ uses

$$rotate\left(u, \psi^{2N',w}_{\lfloor \frac{t_B}{2N'} \rfloor \bmod \text{lcm}(2N',w)/w, i-1}\right)$$

  as its CH sequence, where t_B is the BS's local clock time (i.e., according to the BS's local clock, it is the t_B-th time slot).
- $\forall 1 \leq j \leq U, s_j = u$.

An example illustrating the CH sequences of A-Broadcast when $N' = 4$ is shown in Fig. 7.

The A-Broadcast protocol has the following properties [4].

- A-Broadcast has zero broadcast latency.
- It achieves full delivery channel diversity. And the interval (i.e., $2N'$) is bounded – within every $2N'$ time slots, it achieves full delivery channel diversity.
- The delivery ratio is $\frac{1}{N'}$.
- In every time slot, every user can receive broadcast delivery from at least $2q$ BS radios, and on average $\frac{R}{N'}$ radios.

L-Broadcast when $R < 2N'$: If the number of BS broadcast radios R is less than $2N'$, we can also use the balance sequence to achieve delivery channel diversity and maximize delivery ratio. L-Broadcast is an ELP-based protocol, which is described as follows:

- $\forall 1 \leq i \leq R$, from time slot $\lfloor \frac{t_B}{2N'} \rfloor$ to time slot $\lfloor \frac{t_B}{2N'} \rfloor + (2N' - 1)$, radio r_i uses

$$rotate\left(u, \psi^{2N',R}_{\lfloor \frac{t_B}{2N'} \rfloor \bmod \text{lcm}(2N',R)/R, i-1}\right)$$

  as its CH sequence, where t_B is the BS's local clock time (i.e., according to the BS's local clock, it is the t_B-th time slot).
- $\forall 1 \leq j \leq U, s_j = u$.

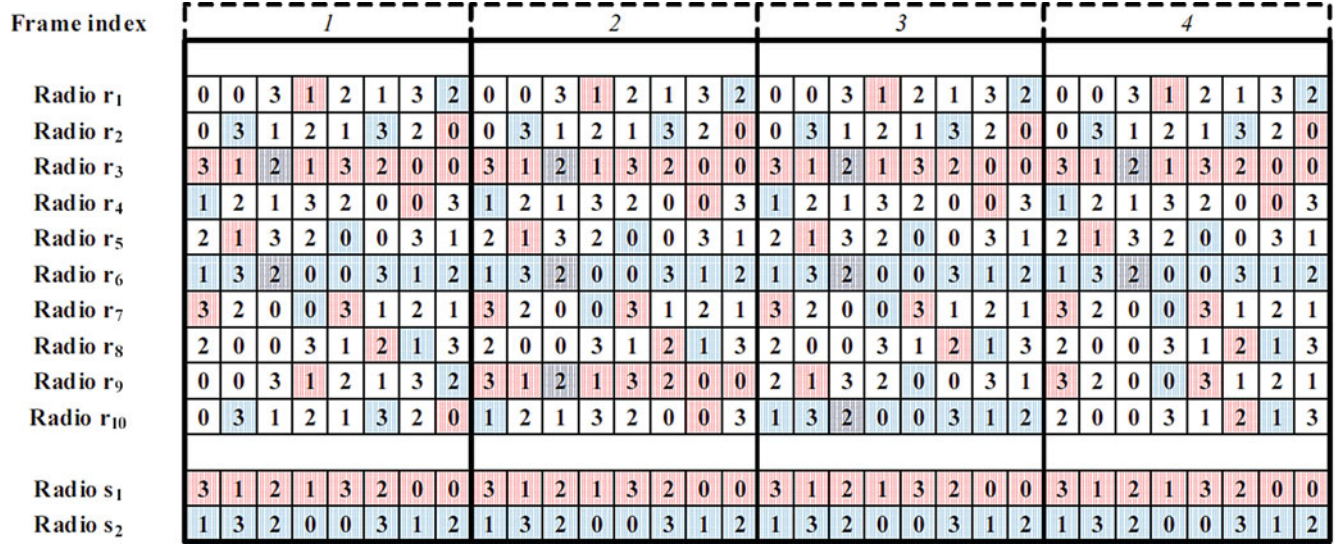

Fig. 7 Example illustrating the CH sequences of A-Broadcast when $N' = 4$. Radios $r_1, r_2, r_3, \ldots, r_{10}$ are the BS's broadcast radios and there are two users – radio s_1 and radio s_2. The clock of radio s_1 is two time slots behind (or six time slots ahead of) that of the BS while the clock of radio s_2 is three times lots ahead of (or five time slots behind) that of the BS. The blocks with *red/blue* fill pattern represents the time slots in which radio s_1/s_2 receives successful broadcast delivery from the BS, respectively, while the blocks with gray fill pattern represents the time slots in which both users (radios s_1 and s_2) receive successful broadcast delivery from the BS simultaneously. Both users can receive broadcast delivery from at least $2q = 2\lfloor \frac{10}{8} \rfloor = 2$ and on average $\frac{R}{N'} = \frac{10}{4} = 2.5$ BS's broadcast radios every time slot and achieve full broadcast channel diversity

An example illustrating the CH sequences of L-Broadcast when $N' = 4$ is shown in Fig. 8.

The L-Broadcast protocol has the following properties [4].

- The broadcast latency of the AMB system that implements L-Broadcast is at most $2N' - 1$.
- It achieves full delivery channel diversity. And the interval (i.e., $2N' \cdot \lceil \frac{2N'}{R} \rceil$) is bounded – it achieves full delivery channel diversity every $2N' \cdot \lceil \frac{2N'}{R} \rceil$ slots.
- In every time slot, every user can receive broadcast delivery from $\frac{R}{N'}$ radios on average.

Simulation

This section compares the performance of the proposed Mc-Broadcast protocol and other existing protocols, including the distributed broadcast protocol (or simply called "distributed") proposed in [43] and the random channel hopping scheme, via simulation results. In each simulated network cell, the BS has R broadcast radios available; a number of U users are connected to the BS, and each user has a single radio interface; each radio can access N broadcast channels (i.e., the number of broadcast channels available to the network is N). The BS or its connected users generate their CH sequences using the agreed broadcast scheme (i.e., either Mc-Broadcast, the distributed protocol, or the random channel hopping protocol) and perform CH in accordance with the sequences. Once two nodes hop onto the same channel that is free of primary user signals, the broadcast delivery between them is successful.

Traffic model. A number of X primary transmitters are simulated, operating on X channels independently, and these channels were randomly chosen in each simulation run. In most existing work, it is assumed that a primary user transmitter follows a "busy/idle" transmission pattern on a licensed channel [12, 18], and the same traffic pattern is assumed here. That is, the busy period has a fixed length of b time slots, and the idle period follows an exponential distribution with a mean of l time slots. A channel is considered "unavailable" when PU signals are present in it. The intensity of primary user traffic can be characterized as $PU = \frac{X}{N} \cdot \frac{b}{l+b}$.

Random clock drift. In a CR network, the BS and the user may lose clock synchronization or even link connectivity at any time when they experience the broadcast failure problem due to primary user affection. Hence, the clock of the BS and those of the users are not necessarily synchronized. In each simulation run, each secondary node (the BS and the users) determines its clock time independently of other nodes. Note that the radios of the BS are synchronized, and there is a random clock drift between the BS and any of its connected users.

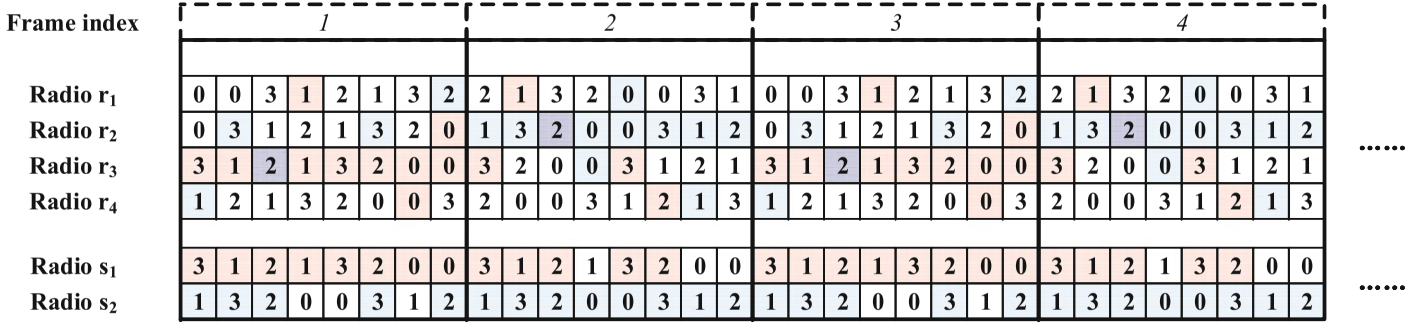

Fig. 8 Example illustrating the CH sequences of L-Broadcast when $N' = 4$. Radios r_1, r_2, r_3, r_4 are the BS's broadcast radios and there are two users – radio s_1 and radio s_2. The clock of radio s_1 is two time slots behind (or six time slots ahead of) that of the BS, while the clock of radio s_2 is three time slots ahead of (or five time slots behind) that of the BS. The blocks with *red/blue* fill pattern represents the time slots in which radio s_1/s_2 receives successful broadcast delivery from the BS, respectively, while the blocks with gray fill pattern represents the time slots in which both users (radios s_1 and s_2) receive successful broadcast delivery from the BS simultaneously. Both users can receive broadcast delivery from $\frac{R}{N'} = \frac{4}{4} = 1$ BS's broadcast radio on average and achieve full delivery channel diversity every $2N' \cdot \lceil \frac{2N'}{R} \rceil = 8 \cdot \frac{8}{4} = 16$ time slots

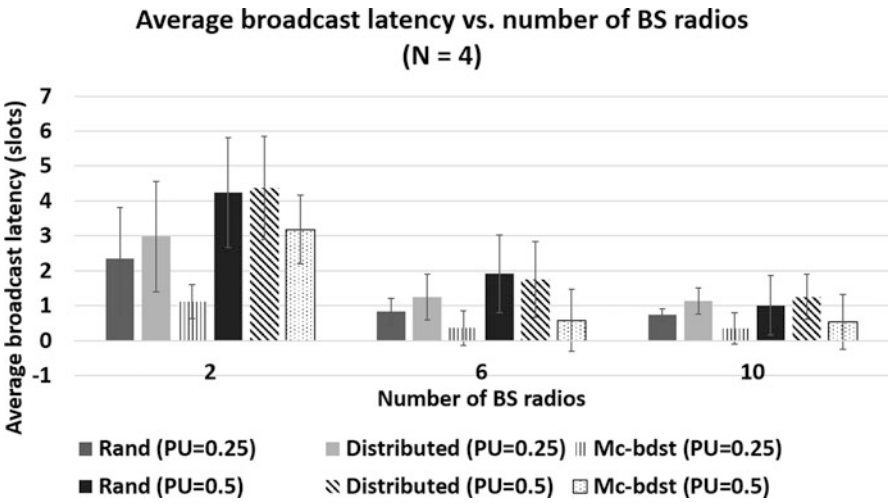

Fig. 9 The average broadcast latency versus the number of broadcast radios at the base station ($N = 4$), with a 95% confidence interval attached to each bar

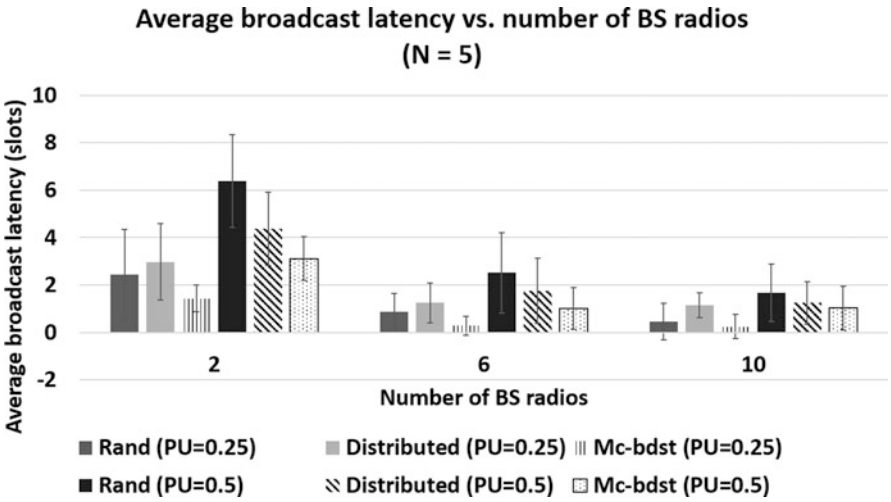

Fig. 10 The average broadcast latency versus the number of broadcast radios at the base station ($N = 5$), with a 95% confidence interval attached to each bar

Average broadcast latency. Figures 9 and 10 show the simulation results with respect to the average broadcast latency under the conditions $N = 4$, 5 and 8, respectively. It is illustrated that as the number of broadcast radios increases, it takes fewer time slots on average before the first successful delivery for both schemes under different PU traffic. This implies that a greater number of broadcast radios is conducive to mitigating the average broadcast latency.

It is noteworthy that for different numbers of available channels and different PU traffic, the average latency of Mc-Broadcast is smaller than those of other existing broadcast protocols.

Spectrum Sharing Problem

This section investigates the spectrum sharing problem among coexisting heterogeneous cellular networks.

To address this problem, it is needed to establish a coexistence framework that employs an *indirect* coordination method for enabling collaborative coexistence among networks. The proposed framework was inspired by the interspecies relations that exist in biological ecosystems. A *symbiotic* relation is a term used in biology to describe the coexistence of different species that form relations via indirect coordination. It exploits a *mediator* system (e.g., the 802.19.1 system) that forwards *sanitized* data to establish the indirect coordination mechanism between coexisting networks. It employs an *ecology inspired spectrum sharing* algorithm inspired by an interspecific resource competition model that enables each CR network to autonomously determine the amount of spectrum that it should appropriate without direct negotiation with competing networks. Results show that this framework guarantees weighted fairness in partitioning spectrum and improves spectrum utilization.

The Mediator System

The recently formed IEEE 802.19.1 task group (TG) was chartered with the task of developing standardized methods, which are radio access technology independent, for enabling coexistence among dissimilar or independently operated wireless networks [21]. This standard is currently being developed, and it has yet to prescribe solid solutions. The IEEE 802.19.1 system is a good candidate to serve as the mediator. The IEEE 802.19.1 system [21] defines a set of logical entities and a set of standardized interfaces for enabling coordination between heterogeneous CR networks. Figure 11 shows the architecture of an 802.19.1 system which includes three entities in the grey box: (1) the coexistence manager (CM) acts as the

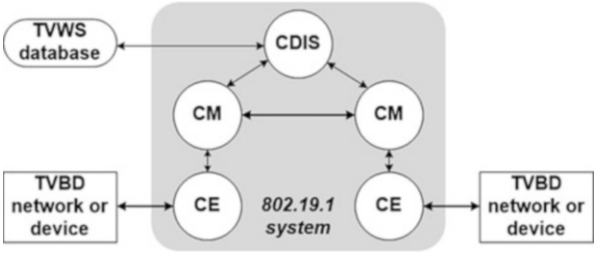

Fig. 11 IEEE 802.19.1 system architecture

local decision-maker of the coexistence process; (2) the coexistence database and information server (CDIS) provides coexistence-related control information to the CMs, and (3) the coexistence enabler (CE) enables communications between the 802.19.1 system and the TV band device (TVBD) network. The TVWS database indicates the list of channels used by primary users and their locations, and it is connected to the 802.19.1 system via backhaul connections.

Interspecific Competition in Ecology

In ecology, interspecific competition is a distributed form of competition in which individuals of different species compete for the same resource in an ecosystem without direct interactions between them [45]. The impact of interspecific competition on populations have been formalized in a mathematical model called the Lotka-Volterra (L-V) competition model [34,46]. In this model, the impact on population dynamics of species i can be calculated separately by a differential equation given below:

$$\frac{dN_i}{dt} = r_i N_i \left(1 - \frac{N_i + \sum_{j \neq i} \alpha_{ij} N_j}{K_i}\right). \tag{3}$$

In this equation, N_i is the population size of species i, K_i is the carrying capacity (which is the maximum population of species i if it is the only species present in the environment), r_i is the intrinsic rate of increase, and α_{ij} is the competition coefficient which represents the impact of species j's population growth on the population dynamics of species i.

Framework Overview

Consider n heterogeneous networks are co-located, and they coexist in the same spectrum band that includes N channels with an identical bandwidth. Let $\mathscr{K}$ denote this set of networks, and all of these networks in $\mathscr{K}$ are registered with the mediator system. Every network is composed of multiple devices and a base station (BS) (or access point). Channels are labeled with indices $0, 1, \ldots, N-1$.

Time-spectrum blocks. Time is divided into periods, each period contains a number of u superframes, and each super-frame contains f frames (such a structure based on frames can be found in IEEE 802.16 and 802.22). A time-spectrum block is the minimum unit for spectrum allocation, which can be defined by a channel index and a frame index. Specifically, a time-spectrum block can be represented using a three-tuple (i, j, k) – i.e., the k-th frame in the j-th superframe over channel i. Over channel i, there are a number of uf blocks that can be allocated during a period. It is assumed that a BS or network with multiple radios is able to scan and access

multiple time-spectrum blocks on different channels simultaneously. Furthermore, define the capacity, C, as the total number of spectrum-time blocks during a period, given N channels.

The bandwidth requirement. Define the *bandwidth requirement* of a network as the number of time-spectrum blocks that it needs to satisfy the QoS requirements of its traffic load. Let R_i denote the bandwidth requirement of network i.

The mediator-based indirect coordination. SHARE establishes a mediator-based *indirect* coordination mechanism between coexisting networks. There is no direct coordination between the coexisting networks, and they have to interact with each other by exchanging control information through a third-party mediator. Specifically, SHARE utilizes a CDIS (which is one of the components of an 802.19.1 system) as a mediator. Note that CDIS is not a global or centralized decision-maker, but rather it is an information directory server with simple data processing capabilities.

Necessity of sanitized information. The mediator helps address conflict-of-interest issues and customer privacy concerns, which may arise when coexisting networks operated by competing service providers are required to exchange sensitive traffic information in order to carry out coexistence mechanisms. The mediator *sanitizes* the sensitive information received from the coexisting networks and then returns the sanitized information back to them. The coexisting networks execute their coordinated coexistence mechanisms using the sanitized data.

Ecology Inspired Spectrum Allocation

As mentioned before, spectrum allocation among the coexisting networks through *direct* coordination may not be possible (due to a lack of infrastructure), may be too costly, or may be shunned by the competing network operators because they do not want to provide their sensitive information. Instead of direct coordination, the SHARE framework adopts an indirect coordination mechanism, which is inspired by an interspecific competition model from theoretical ecology.

Design objective. In a spectrum sharing process, a network has to figure out how much spectrum it can appropriate given its bandwidth requirement. Suppose a time-spectrum block is the minimum unit amount of spectrum allocation. Let S_i denote the *number of time-spectrum blocks* allocated to network $i \in \mathcal{K}$, and S_i refers to as the *spectrum share* of network i.

The objective is that the spectrum sharing process will eventually reach a state of equilibrium, where the number of allocated blocks to each network is proportional to its reported bandwidth requirement.

Inspiration from ecology. In ecology, the population dynamics of a species in the interspecific resource competition process can be captured by the L-V competition

model. In the context of network coexistence, a *weighted* competition model is built to help a network to determine the *dynamics of its allocated spectrum*, given its bandwidth requirement.

Information exchange between the mediator and a network. The mediator exchanges two types of control information with every CR network:

1. *Upload of local report*. Network i reports the current value of S_i to the mediator.
2. *Download of sanitized data*. The mediator replies back to network i with the sanitized data, i.e., sum of numbers of time-spectrum blocks of all other coexisting networks, i.e., $\sum_{j \neq i, j \in \mathscr{K}} S_j$.

Problem Formulation

Suppose that $\mathscr{K}$ denotes a set of n co-located networks that have individual bandwidth requirements $R_1, R_2, \ldots, R_n$, and operate over the same WS. The first objective for coexisting networks is to split the WS into n pieces that are proportional to their individual bandwidth requirements, without sharing individual bandwidth requirements with each other.

Let $\mathbf{S}(\mathscr{K}) = [S_1, S_2, \ldots, S_n]$ denote the *spectrum share vector* for $\mathscr{K}$ over the white space. The *fairness index*, $F(\mathbf{S}(\mathscr{K}))$, for networks in $\mathscr{K}$ is defined as follows:

$$F(\mathbf{S}(\mathscr{K})) = \frac{\left(\sum_{i \in \mathscr{K}} S_i\right)^2}{\sum_{i \in \mathscr{K}} R_i \cdot \sum_{i \in \mathscr{K}} R_i \left(\frac{S_i}{R_i}\right)^2}. \tag{4}$$

The maximum value of $F(\mathbf{S}(\mathscr{K}))$ is one (the best or weighted fair case), where the allocated spectrum share value of a network is proportional to its bandwidth requirement.

Let $\mathscr{I}_i$ denote the *set of shared control information* known by network i, and it is easy to see that $R_i \in \mathscr{I}_i$. However, it is assumed that $R_j \notin \mathscr{I}_i$ – i.e., co-located networks, i and j, do not know each other's bandwidth requirements.

A *weighted fair spectrum sharing allocation* problem is formulated for heterogeneous networks to dynamically determine their spectrum share values.

Problem 1. Given a set of n co-located networks, $\mathscr{K}$, operating over N channels, one has to solve the following problem to find the spectrum share vector for $\mathscr{K}$:

$$\begin{aligned} &\text{Maximize} \quad F(\mathbf{S}(\mathscr{K})) \\ &\text{subject to} \quad \frac{S_i}{S_j} = \frac{R_i}{R_j}, R_j \notin \mathscr{I}_i, \forall i, j \in \mathscr{K}. \end{aligned}$$

The first constraint $\frac{S_i}{S_j} = \frac{R_i}{R_j}$ guarantees the weighted fairness.

An Ecology-Inspired Spectrum Share Allocation Algorithm

The Stable Equilibrium of the L-V Competition Model

The L-V competition model provides a method for defining a state of "stable equilibrium" and finding the sufficient conditions for achieving it. If one considers the interspecific competition process described by equation (3), when $K_i = K_j$ and $\alpha_{ij} = \alpha_{ji}$ for any two species i and j, then the sufficient condition for stable equilibrium is $\alpha_{ij} < 1$.

The Basic Spectrum Competition Model

Table 1 shows a number of analogies between a biological ecosystem and a network system. Based on equation (3) and the analogies, the following *basic* spectrum competition model is obtained:

$$\frac{dS_i}{dt} = rS_i\left(1 - \frac{S_i + \alpha\sum_{j\neq i} S_j}{C}\right), \tag{5}$$

where S_i is the spectrum share for network i, and r is an intrinsic rate of increase. In equation (5), the carrying capacity is equal to the number of time-spectrum blocks in a period given N channels. A competition coefficient $\alpha < 1$ will guarantee a stable equilibrium – i.e., all the competing networks will have the same spectrum share value.

Next section shows how to extend the basic competition model to a weighted fair spectrum competition model that complies with the weighted fairness requirement (i.e., $\frac{S_i}{S_j} = \frac{R_i}{R_j}$ for any two networks i and j) in a state of stable equilibrium.

The Weighted Fair Spectrum Competition Model

The basic spectrum competition model guarantees a stable equilibrium where all the competing networks have the same spectrum share value. However, solutions to Problem 1 must satisfy the requirement of weighted fairness, which implies that the competing networks' spectrum share values are proportional to their bandwidth requirements. For example, if network i has a bandwidth requirement that is twice that of network j, then network i's allocated spectrum share should also be twice the allocated spectrum share of network j.

To support the weighted fairness in spectrum share allocation, a weighted fair spectrum competition model introduces the concept of "subspecies." A network with a higher bandwidth requirement would have a greater number of subspecies than a network with a lower bandwidth requirement. The bandwidth requirement R_i is used as the number of sub-species of network i.

Let $S_{i,k}$ denote the spectrum share allocated to the subspecies k of network i, where $k \in [1, R_i]$. In the *weighted* competition model, every subspecies k of network i calculates the change in its spectrum share according to the following equation:

$$\begin{aligned} \delta_{i,k} &= \frac{dS_{i,k}}{dt} \\ &= rS_{i,k}\left(1 - \frac{S_{i,k} + \alpha \sum_{\kappa \neq k} S_{i,\kappa} + \alpha \sum_{j \neq i} S_j}{C}\right). \end{aligned} \tag{6}$$

Then, network i obtains its spectrum share value by combining the spectrum share values of all its subspecies, i.e., $S_i = \sum_k S_{i,k}$.

Every network i periodically sends its spectrum share value S_i to the mediator, and then the mediator sends back the sanitized data $\beta_i = \sum_{j \neq i} S_j$ to network i. The spectrum share allocation process terminates when $\delta_{i,k} = 0$ for all i and k. Note that the sanitized data β_i is used (instead of actual bandwidth requirement information) to mitigate conflict of interest and privacy issues that may arise between competing networks. The use of sanitized data coincides with the second constraint of Problem 1. The procedure is described as below.

1. A network i starts its spectrum share allocation process by creating a number of R_i sub-species.
2. At the beginning of every frame, every sub-species calculates the change rate of its spectrum share (i.e., $\frac{dS_{i,k}}{dt}$) using the sanitized data β_i obtained from the mediator.
3. If the change rate of the spectrum share is positive (or negative), a subspecies increases (or decreases) its spectrum share by randomly selecting a number of time-spectrum blocks to access (or releasing/freeing a number of occupied time-spectrum blocks).
4. At the end of every iteration, every network i calculates its new spectrum share value by $S_i = \sum_k S_{i,k}$, and sends S_i to the mediator. Meanwhile, the network updates the value of β_i from the mediator.
5. Last three steps are repeated until there is no subspecies with a non-zero change rate of spectrum share; that is $\frac{dS_{i,k}}{dt} = 0$ for every subspecies k of any network i.
6. The allocated spectrum share for network i is $\sum_k S_{i,k}$.

In this framework, the spectrum share allocation algorithm satisfies the requirement of weighted fairness.

Simulation

This section evaluates the performance of the proposed approach by looking into the stable equilibrium achieved by the weighted fair spectrum share allocation scheme.

Consider two CR networks that coexist in a block of spectrum that is divided into 20 channels, and fix the bandwidth requirements of the two networks as $R_1 = 2$ and $R_2 = 3$, which implies that network 1 has two subspecies and network 2 has three in the spectrum share allocation process. In the L-V competition model, the competition coefficient $\alpha < 1$ and the intrinsic rate of increase $r < 2$ [35]. The discussions on how to choose appropriate parameter values to achieve fast convergence to an equilibrium can be found in [35]. In this set of simulations, $\alpha = 0.9$ and $r = 1.95$.

Convergence to an equilibrium. Figure 12 shows the dynamics of the spectrum share value of each network and each subspecies within a network. "Subspecies (i, j)" in the figure legend represents sub-species j within network i. The system converges to an equilibrium state in finite time where all subspecies of every network are allocated the same spectrum share value. The aggregate spectrum share value allocated to a network is proportional to its bandwidth requirement.

Weighted Fairness. In each simulation run, the bandwidth requirement, R_i, of each network i is randomly chosen from the range $[1, 5]$. A "noncollaborative" allocation scheme implies that every coexisting network determines its spectrum share value without coordinating with others. This is equivalent to splitting the available spectrum "randomly" to n pieces and allocates them to n coexisting networks. The fairness values are measured using the fairness index defined in (4). Figure 13 clearly shows that SHARE allocates spectrum in a weighted fair manner, whereas the noncollaborative allocation scheme does not.

Channel Contention Problem

When coexisting networks have a means for direct coordinations, the channel contention protocol is a viable way of addressing the heterogeneous coexistence problem.

A channel contention protocol facilitates the dynamic spectrum allocation among coexisting networks in a *distributed* manner when a network is in need of spectrum to satisfy its *service requirement*. There is no need to start the spectrum sharing process for self-coexistence when the available spectrum is *sufficient* to satisfy all coexisting networks.

When the available spectrum is *insufficient*, every network (or network BS) occupies an amount of spectrum that is no more than it needs (i.e., its service

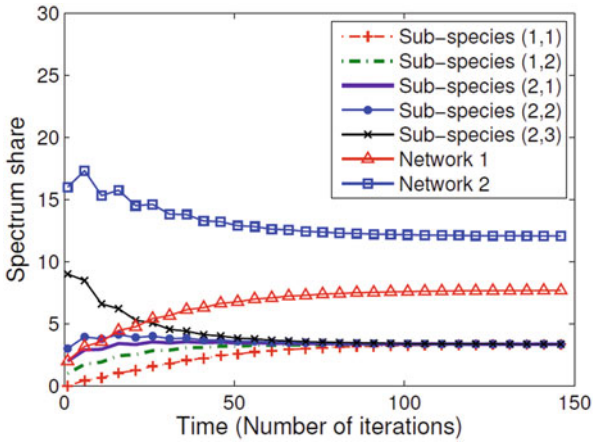

Fig. 12 Convergence to the equilibrium

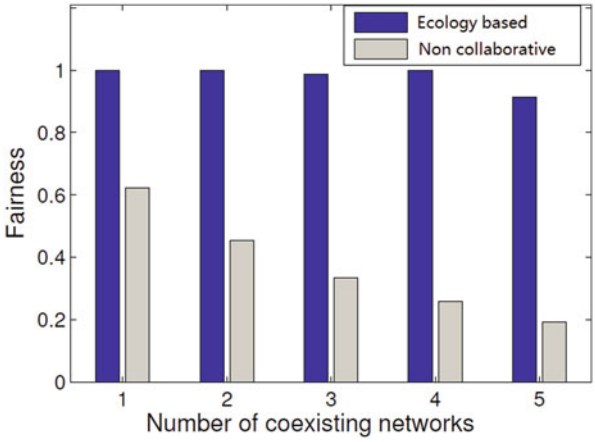

Fig. 13 Measured fairness values

requirement). IEEE 802.22 defines an inter-BS *spectrum contention* protocol for network cells to achieve the goal of self-coexistence.

- A BS that is in need of spectrum (*contention source* BS) is allowed to win channels via pairwise contentions with its neighboring BSs (*contention destination* BSs).
- If the contention source wins the contention, it occupies the contended channels exclusively, while the contention destinations vacate those channels via channel switching.

To ensure the fairness in the contention process, existing proposals adopt a simple *unbiased* contention resolution rule based on random number selection [16, 17], such that either a contention source or a contention destination has an equal probability of winning the pairwise contention.

However, the existing design of a coexistence protocol fails to consider the *successive* events that may be triggered by the spectrum redistribution during a *local* spectrum contention process. For example, the channel redistribution via contentions may satisfy the contention source, but meanwhile the contention destination that loses spectrum may become short of spectrum and successively initiate a *cascading* spectrum contention process to acquire more spectrums.A *cascade* is a series of events, in which the occurrence of an event can trigger the occurrence of successive events. As a result, unrestricted local spectrum contentions may trigger a series of successive contention instances that proliferate over the whole network, which may waste the network resources.

This section systematically studies the *spectrum contention* problem using the percolation theory in the context of coexisting cellular networks. The process of cascading spectrum contentions under existing spectrum contention resolution rules is equivalent to a *site percolation* process that can readily lead to a network-wide cascade. Moreover, a biased spectrum contention protocol is presented to mitigate this problem.

Spectrum Contention

When available spectrum is insufficient to satisfy all coexisting BSs, an 802.22 BS in need of spectrum can initiate an *inter-BS spectrum contention* process so that better channels or more channels can be acquired from neighboring BSs to satisfy the QoS of its workload [22].

1. The BS that initiates the spectrum contention process is the *contention source (SRC)*. A spectrum contention process consists of a number of pairwise contentions, and every pairwise contention is carried out between the SRC and a neighboring BS that is referred to as the *contention destinations (DST)*.
2. The SRC sends a contention request message to contend for a target channel that is currently occupied by a DST. The DST uses a specific *contention resolution rule* to determine the winner of the contention.
3. In the *unbiased* contention resolution rule [16, 17], every BS (either SRC or DST) is required to select a spectrum contention number (SCN) that is uniformly distributed in the range $[0, W-1]$, and exchange the SCN values, where W is a constant representing the contention window size.
4. The BS that has selected the *largest* CN among all participating BSs is the winner of the contention. Other BSs (and their 802.22 networks) that fail to win will vacate the channel.

Site Percolation

A *percolation* process resides in a graph including sites (vertices) or bonds (edges). The most common percolation model takes the graph structure of a regular lattice

(e.g., a square lattice). In the *site percolation process*, every site is either *open* (i.e., open to flow, diffusion, etc.) randomly and independently with probability p, or *closed* (i.e., closed to flow, diffusion, etc.) with probability $1 - p$.

Definition 2. A path is *open* if all its sites are open and it is *close* if all its sites are closed. Sites u and v are said to be *open connected* if there exists an open path that connects u and v. Define v to be open connected to itself.
It follows immediately that open connection is an equivalence relation. Write $u \leftrightarrow v$ if u and v are open connected, and $u \nleftrightarrow v$ if u and v are not open connected.

Definition 3. The *open cluster* $C(v)$ at site v is the set of all sites that are open connected to v, represented as

$$C(v) = \{u \in V | u \leftrightarrow v\}.$$

Intuitively, as p increases, the size of an open cluster also increases. At a critical value of p, the long-range connectivity in the network appears – there is a transition in the topological structure of the network from a macroscopically disconnected to a connected one – and thus this critical value is called the *percolation threshold* or *critical probability* [14]. Let p_c denote the percolation threshold, the following fundamental results can be obtained from percolation theory [14]:

- when $p > p_c$, with probability one, there exists an infinite cluster, and with a positive probability, the origin (or any other fixed point) belongs to an infinite cluster
- when $p < p_c$, all clusters are finite

When the graph structure resides in continuous space (e.g., a random geometric graph), the resulting percolation model is described as *continuum* percolation.

Network Model

Network graph. The placement of BSs of CR networks could transform to an undirected *network graph* $G = (V, E)$, where V is the set of vertices and E is the set of edges. Each vertex $i \in V$ represents a BS of a network cell, and the BS represented by a vertex i is called BS i. If two BSs i and j are neighboring to each other in the network, there is an edge $\{i, j\} \in E$ connecting the two vertices $i, j \in V$ (i.e., an inter-BS communication link connecting the two BSs). In this case, vertex j is said to be a *neighbor* of vertex i. Let $N(i)$ denote the set of all neighbors of vertex i in graph G: $N(i) = \{j \in V | \{i, j\} \in E\}$. The cardinality of $N(i)$ is called the degree of vertex i, written as $d(i) = |N(i)|$.

Base station placement on a lattice. In an 802.22 system, the rural area is divided into regular-shaped cells, which can be hexagonal, square, or some other irregular shapes. They are generalized to the notion of *lattice* [1], and three common types of lattices are triangular, square, and honeycomb lattices.

Service requirement Every BS i requires r_i channels to satisfy the QoS of its admitted workload, and N is the maximum number of available channels. The value of r_i, called the *service requirement of BS* i, depends on the intra-cell traffic demand raised by the secondary users (i.e., CPEs) connected to the BS i. Let A_i denote the set of channels that are occupied by BS i.

Every BS i tries to claim as many unoccupied channels as possible until $|A_i| = r_i$ or there is no unoccupied channels that can be claimed. Thus, $|A_i| \leq r_i$ for any BS i. To avoid co-channel interference, neighboring BSs i and j occupy disjoint sets of channels, i.e., $A_i \cap A_j = \varnothing$.

Network states. Every BS i occupies an amount of spectrum that is no more than its service requirement. It is assumed there are two states for a given CR network – a state wherein the BS is in need of spectrum, and a state wherein the BS does not need additional spectrum. These two states are called "starving" and "satisfied," respectively.

- When $|A_i| < r_i$, BS i is a *starving BS*.
- When $|A_i| = r_i$, BS i is a *satisfied BS*.

Causes for spectrum contention. The root cause for incurring spectrum contention is the existence of a starving BS. There are three factors that make a satisfied BS i become starving: (1) the reclaim of occupied channels in A_i by the primary user, (2) the increase of r_i due to an increased intra-cell workload, and (3) losing channels in A_i due to spectrum contentions.

The probability that a satisfied BS i becomes starving due to all these factors is called the *starving probability* of BS i, denoted by p_i. Meanwhile, call the probability that a satisfied BS i becomes starving due to non-contention (the first two) factors as *spontaneous starving probability*, denoted by $p_{i,0}$.

Problem Formulation

In an inter-BS spectrum contention process, the channel redistribution may satisfy the contention source BS i, but meanwhile a contention destination BS j that loses the target channel may become starving and successively initiate a cascading contention process. Therefore, the event that a BS j becomes starving is caused by a spectrum contention initiated by a starving BS i. That is, a local spectrum contention initiated by a BS may cause a cascade of spectrum

contentions, which will result in futile contention results and waste network resources. Such a phenomenon is referred to as a *cascading spectrum contention*, which is formulated as a site percolation process over the network graph as follows.

Similar to the definitions of open/closed sites (vertices) in the percolation process, define open/closed BSs in the context of CR networks. A vertex i in the network graph G is *open* if BS i is a starving BS, and call it an *open* BS. Otherwise, the vertex i is *closed* if BS i is a satisfied BS, and call it a *closed* BS.

Two BSs i and j are said to be *open connected* if there exists a path in the network graph that connects vertices i and j, and every vertex in this path is open. The *open cluster* at BS i is the set of all BSs that are open connected to BS i.

It is believed that BSs i and j in the same open cluster are related in a certain relationship of spectrum contentions, e.g., there may exist a path starting at BS i and ending at BS j, where a pairwise contention occurs between every pair of BSs along this path, or there exist two contention paths between k and i, k and j, where k is a third BS in the same cluster. The open cluster in the network graph describes the set of BSs that are in the "starving" state that may be caused by cascading spectrum contentions.

The size of an open cluster. Metrics in the percolation theory are used to quantify the magnitude of cascading spectrum contentions. Define the mean open cluster size at BS i as

$$\chi_i(p_i : i \in V) = E_{(p_i:i\in V)}(|C(i)|),$$

where $E_{(p_i:i\in V)}(X)$ denotes the expectation of a random variable X, given that BS i is open independently with probability p_i $(i \in V)$.

Lower bound case with starving probability p. There is a lower bound p of p_i's, i.e., $p \le p_i$, $\forall i \in V$. Thus $\chi_i(p_i : i \in V) \ge \chi_i(p) \triangleq E_p(|C(i)|)$, where $E_p(X)$ denotes the expectation given that every BS is open independently with probability p, i.e. $\chi_i(p)$ is a lower bound of $\chi_i(p_i : i \in V)$.

So far the study of $\chi_i(p_i : i \in V)$ is transformed into the study of $\chi_i(p)$ in a lower bound case where every BS i is open independently with probability p.

Since the placement of BSs of CR networks form a lattice $G = (V, E)$, whose automorphism group acts transitively upon V (also known as *vertex-transitive*) [1], then $\forall i, j \in V$, $C(i) = C(j)$ and $\chi_i(p) = \chi_j(p)$ due to the homogeneity of a lattice. Hence, simply use C and $\chi(p)$ instead of $C(i)$ and $\chi_i(p)$.

Therefore, the cascading spectrum contention process in CR networks is mapped to the lower bound site percolation process over the network graph where every vertex (BS) is open independently with probability p.

Global and Severe Cascades

Since $\chi(p)$ is defined to characterize the magnitude of cascading spectrum contentions, a *global* cascade of spectrum contentions occurs if the mean open cluster size is infinite, i.e., $\chi(p) = \infty$. According to the percolation theory, an infinite open cluster exists ($\chi(p) = \infty$) with probability one, if and only if $p \geq p_c$, where p is the starving probability and p_c is the critical probability.

In the subcritical phase when $p < p_c$, a severe cascade of spectrum contentions is to said to occur if the mean open cluster size $\chi(p) \geq \chi$ (χ is a predefined threshold, e.g., that χ is set to be 50 means that a cascade involving in over 50 BSs is considered to be a severe cascade), which suggests that an average open cluster of BSs is large.

A Biased Spectrum Contention Protocol

Contention Resolution Rule

A biased contention resolution rule is found to be effective to mitigate this problem by reducing the winning probability of a contention source in a pairwise contention. Define a *contention path* between BSs i and j as a path between vertices i and j in the network graph, such that the channel redistribution via a pairwise contention process occurs for every pair of neighboring BSs that belong to the path. The procedure for the biased contention resolution is described below.

1. In the contention request, every contention source BS i includes the target channel number h, its SCN s_i chosen from $[0, W-1]$, and the current length of the contention path l_i measured by BS i. If the BS i does not belong to any contention path, it sets $l_i = 0$, which implies that it is the starting vertex of a new contention path.
2. Every contention destination BS j checks the values of l_i and SCN s_i in the contention request from the contention source BS i. Let $S(j)$ denote the set of contention sources that send contention requests to BS j during a self-coexistence window.
3. If $|S(j)| > 1$, BS j is being reached by more than one contention paths. The contention destination BS j measures its l_j as $\max_{i \in S(j)}\{l_i\} + 1$ and generates its own SCN s_j from a modified contention window $[0, l_j \cdot W - 1]$. The measured value of l_j will be used by BS j in future contention requests if it becomes a contention source.
4. If the contention destination BS j has the greatest SCN value, it wins the contention. Otherwise, the contention source who has the greatest SCN value wins, and the contention destination BS j releases the target channel.

If $p_0 \geq p_c$, a global cascade of spectrum contentions is inevitable. The fact that $p_0 \geq p_c$ strongly suggests the insufficiency of overall spectrum resources. Next section discusses the case when $p_{i,0} < p_c$ for all $i \in V$.

Finite Cluster Size

Decreasing the winning probability of a contention source can prevent the occurrence of infinite contention paths. There is no infinite contention path if the biased contention resolution rule is used for contention resolution in the case of $p_{i,0} < p_c$, $\forall i \in V$.

Simulation

This section compares two contention resolution rules, namely, the unbiased rule and the proposed biased rule, in terms of feasibility of invoking the cascade phenomenon in spectrum contentions under various conditions in CR networks.

Simulation Setup

Topology. Consider simulating three typical lattices: coexisting BSs are placed on a honeycomb lattice ($d = 3$), a square lattice ($d = 4$), and a triangular lattice ($d = 6$), respectively.

Self-coexistence window and inter-BS spectrum contention. In a network cell, the BS provides broadband access to secondary users according to a time schedule consisting of *superframes*. 802.22 provides the inter-BS synchronization mechanism for neighboring BSs to align their superframes. In 802.22, a superframe has 16 frames, and a self-coexistence window (SCW) is periodically scheduled in every frame for spectrum contention.

Service requirement. There are a total number of $N = 30$ channels in the simulations. Every BS requires 10, 20, or 30 channels to satisfy the QoS of its admitted workload. Neighboring BSs occupy disjoint sets of channels, and a BS claims a number of channels which is no more than its service requirement.

Primary user (PU) traffic generation. It is assumed that there is one primary transmitter per cell, and every primary transmitter randomly selects $X \in [0, N_a]$ channels to emit its signals, where N_a is the number of PU's active channels. In most existing work, it is assumed that a primary transmitter follows a "busy/idle" traffic pattern on a licensed channel [12]. Hence, a "busy/idle" pattern is simulated for each primary transmitter: the busy period has a fixed length of b time slots, and the idle period follows an exponential distribution with a mean of l frames. Thereafter, the notation $\lambda_e = \frac{1}{l}$ is the *primary transmission rate*. Every BS is able to detect the signals from the primary transmitter in the same cell. A channel is considered "unavailable" when primary user signals are present in it. All secondary users (BSs) should vacate unavailable channels during the period of primary user transmission.

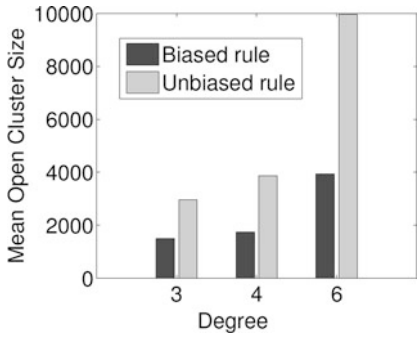

Fig. 14 Mean open cluster size vs. lattice degree

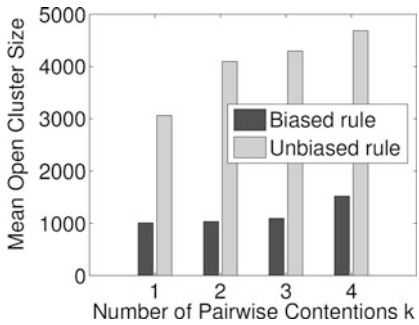

Fig. 15 Mean open cluster size vs. number of pairwise contentions

Phenomenon of Cascading Spectrum Contentions

The mean cluster size, χ, is measured when varying the following parameters: the degree d of the lattice where BSs are placed, the number k of pairwise contentions initiated by a contention source, and the PU traffic pattern (the number N_a of PU's active channels and the primary transmission rate λ_e).

Impact of lattice degree. In this set of simulations, we fix $r = k/d = 1$. In the honeycomb lattice case ($d = 3$), the mean open cluster size is the smallest, while the triangular lattice ($d = 6$) shows the largest mean open cluster size (Fig. 14). These results coincide with the previous conclusion, with $r = k/d$ fixed, there is a positive correlation between χ and d.

Impact of number of pairwise contentions. As is shown in Fig. 15, the more pairwise contentions initiated by a contention source, the larger the mean open cluster size.

Conclusion and Future Directions

This chapter reviews four important research problems for coexistence of heterogeneous cellular networks using cognitive radio technologies. Specifically, the hidden terminal problem can be factored into two types of collision problems, and the

beacon transmission scheme and the dynamic quiet period scheme can address them respectively. Next, it is showed that the channel hopping technique is useful to alleviate the broadcast failure problem in cellular CR networks by leveraging the Langford paring for creating channel hopping sequences. When the inter-network direct coordination is not feasible, a mediator system is able to establish an indirect coordination mechanism for spectrum sharing between networks. On the other hand, when the inter-network direct coordination is not supported, a local controller helps a CR network in need of more spectrum resources to acquire channels from neighboring networks via channel contention without causing the cascading contention problem.

Future work lies in three directions: (1) the evaluation of the coexistence schemes in the real-world scenarios of heterogeneous cellular networks, (2) how to address the violation to the conflict of interests and customer privacy when heterogeneous coexistence of cognitive cellular networks is feasible, and (3) the application of the cutting-edge machine learning techniques to upgrade the existing design principles and frameworks for the coexistence of heterogeneous cellular networks.

Abstract

Device-to-device (D2D) communication, which enables direct communication between nearby mobile devices, is an attractive add-on component to improve spectrum efficiency and user experience by reusing licensed cellular spectrum. Nowadays, LTE-unlicensed (LTE-U) emerges to extend the cellular network to the unlicensed spectrum to alleviate the spectrum scarcity issue. In this chapter, we propose to enable D2D communication in unlicensed spectrum (D2D-U) as an underlay of the uplink cellular network to further boom the network capacity. A sensing-based protocol is designed to support the unlicensed channel access for both LTE and D2D users, based on which we investigate the subchannel allocation problem to maximize the sum-rate of LTE and D2D users while taking into account their interference to the existing Wi-Fi systems. Specifically, we formulate the subchannel allocation as a many-to-many matching problem with externalities and develop an iterative user-subchannel swap algorithm. Analytical and simulation results show that the proposed D2D-U scheme can significantly improve the network capacity.

Introduction

With the explosive growth of mobile devices and bandwidth-hungry applications such as video streaming and multimedia file sharing, user demands for mobile broadband are undergoing an unprecedented rise, which pushes the limits of current LTE systems [1]. To improve spectrum efficiency and user experience, device-to-device (D2D) communications underlaying LTE networks have been proposed as a promising approach to facilitate high data rate services in a short range and boost the performance of LTE systems [1–3]. D2D communications underlaying LTE networks enable mobile devices in proximity to establish a direct link without traversing the base station (BS) and reuse the spectrum with the LTE system by the control of the BS [4–8]. With the centralized control at BS and the proximity of communication parties, D2D communications enjoy the benefits of fast access to the radio spectrum in terms of proximity gain, reuse gain, and paring gain [3,4,6].

In addition to excavating more capacity on licensed spectrum, the operators are motivated to expand LTE services to the unlicensed spectrum in order to alleviate congestion. Mobile traffic offloading is a conventional method, in which the data is offloaded to Wi-Fi networks [9–12]. However, the offloading schemes commonly suffer from low efficiency and poor guarantee of quality of service (QoS) due to the inferior performance of Wi-Fi and the lack of coordination between LTE and Wi-Fi systems [13]. In light of these issues, the 3rd Generation Partnership Project (3GPP) has initialed the research on Licensed Assisted Access (LAA) to integrate the unlicensed carriers with the licensed ones for data transmission [14]. Based on

the LAA scheme, the LTE-unlicensed (LTE-U) technology is proposed to extend LTE to the unlicensed spectrum to leverage the existing carrier aggregation (CA) technology [15, 16].

As LTE-U technology shows satisfying performance, a natural idea to further improve spectrum efficiency and system throughput is to extend D2D communications to the unlicensed spectrum, that is, D2D communications work as the underlay of LTE system in not only the licensed spectrum but also the unlicensed one. However, due to the mutual interference among LTE-U users, D2D users, and the opportunistic feature of unlicensed channel access in existing Wi-Fi systems, this extension turns out to be much complicated. In this work, we investigate the extension of the underlaid D2D communications to LTE-U networks, which we refer to as D2D-unlicensed (D2D-U). Different from most previous peer-to-peer communication technologies in the unlicensed spectrum such as Wi-Fi Direct [17–19], which builds the network upon the IEEE 802.11 infrastructure mode and allows users to negotiate with each other in an AP-like method, D2D-U requires assist and control from the central BS. With the involvement of BS, D2D users can work as an underlay of LTE system in both licensed and unlicensed spectra.

As aforementioned, the major challenges of implementing D2D-U are (1) the opportunistic feature of unlicensed channel access due to current 802.11 mechanism adopted by Wi-Fi systems and (2) the interference management issue among the three types of systems, i.e., the access and transmission of D2D-U users cannot cause too much additional interference to the existing Wi-Fi system as well as the LTE-U system. To cope with the first challenge, we design an access protocol in the unlicensed bands for D2D-U and LTE-U users, which is based on the sensing mechanism, to mitigate collision with the ongoing Wi-Fi transmissions. To deal with the second challenge, we first find the cleanest channel for data transmission and elaborate an approximated model to evaluate the interference to Wi-Fi networks. Then, we investigate the subchannel allocation problem to leverage the maximization of the sum-rate of LTE-U and D2D-U users and the protection of Wi-Fi performance. This subchannel allocation problem is originally a mixed integer nonlinear programming (MINLP) problem, which is generally NP-hard. For this reason, we reformulate it as a many-to-many game with externalities [20–24] and solve it with low computational complexity by designing an iterative user-subchannel swap matching algorithm.

The rest of the chapter is organized as follows. In section "Characteristics of LTE-U, D2D, and Wi-Fi Networks", we first introduce the PHY/MAC features of LTE, D2D, and Wi-Fi systems. In section "System Model", we describe the system model for the coexistence among LTE, D2D, and Wi-Fi users and discuss the interference issues. In section "Sensing-Based D2D-U Protocol", a sensing based protocol is elaborated to support LTE-U and D2D-U users in the unlicensed band [25]. Then we formulate the optimization problem for subchannel allocation as a many-to-many matching game with externalities in section "Problem Formulation". In section "Many-to-Many Matching-Based Subchannel Allocation", an iterative algorithm is designed to find a stable matching in the many-to-many matching game. In section "Performance Analysis", the system performance is discussed.

Numerical results in section "Simulation Results" evaluate the proposed algorithm and the performance of the D2D-U. Finally, conclusion remarks are drawn in section "Conclusions".

Characteristics of LTE-U, D2D, and Wi-Fi Networks

In this part, we sequentially elaborate the PHY/MAC characteristics of the coexisting systems, i.e., LTE and D2D users in the licensed/unlicensed bands, and existing Wi-Fi characteristics in the unlicensed band.

LTE-U Network

In PHY layer, LTE-U users can utilize both the licensed and unlicensed spectra, in which the spectrum bandwidth is divided into a series of orthogonal subchannels. We assume that each user is able to occupy multiple subchannels in one subframe. In addition, to guarantee reliable transmission of the control signaling, an active LTE-U user must hold at least one licensed subchannel [16].

For the sake of Wi-Fi protection, the LTE-U system are not allowed to keep occupying the unlicensed channel forever. Instead, there exists reserved transmission period for the Wi-Fi systems, in which the LTE-U users need to evacuate the unlicensed spectrum and allow the Wi-Fi systems enough time for transmission [16]. The reserved duration for Wi-Fi system can be adjusted by the current traffic. In particular, if the channel is sensed clean in the sensing phase, the LTE-U users can occupy the channel for the whole duty cycle.

And as for the MAC layer, the LTE-U system adopts a centralized MAC protocol, which always allocates the subchannels to the user that can maximize the target metric in every subframe.

Underlaid D2D Users

D2D users is allowed to utilize the licensed and unlicensed spectra in the underlay method. That is to say, multiple D2D users are allowed to work in licensed/unlicensed subchannels concurrently occupied by LTE users. Co-channel assignment of the LTE and D2D users will be more efficient and profitable for operators for it can achieve a better overall system performance. Similar to the LTE-U network, a D2D user also needs to occupy one licensed subchannel for control signaling. Besides, due to the low transmit power and short transmission range of D2D communications, the D2D communications are allowed to transmit in the unlicensed spectrum even in the reserved subframes for Wi-Fi system so long as the operating channel is sensed idle by the D2D transmitter.

In the MAC layer, a centralized protocol is also utilized, the BS controls the access of both types of users and decides the subchannel allocation in a centralized

manner to mitigate mutual interference or maximize the system sum-rate after receiving the estimated channel state.

Wi-Fi Systems

The Wi-Fi systems operate only in the unlicensed spectrum. Different from the OFDMA-based channel utilization in LTE systems, the Wi-Fi transmission covers the whole unlicensed channel. Thus, Wi-Fi systems allow only one user to occupy the channel at a time, and concurrent transmission leads to collision. In addition, the OFDM symbol durations in these two systems are different. For LTE the symbol duration is 71.4 ms, while Wi-Fi has a granularity of 4 ms. The PHY layer comparison of these two systems is shown in Fig. 1 [26].

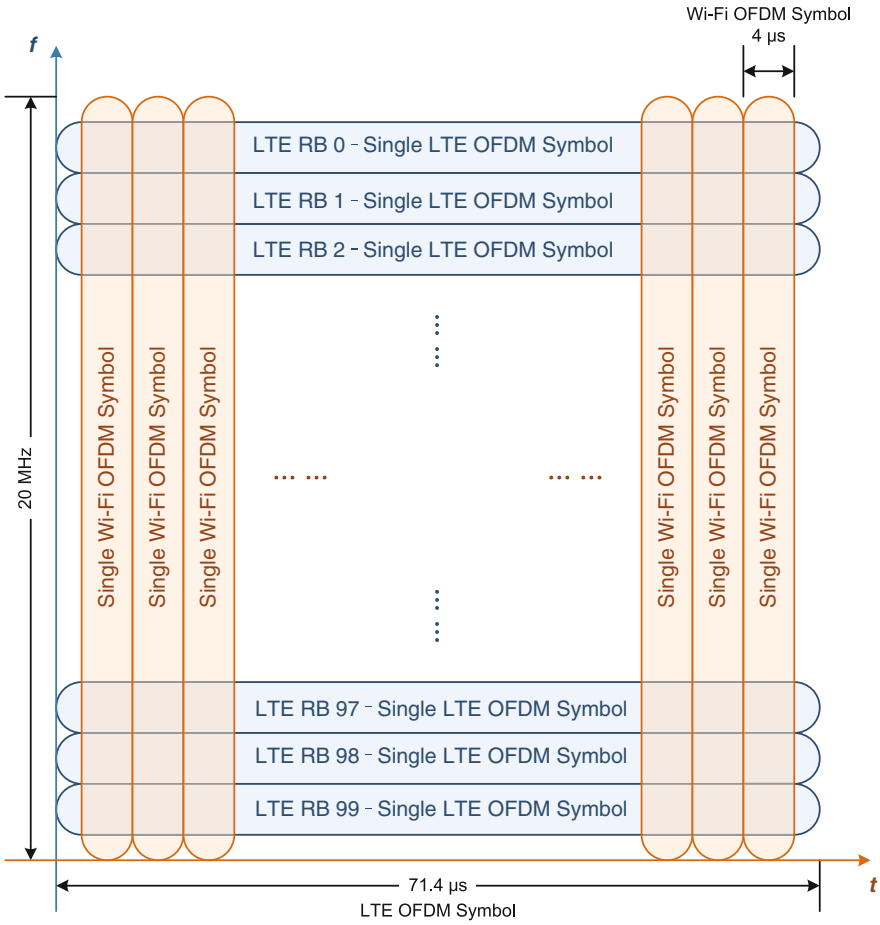

Fig. 1 PHY layer comparisons between LTE and Wi-Fi systems in both time and frequency domains

For the MAC layer, without a central controller, the Wi-Fi systems adopt a sensing and contention-based MAC protocol, i.e., carrier sense multiple access with collision avoidance (CSMA/CA) [27]. Specifically, before transmission, a Wi-Fi user first listens to the intended channel. If the channel is unoccupied, the Wi-Fi user begins backoff process to avoid collision; otherwise, the Wi-Fi user keeps sensing until the channel is judged idle.

System Model

In this section, we present the coexistence scenario of LTE, D2D, and Wi-Fi systems in both licensed and unlicensed spectra. Then, we discuss the interference issues within the coexistence network.

Scenario Description

As shown in Fig. 2, we consider an uplink scenario in an LTE network with one BS and Q Wi-Fi access points (APs), denoted by $q \in \mathcal{Q} = \{1, \ldots, Q\}$. The BS is located at the center, and the APs are randomly located around the BS. There exist N LTE users, denoted by $n \in \mathcal{N} = \{1, \ldots, N\}$, and M D2D users, denoted by $m \in \mathcal{M} = \{1, \ldots, M\}$. The LTE system owns licensed spectrum, and the bandwidth

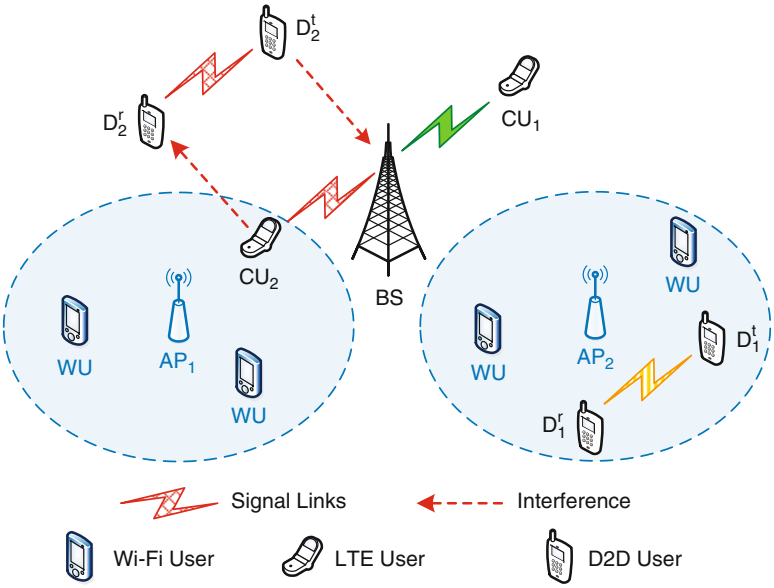

Fig. 2 System model for LTE, D2D, and Wi-Fi coexistence in both licensed and unlicensed spectra

is divided into K subchannels to support orthogonal frequency division multiple access (OFDMA) transmissions. The licensed subchannels are denoted by $\mathscr{K} = \{1, \ldots, K\}$, with uniform bandwidth B_l.

For the Wi-Fi system, we assume that within the coverage of AP q, there exist F_q Wi-Fi users marked by f_q ($f_q = 1, \ldots, F_q$). Besides, we assume that there are L unlicensed channels to support different APs, e.g., there are 23 channels for IEEE 802.11n in the 5 GHz band, and BS will select one of them to support LTE-U/D2D-U users. Since the unlicensed channel is much wider than one licensed subchannel in LTE system, each LTE-U or D2D user only requires a fraction of the unlicensed channel. Thus, to reuse the unlicensed channel more efficiently, the unlicensed channel is divided to K^u unlicensed subchannels with bandwidth B_u [28], marked by $\mathscr{K}^u = \{K + 1, \ldots, K + K^u\}$, so that multiple LTE-U and D2D users can transmit on the unlicensed channel concurrently.

We also assume that all devices transmit with fixed power, specifically, an LTE-U or D2D user transmits on any subchannel with power P^c or P^d, and the transmit power of the APs as well as the Wi-Fi users over the whole unlicensed channel is fixed on P^w. The free-space propagation path loss model with Rayleigh fading is adopted to model the channel gain between any two devices in the network, i.e., for the link from device i to device j, the received power can be expressed as

$$p_{i,j}^r = p_i^t \cdot |h_{i,j}|^2 = p_i^t \cdot G \cdot d_{i,j}^{-\alpha} \cdot |h_0|^2, \tag{1}$$

where p_i^t represents the transmit power of user i, $d_{i,j}$ is the distance between devices i and j, α is the path loss exponent, G is the constant power gains factor introduced by amplifier and antenna, and $h_0 \sim \mathrm{CN}(0, 1)$ is a complex Gaussian variable representing Rayleigh fading. Besides, we assume that the thermal noise at each device satisfies independent Gaussian distribution with zero mean and the same variance σ^2.

Evaluation of Interference to Wi-Fi Systems

When LTE-U and D2D-U users occupy the unlicensed channel, the nearby Wi-Fi users cannot work normally, and the performance of Wi-Fi system would be severely degraded. To quantify the performance degradation brought by LTE-U and D2D users, we introduce the concept of *interference range* on the Wi-Fi network. The interference range is defined as the area in which the Wi-Fi users can detect the reservation signal from the LTE-U/D2D users and suspend their transmission attempts. More specifically, each Wi-Fi user is able to detect the channel unavailable if the received signal power is beyond a certain threshold. With the free-space path loss model, if an LTE-U or D2D user is occupying the unlicensed spectrum, the interference range to the Wi-Fi network is a circle centered at the transmitter, whose radius is positively proportional to the transmit power. Intuitively, the users with large interference range has low probability of being allocated the unlicensed subchannels, because a large number of Wi-Fi users will be interfered by this user.

On contrary, the users with small interference range are more likely to utilize the unlicensed subchannels due to their insignificant interference to the Wi-Fi network.

However, when multiple LTE-U and D2D users transmit on the unlicensed spectrum concurrently, their individual interference circles may overlap, which is hard to derive the closed form expression for the area of the total interference range. In the following of this part, we present an approximated model of the interference range to evaluate the performance degradation in Wi-Fi system. Intuitively speaking, a smaller interference range can be obtained if BS allocates the unlicensed subchannels to those users which are close to each other rather than those whose interference ranges do not overlap. Inspired by this observation, we use the minimum distance between a new LTE-U/D2D users to others to approximate the additional interference introduced by this add-on user. Let L_c and L_d denote the radii of individual interference circles of LTE-U and D2D users, respectively, where $L_d \leq L_c$. Besides, we define $\mathscr{C}^u$ as the user set in which users are allocated to the unlicensed subchannels. With these notations, the weight functions for LTE-U and D2D users are given as below.

LTE-U user

When LTE user n is allocated to the unlicensed subchannel for the first time, and LTE user j, the increased interference range is related to the distance between LTE users n and j, denoted by $L^c_{n,j}$. When the interference ranges of these two LTE users overlaps, i.e., $L^c_{n,j} < 2L_c$, as LTE user 1 and user 2 in Fig. 3, we assume the weight is proportional to the distance $L^c_{n,j}$. And as LTE users 1 and 3 illustrated in Fig. 3, their interference ranges do not overlap, i.e., $L^c_{n,j} \geq 2L_c$, the increased area

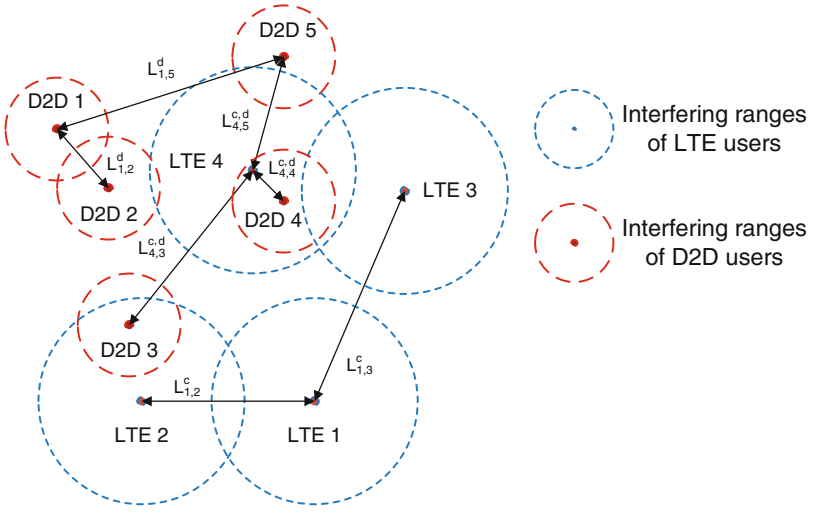

Fig. 3 Illustrations for interference range

will not grow as the distance $L^c_{n,j}$. Therefore, the weight function for the increased area $w^c_{n,j}$ can be expressed as

$$w^c_{n,j} = \begin{cases} L^c_{n,j}, & L^c_{n,j} < 2L_c, \\ 2L_c, & L^c_{n,j} \geq 2L_c. \end{cases} \tag{2}$$

On the other hand, given D2D user m, the increased interference range is also related to the distance between D2D users n and m, $L^{c,d}_{n,m}$. Note that $L_d \leq L_c$, when the interference range of D2D user m is contained by that of LTE user n as LTE user 4 and D2D user 4 in Fig. 3, i.e., $L^{c,d}_{n,m} \leq L_c - L_d$, the increased area is proportional to the increased diameter $2(L_c - L_d)$. When the interference range of LTE user n overlaps with but does not contain that of D2D user m as D2D user 5 and LTE user 4, that is, $L_c - L_d < L^{c,d}_{n,m} < L_c + L_d$, the weight is proportional to the distance $L^{c,d}_{n,m}$ as well. Besides, when the interference ranges of D2D user m and LTE user n do not overlap, such as LTE user 4 and D2D user 3, i.e., $L^{c,d}_{n,m} \geq L_c + L_d$, the increased area is a constant. Therefore, the weight function for the increased area $w^{c,d}_{n,m}$ is written by

$$w^{c,d}_{n,m} = \begin{cases} 2(L_c - L_d), & L^{c,d}_{n,m} \leq L_c - L_d, \\ L^{c,d}_{n,m} + L_c - L_d, & L_c - L_d < L^{c,d}_{n,m} < L_c + L_d, \\ 2L_c, & L^{c,d}_{n,m} \geq L_c + L_d. \end{cases} \tag{3}$$

The weight of an LTE-U user n is the minimum increased interference range between LTE user n and any user allocated to the unlicensed subchannels, that is,

$$w^c_n = \min_{j,m \in \mathscr{C}^u} (w^c_{n,j}, w^{c,d}_{n,m}). \tag{4}$$

D2D user

Similar to the LTE-U users, if D2D users m is allocated to the unlicensed subchannel for the first time, and D2D user j is a D2D user utilizing the unlicensed subchannels, the increased range is related to the distance between the transmitter of D2D user m and the receiver of D2D user j. As illustrated in Fig. 3, the increased range can be calculated under two conditions: (1) the interference ranges of these two D2D users overlap and (2) their interference ranges do not overlap. Thus, the weight function $w^d_{m,j}$ between D2D users m and j is provided by

$$w^d_{m,j} = \begin{cases} L^d_{m,j}, & L^d_{m,j} < 2L_d, \\ 2L_d, & L^d_{m,j} \geq 2L_d. \end{cases} \tag{5}$$

In addition, if there already exists one LTE-U user n, the increased area $f^{c,d}_{n,m}$ is also related to the distance $L^{d,c}_{m,n}$ between LTE user n and D2D user m, which can be given by

$$w_{n,m}^{c,d} = \begin{cases} 0, & L_{m,n}^{d,c} \le L_c - L_d, \\ L_{n,m}^{c,d} + L_d - L_c, & L_c - L_d < L_{m,n}^{d,c} < L_c + L_d, \\ 2L_c, & L_{m,n}^{d,c} \ge L_c + L_d. \end{cases} \tag{6}$$

Therefore, the weight of D2D user m is

$$w_m^d = \min_{j,n \in \mathscr{C}^u} (w_{m,j}^d, w_{m,n}^{d,c}). \tag{7}$$

Interference in the LTE-U/D2D Network

The mutual interference between the LTE-U and D2D users is analyzed in this subsection. We assume that one subchannel can be allocated to a maximum of one LTE user, and a subchannel can be allocated to at most V^s users for the sake of QoS. Besides, we also assume that a user can utilize at most V^u subchannels including licensed and unlicensed ones for the sake of fairness.

First, some notations are listed as follow. The subchannel allocation matrix for LTE and D2D users is denoted by

$$A_{(N+M)\times(K+K^u)} = \begin{pmatrix} \Phi_{N\times(K+K^u)} \\ \Theta_{M\times(K+K^u)} \end{pmatrix}, \tag{8}$$

where $\Phi_{N\times(K+K^u)} = [\phi_{n,k}]$, and $\Theta_{M\times(K+K^u)} = [\theta_{m,k}]$ stand for the subchannel allocation matrices for the LTE-U and D2D users, respectively. The values of $\phi_{n,k}$ and $\theta_{m,k}$ are defined as

$$\phi_{n,k} = \begin{cases} 1, & \text{when subchannel } k \text{ is allocated to LTE user } n, \\ 0, & \text{otherwise,} \end{cases} \tag{9}$$

and

$$\theta_{m,k} = \begin{cases} 1, & \text{when subchannel } k \text{ is allocated to D2D user } m, \\ 0, & \text{otherwise.} \end{cases} \tag{10}$$

Besides, we define the access indicators s_n^c ($n \in \mathscr{N}$) and s_m^d ($m \in \mathscr{M}$) to respectively represent whether the LTE and D2D users can access the unlicensed channel. If the LTE user n can access the unlicensed channel, $s_n^d = 1$, otherwise, $s_n^d = 0$. And it is the same for D2D users. We also define $\mathscr{C}_k$ to represent the set of LTE and D2D users to which subchannel k is allocated.

With this approximated model, the BS only needs to measure the distances between any two users applied for accessing the unlicensed spectrum and evaluates the increased interference range for each pending user compared to the current

subchannel allocation scheme. The increased interference range is regarded as a penalty term in the subsequent subchannel allocation process.

Interference Analysis in the Licensed Spectrum

In the licensed subchannels, under the assumption that a subchannel can be allocated to a maximum of one LTE user, the LTE users can only receive the co-channel interference from the underlaying D2D users, while the interference received by D2D users might be from LTE users and other co-channel D2D users. The SINR at the receiver of BS from LTE user n over licensed subchannel k can be given by

$$\gamma_{n,k}^{c} = \frac{\phi_{n,k} P^{c} |h_{n,B}^{c}|^2}{\sigma^2 + \sum\limits_{m=1}^{M} \theta_{m,k} P^{d} |h_{m,B}^{d}|^2}, \tag{11}$$

where $h_{n,B}^{c}$ and $h_{m,B}^{d}$ represent the channel gains from LTE user n and the transmitter of D2D user m to the BS, respectively. The SINR at the receiver of D2D user m over licensed subchannel k can be expressed as

$$\gamma_{m,k}^{d} = \frac{\theta_{m,k} P^{d} |h_{m,m}^{d}|^2}{\sigma^2 + \sum\limits_{m \neq m', m'=1}^{M} \theta_{m',k} P^{d} |h_{m',m}^{d}|^2 + \sum\limits_{n=1}^{N} \phi_{n,k} P^{c} |h_{n,m}^{c}|^2}, \tag{12}$$

where $h_{m',m}^{d}$ and $h_{n,m}^{c}$ are the channel gains from the transmitter of D2D user m' and LTE user n to the receiver of D2D user m, respectively. The data rates of LTE user n and D2D user m over licensed subchannel k are respectively given by

$$\begin{aligned} R_{n,k}^{c} &= B_l \log_2(1 + \gamma_{n,k}^{c}), \\ R_{m,k}^{d} &= B_l \log_2(1 + \gamma_{m,k}^{d}). \end{aligned} \tag{13}$$

Interference Analysis in the Unlicensed Spectrum

In the unlicensed subchannels, the D2D-U and LTE-U users will not only receive the mutual interference from D2D-U and LTE-U users as in the licensed subchannels but also the interference from the Wi-Fi system. Therefore, the SINR at BS from LTE-U user n over unlicensed subchannel k is

$$\gamma_{n,k}^{c,u} = \frac{\phi_{n,k} P^{c} |h_{n,B}^{c}|^2}{\sigma^2 + \sum\limits_{m=1}^{M} \theta_{m,k} P^{d} |h_{m,B}^{d}|^2 + I_{w}^{c}}, \tag{14}$$

where I_{w}^{c} is the total interference from Wi-Fi system to BS, which can be calculated as $I_{w}^{c} = \sum\limits_{q \in \mathcal{Q}} \frac{P^{w}}{K^{u}} |h_{f,B}^{q}|^2$, where $h_{f,B}^{q}$ is the channel gain from the transmitting Wi-Fi user f associated with AP q to BS. Similarly, the SINR at the receiver of D2D user m over unlicensed subchannel k can be written as

$$\gamma_{m,k}^{d,u} = \frac{\theta_{m,k} P^d |h_{m,m}^d|^2}{\sigma^2 + \sum\limits_{m \neq m', m'=1}^{M} \theta_{m',k} P^d |h_{m',m}^d|^2 + \sum\limits_{n=1}^{N} \phi_{n,k} P^c |h_{n,m}^c|^2 + I_w^d}, \tag{15}$$

where I_w^d is the interference from Wi-Fi system to the receiver of D2D user m, whose value is $I_w^d = \sum\limits_{q \in \mathcal{Q}} \frac{P^w}{K^u} |h_{f,m}^q|^2$, with $h_{f,m}^q$ representing the channel gain from the active Wi-Fi user f to the receiver of D2D user m.

The data rates of LTE user n and D2D user m over unlicensed subchannel k are respectively given by

$$\begin{aligned} R_{n,k}^{c,u} &= B_u \log_2(1 + \gamma_{n,k}^{c,u}), \\ R_{m,k}^{d,u} &= B_u \log_2(1 + \gamma_{m,k}^{d,u}). \end{aligned} \tag{16}$$

Sensing-Based D2D-U Protocol

In this section, we propose a duty cycle-based [29] protocol for LTE-U and D2D-U users to share the unlicensed spectrum with Wi-Fi systems. The basic principle of the protocol is to allow the LTE-U and D2D-U users a chance to access the unlicensed spectrum while protecting the incumbent Wi-Fi performance. Note that the behavior of LTE and D2D-U users on the licensed spectrum still follows the current LTE standard. In this chapter, we only provide the protocol design for accessing the unlicensed spectrum in Fig. 4.

Overview of the Proposed Protocol

As illustrated in Fig. 4, similar to the LTE standard, the timeline is slotted into subframes with length T_{sub} (e.g., 1ms in the LTE standard). There are three types of subframes, namely, sensing subframes (SSs), transmission subframes, and reserved Wi-Fi subframes. The SSs are inserted before the LTE-U, and D2D-U users attempt to initiate a transmission to avoid collision with the ongoing Wi-Fi transmissions. In transmission subframes, the LTE-U and D2D-U users perform transmission as in the conventional LTE standard. Then, to further protect the Wi-Fi performance, we reserve several subframes for Wi-Fi transmission, during which the LTE-U users are not allowed to utilize the unlicensed spectrum, and then the long successive transmission period of LTE-U and D2D-U users follows. The transmission periods for LTE-U and D2D-U systems as well as the Wi-Fi network can be adjusted according to their desired performance; specifically, when the channel is clean, LTE-U and D2D-U users can start transmission at once.

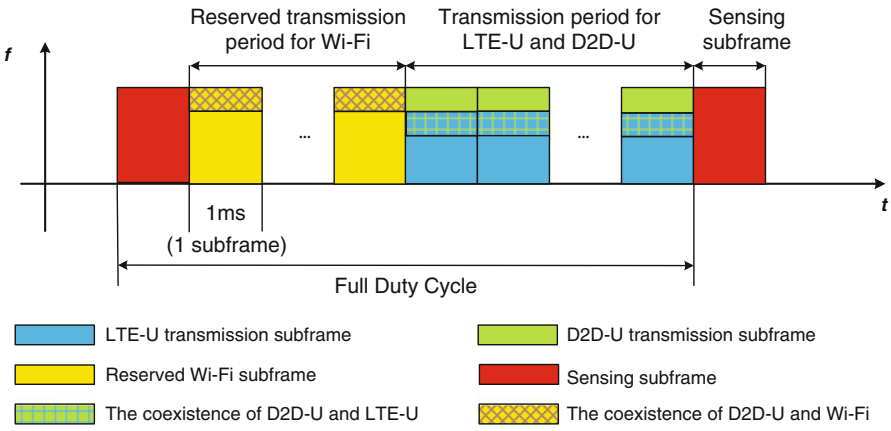

Fig. 4 Sensing-based protocol for LTE and D2D users accessing the unlicensed spectrum

Coexistence Mechanism

In this protocol, two mechanism are used to safeguard that LTE-U/D2D-U users do not bring severe interference to their neighboring users in the unlicensed spectrum. First, channel selection is performed to choose the cleanest channel avoiding the interference between Wi-Fi users and LTE-U/D2D-U users. In the case that no clean channel is found, channel sensing transmission is used to support transmission for D2D-U/LTE-U users, in which LTE-U users are applied with TDM transmission, and D2D-U users are selectively activated, based on the channel sensing result.

Channel Selection

In SS, LTE-U/D2D-U users will scan the unlicensed spectrum and identify a cleanest channel from the L unlicensed channels for uplink data transmission. For a LTE-U/D2D-U users, the transmitter will perform energy detection, and measure the interference level as in CSMA/CA method. If the interference is sensed less than the predefined threshold, the channel will be regarded as clean for this LTE-U/D2D-U user. Then, the LTE-U/D2D-U users will inform the BS whether they are interfered by Wi-Fi users according to the measured result. In the operating channel, if the number of interfered users is larger than a given threshold, and there is another cleaner channel available, i.e., the number of interfered users in this channel is less than that in the operating channel, the transmission will be switched to the new channel.

Some technologies are also used to improve detection sensitivity. For example, Wi-Fi preambles are detected to estimate the number of neighboring Wi-Fi APs in the given channel. In addition, device-assisted enhancements, such as 802.11k, in which users can measure the received signal and recognize the hidden nodes, can be used to address the hidden node effect and thus help to select a better channel.

Channel-Sensing Transmission

For most deployments, the channel selection is usually sufficient to meet the coexistence requirements. While in hyper-dense deployment, there is a possible that no clean channel can be found. For LTE-U users, carrier-sensing adaptive transmission (CSAT) algorithm [29] is used to support the coexistence of LTE-U and Wi-Fi users. In the CSAT scheme, LTE-U and Wi-Fi users coexist in a TDM fashion. In particular, a duty cycle is defined where LTE-U users transmit in a fraction of the cycle and gates off in the remaining time to hand over the unlicensed channel to Wi-Fi users.

However, due to the short transmission range and low transmit power of D2D communications, it is possible to share the unlicensed spectrum with Wi-Fi users during the full duty cycle. After the SS, the unlicensed channel can be still utilized by Wi-Fi users to resume the ongoing data transmission. In these reserved subframes, those D2D-U users which have sensed that the channel idle in SS can utilize the unlicensed subchannels for data transmission, while other D2D and LTE users are only allowed to utilize licensed subchannels. When the reserved subframes for Wi-Fi transmission expires, all the LTE-U/D2D-U users are activated in the unlicensed subchannels. At the beginning of each subframe, the BS allocates licensed and unlicensed subchannels to the LTE-U/D2D-U users; in particular, only active LTE-U/D2D-U users have possibility to utilize unlicensed subchannels, which is elaborated in section "Many-to-Many Matching-Based Subchannel Allocation".

Problem Formulation

In this section, we first formulate subchannel allocation problem considering both the performance of Wi-Fi and the total sum-rate of LTE and D2D users and then reformulate this problem into a many-to-many matching problem in consideration of its computation complexity.

Sum-Rate Maximization Problem Formulation

Our objective is to maximize the total sum-rate of the LTE and D2D users while minimizing the interference range by setting the subchannel allocation variables $\{\phi_{n,k}, \theta_{m,k}\}$ in each subframe.

Since the BS does not hold the information of the interference from LTE-U and D2D users to Wi-Fi systems, we use the approximate model described in the section "Overview of the Proposed Protocol" to evaluate the performance degradation of Wi-Fi system and add it in the objective function as a penalty term. Assumed that the Wi-Fi users are uniformly located in this plane, the number of interfered Wi-Fi users is positively proportional to the interference area, which can be an indicator of the performance degradation of Wi-Fi system. Besides, provided that at least one unlicensed subchannels is allocated to CU_n or D_m, the Wi-Fi users in its interference range cannot perform data transmission; the penalty term is in the

form of sign function. Thus, the penalty items W_n^c and W_m^d for LTE user n and D2D user m are respectively given by

$$\begin{aligned} W_n^c &= w_n^c \operatorname{sgn}\left(\sum_{k\in\mathscr{K}^u} \phi_{n,k}\right), \\ W_m^d &= w_m^c \operatorname{sgn}\left(\sum_{k\in\mathscr{K}^u} \phi_{m,k}\right). \end{aligned} \tag{17}$$

where $\operatorname{sgn}(\cdot)$ is the sign function. Taking the penalty into consideration, the subchannel allocation can be formulated as the following optimization problem:

$$\max_{\{\phi_{n,k},\theta_{m,k}\}} \sum_{k\in\mathscr{K}} \sum_{\mathscr{C}_k} \left(R_{n,k}^c + R_{m,k}^d\right) + \sum_{k\in\mathscr{K}^u} \sum_{\mathscr{C}_k} \left(R_{n,k}^{c,u} + R_{m,k}^{d,u}\right) - \lambda \left(\sum_{n\in\mathscr{N}} W_n^c + \sum_{m\in\mathscr{M}} W_m^d\right), \tag{18a}$$

$$s.t. \sum_{n\in\mathscr{N}} \phi_{n,k} \le 1, \forall k \in \mathscr{K}, \tag{18b}$$

$$\sum_{k\in\mathscr{K}\cup\mathscr{K}^u} \phi_{n,k} \le V^u, \forall n \in \mathscr{N}, \sum_{k\in\mathscr{K}\cup\mathscr{K}^u} \theta_{m,k} \le V^u, \forall m \in \mathscr{M}, \tag{18c}$$

$$\sum_{n\in\mathscr{N}} \phi_{n,k} + \sum_{m\in\mathscr{M}} \theta_{m,k} \le V^s, \forall k \in \mathscr{K} \cup \mathscr{K}^u, \tag{18d}$$

$$\sum_{k\in\mathscr{K}} \phi_{n,k} \ge 1, \forall n \in \mathscr{N}, \sum_{k\in\mathscr{K}} \theta_{m,k} \ge 1, \forall m \in \mathscr{M}, \tag{18e}$$

$$s_n^c \phi_{n,k} = \phi_{n,k}, s_m^d \theta_{m,k} = \theta_{m,k}, \forall k \in \mathscr{K}^u, \tag{18f}$$

where $\lambda \ge 0$ is the sensitivity factor for Wi-Fi systems. Constraint (18b) is given under the assumption that one subchannel can be utilized by at the maximum of one LTE user. Constraints (18c) and (18d) imply that a user utilize at most V^u subchannels, and a subchannel can be utilized by a maximum of V^s users. According to the CA property, each LTE-U or D2D-U user needs to occupy at least one licensed subchannel for control signals, and thus constraint (18e) needs to be satisfied. Constraint (18f) is the sensing constraint, only the LTE-U and D2D-U users which have sensed that the channel is idle can access the unlicensed channel.

Note that the aforementioned problem is an MINLP problem, which is NP-hard [30]. Considering the computational complexity, we reformulate the subchannel allocation as a many-to-many two-sided matching problem, which can be efficiently solved by utilizing the matching games.

Matching Formulation

We consider the set of LTE and D2D users, $\mathscr{U} = \mathscr{M} \cup \mathscr{N}$, and the set of subchannels including licensed and unlicensed, $\mathscr{S} = \mathscr{K} \cup \mathscr{K}^u$, as two disjoint sets of selfish players aiming to maximize their own benefits. Each player can exchange information with one another without extra signaling cost (The BS is assumed to have the full knowledge of the channel side information (CSI), and performs subchannel allocation based on the obtained CSI.), that is, the players have complete information about others. In this many-to-many matching model, if subchannel k is assigned to LTE user n, then LTE user n is said to be matched with subchannel k and form a matching pair, marked by (n, k).

A matching is an assignment of subchannels in $\mathscr{S}$ to users in $\mathscr{U}$, which can be defined as:

Definition 1. Given two disjoint sets, $\mathscr{U} = \mathscr{M} \cup \mathscr{N}$ of the users, and $\mathscr{S} = \mathscr{K} \cup \mathscr{K}^u$ of the subchannels, a many-to-many matching Ψ is a mapping from the set $\mathscr{U} \cup \mathscr{S}$ to the set of all subsets of $\mathscr{U} \cup \mathscr{S}$ such that for every user $n \in \mathscr{N}$ or $m \in \mathscr{M}$, and subchannel $k \in \mathscr{S}$:

1. $\Psi(n) \in \mathscr{S}, \Psi(m) \in \mathscr{S}$;
2. $\Psi(k) \in \mathscr{U}$;
3. $|\Psi(n)| \leq V^u, |\Psi(m)| \leq V^u$;
4. $|\Psi(k)| \leq V^s$;
5. $|\Psi(n) \cap \mathscr{K}| \geq 1, |\Psi(m) \cap \mathscr{K}| \geq 1$;
6. $s_m^d = 0 \Leftrightarrow \Psi(m) \cap \mathscr{K}^u = \emptyset, s_n^c = 0 \Leftrightarrow \Psi(n) \cap \mathscr{K}^u = \emptyset$;
7. $k \in \Psi(n) \Leftrightarrow n \in \Psi(k), k \in \Psi(m) \Leftrightarrow m \in \Psi(k)$.

Conditions 1 and 2 state that each LTE or D2D user is matched with a subset of subchannels, and each subchannel is matched with a subset of users. Conditions 3 and 7 show the utilization constraints for a user and a subchannel. Due to the CA requirement, the users need to occupy to at least one licensed subchannel, as expressed in condition 4. Condition 5 implies that only those users sensed idle unlicensed subchannel can utilize the unlicensed subchannels.

Considering mutual interference items in (12) and (15), any D2D user's sum-rate over its allocated subchannels is related to the set of other LTE users and D2D users sharing this subchannel. Besides, the penalty term in (18a) indicates that the objective of the LTE-U and D2D users is relevant to other users operating in the unlicensed spectrum as well. Thus, each user cares about not only which subchannel it is matched with but also the set of users matching with the same subchannel. For this reason, the aforementioned matching game is a many-to-many matching game with *externalities* [23] or *peer effects* [24].

Affected by the peer effects, the outcome of this matching game greatly depends on the dynamic interactions among the users sharing the subchannels. To better

describe the selection behavior and decision process of each player, we introduce a concept of preference relation $>$ for both users and subchannels. For any two subchannels $k, k' \in \mathscr{S}, k \neq k'$, and any two matchings $\Psi, \Psi', k \in \Psi(m), k' \in \Psi'(m)$:

$$(k, \Psi) >_m (k', \Psi') \Leftrightarrow R^d_{m,k}(\Psi) > R^d_{m,k'}(\Psi'), \tag{19}$$

where $R^d_{m,k}$ is related to the current subchannel allocation results. If D2D user m has not been allocated to unlicensed subchannels, the data rate $R^d_{m,k}$ needs to deduct the penalty item. This implies that the D2D user m prefers k in Ψ to k' in Ψ' if m can have a higher data rate over k than k'. The same process will be done for an LTE user $n \in \mathscr{N}$. LTE-U user n will also prefer the subchannel which can achieve higher data rate.

As for any subchannel $k \in \mathscr{S}$, its preference relation $>_k$ over the set of users can be given in a uniform method. For any two subsets of users $T, T \in \mathscr{U}, T \neq T'$, and any two matchings $\Psi, \Psi', T = \Psi(k), T' = \Psi'(k)$:

$$(T, \Psi) >_k (T', \Psi') \Leftrightarrow R_k(\Psi) > R_{k'}(\Psi'), \tag{20}$$

where R_k also includes the penalty items. This indicates that subchannel k prefers the set of users T to T' only when k can get a higher data rate from T. $(T, \Psi) \geq_k (T', \Psi')$ is also used to indicate that subchannel k likes the set of users T at least as well as T'.

Different from traditional many-to-many matchings in which the players' preferences are substitutable, subchannels' preferences do not satisfy *substitutability*. Specifically, given a subchannel $k \in \mathscr{S}$, let $\mathscr{T}_k \subseteq \mathscr{U}$ represent its most preferred user set that contains two D2D users m and i. Besides, the data rate $R^d_{m,k}$ of D2D user m is higher than $R^d_{i,k}$ of D2D user i when they utilize subchannel k independently. If $m \notin \mathscr{T}_k$, then it is not necessary that $i \in \mathscr{T}_k / \{m\}$. Due to the mutual interference, the data rate may have changed after m is removed from $\mathscr{T}_k$, and thus, k may not prefer i any more.

Due to the externalities, the many-to-many matching model in this work is more complicated than the conventional two-sided matching models. Under traditional definition of stable matching (Traditional stable matching refers to a matching in which there do not exist two players from opposite sets prefer each other to at least one of their current matches such that they form a new matching pair together for the sake of their interests, that is, there are no blocking pairs in a stable matching.) in [23], there is no guarantee that a stable matching exists even in many-to-one matchings. Because of the lack of substitutability, traditional deferred acceptance algorithm [23] cannot be applied to this model anymore. To solve this matching problem, we introduce the swap matching [24] and propose a matching algorithm in section "Many-to-Many Matching-Based Subchannel Allocation".

Many-to-Many Matching-Based Subchannel Allocation

In this section, we propose a matching algorithm to solve the problem formulated in section "Problem Formulation". We first introduce the notations and definitions of *swap matching* and *stability* into our many-to-many matching model and then elaborate on the matching algorithm.

Notations and Definitions

The concepts of *swap matching* and *swap-blocking pair* are defined as below.

Definition 2. Given a matching Ψ, two matching pairs (i, p) and (j, q) with subchannels $p \in \Psi(i)$, $q \in \Psi(j)$, $p \notin \Psi(j)$, and $q \notin \Psi(i)$, *a swap matching* is defined as:

$$\Psi_{i,p}^{j,q} = \{\Psi \backslash \{(i, p), (j, q)\}\} \cup \{(i, q), (j, p)\}. \tag{21}$$

A swap matching is generated via swap operations, which is the two-sided version of the *exchange* operation [31, 32]. In the swap operation, a pair of players exchange their matches while all other matchings remain unchanged. Different from conventional strategy change in one-to-one matching performed by the individual player, the swap operation needs to be approved by both involved players. In the following, we provide the conditions in which the swap operations can be approved by introducing the concepts of *swappable set* and *swap-blocking pair*.

Definition 3. For LTE-U user n or D2D user m, its *swappable set* is defined as a subchannel subset in which the user can swap for subchannel via swap matching. Specifically, if the sensing vector $s_m^d = 1$, the swappable set Ω_m of D2D user m is subchannels set $\mathscr{S}$ including licensed and unlicensed ones; otherwise, its swappable set Ω_m is licensed subchannels set $\mathscr{K}$. And it does the same for LTE user n.

Note that in the reserved subframe for Wi-Fi transmission, only the fraction of D2D users which have sensed the operating channel idle in SS have the unlicensed subchannels in their swappable sets, other users can only swap for licensed subchannels in the swappable sets.

Definition 4. Provided a matching Ψ and a user pair $(i, j), i, j \in \mathscr{U}$, i and j are matched in Ψ, and let Ω_i and Ω_j, respectively, represent the swappable sets of i and j. If there exist subchannels $p \in \Psi(i)$, $p \in \Omega_j$, $q \in \Psi(j)$, and $q \in \Omega_i$ such that:

1. $\forall t \in (i, j, p, q), (\Psi_{i,p}^{j,q}, \Psi_{i,p}^{j,q}(t)) \succeq_t (\Psi, \Psi(t))$,
2. $\exists t \in (i, j, p, q), (\Psi_{i,p}^{j,q}, \Psi_{i,p}^{j,q}(t)) \succ_t (\Psi, \Psi(t))$,
3. $\forall t \in (i, j), |\Psi_{i,p}^{j,q}(t) \cap \mathscr{K}| \geq 1$,

then the swap matching $\Psi_{i,p}^{j,q}$ is *approved*, and the pair (i, j) is called *a swap-blocking pair* in the matching Ψ.

The third condition in Definition 4 is to satisfy the CA requirement in which each user needs to utilize at least one licensed subchannel. The definition implies that once a swap matching is approved, at least one player's data rates will increase, which leads to the increase in the total data rate.

Definition 5. A matching Ψ is *two-sided exchange-stable (2ES)* if and only if there does not exist a swap-blocking pair.

Intuitively speaking, from the perspective of network, a matching Ψ is said to be 2ES implies that there is not any user i or subchannel q, in which i prefers another subchannel p to its match q, or q likes another user j rather than its match i. Such a network-wide stable can be achieved by guaranteeing the involved players are beneficial from the swap operations, given the externalities in current matching Ψ.

Algorithm Description

With the notations of swap matching and the definition of stability, we propose a user-subchannel matching algorithm (Algorithm 1) to obtain a 2ES matching. This algorithm is an extension of the many-to-one matching algorithm proposed in [33] with constraints that $|\Psi(n)| \geq V^u$, $|\Psi(m)| \geq V^u$, and $|\Psi(k)| \geq V^s$.

As a part of Algorithm 1, each LTE or D2D user needs to maintain a preference list. The preference list is established according to the following principles:

1. The subchannels in the preference list need to be contained in the swappable set.
2. The matched subchannel is removed from the preference list for each user.
3. The subchannels which have matched with V^s users is removed from the preference list.
4. If the user is unmatched, i.e., the user has not been allocated to any subchannels, the licensed subchannels have priorities over the unlicensed ones.
5. The preference list is established based on the data rate over each subchannel.

In Algorithm 1, each user will send a proposal to the BS. According to Definition 3, the proposed subchannel needs to be contained by swappable set. For each user, removing the matched subchannel is to avoid multiple proposals for the same subchannel. In addition, under the utilization constraints for a subchannel, the users can only send proposal to the available subchannels. The forth principle is designed in accordance with the CA requirement. This implies that if the user cannot compete for a licensed subchannel, the user needs to be silent. And according to the definition of preference relation in (19), the preference list is maintained based on

Algorithm 1 User-subchannel matching algorithm for LTE and D2D users

Output: A 2ES matching Ψ.
begin
  while $\Psi \neq \Psi'$ **do**
    Let $\Psi' = \Psi$ The preference lists are updated based on the current matching Ψ **if** *i has not been matched with V^u subchannels* **then**
      i sends a proposal to the first subchannel q in the preference list **if** *swap operation $\Psi_{i,0}^{0,q}$ is approved* **then**
        User i matches with subchannel q The current matching Ψ is replaced by swap matching $\Psi_{i,0}^{0,q}$
      else
        User i cannot get access to subchannel q
      end
      The BS searches for swap-blocking pairs **if** *swap operation $\Psi_{i,p}^{j,q}$ is approved* **then**
        User i exchanges its match SC_p with U_j for subchannel q The current matching Ψ is replaced by swap matching $\Psi_{i,p}^{j,q}$
      else
        User i keeps its match subchannel p
      end
    else
      User U_i keeps its matches.
    end
  end
  Terminate with the final matching result Ψ
end

the data rate. Due to the externalities, the preference list is dynamic in the swap matching process. Thus, in each iteration, the preference list will be updated based on the current matching.

The key idea of Algorithm 1 is to consider approving swap matchings among the players so as to obtain a 2ES matching. The algorithm is composed of two phases: initialization phase and swap matching phase. In the initialization phase, the BS will evaluate the channel gains for all users and interference from Wi-Fi system. The swap matching phase contains multiple iterations in which the BS keeps executing the swap matching if there exist swap-blocking pairs and updates the current matching. Note that the higher a user's data rate is, the higher probability it has to be accepted by the subchannel. In each iteration, the user i updates its preference list and sends a proposal to the subchannel q ranked the first in the preference list unless it has been matched with V^u subchannels. The acceptance can be regarded as a swap operation $\Psi_{i,0}^{0,q}$, where the element $\{0\}$ denotes a virtual user or subchannel. If this swap matching is approved, the proposed user i is accepted by the subchannel q, and the matching is updated. Then, the BS will search other swap-blocking pairs and execute the swap matching to renew the current matching. The iterations stop until current matching is the same as the matching in the last iteration, and a final matching is determined.

Performance Analysis

In this section, we first analyze the proposed duty cycle-based protocol regarding the compatibility and signaling issues. Then, we analyze the effectiveness and efficiency of the proposed algorithm and remark some key properties of the LTE-U/D2D network. In the first part, the effectiveness and efficiency of the proposed algorithm is proved. Finally, we discuss how the selection of the sensitivity factor λ impacts the subchannel allocation strategy at the end of this section.

Analysis of the Protocol

Compatibility Analysis

For LTE system, unlike the LBT-based protocol for D2D-U in [34] which requires LBT waveform and transmission modification of current LTE standard, our proposed protocol follows the current LTE PHY/MAC standards, such as frame structures, resource scheduling, and signaling, and thus, it can be directly implemented to current LTE network. And as for Wi-Fi system, D2D/LTE-U users also perform energy detection to avoid the collision with Wi-Fi users. In addition, in a hyper-dense scenario, the protocol support the coexistence of the LTE-U/D2D and Wi-Fi users in a TDM fashion. Therefore, the LTE-U and D2D network can be a good neighbor of Wi-Fi network.

Signaling Analysis

To describe the signaling cost over the control channels for the proposed protocol, we assume that η messages are required to inform the BS, the channel information sensed by a D2D/LTE-U user; μ messages are required for a user to report its location and subchannel estimation results; and ν messages are required for the BS to notify a user the allocated subchannels. In SS, each D2D/LTE-U user $n \in \mathcal{N} \cup \mathcal{M}$ needs to report the sensing result over each channel. Therefore, at most $\eta(M+N)L$ messages are required in the SS. And before each transmission subframe, each LTE-U/D2D user n needs to report their locations and the subchannel estimation results for subchannel allocation, which requires $\mu(M+N)$ messages. Then, the BS will perform resource allocation process with extra information and notify each user by sending $\nu(M+N)$ messages.

Note that in one duty cycle, each LTE-U/D2D user only perform one energy detection over one channel; thus, the signaling cost is under a tolerable level. In addition, the signaling cost of resource allocation is positively proportional to the number of D2D/LTE-U users, which is constrained by the limited subchannel resources. In each subframe, the signaling cost of the resource allocation can be restricted to a tolerable level. Therefore, the signaling cost of the proposed duty cycle-based protocol is acceptable for a practical system.

Stability, Convergence, Complexity, and Optimality

Given the proposed Algorithm 1, we then give remarks on the stability, convergence, complexity, and optimality.

Stability and Convergence

We now provide the stability and convergence of Algorithm 1.

Lemma 1. *Phase II in Algorithm 1 converges after a limited number of swap operations.*

Proof. In each iteration of Algorithm 1, the matching Ψ is updated after a swap operation. Without the loss of generality, we assume that after swap operation l, the matching result is updated by swap matching $\Psi_l = \Psi_{l-1}{}_{i,p}^{j,q}$. According to Definition 4, after swap operation l, the sum-rates of subchannels p and q satisfy $R_p(\Psi_l) \geq R_p(\Psi_{l-1})$ and $R_q(\Psi_l) \geq R_q(\Psi_{l-1})$, and these two equations cannot hold at the same time, while the sum-rates of other subchannels remain unchanged. Therefore, the total sum-rate over all subchannels strictly increases.

Note that the number of potential swap-blocking pairs is finite since the number of users is limited, and the total sum-rate has an upper bound due to limited subchannels. Therefore, there exists a swap operation after which no swap-blocking pairs can be found, and the total sum-rate stops increasing. Then Algorithm 1 converges.

Proposition 1. *Upon the convergence of Phase II, Algorithm 1 reaches a 2ES matching.*

Proof. The proof follows from these two considerations. First, the swap operations only occur when the players' data rate strictly increases. Second, due to the convergency of Phase II, for any user $i \in \mathscr{U}$, it cannot find another user $j \in \mathscr{U}$ to form a swap-blocking pair with their matches when Algorithm 1 terminates. The matches of user M_i must be the best choice for it in current matching. Hence, the terminal matching obtained by Algorithm 1 is 2ES.

Complexity

Having proved the convergence of Algorithm 1, we can then discuss its computational complexity.

Note that in the swap matching phase, a number of iterations are performed to reach the 2ES matching. In every iteration, the BS needs to search for swap-blocking pairs, and all the approved swap operations are executed. Thus, the complexity of the swap matching phase lies in the number of both iterations and potential swap matchings in each iteration.

Proposition 2. *In the t-th iteration of Algorithm 1, at most $(M+N)*[(M+N-1)*(t-1)+1]$, swap matchings need to be considered.*

Proof. In each iteration of Algorithm 1, at most $M + N$, users send proposal to the subchannels which rank first in their preference lists. Therefore, in this step, at most $M + N$, swap matchings need to be considered.

If the proposals from users are accepted by subchannels, they might execute swap matchings with the existing matches. For user U_i, it sends proposal to subchannel p and is accepted. According to Definition 2, this match can only execute swap matchings with matches which do not contain user i and subchannel p. In each iteration, at most 1, match can be added to the current matching for each user. Therefore, for match pair (i, q), there are at most $(M + N - 1) * (t - 1)$ potential swap matchings in the t-th iteration. In the worst case, all the proposal for users are accepted by subchannels, and thus, there are a maximum of $(M + N) * (M + N - 1) * (t - 1)$ potential swap matchings.

Above all, at most $(M+N)*[(M+N-1)*(t-1)+1]$, swap matchings need to be considered in the t-th iteration. In practice, one iteration requires a significantly low number of swap operations, since only a small number of proposals from users can be accepted.

Optimality

We show whether Algorithm 1 can achieve an optimal matching.

Proposition 3. *All local maxima of total sum-rate correspond to a 2ES matching.*

Proof. Suppose the total data rates of matching Ψ is a local maximum value. If Ψ is not a 2ES matching, then there exists at least one swap-blocking pair, and any swap matching strictly increases data rates according to Definition 2. However, this is in contradiction to the assumption that Ψ is a local maximum value. Therefore, Ψ must be 2ES.

However, not all 2ES matchings obtained from Algorithm 1 are local maxima of total data rates. For example, there exists a possibility that a user i does not approve a swap matching $\Psi_{i,p}^{j,q}$, since its data rate will decrease, but the other user j will benefit from this swap matching, and the sum-rates of subchannels p and q increase as well. The total sum-rates will increase at the expense of stability if the swap operation is forced to execute.

To obtain a global optimum matching, we utilize an algorithm (GO Algorithm) proposed in [24] by utilizing a Markov chain Monte Carlo heat bath method. In GO Algorithm, the swap matching does not need to be approved anymore; instead, a swap matching $\Psi_{i,p}^{j,q}$ is executed with a probability P_{swap} which depends on the total sum-rate as shown below:

$$P_{\text{swap}} = \frac{1}{1 + e^{-T[R_{\text{total}}(\Psi_{i,p}^{j,q}) - R_{\text{total}}(\Psi)]}}, \tag{22}$$

where T is a probability parameter. The algorithm keeps track of the optimum matching found so far, even as it moves to worse matchings. After sufficiently large amount of iterations, the matching moves toward the global optimal one [35].

Selection of the Sensitivity Factor λ

Let $R^d_{\max}$ be the maximum rate for a D2D user in an unlicensed subchannel, $R^c_{\max}$ be the maximum rate for an LTE user, and generally $R^d_{\max}/L_d \geq R^c_{\max}/L_c$. How the value of the sensitivity factor λ tunes the performance can be analyzed in the following cases.

- $\lambda \geq R^d_{\max}/(2L_d)$: This case implies that neither a D2D nor LTE user can get access to an unlicensed subchannel; the value of penalty terms is sufficiently large that cannot satisfy all the conditions of swap matching. Therefore, in this case, any D2D or LTE users cannot occupy unlicensed subchannels; the LTE and D2D users can only utilize the licensed spectrum for total sum-rate maximization.
- $R^c_{\max}/(2L_c) \leq \lambda \leq R^d_{\max}/(2L_d)$: This case implies that a D2D user get access to unlicensed subchannels. In this case, any LTE users cannot utilize unlicensed subchannels. As for the D2D users, they can utilize both licensed and unlicensed subchannels. If one D2D user get access to an unlicensed subchannel, those D2D users whose interference ranges overlap with the accessed one will become more easier to get access to the unlicensed subchannels, because the increased interference ranges will be less than that when this D2D user is the first one to get access to the unlicensed subchannels. Thus, in the view of geography, those D2D users over unlicensed subchannels trend to form several clusters.
- $0 < \lambda < R^c_{\max}/(2L_c)$: This case means that both LTE and D2D users can get access to unlicensed subchannels. Similar to case 2, the users accessed to unlicensed subchannels also form several clusters. In addition, the accessed LTE users will decrease with the value of λ grows because of the large interference range; that is, more unlicensed subchannels are allocated to D2D users, and the LTE users are more likely to utilize licensed subchannels.
- $\lambda = 0$: This case is the same as resource allocation problem in licensed scenario. In this case, both licensed and unlicensed subchannels can be regarded as a uniform subchannel; D2D and LTE users will make full use of the whole spectrum to maximize the total sum-rate.

Simulation Results

In this section, we present the simulation results of Algorithm 1, in comparison to the GO Algorithm, a greedy allocation algorithm, and the scenario without D2D, where all the users are LTE users. In the greedy scheme, the users will maintain a static preference list and send proposal to the subchannels according to the preference list. We set the number of iterations as 10^6, $T = 0.5$ in GO Algorithm such that the outcome of GO Algorithm can be regarded as the upper bound of the total sum-rate. Note that the upper bound is unrealistic since the computational complexity is rather high. And the subchannels in the scenario without D2D are also allocated by Algorithm 1. For the simulations, we consider a single-cell layout,

Table 1 Parameters for simulation

LTE-U and D2D-U parameters	Values
Cell radius	500 m
Maximum D2D user distance $D_{\max}$	20 m
LTE's transmit power P^c	13 dBm
D2D's transmit power P^d	3 dBm
Subchannel bandwidth B_l	180 kHz
Number of subchannels	40
Carrier frequency	1.9 GHz
Noise figure	5 dB
Decay factor of the path loss α	3
Power gains factor G	−31.5 dB
Maximum number of subchannels V^s	4
Maximum number of users V^u	4
Wi-Fi parameters	Values
Number of subchannels	40
Subchannel bandwidth B_u	180 kHz
Wi-Fi user's transmit power P^w	23 dBm
Number of APs Q	3
LTE-U interference radius L_c	50 m
D2D-U interference radius L_d	23 m

where the LTE and D2D users are distributed randomly, and the communication distance of D2D users cannot exceed a predefined value. The simulation parameters based on existing LTE/LTE-Advanced specifications [36] are given in Table 1. Note that the transmission power of Wi-Fi user is over the whole unlicensed channel, while the transmission power of LTE or D2D user is over one subchannel.

Figure 5 shows the total sum-rate vs. the number of active D2D users N, with the number of LTE users $M = 20$ and the sensitivity factor $\lambda = 0.1$. We observe that the total sum-rate increases with N. And it can be observed that the sum-rate obtained by proposed Algorithm 1 is 9.23% higher than the greedy algorithm, and 168.5% higher than the scenario without D2D, while it only has 3% gap to the upper bound when $N = 20$. This further implies that the BS can make full use of the unlicensed spectrum resources via D2D communications. The simulation results correspond to optimality analysis in section "Stability, Convergence, Complexity, and Optimality".

Figure 6 shows the total sum-rate vs. the number of active D2D users with the number of LTE users $M = 20$. It can be easily observed that the total sum-rate will decrease as the sensitivity factor λ increases. According to discussions on section "Selection of the Sensitivity Factor λ", $\lambda = 0$ means every D2D and LTE user can use the unlicensed spectrum, the subchannels are sufficient, and the total sum-rate is the maximum. $\lambda = 1$ means that almost they cannot use the unlicensed spectrum; both LTE and D2D users can only utilize the licensed subchannels. Because there are half of subchannels can be utilized, the total sum-rate is close

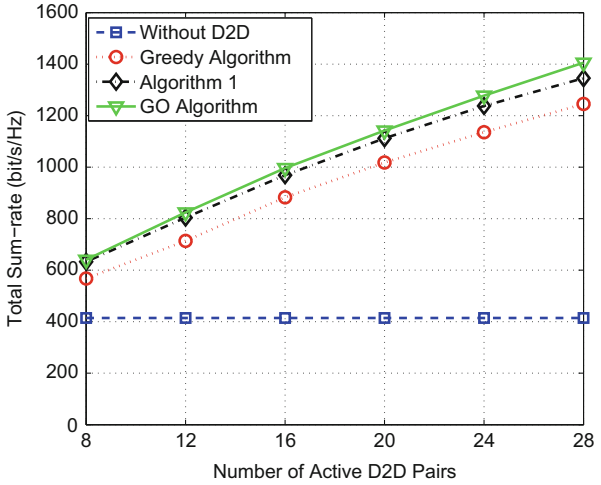

Fig. 5 Total sum-rate vs. number of active D2D users, with the number of LTE users $M = 20$ and $\lambda = 0.1$

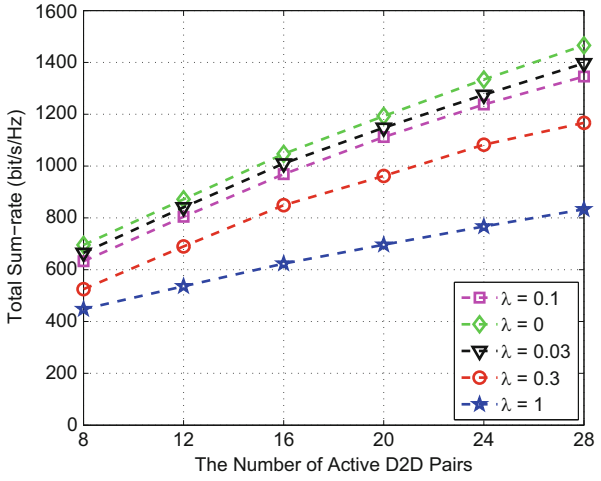

Fig. 6 Total sum-rate vs. number of active D2D users, with the number of LTE users $M = 20$

to the half of sum-rate with $\lambda = 0$. And $\lambda = 0.3$ implies that most LTE users cannot use the unlicensed spectrum; most unlicensed subchannels are used by D2D users. Because of less available subchannels, the total sum-rates decreases.

In Fig. 7, we provide the interference ranges vs. the number of active D2D users N with the number of LTE users $M = 20$. We use a uniform sampling and judge whether this sampling point is in the interference range of any LTE or D2D user using the unlicensed spectrum. The percentage of sampling points in the interference ranges is regarded as the interference ranges. From Fig. 7, it can be observed that the

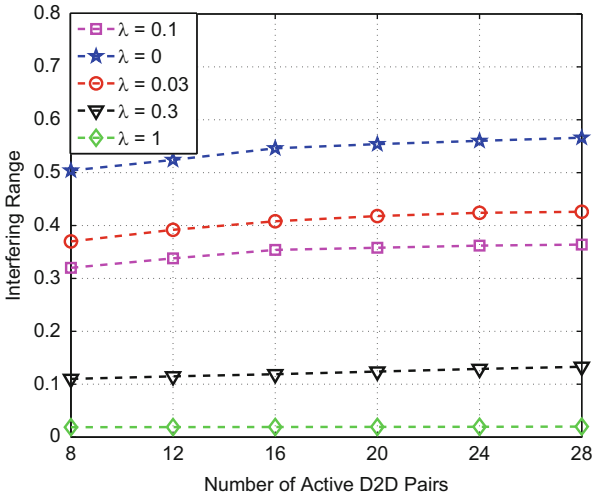

Fig. 7 Interference ranges vs. number of active D2D users, with the number of LTE users $M = 20$

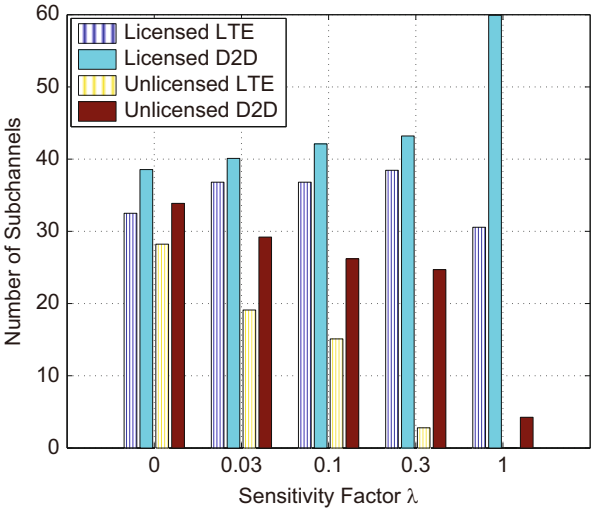

Fig. 8 Number of subchannels vs. sensitivity factor λ, with the number of LTE users $M = 20$ and the number of D2D users $N = 20$

interference ranges will decrease as the value of sensitivity factor λ grows. We can also find out the decrease in interference ranges is at the expense of the total sum-rate from Fig. 7. We can learn that we can use the unlicensed spectrum according to different requirement for the interference by properly setting the value of λ.

Figure 8 provides that the number of subchannels in both licensed and unlicensed spectra vs. the value of sensitivity factor λ with the number of LTE users $M = 20$ and the number of D2D users $N = 20$. Based on the constraint that a user can utilize at most $V^u = 4$ subchannels, the total subchannels of LTE users or D2D

users cannot exceed 80 subchannels. It can be also observed that when the value of λ increases, LTE users can occupy more licensed subchannels, while D2D users will utilize more unlicensed subchannels due to its smaller interference ranges. This is consistent with the discussions in section "Selection of the Sensitivity Factor λ".

Conclusions

In this chapter, we investigate the D2D-U technology, in which the D2D users operate as an underlay to the LTE system in both licensed and unlicensed spectra. A sensing-based D2D-U protocol has been designed for LTE-U and D2D-U users to access the unlicensed spectrum while protecting the existing Wi-Fi systems. Considering the complicated mutual interference between LTE-U, D2D, and Wi-Fi systems, we study the subchannel allocation problem for D2D and LTE-U users sharing both licensed and unlicensed spectra to leverage the performance degradation in Wi-Fi systems and the maximization of the sum-rate in LTE/D2D networks. Specifically, we formulate the allocation problem as a many-to-many matching game with externalities and develop a low-complexity user-subchannel swap matching algorithm. Analytical and simulation results show that enabling D2D communications in LTE-U network can significantly improve the network capacity. Besides, the subchannel allocation strategy for LTE and D2D users is closely related to how the BS adjusts the interference to Wi-Fi systems. In an aggressive strategy where the Wi-Fi performance degradation is not considered seriously, the BS allows more D2D and LTE users to transmit on the unlicensed spectrum. On contrary, in a Wi-Fi-friendly strategy, the BS tends to permit only a small fraction of D2D users to transmit on the unlicensed spectrum, and most of the LTE users are only allocated with licensed subchannels.

networks (CCNs). Such an integration can improve spectrum utilization and energy efficiency of wireless communication services. In CCNs with RF energy harvesting capability, when cellular base stations, i.e., primary transmitters, transmit signals to their mobile devices, secondary users (SUs) can harvest energy from the cellular channel, i.e., the primary channel, and store the energy in their batteries. Then, when the cellular channel becomes idle, the SUs can use the harvested energy to transmit data to their receivers. As such, we can utilize not only the available spectrum when the channel is idle but also energy scavenging when the channel is busy. This chapter first presents an overview of RF-based energy harvesting CCNs. Then, limitations are discussed, and some new solutions using ambient backscattering communication techniques are introduced to overcome the limitations. Finally, the chapter concludes with a discussion on the development of such networks and possible research directions.

Introduction

RF Energy Harvesting

Basic Concepts

RF energy transfer is a technique which enables energy transmission from an RF emitter to a distant destination (up to a few kilometers) based on the electromagnetic radiation, i.e., electromagnetic waves propagating through the space. According to Maxwell's theory [1], for electromagnetic waves, changes in the electrical field are always associated with a wave in the magnetic field in one direction and vice versa. This phenomenon happens continuously in the direction of the wave propagation and enables electromagnetic waves to carry information as well as energy to a far distance.

Wireless signal is a typical example of the electromagnetic waves, which is used widely in practice. In order to harvest energy from wireless signals, a mobile device needs to be equipped with a receive antenna, a matching circuit, and an RF-DC conversion circuit, as illustrated in Fig. 1. The mobile signals received at the receive antenna will be transferred to the matching circuit with the aim of maximizing power delivery from the antenna to the remaining circuit and minimizing signal reflections. After that, the RF-DC conversion circuit will convert these signals to DC voltage which can be stored in the mobile device's battery for future use. It was shown in [2] that the efficiency of the RF energy harvesting techniques strongly depends on the sensitivity of the receive antenna, the accuracy of the impedance matching circuit, and the proficiency between the voltage multiplier and the capacitor. The recent prototype implementation [3] demonstrated that RF energy harvesting techniques can achieve the efficiency up to 84% with a 5.8 dBm input power.

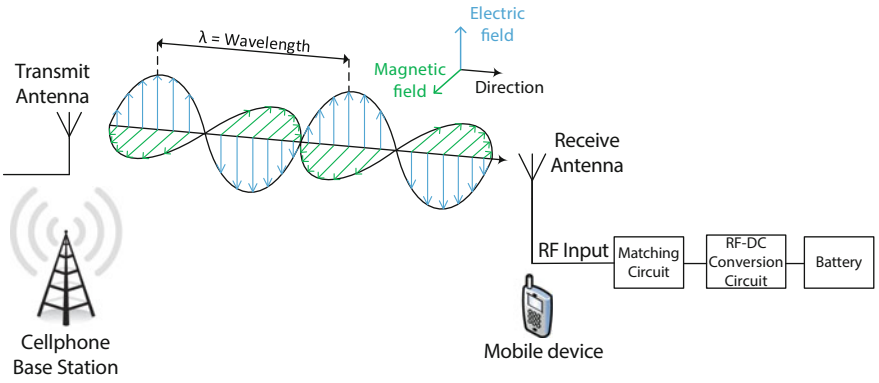

Fig. 1 RF energy harvesting in cellular networks

Energy Propagation Models

There are three RF energy propagation models which are often used to determine the amount of energy harvested at the mobile node.

- *Free space model:* In a free space environment, the energy received at the mobile node can be determined by the Friis equation [4] as follows:

$$P_R = P_T \frac{G_T G_R \lambda^2}{(4\pi d)L}, \tag{1}$$

  where P_R is the received power at the mobile node, P_T is the transmit power of the RF emitter or wireless signal source, e.g., a base station, L is the path loss factor, G_T is the transmit antenna gain, G_R is the receive antenna gain, λ is the mobile wavelength emitted, and d is the distance from the signal source to the mobile device.
- *Two-ray ground model:* In the free space model, there is only one single path from the signal source to the mobile device. However, in practice, signals received at the mobile device are from multiple paths due to the RF scattering and reflection. In this case, the two-ray ground model, which considers the received wireless signals pass through a line-of-sight path and a ground reflected path, can be used. The receive power is calculated from

$$P_R = P_T \frac{G_T G_R h_t^2 h_r^2}{d^4 L}, \tag{2}$$

  where h_t and h_r are the heights of the signal source and mobile device from the ground, respectively.
- *Rayleigh model:* Different from two aforementioned models which characterize RF propagation based on deterministic parameters, Rayleigh model [5] using

probability distribution parameters allows modeling energy propagation process in a more realistic manner. The Rayleigh model is therefore widely used in practice. In the Rayleigh model, the power received at the mobile device is determined as follows:

$$P_R = P_R^d 10^L |r|^2, \tag{3}$$

where P_R^d is the received RF power derived by a deterministic model, $L = -\alpha \log 10(d/d_0)$ is the path loss factor (d_0 is a reference distance), and r is a random number following Gaussian distribution.

Advantages of RF Energy Harvesting to Cognitive Cellular Networks

While there are a few available wireless energy harvesting techniques, e.g., inductive coupling and magnetic resonant coupling, RF energy harvesting is considered as a particularly appropriate solution for cognitive cellular networks because of the following advantages.

- *Pervasive environment:* wireless signals are available almost everywhere now, which provides an abundant energy source for mobile devices.
- *Long distance:* mobile signals can propagate and transfer over long distances, which creates favorable conditions for mobile devices.
- *Multiple directions:* cellular base stations can broadcast signals in all directions, and thus multiple mobile devices can harvest energy from the same source simultaneously.
- *Controllable power:* the amount of transferred energy can be controlled by adjusting the transmit power at the cellular base stations.
- *Stability:* RF energy supply is much more stable than other ambient energy sources such as solar, wind, and vibration.

Challenges and Solutions of Integrating RF Energy Harvesting Techniques into Cognitive Cellular Networks

Although RF energy harvesting is considered as a promising solution to cognitive cellular networks (CCNs), how to efficiently integrate this technique into CCNs is still a challenge. This section reviews related literature.

Channel Access

In [6], a secondary user (SU) harvests energy from primary signals when it is close enough to primary transmitters and stores the energy in a finite energy buffer. In addition, the SU can transmit data to its destination when it is sufficiently far away from primary transmitters. Based on these assumptions, the authors proposed a stochastic geometry model for the CCN where primary users (PUs) and SUs are distributed as independent homogeneous Poisson point processes (HPPPs). In this model, the PUs are protected from interference from the SU by a *guard zone*, and

they transfer a significant amount of RF energy to the SU when they are located in a *harvesting zone*. Based on the stochastic geometry model, the authors used a Markov chain to derive the transmission probability of the SU and then applied a Poisson approximation method to derive the maximum throughput for the SU. An important result found in this paper is that the maximum throughput of the SU is linearly increasing with increasing PUs' density. Furthermore, the PUs' density is inversely proportional to the transmission probability of the SU.

In [6], the authors assumed that all SUs have to be fully charged before they can transmit data. This implies that all SUs transmit data with the same power which may limit the network capacity for the secondary system. Therefore, the authors in [7] proposed the energy-based opportunistic spectrum access (OSA) strategy which allows the SUs to use the variable power mode to transmit data instead of waiting until full charging as in [6]. With the proposed OSA strategy, an SU can transmit data when it is outside of the guard zone, and its harvested energy level is greater than a predefined threshold. As a result, the reliability and stability of the secondary system can be significantly improved.

Park et al. [8] studied an optimal mode selection policy for an SU in a CCN with RF energy harvesting capability. It was assumed that the SU can harvest energy when the PU transmits data or the SU can transmit data when the PU is idle. However, the SU cannot harvest RF energy and access the primary channel simultaneously. Thus, it has to opt between *access mode* and *harvest mode* at the beginning of each time slot. Alternatively, it is assumed that the SU does not have any information about the current state of the channel in advance, but it knows part of channel state (e.g., idle channel probability). Therefore, the partially observable MDP (POMDP) framework was adopted to obtain the optimal mode selection policy for the SU. In order to improve the energy efficiency as well as the spectrum usage efficiency of the proposed model, the authors then introduced appropriate solutions in [9] and [10]. In particular, in [9], the authors developed a method to adjust the energy causality constraint and the collision constraint, which results in increasing the probability of accessing the occupied channel. Likewise, in [10], a theoretical upper bound on the maximum achievable throughput given the aforementioned constraints was derived with the main aim of deeply examining impacts of the temporal correlation of the primary system to the secondary system. Then, in [11], Park et al. designed an optimal spectrum access strategy in order to obtain the theoretical maximum achievable throughput. The numerical results then verified that by taking the temporal correlation of the primary system into account, the proposed strategy can achieve high efficiency in using the harvested energy.

Time Scheduling

In CCNs using energy harvesting techniques, SUs not only find opportunities to access primary channels but also have to harvest energy. The problem is that if the energy harvesting time is too long, the data transmission time will be reduced. By contrast, if the energy harvesting time is insufficient, the harvested energy will not be adequate for the data transmission phase. This leads to the problem of how to

balance between the energy harvesting time and the data transmission time for SUs to maximize their performance.

In [12], the authors proposed an online solution to find the optimal trade-off time between the energy harvesting phase (EHP) and the data transmission phase (DTP) for an underlay CCN. In the first phase, i.e., the EHP, the SU harvests energy from PU's signals and uses this energy to transmit data in the second phase, i.e., the DTP, under interference constraints with the primary system. Then, to find the optimal trade-off time between the EHP and the DTP, the authors adopted the convex optimization technique and derived the optimal value for the time-sharing ratio in a similar way as in [13]. With the proposed solution, the authors showed that the interference constraints with the primary system are under control, and the average achievable rate of the SU is maximized.

The same scenario was also examined in [14], but in [14] the authors also considered a cooperation scenario between the primary system and the secondary system. Specifically, in the second phase, the SU can opt to transmit data to its destination or relay data for the primary system. Consequently, the SU now has to determine not only how much time on the EHP but also how much power for data relay or data transmission to allocate. For both cases, i.e., cooperation and noncooperation, the authors proposed corresponding optimal solutions by using close-form solutions with numerical analysis. Simulation results showed that the proposed solutions can achieve better performance than that of the stochastic cooperation protocol and the optimal underlay transmission protocol.

Li et al. [15] introduced a strategy, called one-step-ahead spectrum sensing, with the aim of balancing the time allocation among three phases, i.e., EHP, SSP, and DTP. For the proposed strategy, based on the information about the current system state, e.g., available channels, the current energy level, and idle channel probabilities, and the estimation about the next state, the SU will make the best decision to maximize its throughput. However, the proposed strategy just can obtain a myopic solution, and thus an optimal saving-sensing-transmitting structure was proposed in [16] to maximize the average throughput for the SU. In particular, the authors first formulated the time allocation optimization problem as a mixed integer nonlinear programming problem and then employed a heuristic algorithm developed from the different evolution algorithms to derive the optimal time structure for three phases. Simulation results verified the efficiency of the proposed solution compared with a stochastic sensing strategy.

Relaying

Relaying for Secondary Systems

Lu et al. [17] studied an application of RF energy harvesting technique in a cognitive amplify-and-forward relaying network. In particular, there is a cognitive radio network with one PU and three SUs, called a source SU (SS), a relay SU (RS), and a destination SU (DS), as illustrated in Fig. 2. The RS forward the information

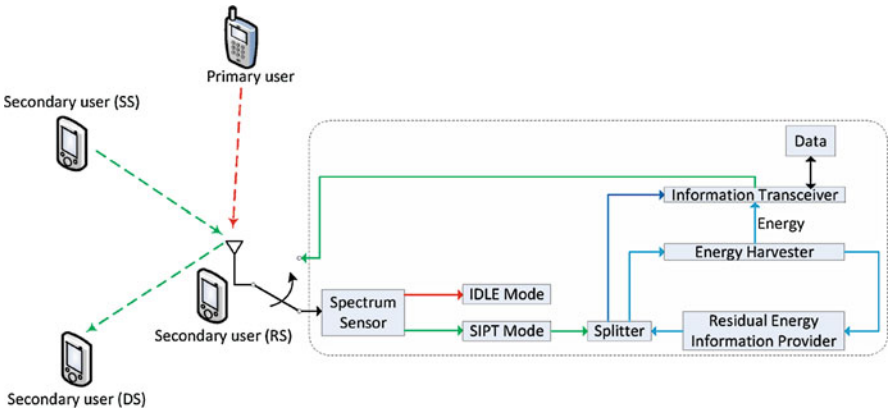

Fig. 2 Relay-assisted cognitive radio networks

received from SS to the DS by using the energy harvested from RF signals of the SS with the aim to maximize the throughput of the secondary system. At the beginning of each time slot, the SUs sense the primary channel. If the primary channel is busy, SUs use the IDLE mode. On the other hand, if the primary channel is idle, SUs can perform the transmit data process which consists of two phases, i.e., from SS to RS and from RS to DS (each phase lasts for $\frac{1}{2}$ time slot). Given the proposed system, the authors formulated the throughput maximization problem and then adopted an approximation method using the upper bound to mitigate the complexity of the optimization problem. In addition, a suboptimal algorithm was developed in order to achieve the near-optimal throughput performance. The results demonstrated that the throughput obtained by the proposed approximation algorithm is close to that of the optimal solution, and it has a significant gain compared with the separate management algorithm. A similar model was investigated in [18], but under the underlay CCN. Moreover, in [18], the authors focused on deriving the outage probability for the secondary system with the aim of improving the energy conversion efficiency for such a secondary system.

In [19], a similar relay cognitive radio model with RF energy harvesting techniques was studied, but different from [17, 18]; in [19] the relay node harvests energy from the primary transmitter's signals instead of the secondary transmitter's signals. In addition, different from [17] which considers an overlay spectrum sharing cognitive radio with the amplify-and-forward relaying technique, in [19], the authors took an underlay spectrum sharing cognitive radio with the decode-and-forward relaying technique into account. The aim of [19] is to demonstrate that the use of relay CCNs with simultaneous wireless information and power transfer (SWIPT) will not cause any loss of diversity gain, although it can reduce the outage performance of the system. Thus, it was concluded that, to improve the network performance, one of the possible ways is adopting the MIMO technique for SWIPT CCNs.

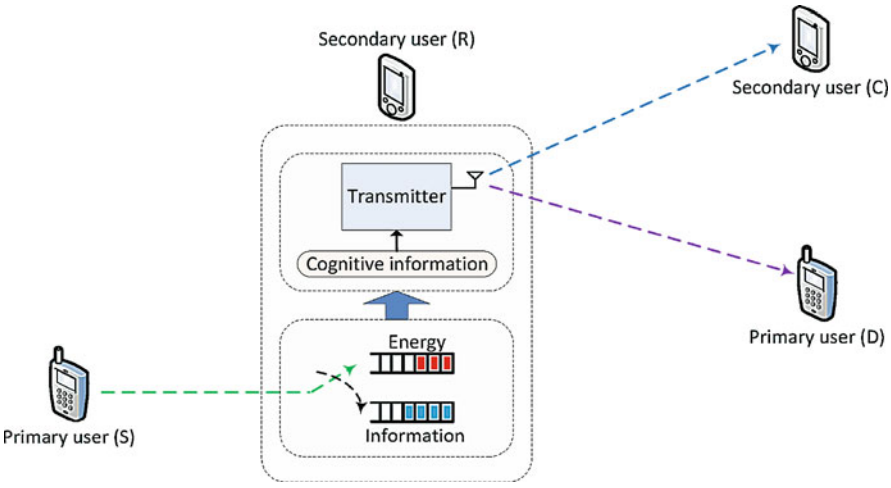

Fig. 3 Two-way cognitive relay network

Relaying for Primary Systems

Wang et al. [20] considered a scenario in which there are two primary users, denoted by S and D, who want to exchange information, but the distance between them is too far and thus they cannot communicate directly with each other. However, there is a secondary user R who volunteers to relay signals for primary users S and D. At the same time, the secondary relay node R also has its own information and wants to transmit to the secondary user C as illustrated in Fig. 3. Consequently, the node R has to transmit the primary relay information and its own information simultaneously. It is assumed that when the relay node R receives signals from the primary node, it is able to extract information and energy from the received RF signals. Then, by using the harvested energy, the relay node can transmit information to primary and secondary nodes. For the proposed aforementioned network, the authors formulated the outage probability expressions for the primary system and derived lower/upper bounds of outage probability for the secondary system. From analysis results, it was demonstrated that the proposed protocol has better outage performance than direct transmission without spectrum sharing. More numerical results can be found in [21].

A similar model was also considered in [22]. However, instead of using the decode-and-forward protocol as in [20], the authors in [22] adopted the amplify-and-forward protocol for the relay process. In addition, in [22], the authors proposed three schemes for the energy and information cooperation problem between PUs and SUs. For each scheme, the authors introduced corresponding optimization solutions, and they also indicated that the scheme based on the power splitting can achieve larger rate region than that of the time splitting scheme if the harvested energy is sufficient. Nevertheless, in [22], the authors did not consider the time constraint in which a secondary relay node needs to forward the whole received PU's signals to the primary receiver. To overcome this issue, the authors in [23] proposed a

time-divided power splitting scheme taking both the influence of time division proportion and the power splitting into account. By using this scheme, it was proved that the relay SU will have enough time to forward all received data from the PU if the energy supply is sufficient.

Power Allocation

Li et al. [24] studied the power allocation problem for a secondary network in which the secondary receiver (SR) is able to harvest RF energy from its secondary transmitter (ST) as well as from a primary transmitter (PT). It was assumed that the secondary system adopts the orthogonal frequency division multiplexing (OFDM) modulation for transmitting data from ST to SR. Thus the main goal of this paper is to find the optimal power allocation policy on each subcarrier and the power splitting ratio (i.e., the power ratio between the energy harvesting process and the information decoding process) at the ST in order to maximize the energy efficiency of the secondary system. The optimization power allocation problem is transformed to an equivalent convex problem that is solved efficiently by using an iterative algorithm. Simulation results showed that the iterative algorithm can achieve a great trade-off between the energy efficiency and high SINR regions.

Differently from [24,25] examined the power allocation problem for the primary system and then analyzed its impacts on both the primary system and the secondary system. First, in the secondary system, the secondary transmitter is allowed to transmit packets to the primary channel iff the channel is not occupied by the PU. In addition, ST can harvest energy from the primary transmitter's signals as well as from the environment. Then, the authors introduced a power allocation scheme for the primary system in which the PT sets the transmission power at time slot t based on the following equation $P_p^*(t) = \frac{N_o W(2^{R_p}-1)}{h_{ppd}(t)}$ where N_o is the additive white Gaussian noise power spectral density, W is the channel bandwidth, R_p is the targeted primary spectral efficiency, and h_{ppd} is the instantaneous channel gain. Under the proposed power allocation policy, the authors analyzed its impacts to both systems and concluded that by using the proposed policy at the primary system and implementing the RF energy harvesting at the secondary system, the throughput for both systems can be enhanced.

Scheduling and Security

In [26], the authors considered a primary system coexisting with an underlay secondary system which consists of one secondary transmitter (ST) and multiple secondary receivers (SU-Rx$_N$). Each SU-Rx$_n$ is able to harvest RF energy from the PU's signals or decode information received from the ST at a time. It means that SU-Rx$_n$ cannot carry out both processes concurrently. To avoid the collision among SU-Rx$_n$' transmissions, there is only one SU-Rx selected to decode information from the ST. Consequently, the SU-Rx with the best channel condition will be scheduled to decode information from the ST, while other SU-Rx will harvest RF energy from the ST's transmission. Then, in order to maximize the network throughput for the secondary system, a threshold condition using the Max-SNR

scheduling [27] was adopted to find the best SU-Rx at each time epoch. Numerical results showed that the proposed scheduling strategy can obtain a desirable QoS for the secondary system.

Similar to [26], the authors in [28] also investigated the scheduling problem for the secondary system by choosing only one secondary receiver at each time slot for data transmission. However, in [28], to guarantee the communication security in the secondary system, the authors employed a resource allocation algorithm which treats both idle secondary receivers and primary receivers as potential eavesdroppers. In addition, different from [26], a non-convex multi-objective optimization problem is formulated with the aim of jointly minimizing the total transmission power of the multi-antenna secondary transmitter and maximizing the efficiency of harvesting energy, while guaranteeing to minimize the interference power leakage-to-transmit power ratio for the primary system. Numerical results then figured out an interesting trade-off between the considered conflicting system design objectives.

Channel Selection

All aforementioned research works just consider only one primary channel at a time. However, in practice, there are multiple channels that the secondary system can utilize at the same time. Different channels have different capacities, e.g., high or low idle channel probabilities. Thus, the secondary transmitter needs to choose the best channel to access at each time slot such that its average throughput is maximized. For example, in the case that the ST wants to transmit data, it will select the channel with a high idle probability. By contrast, if the ST wants to harvest energy, it will prefer the channel with a low idle probability.

To address this problem, the authors in [29] proposed a model which allows secondary users to select the best channel to maximize their throughput. In particular, the authors formulated the channel selection problem for a secondary user by using Markov decision process and used the linear programming technical to find the optimal policy for the secondary user. To deal with the curse-of-model problem in the case when the secondary user has no information about its surrounding environment, the authors proposed a learning algorithm developed from the simulation-based method to find the optimal policy for the secondary user in an online fashion. Through simulation results, the authors showed that the performance of the proposed learning algorithm achieves close to that of the optimal solution, and it can improve the network through for the secondary system significantly.

This work was then extended in [30] with multiple secondary users coexisting in the same environment. Specifically, the authors considered two scenarios in which the secondary users cooperate in centralized and decentralized manner. In the case of centralized cooperation, TDMA method together with the learning algorithm introduced in [29] were adopted to find optimal policies for users. In the case of decentralized cooperation, the authors proposed a decentralized learning algorithm which allows users to determine their optimal policies in an online fashion with a little amount of information exchange. The simulation results clearly showed the

convergence of the learning algorithms as well as their efficiency in terms of network throughput.

Ambient Backscatter Communications: A New Communication Method in Cognitive Cellular Networks

In RF-powered cognitive cellular systems, secondary transmitters are required to harvest energy from radio signals and then use this energy to transmit data to their receivers. However, a new communication method has been introduced, called ambient backscatter communication, which enables secondary users to communication without requiring the energy harvesting process. In ambient backscatter communication, when secondary transmitter (ST) wants to send data to the secondary receiver (SR), the ST first backscatters ambient signals, e.g., mobile signals, to its receiver. The receiver then can decode and obtain the data by using averaging mechanisms.

In the following, the method used by the SR to extract information from the ST in the ambient backscatter communication will be briefly explained. For more details, the readers are referred to [32]. The core idea of ambient backscatter communication is that the ST backscatters information at a lower rate than that of ambient signals, i.e., signals from the PT. Thus, the SR is able to distinguish two signals by using averaging mechanisms. First, the case in which the secondary user is equipped with an analog-to-digital converter (ADC) to perform digital samples and extract information through the signal backscattering process will be considered. Then, based on the concept of signal sampling, the information decoding method using analog circuits which can remarkably reduce the energy consumption for secondary users will be presented.

Extracting Backscatter Information from Ambient Signals Using ADC

Consider a continuous time additive white Gaussian noise (AWGN) channel with bandwidth W Hz, the passband-baseband conversion and the sampling theory [31] (Chapter 5) with the sampling rate at the Nyquist-information rate of the RF signal will be adopted. Then, the received samples at the SR, i.e., $y[n]$, is a combination of the PT signals and the ST's backscattering signals, which can be expressed as:

$$y[n] = x[n] + \eta B[n]x[n] + w[n], \tag{4}$$

where $x[n]$ is the samples of the PT signals received at the SR, $w[n]$ is the noise, η is the complex-valued channel attenuation of the backscattered signals, and $B[n]$ are the bits transmitted by the ST. Here, since the distance between the ST and SR is assumed to be very small (within 1 m), the signal delay between the ST and SR can be ignored, and thus the signal received at the SR by backscattering from the ST is $\eta B[n]x[n]$.

If we assume that the ST transmits information at a fraction of the PT Nyquist rate, e.g., $\frac{1}{N}$, then $B[Ni + j]$ are all equal for $j = 1$ to N. Therefore, if the SR averages the instantaneous power of the N received samples which correspond to a single backscattered bit, it can be derived that

$$\frac{1}{N}\sum_{n=1}^{N}|y[n]|^2 = \frac{1}{N}\sum_{n=1}^{N}\left|x[n] + \eta B x[n] + w[n]\right|^2, \tag{5}$$

where B is either "0" or "1". Since PT signal $x[n]$ is uncorrelated with noise $w[n]$, (5) can be written as

$$\frac{1}{N}\sum_{n=1}^{N}|y[n]|^2 = \frac{|1+\eta B|^2}{N}\sum_{n=1}^{N}x[n]^2 + \frac{1}{N}\sum_{n=1}^{N}w[n]^2. \tag{6}$$

If P is denoted as the average received power at the SR, then $P = \frac{1}{N}\sum_{n=1}^{N}|y[n]|^2$. Ignoring the noise, the received average powers at the SR are $|1+\eta|^2 P$ and P corresponding to $B = 1$ or $B = 0$, respectively. Therefore, even under the change of the PT signals, the SR can still decode information from the ST.

Extracting Backscatter Information from Appropriate Analog Circuit

By using an ADC, the SR can extract information from ambient signals received from the ST. Nevertheless, ADC circuits may consume a significant amount of energy from the wireless nodes. Alternatively, analog circuit can be designed to imitate the operations of ADC circuits, but with less energy consumption.

Figure 4 shows a simple circuit diagram to demodulate the information for the SR. There are two stages, i.e., averaging stage and computing threshold stage. In the first stage, the SR smoothens and averages the natural variations of the PT signals. The output of the averaging stage yields two signal levels, corresponding to the voltage V_0 (bit "0") and the voltage V_1 (bit "1") for $V_1 > V_0$. Then, in the second stage, the SR computes the threshold between these two levels, which is the average of the two signal levels, i.e., $\frac{V_0+V_1}{2}$. If the received signal is higher than

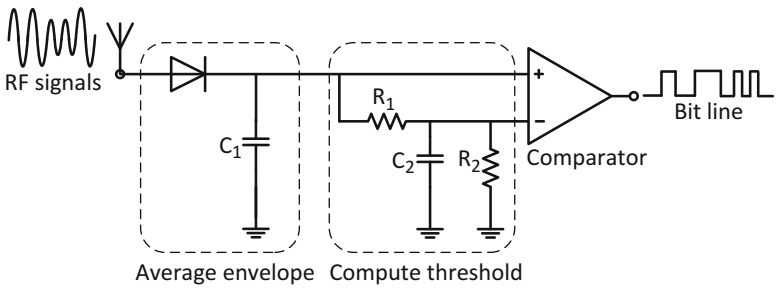

Fig. 4 Circuit diagram for the SR demodulator in the backscatter mode

the threshold, the SR concludes that the received signal is V_1 and V_0 otherwise. Finally, the comparator takes two voltages as inputs and generates a bit "0" or "1" accordingly.

Ambient backscatter communication was first introduced in [32] with the aim of enabling two wireless nodes to communicate without relying on batteries or wires for power. This idea has quickly received great attentions from research communities because it is expected to "*bring us closer to an Internet of Things*" [33]. Recent research work has been focusing on improving the performance for ambient backscatter communication. Specifically, in [34], the authors extended [32] by employing multiple antennas and a novel coding mechanism to improve the backscatter transmission rate as well as the communication range. Through experiments, it was shown in [34] that the backscatter transmission rate and the backscatter communication range can be extended up to 1 Mbps and 20 m, respectively. In [34], Parks et al. developed a coding scheme based on the spread spectrum techniques in which each data bit is represented by one symbol, and each symbol in turn is represented by a predefined chip sequence. Moreover, the authors in [35] proposed a new coding scheme which encodes several bits in a single symbol with the aim of increasing the data rate for ambient backscatter communication. Additionally, there are some other works which considered the security problem [36] and signal detection together with BER analysis [37] for ambient backscatter communication systems.

RF-Powered Cognitive Cellular Networks with Ambient Backscatter Communications: A New Approach

In an RF-powered cognitive cellular network, the secondary transmitter (ST) is able to harvest energy from primary signals and then uses the harvested energy to transmit data to its secondary receiver (SR) through the primary channel without causing harmful interference to primary users. The transmission used in the current RF-powered CCNs is therefore known as the harvest-then-transmit protocol/mode. However, the performance of RF-powered CCNs is dependent largely on the amount of harvested energy and the primary channel activity. For example, when the amount of harvested energy is too small and/or the idle channel period of the overlay CCNs is too short, the total transmitted bits will be remarkably reduced.

Therefore, this chapter introduces an RF-powered backscatter CCN which enables the ST not only to harvest energy from primary signals but also to backscatter these signals to its receiver for data transmission. Nevertheless, as stated in [38], ambient backscatter communication and RF energy harvesting processes cannot be performed concurrently in practice. If the ST backscatters signals, the RF carrier will be modulated by reflection, causing significant reduction in the harvested energy, and mostly it is insufficient to transmit data. Consequently, this leads to a question of how to choose the best mode, i.e., the harvest-then-transmit mode or backscatter mode, given the current radio conditions such that the total transmitted bits received at the SR per time unit is maximized. In the following, two scenarios

will be discussed, i.e., overlay and underlay cognitive cellular networks, and each scenario will present how to find the best trade-off time for the secondary user to maximize its throughput.

RF-Powered Backscatter Overlay Cognitive Cellular Network

Network Model

This section considers an RF-powered backscatter overlay cognitive cellular network (CCN) composed of a primary transmitter (PT) and a secondary transmitter (ST) [39]. In this network, the secondary transmitter (ST) is allowed to transmit signals to a primary channel iff this channel is currently not occupied by primary users. The ST communicates with a secondary receiver (SR). The ST is equipped with an RF energy harvesting module and a backscatter circuit to harvest RF energy and backscatter radio signals, respectively. The ST can also transmit data as normal wireless transmission. When the PT, e.g., a cellular base station (BS), transmits RF signal to its primary receiver (PR), the primary channel is busy. At the same time, the ST can either harvest energy and store it in an energy storage or backscatter the signal for data transmission [32]. The harvested energy is used for direct wireless data transmission to the SR when the primary channel becomes idle. This is referred to as the harvest-then-transmit mode, while the other is referred to as the backscatter mode. It is assumed that the SR perfectly knows the transmit mode of the ST and applies corresponding demodulators to extract useful information.

In the proposed system, when the PT transmits signals, i.e., the primary channel is busy, the ST can transmit data to the SR using backscatter communication (Fig. 5a) or harvest energy (Fig. 5b). Let β denote the normalized channel idle period and $(1-\beta)$ denote the normalized channel busy period as shown in Fig. 5. When the channel is busy, α denotes the time fraction for energy harvesting, and thus $(1-\alpha)$ denotes the time fraction for backscatter communication. The energy harvested

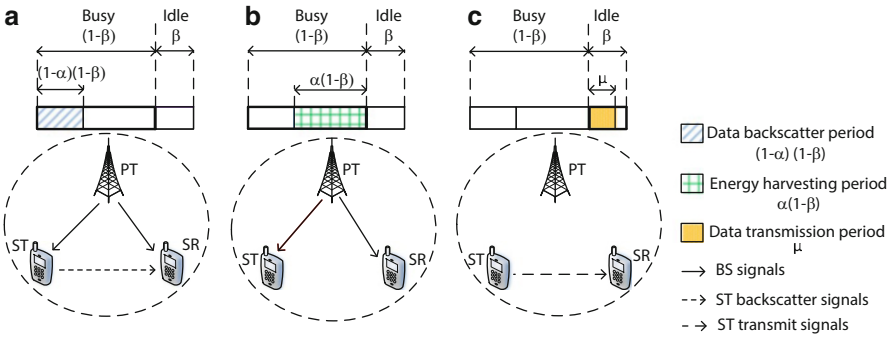

Fig. 5 RF-powered overlay cognitive radio network with ambient backscatter communication. (**a**) Backscattering data. (**b**) Harvesting energy. (**c**) Transmitting data

during the time fraction α will be stored in the ST's energy storage before it is used for direct data transmission during the idle channel period (Fig. 5c). It is observed that there is a trade-off between the time fractions for backscatter communication and energy harvesting. Clearly, the ST can achieve an optimal overall transmission rate through the dual mode of harvest then transmit and backscatter by balancing between backscatter communication and energy harvesting during the busy channel period. Thus, in the following, formulation and solution for the time optimization problem to find an optimal value of α for the ST will be presented.

Problem Formulation

We aim at maximizing the overall transmission rate of the secondary system, which is the number of information bits transmitted by the ST per time unit. We denote R as the overall transmission rate which is obtained as

$$R = R_{\mathrm{b}} + R_{\mathrm{h}}, \tag{7}$$

where R_{b} and R_{h} are the numbers of transmitted bits using the backscatter mode and the harvest-then-transmit mode in a time unit, respectively. Here, note that in the case of the backscatter mode, the interference to the primary receiver does not need to consider because through real experiments in [32], it was demonstrated that the backscattering transmitter does not create any noticeable glitches at the primary receiver unless it is less than 7 in.

Backscatter Mode

Transmission Rate of Backscatter Mode

It was shown in [32] that the transmission rate of the ambient backscatter communication depends on the setting of the RC circuit elements. For example, to transmit data at the transmission rate of 1 and 10 kbps, the values of circuit elements, i.e., R_1, R_2, C_1, and C_2, are set as (150 kΩ, 10 MΩ, 4.7 nF, 10 nF) and (150 kΩ, 10 MΩ, 680 pF, 1 μF), respectively. Therefore, let B_{b} denote the transmission rate of the ambient backscatter communication, i.e., the backscatter transmission rate. The total number of bits transmitted using the backscatter mode per time unit for the RF-powered backscatter CCN is expressed as follows:

$$R_{\mathrm{b}} = (1-\beta)(1-\alpha)B_{\mathrm{b}}. \tag{8}$$

Here, note that based on real implementations in [32], when the ST backscatters signals to the SR, the ST can still harvest energy from RF signals (i.e., when RF signals are absorbed for binary "0"). Although the amount of harvested energy is not enough to transmit data when the channel is idle, it is sufficient to sustain backscatter operations of the ST. Therefore, in (8), there is no need to consider the circuit energy consumption for the backscatter mode.

Harvest-Then-Transmit Mode

The harvest-then-transmit mode includes two phases. First, the ST harvests energy from the PT signals when the channel is busy. Then, the ST uses the harvested energy to transmit data when the primary channel becomes idle.

Harvesting Energy

From the Friis equation [4], the harvested RF power from the PT signals at the ST in a free space can be determined by

$$P_{\mathrm{R}} = \delta P_{\mathrm{T}} \frac{G_{\mathrm{T}} G_{\mathrm{R}} \lambda^2}{(4\pi d)^2}, \tag{9}$$

where P_{R} is the harvested power of the ST, P_{T} is the PT transmit power, $\delta \in [0, 1]$ is the energy harvesting efficiency, G_{T} is the PT antenna gain, G_{R} is the ST antenna gain, λ is the emitted wavelength, and d is the distance between the PT and ST. The total amount of harvested energy over the energy harvesting period $\alpha(1-\beta)$ then can be derived as follows:

$$E_{\mathrm{h}} = \alpha(1-\beta) P_{\mathrm{R}} = \alpha(1-\beta)\delta P_{\mathrm{T}} \frac{G_{\mathrm{T}} G_{\mathrm{R}} \lambda^2}{(4\pi d)^2}. \tag{10}$$

Transmitting Data

After harvesting energy, the ST uses all harvested energy deducted by the circuit energy consumption to transmit data over the data transmission period μ when the channel is idle. Let P^{tr} denote the transmit power of the ST in the data transmission period μ ($\mu \in [0, \beta]$ as shown in Fig. 5c) when the channel is idle. Then, P^{tr} can be obtained from

$$P^{\mathrm{tr}} = \frac{E_{\mathrm{h}} - E_{\mathrm{c}}}{\mu}, \tag{11}$$

where E_{h} is the total harvested energy and E_{c} is the circuit energy consumption. From [40], given the transmit power P^{tr}, the transmit data rate can be determined as follows:

$$r_{\mathrm{h}} = \kappa W \log_2 \left(1 + \frac{P^{\mathrm{tr}}}{P_0}\right), \tag{12}$$

where $\kappa \in [0, 1]$ is the transmission efficiency, W is the bandwidth of the primary channel, and P_0 is the ratio between the noise power N_0 and the channel gain coefficient h, i.e., $P_0 = \frac{N_0}{h}$.

Then, the number of transmitted bits per time unit using the harvest-then-transmit mode is given by

$$R_{\mathrm{h}} = \mu\kappa W \log_2 \left(1 + \frac{P^{\mathrm{tr}}}{P_0}\right) = \mu\kappa W \log_2 \left(1 + \frac{E_{\mathrm{h}} - E_{\mathrm{c}}}{\mu P_0}\right). \tag{13}$$

Here, since R_h in (13) must be non-negative, P^{tr} in (11) must be also non-negative. Therefore, from (11), the following condition is derived

$$E_h = \alpha(1-\beta)P_R \geq E_c, \tag{14}$$

it means

$$\alpha \geq \frac{E_c}{(1-\beta)P_R}. \tag{15}$$

Let's denote $\alpha^\dagger = \frac{E_c}{(1-\beta)P_R}$ as the minimum energy harvesting time to obtain enough energy for supplying the circuit of the ST to use the harvest-then-transmit mode. Then, $\alpha \geq \alpha^\dagger$. Note that since $\alpha \leq 1$, therefore if $\alpha^\dagger \leq 1$, then R_h can be greater than zero. Let's denote $m = \frac{(1-\beta)}{P_0\mu}P_R$ and $n = 1 - \frac{E_c}{P_0\mu}$. Then, from (13), it is derived that

$$R_h = \begin{cases} \mu\kappa W \log_2(n+m\alpha), & \text{if } \alpha^\dagger \leq 1 \text{and } \alpha^\dagger \leq \alpha, \\ 0, & \text{otherwise.} \end{cases} \tag{16}$$

Here, $m > 0$ and $(n + m\alpha) \geq 1$, $\forall \alpha \in [\alpha^\dagger, 1]$.

Then, to maximize the overall transmission rate of the secondary system, an optimization problem can be formulated as

$$\max_{\alpha,\mu} R(\alpha,\mu) = \begin{cases} (1-\beta)(1-\alpha)B_b + \mu\kappa W \log_2(n+m\alpha), & \text{if } \alpha^\dagger \leq 1 \text{ and } \alpha^\dagger \leq \alpha, \\ (1-\beta)(1-\alpha)B_b, & \text{otherwise.} \end{cases} \tag{17}$$

Proposed Solution

First, from (17), when $R(\alpha,\mu) = (1-\beta)(1-\alpha)B_b$, it is easy to show that

$$\max_{\alpha,\mu} R(\alpha,\mu) = R(\alpha=0) = (1-\beta)B_b, \forall \alpha \in [0,1]. \tag{18}$$

This implies that the ST will use only the backscatter mode when the primary channel is busy in this case.

Second, through Theorem 1, it will be proved that when $\alpha^\dagger \leq 1$ and $\alpha^\dagger \leq \alpha$, an optimal overall transmission rate is achieved when the ST transmits data over the entire channel idle period, i.e., $\max_{\alpha,\mu} R(\alpha,\mu) = R(\alpha,\beta)$.

Theorem 1. *When $\alpha^\dagger \leq 1$ and $\alpha^\dagger \leq \alpha$, if R_h from (16) is considered as a function of μ, then R_h reaches the highest value if and only if $\mu = \beta$. In other words,*

$$\max_{\mu} R_h(\mu) = R_h(\beta), \forall \mu \in [0,\beta]. \tag{19}$$

Proof. Since $\alpha^\dagger \leq 1$ and $\alpha^\dagger \leq \alpha$, then from (16), it will be derived that

$$R_{\mathrm{h}} = \mu\kappa W \log_2\left[1 + \frac{1}{P_0\mu}\big(\alpha(1-\beta)P_{\mathrm{R}} - E_{\mathrm{c}}\big)\right]. \tag{20}$$

To prove Theorem 1, let's denote $a = \kappa W$, $b = \frac{1}{P_0}\big(\alpha(1-\beta)P_{\mathrm{R}} - E_{\mathrm{c}}\big)$, where a and b are positive constants since now R_{h} is considered as a function of μ. Then, (16) becomes

$$R_{\mathrm{h}}(\mu) = a\mu \log_2\left(1 + \frac{b}{\mu}\right). \tag{21}$$

Then the first and second derivatives of R_{h} with respect to μ can be derived as follows:

$$R'_h(\mu) = a\log_2\left(1 + \frac{b}{\mu}\right) - \frac{ab}{(\mu+b)\ln 2}, \tag{22}$$

$$R''_h(\mu) = -\frac{ab^2}{\mu(\mu+b)^2\ln 2}. \tag{23}$$

From (23), it is observed that $R''_h < 0$ since a, b, and μ are greater than 0. Hence, $R'_h(\mu)$ is a decreasing function with respect to μ. Moreover, from (22), the following result can be derived

$$\lim_{\mu\to+\infty} R'_h(\mu) = \lim_{\mu\to+\infty} a\log_2\left(1 + \frac{b}{\mu}\right) - \lim_{\mu\to+\infty}\frac{ab}{(\mu+b)\ln 2} = 0. \tag{24}$$

Since when $\mu \to +\infty$, $R'_h(\mu) = 0$, this implies that $R'_h(\mu) > 0, \forall\mu \in [0,\beta]$. As a result, $R_{\mathrm{h}}(\mu)$ is an increasing function over $\mu \in [0,\beta]$, and thus $\max_\mu R_{\mathrm{h}}(\mu) = R_{\mathrm{h}}(\beta), \forall\mu \in [0,\beta]$.

The proof now is completed.

From Theorem 1, the optimization problem in (17) can be rewritten with only one variable α as follows:

$$\max_{\alpha} R(\alpha) = \begin{cases} (1-\beta)(1-\alpha)B_{\mathrm{b}} + \beta\kappa W\log_2(n+m\alpha), & \text{if } \alpha^\dagger \le 1 \text{ and } \alpha^\dagger \le \alpha, \\ (1-\beta)B_{\mathrm{b}}, & \text{otherwise.} \end{cases} \tag{25}$$

Then, the following theorem is hold.

Theorem 2. *When $\alpha \in [\alpha^\dagger, 1]$ and $\alpha^\dagger \le 1$ and the backscatter transmission rate $B_{\mathrm{b}} \in (\frac{\beta\kappa Wm}{(m+n)(1-\beta)\ln 2}, \frac{\beta\kappa Wm}{(m\alpha^\dagger+n)(1-\beta)\ln 2})$, there exists a globally optimal solution of $\alpha^* \in [\alpha^\dagger, 1]$ which maximizes R.*

Proof. For $\alpha \in [\alpha^\dagger, 1]$ and $\alpha^\dagger \le 1$, from (25) the first and second derivatives of $R(\alpha)$ with respect to α can be obtained as follows:

$$R'(\alpha) = -B_{\mathrm{b}}(1-\beta) + \frac{\beta\kappa W m}{(m\alpha+n)\ln 2}, \tag{26}$$

$$R''(\alpha) = -\frac{\beta\kappa W m^2}{(m\alpha+n)^2 \ln 2} < 0, \forall\alpha. \tag{27}$$

From (27), it can be inferred that $R'(\alpha)$ is a decreasing function with respect to α. Furthermore, to guarantee that there exists a value of $\alpha \in [\alpha^\dagger, 1]$ such that $R'(\alpha) = 0$, the following boundary conditions must be satisfied

$$\begin{aligned} R'(\alpha^\dagger) &= -B_{\mathrm{b}}(1-\beta) + \frac{\beta\kappa W m}{(m\alpha^\dagger+n)\ln 2} > 0, \text{ and} \\ R'(1) &= -B_{\mathrm{b}}(1-\beta) + \frac{\beta\kappa W m}{(m+n)\ln 2} < 0. \end{aligned} \tag{28}$$

Then, from (28), the following condition is hold

$$B_{\mathrm{b}} \in \left(\frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}, \frac{\beta\kappa W m}{(m\alpha^\dagger+n)(1-\beta)\ln 2} \right). \tag{29}$$

Here, let $\alpha^* \in [\alpha^\dagger, 1]$ correspond to an optimal point of the objective function $R(\alpha)$. From (26), it is derived that

$$\alpha^* = \frac{\beta\kappa W}{B_{\mathrm{b}}(1-\beta)\ln 2} - \frac{n}{m}. \tag{30}$$

Then, it can be concluded that if the condition in (29) is met, an optimal solution $\alpha^* \in [\alpha^\dagger, 1]$ will be always found such that $R'(\alpha^*) = 0$.

From (27), it will be showed that $R(\alpha)$ is a concave function. This implies that the optimal value of α^* is a globally optimal solution and it yields the maximum value of R. Specifically, if $B_{\mathrm{b}} \in \left(\frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}, \frac{\beta\kappa W m}{(m\alpha^\dagger+n)(1-\beta)\ln 2}\right)$, then a globally optimal solution can always be found $\alpha^* = \frac{\beta\kappa W}{B_{\mathrm{b}}(1-\lambda)\ln 2} - \frac{n}{m}$ which maximizes the objective function R.

The next theorem shows that if the backscatter transmission rate is high, the ST will backscatter as much as possible. Conversely, if the backscatter transmission rate is low, the ST will harvest energy for data transmission as much as possible.

Theorem 3. *For $\alpha \in [\alpha^\dagger, 1]$ and $\alpha^\dagger \leq 1$, if $B_{\mathrm{b}} \geq \frac{\beta\kappa W m}{(m\alpha^\dagger+n)(1-\beta)\ln 2}$, then $\alpha^* = \alpha^\dagger$. Moreover, when $B_{\mathrm{b}} \leq \frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}$, then $\alpha^* = 1$.*

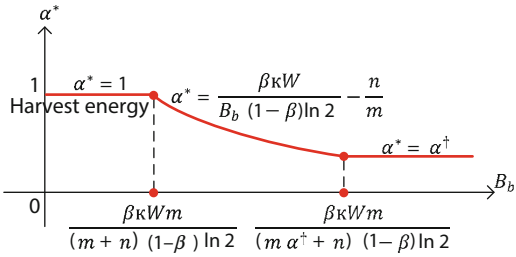

Fig. 6 Optimal value of α under the variation of B_b when $R_\mathrm{h} \geq 0$

Proof. First, it will be proved that if $B_\mathrm{b} \geq \frac{\beta\kappa W m}{(m\alpha^\dagger+n)(1-\beta)\ln 2}$, then $\alpha^* = \alpha^\dagger$. Since $B_\mathrm{b} \geq \frac{\beta\kappa W m}{(m\alpha^\dagger+n)(1-\beta)\ln 2}$, from (26), it will be derived that

$$R'(\alpha) \leq -\frac{\beta\kappa W m}{(m\alpha^\dagger+n)\ln 2} + \frac{\beta\kappa W m}{(n+m\alpha)\ln 2} = \frac{\beta\kappa W m^2(\alpha^\dagger-\alpha)}{(n+m\alpha)(m\alpha^\dagger+n)\ln 2} \leq 0. \tag{31}$$

From (31), there are two cases, i.e., $R'(\alpha) = 0$ or $R'(\alpha) < 0$. If $R'(\alpha) = 0$, i.e., $\alpha = \alpha^\dagger$, then $\alpha^* = \alpha^\dagger$. If $R'(\alpha) < 0$, then $R(\alpha)$ is a decreasing function with respect to α. In other words, $R(\alpha)$ decreases as α increases from $\alpha^\dagger$ to 1. Therefore, $R_{\max}(\alpha) = R(\alpha^\dagger)$. It means that $\alpha^* = \alpha^\dagger$.

Second, it will be proved that for $B_\mathrm{b} \leq \frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}$, the ST will always select the harvest-then-transmit mode in order to maximize the objective function R. Since $B_\mathrm{b} \leq \frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}$, from (26), it will be derived that

$$R'(\alpha) \geq -\frac{\beta\kappa W m}{(m+n)\ln 2} + \frac{\beta\kappa W m}{(n+m\alpha)\ln 2} = \frac{\beta\kappa W m^2(1-\alpha)}{(m+n)(n+m\alpha)\ln 2}. \tag{32}$$

Since $(n+m\alpha) > 0$ and $m > 0$ (from (16)), then $(n+m) > (n+m\alpha) > 0$, $\forall\alpha \in [\alpha^\dagger, 1]$. Consequently, $R'(\alpha) \geq 0, \forall\alpha \in [\alpha^\dagger, 1]$. Here, there are two cases, i.e., $R'(\alpha) = 0$ or $R'(\alpha) > 0$. If $R'(\alpha) = 0$, i.e., $\alpha = 1$, then $\alpha^* = 1$. If $R'(\alpha) > 0$, then $R(\alpha)$ is an increasing function with respect to α. It means that as α increases from $\alpha^\dagger$ to 1, $R(\alpha)$ will also increase. Therefore, for $\alpha^* = 1$, the ST will always choose the harvest-then-transmit mode to maximize its overall transmission rate when $B_\mathrm{b} \leq \frac{\beta\kappa W m}{(m+n)(1-\beta)\ln 2}$.

The proof is now completed.

From Theorems 2 and 3, it will be showed graphically in the optimal solution $\alpha^* \in [\alpha^\dagger, 1]$ under the variation of B_b in Fig. 6. Note that the convexity of the objective function R is proved in Theorem 2 and demonstrated in Fig. 11a.

Finally, the maximum value of R can be derived by

$$R_{\max} = \begin{cases} \max\left[(1-\beta)B_\mathrm{b}, (1-\beta)(1-\alpha^*)B_\mathrm{b} + \beta\kappa W \log_2(n+m\alpha^*)\right], & \text{if } \alpha \in [\alpha^\dagger, 1], \\ (1-\beta)B_\mathrm{b}, & \text{otherwise.} \end{cases} \tag{33}$$

RF-Powered Backscatter Underlay Cognitive Radio Network

Network Model

Unlike "overlay" CCNs where the secondary transmitter (ST) can harvest RF energy when the primary channel is busy and transmit data when the channel is idle, in the "underlay" CCN, the primary channel is assumed to be always busy. Therefore, the ST has to control the transmit power in order to avoid causing harmful interference to the primary receiver (PR). Therefore, different from the RF-powered backscatter "overlay" CCN studied in section "RF-Powered Backscatter Overlay Cognitive Cellular Network" where we need to find the optimal trade-off between backscattering time and energy harvesting time, in the RF-powered backscatter "underlay" CCN, we need to determine the optimal trade-off among backscattering time, harvesting time, and transmitting time such that the overall transmission rate is maximized. Moreover, the interference to the primary system must be guaranteed under a predefined threshold. Note that the transmit power of the secondary system can be expressed as a function of the transmitting time. This is because the transmit power is equal to the harvested energy from the harvesting time divided by the total transmitting time. Hence, in the following, an optimization problem considering the transmitting time of the ST as a decision variable instead of the transmit power will be presented.

Similar to the case of the overlay CCN, let's denote α as the time fraction for energy harvesting. However, the variable β now stands for the time fraction for data transmission instead of the idle channel period as in section "RF-Powered Backscatter Overlay Cognitive Cellular Network". Consequently, the time fraction for backscattering will be $(1-\alpha-\beta)$ as illustrated in Fig. 7. Then, the following conditions are hold, i.e., $\mathbf{C}_0$, for the values of α and β.

$$\mathbf{C}_0 \quad \text{s.t.} \begin{cases} \alpha, \beta \geq 0, \\ \alpha + \beta \leq 1. \end{cases} \tag{34}$$

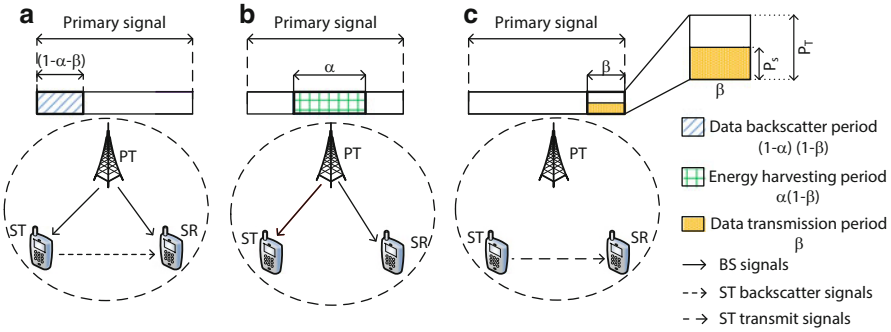

Fig. 7 RF-powered underlay cognitive radio network with ambient backscatter communication. (**a**) Backscattering data. (**b**) Harvesting energy. (**c**) Transmitting data

Problem Formulation

Again, let's denote R, R_b, and R_h as the total number of transmitted bits of the secondary system, the number of transmitted bits of the backscatter mode, and the number of transmitted bits of the harvest-then-transmit mode, respectively. For the case of an underlay CCN, it aims maximizing the overall transmission rate for the secondary system, i.e., R, under the transmit power constraint. First, the optimization problem is formulated, and then the solution to find the optimal trade-off for the ST is proposed by investigating the relation between the values of α and β.

Backscatter Mode

Similar to the previous section, the total number of bits transmitted by using the backscatter mode per time unit is determined as follows:

$$R_b = (1 - \alpha - \beta) B_b, \tag{35}$$

where B_b is the transmission bit rate of the backscatter mode. This rate depends on the hardware configuration of the wireless nodes as shown in [32].

Harvest-Then-Transmit Mode

Harvesting Energy

From the Friis equation [4], the received RF power from the PT at the ST is given in (9). The total amount of harvested energy over the energy harvesting period α in the case of an underlay CCN is obtained as follows:

$$E_h = \alpha P_R = \alpha \delta P_T \frac{G_T G_R \lambda^2}{(4\pi d)^2}. \tag{36}$$

Transmitting Data

After harvesting energy in the first phase, the ST uses all harvested energy deducted by the circuit energy consumption to transmit data over the data transmission period β. Let P_S denote the transmit power of the ST in the data transmission period β. Thus, P_S can be obtained from

$$P_S = \frac{E_h - E_c}{\beta}, \tag{37}$$

where E_h is the total harvested energy and E_c is the circuit energy consumption. If P_c is denoted as the circuit power consumption of the ST, then $E_c = \beta P_c$. Note that this case just considers the circuit energy consumption when the ST transmits data. When the ST harvests energy, the circuit energy consumption can be negligible [9, 13, 14, 22]. For the considered underlay CCN, the transmit power of the ST must be lower than a threshold to guarantee that the interference to the PR is acceptable. Thus, the following constraint is required

$$P_{\mathrm{S}} \leq P^{\ddagger}, \tag{38}$$

where $P^{\ddagger}$ is the maximum transmit power allowed for the ST. From (38), the constraint for α and β can be derived as follows:

$$\begin{aligned} \frac{\alpha P_{\mathrm{R}} - E_{\mathrm{c}}}{\beta} &\leq P^{\ddagger}, \\ \alpha P_{\mathrm{R}} &\leq \beta P_{\mathrm{c}} + \beta P^{\ddagger}, \\ \alpha &\leq \beta \frac{P_{\mathrm{c}} + P^{\ddagger}}{P_{\mathrm{R}}}. \end{aligned} \tag{39}$$

From [40], given the transmit power P_{S}, the transmission rate can be obtained in a similar way as presented in (12) as follows:

$$r_{\mathrm{h}} = \kappa W \log_2 \left(1 + \frac{P_{\mathrm{S}}}{P_0}\right). \tag{40}$$

Then, the number of transmitted bits per time unit using the harvest-then-transmit mode is given by

$$\begin{aligned} R_{\mathrm{h}} &= \beta \kappa W \log_2 \left(1 + \frac{P_{\mathrm{S}}}{P_0}\right) = \beta \kappa W \log_2 \left(1 + \frac{E_{\mathrm{h}} - E_{\mathrm{c}}}{\beta P_0}\right) \\ R_{\mathrm{h}} &= \beta \kappa W \log_2 \left(1 + \frac{\alpha P_{\mathrm{R}} - \beta P_{\mathrm{c}}}{\beta P_0}\right). \end{aligned} \tag{41}$$

Here, since R_{h} in (41) must be no n-negative, P_{S} in (37) must be also non-negative. Consequently, from (36) and (37), the following condition is hold

$$\begin{aligned} E_{\mathrm{h}} = \alpha P_{\mathrm{R}} \geq E_{\mathrm{c}}, \quad &\text{it means} \\ \alpha \geq \frac{E_{\mathrm{c}}}{P_{\mathrm{R}}} &= \frac{\beta P_{\mathrm{c}}}{P_{\mathrm{R}}}, \\ \alpha \geq \beta \frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}&. \end{aligned} \tag{42}$$

The constraint in (42) implies that the length of the harvesting period must be sufficient long to yield energy greater than the circuit energy consumption of the ST to use the harvest-then-transmit mode. Then, from (34), (39), and (42), the constraints for variables α and β can be derived as shown in Fig. 8.

- In Fig. 8, the triangle (OAB) represents the feasible region of α and β which satisfies the constraint $\mathbf{C}_0$.

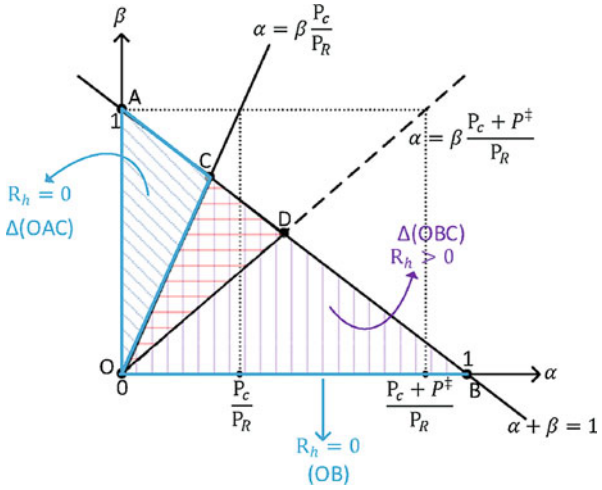

Fig. 8 Variable constraints

- The triangle (OAC) and the segment (OB) correspond to the case when $R_\mathrm{h} = 0$, i.e., when the amount of harvested energy is not enough to transmit data, i.e., $\alpha \leq \beta \frac{P_\mathrm{c}}{P_\mathrm{R}}$, and when the transmission period is zero, i.e., $\beta = 0$, respectively.
- The triangle (OBC) (not including the segments (OC) and (OB)) is the feasible region corresponding to the case when $R_\mathrm{h} > 0$.
- The triangle (ODB) (not including the segments (OB) and (OD)) corresponds to the case when $P_\mathrm{S} > P^{\ddagger}$.
- The triangle (ODC) excluding segment (OC) corresponds to the feasible region in which $R_\mathrm{h} > 0$, and the power constraint of the secondary transmitter, i.e., $\alpha \leq \beta \frac{P_\mathrm{c}+P^{\ddagger}}{P_\mathrm{R}}$, is satisfied.

Note that when $\alpha = 0$, i.e., there is no energy harvesting, β must be zero. Likewise, when $\beta = 0$, i.e., there is no data transmission, then α must be zero because the harvested energy will not be used. Thus, from Fig. 8 and (41), it can be derived that

$$R_\mathrm{h} = \begin{cases} \beta \kappa W \log_2\left(1 + \frac{\alpha P_\mathrm{R} - \beta P_\mathrm{c}}{\beta P_0}\right), & \text{if } \alpha + \beta \leq 1, \alpha > 0, \beta > 0, \text{ and } \alpha > \beta \frac{P_\mathrm{c}}{P_\mathrm{R}}, \\ 0, & \text{if } \alpha + \beta \leq 1, \alpha > 0, \beta > 0, \text{ and } \alpha \leq \beta \frac{P_\mathrm{c}}{P_\mathrm{R}}, \\ & \text{OR if } \alpha\beta = 0, \end{cases}$$

$$\text{s.t. } \alpha \leq \beta \frac{P_\mathrm{c} + P^{\ddagger}}{P_\mathrm{R}}. \tag{43}$$

In (43), the constraint $\alpha \leq \beta \frac{P_\mathrm{c}+P^{\ddagger}}{P_\mathrm{R}}$ is applied when $R_\mathrm{h} > 0$ only. This is because when $R_\mathrm{h} = 0$, there is no interference to the primary system, and thus this constraint is not required. Then, the optimization problem can be formulated as follows:

$$\max_{\alpha,\beta} R(\alpha,\beta) =$$

$$\begin{cases} (1-\alpha-\beta)B_{\mathrm{b}} + \beta\kappa W \log_2\left(1+\frac{\alpha P_{\mathrm{R}}-\beta P_{\mathrm{c}}}{\beta P_0}\right), & \text{if } \alpha+\beta \le 1, \alpha>0, \beta>0, \\ & \text{and } \alpha > \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \\ (1-\alpha-\beta)B_{\mathrm{b}}, & \text{if } \alpha+\beta \le 1, \alpha>0, \beta>0, \\ & \text{and } \alpha \le \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \text{OR if } \alpha\beta = 0 \end{cases}$$

$$\text{s.t. } \alpha \le \beta\frac{P_{\mathrm{c}}+P^{\ddagger}}{P_{\mathrm{R}}}. \tag{44}$$

In (44), it is easy to show that when $R(\alpha,\beta) = (1-\alpha-\beta)B_{\mathrm{b}}$, i.e., only the backscatter mode is used by the ST, the optimization problem is simplified to

$$\max_{\alpha,\beta} R(\alpha,\beta) = R(0,0) = B_{\mathrm{b}}. \tag{45}$$

Accordingly, the optimization problem in (44) can be written as follows:

$$\mathbf{P}_1 \quad \max_{\alpha,\beta} R(\alpha,\beta) =$$

$$\begin{cases} (1-\alpha-\beta)B_{\mathrm{b}} + \beta\kappa W \log_2\left(1+\frac{\alpha P_{\mathrm{R}}-\beta P_{\mathrm{c}}}{\beta P_0}\right), & \text{if } \alpha+\beta \le 1, \alpha>0, \beta>0, \\ & \text{and } \alpha > \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \\ B_{\mathrm{b}}, & \text{if } \alpha+\beta \le 1, \alpha>0, \beta>0, \\ & \text{and } \alpha \le \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \text{ OR if } \alpha\beta = 0, \end{cases}$$

$$\mathbf{C}_1 \quad \text{s.t. } \alpha \le \beta\frac{P_{\mathrm{c}}+P^{\ddagger}}{P_{\mathrm{R}}}. \tag{46}$$

Proposed Solution

It is observed that α and β are not separate variables. For the harvest-then-transmit mode, they are dependent as indicated in [12, 13]. Therefore, the relation between α and β needs to be examined, and then the optimization problem with two variables will be transformed into a new optimization problem with only one variable, which is easier to solve and analyze.

Optimal Time Allocation for Harvest-Then-Transmit Mode

Here, it will be showed that an optimal ratio between the energy harvesting period and the data transmission period can be found. Let γ denote the time fraction for the data transmission and $(1-\gamma)$ denote the time fraction for the energy harvesting as shown in Fig. 9.

Similar to the previous section, the number of transmitted bits per time unit using the harvest-then-transmit mode can be derived by replacing $\alpha = (1-\gamma)$ and $\beta = \gamma$ in (43), i.e.,

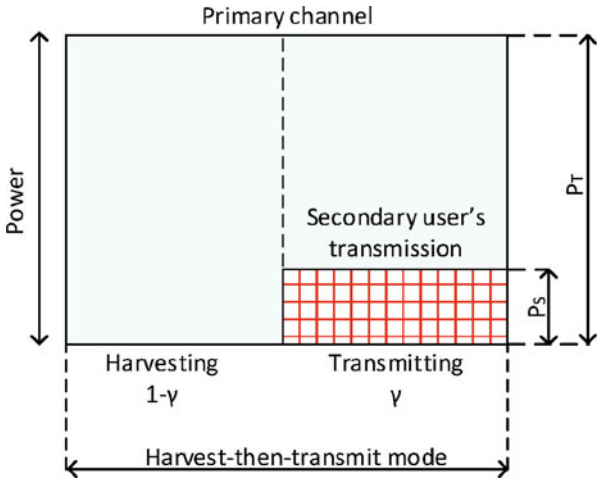

Fig. 9 Optimal time allocation for harvest-then-transmit mode

$$R_{\mathrm{h}} = \begin{cases} \gamma\kappa W \log_2\left(1 + \frac{(1-\gamma)P_{\mathrm{R}} - \gamma P_{\mathrm{c}}}{\gamma P_0}\right), & \text{if } \alpha + \beta \le 1, \alpha > 0, \beta > 0, \text{ and } \alpha > \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \\ 0, & \text{if } \alpha + \beta \le 1, \alpha > 0, \beta > 0, \text{ and } \alpha \le \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}} \\ & \text{OR if } \alpha\beta = 0, \end{cases}$$

$$\text{s.t. } \alpha \le \beta\frac{P_{\mathrm{c}} + P^{\ddagger}}{P_{\mathrm{R}}}. \tag{47}$$

The first condition $\alpha + \beta = (1-\gamma) + \gamma \le 1$ is always satisfied. The second and third conditions

$$\alpha > 0 \text{ and } \beta > 0 \text{ are to ensure that } \gamma < 1 \text{ and } \gamma > 0. \tag{48}$$

For the fourth condition in (47), it will be derived that

$$\alpha > \beta\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}, \text{so } 1 - \gamma > \gamma\frac{P_{\mathrm{c}}}{P_{\mathrm{R}}}. \text{ Thus } \gamma < \frac{P_{\mathrm{R}}}{P_{\mathrm{c}} + P_{\mathrm{R}}}. \tag{49}$$

For the last condition in (47), it will be derived that

$$\alpha\beta = 0, \text{so } (1-\gamma)\gamma = 0, \text{i.e., } \gamma = 0 \text{ or } \gamma = 1. \tag{50}$$

From the constraint in (47), it will be derived that

$$\begin{aligned} \alpha P_{\mathrm{R}} &\le \beta P_{\mathrm{c}} + \beta P^{\ddagger}, \\ (1-\gamma)P_{\mathrm{R}} &\le \gamma P_{\mathrm{c}} + \gamma P^{\ddagger}, \\ \frac{P_{\mathrm{R}}}{P_{\mathrm{c}} + P^{\ddagger} + P_{\mathrm{R}}} &\le \gamma. \end{aligned} \tag{51}$$

Finally, from (48), (49), (50), and (51), it will be derived that

$$R_{\mathrm{h}} = \begin{cases} \gamma\kappa W \log_2\left(1 + \frac{(1-\gamma)P_{\mathrm{R}} - \gamma P_{\mathrm{c}}}{\gamma P_0}\right), & \text{if } \gamma \in \left(0, \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}\right), \\ 0, & \text{if } \gamma \in \left[\frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}, 1\right) \text{ OR if } (1-\gamma)\gamma = 0, \end{cases}$$

$$\text{s.t. } \gamma \geq \frac{P_{\mathrm{R}}}{P_{\mathrm{c}} + P^{\ddagger} + P_{\mathrm{R}}}. \tag{52}$$

Since $\frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P^{\ddagger}+P_{\mathrm{R}}} < \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}$, for $\gamma \in (0, \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}})$, the optimization problem for the harvest-then-transmit mode becomes

$$\mathbf{P}_2 \quad \max_{\gamma} R_{\mathrm{h}}(\gamma) = \gamma\kappa W \log_2\left(1 + \frac{(1-\gamma)P_{\mathrm{R}} - \gamma P_{\mathrm{c}}}{\gamma P_0}\right), \tag{53}$$

$$\mathbf{C}_2 \quad \text{s.t.} \begin{cases} \gamma < \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}, \\ \gamma \geq \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P^{\ddagger}+P_{\mathrm{R}}}. \end{cases}$$

To simplify the presentation, let's denote

$$a = \kappa W, \quad b = 1 - \frac{P_{\mathrm{R}} + P_{\mathrm{c}}}{P_0}, \quad \text{and} \quad c = \frac{P_{\mathrm{R}}}{P_0}. \tag{54}$$

The transmission rate of the harvest-then-transmit mode can be expressed as follows:

$$R_{\mathrm{h}}(\gamma) = a\gamma \log_2\left(b + \frac{c}{\gamma}\right). \tag{55}$$

From (55), the first derivative of R_{h} with respect to γ can be obtained as follows:

$$R'_h = a \log_2\left(b + \frac{c}{\gamma}\right) - \frac{ac}{(b\gamma + c)\ln 2}. \tag{56}$$

In the following, it will be showed that $R'_h = 0$ has a unique solution of γ.

Theorem 4. *If* $1 - \frac{P_{\mathrm{R}}+P_{\mathrm{c}}}{P_0} \geq (1 + \frac{P^{\ddagger}}{P_0})(1 - \ln(1 + \frac{P^{\ddagger}}{P_0}))$, *then a globally optimal solution* γ_1^* *for the optimization problem* $\mathbf{P}_2$ *with the constraint* $\mathbf{C}_2$ *that maximizes* R_{h} *can always be found.*

Proof. Let's define $X = b + \frac{c}{\gamma}$. Then, it will be proved that $X > 1$ and $X \leq 1 + \frac{P^{\ddagger}}{P_0}$ if γ satisfies $\mathbf{C}_2$. From the first constraint in $\mathbf{C}_2$, it will be derived that $\gamma < \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}$, so

$$X = b + \frac{c}{\gamma} > b + \frac{c}{\frac{P_R}{P_c+P_R}} > 1 - \frac{P_R + P_c}{P_0} + \frac{\frac{P_R}{P_0}}{\frac{P_R}{P_c+P_R}} > 1. \tag{57}$$

From the second constraint in $\mathbf{C}_2$, it will be derived that $\gamma \geq \frac{P_R}{P_c+P^{\ddagger}+P_R}$, so

$$X = b + \frac{c}{\gamma} \leq b + \frac{c}{\frac{P_R}{P_c+P^{\ddagger}+P_R}} \leq 1 - \frac{P_R + P_c}{P_0} + \frac{\frac{P_R}{P_0}}{\frac{P_R}{P_c+P^{\ddagger}+P_R}} \leq 1 + \frac{P^{\ddagger}}{P_0}. \tag{58}$$

From (56), it will be derived that

$$\begin{aligned} g(X) = R'_h &= a \log_2 \left(b + \frac{c}{\gamma}\right) - \frac{ac}{(b\gamma + c)\ln 2}, \\ &= a \frac{\ln\left(b + \frac{c}{\gamma}\right)}{\ln 2} - \frac{\left(b + \frac{c}{\gamma} - b\right)a}{\left(b + \frac{c}{\gamma}\right)\ln 2}, \\ &= a \frac{\ln\left(b + \frac{c}{\gamma}\right)}{\ln 2} + \frac{ab}{\left(b + \frac{c}{\gamma}\right)\ln 2} - \frac{a}{\ln 2}, \\ &\quad \frac{a}{\ln 2}\left(\ln\left(b + \frac{c}{\gamma}\right) + \frac{b}{b + \frac{c}{\gamma}} - 1\right), \\ &= \frac{a}{\ln 2}\Big(\ln X + \frac{b}{X} - 1\Big), \\ &= \frac{a}{X \ln 2}\Big(X \ln X + b - X\Big). \end{aligned} \tag{59}$$

Then, we need to find the value of $X \in \left(1, 1 + \frac{P^{\ddagger}}{P_0}\right]$ that satisfies $g(X) = R'_h(\gamma) = 0$. It means

$$\frac{a}{X \ln 2}\Big(X \ln X + b - X\Big) = 0,$$

$$X - X \ln X = b \ \ (\text{since } \ a > 0 \ \text{ and} X > 1). \tag{60}$$

Let's denote $G(X) = X - X \ln X$. Then from Fig. 10, it can be concluded that if $b \in [G(1 + \frac{P^{\ddagger}}{P_0}), G(1))$, then a unique solution X^* satisfying the condition in (59) can always be found.

Since $X = b + \frac{c}{\gamma}$, it can be concluded that if $b \in [G(1 + \frac{P^{\ddagger}}{P_0}), G(1))$, then a unique solution $\gamma_1^* = \frac{c}{X^* - b}$ which satisfies $R'_h(\gamma_1^*) = 0$ can always be found. Moreover, since $b = 1 - \frac{P_R + P_c}{P_0}$, $b < G(1) = 1$ is hold. Therefore, if $b = 1 - \frac{P_R + P_c}{P_0} \geq$

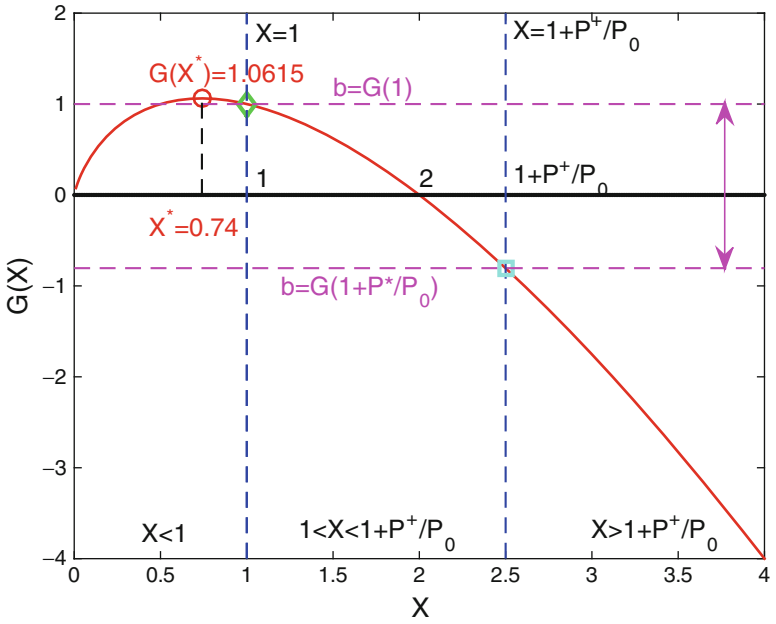

Fig. 10 Function $G(X)$

$G(1+\frac{P_0^\ddagger}{P_0}) = (1+\frac{P_0^\ddagger}{P_0})(1-\ln(1+\frac{P_0^\ddagger}{P_0}))$, then a unique solution γ_1^* such that $R_h'(\gamma_1^*) = 0$ can alawys be found.

Moreover, from (56), the second derivative of R_h can be derived as follows:

$$R_h'' = -\frac{ac^2}{(b\gamma + c)^2 \gamma \ln 2}. \tag{61}$$

Here, since $a = \kappa W > 0$, $\gamma > 0$, and $c > 0$, $R_h'' < 0$. This means that R_h is a concave function. Therefore, if γ_1^* is an optimal solution of $\mathbf{P}_2$, then it is a unique globally optimal solution, and γ_1^* maximizes the objective function R_h.

The proof is now completed.

Theorem 5. *If* $1-\frac{P_\mathrm{R}+P_\mathrm{c}}{P_0} < (1+\frac{P_0^\ddagger}{P_0})(1-\ln(1+\frac{P_0^\ddagger}{P_0}))$, *then a globally optimal solution* γ_2^* *for the optimization problem* $\mathbf{P}_2$ *with constraint* $\mathbf{C}_2$ *which maximizes* R_h *can always be found.*

Proof. From (59), it can be derived that $R_h'(\gamma) = g(X) = \frac{a}{X\ln 2}(b - G(X))$. Since $X \in (1, 1+\frac{P_0^\ddagger}{P_0}]$, from Fig. 10, if $b < G(1+\frac{P_0^\ddagger}{P_\mathrm{R}})$, i.e., $1-\frac{P_\mathrm{R}+P_\mathrm{c}}{P_0} < (1+\frac{P_0^\ddagger}{P_0})(1-\ln(1+\frac{P_0^\ddagger}{P_0}))$, then $R_h'(\gamma) = g(X) < 0$. This implies that R_h is a decreasing function. Thus, there exists a unique value of γ_2^* such that $R_\mathrm{h}(\gamma_2^*)$ is maximized. Additionally, from $\mathbf{C}_2$, it can be derived that $\gamma \in [\frac{P_\mathrm{R}}{P_\mathrm{c}+P^\ddagger+P_\mathrm{R}}, \frac{P_\mathrm{R}}{P_\mathrm{c}+P_\mathrm{R}})$. Thus, $\gamma_2^* = \frac{P_\mathrm{R}}{P_\mathrm{c}+P^\ddagger+P_\mathrm{R}}$.

The proof is now completed.

From Theorems 4 and 5, the optimal value of γ and R_{h} can be derived as follows:

$$(\gamma^*, R_{\mathrm{h}}^*) = \begin{cases} (\gamma_1^*, R_{\mathrm{h}}(\gamma_1^*)), \text{ if } 1 - \frac{P_{\mathrm{R}}+P_{\mathrm{c}}}{P_0} \geq \left(1 + \frac{P^{\ddagger}}{P_0}\right)\left(1 - \ln\left(1 + \frac{P^{\ddagger}}{P_0}\right)\right), \\ (\gamma_2^*, R_{\mathrm{h}}(\gamma_2^*)), \text{ if } 1 - \frac{P_{\mathrm{R}}+P_{\mathrm{c}}}{P_0} < \left(1 + \frac{P^{\ddagger}}{P_0}\right)\left(1 - \ln\left(1 + \frac{P^{\ddagger}}{P_0}\right)\right), \end{cases} \tag{62}$$

where $\gamma_1^* = \frac{c}{X^* - b}$ and $\gamma_2^* = \frac{P_{\mathrm{R}}}{P_{\mathrm{c}} + P^{\ddagger} + P_{\mathrm{R}}}$.

Optimal Time Trade-Off for Backscatter and Harvest-Then-Transmit Modes

Let's denote

$$\gamma^* = \begin{cases} \gamma_1^*, \text{ if } 1 - \frac{P_{\mathrm{R}}+P_{\mathrm{c}}}{P_0} \geq \left(1 + \frac{P^{\ddagger}}{P_0}\right)\left(1 - \ln\left(1 + \frac{P^{\ddagger}}{P_0}\right)\right), \\ \gamma_2^*, \text{ if } 1 - \frac{P_{\mathrm{R}}+P_{\mathrm{c}}}{P_0} < \left(1 + \frac{P^{\ddagger}}{P_0}\right)\left(1 - \ln\left(1 + \frac{P^{\ddagger}}{P_0}\right)\right), \end{cases} \tag{63}$$

where $\gamma^* \in \left[\frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P^{\ddagger}+P_{\mathrm{R}}}, \frac{P_{\mathrm{R}}}{P_{\mathrm{c}}+P_{\mathrm{R}}}\right)$. Also, let $\tau = \alpha + \beta$, then the following results can be derived $\alpha = (1 - \gamma^*)\tau$ and $\beta = \tau\gamma^*$.

Now the optimization problem has been simplified to find an optimal time ratio, i.e., τ, between the backscatter mode and the harvest-then-transmit mode such that the overall transmission rate of the ST is maximized. Then, for $\tau \in [0, 1]$, the optimization problem $\mathbf{P}_1$ can be rewritten as follows:

$$\mathbf{P}_3 \quad \max_{\tau} R(\tau) = \begin{cases} (1-\tau)B_{\mathrm{b}} + \tau\gamma^*\kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right), & \text{if } \tau \in (0, 1], \\ B_{\mathrm{b}}, & \text{if } \tau = 0. \end{cases} \tag{64}$$

For $\tau \in (0, 1]$, it is observed that $R(\tau)$ is a linear function with respect to τ and

$$R'(\tau) = -B_{\mathrm{b}} + \gamma^*\kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right), \tag{65}$$

thus

$$R(\tau) \begin{cases} \text{is a decreasing function, if } R'(\tau) < 0, \\ \text{is an increasing function, if } R'(\tau) > 0. \end{cases} \tag{66}$$

Therefore, the following result is hold

$$\max_{\tau} R(\tau) = \begin{cases} R(\tau = 0) = B_{\mathrm{b}}, & \text{if } R'(\tau) < 0, \\ R(\tau = 1) = \gamma^*\kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right), & \text{if } R'(\tau) > 0. \end{cases} \tag{67}$$

In other words, the ST will select the backscatter mode if $B_{\mathrm{b}} > \gamma^*\kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right)$ and the harvest-then-transmit mode otherwise. Here, note that for

$B_{\mathrm{b}} = \gamma^* \kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right)$, then it will be derived that $R(\tau) = B_{\mathrm{b}} = \gamma^* \kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right)$. This implies that $R(\tau)$ is a constant. Therefore, the ST can choose either the backscatter mode or the harvest-then-transmit mode since both modes have the same transmission bit rate.

Let $B_{\mathrm{b}}^* = \gamma^* \kappa W \log_2\left(1 + \frac{(1-\gamma^*)P_{\mathrm{R}} - \gamma^* P_{\mathrm{c}}}{\gamma^* P_0}\right)$ denote the threshold of the transmission rate of the backscatter mode, then the optimal transmission policy for the ST in this case can be expressed as a step function as follows:

$$\text{ST's Action} = \begin{cases} \text{Backscatter mode}, & \text{if } B_{\mathrm{b}} \geq B_{\mathrm{b}}^* \\ \text{Harvest-then-transmit mode}, & \text{if } B_{\mathrm{b}} < B_{\mathrm{b}}^*. \end{cases} \tag{68}$$

Numerical Results and Performance Evaluation

To evaluate the performance for the proposed solution, simulation experiments for two scenarios, i.e., RF-powered "overlay" and "underlay" CCNs, will be presented. For each scenario, the overall transmission rate of the proposed solution with the primary signal being FM signal and examine the cases with other PTs, i.e., TV signal, 3G signal, and WiFi signal, will be showed. Then, the transmission policy of the secondary transmitter (ST) under the variation of parameters will be investigated, and the performance of the proposed solution will be compared with other baseline policies, i.e., the harvest-then-transmit protocol [12, 13], and ambient backscatter communication [32].

Experiment Setup

The parameters of the signals are provided in Table 1. Here, note that the transmit power from a macrocell base station is capped at 46 and 24 dBm for a small-cell access point. Therefore, the transmit power of the small-cell and WiFi access points is set at 10 dBm.

The other parameters are set as follows. The PT antenna gain and ST antenna gain are 6 dBi as in [41], and the circuit power consumption is −35 dBm. The energy harvesting efficiency and data transmission efficiency are 0.6. The idle channel ratio, the backscatter transmission rate, the transmit power constraint for the case

Table 1 Referenced parameters

RF source	Transmit power	Frequency	Bandwidth	Distance
FM tower	17 kW	100 MHz	100 KHz	6.7 miles
TV tower	17 kW	915 MHz	6 MHz	2 km
Cellular BS	10 dBm	2.15 GHz	14 MHz	100 m
WiFi AP	10 dBm	2.4 GHz	20 MHz	2 m

of the underlay CCN, and the TV signal frequency will be varied to evaluate the performance as well as the policy of the secondary system.

Overlay Cognitive Radio Networks

Figure 11a shows the overall transmission rate $R(\alpha)$ in (25) as the value of α is varied. Here, the idle channel ratio is set at 0.3 (i.e., the RF source transmits signals 70% of the total time) and the backscatter transmission rate at 33 kbps. In Fig. 11a, it is observed that if the ST uses either the backscatter mode or the harvest-then-transmit mode, then the overall transmission rates of the ST are 23.1 and 22.563 kbps, respectively. However, if the ST spends 41.125% of time (in the busy channel period) for the energy harvesting, i.e., $\alpha = 0.41125$, and 58.875% for backscattering, then the overall transmission rate of the secondary system can be up to 25.2264 kpbs. This can be explained through Fig. 11b. As the value of α increases, R_{b} decreases linearly, while R_{h} increases following the logarithmic function. This is because when α is too small, i.e., the ST spends much time for the backscattering, the ST cannot fully utilize the channel idle period for data transmission because of the small amount of harvested energy. Alternatively, if the value of α is too high, i.e., the ST spends much time for harvesting energy, the overall transmission rate will be low because the backscatter mode is not efficiently utilized during the channel busy period.

Then, the channel idle ratio β is varied, and its impact on the transmission policy as well as performance of the secondary system will be analyzed. As shown in Fig. 12a, when the channel idle ratio is increased from 0.1 to 0.5, the optimal value of α increases quickly from 0.1 to 0.95, and it then remains stable at 1 when β is greater than 0.5. Clearly, for the primary channel with low channel idle ratio, the ST will spend more time for the backscatter mode. By contrast, for the primary channel with a high idle channel ratio, the ST prefers the harvest-then-transmit mode. This is from the fact that the harvest-then-transmit mode can provide higher transmission rate than that of the backscatter mode. Hence, when the channel idle ratio is high, the ST will spend the whole time to harvest energy when the channel is busy.

Figure 12b shows the overall transmission rate obtained by the proposed solution and comparison with two baseline policies, namely, the backscatter only policy (BP) and harvest-then-transmit only policy (HP). With our proposed solution, the overall transmission rate is approximately 2 times greater than that of the HP and 1.3 times greater than that of the BP when the channel idle ratios are 0.1 and 0.6, respectively. Here, for the HP policy, its transmission rate first increases when β increases from 0.1 to 0.3, but if β keeps increasing, its transmission rate will be reduced. The reason is that when the channel idle ratio is low, the ST will have less time to transmit data. On contrary, if the channel idle ratio is high, the ST will have less time for harvesting energy. Therefore, both result in low transmission rate.

Next, the backscatter transmission rate is varied, and the optimal solution together with the performance of the secondary system is evaluated. Here, the idle

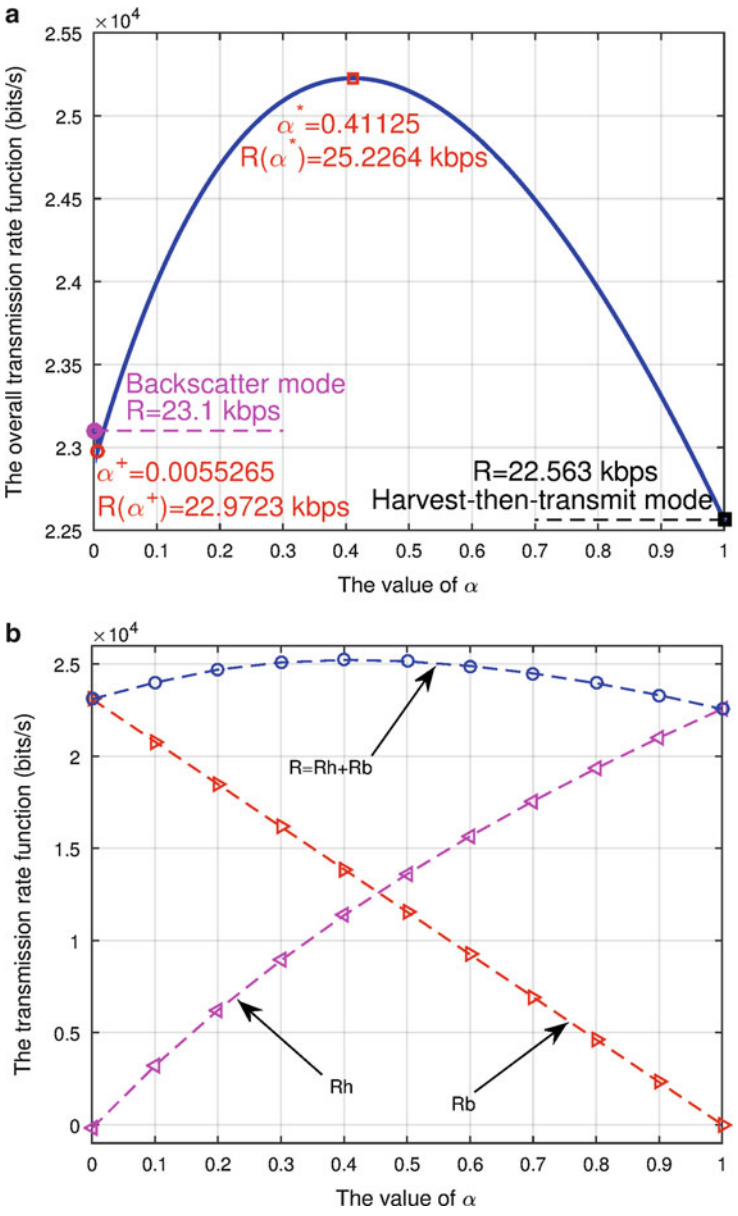

Fig. 11 The overall transmission rate under different values of alpha

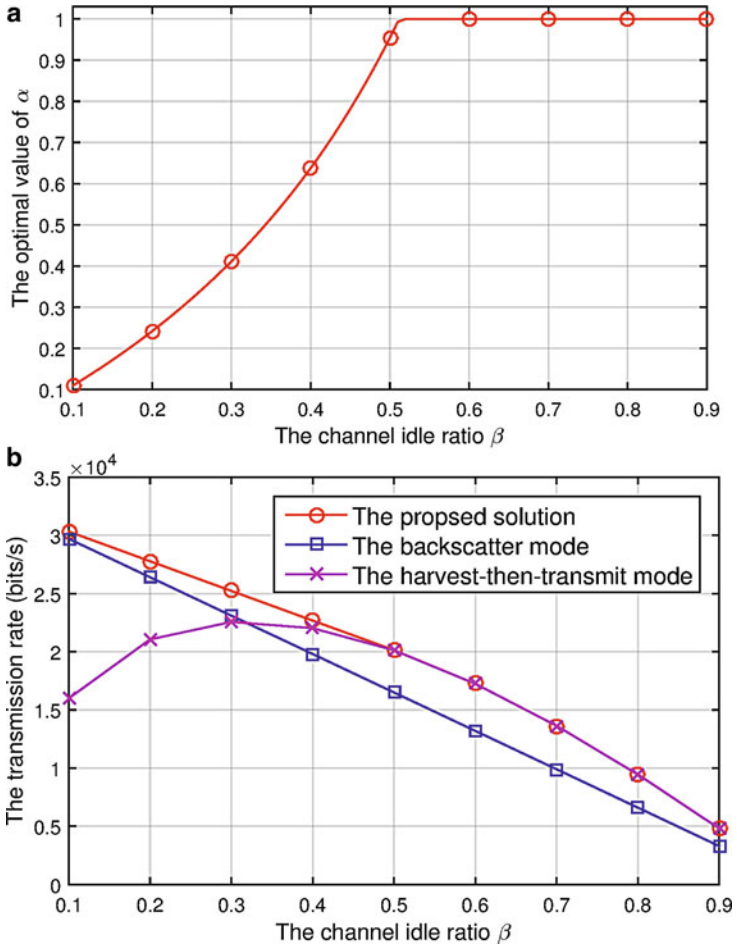

Fig. 12 The performance of the system under the variation of channel idle ratio

channel ratio is set at 0.3. In particular, as shown in Fig. 13a, as the backscatter transmission rate is increased from 1 to 21 kbps, the ST will always choose the harvest-then-transmit mode, i.e., $\alpha = 1$. However, if the backscatter transmission rate keeps increasing, the ST will spend more time for the backscatter mode. When it is greater than 45 kbps, the ST will use the backscatter mode only. Again, here the proposed solution always achieves the best performance compared with those of the BP and the HP as showed in Fig. 13b.

Then, the transmission policy of the ST under different wireless signals from selected practical RF sources is examined. Specifically, Fig. 13c studies three different signals, i.e., FM signals, TV signals, and WiFi signals. As observed in Fig. 13c, the ST will only select the harvest-then-transmit mode when the

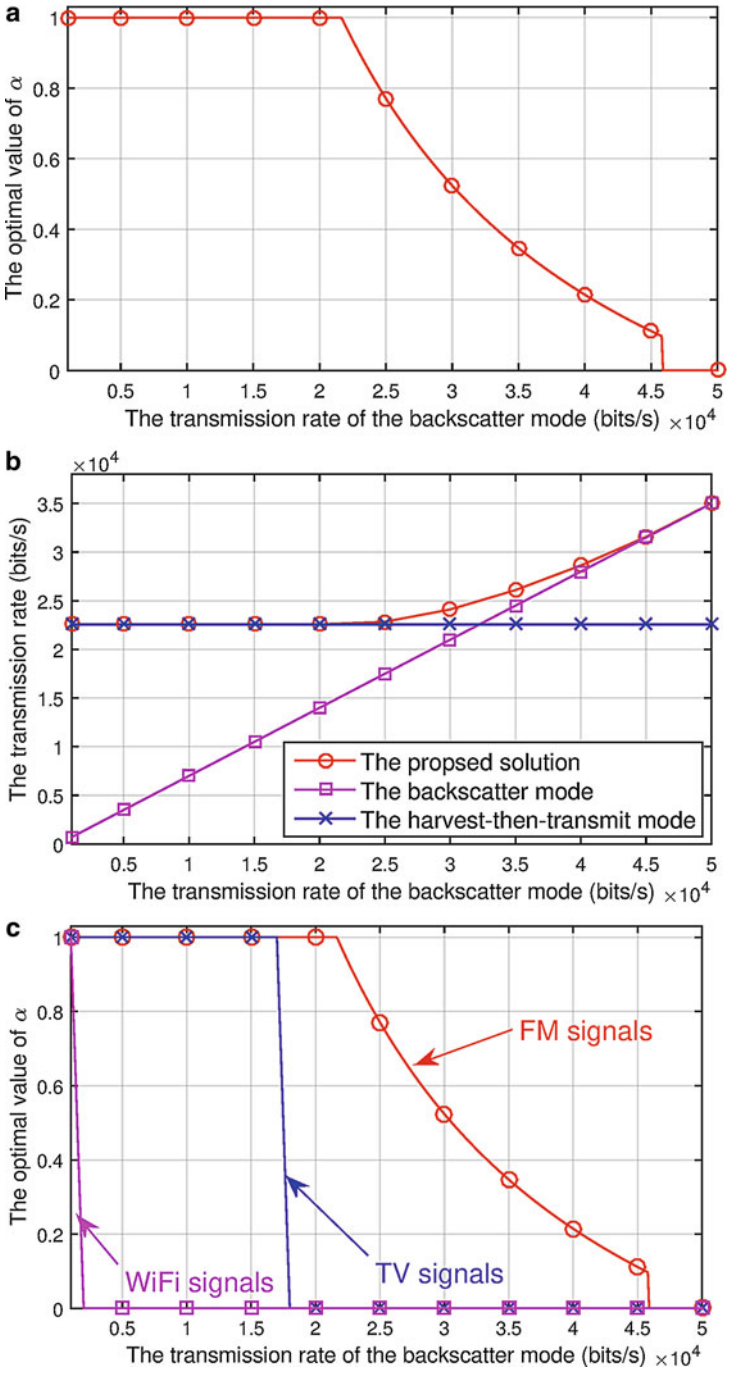

Fig. 13 The performance of the system under the variation of backscatter transmission rate

backscatter transmission rate is lower than 17 and 1 kbps, for TV signals and WiFi signals, respectively. This can be explained through the Friis equation in (9). In particular, for TV signals and WiFi signals, because they are transmitted at high frequencies (i.e., 915 MHz and 2.4 GHz, respectively), the amount of energy harvested at the ST will be reduced significantly, as compared with the FM signal. For WiFi signals, although the secondary system can be placed near the power source, e.g., access point, the source transmit power is relatively small (around 10 dBm as shown in Table 1) and the frequency is very high (few GHz). Therefore, the amount of harvested energy is very small. Consequently, the ST tends to spend more time for the backscatter mode.

Underlay Cognitive Radio Networks

In this section, the objective function of overall transmission rate under the variation of the α and β, i.e., $R(\alpha, \beta)$, is first examined in (46). Figure 14a, b consider two cases, i.e., $B_b = 10$ and 30 kbps, respectively. For $B_b = 10$ kbps, the optimal value of α and β are 0.682 and 0.318, respectively. This corresponds to the case when $\tau = \alpha + \beta = 1$, i.e., the ST will select the harvest-then-transmit mode. Conversely, for $B_b = 30$ kbps (Fig. 14b), the optimal solution is at $\alpha = 0$ and $\beta = 0$ (corresponding to $\tau = 0$). This implies that the ST will use the backscatter mode in this case. This result is also to illustrate the findings in section "RF-Powered Backscatter Underlay Cognitive Radio Network", i.e., the optimal transmission policy of the ST is a step function.

Then, the transmission rate of the backscatter mode is varied, and the policy along with the performance of the secondary system will be evaluated. As observed in Fig. 15a, as the backscatter transmission rate increases, the optimal value of τ will be reduced. Here, note that as stated in section "RF-Powered Backscatter Underlay Cognitive Radio Network", the variation of τ is a step function. In particular, in Fig. 15a, the ST will select the harvest-then-transmit mode if the backscatter transmission rate is lower than 22.6 kpbs and the backscatter mode otherwise. Again, as shown in Fig. 15b, it is confirmed that the proposed solution always achieves the best performance in terms of the overall transmission rate for the secondary system.

Figure 15c, similar to overlay CCNs, also compares the proposed solution of the ST under different types of wireless signals. Four different kinds of signals are examined, i.e., FM signals, TV signals, WiFi signals, and 3G mobile signals, which are generally considered in underlay CCNs. Similar to the overlay CCN, the decision of the ST also depends much on the characteristic of the received signal. For WiFi and 3G signals, although the secondary system can be placed near the power source, e.g., access point and cellular base station, the source transmit power is relatively small (around 10 dBm as shown in Table 1) and the frequency is very high (few GHz). Therefore, the amount of harvested energy is very small, and the ST will prefer using the backscatter mode in the cases of WiFi and 3G signals.

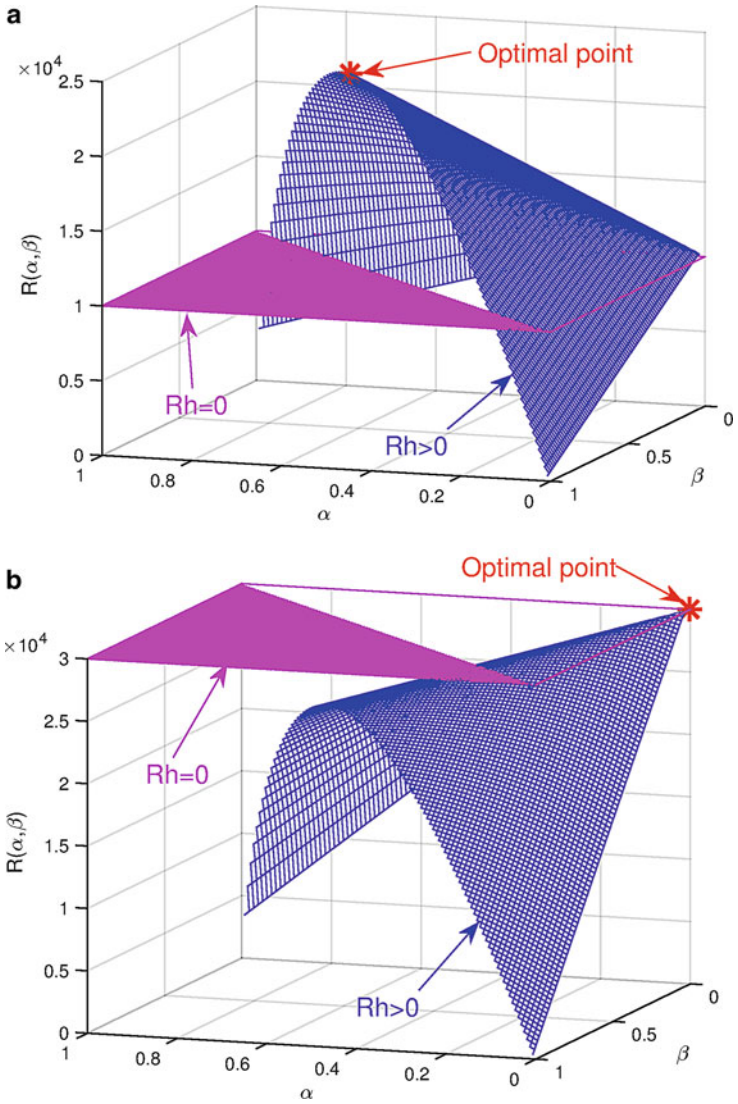

Fig. 14 The overall transmission rate $R(\alpha, \beta)$ under different value of B_b. (**a**) $B_b = 10$ kpbs. (**b**) $B_b = 30$ kpbs

Then, the signal frequency (Fig. 16) and the transmit power constraint (Fig. 17) of the secondary system are varied to investigate their impacts to the optimal policy of the ST. In particular, Fig. 16 shows that as the frequency of the signal increases, the amount of harvested energy will be reduced (Fig. 16a). Consequently, the backscatter mode will be more preferable (Fig. 16b). In Fig. 17, it is observed that when the transmit power constraint of the secondary system is more relaxed

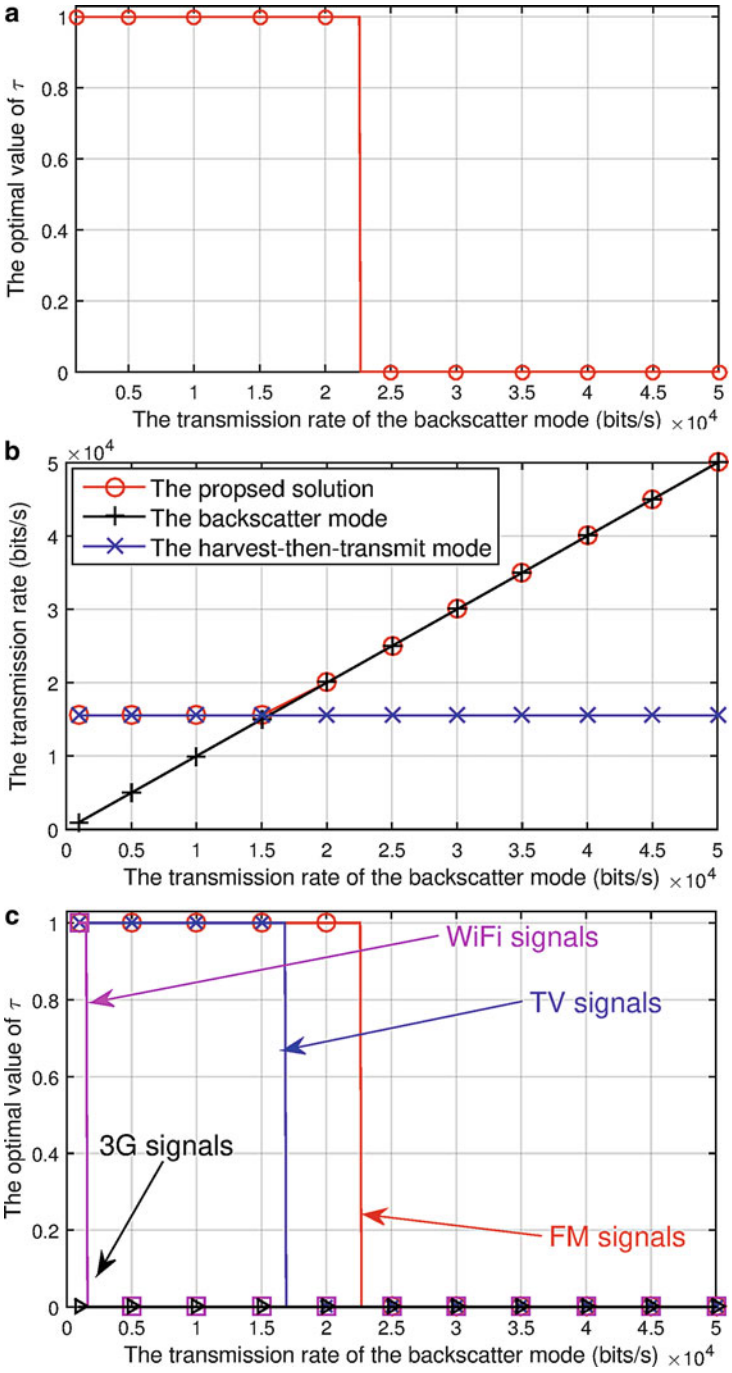

Fig. 15 The performance of the system under the variation of transmission bit rate of the backscatter mode

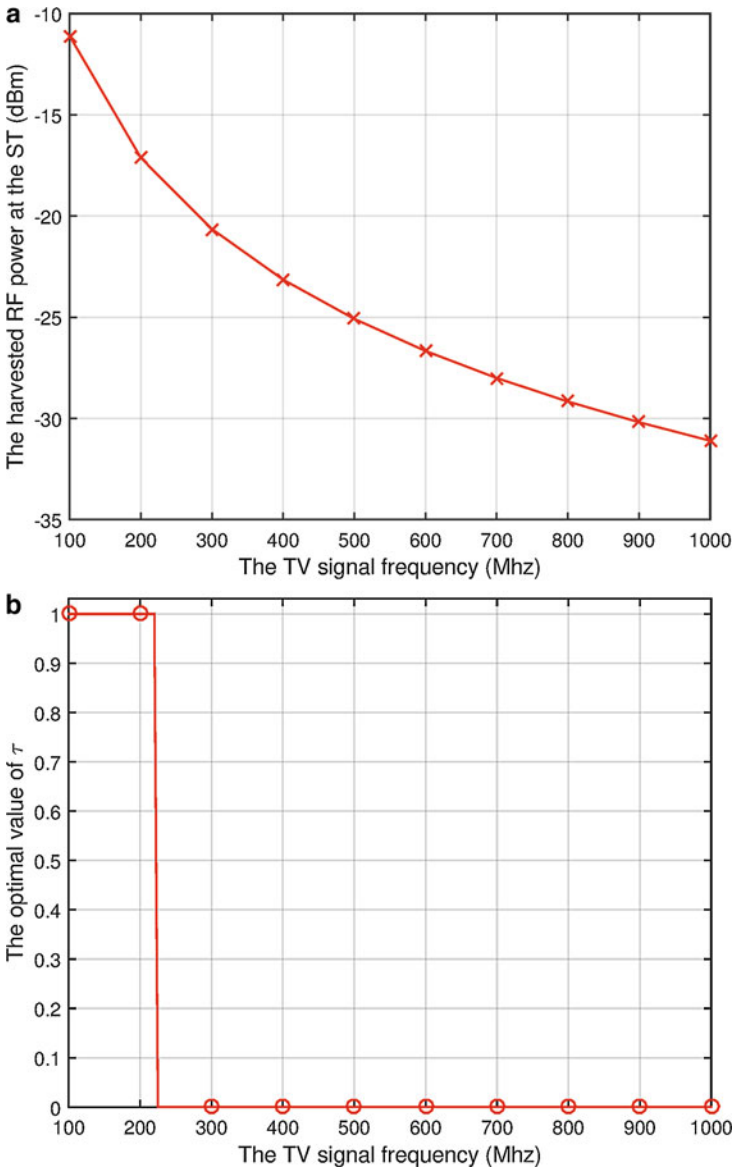

Fig. 16 The harvested RF power and the optimal policy of the ST when the TV signal frequency is varied

(i.e., the power threshold increases), the optimal value of τ also increases. This implies that the ST tends to choose the harvest-then-transmit mode. The reason is that when the transmit power constraint is limited at a low level, the secondary transmitter cannot fully utilize the harvested energy. Consequently, the ST will use the backscatter mode instead.

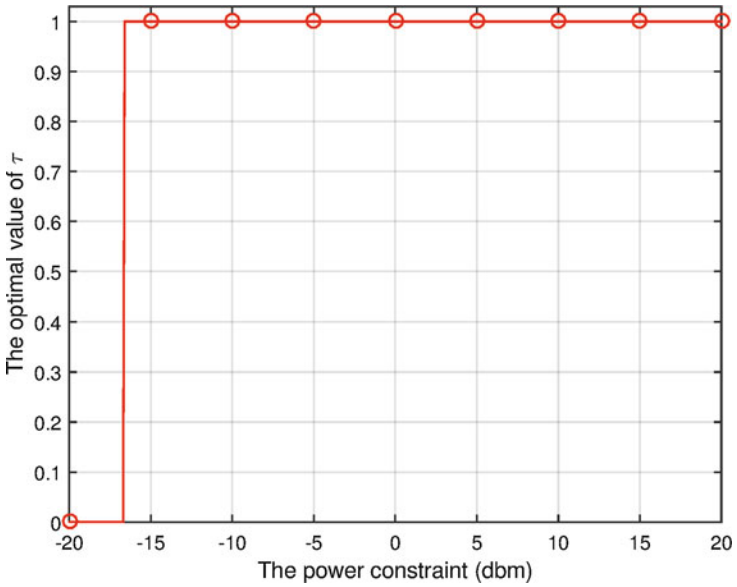

Fig. 17 The optimal policy of the ST under the variation of the power constraint $P^{\ddagger}$

Conclusions and Future Directions

The development of RF energy harvesting techniques together with ambient backscattering communication has opened great opportunities for cognitive cellular systems. In RF-powered cognitive cellular networks with ambient backscattering, secondary users can utilize not only the available spectrum holes when the channel is idle but also energy scavenging when the channel is busy, thereby improving network throughput of secondary systems significantly. This chapter first presents fundamental background on RF energy harvesting techniques and ambient backscattering communications. Then, the challenges of implementing these techniques in cognitive cellular networks are discussed, and the solutions are introduced. After that, two new approaches are presented based on two scenarios in cognitive cellular networks, i.e., overlay and underlay networks. Through numerical results, it is demonstrated that by incorporating the ambient backscatter communication and the conventional harvest-then-transmit protocol in RF-powered cellular cognitive radio networks, the secondary system always achieves the best performance under different setups. Moreover, the numerical results can provide insightful guidance to help a wireless node to choose the best mode.

There are some research directions in this topic.

- *Multiple secondary systems:* This chapter only considers a single secondary system. However, in practice, multiple secondary systems may coexist in the same cognitive cellular network. In this case, the optimal time trade-off problem

is much more complicated because we have to balance the time allocation among multiple secondary transmitters such that the overall network throughput is maximized and QoS requirements of all STs are satisfied. To address this problem, optimization techniques for multiple objectives presented in [13] could be a potential solution.

- *Economic models and game theory:* In the case when the secondary transmitter (ST) and receiver (SR) belong to different entities, the SR may not be interested in decoding information for the ST in the backscattering mode as the SR will lose energy in this process. To encourage an SR to decode information, the ST should incentivize the SR based on its demand on the backscattering time. As a result, economic models, e.g., Stackelberg game, can be adopted in this case. Alternatively, in the case when there are multiple secondary systems coexisting in the same environment, and they do not want to cooperate for the backscattering process as well as harvest-then-transmit process, noncooperative game models can be used to deal with this problem.
- *Extend the communication range:* In particular, because the transmission range of the ambient backscatter technique is relatively limited, i.e., within few meters. Thus, to extend the communication range, the backscatter process can be performed through relay nodes. It means the source node backscatters signals to the relay node, and then the relay node backscatters signals to the destination node. Thus, the transmission range for ambient backscattering systems can be extended greatly.

Abstract

Drone networks are aerial base stations that can be used to support cellular networks. The underlay spectrum sharing between the three-dimensional (3D) drone small cells (DSCs) downlink network modeled by a 3D Poisson point process and traditional cellular networks modeled by a 2D Poisson point process is introduced. To maximize the DSC network throughput while satisfying the cellular network efficiency constraint, the optimal density of DSC aerial base stations is discussed. The maximum throughput of the DSC user increases almost linearly with the increase of the DSC outage constraint. Effects of directional transmission on DSC networks is further discussed. Besides density control, power and beam control can also be applied in the spectrum sharing between unmanned aerial vehicle (UAV) network and ground network. With the mobility pattern information of UAVs, the delay-tolerant transmissions can be constructed and multiple transmission modes are implemented to carry various types of traffic. Exploiting cognition capability on mobility, UAV network can provide high quality of information services in the highly dynamic environment with limited resources.

Introduction

UAV, commonly known as a drone, refers to an aircraft without a human pilot aboard. We can expect drones developing in many interesting applications, such as policing and surveillance and scientific research. As illustrated in Fig. 1, UAVs aerial base stations can establish communication connection between ground node A and B. UAVs can also act as aerial sensors to collect environment data and transmit data to the control station. UAVs can act as aerial base stations or relays, namely, drone small cells (DSCs), to provide communication services to the areas with natural disasters and traffic congestions. DSCs can be deployed in a high-altitude platform (HAP) which is above 10 km height or in low-altitude platform (LAP) below 10 km [1].

DSC network has several advantages over conventional cellular networks. The fifth generation communication utilizing mmWave signals suffers many propagation-related shortcomings, such as relatively short range and vulnerable to blockage. UAVs can exploit its mobility to avoid the blockage and provide seamless coverage. Further, aerial base stations are robust to environmental changes. Another advantage of UAV networks is the flexibility of reconfiguration. For example, UAVs can be deployed to help offloading cellular networks in wireless congestion events with low cost. In [2], optimal deployment altitude of a drone providing maximum coverage is discussed. The deployment design and performance analysis of DSCs at LAP are further studied in [3], in which the optimal altitude maximizing ground coverage and minimizing required transmit power for a single DSC is derived. Their result shows that the optimal deployment altitude varies according to different environment statistics.

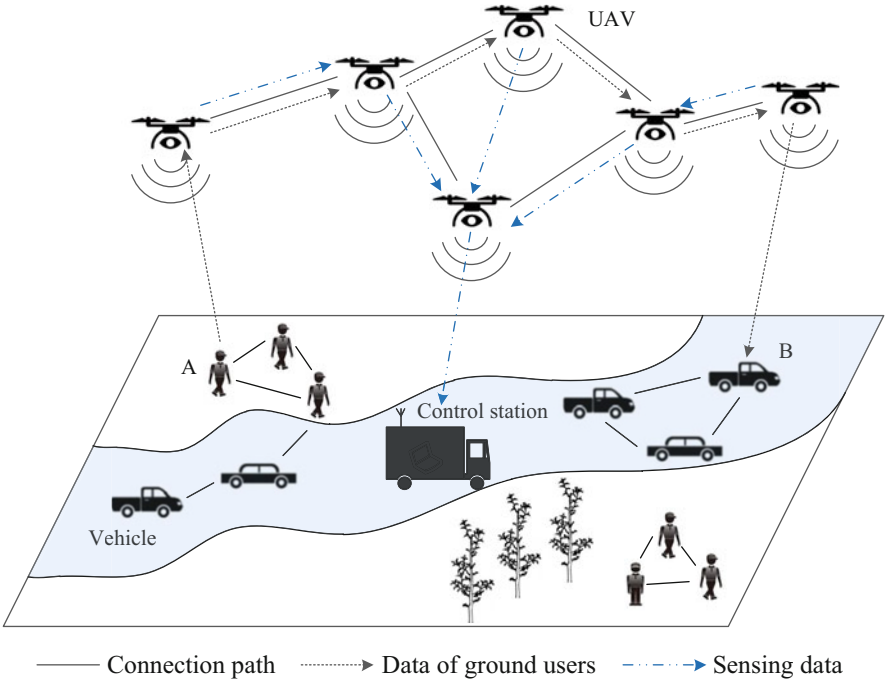

Fig. 1 Application scenario of UAV network

UAVs can be preprogrammed to fly autonomously from the starting point to destination. However, when multiple UAVs acting as cas aerial base stations, the ability of remote control could significantly improve the operation and safety [4]. For instance, if there is a possible collision due to traffic management, it is essential that information is shared to the UAVs promptly. Federal Aviation Administration (FAA) is exploring that each intended UAV use case has certain coverage, latency, and reliability requirements to ensure proper operational control of the UAVs [5]. In a typical multi-UAV network, the ground control station is mainly responsible for dispatching, coordinating, charging, and collecting of UAVs [6].

In the scenario where UAVs have a relatively small transmission range, the traffic is usually generated within the UAVs and transmits to control station via multi-hop transmissions. Repeated data transmissions in multi-hop transmission manner will consume radio resources and decrease network capacity. Thus environment cognition is proposed to improve the capacity of UAV network. Also, broadband UAV network would need to be constructed to support massive data transmission. According to Shannon-Hartley theorem [7], the capacity increases logarithmically with the transmit power. However, the capacity increases linearly with the bandwidth of spectrum. UAVs have limited carrying capacity and energy supply. Thus exploiting more spectrum is a practical way to increase the capacity of UAV network. With multiple sensors such as radar, Global Positioning System (GPS) ,

and camera implemented in UAVs, the environment cognition besides traditional spectrum sensing can be realized to further improve the capacity and adaptability of UAV network.

One of the most important problems on the coexistence between DSC and cellular network is the interference management. Underlay spectrum sharing between a 3D DSC network and a 2D cellular network is proposed for interference management [8, 9]. Underlay spectrum sharing refers to the simultaneous transmissions from DSC network and cellular network as long as the interference level at the cellular user side remains acceptable. The cellular signal would degrade dramatically if DSC network exceeds the predefined tolerable interference threshold. It has been demonstrated in traditional cellular network that spectrum sharing technologies can provide complementary benefits to dedicated spectrum. Effort was made toward spectrum sharing technologies of DSCs [10].

The spectrum sharing of 2D cellular wireless networks has been well studied in recent years [11, 12]. Different interference management strategies in 2D Poisson cognitive radio networks have been developed, for example, inter-cell interference coordination and intra-cell diversity [13]. It is also revealed from [13] that the general stochastic results for PPP base station deployments are independent to the shadow fading distribution as long as the shadowing is independent and identically distributed. The primary exclusive regions (PERs) centered at every primary receiver are designed in [14]. PER is a fixed region centered at each primary receiver in which no secondary transmitter is allowed to transmit signals. Applying PERs provides extra level of control to the network performance. It is often used to further guarantee the primary performance, e.g., when the primary users require a very small outage. The relationship between shadowing with path loss exponent and PERs is further analyzed in [15]. As the idea of PER effectively guarantees the primary service under limited spectrum resources, research efforts have been made to implement PERs into the optimization of different spectrum sharing schemes [16, 17]. Assuming all transmitters are 2D Poisson distributed nodes with limited feedback of channel quality information from their local receiver, two limited feedback-based underlay spectrum sharing schemes are proposed in [16], with and without PERs, respectively.

Further, it is discovered that there exist temporal spectrum opportunities in PER. The architecture of three regions including black, gray, and white regions is proposed in [18]. Black region is surrounded by gray region and gray region is surrounded by white region [18]. In black region, SUs are not allowed to transmit. In gray region, SUs can exploit temporal spectrum opportunities. Namely, SUs can use the spectrum that is not used by primary users (PUs). In white region, because SUs are far away from PUs, SUs can transmit all the time with maximum power. When primary receivers are densely deployed, the union of PERs of all primary receivers forms a layer. When a UAV is located below the layer, it is not allowed to transmit. Moreover, the architecture of three regions can be applied in UAV network. As illustrated in Fig. 2, layer 1 and layer 2 divide the 3D space into three regions. In region 1, since UAVs are close to the ground users, UAVs are not allowed to transmit. In region 2, UAVs are farther to ground users. Thus UAVs can exploit the temporal spectrum opportunities. In region 3, since UAVs are sufficiently high

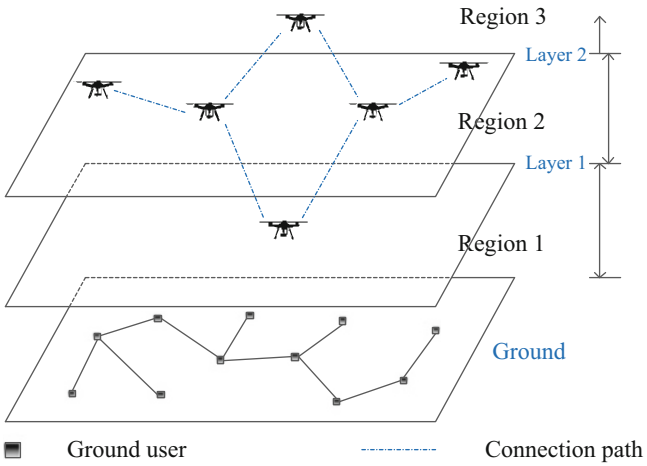

Fig. 2 PER layers of UAV network

above the ground, UAVs can transmit all the time. Regions 1, 2, and 3 are similar to the black, gray, and white regions, respectively in [19]. It is verified in [19] that the capacity of secondary network with three regions is larger than that with PER. Hence the architecture of three regions can also be applied in cognitive UAV network.

Stochastic geometry theory provides effective tools to study the average behavior over spatial realizations of a large wireless network [20]. For 2D networks, there are several empirical and theoretical results indicating that a Poisson point process (PPP) is an appropriate point process to model base station deployments with tractability. PPP is widely used to model different types of networks, for instance, cognitive radio networks [16], cellular networks [21], and wireless sensor networks [22]. It is shown in [23] that under certain appropriate conditions, the stochastic results obtained by modeling wireless networks as spatial PPPs are still valid, even if in reality the positioning of transmitting nodes does not appear Poisson.

One of the future trends of cellular networks is to have smaller cells to deserve the growing number of communications [24]. The standard concept of planar cellular networks is extended into 3D space in [25]. Different cell shapes in 3D cellular networks achieving full coverage are investigated in [26]. It is demonstrated that truncated octahedral cell results in the best strategy. Applying stochastic tools to 3D ultradense cellular networks, different coverage probability and throughput scaling behaviors in terms of the path loss components using a dual path loss model are discussed in [21].

In this chapter, the study of DSC network underlay spectrum sharing with cellular network is presented. Taking advantage of the tractability of Poisson point process, explicit expressions for the DSC coverage probability and achievable throughput are derived by stochastic geometry. To maximize the DSC network throughput while satisfying the cellular network efficiency constraint, the optimal density of DSC aerial base stations is discussed. The maximum throughput of the DSC user increases almost linearly with the increase of the DSC outage constraint. Effects of PERs and directional transmission on DSC networks are further discussed.

Besides density control, power and beam control can also be applied in the spectrum sharing between UAV network and ground network. The traditional cognitive radio technology focuses on spectrum sensing, spectrum decision and spectrum sharing, etc. However, since UAVs are robotic system, the mobility of UAVs can be controlled to improve network capacity. The concept of mobility cognitive UAV network is then proposed. Mobility pattern cognition aims to discover returning UAVs to construct the delay-tolerant transmission scheme, which carries the delay-insensitive traffic with Store-Carry-and-Forward (SCF) mode to avoid multi-hop transmissions consuming radio resources. The delay-sensitive traffic is still carried by multi-hop transmission manner.

Spectrum Sharing of UAV Network

Optimal DSC Density

As shown in Fig. 3, DSC networks distribute in 3D space. Assume that DSC aerial base stations follow a 3D-PPP $\{X_i \in \Phi_d\}$ with density λ_d in an infinite 3D space $\mathbb{V}$, but the height is limited to L, that is, $\mathbb{V} = \{(x, y, z) : x, y \in \mathbb{R}, z \in [0, L]\}$. The channel between any pair of DSC aerial base station and the user here is assumed to undergo path loss and the small-scale fading. The path loss is proportional to $x^{-\alpha}$, where x is the distance between the transmitting aerial base station and the typical user and α is the mean path loss exponent. The power gain of small-scale fading channel h_i is exponentially distributed with unit mean, and the noise N_0 is additive white Gaussian noise following the distribution $N_0 \sim N(0, N)$. DSCs only transmit while they are static [10,27], e.g., moving DSCs will perform transmission on certain "stop points."

Assume that all aerial base stations transmit at the same power level P_d. For a typical link, the received signal power is hence $P_d h_0 D^{-\alpha}$, where D is the distance between a typical user and a typical aerial base station. The transmission is successful if the received SINR at a receiver is larger than a certain threshold. Set the SINR thresholds of DSC users to θ. A typical DSC user at the origin O will receive interference from other transmitting DSC base stations while receiving the desired signal. The received SINR of a typical user at the origin O is:

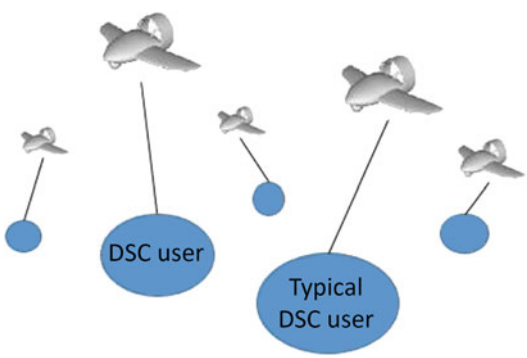

Fig. 3 DSC networks

$$SINR_d = \frac{P_d h_0 D^{-\alpha}}{N + \sum_{x_i \in \Phi_d \setminus \{0\}} P_d h_i x_i^{-\alpha}}. \tag{1}$$

The transmission rate of a network is defined as [11]:

$$T_d = \lambda_d P(SINR_d > \theta) \log(1 + \theta). \tag{2}$$

Assuming that the DSC network has an outage probability constraint $\varepsilon_d \ll 1$, the optimal DSC base station density can be obtained by solving the following optimization problem:

$$\begin{aligned} &\underset{\lambda_d}{\text{maximize}} \quad T_d && (G1) \\ &\text{subject to} \quad P(SINR_d > \theta) > 1 - \varepsilon_d. \end{aligned}$$

Next, the optimal DSC base station density for a single-tier DSC downlink network in 3D space can be derived. Let $I = \sum_{x_i \in \Phi_d \setminus \{0\}} h_i x_i^{-\alpha}$. From (1) we have the coverage probability as

$$\begin{aligned} P(SINR_d > \theta) &= P\left(\frac{h_0 D^{-\alpha}}{\frac{N}{P_d} + I} > \theta\right) && (3) \\ &= \mathbb{E}_I\left[P\left(h_0 > \theta D^{\alpha}\left(\frac{N}{P_d} + I\right)\right) | I\right] \\ &= \mathbb{E}_I\left[\exp\left(-\theta D^{\alpha}\frac{N}{P_d}\right)\exp(-\theta D^{\alpha} I)\right] \\ &= \exp\left(-\theta D^{\alpha}\frac{N}{P_d}\right)\mathscr{L}_I(\theta D^{\alpha}). && (4) \end{aligned}$$

where $\mathscr{L}_I(\theta D^{\alpha})$ is the Laplace transform of the interference $I = \sum_{x_i \in \Phi_d \setminus \{0\}} h_i x_i^{-\alpha}$, which can be further derived as:

$$\begin{aligned} \mathscr{L}_I(\theta D^{\alpha}) &= \mathbb{E}_I[\exp(-\theta D^{\alpha} I)] && (5) \\ &= \mathbb{E}_{\Phi_d, h_i}\left[\prod_{x_i \in \Phi_d \setminus \{0\}} \exp(-\theta D^{\alpha} h_i x_i^{-\alpha})\right] && (6) \\ &= \mathbb{E}_{\Phi_d}\left[\prod_{x_i \in \Phi_d \setminus \{0\}} \mathbb{E}_{h_i}[\exp(-\theta D^{\alpha} h_i x_i^{-\alpha})]\right] && (7) \\ &= \mathbb{E}_{\Phi_d}\left[\prod_{x_i \in \Phi_d \setminus \{0\}} \frac{1}{1 + \theta D^{\alpha} x_i^{-\alpha}}\right]. && (8) \end{aligned}$$

where (7) follows because of the i.i.d. distribution of h_i and its further independence from the point process Φ_d. Equation (8) follows because h_i is exponential distributed with unit mean. The probability generating functional of a set $\mathbb{V}$ is given by [28]:

$$\mathbb{E}\left(\prod_{x_i \in \Phi} f(x)\right) = \exp\left(-\lambda_d \int_{\mathbb{V}} [1 - f(x)] dx\right). \tag{9}$$

Applying (9) into (8), we have

$$\mathscr{L}_I(\theta D^\alpha) = \exp\left(-\lambda_d \int_{\mathbb{V}} \left(1 - \frac{1}{1 + \theta D^\alpha x^{-\alpha}}\right) dx\right) \tag{10}$$

$$= \exp\left(-\lambda_d \int_0^L \int_0^{2\pi} \int_0^\infty \left(1 - \frac{1}{1 + \theta D^\alpha (\sqrt{r^2 + z^2})^{-\alpha}}\right) r dr d\phi dz\right) \tag{11}$$

$$= \exp\left(-2\pi\lambda_d \int_0^L \int_0^\infty \frac{\theta D^\alpha r (\sqrt{r^2 + z^2})^{-\alpha}}{1 + \theta D^\alpha (\sqrt{r^2 + z^2})^{-\alpha}} dr dz\right)$$

$$= \exp(-\lambda_d H(L, \theta, D, \alpha)) \tag{12}$$

where

$$H(L, \theta, D, \alpha) = \int_0^L \int_0^\infty \frac{2\pi\theta D^\alpha r (\sqrt{r^2 + z^2})^{-\alpha}}{1 + \theta D^\alpha (\sqrt{r^2 + z^2})^{-\alpha}} dr dz. \tag{13}$$

With (4), (5), (6), (7), (8), (9), (10), (11), and (12), we are now able to solve the optimization problem $(G1)$.

$$\begin{aligned} &\underset{\lambda_d}{\text{maximize}} \quad T_d \qquad\qquad (G1) \\ &\text{subject to} \quad P(SINR_d > \theta) > 1 - \varepsilon_d. \end{aligned}$$

Since T_d in (2) is unimodal in terms of λ_d and $P(SINR_d > \theta)$ is a decreasing function of λ_d, Karush-Kuhn-Tucker (KKT) conditions [16] are applicable. The Lagrange function of the above optimization problem is given by:

$$\mathscr{L}(\lambda_d) = T_d + \mu(P(SINR_d > \theta) - 1 + \varepsilon_d). \tag{14}$$

where μ is the Lagrange multiplier. Then, the KKT conditions are given as:

$$\frac{d\mathscr{L}(\lambda_d)}{d\lambda_d} = \frac{dT_d}{d\lambda_d} + \mu \frac{dP(SINR_d > \theta)}{d\lambda_d}. \tag{15}$$

$$\mu(P(SINR_d > \theta) - 1 + \varepsilon_d) = 0. \tag{16}$$

$$P(SINR_d > \theta) - 1 + \varepsilon_d \geq 0. \tag{17}$$

$$\mu \geq 0 \quad \text{and} \quad \lambda_d \geq 0. \tag{18}$$

Solving Eqs. (15) to (18) yields the optimal of DSC aerial base stations, as follows:

$$\lambda_d^* = \frac{[-\ln(\frac{1-\varepsilon_d}{\exp(-\theta D^\alpha \frac{N}{P_d})})]^+}{H(L, \theta, D, \alpha)}. \tag{19}$$

where $[.]^+$ denotes $\max(., 0)$. The maximum DSC network throughput is given by

$$T_d^* = \frac{\left[-\ln\left(\frac{1-\varepsilon_d}{\exp(-\theta D^\alpha \frac{N}{P_d})}\right)\right]^+}{H(L, \theta, D, \alpha)}(1 - \varepsilon_d)\log(1 + \theta). \tag{20}$$

It can be seen from (19) that the optimal primary density is obtained when the success probability just meets the outage constraint. Since $\varepsilon_d \ll 1$, we have $\ln(1 - \varepsilon_d) \approx -\varepsilon_d$. Therefore, for small ε_d, both optimal DSC density and potential throughput are linear with the DSC network outage constraint ε_d.

Effect of Different Path Loss Models

In this section, effect of a more specific air-to-ground path loss model is discussed. Different air to ground channel path loss models have been proposed and measured to suit in different environments [29]. Simplified mean path loss model for the spectrum sharing analysis in this chapter is given by:

$$l(x) = x^{-\alpha}. \tag{21}$$

Another air-to-ground path loss model $l(x, \gamma)$ for an air vehicle locating at distance x and elevation angle γ from the origin is given by [1]:

$$l(x, \gamma) = P_{LOS} x^{-\alpha_1} + P_{NLOS} k x^{-\alpha_1}. \tag{22}$$

in which α_1 and k are the path loss exponent and parameter corresponding to different type of links. $P_{NLOS} = 1 - P_{LOS}$. P_{LOS} is the line of sight probability. It is further given by:

$$P_{LOS} = \frac{1}{1 + a\exp(-b[\gamma - a])}. \tag{23}$$

where a and b are parameters determined by environment.

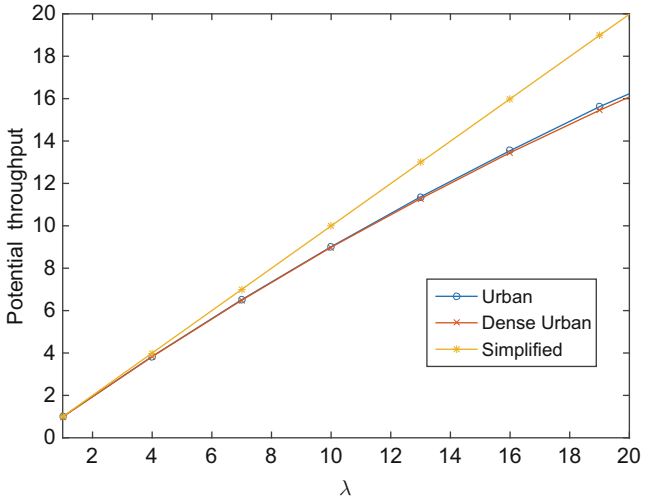

Fig. 4 Potential throughput of different path loss models $L = 0.1$, $D = 0.05$

Table 1 Radio-frequency propagation parameters

Environment	(a,b)	$\alpha(\alpha_1)$	k
Simplified		4	
Urban	(9.61,0.16)	2	20dB
Dense Urban	(12.08,0.11)	2	23dB

Radio frequency 2,000 MHz [1]

Figure 4 plots the scaling behavior of network throughput in terms of the drone density λ by simulations. The numerical values of the parameters of the air-to-ground channels for different environments are presented in Table 1. It can be observed that the potential throughput of drone network monotonically increases with node density for all different path loss models. As the research on modeling the air-to-ground channel is ongoing, the insight of underlay spectrum sharing results in this chapter is applicable for more precise path loss models in the future.

Spectrum Sharing Between DSC Network and Cellular Network

Optimal DSC Density

As shown in Fig. 5, cellular base stations are distributed on the ground as a 2D PPP with density λ_c. The distance between a typical cellular base station and its associated user is d. Similar to that of DSC network, we assume that all cellular base stations transmit with power P_c. The channel between any base station and the user undergoes path loss and the small-scale fading. The power gain of the small-scale

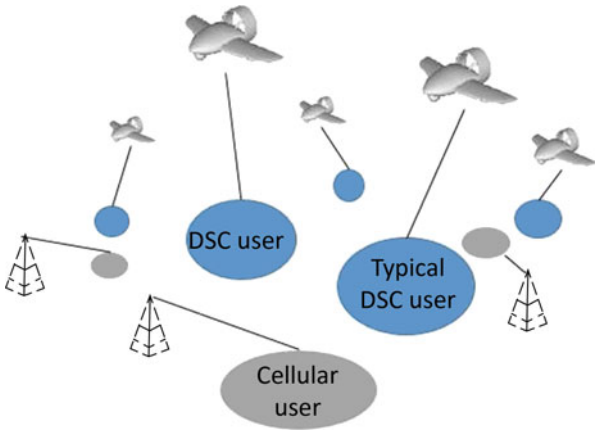

Fig. 5 Spectrum sharing between drone small cells (DSCs) networks and cellular networks

fading channel h_j is exponentially distributed with the unit mean, and the noise is $N_0 \sim N(0, N)$. Each cellular transmitter decides to transmit if the received SINR is larger than a certain threshold θ_c with a 1-bit feedback from the cellular receiver [16]. The active cellular base stations follow a thinned 2D PPP $\{Y_j \in \Phi_c\}$. Considering a typical DSC user at the origin O, it will receive interference not only from transmitting DSC base stations but also from transmitting cellular base stations. The SINR of the typical DSC user is given by

$$SINR_{dc} = \frac{P_d h_0 D^{-\alpha}}{N + P_d \sum_{i \in \Phi_d \setminus \{0\}} h_i x_i^{-\alpha} + P_c \sum_{j \in \Phi_c} h_j y_j^{-\alpha}}. \tag{24}$$

The SINR expressions of a typical cellular user with and without the DSC network are given by, respectively, as follows:

$$SINR_c = \frac{P_c h_0 d^{-\alpha}}{N + P_d \sum_{i \in \Phi_d} h_i x_i^{-\alpha} + P_c \sum_{j \in \Phi_c \setminus \{0\}} h_j y_j^{-\alpha}}. \tag{25}$$

$$SINR'_c = \frac{P_c h_0 d^{-\alpha}}{N + P_c \sum_{j \in \Phi_c \setminus \{0\}} h_j y_j^{-\alpha}}. \tag{26}$$

The throughputs of DSC and cellular networks are:

$$T_{dc} = \lambda_{dc} P(SINR_{dc} > \theta) \log(1 + \theta). \tag{27}$$

$$T_c = \lambda_c P(SINR_c > \theta_c) \log(1 + \theta_c). \tag{28}$$

$$T'_c = \lambda_c P(SINR'_c > \theta_c) \log(1 + \theta_c). \tag{29}$$

where T_c and T_c' are the cellular network throughput with and without DSC network, respectively. Define δ as the cellular efficiency loss ratio $\delta = \frac{T_c - T_c'}{T_c}$ and r_{th} as the cellular efficiency loss constraint [16]. The optimal DSC base station density coexisting with a cellular network λ_{dc} can be obtained by solving the following optimization problem:

$$\begin{aligned} \underset{\lambda_{dc}}{\text{maximize}} \quad & T_{dc} \qquad (G2) \\ \text{subject to} \quad & P(SINR_{dc} > \theta) > 1 - \varepsilon_{dc} \\ & \delta \le r_{th}. \end{aligned}$$

Next, we derive the optimal DSC base station density when coexisting with cellular networks.

Consider the DSC network coexists with a 2D cellular network. Denote $I_c = \sum_{j \in \Phi_c} h_j y_j^{-\alpha}$. The success probability of the typical DSC user is given by

$$P(SINR_{dc} > \theta) = P\left(\frac{h_0 D^{-\alpha}}{\frac{N}{P_d} + I + \frac{P_c}{P_d} I_c} > \theta\right) \tag{30}$$

$$= \exp\left(-\theta D^{\alpha} \frac{N}{P_d}\right) \mathbb{E}_I[\exp(-\theta D^{\alpha} I)] \mathbb{E}_{I_c}\left[\exp\left(-\theta D^{\alpha} \frac{P_c}{P_d} I_c\right)\right]. \tag{31}$$

where I was given in (3). The second term in (31) has been evaluated by (4), (5), (6), (7), (8), (9), (10), (11), and (12). The third term in (31) is the interference from other active cellular base stations following a 2D-PPP and can be derived as [16]:

$$\mathbb{E}_{I_c}\left[\exp\left(-\theta D^{\alpha} \frac{P_c}{P_d} I_c\right)\right] = \exp\left(-\lambda_c C D^2 \left(\frac{P_c}{P_d}\theta\right)^{\frac{2}{\alpha}} \exp\left(-d^{\alpha} \frac{N}{P_c}\theta_c\right)\right). \tag{32}$$

where $C = \frac{2\pi^2}{\alpha \sin\left(\frac{2\pi}{\alpha}\right)}$.

The success probability of a typical DSC user is

$$P(SINR_{dc} > \theta) = A_1 \exp(-A_2 \lambda_d) \exp(-A_3 \lambda_c) \tag{33}$$

where

$$A_1 = \exp\left(-\theta D^{\alpha} \frac{N}{P_d}\right).$$

$$A_2 = H(L, \theta, D, \alpha).$$

$$A_3 = CD^2 \left(\frac{P_c}{P_d}\theta\right)^{\frac{2}{\alpha}} \exp\left(-d^\alpha \frac{N}{P_c}\theta_c\right). \tag{34}$$

With the success probability expressions, we are able to solve the optimization problem (G2):

$$\begin{aligned} \underset{\lambda_{dc}}{\text{maximize}} \quad & T_{dc} \qquad (G2) \\ \text{subject to} \quad & P(SINR_{dc} > \theta) > 1 - \varepsilon_{dc} \\ & \delta \le r_{th}. \end{aligned}$$

Likewise, to derive the success probability of a typical cellular user, along with (28) and (29), the cellular efficiency loss ratio is first calculated:

$$\begin{aligned} \delta &= \frac{T_c - T_c'}{T_c} \\ &= 1 - \exp\left(-H\left(L, \theta_c \frac{P_d}{P_c}, d, \alpha\right)\lambda_{dc}\right). \end{aligned} \tag{35}$$

The Lagrange function of the optimization problem $(G2)$ is hence given by

$$\mathscr{L}(\lambda_{dc}) = T_{dc} + \mu_1(P(SINR_{dc} > \theta)) - \mu_2(\delta - r_{th}). \tag{36}$$

The KKT conditions are listed as follows:

$$\frac{d\mathscr{L}(\lambda_{dc})}{d\lambda_{dc}} = \frac{dT_{dc}}{d\lambda_{dc}} + \mu_1 \frac{d(P(SINR_{dc} > \theta)}{d\lambda_{dc}} - \mu_2 \frac{d\delta}{d\lambda_{dc}}.$$

$$\mu_1(P(SINR_{dc} > \theta) - 1 + \varepsilon_{dc}) = 0. \tag{37}$$

$$\mu_2(\delta - r_{th}) = 0. \tag{38}$$

$$(-1 + \varepsilon_{dc}) \le P(SINR_{dc} > \theta). \tag{39}$$

$$\delta \le r_{th}. \tag{40}$$

$$\mu_1 \ge 0, \mu_2 \ge 0 \quad \text{and} \quad \lambda_{dc} \ge 0. \tag{41}$$

Solving the above equations yields:

$$\begin{aligned} &\text{If} \quad \varepsilon_{dc} < \eta, \\ &\lambda_{dc}^* = \frac{\left[-\ln(1-\varepsilon_{dc}) - D^\alpha \frac{N}{P_d}\theta - A_3\lambda_c\right]^+}{A_2} \\ &\text{If} \quad \varepsilon_{dc} \ge \eta, \end{aligned} \tag{42}$$

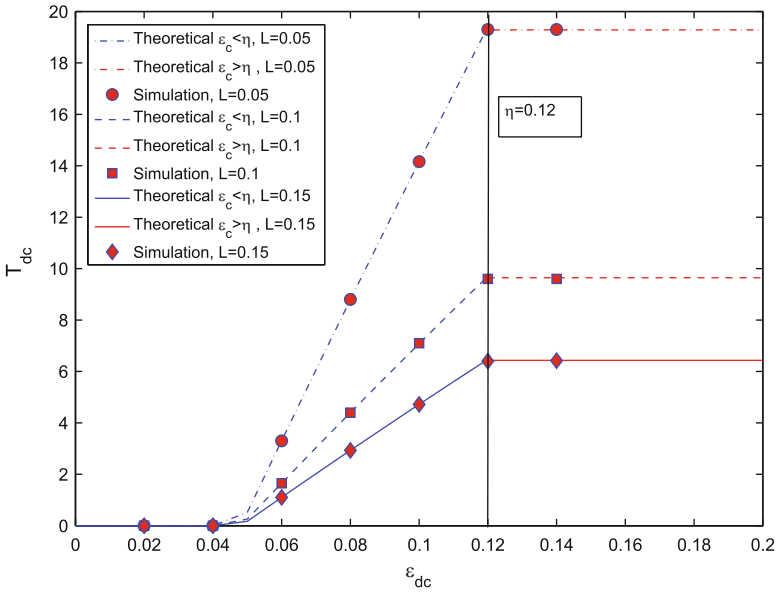

Fig. 6 Maximum throughput of a 3D-PPP with limited height coexisting with a cellular network, $\alpha = 4$, $\theta = 1$, $\theta_c = 5$, $\lambda_c = 1$, $P_d = 1$, $P_c = 1$

$$\lambda_{dc}^{*} = \frac{-\ln(1-r_{th})}{H(L, \theta_c \frac{P_d}{P_c}, d, \alpha)}. \tag{43}$$

where $\eta = 1-\exp(-A_3\lambda_c)A_1(1-r_{th})^{\frac{A_2}{H(L,\theta_c\frac{P_d}{P_c},d,\alpha)}}$. We have the maximized potential throughput:

$$T_{dc}^{*} = \lambda_{dc}^{*} P(SINR_{dc*} > \theta)\log(1+\theta). \tag{44}$$

where $P(SINR_{dc*} > \theta)$ can be evaluated by substituting λ_{dc}^{*} into (33). For $\varepsilon_{dc} < \eta$, since $1-\varepsilon_{dc} \approx 1$, $\ln(1-\varepsilon_{dc}) \approx -\varepsilon_{dc}$. The approximated optimal DSC density and potential throughput are both linear with the DSC network outage constraint ε_{dc}. For $\varepsilon_{dc} > \eta$, both optimal DSC density and potential throughput are constants which are independent of ε_{dc}.

Numerical Examples

In this section, some numerical examples are given to validate the theoretical results and discuss the effects of several parameters on the coverage and rate of DSCs and cellular networks.

In Fig. 6, the simulation results of the maximal throughput of a 3D DSC network with the coexistence of a cellular network are compared with the analytical results derived from (44). The simulation of optimal node density is done by two steps. The optimal DSC base station density and the maximal throughput are plotted as functions depending on the DSC outage constraint. The values of λ_d and T_d are zero at the small ε region since the outage probability cannot satisfy its outage constraint. In the region where the outage probability is able to satisfy its outage constraint, both λ_{dc} and T_{dc} increase almost linearly with the increase of ε_{dc}, until they flatten out and coincide with (43). The flattening is because cellular network constraints are restricting the DSC node density, even more DSC outage could be tolerated by the DSC network. Moreover, it is noticed that η is independent of the limited height of the 3D network, as it represents when the cellular network interference constraints become dominant. The scaling behaviors of DSC outage constraints provide us the following insight: as we relax the restrictions for DSC network, the dependence of optimal DSC base station deployment moves from the constraints of DSC network to constraints of cellular network.

Spectrum Sharing of UAV Networks with Directional Antennas

UAVs are above the ground with a certain altitude, which creates opportunities for UAV network to share the spectrum of ground network. In this section, we present the study of UAV network spectrum sharing exploring the benefits of beam and power control in 3D and 2D deployment scenarios, respectively.

3D Deployment

Density and Power Control

When UAVs are deployed in 3D space and share the spectrum of ground networks, the density and transmit power of UAVs need to be controlled to mitigate the interference to ground network. In section "Spectrum Sharing Between DSC Network and Cellular Network", UAV network shares spectrum with a ground cellular network, where the density of UAV network is optimized to maximize the network capacity with the constraints of the outage probability of UAV network and the capacity loss of cellular network. Besides density control, power control can also be applied in the spectrum sharing between UAV network and ground network. UAVs with low altitude should transmit with small transmit power to mitigate the interference to ground users. Meanwhile, UAVs with high altitude can transmit with a relatively large transmit power because they are distant from the ground users. With power control, the deployment density and capacity of UAVs can be improved.

Beam and Power Control

In previous sections, UAVs are implemented with omnidirectional antennas. When UAVs are implemented with directional antenna, more efficient spectrum sharing

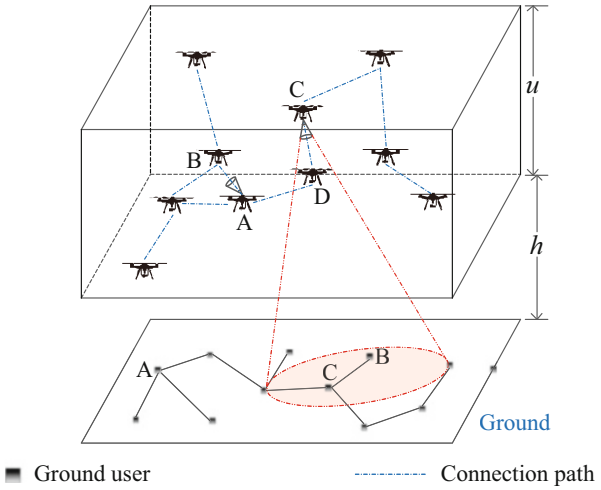

Fig. 7 Directional transmission scenario of UAV network

schemes can be explored. As illustrated in Fig. 7, UAVs are distributed in 3D space and transmit directionally. The 3D space is modeled by a cuboid with height u and the height of the bottom of this cuboid from the ground is h. Notice that the UAVs with low altitude have small probability to transmit downward because their destinations have large probability to be located above them. However, when a UAV transmits downward, it may cause interference to ground nodes, such as UAV C in Fig. 7. If the signal radiation of a UAV is modeled as a spherical cone, the projection of the signal on ground is an ellipse. If the beam of signal is sufficiently narrow, the probability that the signal of UAV causes interference to ground nodes is small. Besides, power control can also be applied to control the interference from UAVs to ground users.

However, the control of beam and power is not necessary for each direction. There is a beam control angle for each UAV. When transmission direction is not in the beam control angle, the beam and power control are not necessary. In Fig. 8, the beam control angles of UAVs A, B, and C are α_1, α_2, and α_3, respectively, where $\alpha_3 = 0$. With the increase of the altitude of UAV, the beam control angle is decreasing. The beam control angle can be derived as follows. Take UAV A as an example; the distance between UAV A and a ground user A$'$ is X_1. When X_1 is increasing, γ_1 is decreasing and the probability of non-line-of-sight (NLoS) transmission between UAV A and ground node A$'$ is increasing. With the increase of X_1 and NLOS probability, the interference from UAV A to ground node A$'$ is decreasing. When the distance X_1 is increased to X_1^* such that the expectation of the interference from UAV A to ground node A$'$ is smaller than a threshold, the beam control angle α_1 is determined. When a UAV is high above the ground such that the interference to the ground node is small, the beam control angle for this UAV does not exist.

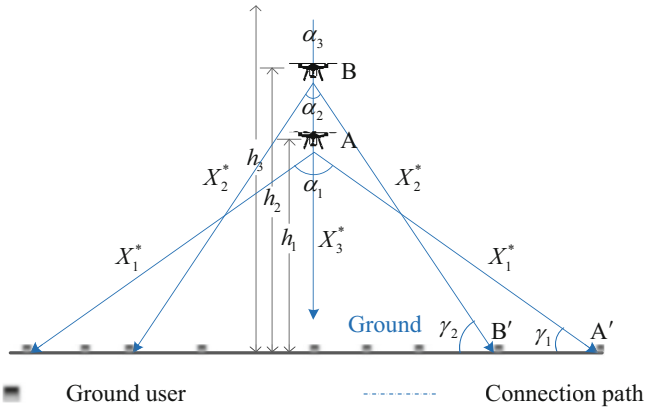

Fig. 8 Directional transmission in UAV network with different angles

In Fig. 8, the beam control angles of three UAVs are illustrated. Notice that if we do not consider the NLOS transmissions, the value of X_1^* equals X_2^*. However, because the UAV with high altitude has a larger angle of elevation compared with the UAV with low altitude, the length of X_1^* is smaller than X_2^*. UAV can freely transmit in the non-beam control angle. However, if a UAV transmits in the beam control angle, more sophisticated transmission schemes need to be implemented. The following schemes may be applicable:

1. Spectrum sensing If a UAV transmits in the beam control angle, it performs spectrum sensing and transmits when ground users are absent.
2. Narrow beam If a UAV transmits in the beam control angle with narrow beam, the interference probability to ground users will decrease. However, this requires sophisticated beamforming algorithm.
3. Power control When a UAV transmits in the beam control angle, if the power of UAV can be controlled to mitigate the interference to ground users, the transmission opportunities can also be exploited.

With these schemes, UAVs can share the spectrum of ground users in every direction and altitude, which will increase the number of wireless channel and improve the capacity of UAV network.

2D Deployment

In previous section, we explore the spectrum sharing between 3D UAV network and 2D ground network. However, when UAVs are used to monitor or search specific targets on ground, they may be distributed in an aerial 2D plane, which is illustrated

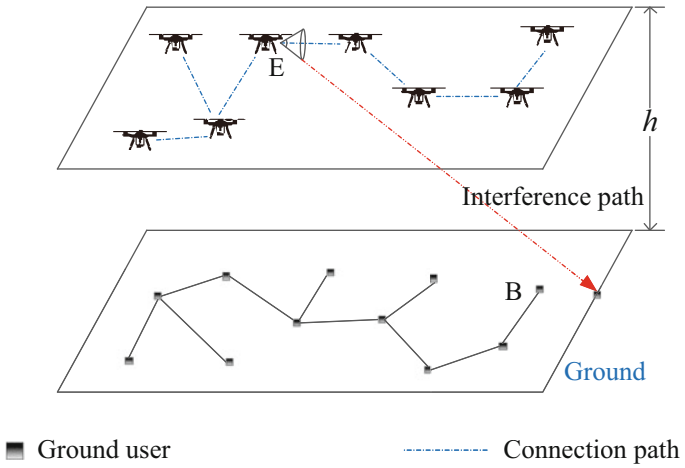

Fig. 9 2D UAV networks with 2D ground networks

in Fig. 9. In this section, we discuss the spectrum sharing between 2D UAV network and 2D ground network.

Altitude, Density, and Power Control

When UAVs are deployed in an aerial 2D plane, the altitude, density, and transmit power can be coordinated to mitigate the interference to ground users. In [30], assuming UAV network has air-to-ground transmissions, we derived the optimal altitude of UAVs with fixed transmit power and density. When the altitude of UAVs is fixed, the density and transmit power of UAVs can be optimized to maximize the capacity of UAV network with the constraint of capacity loss of ground network. Furthermore, the altitude, density, and power of UAVs can be jointly optimized.

Beam Control

Similar with section "Beam and Power Control", when UAVs are implemented with directional antennas, efficient spectrum sharing schemes can be designed. As illustrated in Fig. 9, when UAV E transmits directionally, it will not cause interference to ground node B. Assuming that the beam width of UAV is β, when β is decreasing, the interference from UAV network to ground users is correspondingly decreasing. Thus beam control can realize interference coordination between UAV network and ground network. Intuitively, the directional transmission in UAV network is equivalent to increasing the altitude of UAVs. Thus with beam control of UAV network, the spectrum sharing between UAV network and ground network is feasible.

Numerical Results

The spectrum sharing between an aerial 2D UAV network and a ground ad hoc network is investigated in [30]. The scenario of Fig. 9 is simulated. Namely, UAV network shares spectrum with a ground ad hoc network and UAVs are implemented with directional antennas. Assume that the signal to interference and noise ratio (SINR) threshold for signal reception is 1. In a 1000×1000 m area, 100 ground users are uniformly deployed and 25 UAVs are uniformly deployed above the ground users. The path loss exponent of ground-to-ground channel is 3, and the path loss exponent of air-to-ground channel is 2. The air-to-ground channel model is borrowed from [10], where the probability of line-of-sight (LOS) is an increasing function of the angle of elevation.[1] The transmit power of UAV is 5 W and the transmit power of ground node is 1 W. With these parameters configuration, the coverage probability of ground ad hoc network is provided in Fig. 10. The interference from UAV network to ground network has an impact on the coverage probability of ground network. With the increase of the altitude of UAVs, the length of propagation path from UAV to ground user is increasing. Meanwhile, the angle of elevation from ground user to UAV is increasing. The increase of propagation path will decrease the interference from UAV to ground user. However, the increase of the angle of elevation will enlarge the probability of LOS and increase the interference from UAV to ground user. In Fig. 10, for UAV networks with omnidirectional antennas, when the altitude of UAVs is smaller than h^*, the angle of elevation is dominated. Thus with the increase of the altitude, the interference from UAV network to ground user is increasing and the coverage probability of ground network is decreasing. However, when the altitude of UAVs is larger than h^*, the length of the propagation path is dominated. The interference from UAV network to ground users is decreasing with the increase of the altitude in this situation. Thus the coverage probability is increasing with the increase of altitude.

When the beam width of UAV, namely, β is decreasing, the interference from UAVs to ground network is reduced and the coverage probability of ground network is improved. As illustrated in Fig. 10, when $\beta = 2\pi/3$, the improvement of coverage probability is not significant. However, when $\beta = \pi/6$, the coverage probability will rapidly increase to the maximum value with the increase of altitude. Thus directional transmission in UAV network creates spectrum sharing opportunities between UAVs and ground network.

Mobility Pattern Cognition of UAV Networks

UAVs have specific mobility pattern and the mobility of UAVs can be exploited to improve network capacity. With the mobility pattern information of UAVs, the delay tolerant transmissions can be constructed and multiple transmission modes

[1] Reader could refer to (8) and (9) in [10] for the details of air-to-ground channel model.

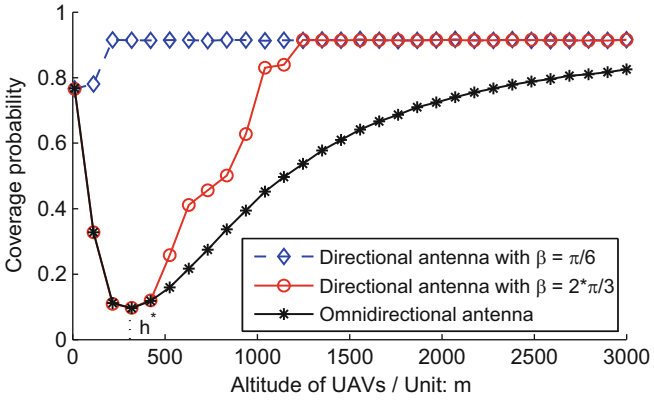

Fig. 10 The coverage probability of ground ad hoc network

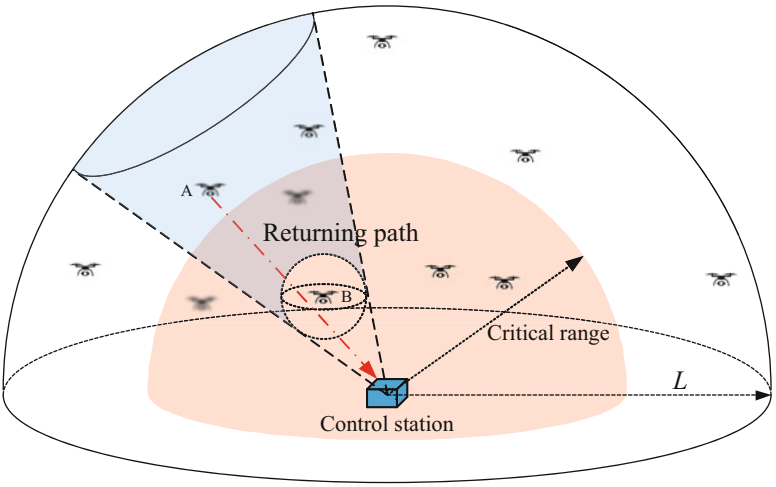

Fig. 11 UAV network with mobility pattern cognition. UAV sensors are deployed in 3D space

are implemented to carry various types of traffic. Figure 11 illustrates the scenario that UAVs act as aerial sensors and transmit sensing data to control station.

In Fig. 11, when UAV A returns, it will encounter UAV B. The returning UAV A can store and carry the data of UAV B to control station. Thus in addition to multi-hop transmission mode, the delay-tolerant transmission mode is constructed to improve the capacity of UAV networks. UAV network with multi-hop and SCF transmission modes can adapt the demands of diverse traffic. The delay-insensitive and delay-sensitive traffic can be forwarded through SCF transmission mode and multi-hop transmission mode, respectively. In the following sections, we discuss the SCF transmission modes.

Mobility Pattern Cognition

The process of the discovery of a returning UAV and the establishment of communication link between the returning UAV and a UAV along the returning path is illustrated in Fig. 12. Assume that UAV A will return to the control station and UAV B is located in the returning path of UAV A. Each UAV has a state bit. When a UAV is returning, the state bit is set as 0. Otherwise, the state bit is set as 1. The neighbor discovery function of UAV B will detect nearby UAVs. Once UAV B detects a UAV, it sends synchronize (SYN) signal. Meanwhile, the returning UAV A is also detecting the UAVs along its returning path. Once UAV A discovers a UAV and this UAV is sending SYN signal, UAV A feedbacks the state bit indicating that it is returning and synchronize/acknowledge (SYN/ACK) signal containing channel information for communication link establishment. Then UAV B sends ACK signal and establishes communication connection. When the data transmission is finished, the communication session is released and UAV A continues returning.

With mobility pattern information, the SCF transmission modes for 3D and 2D UAV network are introduced in the following sections.

3D UAV Deployment

As illustrated in Fig. 11, when UAV A returns, it can store and carry the data of UAV B to the control station. Assume that UAVs return in straight line path. In Fig. 11, when the UAVs in the shaded region return, they will assist UAV B to deliver data to control station. With the increase of the distance between the control station and UAV B, the volume of shaded region is decreasing and the number of returning UAVs assisting the data transmission of UAV B is also decreasing.

In [6], a critical range is discovered, which is illustrated in Fig. 11. Within critical range, the number of returning UAVs is sufficiently large, such that the capacity of UAVs within critical range contributed by SCF mode is higher than that outside of critical range. Thus the mobility of the returning UAVs outside of critical range needs to be controlled to improve the capacity. Mobility control schemes are as follows:

1. Returning path control: The returning path outside of critical range should be fold line such as zigzag curve to increase the length of returning path, such that more data can be delivered with SCF mode.
2. Pause time control: The returning UAVs outside of critical range pause for a time to gather the data of neighbor UAVs, such that the capacity of SCF mode can be improved.

However, all the mobility control scheme aiming to improve the capacity of SCF mode will increase the energy consumption of UAVs because the returning time will be longer than that without mobility control. Hence there is a trade-off between energy consumption and capacity improvement.

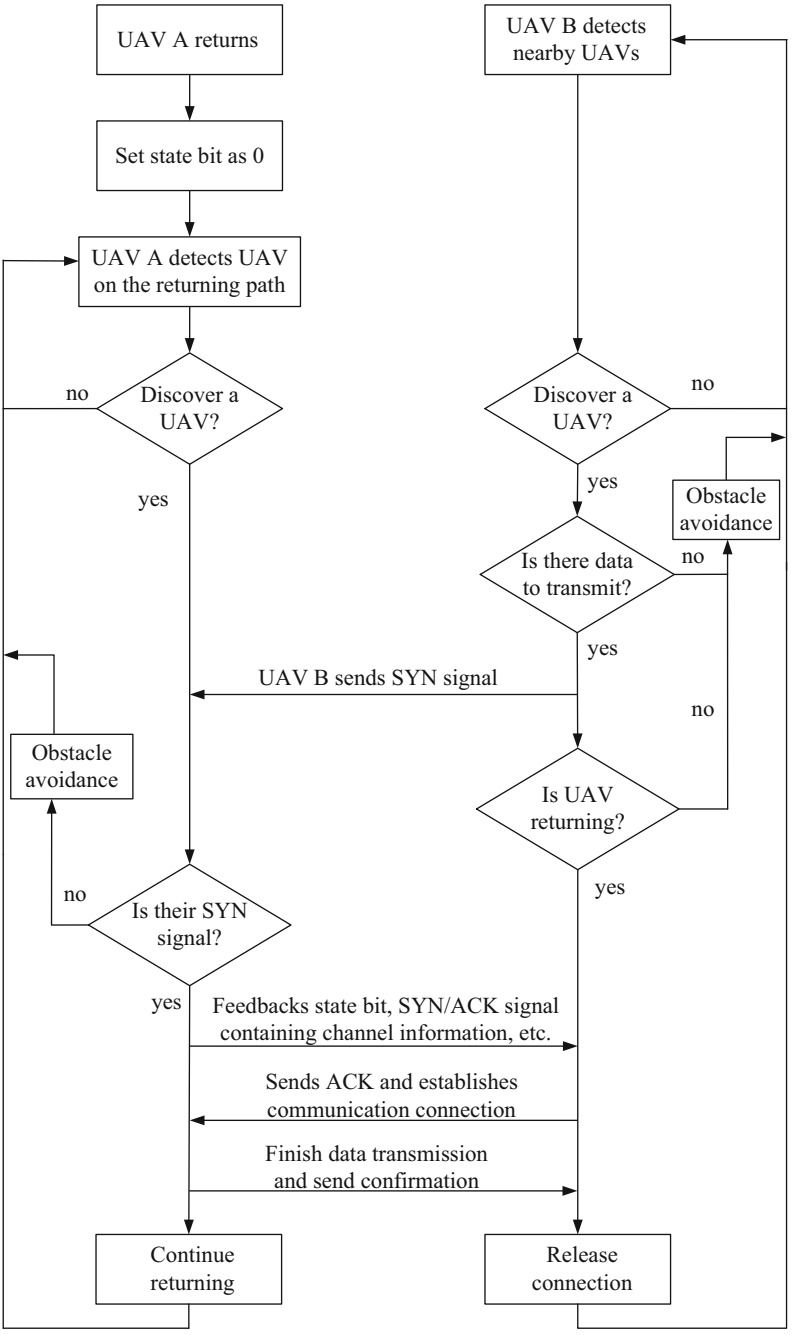

Fig. 12 The establishment of SCF transmission link

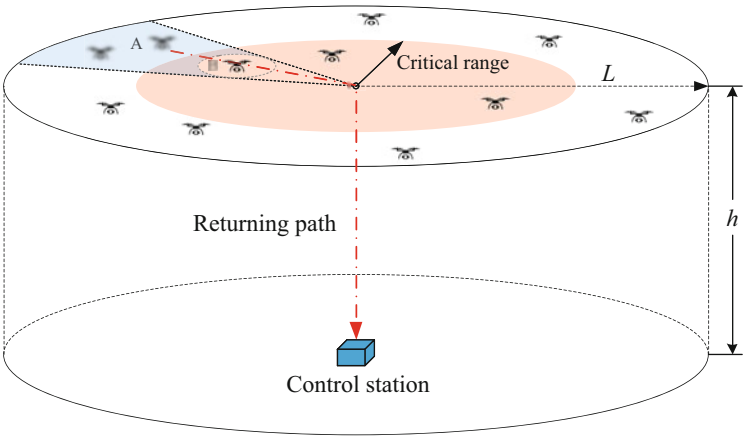

Fig. 13 UAV network with mobility pattern cognition. UAV sensors are deployed in an aerial 2D plane

2D UAV Deployment

When UAVs are deployed in an aerial 2D plane, the returning path of UAV is redesigned. As illustrated in Fig. 13, the UAVs are deployed in a circle above the ground. When UAV A returns, it will firstly flies to the center of the circle. Then UAV A flies downward to control station. With this returning path, the returning UAV A can deliver the data of UAV B to control station with SCF mode. In 2D deployment of UAVs, the critical range also exists and the mobility of the returning UAVs outside of critical range should be controlled to improve the capacity of SCF mode.

The previous discussions consider the scenario that UAVs act as aerial sensors. In the scenario that UAVs act as aerial base stations, the mobility pattern information can also be applied to construct SCF transmission mode. As illustrated in Fig. 14, UAVs are deployed in the sky to provide communication connections for ground nodes. For example, when ground node C transmits data to ground node D, it will firstly transmit to UAV A, then UAV A will transmit the data with multi-hop manner to UAV B. Finally, the data is forwarded from UAV B to ground node D. However, with SCF mode, if UAV A is a returning UAV passing ground node C, ground node C will forward data to UAV A. Then the data is brought to control station via UAV A. When UAV B is departing from control station and passing ground node D, UAV B will bring the data of ground node C and forward the data to ground node D. In this way, the multi-hop transmission can be avoided, such that the wireless channels will not be consumed by repeated data transmission in multi-hop transmission.

Summary and Future Work

This chapter presents the spectrum sharing between the drone network and traditional ground cellular network under different scenarios. It has provided explicit solutions of the optimal density of DSCs modeled by a 3D Poisson point process with limited height. It was demonstrated that larger deployment height limit results larger optimal DSC density. For DSC network underlay spectrum sharing with cellular network, as we relax the restrictions for DSC network, the dependence of optimal DSC base station deployment moves from the constraints of DSC network to constraints of cellular network. Effects of directional transmission on DSC networks are further discussed. Exploiting cognition capability on mobility, UAV network can provide high quality of information services in the highly dynamic environment with limited resources.

The spectrum sharing of drone networks is an emerging field with numerous interesting applications. We conclude by discussing some fruitful avenues for future research:

- *UAV Channel Modeling* As mentioned in the chapter, the characteristics of UAV wireless channels are very different from those of terrestrial wireless channels. More empirical measurements can be expected for developing more accurate channel models.
- *Multi-UAV Scheduling* Based on the analytical framework for drone spectrum sharing presented, it would be interesting to further design the scheduling scheme for multiple UAVs. The cooperation between UAVs can further improve the network performance.
- *UAV to Infrastructure/Vehicle Spectrum Sharing* We have focused on the spectrum sharing between UAVs and conventional cellular networks. There are

also ongoing thrusts on the coexisting between UAV and infrastructure/vehicle networks. Since UAVs can provide extra coverage, how to integrate the aerial base stations and relays with the existing ground networks deserves further study.

Abstract

With the increase of mobile video applications in people's daily life as well as industrial manufacture, such as video streaming, surveillance, and so on, video has been the main service in cellular networks. Operators and service providers are struggling to enhance the mobile video service, while user requirements for abundant, high-definition, and low-delay video have nearly drained the transmission capacity of current networks. Moreover, the large population of user equipments (UEs) exhibit differentiated video demands and various network transmission environments. Traditional networking, which is static and base station (BS) concentric, can hardly deal with these challenges. Thus, adaptive video transmission schemes are needed by jointly considering the interplay among user demand, video source characteristics, and networking. This work focuses on user-cognizant scalable video transmission over heterogeneous cellular networks. The video source is encoded using scalable video coding, which enables dynamic adaption of source information to the requirements of UEs and is suitable for cellular networks in which the transmission link quality varies substantially over space and time. Three novel transmission schemes are proposed, layered digital transmission, layered hybrid digital-analog transmission, and cooperative digital transmission. Leveraging tools from stochastic geometry, a comprehensive analysis is conducted focusing on three key performance metrics: outage probability, high-definition probability, and average distortion. The associated spectrum allocation and video transmission are chosen based on the user-cognizant information, such as the requirements for video service, wireless channel status, and the connections with the BSs. The results show that the proposed user-cognizant transmission schemes can provide a scalable video experience for UEs.

Introduction

Emerging wireless communication technologies as well as powerful and versatile mobile terminal devices have changed people's daily life, and the data traffic grows explosively, among which a substantial portion is attributed to multimedia such as mobile video. According to the Cisco Visual Networking Index, mobile video is expected to grow at an average growth rate of 62% until 2020, and within the 30.6 exabytes of data per month crossing mobile networks by 2020, 23.0 exabytes will be video related, such as video on demand, real-time streaming video, video

conferencing, and so on. The ever-increasing demand for abundant, high-definition, and low-latency mobile video brings great challenges to the mobile network with time-varying wireless channel. Moreover, with the release of different types of UEs, the requirements on data rate of video transmission vary in a wide range.

Compared to the IP transmission network and cellular core network, the bottleneck of the end-to-end transmission degrading the Quality of Experience (QoE) of video lies in the radio access network due to user traffic congestion and packet loss. Current LTE/LTE-A networks are not inheritably built for QoE-aware video delivery. The application-specific information exists at Packet Data Network Gateway (P-GW), while the wireless channel quality and connection status are restrictively known by eNodeB.

State-of-art design of cellular networks is base station (BS) concentric, which means that the resource allocation and transmission schedule are completed at the BSs and are not on-demand for UEs. The information bits are treated equally and the transmission strategy is not UE specific. As for the video transmission of a typical UE, the UE would require the video content with different video qualities based on its terminal capacity. Meanwhile, the UE can choose different service mechanisms provided by the cellular network based on the connection status.

Taking into account of time-varying wireless channel conditions and congestion, video streams are adapted to reduce the transmission bitrates. Traditionally, rate adaptation of video streams is realized by packet/frame dropping or transcoding with some serious drawbacks, since packet/frame dropping significantly degrades the video quality and transcoding is computationally complex. Advanced source coding techniques provide a new dimension of dynamically provisioning wireless resources for the varying requirements and the varying link conditions of UEs, thus creating the possibility of extracting video scaled in multiple dimensions, e.g., spatial, temporal, and quality. Scalable Video Coding (SVC) is an extension of the H.264/MPEG-4 AVC video compression standard [1] and has been evolved to Scalable High-Efficiency Video Coding (SHVC) [2], in which the bitstream is encoded into multiple layers, namely, a base layer (BL) and at least one enhancement layer (EL). The quality of reconstructed video depends on the number of layers decoded and stays the same until a higher enhancement layer is successfully decoded. The number of layers and their code rates may be determined by the requirement and the link condition of the subscribing UE.

On the other hand, cellular networks are evolving from a homogenous architecture to a composition of heterogeneous networks, comprised of various types of base stations (BSs) [3, 4]. Each type of BSs has its characteristic transmit power and deployment intensity: for example, macro BSs (MBSs) have larger transmit power, aiming at providing global coverage; femto access points (FAPs) are small BSs targeted for home or small business usages. As the distance between a UE and its serving FAP is small, the UE enjoys a high-quality link and achieves power savings. Meanwhile, the reduced transmission range also enhances spatial reuse and alleviates multiuser interference. In addition, different types of BSs can transmit cooperatively the same video content to the UE to enhance the quality of experience. The user-cell association approach for heterogenous networks should be addressed

to exploit context information as well as channel-related information extracted from UEs. Generally speaking, there are two different service modes, separate mode and cooperative mode. In separate mode, the macro cells and the small cells (e.g., femto cells) transmit different video streams to the UEs in a manner of dual connectivity. In cooperative mode, both the macro cells and small cells transmit the same video content to the UE in a manner of coordinated multipoint transmission. In this paper, we study the problem of scalable transmission over heterogeneous networks and demonstrate the performances of several user-cognizant transmission schemes to exploit the combination of multi-layer video transmission and multitier cellular networks.

Related Work

The prior works that consider video transmission over wireless networks mainly focus on scalable coding of video source or adaptive networking techniques separately. Furthermore, UE is regarded as a dummy terminal, and thus their differentiated demand and status are neglected. The analysis usually focuses on homogeneous networks, and the common feature of the layered structure of SVC and HCNs is not exploited. In [5], an overview of SVC and its relationship to mobile content delivery are discussed focusing on the challenges due to the time-varying characteristics of wireless channels. In [6], a per-subcarrier transmit antenna selection scheme is employed to support multiple scalable video sequences over a downlink cognitive network, and the outage probability is reduced because of video scalability. In [7], real-time use cases of mobile video streaming are presented, for which a variety of parameters like throughput, packet loss ratio, and delay are compared with H.264 single-layer video under different degrees of scalability. In [8], the proposed scheme employs WiFi: the BL is always transmitted over a reliable network such as cellular, whereas the EL is opportunistically transmitted through WiFi. Technical issues associated with the simultaneous use of multiple networks are discussed. In [9], HCNs with storage-capable small-cell BSs are studied: versions and layers of video have different impacts on the delay-servicing cost tradeoff, depending on the user demand diversity and the network load.

Some works related to QoE-aware or adaptive strategies have also been studied previously. Chen et al. [10] proposed an admission control strategy that was designed to maximize the number of video users satisfying the QoE constraints on their second-order statistics. Although the admission control strategy damages the QoE of the blocked users, the overall percentage of users satisfying the QoE constraints among both admitted and blocked users can be significantly improved. Thakolsri et al. [11] proposed a content-aware scheduling and resource allocation, taking into account the content characteristics of the video streams, and performs video rate adaptation at the BS. Fu et al. [12] proposed a QoE-aware video delivery by considering the hierarchical architecture of LTE/LTE-A network. Different video flows are marked at the core network to transform the video content information into QoE-aware priority classes. A packet dropping strategy addressing the transmission

capacity at the eNodeB is also proposed. But the priority marking process at the core network is unaware of channel status.

Considering the wireless video transmission techniques, there are several approaches to enhance the QoE of video users. The above literature is based on digital transmission, consisting of digital source coding (e.g., quantization and entropy coding), digital modulation (e.g., QPSK, 64QAM), and digital channel coding (e.g., turbo or LDPC). Unfortunately, digital transmission results in cliff effect. The cliff effect refers to the drastic degradation in video quality when the signal strength fades below the decoding threshold (as opposed to a graceful degradation). There exist certain SINR thresholds at which the video quality changes drastically; in between these thresholds, the quality stays approximately constant. The recently revitalized analog transmission has shown promising potential in handling channel variations and user heterogeneities for wireless video communication. The analog scheme consists of analog source coding and analog modulation that directly maps a source signal into a linearly transformed channel signal without channel coding. SoftCast [13] is an analog video broadcast scheme that transmits a linear transform of the video signal without quantization, entropy coding, or channel coding. It is claimed to realize continuous quality scalability. However, information-theoretic studies (such as [14,15]) show that analog schemes with linear mapping (from source signals to channel signals) are relatively inefficient for video transmission, while hybrid digital-analog transmission is asymptotically optimal under matched channel conditions for optimally chosen power allocations between the analog and digital parts. The hybrid digital-analog scheme combines digital with analog schemes, transmitting digital and analog signals simultaneously using TDMA, FDMA, or superposition transmission. The authors in [16] propose a hybrid digital-analog scheme for broadcasting, showing a substantial performance gain. However, these works did not consider the impacts of HCNs and the spatial distribution of wireless networks, let alone the design of scalable transmission algorithms utilizing the structure of HCNs.

Moreover, coordinated multipoint (CoMP) transmission is intensively studied to enhance the system performance of LTE-A. By coordinating multiple BSs, the interference at the UE can be alleviated, or multiple received signals can be merged. The studies in [17, 18] evaluate the potential system gain of CoMP and discuss the appropriate deployment scenarios. The authors also review the necessary techniques of signal processing, backhaul link design, and supported protocols. There exist two types of cooperative transmissions, namely, coherent and noncoherent joint transmission. Many previous studies considered noncoherent joint transmission because it requires less channel status information. The authors in [19,20] analyze the performance of noncoherent joint transmission in heterogeneous cellular networks and give the distribution of SINR for a user in a random position and cell edge, respectively. In addition, the impact of channel status information is also studied. Most previous works neglect the spectrum sub-band allocation, but the same sub-band is required when two BSs transmit cooperatively. Bang et al. [21] combines frequency fraction reuse and CoMP, and proposes an allocation to minimize the system power. Zhang et al. [22] and Kosmanos et al. [23] propose a

joint sub-band allocation and power optimization scheme to improve the spectrum efficiency for LTE-A when BS and relay transmit cooperatively.

In order to give a theoretic analysis of the system performance, stochastic geometry has been utilized as an effective tool for modeling and analyzing cellular networks; see, e.g., [24–26] and references therein. Generally, the spatial distribution of BSs is modeled as a spatial point process, such as the homogeneous Poisson point process (PPP) for single-tier networks, for which the coverage probability is derived in [27]. For HCNs, the spatial distribution of heterogeneous BSs is often modeled as multiple independent tiers of PPPs, and several key statistics are analyzed in [20, 28]. A comprehensive treatment of the application of stochastic geometry in wireless communication and content can be found in [29, 30].

A User-Cognizant Solution

Most existing works on heterogenous networks have focused on admission control, resource allocation, and transmission coordination. The serving BS associated to a particular UE is assigned based on indicators of the wireless link quality at the UEs, such as the received signal strength indicators (RSSIs) or the SINRs. The same priority is allocated to each information bit for different video data flows in the scheduling stage. All these networking designs again verify that the current network is inefficient for video transmission. To enhance the QoE, one promising approach for efficient networking is by making the network better informed of its environment and user requirements.

Thus, considering scalable video transmission over HCNs, we have previously proposed two user-cognizant transmission schemes. In [31], the common layer structures of both video source data and network topology are employed to enhance the video transmission, based on the user's video requirement and association status. In [32], analog transmission of enhancement layer of video stream is proposed in order to make the video reception quality changing continuously with channel quality, thus degrading the staircase effect of digital transmission. Here the cooperative transmission is taken into consideration, where the macro BS and small BS work in a manner of coordinated multipoint transmission.

In all, three user-cognizant transmission schemes are proposed, which are layered digital transmission, layered hybrid digital-analog transmission, and cooperative digital transmission, respectively. The user is cognizant of its video service requirement, mobility, and connection status.

An analytical performance assessment of user-cognizant SVC transmission over two-tier HCNs utilizing tools from stochastic geometry is studied. The contributions of the are:

1. Three user-cognizant transmission schemes are proposed to enhance the QoE of video users exploiting the interplay among user demand, video source characteristic, and networking.

2. An analytical framework is proposed for scalable video transmission exploiting the common feature of a layered structure of SVC and HCNs. A digital and a hybrid digital-analog transmission scheme are proposed and studied. The impact of UE load, i.e., the number of UEs served in a cell, is also considered.
3. The power allocation between the digital BL signal and the analog EL signal is also analyzed to minimize the average distortion. The hybrid digital-analog scheme can further improve the system performance by avoiding the cliff effect and realizing continuous quality scalability when the proportion of frequency resource allocated to the femto tier exceeds a certain threshold.
4. A noncoherent joint transmission cooperative scheme is proposed, and moreover, the impact of sub-band allocation is also studied.

The remaining part of this paper is as follows: section "System Model" describes the system model, including the transmission schemes and spectrum allocation methods. Section "UE Load and Sub-band Occupancy" derives the distributions of the number of UEs per cell and sub-band occupancy probabilities. Section "SINR Distribution and Data Rate" derives the SINR and data rate distributions. Section "System Performances" evaluates the performance metrics, namely, outage probability, HD probability, and average distortion. Section "Simulation and Discussion" presents simulation results and related discussions. Section "Conclusion and Future Directions" concludes this paper.

System Model

The downlink performance of SVC over a two-tier HCN is considered; see Fig. 1. When a video user needs to request for a particular video, it would first collect the information about video quality requirement due to possessing ability of the UE and connection status due to its mobility and the network topology. The user sends the user-cognizant information to the serving BS (or BSs), and the BS or BSs choose an appropriate transmission strategy. The video data stream is traversing through the video server, IP transmission network, cellular core network, radio access network, and finally reaching at the user.

Layered Video Model

The SVC video content is split into two layers, BL and EL. The BL is always modulated into a digital signal, and the data rate is R_{B}, while the EL is modulated into a digital signal or an analog signal in these transmission schemes accordingly. If the EL is modulated into a digital signal, then the data rate is R_{E}. Here we focus on the streaming video service; the video can be decoded successfully when the data rate requirements of the BL and the EL are met.

Actually, the proposed analytical framework can be extended to video signals that are encoded to J layers using a fine granularity, and the BS chooses the first

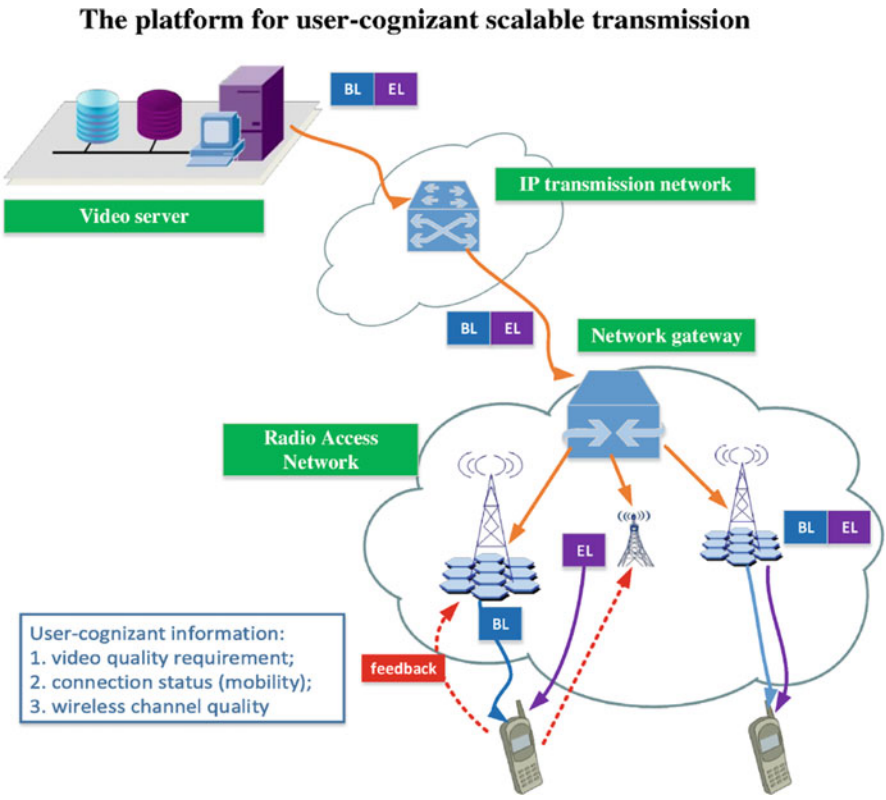

Fig. 1 Illustration of the platform for user-cognizant scalable transmission

J_1 layers for the BL and the following J_2 layers for the EL based on the channel quality for each UE, where $J_1 + J_2 \leq J$.

It should be aware that SVC allows three types of scalable encoding (spatial, temporal, SNR quality) to be combined and create a single layer [1,5]. The proposed layered video model is generic and is not restricted by the specifications of the layered encoding and the optimal selection of scalability combinations. Each layer is generated by some combinations of video scalabilities, and the required data rates are the main parameters from the view of networking.

Network Model

The two-tier HCN consists of two types of BSs, namely, MBSs and FAPs. These two types of BSs are modeled by two independent tiers of homogeneous PPPs, Φ_{mb} and Φ_{fb}, whose intensities are λ_{mb} and λ_{fb}, respectively. FAPs aim at providing network access to UEs in their vicinity within a coverage radius R_{f}. Suppose that there exist

N sub-bands each of bandwidth W. The transmit powers of an MBS and an FAP over each sub-band are set as P_{m} and P_{f}, respectively. The path loss model is $r^{-\alpha}$, and here for simplicity, it is assumed that the path loss exponent is the same for MBS and FAP, and the effect of shadowing is ignored. The small-scale fading distribution is exponential with mean unity in squared magnitude, i.e., Rayleigh fading. The fading is assumed to be frequency flat within each sub-band and independent among different sub-bands. The noise variance at each UE is denoted by σ^2.

There are two types of UEs, macro UEs and femto UEs. The locations of macro UEs form a homogeneous PPP Φ_{mu} with intensity λ_{mu}, and each macro UE connects to the nearest MBS. The locations of the femto UEs form a Matern cluster process Φ_{fu} [30] with parent process Φ_{fb} (the FAPs), i.e., the UEs in each cluster form a finite PPP of intensity λ_{fu} on the disk of radius R_{f} centered at each FAP, implying that the mean number of users per cluster is $\bar{U}_{\mathrm{f}} = \lambda_{\mathrm{fu}} \pi R_{\mathrm{f}}^2$. Each femto UE connects to the FAP located at the parent point of the corresponding cluster, called the parent FAP. The access mechanism is as follows: a femto UE always connects to its parent FAP when accessing a femto BS and connects to the MBS closest to its parent FAP when accessing a macro BS; a macro UE can only connect to the nearest MBS, even if it is situated within the coverage of an FAP. This corresponds to a closed-access femto network, in which only subscribers are allowed to be served by an FAP.

Transmission Schemes

Considering the connection status of UEs and their differentiated demand, three transmission schemes are proposed, i.e., layered digital (LD) [31], layered hybrid digital-analog (LHDA) [32], and cooperative digital (CD). For the macro UEs, they only connect to the MBS. Since the MBS aims at providing the coverage service, macro UEs attempt to obtain their BL contents from their serving MBSs and forego the EL. For the femto UEs, since they are covered by the MBS and the FAP, they have two choices: one is that they attempt to obtain their EL contents from their serving FAPs, and they attempt to obtain their BL contents either from their serving MBSs with probability p or from their serving FAPs with probability $1 - p$. The other one is that they receive the video contents which are transmitted cooperatively by the MBS and the FAP in the manner of CoMP.

1. *LD transmission*: See Fig. 2. Both the BL and the EL are modulated into digital signals. For a macro UE, the data stream of encoded BL signals is transmitted from the serving MBS. For a femto UE, the data stream of encoded BL signals for small SINR or jointly encoded signals of both the BL and the EL for large SINR is transmitted from the serving FAP when $p = 0$; the digital BL data stream is transmitted from its serving MBS, while the digital EL data stream is transmitted from its serving FAP when $p = 1$; a mixed transmission is adopted when $0 < p < 1$.
2. *LHDA transmission*: See Fig. 2. The BL is modulated into a digital signal, while the EL is modulated into an analog signal. For a macro UE, the data stream of

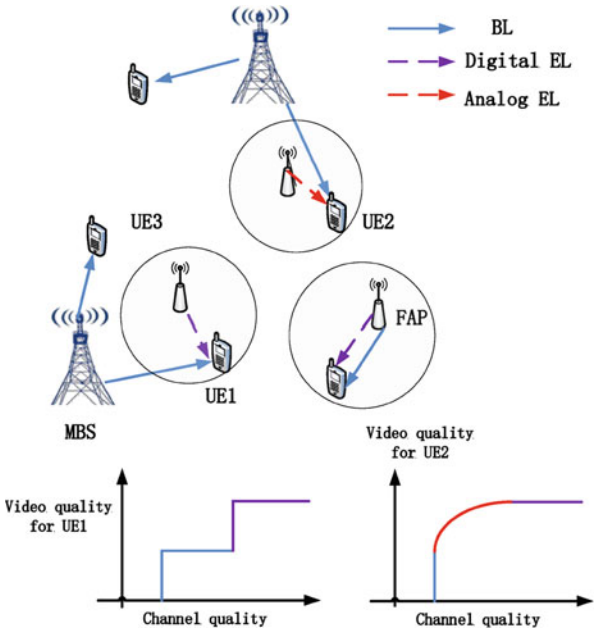

Fig. 2 Qualitative illustration of the performances of LD and LHDA transmissions. LD transmission shows a staircase effect, while LHDA transmission shows continuous quality reception with respect to the channel quality

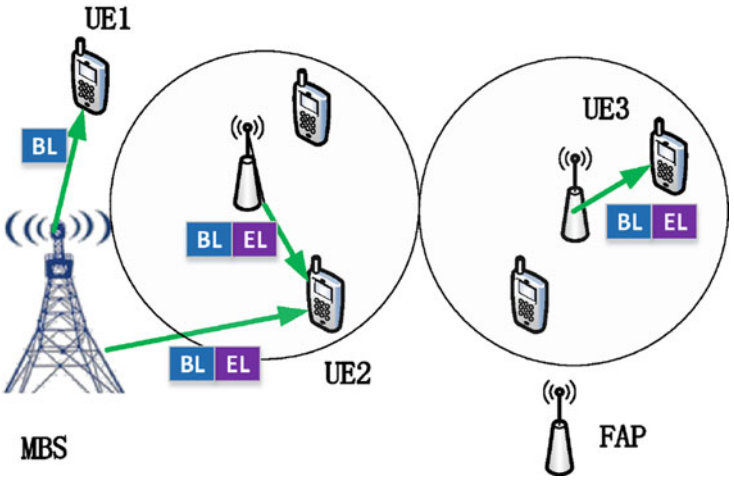

Fig. 3 Illustration of the CD transmission model

encoded BL signals is transmitted from the serving MBS. For a femto UE, the superposition of the digital BL signal and the analog EL signal is transmitted from the serving FAP when $p = 0$; the digital BL data stream is transmitted from its serving MBS, while the analog EL data stream is transmitted from its serving FAP when $p = 1$; a mixed transmission is adopted when $0 < p < 1$.

3. *CD transmission*: See Fig. 3. Both the BL and the EL are modulated into digital signals. For a macro UE, the data stream of encoded BL signals is transmitted from the serving MBS. For a femto UE, if it can claim the same sub-band from both the MBS and the FAP, then the data stream of jointly encoded signals of both the BL and the EL is transmitted from the serving MBS and FAP cooperatively in the manner of noncoherent joint transmission, otherwise, the data stream of jointly encoded signals of both the BL and the EL is transmitted from the serving FAP.

Since the video source is encoded into multiple layers, different layers are transmitted to the UE based on the channel quality, thus providing scalable video quality. Specifically, for those UEs in less favorable conditions, only the BL with relatively low data rate is received in order to ensure basic video experience. When the channel quality improves, the EL is also received for enhanced video experience. Thus, the LD and CD transmissions can provide two-level scalable video for the UEs, and LHDA can provide a continuous quality scalability.

UE Load and Sub-band Occupancy

UE Load

Since the distribution of femto UEs in an FAP coverage disk is a PPP with intensity λ_{fu}, the number of femto UEs connected to an FAP is a Poisson random variable (r.v.) with mean $\bar{U}_{\mathrm{f}}$,

$$\mathbb{P}\{U_{\mathrm{f}} = i\} = \frac{(\bar{U}_{\mathrm{f}})^i}{i!} e^{-\bar{U}_{\mathrm{f}}}, \quad i = 0, 1, \cdots. \tag{1}$$

For LD and LHDA transmissions, an MBS not only serves the macro UEs situated in its Voronoi cell but also the femto UEs that belong to the FAPs in this Voronoi cell and connect to the MBS to receive the BL contents. We denote the number of macro UEs in the Voronoi cell as U_{MBS} and the total number of femto UEs served by the MBS as U_{FAP}, which is given by $U_{\mathrm{FAP}} = \sum_{i=1}^{N_{\mathrm{c}}} N_{\mathrm{f},i}$, where N_{c} denotes the number of the FAPs in the Voronoi cell and $N_{\mathrm{f},i}$ denotes the number of femto UEs which belong to the ith FAP but connect to the MBS to receive the BL contents. The total number of UEs served by an MBS is thus

$$U_{\mathrm{m}} = U_{\mathrm{MBS}} + U_{\mathrm{FAP}}. \tag{2}$$

U_{MBS} is conditionally independent of U_{FAP} given the area of the Voronoi cell. Denote the area of a Voronoi cell by S; the probability generating function (pgf) of U_{m} conditioned on S, denoted by $G_{\mathrm{m}}(z \mid S)$, is

$$G_{\mathrm{m}}(z \mid S) = G_{\mathrm{MBS}}(z \mid S) G_{\mathrm{FAP}}(z \mid S), \tag{3}$$

where $G_{\mathrm{MBS}}(z \mid S)$ and $G_{\mathrm{FAP}}(z \mid S)$ are the pgfs of U_{MBS} and U_{FAP} conditioned on S, respectively.

U_{MBS} is a Poisson r.v. with mean $\lambda_{\mathrm{mu}} S$, and the conditional pgf of U_{MBS} is

$$G_{\mathrm{MBS}}(z \mid S) = e^{\lambda_{\mathrm{mu}} S(z-1)}. \tag{4}$$

Since a femto UE attempts to connect to its serving MBS with probability p in LD and LHDA transmissions, a thinning occurs, i.e., $N_{\mathrm{f},i}$ is a Poisson random variable with mean $p\bar{U}_{\mathrm{f}}$. Meanwhile, N_{c} is also a Poisson r.v. with mean $\lambda_{\mathrm{fb}} S$ because of the PPP distribution of the FAP locations. U_{FAP} is a compound Poisson r.v. with conditional pgf

$$G_{\mathrm{FAP}}(z \mid S) = e^{\lambda_{\mathrm{fb}} S(e^{p\bar{U}_{\mathrm{f}}(z-1)}-1)}. \tag{5}$$

There is no known closed form expression of the probability density function (pdf) of the area S of the typical Poisson Voronoi cell, but the following approximation [33]

$$f_S(x) \approx \frac{(\lambda_{\mathrm{mb}} c)^c}{\Gamma(c)} x^{c-1} e^{-c\lambda_{\mathrm{mb}} x}, \tag{6}$$

where $c = \frac{7}{2}$ and $\Gamma(c) = \int_0^\infty t^{c-1} e^{-t} \mathrm{d}t$, has been known to be handy and sufficiently accurate (see, e.g., [34]). Aided by this approximation, with some manipulations, the pgf of U_{m} is

$$G_{\mathrm{m}}(z) = c^c \left(c - \frac{\lambda_{\mathrm{mu}}}{\lambda_{\mathrm{mb}}}(z-1) + \frac{\lambda_{\mathrm{fb}}}{\lambda_{\mathrm{mb}}} \left(1 - e^{p\bar{U}_{\mathrm{f}}(z-1)} \right) \right)^{-c}, \tag{7}$$

and the distribution of U_{m} follows as

$$\mathbb{P}\{U_{\mathrm{m}} = i\} = \frac{G_{\mathrm{m}}^{(i)}(0)}{i!}, \quad i = 0, 1, \cdots, \tag{8}$$

where $G_{\mathrm{m}}^{(i)}(0)$ is the i-th derivative of $G_m(z)$ evaluated at $z = 0$.

For CD transmission, all the femto UEs attempt to connect to the MBS to obtain cooperative gain; thus distribution of U_{m} is similar to that in LD and LHDA transmissions with $p = 1$.

Sub-band Occupancy

Since the number of served UEs for each BS is random, the sub-band frequency resource will be underutilized in some BSs and overutilized in some other BSs. As

the UE loads in the MBS and the FAP are different under different transmission schemes, the sub-band occupancy is calculated accordingly.

Spectrum Allocation for LD and LHDA

Of the N sub-bands, let N_{m} sub-bands be allocated to the macro tier and N_{f} sub-bands to the femto tier. Each UE requires one sub-band for each transmission. We consider the following two spectrum allocation methods [35]:

1. *Orthogonal spectrum allocation:* The N sub-bands are split as $N = N_{\mathrm{m}} + N_{\mathrm{f}}$, where the N_{m} sub-bands used by all the MBSs of the macro tier are orthogonal to those N_{f} sub-bands used by all the FAPs of the femto tier. So there is no inter-tier interference.

   It is assumed that the available sub-bands are uniformly and independently allocated to the UEs by the BS. There are N_{m} available sub-bands for the MBS, and each sub-band is equally likely to be chosen. If the number of UEs is smaller than that of sub-bands, the MBS randomly chooses U_{m} out of the total N_{m} sub-bands. Otherwise, all the sub-bands are chosen. The probability that a sub-band is used by an MBS is

$$P_{\mathrm{busy}}^{\mathrm{m},\perp} = \frac{1}{N_{\mathrm{m}}} \sum_{i=0}^{\infty} \min\{i, N_{\mathrm{m}}\} \mathbb{P}\{U_{\mathrm{m}} = i\}, \tag{9}$$

   and similarly the probability that a sub-band is used by an FAP is

$$P_{\mathrm{busy}}^{\mathrm{f},\perp} = \frac{1}{N_{\mathrm{f}}} \sum_{i=0}^{\infty} \min\{i, N_{\mathrm{f}}\} \mathbb{P}\{U_{\mathrm{f}} = i\}. \tag{10}$$

2. *Non-orthogonal spectrum allocation:* Compared with the orthogonal case, here the two sets of sub-bands may overlap: each MBS (resp. FAP) independently randomly selects N_{m} (resp. N_{f}) sub-bands from the N sub-bands. The values of both N_{m} and N_{f} can be chosen from 1 to N flexibly and need not add to N. So there is inter-tier interference, while the available spectrum will be abundant as N_{m} and N_{f} grow large.

   For the non-orthogonal case, both the MBS and the FAP choose a sub-band randomly from N sub-bands, so the probability that a sub-band is used by an MBS is

$$P_{\mathrm{busy}}^{\mathrm{m},\not\perp} = \frac{1}{N} \sum_{i=0}^{\infty} \min\{i, N_{\mathrm{m}}\} \mathbb{P}\{U_{\mathrm{m}} = i\}, \tag{11}$$

   and similarly the probability that a sub-band is used by an FAP is

$$P_{\mathrm{busy}}^{\mathrm{f},\not\perp} = \frac{1}{N} \sum_{i=0}^{\infty} \min\{i, N_{\mathrm{f}}\} \mathbb{P}\{U_{\mathrm{f}} = i\}. \tag{12}$$

The spatial point process of BSs that use a given sub-band is an approximately independent thinning of the original point process Φ_{mb} (resp. Φ_{fb}) by the probability $P_{\text{busy}}^{\text{m,s}}$ (resp. $P_{\text{busy}}^{\text{f,s}}$), denoted by $\tilde{\Phi}_{\text{mb}}$ (resp. $\tilde{\Phi}_{\text{fb}}$) with the intensity $\tilde{\lambda}_{\text{mb}} = \lambda_{\text{mb}} P_{\text{busy}}^{\text{m,s}}$ (resp. $\tilde{\lambda}_{\text{fb}} = \lambda_{\text{mb}} P_{\text{busy}}^{\text{m,s}}$) [34], where the superscript $\text{s} \in \{\perp, \not\perp\}$ indicates whether the orthogonal or the non-orthogonal spectrum allocation method is used.

Spectrum Allocation for CD

Since both the macro UEs and femto UEs connect to the MBS, if the number of UEs connected to MBS $U_{\text{m}} \leq N$, each UE is allocated one sub-band, otherwise, if $U_{\text{m}} \geq N$, all the UEs share the sub-bands in a round-robin mechanism. Then the FAPs allocate sub-bands to femto UEs in a similar way by comparing U_{f} and N. For a femto UE, if it is chosen by both the MBS and the FAP, the MBS and the FAP allocate the same sub-band to the UE, thus making it working in a cooperative mode. Otherwise it is only served by the FAP and works in a noncooperative mode.

Since both the macro and femto tiers employ the total N sub-bands, similar to that of the LD case, the probability that a sub-band is used by an MBS is

$$P_{\text{busy}}^{\text{m,CoMP}} = \frac{1}{N} \sum_{i=0}^{\infty} \min\{i, N_{\text{m}}\} \mathbb{P}\{U_{\text{m}} = i\}, \tag{13}$$

and similarly the probability that a sub-band is used by an FAP is

$$P_{\text{busy}}^{\text{f,CoMP}} = \frac{1}{N} \sum_{i=0}^{\infty} \min\{i, N_{\text{f}}\} \mathbb{P}\{U_{\text{f}} = i\}. \tag{14}$$

SINR Distribution and Data Rate

SINR Distribution

The complementary cumulative distribution function (ccdf) of the SINR is defined as $\mathcal{P}(\theta) = \mathbb{P}\{\text{SINR} > \theta\}$, where θ is the SINR threshold. The SINR distributions of a UE connected to the MBS and the FAP are derived under three transmission schemes.

LD Transmission

For analytical tractability, we assume that both the BL and the EL are modulated into digital signals according to a Gaussian codebook.

For the typical UE which is assumed to be located at the origin and connected to its MBS, the received signal denoted by Y can be written as

$$Y = P_{\mathrm{m}}^{1/2}\|x_0\|^{-\alpha/2}h_{x_0}X_{x_0} + \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}^{1/2}\|x\|^{-\alpha/2}h_x X_x + \kappa \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}^{1/2}\|y\|^{-\alpha/2}h_y X_y + Z, \tag{15}$$

where the first item of right side of the equation denotes the received signal symbol, the second and the third items denote the interference symbols from the macro and the femto tier, respectively, and Z denotes the Gaussian noise with zero mean and variance σ^2. We use x_0 to denote the location of the serving MBS. X_{x_0} is the signal symbol, while X_x is the interference symbol transmitted by the interfering MBS x. $X_{x_0}, X_x \sim \mathbb{CN}(0,1)$. X_y is the interference symbol transmitted by the interfering FAP y, and $X_y \sim \mathbb{CN}(0,1)$. The indicator $\kappa \in \{0,1\}$ indicates the orthogonal and non-orthogonal spectrum allocation methods, respectively.

Thus, the received SINR is

$$\gamma_{\mathrm{LD}}^{\mathrm{m}} = \frac{P_{\mathrm{m}}\|x_0\|^{-\alpha}|h_{x_0}|^2}{I_{\mathrm{m}} + \kappa I_{\mathrm{f}} + \sigma^2}, \tag{16}$$

where $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_x|^2$ is the interference from the macro tier, and $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ is the interference from the femto tier.

For the typical femto UE which is assumed to be located at the origin and connected to its FAP, the received signal can be written as

$$Y = P_{\mathrm{f}}^{1/2}\|y_0\|^{-\alpha/2}h_{y_0}X_{y_0} + \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus\{y_0\}} P_{\mathrm{f}}^{1/2}\|y\|^{-\alpha/2}h_y X_y + \kappa \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}^{1/2}\|x\|^{-\alpha/2}h_x X_x + Z, \tag{17}$$

where y_0 denotes the location of the serving FAP. Note that the FAP transmits the encoded EL signals only or the jointly encoded signals of both the BL and the EL to the typical UE based on user request. X_{y_0} is the signal symbol transmitted by the serving FAP, and X_y is the interference symbol transmitted by the interfering FAP y.

Thus, the received SINR is

$$\gamma_{\mathrm{LD}}^{\mathrm{f}} = \frac{P_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2}, \tag{18}$$

where $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus\{y_0\}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ denotes the interference from the femto tier and $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_x|^2$ denotes the interference from the macro tier.

The following theorem gives the ccdf of the SINR for the typical UE,

Theorem 1. *For LD transmission, the ccdf of the SINR for the typical UE connected to its serving MBS is*

$$\mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta) = \mathbb{P}\{\gamma_{\mathrm{LD}}^{\mathrm{m}} > \theta\}$$
$$= \int_0^{\infty} \pi\lambda_{\mathrm{mb}} \exp\Bigg(- \pi v(\lambda_{\mathrm{mb}} + \tilde{\lambda}_{\mathrm{mb}}\rho(\theta,\alpha))$$
$$- \frac{\theta v^{1/\delta}\sigma^2}{P_{\mathrm{m}}} - \kappa\left(\frac{P_{\mathrm{f}}\theta}{P_{\mathrm{m}}}\right)^{\delta} v\tilde{\lambda}_{\mathrm{fb}}\delta\pi^2\csc(\delta\pi)\Bigg)\mathrm{d}v, \tag{19}$$

and the ccdf of the SINR for the typical femto UE connected to its serving FAP is

$$\mathcal{P}_{\mathrm{LD}}^{\mathrm{f}}(\theta) = \mathbb{P}\{\gamma_{\mathrm{LD}}^{\mathrm{f}} > \theta\}$$
$$= \int_0^{R_{\mathrm{f}}^2} \frac{1}{R_{\mathrm{f}}^2} \exp\left(- \frac{\theta v^{1/\delta}\sigma^2}{P_{\mathrm{f}}} - \delta\pi^2\csc(\delta\pi)\theta^{\delta} v\left(\tilde{\lambda}_{\mathrm{fb}} + \kappa\left(\frac{P_{\mathrm{m}}}{P_{\mathrm{f}}}\right)^{\delta}\right)\tilde{\lambda}_{\mathrm{mb}}\right)\mathrm{d}v, \tag{20}$$

where $\delta = 2/\alpha$, $\tilde{\lambda}_{\mathrm{mb}} = \lambda_{\mathrm{mb}} P_{\mathrm{busy}}^{\mathrm{m,s}}$, $\tilde{\lambda}_{\mathrm{fb}} = \lambda_{\mathrm{fb}} P_{\mathrm{busy}}^{\mathrm{f,s}}$, *and* $\rho(\theta,\alpha) = \theta^{\delta}\int_{\theta^{-\delta}}^{\infty} \frac{1}{1+x^{1/\delta}}\mathrm{d}x$. *In orthogonal spectrum allocation,* $\kappa = 0$, *while in non-orthogonal spectrum allocation,* $\kappa = 1$.

Proof. Let $\|x_0\|$ be the distance from the typical UE to its serving MBS, which is the nearest MBS, so the pdf of $\|x_0\|$ is $f_{\|x_0\|}(r) = e^{-\lambda_{\mathrm{mb}}\pi r^2} 2\pi\lambda_{\mathrm{mb}} r$.

The SINR experienced by the typical UE connected to its serving MBS is given by $\gamma_{\mathrm{LD}}^{\mathrm{m}} = \frac{P_{\mathrm{m}}\|x_0\|^{-\alpha}|h_{x_0}|^2}{I_{\mathrm{m}}+\kappa I_{\mathrm{f}}+\sigma^2}$, where $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_{x_0}|^2$ is the interference from the macro tier, and $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ is the interference from the femto tier. $\kappa \in \{0,1\}$ is the indicator that whether the orthogonal or the non-orthogonal spectrum allocation is used. Due to the independent thinning approximation, the set of interfering MBSs is a PPP $\tilde{\Phi}_{\mathrm{mb}}$ with intensity $\tilde{\lambda}_{\mathrm{mb}}$, and the set of interfering FAPs is a PPP $\tilde{\Phi}_{\mathrm{fb}}$ with intensity $\tilde{\lambda}_{\mathrm{fb}}$.

The ccdf of the SINR experienced by the typical UE connected to its serving MBS

$$\mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta) = \mathbb{P}\{\gamma_{\mathrm{LD}}^{\mathrm{m}} > \theta\}$$
$$= \int_0^{\infty} 2\pi\lambda_{\mathrm{mb}} r e^{-\pi\lambda_{\mathrm{mb}}r^2}\mathbb{P}\left\{\frac{P_{\mathrm{m}}|h_{x_0}|^2 r^{-\alpha}}{I_{\mathrm{m}}+\kappa I_{\mathrm{f}}+\sigma^2} > \theta\right\}\mathrm{d}r$$
$$\overset{(a)}{=} \int_0^{\infty} 2\pi\lambda_{\mathrm{mb}} r e^{-\pi\lambda_{\mathrm{mb}}r^2 - \frac{\theta r^{\alpha}\sigma^2}{P_{\mathrm{m}}}}\mathcal{L}_{I_{\mathrm{m}}+\kappa I_{\mathrm{f}}}\left(\frac{\theta r^{\alpha}}{P_{\mathrm{m}}}\right)\mathrm{d}r. \tag{21}$$

where (a) follows from $|h_{x_0}|^2 \sim \mathrm{Exp}(1)$.

After excluding the serving BS x_0, $\tilde{\Phi}_{\mathrm{mb}} \setminus \{x_0\}$ is still a PPP, so we apply the pgfl of PPP to obtain the Laplace transform of I_{m}

$$\mathcal{L}_{I_{\mathrm{m}}}(s) = \exp\left(-2\pi\tilde{\lambda}_{\mathrm{mb}}\int_r^{\infty}\left(1-\frac{1}{1+sP_{\mathrm{m}}x^{-\alpha}}\right)x\mathrm{d}x\right)$$
$$= e^{-\pi\tilde{\lambda}_{\mathrm{mb}}r^2\rho\left(\frac{sP_{\mathrm{m}}}{r^{\alpha}},\alpha\right)}. \tag{22}$$

Since $\tilde{\Phi}_{\mathrm{fb}}$ is a PPP, the Laplace transform of I_{f} is

$$\mathcal{L}_{I_{\mathrm{f}}}(s) = \exp\left(-2\pi\tilde{\lambda}_{\mathrm{fb}}\int_0^{\infty}\left(1-\frac{1}{1+sP_{\mathrm{f}}x^{-\alpha}}\right)x\mathrm{d}x\right)$$
$$= e^{-\delta\pi^2\csc(\delta\pi)\tilde{\lambda}_{\mathrm{fb}}(sP_{\mathrm{f}})^{\delta}}. \tag{23}$$

Substituting (22) and (23) into $\mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta)$, we can obtain (19).

Let y_0 be the distance between the typical femto UE and its serving FAP. Since femto UEs are uniformly distributed in the circular coverage area of radius R_{f} of each FAP, the pdf of y_0 is given by $f_{y_0}(r) = \frac{2r}{R_{\mathrm{f}}^2}$.

The received SINR for the typical femto UE connected to its serving FAP follows as $\gamma_{\mathrm{LD}}^{\mathrm{f}} = \frac{P_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}+\sigma^2}$, where $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ is the interference from the femto tier, and $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_{x_0}|^2$ is the interference from the macro tier.

The ccdf of the SINR experienced by the typical femto UE connected to its serving FAP is

$$\mathcal{P}_{\mathrm{LD}}^{\mathrm{f}}(\theta) = \mathbb{P}\{\gamma_{\mathrm{LD}}^{\mathrm{f}} > \theta\}$$
$$= \int_0^{R_{\mathrm{f}}} \frac{2r}{R_{\mathrm{f}}^2}\mathbb{P}\left\{\frac{P_{\mathrm{f}}|h_{y_0}|^2 r^{-\alpha}}{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}+\sigma^2} > \theta\right\}\mathrm{d}r$$
$$= \int_0^{R_{\mathrm{f}}} \frac{2r}{R_{\mathrm{f}}^2} e^{\frac{-\theta r^{\alpha}\delta^2}{P_{\mathrm{f}}}}\mathcal{L}_{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}}\left(\frac{\theta r^{\alpha}}{P_{\mathrm{f}}}\right)\mathrm{d}r, \tag{24}$$

which, after expanding the Laplace transform of I_{m}, I_{f}, and further manipulations, leads to (20).

LHDA Transmission

The BL is modulated to a digital signal, while the EL is modulated to an analog signal. The digital modulation is based on a Gaussian codebook, and the EL signal after analog modulation is also modeled as a Gaussian source with zero mean and unit variance [36, 37]. For analog modulation, it is assumed that the source bandwidth is equal to the channel bandwidth [14, 16].

For the typical UE which is assumed to be located at the origin and connected to its serving MBS, the received signal can be written as

$$Y = P_{\mathrm{m}}^{1/2}\|x_0\|^{-\alpha/2}h_{x_0}X_{x_0} + \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}^{1/2}\|x\|^{-\alpha/2}h_x X_x + \kappa \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}^{1/2}\|y\|^{-\alpha/2}h_y X_y + Z, \tag{25}$$

which is nearly the same as (15) in LD transmission, the difference lies in that X_y is the analog EL interference symbol or the superposition of digital BL and analog EL interference symbol transmitted by the interfering FAP y based on the transmission scheme of y, and $X_y \sim \mathbb{CN}(0,1)$.

Thus the received SINR is

$$\gamma_{\mathrm{LHDA}}^{\mathrm{m}} = \frac{P_{\mathrm{m}}\|x_0\|^{-\alpha}|h_{x_0}|^2}{I_{\mathrm{m}} + \kappa I_{\mathrm{f}} + \sigma^2}, \tag{26}$$

where $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_x|^2$ is the interference from the macro tier and $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ is the interference from the femto tier.

For the typical femto UE which is assumed to be located at the origin and connected to its FAP, according to the transmission scheme, it receives only the EL, or it receives the superposition of the digital BL signal and the analog EL signal.

- *Case 1:* The typical femto UE connected to its FAP receives only the EL. The received signal for the typical femto UE is

$$Y = P_{\mathrm{f}}^{1/2}\|y_0\|^{-\frac{\alpha}{2}}h_{y_0}X_{y_0}^{\mathrm{E}} + \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus\{y_0\}} P_{\mathrm{f}}^{1/2}\|y\|^{-\frac{\alpha}{2}}h_y X_y + \kappa \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}^{1/2}\|x\|^{-\frac{\alpha}{2}}h_x X_x + Z, \tag{27}$$

  where $X_{y_0}^{\mathrm{E}}$ is the EL signal symbol transmitted by the serving FAP and X_y is the interference symbol transmitted by the interfering FAP y.

  Thus, the received SINR for the femto UE connected to its FAP to receive the EL is

$$\gamma_{\mathrm{LHDA}}^{\mathrm{f}} = \frac{P_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2}, \tag{28}$$

  where $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus\{y_0\}} P_{\mathrm{f}}\|y\|^{-\alpha}|h_y|^2$ is the interference from the femto tier and $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}\|x\|^{-\alpha}|h_x|^2$ is the interference from the macro tier.
- *Case 2:* The typical femto UE connected to its FAP receives the superposition of the digital BL signal and the analog EL signal. The received signal for the typical femto UE is

$$Y = \|y_0\|^{-\alpha/2} h_{y_0} \left(\sqrt{P_{\mathrm{f}}^{\mathrm{B}}} X_{y_0}^{\mathrm{B}} + \sqrt{P_{\mathrm{f}}^{\mathrm{E}}} X_{y_0}^{\mathrm{E}} \right) + \sum_{y \in \tilde{\Phi}_{\mathrm{fb}} \setminus \{y_0\}} P_{\mathrm{f}}^{1/2} \|y\|^{-\alpha/2} h_y X_y + \kappa \sum_{x \in \tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}^{1/2} \|x\|^{-\alpha/2} h_x X_x + Z, \tag{29}$$

where $X_{y_0}^{\mathrm{B}}$ is the BL signal symbol transmitted by the serving FAP, and $X_{y_0}^{\mathrm{E}}$ is the EL signal symbol transmitted by the serving FAP.

Thus, the received SINR for the typical femto UE connected to its FAP to receive the BL, denoted by $\gamma_{\mathrm{LHDA}}^{\mathrm{f,B}}$, is

$$\gamma_{\mathrm{LHDA}}^{\mathrm{f,B}} = \frac{P_{\mathrm{f}}^{\mathrm{B}} \|y_0\|^{-\alpha} |h_{y_0}|^2}{P_{\mathrm{f}}^{\mathrm{E}} \|y_0\|^{-\alpha} |h_{y_0}|^2 + I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2}. \tag{30}$$

Successive interference cancellation (SIC) [38] is adopted to demodulate the EL signal. Conditioned on the successful reception of the BL, the received SINR for the typical femto UE connected to the FAP to receive the EL signal, denoted by $\gamma_{\mathrm{LHDA}}^{\mathrm{f,E}}$, is

$$\gamma_{\mathrm{LHDA}}^{\mathrm{f,E}} = \frac{P_{\mathrm{f}}^{\mathrm{E}} \|y_0\|^{-\alpha} |h_{y_0}|^2}{I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2}. \tag{31}$$

The following theorem gives the ccdf of the SINR for the typical UE:

Theorem 2. *For LHDA transmission, the ccdf of the SINR for the typical UE connected to its serving MBS is*

$$\mathcal{P}_{\mathrm{LHDA}}^{\mathrm{m}}(\theta_{\mathrm{B}}) = \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{m}} > \theta_{\mathrm{B}}\} = \mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta_{\mathrm{B}}); \tag{32}$$

the ccdf of the SINR for the typical femto UE connected to its serving FAP to receive the EL is given by:

$$\mathcal{P}_{\mathrm{LHDA}}^{\mathrm{f}}(\theta_{\mathrm{E}}) = \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{f}} > \theta_{\mathrm{E}}\} = \mathcal{P}_{\mathrm{LD}}^{\mathrm{f}}(\theta_{\mathrm{E}}), \tag{33}$$

and the joint ccdf of the SINR for the typical femto UE connected to its serving FAP to receive the superposition of the digital BL and the analog EL is given by (40).

Proof. Similar to the derivation of $\mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta)$, the ccdf of $\gamma_{\mathrm{LHDA}}^{\mathrm{m}}$ follows as:

$$\mathcal{P}_{\mathrm{LHDA}}^{\mathrm{m}}(\theta) = \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{m}} > \theta\} = \mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta). \tag{34}$$

According to the transmission scheme, the FAP transmits the analog EL signal with probability p or the superposition of the digital BL signal and the analog EL signal with probability $1 - p$.

Case 1: The received SINR for the typical femto UE connected to the FAP receives the EL follows as $\gamma^{\mathrm{f}}_{\mathrm{LHDA}} = \frac{P_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}+\sigma^2}$. Similar to the derivation of $\mathcal{P}^{\mathrm{f}}_{\mathrm{LD}}(\theta)$, the ccdf of $\gamma^{\mathrm{f}}_{\mathrm{LHDA}}$ follows as

$$\mathcal{P}^{\mathrm{f}}_{\mathrm{LHDA}}(\theta) = \mathbb{P}\{\gamma^{\mathrm{f}}_{\mathrm{LHDA}} > \theta\} = \mathcal{P}^{\mathrm{f}}_{\mathrm{LD}}(\theta). \tag{35}$$

Case 2: The received SINR for the typical femto UE connected to the FAP receives the superposition of the digital BL signal and the analog EL signal is

$$\gamma^{\mathrm{f,B}}_{\mathrm{LHDA}} = \frac{P^{\mathrm{B}}_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{P^{\mathrm{E}}_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2 + I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2}, \tag{36}$$

where $P^{\mathrm{E}}_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2$ is the interference of the superposed EL.

$$\begin{aligned}\mathbb{P}\{\gamma^{\mathrm{f,B}}_{\mathrm{LHDA}} > \theta\} &= \int_0^{\infty} \frac{2r}{R_{\mathrm{f}}^2} e^{-\frac{\theta r^{\alpha}\sigma^2}{P^{\mathrm{B}}_{\mathrm{f}}-\theta P^{\mathrm{E}}_{\mathrm{f}}}} \mathcal{L}_{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}}\left(\frac{\theta r^{\alpha}}{P^{\mathrm{B}}_{\mathrm{f}}-\theta P^{\mathrm{E}}_{\mathrm{f}}}\right) \mathrm{d}r \\ &= \int_0^{R_{\mathrm{f}}^2} \frac{1}{R_{\mathrm{f}}^2} \exp\Bigg(-\frac{\theta v^{1/\delta}\sigma^2}{P^{\mathrm{B}}_{\mathrm{f}}-\theta P^{\mathrm{E}}_{\mathrm{f}}} - \delta\pi^2 \csc(\delta\pi)\theta^{\delta} v \\ &\quad \times \left(\tilde{\lambda}_{\mathrm{fb}}\left(\frac{P_{\mathrm{f}}}{P^{\mathrm{B}}_{\mathrm{f}}-\theta P^{\mathrm{E}}_{\mathrm{f}}}\right)^{\delta} + \kappa\tilde{\lambda}_{\mathrm{mb}}\left(\frac{P_{\mathrm{m}}}{P^{\mathrm{B}}_{\mathrm{f}}-\theta P^{\mathrm{E}}_{\mathrm{f}}}\right)^{\delta}\right)\Bigg)\mathrm{d}v.\end{aligned} \tag{37}$$

SIC is adopted to decode the EL signal. After successful reception of the BL, the received SINR for the EL signal is $\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}} = \frac{P^{\mathrm{E}}_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}+\sigma^2}$.

The ccdf of $\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}}$ follows as:

$$\begin{aligned}\mathbb{P}\{\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}} > \theta\} &= \int_0^{\infty} \frac{2r}{R_{\mathrm{f}}^2} e^{-\frac{\theta r^{\alpha}\sigma^2}{P^{\mathrm{E}}_{\mathrm{f}}}} \mathcal{L}_{I_{\mathrm{f}}+\kappa I_{\mathrm{m}}}\left(\frac{\theta r^{\alpha}}{P^{\mathrm{E}}_{\mathrm{f}}}\right) \mathrm{d}r \\ &= \int_0^{R_{\mathrm{f}}^2} \frac{1}{R_{\mathrm{f}}^2} e^{-\frac{\theta v^{1/\delta}\sigma^2}{P^{\mathrm{E}}_{\mathrm{f}}} - \delta\pi^2\csc(\delta\pi)\theta^{\delta} v\left(\tilde{\lambda}_{\mathrm{fb}}\left(\frac{P_{\mathrm{f}}}{P^{\mathrm{E}}_{\mathrm{f}}}\right)^{\delta} + \kappa\tilde{\lambda}_{\mathrm{mb}}\left(\frac{P_{\mathrm{m}}}{P^{\mathrm{E}}_{\mathrm{f}}}\right)^{\delta}\right)} \mathrm{d}v.\end{aligned} \tag{38}$$

The joint ccdf of $\gamma^{\mathrm{f,B}}_{\mathrm{LHDA}}$ and $\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}}$ is

$$\begin{aligned}\mathcal{P}_{\mathrm{LHDA}}(\theta_{\mathrm{B}}, \theta_{\mathrm{E}}) &= \mathbb{P}\{\gamma^{\mathrm{f,B}}_{\mathrm{LHDA}} > \theta_{\mathrm{B}}, \gamma^{\mathrm{f,E}}_{\mathrm{LHDA}} > \theta_{\mathrm{E}}\} \\ &= \mathbf{1}\left(\theta_{\mathrm{B}} > \frac{\theta_{\mathrm{E}} P^{\mathrm{B}}_{\mathrm{f}}}{(1+\theta_{\mathrm{E}})P^{\mathrm{E}}_{\mathrm{f}}}\right)\int_0^{R_{\mathrm{f}}^2}\end{aligned}$$

$$\frac{1}{R_{\mathrm{f}}^2} e^{-\frac{\theta_{\mathrm{B}} v^{1/\delta} \sigma^2}{P_{\mathrm{f}}^{\mathrm{B}} - \theta_{\mathrm{B}} P_{\mathrm{f}}^{\mathrm{E}}} - \delta\pi^2 \csc(\delta\pi) \theta_{\mathrm{B}}^{\delta} v \left(\frac{\tilde{\lambda}_{\mathrm{fb}} P_{\mathrm{f}}^{\delta} + \kappa \tilde{\lambda}_{\mathrm{mb}} P_{\mathrm{m}}^{\delta}}{\left(P_{\mathrm{f}}^{\mathrm{B}} - \theta_{\mathrm{B}} P_{\mathrm{f}}^{\mathrm{E}}\right)^{\delta}} \right)} \mathrm{d}v$$

$$+ \mathbf{1}\left(\theta_{\mathrm{B}} \leq \frac{\theta_{\mathrm{E}} P_{\mathrm{f}}^{\mathrm{B}}}{(1+\theta_{\mathrm{E}}) P_{\mathrm{f}}^{\mathrm{E}}}\right) \int_0^{R_{\mathrm{f}}^2}$$

$$\frac{1}{R_{\mathrm{f}}^2} e^{-\frac{\theta_{\mathrm{E}} v^{1/\delta} \sigma^2}{P_{\mathrm{f}}^{\mathrm{E}}} - \delta\pi^2 \csc(\delta\pi) \theta_{\mathrm{E}}^{\delta} v \left(\tilde{\lambda}_{\mathrm{fb}} \left(\frac{P_{\mathrm{f}}}{P_{\mathrm{f}}^{\mathrm{E}}} \right)^{\delta} + \kappa \tilde{\lambda}_{\mathrm{mb}} \left(\frac{P_{\mathrm{m}}}{P_{\mathrm{f}}^{\mathrm{E}}} \right)^{\delta} \right)} \mathrm{d}v. \tag{39}$$

$$\begin{aligned}
\mathcal{P}_{\mathrm{LHDA}}(\theta_{\mathrm{B}}, \theta_{\mathrm{E}}) &= \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{f,B}} > \theta_{\mathrm{B}}, \gamma_{\mathrm{LHDA}}^{\mathrm{f,E}} > \theta_{\mathrm{E}}\} \\
&= \mathbb{P}\left\{ |h_{x0}|^2 > \frac{\theta_{\mathrm{B}} I_{\mathrm{total}}}{(P_{\mathrm{B}} - \theta_{\mathrm{B}} P_{\mathrm{E}}) \|x_0\|^{-\alpha}}, |h_{x0}|^2 > \frac{\theta_{\mathrm{E}} I_{\mathrm{total}}}{P_{\mathrm{E}} \|x\|^{-\alpha}} \right\} \\
&= \mathbb{P}\left\{ |h_{x0}|^2 > \max\left(\frac{\theta_{\mathrm{B}} I_{\mathrm{total}}}{(P_{\mathrm{B}} - \theta_{\mathrm{B}} P_{\mathrm{E}}) \|x_0\|^{-\alpha}}, \frac{\theta_{\mathrm{E}} I_{\mathrm{total}}}{P_{\mathrm{E}} \|x\|^{-\alpha}} \right) \right\} \\
&= \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{f,B}} > \theta_{\mathrm{B}}\} \mathbf{1}\left(\theta_{\mathrm{B}} > \frac{\theta_{\mathrm{E}} P_{\mathrm{f}}^{\mathrm{B}}}{(1+\theta_{\mathrm{E}}) P_{\mathrm{f}}^{\mathrm{E}}} \right) \\
&\quad + \mathbb{P}\{\gamma_{\mathrm{LHDA}}^{\mathrm{f,E}} > \theta_{\mathrm{E}}\} \mathbf{1}\left(\theta_{\mathrm{B}} \leq \frac{\theta_{\mathrm{E}} P_{\mathrm{f}}^{\mathrm{B}}}{(1+\theta_{\mathrm{E}}) P_{\mathrm{f}}^{\mathrm{E}}} \right),
\end{aligned} \tag{40}$$

where $I_{\mathrm{total}} = I_{\mathrm{f}} + \kappa I_{\mathrm{m}} + \sigma^2$.

CD Transmission

For the macro UE, the video transmission from the serving MBS is the same as that of LD; thus the ccdf of the SINR denoted by $\mathcal{P}_{\mathrm{CD}}^{\mathrm{m}}(\theta)$ is equal to $\mathcal{P}_{\mathrm{LD}}^{\mathrm{m}}(\theta)$ with $p = 1$ and $\kappa = 1$.

For the femto UE, based on the sub-band allocation from the MBS and the FAP, it can work in a cooperative or noncooperative modes.

- In the noncooperative case, since the femto UE can only connect to the FAP, the received signal can be written as

$$\begin{aligned}
Y &= P_{\mathrm{f}}^{1/2} \|y_0\|^{-\frac{\alpha}{2}} h_{y_0} X_{y_0} + \sum_{y \in \tilde{\Phi}_{\mathrm{fb}} \setminus \{y_0\}} P_{\mathrm{f}}^{1/2} \|y\|^{-\frac{\alpha}{2}} h_y X_y \\
&\quad + \sum_{x \in \tilde{\Phi}_{\mathrm{mb}}} P_{\mathrm{m}}^{1/2} \|x\|^{-\frac{\alpha}{2}} h_x X_x + Z,
\end{aligned} \tag{41}$$

Thus, the received SINR is

$$\gamma_{\mathrm{CD}}^{\mathrm{f,non}} = \frac{P_{\mathrm{f}}\|y_0\|^{-\alpha}|h_{y_0}|^2}{I_{\mathrm{f}} + I_{\mathrm{m}} + \sigma^2}. \tag{42}$$

The ccdf of the $\gamma_{\mathrm{CD}}^{\mathrm{f,non}}$, denoted as $\mathcal{P}_{\mathrm{CD}}^{\mathrm{f,non}}(\theta)$, is equal to $\mathcal{P}_{\mathrm{LD}}^{\mathrm{f}}(\theta)$ with $p = 1$ and $\kappa = 1$.

- In the cooperative case, since the femto UE is served jointly by the MBS and the FAP, the received signal can be written as

$$Y = P_{\mathrm{m}}^{1/2}\|x_0\|^{-\alpha/2}h_{x_0}X_0 + P_{\mathrm{f}}^{1/2}\|y_0\|^{-\alpha/2}h_{y_0}X_0 + \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus\{x_0\}} P_{\mathrm{m}}^{1/2}\|x\|^{-\alpha/2}h_x X_x + \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus\{y_0\}} P_{\mathrm{f}}^{1/2}\|y\|^{-\alpha/2}h_y X_y + Z, \tag{43}$$

where the fist and second items of right side of the equation denote the received signal symbols from the serving MBS and FAP, respectively, and the following two items denote the interference symbols from the macro and femto tiers, respectively

The noncoherent joint transmission is adopted, and the SINR of the received signal is

$$\gamma_{\mathrm{CD}}^{\mathrm{f,CoMP}} = \frac{\left|P_{\mathrm{m}}^{1/2}\|x_0\|^{-\alpha/2}h_{x_0} + P_{\mathrm{f}}^{1/2}\|y_0\|^{-\alpha/2}h_{y_0}\right|^2}{I_{\mathrm{m}} + I_{\mathrm{f}} + \sigma^2}, \tag{44}$$

where the interference from the macro tier is $I_{\mathrm{m}} = \sum_{x\in\tilde{\Phi}_{\mathrm{mb}}\setminus x_0} P_{\mathrm{m}}\|x\|^{-\alpha}h_x$, and the interference from the femto tier is $I_{\mathrm{f}} = \sum_{y\in\tilde{\Phi}_{\mathrm{fb}}\setminus y_0} P_{\mathrm{f}}\|y\|^{-\alpha}h_y$.

Theorem 3. *For CD transmission, when the femto UE works in a cooperative mode, the ccdf of the SINR is*

$$\mathcal{P}_{\mathrm{CD}}^{\mathrm{f,CoMP}}(\theta) = \int_0^\infty \int_0^{R_{\mathrm{f}}} e^{-\frac{\mu\theta\sigma^2}{P_{\mathrm{m}}r_{\mathrm{m}}^{-\alpha}+P_{\mathrm{f}}r_{\mathrm{f}}^{-\alpha}} - \pi\tilde{\lambda}_{\mathrm{mb}}r_{\mathrm{m}}^2\rho\left(\frac{\theta}{1+\frac{P_{\mathrm{f}}r_{\mathrm{f}}^{-\alpha}}{P_{\mathrm{m}}r_{\mathrm{m}}^{-\alpha}}},\alpha\right) - \pi\tilde{\lambda}_{\mathrm{fb}}r_{\mathrm{f}}^2\rho\left(\frac{\theta}{1+\frac{P_{\mathrm{m}}r_{\mathrm{m}}^{-\alpha}}{P_{\mathrm{f}}r_{\mathrm{f}}^{-\alpha}}},\alpha\right) - \lambda_{\mathrm{mb}}\pi r_{\mathrm{m}}^2} \times 2\pi\lambda_{\mathrm{mb}}r_{\mathrm{m}}\frac{2r_{\mathrm{f}}}{R_{\mathrm{f}}^2}\mathrm{d}r_{\mathrm{m}}\mathrm{d}r_{\mathrm{f}}. \tag{45}$$

Proof. Let $\|x_0\|$ be the distance from the typical femto UE to its serving MBS, and the pdf of $\|x_0\|$ is $f_{\|x_0\|}(r_{\mathrm{m}}) = e^{-\lambda_{\mathrm{mb}}\pi r_{\mathrm{m}}^2}2\pi\lambda_{\mathrm{mb}}r_{\mathrm{m}}$.

Let $\|y_0\|$ be the distance from the typical femto UE to its serving FAP, and the pdf of r_f is $f_{\|y_0\|}(r_\mathrm{f}) = \frac{2r_\mathrm{f}}{R_\mathrm{f}^2}$.

The ccdf of SINR $\gamma_{\mathrm{CD}}^{\mathrm{f,CoMP}}$ is

$$\begin{aligned}
\mathcal{P}_\mathrm{f}^{\mathrm{CoMP}}(\theta) &= \mathbb{P}\{\gamma_\mathrm{f}^{\mathrm{CoMP}} > \theta\} \\
&= \mathbb{P}\left\{\left|P_\mathrm{m}^{\frac{1}{2}} r_\mathrm{m}^{-\frac{\alpha}{2}} h_\mathrm{m} + P_\mathrm{f}^{\frac{1}{2}} r_\mathrm{f}^{-\frac{\alpha}{2}} h_\mathrm{f}\right|^2 > \theta(I_\mathrm{m} + I_\mathrm{f} + \sigma^2)\right\} \\
&\overset{(a)}{=} \mathbb{E}_{I_\mathrm{m}, I_\mathrm{f}, r_\mathrm{m}, r_\mathrm{f}}\left\{e^{-\frac{\mu\theta(I_\mathrm{m}+I_\mathrm{f}+\sigma^2)}{P_\mathrm{m} r_\mathrm{m}^{-\alpha} + P_\mathrm{f} r_\mathrm{f}^{-\alpha}}}\right\} \\
&= \mathbb{E}_{r_\mathrm{m}, r_\mathrm{f}}\left\{e^{-\frac{\mu\theta\sigma^2}{P_\mathrm{m} r_\mathrm{m}^{-\alpha} + P_\mathrm{f} r_\mathrm{f}^{-\alpha}}} \mathcal{L}_{I_\mathrm{m}}\left(-\frac{\mu\theta}{P_\mathrm{m} r_\mathrm{m}^{-\alpha} + P_\mathrm{f} r_\mathrm{f}^{-\alpha}}\right)\right. \\
&\quad \left.\mathcal{L}_{I_\mathrm{f}}\left(-\frac{\mu\theta}{P_\mathrm{m} r_\mathrm{m}^{-\alpha} + P_\mathrm{f} r_\mathrm{f}^{-\alpha}}\right)\right\}, \qquad (46)
\end{aligned}$$

where (a) follows that h_m and h_f are independent Gaussian variable $\mathcal{N}(0, 1)$.

The Laplace transform of I_m is

$$\begin{aligned}
\mathcal{L}_{I_\mathrm{m}}(s) &= \exp\left(-2\pi\tilde{\lambda}_\mathrm{mb} \int_{r_\mathrm{m}}^{\infty} (1 - \mathcal{L}_h(sP_\mathrm{m} x^{-\alpha}))x\mathrm{d}x\right) \\
&= e^{-\pi\lambda'_m r_\mathrm{m}^2 \rho(\frac{sP_\mathrm{m}}{\mu r_\mathrm{m}^{\alpha}}, \alpha)}. \qquad (47)
\end{aligned}$$

The Laplace transform of I_f is

$$\begin{aligned}
\mathcal{L}_{I_\mathrm{f}}(s) &= \exp\left(-2\pi\tilde{\lambda}_\mathrm{fb} \int_{r_\mathrm{f}}^{\infty} (1 - \mathcal{L}_h(sP_\mathrm{f} x^{-\alpha}))x\mathrm{d}x\right) \\
&= e^{-\pi\lambda'_f r_\mathrm{f}^2 \rho(\frac{sP_\mathrm{f}}{\mu r_\mathrm{f}^{\alpha}}, \alpha)}. \qquad (48)
\end{aligned}$$

Data Rate

The instantaneous data rate that a sub-band channel of bandwidth W can accommodate is $R = W \log_2(1 + \mathrm{SINR})$. For LD transmission, since both the MBS and the FAP transmit digital signals; the channel from the typical UE to its serving MBS can accommodate the data rate $R_\mathrm{m} = W \log_2(1 + \gamma_{\mathrm{LD}}^{\mathrm{m}})$, and the channel from the typical UE to its serving FAP can accommodate the data rate $R_\mathrm{f} = W \log_2(1+\gamma_{\mathrm{LD}}^{\mathrm{f}})$. For LHDA transmission, only the BL is modulated to a digital signal, so the data rate is defined only for the BL, the channel from the typical UE to its serving MBS

can accommodate the data rate $R_{\mathrm{m}} = W \log_2(1 + \gamma_{\mathrm{LHDA}}^{\mathrm{m}})$, and the channel from the typical UE to its serving FAP can accommodate data rate $R_{\mathrm{f}} = W \log_2(1 + \gamma_{\mathrm{LHDA}}^{\mathrm{f,B}})$.

The actually achieved UE data rates, after taking into consideration the UE load and sub-band occupancy, are given below. Without loss of generality, we take an MBS as an example. When the number of UEs in a macro cell does not exceed the total number of sub-bands (i.e., $U_{\mathrm{m}} \leq N_{\mathrm{m}}$), each UE can exclusively occupy a sub-band, and its achieved data rate is R_{m}; when $U_{\mathrm{m}} > N_{\mathrm{m}}$, the U_{m} UEs share the N_{m} sub-bands, and the data rate is thus discounted into $\frac{N_{\mathrm{m}}}{U_{\mathrm{m}}} R_{\mathrm{m}}$, assuming a round-robin sharing mechanism. So the average achieved data rate of a UE served by an MBS is given by:

$$R_{\mathrm{mu}} = \xi_{\mathrm{m}} R_{\mathrm{m}}, \tag{49}$$

where ξ_{m} is the scheduling index denoting the probability that a UE is scheduled by the MBS,

$$\xi_{\mathrm{m}} = \frac{\sum_{i=1}^{N_{\mathrm{m}}} \mathbb{P}\{U_{\mathrm{m}} = i\} + \sum_{i=N_{\mathrm{m}}+1}^{\infty} \mathbb{P}\{U_{\mathrm{m}} = i\} \frac{N_{\mathrm{m}}}{i}}{1 - \mathbb{P}\{U_{\mathrm{m}} = 0\}}. \tag{50}$$

Similarly, the average achieved data rate of a UE served by an FAP is given by

$$R_{\mathrm{fu}} = \xi_{\mathrm{f}} R_{\mathrm{f}}, \tag{51}$$

where ξ_{f} is the scheduling index denoting the probability that a UE is scheduled by the FAP,

$$\xi_{\mathrm{f}} = \frac{\sum_{i=1}^{N_{\mathrm{f}}} \mathbb{P}\{U_{\mathrm{f}} = i\} + \sum_{i=N_{\mathrm{f}}+1}^{\infty} \mathbb{P}\{U_{\mathrm{f}} = i\} \frac{N_{\mathrm{f}}}{i}}{1 - \mathbb{P}\{U_{\mathrm{f}} = 0\}}. \tag{52}$$

System Performances

In this section we evaluate several important performance metrics, namely, the outage probability, the HD probability, and the average distortion. The outage probability is the probability that a UE cannot receive the BL, namely, the UE data rate is less than R_{B}. The HD probability is the probability that a UE can receive high-definition content, i.e., both the BL and the EL, namely, the UE data rate is greater than $R_{\mathrm{B}} + R_{\mathrm{E}}$. The average distortion evaluates the difference between the received video and source video, which is measured using the distortion-rate function. Note that, for LHDA transmission, the HD probability for the femto UE is not defined since the EL is transmitted as an analog signal and the data rate for an analog signal is undefined.

LD Transmission

For a macro UE, only the BL is transmitted from its serving MBS, so the outage probability, denoted by $P_{\text{out}}^{\text{LD,m}}$, is

$$\begin{aligned} P_{\text{out}}^{\text{LD,m}} &= \mathbb{P}\{R_{\text{mu}} < R_{\text{B}}\} \\ &= \mathbb{P}\left\{\gamma_{\text{LD}}^{\text{m}} < 2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right\} \\ &= 1 - \mathcal{P}_{\text{LD}}^{\text{m}}\left(2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right). \end{aligned} \tag{53}$$

For a femto UE, it either connects to its serving MBS with probability p or its serving FAP with probability $1-p$ to receive the BL, so the outage probability, denoted by $P_{\text{out}}^{\text{LD,f}}$, is

$$\begin{aligned} P_{\text{out}}^{\text{LD,f}} &= p\mathbb{P}\{R_{\text{mu}} < R_{\text{B}}\} + (1-p)\mathbb{P}\{R_{\text{fu}} < R_{\text{B}}\} \\ &= p\mathbb{P}\left\{\gamma_{\text{LD}}^{\text{m}} < 2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right\} + (1-p)\mathbb{P}\left\{\gamma_{\text{LD}}^{\text{f}} < 2^{\frac{R_{\text{B}}/\xi_{\text{f}}}{W}} - 1\right\} \qquad (54) \\ &= p\left(1 - \mathcal{P}_{\text{LD}}^{\text{m}}\left(2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right)\right) + (1-p)\left(1 - \mathcal{P}_{\text{LD}}^{\text{f}}\left(2^{\frac{R_{\text{B}}/\xi_{\text{f}}}{W}} - 1\right)\right). \qquad (55) \end{aligned}$$

To receive the high-definition video content, a femto UE receives the BL from the MBS and receives the EL from the FAP with probability p, or it receives both the BL and the EL from the FAP with probability $1-p$. Thus, the HD probability for a femto UE, denoted by P_{HD}^{f}, is

$$\begin{aligned} P_{\text{HD}}^{\text{f}} &= p\mathbb{P}\{R_{\text{mu}} > R_{\text{B}}, R_{\text{fu}} > R_{\text{E}}\} + (1-p)\mathbb{P}\{R_{\text{fu}} > R_{\text{B}} + R_{\text{E}}\} \\ (a) &= p\mathbb{P}\{R_{\text{mu}} > R_{\text{B}}\}\mathbb{P}\{R_{\text{fu}} > R_{\text{E}}\}(1-p)\mathbb{P}\{R_{\text{fu}} > R_{\text{B}} + R_{\text{E}}\} \\ &= p\mathbb{P}\left\{\gamma_{\text{LD}}^{\text{m}} > 2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right\}\mathbb{P}\left\{\gamma_{\text{LD}}^{\text{f}} > 2^{\frac{R_{\text{E}}/\xi_{\text{f}}}{W}} - 1\right\} \\ &\quad + (1-p)\mathbb{P}\left\{R_{\text{fu}} > 2^{\frac{(R_{\text{B}}+R_{\text{E}})/\xi_{\text{f}}}{W}} - 1\right\} \\ &= p\mathcal{P}_{\text{LD}}^{\text{m}}\left(2^{\frac{R_{\text{B}}/\xi_{\text{m}}}{W}} - 1\right)\mathcal{P}_{\text{LD}}^{\text{f}}\left(2^{\frac{R_{\text{E}}/\xi_{\text{f}}}{W}} - 1\right) + (1-p)\mathcal{P}_{\text{LD}}^{\text{f}}\left(2^{\frac{(R_{\text{B}}+R_{\text{E}})/\xi_{\text{f}}}{W}} - 1\right), \end{aligned} \tag{56}$$

where (a) follows from the tier independence approximation.

The distortion-rate function $D(R)$ [14, 39] is used to measure the distortion per source sample when the source rate is R bits/sample. As the bandwidth of a sub-band is W and the data rate of the BL (resp. the EL) is R_{B} (resp. R_{E}), the source rate is $\frac{R_{\text{B}}}{W}$ (resp. $\frac{R_{\text{E}}}{W}$). Since the source signal is modeled as a Gaussian signal with zero mean and unit variance, the distortion of the received video signal can be divided into three cases based on the reception. If the BL is not decoded correctly,

the distortion is $D_0 = 1$; if the BL is decoded correctly while the EL is not, then the distortion is $D_{\mathrm{B}} = 2^{-2\frac{R_{\mathrm{B}}}{W}}$; if both the BL and the EL are decoded correctly, the distortion is $D_{\mathrm{HD}} = 2^{-2\frac{R_{\mathrm{B}}+R_{\mathrm{E}}}{W}}$.

The average distortion for femto UEs, denoted by D_{LD}, is given by

$$D_{\mathrm{LD}} = P_{\mathrm{out}}^{\mathrm{LD,f}} D_0 + (1 - P_{\mathrm{out}}^{\mathrm{LD,f}} - P_{\mathrm{HD}}^{\mathrm{f}}) D_{\mathrm{B}} + P_{\mathrm{HD}}^{\mathrm{f}} D_{\mathrm{HD}}. \tag{57}$$

LHDA Transmission

For a macro UE, only the BL is digitally transmitted from its serving MBS; just the same as that in LD transmission, the outage probability $P_{\mathrm{out}}^{\mathrm{LHDA,m}}$ is

$$P_{\mathrm{out}}^{\mathrm{LHDA,m}} = \mathbb{P}\{R_{\mathrm{mu}} < R_{\mathrm{B}}\} = P_{\mathrm{out}}^{\mathrm{LD,m}}. \tag{58}$$

For a femto UE, since it receives the BL from the MBS with probability p or receives the BL from the FAP with probability $1-p$, the outage probability, denoted by $P_{\mathrm{out}}^{\mathrm{LHDA,f}}$, is

$$\begin{aligned} P_{\mathrm{out}}^{\mathrm{LHDA,f}} &= p\mathbb{P}\{R_{\mathrm{mu}} < R_{\mathrm{B}}\} + (1-p)\mathbb{P}\{R_{\mathrm{fu}} < R_{\mathrm{B}}\} \\ &= p\mathbb{P}\left\{\gamma_{\mathrm{LHDA}}^{\mathrm{m}} < 2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{m}}}{W}} - 1\right\} + (1-p)\mathbb{P}\left\{\gamma_{\mathrm{LHDA}}^{\mathrm{f,B}} < 2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1\right\} \\ &= p\left(1 - \mathcal{P}_{\mathrm{LHDA}}^{\mathrm{m}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{m}}}{W}} - 1\right)\right) + (1-p)\left(1 - \mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, 0\right)\right). \end{aligned} \tag{59}$$

The femto UE has two choices to receive the video content, and the average distortion is calculated accordingly.

1. *Case 1:* The femto UE receives the BL from MBS and receives the EL from FAP. Since the EL signal is analog, an MMSE estimator is employed for the estimation of the EL, and thus we have MMSE $= \frac{1}{1+\gamma_{\mathrm{LHDA}}^{\mathrm{f}}}$, where $\gamma_{\mathrm{LHDA}}^{\mathrm{f}}$ is the received SINR. Since there are multiple femto UEs in a FAP, a round-robin mechanism is used to schedule time slots for each femto UE to transmit the EL. If a UE is scheduled, its distortion for the EL is MMSE; otherwise, its distortion is unity. So the distortion is $e_{\mathrm{LHDA}} = \xi_{\mathrm{f}} \cdot \frac{1}{1+\gamma_{\mathrm{LHDA}}^{\mathrm{f}}} + (1-\xi_{\mathrm{f}}) \cdot 1$. Since the EL is estimated only if the BL is decoded successfully, the cdf of e_{LHDA} conditioned on the successful reception of the BL is given by

$$\begin{aligned} \mathbb{P}\{e_{\mathrm{LHDA}} < T \mid R_{\mathrm{mu}} \geq R_{\mathrm{B}}\}(a) &= \mathbb{P}\{e_{\mathrm{LHDA}} < T\} \\ &= \mathbb{P}\left\{\xi_{\mathrm{f}} \frac{1}{1+\gamma_{\mathrm{LHDA}}^{\mathrm{f}}} + (1-\xi_{\mathrm{f}})1 < T\right\} \end{aligned}$$

$$= \mathbb{P}\left\{\gamma^{\mathrm{f}}_{\mathrm{LHDA}} > \frac{1-T}{T-1+\xi_{\mathrm{f}}}\right\}$$
$$= \mathcal{P}^{\mathrm{f}}_{\mathrm{LHDA}}\left(\frac{1-T}{T-1+\xi}\right), \tag{60}$$

where (a) follows from the tier independence approximation.

Since for a positive random variable X, $\mathbb{E}\{X\} = \int_{t>0} \mathbb{P}\{X > t\}\mathrm{d}t$, the mean distortion for the EL, denoted by D_{E}, is

$$D_{\mathrm{E}} = \mathbb{E}\{e_{\mathrm{LHDA}} \mid R_{\mathrm{mu}} \geq R_{\mathrm{B}}\}$$
$$= 1 - \xi_{\mathrm{f}} + \int_{1-\xi_{\mathrm{f}}}^{1}\left(1 - \mathcal{P}^{\mathrm{f}}_{\mathrm{LHDA}}\left(\frac{1-T}{T-1+\xi_{\mathrm{f}}}\right)\right)\mathrm{d}T. \tag{61}$$

Since the EL corresponds to the residual between the BL and the source signal, the distortion when both the BL and the EL are received, denoted by D_{HD}, is given by $D_{\mathrm{HD}} = D_{\mathrm{B}} D_{\mathrm{E}}$.

So the average distortion for the femto UE in *Case 1*, denoted by $D^{(1)}_{\mathrm{LHDA}}$, is

$$D^{(1)}_{\mathrm{LHDA}} = \mathbb{P}\{R_{\mathrm{mu}} < R_{\mathrm{B}}\}D_0 + \mathbb{P}\{R_{\mathrm{mu}} \geq R_{\mathrm{B}}\}D_{\mathrm{HD}}$$
$$= 1 - \mathcal{P}^{\mathrm{m}}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}}{\xi_{\mathrm{m}}W}} - 1\right) + \mathcal{P}^{\mathrm{m}}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}}{\xi_{\mathrm{m}}W}} - 1\right)2^{-2R_{\mathrm{B}}}$$
$$\times\left(1 - \xi_{\mathrm{f}} + \int_{1-\xi_{\mathrm{f}}}^{1}\left(1 - \mathcal{P}^{\mathrm{f}}_{\mathrm{LHDA}}\left(\frac{1-T}{T-1+\xi_{\mathrm{f}}}\right)\right)\mathrm{d}T\right). \tag{62}$$

2. *Case 2:* The femto UE receives both the BL and the EL from the FAP. Since the EL signal is analog and superposed with the digital BL signal, an MMSE estimator is employed for the estimation of the EL conditioned on the correct reception of the BL; thus we have MMSE $= \frac{1}{1+\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}}}$, where $\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}}$ is the received SINR after the cancellation of the BL. The distortion for the EL is $e_{\mathrm{LHDA}} = \xi_{\mathrm{f}}\frac{1}{1+\gamma^{\mathrm{E}}_{\mathrm{LHDA}}} + (1-\xi_{\mathrm{f}})1$. The cdf of e_{LHDA} conditioned on the successful reception of the BL is given by

$$\mathbb{P}\{e_{\mathrm{LHDA}} < T \mid R_{\mathrm{fu}} \geq R_{\mathrm{B}}\} = \mathbb{P}\left\{\xi_{\mathrm{f}}\frac{1}{1+\gamma^{\mathrm{E}}_{\mathrm{hc}}} + (1-\xi_{\mathrm{f}})1 < T \;\middle|\; R_{\mathrm{fu}} \geq R_{\mathrm{B}}\right\}$$
$$= \mathbb{P}\left\{\gamma^{\mathrm{f,E}}_{\mathrm{LHDA}} > \frac{1-T}{T-1+\xi_{\mathrm{f}}} \;\middle|\; \gamma^{\mathrm{f,B}}_{\mathrm{LHDA}} > 2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1\right\}$$
$$= \frac{\mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, \frac{1-T}{T-1+\xi_{\mathrm{f}}}\right)}{\mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi}{W}} - 1, 0\right)}. \tag{63}$$

Then, we can obtain the distortion of the EL as

$$\begin{aligned} D_{\mathrm{E}} &= \mathbb{E}\{e_{\mathrm{LHDA}} < T \mid R_{\mathrm{fu}} \geq R_{\mathrm{B}}\} \\ &= 1 - \xi_{\mathrm{f}} + \int_{1-\xi_{\mathrm{f}}}^{1} \left(1 - \frac{\mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}}{W\xi_{\mathrm{f}}}} - 1, \frac{1-T}{T-1+\xi_{\mathrm{f}}}\right)}{\mathcal{P}_{\mathrm{LHDA}}(2^{\frac{R_{\mathrm{B}}}{W\xi_{\mathrm{f}}}} - 1, 0)} \right) \mathrm{d}T. \end{aligned} \tag{64}$$

So the average distortion for the femto UE in *Case 2*, denoted by $D_{\mathrm{LHDA}}^{(2)}$, is

$$\begin{aligned} D_{\mathrm{LHDA}}^{(2)} &= \mathbb{P}\{R_{\mathrm{fu}} < R_{\mathrm{B}}\} D_0 + \mathbb{P}\{R_{\mathrm{fu}} \geq R_{\mathrm{B}}\} D_{\mathrm{HD}} \\ &= 1 - \mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, 0\right) + \mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, 0\right) 2^{-2R_{\mathrm{B}}} \Bigg(1 - \xi_{\mathrm{f}} \\ &\quad + \int_{1-\xi_{\mathrm{f}}}^{1} \left(1 - \frac{\mathcal{P}_{\mathrm{LHDA}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, \frac{1-T}{T-1+\xi_{\mathrm{f}}}\right)}{\mathcal{P}_{\mathrm{LHDA}}(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1, 0)} \right) \mathrm{d}T \Bigg). \end{aligned} \tag{65}$$

Since a femto UE follows *Case 1* with probability p and follows *Case 2* with probability $1 - p$, the average distortion for a femto UE, denoted by D_{LHDA}, is

$$D_{\mathrm{LHDA}} = pD_{\mathrm{LHDA}}^{(1)} + (1-p)D_{\mathrm{LHDA}}^{(2)}. \tag{66}$$

CD Transmission

For a macro UE, only the BL is transmitted from MBS, so the outage probability, denoted by $P_{\mathrm{out}}^{\mathrm{CD,m}}$, is

$$\begin{aligned} P_{\mathrm{out}}^{\mathrm{CD,m}} &= \mathbb{P}\{R_{\mathrm{mu}} < R_{\mathrm{B}}\} \\ &= 1 - \mathcal{P}_{\mathrm{CD}}^{\mathrm{m}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{m}}}{W}} - 1\right). \end{aligned} \tag{67}$$

For a femto UE, if it is chosen by the MBS and the FAP, it works in a cooperative mode with the probability $\eta = \xi_{\mathrm{m}}/\xi_{\mathrm{f}}$. Thus, the outage probability, denoted by $P_{\mathrm{out}}^{\mathrm{CD,f}}$ is

$$\begin{aligned} P_{\mathrm{out}}^{\mathrm{CD,f}} &= \mathbb{P}\{R_{\mathrm{fu}} < R_{\mathrm{B}}\} \\ &= \eta\left(1 - \mathcal{P}_{\mathrm{CD}}^{\mathrm{f,CoMP}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1\right)\right) + (1-\eta)\left(1 - \mathcal{P}_{\mathrm{CD}}^{\mathrm{f,non}}\left(2^{\frac{R_{\mathrm{B}}/\xi_{\mathrm{f}}}{W}} - 1\right)\right). \end{aligned} \tag{68}$$

For a femto UE, the HD probability, denoted as $P_{\mathrm{HD}}^{\mathrm{CD,f}}$, is

$$P_{\mathrm{HD}}^{\mathrm{CD,f}} = \mathbb{P}\{R_{\mathrm{fu}} > R_{\mathrm{B}} + R_{\mathrm{E}}\} = \eta \mathcal{P}_{\mathrm{CD}}^{\mathrm{f,CoMP}} \left(2^{\frac{(R_{\mathrm{B}}+R_{\mathrm{E}})/\xi_{\mathrm{f}}}{W}} - 1\right) + (1-\eta)\, \mathcal{P}_{\mathrm{CD}}^{\mathrm{f,non}} \left(2^{\frac{(R_{\mathrm{B}}+R_{\mathrm{E}})/\xi_{\mathrm{f}}}{W}} - 1\right). \quad (69)$$

Simulation and Discussion

In this section, the outage probabilities, the HD probabilities, and the average distortions are evaluated for the three transmission schemes. Meanwhile, the optimal power allocation for the digital BL and the analog EL for LHDA transmission is assessed. Unless otherwise specified, the system parameters are listed in Table 1.

Figure 4a displays the performance of LD transmission in the orthogonal case. In that case, N_{m} sub-bands for the macro tier and N_{f} sub-bands for the femto tier that are orthogonal with $N_{\mathrm{m}}+N_{\mathrm{f}} = N$. As N_{m} increases, more resources are allocated to the macro tier, and the outage probabilities decrease for both macro UEs and femto UEs, except that the femto UE outage probabilities slightly increase for very large values of N_{m}. The HD probability of the femto UE with $p = 0$ decreases with N_{m} because the EL transmission via FAPs deteriorates as the resources for the femto tier are reduced. The HD probabilities of the femto UE for $p = 0.5$ and $p = 1$ increase for small N_{m} and then decrease as N_{m} grows large, reflecting the tension between the resources for the BL transmission and the EL transmission.

Figure 4b displays the performance of LD transmission in the non-orthogonal case. For comparison with Fig. 4a, we still let $N_{\mathrm{m}} + N_{\mathrm{f}} = N$ but let the sub-bands be selected by each BS independently. The general trend is similar to that in the orthogonal case, but the difference lies in that the curves show less variability with

Table 1 System parameters

Symbol	Description	Typical value
N	Number of sub-bands	20
W	Bandwidth of a sub-band (MHz)	5
P_{m}	MBS transmit power per sub-band (dBm)	39
P_{f}	FAP transmit power per sub-band (dBm)	13
σ^2	Noise power (dBm)	−104
λ_{mb}	MBS intensity (m^{-2})	1E-5
λ_{fb}	FAP intensity (m^{-2})	5E-5
λ_{mu}	Macro UE intensity (m^{-2})	2E-4
λ_{fu}	Femto UE intensity in coverage (m^{-2})	8E-3
R_{f}	Coverage radius of FAP (m)	20
α	Path loss exponent	4
R_{B}	Rate for the BL transmission (Mbps)	0.5
R_{E}	Rate for the EL transmission (Mbps)	4.5

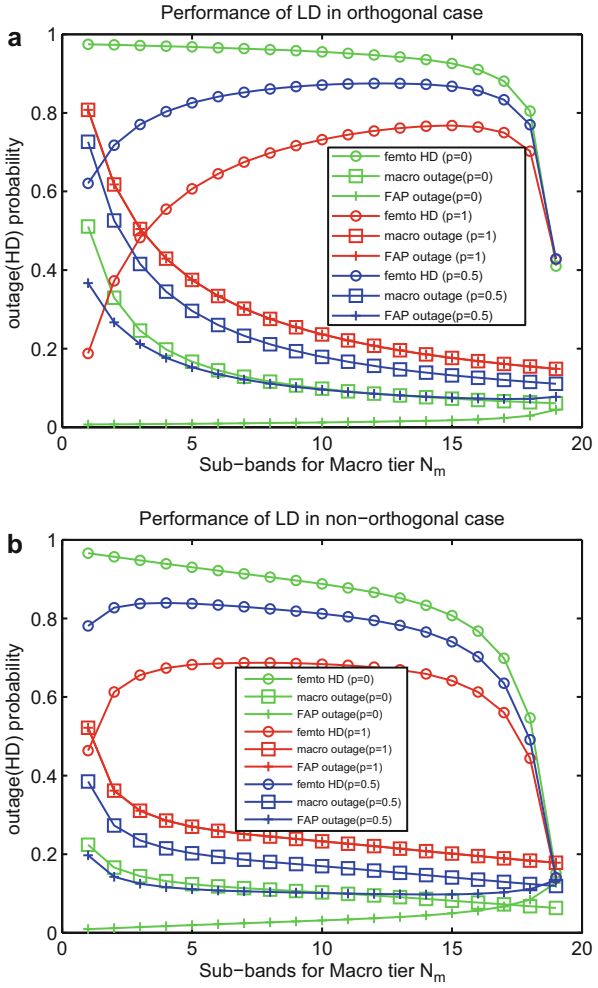

Fig. 4 Performances of LD in both orthogonal and non-orthogonal cases

N_{m} (except for those values near to N). The reason for such a practically desirable insensitivity is due to the lessened tension between the resources for macro tiers and femto tiers from randomized sub-band selection.

Note that if p is large, the femto UE tends to connect to an MBS to receive the BL; the outage probability increases, and the HD probability decreases, i.e., the performance deteriorates. However, since an MBS can provide continuous coverage while an FAP cannot, if a femto UE is moving, then it may prefer to connect to an MBS to receive the BL, which prevents frequent handover between femto cells and enables uninterrupted reception of the BL video.

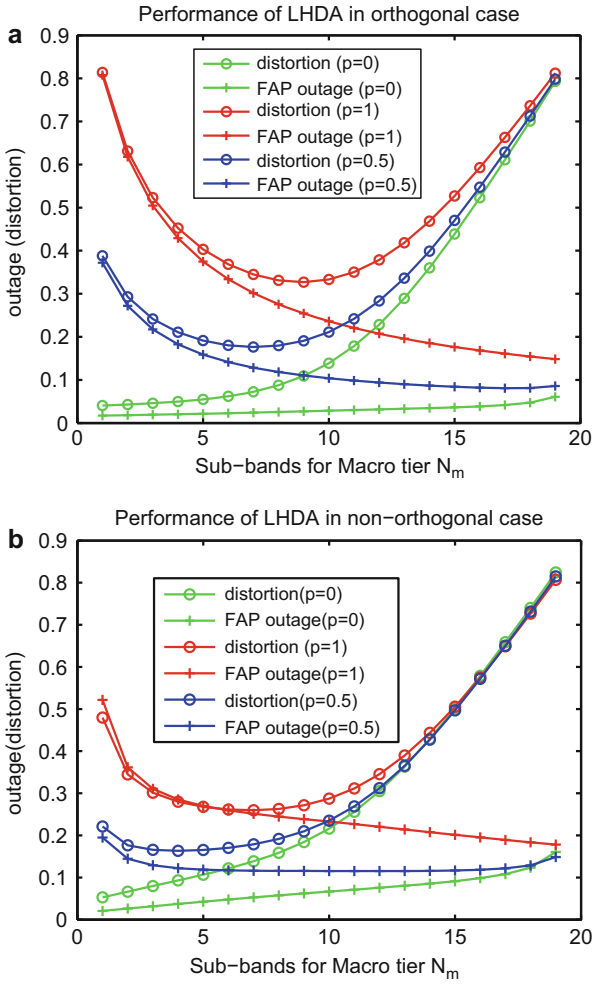

Fig. 5 Performances of LHDA in both orthogonal and non-orthogonal cases

Figure 5a displays the performance of LHDA transmission in the orthogonal case. The outage probability for macro UE is the same as that in LD transmission, so we just neglect it in LHDA transmission. Since the frequency resource allocated to the macro tier increases, the resource for the femto tier decreases. The outage probability for the femto UE connected to the FAP (corresponding to $p = 0$) to receive the BL increases, while the outage probability for the femto UE connected to the MBS (corresponding to $p = 1$) to receive the BL decreases. The case where $p = 0.5$ shows a tradeoff of these two extreme cases: the outage probability for femto UE first decreases and then slightly increases when the allocated resource for the FAP is small. When N_{m} is small, the performance of the macro tier is poor, and

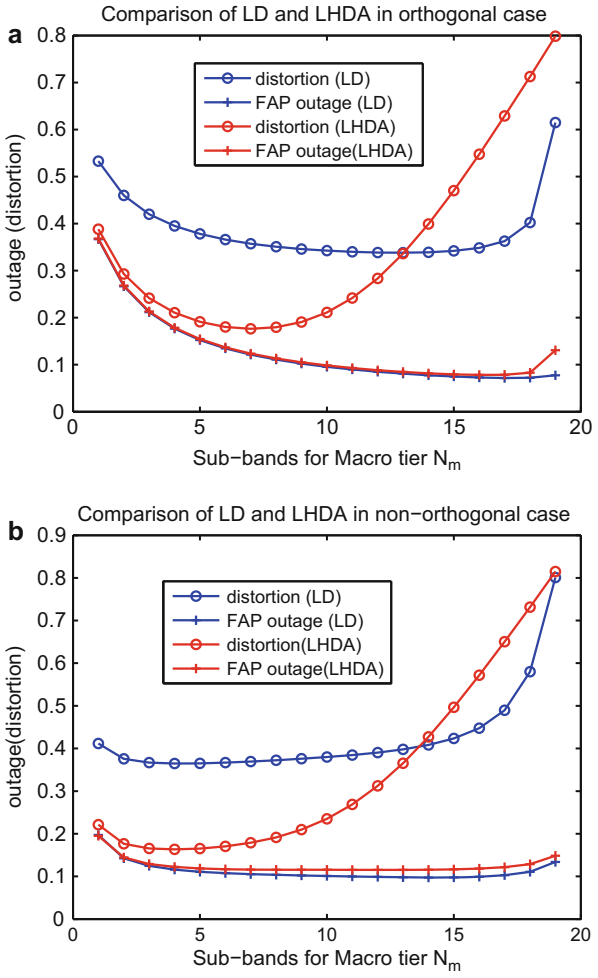

Fig. 6 Comparisons between LD and LHDA in both orthogonal and non-orthogonal cases

thus the distortion for the UE connected to the MBS to receive the BL is large. When increasing N_{m}, the performance of the macro tier becomes good, while that of the femto tier is poor.

Figure 5b displays the performance of LHDA transmission in the non-orthogonal case. The general trends of the curves of the outage and the average distortion are almost the same as that of Fig. 5a. The difference lies in that the outage probability is lower in the non-orthogonal case than that in the orthogonal case when N_{m} is small.

Figure 6 displays the comparison between LD transmission and LHDA transmission. Since the comparisons for different p are more or less the same, we set $p = 0.5$

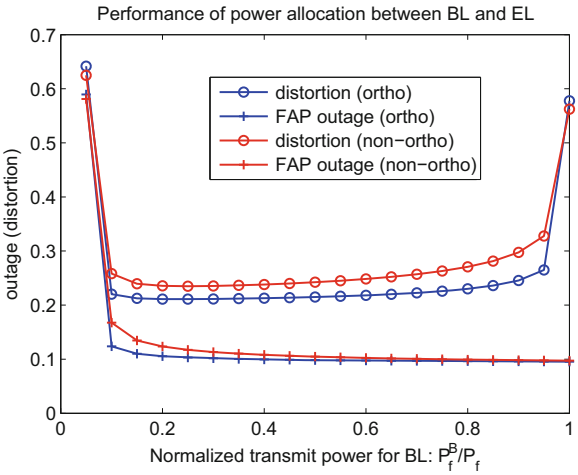

Fig. 7 Power allocation between the BL and the EL in FAPs for LHDA transmission

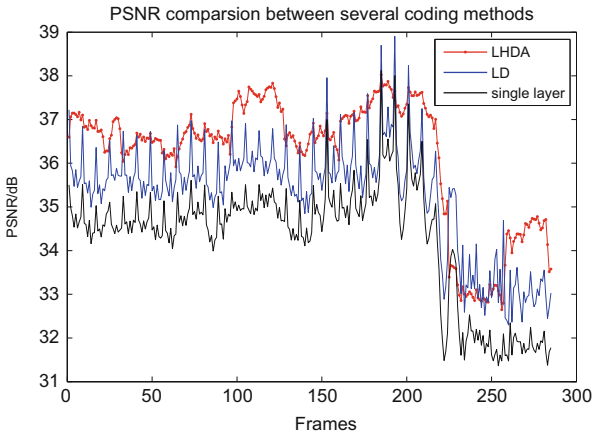

Fig. 8 Comparisons of LHDA and LD and single-layer coding video transmission

as an example. In both orthogonal and non-orthogonal cases, LHDA outperforms LD when the proportion of frequency resource allocated to the femto tier exceeds a certain threshold, for example, 35% (i.e., $N_f \geq 7$) in the current deployment, as the outage probability is slightly increasing while the average distortion is obviously decreasing when N_m is small. The reason is that analog transmission avoids the cliff effect and offers the continuous quality scalability.

Figure 7 displays the power allocation between the digital BL and the analog EL for LHDA transmission. If the power allocated to the BL is increasing, the outage probability decreases monotonously and then approaches stable as the network is interference limited. With P_f^B increasing, the distortion for the BL is sharply decreasing, while the distortion for the EL is increasing. Thus, the total distortion firstly decreases owing to superior transmission of the BL and then increases owing to inferior transmission of the EL. Because of the tradeoff between the transmissions

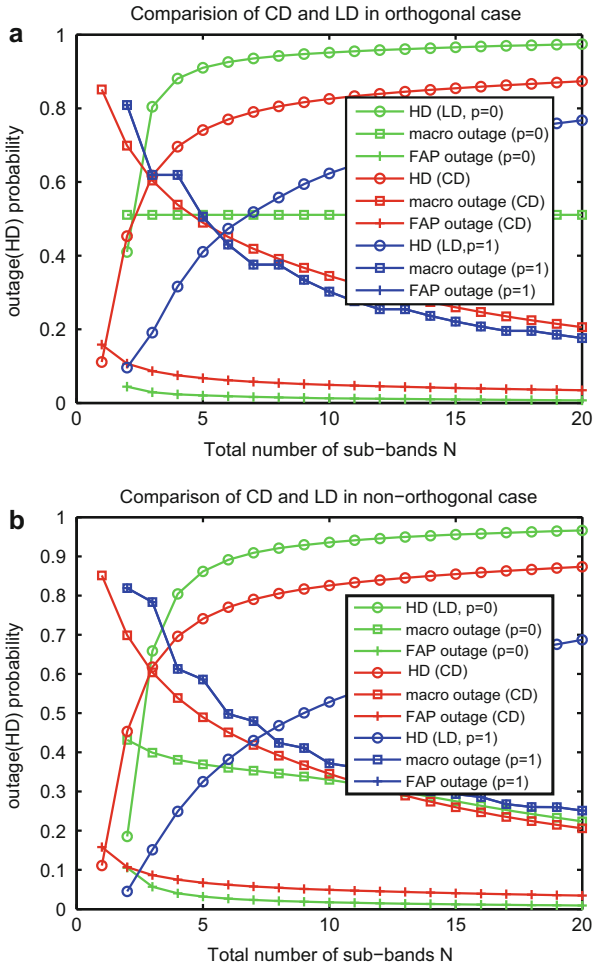

Fig. 9 Comparisons of CD and LD in both orthogonal and non-orthogonal cases

of the BL and the EL, the average distortion varies little when the power allocation ratio $P_{\mathrm{f}}^{\mathrm{B}} / P_{\mathrm{f}}$ lies in a wide range; thus the power allocation is robust.

QoE reflects the user experience and satisfaction, and its evaluation can be performed via subjective tests with the help of a panel of users. The mean opinion score (MOS) which reflects the quality perceived by the observers is dependent on human observation as well as time demanding and costly, while objective video metrics are mathematical-based metrics which are easy and fair to evaluate. The peak signal-to-noise ratio (PSNR) is usually chosen as the objective video metric.

Figure 8 displays the comparisons of performance of LHDA and LD and single-layer coding video transmission in a practical scenario. A standard video called Foreman.yuv is chosen, then it is encoded through H.264/AVC to a single layer or is

encoded through H.264/AVC to two layers to exploit the spatial scalability. LHDA and LD are employed to transmit the layered video contents. The performance peak signal-to-noise ratio (PSNR) of all the 288 frames is compared for the three transmission schemes. The performance of LHDA is the best, since it achieves the highest PSNR, and the variation of PSNR with respect to different frame is stable. The performance of LD is better than single-layer coding video transmission.

Figure 9 displays the comparison between CD transmission and LD transmission with $p = 0$ and $p = 1$ under orthogonal and non-orthogonal spectrum allocation methods. Since different N_{m} result in different performance, here the optimal N_{m} is chosen to achieve the minimal outage probability given the total number of sub-bands is N. It can be found that the HD probability of CD is between that of LD with $p = 0$ and $p = 1$. Meanwhile the outage probabilities of macro UE and femto UE are nearly minimal.

Conclusion and Future Directions

In order to overcome the challenges of the mobile networks induced by the rapidly growing video traffic, efficient networking strategy as well as providing optimal QoE is an urgent task for mobile operators. In this work, we proposed an analytical framework for user-cognizant scalable video transmission, which exploits the interplay among user demand, video source characteristic, and networking.

Specifically, three scalable transmission schemes are presented, i.e., LD, LHDA, and CD, which are shown to be an effective means for providing differentiated services for users. Through the analysis and comparison of system performance metrics, i.e., outage probability, HD probability, and average distortion, under different spectrum allocation methods, it is observe that:

(1) Compared to the traditional non-scalable video transmission, our schemes can adaptively provide basic or high-definition video.
(2) The frequency resource should be elaborately allocated between tiers to achieve good performance, and the choice of orthogonal and non-orthogonal spectrum allocation methods for LD and LHDA depend on the system configuration.
(3) The hybrid digital-analog transmission can further improve the system performance by reducing video distortion and providing continuous quality scalability of high-definition video, and the performance is quite insensitive to the power allocation between the digital BL and the analog EL.
(4) Cooperative video transmission can achieve relatively high HD probability with a little increase of outage probability.

To further enhance the networking performance and user QoE, the work can be extended to incorporate wireless caching and rateless codes. The heterogeneity of video quality and video popularity can be exploited to optimize the caching and transmission schemes [40]. Since the UE may simultaneously connect to the MBS and the FAP, rateless codes such as fountain codes [41, 42] can be employed

to reduce the complexity of synchronization of these two links. Moreover, rate adaption and shaping strategies can also be studied with some background traffic, such as file downloading and over-the-top (OTT) services.

Precoding and Power Allocation for Two-Tier Heterogeneous Networks

40

Shengjie Guo and Xiangwei Zhou

Contents

Abstract

In two-tier heterogeneous networks, the cross-tier interference and co-tier interference significantly affect the network performance. In this chapter, cascaded precoders in orthogonal frequency-division multiplexing systems are investigated to protect *macro-cell user equipments* (MUEs) from the cross-tier interference caused by co-located small cells and at the same time to satisfy the *quality-of-service* (QoS) requirements of *small-cell user equipments* (SUEs). An outer precoder ensures that the signals intended for the SUEs are orthogonal to the MUEs thus avoids the cross-tier interference from the second tier. Moreover, optimal power allocation through an inner precoder at each *small base station* (SBS) yields better performance of the SUEs and guarantees their

QoS requirements. With consideration of the dense deployment of SBSs, an SBS selection algorithm is studied to further reduce the computational complexity. Simulation results demonstrate that the cascaded precoders are effective in mitigating the interference and enhancing the capacity of small cells.

Introduction

Recently, the deployment of *small base stations* (SBSs) such as femtocells has emerged as a promising technology to extend service coverage, increase network throughput, and improve energy efficiency [1–3]. Because of their low-power and low-cost features, SBSs are mostly installed in offices or at homes for better indoor performance [4]. Since SBSs are usually deployed to overlay with *macro base stations* (MBSs), cross-tier interference is introduced, which limits the performance of two-tier networks. Moreover, since both cross-tier interference and co-tier interference need to be considered, the complexity in designing algorithms increases. To address these issues, an effective scheme with cascaded precoders will be disscussed in this chapter.

Coexistence Problem in Two-Tier Networks

In two-tier heterogeneous networks, both small cells and macro cells face the cross-tier interference and co-tier interference from the network elements belonging to different and the same tiers, respectively. When SBSs are randomly deployed with high density, the cross-tier interference and co-tier interference dramatically limit the performance of the heterogeneous network [5].

Current Techniques

To address the above issues, many researches have been devoted to frequency partitioning, power allocation, and precoding.

Frequency Partitioning

To avoid cross-tier interference, frequency partitioning is a direct and effective method [6–9]. By dividing frequencies into multiple nonoverlapping blocks, the network assigns different tiers to different blocks that can totally avoid cross-tier interference.

According to locations [6,7], traffic volumes [8], and user types [9], different frequency partitioning schemes for two-tiered heterogeneous networks serve different purposes.

Power Allocation

Power allocation is widely adopted in two-tiered heterogeneous networks to mitigate both cross-tier and co-tier interference, especially when the frequency is shared within two tiers. The main idea of power allocation is limiting the transmit power to alleviate the interference to the other parties in the shared frequency [10–13].

The power allocation method has been exploited from various aspects, i.e., game theory [10, 11], sleep mode [12], and distributed manner [13]. Power allocation renders a trade-off between interference mitigation and spectrum efficiency.

Precoding

Precoding scheme exploits the diversity and *degree of freedom* (DoF) of the transmission. Recently, several state-of-art precoding schemes have been presented in [14–18] to deal with the cross-tier interference and co-tier interference in two-tier heterogeneous networks. The precoding schemes utilize the spatial DoF [14] and frequency DoF [15–18] in multi-cell multiple-input-multiple-output networks and cognitive two-tier networks, respectively.

For better spectrum efficiency, frequency partitioning method is not discussed in this chapter and the focus of this chapter is to study precoding and power allocation in two-tier heterogenous networks. With consideration of combining power allocation and precoding, cascaded precoders dealing with both the cross-tier interference and co-tier interference in heterogeneous networks are discussed. First, an outer precoder is designed at each SBS to eliminate the cross-tier interference to the existing *macro-cell user equipments* (MUEs). Then to mitigate the co-tier interference in the second tier, an inner precoder for power allocation is studied.

The rest of this chapter is organized as follows. A two-tier heterogeneous system model is presented in section "System Model". In section "Cascaded Precoders", the cascaded precoders for two-tier networks are studied. An SBS selection algorithm to reduce the complexity of the cascaded precoders and the system performance under channel estimation are discussed in section "Discussion". Simulation results are given in section "Simulation Results". Finally, conclusions and future directions are provided in section "Conclusion and Future Directions".

System Model

As shown in Fig. 1, the coexistence of one MBS and K SBSs in a downlink system is considered. The MBS serves M single-antenna MUEs and each SBS serves one single-antenna SUE. The MBS adopts *orthogonal frequency-division multiple* (OFDM) based transmission with N subcarriers and a *cyclic prefix* (CP) of length L to avoid inter-symbol interference. Since the MBS usually covers a large area, the first tier is regarded as a primary user and oblivious of the existence of the second tier. The cross-tier interference mitigation strategy is only implemented in the second tier. No cooperation is considered between different tiers or among different SBSs in the same tier. Therefore, the precoders are designed in a distributed manner. All transmissions are assumed to be synchronized and no radio frequency

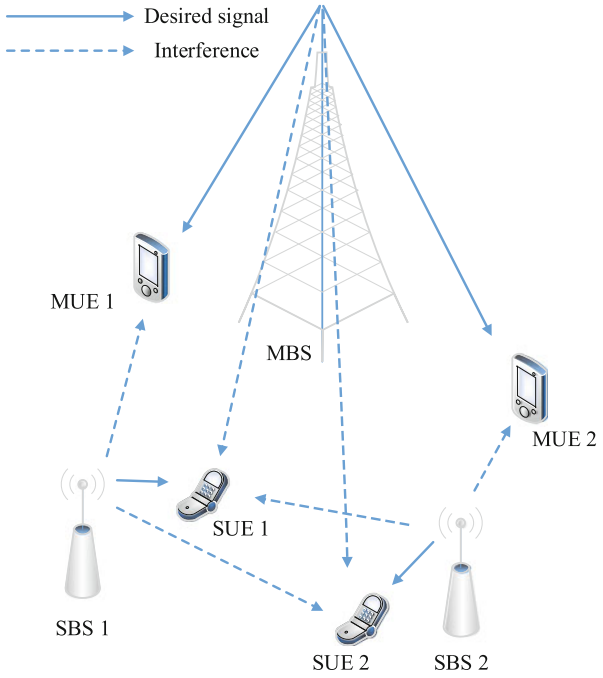

Fig. 1 System model

impairments at the receiver are considered. The knowledge of perfect *channel state information* (CSI) for all links is assumed. The influence of imperfect CSI will be discussed in section "Discussion".

Subscript s denotes the SBSs and m denotes the MBS. $\mathbf{x}_s^{(i)} \in \mathbb{C}^{(N+L)\times 1}$ denotes the precoded signal vector in time domain at the i-th SBS. Then

$$\mathbf{x}_s = [\mathbf{x}_s^{(1)T}, \mathbf{x}_s^{(2)T}, \ldots, \mathbf{x}_s^{(K)T}]^T \in \mathbb{C}^{K(N+L)\times 1} \tag{1}$$

is the equivalent aggregate signal vector of the SBSs. $\mathbf{H}_{sm}^{(i,j)}$ denotes the channel matrix from the i-th SBS to the j-th MUE. Then

$$\mathbf{H}_{sm}^{(j)} = [\mathbf{H}_{sm}^{(1,j)}, \mathbf{H}_{sm}^{(2,j)}, \ldots, \mathbf{H}_{sm}^{(K,j)}] \in \mathbb{C}^{N\times K(N+L)} \tag{2}$$

is the aggregate channel matrix from the SBSs to the j-th MUE and expressed as

$$\mathbf{H}_{sm}^{(i,j)} = \begin{bmatrix} h_{sm}^{(i,j)}(L) & \cdots & h_{sm}^{(i,j)}(0) & 0 & \cdots & 0 \\ 0 & \ddots & & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & & \ddots & 0 \\ 0 & \cdots & 0 & h_{sm}^{(i,j)}(L) & \cdots & h_{sm}^{(i,j)}(0) \end{bmatrix}, \tag{3}$$

where $h_{sm}^{(i,j)}(L)$, $h_{sm}^{(i,j)}(L-1)$, …, and $h_{sm}^{(i,j)}(0)$ represent the channel taps from the i-th SBS to the j-th MUE.

The received signal vectors of length N in frequency domain at the j-th MUE and i-th SUE are expressed as

$$\mathbf{y}_m^{(j)} = \mathbf{F}(\mathbf{H}_{mm}^{(j)}\mathbf{A}\mathbf{F}^{-1}\mathbf{s}_m^{(j)} + \mathbf{H}_{sm}^{(j)}\mathbf{x}_s + \mathbf{n}_m^{(j)}) \tag{4}$$

and

$$\mathbf{y}_s^{(i)} = \mathbf{F}(\mathbf{H}_{ss}^{(i,i)}\mathbf{x}_s^{(i)} + \sum_{\substack{u=1 \\ u\neq i}}^{K} \mathbf{H}_{ss}^{(u,i)}\mathbf{x}_s^{(u)} + \mathbf{H}_{ms}^{(1,i)}\mathbf{A}\mathbf{F}^{-1}\mathbf{s}_m^{(j)} + \mathbf{n}_s^{(i)}), \tag{5}$$

respectively, where $\mathbf{s}_m^{(j)} \in \mathbb{C}^{(N+L)\times 1}$ is the input signal vector in time domain at the MBS for the j-th MUE, $\mathbf{n}_m^{(j)}$ and $\mathbf{n}_s^{(i)}$ are the corresponding equivalent noise vectors for the MUEs and SUEs, respectively, $\mathbf{F}$ is an $N \times N$ unitary discrete Fourier transform matrix with the entry in the $(k+1)$-th row and $(l+1)$-th column $[\mathbf{F}]_{(k+1),(l+1)} = \frac{1}{\sqrt{N}} e^{-i2\pi\frac{kl}{N}}$ for $k, l = \{0, \ldots, N-1\}$, $\mathbf{A}$ is an $(N+L) \times N$ cyclic prefix insertion matrix given by

$$\mathbf{A} = \begin{bmatrix} \mathbf{0_{L,N-L}}, \mathbf{I_L} \\ \mathbf{I_N} \end{bmatrix}, \tag{6}$$

where $\mathbf{0_{N,L}}$ and $\mathbf{I_N}$ denote an $N \times L$ zero matrix and an $N \times N$ identity matrix, respectively, $\mathbf{H}_{mm}^{(j)} \in \mathbb{C}^{N\times(N+L)}$ is the channel matrix from the MBS to the j-th MUE, which is

$$\mathbf{H}_{mm}^{(1,j)} = \begin{bmatrix} h_{mm}^{(1,j)}(L) & \cdots & h_{mm}^{(1,j)}(0) & 0 & \cdots & 0 \\ 0 & \ddots & & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & & \ddots & 0 \\ 0 & \cdots & 0 & h_{mm}^{(1,j)}(L) & \cdots & h_{mm}^{(1,j)}(0) \end{bmatrix}, \tag{7}$$

where $h_{mm}^{(1,j)}(L)$, $h_{mm}^{(1,j)}(L-1)$, …, and $h_{mm}^{(1,j)}(0)$ are the channel taps between the MBS and the j-th MUE, $\mathbf{H}_{ss}^{(u,i)}$ and $\mathbf{H}_{ms}^{(1,i)}$ are the channel matrices from the u-th SBS and the MBS to the i-th SUE, respectively, and constructed as

$$\mathbf{H}_{ss}^{(u,i)} = \begin{bmatrix} h_{ss}^{(u,i)}(L) & \cdots & h_{ss}^{(u,i)}(0) & 0 & \cdots & 0 \\ 0 & \ddots & & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & & \ddots & 0 \\ 0 & \cdots & 0 & h_{ss}^{(u,i)}(L) & \cdots & h_{ss}^{(u,i)}(0) \end{bmatrix}, \tag{8}$$

and

$$\mathbf{H}_{ms}^{(1,i)} = \begin{bmatrix} h_{ms}^{(1,i)}(L) & \cdots & h_{ms}^{(1,i)}(0) & 0 & \cdots & 0 \\ 0 & \ddots & & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & & \ddots & 0 \\ 0 & \cdots & 0 & h_{ms}^{(1,i)}(L) & \cdots & h_{ms}^{(1,i)}(0) \end{bmatrix}, \tag{9}$$

where $h_{ms}^{(1,i)}(L)$, $h_{ms}^{(1,i)}(L-1)$, …, $h_{ms}^{(1,i)}(0)$ and $h_{ss}^{(u,i)}(L)$, $h_{ss}^{(u,i)}(L-1)$, …, and $h_{ss}^{(u,i)}(0)$ represent the L channel paths from the MBS to the i-th SUE and from the u-th SBS to the i-th SUE, respectively.

Cascaded Precoders

In this section, cascaded precoders are studied. Specifically, the outer precoder and inner precoder are designed and analyzed.

The structure of cascaded precoders is illustrated in Fig. 2. The precoded signal vector is obtained from the direct input symbol vector. Specifically,

$$\mathbf{x}_s^{(i)} = \mathbf{W}^{(i)}\mathbf{s}^{(i)}, \tag{10}$$

where $\mathbf{s}^{(i)} \in \mathbb{C}^{L\times 1}$ is an *independent identical distributed* (i.i.d.) zero-mean unit-variance direct input symbol vector from the i-th SBS and $\mathbf{W}^{(i)}$ is the overall precoding matrix for the i-th SBS, which is constructed from two cascaded precoders,

$$\mathbf{W}^{(i)} = \mathbf{E}^{(i)}\mathbf{G}^{(i)}, \tag{11}$$

where $\mathbf{E}^{(i)}$ is the outer precoder to cancel the cross-tier interference from the i-th SBS to the MUEs and $\mathbf{G}^{(i)}$ is the inner precoder to mitigate the co-tier interference from the i-th SBS through power allocation in the second tier.

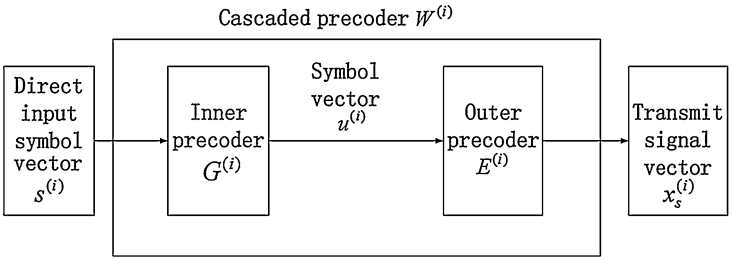

Fig. 2 Proposed cascaded precoder structure

Out Precoder Design

The outer precoder is designed to prevent the first tier from the cross-tier interference. To protect the j-th existing MUE, it is preferred to eliminate the cross-tier interference from the second tier, i.e.,

$$\mathbf{H}_{sm}^{(j)}\mathbf{x}_s = \mathbf{0}, \quad \forall\, j \in 1, 2, \ldots, M. \tag{12}$$

The transmitted signal $\mathbf{x}_s^{(i)}$ from the i-th SBS is designed as

$$\mathbf{x}_s^{(i)} = \mathbf{E}^{(i)}\mathbf{u}^{(i)}, \tag{13}$$

where $\mathbf{u}^{(i)} \in \mathbb{C}^{L\times 1}$ is the symbol vector at the i-th SBS and $\mathbf{E}^{(i)} \in \mathbb{C}^{(N+L)\times L}$ is a linear precoder for the i-th SBS to render

$$\mathbf{H}_{sm}^{(i,j)}\mathbf{E}^{(i)} = \mathbf{0}. \tag{14}$$

Since $\mathbf{H}_{sm}^{(i,j)}$ is an $(N + L)$ by N matrix with independent elements, the rank of $\mathbf{H}_{sm}^{(i,j)}$ is N and thus the dimension of the null space of $\mathbf{H}_{sm}^{(i,j)}$ is $(N + L) - N = L$. Therefore, the LQ decomposition method [17] can be used to construct an $(N + L) \times L$ precoder $\mathbf{E}^{(i)}$ to transmit L symbols aligned with the null space of $\mathbf{H}_{sm}^{(i,j)}$. The equivalent channel matrix $\mathbf{H}_{sm}^{(i,j)}$, representing the interfering link between the i-th SBS and the j-th MUE, is decomposed as

$$\mathbf{H}_{sm}^{(i,j)} = \mathbf{L}_{sm}^{(i,j)}\mathbf{Q}_{sm}^{(i,j)}, \tag{15}$$

where $\mathbf{L}_{sm}^{(i,j)} \in \mathbb{C}^{N\times(N+L)}$ is a lower triangular matrix and $\mathbf{Q}_{sm}^{(i,j)} \in \mathbb{C}^{(N+L)\times(N+L)}$ is a unitary matrix given by

$$\mathbf{Q}_{sm}^{(i,j)} \triangleq [\mathbf{q}_1, \mathbf{q}_2, \cdots, \mathbf{q}_{N+L}]. \tag{16}$$

Then the outer precoder $\mathbf{E}^{(i)}$ is constructed as

$$\mathbf{E}^{(i)} \triangleq [\mathbf{q}_{N+1}, \mathbf{q}_{N+2}, \cdots, \mathbf{q}_{N+L}] \tag{17}$$

and therefore the equivalent signal model in the first tier is rewritten as

$$\mathbf{y}_m^{(j)} = \mathbf{F}(\mathbf{H}_{mm}^{(j)}\mathbf{A}\mathbf{F}^{-1}\mathbf{s}_m^{(j)} + \mathbf{n}_m^{(j)}), \tag{18}$$

which is free of the cross-tier interference from the second tier.

Inner Precoder Design

To reduce the influence of the co-tier interference and achieve higher throughput, an inner precoder is designed to render optimal power allocation.

The Inner Precoder Structure

The inner precoding matrix $\mathbf{G}^{(i)} \in \mathbb{C}^{L\times L}$ is used to generate the symbol vector of the i-th SBS, i.e.,

$$\mathbf{u}^{(i)} = \mathbf{G}^{(i)}\mathbf{s}^{(i)}. \tag{19}$$

The received signal vector at the i-th SUE is

$$\mathbf{y}_s^{(i)} = \mathbf{F}(\mathbf{H}_{ss}^{(i,i)}\mathbf{E}^{(i)}\mathbf{G}^{(i)}\mathbf{s}^{(i)} + \sum_{\substack{u=1\\u\neq i}}^{K}\mathbf{H}_{ss}^{(u,i)}\mathbf{E}^{(u)}\mathbf{G}^{(u)}\mathbf{s}^{(u)} + \mathbf{v}_s^{(i)}), \tag{20}$$

where $\mathbf{v}_s^{(i)} = \mathbf{H}_{ms}^{(1,i)}\mathbf{A}\mathbf{F}^{-1}\mathbf{s}_m^{(j)} + \mathbf{n}_s^{(i)}$.

Define matrix $\widetilde{\mathbf{F}}$ such that

$$\widetilde{\mathbf{F}} = \mathbf{F}\widetilde{\mathbf{A}}, \tag{21}$$

where $\widetilde{\mathbf{A}}$ denotes the cyclic prefix removal matrix, which is

$$\widetilde{\mathbf{A}} = \left[\mathbf{0}_{\mathbf{N},\mathbf{L}}, \mathbf{I}_{\mathbf{N}}\right]. \tag{22}$$

Then the precoded symbol of the i-th SBS in frequency domain, $\mathbf{X}_s^{(i)}$, can be expressed as

$$\mathbf{X}_s^{(i)} = \widetilde{\mathbf{F}}\mathbf{E}^{(i)}\mathbf{G}^{(i)}\mathbf{s}^{(i)}. \tag{23}$$

The average transmit power of the i-th SBS over the j-th subcarrier, $P^{(i,j)}$, is given by

$$P^{(i,j)} = \mathbb{E}\{[\mathbf{X}_s^{(i)}]_{(j,1)}^2\}, \tag{24}$$

where $\mathbb{E}\{\cdot\}$ denotes the expectation operation. Because $\mathbf{s}^{(i)}$ is i.i.d. with zero-mean and unit-variance,

$$P^{(i,j)} = [\widetilde{\mathbf{F}}\mathbf{E}^{(i)}\mathbf{G}^{(i)}\mathbf{G}^{(i)T}\mathbf{E}^{(i)T}\widetilde{\mathbf{F}}^{T}]_{(j,j)}. \tag{25}$$

Let $\mathbf{B}^{(i)} = \widetilde{\mathbf{F}}\mathbf{E}^{(i)}\mathbf{G}^{(i)}$ and the entry in the m-th row and n-th column be $b_{(m,n)}^{(i)}$. The following N equations are obtained

$$\begin{aligned} b_{(1,1)}^{(i)2} + b_{(1,2)}^{(i)2} + \cdots + b_{(1,L)}^{(i)2} &= P^{(i,1)}, \\ b_{(2,1)}^{(i)2} + b_{(2,2)}^{(i)2} + \cdots + b_{(2,L)}^{(i)2} &= P^{(i,2)}, \\ &\vdots \\ b_{(N,1)}^{(i)2} + b_{(N,2)}^{(i)2} + \cdots + b_{(N,L)}^{(i)2} &= P^{(i,N)}. \end{aligned} \tag{26}$$

Define matrix $\mathbf{C}_n$ as

$$\mathbf{C}_n = \begin{bmatrix} \sqrt{P^{*(1,nL+1)}} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \sqrt{P^{*(1,nL+L)}} \end{bmatrix}. \tag{27}$$

To achieve the desired power $P^{*(i,j)}$ for $j = 1, 2, \cdots, N$, $\mathbf{B}^{(i)}$ should be designed as

$$\mathbf{B}^{(i)} = \begin{bmatrix} \mathbf{C}_1 \\ \mathbf{C}_2 \\ \vdots \\ \mathbf{C}_z \\ \mathbf{C}'_{z+1} \end{bmatrix}, \tag{28}$$

where z is the largest integer that is smaller than $\frac{N}{L}$ and $\mathbf{C}'_{z+1}$ is constructed with the first $(N - zL)$ rows of $\mathbf{C}_{z+1}$. Then the full rank inner precoding matrix $\mathbf{G}^{(i)}$ can be obtained through

$$\mathbf{G}^{(i)} = ((\widetilde{\mathbf{F}}\mathbf{E}^{(i)})^H \widetilde{\mathbf{F}}\mathbf{E}^{(i)})^{-1} (\widetilde{\mathbf{F}}\mathbf{E}^{(i)})^H \mathbf{B}^{(i)}, \tag{29}$$

where superscript H denotes the Hermitian transpose operation.

The Optimal Power Allocation

Power allocation at each SBS is optimized through the designed inner precoder. Since the power allocation of the MBS is not affected by the second tier, the interference from the first tier is always fixed during the power allocation of the SBSs. Therefore, the interference from the MBS is treated as noise with fixed power during the SBS power optimization and absorbed in the noise expression, $\sigma_{(i,j)}^2$, for simplicity.

Through the precoding matrix $\mathbf{G}^{(i)}$, the transmit power $P^{(i,j)}$ is allocated to maximize the achievable rate $R^{(i)}$ of the i-th SUE. Thus the following optimization problem is formulated

Algorithm 1 QoS guarantee algorithm

Initialize: The total transmit power of the i-th SBS $P^{(i)} = P^{(i)}_{\max}$, $P^{(i,j)} = 0$, i = 1,2,. . .,K, j = 1,2,. . .,N.
loop
  loop
    Solve (30) for all $i = 1, 2, \ldots, K$ and $j = 1, 2, \ldots, N$. Set $P^{(i,j)}$ and transmit power $P^{(i)}$.
    Set $R^{(i)}$ according to (30).
  end loop
  for i = 1 to K,
    if $R^{(i)} > R_{re} + \varepsilon$, set $P^{(i)} = P^{(i)} - \xi$.
    if $R^{(i)} < R_{re}$, set $P^{(i)} = P^{(i)} + \xi$.
    if $P^{(i,j)} > P^{(i)}_{\max}$, $P^{(i,j)} = P^{(i)}_{\max}$.
  end for
  until $R^{(i)} > R_{re}$ for all $i = 1, 2, \ldots, K$. Then set $P^{(i,j)} = P^{*(i,j)}$.
end loop

$$\max R^{(i)} = \sum_{j=1}^{N} \log_2 \left(1 + \frac{|g^{(j)}_{i,i}| P^{(i,j)}}{\sum_{u \in \mathscr{S}^{[i]}} |g^{(j)}_{u,i}| P^{(u,j)} + \sigma^2_{(i,j)}} \right),$$

$$\text{subject to} \sum_{j=1}^{N} P^{(i,j)} \leq P^{(i)}_{\max}, \tag{30}$$

where $P^{(i)}_{\max}$ is the maximum transmit power of the i-th SBS, $\mathscr{S}^{[i]}$ denotes the set of SBSs excluding the i-th SBS, $\sigma^2_{(i,j)}$ is the noise power for the i-th SUE over the j-th subcarrier, and $|g^{(j)}_{u,i}|$ denotes the channel gain from the u-th SBS to the i-th SUE over the j-th subcarrier, which can be obtained from $\mathbf{H}^{(u,i)}_{ss}$ as

$$|g^{(j)}_{u,i}| = |[\mathbf{F}\mathbf{H}^{(u,i)}_{ss}\mathbf{F}'^{H}(\widetilde{\mathbf{F}}\widetilde{\mathbf{F}}^{H})^{-1}]_{(j,j)}|^2. \tag{31}$$

The Lagrangian function for (30) is

$$\begin{aligned} &\mathscr{L}(P^{(i,j)}, \alpha_i) \\ &= -\sum_{j=1}^{N} \log_2 \left(1 + \frac{|g^{(j)}_{i,i}| P^{(i,j)}}{\sum_{u \in \mathscr{S}^{[i]}} |g^{(j)}_{u,i}| P^{(u,j)} + \sigma^2_{(i,j)}} \right) \\ &+ \alpha_i \left(\sum_{j=1}^{N} P^{(i,j)} - P^{(i)}_{\max} \right), \end{aligned} \tag{32}$$

where α_i is a Lagrangian multiplier.

By setting the differentiation of (32) with respect to $P^{(i,j)}$ to be 0, the power allocated over the j-th subcarrier of the i-th SBS is

$$P^{(i,j)} = \left[\frac{1}{\alpha_i \ln 2} - \frac{1}{\beta}\right]^+, \tag{33}$$

where $\frac{1}{\alpha_i \ln 2}$ is a constant that ensures the power constraint (30) to be satisfied and $\beta = \frac{|g_{i,i}^{(j)}|}{\sum_{u \in \mathscr{S}^{[i]}} |g_{u,i}^{(j)}| P^{(u,j)} + \sigma_{(i,j)}^2}$. Here, $[x]^+ = \max(x, 0)$. Equation (33) is a standard form of water-filling power allocation. Given the coupled power allocation in (30) for different i's, the iterative water-filling in [19] is effective to optimize the power allocation $P^{(i,j)}$.

To guarantee the QoS of SUEs, Algorithm 1 is adopted to ensure that the achievable rate satisfies the rate requirement R_{re} for each SUE by adjusting the power allocation. Here the parameters ε and ξ are used to reach the desired accuracy. With the optimal power $P^{*(i,j)}$ for the i-th SBS over the j-th subcarrier, the precoding matrix $\mathbf{G}^{(i)}$ can be designed according to (27), (28), and (29).

Discussion

Algorithm to Reduce Computational Complexity

Given channel fading and path loss, an SBS may not introduce interference to the other SUEs even with the maximum transmit power. Thus Algorithm 2 is considered to exclude the SBSs from set $\mathscr{S}^{[i]}$ that do not interfere with the i-th SBS, which reduces the computational complexity of the algorithm.

Algorithm 2 SBS selection algorithm

1: **Initialize**: Set $P_{\text{cons}}^{(u)}$ for $u = 1, 2, \ldots, K$. Set $\mathscr{S}^{[i]} = \emptyset$, for $i = 1, 2, \ldots, K$.
2: **for** $i = 1$ to K,
3: **for** $u = 1$ to K, $u \neq i$,
4: Calculate $P_{arrive}^{(u,i)}$ according to (34).
5: **if** $P_{arrive}^{(u,i)} \geq \varepsilon_p$, set $\mathscr{S}^{[i]} = \mathscr{S}^{[i]} + \{u\}$.
6: **if** $P_{arrive}^{(u,i)} < \varepsilon_p$, set $\mathscr{S}^{[i]} = \mathscr{S}^{[i]}$.
7: **end for**
8: **end for**

Let $P_I^{(u,i)}$ be the interference power from the u-th SBS at the i-th SUE. If $P_I^{(u,i)}$ does not exceed the threshold ε_p when the u-th SBS uses the maximum power allowed, $P_{\max}^{(u)}$, the u-th SBS will not be considered as an interferer to the i-th SUE.

Given channel fading and path loss, $P_I^{(u,i)}$ can be expressed as

$$P_{I(dBm)}^{(u,i)} = \gamma_{u,i\,(dB)} + P_{\max(dBm)}^{(u)} - P_{L(dB)}^{(u,i)}, \tag{34}$$

where $\gamma_{u,i}$ is the channel fading coefficient from the u-th SBS to the i-th SUE and $P_L^{(u,i)}$ denotes the path loss from the u-th SBS to the i-th SUE.

For a system with K SBSs and N subcarriers, the complexity of the power allocation optimization and inner precoding matrix design increases with the number of SBSs, K. Through the SBS selection algorithm, the number of SBSs involved in the computation decreases and thus the complexity of optimization reduces.

Imperfect Channel Estimation

In section "Cascaded Precoders", perfect CSI is assumed to obtain the proposed precoder. However, in practice, it is difficult to obtain perfect CSI. Therefore, the performance of the proposed cascaded precoding scheme under channel estimation is analyzed in this subsection. There has been some discussion regarding the cross-tier interference elimination outer precoder under estimated channel in [15]. As in [20], the estimated channel matrix from the i-th SBS to the j-th SUE $\widehat{\mathbf{H}}_{ss}^{(i,j)}$ can be written as

$$\widehat{\mathbf{H}}_{ss}^{(i,j)} = \mathbf{H}_{ss}^{(i,j)} - \widehat{\mathbf{Er}}_{\mathbf{ss}}, \tag{35}$$

where $\widehat{\mathbf{Er}}_{\mathbf{ss}}$ denotes the channel estimation error that is a zero-mean circularly symmetric complex Gaussian matrix, i.e., $\widehat{\mathbf{Er}}_{\mathbf{ss}} \sim (0, \sigma^2_{\widehat{Er}_{ss}}\,\mathbf{I})$, with variance $\sigma^2_{\widehat{Er}_{ss}} = \mathbb{E}(|\mathbf{H}_{ss}^{(i,j)}|^2) - \mathbb{E}(|\widehat{\mathbf{H}}_{ss}^{(i,j)}|^2)$. With the estimated channel matrix, the received signal at the i-th SUE is given by

$$\begin{aligned}
\mathbf{y}_s^{(i)} =& \mathbf{F}(\widehat{\mathbf{H}}_{ss}^{(i,i)}\mathbf{E}^{(i)}\widehat{\mathbf{G}}^{(i)}\mathbf{s}^{(i)} + \sum_{u\in\mathscr{S}^{[i]}} \widehat{\mathbf{H}}_{ss}^{(u,i)}\mathbf{E}^{(u)}\widehat{\mathbf{G}}^{(u)}\mathbf{s}^{(u)} + \mathbf{v}_s^{(i)}) \\
=& \mathbf{F}(\mathbf{H}_{ss}^{(i,i)}\mathbf{E}^{(i)}\widehat{\mathbf{G}}^{(i)}\mathbf{s}^{(i)} + \sum_{u\in\mathscr{S}^{[i]}} \mathbf{H}_{ss}^{(u,i)}\mathbf{E}^{(u)}\widehat{\mathbf{G}}^{(u)}\mathbf{s}^{(u)} + \mathbf{v}_s^{(i)} \\
& \underbrace{- \widehat{\mathbf{Er}}_{ss}^{(i,i)}\mathbf{E}^{(i)}\widehat{\mathbf{G}}^{(i)}\mathbf{s}^{(i)} - \sum_{u\in\mathscr{S}^{[i]}} \widehat{\mathbf{Er}}_{ss}^{(u,i)}\mathbf{E}^{(u)}\widehat{\mathbf{G}}^{(u)}\mathbf{s}^{(u)}}_{\text{channel estimation error part}}),
\end{aligned} \tag{36}$$

where $\widehat{\mathbf{G}}^{(i)}$ is the inner precoding matrix of the i-th SBS considering channel estimation error. To design the elements of $\widehat{\mathbf{G}}^{(i)}$, the power allocation under channel

estimation, $\widehat{P}^{(i,j)}$, is obtained by replacing channel power gain $g_{u,i}^{(j)}$ with $\widehat{g}_{u,i}^{(j)}$ in the optimization problem (30).

The data rates with perfect and imperfect CSI, respectively, have a gap introduced by the channel estimation error part, which will be discussed with simulation results.

Simulation Results

In this section, simulation results are presented to illustrate the performance with the cascaded precoders. In the simulation, $K = 12$ SBSs are randomly deployed in a circle with radius $R = 50$ m and each SBS serves one SUE. The maximum transmit power is 100 mW for each SBS and 10 W for the MBS. The number of subcarriers and the length of CP are $N = 64$ and $L = 16$, respectively. According to [21], a path loss model $37 + 32\log_{10}(d)$ in decibels for all links is adopted, where d is the distance between a base station and a user.

In Fig. 3, the evolution of SUE data rates is illustrated with the iterations in Algorithm 1. The data rate requirement is $R_{re} = 5$ bps/Hz and the data rates of 3 selected SUEs are shown in Fig. 3. The data rate requirement is satisfied for all the SUEs. And the data rates of the SUEs converge fast in a few iterations while the QoS requirements of all the SUEs are met.

The average data rates of all the SUEs with perfect CSI and imperfect CSI under channel estimation are compared in Fig. 4. As shown in the figure, there is a gap

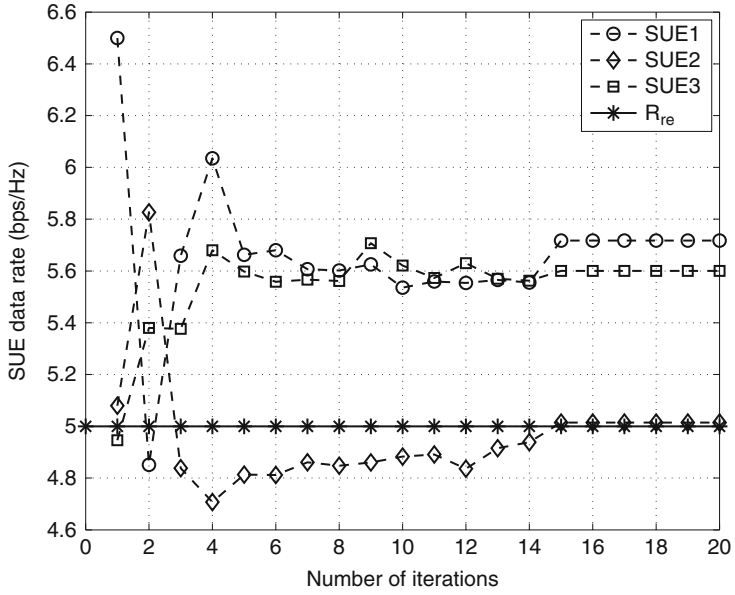

Fig. 3 SUE data rate versus number of iterations

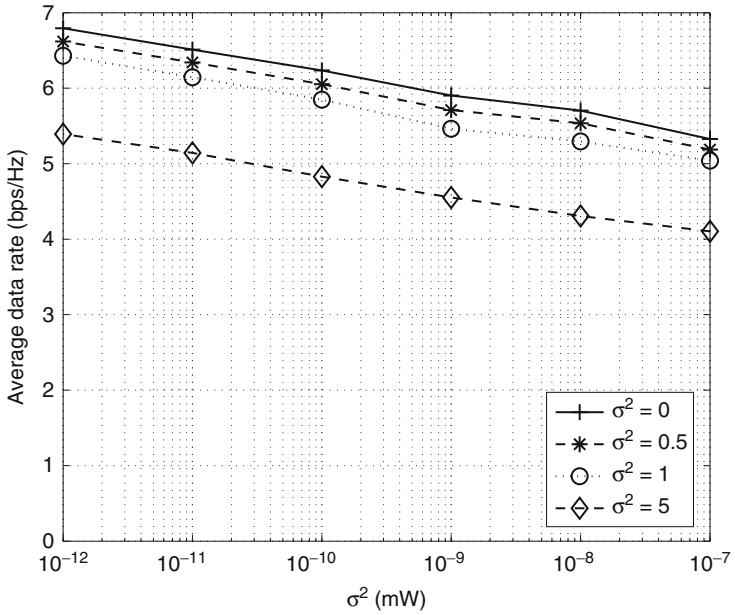

Fig. 4 Average data rate versus noise power under channel estimation

between the network performance with perfect CSI and imperfect CSI. It is obvious that the performance is becoming worse when the error variance increases. However, the average data rate under channel estimation is comparable with the perfect case when the error variance is 1, which is large enough in channel estimation according to [20]. Therefore, the cascaded precoders achieve acceptable performance with imperfect CSI.

In Fig. 5, the performance of the second tier with and without SBS selection algorithm is illustrated. Because of the random deployment and varying channel conditions, some SBSs do not cause co-tier interference to others even in dense deployment with the maximum power. With the SBS selection algorithm, the SBSs not affecting the i-th SBS will be eliminated from set $\mathscr{S}^{[i]}$. Then each SBS could serve its SUE with a higher power to achieve a better data rate and reduce the computational complexity with a smaller number of SBSs included in the optimization.

The performance of equal power allocation without inner precoder and with cascaded precoders is shown in Fig. 6. The cascaded precoders that suppress the co-tier interference render obviously higher data rate than the equal power allocation. Since the fixed co-tier interference in (30) dominates in the equal power allocation scheme, the performance gap increases when the noise power decreases.

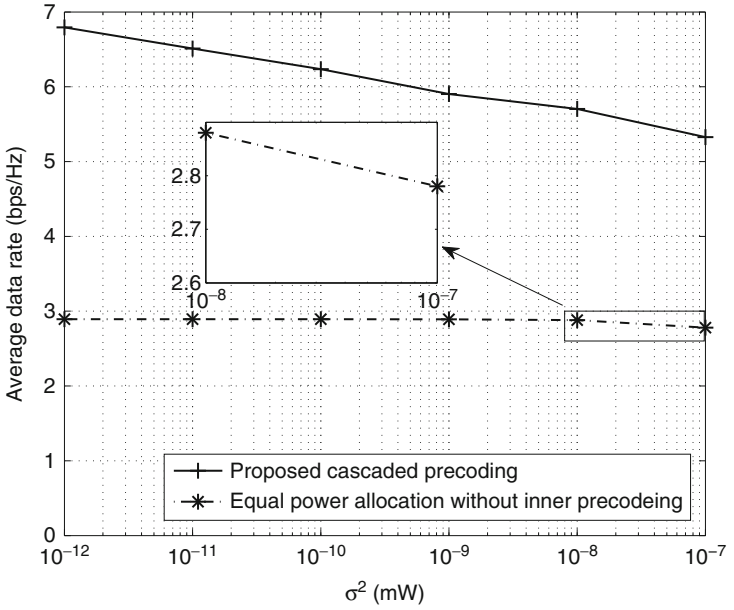

Fig. 6 Average data rate versus noise power in different schemes

Conclusion and Future Directions

In this chapter, cascaded precoders combining precoding and power allocation are discussed to enhance the throughput of the two-tier heterogeneous networks. With the designed outer precoder, the cross-tier interference from SBSs to MUEs is eliminated. Meanwhile, an inner precoder is derived to improve the performance of the second tier, which allocates the powers of SBSs optimally. Moreover, an SBS selection algorithm is presented to reduce the computational complexity of the proposed scheme. The system performance under channel estimation is also discussed. Simulation results illustrate the effectiveness of the cascaded precoders.

For further directions, the interference from the first tier to the second tier can be considered to design more advanced precoders. The precoding and power allocation in cooperative two-tier heterogeneous networks and MIMO networks are expected to be exploited.

Abstract

The explosive development of mobile data service makes our lives convenient and efficient. However, due to the limitation of resources and high flexibility of users' requirements, the resource management and allocation remain challenging. In this chapter, we first overview the development of mobile network. Based on the increasingly complicated mobile network, we analyze the current trends for service architecture, and show the features of distributive control and network

virtualization in the future data services. According to the service architecture, game theory is adopted to discuss the distributed behaviors of each service provider and user. We model the resource allocation problem as a hierarchical game, where the strategies for each service provider and each mobile user is proposed to achieve optimal and stable utilities. Finally, we conclude the chapter and put forwards future directions for distributed resource allocation problem in the virtualized data service network.

Development of Mobile Network

Ever since the digital revolution, the past half century has witnessed the information explosion in every perspective of the world. Nowadays, with the increasing popularity of smart mobile devices, a large variety of wireless data services and applications have effectively improved the efficiency and convenience of business and our daily lives. According to Cisco [1], at the end of 2016, global mobile data traffic has reached 7.2 EB (EB is equivalent to one billion GB) per month, which is 63% more compared with the global mobile data traffic of 4.4 EB at the end of 2016, and 18-fold over the past 5 years, compared with the global mobile data traffic of 400 PB (PB is equivalent to one million GB) per month at the end of 2011. Moreover, most emerging data services and applications, such as augmented reality, vehicle-to-vehicle communication, and live video feed, not only require large volume of transmitted data but also low service delay and delay jitter, which plays significant role on the quality of service (QoS) for mobile users [2].

In order to perform wireless data transmission from service providers to mobile users, the traditional cellular network is able to provide the coverage for data services. As shown in Fig. 1a, within a large communication cell, the base station processes and transmits data for mobiles users and forwards the data to the core network via backhaul. However, due to the limited amount of wireless resources, when there are mobile users requesting large volume of data transmission within the same communication cell, the base station cannot allocate sufficient wireless resources for all mobile users, and the QoS of mobile users at the cell edge is severely affected. Accordingly, in order to meet the requirements for the increasing data transmission trends, in these years, many solutions have been proposed for the communication network and can be generally summarized in the following three directions.

The Heterogeneous Architecture Within the Cellular Network

In urban areas, considering the high density of mobile users in specific areas and poor indoor coverage with the traditional cellular network, it is significant and beneficial to add different sizes of the communication cells, such as microcell, picocell, and femtocell, on the traditional macrocell network and form a heterogeneous wireless service architecture. As shown in Fig. 1b, in the areas with high volume of data transmission, the implementation of small cells reduce the data transmission

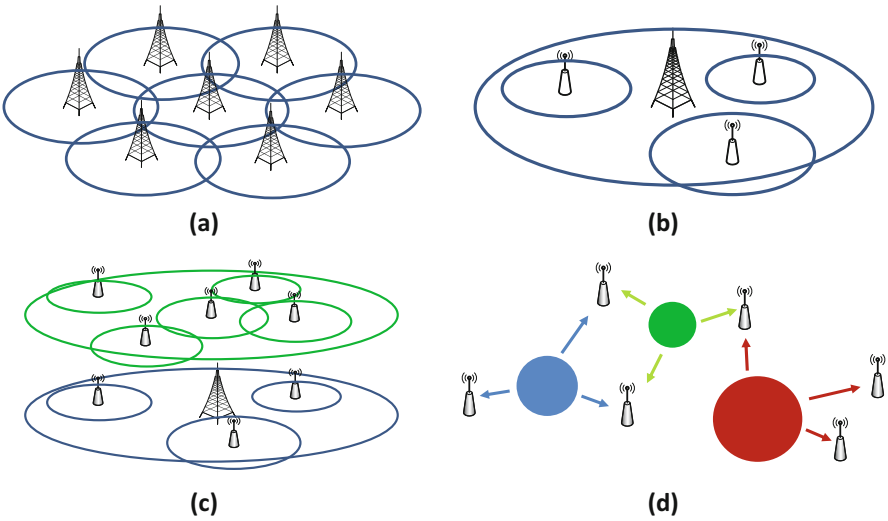

Fig. 1 Development of mobile network

distance between transmitters and receivers, resulting in high capacity for mobile users and high spectrum reuse factors for service providers. Meanwhile, in other areas with limited nomadic users, the macrocells are required and sufficient to guarantee the data transmission coverage. Accordingly, based on the distribution of data requirements, the heterogeneous network is able to efficiently improve the QoS of all mobile users.

Service Cooperation with Other Networks

The heterogeneous architecture of communication network is able to significantly improve the efficiency of wireless resources. However, when the total amount of wireless resource is limited but the volume of data transmission requirements keeps increasing, the QoS for mobile users eventually decreases. Therefore, it is fundamental to increase the total amount of feasible spectrum for wireless communication. As currently the majority of radio spectrum is licensed to other users or networks, while the application within the radio spectrum is spare sometimes, it is promising to explore the cooperations with other users or networks and obtain a large amount of available radio spectrum for data transmission, as shown in Fig. 1c. Such cooperations have been widely applied in cellular network with several examples shown as follows.

- In 1998, the concept of cognitive radio was initially put forward by Joseph Mitola in a seminar at KTH Royal Institute of Technology in Stockholm, and the article [3] was published with Gerald Q. Maguire in the following year. In the cognitive

radio network, the primary users are allocated with a large amount of spectrum resources, while the secondary users, without sufficient spectrum, try to reuse the licensed spectrum from primary users without causing interference. Accordingly, the secondary users are required to quickly sense the radio environment and effectively capture the vacant channels from primary users [4]. In IEEE 802.22 standard, the white spaces in the television frequency spectrum are allowed to be accessed for wireless regional area network with cognitive radio technology [5].

- With fast development in wireless local area network (WLAN), in 2008, the 802.11ac and 802.11ad standards have already been able to achieve the data rate of 6.9 and 6.7 Gbps, respectively. Accordingly, it is beneficial for the wireless cellular network to off-load its data services to WLAN to achieve high performance. By 2009, AT&T Inc. has deployed over 20,000 Wi-Fi hotspots to assist data transmission in the USA [6], and nearly 27 million AT&T customers receive access to the domestic Wi-Fi services. Moreover, as shown in Cisco, in 2016, 60% of total mobile data traffic has off-loaded onto Wi-Fi or femtocell [1].

Content-Centric Analysis for Resource Allocation

With the increasing popularity of smart mobile devices, the wireless services are experiencing a fundamental transition from the traditional connection-centric communications, such as phone calls and emails, to the content-centric communication, such as various mobile applications and video streaming [7]. Accordingly, the resource allocation protocol is no longer focused on the network links, but on the features and influences of content or data itself, as shown in Fig. 1d. Due to the content diversity [8] or content reuse [9], the same content may be requested by multiple mobile users. Therefore, the multi-casting and caching are able to be adopted to improve the QoS of mobile users.

Moreover, in cloud computing, the data storage and computation are normally applied by massive data centers, which are located far away from mobile users, causing high transmission cost and transmission delay. In order to fulfill the requirement of real-time applications, it is necessary to pull the cloud closer to mobile users. In the Internet of things (IoT), fog computing is put forward by Cisco as a promising solution, where multiple low-power computing or storage devices, known as the fog nodes, are allocated close to the users and can provide disaster resilient, fast response and location-awareness services. Similarly, in wireless radio access network, the concept of mobile edge computing is put forward by ETSI (European Telecommunications Standards Institute), where the network edge are able to perform data computation and storage in an isolated environment, so as to reduce network congestion and improve QoS. Therefore, considering the purpose of transmitted data and the deployment of multiple fog nodes or small computing devices, the allocated resources for both networking and computation are supposed to be considered simultaneously to further improve the QoS.

Service Architecture

According to the development of mobile network, the structure is becoming increasingly complicated. It is trending that the resource allocation in data transmission, computation and storage should be jointly considered, and various cooperations and competitions among multiple autonomous characters in the data services are included during the data services. In order to clearly show the complex service architecture for further analysis, we summarize the key framework in the mobile data services and itemize them as follows:

- **Service layer**: In service layer, a large variety of mobile data applications are provided by service operators. Based on different demands of the data services and applications, the service authorization, billing, network routing, and mobility managements are considered and adopted in the layer.
- **Infrastructure layer**: The infrastructure layer consists of various physical facilities which are able to perform data computation, data storage or caching, and data transmission for provided mobile data services. The facilities not only contain massive data centers or macrocell base stations which are established and maintained by professional corporations but also include enterprise data centers or personal mobile devices which are owned by small groups or individuals.
- **Resource layer**: The resource layer includes all kinds of resources required for data computation, storage, and transmission in mobile data services. Some resources may be offered and charged by resource providers such as computation resources from personal mobile devices in the neighborhood, while some may be public and free for data services such as unlicensed spectrum for wireless communication.
- **User layer**: The user layer contains all kinds of mobile users requesting various mobile data services from service providers.

According to the framework, in the following subsections, we analyze the current trends of resource allocation in mobile data services and further depict the future network architecture with network virtualization.

Traditional Service Architecture

In the traditional data service network, in order to provide mobile service to users, each service provider is required to purchase and maintain its own facilities and resources. As shown in Fig. 2, we observe that the facilities and resources for the mobile data services are combined with unique service providers vertically in the architecture. Accordingly, in peak hours, there are many mobile users subscribing the data services from one service provider, in order to meet the requirements of all mobile users, the service provider is required to purchase large amount of facilities and resources. However, most of the time, few data services are requested by mobile

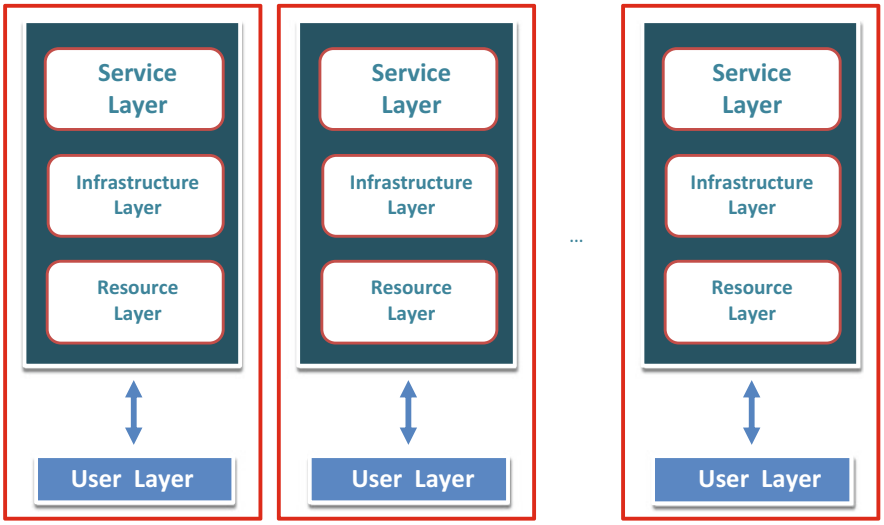

Fig. 2 Traditional service architecture

users, which brings big waste and low efficiency for the usage of facilities and resources. Moreover, due to the high cost on the purchasing and maintenance of facilities and resources, the mobile users may suffer high service price from the service provider.

The Development of Service Architecture

In order to improve the efficiency and capacity of mobile data services, based on the development of mobile network, in these years, the service architecture changes correspondingly. Based on the proposed service framework, we take the following two examples in mobile network to further analyze the development of data service architecture.

The Mobile Data Service in Heterogeneous Network

In the heterogeneous network, as some small cell base stations are purchased and maintained by private enterprises, families, or individuals, the closed access mode is adopted and a private wireless network is established in the indoor environment. However, due to the high cost and low efficiency when allocating unique licensed spectrum for small cell services, the small cell base stations are required to share the spectrum resources with traditional cellular network. Therefore, strong interference may occur between the macrocells and small cells and aggravate the performance of mobile data services. Accordingly, as shown in the Fig. 3, the small cell service network is required to cognitively sense the usage of resource layer of traditional

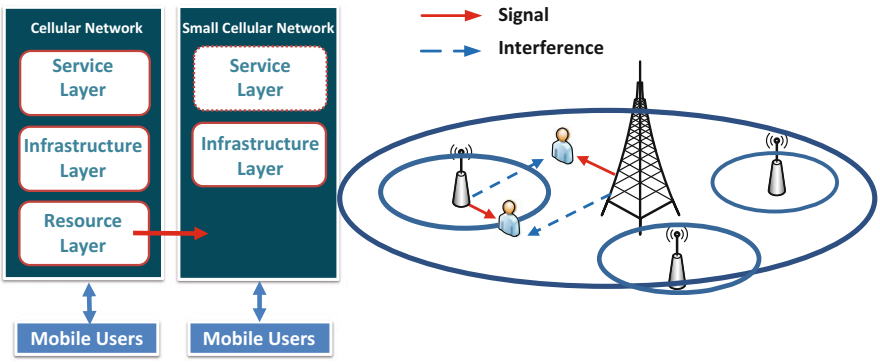

Fig. 3 The mobile data service in heterogeneous network

cellular network and smartly allocate some licensed spectrum with proper transmit power to guarantee the performance of mobile users in traditional cellular network.

Based on the service architecture, further spectrum allocation between the macrocell and small cells have been studied in literature. In [10], in order to obtain sufficient spectrum resources, wireless cooperations are established where the small cell base stations help macrocell base stations to off-load some data services and gain licensed spectrum as rewards. In [11], the optimal power strategies have been analyzed considering the possible cheating behaviors of small cells during the wireless cooperation between small cells and macrocells.

The Mobile Data Service with Visible Light Communication

Visible light communication (VLC) utilizes the illuminating LED for mobile data transmission, which can provide large amount of spectrum resources for wireless data transmission. However, because of the natural property of the visible light, transmission signals are easy to be blocked or severely interfered by other lighting sources. Thus, the coverage region for VLC is limited. Considering the ubiquitous distribution of mobile devices, it is promising to combine the VLC with device-to-device communication (D2D) to help serve mobile users [12]. As shown in Fig. 4, during the service, the VLC network is required to rent the mobile devices from other networks and allocate licensed spectrum for the D2D communication from cellular networks. The whole data service process cannot be finished with the facilities and resources of the VLC networks alone.

Future Service Architecture

According to above analysis, compared with the traditional service architecture, the infrastructure layer and resource layer tends to be separated from its service layer and flexibly allocated to other service providers. Moreover, as the service provider is able to rent the facilities and resources from other networks, it may reduce the total

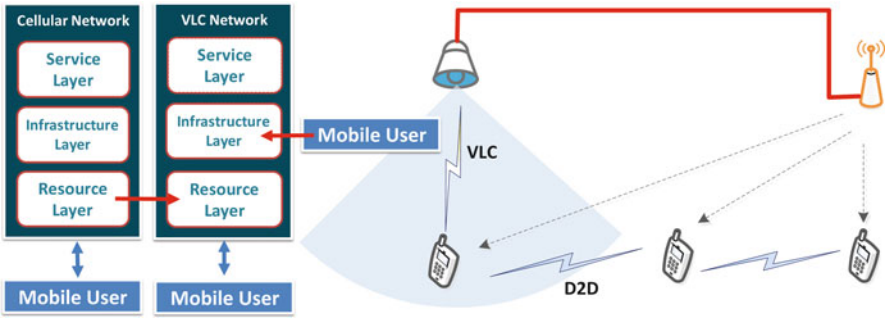

Fig. 4 The mobile data service with VLC

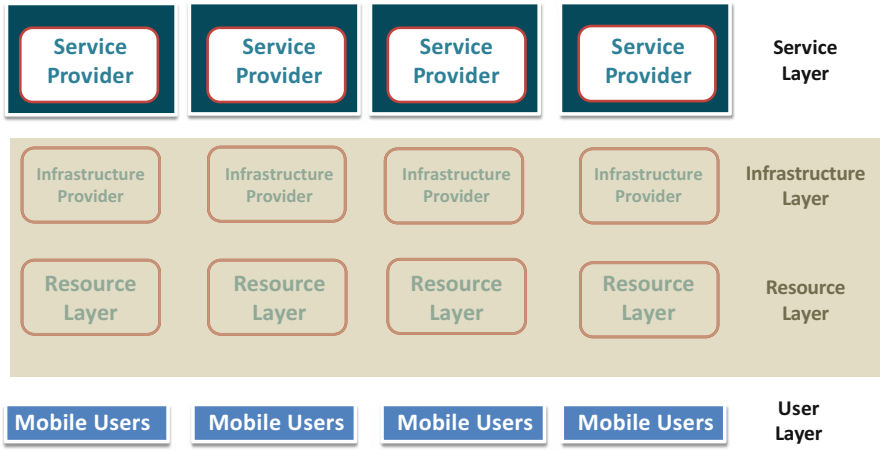

Fig. 5 Future service architecture

amount of purchasing facilities and resources for data services. Thus, there exist new infrastructure providers or resource providers which purchase and maintain the facilities or resources only and provide them to the service providers.

Based on the above, we depict the future service architecture as shown in Fig. 5, where there exist multiple service providers, infrastructure providers, and resource providers in the service layer, infrastructure layer, and resource layer, respectively. The service providers, infrastructure providers, and resource providers are autonomous companies or individuals, which are able to make smart decisions independently for high revenues. Notably, based on different purposes and requirements, some companies or individuals may act as some service providers, infrastructure providers, and resource providers at the same time.

During the data service, due to the security and complexity of the network, the infrastructure layer and resource layer are unknown to mobile users. Thus, the mobile users are only required to determine its service providers for its data services.

As the service provider actually doesn't provide any physical connections and services for the mobile users, we denote the interactions between the service providers and mobile users as a virtualized network, where the virtualized data services are able to be offered by the service providers based on all kinds of requirements of subscribed mobile users. In order to map the physical data connections and services to the virtualized network, the service provider is required to motivate infrastructure provider and resource provider to offer suitable facilities and resources for the data services the mobile users. Accordingly, based on the motivation and selection of service providers, some infrastructure provider and resource provider are able to provide suitable physical facilities and resources for the data services of mobile users. Thus, the facilities and resources in the mobile network can be flexibly and efficiently adopted, and all service providers, infrastructure providers, resource providers, and mobile users are able to achieve high revenues from the data services.

Hierarchical Game Analysis for Resource Allocation

Considering the future service architecture, all service providers, infrastructure providers, resource providers, and users are assumed to be autonomous and selfish, which are required to make decisions distributively to achieve high revenues for themselves. Game theory, which has been shown as an effective and powerful tool, can be applied for the distributed resource allocation problem in the modeled service architecture [13]. In this chapter, based on the relations among all service providers, infrastructure providers, resource providers, and mobile users, a hierarchical game approach is proposed, which consists of three sub-games corresponding to the interactions between service providers and mobile users, between service providers and infrastructure and resource providers, and between infrastructure and resource providers and mobile users. As shown in Fig. 6, following the sequential manner, we summarize the hierarchical game structure as follows:

- We first consider the virtualized data service between the service providers and mobile users as Stackelberg game, where the service providers, acting as leaders, charge mobile users for their virtualized data services, and the mobile users, i.e., the followers, determine the total amount of virtualized resources to purchase to achieve high utilities. The utility of the mobile users is defined as the total revenues received from the mobile data service minus service delay penalty as well as the payment for service providers. The utility of the service provider consist of the total income from the mobile users' payment minus the rewards for motivating the infrastructure & resource providers.
- Based on the prediction of subscribed virtualized data services from the mobile users, the service providers motivates the infrastructure providers and resource providers to offer physical facilities and resources for the data services with moral hazard, considering the utility of each infrastructure & resource provider, which is defined as the total rewards minus the cost for serving different mobile users.

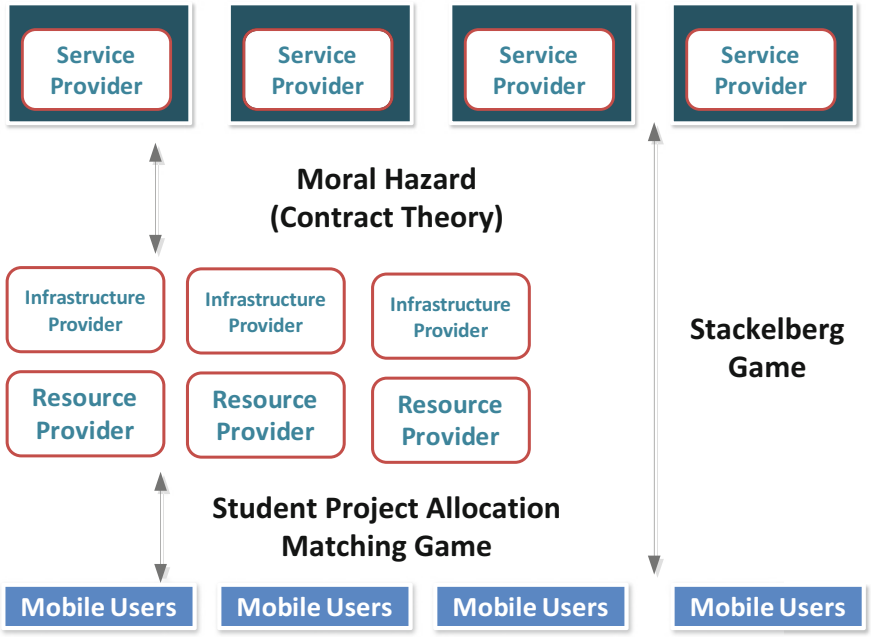

Fig. 6 Hierarchical game model

- According to the total amount of offered resources in physical facilities from infrastructure & resource providers and the total amount of virtual resource requested by the mobile users, a student-project allocation matching game is employed between resources and mobile users, where the mobile users prefers to be served with high QoS, while the infrastructure & resource providers selects its preferred mobile users based on the ratio of collected rewards over the service delay.

In the following sections, with backward induction, we sequentially analyze the interactions between the players within two different layers, which are the interactions between infrastructure and resource providers and mobile users, between service providers and infrastructure and resource providers, and between service providers and mobile users, so as to determine the optimal strategies for all service providers, infrastructure providers, resource providers, and mobile users.

Interactions Between Infrastructure and Resource Providers and Mobile Users

In this section, we suppose the offered facilities and the amount of resources from the infrastructure and resource providers and the requested amount of resources from each mobile user are known. The resource is defined as the combination of both

computation and storage resources within the offered facilities and radio resources from the offered facilities to the mobile users, which is regarded as a resource pair and mapped to requested mobile users. The mapping between the resource pairs and mobile users can be suitably modeled as a student project allocation problem [14], which belongs to a many-to-many stable matching problem. The original problem is described as follows. During the studies in universities, students are instructed to select a number of projects in classes by lecturers. With different judgements, students have different preferences on the projects. Aiming to train students for their expertise, the lecturers may also have different preferences over different (student, project) pairs. In order to guarantee the quality of the class, the maximum number of joining students for each project is constrained, called the capacity of the project. Accordingly, based on the preferences of both students and lecturers, it is expected to achieve a stable matching result where no students in the matched (student, project) pairs are able to find other available projects with higher preferences.

When mapping the student project allocation problem to the resource allocation problem in mobile data service network, the service providers, resource pairs, and mobile users act as lecturers, projects, and students, respectively [15]. The preference list of each mobile user is established according to the total profits obtained from the mobile data service minus delay penalty as well as the payment to the service provider. Moreover, in the perspective of the service provider, the payment from the mobile users is able to increase its revenues, while the service delay with a certain resource pair reduces its profits. Thus, the service providers set high priorities to the mobile users which are willing to pay high prices. The preference list of each service provider over a certain resource pair is based on the ratio of price collected from a mobile user over its delay. In order to achieve a stable matching between service providers and mobile users, the SPA-(S,P) algorithm can be adopted based on the set-up preference lists of both sides [15, 16]. In the algorithm, according to the preference list, each mobile user firstly proposes to its currently most preferred resource pair. For each resource pair, if the total amount of proposals from mobile users exceeds its capacity, then the service provider ranks the combination of resource pairs and mobile users based on its preference list, selects the worst one and rejects its corresponding mobile user. Receiving the rejected notification, the mobile user deletes the resource pair from its preference list and continues to propose to the next favorite one in its list. The proposals of all mobile users iterates until all mobile users are either matched with a resource pair or have an empty preference list. By the iterated proposing and rejecting actions of mobile users and service providers, the algorithm is guaranteed to converge eventually, with a stable matching result.

In Fig. 7, we evaluate the relations between mobile users and service delay with the proposed SPA-(S,P) algorithm. When the number of mobile increases, due to the limited amount of resource pairs, generally, the ratio of mobile users which are qualified for the delay requirement decreases. Compared with the random matching result, the ratio of mobile users with low delays in the proposed SPA-(S,P) algorithm is able to keep in higher values.

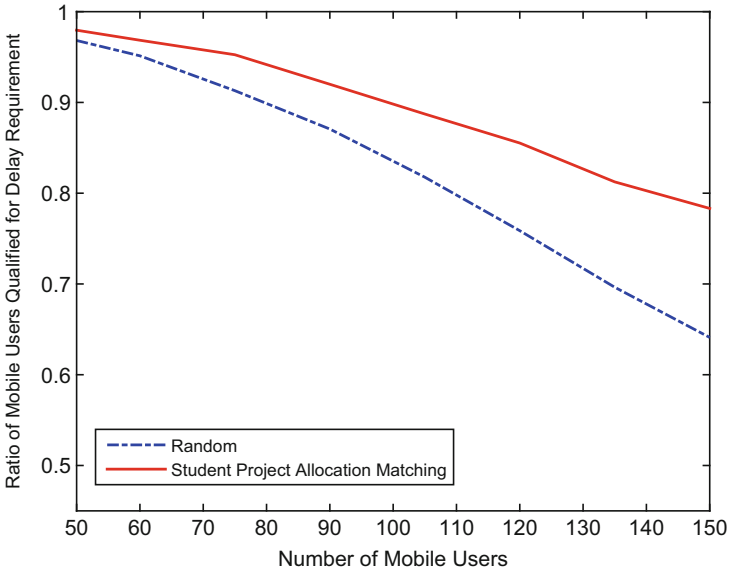

Fig. 7 The performance evaluation of SPA-(S,P)

Interactions Between Service Providers and Infrastructure and Resource Providers

Considering the possible matching results between the infrastructure and resource providers and mobile users, given the amount of subscribed virtual resource from mobile users, each service provider is required to consider the motivation strategies for infrastructure and resource providers to supply the suitable facilities and resources with high QoS for mobile users.

The motivation problem from mobile users to infrastructure and resource providers can be considered as a moral hazard in contract theory. The problem of moral hazard refers to the situations that the employees' actions are hidden form the employers [17]. As the service provider, acting as employers, do not know the resource usage information within each infrastructure and resource provider, if one service provider off-loads its mobile data services to infrastructure and resource providers with limited resource or facilities far from mobile users, the mobile users will suffer poor QoS and switch to other service providers. Accordingly, such a kind of asymmetric information between service providers and infrastructure and resource providers severely reduces the revenues of both service providers and mobile users.

In order to overcome the problem, a resource payment bundle (a, r) in the contract is proposed between service providers and infrastructure and resource providers. a refers to the physical facilities and resources offered by infrastructure and resource providers, and r denotes rewards from service providers to

infrastructure and resource providers. Therefore, in order to motivate the infrastructure and resource providers to offer more physical facilities and resources, the rewards r should be increased correspondingly. Notably, considering different data requirements, usage and transmission distance between infrastructure and resource providers and mobile users, the relations between a and r is also different.

In order to motivate infrastructure and resource providers to offer sufficient resource and suitable facilities, when one infrastructure and resource provider agrees to provide resources or facilities for mobile users, the service provider pays fixed payment to the infrastructure and resource providers. Furthermore, if the infrastructure and resource provider can offer more resource to improve the QoS of mobile users, the service operator will supplement an extra bonus. Thus, the rewards from each service operator to infrastructure and resource providers can be denoted as the addition of both the fixed payment plus extra bonus. The utility of each infrastructure and resource provider is defined as the total rewards from service providers minus the costs of operations. The utility of each service provider is denoted as the revenues from mobile users minus the total rewards for infrastructure and resource providers. In order to maximize the utility of each service provider with the selfish behaviors of infrastructure and resource providers, the optimal value of fixed payment and extra bonus is determined for each infrastructure and resource provider in a contract.

In simulation results, the proposed payment method is compared with four other motivation strategies. In the single bonus plan, we assume each infrastructure and resource provider can offer limited amount of resource to each service provider. In the stochastic independent plan, we assume the measurement error from the service operator to all infrastructure and resource providers equals zero. For the technologically independent plan, the cost for adopting resource within each infrastructure and resource provider is assumed to be independent from each other. The independent plan combines both stochastic independent and technologically independent plans. As shown in Fig. 8, when the cost coefficients of resource increase, as the service operator should pay more to motivate infrastructure and resource providers, the utility of the service provider generally decreases. Furthermore, when the amount of asymmetric information between service providers and infrastructure and resource providers increases, the utility of service provider decreases. Accordingly, the utility of the service provider in the independent payment plan is the highest, followed by the utilities in the stochastic independent plan, technologically independent plan, and our proposed plan. The single bonus plan has the lowest utility, due to the limited amount of offered resource.

Interactions Between Service Providers and Mobile Users

Considering the motivation strategies for infrastructure and resource providers and the matching results between the offered physical resources and the requested virtualized resource, each service provider determines its service price to the mobile users for high utility. In the virtualized data service network, all service providers

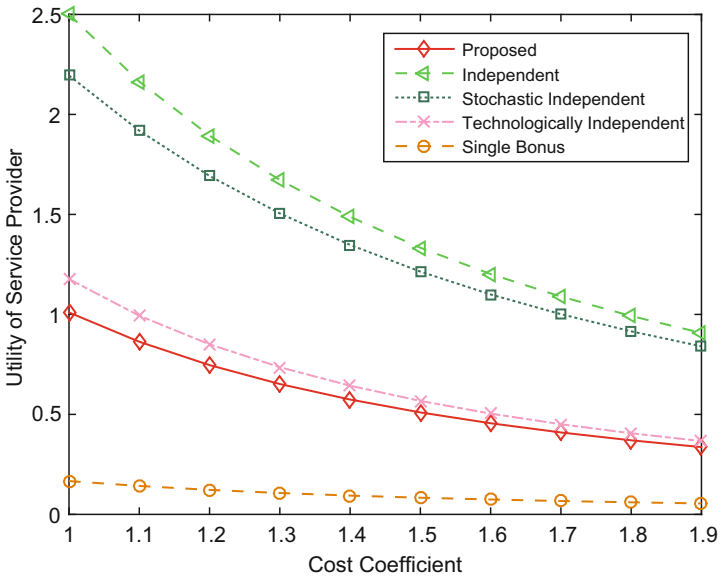

Fig. 8 The performance in moral hazard between service providers and infrastructure & resource providers

first broadcast the prices of their virtualized services. Based on different prices, each mobile user selects its preferred service provider and purchase optimal amount of virtual resources. The relations between service providers and mobile users can be modeled as Stackelberg game, where the service providers play as the leaders and the mobile users play as the followers. Due to the first-mover advantage, each service provider is able to predict the reactions of its serving mobile users and set its optimal service price for the highest utility. As neither service providers nor mobile users are able to change its behaviors for higher utility, the Stackelberg equilibrium exists between service providers and mobile users [18, 19].

Furthermore, the service providers also compete with each other to serve mobile users. If one service provider sets prices much higher than other service providers, the mobile users may switch to other service providers for low payment. Therefore, in the relations among multiple service providers, there is also a noncooperative game. Accordingly, in order to attract more mobile users and maintain high utility at the same time, each service provider can follow the sub-gradient algorithms in [18, 19], where each service provider initially sets its service price in high values and no mobile users are willing to choose its data services. Based on the utility it can achieve, the service provider then adjusts its service price with a small value. If the adjustment is able to improve the utility, the service provider set the adjusted prices in the next round. If the adjustment reduce the utility, the DSO keeps the service price unchanged in the next round. The iteration continues with reduced size of adjustment values until no service operators can change its prices for higher utility.

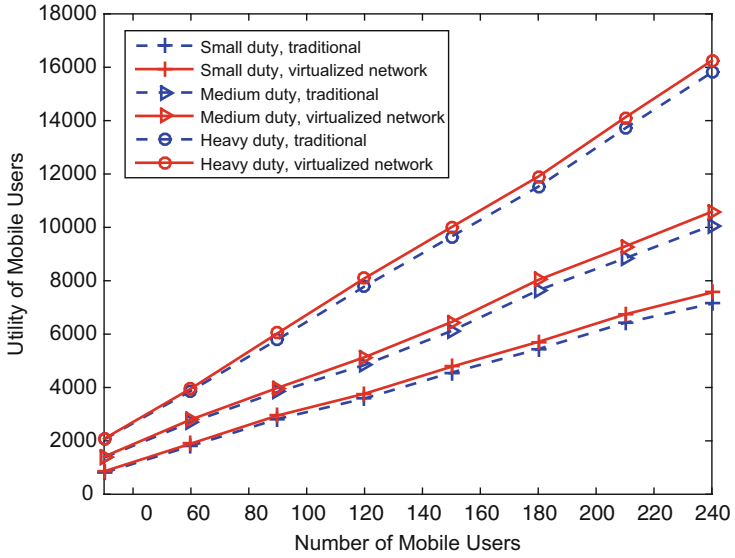

Fig. 9 The utility of all mobile users versus the number of mobile users

Based on the strategies of service operators and mobile users in the Stackelberg game, we evaluate the performances of mobile users in mobile data service network. As shown in Fig. 9 [19], when the number of mobile users increases, whatever the data size for services, the total utility of mobile users generally increases. In addition, when the service price of the service providers and data size for services are fixed, due to the flexible resource allocation with low transmission delay, the utility of the mobile users in the virtualized network performs better than the utility in traditional network. Nevertheless, as the service providers can announce high prices in the virtualized network to gain high revenues, the improvement gap of the mobile users utility from virtualized network to the traditional network is limited.

Conclusion Remarks and Future Works

With all kinds of distributions and demands from mobile data services and applications, the mobile network is becoming increasingly complicated. In order to meet the requirements of all mobile users, the network virtualization is the current trends for resource allocation and management. In this chapter, we first put forward the mobile data service framework, which is constitute of service layer, infrastructure layer, resource layer, and user layer. Based on the distributed and autonomous behaviors of service providers, infrastructure providers, resource providers, and users, the hierarchical game approach is proposed based on the general data service architecture, which provides distributed strategies for each service provider, infrastructure provider, resource provider, and user to gain high and stable revenues.

Based on the three-layer hierarchical game architecture, there are still potentials to analyze the optimal strategies of service operators, infrastructure and resource providers, and mobile users suitable to different scenarios. In this section, we list several future research directions that can be explored in mobile data service network.

Considerations of Both Competitive and Coordinated Behaviors for Service Providers

In the network, not only the competitive strategy but also some coordinated behaviors may exist among the service providers. The coordination among service providers are able to improve the total utility, but the fairness cannot be guaranteed. In order to further improve the total utilities of coordinated service providers, some potential coordinated algorithms can be considered. Following the ideas in [20], the Kalai-Smorodinsky bargaining game can be designed among service providers when setting prices to mobile users. The Kalai-Smorodinsky bargaining game is able to maintain the ratios of maximal gains when all coordinated service providers set prices, so the fairness among service providers can be guaranteed.

Coalition Game Among Infrastructure and Resource Providers

During the resource allocation between physical resource provided by the infrastructure and resource providers and the virtualized resource requested by the mobile users, if there exist cooperations before the matching, the utility of both infrastructure and resource providers and mobile users can be further improved. In [21], a combination of coalitional game and matching game is proposed. As the coalitions of infrastructure and resource providers are able to improve quality of matching results, the total utility is proved to have significant improvement. Therefore, in the student project matching game between infrastructure and resource providers and mobile users, if the infrastructure and resource providers are able to cooperate and form coalitions, the mobile users may be able to further receive higher QoS with low costs.

Switches Between Infrastructure and Resource Providers and Mobile Users

As the mobile users and infrastructure and resource providers may switch to each other, the mobile users and infrastructure and resource providers may be regarded as the same type of players. Considering the possible data transmission between any pair, a graphical game is a promising analytical tool [12], where players are regarded as nodes and the transactions between players are denoted as edges. Accordingly, a general graph is formed where each node considers its optimal

strategies. As the graphical game design considers the flexible switches between infrastructure and resource providers and mobile users, the total utility for each mobile user or infrastructure and resource provider within a long-time interval may be significantly improved.

Contents

Abstract

In cognitive radio networks, service providers with spare channels can sell the spectrum to those in need of them. The redistribution of the spectrum among service providers reduces the waste of spare spectrum, therefore enhances the spectrum utilization. It also provides the service provider more revenue from the sail of spectrum. Traditional method of spectrum trading mainly based on double auction, which requires an auctioneer, is a trustworthy third-party authority, to centrally enforce a certain spectrum allocation policy. In this chapter, we take a

different and new perspective, proposing to use matching as an alternative tool to realize spectrum trading in a distributed way for a free market, which consists of only buyers and sellers, without a trustworthy third-party authority. In this chapter, we will first give a brief introduction of the whole chapter in the first section and then present the fundamentals of the matching theory in the second section. In the third section, matching theory is leveraged in spectrum trading among service providers to decide the spectrum allocation and trading price, the distinctive challenge of spectrum matching compared with conventional matching is analyzed, and a two-stage distributed algorithm is proposed to solve the spectrum matching problem. In the fourth section, we considered a more general case, where multiple channels can be bought by the same service provider, and the spectrum matching algorithm for combinatorial spectrum trading is proposed to enable the spectrum allocation. For both algorithms, the proposed algorithm can achieve a Nash-stable matching, and the simulation shows that the proposed algorithms achieve good performance compared with centralized schemes.

Introduction

To support the ever-increasing volume of wireless traffic with limited spectrum availability, dynamic spectrum access has been proposed to better leverage the underused channels [1, 2]. A wireless service provider can sell spare spectrum to others when her traffic demand is light and buy additional spectrum from others when her demand becomes heavy. Conventionally, such spectrum exchange is assumed to be achieved via double auctions, where a third-party auctioneer determines the spectrum allocation in a centralized manner, based on auction participants' bids and certain optimization objectives.

A truthful spectrum double auction was first proposed in [3]. In [4], a multi-auctioneer progressive auction mechanism was designed, with all sellers assuming the role of auctioneers. In [5], local availability of the spectrum license and its influence on spectrum auctions were studied. In [6, 7], heterogeneous interference graphs for different channels were built for spectrum reuse. Apart from single-round auction mechanisms, dynamic spectrum auction mechanisms were proposed in [8, 9]. The major drawback of double auctions is the need for a third-party authority to enforce the spectrum allocation in a centralized way, which is not applicable for the free spectrum markets with only buyers and sellers but no third-party rule-enforcing authorities.

Taking a completely different viewpoint, we propose to leverage *matching* as an alternative framework for spectrum redistribution. The seminal work of Gale and Shapley [10] pioneers the research on matching items in two different sets

with stability. The concept of stable matching, compared with optimal matching (i.e., the social welfare of buyers and sellers is the highest), matters more in free spectrum markets for two reasons. Firstly, stable matching ensures that no buyer or seller is willing to deviate from the current matching result. Optimal matching, if unstable, will not be obeyed by buyers and sellers, unless it is enforced by a third-party authority. Secondly, stable matching can be realized through *deferred acceptance*, an algorithm that is both efficient and fully distributed. Stable matching has been widely applied to computer science, such as resource management in the cloud [11], user association in small cells [12], as well as resource sharing in device-to-device communication [13]. We will introduce the fundamentals of matching theory in section "Fundamentals on Matching Theory".

Finding a stable matching in free spectrum markets is quite challenging. In this chapter, we refer this challenge problem as the *spectrum matching* problem. This spectrum matching problem is quite different from traditional matching problems, such as the well-known college admission problem [10]. In the college admission problem, each student can attend only one college, and each college can admit multiple students but subject to a fixed quota. In spectrum matching, the fundamental constraint is no longer fixed quotas but *interference:* non-interfering buyers can freely reuse the same channel, while interfering buyers have to operate on separate channels. In other words, the "quota" of a channel is infinite for non-interfering buyers but reduced to one for interfering buyers. The unique feature of spectrum reusability has been widely discussed in spectrum auctions yet has never been considered within a stable matching framework.

In section "System Model", we propose to use the spectrum matching framework as a new economic model for distributed spectrum exchange in free spectrum markets. Sellers who own multiple channels and buyers who demand multiple channels are represented by corresponding numbers of dummies. In this way, spectrum exchange can be formulated as a many-to-one matching problem, where a buyer can be matched to no more than one seller and a seller can be matched to multiple non-interfering buyers (spectrum reuse). To address spectrum heterogeneity, different interference graphs are constructed for different channels to determine spectrum reuse.

In this context, we propose a two-stage distributed algorithm to achieve the objective of stable spectrum matching (section "Spectrum Matching"). The final matching result is proved to be individual rational and Nash-stable. Through extensive simulations, we demonstrate that our proposed distributed algorithm can achieve more than 90% of the maximum social welfare obtained by centralized optimal (but unstable) matching.

In section "Spectrum Matching", a more general case is considered, where multiple channels can be bought by the same service provider, and the value of multiple spectrum combination is different from the sum of each spectrum, which is a unique characteristic of spectrum compared with other commodity. Under this scenario, the spectrum matching algorithm for combinatorial spectrum trading is proposed to enable the spectrum allocation. Buyers can freely express their preferences for different combinations of channels, and the same channel can

be reused by multiple non-interfering buyers. To address spectrum heterogeneity, different interference graphs are constructed for different channels to determine spectrum reuse [7]. We prove that the matching result is individual rational, strong pairwise stable, and is a subgame-perfect Nash equilibrium of the corresponding spectrum bargaining game. Extensive simulations are conducted to evaluate the performance of the proposed many-to-many spectrum matching framework. It is shown that it takes only a few iterations for the proposed algorithm to reach a stable matching result.

Fundamentals on Matching Theory

Gale and Shapley first studied the problems of stable matching in [10] and proposed the deferred-acceptance algorithm to achieve a stable matching in a distributed way.

The stable marriage problem has been stated as follows: Given n men and n women, where each person has ranked all members of the opposite sex in order of preference, marry the men and women together such that there are no two people of opposite sex who would both rather have each other than their current partners. When there are no such pairs of people, the set of marriages is deemed stable.

David Gale and Lloyd Shapley [10] proved that, for any equal number of men and women, it is always possible to solve the SMP and make all marriages stable. They presented an algorithm to do so.

The Gale-Shapley algorithm involves a number of "rounds" (or "iterations"). In the first round, first (a) each unengaged man proposes to the woman he prefers most, and then (b) each woman replies "maybe" to her suitor she most prefers and "no" to all other suitors. She is then provisionally "engaged" to the suitor she most prefers so far, and that suitor is likewise provisionally engaged to her. In each subsequent round, first (a) each unengaged man proposes to the most preferred woman to whom he has not yet proposed (regardless of whether the woman is already engaged), and then (b) each woman replies "maybe" if she is currently not engaged or if she prefers this guy over her current provisional partner (in this case, she rejects her current provisional partner who becomes unengaged). The provisional nature of engagements preserves the right of an already-engaged woman to "trade up" (and, in the process, to "jilt" her until-then partner). This process is repeated until everyone is engaged. The algorithm is also called defer and acceptance algorithm.

This algorithm guarantees that:

- *Everyone gets married*: At the end, there cannot be a man and a woman both unengaged, as he must have proposed to her at some point (since a man will eventually propose to everyone, if necessary) and, being proposed to, she would necessarily be engaged (to someone) thereafter.
- *The marriages are stable*: Let Alice and Bob both be engaged, but not to each other. Upon completion of the algorithm, it is not possible for both Alice and Bob to prefer each other over their current partners. If Bob prefers Alice to his current partner, he must have proposed to Alice before he proposed to his current

partner. If Alice accepted his proposal, yet is not married to him at the end, she must have dumped him for someone she likes more and therefore does not like Bob more than her current partner. If Alice rejected his proposal, she was already with someone she liked more than Bob.

Afterwards, the research in economics explores all kinds of variants of matching problems [14, 15]. Matching has been widely used for resource allocation in computer science. In [11], online and offline algorithms were proposed to match virtual machines to heterogeneous sized jobs in the cloud. In [12], matching was used to associate users to small cells. In [13], device-to-device users were matched to cellular users for resource sharing. In [16], secondary users were matched to primary users for data relay. In [17, 18], a friendly jammer was matched to a transmission pair to help protect them from eavesdropping.

Non-combinatorial Many-to-Many Spectrum Matching

According to section "Fundamentals on Matching Theory", stable matching compared with optimal matching (i.e., the social welfare of buyers and sellers is the highest) matters more in free spectrum markets for two reasons. Firstly, stable matching ensures that no buyer or seller is willing to deviate from the current matching result. Optimal matching, if unstable, will not be obeyed by buyers and sellers, unless it is enforced by a third-party authority. Secondly, stable matching can be realized through *deferred acceptance*, an algorithm that is both efficient and fully distributed. Stable matching has been widely applied to computer science, such as resource management in the cloud [11], user association in small cells [12], as well as resource sharing in device-to-device communication [13]. Stable matching can also be used in spectrum trading problem.

Unfortunately, the *spectrum matching* problem is quite different from traditional matching problems, such as the well-known college admission problem [10]. In the college admission problem, each student can attend only one college, and each college can admit multiple students, but subject to a fixed quota. In spectrum matching, the fundamental constraint is no longer fixed quotas but *interference:* non-interfering buyers can freely reuse the same channel, while interfering buyers have to operate on separate channels. In other words, the "quota" of a channel is infinite for non-interfering buyers but reduced to one for interfering buyers. The unique feature of spectrum reusability has been widely discussed in spectrum auctions yet has never been considered within a stable matching framework.

In this section, we introduce the spectrum matching framework as a new economic model for distributed spectrum exchange in free spectrum markets (section "System Model"). Sellers who own multiple channels and buyers who demand multiple channels are represented by corresponding numbers of dummies. In this way, spectrum exchange can be formulated as a many-to-one matching problem, where a buyer can be matched to no more than one seller and a seller can be

matched to multiple non-interfering buyers (spectrum reuse). To address spectrum heterogeneity, different interference graphs are constructed for different channels to determine spectrum reuse.

In this context, we propose a two-stage distributed algorithm to achieve the objective of stable spectrum matching (section "Spectrum Matching"). Stage I is inspired by the deferred-acceptance (Gale-Shapley) algorithm, which we adapt to enable spectrum reuse and avoid interference among buyers. Stage I converges to an interference-free but unstable matching, due to the complicated interference relationship among buyers. Therefore, we introduce Stage II, which allows buyers to transfer to more preferred channels and sellers to invite previously rejected buyers, if the interference condition permits. The final matching result is proved to be individual rational and Nash-stable.

To address the synchronization problems in the real implementation of the proposed two-stage algorithm, i.e., buyers and sellers are not coordinated to end Stage I and enter Stage II simultaneously, we design rules for individual buyers and sellers to independently decide the timing of their stage transition (section "Implementation of Spectrum Matching").

Through extensive simulations (section "Simulation"), we demonstrate that our proposed distributed algorithm can achieve more than 90% of the maximum social welfare obtained by centralized optimal (but unstable) matching. We also show the influence of different parameters on the final matching results. One interesting finding is that, if buyers have diverse utilities in using different channels, the overall social welfare will be higher, because more buyers will be matched to their desired channels.

System Model

Spectrum Market

In a free spectrum market, service providers with spectrum supply or demand serve as sellers or buyers, respectively. Spectrum reuse must conform to interference constraints.

Market participants. Assume that there are I sellers and J buyers in the spectrum market. Seller i owns m_i channels, and buyer j requests n_j channels. Let $\sum_{i=1}^{I} m_i = M$ and $\sum_{j=1}^{J} n_j = N$ denote the total numbers of supplied and demanded channels, respectively. Inspired by the idea in [7], we create m_i and n_j dummies for seller i and buyer j, respectively. Hence, there are M virtual sellers and N virtual buyers, and each virtual buyer or seller can trade only one channel. In the remainder of this chapter, we omit the term "virtual" without confusion (For simplicity, we assume that channels are independent from each other. Therefore, the value of a combination of channels is exactly the sum of values of each individual channel. We will consider that channels may be complementary or substitute goods (e.g., in a combinatorial auction) in the future. We also use the index of a seller for her channel, e.g., seller i's channel is referred to as channel i.

Utility of buyers and sellers. A service provider obtains different utilities when operating on different channels. We assume that buyer j has a utility vector $B_j = (b_{1,j}, b_{2,j}, \ldots, b_{M,j})$, in which $b_{i,j}$ is the utility for her to use channel i. The higher $b_{i,j}$ is, the more valuable channel i is to buyer j, and buyer j is willing to pay more for channel i. We assume that $b_{i,j}$ is also the price that buyer j offers to seller i. A seller's utility equals the total offered price of all buyers matched to her.

Interference relationship. The key feature of the spectrum resource is interference-restricted reuse. To characterize interference heterogeneity of different channels [7], we construct a series of interference graphs $\{G^i = (V, E^i)\}_{i=1}^{M}$, in which each node $v \in V$ represents a buyer and each edge $e^i \in E^i$ connects a pair of interfering buyers on channel i. If two virtual buyers originate from the same buyer, they are viewed as interfering buyers, since they should not be matched to the same channel. Let $e^i_{j,j'} \in \{0, 1\}$ denote the interference status between buyers j and j' regarding channel i.

Optimal Matching

We introduce the optimal matching as a benchmark to be compared later with our proposed stable matching. The optimal matching maximizes social welfare while complying with the interference constraint. Following the norm of spectrum auctions, we define social welfare as the sum of buyers' utility from acquiring the channels through spectrum matching. Let $\{x_{i,j}\}_{i=1,j=1}^{i=M,j=N}$ denote the matching result. $x_{i,j} = 1$ if and only if buyer j is matched to seller i. The optimal matching is the solution to the following centralized maximization problem:

$$\max_{x_{i,j}} \sum_{i=1}^{M} \sum_{j=1}^{N} b_{i,j} x_{i,j}, \tag{1}$$

$$\text{subject to} \sum_{i=1}^{M} x_{i,j} \leq 1, \forall j, \tag{2}$$

$$x_{i,j} \cdot x_{i,j'} = 0, \text{if } e^i_{j,j'} = 1, j \neq j', \forall i, j, j', \tag{3}$$

$$x_{i,j} \in \{0, 1\}, \forall i, j. \tag{4}$$

The first constraint indicates that each (virtual) buyer can only get one channel. The second constraint restricts that no interfering buyers can be matched to the same channel. The optimal matching, if unstable, can only be implemented by a third-party authority, who solves the above nonlinear integer programming problem, which is NP-hard. In comparison, our proposed distributed matching algorithm can reach an interference-free stable matching in linear time, and our simulation results show that it can achieve 90% of maximum social welfare yielded by the optimal matching.

Spectrum Matching

Preliminaries

We formally define spectrum matching as follows.

Definition 1 (Spectrum matching). Given the set of sellers $\mathscr{M}$ and the set of buyers $\mathscr{N}$, a spectrum matching is a function μ from $\mathscr{M} \cup \mathscr{N}$ to subsets of $\mathscr{M} \cup \mathscr{N}$, such that

- For every buyer $j \in \mathscr{N}$, $\mu(j) = \{i\}$ if buyer j is matched to seller i, and $\mu(j) = \{j\}$ if buyer j is unmatched;
- For every seller $i \in \mathscr{M}$, $\mu(i) \subseteq \mathscr{N}$;
- For every seller i and buyer j, $\mu(j) = \{i\}$ if and only if $j \in \mu(i)$.

In the traditional college admission problem, a preference profile is built for each student, indicating her willingness of attending different colleges; a preference profile is also built for each college, indicating its willingness of accepting different students. In spectrum matching, however, a buyer's willingness to be matched to a channel depends not only on her utility of using the channel but also on whether her interfering neighbors are matched to the same channel. In comparison, in the college admission problem, a student's willingness of attending a college will not be affected by other students at the same college. We assume that if a buyer is matched to a channel without her interfering neighbors, she obtains full utility; otherwise, she gets zero utility because of interference. To deal with such peer effects in spectrum matching, we construct preference profiles on spectrum coalition, rather than individual buyers or sellers. A spectrum coalition consists of a seller and the buyer's matched to this seller or includes a single unmatched seller or buyer.

For buyer j, we can construct a complete, reflexive, and transitive preference relation $\triangleright$ over all spectrum coalitions, based on her utility in the coalition. Assume that buyer j is a member of two coalitions C^{i_1} and C^{i_2}, containing seller i_1 and seller i_2, respectively. Buyer j prefers C^{i_1} to C^{i_2} in two cases: (1) buyer j prefers channel i_1 to channel i_2, and buyer j does not have any interfering neighbor in C^{i_1}; (2) buyer j has some interfering neighbors in C^{i_2}. We implicitly assume that a buyer is indifferent toward two coalitions both involving her interfering neighbors, and she is indifferent towards a coalition of herself (unmatched) and a coalition with her interfering neighbors.

$$C^{i_1} \triangleright_j C^{i_2} \Longleftrightarrow \begin{cases} \forall j' \in C^{i_1}, e^{i_1}_{j,j'} = 0, b_{i_1,j} > b_{i_2,j}, \text{or} \\ \exists j' \in C^{i_2}, e^{i_2}_{j,j'} = 1. \end{cases} \tag{5}$$

For seller i, we can also build a preference relation over all coalitions, based on her utility in the coalition. Assume that seller i is a member of two coalitions C^i and C'^i, containing different groups of buyers. Seller i prefers C^i to C'^i in two cases: (1) the total offered price of buyers in C^i is higher than that of buyers in C'^i, and buyers

in C^i are all noninterfering; (2) there are interfering buyers in C'^i. We also assume that a seller is indifferent toward two coalitions both involving interfering buyers, and she is indifferent toward a coalition of herself (unmatched) and a coalition with interfering buyers.

$$C^i \rhd_i C'^i \iff \begin{cases} \forall j, j' \in C^i, e^i_{j,j'} = 0, \sum\limits_{j \in C^i} b_{i,j} > \sum\limits_{j \in C'^i} b_{i,j}, \text{or} \\ \exists j, j' \in C'^i, e^i_{j,j'} = 1. \end{cases} \tag{6}$$

Distributed Matching Algorithm

Stage I: Adapted Deferred Acceptance

Algorithm 1 Stage I: adapted deferred acceptance

Initialization
$\forall i \in \mathcal{M}$, the waiting list $\mathcal{L}_i = \Phi$, the current proposer list $\mathcal{P}_i = \Phi$.
$\forall j \in \mathcal{N}$, the unproposed seller list $\mathcal{A}_j = \mathcal{M}$.

for all $j \in \mathcal{N}$ **do**
  if $\exists i, j \in \mathcal{L}_i$ **then**
    $\mu(j) = \{i\}$.
  else
    $\mu(j) = \{j\}$.
  end if
end for

The traditional deferred-acceptance algorithm, designed to solve the college admission problem, runs as follows [10]. There is a set of students to be admitted to a set of colleges, each with a fixed quota. In the first round, each student applies to her favorite college. Among all applicants, a college with a quota q temporarily puts the top q students in the waiting list, or all students if the number of applicants is smaller than q, and rejects others. In the following rounds, each rejected student applies to her most preferred college which has never rejected her before. Each

college updates its waiting list by selecting the top q students among the current applicants and those in the previous waiting list. This process is repeated until all students have exhausted their applications.

We adapt the original deferred-acceptance algorithm for spectrum matching in Algorithm 1. Unlike the college admission problem, we are not able to determine the "quota" of each seller, since the "quota" depends on the interference relationship among buyers. Instead, at each round, we let a seller to form her most preferred spectrum coalition, i.e., to select a group of buyers who do not interfere with each other according to the interference graph, and whose total offered price is the highest. To find a group of non-interfering buyers with maximum offered price is equivalent to finding a maximum weighted independent set on the interference graph, which is NP-hard. Greedy algorithms have been proposed to solve the maximum weighted independent set (MWIS) problem in linear time [19], which we will adopt in our algorithm.

Proposition 1. *Algorithm 1 is guaranteed to converge, and the running time is* $O(MN)$.

Proof. Each time an unmatched buyer makes a proposal, she will remove one seller from her unproposed seller list. Therefore, each buyer will eventually become matched or exhaust her unproposed seller list; thus, Algorithm 1 comes to an end.

The worst case is that the interference graph on every channel is a complete graph. Then, the spectrum matching problem is reduced to a one-to-one matching problem, and Algorithm 1 is equivalent to the original deferred-acceptance algorithm, whose running time is $O(MN)$.

Toy example. As shown in Fig. 1, there are five buyers $\{1, 2, 3, 4, 5\}$ and three sellers $\{a, b, c\}$. The interference graph on each channel is shown in Fig. 1a; the buyers' utility vectors are shown in Fig. 1b. We make the simplified assumption that $f(b_{i,j}) = b_{i,j}$. Figure 2 shows the process of the adapted deferred-acceptance algorithm. In the first round, buyer 1 and buyer 2 propose to seller a; buyer 3

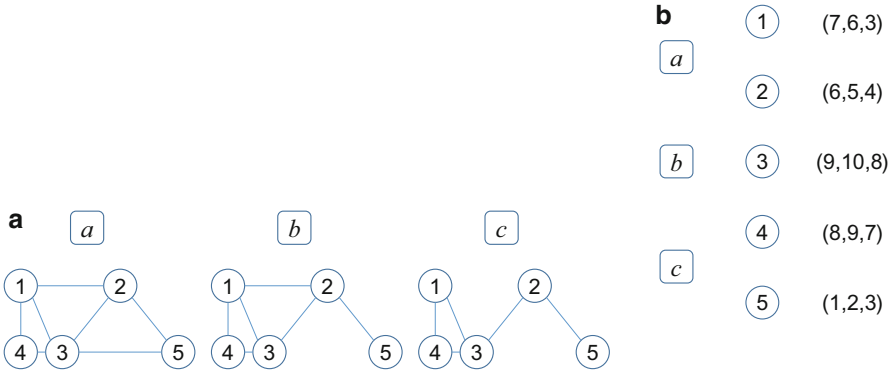

Fig. 1 Toy example. (**a**) Interference graph. (**b**) Preference relations

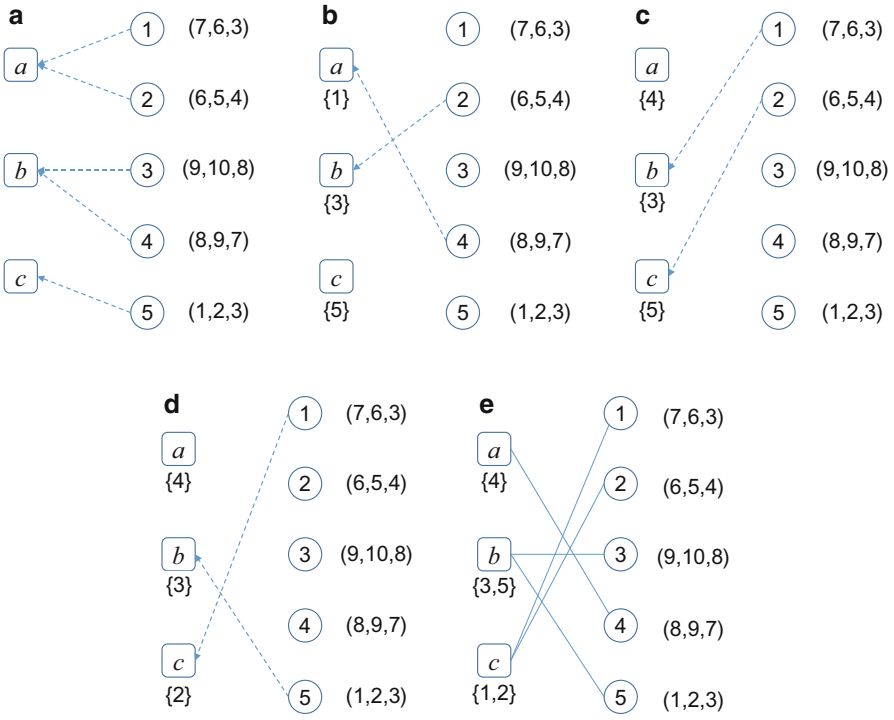

Fig. 2 Stage I: adapted deferred acceptance. (**a**) First round proposal. (**b**) Second round proposal. (**c**) Third round proposal. (**d**) Fourth round proposal. (**e**) Matching result

and buyer 4 propose to seller b; and buyer 5 proposes to seller c, as shown in Fig. 2a. After the first round, all sellers' waiting lists are shown in Fig. 2b. Then, the unmatched buyer 2 and buyer 4 propose to seller b and seller a, respectively. Seller a evicts buyer 1 to form a better coalition with buyer 4 in the waiting list. Figure 2c, d shows the following rounds, and the final matching result is shown in Fig. 2e, with a social welfare of 27.

Stage II: Transfer and Invitation

The deferred-acceptance algorithm produces a stable matching result for college admission problem [20], i.e., there is no pair of student and college who both prefer each other to their current choices. However, the matching result of the adapted deferred-acceptance algorithm is not stable for spectrum matching. For instance, in Fig. 2e, buyer 2 can be matched to seller a without interfering with buyer 4, and both buyer 2 and seller a are better off. This instability is a result of the peer effect of spectrum matching, caused by complicated interference relationship among buyers. Buyer 2 has a better chance of being chosen by seller a in the presence of her non-interfering buyer 4, but a worse chance in the presence of her interfering neighbor 1 (e.g., in the first round).

To improve the matching result and achieve a stable matching, we propose a transfer and invitation algorithm as a second stage, as shown in Algorithm 2. At Stage II Phase 1, buyers send transfer applications to sellers who are more preferred than their currently matched sellers. This means that buyers send transfer applications to sellers whom they have proposed to in Stage I. But unlike Stage I, sellers cannot evict any currently matched buyers in Stage II. Hence, a buyer's transfer application to a seller can only be accepted if she does not interfere with any buyers matched to the seller. In Stage I, we do not allow buyers to re-propose to sellers who have rejected them, because this may lead to ping-pong effect, where buyers continuously make proposals and the algorithm never converges. In Stage II, such ping-pong effect would not happen because each buyer can only send transfer application *once* to each seller who is more preferred than her currently matched seller, and the number of such sellers is *limited*.

At Stage II Phase 2, as a seller's previously matched buyers may have transferred to other sellers, she can invite some of the buyers whom she has rejected in Phase 1. In simulations, we find that the invitation opportunities are scarce, but Stage II Phase 2 has to be included to guarantee the stability of the final matching result.

Toy example. Figure 3 shows the process of our transfer and invitation algorithm. Given the matching result in Fig. 2e, buyer 1 and buyer 2 send transfer applications

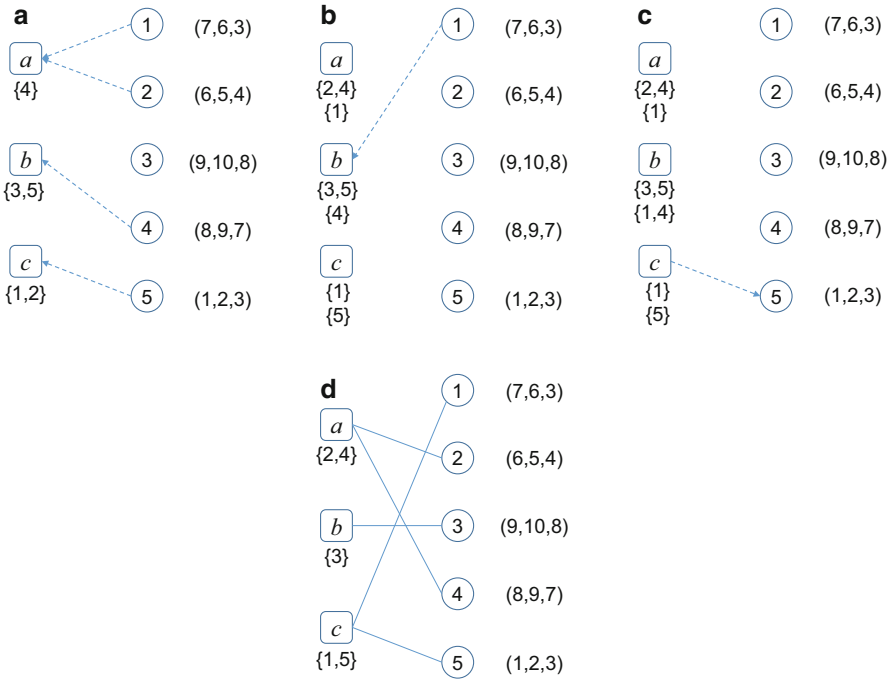

Fig. 3 Stage II: transfer and invitation. (**a**) First round transfer. (**b**) Second round transfer. (**c**) First round invitation. (**d**) Final matching result

to seller a; buyer 4 sends transfer application to seller b; and buyer 5 sends transfer application to seller c. Buyer 2's application is granted, while other buyers are rejected and added to the sellers' rejecting lists, shown under the matching lists. After Phase 1, seller c sends invitation to buyer 5, and the final matching result is shown in Fig. 3d, with a social welfare of 30.

Algorithm 2 Stage II: transfer and invitation

Initialization
$\forall i \in \mathscr{M}$, the current applicant list $\mathscr{D}_i = \Phi$, the invitation list $\mathscr{R}_i = \Phi$.
$\forall j \in \mathscr{N}$, the unapplied seller list $\mathscr{T}_j = \{i | b_{i,j} > b_{\mu(j),j}\}$.
Phase 1: Transfer
while $\exists$ buyers with nonempty unapplied seller list **do**
  for all Buyer j with nonempty unapplied seller list **do**
    i = the most preferred seller in $\mathscr{T}_j$.
    Buyer j sends a transfer application to seller i.
    Add buyer j to seller i's current applicant list $\mathscr{D}_i = \mathscr{D}_i \cup \{j\}$.
    Remove seller i from the unapplied seller list $\mathscr{T}_j = \mathscr{T}_j \setminus \{i\}$.
  end for
  for all Seller i with nonempty current applicant list **do**
    Select the most preferred coalition $C^i = \mu(i) \cup \mathscr{S}, \mathscr{S} \subseteq \mathscr{D}_i, \forall C'^i = \mu(i) \cup \mathscr{S}', \mathscr{S}' \subseteq \mathscr{D}_i, C^i \triangleright_i C'^i$.
    Update the matching, $\mu(i) = C^i, \forall j \in C^i, \mu(j) = i$.
    Set the invitation list as $\mathscr{R}_i = \mathscr{R}_i \cup \mathscr{D}_i \setminus \mathscr{S}$.
  end for
end while
Phase 2: Invitation
for all $i \in \mathscr{M}$ **do**
  Screen non-interfering buyers in the invitation list $\mathscr{R}_i = \{j | j \in \mathscr{R}_i, \forall j' \in \mu(i), e^i_{j,j'} = 0\}$.
end for
while $\exists$ seller with nonempty invitation list **do**
  for all Seller i with nonempty invitation list **do**
    j = buyer with the highest offered price.
    Seller i send invitation to buyer j.
    if Seller i is more preferred than $\mu(j)$ **then**
      Buyer j accepts invitation.
      Update the matching, $\mu(i) = \mu(i) \cup \{j\}, \mu(j) = i$.
      Remove buyer j's interfering neighbors in the invitation list $\mathscr{R}_i = \mathscr{R}_i \setminus \{j | j' \in \mathscr{R}_i, e^i_{j,j'} = 1\}$.
    end if
    Remove buyer j from the invitation list $\mathscr{R}_i = \mathscr{R}_i \setminus \{j\}$.
  end for
end while

Proposition 2. *Algorithm 2 is guaranteed to converge, and the running time of Phase 1 is $O(M)$, of Phase 2 is $O(N)$.*

Proof. Each buyer sends transfer application once to each more preferred seller, so Phase 1 will terminate in a limited number of rounds. In Phase 2, each seller has a

finite invitation list and only sends invitation at most once to each buyer in the list; thus, Phase 2 will also end in a limited number of rounds.

In Phase 1, each buyer has at most M more preferred sellers, so the running time is $O(M)$. Unlike Stage I, no buyer will be evicted in Stage II; therefore, the running time is $O(M)$ rather than $O(MN)$. In Phase 2, each seller has at most N buyers in the invitation list, so the running time is $O(N)$.

Properties

In this section, we prove that the matching result of the proposed distributed algorithm is individual rational and Nash-stable.

Definition 2 (Individual rational).

A matching result is blocked by seller i if she prefers not to be matched to some of her currently matched buyers. In other words, $\exists \mathscr{S} \subseteq \mu(i), \mathscr{S} \neq \Phi, C^i = \{i\} \cup \mu(i), C'^i = \{i\} \cup \big(\mu(i) \setminus \mathscr{S}\big), C'^i \rhd_i C^i$.

A matching result is blocked by buyer j if she prefers being unmatched to being matched to the current seller. In other words, $\{j\} \rhd_j \big(\mu(j) \cup \mu(\mu(j))\big)$.

A matching result is individual rational if it is not blocked by any buyer or seller.

Proposition 3. *The matching result of the proposed distributed algorithm is individual rational.*

Proof. For seller i, the matching result $\mu(i)$ of the proposed algorithm is interference-free. In this case, removing any buyers in $\mu(i)$ will reduce the total offered price and result in a less preferred matching result.

For a matched buyer j, she does not have interference neighbors in $\mu(\mu(j))$. Therefore, her utility is positive, higher than the utility of being unmatched, which is zero.

Deferred-acceptance algorithm can achieve pairwise stability for the college admission problem, i.e., no pair of detached student and college would both be better off if they are matched together. Due to peer effects in spectrum matching, pairwise stability cannot be preserved, whereas we can guarantee a weaker form of stability.

Definition 3 (Nash-stable). A matching result is Nash-stable if no buyer prefers to be a member of another spectrum coalition rather than stay in the current spectrum coalition, i.e., $\forall j \in \mathscr{N}, i = \mu(j), i' \neq i, \big(i \cup \mu(i)\big) \rhd_j \big(i' \cup \mu(i') \cup j\big)$.

Proposition 4. *The matching result of the proposed distributed algorithm is Nash-stable.*

Proof. We prove this by contradiction. Assume that the final matching result is not Nash-stable. There exists at least one buyer j who prefers to join another spectrum coalition with seller $i \neq \mu(j)$. This implies that in Stage II Phase 1, buyer j must have sent a transfer application to seller i because buyer j prefers i to $\mu(j)$. Seller

i must have rejected j and put j in her rejecting list. In Stage II Phase 2, seller i cannot have sent an invitation to buyer j; otherwise, j will accept the invitation and be matched to seller i. This implies that buyer j must interfere with some buyers in $\mu(i)$. Therefore, buyer j would not like to join seller i's spectrum coalition because her utility will become zero, which contradicts the assumption. Hence, the matching result of the proposed algorithm is Nash-stable.

Discussions

In this section, we discuss the limitations of the proposed matching algorithm. The deferred acceptance can achieve a matching result that is pairwise stable and student-optimal for the traditional college admission problem. (Note that the definition of the optimal matching here is different from that in section "System Model".) Unfortunately, our two-stage algorithm based on adapted deferred acceptance cannot achieve these two ideal properties, which may inspire future research in this direction.

Definition 4 (Pairwise stability). A matching is blocked by a pair of seller i and buyer $j \notin \mu(i)$, if there exists $\mathscr{S} \subseteq \mu(i)$ such that:

- Non-interfering condition: $\forall j' \in \mathscr{S}, e^i_{j,j'} = 0$.
- Seller improvement: $\big(\{i\} \cup \{j\} \cup \mathscr{S}\big) \rhd_i \big(\{i\} \cup \mu(i)\big)$.
- Buyer improvement: $\big(\{i\} \cup \{j\} \cup \mathscr{S}\big) \rhd_j \big(\mu(j) \cup \mu(\mu(j))\big)$.

A matching is pairwise stable if it is not blocked by any seller-buyer pair.

Unfortunately, the proposed spectrum matching algorithm cannot ensure pairwise stability. A counterexample is given in Figs. 5 and 4. We ignore Stage II since the matching result will not change in this example. Given the final matching result in Fig. 4e, seller b and buyer 2 form an unstable pair. According to Definition 4, we know that $\mathscr{S} = \{3, 7\}$; seller b prefers the spectrum coalition $\{b, 2, 3, 7\}$ to the current spectrum coalition $\{b, 3, 4, 7\}$; and buyer 2 prefers seller b to the currently matched seller c. Seller b and buyer 2 have incentives to be matched together at the sacrifice of buyer 4, which is, however, not allowed by the proposed matching algorithm.

Another nice property of the deferred-acceptance algorithm is that its matching result realizes an optimal assignment of students among all pairwise stable matching result, that is, no student can get admitted by a better college in another pairwise stable matching result. (When the students initiate the proposal, the matching result is optimal for students but is not guaranteed to be optimal for colleges.) As the spectrum matching can only achieve Nash-stability, we give the following definition for optimality regarding Nash-stable matching.

Definition 5 (Optimality). A Nash-stable matching result μ is buyer-optimal, if there does not exist another Nash-stable matching result μ', in which no buyer

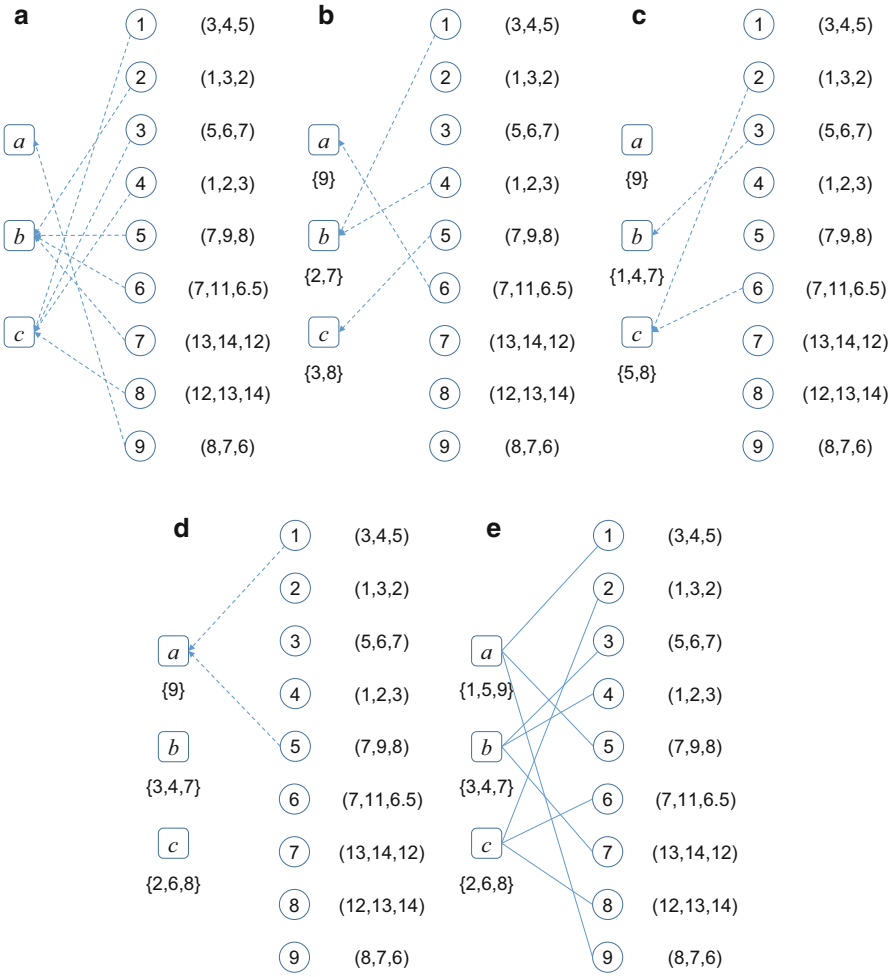

Fig. 4 Counterexample, proposed spectrum matching algorithm. (**a**) First round proposal. (**b**) Second round proposal. (**c**) Third round proposal. (**d**) Fourth round proposal. (**e**) Final matching result

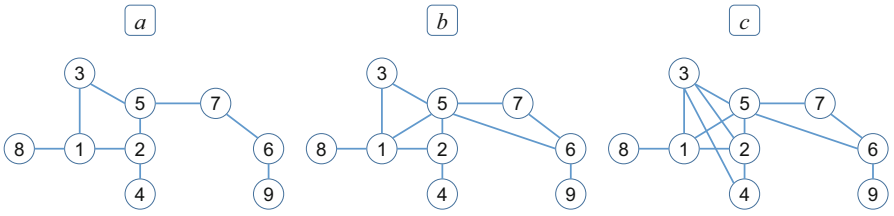

Fig. 5 Counter example, interference graph

is worse off and some buyers are better off. In other words, $\forall j \in \mathcal{N}, \left(\mu(j) \cup \mu(\mu(j))\right) \rhd_j \left(\mu'(j) \cup \mu'(\mu'(j))\right), \forall \mu'$ that is Nash-stable.

Using the same counterexample in Figs. 5 and 4, we show that the matching result of the proposed algorithm is not optimal. Swap buyer 2 and buyer 4 to seller b and seller c, respectively. It can be easily checked that the new matching result is Nash-stable. The new matching result is strictly better than the one produced by the proposed algorithm, in that not only buyer 2 and buyer 4 but also seller b and seller c are better off, and other buyers and sellers are unaffected. In Stage II Phase 1, such a swap cannot be accomplished because seller b is not aware that buyer 4 can transfer to seller c, as long as she accepts the transfer application from buyer 2, who is matched to seller c and interferes with buyer 4. How to enable such a swap, which requires a coordination among different sellers and buyers, is an interesting topic for future works.

Implementation of Spectrum Matching

The proposed two-stage matching algorithm runs in a distributed fashion within each stage and each phase. Nevertheless, asynchronization problem arises during stage or phase transition. More specifically, Stage II commences when all buyers exhaust their proposals and start the transfer application. Unfortunately, it is impossible for a buyer to know whether all other buyers have stopped making proposals. Similar problem exists during phase transition in Stage II. Therefore, in this section, we specify practical rules for stage or phase transition, facilitating the implementation of the proposed two-stage matching algorithm in perfectly distributed manner.

Assume that each round in the proposed algorithm takes one time slot. Propositions 1 and 2 give the running time of Algorithms 1 and 2, respectively, based on which we have the following default transition rule.

Default transition rule. From the very beginning, all buyers and sellers wait for MN time slots to transit to Stage II, then M time slots to transit to Stage II Phase 2, and finally N time slots to end the matching process.

The default transition rule can be extremely inefficient. For instance, given the toy example in Fig. 9, according to the default transition rule, the whole matching process takes 23 time slots, but in fact, 7 time slots are enough to reach the final matching result as shown in Figs. 2 and 3. To tackle this problem, we design the following transition rules.

Stage Transition Rules on Buyers' Side

For a buyer, the risk of a premature entrance into Stage II is being evicted after she starts to send transfer applications but no more proposals. A transfer application has a lower chance of being accepted than a proposal, as the seller will not evict any currently matched buyers upon a transfer application. Therefore, a buyer should transit to Stage II only when her risk of being evicted by the currently matched seller

is low. One observation is that a buyer only faces the threat from her interfering neighbors, so we have the following transition rule.

Stage Transition Rule I for Buyers
A buyer can transit to Stage II if all her interfering neighbors have proposed to her currently matched seller. Stage transition rule I for buyers guarantees that a buyer's matching result in Stage I will not change anymore, but the condition may be hard to meet. For example, in Fig. 2, buyer 4 will never detect buyer 3's proposal to seller a because buyer 3 never proposes to seller a.

To design a more operable rule, we estimate the probability of a buyer being evicted after she performs the stage transition. The smaller this probability is, the less risky for the buyer to enter Stage II. Assume that all buyers' prices follow identically independent distribution (i.i.d.) with a cumulative distributed function $F(\cdot)$.

Consider buyer j who is matched to seller i till the $(k-1)$th round, and n of her interfering neighbors have not proposed to seller i yet. Let p_x^k denote the probability that, at the kth round, x of buyer j's interfering neighbors proposes to seller i, and at least one of their offered prices is higher than buyer j's.

$$p_x^k = \binom{n}{x}\left(\frac{1}{M}\right)^x\left(1-\frac{1}{M}\right)^{n-x}\left(1-F^x(b_{i,j})\right). \tag{7}$$

The probability of buyer j being evicted in the kth round can be estimated as $p^k = \sum_{x=1}^{n} p_x^k$. The probability of buyer j being evicted in the $(k+1)$th round but not in the kth round is $(1-p^k)p^k$. Following the same logic, the probability of buyer j being evicted through the kth round till the MNth round is

$$\begin{aligned} P^k &= p^k + (1-p^k)p^k + \cdots + (1-p^k)^{MN-k}p^k \\ &= 1-(1-p^k)^{MN-k+1} \end{aligned} \tag{8}$$

P^k decreases with k, so it is more secure for a buyer to commence Stage II at a later round.

Stage Transition Rule II for Buyers
A buyer can transit to Stage II at the kth round if P^k is less than a threshold.

We have one more transition rule for buyers that are incurred by sellers. When a seller determines to carry out stage transition, she will inform all her currently matched buyers, which ensures that the seller will no longer evict these buyers.

Stage Transition Rule III for Buyers
A buyer can transit to Stage III if she receives the transition notification from her currently matched seller.

Stage Transition Rule on Sellers' Side

A seller has to make the stage transition decision if she receives no proposal but some transfer applications in the current time slot. After stage transition, a seller cannot grant proposals anymore. In other words, none of her currently matched buyers can be expelled to make room for new buyers. We estimate the probability of a seller getting better proposals after she makes the stage transition. If the probability is low, a seller may begin to process the transfer applications, thus completing the stage transition.

Consider seller i who is, at the $(k-1)$th round, matched to a group of buyers, among which buyer j has the lowest offered price of $b_{i,j}$. There are n buyers who haven't proposed to seller i yet. Let θ denote the probability that an unproposed buyer does not interfere with anyone in $\mu(i)$ except buyer j. θ is an empirical value, which can be estimated by analyzing the interference relationship between buyers in and out of $\mu(i)$. Let q_y^k denote the probability that, at the kth round, y buyers propose to seller i, and at least one of them offers a price higher than $b_{i,j}$, and this buyer do not interfere with anyone in $\mu(i)$ other than buyer j.

$$q_y^k = \binom{n}{y}\left(\frac{1}{M}\right)^y\left(\frac{M-1}{M}\right)^{n-y} \left[1-\Big(F(b_{i,j})+(1-\theta)(1-F(b_{i,j}))\Big)^y\right]. \tag{9}$$

Similar to (8), the probability of seller i receiving better proposals through the kth round till the MNth round is $Q^k = 1-(1-q^k)^{MN-k+1}$, in which $q^k = \sum_{y=1}^{n} q_y^k$. Q^k also decreases with k, thus it is less likely for a seller to obtain more favorable proposals at a later round.

Stage Transition Rule for Sellers

A seller can transit to Stage II at the kth round if Q^k is less than a threshold.

Upon stage transition, a seller will notify all her currently matched buyers, and these buyers will transit to Stage II as well, as specified by stage transition rule III for buyers.

Phase Transition Rule and Matching Termination

We will use the default transition rule for phase transition in Stage II, as the simulation results show that Stage II Phase 1 lasts for approximately M rounds. Buyers and sellers have to decide when to terminate the matching process so that spectrum exchange can be finalized. The simulation results show that Stage II Phase 2 only runs a few rounds, as the opportunities for sellers to send invitations to buyers are rare. Nonetheless, the invitation phase is indispensable to guarantee the stability of the final matching result. We set the rule that each seller will put an end to the matching process when she has no invitation to make and let the user to access her channel.

Simulation

Simulation Settings

We assume that buyers are randomly located in a 10×10 area. The transmission range of each channel is randomly chosen in the range $(0, 5]$. The interference graph of each channel is established based on users' locations and the transmission range of the channel. Users' utility vectors are independently and identically distributed (i.i.d.), following a uniform distribution in $[0, 1]$. The numbers of buyers and sellers are specified in each simulation scenario. The similarity across buyers' utility vectors are quantified by the Spearman's rank correlation coefficient (SRCC) [21], which assesses whether the relationship between two variables can well be described as monotonic. We compute the SRCC for every pair of buyer's utility vectors and obtain the average value. If the result is close to 1, buyers' utility vectors are perfectly similar to one another. If the result is close to 0, buyers' utility vectors are perfectly random and independent from one another. To study the utility similarity and its influence on the matching result, we maneuver buyers' utility vectors as follows. First, we sort all buyers' utilities in the ascending (or descending) order. In this way, the average SRCC is 1. Then, for each buyer, we randomly select m out of M items from her utility vector and perform an $m-$permutation. As m increases, the average SRCC will decrease, indicating that the buyers' utility vectors become more dissimilar to one another. When $m = M$, the SRCC is approximately 0.

Performance of the Proposed Matching Algorithm

We compare the social welfare of the matching result generated by the proposed algorithm and that of the optimal matching result derived by (1) (the optimal matching result is derived by the brute-force approach. As the running time exponentially increases with the numbers of buyers and sellers, we can only simulate small-scale spectrum markets), as shown in Fig. 6. Our proposed distributed matching algorithm can obtain more than 90% of the social welfare from the optimal matching result. Moreover, the running time of the proposed algorithm is only $O(MN)$, while the optimal matching problem in (1) is NP-hard. The social welfare grows with the number of buyers or sellers. If the buyers' utility vectors are similar to each other, multiple buyers will compete for the same channel, and it is hard to satisfy every buyer's requirement; on the contrary, if buyers' utility vectors are more diverse, they will pursue different channels, and the final matching result can satisfy more buyers.

Two-Stage Distributed Algorithm

In Figs. 7 and 8, we demonstrate the social welfare and running time of different stages and phases in our proposed two-stage matching algorithm. Note that the social welfare is accumulated with each stage and phase, while the running time is separately counted for each stage and phase. Most of the social welfare improvement in Stage II comes from Phase 1, while Phase 2 makes a minor contribution. Nevertheless, Phase 2 is indispensable to guarantee the stability of the final matching result.

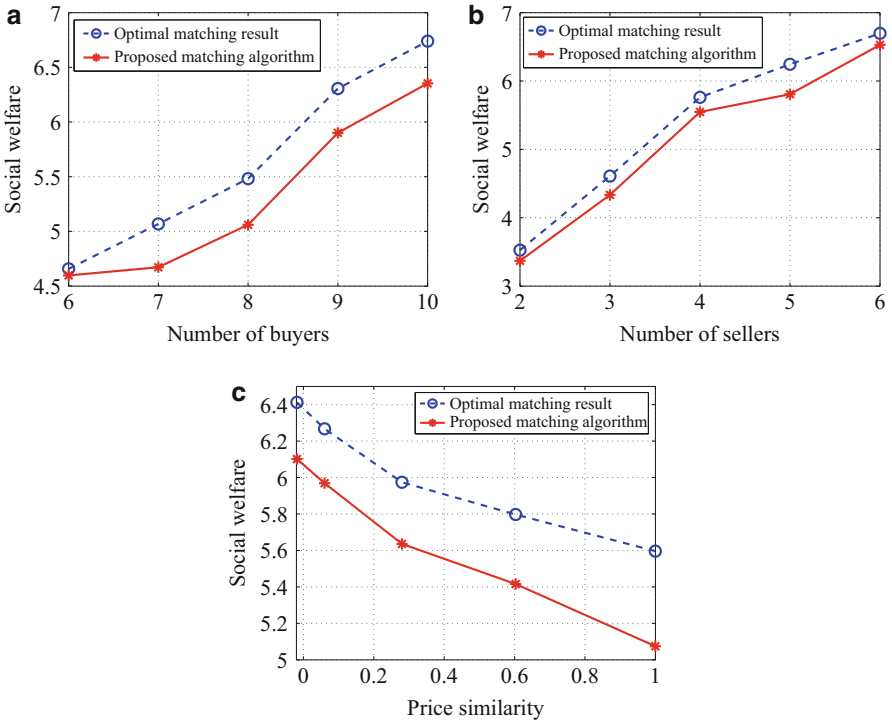

Fig. 6 Optimal matching result versus the proposed distributed spectrum matching algorithm. (**a**) $M = 4$; (**b**) $N = 8$; (**c**) $M = 5, N = 8$

When the number of buyers is far greater than the number of sellers, the running time of Stage I is mostly influenced by the number of sellers. The running time of Stage II Phase 1 is theoretically $O(M)$: it linearly increases with the number of sellers, irrespective of the number of buyers and their offered prices, as shown in Fig. 8. Stage II Phase 2 only runs for a few rounds, as opportunities for sellers to send invitations to buyers are rare.

Combinatorial Many-to-Many Spectrum Matching

In section "Non-combinatorial Many-to-Many Spectrum Matching", we simply assume that channels are independent from each other, i.e., the value of a combination of channels is exactly the sum of values of each individual channel. However, this assumption is not true in real case. The service providers usually value more on two continuous channels than the sum of the individuals, because the effective bandwidth is increased to save the guard band. This is significantly different from conventional commodity where the value is usually in linear proportional with the quantity of the commodity. To take this characteristic into consideration,

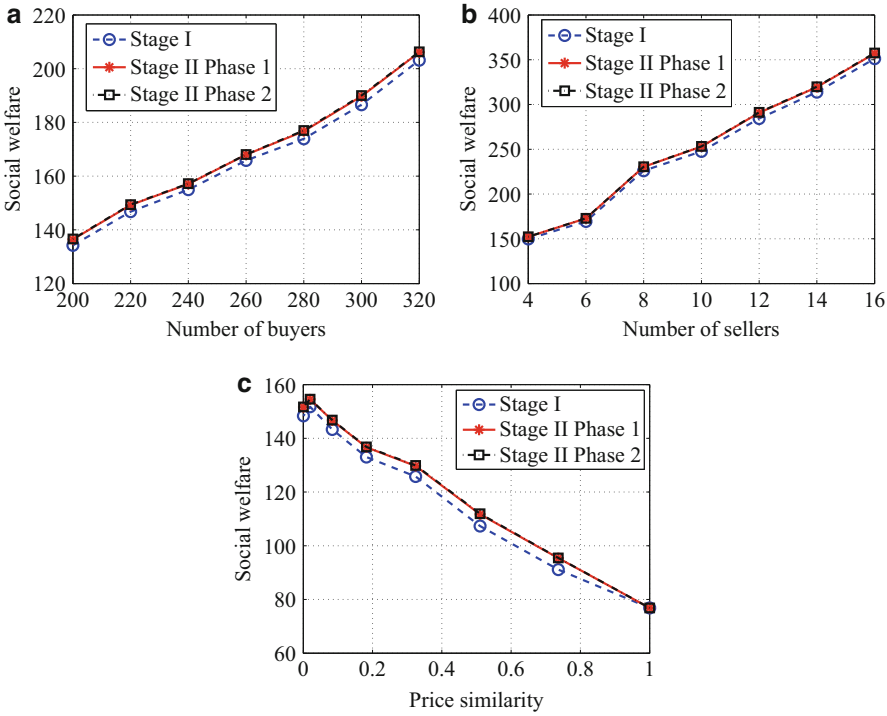

Fig. 7 The social welfare of the two-stage distributed spectrum matching algorithm. (**a**) $M = 10$; (**b**) $N = 500$; (**c**) $M = 8, N = 300$

the spectrum trading becomes a combinatorial spectrum trading, where for each combination of spectrum, the value needs to be redefined. There are many previous works on combinatorial auction. Due to the intractability of combinatorial auctions, a number of greedy algorithms have been proposed with bounded approximation ratio [22–24]. Combinatorial spectrum auction is studied in [25,26]. However, the combinatorial auction has the disadvantage of intractability and collusion problem, which can be addressed by the spectrum matching framework.

In the rest of the section, we leverage matching as an alternative framework for dynamic spectrum access. More specifically, to realize a combinatorial auction alike spectrum market, we propose to use many-to-many matching, where a buyer can purchase multiple channels, and a seller's channel can be assigned to multiple non-interfering buyers. Instead of maximizing social welfare, the aim of matching is to achieve a stable status. The stability concept is attractive because it keeps an equilibrium status for both sellers and buyers. Besides, the matching process can be free from a third-party auctioneer, avoiding potential collusion between the auctioneer and the buyers or sellers. In fact, stable matching has been widely applied to computer science, such as resource management in the cloud [11].

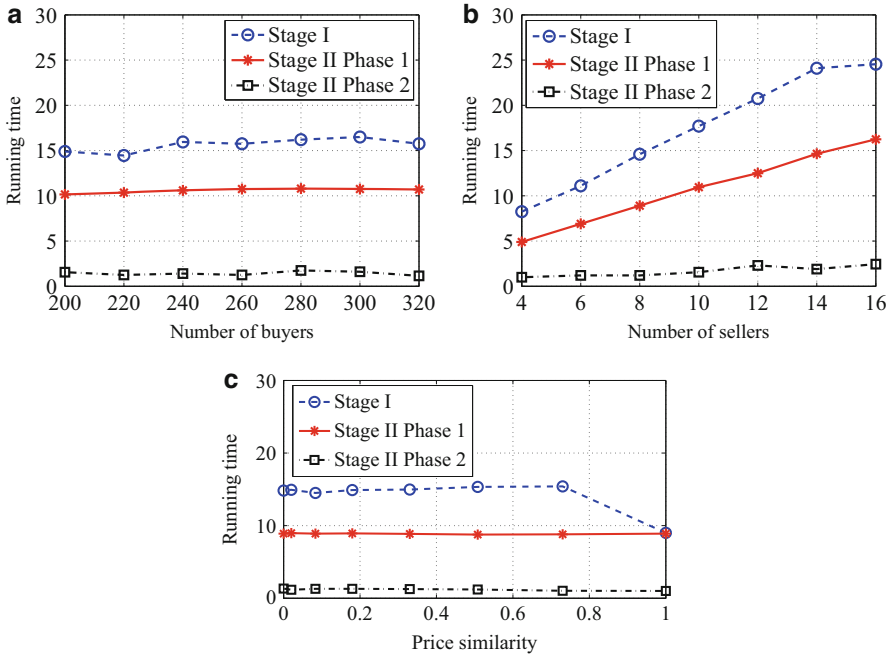

Fig. 8 The running time of the two-stage distributed spectrum matching algorithm. (**a**) $M = 10$; (**b**) $N = 500$; (**c**) $M = 8, N = 300$

Matching has been widely studied in the economics and mathematics communities. In the pioneer work of David Gale and Lloyd Shapley [10], *deferred-acceptance* algorithms are proposed to reach a stable matching for the marriage problem (one-to-one matching) and the college admission problem (many-to-one matching). Compared with one-to-one matching and many-to-one matching, many-to-many matching is much more complicated, and it is more difficult to reach a stable matching result. Based on the deferred-acceptance algorithm, in [27], the authors proposed a competitive adjustment process for labor markets with perfect information. In [28], an iterative T-algorithm is proposed, which can realize many nice properties, such as pairwise stability, setwise stability, and core stability.

In this section, we propose a novel many-to-many spectrum matching framework for combinatorial spectrum trading. Buyers can freely express their preferences for different combinations of channels, and the same channel can be reused by multiple non-interfering buyers. To address spectrum heterogeneity, different interference graphs are constructed for different channels to determine spectrum reuse [7]. We propose an algorithm, which can reach a stable matching result and also improve spectrum utilization through spectrum reuse. We make the following key contributions:

- We propose a many-to-many spectrum matching framework to realize combinatorial spectrum trading for dynamic spectrum access.
- We propose a matching algorithm which addresses spectrum heterogeneity and spectrum reuse. We prove that the matching result is individual rational, is strong pairwise stable, and is a subgame-perfect Nash equilibrium of the corresponding spectrum bargaining game.
- We conduct extensive simulations to evaluate the performance of the proposed many-to-many spectrum matching framework. It is shown that it takes only a few iterations for the proposed algorithm to reach a stable matching result.

The rest of the section is organized as follows. We describe the system model in details in section "System Model". In section "Spectrum Matching", we present the many-to-many spectrum matching framework and matching algorithm. Simulation results are shown in sections "Simulation".

System Model

Assume there is a set of sellers $\mathscr{M} = \{1, 2, \ldots, m\}$ and a set of buyers $\mathscr{N} = \{1, 2, \ldots, n\}$ in the market. Each seller owns one channel, which can be matched to multiple non-interfering buyers. Buyer j has a basic price offer for all channels $B_j = (b_{1,j}, b_{2,j}, \ldots, b_{m,j})$, in which $b_{i,j}$ is buyer j's valuation for a single channel i. For a bundle of channels $\mathscr{A}$, buyer j may be willing to pay more than the sum $\sum_{i \in \mathscr{A}} b_{i,j}$, for example, two continuous channels may bring more benefit to a buyer. We will express such complementariness of channels in buyers' preference profiles.

The key feature of spectrum allocation is interference-restricted spatial reuse. To characterize interference heterogeneity of different channels, we construct a series of interference graphs $\{G^i = (V, E^i)\}_{i=1}^m$, in which each node $v \in V$ represents a buyer and each edge $e^i \in E^i$ connects a pair of interfering buyers on channel i. Let $e^i_{j,j'} \in \{0, 1\}$ represent the interference status between buyers j and j' regarding channel i.

The preference profile $\succ_i$ of seller i is a complete, reflexive, and transitive binary relation on all sets of buyers $2^{\mathscr{N}}$. Due to interference constraint, a seller prefers the empty set $\emptyset$ to any buyer set that contains interfering buyers. For two buyer sets that are both interference-free (not any two buyers in the set interfere with each other), the seller prefers the one with a higher aggregate basic offer price. Let $\mathscr{S}, \mathscr{S}' \in 2^{\mathscr{N}}$ denote buyer sets, we have:

- If $\mathscr{S}$ is interference-free, $\mathscr{S} \succ_i \emptyset$; if $\mathscr{S}$ is not interference free, $\emptyset \succ_i \mathscr{S}$.
- If $\mathscr{S}$ is interference-free, but $\mathscr{S}'$ is not, $\mathscr{S} \succ_i \mathscr{S}'$, vice versa.
- If both of $\mathscr{S}$ and $\mathscr{S}'$ are interference-free, $\mathscr{S} \succ_i \mathscr{S}' \iff \sum_{j \in S} b_{i,j} > \sum_{j' \in S'} b_{i,j'}$.
- If neither of $\mathscr{S}$ and $\mathscr{S}'$ is interference-free, the seller randomly decides the preference relation between $\mathscr{S}$ and $\mathscr{S}'$.

The preference profile $\succ_j$ of buyer j is a complete, reflexive, and transitive binary relation on all sets of channels (sellers) $2^{\mathscr{M}}$. The preference profile on all sets of channels instead of individual channels is quite expressive to cater to buyers' requirements. First, buyers are able to express their preference for certain bundles of channels. For example, buyer j may have $\{s_1, s_2\} \succ_j \{s_1, s_3\}$, which means that she prefers the continuous channels $\{s_1, s_2\}$ to non-continuous channels $\{s_1, s_3\}$. Second, buyers can easily comply with their budget constraints by preferring empty set to large (therefore expensive) channel bundles. For example, buyer j may have $\emptyset \succ_j \{s_1, s_2, s_3\}$ since the aggregate basic offer price of $\{s_1, s_2, s_3\}$ exceeds her budget. Our proposed many-to-many spectrum matching algorithm works with general preference profiles without any restrictions.

Spectrum Matching

Preliminaries

We formally define many-to-many spectrum matching as follows.

Definition 6 (Many-to-Many Spectrum Matching). Given the set of sellers $\mathscr{M}$ and the set of buyers $\mathscr{N}$, a many-to-many spectrum matching is a mapping μ from the set $\mathscr{M} \bigcup \mathscr{N}$ into the set of all subsets of $\mathscr{M} \bigcup \mathscr{N}$ (i.e., $2^{\mathscr{M} \cup \mathscr{N}}$), such that

- For every seller $i \in \mathscr{M}$, $\mu(i) \subseteq 2^{\mathscr{N}}$;
- For every buyer $j \in \mathscr{N}$, $\mu(j) \subseteq 2^{\mathscr{M}}$;
- For every seller i and buyer j, $j \subseteq \mu(i)$ if and only if $i \subseteq \mu(j)$.

We also define the pre-matching, which will be the intermediate result in our proposed matching algorithm.

Definition 7 (Pre-matching). A pre-matching is a pair $\nu = (\nu_m, \nu_n)$, in which ν_m is a mapping from the seller set $\mathscr{M}$ into all subsets of buyers $2^{\mathscr{N}}$ and ν_n is a mapping from the buyer set $\mathscr{N}$ into all subsets of seller $2^{\mathscr{M}}$, that is,

- For every seller $i \in \mathscr{M}$, $\nu_m(i) \in 2^{\mathscr{N}}$;
- For every buyer $j \in \mathscr{N}$, $\nu_n(j) \in 2^{\mathscr{M}}$.

Note that a pre-matching is a matching if ν is such that $\nu_m(i) = j$ if and only if $\nu_n(j) = i$ for all $i \in \mathscr{M}$, $j \in \mathscr{N}$.

Given a buyer j and a set of sellers $\mathscr{S}$, let $Ch(\mathscr{S}, \succ_j)$ denote buyer j's most preferred subset of $\mathscr{S}$ according to j's preference relation $\succ_j$. More specifically, $Ch(\mathscr{S}, \succ_j)$ is the unique subset $\mathscr{S}'$ of $\mathscr{S}$ such that $\mathscr{S}' \succ_j \mathscr{S}''$ for all $\mathscr{S}'' \subseteq \mathscr{S}, \mathscr{S}'' \neq \mathscr{S}'$. Similarly, given seller i and a set of buyers $\mathscr{S}$, $Ch(S, \succ_i)$ is seller i's most preferred subset of $\mathscr{S}$ according to i's preference relation $\succ_i$.

Matching Algorithm

We propose a many-to-many matching algorithm to realize a stable and interference-free spectrum matching, as shown in Algorithm 3. The key component in the matching algorithm is the $T(\cdot)$ operation on the pre-matching ν. We iteratively perform the $T(\cdot)$ operation until we reached the fixed point ($T(\nu) = \nu$) or the number iterations reached the threshold. To define the $T(\cdot)$, we first introduce two sets. Given a pre-matching $\nu = (\nu_m, \nu_n)$, we have:

$$\begin{aligned} U(i,\nu) &= \{j \in \mathscr{N} : i \in Ch(\nu_n(j) \cup \{i\}, \succ_j)\} \\ V(j,\nu) &= \{i \in \mathscr{M} : j \in Ch(\nu_m(i) \cup \{j\}, \succ_i)\} \end{aligned} \tag{10}$$

The set $U(i,\nu)$ is the set of buyers who are willing to obtain seller i's channel, given their currently matched channels. Similarly, the set $V(j,\nu)$ is the set of sellers who are willing to sell their channels to buyer j, given their currently matched buyers (and their interference relationships).

Now, we can define the $T(\cdot)$ operation as:

$$T(\nu) = \begin{cases} Ch(U(i,\nu), \succ_i), \forall i \in \mathscr{M} \\ Ch(V(j,\nu), \succ_j), \forall j \in \mathscr{N} \end{cases} \tag{11}$$

The purpose of the $T(\cdot)$ operation on seller i is to find the optimal set of buyers among those who are willing to purchase seller i's channel. Likewise, the purpose the $T(\cdot)$ operation on buyer j is to find the optimal set of sellers (channels) among those who are willing to sell their channels to buyer j.

Though similar to the definition in [28], the $T(\cdot)$ operation is quite different for spectrum matching. The main reason is that spectrum matching exhibits buyer externality: the matching result of a buyer will affect those of other buyers. More specifically, if a buyer is matched to a seller, her interfering neighbors will be unwilling to be matched to the same seller, even if they have a high preference for that seller's channel. For the same reason, when choosing the optimal set of buyers, a seller not only considers their basic offer price but also their interference relationship.

In (11), the operation $Ch(U(i,\nu), \succ_i)$ requires seller i to find the optimal set of buyers with the highest total basic offer price, given the set $U(i,\nu)$. This is equivalent to finding the maximum weighted independent set (MWIS) on the interference graph G^i regarding buyers in $U(i,\nu)$. However, it has been proved that the MWIS problem is NP-hard. A naive brute-force solution is to exhaustively search all possible subsets of $U(i,\nu)$, resulting in exponential running time. To address this problem, we adopt the greedy algorithm in [19]. The key idea of the greedy algorithm is to select the buyer with the maximum price/degree ratio, remove her and all her neighbors, and repeat this process until the graph becomes empty. The selected buyers at all iterations are the output independent set.

It is proved in [28] that the fixed point $\nu = T(\nu)$ is a matching, that is, $\nu_m(i) = j$ if and only if $\nu_n(j) = i$ for all $i \in \mathscr{M}$ and $j \in \mathscr{N}$. However, due to the complexity

of spectrum matching, it is analytically difficult to prove that this property can still be preserved. Our simulation results in section "Simulation" numerically show that the output of Algorithm 3 is indeed a matching, the properties of which we will analyze in section "Properties". We will work on theoretically proving this in our future work.

In Algorithm 3, the input pre-matching ν is not specified. The simplest way is to initiate the pre-matching as $\nu_m(i) = \emptyset, \nu_n(j) = \emptyset, \forall i \in \mathscr{M}, j \in \mathscr{N}$. An alternative way is to randomly assign one buyer to one channel at the start (assuming there are more buyers than sellers), i.e., $\nu_m(i) = j, \forall i \in \mathscr{M}; \nu_n(j) = i$, if $\exists i, \nu_m(i) = j$, otherwise, $\nu_n(j) = \emptyset$. Now we give a toy example to show how the proposed algorithm works.

Algorithm 3 Many-to-many spectrum matching

Require: Preference relation $\succ$; interference graphs $\{G^i\}_{i=1}^M$; interference-free pre-matching ν_0; iteration threshold Num.
Ensure: An interference-free (pre-)matching ν
1: $iteration = 0$.
2: $\nu = T(\nu_0)$.
3: **while** $\nu \neq \nu_0$ or $iteration \leq Num$ **do**
4: $\quad \nu_0 = \nu$.
5: $\quad \nu = T(\nu_0)$.
6: $\quad iteration = iteration + 1$.
7: **end while**

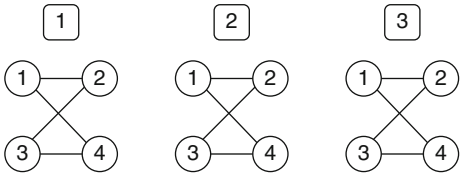
Toy example. Suppose the set of sellers is $\mathscr{M} = \{i_1, i_2, i_3\}$ and the set of buyers is $\mathscr{N} = \{j_1, j_2, j_3, j_4\}$. The basic offer of buyer j_1 is $(1, 3, 5)$, of buyer j_2 is $(5, 1, 3)$, of buyer j_3 is $(1, 5, 3)$, and of buyer j_4 is $(3, 5, 1)$. Therefore, we can construct the buyers' preference profiles as:

$$\begin{aligned}
&\succ_{j_1}: \{i_2, i_3\} \succ_{j_1} \{i_1, i_3\} \succ_{j_1} \{i_1, i_2\} \succ_{j_1} i_3 \succ_{j_1} i_2 \succ_{j_1} i_1 \\
&\succ_{j_2}: \{i_1, i_3\} \succ_{j_2} \{i_1, i_2\} \succ_{j_2} \{i_2, i_3\} \succ_{j_2} i_1 \succ_{j_2} i_3 \succ_{j_2} i_2 \\
&\succ_{j_3}: \{i_2, i_3\} \succ_{j_3} \{i_1, i_2\} \succ_{j_3} \{i_1, i_3\} \succ_{j_3} i_2 \succ_{j_3} i_3 \succ_{j_3} i_1 \\
&\succ_{j_4}: \{i_1, i_2\} \succ_{j_4} \{i_2, i_3\} \succ_{j_4} \{i_1, i_3\} \succ_{j_4} i_2 \succ_{j_4} i_1 \succ_{j_4} i_3
\end{aligned} \tag{12}$$

We assume that no buyer can afford the set $\{i_1, i_2, i_3\}$, so we omit this set, which is less preferred than the empty set due to budget constraint. The buyers' interference graph is shown in Fig. 9, so we can construct the sellers' preference profiles which are:

$$\begin{aligned}
&\succ_{i_1}: \{j_2, j_4\} \succ_{i_1} j_2 \succ_{i_1} j_4 \succ_{i_1} \{j_1, j_3\} \succ_{i_1} j_1 \succ_{i_1} j_3 \\
&\succ_{i_2}: \{j_1, j_3\} \succ_{i_2} \{j_2, j_4\} \succ_{i_2} j_3 \succ_{i_2} j_4 \succ_{i_2} j_1 \succ_{i_2} j_2 \\
&\succ_{i_3}: \{j_1, j_3\} \succ_{i_3} j_1 \succ_{i_3} \{j_2, j_4\} \succ_{i_3} j_2 \succ_{i_3} j_3 \succ_{i_3} j_4
\end{aligned} \tag{13}$$

Fig. 9 A Toy example



The interference graph.

Table 1 A Toy example

	$\nu_m(i_1)$	$\nu_m(i_2)$	$\nu_m(i_3)$	$\nu_n(j_1)$	$\nu_n(j_2)$	$\nu_n(j_3)$	$\nu_n(j_4)$
0	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$
1	$\{j_2, j_4\}$	$\{j_1, j_3\}$	$\{j_1, j_3\}$	$\{i_2, i_3\}$	$\{i_1, i_3\}$	$\{i_2, i_3\}$	$\{i_1, i_2\}$
2	$\{j_2, j_4\}$	$\{j_1, j_3\}$	$\{j_1, j_3\}$	$\{i_2, i_3\}$	i_1	$\{i_2, i_3\}$	i_1
3	$\{j_2, j_4\}$	$\{j_1, j_3\}$	$\{j_1, j_3\}$	$\{i_2, i_3\}$	i_1	$\{i_2, i_3\}$	i_1

We assume that the pre-matching is $\nu_m(i) = \nu_n(j) = \emptyset, \forall i, j$. In the first iteration, for seller i_1, $U(i_1, \nu) = \mathscr{N}$, and it can be easily found that the optimal buyer set is $\nu_m(i_1) = \{j_2, j_4\}$; for buyer j_1, $V(j_1, \nu) = \mathscr{M}$, so that after the $T(\cdot)$ operation, we have $\nu_n(j_1) = \{i_2, i_3\}$. The results after the first iteration is shown in the third row of Table 1. Similarly, we can proceed through the second iteration, whose result can be checked as a fixed point and a matching.

Properties

In this section, we first prove that the matching result of the proposed Algorithm 3 is individual rational in general cases. Then, we show that with specific preference profiles, the matching result is strong pairwise stable and is a subgame-perfect Nash equilibrium of the corresponding spectrum bargaining game.

Definition 8 (Individual rational).

A matching result is blocked by seller i if she prefers not to be matched to some of her currently matched buyers. In other words, $\exists S \subseteq \mu(i), \left(\mu(i) \setminus S\right) \succ_i \mu(i)$.

A matching result is blocked by buyer j if she prefers not to be matched to some of her currently matched sellers. In other words, $\exists S \subseteq \mu(j), \left(\mu(j) \setminus S\right) \succ_j \mu(j)$.

A matching result is individual rational if it is not blocked by any buyer or seller.

Proposition 5. *The matching result of the proposed Algorithm 3 is individual rational.*

Proof. Let μ be the matching result. μ is a fixed point of the $T(\cdot)$ operation. So for any buyers $j \in \mathscr{N}$:

$$\begin{aligned} Ch(\mu_n(j), \succ_j) &= Ch(U(Ch(U(j, \mu), \succ_j)), \succ_j) \\ &= Ch(U(j, \mu), \succ_j) = \mu_n(j) \end{aligned} \tag{14}$$

$Ch(\mu_n(j), \succ_j) = \mu_n(j)$ indicates that there is no *block* for buyers. The proof for sellers is similar. Therefore, the matching result of the proposed Algorithm 3 is individual rational.

Now, we consider a special constraint, *substitutability*, on buyers' preference profiles. First introduced in [27], substitutability is widely studied in the matching literature.

Definition 9 (Substitutability). A buyer j's preference profile $\succ_j$ satisfies substitutability, if for any seller set S and $S' \subseteq S, i \in Ch(S \cup i, \succ_j) \Rightarrow i \in Ch(S' \cup i, \succ_j)$.

An interpretation of substitutability is that, if buyer j wants to have channel i among an available channel set $S \cup i$, then she still wants channel i among a smaller channel set $S' \cup i$. Substitutable preference profile can be easily satisfied, as shown by the following example. There are three sellers/channels $\{i_1, i_2, i_3\}$, buyer j's basic offer is $(b_{i_i,j}, b_{i_2,j}, b_{i_3,j}) = (1, 2, 3)$. For any two-channel bundles of i and i', buyer j is willing to pay $1.1 * (b_{i,j} + b_{i',j})$. The three-channel bundle exceeds buyer j's budget constraint. Following this logic, buyer j's preference profile is:

$$\begin{aligned} \{i_2, i_3\} \succ_j \{i_1, i_3\} \succ_j \{i_1, i_2\} \succ_j i_3 \\ \succ_j i_2 \succ_j i_1 \succ_j \emptyset \succ_j \{i_1, i_2, i_3\} \end{aligned} \tag{15}$$

It can be easily checked that this preference profile is substitutable. When all buyers' preference profiles satisfy substitutability, the matching results of the proposed Algorithm 3 are strong pairwise stable and are a subgame-perfect Nash equilibrium of the corresponding spectrum bargaining game.

Definition 10 (Strong pairwise stability). A matching result is blocked by a pair $(S, j) \in 2^{\mathscr{M}} \times \mathscr{N}$ in which $S \neq \emptyset$, if $S \cap \mu(j) = \emptyset$, $S \subseteq Ch(\mu(j) \cup S, \succ_j)$, and $j \in Ch(\mu(i) \cup j, \succ_i)$ for all $i \in S$.

A matching result is strong pairwise stable if it is not blocked by any pair of buyer and seller and individual rational.

Proposition 6. *The matching result of the proposed Algorithm 3 is strong pairwise stable.*

Proof. Assume there is a block pair (S, j) and $S \neq \emptyset$. Since $j \in Ch(\mu(i) \cup j, \succ_i)$, $\forall i \in S$, by definition of $V(j, \mu)$, we have $S \subseteq V(j, \mu)$. Thus, for any subset $A \subseteq \mu(j)$, as $\mu(j) \subseteq V(j, \mu)$, we have $A \cup S \subseteq V(j, \mu)$. Due to individual rationality, $\mu(j) = Ch(V(j, \mu), \succ_j)$. So $\mu(j) \succeq_j Ch(A \cup S, \succ_j) \succeq_j A \cup S$, in which $\succeq_j$ means that the two sets may be the same. This contradicts the fact that $S \cap \mu(j) = \emptyset$ and $S \subseteq Ch(\mu(j) \cup S, \succ_j)$. Therefore, there cannot be any blocks in the matching result μ.

Now we regard the spectrum matching as a noncooperative bargaining game. To begin with, every buyer j proposes a set of channels $\eta_j \subseteq \mathscr{M}$. After observing the proposals, every seller i proposes a set of buyers $\xi_i \subseteq \mathscr{N}$. All buyers or sellers make the proposals simultaneously. A buyer and a seller will be matched if seller i

proposes to buyer j and buyer j proposes to seller i. The strategy space for buyer j is $\eta_j \subseteq \mathscr{M}$ and for seller i is $\xi_i(\eta) \subseteq \mathscr{N}$. Now we define *subgame-perfect Nash equilibrium* (SPNE) for such a bargaining game.

Definition 11 (Subgame-perfect Nash equilibrium). Given the preference profiles $\succ$ of buyers and sellers, a strategy profile (η^*, ξ^*) is called a subgame-perfect Nash equilibrium (SPNE), if $\forall i \in \mathscr{M}, j \in \mathscr{N}$,

$$\begin{aligned} &\eta_j^* \cap \{i : j \in \xi_i^*(\eta^*)\} \succeq_i P \cap \{i : j \in \xi_i^*(P, \eta_{-j}^*)\}, \forall P \subseteq \mathscr{M} \\ &\xi_i^*(\eta) \cap \{j : i \in \eta_j^*\} \succeq_j S, \forall S \subseteq \{j : i \in \eta_j^*\} \end{aligned} \tag{16}$$

In other words, (η^*, ξ^*) is SPNE if η_j^* is optimal given other buyers' proposal η_{-j}^*, and $\xi_i^*(\eta^*)$ is an optimal proposal given all buyers' proposal η^*.

Proposition 7. *The matching result of the proposed Algorithm 3 is an SPNE of the spectrum bargaining game.*

Proof. Let μ be the matching result of the proposed Algorithm 3. Define (η^*, ξ^*) as $\eta_j^* = \mu(j)$ and $\xi_i^*(\eta^*) = Ch(\{j : i \in \eta_j^*\}, \succ_i)$. Let μ' be the outcome of the strategy (η^*, ξ^*). Now we show that (η^*, ξ^*) is an SPNE and $\mu' = \mu$.

For any i and j, $\{j : i \in \eta_j^*\} \cup j = \mu(i) \cup j$, therefore,

$$\begin{aligned} &\{i : j \in Ch(\{j : i \in \eta_j^*\} \cup j, \succ_i)\} \\ &= \{i : j \in Ch(\mu(i) \cup j), \succ_i\} = U(i, \mu). \end{aligned} \tag{17}$$

So we have $\eta_j^* = \mu(j) = Ch(U(j, \mu), \succ_j)$, which means that η_j^* is optimal given η_{-j}^*. By definitions we know that $\xi_i^*(\eta')$ is optimal, given η^*. Thus (η^*, ξ^*) is an SPNE.

Since μ is a matching, we have $j \in \mu(i)$ if and only if $i \in \mu(j) = \eta_j^*$, so that $\{j : i \in \eta_j^*\} = \mu(i)$. According to individual rationality, we have $\xi_i^*(\eta^*) = Ch(\{j : i \in \eta_j^*\}, \succ_i) = Ch(\mu(i), \succ_i) = \mu(i)$. Therefore, $i \in \mu'(j)$ if and only if $i \in \eta_j^* = \mu(j)$, and $j \in \mu'(i)$ if and only if $j \in \xi_i^* = \mu(i)$. This proves that $\mu' = \mu$.

Simulation

Simulation Settings

We assume that buyers are located in a 10×10 square. The transmission range of a channel is randomly chosen in the range $(0, 5]$. Based on buyers' locations and the transmission range of a channel, we can construct the interference graph of each channel. Preference profiles are generated as follows. We first assume that buyers' basic offer prices for individual channels are uniformly distributed in $(0, 10]$, based on which we can construct sellers' preference profiles according to section "System

Model". Then, we assume that for a combination of channels S, buyer j is willing to pay $\alpha \sum_{i \in S} b_{i,j}$, in which $\alpha > 1$ is a gain factor. If the number of channels in the combination is higher, α is higher. But there is a threshold on the size of a combination, beyond which we assume that the buyer is not willing to purchase the combination due to budget constraint. Buyers' preference profile is based on their willingness to pay for a combination of channels.

Performance of the Proposed Matching Algorithm

The influence of the number of buyers, the number of sellers, and the budget constraint (the threshold on the size of channel combinations) on social welfare of the matching result is shown in Fig. 10. When the number of buyers increases, social welfare grows quickly at first and then slows down because more buyers compete for limited channels, and the chance of obtaining channels becomes smaller. Social welfare also goes up with the number of sellers because more channels are available for the buyers to acquire. As buyers have higher budget, social welfare improves, because buyers can attain more channels with higher budget. We have checked that all fixed points of the simulation results are matching (instead of pre-matching), and the iteration times of the proposed many-to-many matching algorithm is shown

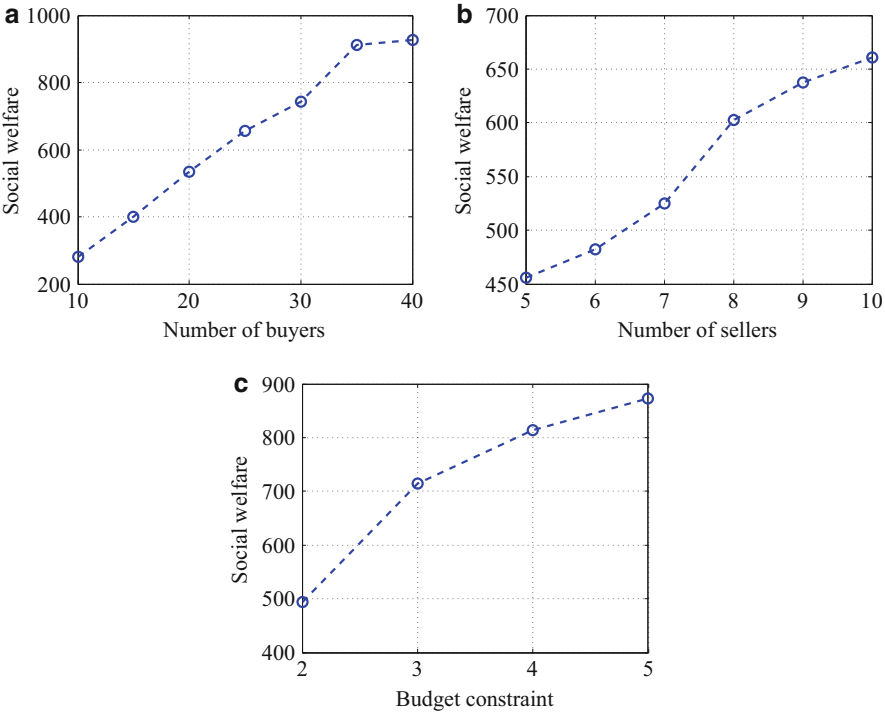


Fig. 10 Social welfare of the proposed many-to-many matching algorithm. (**a**) $M = 10$; (**b**) $N = 25$; (**c**) $M = 8, N = 30$

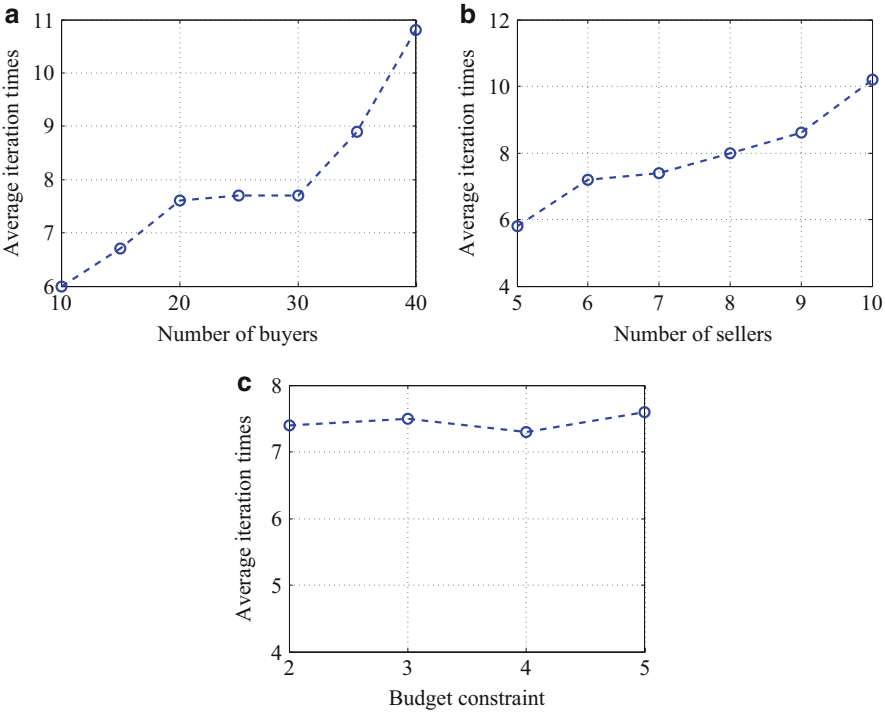

Fig. 11 Iteration times of the proposed many-to-many matching algorithm. (**a**) $M = 10$; (**b**) $N = 25$; (**c**) $M = 8, N = 30$

in Fig. 11. We can see that the proposed algorithm can converge to the fixed point within a few iterations. The iteration times are mainly affected by the number of buyers and the number of sellers. The change of budget constraint does not have a significant impact on iteration times as the number of buyers and sellers stay the same.

Conclusion and Future Directions

In this chapter, we first present the matching framework for distributed spectrum exchange in a free spectrum market and then propose the many-to-many matching framework for combinatorial spectrum trading. In stark contrast to prior double auction mechanisms, spectrum matching in section "Non-combinatorial Many-to-Many Spectrum Matching" does not require the centralized management of a third-party authority. We have designed a two-stage distributed algorithm, with consideration of the interference constraint in spectrum matching. We have theoretically proved the convergence of our algorithm, as well as the stability of the matching result. Simulations have demonstrated the efficiency of the proposed distributed algorithm,

as the final matching results can attain 90% of the maximum social welfare from optimal matching that needs centralized enforcement.

Compared with combinatorial auction which is usually NP-hard, spectrum matching in section "Combinatorial Many-to-Many Spectrum Matching" is easier to implement and is immune to collusion between the auctioneer and buyers or sellers. We theoretically prove that the matching result is individual rational, is strong pairwise stable, and is a subgame-perfect Nash equilibrium of the corresponding spectrum bargaining game. We conducted extensive simulations to evaluate the performance of the proposed many-to-many matching framework. It is shown that social welfare increases with the number of buyers or sellers, as well as buyers' budget constraint. The iteration times only depend on the number of buyers or sellers.

Matching is very promising in spectrum trading market and can be carried out easily since it requires only buyers and sellers but no third-party rule-enforcing authorities. Future work will be dedicated to investigating more research challenges. In particular, online spectrum trading where buyers and sellers join or leave the market dynamically should be taken into consideration. And the computation complexity of the algorithm also needs further discussion when testing on practical market.

Abstract

A recent drive by mobile network operators to mitigate the network capacity crunch and to improve indoor coverage involves the development of cellular heterogeneous networks. Cellular heterogeneous networks consist of the existing macrocells plus shorter range cells referred to as small cells. Coexistence of macrocells and small cells sharing the same spectrum represents a special case of cognitive networking, where small cells and their users can be viewed as secondary users, whereas the macrocell and its users act as the primary legacy users. Unlike the traditional listen-before-talk concept in cognitive radio spectrum sensing, this chapter presents techniques for utilizing inherent Radio Link Control (RLC) messages and feedback information in existing cellular systems. It develops a more-advanced cognitive approach that takes into account actual

primary user's interference tolerance and facilitates more efficient spectrum sharing. The chapter first introduces the idea of implicit cooperation through the use of inherent feedback information in cellular heterogeneous networks. Explicit cooperation is then discussed in the chapter before introducing the concept of cooperation in hybrid-access cellular heterogeneous networks as well as in dense enterprise femtocell deployments. The chapter concludes by summarizing the most recent trend of integrated access between both cellular and wireless local area network (WLAN) interfaces at small cells for traffic offloading and for improving network capacity.

Introduction

Mobile network operators (MNOs) have been facing a difficult challenge to meet the increasing demand of expansive high-data services given their limited spectrum resources. Acquisition of more spectrum is not only costly but also requires actions from the typically slow regulatory entities. Thus, MNOs have been searching in other dimensions to increase their system capacity while preparing for fifth-generation (5G) cellular systems. The concept of cell densification has been envisioned for 5G systems by deploying smaller range and lower power cells such as picocells and femtocells that are collectively referred to as small cells, in addition to the existing macrocells [1]. Throughout this chapter, femtocell is exchangeably referred to as femto base station (FBS) or home eNode B (HeNB). Similarly, femtocell user equipment (FUE) is exchangeably referred to as home user equipment (HUE).

The coexistence of macrocells, picocells, and femtocells has given rise to the concept of cellular heterogeneous networks. Macrocells and small cells can, in principle, occupy different spectra, which is not generally favored by MNOs due to the scarcity of spectrum resources. Alternatively, the common configuration of cellular heterogeneous networks is for macrocells and small cells to share the spectrum, thereby giving rise to a cognitive overlay scenario. Coexistence in cellular heterogeneous networks can happen through explicit coordination between the legacy macrocells and the newly deployed picocells/femtocells or through cognitive deployment of picocells/femtocells in the coverage of macrocells. This chapter focuses on techniques for cognitive coexistence in cellular heterogeneous networks while providing insight into cooperative operation in cellular heterogeneous networks in general.

Spectrum sharing in cellular heterogeneous networks is a direct application of the cognitive radio concept, in which small cells (e.g., picocells or femtocells) act as the secondary transmitter during downlink to serve their associated user equipments (UEs) acting as the secondary receivers. Currently, the spectrum is occupied only by the existing macrocell and its subscribers acting as the primary transmitter and receivers, respectively. We first describe various schemes for applying implicit

cooperation in cognitive networks by exploiting the concept of overhearing in cellular heterogeneous networks for resource allocation and interference management. The scope is then expanded to scenarios with limited explicit cooperation between primary users (or PUs) in the macrocells and secondary users (or SUs) in the femtocells.

Traditional cognitive radios have often focused on the idea of sensing-before-transmitting or listen-before-talk (LBT) [2], where a secondary user searches for unoccupied channel vacancies (bands) to avoid collision with the primary user transmissions. However, we note that cellular networks have inherent Radio Link Control (RLC) signaling and feedback information that may be utilized by secondary users in more efficient ways beyond the LBT paradigm. Such RLC information is already available in practical cellular systems such as LTE, including Channel Quality Indicator (CQI), power control information, and receiver ACK/NACK. Thus, they require no additional cost. Exploiting such information by secondary users (SUs) makes it possible to achieve better spectrum efficiency while satisfying the Quality of Service (QoS) requirements of primary users (PUs). Moreover, such information reflects primary receiver's actual service experience (e.g., level of interference from different sources) more accurately than spectrum sensing which focuses on transmitter activities. The basic principle of implicit cooperation in cognitive cellular networks is illustrated in Fig. 1.

In this model, secondary users transmitters (SU-Tx) and receivers (SU-Rx) can listen to primary user transmitter (PU-Tx) and can overhear link layer signal feedback reports from the primary user receiver (PU-Rx). Utilizing such feedback information represents a more mature and sophisticated level of secondary user

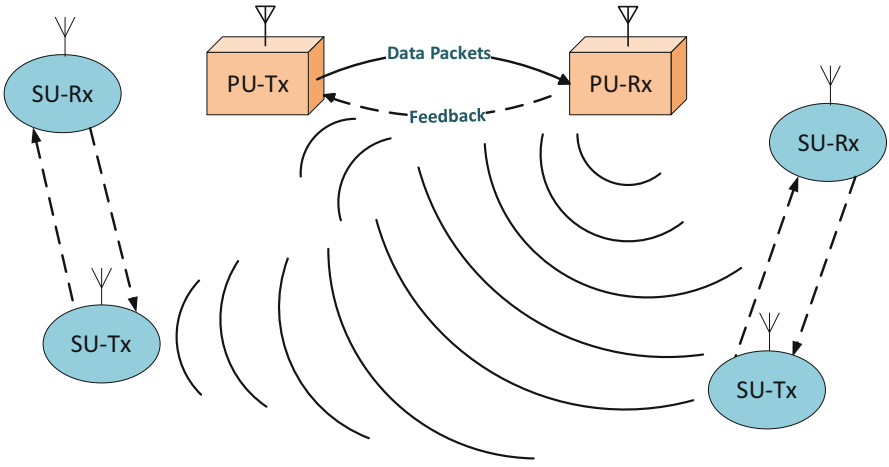

Fig. 1 Feedback overhearing concept in cellular heterogeneous networks

cognitive capability. This "overhearing concept" where secondary users can overhear the feedback information of primary transmission is at the core of various techniques to be presented in this chapter.

Implicit Cooperation in Cellular Heterogeneous Networks

This section presents a survey of various works under the implicit cooperation framework addressing different aspects of coexistence in cellular cognitive networks. In these schemes, there is no explicit cooperation between the PUs and SUs.

Dynamic Spectrum Access with Network-Layer Performance Assurance

A general requirement in cognitive radio deployments is to guarantee the performance of the PU. A PU would not be satisfied if its performance is seriously degraded by the presence of an SU overlaying on the PU spectrum. Various works have focused on PU protection from Physical (PHY) layer perspective such as limiting interference power from SU [3] or link layer perspective such as imposing collision probability constraints [4].

In [5], PU network-layer performance is characterized in terms of PU queue stability. A network access optimization for cognitive radio nodes is developed with the objective of throughput maximization for the SU under the constraint of PU queue stability. This work depends on opportunistic access by allowing the SU to overhear and utilize the ACK/NACK feedback signal, as well as PU activity/inactivity, where PU inactivity is an indication of empty PU queue. This work develops a Lagrangian formulation for SU rate maximization and links the resulting Lagrange multiplier to the PU's queue length to achieve PU rate assurance. The proposed forward equilibrium loading algorithm (FELA) for distributive SU transmission control achieves near optimal SU throughput with PU queue stability in both single SU link and multiple SU link applications.

Dual Sensing for Primary User Detection

Traditional cognitive radios employ spectrum sensing as the main approach for assessing the presence and/or activity of a PU on a specific channel [6]. The main drawback of this traditional approach is that the SU yields to the PU transmissions irrespective of the SU's transmission impact on the PU receivers. In [7, 8], a dual sensing approach is presented for PU detection. In this approach, the SU detects both the spectrum occupancy of the user band that it attempts to access and also decodes the PU Rx feedback signals that it overhears which can reflect the quality

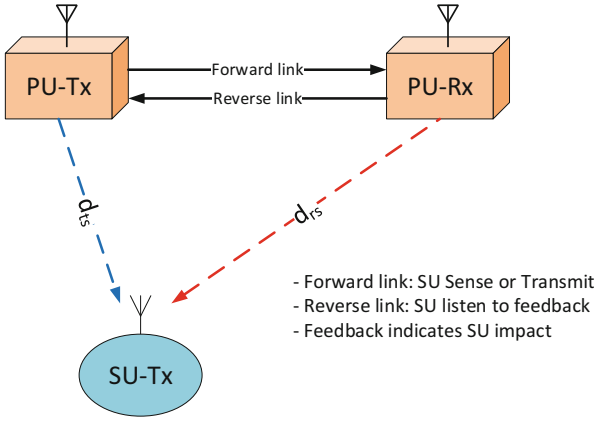

Fig. 2 Dual sensing for primary user detection

of the PU channel as well as the impact of the SU transmissions on the PU Rx, as shown in Fig. 2. This information allows a better control of the SU channel access.

The major advantage of this dual sensing approach is that noticeable change in SU-Tx channel access parameters will be reflected in feedback information of the PU-Rx. This work focuses on monitoring the ACK/NACK signal of the PU link as the main feedback information reflecting the impact of SU transmission. To devise an admission control policy for secondary users, this work uses a partially observable Markov decision process (POMDP) given a general primary busy/idle distribution. The true state (quality) of the forward link at time t, s_t, is defined as a binary state taking the value 0 when the primary channel is busy or 1 when it is idle. The state s_t is partially observable by the SU through both spectrum sensing of PU transmission and overhearing PU Rx feedback information. This approach uses past and current observations to estimate the traffic transition of the primary user through a maximum a posteriori (MAP) estimator. The use of this MAP estimator achieves high-network throughput for the secondary users while guaranteeing robust protection of the primary users.

Resource Allocation in Heterogeneous Networks Using Shadow Chasing

We have studied in [9] femtocell opportunistic resource allocation in shared spectrum heterogeneous networks. Our work presents a resource allocation scheme at FBS that maximizes the throughput of FUEs and mitigates downlink interference to nearby macrocell user equipments (MUEs). In this work, we propose a resource allocation framework called Shadow Chasing for femtocell resource allocation to achieve interference mitigation in heterogeneous networks serving both MUEs and

FUEs. A Shadow Chasing FBS uses downlink control information (DCI) together with overheard MUE ACK/NACK feedbacks and CQI reports to assign its own downlink resources to mitigate downlink interference to MUEs. Since the FBS receives outdated DCI due to backhaul delay, a likelihood metric for each resource unit being either empty or assigned to a (low-interference) outdoor MUE based on a finite-state Markov chain (MC) model for each resource unit is derived. By dynamically separating MUE and FUE assignments, the Shadow Chasing scheme can better control the downlink interference to MUEs for QoS assurance. It effectively reduces the probability of resource collision and MUE interference compared to schemes not considering backhaul delay effect or user feedbacks.

The principle of Shadow Chasing is illustrated in Fig. 3. The DCI messages are received and decoded at the FBS after a delay D that accounts for the delay of the backhaul connection plus the decoding delay. In the figure, T_m is the MBS scheduling period in Transmission Time Interval (TTI) units and we assume that $T_m \geq D$. The larger the MUE scheduling period T_m is relative to the backhaul delay D, the more confident the FBS is in the outdated DCI information it receives. On the other hand, if T_m is comparable to D, the actual MUE resource chunk assignment may be completely different from the received outdated DCI which leads more likely to incorrect FBS assignment decisions.

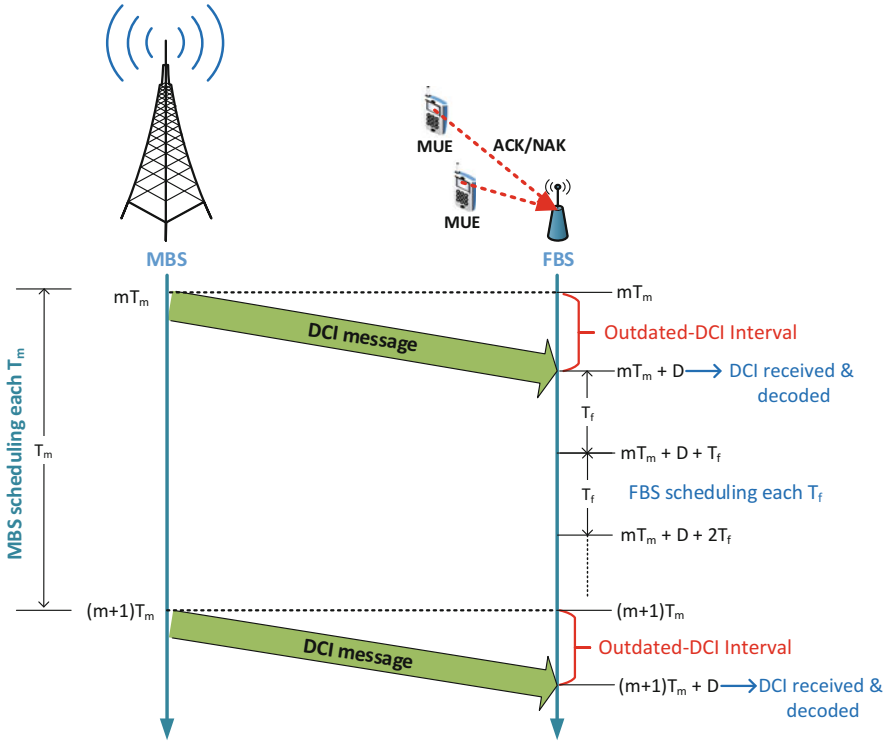

Fig. 3 Shadow chasing principle

The FBS classifies MUEs as outdoor/indoor using the DCI together with the overheard ACK/NACK in MUEs uplink feedback. From the DCI, the FBS knows Physical Resource Block (PRB) assignment pattern of different UEs. If the DCI shows that some PRBs are assigned to a certain MUE but neither ACKs nor NACKs are heard from that MUE, this means that monitored MUE is far enough such that we can fairly assume the MUE to be outdoor and unaffected. On the other hand, if either ACKs or NACKs are received from an MUE, then it is likely to be close as the FBS is already able to hear its feedback signals. Moreover, the FBS can learn from the DCI if some PRBs are not assigned to any UE.

Based on UE classification, each resource follows an MC model with three states: empty, indoor, and outdoor. The three states are defined as follows:

- State 0 : PRB/resource chunk is empty (unoccupied).
- State 1 : PRB/resource chunk is assigned to the outdoor MUE (M_o).
- State 2 : PRB/resource chunk is assigned to the indoor MUE (M_i).

The trellis diagram for this MC model is shown in Fig. 4.

The FBS assumes a certain MUE resource allocation policy that can be shared between the MBS and FBS statically or semi-statically through backhaul. An example of such MUE resource allocation policy is that an MUE assigned a PRB/resource chunk k at time $n-1$ will be assigned the same PRB/resource chunk at time n if one of the following is true:

- The MUE has good channel quality on PRB/resource chunk k at time n.
- The MUE does not have good channel quality on PRB/resource chunk k but there are no sufficient empty and good PRBs/resource chunks at time n for the MUE.

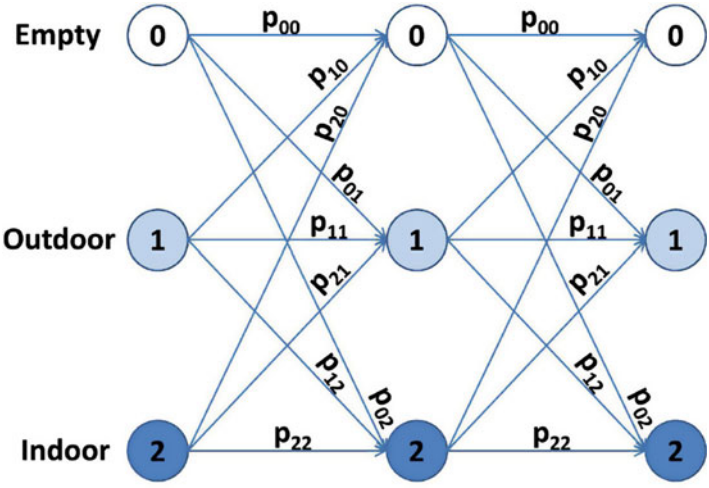

Fig. 4 Markov chain trellis diagram for shadow chasing

The probability of an MUE having a good channel quality can be defined as the probability that the CQI value reported by the MUE is greater than or equal to a channel quality threshold γ. Therefore, the probability that an outdoor MUE M_o has good channel quality on PRB/resource chunk k at time n is given by

$$p_{g_1}(k,n) = Pr(\mathrm{CQI}_1(k,n) \geq \gamma). \tag{1}$$

Based on the probabilities that a PRB/resource chunk assigned to an outdoor MUE, $p_{g_1}(k,n)$, or indoor MUE, $p_{g_2}(k,n)$, the FBS calculates the transition probabilities in Fig. 4 and forms a transition probability matrix $\mathscr{P}_k$. Moreover, at each DCI update time instance, $mT_m + D$, the FBS updates the initial state of the MC model based on the received DCI as follows:

$$p_k^{(0)} = \begin{cases} [1\ 0\ 0] & \text{resource chunk } k \text{ is empty} \\ [0\ 1\ 0] & \text{resource chunk } k \text{ is assigned to } M_o \\ [0\ 0\ 1] & \text{resource chunk } k \text{ is assigned to } M_i, \end{cases} \tag{2}$$

where $p_k^{(0)}$ denotes the initial state of the MC of PRB/resource chunk k. Referring to Fig. 3, after receiving and decoding a new DCI message at time $mT_m + D$, the FBS does not need to update the MC state till $(m+1)T_m + D$. Next in the Outdated-DCI interval $[(m+1)T_m, (m+1)T_m + D)$, the FBS updates the MC state since the MBS scheduling in this interval is uncertain to the FBS. Thus, an MC state update time index n' is defined as follows:

$$n' = \begin{cases} n - \left\lfloor \frac{n}{T_m} \right\rfloor T_m, & n \in [mT_m, mT_m + D) \\ 0 & n \in [mT_m + D, (m+1)T_m), \end{cases} \tag{3}$$

where $\lfloor x \rfloor$ is the largest integer less than or equal to x. Assuming a homogeneous MC, the state probabilities at time n can thus be given as

$$p_k^{(n)} = p_k^{(0)} \mathscr{P}_k^{n'}. \tag{4}$$

The probability of a PRB/resource chunk k being empty, outdoor, or indoor at time n is, consequently, given by $p_e(k,n) = p_k^{(n)}(0)$, $p_o(k,n) = p_k^{(n)}(1)$, or $p_i(k,n) = p_k^{(n)}(2)$, respectively. The FBS develops a likelihood metric for each resource being empty, outdoor, or indoor as follows:

$$L(k,n) = \begin{bmatrix} p_e(k,n) & p_i(k,n) & p_o(k,n) \end{bmatrix}. \tag{5}$$

Based on this likelihood metric, the order of preference for FBS resource scheduling to the FUE will be empty PRBs (if any), outdoor PRBs (since this results in very little interference), then indoor PRBs (if needed).

Figure 5 compares the sum MUE rate for three schemes, namely, "Random Assignment," "DCI-Following" (where the FBS uses the DCI information about MBS scheduling but without accounting for backhaul delay), and the proposed

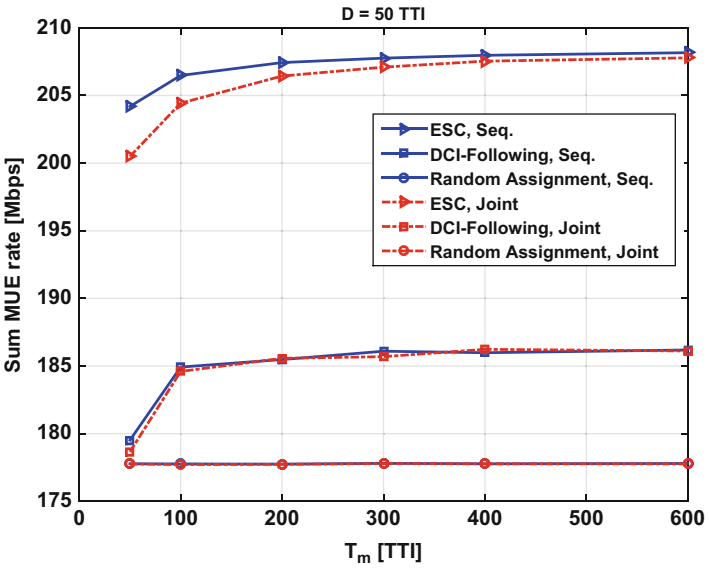

Fig. 5 Shadow chasing performance

Enhanced Shadow Chasing (ESC) scheme. As the MBS scheduling period, T_m, increases relative to the backhaul delay, D, the probability of FBS interference to the indoor MUE drops and, hence, the effect of D becomes less significant. Consequently, in the following figure, the sum MUE rate improves. The figure also shows that sequential scheduling at the MBS gives higher sum MUE rate compared to joint scheduling when associated with Shadow Chasing at the FBS. The reason for this difference is that sequential scheduling is a two-step approach that inherently allows swapping between resource chunks assigned to indoor and outdoor MUEs whereas joint scheduling is done in one step with no swapping between resource chunks assigned to indoor and outdoor MUEs. Thus, sequential scheduling can provide more good resource chunks for both MUEs versus joint scheduling that is limited by the availability of empty resource chunks with good CQI qualities.

Resource Allocation in Cellular Heterogeneous Networks Using CQI Feedback

Another work [10,11] that exploits the "overhearing concept" addresses the resource allocation problem in femtocells using MUE CQI feedback to the MBS to estimate the channel gain distribution. This work provides a decentralized technique for FBS resource scheduling using the overheard CQI report and a priori statistical channel information. In order to achieve this objective, each FBS has to use certain cognitive capabilities that allow it to sense the CQI of neighboring MUEs. Unlike

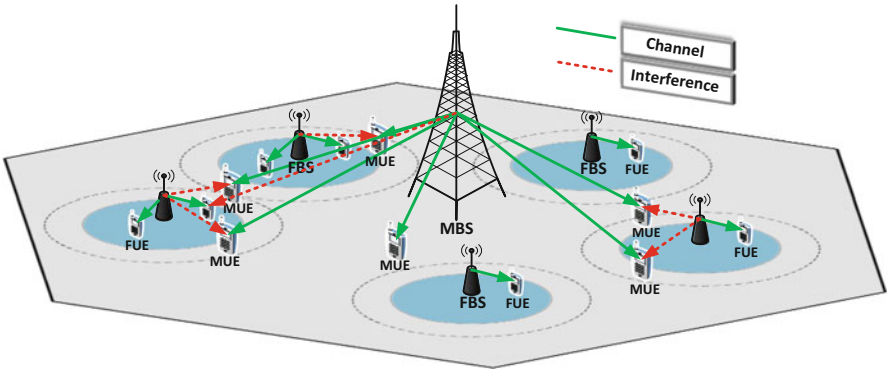

Fig. 6 Network model for closed access FBSs

most of existing works [12–14], this work does not assume channel gain information exchange between FBS and MBS, hence considered implicit cooperation. Specifically, the work studies femtocell downlink scheduling and power assignment based on listening to CQI reports from nearby and impacted MUEs to the MBS. The objective is to maximize the FBS total mean capacity while maintaining minimum QoS for the MUEs that share the same downlink spectrum.

This work considers femtocells in closed access mode where the cellular network adopts the standard LTE-A time division duplex (TDD) frame structure. Figure 6 depicts a two-tier macro-femto network, consisting of a central MBS, owned and operated by a cellular service operator, and a number of FBSs deployed by the femto clients with cellular subscription. Each FBS shares its assigned bandwidth with the MBS while avoiding the intra-tier interference with other FBSs. Due to the orthogonal resource assignments for adjacent femtocells, the intra-tier interference effect is avoided [15, 16]. Each FBS will be provided with cognitive capabilities in order to assist in the scheduling and power assignment process. Additional details on how these cognitive capabilities can assist the FBS to acquire the needed information are discussed in [10].

Also this work assumes that each FBS has a signal footprint (shown by the dashed circle in Fig. 6) such that the MUEs within this footprint and assigned the same FBS bandwidth will experience noticeable FBS interference (represented by red dashed lines in Fig. 6) due to spectrum sharing. Such co-channel interference outside the footprint is neglected. The presented formulation focuses on one MBS and one FBS in isolation by allocating orthogonal channels to adjacent FBSs, justified by the possibility for each FBS in the network to use the proposed scheme independently.

According to [11], the network channel gains are classified into known and unknown channels. Any channel gain that the FBS can estimate directly or can be estimated by the user and reported to the FBS through a control channel (indirectly) is considered known, while unknown channels cannot be estimated by the FBS directly or indirectly. Channel estimation error is included in the known channel

model for robustness considerations, while for the unknown channels, channel modeling relied on the overheard MUE CQI information.

To provide a decentralized technique, the problem formulation captures the scheduling of all FBSs in the heterogeneous network. The main objective is to maximize the mean total rate for all the FUEs served by the FBS subject to resource assignment, QoS, and power constraints while optimizing the users' assigned power levels (**P**) as well as the assignment indicator (**A**). The problem formulation is given as

$$\max_{\mathbf{P},\mathbf{A}} \left(\sum_{i=1}^{N_f} \sum_{j=1}^{N_c} a_{i,j} \mathbf{E}[R_{i,j}] \right) \tag{6a}$$

$$s.t. \quad \sum_{i=1}^{N_f} a_{i,c} \leq 1 \qquad \sum_{j=1}^{N_c} a_{u,j} = 1, \tag{6b}$$

$$\mathbf{Pr}\left(\sum_{j=1}^{N_c} a_{u,j} \gamma_{u,j} \geq \gamma_r \right) \geq \alpha, \quad u = 1 \ldots N_f, \tag{6c}$$

$$\mathbf{Pr}\left(\sum_{j=1}^{N_c} \xi_{v,j} \gamma_{v,j} \geq \gamma_r \right) \geq \beta, \quad v = 1 \ldots N_M, \tag{6d}$$

$$P_b \leq P_{u,c} \leq P_t, \quad u = 1 \ldots N_f, \quad c = 1 \ldots N_c, \tag{6e}$$

where $a_{i,j}$, $\xi_{i,j} = \{0, 1\}$ are indicator variables for FUEs and MUEs to indicate whether or not user i occupies channel j. $R_{i,j}$ and $\gamma_{i,j}$ are the rate and signal to interference-plus-noise ratio (SINR) of UE i when using channel j, respectively. The parameters N_f, N_c, and N_M are the number of FUEs, number of available channels, and number of neighboring MUEs, respectively. **P** is $(N_f \text{x} N_c)$ matrix representing FUE power assignments and is expressed as $\mathbf{P} = [P_{i,j}]$ where $P_{i,j}$ is the power assigned for FUE i on channel j. **A** is the matrix of indicator coefficients of FUEs and is expressed as $\mathbf{A} = [a_{i,j}]$ $\forall i \in \{1, 2 \ldots N_f\}, j \in \{1, 2 \ldots N_c\}$. Based on its cognitive capabilities, the authors assume that FBS can overhear the scheduling information $(\xi_{i,j}(t))$ of the neighboring MUEs [10]. To ensure QoS for all UEs, FUE QoS constraint is considered in (6c), meanwhile (6d) guarantees an acceptable interference level at neighboring MUE sharing the same spectrum.

The presented optimization problem is considered to be a mixed integer nonlinear (MINL) optimization problem which is non-convex and NP hard in general [17]. To overcome the high complexity of conventional solutions, problem reduction can help develop a solution.

The main idea is to transform the underlying problem from a general form (MINL) to a known form for which there exists a known optimal and efficient algorithm. One common use of problem reduction is to show that a specific problem belongs to a certain class of complexity like P, NP, or NP-complete [18]. The

reduction method is based on the users SINR distribution analysis made for two different channel models.

In the problem formulation, we added FUE and MUE QoS coverage probability constraints. These constraints can be transformed into power constraints using the cumulative distribution function (CDF) of the UE SINR. Moreover, our algorithm transforms the given problem into maximum weighted bipartite matching problem that can be solved optimally using the (Kuhn-Munkres) Hungarian algorithm in polynomial time or even suboptimally by applying greedy algorithm in linear time [19,20].

The work in [10] illustrates the importance of considering estimation error through comparing the maximum total mean capacity of the served FUEs with and without considering estimation error in the channel model. It also compares the Hungarian and greedy algorithm performance. Figure 7 shows the total mean capacity of the served FUEs versus the coverage probability β, from which we can observe the performance difference for considering and ignoring estimation error. Furthermore, this result verifies the achievable gain when applying the Hungarian algorithm versus the greedy algorithm.

Another work in [11] focuses on presenting the performance when using the available feedback information (CQI) instead of explicitly transmitting the channel gain information. Two cases are considered: in the first case (Case I), the FBS receives the channel gain information for all MBS-MUE channels at $t-1$ ($G_{M,v}(t-1)$), whereas in the second case (Case II), the FBS overhears the CQI of neighboring MUEs to estimate the distribution of their channel gains based

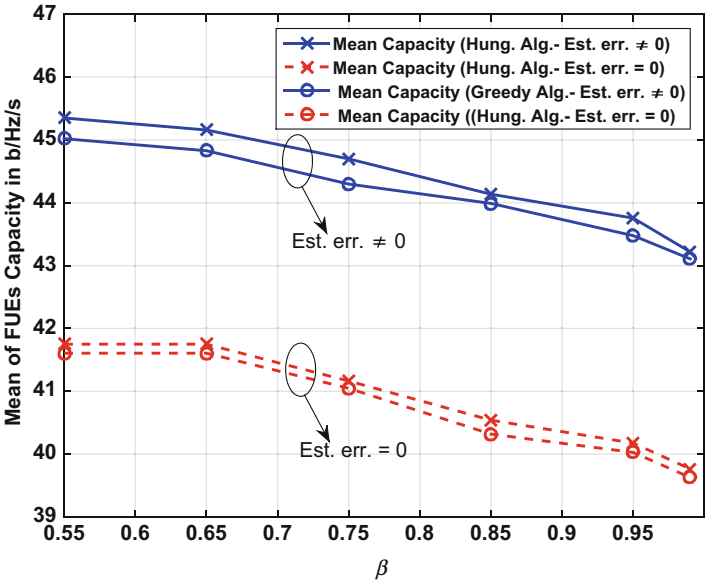

Fig. 7 Solutions results according to error assumptions for different β

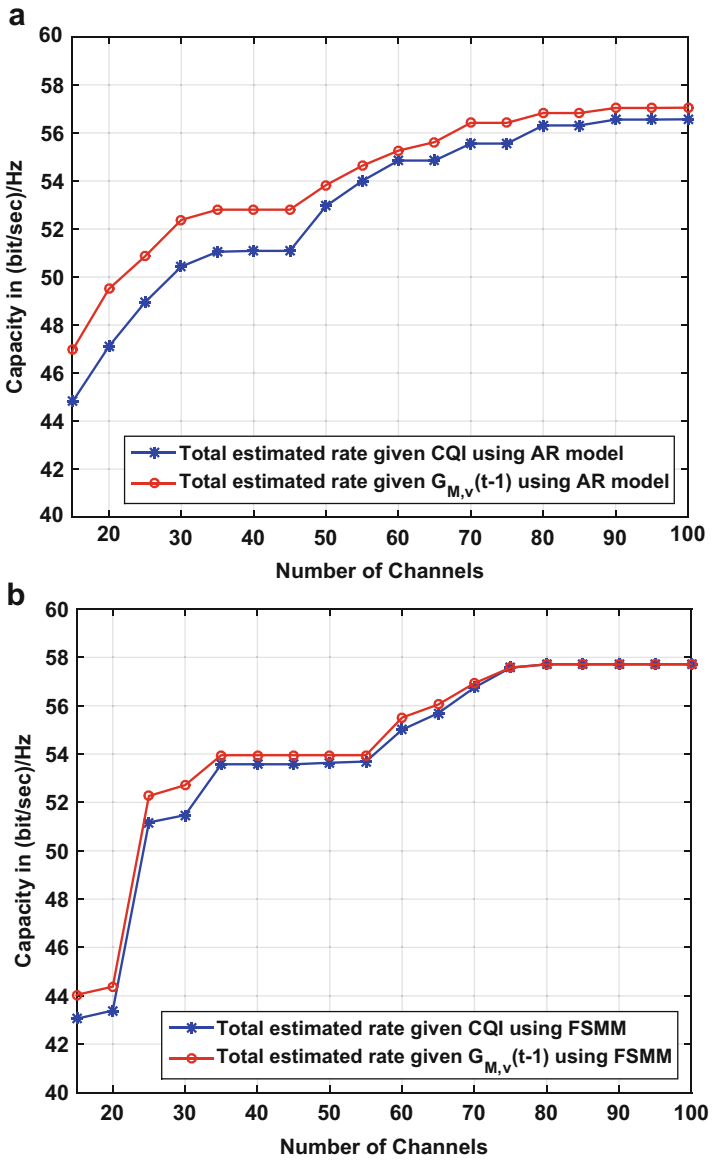

Fig. 8 (**a**) Total mean capacity versus the available number of channels using AR model; (**b**) Total mean capacity versus the available number of channels using FSM model

on the CQI report. Figure 8 depicts the total mean capacity as the number of channels grow using two different channel models, the 1st order autoregressive (AR) channel model and the finite state Markov model (FSMM). Clearly, as the number of available channels for scheduling increases, the gap between the two cases becomes increasingly insignificant.

Explicit Cooperation in Cellular Heterogeneous Networks

This section describes schemes where macrocells and femtocells cooperate for resource allocation and/or interference management. Interference coordination in cellular heterogeneous networks has been discussed actively in 3GPP standards under the Enhanced Inter-Cell Interference Coordination (eICIC) framework [21, 22]. Such techniques entail explicit coordination of messages between the macrocell and femtocells for interference mitigation [23]. Examples of these eICIC techniques include time domain techniques such as the use of almost blank subframes (ABSFs) as well as frequency domain techniques such as orthogonalizing control and reference signals of macrocells and small cells [24]. In ABSFs, a femtocell only sends reference signals such as pilots, i.e., it does not send any data or control information in order to reduce the interference to nearby MUEs. Frequency-domain eICIC techniques include transmitting control and reference signals on non-overlapping frequencies. Such orthogonalization can be done statically or dynamically through coordination between the macrocell and small cells. For examples, when there are some victim MUEs in the vicinity of a small cell and the macrocell detects this through the MUE feedback reports, the macrocell can send this information to the interfering small cell to send its control and reference signals on a different frequency channel.

Another example of explicit cooperation in cellular heterogeneous networks is based on MIMO precoding in the framework of using MUE feedback signals overheard by the femtocell as in the rest of the techniques in this chapter or delivered to the femtocell by the macrocell through backhaul. Both approaches are feasible in cellular heterogeneous networks where the different tiers of the heterogeneous networks are generally operated by the same cellular carrier. The work in [25] investigates interference mitigation in cellular heterogeneous networks consisting of traditional macrocells and overlaid femtocells through dynamic MIMO precoding by designing distributed low-complexity beamforming mechanisms that are compliant with current cellular technology standards. In this work, we also provide an analysis of the mean throughput under the proposed precoding schemes in the format of a simple closed form that provides insight on how the mean throughput depends on basic transmitter, channel, and receiver parameters.

The paper takes advantage of a special LTE standard feature known as MIMO precoder restriction for interference control between HeNB and MUE. Based on MUE feedback signals overheard at the HeNB, the HeNB can choose a precoder for downlink transmission to HUEs that can effectively reduce interference to MUE which share the same frequency spectrum. The paper presents three beamforming schemes for interference mitigation that take into account the QoS requirement of both femtocell and macrocell clients. These MIMO precoding strategies improve flexibility in resource provisioning and signaling requirement while responding to different QoS needs. For example in the MUE Restricted Subset (MRS) scheme, a connection is established between the MUE and the interfering HeNB. This connection is used to exchange information between the HeNB and the MUE. First, MUE estimates the cross-channel response based on HeNB downlink reference

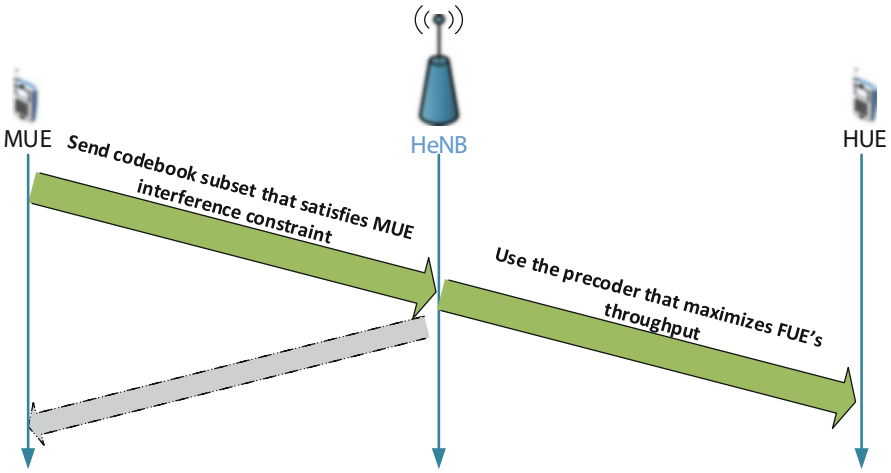

Fig. 9 MRS MIMO precoding scheme in cellular heterogeneous networks

signals (pilots). The MUE sends to the HeNB a subset of indices in the codebook that meet its QoS requirement. The QoS requirement of the MUE is expressed as a maximum tolerable HeNB interference level. After receiving the set of indices satisfying MUE requirement, the HeNB chooses the one that maximizes the SINR to its HUEs. This procedure is summarized in Fig. 9.

The proposed algorithms achieve HeNB precoder selection in two steps: precoder subset restriction at the MUE or HeNB and final precoder selection out of the restricted subset at the HeNB or MUE, respectively. For example, in the MRS scheme, the MUE first selects a subset of precoders that meet its maximum tolerable interference requirement as follows:

$$\mathscr{W}_1 = \left\{ \mathbf{w}_i : \; P_f G_{10} \left\| \mathbf{H}_{10} \mathbf{w}_i \right\|^2 \leq \varepsilon \right\}. \tag{7}$$

where ε is the maximum tolerable interference power at the MUE, $\mathscr{W}_1$ is the set of restricted precoders for the MRS scheme, P_f is the HeNB transmission power, and $\mathbf{H}_{10}$ and G_{10} are the channel and power gain between the HeNB and the MUE, respectively. This subset is sent to the HeNB, which, accordingly, selects the optimum precoder $\mathbf{w}_{i*}$ out of this subset that maximizes its HUEs SINR as

$$w_{i*} = \max_{\mathbf{w}_i \in \mathscr{W}_1} \frac{P_f G_{11} \left\| \mathbf{H}_{11} \mathbf{w}_i \right\|^2}{P_m G_{01} \left\| \mathbf{H}_{01} \mathbf{w}_{m*} \right\|^2 + N_0 B_f}, \tag{8}$$

where P_m is the macrocell transmission power, $\mathbf{w}_{m*}$ is the precoder used by the macrocell, $\mathbf{H}_{11}$ and G_{11} are the channel and power gain between the femtocell and the HUE, respectively, $\mathbf{H}_{01}$ and G_{01} are the channel and power gain between the macrocell and the HUE, respectively, N_0 is the noise power, and B_f is the HUE bandwidth.

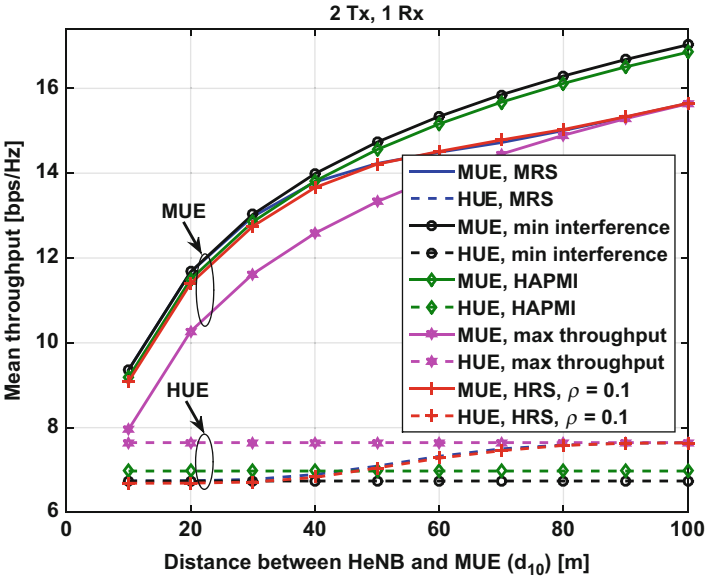

Fig. 10 Performance comparison for MIMO precoding schemes in cellular heterogeneous networks

Figure 10 shows the 5% outage capacity of both MUE and HUE versus HeNB-to-MUE distance, d_{10} for the different proposed schemes. As shown in the figure, the system has the flexibility to assign priority to MUE interference mitigation in heavily loaded networks (by using the MRS scheme) or to HUE throughput maximization in lightly loaded networks (by using the HUE Augmented PMI (HAPMI) scheme). For the MRS scheme, we notice that as d_{10} increases, HUEs throughput grows because the interference power at the MUE drops and, therefore, it becomes easier to satisfy the maximum interference conditions. Consequently, the size of precoder subset becomes larger which gives more flexibility for HUEs throughout maximization. The HRS (HeNB Restricted Subset) scheme in Fig. 10 is a modification of the MRS scheme, where the HeNB estimates the channel between itself and the MUE based on channel reciprocity with a reciprocity error variance of ρ. This scheme does not need any explicit coordination between the HeNB and the macrocell. Therefore, the HRS scheme can be considered an example of implicit cooperation in cellular heterogeneous networks.

Cooperation in Hybrid Access Cellular Heterogeneous Networks

In explicit cooperation scenarios, there exists a better chance to get more cooperation between MBS and FBSs. This kind of cooperation can be used to increase the network throughput. One example for such cooperation is shown in [26], where it

is used to motivate FBS to adopt hybrid access mode instead of the closed access mode. Basically, user access to femtocells can be one of three types: open access, closed access, and hybrid access [27–29].

In open access, all network users (MUEs or FUEs) can access the FBSs. In closed access, only subscriber FUEs are granted FBS access but not MUEs. In general, open access is advantageous from the MUE's perspective [27, 30]. For limited FBS resources, FUE performance in open access may be negatively affected by too many MUEs [28]. On one hand, closed access is easy to implement and gives FUEs better rate and privacy. On the other hand, certain MUEs may receive weak signal from MBS but suffer from strong interference signal by the FBS. Furthermore, spectrum utilization of closed access networks is lower due to the lack of flexibility to serve MUEs even if spare resource is available.

Hybrid access mode offers a trade-off between the first two modes, allowing MUEs to access the FBS so long as the QoS of target FUEs are guaranteed. This means that MUEs can access the FBS without causing serious harm to FUEs. In [31] and [32], the authors have shown that hybrid access outperforms either closed access or open access by significantly reducing cross-tier interference while guaranteeing the performance of FUEs. The practical challenge in hybrid access femtocell is basically how to incentivize FBS to share their spare resources with the MUEs when it can afford to [33, 34]. In [26], we assume that FBS and MBS do not possess prior knowledge of all interference channel state information (CSI), unlike existing work. Practically, such prior knowledge on CSI would require well-coordinated measurement control and signaling. Furthermore, substantial network bandwidth or backhaul must be used to exchange the measured link and interference CSI. Thus, the problem is motivated by the network need for interference management while, at the same time, reducing the excessive burden for interference CSI measurement and transfer.

We develop a refunding framework to stimulate the FBS to serve MUEs with poor channel conditions referred to as hybrid MUEs (hMUEs). This framework will require cooperation between MBS and underlying FBSs and accordingly will reward FBSs when serving MUEs while guaranteeing minimum QoS for the served users (FUEs and MUEs). We formulate this optimization problem as follows:

$$\max_{\mathbf{A},\mathbf{b},\mathbf{P},\mathbf{P}^F} \mathscr{H}(g_F) - \nu F_r \tag{9a}$$

$$s.t. \quad \sum_{i=1}^{N_f} a_{i,c} \leq 1 \qquad \sum_{j=1}^{N_c} a_{u,j} = 1, \tag{9b}$$

$$\mathbf{Pr}\left(\sum_{j=1}^{N_c} a_{u,j}\gamma_{u,j} \geq \bar{\gamma}\right) \geq \alpha, \quad u = 1, 2 \ldots N_f, \tag{9c}$$

$$\mathbf{Pr}\left(\sum_{j=1}^{N_c} \xi_{v,j}\gamma_{v,j} \geq \bar{\gamma}\right) \geq \beta, \quad v = 1, 2 \ldots N_m, \tag{9d}$$

$$\mathbf{Pr}\big(\eta_w \geq \bar{\eta}\big) \geq \varepsilon, \qquad w = 1, 2 \ldots N_h, \tag{9e}$$

$$F_r + \sum_{i=1}^{N_h} b_i \mathbf{E}[R_i^F] \leq R_T, \tag{9f}$$

$$P_b \leq P_i^F \leq P_t, \quad i = 1, 2 \ldots N_f + N_h, \tag{9g}$$

where N_f, N_h, N_m, and N_c are the number of FUEs, hMUEs, MUEs, and channels, respectively, g_F is the FBS gain function, F_r is the expected sum rate of the FUEs in the femtocells, and $\mathscr{H}(.)$ is a 1-to-1 monotone function that converts power to rate, in order to unify the units of g_F and F_r (g_F is summation of power). $\mathbf{P}$ is $(N_f \mathrm{x} N_c)$ matrix representing FUE power assignments and is expressed as $\mathbf{P} = [P_{i,j}]$, while $\mathbf{A}$ is the matrix of indicator coefficients of FUEs and is expressed as $\mathbf{A} = [a_{i,j}]\ \forall i \in \{1, 2 \ldots N_f\}, j \in \{1, 2 \ldots N_c\}$. Also $\mathbf{P}^F$ and $\mathbf{b}$ represent $(1 \times N_h)$ vectors containing power assignments and indicator coefficients of the hMUEs, respectively, such that entries of $\mathbf{P}^F = [P_i^F]$ and $\mathbf{b} = [b_i]\ \forall i \in \{1, 2 \ldots N_h\}$. P_b, P_t are the minimum and maximum power levels allowed for each user respectively, while $P_{i,j}$, P_i^F are the power assigned for user i on channel j and the power assigned for user i from the FBS respectively. $a_{i,j}$, $\xi_{i,j} = \{0, 1\}$ are respectively indicator variables for FUEs and MUEs to indicate whether or not user i occupies channel j, while $b_i = \{0, 1\}$ is indicator variable for hybrid MUEs to indicate whether or not user i will be served by the FBS. $\gamma_{u,j}, \gamma_{v,j}$ are the SINR of the FUE u, MUE v on channel j respectively, η_w is the SNR of hMUE w, while $\bar{\gamma}$ and $\bar{\eta}$ are respectively the required SINR and SNR that guarantee reliable communication for the requested service. $\alpha, \beta, \varepsilon$ are the coverage probability values (outage probability additive inverse). R_T is the upper bound on the average backhaul rate for the FBS and $\mathbf{E}[R_i^F]$ represents is the expected rate of the hMUE i.

We refer to the constraints shown in (9b) as the assignment constraints which guarantee that each user will be assigned no more than one channel, while (9c), (9d) and (9e) are noted as the QoS constraints. These constraints are meant to keep the QoS of the users above certain threshold. Using (9f), the FBS will limit overall FBS backhaul rate such that the total expected rate of all users served by the FBS (FUEs and hMUEs) should not exceed the backhaul rate limit R_T.

The constant $\nu \in \{0, 1\}$ determines the FBS objective dependency. On one hand, when $\nu = 0$, the FBS objective will fully depend on the gain from serving hMUEs as long as the FUEs QoS and power constraints are satisfied. On the other hand, when $\nu = 1$, the FBS will try to minimize the mean sum rate of the FUEs while maximizing the FBS gain. Basically, by varying the value of ν, the problem remains unchanged. To be more specific, in terms of the optimum solution sets for each case, the solution set of the problem when $\nu = 1$ is included in the solution set when $\nu = 0$. Therefore, by setting $\nu = 1$, we only tighten our optimum solution set.

A two-step solution approach was proposed in [26]. Step (1) starts by decomposing the given optimization problem into two decoupled problems. The first problem handles the FUE scheduling such that each user maintains the required QoS, while the second problem deals with the hMUE power assignments. Moreover, the FBS backhaul rate limitation is considered, which will directly affect the FBS capacity to serve hMUEs. Additionally, Step (2) reduces the decomposed problems into well-known forms as in [10,11]. The provided reduction is based on the SINR distribution analysis results.

The optimality of the proposed solution was tested through comparing it with the exhaustive search solution as shown in Fig. 11. Moreover, the paper provides a comparison between the proposed mechanism and the fractional frequency reuse (FFR) presented in [35]. FFR is based on dividing the entire spectrum into sub-bands and assigning each base station different sub-bands. Allocating non-overlapped spectrum will mitigate the induced intra-tier interference between FBSs as well as the cross-tier interference between each FBS and the MBS. The results in Fig. 12 illustrate that the proposed algorithm in [26] provides a negligible difference in the mean sum rate compared to FFR at different levels of spectrum/bandwidth saving. This bandwidth saving benefit is made possible by trading more power for better spectral efficiency, as shown in Fig. 12b. The results in Fig. 12b show that the proposed scheme requires higher FBS power consumption as the percentage of bandwidth saving increases. It is clear that because of the higher spectral efficiency of the proposed technique in [26], the power needed to deliver the same service is higher.

Cooperation in Dense Enterprise Femtocell Networks

This section discusses cooperation in dense enterprise deployments consisting of multiple neighboring femtocells such as in corporate premises, shopping malls, stadiums, or conference venues. Unlike home deployments of femtocells, enterprise deployments are generally dense resulting in large co-channel interference among femtocells if they reuse the same frequency. On the other hand, orthogonal frequency allocation can result in lower area spectral efficiency. Due to the large amount of cooperation needed for resource allocation and interference management in enterprise deployments, a central controller is generally needed as in [36–38].

Our work in [38] addresses the problem of interference management and coarse resource allocation using a central controller through an adaptive graph coloring approach (AGC). The block diagram of the solution presented in [38] is shown in Fig. 13. Each femtocell estimates the total number of resources needed to meet the requirements of its associated FUEs based on their traffic type, in a step referred to as Load Estimation. To minimize interference to adjacent femtocells, each femtocell n solves an optimization problem with the objective of minimizing the number of resources (PRBs) needed to meet minimum rate requirements of the associated FUEs as follows:

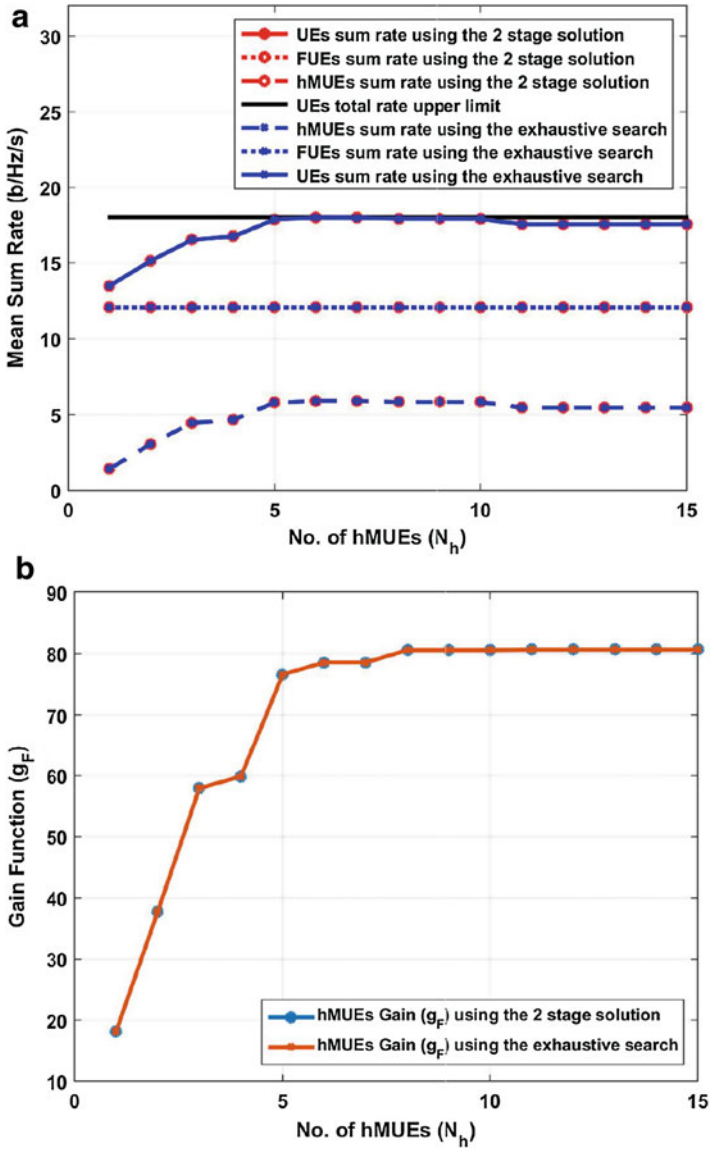

Fig. 11 (**a**) The UEs (FUEs, hMUEs) mean sum rate at $\nu = 1$; (**b**) FBS gain function (g_F) at $\nu = 1$

$$\min_{\{w_i^{(n)}, P_i^{(n)}\}} \sum_{i \in \Omega_n} w_i^{(n)} \tag{10a}$$

$$s.t.\ w_i^{(n)} \frac{B}{K} \log_2 \left(1 + \frac{P_i^{(n)} H_i^{(n)}}{w_i^{(n)} \sigma^2}\right) \geq \bar{r}_i^{(n)}, \quad \forall i \in \Omega_n, \tag{10b}$$

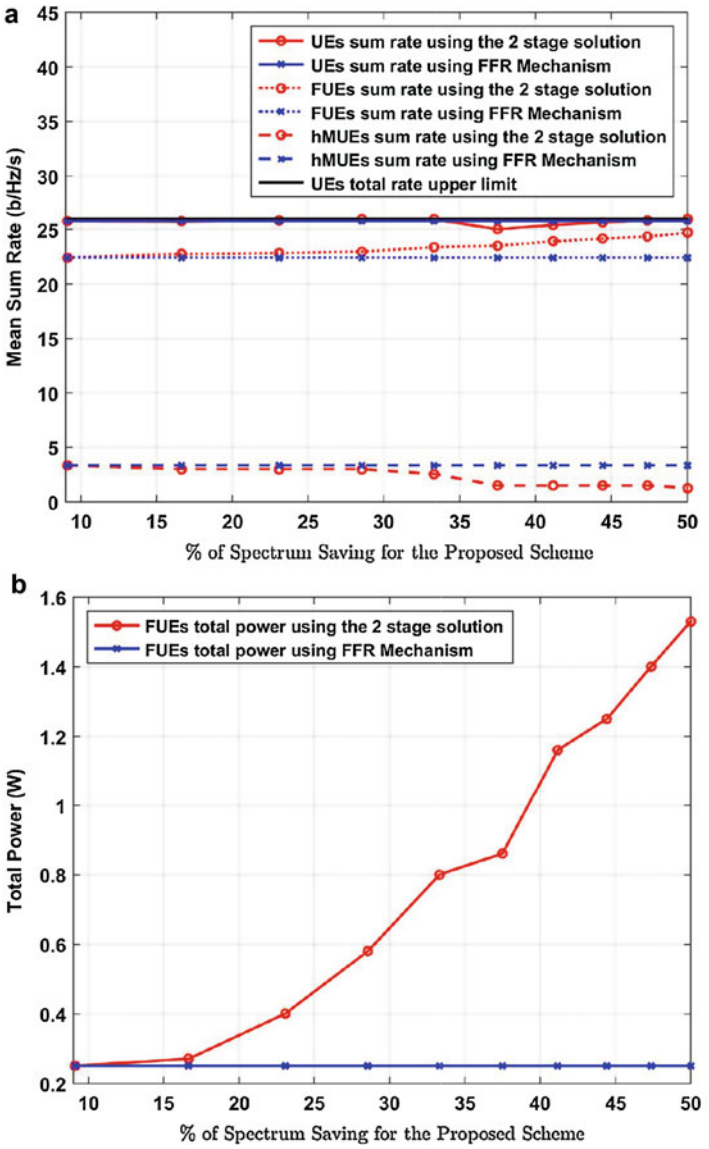

Fig. 12 (**a**) The UEs (FUEs, hMUEs) mean sum rate variation with the percentage of spectrum saving; (**b**) FBS total power consumption variation with the percentage of spectrum saving

$$\sum_{i \in \Omega_n} P_i^{(n)} \leq P_{\max}^{(n)} \tag{10c}$$

$$\sum_{i \in \Omega_n} w_{i,c}^{(n)} \leq K \tag{10d}$$

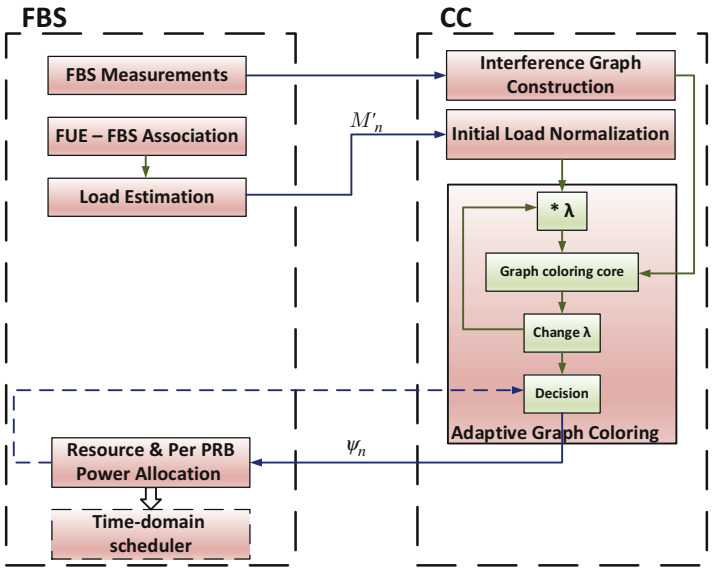

Fig. 13 Adaptive graph coloring block diagram

$$P_i^{(n)} \geq 0, \ \forall i \in \Omega_n \tag{10e}$$

$$w_{i,c}^{(n)} \geq 0, \ \forall i \in \Omega_n, \ \forall c \in C_i^{(n)} \tag{10f}$$

In (10), $w_i^{(n)}$ and $\bar{r}_i^{(n)}$ are the estimated number of required PRBs and the minimum rate requirement for FUE i associated with femtocell n, respectively, $P_i^{(n)}$ is the average per-PRB power allocated to FUE i, $P_{\max}^{(n)}$ is the maximum transmission power of femtocell n, Ω_n is the set of FUEs associated with femtocell n, B is the total system bandwidth, K is the total number of PRBs, and $H_i^{(n)}$ is the average channel power between femtocell n and FUE i. The formulation in (10) is a convex optimization problem in the variables $w_i^{(n)}$ and $P_i^{(n)}$. The outcome of this load estimation step at each femtocell n is the sum of the number of PRBs required for the FUEs associated with femtocell n, denoted as $M'_n = \sum_{i \in \Omega_n} w_i^{(n)}$. This estimated load represents a coarse estimate of the actual number of resources needed by the FUE since interference from neighboring femtocells is not considered in this step yet.

Based on the estimated load from each femtocell, the central controller then performs resource allocation among the femtocells using a graph coloring approach. The graph coloring approach allocates resources among femtocells in an iterative greedy fashion allowing frequency reuse and minimizing inter-cell interference among femtocells. The outcome of the graph coloring step is a set of resources, Ψ_n, for each femtocell n that can then be used by the femtocell locally to distribute

among its associated FUEs. The central controller also calculates the amount of interference among femtocells based on graph coloring results and sends this information to each femtocell.

After the graph coloring step, each femtocell locally performs resource and per-PRB power allocation to its associated FUEs. Different objective functions for resource allocation at each femtocell can be max-min fairness or sum rate maximization. For example, the max-min fairness optimization problem is formulated as follows:

$$\max_{\{p_{i,k}^{(n)}, s_{i,k}^{(n)}\}} \min_{i} \quad \frac{B}{K} \sum_{k \in \Psi_n} s_{i,k}^{(n)} \log_2 \left(1 + \frac{p_{i,k}^{(n)} h_{i,k}^{(n)}}{s_{i,k}^{(n)} (\sigma^2 + \sum_{m \in \mathscr{I}_k} P_k^{(m)} G_{mni})} \right) \tag{11a}$$

$$s.t. \quad R_i^{(n)} \geq \bar{r}_i^{(n)} \tag{11b}$$

$$\sum_{k \in \Psi_n} \sum_{i \in \Omega_n} p_{i,k}^{(n)} \leq P_{\max}^{(n)} \tag{11c}$$

$$\sum_{i \in \Omega_n} s_{i,k}^{(n)} = 1, \ \forall k \in \Psi_n \tag{11d}$$

$$p_{i,k}^{(n)} \geq 0, \ \forall i \in \Omega_n, \forall k \in \Psi_n \tag{11e}$$

$$s_{i,k}^{(n)} \geq 0, \ \forall k \in \Psi_n, \tag{11f}$$

where B is the total system bandwidth, K is the total number of PRBs, $s_{i,k}^{(n)}$ is the time sharing coefficient of PRB k for FUE i connected to FBS n, $p_{i,k}^{(n)}$ and $h_{i,k}^{(n)}$ are the transmission power and channel gain from FBS n to FUE i on PRB k, respectively, σ^2 is the noise power, $\mathscr{I}_k$ is the set of interfering FBSs on each PRB k, $P_k^{(m)}$ is the average transmission power of every interfering FBS m in the set $\mathscr{I}_k$ on PRB k, and G_{mni} is the path loss from FBS m to FUE i associated with FBS n. The problem in (11) is a convex optimization in the variables $p_{i,k}^{(n)}$ and $s_{i,k}^{(n)}$.

On top of the described baseline graph coloring approach, paper [38] presents an adaptive graph coloring scheme that finds the best trade-off between frequency reuse and orthogonal allocation among femtocells. In low-interference regimes, a higher frequency reuse allows better spectral efficiency, whereas in high-interference regimes, orthogonal allocation would be preferred. To reach a good compromise between both extremes, the central controller searches for the best scale parameter λ for the number of resources assigned to femtocells to achieve a certain objective function. Two methods are proposed for adapting the scale parameter λ, namely, estimation-based adaptive graph coloring (EB-AGC) and feedback-based adaptive graph coloring (FB-AGC). In EB-AGC, the central controller estimates the rate of each femtocell based on candidate graph coloring results and in FB-AGC, each femtocell reports to the central controller its attained rate to aid in choosing the best graph coloring result for the whole network.

Besides the EB-AGC and FB-AGC schemes, the following resource allocation schemes are considered for performance comparison:

- **Uniform Zero Frequency Reuse (Uniform ZFR)**
  Orthogonal resource allocation with each femtocell allocated an equal number of PRBs given by $M_n = \left\lfloor \frac{K}{N} \right\rceil \quad \forall n$ regardless of the actual FBS load.
- **Proportional Zero Frequency Reuse (Proportional ZFR)**
  Orthogonal resource allocation among femtocells with proportional allocation to the initial estimated load by each femtocell as in (10).
- **Full Frequency Reuse (FuFR)**
  Reusing all available resources for all femtocells, i.e., each femtocell is allocated all K available PRBs ($M_n = K \quad \forall n$).

Figure 14 shows the average minimum FUE achieved rate using max-min fairness criteria at each femtocell versus the normalized noise power level in dBm/Hz. The normalized noise power level represents the sum of all noise sources including cellular or noncellular interference. In this figure, a sparse femtocell deployment with nine femtocells in a $180 \times 180\,\mathrm{m}^2$ square area with FUE density of $0.001/\mathrm{m}^2$ is considered. The minimum required rate for each FUE, $\bar{r}_i^{(n)}$, is set as 1 Mbps. As shown in Fig. 14, for interference-limited region where noise power level is low, Proportional ZFR gives higher average minimum FUE rate than FuFR. On the other

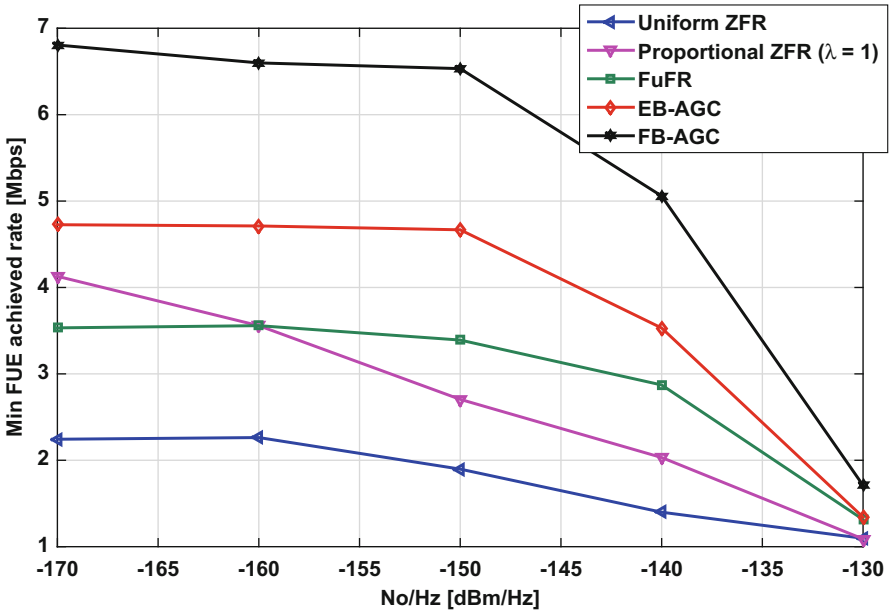

Fig. 14 Minimum FUE rate vs. noise power level

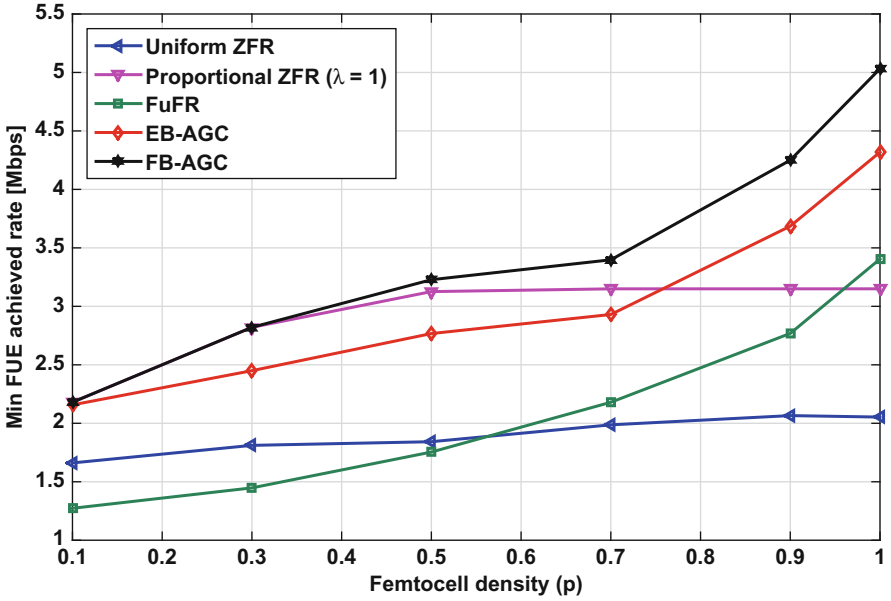

Fig. 15 Minimum FUE rate vs. femtocell density p

hand, in bandwidth-limited region with high noise power level, FuFR achieves better spectral efficiency and higher minimum FUE throughput than orthogonal allocation. Both AGC schemes can achieve better minimum FUE throughput for different levels of normalized noise power. The gain for AGC schemes arise from selecting a better fractional frequency reuse compromise between orthogonal resource allocation and full frequency reuse.

Figure 15 studies the performance of the aforementioned algorithms in dense enterprise deployments. A 5×5 grid model is considered in a $50 \times 50\,\mathrm{m}^2$ square area representing a single-floor building with 25 blocks of $10 \times 10\,\mathrm{m}^2$ each [39]. Along with the higher femtocell density compared to Fig. 14, a higher FUE density of $0.03/\mathrm{m}^2$ is also considered. For each block, a femtocell is randomly dropped with a probability p. As p increases, the femtocell density increases. Moreover, unlike the results in Fig. 14, the random femtocell deployment here can result in an irregular deployment.

As shown in Fig. 15, the FB-AGC algorithm gives higher minimum FUE rate compared to other schemes for different femtocell densities p. As p increases, the number of femtocells covering the whole area increases, and, thus, the number of FUEs per femtocell increases leading to a higher minimum achieved FUE rate. This shows that the FB-AGC can achieve a better solution than both orthogonal allocation and full frequency reuse for femtocell densities ranging from a sparse deployment with $p = 0.1$ to a very dense deployment with $p = 1$, i.e., 25 femtocells in a $50 \times 50\,\mathrm{m}^2$ square area.

Cooperation in Integrated WLAN-Cellular Heterogeneous Networks

A recent trend in the deployment of cellular heterogeneous networks is the integration of both WLAN (e.g., WiFi) and cellular (e.g., 3G and LTE) technologies at small cells. The large number of WiFi hotspots and the adoption of WiFi interfaces in almost all smart phones and portable devices make it increasingly attractive to MNOs to offload traffic from congested cellular networks to WiFi hotspots.

In [40, 41], we present a resource allocation and inter-cell interference management scheme for small cells with integrated licensed and unlicensed band interfaces. We propose a joint and adaptive allocation of resources over both bands with fairness constraints among small cell user equipments (SUEs), implemented as minimum SUE rate constraints, and QoS guarantees to neighboring MUEs, implemented as maximum tolerable interference constraints. The QoS requirements of different types of traffic for the SUEs are considered by controlling the distribution of resources over both licensed and unlicensed bands. For example, QoS cannot be guaranteed over WiFi networks for delay-sensitive applications such as voice conversations and real-time gaming.

The system model considered in [40] is shown in Fig. 16, where the MBS has M associated MUEs and the Small eNode B (SeNB) has S SUEs with both cellular (licensed) and WLAN air (unlicensed) interfaces as well as W wireless nodes (WNs) with WLAN air interface only. The rate of an SUE i in the licensed band is denoted $R_\ell^{(i)}$ and is given by

$$R_\ell^{(i)} = \alpha^{(i)} \psi_\ell^{(i)} B = \alpha^{(i)} \eta_b \eta_c \left[\beta \log_2 \left(1 + \frac{P_s |G_i|^2}{(N_o + P_m |J_i|^2) \eta_s} \right) + (1 - \beta) \log_2 \left(1 + \frac{P_s |G_i|^2}{N_o \eta_s} \right) \right] B, \tag{12}$$

where $\alpha^{(i)}$ is the probability that a PRB is assigned to SUE i associated to the SeNB, $\psi_\ell^{(i)}$ is the average effective spectral efficiency attained by SUE i, and B is the total SeNB bandwidth. The parameter $\alpha^{(i)}$ can also be thought of as the percentage of the total bandwidth assigned to SUE i. Similarly, β is the access probability of the MBS for a given PRB, i.e., the probability that a PRB is assigned by the MBS to any of its associated MUEs. P_s is the transmit power of the SeNB, G_i and J_i are respectively the channel gain between the SeNB and SUE i and the MBS and SUE i, N_0 is the noise power per PRB, and the parameters η_b, η_c, and η_s are modeling the throughput of a typical practical cellular system as a function of bandwidth and SINR implementation efficiency. With probability β, a PRB will be used by the MBS and therefore suffers interference from the MBS to SUE i as in the first term in the square bracket in (12), and with probability $1 - \beta$ the PRB will not suffer interference as in the second term.

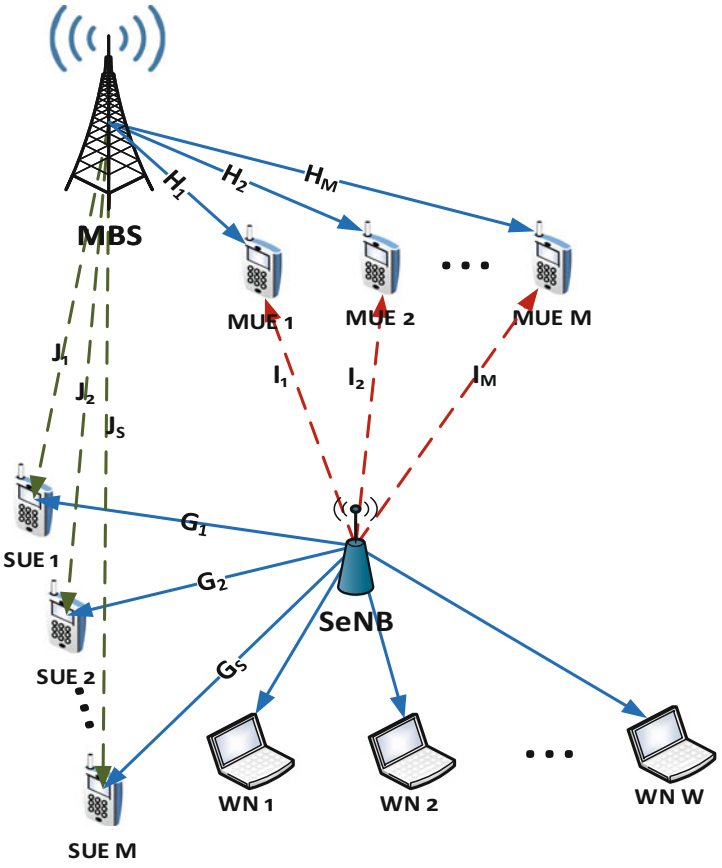

Fig. 16 Integrated WLAN-cellular heterogeneous networks system model

The QoS of MUEs is maintained by limiting the interference caused by the SeNB at MUE j below a predetermined threshold ε_j. This is formulated as $Pr[\alpha_s \beta^{(j)} P_s |I_j|^2 \leq \varepsilon_j] \geq \zeta,\ j = 1, \ldots, M,$, where I_j is the channel gain between the SeNB and MUE j and ζ is the QoS guarantee probability, e.g., 95%. The interference channel I_j can be decomposed into large scale fading component I_j^{ℓ} representing path gain and small scale fading random component I_j^s. Assuming I_j^s to be a complex Gaussian scalar random variable with zero mean and unity variance, the random variable $|I_j^s|^2$ becomes exponentially distributed with rate parameter of 1. The maximum interference constraint can thus be rewritten as:

$$1 - \exp\left(\frac{-\varepsilon_j}{\alpha_s \beta^{(j)} P_s |I_j^{\ell}|^2}\right) \geq \zeta,$$

or alternatively,

$$\alpha_s \leq \frac{\varepsilon_j}{\beta^{(j)} P_s |I_j^{\ell}|^2 \ln(\frac{1}{1-\zeta})}.$$

The joint resource allocation on both licensed and unlicensed bands can be formulated as an optimization problem with the objective of maximizing sum SUE rate while maintaining both minimum SUE rate and maximum MUE interference requirements as follows:

$$\max_{\{\boldsymbol{\alpha}, \boldsymbol{R_u}\}} \quad \sum_{i=1}^{S} \left[\alpha^{(i)} \psi_{\ell}^{(i)} B + R_u^{(i)}\right], \tag{13a}$$

$$s.t. \quad \sum_{i=1}^{S} R_u^{(i)} \leq R_{AP} - \sum_{k=1}^{W} r_w^{(k)}, \tag{13b}$$

$$\alpha^{(i)} \psi_{\ell}^{(i)} B + R_u^{(i)} \geq r^{(i)}, \; i = 1, \ldots, S, \tag{13c}$$

$$Pr[\alpha_s \beta^{(j)} P_s |I_j|^2 \leq \varepsilon_j] \geq \zeta, \; j = 1, \ldots, M, \tag{13d}$$

$$\sum_{i=1}^{S} \alpha^{(i)} \leq \rho - \beta = \bar{\alpha}_s, \tag{13e}$$

$$0 \leq \alpha^{(i)} \leq 1, \; i = 1, \ldots, S, \tag{13f}$$

$$0 \leq R_u^{(i)} \leq R_{u,\max}^{(i)}, \; i = 1, \ldots, S, \tag{13g}$$

where $R_u^{(i)}$ is the throughput of SUE i in the unlicensed band, R_{AP} is the SeNB throughput on the unlicensed band, $r_w^{(k)}$ and $r^{(i)}$ are the minimum rate requirement for WN k and SU i, respectively, and ρ controls the percentage of probabilistic bandwidth sharing between the MBS and the SeNB. The parameter $R_{u,\max}^{(i)}$ sets an upper bound on the unlicensed band rate for SUE i which is chosen as a function of the traffic type for each SUE. The optimization problem in (13), can be reformulated as a linear program in the variables $\boldsymbol{\alpha} = [\alpha^{(1)} \; \cdots \; \alpha^{(S)}]$ and $\boldsymbol{R_u} = [R_u^{(1)} \; \cdots \; R_u^{(S)}]$ representing resource allocation on both licensed and unlicensed bands, respectively.

Figure 17 shows the sum rate of MUEs, SUEs (with both LTE and WiFi interfaces), and WNs (with WiFi interface only) for different resource allocation schemes. The figure compares the proposed joint optimization approach (Proposed) against two existing solutions, namely, WiFi offloading and Conventional femto, and two other baseline schemes with LTE and WiFi integration, namely, Fixed and Sequential allocation schemes. The results show that the proposed solution

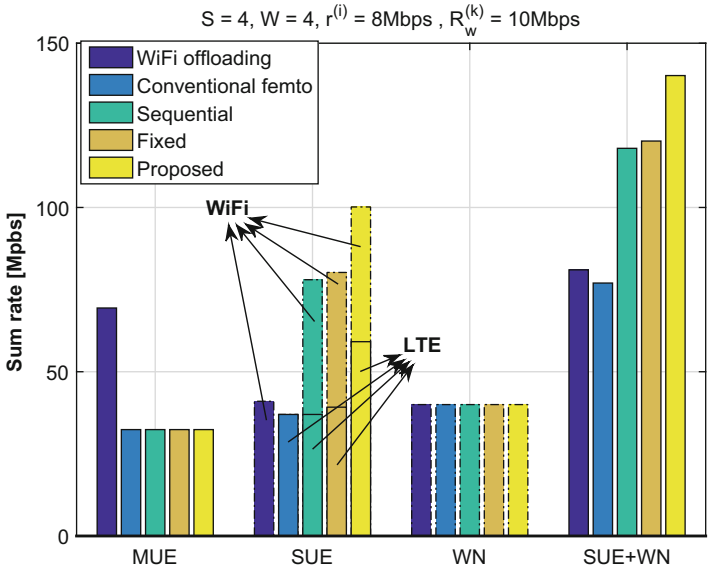

Fig. 17 Sum rate comparison for different algorithms for dual-access small cells

achieves better (or at least the same) performance compared to other schemes while maintaining fairness among SUEs and controlling the amount of inter-cell interference to neighboring MUEs. In this simulation, conventional femto, sequential, fixed, and proposed schemes generate the same amount of interference to MUEs, resulting in the same sum MUE rate, whereas the WiFi offloading scheme causes no interference to MUEs and, therefore, gives the largest sum MUE rate. Although both conventional femto and the proposed schemes use the same resource allocation method in the licensed band, the throughput obtained by SUEs on the licensed band in the proposed scheme is larger than that obtained by conventional femto. The reason for this is that the proposed scheme has more flexibility in satisfying the minimum SUE rate requirements compared to conventional femto as the proposed scheme can satisfy each individual constraint using the licensed and/or unlicensed bands rather than the licensed band only for the conventional femto case. Additionally, compared to the sequential and fixed schemes that also use both the licensed and unlicensed band, the proposed scheme gives higher sum SUE rate. The reason for this is that the proposed scheme solves the resource allocation problem over both bands jointly, in contrast with the sequential scheme, and adaptively (i.e., the distribution of traffic over both bands is adapted to the channel condition, availability of LTE resources and WiFi capacity, and rate requirement of each SUE), in contrast with fixed partitioning of traffic over both bands in the fixed scheme. This joint and adaptive allocation of resources over the licensed and unlicensed bands allows the proposed scheme to achieve higher sum throughput for the SUEs compared to other solutions.

Conclusion and Future Directions

This chapter introduced several techniques for cooperative spectrum sharing in heterogeneous networks by exploiting the inherently available feedback information in most communication systems such as CQI and ACK/NACK feedback. Taking advantage of such information within different types of cooperation by different network players can achieve better overall QoS and network throughput.

Several research thrusts have demonstrated efficient utilization of implicit and explicit cooperation between the MBS and overlaying small cells in order to reduce the direct information transfer among BSs. One major challenge that this chapter addresses is the spectrum sharing of macrocell and small cells while guaranteeing MUE's QoS. From the interference perspective, such implicit feedback information can help secondary transmitters to partially observe the unknown interference channel state and learn severity of its interference to the primary receiving users (e.g., MUEs). The chapter also presented works on resource allocation and interference management in dense deployment scenarios through a central controller to coordinate spectrum allocation among neighboring femtocells. Moreover, cooperation in heterogeneous networks can be extended to more general cooperative networks integrating both cellular and noncellular access.

One potentially interesting extension for the present direction is to reformulate a number of interference management problems by taking advantage of the inherent signal feedback in most two-way communication systems. A number of existing works on interference management in wireless networks often rely on assumptions of available information that are often either impractical or costly. Revisiting some of these important design challenges by utilizing inherent feedback signals to relax their originals assumptions can lead to highly exciting solutions to important practical problems.

Abstract

Cellular network service providers are facing acute spectrum shortage due to surging mobile data traffic demand. On the contrary, spectrum measurement studies reveal that large part of the licensed spectrum is being underutilized.

In this chapter, a cognitive multihoming (CM) framework is presented for the cellular network service providers to meet the escalating data demands and provide enhanced quality of service (QoS) to the users. In CM, the conventional cellular base stations (BS) are enabled with cognitive radio (CR) access functionality. Thus, these CR-enabled BS transmit simultaneously to the users over the licensed cellular bands as well as over the CR bands. Communication over CR incurs lower transmission cost at the expense of higher energy consumption due to frequent channel sensing. On the other hand, communication over licensed cellular bands is expensive due to its licensing premium. Performance of CM is analyzed in two scenarios. Multiple real-time (RT) and non-RT users requesting for unicast downlink content are considered in the first scenario, while the second scenario considers multiple users requesting for scalable video content from the network. For the two scenarios, optimal resource allocation and call admission control algorithm are presented. Through the performance results presented in this chapter, it is inferred that the CM strategy can enable the cellular network providers to serve a higher number of users as well as improve the user's QoS in terms of reduced service cost.

Introduction

There has been a manifold growth in Internet traffic demand in recent times. Recent research report by Cisco indicates that the mobile data traffic is expected to grow 10 times by 2022 [1]. Due to these increased demands, it is expected that the present cellular network infrastructure will fall short of providing adequate and high-quality service to the users in the upcoming years [2]. Main reason for this accounts for the lack of adequate licensed spectrum availability. On the other hand, various spectrum measurement studies have indicated that only a small fraction of the licensed spectrum is being used [3]. Cognitive radio (CR) techniques can be employed to combat spectrum resource scarcity in the conventional cellular bands for mobile broadband quality of service (QoS) support.

On the receiver technology front, emergence of multihomed devices (multi-radio clients) [4] has enabled simultaneous access to multiple radio access technology (RAT) in a heterogeneous network. Conventionally, multihoming capability of user devices is used for concurrent multipath transfer (CMT) [5] of data from remotely located source via multiple networks. This approach invites challenges due to network dynamics, leading to selective packet loss over multiple paths and hence the user's difficulty in data decodability. In order to alleviate the spectrum scarcity problem in licensed cellular networks (LCNs) and quality degradation in conventional CMT via wireless networks, a novel paradigm, called cognitive multihoming (CM), was proposed in [6, 7].

Cognitive Multihoming

As depicted in Fig. 1, in CM system the cellular network BS is also equipped with the CR functionality. The BS controller buffers the data packets from the remote data server across the Internet and divides the data stream suitably as per the available LCN and CR network (CRN) resources, and the BS transmits them to the user via LCN and CRN, simultaneously. Multihoming capable users are considered which are equipped with the functionality to operate on both the networks simultaneously. It is considered that the network operates over at least one licensed cellular band and one CR band. LCN can include one of the cellular networks, for example, LTE, WCDMA standards, etc. On the other hand, CRNs can operate over the TVWS bands, ISM bands, etc., utilizing one of the existing IEEE standards such as IEEE 802.22, IEEE 802.11af, etc. Thus, the band over which the LCN and CRN operate are different.

Let us consider downlink communication from BS to the users. In general, the downlink communication is the main bottleneck in providing broadband access to the users. While providing service, the content to be transmitted to the users is pre-buffered at the BS from the external server. Consider that the BSs are enabled with high bandwidth backhaul network such that the content requested by the users can be made available at the BS at a lower delay. Once the user content is buffered, the BS splits the data optimally across the two networks and transmits simultaneously to the users across both the networks.

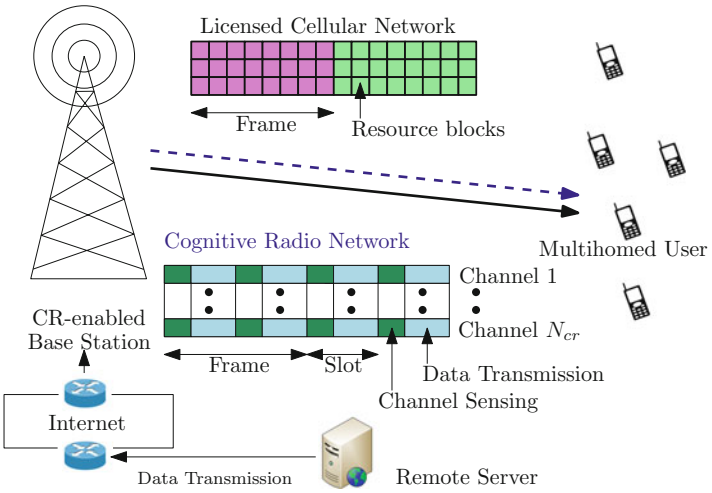

Fig. 1 Illustration of cognitive multihoming

One of the advantage of CM is that the data is split at the BS (last hop to the user) and the external server from which the data is being fetched is not involved in this split. Thus, any additional overhead between BS and data server is saved which is usually not the case in concurrent multipath transmissions. Further, in CMT, packets may arrive out of order due to variable delays along multiple paths leading to congestion-related delays. Thus, this congestion-related delays present in conventional multihoming are not present in CM.

To meet dynamic demands of the real-time users, the service provider (SP) would want to keep its licensed band as idle as possible by making most use of CRN resource. To encourage usage of more CRN resources, data transmission over the CRN is offered at a discounted rate. This is in consonance with the fact that the cellular bands are costly, as the SP pays a huge premium for licensing. Operations over CRNs do not levy high cost to the users due to the opportunistic (secondary) usage of the PU bands.

Transmission cost could be reduced if most of the content is transmitted via CRN. However, due to intermittent PU arrivals and imperfect channel sensing, there could be low throughput over CRN. Moreover, the channel needs to be sensed at regular intervals which further reduces the throughput and energy efficiency. Hence, reception over CRN can be characterized by low cost, low QoS, and low energy efficiency. On the other hand, transmissions over LCN are marked by high cost and high QoS. So, there is an apparent cost-quality-energy tradeoff. The possible degradation in energy efficiency and QoS in CRN can be controlled in CM by optimally allocating resources from LCN and CRN as a function of a user's demand.

LCN and CRN system specific models and assumptions are presented below.

Transmission over LCN

For LCN, let us consider a framework similar to the LTE networks. The LCN resources are divided into time-frequency resource blocks (RBs). Denote B_{rb} and T_{rb}, respectively, as the bandwidth and time duration of an RB. Transmitter rate over an RB depends on the channel conditions. Consider block fading across an RB such that the channel gain remains constant over an RB duration T_{rb}. Let $P_{(lc,tx)}$ denote the BS transmit power. The received signal power $P_{(lc,rx)}$ at a location r distance away from the BS is given by the Friis formula:

$$P_{(lc,rx)} = P_{(lc,tx)} \mathsf{G}_T \mathsf{G}_R \left(\frac{\Lambda}{4\pi r} \right)^{\varepsilon}.$$

Here, G_T and G_R are, respectively, the transmitter and receiver antenna gains, ε is the path loss coefficient, and Λ is the transmitted signal wavelength. Consider Rayleigh fading with zero mean and unit variance between the BS and user. The rate offered to the user by the BS over an RB is given by Shannon's capacity formula $I = B_{rb} \log_2 \left(1 + \frac{h_{lc} P_{(lc,rx)}}{\sigma^2_{(lc,n)}} \right)$, where h_{lc} is the channel fading power gain and

$\sigma^2_{(lc,n)}$ is the noise variance. Outage probability at the user while the BS transmits at rate R bps is given as:

$$P_{out,lc}(R) = Pr(I \leq R) = 1 - exp\left(-\frac{\sigma^2_{(lc,n)}(2^{R/B_{rb}} - 1)}{P_{(lc,rx)}}\right). \tag{1}$$

Transmission over CRN

CRNs make opportunistic use of the licensed PU channels. Consider that there are N_{ch} number of PU channels available at the BS with each PU channel having bandwidth B_{cr}. Time is slotted with each slot duration of T_{cr} units. ON-OFF model [8] for PU transmission is considered over the cognitive radio bands. In this ON-OFF model, PU transmits over a slot in a particular channel with a certain fixed probability. The probability of kth PU channel being idle in a slot is denoted as $p_{cr,k}$. Transmission over CR bands requires sensing the channel for certain duration and transmitting only when the channel is sensed idle. The CR-enabled BS senses the channel for a duration ζ over a slot. If the channel is sensed idle, it transmits over the channel for the remaining time $T_{cr} - \zeta$. The users and the BS are considered colocated in a small geographical area relative to the PU coverage area. Thus, channel conditions at the BS and the users are similar. Probabilities of false alarm $p_{fa}(\zeta)$ and misdetection $p_{md}(\zeta)$ as a function of sensing duration ζ are, respectively, given as [9]:

$$p_{fa}(\zeta) = \text{erfc}\left(\left(\frac{\varepsilon}{\sigma^2_{(cr,u)}} - 1\right)\sqrt{\zeta f_s}\right) \tag{2}$$

$$p_{md}(\zeta) = \text{erfc}\left(\left(\frac{\varepsilon}{\sigma^2_{(cr,u)}} - \gamma - 1\right)\sqrt{\frac{\zeta f_s}{2\gamma + 1}}\right) \tag{3}$$

where $\sigma^2_{(cr,u)}$ is the noise power variance, ε is the sensing threshold, f_s is the channel sampling frequency, and γ is the PU signal SNR at the CR node. The BS transmits to the user over the remaining part of the slot at the rate of R bps if the channel is sensed idle. Packet transmission probability over CRN in a slot is given as:

$$J(\zeta) = (1 - p_{cr})p_{md}(\zeta) + p_{cr}(1 - p_{fa}(\zeta)). \tag{4}$$

Similar to (1), outage probability over the PU channel in CRN due to channel fading is:

$$P_{out,cr}(R) = 1 - exp\left(-\frac{\sigma^2_{(cr,n)}(2^{R/B_{cr}} - 1)}{P_{(cr,rx)}}\right) \tag{5}$$

where $\sigma^2_{(cr,n)}$ is the channel noise variance and $P_{(cr,rx)}$ is the received power over the CRN.

Consider that there are N_u users in the network. Each user requests for a unicast content over the downlink. BS allocates resources over a frame duration. Frame duration $\mathscr{T}$ could be taken as the time over which the packets in a delay-sensitive application are correlated (e.g., duration of group of pictures (GOP) in a video). Denote $\mathscr{N}_{rb}$ as the maximum number of RBs available to the users in a GOP. Channel is sensed by the BS in each slot, and it transmits over the remaining slot if the channel is sensed idle. It is assumed that the BSs efficiently manage the PU bands over which each of them would operate such that there is no interference caused to the users due to transmissions from different BSs operating over CRN.

To understand the performance of CM, two example scenarios are considered. In the general scenario, multiple heterogeneous users request different type of traffic (real-time (RT) or non-RT (NRT)), with each user having different rate requirements and cost constraints. The resources from the two networks can be split according to the cost constraints of the different users to ensure their satisfaction while maintaining some degree of fairness. Due to a minimum rate requirement for the RT users, all RT-QoS requests may not be admitted. To this end, call admission control along with the optimal multihomed resource allocation algorithm is presented to maximize the network utility.

In the application-specific scenario, the multihomed users request unicast scalable video encoded content from the CM network. For battery-operated devices, user satisfaction depends on the received video quality, device battery level, and the cost it paid for the content reception. To this end, in addition to transmission rate adaptation over single network [10], in the presented CM approach, two novel techniques of video packet priority-dependent sensing duration adaptation and network selection for packet retransmission are included to enhance user experience (QoS, energy saving, cost) without causing PU performance degradation.

Performance Evaluation of CM-Based Access

Performance of CM is evaluated against two test scenarios. In the first scenario, multiple multihomed users request either real-time (RT) or non-RT traffic. In the second scenario, users request for unicast scalable video from the network.

General Performance Measures

In this scenario, multiple multihomed users are considered requesting heterogeneous content from the network. Users request heterogeneous content which can be broadly classified under two types: RT and NRT. An RT application, like video streaming and voice over IP, typically requires a minimum data rate d_{min} for its operation, while its requested rate is d_{req} to ensure a high QoS. For NRT (delay-tolerant) applications, such as file transfers and web browsing, the typical demanded

rate per user is d_{req}, while $d_{min} = 0$. For the analytical exposition, all users' rates d_{min} and d_{req} are denoted as per-frame rates.

Consider that the BS transmits to the users at a fixed rate of R_{lc} bps over LCN and $R_{cr,k}$ bps over the kth PU channel. The probability of successful packet transmission over an RB is given as $s_{lc} = 1 - P_{out,lc}(R_{lc})$. Data transmitted per RB is $d_{rb} = R_{lc}T_{rb}$. Over the CRN, consider that the BS senses the PU channel for a fixed duration of ζ. The successful packet transmission probability over the kth PU channel is given as $s_{cr,k} = (1 - p_{cr,k})(1 - p_{fa}(\zeta))(1 - P_{out,cr}(R_{cr,k}))$. The amount of data transmitted over the kth PU channel is $d_{cr,k} = R_{cr,k}(T_{cr} - \zeta)$ bits per slot.

User satisfaction can be expressed in terms of QoS offered and cost charged. QoS of a user is defined as the quality of content received, which is modeled as a utility function. Users are charged based on the amount of data they receive via CM. A cost constraint metric $\chi \in [0, 1]$ is maintained by each user. This metric indicates *the maximum fraction of cost (compared to the cost required for service through LCN) the user is willing to pay for its service*. A higher χ indicates that the user is willing to pay a higher premium for its service.

The SP's goal is to maximize the network utility, which is the sum of all users utility. This is achieved by optimally allocating the resources across different networks to the different users in CM. User's utility and cost are introduced next.

User Utility and Cost

User QoS is modeled in terms of a utility function, which is expressed as a function of the amount of resources allocated to the user by the network [11]. User's utility $\mathscr{U}$ depends on whether the user requests for an RT or an NRT traffic. The successful transmission rate of a user per frame is denoted as d_{suc}. $\mathscr{U}$ is given as [12]:

$$\mathscr{U} = \begin{cases} 1 - e^{(-c_1 d_{suc}/d_{req})}, & \text{NRT application} \\ \frac{1}{1+c_2 e^{(-c_3 d_{suc}/d_{req})}}, & \text{RT application} \end{cases}. \tag{6}$$

c_1, c_2, and c_3 are positive constants determined by the minimum and maximum utility obtained by the users corresponding to their successful transmission rates $d_{suc} = \{0, d_{req}\}$. Figure 2a plots the utility for NRT users which shows a steeply increasing nature with the increase in d_{suc}. On the other hand, Fig. 2b presents the utility for the RT users which follows the sigmoid function.

Denote a_{lc} as the total number of RBs allocated to the user from LCN and denote $a_{cr,k}$ as the number of slots allocated over the kth channel of CRN per frame. These are determined by the resource allocation algorithm presented in section "Resource Allocation Optimization Problem". Successful data transmission $d_{suc} = b_{lc}d_{lc} + \sum_{k=1}^{N_{ch}} b_{cr,k}d_{cr,k}$, where b_{lc} is the number of RBs out of a_{lc} with successful packet transmission and $b_{cr,k}$ is the number of successful transmission slots in $a_{cr,k}$ allocated slots.

Next, let us arrive at a relation between b_{lc} (or $b_{cr,k}$) and a_{lc} (or $a_{cr,k}$). The user utility depends on the successful transmissions per frame. Probability that $b_{lc} = j$ out of a_{lc} RBs in LCN is successful is expressed as:

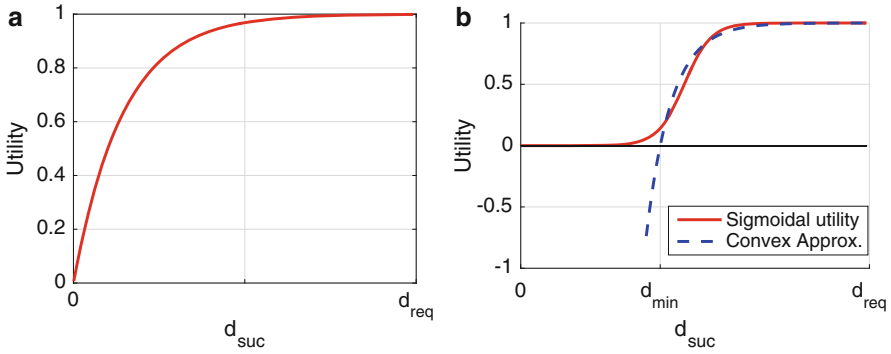

Fig. 2 User utility plot for RT and NRT traffic. (**a**) Non real-time. (**b**) Real-time

$$Pr(b_{lc} = j) = \binom{a_{lc}}{j} (s_{lc})^j (1 - s_{lc})^{(a_{lc} - j)} \tag{7}$$

which follows a binomial distribution. Similarly the probability of $b_{cr,k} = j$ successful slots out of $a_{cr,k}$ over CRN is:

$$Pr(b_{cr,k} = j) = \binom{a_{cr,k}}{j} (s_{cr,k})^j (1 - s_{cr,k})^{(a_{cr,k} - j)}. \tag{8}$$

The total number of successful slots for a user is given as:

$$d_{suc} = b_{lc} d_{lc} + \sum_{k=1}^{N_{ch}} b_{cr,k} d_{cr,k}. \tag{9}$$

d_{suc} is the sum of $N_{ch} + 1$ binomial random variables. Probability mass function (pmf) of d_{suc} is obtained by the convolution of (7) and (8) $\forall\ k = 1, 2, \cdots, N_{ch}$ PU channels. Closed form expression for pmf of d_{suc} is not possible. Hence, numerical techniques must be used as suggested in [13].

As computation of d_{suc} is analytically intractable (the closed form for d_{suc} cannot be obtained) and computationally intensive (obtaining d_{suc} using numerical methods scales up exponentially with N_{ch}), the mean value of d_{suc}, i.e., $d_{suc} = a_{lc} d_{lc} s_{lc} + \sum_{k=1}^{N_{ch}} a_{cr,k} d_{cr,k} s_{cr,k}$ is considered for the utility computation in further analysis.

The cost $\mathscr{C}$ to a user is the price charged by the SP in successfully transmitting the data via CM. This is given as:

$$\mathscr{C} = b_{lc} d_{rb} \mathscr{C}_{lc} + \sum_{k=1}^{N_{ch}} b_{cr,k} d_{cr,k} \mathscr{C}_{cr} \tag{10}$$

where $\mathscr{C}_{lc}$ is the price charged per successful bit transmission over LCN by the SP, while $\mathscr{C}_{cr}$ is the price charged by the SP per successful bit transmission over the CRN. A user maintains a cost constraint χ, which specifies the maximum amount it is willing to pay for its request. Accounting χ, user's cost is bounded by

$$\mathscr{C} \leq c_{max} = \chi d_{req} \mathscr{C}_{lc}. \tag{11}$$

Resource Allocation Optimization Problem

There are a total of N_u users in the system requesting for unicast downlink content from the BS. Each RT user specifies its d_{min}, d_{req}, and the cost constraint χ. Similarly, each NRT user specifies its d_{req} and χ. To indicate the individual requirements, for the ith user, the superscript i is used over the variable.

The controller objective is to maximize the overall network utility, which is a sum of all users' utility. The optimization problem can be formulated as:

$$\begin{aligned}
\underset{a^i_{lc}, a^i_{cr,k}}{\text{maximize}} \quad & \sum_{i=1}^{N_u} \mathscr{U}^i \\
\text{s.t.} \quad & \mathscr{C}^i \leq c^i_{max}, \ \forall i = 1, 2, \cdots, N_u, \\
& \frac{\left(\sum_{i=1}^{N_u} \sum_{k=1}^{N_{ch}} a^i_{cr,k} d_{cr,k}\right)^2}{N_u \sum_{i=1}^{N_u} \left(\sum_{k=1}^{N_{ch}} a^i_{cr,k} d_{cr,k}\right)^2} \geq \beta, \\
& \sum_{i=1}^{N_u} a^i_{lc} \leq \mathscr{N}_{rb}, \\
& \sum_{i=1}^{N_u} a^i_{cr,k} \leq \frac{\mathscr{T}}{T_{cr}}, \ k = 1, \ldots, N_{ch}.
\end{aligned} \tag{12}$$

In the above optimization problem, the first constraint limits the cost incurred by the users to their maximum desired cost. The second constraint limits a fair usage of CRN resources among different users. The left-hand side of the second constraint is based on Jain's fairness index [14] on resources allocated to the users via CRN. For the ith user, $\sum_{k=1}^{N_{ch}} a^i_{cr,k} d_{cr,k}$ is the resource allocated via CRN. The fairness index is lower bounded to a constraint β to ensure that the low-cost CRN resources are fairly allocated among the users. This ensures that the greedy users are not unduly benefited by choosing a low χ. The third and the forth constraints are the maximum resource availability constraints.

The utility function of RT users is a sigmoid function which is nonconvex. The first, third, and forth constraints in this problem are linear, while the second constraint is convex. To obtain an equivalent convex problem for this optimization problem, the convex approximation of the sigmoid function is presented next followed by the solution to this problem.

Solution to the Optimization Problem and Call Admission Control Algorithm

The utility function for an RT application is a sigmoid function (cf. (6)) which is nonconvex. Consider $\mathscr{U}_c$ as the convex approximation to this function, which is given as:

$$\mathscr{U}_c = 1 - e^{-c_4(d_{suc} - d_{min})/d_{req}} \tag{13}$$

where c_4 is a constant. Here, it is noted that the utility function of the RT users for $d_{suc} < d_{min}$ is close to 0 as shown in Fig. 2b. This is indicative of the fact that RT applications require a minimum resource d_{min} to work. With $\mathscr{U}_c$, the convex approximation function closely matches with the sigmoid function in the range $d_{suc} \geq d_{min}$. However, for $d_{suc} < d_{min}$, the value of the convex approximation is negative which serves as a penalty, indicating that for an RT application, rate lower than d_{min} is inadmissible. If, for a particular RT user, its $\mathscr{U}_c$ turns out to be negative after optimization, it is better to drop the user because in this case the network is unable to provide the user its minimum data rate requirement. This would be seen later in this section.

A new convex optimization problem is formulated with the utility function of RT users replaced by its convex approximation as seen in (13). Typically the network operates in the saturation region where all the network resources are allocated to the users. Hence $\sum_{i=1}^{N_u} \sum_{k=1}^{N_{ch}} a_{cr,k}^i d_{cr,k}$ can be taken equal to $\sum_{k=1}^{N_{ch}} d_{cr,k} \mathscr{T}/T_{cr}$. The optimal allocation of resources (a_{lc}^i and $a_{cr,j}^i$) to the ith user can be obtained by solving the formed convex optimization problem using the dual decomposition and subgradient method [15].

After optimization of the formulated convex optimization problem, for some RT users, their obtained utility from the approximated convex function could be negative. This is because the network is unable to provide a minimum data rate d_{min} to these users. Hence, the network chooses to block these users resulting in nonadmission into the network. In the resource allocation optimization process, the RT user with most negative $\mathscr{U}_c$ is blocked/dropped, a new optimization problem with the remaining users is solved using similar method, and the process is repeated. The process is repeated until all the users obtain positive $\mathscr{U}_c$. At this point, the solution obtained is considered the optimal solution to the optimization problem. Figure 3 presents a flowchart for the admittance of users in the network and computation of the optimal resource allocation.

Algorithm Performance

Two example scenarios are considered to demonstrate the performance of the presented convex approximation algorithm. In the first scenario, a network consisting of 50 RT users is considered, while, in the second scenario, network with 40 RT users is considered. All RT users request for data rate uniformly distributed in the range of 0.5 to 1 Mbps. For the two scenarios, the actual network utility and the network utility corresponding to the convex approximation function (cf. (13)) are plotted

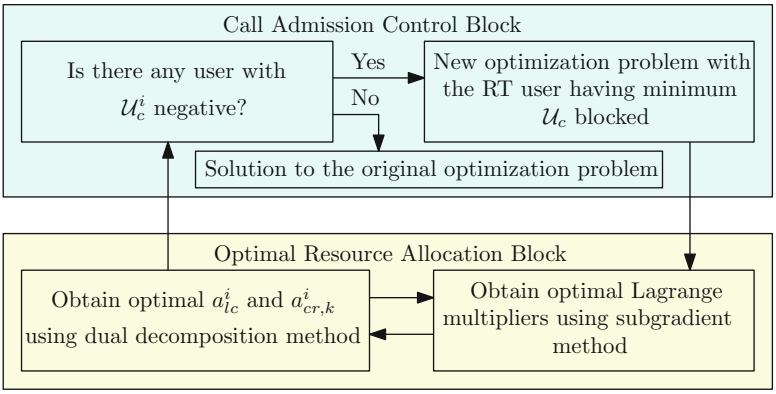

Fig. 3 Algorithm for optimal resource allocation

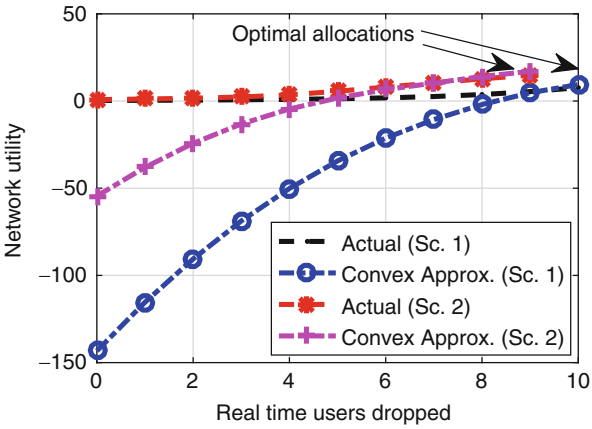

Fig. 4 Convergence of the presented convex approximation algorithm. $\beta = 0.7$. (Sc.: Scenario)

in Fig. 4. A user is blocked at each iteration whenever its utility corresponding to the convex approximation function $\mathscr{U}_c$ is negative at the optimal resource allocation. After each iteration, the optimization problem is solved with the remaining users and the resources are again allocated among those users. It is observed that the network utility via convex approximation converges toward the actual network utility at each iteration. At the optimal point, it is concluded that the actual utility and the utility via convex approximation closely match. Additionally, the number of iterations is upper bounded by the number of RT users present in the system.

CM performance in the video-specific application scenario is presented below.

Application-Specific Considerations

In this scenario, multiple multihoming capable users request unicast scalable video encoded content from the network. The user devices are battery operated. For these

devices, user satisfaction depends on the video quality received, device battery level, and the cost the user paid for the content reception. Toward this goal, in the considered CM approach, video packet priority-dependent sensing duration and transmission rate adaptation and network selection for packet retransmission are included to enhance user experience (QoS, energy saving, cost) without causing PU performance degradation.

The video traffic model, user device capabilities, and video transmission mechanism to a CM user are briefly introduced below.

Video Traffic Model

Multihomed users request for scalable video coding (SVC) encoded video content from the network. SVC video encoder allows graceful degradation of video quality caused by wireless channel fading. It consists of a base layer (denoted as layer 1) and several enhancement layers (denoted as layers $2, 3, \cdots, L$). Layer l_1 has a higher priority over layer l_2 if $l_1 < l_2$. Base layer provides the basic quality level of the video, and it is decoded independently of the higher layers. Enhancement layer l_1 can only be decoded once all the layers $l < l_1$ are decoded. Each layer is independently encoded at a specific rate.

Similar to the approaches in [4, 16], distortion of H.264/SVC encoded video can be quantified in terms of video encoding-induced distortion and distortion due to packet loss in video transmission. It can be quantified as $\mathscr{D} = \mathscr{D}_{enc} + \mathscr{D}_{loss}$. $\mathscr{D}_{enc}$ is the average encoding distortion, given as $\mathscr{D}_{enc} = D_0 + \frac{\theta_0}{X - \mathscr{R}_0}$. Here, X is the average bit rate, and parameters D_0, θ_0, and $\mathscr{R}_0$ are constants that depend on the encoder and video characteristics. Packet-loss-induced distortion $\mathscr{D}_{loss}$ is independent of $\mathscr{D}_{enc}$. Denoting φ_l as the probability of lth layer content loss, $\mathscr{D}_{loss}$ can be expressed as:

$$\mathscr{D}_{loss} = \sum_{l=1}^{L} \varphi_l \Omega_l, \quad \text{where } \Omega_l = \left(\frac{\theta_0}{X_{l-1} - \mathscr{R}_0} - \frac{\theta_0}{X_l - \mathscr{R}_0} \right). \tag{14}$$

Ω_l is the weight associated with the lth layer and X_l is the rate of the video content up to l layers.

Video quality metric $\mathscr{Q}$ is defined as the distortion impact of the packets received correctly to the total available packets [17]. It is given as:

$$\mathscr{Q} = \frac{\sum_{l=1}^{L} \Omega_l (1 - \varphi_l)}{\sum_{l=1}^{L} \Omega_l} \cdot 100\%. \tag{15}$$

Video stream is divided into group of pictures (GOP) with each GOP duration of $\mathscr{T}$ units.

User Device Capability

The users are equipped with multihoming capable devices. All user devices are considered battery operated, and therefore their respective reception processes are sensitive to the remaining battery energy. Part of this energy consumption is due to

reception of the video content over the two networks. Consequently, the remaining battery level determines the upper bound on energy consumption for video reception and the quality of video (number of layers) requested by the user.

As noted in the experimental studies in [18, 19], energy consumption in mobile devices due to network interface is mainly on three fronts, namely, ramp, tail, and data transfer energy. Ramp energy is consumed when the radio transits from *idle* state to *transmit* state. Data transfer energy is proportional to the duration of time the radio is transmitting/receiving. Tail energy refers to the lingering of the radio at high-energy states during the inactivity period after the transmission is over, which is on the order of tens of seconds [18]. The network transmits to the device for a fraction of time in a GOP. Thus, reception energy is consumed for the time device is actually receiving, and the tail energy is consumed when the device is idle in a GOP. The device does not incur ramp energy consumption, as the radio mostly remains in the high-energy state during the reception.

Along with meeting the energy consumption constraints, the network should ensure high-quality video reception to the user end at a low cost. The communication cost (cost charged to the user) is proportional to the amount of resources allocated via the two networks. A user is more satisfied when it receives the video content at a lower cost while satisfying its energy consumption constraint.

Video Transmission to CM User

The BS transmits video stream to a user optimally across the two networks such that the user's cost is minimized subject to the user's energy consumption and video quality constraints. Note that the user cost minimization by SP does not affect its revenue maximization objective, as the profit to SP may be completely different over the two networks. Video content for a GOP is considered available at the BS before the GOP starts. Consider that the BS is capable of performing layer-based video transmission. It can form packets of desired length and transmits them to a user. A lost packet is retransmitted by the BS (based on acknowledgement (ACK) notification via independent LCN RBs) to the user up to a layer-dependent predefined number (n_l) of retransmission attempts. The undelivered packets within a GOP duration are dropped, resulting in distortion. For enhanced user experience, transmission rate adaptation over the LCN, sensing duration and transmission rate adaptation over the CRN, and number of retransmission attempts and network selection for retransmission are optimized for each layer of video transmission. These three mechanisms are detailed as follows.

Transmission rate adaptation over LCN/CRN: According to (1) and (5), a higher transmission rate has a lower probability of success. However, higher transmission rate introduces lower cost as well as energy consumption to the user. Hence, while the lower layers (high distortion impact) are transmitted at a lower rate so that their correct reception probability is higher, the higher layers are transmitted at a higher rate.

Sensing duration adaption over CRN: Sensing duration ζ over a slot plays a key role in determining the reception performance. With a small ζ, probabilities of misdetection and false alarm are large, but the available transmission duration is also longer. Therefore, for balanced cost and quality, the different priority of video packets ζ can be accordingly chosen.

Cross network retransmissions: Video packets transmitted can be lost due to path loss, channel fading, or channel sensing misdetections. Such packets are retransmitted within the allowable GOP time window to reduce distortion at the receiver. Network selection for retransmission is also critical. Retransmission over CRN could reduce cost, however, at a higher energy consumption. If the retransmission request for the lth layer content initially transmitted over LCN is received by the BS, it can either retransmit the content over LCN or CRN.

Analysis of CM-Based Resource Allocation

The multiuser scenario is considered, where a fixed pool of total channel resource is traded with multiple user demands of video content delivery. First, the multiuser resource allocation optimization problem is presented. Subsequently, to achieve solution of the multiuser optimization, for an individual user, single-user cost minimization problem is solved.

Problem Formulation

Due to limited resource availability at the BS, out of N_u users requesting scalable video content, some of the user requests may not be fulfilled, leading to their nonadmission to the network. Resource allocation by the BS is such that the user cost is minimized while the number of users served is maximized. In this example scenario, only a single PU channel is considered available at the BS to serve the users.

For a user requesting L layers of video content, let d_l amount of data (in bits) be transmitted for the lth layer content over a GOP. The BS transmits data of layer l at a rate $R_{lc,l}$ over LCN and at a rate $R_{cr,l}$ over CRN. Denote the sensing duration for layer l packet as ζ_l. Also, denote that the lth layer content can be retransmitted at most $\lceil n_l \rceil$ times, where n_l can take a fractional value in general. It is upper bounded by n_{max}, which is the maximum number of retransmissions allowed for any individual packet within a GOP. Let $p_{lc,l}^{rtx}$ (respectively, $p_{cr,l}^{rtx}$) be the probability that the retransmission of lth layer content transmitted initially over LCN (respectively, CRN) is carried out over LCN (respectively, CRN) itself.

As the data stream d_l is split across the two networks, let u_l amount be initially transmitted over CRN. The remaining data volume $(d_l - u_l)$ is initially transmitted over LCN. To compute the total traffic over LCN for the lth layer content, it is noted that, due to wireless channel uncertainties, part of the failed

data is retransmitted over LCN (with probability $p_{lc,l}^{rtx}$). The remaining volume of retransmission is over CRN, with probability $(1 - p_{lc,l}^{rtx})$. Given the maximum number of retransmissions n_l for the lth layer, $\sum_{i=0}^{n_l} P_{out,lc}(R_{lc,l})^i = \frac{1-P_{out,lc}(R_{lc,l})^{n_l+1}}{1-P_{out,lc}(R_{lc,l})}$ is the expected number of transmission attempts carried out including the initial transmission for the part of data retransmitted over LCN. Hence, for transmitting $(d_l - u_l)$ data over LCN, the expected data transmission over LCN is $(d_l - u_l)\left(p_{lc,l}^{rtx}\left(\frac{1-P_{out,lc}(R_{lc,l})^{n_l+1}}{1-P_{out,lc}(R_{lc,l})}\right) + 1 - p_{lc,l}^{rtx}\right)$. The data transmitted over CRN could also be lost due to misdetection in channel sensing, path loss, and channel fading. The probability of packet transmission failure $P_{e,cr}(\zeta_l, R_{cr,l})$ over CRN is given as:

$$P_{e,cr}(\zeta_l, R_{cr,l}) = (1 - p_{cr})p_{md}(\zeta_l) + p_{cr}(1 - p_{fa}(\zeta_l))P_{out,cr}(R_{cr,l}). \tag{16}$$

Part of the lost data is retransmitted over LCN. Out of the original share of transmitted data u_l over CRN, the amount of data retransmitted over LCN is $u_l(1 - p_{cr,l}^{rtx})P_{e,cr}(\zeta_l, R_{cr,l})$. The expected number of retransmissions over LCN is $\sum_{i=0}^{n_l-1} P_{out,lc}(R_{lc,l})^i = \frac{1-P_{out,lc}(R_{lc,l})^{n_l}}{1-P_{out,lc}(R_{lc,l})}$ for the data retransmitted over LCN. Overall, the total amount of data transmitted over LCN for the lth layer in a GOP is:

$$\begin{aligned} w_{lc,l} =& (d_l - u_l)\left(p_{lc,l}^{rtx}\left(\frac{1 - P_{out,lc}(R_{lc,l})^{n_l+1}}{1 - P_{out,lc}(R_{lc,l})}\right) + 1 - p_{lc,l}^{rtx}\right) \\ &+ u_l(1 - p_{cr,l}^{rtx})P_{e,cr}(\zeta_l, R_{cr,l})\frac{1 - P_{out,lc}(R_{lc,l})^{n_l}}{1 - P_{out,lc}(R_{lc,l})}. \end{aligned} \tag{17}$$

Similarly, total lth layer data transmission over CRN in a GOP is obtained as:

$$\begin{aligned} w_{cr,l} =& u_l\left(p_{cr,l}^{rtx}\left(\frac{1 - P_{e,cr}(\zeta_l, R_{cr,l})^{n_l+1}}{1 - P_{e,cr}(\zeta_l, R_{cr,l})}\right) + 1 - p_{cr,l}^{rtx}\right) \\ &+ (d_l - u_l)(1 - p_{lc,l}^{rtx})P_{out,lc}(R_{lc,l})\frac{1 - P_{e,cr}(\zeta_l, R_{cr,l})^{n_l}}{1 - P_{e,cr}(\zeta_l, R_{cr,l})}. \end{aligned} \tag{18}$$

Probability of packet transmission failure for the data transmitted (including retransmission) via LCN is $P_{out,lc}(R_{lc,l})^{n_l+1}$, while that for the data transmitted over LCN and retransmitted over CRN is $P_{out,lc}(R_{lc,l})P_{e,cr}(\zeta_l, R_{cr,l})^{n_l}$. Hence, for $(1 - u_l/d_l)$ fraction of lth layer content initially transmitted over LCN, probability of failure after retransmissions is $(p_{lc,l}^{rtx}P_{out,lc}(R_{lc,l})^{n_l+1} + (1 - p_{lc,l}^{rtx})P_{out,lc}(R_{lc,l})P_{e,cr}(\zeta_l, R_{cr,l})^{n_l})$. Similarly for u_l/d_l fraction of the lth layer content, the probability of transmission failure is $\left(p_{cr,l}^{rtx}P_{e,cr}(\zeta_l, R_{cr,l})^{n_l+1} + (1 - p_{cr,l}^{rtx})P_{e,cr}(\zeta_l, R_{cr,l})P_{out,lc}(R_{lc,l})^{n_l}\right)$. Consolidating, probability of lth layer content loss is given as:

$$\varphi_l = \left(1 - \frac{u_l}{d_l}\right)\left(p_{lc,l}^{rtx} P_{out,lc}(R_{lc,l})^{n_l+1} + (1 - p_{lc,l}^{rtx}) P_{out,lc}(R_{lc,l}) P_{e,cr}(\zeta_l, R_{cr,l})^{n_l}\right) + \frac{u_l}{d_l}\left(p_{cr,l}^{rtx} P_{e,cr}(\zeta_l, R_{cr,l})^{n_l+1} + (1 - p_{cr,l}^{rtx}) P_{e,cr}(\zeta_l, R_{cr,l}) P_{out,lc}(R_{lc,l})^{n_l}\right). \tag{19}$$

The overall received video quality is quantified using (15).

A packet is transmitted per RB/slot with a header overhead of H_l bits. From (17), the amount of LCN RBs required by the user is given as:

$$N_{rb} = \sum_{l=1}^{L} \frac{w_{lc,l}}{(R_{lc,l} T_{rb} - H_l)} \tag{20}$$

while the spectrum leasing duration over CRN using (18) is:

$$T = T_{cr} \sum_{l=1}^{L} \frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)}. \tag{21}$$

Over LCN, cost of communication charged to the user is proportional to the number of RBs allocated to the user. Denoting cost charged per unit time as $\mathbb{C}_{lc}$, cost to the user over LCN is:

$$\mathscr{C}_{lc} = \mathbb{C}_{lc} T_{rb} \sum_{l=1}^{L} \frac{w_{lc,l}}{(R_{lc,l} T_{rb} - H_l)}. \tag{22}$$

Over the CRN, cost to the user is considered proportional to the time duration the spectrum is leased for its service. Let $\mathbb{C}_{cr}$ be the cost to the user per unit time. So, the user cost over CRN is:

$$\mathscr{C}_{cr} = \mathbb{C}_{cr} T_{cr} \sum_{l=1}^{L} \frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)}. \tag{23}$$

Energy consumption on account of reception over LCN is:

$$\Phi_{lc} = (\xi_{lc,rx} - \xi_{lc,ta}) T_{rb} \sum_{l=1}^{L} \frac{w_{lc,l}}{(R_{lc,l} T_{rb} - H_l)} + \xi_{lc,ta} \mathscr{T} \tag{24}$$

where reception and tail power consumption over LCN are, respectively, $\xi_{lc,rx}$ and $\xi_{lc,ta}$. Over CRN, the device remains in receive mode in the entire slot duration. Denoting receive and tail power consumption over CRN, respectively, as $\xi_{cr,rx}$ and $\xi_{cr,ta}$, total energy consumption in reception over CRN is:

$$\Phi_{cr} = (\xi_{cr,rx} - \xi_{cr,ta}) T_{cr} \sum_{l=1}^{L} \frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)} + \xi_{cr,ta} \mathscr{T}. \tag{25}$$

For the multiuser resource allocation optimization formulation, superscript k is used over a variable to denote it for the kth user. Depending on the remaining battery level, the kth user requests $L^{(k)}$ layers of the video content at a minimum quality threshold $\mathscr{Q}_{th}^{(k)}$ and a maximum energy consumption constraint $E_{th}^{(k)}$. Let $\psi^{(k)} = 1$ (respectively, 0) denote the user k served (respectively, not served). A reward Θ is associated with each user admitted. The resource allocation optimization problem is presented in (26).

$$\mathscr{C}_{net}^{*} = \text{minimize} \sum_{k=1}^{N_u} \left(\mathscr{C}_{lc}^{(k)} + \mathscr{C}_{cr}^{(k)} - \Theta \right) \psi^{(k)} \tag{26}$$

$$\text{s.t.} \quad C1: \frac{\sum_{l=1}^{L^{(k)}} \Omega_l^{(k)} \left(1 - \varphi_l^{(k)}\right)}{\sum_{l=1}^{L} \Omega_l^{(k)}} \cdot 100\% \geq \mathscr{Q}_{th}^{(k)}, \; k \in 1, 2, \cdots, N_u,$$

$$C2: \Phi_{lc}^{(k)} + \Phi_{cr}^{(k)} \leq E_{th}^{(k)}, \; k \in 1, 2, \cdots, N_u,$$

$$C3: p_{md}^{(k)}(\zeta_l) \leq p_{md}^{th}, \; \forall \; l \in 1, 2, \cdots, L^{(k)}, \; k \in 1, 2, \cdots, N_u,$$

$$C4: n_l^{(k)} \leq n_{max}, \; \forall \; l \in 1, 2, \cdots, L^{(k)}, \; k \in 1, 2, \cdots, N_u,$$

$$C5: u_l^{(k)} \leq d_l^{(k)}, \; \forall \; l \in 1, 2, \cdots, L^{(k)} \; k \in 1, 2, \cdots, N_u,$$

$$C6: \sum_{k=1}^{N_u} N_{rb}^{(k)} \psi^{(k)} \leq \mathscr{N}_{rb},$$

$$C7: \sum_{k=1}^{N_u} T^{(k)} \psi^{(k)} \leq \mathscr{T},$$

$$C8: \psi^{(k)} \in \{0, 1\}, \; \forall \; k \in 1, 2, \cdots, N_u.$$

The optimization problem (26) jointly maximizes the number of users served and minimizes the cost of video transmission to the users while ensuring their demanded quality (cf. C1) and energy consumption (cf. C2) constraints. To protect the PUs from interference due to CR activity, the sensing duration is chosen such that the probability of misdetection is upper bounded by p_{md}^{th} (cf. C3). C4 bounds the number of packet retransmissions to n_{max}, while C5 upper bounds u_l to the lth layer content d_l. Constraints C6 and C7 are the resource availability constraints, respectively, over LCN and CRN.

Due to the integer variable $\psi^{(k)}$, the above problem is an integer optimization problem which is NP hard. The solution to this problem is presented below.

Algorithm 1: Resource allocation in multiuser scenario

1. Obtain optimal resource requirements for each user k. Optimal cost to the user, number of LCN RBs, and PU channel leasing duration are $\mathscr{C}^{(k)*}$, $N_{rb}^{(k)*}$, and $T^{(k)*}$, respectively;
2. Arrange the users in the increasing order of their optimal cost $\mathscr{C}^{(k)*}$;
3. Set the available resources: $N_{rb}^{a} \leftarrow \mathscr{N}_{rb}$ and $T^{a} \leftarrow \mathscr{T}$ and $j = 1$;

while $j \leq N_u$ **do**
  if $N_{rb}^{(j)*} \leq N_{rb}^{a}$ *and* $T^{(j)*} \leq T^{a}$ **then**
    4. Allocate resources to the jth user;
    5. Update the available resources $N_{rb}^{a} \leftarrow N_{rb}^{a} - N_{rb}^{(j)*}$ and $T^{a} \leftarrow T^{a} - T^{(j)*}$;
    6. $j \leftarrow j + 1$;
  else
    if $N_{rb}^{(j)*} > N_{rb}^{a}$ **then**
      7. Drop the user ;
      8. $j \leftarrow j + 1$;
    else
      9. Recompute optimal resource requirements with available CRN resource constraint $T^{(j)} \leq T^{a}$;
      10. Sort the remaining users (including the jth user) again in the increasing order of their optimal cost $C^{(j)*}$;
    end
  end
end

Solution to the Optimization Problem

A higher number of users can be served if the users are allocated resources in the increasing order of their demands. From (22) and (23), it is noted that the cost to a user is directly proportional to the resource allocated. For each user, the optimal resource requirement and corresponding optimal cost to the user are independently computed (as would be seen later in this section). A user with lower cost is served first, subject to resource availability. As noted later in section "Multiuser Operation", the users with stronger energy consumption constraint are allocated resources via LCN as they cannot be supported by CRNs. Thus, if for a user the available LCN RBs are less than the required RBs, the user would not be admitted in to the network. On the other hand, if the available CRN resource is less than the required CRN resource for a user, then optimal resource requirement for the user is recomputed after updating the CRN resource constraint. The remaining users are again sorted in the increasing order of their optimal cost and the allocation process continues. The algorithm is presented in Algorithm 1, which provides an optimal solution as it simultaneously achieves low cost to the users while maximizing the number of users served.

Resource allocation optimization to single user: In steps 1 and 9 of Algorithm 1, the optimal resource and cost to the individual users are required. To obtain this, a cost minimization problem is solved for a single user. The optimization problem

is formulated in (27), where superscript k (to indicate the kth user) is omitted for brevity.

$$\mathscr{C}^* \triangleq \mathscr{C}^*_{lc} + \mathscr{C}^*_{cr} = \underset{\substack{R_{lc,l},\zeta_l,R_{cr,l},u_l,\\ n_l,p^{rtx}_{lc,l},p^{rtx}_{cr,l}}}{\text{minimize}} \sum_{l=1}^{L} \left(\mathbb{C}_{lc} T_{rb} \frac{w_{lc,l}}{(R_{lc,l} T_{rb} - H_l)} + \mathbb{C}_{cr} T_{cr} \frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)} \right) \tag{27}$$

s.t. $C1 - C5$ from (26) (superscript k removed for brevity),

$$C6a : \sum_{l=1}^{L} \frac{w_{lc,l}}{(R_{lc,l} T_{rb} - H_l)} \leq N^a_{rb},$$

$$C7a : \sum_{l=1}^{L} \frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)} \leq \frac{T^a}{T_{cr}},$$

$$C9 : (d_l - u_l) \left(p^{rtx}_{lc,l} \left(\frac{1 - P_{out,lc}(R_{lc,l})^{n_l+1}}{1 - P_{out,lc}(R_{lc,l})} \right) + 1 - p^{rtx}_{lc,l} \right) + u_l (1 - p^{rtx}_{cr,l}) \cdot P_{e,cr}(\zeta_l, R_{cr,l}) \frac{1 - P_{out,lc}(R_{lc,l})^{n_l}}{1 - P_{out,lc}(R_{lc,l})} = w_{lc,l} \ \forall\ l \in 1, 2, \cdots, L,$$

$$C10 : u_l \left(p^{rtx}_{cr,l} \left(\frac{1 - P_{e,cr}(\zeta_l, R_{cr,l})^{n_l+1}}{1 - P_{e,cr}(\zeta_l, R_{cr,l})} \right) + 1 - p^{rtx}_{cr,l} \right) + (d_l - u_l)(1 - p^{rtx}_{lc,l}) \cdot P_{out,lc}(R_{lc,l}) \frac{1 - P_{e,cr}(\zeta_l, R_{cr,l})^{n_l}}{1 - P_{e,cr}(\zeta_l, R_{cr,l})} = w_{cr,l} \ \forall\ l \in 1, 2, \cdots, L.$$

N^a_{rb} in C6a and T^a in C7a are the available resources over LCN and CRN, respectively. C9 and C10 are the constraints corresponding to the amount of lth layer content transmitted over LCN ($w_{lc,l}$) and CRN ($w_{cr,l}$), respectively.

The factor $J(\zeta_l)$ appearing in the energy (cf. (25)), cost (cf. (23)), and in the CRN resource constraint C7a is nonconvex in ζ_l. The terms $P_{out,lc}(R_{lc,l})$ and $P_{e,cr}(\zeta_l, R_{cr,l})$ in constraints C1, C9, and C10 are also nonconvex. Hence, the overall optimization problem is nonconvex with nonconvex constraints. Therefore, solution to (27) is NP hard. In the following, the problem is transformed to a difference of convex (DC) optimization problem and solved using the convex-concave procedure (CCP). Before proceeding further, the DC optimization problem is briefly discussed along with some useful lemmas.

DC optimization problem: A DC optimization problem can be written in the following form:

$$\begin{aligned} \underset{\mathbf{x}}{\text{minimize}} \quad & f_0(\mathbf{x}) - g_0(\mathbf{x}) \\ \text{s.t.} \quad & f_i(\mathbf{x}) - g_i(\mathbf{x}) \leq 0, \forall\, i \in 1, 2, \cdots M \end{aligned} \tag{28}$$

where f_i and g_i are convex functions of vector $\mathbf{x}$. The following two lemmas are used to transform (27) to a DC optimization problem.

Lemma 1. *A function of product of two convex functions $f(x) \cdot g(x)$, $x \in \mathbb{R}$ is convex if $f(x)$ and $g(x)$ are positive and both the functions are either increasing or decreasing.*

Proof. Let us express $h(x) = f(x) \cdot g(x)$. Hessian h''_{xx} of $h(x)$ is:

$$h''_{xx} = f''_{xx} g(x) + f(x) g''_{xx} + 2 f'_x g'_x.$$

Hessian of a convex function is positive. Thus, f''_{xx} and g''_{xx} are > 0. As $f(x)$ and $g(x)$ are positive, the first two terms in h''_{xx} expression are positive. Given that both the functions are either increasing or decreasing, their derivatives are of same sign (either positive or negative). Thus, the last term is also positive. Consequently, h''_{xx} is positive, and hence $h(x)$ is convex.

Lemma 2. *A function of product of two convex functions $f(x) \cdot g(y)$, $(x, y) \in \{\mathbb{R}^2 | f(x) + g(y) \geq 0\}$ can be written as a difference of two convex functions as:*

$$f(x) \cdot g(y) = \frac{(f(x) + g(y))^2}{2} - \left(\frac{f(x)^2}{2} + \frac{g(y)^2}{2} \right). \tag{29}$$

Proof. Using binomial expansion of $(f(x)+g(y))^2$, the above expression for $f(x) \cdot g(y)$ is obtained. From Lemma 1, square of a convex function is convex. Thus, $f(x)^2/2$ and $g(y)^2/2$ are convex. Consider $h(x, y) = (f(x) + g(y))^2$. Hessian $\mathbf{h}''$ of $h(x, y)$ is given as:

$$\begin{bmatrix} 2f''_{xx}(f(x) + g(y)) + 2(f'_x)^2 & 2f'_x g'_y \\ 2f'_x g'_y & 2g''_{yy}(f(x) + g(y)) + 2(g'_y)^2 \end{bmatrix}$$

Given that $f(x)$ and $g(y)$ are convex, diagonal terms in $\mathbf{h}''$ are positive. Determinant of $\mathbf{h}''$ is $4f''_{xx}g''_{yy}(f(x) + g(y)) + 4f''_{xx}(f(x) + g(y))(g'_y)^2 + 4g''_{yy}(f(x) + g(y))(f'_x)^2$. As $(x, y) \in \{\mathbb{R}^2 | f(x) + g(y) \geq 0\}$, determinant of $\mathbf{h}'' > 0$. Hence, $(f(x) + g(y))^2$ is also convex.

These two lemmas are used to reformulate (27) to a DC optimization problem as described below.

Optimization problem reformulation into DC: The number of RBs over LCN and number of slots over CRN used for the lth layer video transmission obtained from (22) and (23), respectively, are nonconvex. Using epigraphs, these expressions are transformed into constraints as follows:

$$\frac{w_{lc,l}}{(R_{lc,l}T_{rb} - H_l)} \leq \omega_l \tag{30}$$

$$\frac{w_{cr,l}}{J(\zeta_l)(R_{cr,l}(T_{cr} - \zeta_l) - H_l)} \leq \upsilon_l. \tag{31}$$

By replacing the above expressions in (27) with ω_l and υ_l, (27), C2, C6a, and C7a are transformed to linear functions of ω_l and υ_l. These newly introduced constraints are converted to DC constraints as follows: Rewriting (30) as $w_{lc,l} - \omega_l R_{lc,l} T_{rb} + \omega_l H_l \leq 0$. The term $\omega_l R_{lc,l} T_{rb}$ is nonconvex, which is converted to DC by using Lemma 2. Similarly, (31) is rewritten using (4) as $w_{cr,l} - \upsilon_l(p_{cr} p_{md}(\zeta_l) + (1 - p_{cr})(1 - p_{fa}(\zeta_l)))(R_{cr,l}(T_{cr} - \zeta_l) - H_l) \leq 0$. The terms $(1 - p_{cr})(1 - p_{fa}(\zeta_l))R_{cr,l}\zeta_l$ and $\upsilon_l p_{cr} p_{md}(\zeta_l)$ in the above expression are nonconvex and are converted to DC by Lemma 2.

The probability of transmission failure $P_{out,lc}(R)$ over a LCN RB and the probability of transmission failure $P_{out,cr}(R)$ due to channel fading and path loss over a slot in CRN from (1) and (5), respectively, are nonconvex. Similarly, the expressions $\frac{1-P_{out,lc}(R_{lc,l})^{n_l+1}}{1-P_{out,lc}(R_{lc,l})}$, $\frac{1-P_{out,lc}(R_{lc,l})^{n_l}}{1-P_{out,lc}(R_{lc,l})}$, $\frac{1-P_{e,cr}(\zeta_l,R_{cr,l})^{n_l}}{1-P_{e,cr}(\zeta_l,R_{cr,l})}$, $\frac{1-P_{e,cr}(\zeta_l,R_{cr,l})^{n_l+1}}{1-P_{e,cr}(\zeta_l,R_{cr,l})}$, $P_{out,lc}(R_{lc,l})^{n_l}$, and $P_{e,cr}(\zeta_l, R_{cr,l})^{n_l}$ appearing in the constraints C1a, C9, and C10 are also nonconvex. These are linear approximated using the first order Taylor series. For a function $f(x)$, its linear approximation is $f(x_\kappa) + \bigtriangledown f_x(x_\kappa)'(x - x_\kappa)$ around a point x_κ. Once these are approximated, the original constraints are expressed in DC using Lemmas 1 and 2.

Thus, the modified optimization problem constitutes a convex objective with DC constraints. Below, the convex-concave procedure (CCP) [20] is used to solve the DC optimization problem.

Solution to the DC optimization problem: In CCP, the DC functions $f_i(\mathbf{x}) - g_i(\mathbf{x})$ are approximated to convex functions. Linear approximation of the negative convex part, i.e., $g_i(\mathbf{x})$, is used to convert the DC to convex function. First order Taylor series is used to obtain the linear approximation. At a point $\mathbf{x}_k$, the linear approximation of the DC function is given as $f_i(\mathbf{x}) - g_i(\mathbf{x}) \approx f_i(\mathbf{x}) - g_i(\mathbf{x}_\kappa) - \bigtriangledown g_i(\mathbf{x}_\kappa)'(\mathbf{x} - \mathbf{x}_\kappa)$. Once the DC functions are convex approximated, convex optimization is applied to obtain the solution. At each iteration, once the optimal values are obtained, the approximation to the DC functions is improved to obtain a better solution. Convergence of this algorithm has been provided in [21].

A feasible initial point is required as input to this algorithm, which may be challenging given the number of variables involved. In [22], it was shown that the need for an initial feasible point could be overcome by making use of slack variables in the constraints and penalizing the violations. Naming this modified algorithm as

Algorithm 2: Penalty convex-concave procedure

Initial point $\mathbf{x}_0$, $\tau_0 > 0$, τ_{max}, $\varkappa$, and ε. $\kappa = 0$
while $|F_\kappa - F_{\kappa-1}| < \varepsilon$ **do**
1. Form $\hat{g}_j(\mathbf{x}; \mathbf{x}_\kappa) \triangleq g_j(\mathbf{x}_\kappa) + \nabla g_j(\mathbf{x}_\kappa)'(\mathbf{x} - \mathbf{x}_\kappa)$ for $j = 0, 1, \cdots, M$.
2. Set the value of $\mathbf{x}_{\kappa+1}$ to the solution of

$$
\begin{aligned}
F_\kappa = \underset{\mathbf{x}}{\text{minimize}} \quad & f_0(\mathbf{x}) - \hat{g}_0(\mathbf{x}, \mathbf{x}_\kappa) + \tau_\kappa \sum_{j=1}^{M} v_j \\
\text{subject to} \quad & f_j(\mathbf{x}) - \hat{g}_j(\mathbf{x}; \mathbf{x}_\kappa) \leq v_j, \forall\ j \in 1, 2, \cdots M, \\
& v_j \geq 0, j = 1, 2, \cdots, M.
\end{aligned}
$$

3. Update τ: $\tau_{\kappa+1} = min(\varkappa \tau_\kappa, \tau_{max})$.
end

penalty CCP, Algorithm 2 describes the steps involved. In step 1, the DC constraints are linear approximated around point $\mathbf{x}_\kappa$. Slack variable v_j is considered for each constraint, τ is the penalty factor added to the objective, and $\varkappa$ is the multiplying factor which increments the penalty factor in each iteration. τ_{max} is the upper limit of τ. In each iteration, an approximate convex optimization problem is solved in step 2. The algorithm stops when the change in the objective function value is less than a small constant ε.

Complexity analysis and convex problem decomposition: In step 2 of the Algorithm 2, a convex optimization problem is solved. For solving (27), a number of variables are $(20L + 4)$, where $7L$ are the required parameters ($R_{lc,l}$, ζ_l, $R_{cr,l}$, u_l, n_l, $p_{lc,l}^{rtx}$, and $p_{cr,l}^{rtx}$), $4L$ are the additional introduced variables ($w_{lc,l}$, $w_{cr,l}$, ω_l, and υ_l), and $9L+4$ are slack variables (v_i) corresponding to each constraint. Solving this convex problem involves high complexity. Therefore, the decomposition method is employed to solve this convex problem.

Due to the specific structure of the problem, it is decomposed with each layer forming a separate subproblem. The Lagrange function of the approximated convex problem is decomposed into L subproblems corresponding to each layer and $9L + 4$ subproblems corresponding to the slack variables. The subproblems corresponding to each layer are nonlinear, while the subproblems corresponding to the slack variables are linear. The problem is iteratively solved, where the subproblems are fed with the Lagrange multipliers to obtain the optimal parameters. Using these optimal values from each subproblem, the main problem computes the optimal Lagrange multipliers using the subgradient method [23].

This decomposition results in a total of $10L + 4$ subproblems with 15 variables for the L subproblems corresponding to each layer and 1 variable for the $9L + 4$ subproblems corresponding to each slack variable. Complexity for solving subproblems corresponding to L layers is $\mathcal{O}(15^3)$, and they can be solved in parallel. Closed form expressions are obtained for solving the $9L + 4$ subproblems corresponding to

each slack variable. Their computation complexity is negligible. The computation of optimal Lagrange multipliers requires only a few arithmetic operations. Thus, the decomposition method reduces the complexity significantly.

For CM-basic, the parameters in (27) are made layer independent. Thus, decomposition method is not required in CM-basic. The solution to (27) for CM-basic is obtained using the penalty CCP method as presented in Algorithm 2. There are 22 variables, where 7 are the desired parameters, 4 are the additional variables introduced, and 13 are the slack variables corresponding to the constraints. Complexity of solving this problem is $\mathcal{O}(22^3)$. Though its complexity is lower than CM-optimal, as will be noted in section "Video Application-Specific Performance", the performance of CM-basic is inferior to CM-optimal.

Discussion: The optimization problem (27) provides optimal parameters for the transmission of L-layer video content via the two networks. The user-provided parameters (viz., $E_{th}^{(k)}$, $\mathcal{Q}_{th}^{(k)}$, and $L^{(k)}$) change with the remaining battery level of the device, which is on the order of minutes. While these computations are done on the BS, which have high processing capabilities, the optimization problem computation can be easily parallelized to meet the deadlines.

Results

Performance of the CM system is captured in two scenarios. The performance of the CM network is compared against single network access (SNA) scheme, where the users associate themselves to a single network either LCN (SNA-LCN) or CRN (SNA-CRN).

General Performance

In this section, numerical results are presented to demonstrate the performance of CM in the general scenario with heterogeneous user traffic demands. Frame duration $\mathcal{T}$ is taken as 260 ms considering the case of video transmission of 30 fps with GOP duration of 8 pictures. LTE network is considered as LCN with 5 MHz bandwidth available. Slot duration in LTE is 0.5 ms with 50 RBs per slot. Data transmission over each RB is 0.5 Kb. Over the CRN, 2 channels of bandwidth 7 MHz each are considered with the data rate over each channel is 26.7 Mbps (as in IEEE 802.11af). Slot duration is taken as 0.5 ms. SU channel sensing duration is taken such that the probability of misdetection is bounded within 0.1. PU channel activity parameter is taken as $p_{cr} = \{0.3, 0.4\}$ [24]. For demonstration purpose, consider cost per bit transmission in LCN ($\mathscr{C}_{lc}$) and CRN ($\mathscr{C}_{cr}$) as 0.1 and 0.05, respectively. Fairness constraint β is taken to be 0.7, unless otherwise stated.

As stated earlier, for comparison purpose, SNA scheme is considered where the users are allocated resources via a single network. Users associate themselves to

a specific network based on their cost constraint χ. Low χ users (say, $\chi < \chi_{th}$) are low-paying users and hence they choose CRN, while the high χ users choose LCN. Depending upon the users in each network, the controller in each network allocates resources such that their individual network utility is maximized. The overall network utility is taken as the sum of the individual network utility of the two networks. It is of interest to obtain the optimal threshold χ^*_{th} that maximizes the network utility.

Comparative Performance of CM

A network of 60 users is considered where the percentage of RT users varied as $\{10, 30, 50, 70, 90\}\%$ of the total users. Users are randomly deployed across the cell. Each user uniformly chooses its $d_{req} \in [0.2, 1]$ Mbps and cost constraint $\chi \in (0.2, 1)$. d_{min} for RT users is considered 40% of d_{req}. Constants c_1, c_2, c_3, and c_4 are taken as 10, 1000, 25, and 15, respectively.

Figure 5 plots the user utility in CM and SNA along with their cost constraint χ for the network with 50% RT users. In SNA, via simulations maximum network utility (sum of the network utility of the two networks) is obtained. Corresponding to the maximum network utility is the optimal $\chi^*_{th}(SNA)$. The users with $\chi < \chi^*_{th}(SNA)$ associate themselves to the CRN, while the others associate

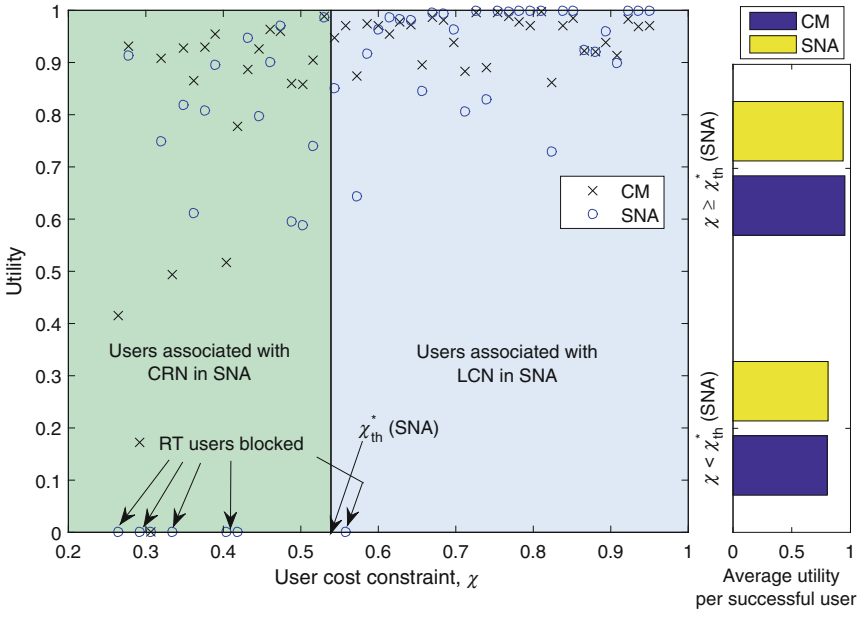

Fig. 5 Users' utility along with their cost constraint (χ) and average utility observed by successful users in different χ regimes for the network with 50% RT users. $\beta = 0.7$

themselves with the LCN in SNA. Bar plot shows the average utility obtained by the successful users (those users which have been provided service) in the two χ regimes, i.e., $\chi < \chi^*_{th}(SNA)$ and $\chi \geq \chi^*_{th}(SNA)$.

From the plot, it is observed that the utility for high χ users is higher in CM as compared to SNA. Users operating over SNA in this regime obtain their resources via LCN only which is an expensive resource. In SNA, the users with moderate χ suffer as they can only be allocated a fraction of their required resource via LCN due to their cost constraint. CM does better in QoS because of flexible shared resource allocation.

In the low χ regime ($\chi < \chi^*_{th}(SNA)$), all users are associated with CRN in SNA. Because of intermittent PU activity in CRN, SNA in this regime offers a much lower user utility compared to that in CM. Average utility per successful user is comparable in both the cases. This is because, a higher number of users are blocked in SNA. Similar conclusion can be drawn for network with different proportion of RT users. Thus, CM offers a high QoS to the users at low cost (low to moderate χ users) along with high-paying users, while SNA can provide high QoS only to high-paying LCN users.

Figure 6a shows the percentage of users blocked in CM and SNA for various network instances. As the proportion of RT users increases in the network, a higher number of users are blocked because it becomes difficult for the network to meet the minimum rate requirements of all these RT users. The blocked users are mostly

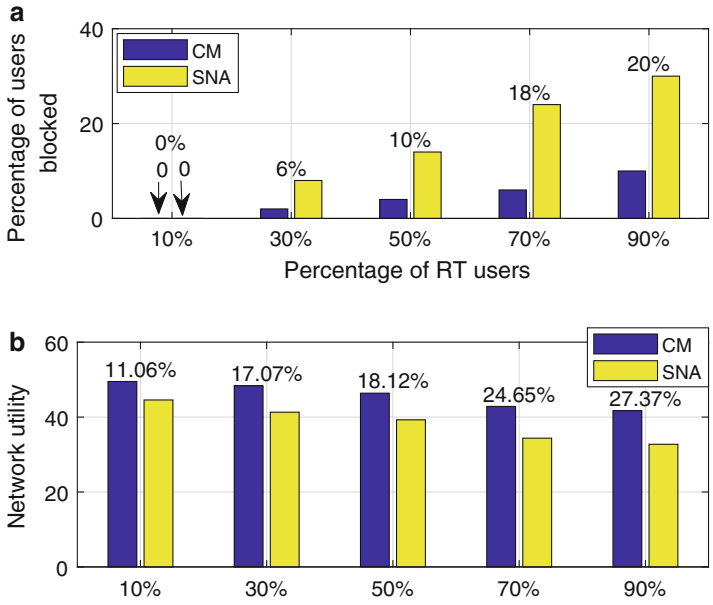

Fig. 6 (**a**) Number of users blocked and (**b**) network utility obtained. $\beta = 0.7$. Values above the bar shows the percentage gain in CM

low-χ users (see Fig. 5), because these users seek most resource from CRN, which is a scarce resource (due to high demand of CRN resources by other users and also due to intermittent PU activity). In the CM system, a lower number of users get blocked as compared to the SNA due to optimal allocation of resources to the users via the two networks. It is noted that, in the chosen RT versus NRT user scenarios, on average 10.8% less users are blocked in CM.

Network utility in CM and SNA scheme is shown in Fig. 6b. As expected, CM performs better than the SNA in all cases as the resources are optimally and fairly allocated to the users according to their cost constraints and required resources. It is also observed that the gain increases with the proportion of RT users in the network as high number of users get blocked in SNA for higher RT users proportion in the network. Gain in network utility is seen to vary from 11% to 27%, with an average gain of 19.6%.

Effect of Fairness Constraint

Finally, to observe the effect of fairness constraint β, the network utility versus β is plotted in Fig. 7. Fairness constraint limits the controller to allocate the CRN resources unevenly among users. A stringent fairness threshold pushes the controller to allocate the CRN resources more evenly among users. This adversely affects the low χ users leading to low network utility, though at the cost of maintaining high degree of fairness. Thus, the inclusion of fairness constraint in the optimization problem ensures that the greedy users are not unduly benefited from the CRN by having low-cost constraint.

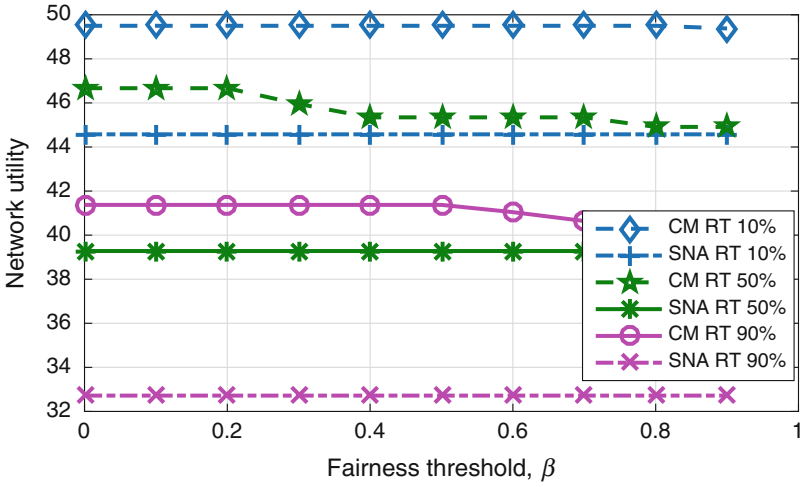

Fig. 7 Network utility as a function of fairness constraint, β

Video Application-Specific Performance

The user cost in video reception via CM is evaluated in this subsection. A single cell scenario is considered with 1 Km cell radius. The CR-enabled BS is located at the cell center. LCN RBs are of duration 0.5 ms with bandwidth of 5 MHz (LTE in 900 MHz band is considered). CRN operation is considered over UHF band (500 MHz) with PU channel bandwidth of 6 MHz. Slot duration is 10 ms (as in IEEE 802.22). Channel idling probability is 0.7 [24]. Misdetection probability threshold is set to 0.05 [8]. Transmission power over LCN and CRN is 24 and 20 dBm, respectively, while noise variance is 10^{-4} [25]. Path loss exponent is 3.76 [26].

$\mathbb{C}_{CR}/\mathbb{C}_{LC} \triangleq \rho$ is the ratio of cost charged by CRN and LCN per unit time. In this study, it is considered that the user is charged monetary cost 100 units per unit time for operation over LCN, and $\rho = 0.5$ (50 units per unit time for PU spectrum leasing). Device power consumption for reception is 1737 mW, while its tail power consumption is 1325 mW [18]. Device energy consumption is a function of the number of layers it intends to receive. In 3GPP, channel state feedback is provided within 6 ms [27]. Hence, for each packet reception error, the receiver can inform the BS almost within the next CRN slot. For this study, maximum retry limit n_{max} is considered to be 5.

City and *Mobile* QCIF video sequences are encoded into SNR scalable bitstreams with a base layer and 3 enhancement layers, with 30 frames per second (fps) and with GOP of duration 16 frames having structure "IPPPPPPPPPPPPPPP." For the *City* sequence, base layer data rate is 71 Kbps, while the enhancement layers 2, 3, and 4 are encoded at rates 34, 110, and 236 Kbps, respectively. For the *Mobile* sequence, base layer data rate is 162 Kbps, while the enhancement layers 2, 3, and 4 are encoded at rates 203, 535, and 1497 Kbps, respectively. The encoding is done using JSVM [28]. This data is suitably divided into packets with per-packet overhead of 24 Bytes, as in IEEE 802.11.

The performance of the CM is compared with CM-basic, SNA-LCN, and SNA-CRN. If the user is associated only with LCN (i.e., SNA-LCN), transmission rate is optimized for its optimal performance. In SNA-CRN, where the user is only associated with CRN, sensing duration and transmission rate adaptation are performed to guarantee optimal performance. To explicitly demonstrate the benefit of layer-dependent parameter adaptation in the CM (call it as optimized CM, or CM-optimal), the comparative scheme, namely, basic CM (CM-basic), is considered. In CM-basic, transmission rate adaptation over the LCN and CRN, sensing time adaptation, and number of retransmission and network selection for retransmission are optimally chosen for all video packets without distinguishing their respective priority levels, to obtain low-cost transmission to the users.

Video Transmission to a Single CM User

A user located at a distance of 0.5 Km from the BS requests for *City* video sequence with 4 layers. The minimum desirable video quality is 95%. In the following, the single-user performance is presented in terms of device and network constraints and user preference.

Effects of User Preference

Figure 8a, b present, respectively, the user cost and energy consumed versus energy consumption threshold. Compared to SNA-LCN, SNA-CRN offers service at a lower cost due to its opportunistic spectrum access. However, operation over CRN requires a higher minimum energy E_{th}^{*} as opposed to $E_{th}^{\#}$ in SNA-LCN (i.e., $E_{th}^{*} \geq E_{th}^{\#}$, as noted in Fig. 8b), because of the additional activity of the device due to intermittent sensing and channel imperfections. CM-basic provides service in all regimes as it exploits both CRN and LCN. For $E_{th} > E_{th}^{*}$, cost is same as in SNA-CRN, because all content is transmitted via CRN. As the device energy consumption constraint becomes more stringent ($E_{th} < E_{th}^{\#}$), the SNA-LCN and CM-basic go into outage because energy consumption in SNA-LCN exceeds the threshold. In contrast, less resource requirement in CM-optimal allows to serve a user with even more stringent energy constraints. Though the energy consumption in CM-optimal is higher than that in SNA-LCN, CM-optimal serves the user at a lower cost due to concurrent transmissions via LCN and CRN. Overall, CM-optimal outperforms CM-basic (hence SNA-LCN and SNA-CRN) by reducing the cost on average by up to 44.1%.

Figure 9 presents the impact of video quality threshold $\mathcal{Q}_{th}$ on user cost. $\mathcal{Q}_{th}$ is varied from 90% to 99%, with $E_{th} = 680$ mJ. A higher $\mathcal{Q}_{th}$ requires higher resources, thereby increasing energy consumption and cost. With the considered E_{th}, SNA-CRN can guarantee service only up to $\mathcal{Q}_{th} \leq \mathcal{Q}_{th}^{*}$. In contrast, SNA-LCN meets the user demand at a lower energy consumption, though at a higher cost. CM performs better by using CRN at lower $\mathcal{Q}_{th}$ for reduced cost and optimally dividing the stream over LCN and CRN to meet higher $\mathcal{Q}_{th}$ at a reduced cost. Compared to SNA, CM-optimal provides on an average 42% cost reduction along with providing service to the users with more stringent E_{th} and $\mathcal{Q}_{th}$ requirements.

Effects of Network Parameters

Figure 10a shows the cost to the user in various schemes with the change in CRN versus LCN cost ratio ρ. Observe that cost to the user increases with the increase in ρ (ϕ_{cr}). User cost in SNA-CRN surpasses SNA-LCN at $\rho = \rho^{*}$. To achieve a low-cost transmission, the CM-optimal delivers all the data via CRN for $\rho < \rho^{*}$, while the data is transmitted via LCN for $\rho > \rho^{*}$.

The effect of PU activity parameter on user cost is plotted in Fig. 10b. PU channel idling probability p_{cr} is varied from 0.25 to 1. Lower idling probability induces the use of higher number of CRN slots to transmit a video content, thus increasing energy consumption and cost. For $p_{cr} < p_{cr}^{*}$, the energy consumption constraint is violated in SNA-CRN resulting in service outage. CM-optimal chooses the radio access optimally to maintain low cost to the user at all times.

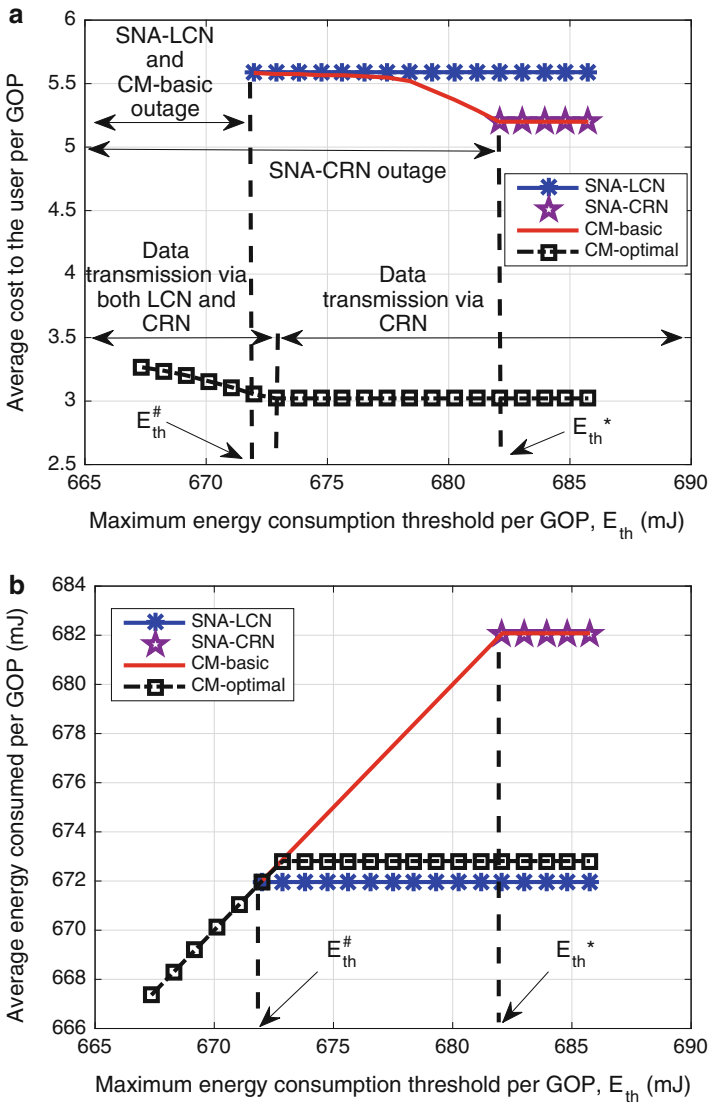

Fig. 8 Variation in (**a**) user cost and (**b**) energy consumed, versus energy consumption threshold. $\mathscr{Q}_{th} = 95\%$. $\rho = 0.5$, $p_{cr} = 0.7$, $L = 4$

Effects of User Device Battery Energy Constraint

As discussed in section "User Device Capability", to aid continued reception, user's requested video quality and maximum energy consumption constraint has been considered to be a function of its remaining battery level. For demonstration, let us consider a mobile device with maximum energy consumption threshold and requested number of video layers L, as shown in Fig. 11.

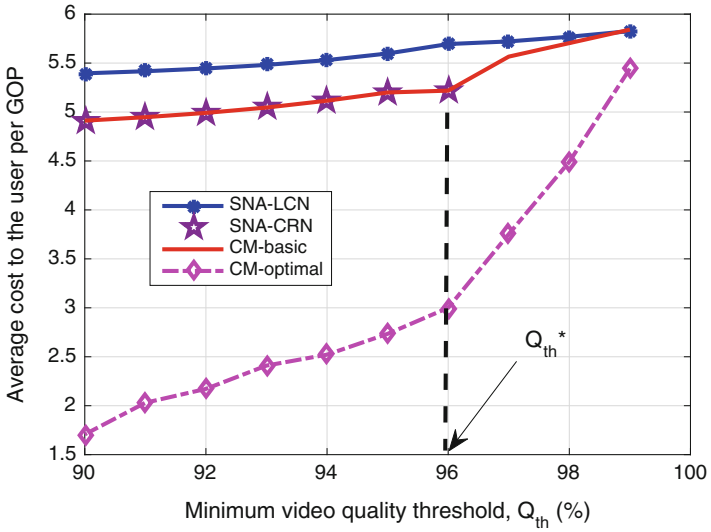

Fig. 9 Variation in user cost versus video quality constraint. $E_{th} = 680$ mJ, $\rho = 0.5$, $p_{cr} = 0.7$, $L = 4$

A lower remaining battery level induces lower video quality and E_{th}. $\mathscr{Q}_{th}$ is maintained at 95%. Figure 12a presents the user cost in video transmission in the various schemes. SNA-CRN goes into outage for some E_{th} regimes, though providing service at a lower cost. The gain in CM-optimal as compared to SNA as well as CM-basic scheme is higher when L is higher. This is because the advantage with layer-dependent parameter adaptation diminishes for lower number of requested layers. Figure 12b presents the mean received video PSNR for different battery levels of the user device. The PSNR increases with the increased number of layers requested. As $\mathscr{Q}_{th}$ is maintained at 95%, the PSNR remains constant for a fixed number of layers requested. Thus, CM-optimal intelligently distributes data via the two networks depending on the individual network cost and availability, to ensure low cost to the user without affecting the video reception quality.

Multiuser Operation

Let us consider a single cell scenario with 80 CM users uniformly randomly distributed across the cell. Three network scenarios are considered. In the first, all users request *"City"* video sequence, while in the second all users request *'Mobile'* video sequence. In the third scenario, the users request one of the two video sequences: *"City"* or *"Mobile"*, with equal probability. Remaining battery level of user device is distributed uniformly between [0 100]%. Depending on the remaining battery level, the user's maximum energy consumption constraint and number of

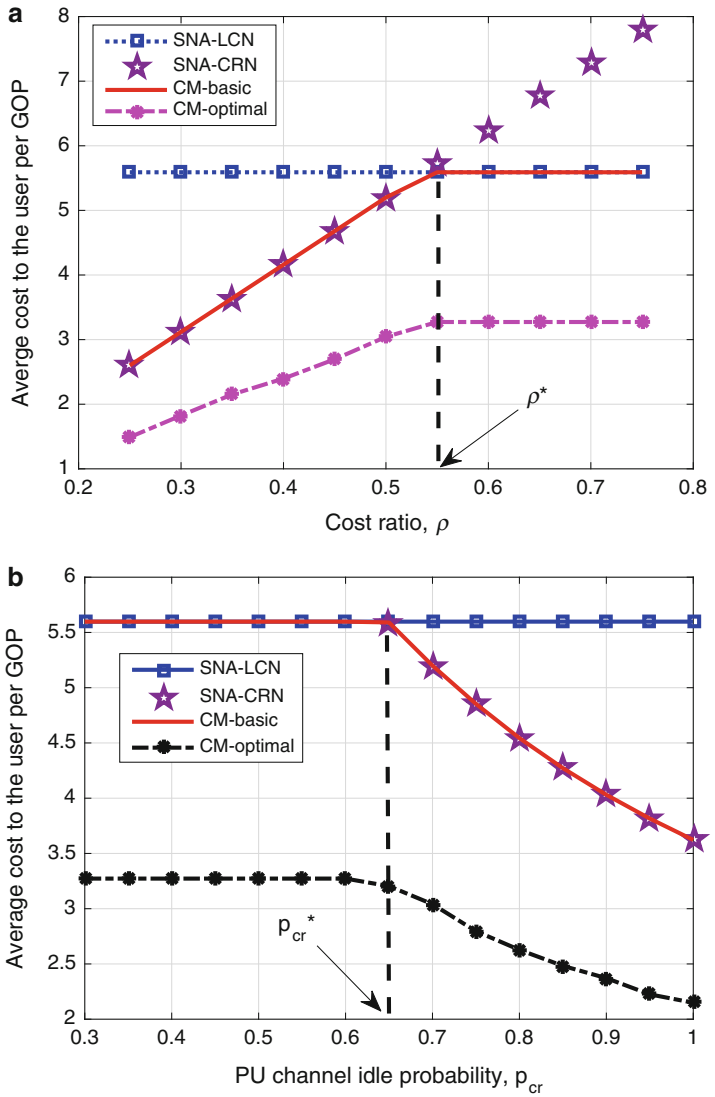

Fig. 10 User cost versus change in (**a**) cost ratio ρ, with $p_{cr} = 0.7$; (**b**) PU channel idling probability p_{cr}, with $\rho = 0.5$. $\mathcal{Q}_{th} = 95\%$, $E_{th} = 680$ mJ, and $L = 4$

layers requested are obtained from the characteristics in Fig. 11. The minimum video quality constraint is fixed to 95% for all users. Three random instances of the network in each of the three scenarios are studied, and the average performance is evaluated.

Figure 13 presents an example of resources requested/allocated via the two networks for a random network instance in the third scenario. Optimal resources

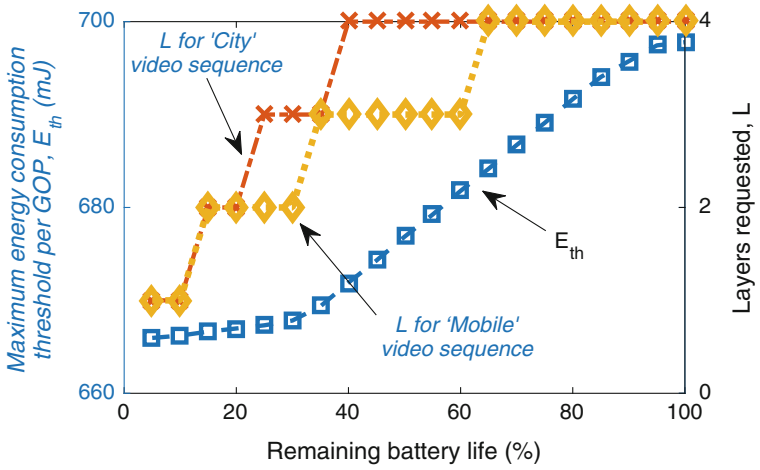

Fig. 11 User's demanded video quality and energy constraint with the remaining battery level

requested by the individual users are computed using (27). Following Algorithm 1, the users are served in an increasing order of their cost or equivalently the number of layers requested. The users meeting the resource availability criteria are served (marked *allocated* in Fig. 13). If the CRN resources are insufficient, (27) is recomputed to obtain the revised resource allocation. If a user's revised resource allocation is acceptable, the user is served (marked by arrow in Fig. 13). A user is dropped if its resource requirement is not met. Overall, the users requesting lower resources are served, while the users with higher demands are more likely to be dropped.

Figure 14a, b present, respectively, the total network cost $\mathscr{C}^*_{net}$ (cf. (26)) and the average number of users served in the three scenarios. The number of users served is higher in scenario 1 as the data rate of the *City* video sequence is lower compared to the *Mobile* video sequence. Total network cost in SNA schemes is seen to be higher than (inferior to) the CM system because the users are optimally allocated resources from the two networks simultaneously in CM. Further, the number of users served in CM is higher compared to the other schemes. Figure 14c shows the average PSNR of the users served. It is observed that the average PSNR in CM-optimal is better than that in all the other schemes as higher number of users are served in CM-optimal. Due to layer-dependent parameter optimization, CM-optimal outperforms SNA-LCN schemes by serving on average 48.2% more users with about 3% higher PSNR on average.

To gain further insights, Fig. 15a, b present the average cost per user and fraction of users served versus number of layers requested in the first scenario. From Fig. 15a, it is observed that the average cost per user served is the lowest in CM-optimal, which is due to its layer-dependent parameter optimization. Cost reduction in CM-optimal is higher for higher number of requested layers. As the

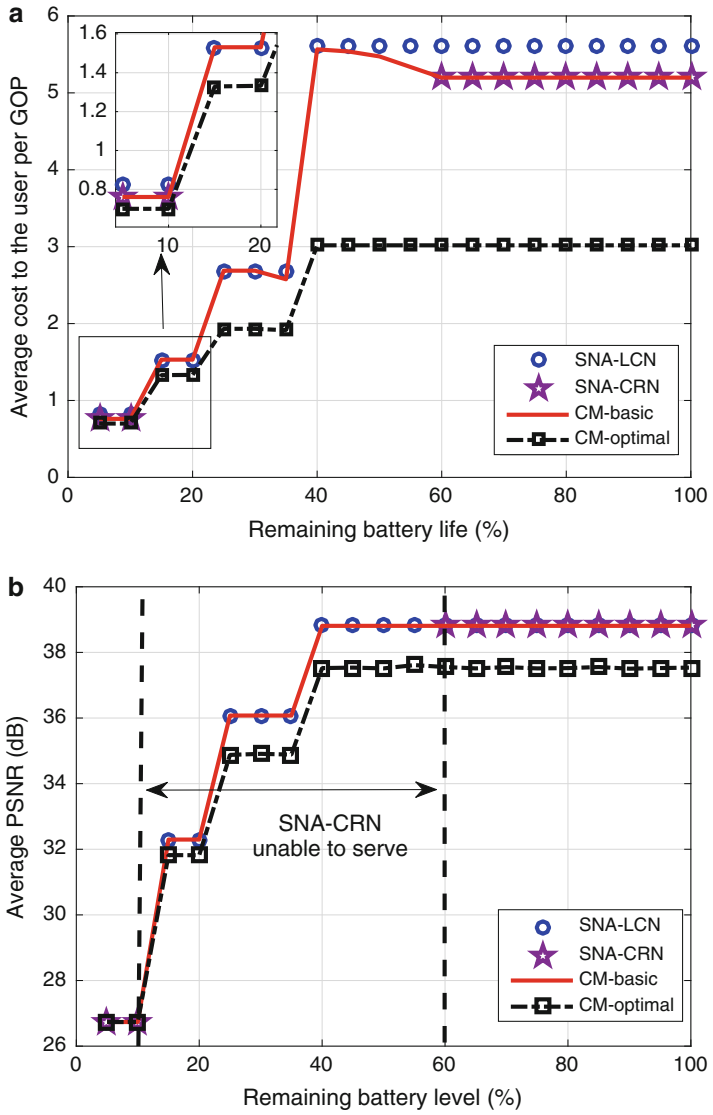

Fig. 12 User (**a**) cost and (**b**) received video quality (PSNR) with the remaining battery level for the *"City"* video request. $\mathscr{Q}_{th} = 95\%$, $\rho = 0.5$, and $p_{cr} = 0.7$

users are served in an increasing order of the number of layers requested, the users requiring higher number of layers are more likely to be dropped (see Fig. 15b). However, in CM system, where the data is optimally transmitted via the two networks, the fraction of users served is higher. Similar trends are observed in the other scenarios as well. Compared to SNA, CM system serves a higher number of users with a higher average video reception quality and at a lower cost.

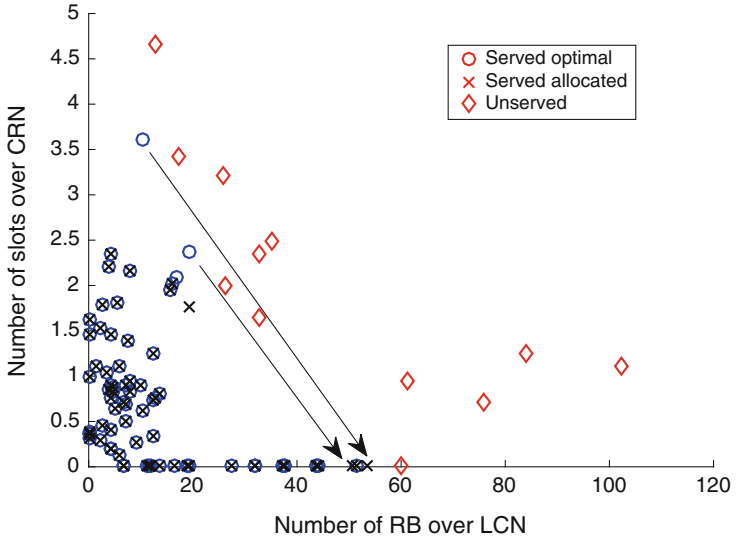

Fig. 13 Requested and allocated resources to the users via the two networks for a network instance in Scenario 3. $N_u = 80$, $\mathcal{Q}_{th} = 95\%$, $\rho = 0.5$, and $p_{cr} = 0.7$

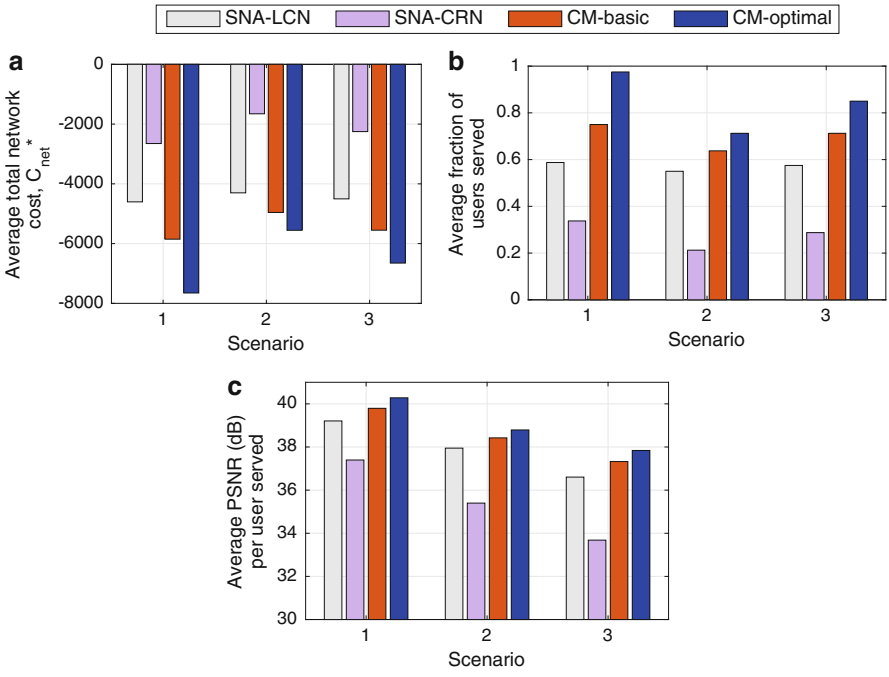

Fig. 14 Average (**a**) total network cost, (**b**) fraction of users served, and (**c**) PSNR per user served in the three scenarios. $N_u = 80$, $\mathcal{Q}_{th} = 95\%$, $\rho = 0.5$, $p_{cr} = 0.7$, and $\Theta = 100$

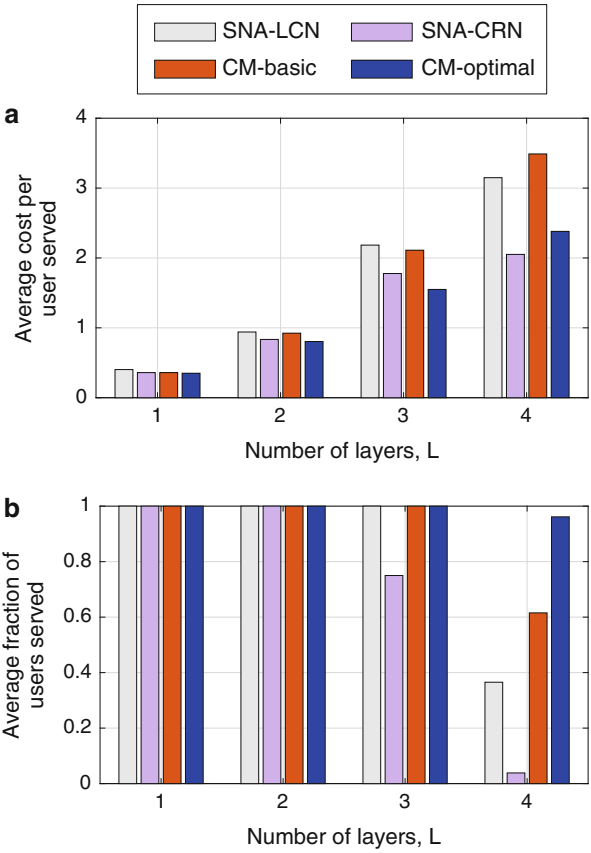

Fig. 15 (**a**) Average cost per user served and (**d**) average fraction of users served for users requesting different number of layers in Scenario 1. $N_u = 80$, $\mathscr{Q}_{th} = 95\%$, $\rho = 0.5$, $p_{cr} = 0.7$, and $\Theta = 100$

Concluding Remarks

Summary and Discussion

In this chapter, a cognitive multihoming system concept has been introduced to enhance the cellular network experience. Here, the user data is optimally split across LCN and CRN before transmission to the multihomed users. The CM approach aids in mitigating the spectrum scarcity problem of LCN, which CRN alone cannot solve. Two test scenarios were considered. In the general scenario, compared to the SNA approach, CM offers about 19% increase in average network utility and about 11% increase in average number of users served. In the application-specific scenario, where the users request for scalable video content, the optimized CM has been shown to outperform the SNA schemes by reducing the cost up to 51% and serving almost 55% more number of users.

Challenges and Future Directions

CM involves aggregating LCN and CRN to provide high-quality service to the users. CM can be easily realized in practice by utilizing the LTE-WiFi aggregation (LWA) technique standardized by the 3GPP in Release-13. LWA offers seamless usage of both LTE and WiFi networks to increase network performance. LWA can be used for CM deployment by replacing the WiFi network component with the CRN.

However, regulations are required to carry out opportunistic transmissions over unused licensed bands. A few countries, for example, the USA and some countries in Europe have introduced regulations for exploiting unused TV spaces. Yet, no regulation has been introduced for dynamic spectrum access in other licensed bands, which is required from the government agencies before CRN techniques could be commercially realized.

Furthermore, the BSs need additional capability of streaming the data stream from the remote data server and splitting the stream optimally across LCN and CRN for each user. This requires servers with high computation power at the BS which can carry out the optimization in real time. One aspect for future works is to study and develop novel real-time algorithms which can be implemented on low-end off-the-shelf hardware platforms and require minimal changes in the existing BS ecosystem.

The discussion in this chapter considers only the downlink communication via CM. Analysis of CM system for uplink transmissions can be studied likewise. There could be multiple cellular networks in a specific geographical region accessing the same CR channels. Coexistence studies among multiple such networks are useful from the point of performance and resource allocation via CM.

Spectrum Policy and Cognitive Radio Standards

Spectrum Policy and Cognitive Radio Standards

45

Oliver Holland

Contents

Abstract

Standards, fundamental in many areas of technology, are particularly vital in communications as they provide the foundations upon which radio devices, network elements, and other essential parts and functionalities in the communication chain can talk to each other. Moreover, standards are of even further accentuated importance in CR and spectrum sharing scenarios, as such scenarios imply direct or indirect interaction involving a wider range of stakeholders,

including regulators – implying different forms of standards (e.g., regulatory conformance standards). Given such observations, this chapter addresses standardization in the context of CR and spectrum sharing, particularly aiming to provide an opening and front matter to the more detailed coverage of some particular standards that are addressed in later chapters of this section of the book. In addition to providing this introductory material, this chapter addresses the broader scope of a number of relevant standards that are not detailed in the dedicated chapters. These include the TVWS regulatory conformance standard ETSI EN 301 598, the IEEE DySPAN-SC and IEEE 1900 series standards on various aspects of spectrum sharing and dynamic spectrum access, the IEEE 802.15.4m wireless personal area networks in TVWS standard, and the ECMA 392 TVWS MAC/PHY standard.

Introduction

Standards serve a number of purposes. On the one hand, they enable elements of communication systems to be developed and operated by a number of different manufacturers and operators, those elements still being able to communicate with each other with given expectations on performance, capabilities, technical characteristics, and overall outcome more generally. This has paved the way for the creation of systems such as GSM, UMTS, and LTE, with end-users and operators not being constrained to the use of mobile phones and network equipment created by a single manufacturer, for example. Such attributes are fundamentally essential to achieve sufficient economies of scale and market diversity to make mobile communications economically viable and also to make mobile communications acceptable from a policy perspective, e.g., not leading to a monopoly or dominance by a single manufacturer.

On the other hand, standards allow for coexistence among different elements or entities using spectrum or another common resource. In this context, there might often be a requirement from an overarching policy entity such as a regulator or regional/international regulatory coordinator (e.g., the CEPT, ITU) that certain standards are adhered to for coexistence and other purposes. This is in order to guarantee compatibility and performance in achieving coexistence, noting that the correctness of coexistence among (and implemented by) the participating entities becomes something of a legal requirement in such contexts.

Particularly in the context of spectrum sharing technologies, coexistence etiquette and associated functional requirements are basic impositions on the range of systems sharing the spectrum, or on the "secondary" users if such sharing is in a primary/secondary context. Standards are often required for key reasons such as to ensure that (i) the decisions or actions on spectrum sharing are either made or implemented correctly; (ii) the correct protocols for communication with a spectrum sharing decision making entity are implemented; (iii) the correct parameters and/or capabilities of spectrum sharing supporting functionalities and other capabilities are implemented; (iv) compatible decisions on spectrum sharing, e.g., from an

interference perspective, are made and implemented; and (v) the correct fail-safe and/or hardware intervention functions are implemented, among many others.

A good example here is the requirement of the UK regulator Ofcom [1] that white space devices imparted the status of "license exempt" for operation in TV White Space (TVWS) in the UK correctly implement the ETSI EN 301 598 standard [2]. Such a requirement equally applies to all European Union (EU) countries that decide to implement TVWS technology, by virtue of ETSI EN 301 598 being a "Harmonized European Standard." This standard specifies aspects such as the white space devices' emission requirements, their communications with geolocation databases and listings of geolocation databases, and their actions based on responses from the geolocation databases, among many other aspects. The adherence to such a standard is ensured at the certification stage of the creation of equipment, noting that no other input to the devices can be required in the operational stage given their status as "license exempt," i.e., the devices must operate without any specific input from the user or other entity, aside from communicating with a geolocation database.

In the following sections, we delve into detail on some of the specific standards and standards coordinating entities in the context of spectrum sharing and white spaces, cognitive radio (CR), and related areas of interest to this book. It is noted again that there are dual intentions here: (i) to provide front matter to the detailed coverage that is given on particular standards in later chapters, and (ii) to address some interesting and related standards that are not covered in the later chapters.

ETSI EN 301 598 Harmonized European Standard

The ETSI EN 301 598 Harmonized European Standard [2] is absolutely central to TVWS in the EU, as it defines the conformance requirements of white space devices in order for them to be allowed to operate in the EU. In essence, it also captures key aspects of the EU framework for TVWS, through the descriptions of the required actions and characteristics of white space devices. In line with this, ETSI EN 301 598 specifies detailed conformance tests that white space devices must pass, each test matching a characteristic or requirement as defined in a mirroring section of the standard.

The aspects of white space devices' characteristics and requirements defined in this standard, hence associated conformance tests, include:

- Definitions of types white space devices and associated requirements: Type A (fixed operation) and Type B (non-fixed operation), and their antenna types, noting that Type A has the additional flexibility in terms of an external antenna being allowed as opposed to only integral or dedicated antennas as for Type B.
- Transmission channel definitions and the need to specify transmission "nominal" channel bandwidths (as per bonding, i.e., a multiple of 8 MHz) and the total "nominal" bandwidth should the white space device use multiple such collections of channels.
- RF power (EIRP) and PSD (EIRP) definitions and limit requirements.

Table 1 ETSI white space device spectrum mask classes ("dB's down" per 100 kHz compared with power in intended 8 MHz channel) [2]

Adjacent channel distance from intended channel n	Adjacent frequency leakage ratio (AFLR)				
	Class 1	Class 2	Class 3	Class 4	Class 5
$n \pm 1$	74	74	64	54	43
$n \pm 2$	79	74	74	64	53
$n \pm 3$ or more	84	74	84	74	64

- Unwanted emission requirements of the white space devices, including:
  - Unwanted emissions outside of the TV band, specified as overall emitted power per 100 kHz in various frequency ranges below 1 GHz, and per 1 MHz above 1 GHz.
  - Unwanted emissions inside the TV band, specified in terms of "dB's down" per 100 kHz compared with the intended 8 MHz channel, for the adjacent channel, the next adjacent channel after that, and the next one again after that for which all further out channels have the same limit. It is noted that ETSI EN 301 598 specifies five different such mask classes, ranging from extremely tough to extremely lenient. Table 1 details these classes.
- White space device reverse intermodulation requirements.
- Identification requirements of white space devices.
- Requirements regarding communication with a regulatory-provided listing of valid geolocation databases.
- Communication of master white space devices characteristics, locations, heights, identities, etc., with the geolocation databases.
  - The correct implementation of the responses from the geolocation database (i.e., allowed EIRPs/channels).
  - Requirements on notification of the database of the chosen channel(s)/EIRP(s) and the reception of an acknowledgement before being allowed to transmit.
- Similar requirements for the slave white space devices, via a master white space device and association with the master white space device; definition of "generic" and "specific" parameters, and associated procedures, supporting this process of initial slave parameter exchange.
- Receiver spurious emission requirements.
- Geolocation capability requirements.
- Software, firmware, and related security requirements.

IEEE 802.22 Wireless Regional-Area Networks in TVWS

IEEE 802.22 is first completed IEEE standard specifically dedicated to the use of white space access. The standard builds on IEEE developments for other contexts of deployment, adapting them to the specific case of TVWS – a particular starting point being the work on IEEE 802.16 (WiMAX) [3]. Through this, IEEE 802.22

has aimed to provide a radio interface serving wireless regional area networks (WRANs), covering (at least in terms of MAC capabilities) ranges of potentially up to 100 km, compared with a few 10's of km which the next-best coverage IEEE specification set, WiMAX wireless metropolitan area networks (WMANs), might achieve. In line with its intended coverage and characteristics through the use of TVWS, and in comparison with the monkers "WiFi" and "WiMAX" of some other prominent IEEE systems, 802.22 has been given the tag "WiFar" – most often represented as "Wi-Far."

The baseline IEEE 802.22 standard was approved for publication in 2011 and is therefore denoted as IEEE Std 802.22™-2011 [4]. IEEE 802.22 has further worked on other standards within its scope, namely, 802.22.1 on "Enhanced Interference Protection of the Licensed Devices" (approved for publication in 2010, denoted as IEEE Std 802.22.1™-2010 [5]), effectively specifying a beaconing network to protect low-power licensed devices, and 802.22.2 "Recommended Practice for Installation and Deployment of IEEE 802.22 Systems" (approved for publication in 2012, denoted as IEEE Std 802.22.2™-2012 [6]), which simply gives recommendations on deployment of IEEE 802.22 networks, noting that such an IEEE Recommended Practice standard is a form of informative content and not binding by definition. IEEE 802.22 has also recently started working on standard 802.22.3, "Standard for Spectrum Characterization and Occupancy Sensing," aiming to define a spectrum sensing system to add value to current 802.22 white space systems through more advanced spectrum sensing capabilities. Among other benefits, this facilitates a better choice of which channel should be used by an 802.22 system based on the channels' characteristics, such as background interference.

IEEE 802.22 has also worked on two amendments to IEEE Std 802.22™-2011, 802.22a "Management and Control Plane Interfaces and Procedures and enhancement to the Management Information Base (MIB)," and 802.22b "Enhancement for Broadband Services and Monitoring Applications." IEEE 802.22a was approved for publication in 2014 (therefore denoted as IEEE Std 802.22a™-2014 [7]), and 802.22b was very recently approved for publication at the end of 2015 (denoted as IEEE Std 802.22b™-2015). At the time of writing, in addition to IEEE 802.22.3, IEEE 802.22 is further working on a revision of the baseline IEEE Std 802.22™-2011, aiming to bring it to other spectrum sharing bands and applications, as well as a revision of IEEE Std 802.22.1™-2010.

IEEE 802.22 Physical Layer

The PHY of 802.22 is heavily based on a variation of the WiMAX amendment standard IEEE 802.16e. The 802.22 PHY use 2,048 OFDM subcarriers irrespective of the utilized channel bandwidth, noting that 802.22 supports bandwidths of 6, 7 and 8 MHz, respectively, with transmission bandwidths of 5.625, 6.561, and 7.499 MHz. Out of these, 368 subcarriers are guard subcarriers, with the utilized

subcarriers comprising 1,440 data subcarriers and 240 pilot subcarriers. The basic unit of resource allocation is known as a sub-channel, defined as 24 data subcarriers plus 4 pilot subcarriers.

IEEE 802.22 supports BPSK, QPSK, 16-QAM, and 64-QAM modulation. Pertaining to various extraordinary modes of operation and preambles, 802.22 uses BPSK in uncoded mode only for CDMA opportunistic mode on the uplink, which is applicable in the USA, as well as QPSK with 1/2-rate coding and repetitions 2, 3, and 4. Repetition 4 is for superframe control header (SCH) transmission and also the superframe preamble, as well as the coexistence beacon protocol (CBP) packet preamble, repetition 3 is for the CBP transmission, and repetition 2 is for frame control header (FCH) transmission as well as the frame preamble. For data communication, more generally, 802.22 supports QPSK, 16-QAM, and 64-QAM modulation, each with convolutional coding rates of 1/2, 2/3, 3/4, or 5/6. The highest rate modulation and coding scheme, 64-QAM modulation with 5/6 coding, can achieve a peak data rate of 22.69 Mbps for a spectral efficiency of 3.78 bps/Hz in a 6 MHz channel assuming the entirety of that channel is used in the denominator of the calculation (i.e., not just the transmission bandwidth). 802.22 also supports three different optional advanced coding methods: duo-binary convolutional turbo codes, shortened block turbo codes, and low-density parity check codes.

Interleaving is achieved using a turbo interleaver, applied to coded bits and to carriers, the latter with different parameters.

Far more information on the 802.22 PHY can be obtained, e.g., from [8].

IEEE 802.22 MAC Layer

The 802.22 MAC is again very similar in form to that of IEEE 802.16 (WiMAX), with additional functionality incorporated to cope with the protection requirements of incumbent services in TVWS. This additional functionality includes geolocation capability and interaction with geolocation databases; synchronicity in the superframe structure achieved by a common clock such as GPS, to allow for spectrum sensing among other benefits; and spectrum sensing itself, among others. The MAC is connection oriented and centralized in terms of resource allocation and QoS control.

The 802.22 frame structure consists of superframes and frames. A superframe is 160 ms long and contains 16 frames of 10 ms duration each. The first frame in a superframe starts with the superframe preamble, the frame preamble, the SCH, and then the FCH. Frames otherwise start with a frame preamble then FCH. The SCH is a broadcast by base stations that can be seen as a type of beacon and carries information that effectively "boots" consumer premises equipment (end users) on to the cell/access, configuring them accordingly based on the characteristics of that cell/access. It is sent with a very robust modulation and coding, as described above, for this reason. The FCH includes information on the downlink and uplink structuring in the frame. As well as the aforementioned preamble, upfront information, and downlink and uplink traffic, the frame structure

of 802.22 includes a third part dedicated to coexistence: termed the self-coexistence window (SCW). This enables intercell communication, utilized for self-coexistence and incumbent protection in CR systems, and is scheduled by the BS at the end of some frames. The SCW extends over five symbols.

As would be expected for a centralized protocol serving CR principles, there are a number of highly sophisticated aspects of its MAC layer design. These capabilities include, among others:

- System-level coordination among cell resource usages.
- Time-sharing of resource usages among cells in the case of over overlapping cells, if desired.
- An urgent messaging procedure to stop transmissions incorporated into the MAC structure for coexistence emergencies (e.g., unexpected emergence/detection of an incumbent spectrum user).
- Fully specified sensing support (not only coordinated quiet periods but also messaging for sensing measurements, fully specified information sets, etc.).
- A highly configurable frame structure, e.g., based on downlink/uplink traffic requirements.

Far more information on the 802.22 MAC can be obtained, e.g., from [8].

IEEE 802.22 Spectrum Manager

In line with the centralized nature of the IEEE 802.22 design, and noting the complexity of spectrum coordination in such cases, 802.22 also includes a centralized "Spectrum Manager" entity. As well as efficient spectrum coordination in the context of spectrum usage within the 802.22 deployment, the entity deals with aspects of incumbent protection and adherence to regulatory policies. More specifically, it is responsible for:

- Maintenance of spectrum availability information.
- Channel classification and selection.
- Association control.
- Regulatory policy enforcement.
- Channel management.
- Self-coexistence with other 802.22 systems.

The maintenance of spectrum availability information is achieved through combining a range of information sets on incumbents, namely, from spectrum sensing and geolocation databases. The channel classification and selection assigns operational statuses of channels to MAC/PHY elements in the 802.22 network. A number of classes are given to channels in these assignments, including operating channels, backup channels, and candidates for backup channels, among others [8]. Association control manages association between CPEs and BSs, granting

association rights accordingly. The regulatory policy enforcement is achieved by interfacing with a regulatory policy entity and instructing all necessary elements in accordance with the response from that. For instance, such information might include the required frequency of checking availability with a geolocation database. Channel management is responsible for the assignment of the actual operational channels to 802.22 network elements, including associated actions such as switching to backup channels, e.g., if an incumbent is detected, perhaps even terminating a cell if there are no appropriate channels, among other aspects. Self-coexistence with other 802.22 networks combines the information from all CPEs of other 802.22 networks in the area and selects channels accordingly or switches to "self-coexistence mode." Self-coexistence mode is the special mode for time-sharing of resources among cells/networks, anticipated to be rarely needed.

Again, far more information on the 802.22 Spectrum Manager, as well as the detail of 802.22 in general, can be obtained, e.g., ▸ Chap. 49, "ETSI-RRS Reconfigurable Radio Systems Standards".

IEEE 802.11af Wireless Local Area Networks in TVWS

IEEE 802.11af (approved for publication in 2013, therefore denoted as IEEE Std 802.11af™-2013 [9]) is the amendment of the IEEE's 802.11 wireless local area networking (WLAN) specification to extend it to operability in TVWS.

IEEE 802.11af Physical Layer

The IEEE 802.11af PHY is heavily based on IEEE 802.11ac, simply downclocking the OFDM-based "very high throughput" 40 MHz PHY mode of 802.11ac. 802.11af supports modulation and coding schemes BPSK 1/2, QPSK 1/2 and 3/4, 16-QAM 1/2 and 3/4, 64-QAM 2/3, 3/4, and 5/6, and 256-QAM 3/4 and 5/6. The theoretical maximum throughput in 6 and 8 MHz channels, respectively, for a short guard interval implementation are 26.7 and 35.6 Mbps. Among other PHY aspects, 802.11af supports convolutional coding and optional LDPC coding, channel aggregation is optionally supported bonding up four channels in one or two contiguous blocks, and up two four spatial multiplexing streams are optionally supported. If all these characteristics are implemented together, the theoretical maximum throughput of 802.11af increases to 426.7 Mbps in 6 MHz channelization, and 568.8 Mbps in 8 MHz channelization. Regarding OFDM structure, 802.11af implements 108 data subcarriers, 6 pilot subcarriers, and 3 null subcarriers per channel.

IEEE 802.11af MAC Layer

Being an amendment to the IEEE 802.11 standard, much of the MAC characteristics and functionalities therein are maintained, as expected. However, there are, by necessity or in order to improve optimality, some key differences and

added functionalities of 802.11af compared with the baseline 802.11 and its other amendments.

Some differences relate to self-coexistence. The 802.11af MAC layer defines the optional concept of the registered location secure server (RLSS). If 802.11af access points (APs) are placed in close proximity, the associated RLSS manages the channel allocation among them. This represents a novel self-coexistence function in order to better coordinate the channel usage in TVWS. However, the conventional IEEE 802.11 self-coexistence mechanism of CSMA is also maintained.

An AP in 802.11af is a master device as per TVWS terminology, and a Station (STA – i.e., the end user device, e.g., a WiFi-capable laptop) is a slave device. However, despite the infrastructure-based hierarchy, 802.11af does not support cellular operation in the sense that 802.22 does. This is in line with the conventional 802.11 wireless local area networks structure as a "nomadic" wireless network. In contrast, 802.11af maintains its support for ad hoc modes of operation as in 802.11, which are not supported by 802.22.

Clearly, in order to be compliant with TVWS rules, 802.11af must implement communications with geolocation databases as well as all other such requirements as specified by regulators. This is implemented by the 802.11af MAC. However, 802.11af does not specify the intricate solutions for sensing-based access, as are specified in 802.22 (see section "IEEE 802.22 Wireless Regional-Area Networks in TVWS"). Our assessment is that this in because 802.22 undertook a lot of its early work at a time when the pending rules for TVWS in the USA were very different from what they are now, being significantly based on sensing until late 2010. The rules then changed almost in totality to being based on geolocation database-enabled access, with sensing-based access only being allowed in the US case and only for an extremely low transmission power of 50 mW in the 6 MHz channel, or −0.4 dBm per 100 kHz PSD, neither of which can be violated. 802.11af was developed entirely within the duration that the new rules applied. However, it is noted that TVWS rules might still vary further internationally; hence, the flexibility that 802.22 has in terms of aspects such as sensing support might have benefits, depending on the implementation scenario.

More information on 802.11af, linked specifically to implementation and trialing of it, can be found in ▸ Chap. 49, "ETSI-RRS Reconfigurable Radio Systems Standards".

IEEE 802.15.4m Wireless Personal Area Networks in TVWS

IEEE 802.15.4m (approved for publication in 2014, therefore denoted as IEEE Std 802.15.4m™-2014 [11]) is the amendment to IEEE 802.15.4 for operation in TVWS. IEEE 802.15 is the standards working group for wireless personal area networks (WPANs), and IEEE 802.15.4 the standard for low-rate such WPANs (LR-WPANs) under that scope. Examples of deployment purposes for such capabilities include smart utility networking, wireless sensor networking, active radio-frequency identification, and low-energy critical infrastructure monitoring, among others.

Like IEEE 802.11af, IEEE 802.15.4m doesn't assume sensing capability up front and therefore doesn't explicitly define it or support capabilities to the extent that IEEE 802.22 does (see section "IEEE 802.22 Wireless Regional-Area Networks in TVWS"); however, 802.15.4m doesn't rule out access being based on sensing either. It is perfectly conceivable for a separate sensing capability to be deployed that will allow such a system to operate in TVWS, e.g., with the much lower channel power limit of 50 dBm as is permitted in such cases in US deployments. 802.15.4m does specify all the geolocation database communications that are necessary in order to allow white space access as the dominant method internationally.

IEEE 802.15.4 specifies two levels of device functionality: full-function devices (FFDs) and reduced-function devices (RFDs). FFDs may serve as coordinators or as simple nodes in the WPANs and can undertake functionalities such as relaying messages in the coordinator role. RFDs are very basic devices, e.g., with very constrained batteries and limited communication capability, and cannot act as coordinators. There is also a higher-level concept of a PAN coordinator that communicates directly with the geolocation database and deals with synchronization of the network. Based on such capabilities, 802.15.4m supports cluster-tree topologies (i.e., interconnections of trees), and star topologies, and can also support mesh-based topologies.

Regarding the PHY of 802.15.4m, keeping in mind that it is an amendment, 802.15.4 and its other amendments define a total of 12 different PHY alternatives. Far more information on these can be obtained from [11, 12]. However, 802.15.4m defines three new PHYs/variants for operation specifically in TVWS: a frequency-shift keying based PHY, a wideband OFDM-based PHY, and a narrow-band OFDM-based PHY. Regarding the MAC of 802.15.4m, interesting capabilities such as "dynamic band switching" are defined, allowing 802.15.4 (as amended by 802.15.4m, and other amendments) to switch back to other bands/modes where TVWS is not available or perhaps not yet permitted under regulations. Power-saving functionality is also defined, involving the scheduling of listening periods and sleep modes in between.

More information on 802.15.4m can be found in [11, 12].

IEEE DySPAN-SC and IEEE 1900 Standards Working Groups

The IEEE Dynamic Spectrum Access Networks Standards Committee (DySPAN-SC) [13] and associated IEEE 1900 working groups (see [14–20]) are concerned with the standardization of aspects of DySPAN and related technologies such as Dynamic Spectrum Access (DSA), CR, and TVWS, among others. DySPAN-SC is responsible for the oversight and sponsoring the development of standards in the IEEE 1900 working groups. Many of the standards that are worked on and developed by IEEE 1900 working groups take an overarching viewpoint. They often intend to be either broadly applicable to generic concepts among a range of types of systems (e.g., the terms and definitions harmonization work of IEEE 1900.1 [26], or the heterogeneous networks management scope of IEEE

1900.4 [29], among other examples), or ultimately applicable to a wide range of use cases (e.g., the white spaces radio interface standard of IEEE 1900.7, among other examples; although it is noted that 1900.7 is still in the process of defining amendment standards that will likely broaden the use cases it covers).

Such a direction has strong links to DySPAN-SC's definition as based on a particular class of technologies (DySPAN/DSA) and therefore standardizing the different and broadly applicable aspects of those technologies. This is in contrast to the IEEE 802 standards committee [21] and its working groups (IEEE 802.11 [22], IEEE 802.15 [23], IEEE 802.16 [24], IEEE 802.22 [25], etc.), which for the most part concentrate on very specific use cases and scenarios for computer communications, such as local area networking, personal area networking, and metropolitan area networking, among others, and therefore define their standards based on those use cases. Further, in defining the scope of IEEE DySPAN-SC and its standards, it is recognized that flexibility is needed in order to serve the capabilities and characteristics of a range of different systems. The broad, often technology-agnostic nature of IEEE DySPAN-SC and some of its IEEE 1900 standards underlines the operational flexibility within which they aim to flourish.

IEEE 1900 Working Groups

The IEEE 1900 working groups and their titles/topics are listed as follows:

- IEEE 1900.1: Definitions and Concepts for Dynamic Spectrum Access: Terminology Relating to Emerging Wireless Networks, System Functionality, and Spectrum Management [14].
- IEEE 1900.2: Recommended Practice for the Analysis of In-Band and Adjacent Band Interference and Coexistence Between Radio Systems [15].
- IEEE 1900.3: Recommended Practice for Conformance Evaluation of Software-Defined Radio (SDR) Software Modules (disbanded) [16].
- IEEE 1900.4: Architectural Building Blocks Enabling Network Device Distributed Decision Making for Optimized Radio Resource Usage in Heterogeneous Wireless Access Networks [17].
- IEEE 1900.5: Policy Language and Policy Architectures for Managing Cognitive Radio for Dynamic Spectrum Access Applications [18].
- IEEE 1900.6: Spectrum Sensing Interfaces and Data Structures for Dynamic Spectrum Access and other Advanced Radio Communication Systems [19].
- IEEE 1900.7: Radio Interface for White Space Dynamic Spectrum Access Radio Systems Supporting Fixed and Mobile Operation [20].

Figure 1 depicts the relationships among the IEEE 1900 working groups, as well as their statuses. In the following sections, we go into a bit more detail on these groups, including their topics, purposes, and current or emerging standards.

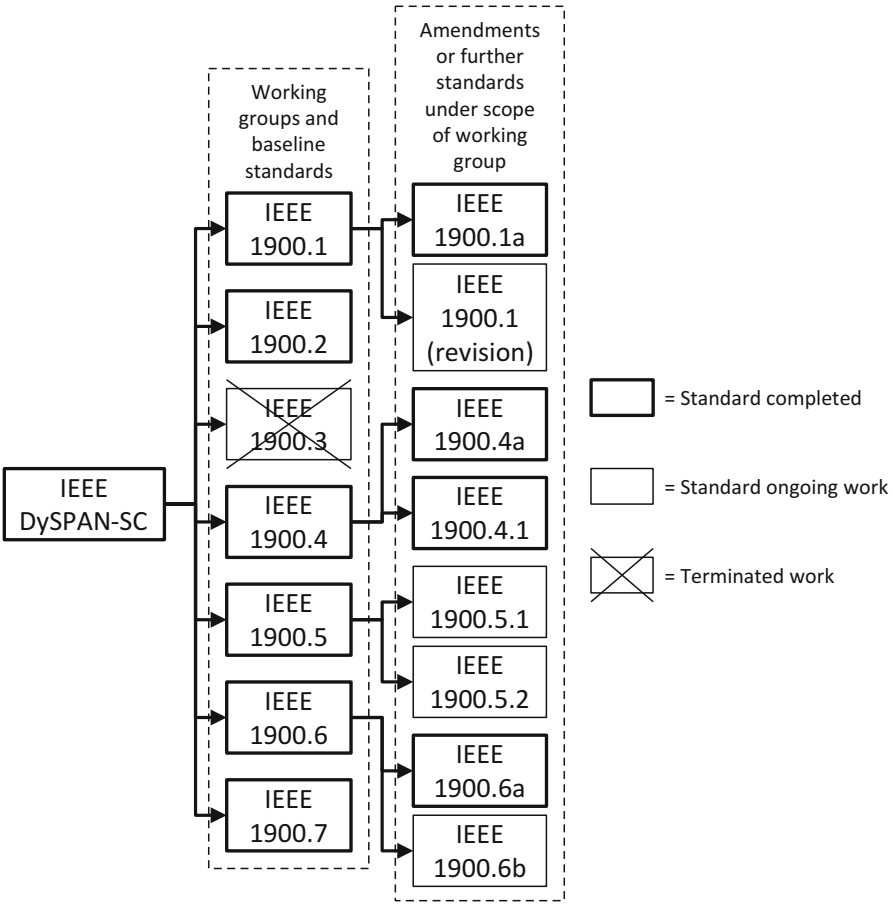

Fig. 1 IEEE DySPAN-SC and IEEE 1900 working groups and standards

IEEE 1900.1

IEEE 1900.1 aims to facilitate the development of DySPAN-related technologies (including DSA, white spaces, CR, etc.) by clarifying the terminology and aspects of how these technologies relate to each other, noting that many of the terms used in the fields of DSA and the wide range of related technologies do not have precise definitions or have multiple/unclear definitions. The baseline 1900.1 standard was approved and published in 2008 (therefore denoted as IEEE Std 1900.1™-2008 [26]), and an amendment covering new terms and definitions that have emerged since the publication of the baseline standard in the scope of other IEEE 1900 working groups was approved in late 2012 and published in January 2013 (therefore denoted as IEEE Std 1900.1a™-2012 [27]). IEEE 1900.1 has since worked on a revision of its published 2008 standard, also incorporating the text of the IEEE

1900.1a-2012 amendment as is usual procedure. This work should complete the end of 2017 at the latest.

The baseline IEEE 1900.1-2008 standard presents terms and definitions in the following categories:

- Definitions of advanced radio system concepts.
- Definitions of radio system functional capabilities.
- Definitions of network technologies that support advanced radio system technologies.
- Spectrum management definitions.
- Glossary of ancillary terminology.

Further, the IEEE 1900.1a-2012 amendment has added the category of definitions of decision making and control concepts that support advanced radio system technologies.

The annexes of the baseline standard, all of which are "informative" in nature, cover additional aspects such as the consideration of the implications of DySPAN and related technologies (e.g., for regulation), some detailed consideration of the relationships between the technologies hence their hierarchical inheritance, and observations on the purposes of the technologies and aspects of their architectures. One example of the latter is a detailed study on the different forms of flexible radio. There is also discussion on roadmapping for such technologies, among other aspects.

The 1900.1 revision is reviewing the terms with regard to and changes in their use in the community, new terms/definitions that are required or the deletion of terms, structuring of the terms, and other aspects. It will also further consider upcoming concepts and related terminology such as those stemming from the commercial dynamic use of shared spectrum.

IEEE 1900.2

IEEE 1900.2 provides guidance, which is primarily technical in nature, on the analysis of the potential for coexistence or interference between radio systems operating in the same frequency band and between different frequency bands. In essence, IEEE 1900.2 facilitates the realization – in a viable way – of a range of spectrum coexistence technologies.

Regarding content of the IEEE 1900.2-2008 baseline standard, published in 2008 (denoted as IEEE Std 1900.2™-2008 [28]), it includes a range of normative content, such as the specification a key concepts such as "harmful interference" and "measurement events," among others, and the definition of scenarios for interference assessment, interference assessment criteria and important variables, and commentary on the analysis and modelling of interference.

IEEE 1900.2 has been dormant since 2008 with no additional work items currently envisaged. IEEE 1900.2 will, however, be required to undergo the usual IEEE process of periodic revisions or affirmations of IEEE standards. Revision or affirmation of published IEEE standards is required to occur every 10 years at most.

IEEE 1900.3

The IEEE 1900.3 standards work was initiated in May 2005, but the working group was disbanded in late 2008 [16]. The intended purpose of the standard was to provide guidance on how to ensure the conformance with relevant specifications (e.g., security in particular) of software intended for deployment in a SDR terminal.

IEEE 1900.4

IEEE 1900.4, until relatively recent years, has been one of the most active of the working groups under IEEE DySPAN-SC. It is currently, however, in hibernation having completed its standards work, awaiting further revisions of those standards if and when necessary and any further upcoming topics.

The baseline IEEE 1900.4 standard (denoted as IEEE Std 1900.4™-2009 [29]) was published in February 2009. The purpose of this standard, and IEEE 1900.4 in general, is to define management capabilities to improve overall composite capacity and quality of service of wireless systems in multiple radio access technology environments, through instantiation of an appropriate system architecture and protocols to facilitate the optimization of radio resource usage. 1900.4 works on the assumption of a three-level resource management hierarchy: The network or inter-network level, then the radio access network (RAN) level under that, and finally the terminal level. It is noted that IEEE 1900.4 facilitates a range of spectrum sharing (and management thereof) technologies of interest to the community, although particularly emphasizes those that are network driven as might be managed by a mobile communications operator, for example, owning a range of spectrum bands and with various radio access technologies available that can adapt to operate in the different bands.

The two key entities of 1900.4 are the Network Reconfiguration Manager (NRM) and Terminal Reconfiguration Manager (TRM). Other entities such as the operator spectrum management (OSM) entity are assumed, although some are not defined in detail – in the OSM example this is because it is taken to be proprietary within the scope of the given network operator. The NRM resides at the top of the management hierarchy, managing resources at the network or inter-network level and producing instructions/constraints (directives, policies) for the TRM accordingly, and also instructing RANs based on its decisions. The TRM implements the instructions/constraints from the NRM and also manages resources at the terminal level but sticking within the constraints conveyed by the NRM. There are also processes of feedback from the TRM to the NRM, with associated functionalities defined, and from RANs to the NRM.

IEEE 1900.4 has also published an amendment to the 1900.4-2009 standard, in the form of 1900.4a (denoted as IEEE Std 1900.4a™-2011 [30]), Architecture and Interfaces for Dynamic Spectrum Access Networks in White Space Frequency Bands, and has published an additional standard within the scope of 1900.4's work, 1900.4.1 (denoted as IEEE Std 1900.4.1™-2013 [31]), IEEE Standard for Interfaces and Protocols Enabling Distributed Decision Making for Optimized Radio Resource Usage in Heterogeneous Wireless Networks. The IEEE 1900.4a-2011 amendment standard considers extensions to the spectrum management cases in 1900.4 to cover

access to TVWS, with minimal constraints on the used radio interface (physical and media access control layers), by defining additional components of the IEEE 1900.4 system. A key addition in 1900.4a is the White Space Manager (WSM) entity, which provides regulatory context information to the networks or composite systems that might be using TVWS. On the network-side, the Cognitive Base Station Reconfiguration Manager (CBSRM) entity is also introduced, in order to enable the control of the base stations white space access according to the regulatory rules and flexibility that is allowed given context information, and a mirroring entity to control the terminal side in white space is also introduced.

The IEEE 1900.4.1-2013 standard provides a description of the interfaces and service access points defined in the baseline 1900.4-2009, enabling distributed decision making in heterogeneous wireless networks and obtaining context information for this decision making. This standard delves into more detail on the information exchanges between the 1900.4 elements and the associated state transitions of those elements based on the information exchanges. It considers precise signaling interactions for the purpose of implementing 1900.4 decisions, among other aspects. Noting that the information model in 1900.4-2009 was abstract in the sense of specifying only the high-level ASN.1 characteristics and requirements, 1900.4.1-2013 delves down to the level of precise bit-level header structures.

IEEE 1900.5

IEEE 1900.5 defines a policy language (or a set of policy languages or dialects) to specify interoperable, vendor-independent control of CR functionality and behavior for DSA resources and services. The definition of such policies is an essential step toward the facilitation of autonomous spectrum coexistence of devices and systems, in primary-secondary access and in other contexts. The distinction is made between policy reasoning and policy generation and validation, in that policy reasoning is accomplished within a defined policy-based radio node and that policy generation and validation is accomplished through a policy generation system prior to provision of the policy to the policy-based radio node.

The baseline standard of IEEE 1900.5 (denoted as IEEE Std 1900.5™-2011 [32]) was published in 2012, and at the time of writing, IEEE 1900.5 is working toward the publication of two further standards within its scope: IEEE 1900.5.1 Draft Standard Policy Language for Dynamic Spectrum Access Systems and IEEE 1900.5.2 Standard Method for Modeling Spectrum Consumption. The latter is in the final stages of approval and publication by the IEEE, whereas the former is still at a relatively early stage in its work. 1900.5.2 specifies a generalized method to model spectrum consumption of any use of spectrum and the associated computations for arbitrating the compatibility among models. The methods of modeling are chosen to support the development of tractable algorithms for determining the compatibility between models and for performing various spectrum management tasks that operate on a plurality of models. This work concentrates on the application of the vision presented in [33, 34] where the Spectrum Consumption Modeling Markup Language (SCMML) is used.

IEEE 1900.5.1 work is toward defining a vendor-independent policy language for managing the functionality and behavior of DySPAN based on the language requirements defined in the IEEE 1900.5 standard. Reflecting the current status and thinking at the time of writing, the standard will take into consideration both the policy language requirements of IEEE 1900.5 and the results of the Modeling Language for Mobility Work Group (MLM-WG) within the Wireless Innovation Forum (SDRF v2) Committee on Advanced Wireless Networking and Infrastructure [35].

IEEE 1900.6

IEEE 1900.6 defines the interfaces and data structures for communication between spectrum sensors and their clients in dynamic spectrum access and other advanced radio communication systems. This might be applicable for cooperative and/or collaborative distributed sensing scenarios, as well as other scenarios where the intelligence that makes spectrum access and other decisions, and spectrum sensors, are at different physical locations – although it is noted that IEEE 1900.6 can also serve cases where subsets of the various entities involved can reside at the same physical location. The logical interfaces and supporting data structures in 1900.6 are defined abstractly, without constraining the sensing technology, client design, or data link between sensors and their clients. Of course, the facilitation of sensing technologies through standards such as IEEE 1900.6 assists many spectral sharing techniques that utilize locally-obtained spectrum information.

The baseline standard of IEEE 1900.6 (denoted as IEEE Std 1900.6™-2011 [36]), addressing its key purposes as mentioned above, was published in April 2011. This standard defines three basic elements: Spectrum sensors, the cognitive engine, and the data archive. These, and the interfaces between them that IEEE 1900.6 addresses, are illustrated in Fig. 2. Among these elements, the relatively simple spectrum sensors are assumed to merely obtain spectrum usage information

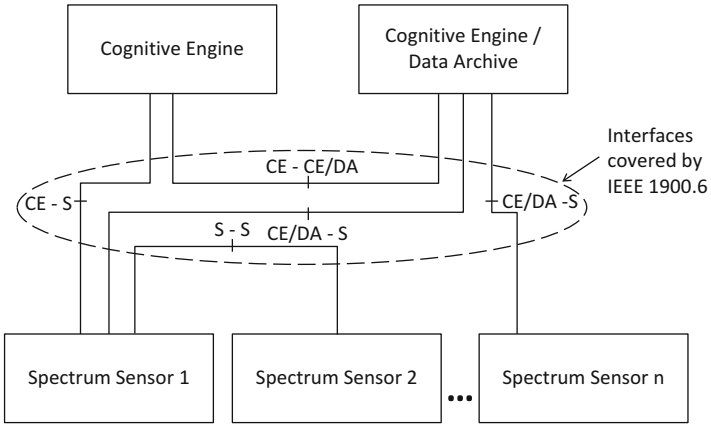

Fig. 2 IEEE 1900.6 entities and considered interfaces

such as the energy in a particular band at a given location, however, there is scope given collaborative spectrum sensing scenarios for example, for some sensors to act as cluster heads for other sensors and undertake limited processing of the sensed information from those other sensors before forwarding the result (e.g., performing a logical OR on sensed decisions to assess if there are any positive results among the sensors). The cognitive engine is the intelligent element that uses the spectrum sensing information, e.g., to make decisions on viable opportunities for spectrum access. The data archive is a store of sensed information that might be utilized to assist decisions, e.g., for learning capabilities based on past experience.

IEEE 1900.6 has also published an amendment (IEEE Std 1900.6a™-2014 [37]), on Procedures, Protocols, and Data Archive Enhanced Interfaces. This covers a number of aspects of the precise nature of the procedure and protocols, including the interaction with non-compliant systems, consideration of professional installations in which sensors may not have location information (e.g., GPS) but may instead have their location professionally verified, data-archive assisted sensing decisions such as related to propagation maps that the data archive has access, support for wideband sparse sensing implementation, and support for use of the 1900.6 subsystem for connectivity awareness, among many other additions.

At the time of writing, IEEE 1900.6 is working on a new amendment, IEEE 1900.6b, covering the application and extension of the standard to the case of spectrum sensing systems being used to augment or otherwise assist spectrum databases – geolocation databases in the context of TVWS being one example thereof. Initial work on this amendment has aimed to satisfy use cases including the application of spectrum sensing to spectrum databases in TVWS, the application to Spectrum Access System and Environmental Sensing Capability capabilities such as employed for the 3.5 GHz Citizens Broadband Radio Service in the USA, and the use of such sensing information by self-organizing networks.

A further work item, at the time of writing recently completed, approved, and published as a corrigendum, is a minor revision of the terms and definitions covered in 1900.6 to harmonize with IEEE 1900.1 terms and definitions and the terms and definitions in IEEE 1900/DySPAN-SC in general.

IEEE 1900.7

IEEE 1900.7 work is concerned with the definition a new radio interface (PHY/MAC, and related aspects) for white space access. The aim is for this radio interface to be generic, applicable to a range of use cases and spectrum bands. However, in practice, 1900.7 has thus far considered TVWS as the most appealing and key focus area, as TV bands are the only bands currently allowed from a regulatory perspective for white space access.

The baseline standard of IEEE 1900.7 (denoted as IEEE Std 1900.7™-2015) has recently been completed and published at the time of writing. It has aimed to address a wide range of use cases, from wireless sensor networking, to in-building provisioning (e.g., wireless local area networking), to backhaul provisioning, and to maritime coverage enhancement through white spaces, among many others. The defined PHY, currently, is based on filter bank multicarrier (FBMC) technology,

Table 2 IEEE 1900.7 modulation and coding schemes, and associated peak throughputs

Modulation	Coding	Peak throughput in 2 MHz/ Mbps	Peak throughput in 8 MHz/ Mbps
BPSK	1/2	0.93	3.78
QPSK	1/2	1.86	7.56
QPSK	1/4	2.79	11.34
16-QAM	1/2	3.72	15.12
16-QAM	3/4	5.58	22.68
64-QAM	2/3	7.44	30.24
64-QAM	3/4	8.37	34.02
64-QAM	5/6	9.30	37.80

and the MAC is based on a variation on the 802.11 CSMA MAC, incorporating an adaptive algorithm in the collision back-off mechanism to enhance fairness and performance. The current published 1900.7 standard also assumes a master-slave mode of operation, noting that such a mode is compatible with regulations for white space as are out there currently.

The 1900.7 PHY assumes multiples of 2 MHz operation, in theory being able to aggregate across channels (even with non-contiguous aggregation) through transmission in subsets of 2 MHz as specified by a mask applied to the set of 2 MHz sub-channels. This fits well with regulatory approaches allowing aggregation (see, e.g., [1, 2]), as well as potential future advancements such as being able to filter out 2 MHz chunks, e.g., to avoid interference with wireless microphones. Regarding modulation and coding, those schemes in Table 2 are defined. The peak rates supported by these modulation and coding schemes are also given in Table 2.

At the time of writing, 1900.7 is considering the initiation of additional possible amendments to its baseline standard, which will likely achieve the objective of satisfying some of the use cases that it is more challenging for FBMC and CSMA to realize: an example being wireless sensor networking. It therefore seems likely that further options for the PHY/MAC will be formulated as part of such work, should it progress, as well as other aspects such as the mode of operation which could conceivably also be expanded. Of course, this would be done compatibly with regulatory requirements.

ETSI Reconfigurable Radio Systems (RRS) Standards

The European Telecommunications Standards Institute (ETSI) has produced and is producing a number of CR- and TVWS-related standards, as well as standards on spectrum sharing technologies in general. ETSI standards on these topics are most commonly developed under the ETSI Reconfigurable Radio Systems (ETSI-RRS) technical committee [38], with the ETSI 301 598 standard, as covered earlier in

section "ETSI EN 301 598 Harmonized European Standard," being a clear exception to this. At the time of writing, ETSI-RRS is divided into four working groups:

- RRS Working Group 1: "System Aspects"
- RRS Working Group 2: "Radio Equipment Architecture"
- RRS Working Group 3: "Functional Architecture and Cognitive Pilot Channel"
- RRS Working Group 4: "Public Safety"

Again at the time of writing, ETSI-RRS has thus far developed 20 standards and technical reports, as follows. ETSI-RRS is currently very active in producing additional standards.

- TR 102 967: Reconfigurable Radio Systems (RRS); Use cases for dynamic equipment reconfiguration
- EN 303 387: Reconfigurable Radio Systems (RRS); Signalling Protocols and information exchange for Coordinated use of TV White Spaces; Interface between Cognitive Radio System (CRS) and Spectrum Coordinator (SC)
- EN 303 146-1: Reconfigurable Radio Systems (RRS); Mobile Device Information Models and Protocols; Part 1: Multiradio Interface (MURI)
- EN 303 143: Reconfigurable Radio Systems (RRS); System architecture for information exchange between different Geo-location Databases (GLDBs) enabling the operation of White Space Devices (WSDs)
- EN 303 144: Reconfigurable Radio Systems (RRS); Enabling the operation of Cognitive Radio System (CRS) dependent for their use of radio spectrum on information obtained from Geo-location Databases (GLDBs); Parameters and procedures for information exchange between different GLDBs
- EN 303 145: Reconfigurable Radio Systems (RRS); System Architecture and High Level Procedures for Coordinated and Uncoordinated Use of TV White Spaces
- TS 103 235: Reconfigurable Radio Systems (RRS); System architecture and high level procedures for operation of Licensed Shared Access (LSA) in the 2300–2400 MHz band
- EN 303 095: Reconfigurable Radio Systems (RRS); Radio Reconfiguration related Architecture for Mobile Devices
- TS 103 146-2: Reconfigurable Radio Systems (RRS); Mobile Device Information Models and Protocols; Part 2: Reconfigurable Radio Frequency Interface (RRFI)
- TS 103 145: Reconfigurable Radio Systems (RRS); System Architecture and High Level Procedures for Coordinated and Uncoordinated Use of TV White Spaces
- TS 103 143: Reconfigurable Radio Systems (RRS); System architecture for information exchange between different Geo-location Databases (GLDBs) enabling the operation of White Space Devices (WSDs)
- EN 302 969: Reconfigurable Radio Systems (RRS); Radio Reconfiguration related Requirements for Mobile Devices

- TS 103 154: Reconfigurable Radio Systems (RRS); System requirements for operation of Mobile Broadband Systems in the 2300–2400 MHz band under Licensed Shared Access (LSA)
- TS 102 946: Reconfigurable Radio Systems (RRS); System requirements for Operation in UHF TV Band White Spaces
- TS 103 146-1: Reconfigurable Radio Systems (RRS); Mobile Device Information Models and Protocols; Part 1:Multiradio Interface (MURI)
- TR 102 947: Reconfigurable Radio Systems (RRS); Use Cases for building and exploitation of Radio Environment Maps (REMs) for intra-operator scenarios
- TR 102 945: Reconfigurable Radio Systems (RRS); Definitions and abbreviations
- TR 103 067: Reconfigurable Radio Systems (RRS); Feasibility study on Radio Frequency (RF) performance for Cognitive Radio Systems operating in UHF TV band White Spaces
- TS 103 095: Reconfigurable Radio Systems (RRS); Radio Reconfiguration related Architecture for Mobile Devices
- TR 102 970: Reconfigurable Radio Systems (RRS); Use Cases for spectrum and network usage among Public Safety, Commercial and Military domains

A dedicated ▸ Chap. 49, "ETSI-RRS Reconfigurable Radio Systems Standards", provides far more detail and background reasoning on this range of standards and technical reports, so we don't address them directly here.

ECMA-392

This standard originates from perhaps a lesser-known group: ECMA. This was the European Computer Manufacturers Association (ECMA) until 1994, since then has been internationalized and just maintained ECMA as a trademark. The ECMA-392 MAC and PHY for Operation in TV White Space standard was the first TVWS standard to actually be completed, having been published in December 2009.

ECMA-392 specifies a MAC sub-layer and a PHY for personal/portable cognitive wireless networks operating in TV bands. It also specifies a MUX sub-layer for higher-layer protocols. It supports master-slave, peer-to-peer, or mesh configurations and three types of devices: master devices, slave devices, and peer devices. The master (or peer) coordinates dynamic frequency selection, transmit power control, and channel measurements.

ECMA-392 names various incumbent protection mechanisms which may be used to meet regulatory requirements; the mechanisms themselves are outside of the scope of ECMA-392, and the geolocation database interaction is seen as a higher-layer function and therefore not specified. However, the network structures defined in ECMA-392 (e.g., the definition of master and slave devices) support current regulatory approaches well, and the information structures defined (e.g., channel availabilities) also assist.

The primary application of ECMA-392 is intended to be in-home multimedia distribution. To this end, the PHY is OFDM-based, comprising 128 subcarriers, out of which 26 are guard subcarriers, 98 are data subcarriers, and 4 are pilot subcarriers. These values stay the same whether the standard is transmitting in the supported 6, 7, or 8 MHz channel widths, with the spacing between sub-channels changing. Modulation schemes QPSK, 16-QAM, and 64-QAM are supported and a range of convolutional coding rates dependent on the modulation, varying from 1/2-rate to 5/6. The highest-rate modulation and coding option (64-QAM, 5/6 coding) can achieve a throughput of 23.74 Mbps, and with 2×2 spatial multiplexing implemented (which is also supported), this can increase to 47.48 Mbps.

The MAC of ECMA-392 consists of superframes and 256 medium access slots (MASs) within each superframe. The MASs are assigned to either a beacon period, a data transfer period, or a contention signaling window. A reservation-based signaling window can also be used, as can quiet periods similarly to the case of IEEE 802.22 in section "IEEE 802.22 Wireless Regional-Area Networks in TVWS." Beacon periods are used to transmit beacons, e.g., on used channels – the master and peer devices are therefore beaconing devices with associated beacon slots in the beacon period. The defined signaling windows are likewise used to convey important network management information, noting that the reservation-based signaling window is not needed for peer-to-peer network deployments.

The ECMA-392 standard is available freely online, at the time of writing, at [39].

Conclusion and Future Directions

In the context of communications, standards can be looked on as defining the spoken language of how systems communicate with each other. In spectrum sharing scenarios, they become even more essential, also defining the protocol for how the spectrum is shared, in a way that is agreeable to those sharing the spectrum, or, in the case of secondary spectrum access (e.g., TVWS), agreeable to the incumbent user of the spectrum. In this context, such standards are not only implemented by stakeholders such as manufacturers and operators, but may also be enforced (and depending on the case in question, implemented) by a higher-level responsible entity such as the regulator.

This section has provided some detail on a range of standards that have been created for CR- and TVWS-related scenarios, mostly in the context of the realization of CR and TVWS communication between devices, but also in one case providing an example of a vital regulatory standard for TVWS operation in Europe, namely, the ETSI EN 301 598 Harmonized European Standard. For fundamental reasons, standards will continue to be absolutely essential to the achievement of CR and white space communications networks, and spectrum sharing in general.

Abstract

TV White Space is expected to make the radio resource utilization more flexible by adopting spectrum sharing concept to TV band. IEEE 802.11af is the world-first standard of PHY and MAC for operation of wireless LAN in the TV band. As

radio regulations, such as spectrum mask and maximum transmission power, are different depending on countries, it is not so simple to implement the standard. Therefore, it is necessary for the standard to conduct investigation on implementation of the standard by prototyping according to the specific regulations, measurements of performances in various use scenarios, and discussion on its feasibility. This chapter covers from the IEEE 802.11af standard to its prototypes and field experiments. It is believed that the chapter helps to understand not only the specific standard but also the concept and practical experiences of TV White Space operations. The prototyping was based on radio regulations of US FCC and UK Ofcom. The field experiments introduced in the chapter were conducted under the TV White Space Pilot organized by UK Ofcom. Measurements were taken through the experiments in indoor and outdoor environments and analyzed to show feasibility and features of the standard and potentials of TV White Space utilization for IP communications. Note that this chapter includes several world-first achievements on IEEE 802.11af related R&D.

Introduction

IEEE 802.11af is an amendment standard that defines modifications to both the 802.11 physical layers (PHY) and the 802.11 medium access control (MAC) layer, to meet the legal requirements for channel access and coexistence in the TV White Space (TVWS). The standard enables Wi-Fi to operate TVWS. Traditional Wi-Fi is operated in 2.4 and 5 GHz, and its transmission range is very limited, normally within several tens meters. However, the expected range of the standard is larger than several km because the operation band is mainly UHF band and the maximum transmission power is 1 W.

The IEEE 802.11af is a combination standard by IEEE 802.11 families as shown in Fig. 1 and the PHY has compatibility with IEEE 802.11ac on the basis of OFDM. Table 1 shows main parameters of IEEE 802.11af. The IEEE802.11ac is based on 40 MHz operation with 128 FFT. But the bandwidth of TV is 6 or 7 or 8 MHz per channel. The downclocking therefore is required. In the case of usage in TV channel with 6 MHz channel spacing, the occupied bandwidth is $6\,\text{MHz} \times 128/144 = 5.33\,\text{MHz}$.

Figure 2 shows the fundamental network architecture based on IEEE 802.11af. All stations (STAs) need to communicate with each other via access points (APs). The APs need to have two new functions. The first is to protect primary users such as TV broadcasting companies because the IEEE 802.11af-based APs and STAs are secondary operation in the TVWS and should not interfere with the primary users. The second is to protect other secondary users that use same communication systems based on IEEE 802.11af.

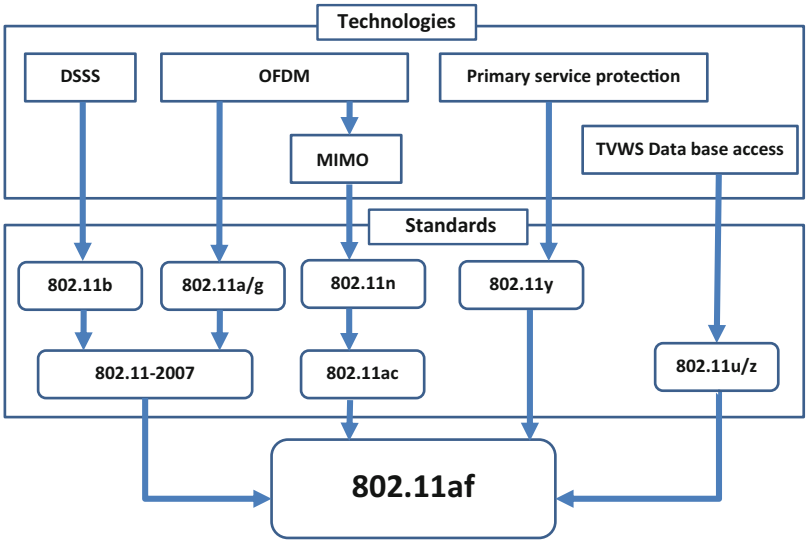

Fig. 1 Configuration of IEEE 802.11af standards

Table 1 Basic parameters of IEEE 802.11af

Parameters	Specification
Frequency range	54–862 MHz
Multiple access	CSMA
Payload modulation	QPSK-OFDM, 16QAM-OFDM, 64QAM-OFDM, 256QAM-OFDM (Option)
FEC coding rate	1/2, 2/3, 3/4, 5/6
Number of FFT-points	128
Number of effective subcarriers	114
Based 802.11ac operational bandwidth	40 MHz
Nominal bandwidth	5.33 MHz (6/7 MHz), 7.11 MHz (8 MHz)
Downclocking factor from 802.11ac 40 MHz bandwidth	7.5 (6/7 MHz), 5.625 (8 MHz)
Maximum number of spatial stream (NSS)	4
Cyclic Prefix (CP) Modes	3.0/ 6 us (6/7 MHz), 2.25/ 4.5 us (8 MHz)
Maximum net throughput	Mandatory 20.0 Mbps (6/7 MHz, 64 QAM, R = 5/6, NSS = 1,CP = 3.0 us), Optional 426.7 Mbps (24/28 MHz, Base 256 QAM, NSS = 4, R = 5/6, CP = 3.0 us)

To protect the primary users, the APs must access to white space database (WSDB) to get available spectrums in the TVWS. Moreover, the control to STAs from AP is also operated to meet the regulatory requirement. There are two ways to configure the system [1].

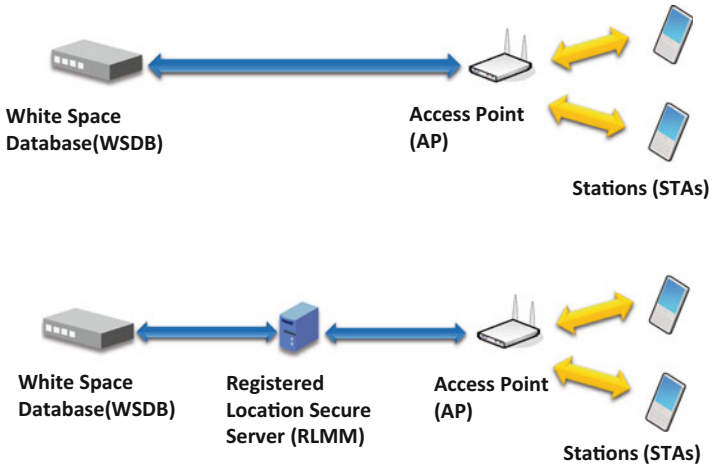

Fig. 2 Basic parameters of IEEE 802.11af

The first is that APs directly talk to the database through the Internet connection that they have. All the APs independently operate according to the available spectrum information obtained from the WSDB. Therefore, this scenario lacks of flexibility of utilizing the neighborhood information of the APs. Assuming APs are located closely, the available spectrum information might be identical. However, the spectrum is not efficiently utilized when the APs blindly choose the same channel to operate.

The second is to deploy a registered location secure server (RLSS) in between APs and WSDB in order to reduce the interference between secondary users' use of IEEE 802.11af. There are several benefits to use such a server. Firstly, the server collects neighborhood information of APs and helps them to choose channels with less collision with both primary and secondary users. Secondly, the APs may request the WSDB through the RLSS to tune their transmission power based on the out-band emissions of the APs.

This chapter is organized as follows. In section "Physical Layer", the PHY layer specification of IEEE 802.11af is introduced. Section "MAC Layer" describes the specification of IEEE 802.11af MAC layer. The IEEE 802.11af prototype has been developed and the detailed information is described in section "Prototypes," and finally the field trial results based on the developed prototype are introduced in section "Field Trials."

Physical Layer

This subsection introduces the overview of the physical layer (PHY) specification of the IEEE 802.11af [2]. The PHY of the IEEE 802.11af is developed for the WLAN operating on TVWS band. Table 2 shows the PHY layer parameters of the

Table 2 IEEE 802.11af PHY layer parameters

Air interface	OFDM
Channel bandwidth	6.0, 7.0, 8.0 (MHz) (Depend on regulation of each country)
Modulation	BPSK, QPSK, 16QAM, 64QAM, 64QAM, 256QAM[a]
Channel coding	Block convolutional coding (BCC), LDPC coding[a]
FFT size	128
Number of data subcarriers	108 (From −58 to −2 and from +2 to +58)
Number of pilot subcarriers	6(−53, −25, 11, +11, +25, +53)
Sampling frequency	6.0 (MHz) × 128/144 = 5.33 (MHz) (For 6.0 MHz channel bandwidth) 7.0 (MHz) × 128/168 = 5.33 (MHz) (For 7.0 MHz channel bandwidth) 8.0 (MHz) × 128/144 = 7.11 (MHz) (For 8.0 MHz channel bandwidth)
Guard interval	Long-GI: 1/4, Short-GI[a]: 1/8
Channel aggregation[a]	1, 2, 4 channels (Contiguous and Non-contiguous)
Spatial multiplexing[a]	Up to 4 steams (users)

[a]indicates option.

IEEE 802.11af. The size of FFT to generate OFDM signal is 128. The PHY layer configuration of the IEEE 802.11af is based on the downclocking PHY of the VHT (Very High Throughput) 40 MHz mode of the IEEE 802.11ac [3]. To operate under the law regulation of each country, several types of channel bandwidth (6.0, 7.0, and 8.0 MHz) are supported. Sampling frequencies are 6.0 MHz × 128/144 = 5.33 MHz, 7.0 MHz × 128/168 = 5.33 MHz, and 8.0 MHz × 128/144 = 7.11 MHz and in cases of the channel bandwidth are 6, 7, and 8 MHz, respectively. Two type guard interval (GI) modes are supported, i.e., Long-GI (mandatory mode) and Short-GI (option mode). The GI length of the Long-GI mode and the Short-GI mode is 1/4 and 1/8 of the IFFT output, respectively. As an option, the IEEE 802.11af supports channel aggregation mode up to four channels, and spatial multiplexing mode up to four streams.

Table 3 shows the modulation and coding scheme (MCS) levels of the IEEE 802.11af. The values of the data rate in this table are with the case of 6.0 MHz channel bandwidth mode using single-input single-output (SISO) transmission mode. As the mandatory mode, BPSK, QPSK, 16QAM, and 64QAM are supported. 256QAM modulation scheme is an option mode. Block convolutional coding (BCC) is adopted to the channel coding scheme as mandatory mode. LDPC coding is also supported as an optional mode.

Figure 3 shows subcarrier allocation of the payload in case of the 6.0 MHz channel bandwidth mode. The payload consists of 108 data subcarriers (subcarrier index, from 58 to 2 and from +2 to +58), 6 pilot subcarriers (subcarrier index, 53, 25, 11, +11, +25, and +53), and 3 null subcarriers (subcarrier index, 1, 0, and +1). The transmit spectrum of the IEEE 802.11af has 583 kHz effective guard band on both side in the 6.0 MHz channel bandwidth case.

Table 3 Modulation and coding schemes (MCS)

MCS index	Modulation scheme	Coding rate	Data rate (Long-GI)	Data rate (Long-GI)
0	BPSK	1/2	1.8 Mbps	2.0 Mbps
1	QPSK	1/2	3.6 Mbps	4.0 Mbps
2	QPSK	3/4	5.4 Mbps	6.0 Mbps
3	16QAM	1/2	7.2 Mbps	8.0 Mbps
4	16QAM	3/4	10.8 Mbps	12.0 Mbps
5	64QAM	2/3	14.4 Mbps	16.0 Mbps
6	64QAM	3/4	16.2 Mbps	18.0 Mbps
7	64QAM	5/6	18.0 Mbps	20.0 Mbps
8[a]	256QAM	3/4	21.6 Mbps	24.0 Mbps
9[a]	256QAM	5/6	24.0 Mbps	26.7 Mbps

[a]indicates option.

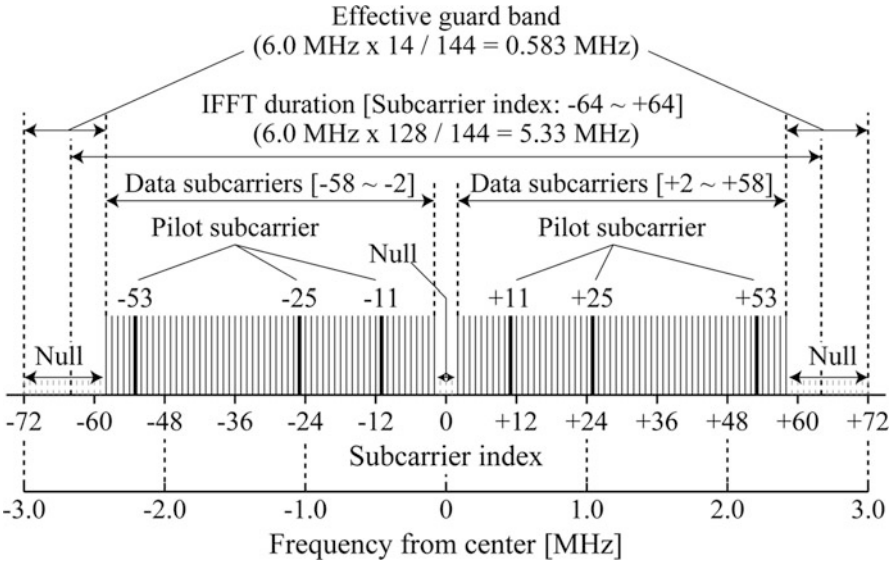

Fig. 3 OFDM subcarrier allocation of IEEE 802.11af TVHT_MODE_1 (Case of 6 MHz mode)

Figure 4 shows the frame configuration of the IEEE 802.11af consists of the Legacy field, the TV High Throughput (TVHT) field, and the payload. The Legacy field includes Legacy Short Training Field (L-STF), Legacy Long Training Field (L-LTF), and Legacy Signal Field (L-SIG). By using the Legacy field, coarse and fine synchronization and automatic gain control (AGC) are operated. The TVHT field includes TVHT-SIGNAL-A (TVHT-SIG-A), TVHT-STF, TVHT-LTF, and TVHT-SIGNAL-B (TVHT-SIG-B). In the TVHT-SIG-A, the required information for demodulation such as the number of channel aggregation, the number of spatial multiplexing, the type of guard interval (GI), and the type of channel coding scheme are included. The number of subcarriers of the TVHT field and the payload is larger than one of the Legacy fields except for TVHT-SIG-A. Therefore, the AGC

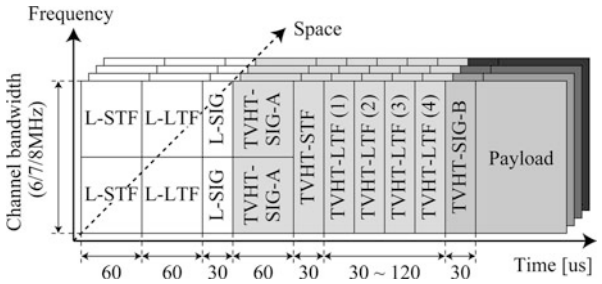

Fig. 4 IEEE 802.11af PHY frame format

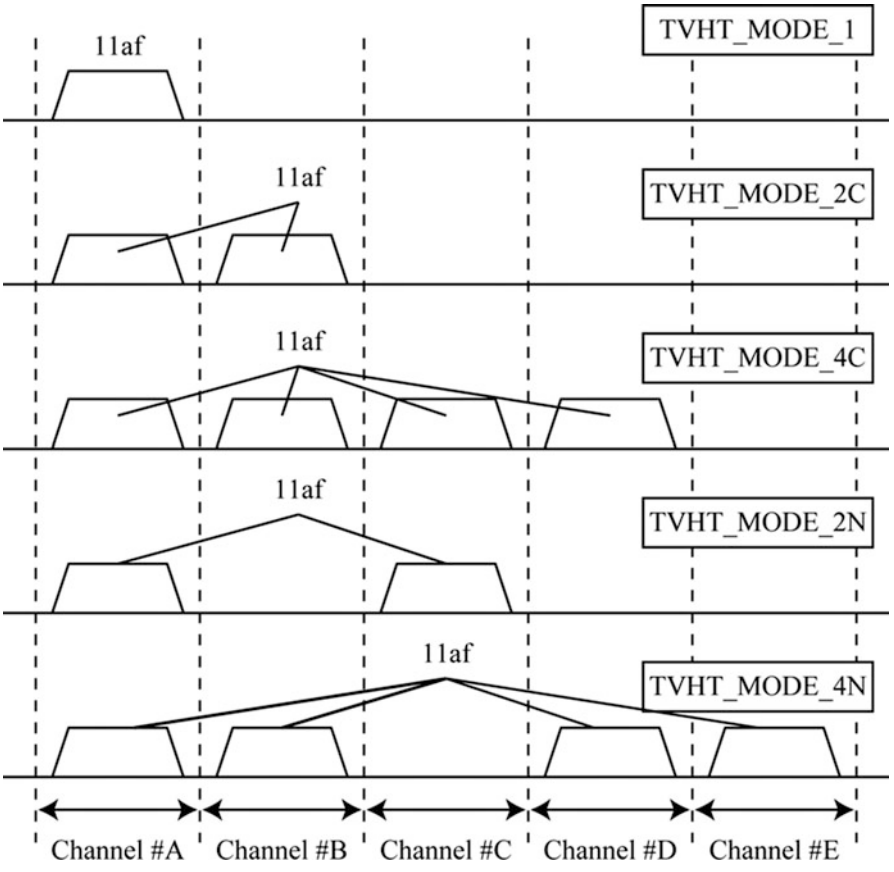

Fig. 5 Channel aggregation pattern

is reoperated by using TVHT-STF. TVHT-LTF is used for the channel estimation to demodulate the payload. Finally, the modulation and coding scheme (MCS) level and the length of the payload for each spatial stream are included in the TVHT-SIG-B.

Furthermore, a multichannel mode is supported as an option. The operating channel can be aggregated up to four channels to increase transmission data rate as shown in Fig. 5.

MAC Layer

The FCC rules of unlicensed operation in TVWS took about 10 years. It started in 2002 with FCC releasing the TV Broadcast Notice of Inquiry. In 2008 and 2010, the base rules were specified and updated based on the comments received from both industry and regulation parties. The final rule was released in 2012. The FCC rules of the secondary users in TVWS rely on geo-location database approach. Protection of the primary users by sensing technologies remains in the final rules and, however, changed from mandatory to optional. Ofcom is the independent telecommunication regulator and competition authority for the communication industries in the UK. In July 2009, Ofcom published its statement report on TVWS usage. According to the report, accessing TV band database with geo-location is the most important mechanism to protect primary users in short and medium terms. The Ofcom final rules were published in 2012. Other countries are also conducting feasibility study on TVWS. The European Conference of Postal and Telecommunications Administrations (CEPT) created a working group to define technical and operational requirements for the operation of cognitive radio systems in the TVWS. In Singapore, the Info-communications Development Authority (IDA) is very active for the promotion of the TVWS. The Ministry of Internal Affairs and Communications (MIC) of Japan has established a discussion group to carry out examination of the new frequency usage such as TVWS.

The challenges of enabling Wi-Fi systems in TVWS mainly come from regulatory requirements. In order to operate in TVWS, there are regulatory rules for the protection of existing primary services. The operation of the Wi-Fi systems must not jeopardize the operation of these existing primary services. Because traditional Wi-Fi systems of 2.4 or 5 GHz bands are unlicensed based, the existing mechanisms are not sufficient for primary user protections. In addition, the propagation characteristics of VHF and UHF bands are quite different from that of 2.4 and 5 GHz bands. The physical layer design of the existing Wi-Fi systems in 2.4 or 5 GHz cannot be directly used in these new bands.

Regulators only permit certain types of device that fulfill the device requirements to operate. Both FCC and Ofcom permit fixed type of device and portable type of device. Fixed devices don't have geo-location capability. Their antenna is permanently mounted on a nonmoving platform by a professional installer or responsible communication provider. On the other hand, portable device is those that don't have a permanently mounted antenna and may change their location upon configurations. Both FCC and Ofcom have the concept of master and slave device in their rules. FCC calls their master device as mode II portable device and slave device as mode I device. Master device has geo-location capability and can talk to the regulatory database for operation parameters, while slave device has to be under control of a master device for operation. The major difference between FCC and Ofcom regarding the device type is that Ofcom allows a fixed device as master or slave device. FCC specified fixed device as a particular device group and doesn't put any master or slave role to fixed device. A Wi-Fi access point can be categorized into a fixed or mode II portable device according to FCC rules and master fixed

or portable device according to Ofcom rules. FCC and Ofcom also support sensing type of devices.

The maximum allowable transmission power is also different. FCC specified fixed maximum transmission power, while Ofcom allows flexibility of tunable maximum transmission power according to the interference level. According to the FCC rules, a fixed device can transmit up to 4 W Effective Isotropic Radiated Power (EIRP) out of the protection contour of primary users. A portable device can transmit up to 100 mW outside of the protection contour of the primary users on co-channel and adjacent channel and reduces EIRP to 40 mW on adjacent channel if being wanted to operate inside the protection contour. Ofcom allows device to report their transmission parameters such as the spectrum mask to the database; database feeds back the maximum allowable transmission power accordingly. There are also strict rules specified for out-of-band emissions to protect primary users on adjacent channels. For fixed device of FCC, the out-of-band emission on the adjacent channel must be lower than −42.8 dBm on every 100 KHz and −52.8 dBm for personal/portable device. Ofcom supports four classes of device with different out-of-band emission requirement. The most relaxed requirement is on class 4 with −54 dBr on the adjacent channel from the 8 MHz TV channel.

Figure 4 presents the network architecture of an 802.11af system. Due to the requirement of database access, the function of a Wi-Fi access point (AP) is extended. More than providing Internet accesses to stations associated, AP is enhanced as a control entity that queries database for available spectrum. There are two typical usage scenarios. The first is that APs directly talk to the database through the Internet. This type of operation meets the FCC ruling that requires mode II portable device to directly talk to the database without a proxy. Assuming APs are located closely, the available spectrum information might be identical. Therefore, when APs blindly choose the same channel to operate, the spectrum is not efficiently utilized. The second is to deploy a registered location secure server (RLSS) between APs and database. RLSS is a proxy for the APs to talk to the database. The proxy approach is supported by Ofcom. There are several benefits of using such server. RLSS collects neighborhood information and helps APs to choose channels with less collision. APs may also request the database through the RLSS to provide tunable transmission power based on the out-of-band emission level.

Figure 5 presents the basic sequence to initiate communications of Wi-Fi devices in TVWS. Before starting operation, APs ask database for the available spectrum information. Both the identification and geo-location information is needed for the database to provide available spectrum information. The identification information indicates what and who the AP is, i.e., AP tells the database what type of device the AP is and what the FCC ID and serial number are. The geo-location information needs to be within the accuracy of 50 m. Once receiving the information, database calculates the available spectrum for the AP to operate based on the interference criteria of licensed operation and feeds back the available spectrum information to the AP. The protocol for the above communication procedure is out of scope of IEEE 802.11af. However, the format to convey the device identification and geo-location information is defined, so that the APs from different manufactures can

talk to the database using the same interface. There are standard groups working on the protocols for database access, such as IETF PAWS.

According the FCC rules, every 60 s, a mode II device needs to confirm its geo-location. If the mode II device finds its position has been changed 100 m (50 m in Ofcom rules) from the place where the last database access took place, the mode II device needs to contact the database again to obtain a new available spectrum. A mobile AP is also a mode II device. The message exchange with the database would be intensive if the mobile AP moves fast. FCC has enhanced the rules to provide better supports on mobile operations. As shown in Fig. 6, mode II devices are allowed to submit several locations before starting operation. The database may respond with the spectrum that is available on the bounded area defined by the locations queried, or the database may respond with the spectrum available on each location and let the device to figure out the common part of available spectrum to use. 802.11af defines interface to support the above two options. The AP submits its current geo-location together with several anchor locations to the database. There is a bounded area defined by the anchor locations and current location. If there is no common spectrum in the bounded area, only the spectrum available on the current location is responded. There is another option supported. Instead of sending multiple locations, the AP may send only two locations, the current location and a second location with an uncertainty value to define the bounded area. For example, an AP may submit a location with uncertainty of 500 m in longitude and 400 m in latitude. Eventually the bounded area will be a $400 \times 500\,m^2$ where the AP can move around without contacting the database. The current location submitted together is for the database to verify that the AP is capable of determining its geo-location within 50 m as required by the rules (Fig. 7).

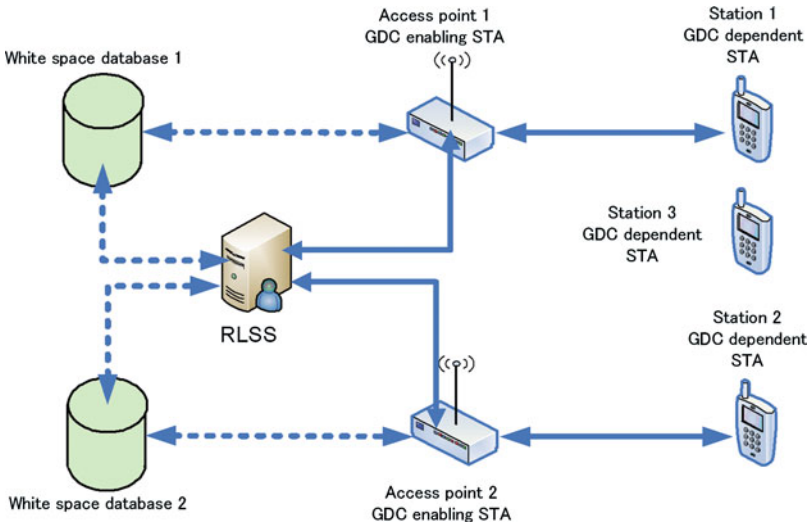

Fig. 6 Network architecture of 802.11af

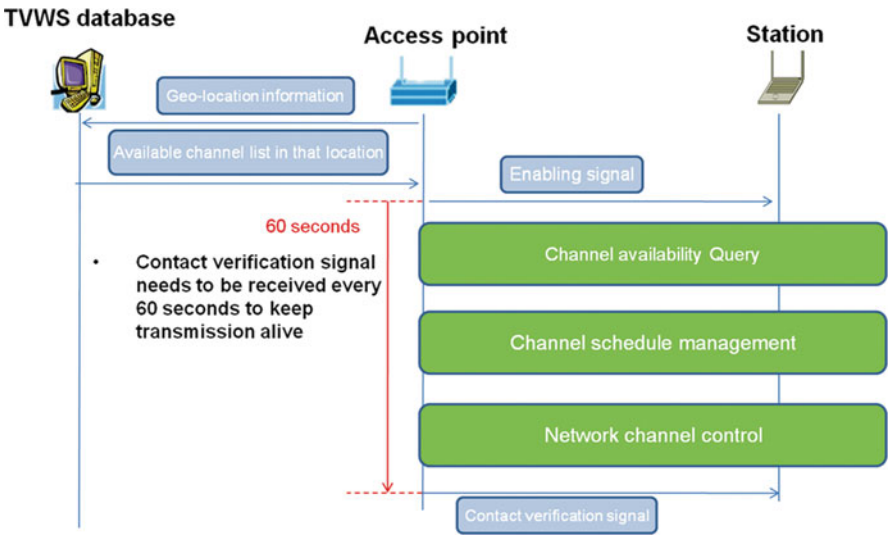

Fig. 7 Major MAC mechanisms specified in 802.11af

FCC rules state that a mode I device has to operate under the control of a mode II device. It can utilize the same spectrum that is available on the mode II device that is controlling it. There are three mechanisms defined in 802.11af to guarantee the control relation between the AP and stations, enabling signal, channel availability query (CAQ), and contact verification signal (CVS).

Enabling Signal

A mode I device is not allowed to release signal on the air unless receiving an enabling signal from a mode II device. 802.11af implements this enabling signal with the beacon frame. AP as a mode II device announces the existence with the beacon. The beacon has to be sent in the TVWS bands. The stations intent to operate in TVWS scan the channels in TVWS. Once a beacon operating as an enabling signal is received, the station is allowed to release signal on TVWS band for initial contact with the AP.

CAQ

A mode I device needs the available spectrum to operate. We have described the procedure for an AP to obtain available spectrum from database. Before a station performs CAQ procedure with an AP, we can assume the AP already obtained the available spectrum from database. The CAQ procedure between a station and an AP is for the station to submit its own identification to the AP; AP verifies this identification with the database whether the station is an authorized mode I device or not. Once the station is verified, AP responses to the station with the available spectrum information. In order to meet the security requirements, the CAQ procedure can only be performed, after secured association and authentication have already been completed.

CVS

In order to make sure the slave device is under control of a master device, FCC specified a rule that a mode I device needs to receive a CVS every 60 s from the mode II device that is controlling it. Beacon is not an option for CVS, because beacon is non-securely broadcasted. Therefore, the CVS of 802.11af is defined as a unicast frame that is sent to all the stations one at a time. The frame is protected by the keys generated during the negotiation of secured association procedure. The frame needs to activate its acknowledgment option to allow station to indicate the receipt of the CVS.

There is another folder of requirement that also needs to be considered. Wi-Fi systems are designed to operate in unlicensed band. Stations content for resource before transmitting frames. This nature makes the successful story of Wi-Fi systems. However, TVWS is different from other unlicensed bands. There is licensed user coexisting in the same bands. The spectrum is not always available there to use. Coordination and interference mitigation mechanisms are the key to efficiently utilize the spectrum. Two important mechanisms that are developed for this purpose in the 802.11af are channel schedule management (CSM) and network channel control (NCC). Both mechanisms are related with the RLSS which serves the role of a proxy to the database and also a local coordinator for spectrum allocation.

CSM

Licensed services such as DTV or wireless microphone have timely characteristics, i.e., the service is not always occupying the channel. For example, a big sport event may require hundreds of wireless microphones for only 1 h. Many DTV channels stop at 2:00 am and restart 6:00 am in the morning. There are 4 h available in between for the unlicensed operation to utilize. FCC has specified that a mode II device obtains the channel schedule information up to 48 h and stores the schedule information to operate in case database access lost. The implication of this rule is to allow the available spectrum to be shared in time domain. The RLSS may further divide the spectrum obtained from database and allocate the spectrum to different Wi-Fi devices to improve spectrum efficiency. 802.11af developed the protocol between AP and RLSS for secured information exchange. And the mechanism, namely, CSM, is developed based on the protocol for the AP to negotiate with RLSS for the available spectrum in time domain. An AP who is requesting the CSM is called a CSM requesting station; the requesting station constructs a CSM query to a CSM responding station asking for schedule information on the interested channels. The responding station normally is the RLSS; it responds to the requesting station with the time periods of available spectrum to operate. Because APs in the neighborhood access the database through RLSS, RLSS understands the interested channel that the APs want to operate. It can smartly allocate spectrum orthogonal in time to different users to avoid interference. RLSS may also reject the request from certain APs when spectrum availability is less in order to reduce the interference to licensed operation. The responding station of a CSM can also be another AP. One AP may obtain the available spectrum and schedule information via another AP.

NCC

NCC is another mechanism developed to improve spectrum efficiency. Different from CSM that handles spectrum in time domain, NCC handles the spectrum in frequency domain. NCC follows the same architecture of requesting and responding stations. Requesting station queries the responding station about the interested channels to operate. When a mode II device obtained available spectrum information from database, all the information is delivered in a form of TV channel across the whole VHF and UHF bands, 6, 7, or 8 MHz depending on the regulatory domain. However, with respect to a Wi-Fi device, it operates in a WLAN channel plan. RLSS as the responding station once receiving the query from a requesting station needs to map the WLAN channel into TV channel and check whether the interested WLAN channels are available for operation. The other important feature of NCC is to deliver the spectrum mask information. Spectrum mask is defined for a device to reduce the out-of-band emissions so that the licensed operation on the adjacent channel is not interfered. FCC and Ofcom have different approaches of suppressing out-of-band emissions. FCC specified a very stringent rule as described in previous section. The rule guarantees protections of licensed operation on the adjacent channel with a price of increased cost of portable Wi-Fi devices. In order to implement a filter to achieve such power suppression, both the size and cost of Wi-Fi chip have to increase. As a consequence, this rule hampers portable Wi-Fi from having a broad market. On the other hand, Ofcom is more flexible in dealing with out-of-band emission. Rather than specifying a very stringent spectrum mask, the rule allows device to provide its own spectrum mask to the database. Database gives less transmission power to the AP, if the spectrum mask is not sharp. This approach encourages AP that is capable of reducing out-of-band emission to transmit more power and consequently obtain more opportunities for the spectrum.

Prototypes

Introduction

IEEE 802.11af-based system has attracted attentions for its superior propagation characteristics in the UHF band enabling 100 m or longer-range communication. On the other hand, leading regulators impose a rigorous spectrum mask limitation on the TVWS (TV White Space) devices to avoid the interference with primary users such as TV broadcasters and wireless microphones. In addition, TVWS (TV White Space) communication systems are necessary to implement some specific functions for acquiring and updating the TVWS availability. Accordingly, IEEE 802.11af-based systems and devices should be developed or prototyped by taking into account these regulations and requirements. In this section, regulations and requirements imposed on the IEEE 802.11af-based systems and devices are briefly summarized first. Then, IEEE 802.11af-based working systems prototyped by NICT (National Institute of Communications Technology, Japan) are introduced.

Requirements

Power and Emission Limits

For the TVWS utilization, each regulator has stated a similar but different policy by reflecting each national circumstance. In the FCC regulations, TVWS devices are classified into four types according to the operation mode as shown in Table 4 [4]. The power limit and the adjacent channel emission limit are individually defined for each category and every limit is specified by an absolute power. Table 5 shows the adjacent channel leakage power (ACLP) limits defined by the ETSI [5] that were applied for the Ofcom TVWS pilot program in 2014. The ETSI basically accepts the same power level as the FCC for the TVWS devices, while the TVWS devices are categorized into five types according to the ACLP performance. Conversely, each category has individual ACLP limit and every limit is specified by a relative value to the transmission power, i.e., the adjacent channel leakage power ratio (ACLR). Here, P_{OOB} which means leakage power in a 100 kHz bandwidth outside the using channel can be calculated by

$$P_{\mathrm{OOB}}\ (\mathrm{dBm}/(100\,\mathrm{kHz})) \leq \max\{P_{\mathrm{IB}}\ (\mathrm{dBm}/(8\,\mathrm{MHz})) - ACLR\ (\mathrm{dB}), -84\ (\mathrm{dBm}/(100\,\mathrm{kHz}))\},$$

where P_{IB} is output power in an 8 MHz bandwidth of the using channel and *ACLR* is defined in Table 5. The IDA in Singapore also defines the original regulations by following the FCC and the ETSI regulations with regard to the power limit and the adjacent channel emission limit [6]. IEEE 802.11af-based TVWS devices must conform to these requirements in actual operations.

Table 4 Power and emission limit regulated by FCC [6]

Type of TV bands device	Power limit (6 MHz)	Power spectrum density limit (100 kHz)	Adjacent channel emission limit (100 kHz)
Fixed	30 dBm (1 W)	12.6 dBm	−42.8 dBm
Sensing only	16 dBm (40 mW)	−1.4 dBm	−56.8 dBm
Personal/portable (adjacent channel)	17 dBm (50 mW)	−0.4 dBm	−55.8 dBm
All other personal/portable	20 dBm (100 mW)	2.6 dBm	−52.8 dBm

Table 5 ACLR for different device emission classes [7]

Where P_{OOB} falls within nth adjacent DTT channel	ACLR (dB)				
	Class 1	Class 2	Class 3	Class 4	Class 5
$n = \pm 1$	74	74	64	54	43
$n = \pm 2$	79	74	74	64	53
$n \geq +3, n \leq -3$	84	74	84	74	64

WSDB Access

Before starting the communication in the TVWS, TVWS devices need to know whether they can transmit the power without any interference to/from primary users and/or other TVWS devices. But, how can they know it? Regulators simply offer two solutions. One is the sensing function recognizing whether the target TV bands are empty or not by the TVWS device itself. The other one is the WSDB access approach for acquiring the availability of the target TV bands. The former requires an implementation of a highly sensing capability to sense a very weak signal level of, for instance, −114 dBm/6 MHz and −107 dBm/100 kHz as defined by the FCC [4]. However, high-performance sensing units are generally costly and not small for implementation in practical consumer devices. The latter is a common function defined by many regulators including the FCC and the Ofcom, because this function only requires constant accessibility to the WSDB via the Internet, while high-performance and expensive units are not necessary. As above, the IEEE 802.11af-based communication system was standardized on a more rational WSDB approach basis.

Implementation

This section is a summary of IEEE 802.11af-based system and device prototypes developed by NICT. Here, three types of prototype devices are described. The first one is a low-power type prototype with superior spectrum emission characteristics. The second one is a high-power type prototype enabling long-haul communication with a maximum output power of +30 dBm. These two prototypes are costly and consuming a lot of power due to the FPGA-based baseband (BB) circuits. The last one is the compact card-type prototype incorporating the world's first IEEE 802.11af-based BB IC. This prototype achieves dramatic downsizing, power saving, and even cost saving and paves the way to the practical use of the IEEE 802.11af-based communication system. This section describes a brief summary of each device. For more detailed information, refer to each reference (Fig. 8).

System Architecture

The IEEE 802.11af-based prototype system shown in Fig. 9 consists of an access point (AP), a station (STA), a WSDB, and a registered location secure server (RLSS). In this system, the AP is operating as a master device and has to access the WSDB via the Internet before starting the communication with the STA. In general, the AP first informs the WSDB of some essential information such as geo-location, antenna height, and device parameters, which are defined by the regulators, and then the WSDB calculates and provides an available channel list with some additional information to the AP. After the AP selects optimal channel(s) to use and starts beacon transmission to its slave devices, i.e., STAs. The beacon also includes some essential information such as permitted maximum output power, and thus, STAs can set the optimal radio parameters. Eventually, STAs answer the AP, and then the TVWS communication starts. The RLSS is an optional component in this system.

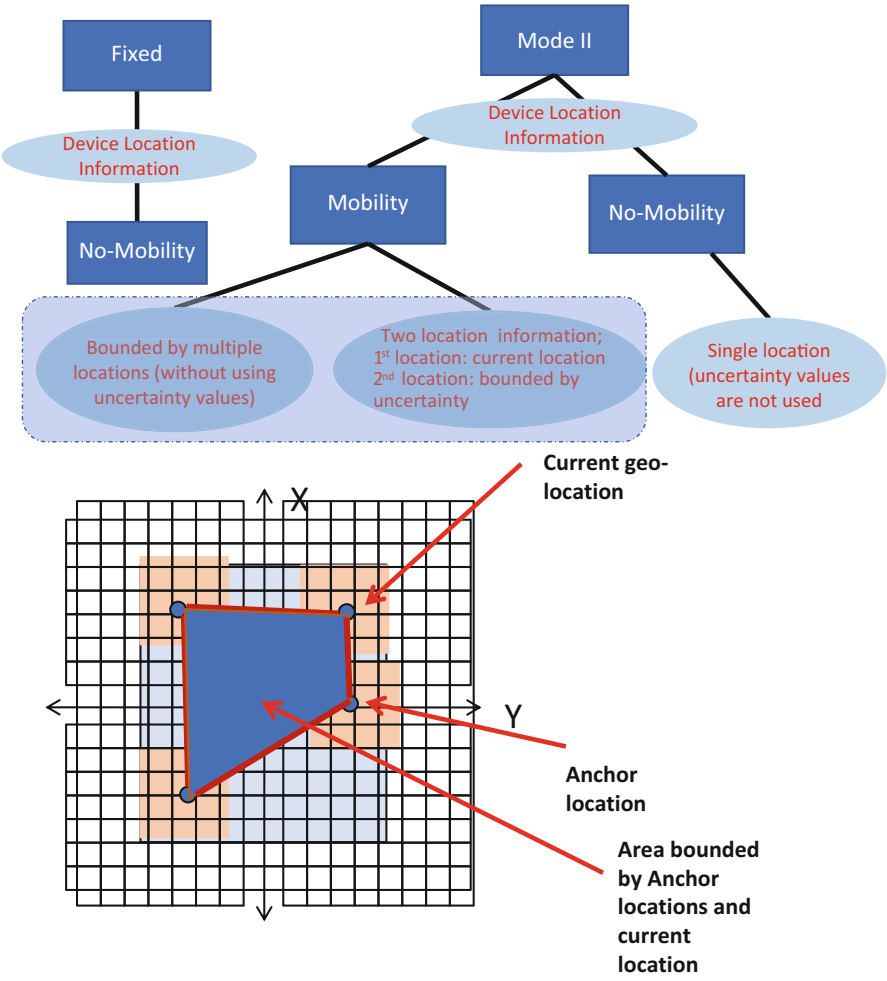

Fig. 8 Multi-location operation of 802.11af

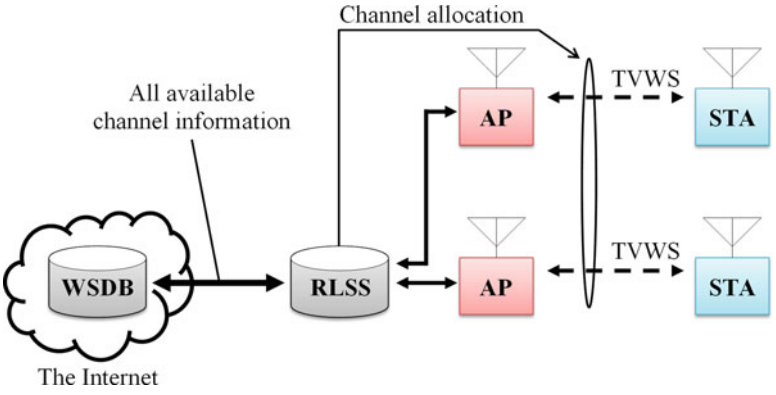

Fig. 9 IEEE 802.11af-based prototype system

If some APs operate in the same area and frequency, they will interfere with each other. To avoid the interference between secondary users, the RLSS allocates an appropriate channel to each AP according to the information from the WSDB and the geo-location information of the AP.

Low-Power Type Prototype Conforming to Both FCC and ETSI Regulations

Figure 10 shows the low-power type prototype [4]. This prototype consists of a CPU board, a BB board, a DAC/ADC board, an RF board, and an antenna. Table 6 shows specifications of the prototype. To conform to the rigorous requirements of the FCC and the ETSI, a three-stage heterodyne architecture is applied in the transmitter for sharply suppressing the adjacent channel emissions, as shown in Fig. 11. The spectrum emission of the prototype complies with the regulations defined by the FCC and the ETSI with an output power of +3.5 dBm, as shown in Fig. 12.

Fig. 10 Low-power type prototype

Table 6 Specification of the low-power type prototype

Item	Description
Supporting frequency range	470–710 MHz
Bandwidth	6 MHz
Maximum output power	+10 dBm
Receiver dynamic range	−88 to −35 dBm
Size	300 mm(W) × 210 mm(L) × 100 mm(H)
Weight	5 kg
Power supply	AC 100–240 V
Current consumption	<70 W

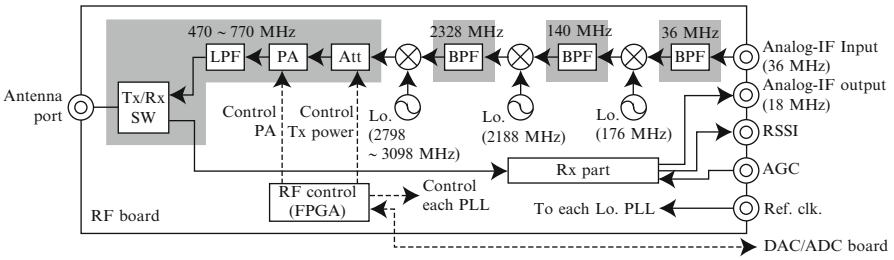

Fig. 11 Transmitter block diagram of the low-power type prototype

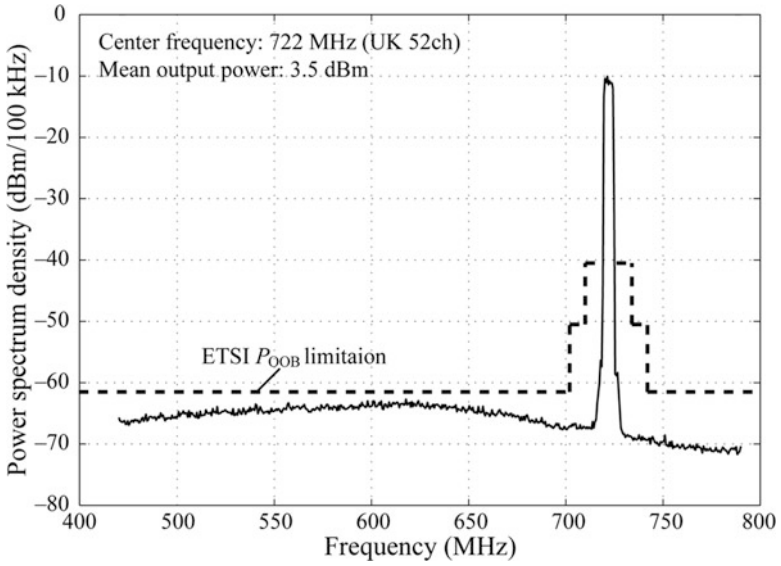

Fig. 12 Spectrum emission characteristics of the low-power type prototype

High-Power Type Prototype Conforming to the ETSI Regulation

Figure 13 shows the high-power type prototype [5]. This prototype is based on the abovementioned low-power type prototype, but direct conversion architecture is applied in the RF circuits as shown in Fig. 14. Table 7 shows the RF specification of the prototype. This prototype is capable of an output power of +30 dBm in conformity to the ETSI regulations, while the supporting frequency range is limited to 500–710 MHz due to the difficulty in a design of a wideband amplifier enabling a high output power of more than +30 dBm in the entire TV band. Figure 15 shows a typical spectrum emission with an output power of +27 dBm. The out-of-band emissions are under the P_{OOB} limitation defined by the ETSI in the entire TV band. By adjusting the output power to less than +20 dBm, spectrum emission conforms to the FCC regulations.

Fig. 13 High-power type IEEE 802.11af-based prototype

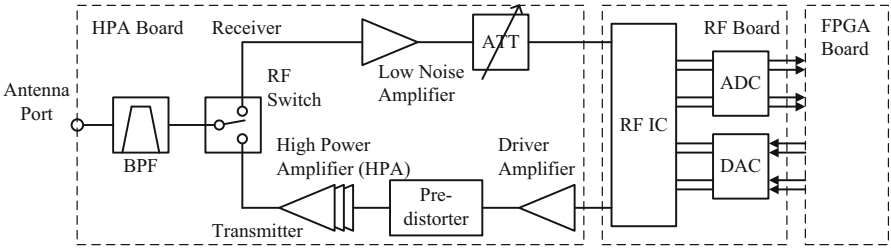

Fig. 14 RF block diagram of high-power type IEEE 802.11af-based prototype

Table 7 Specification of the high-power type prototype

Item	Description
Supporting frequency range	500–710 MHz
Bandwidth	6 MHz
Frequency accuracy	±2ppm
Output power	+30 dBm
Tuning range of output power	>40 dB
Receiver dynamic range	−88 to −20 dBm

Compact Card-Type Prototype Incorporating Baseband IC

For practical use of the IEEE 802.11af-based technologies, there are still some major difficulties in downsizing, power saving, low cost, easy installation, etc. In the low-power and high-power prototype devices, the BB signal processing circuits were designed and implemented by using an FPGA, and thus, practical size and power consumption were difficult to achieve [7, 8]. To solve this problem,

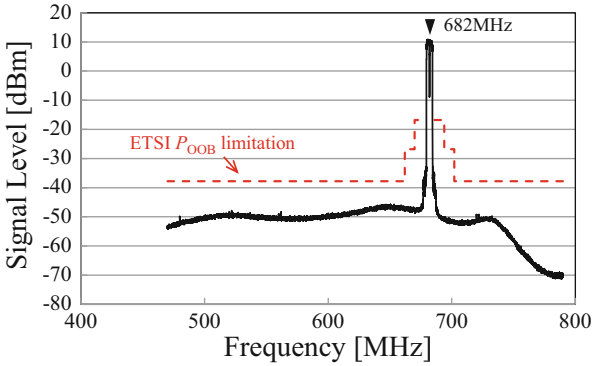

Fig. 15 Spectrum mask with 682 MHz transmission signal

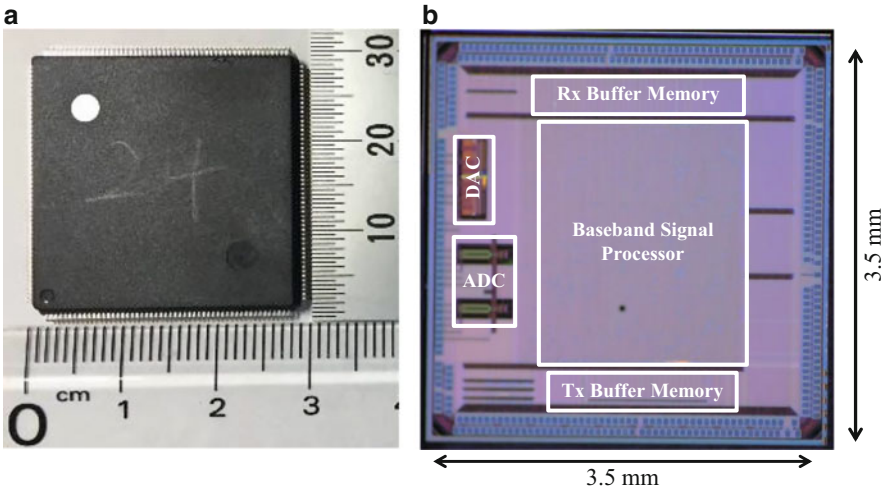

Fig. 16 World's first IEEE 802.11af-based baseband IC

more sophisticated technologies driving downsizing, power saving, and even cost saving are strongly required as well as conventional communication systems such as Wi-Fi and mobile communication systems. An integration of the BB signal processing circuits is one of the promising technologies that wipe out these concerns.

NICT has developed the world's first IEEE 802.11af-based BB IC with a 65-nm mixed CMOS process, as shown in Fig. 16 [9, 10]. The BB circuits are based on the previously developed prototype of the low-power device. By implementing this prototype BB IC, NICT has also developed a compact card-type prototype in all-in-one package including an antenna, as shown in Fig. 17, and has demonstrated

Fig. 17 Card-type IEEE 802.11af-based prototype

Table 8 Specification of the card-type prototype

Item	Description
Supporting frequency range	470–710 MHz
Bandwidth	6 MHz
Maximum output power	+20 dBm
Receiver dynamic range	−86 to −35 dBm
Size	50 mm(W) × 170 mm(L) × 18.8 mm(T)
Weight	170 g
Power supply	DC 5 V
Current consumption	<5 W

the practicality of the prototype BB IC. The card-type prototype is equipped with the USB interface enabling an easy connection to a host PC and a simple control for operation. Table 8 shows specifications of the card-type prototype. By comparing with the low-power type prototype, the card-type prototype achieves 1/40 downsizing, 1/30 weight saving, and 1/15 power saving with a maximum output power of +20 dBm. With regard to the spectrum emissions, the output power is capable of +20 dBm and +16 dBm for the rules regulated by the ETSI and the FCC, respectively. Power consumption of the card-type prototype is about 5 W, and thus, this prototype operates with a power supply from USB3.0 interface.

Registered Location Secure Server (RLSS)

RLSS is an IEEE 802.11af specific functional entity to avoid interference between WSDs conforming to this standard. As IEEE 802.11af defines PHY and MAC; an interface of RLSS is not the scope of the standard.

The specific mechanisms of RLSS is as follows:

— Query channel availability to geographical database(s) (GDB) for an area or a geo-location
— Enable APs to form a network and maintain the network under the control of GDB
— Retrieve the available white space channels and transmit power restrictions
— Schedule channel utilization such as start and end time of each WSD for each available white space channel

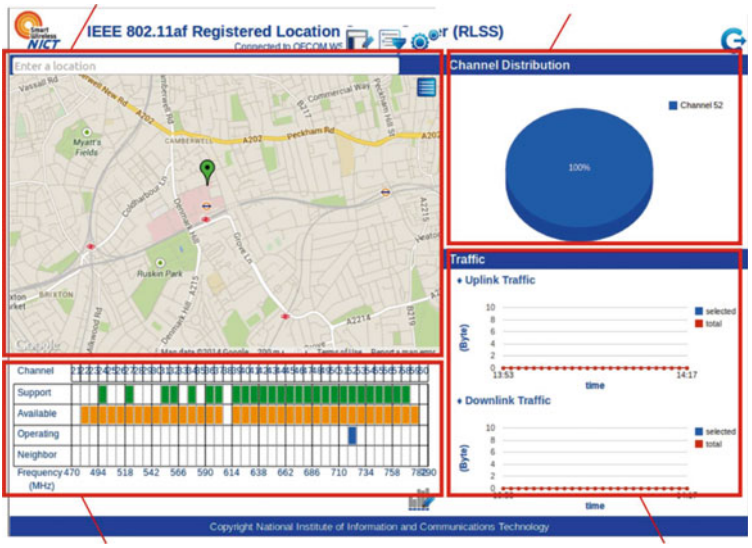

Fig. 18 Screenshot of RLSS management software

The use of RLSS in a particular regulatory domain depends on the specific regulatory requirements. Each of the mechanisms is required, informative, or not applicable according to regulatory requirements. Also, time requirement of each mechanism may be daily, hourly, or minute responsiveness. Implementers of RLSS need to carefully refer to the regulatory sources to be satisfied.

A screenshot of management GUI of a prototype RLSS under operation is shown in Fig. 18, as an example of implementation. Locations of WSDs are shown on a map, so that operators easily grasp overall TVWS operation around a specific area. A list of supported channels, available channels, operating channels, and neighboring channels is shown regarding a WSD specified on the map. The supported channels are channels where the WSD is capable of operation. TV band is quite wide for RF hardware implementation, and therefore the channels for transmission and receiving may be limited on some WSDs. Available channels are channels that a GDB informs to RLSS. Operating channels are channels on which WSDs are operating at this point of time. Operating channels are single or multiple as the PHY and MAC support the multiple TV channel utilization. Neighboring channels indicate channels that are operated by other WSDs nearby within a certain distance enough to be interfered. The neighboring channel is considered in channel

assignment not to overlap with a channel(s) to be operated by other WSDs. Uplink and downlink traffic can be monitored per WSD selected on the map.

Field Trials

To investigate IEEE 802.11af in terms of real field performances and environment-specific issues; the National Institute of Information and Communications Technology (NICT) of Japan conducted experiments in indoor and outdoor environments under TV White Spaces Pilot organized by Ofcom of the UK.

The pilot required a license issued by Ofcom to operate TV White Space devices (WSD), which are AP and STA in case of IEEE 802.11af system. The WSD needs to access one of TVWS databases (WSDB) qualified by Ofcom for the pilot. NICT obtained the licenses for WSD operation and qualification of WSDB operation.

This section explains environments and results in indoor and outdoor use cases. The experiments were conducted jointly with King's College of London (KCL) in July 2014 [7, 8, 11–13].

Indoor Experiment

The indoor experiment was conducted in the second floor of the institute of psychiatry building in the Denmark Hill Campus of KCL [7, 13]. The floor is mainly composed of two corridors (X and Y) and two computer education rooms (A and B) as shown in Fig. 19. Detailed information of the environment is listed in Table 9. Four routes (A to D) are defined for separated measurements. The Routes A and B are along Corridor X; Routes C and D are along Corridor Y. An AP is fixed in between Routes A and B. STA moves along the routes measuring RSSI and throughput. The throughput is measured using the "iperf" tool in UDP mode. The MCS of AP and STA are set to 3. AP, and STA had omnidirectional whip antennas with 2.2 dBi gain at 1.3 m height above the ground using RF cables with 1.0 dB loss. Transmission power was set to 3.5 dBm; therefore, output ERIP was 4.7 dBm as listed in Table 10.

Measured RSSI and throughput on each route are separately shown in the graphs in Fig. 19. The deflection effect is observed near P5 on route C where RSSI is still high regardless of non-line-of-sight (NLoS) from the AP, and therefore throughput is kept as high as in P5 which is line-of-sight (LoS). This is estimated to be due to the TV band which is lower than ordinary wireless LAN bands. Focusing on route B, the throughput is partly deteriorated although RSSI is still high and the STA is LoS from the AP. This is thought to be due to multipath fading. The reason why the RSSI is high on route D is because the penetration loss inside the Room A is not high because of less metal materials metal for walls or bookshelf. The measurements in the indoor environment show that IEEE802.11af AP can cover wider area, that is, not only LoS but also NLoS.

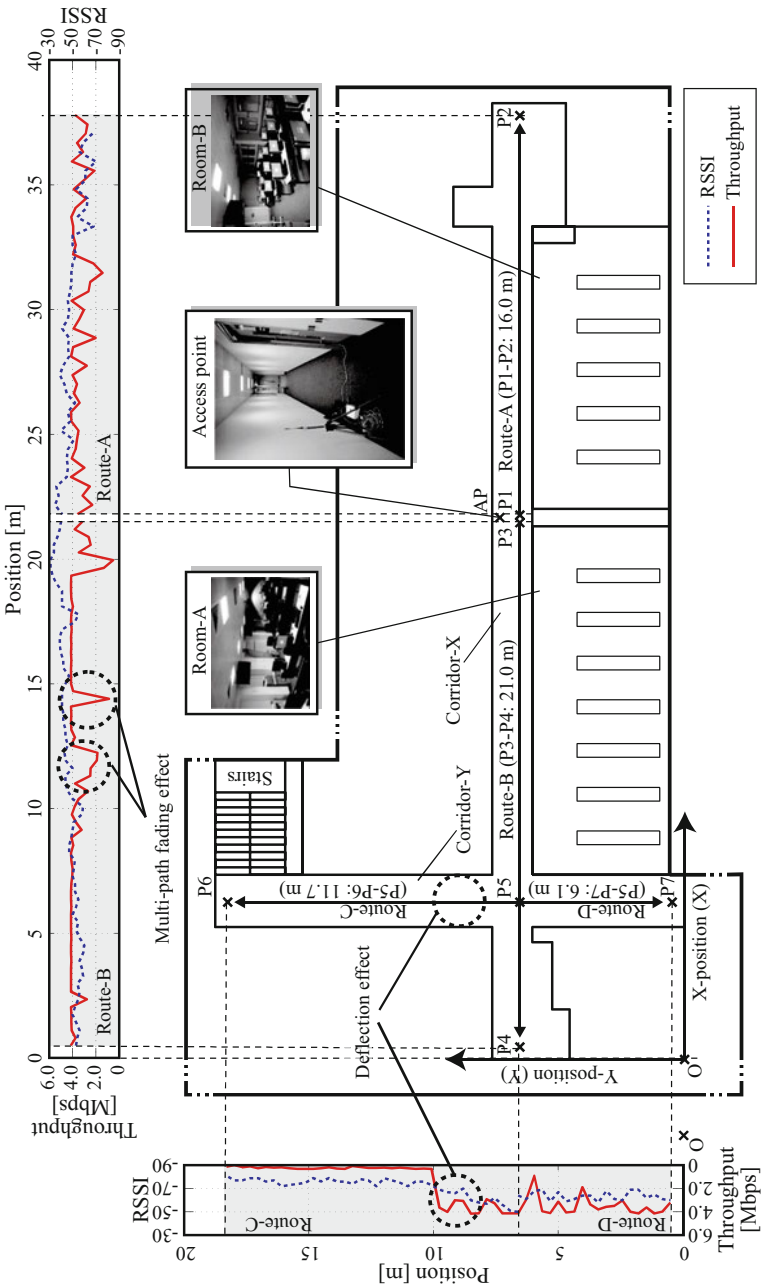

Fig. 19 Indoor experiment environment and measurement results

Table 9 Details of indoor experiment environment

Corridor X	Length: 38.3 m, Width: 1.6 m
Corridor Y	Length: 18.8 m, Width: 2.1 m
Room A	Length: 14.2 m, Width: 5.5 m
Room B	Length: 10.9 m, Width: 5.5 m
Ceiling	Height: 2.4 m
Antenna	Height: 1.3 m

Table 10 Device setup for indoor experiment

Operation mode	IEEE802.11af TVHT_MODE_I
MCS	3 (16QAM, 1/2 coding rate)
Transmission power	3.5 dBm (average)
Antenna gain	2.2 dBi (Omni directional)
RF cable loss	1.0 dB
Transmission ERIP	4.7 dBm

Outdoor Experiment

The outdoor experiment was conducted in the center of London, UK [8]. The purpose of this experiment was to study feasibility of establishment of long-distance link using IEEE 802.11af as a backhaul network. Two fixed sites were selected in London, from campuses of King's College London, Guy's Campus, and Denmark Hill Campus. Distance of the two sites is 3.7 km. A STA and an AP were installed at Guy's and Denmark Hill campuses, respectively. Heights of antenna were 65 and 37 m, respectively, in the same order. Three-element ring Yagi antennas with 7.6 dBi gain were used at the two locations. Directions of the antenna were carefully tuned so to maximize the RSSI at each side. Transmission EIRP at both sides was 36 dBm. As shown in Fig. 20, the antenna was set up inside a glass window at the Guy's Campus, whereas it was open air at the Denmark Hill Campus. Throughput of the link was measured using "iperf" again in UDP mode.

The measured throughput was 2.2 Mbps with MCS 0 where the RSSI was −60 dBm. It was observed that higher throughput could not be obtained with higher MCS than 0. The reason is considered that TV broadcasting signals transmitted from Crystal Palace to London area is quite strong and Crystal Palace is approximately on the same direction as from Guy's Campus to Denmark Hill Campus. This resulted in strong TV signal input to the RF circuit of the STA at the Guy's Campus. For this experiment, the STA and AP had just a broadband front-end filter covering whole the TV band where such extremely strong TV signals were beyond assumption. It is assumed that the signal input caused saturation of RF circuit of the STA. Also, according to other measurements and analysis, penetration loss of the window in front of the antenna at the Guy's Campus is more than 10 dB, which further deteriorated the performance. However, establishment of a long-distance wireless link over 3.7 km was anyway demonstrated based on IEEE 802.11af and feasibility of its functions and protocols was verified. The issue related to the strong signal input needs to be addressed in product development phase.

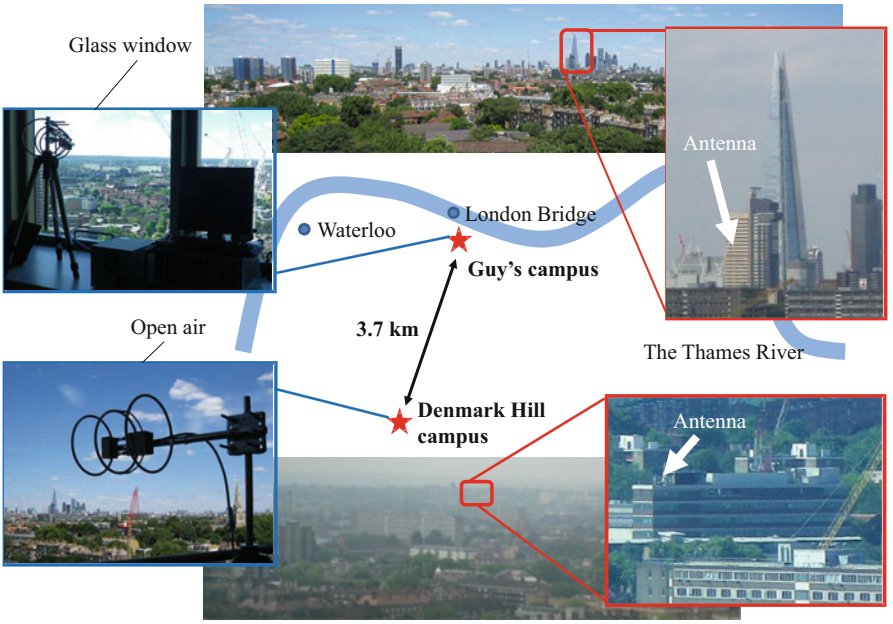

Fig. 20 Overview of outdoor experiment

Conclusion

Utilization of TV White Space is realized based on advanced spectrum sharing concept. Its requirements are hard to protect; TV broadcastings and radio regulations are various according to policies. IEEE 802.11af is one of the standards to enable the TV White Space operation. Especially, since IEEE 802.11af is based on the wireless LAN concept, prices of its products are expected to be reasonable and deployment of its system would be less complicated compared with other TV White Space systems. So far, various use scenarios are proposed to apply TV White Space, backhaul link between islands, mountain area mobile communications, robots for disaster recovery, and so on, taking advantage of good radio propagations in TV band. This chapter is expected to contribute to the development of TV White Space applications.

Cognitive Radio: The Need to Align Regulations with Technology

47

Abstract

Cognitive radio holds an interesting promise for improved utilization of the radio spectrum. However, there is a considerable degree of uncertainty regarding the potential application of cognitive radio. One of the reasons for this uncertainty is the need for changes in the regulatory regime to allow for more dynamic forms of spectrum access. In addressing the necessary changes in regulations, the regulator should be well aware of the perspective of the entrepreneur. Eventually it is the entrepreneur who invests in CR technology and thereby realizes the goal of improved utilization of the radio spectrum.

This chapter addresses the relationship between the regulations and the CR technology. Both the regulations and the CR technology will pose limitations on the possible business cases. It further proposes a way forward to come to a successful exploitation of CR technology in which the objectives of both the entrepreneur and the regulator can be realized.

Keywords
Dynamic spectrum access · Regulations · Licensed shared access · Geolocation database · White space · Spectrum pooling

Introduction

Cognitive radio (CR) is a promising innovative technology that can be used to improve spectrum utilization. Especially the ability of cognitive radiotechnology to provide access to spectrum that is already assigned to other user(s) or usage but partly unused when considered on a time or geographical basis holds an interesting promise. The concept of CR was proposed already more than 15 years ago by Mitola. Trials with the commercial use of cognitive radio are ongoing since the historic decision of the FCC in 2008 to allow CR technology in the TV broadcasting bands. However, commercial use of cognitive radio is still very limited. The question is what went wrong and how to proceed?

One of the main reasons for the limited practical and commercial use of CR technology is uncertainty. An important aspect of this uncertainty is the regulatory model. Although there are possibilities to use cognitive radio under the current radio spectrum management regime, the current regulatory model is not conducive for dynamic access of spectrum made possible by cognitive technology. Regulatory provisions are needed to align the regulations with the new capabilities of CR technology of flexible and more efficient utilization of the radio spectrum [1].

In drafting regulatory provisions, governments are facing a dilemma. The liberalization prevailing policy that suggests a technology-neutral assignment of radio spectrum, while enabling the deployment of a specific technology, i.e., cognitive radiotechnology, is of public interest to achieve more efficient utilization of the radio spectrum. It appears that in this light, regulation to allow the deployment of a specific type of CR technology in parts of the radio spectrum that would otherwise be underutilized or not used at all is justified [11].

As CR encompasses a very versatile set of technologies, the subsequent challenge governments are facing is the choice among some of the more fundamental features of CR technology, such as the technology used to make a CR aware of its radio environment and the band in which the CR is allowed to operate. Their choices will need to be well informed as their choices play a pivotal role in the business models of the entrepreneurs. The way governments allocate the use of radio spectrum to particular radio communication services on the (inter)national level and assign the rights to use the radio spectrum on the national level is determining the viability of the business case for particular radio communication products and services.

In this respect there is the issue of "the chicken and the egg": certain types of radio spectrum rights assignment facilitate certain types of usage, while certain types of perceived usage will require a particular type of assignment. In other words, entrepreneurs are reluctant to invest in new products and/or services based on CR technology because of the degree of regulatory uncertainty, and regulators cannot provide this certainty because it is uncertain if their choices will support a viable business case.

This chapter proposes a way forward to deal with this dilemma by explaining the relationship between the regulations and the CR technology. Choices on both regulations and CR technology will greatly influence possible business cases for the introduction of new products and/or services based on CR technology. It is proposed to use an actor-centric approach to deal with this issue of alignment between the technology and the regulatory provisions. After all, cognitive radio is a technology to share spectrum among various users. The various users of the spectrum, the industry that has to develop the equipment and the government that has to provide the necessary regulations, will have to coordinate to make the right decisions in order to come to a successful exploitation of CR. The actors involved in this coordination will all have their own objectives and incentives.

This chapter is structured as follows. It starts with an explanation of the regulatory provisions and its influence on possible business cases for CR. This is followed by an explanation of the relationship between CR technology and possible business cases. This exploration is used to introduce a framework to assess the alignment between the regulations and the technology. This approach is illustrated by an analysis of the so far best known intended use of CR technology: white space access in the TV bands. Based on the results of this analysis, it is proposed to explore use cases within a community of practice as the way forward for realizing the necessary coordination between the actors involved to facilitate the successful deployment of cognitive radio and to realize – at the same time – the goal of improved utilization of the radio frequency spectrum. This proposal is also based on experiences gained at the national level, in the Netherlands, with a community of practice related to cognitive radio.

Spectrum Regulations of Dynamic Spectrum Access

In the current spectrum management model, radio spectrum is divided into fixed and non-overlapping blocks, separated by so-called guard bands. These blocks are assigned to different services and wireless technologies, while a lot of spectrum usage is only local and limited in time. In an economic sense, there appears to be a paradox whereby the rights to the radio spectrum are fully assigned, but a lot of radio spectrum remains unused in practice when considered on a time or geographical basis.

Cognitive radio, as a technology, is an enabling tool to realize increased flexibility in access to the radio spectrum. The key feature of a cognitive radio is its ability to recognize unused parts of radio spectrum that are assigned to conventional

users and adapt its communication strategy to use these parts while minimizing the interference that it causes to the conventional users. An important consequence is that cognitive radio can be an enabling technology to facilitate a paradigm shift for spectrum management from a regime based on static spectrum assignments to a regime based on more dynamic forms of spectrum access [1, 13].

Scenarios for Dynamic Spectrum Access

There are different possibilities to exploit dynamic spectrum access. It can be used to pool spectrum between a number of users or user groups or it can be used to dynamically access white spaces. Spectrum pooling is the situation in which a common "pool of spectrum" is shared among multiple users [10]. Access to the pool may be restricted to specific users through the use of licenses or the pool may be open to all under certain use restrictions. All users have the same rights to access the spectrum. Therefore, this kind of sharing is also referred to as horizontal sharing.

This is in contrast to the other case in which white space users are only allowed access to the radio spectrum as long as the primary users are not needing access. The white space users are on a secondary level of usage of the spectrum. Therefore, this type of sharing is also referred to as vertical sharing. This secondary usage may also be restricted to specific (licensed) users or open to all.

This leads to four different scenarios for the implementation of dynamic spectrum access. The different scenarios are summarized in the following Table 1.

The way in which the regulatory regime allows access to spectrum will greatly influence the business opportunities. This section gives an overview of the impact of the regulatory regime on the business opportunities.

White Space Access

CR technology is proposed to improve radio spectrum utilization by using white spaces within spectrum that is allocated but actually not used at a given time and location. The question is whether there is enough capacity in these unused white spaces that can be made available to support the underlying business case for CR technology and if the business case is solid enough to recoup the necessary investments in this new technology.

The ease of making unused spectrum available for cognitive use depends on the characteristics of the incumbent user. It is easier to find a white space if conventional user(s) and usage is relatively static than when conventional users are mobile and/or their usage fluctuates.

Table 1 Four different regulatory scenarios for dynamic spectrum access

	Horizontal sharing (spectrum pooling)	Vertical sharing (white space access)
Licensed access	Spectrum owners dynamically share spectrum	Owners of the spectrum grant specific cognitive radio's access to their white spaces
Unlicensed access	All CR devices dynamically share spectrum on an equal footing	cognitive radio's dynamically access white spaces from incumbent users

Moreover, the fact that large parts of the radio spectrum are not utilized does not imply that an attractive business case for the remaining unused parts exists. A simple example can clarify this. A mobile operator will have more radio spectrum is use than in rural areas. The fact that in rural areas mobile spectrum is underutilized does not necessarily mean that there is a viable business case for these unused mobile frequency channels, at least not for mobile communications. The business case for the exploitation of these white spaces will have to be distinctively different from the business case of the conventional user.

In the white space access regimes, the CR devices will always have to respect the needs of the primary user. White space access is only possible as long as there is no need for the spectrum by the primary user and no interference is created to the primary user. This sets limitations to the business case for unlicensed white space access with an unrestricted number of devices. There will never be a guarantee that a CR device can have access to a white space and there is always the possibility that a CR device has to cease its operation because a primary user wants access to the spectrum. This makes this regulatory regime less suitable for time critical CR applications.

White space access can be used to share bands between licensed users and unlicensed short-range devices in bands that were difficult in the classic scenario. A good example of this is the use of the 5 GHz band. In this case, RLANs uses CR technology to sense its radio environment, i.e., to detect and avoid incumbent radar systems.

Licensed owners of spectrum can also grant access to parts of their radio spectrum that they do not need in a certain geographic area and/or for a certain period of time to secondary devices on a non-exclusive (unlicensed) basis. These devices can get access to this spectrum after an explicit request for permission to the owner of the spectrum. The owner will need a mechanism to facilitate requests from secondary devices for permission to use spectrum. Cellular operators can use their existing infrastructure to handle these requests. For example, a mobile operator can set aside a mobile channel for this purpose.

An incentive for licensees to open "its" white spaces might be to introduce easements in spectrum licenses. In other words, if a spectrum owner is in possession of radio spectrum that (s)he actually does not use, everybody is entitled to use this spectrum in an opportunistic way as long as the transmissions of the rightful owner are not subject to interference from this opportunistic spectrum access. This is an incentive which might prevent market players from hoarding spectrum [2].

Licensing of white space devices provides the possibility to restrict access to the white spaces to a specific user group. Since the secondary users are now known, this provides the possibility for active coordination between the incumbent user and the secondary (cognitive) user about the likelihood of interference and on guarantees about access to spectrum. Restricted access may also increase the level of trust for the incumbent user and may make them more willing to share their white spaces with a known and trusted CR user.

This licensed form of white space access has become known as Licensed Shared Access (LSA). LSA is a regulatory approach that focuses on facilitating a more

efficient use of spectrum in frequency bands assigned to one or more incumbent users by introducing additional licensed users on a shared basis allowing predictable quality of service for all rights holders [17].

An example of a service that needs guaranteed access to spectrum but only in a very local area and for a short period of time is public safety. Public safety organizations have their own network for day-to-day operations. However, during an emergency situation, they have a huge demand for communications on the spot [15]. A public safety organization might make an agreement to alleviate their urgent local needs with other frequency users. In the agreement sharing arrangements are covered but the actual spectrum usage can be based on the local conditions and the local use of the primary user.

A good opportunity to start this form of sharing is in bands of the military. The military already have a long-standing practice of cooperation with public safety organizations. This may raise the level of trust to a level that is high enough to start an experiment.

Spectrum Pooling

In case spectrum is pooled between a number of users or user groups, CR technology is used to dynamically share the spectrum resources. In a licensed regime, dynamic access to spectrum is obtained through buying, leasing, or renting access rights from the owners of the spectrum. This regime provides the possibility for active coordination between the incumbent user and the cognitive user about the likelihood of interference and on guarantees about access to spectrum. If the barriers to instant trading are removed, the opportunity to buy and sell rights to access spectrum can be based on the actual demand for spectrum. This creates the opportunity to use dynamic spectrum access for higher valued service offerings, such as mobile telephony, and for a spot market to be introduced. A spot market is a perfect means to acquire or sell rights to spectrum access based on the actual demand at any given moment in time.

A spot market can be used among operators to pool the spectrum in such a way that the rights to spectrum access are based on the actual demand for spectrum by their respective users. One of the suggested implementation scenarios is that mobile operators use a part of their spectrum to provide the basic services to their respective customers and pool the rest of their spectrum to facilitate temporarily high demands for spectrum. However, cooperation between mobile operators that are in direct competition to each other is not likely to happen [4].

This kind of sharing spectrum might be a more viable option for implementation in border areas to ease the problem of border coordination. Nowadays the use of spectrum in border areas is based on an equal split of the use of spectrum between neighboring countries through the definition of preferential rights. However, there is no relationship with the actual demand for spectrum at either side of the border. A prerequisite is that the spectrum market is introduced at both sides of the border or in a region, e.g., the European Union.

Pooling spectrum between different services that are not in direct competition to each other might be a more promising approach. This can help to make licensed

spectrum that is not fully used available to others users. In this case access to spectrum is based on an negotiable acceptable level of interference, instead of the worst case scenarios based on harmful interference that are used by regulators to introduce a new service in an already used band. This may open bands for alternative use which might otherwise be kept closed. The incumbent licensee may now have an incentive to open its spectrum for other, secondary, users. The incumbent licensee is in full control because it can earn money with unused spectrum, while the access to its spectrum of the secondary user is on the incumbents own conditions.

A spectrum market can only function if information about the actual ownership of the spectrum property rights is readily available to facilitate trading. The regulator is ideally positioned to perform the task to keep a record of the ownership of these rights. Inclusion of monitoring information about actual usage of spectrum can further facilitate trading by giving more insights in the possibilities for secondary usage.

A special case of licensed spectrum pooling is pooling whereby a single operator who is the exclusive owner of the spectrum uses cognitive radiotechnology to perform a flexible redistribution of resources among different radio access technologies within its own licensed frequency bands to maximize the overall traffic by an optimum use of spatial and temporal variations of the demand. This could be used by mobile operators to realize a flexible spectrum allocation to the various radio access technologies in use or to have an optimal distribution of spectrum between the different hierarchical layers of the network, for example, to realize an optimal allocation of spectrum to femto cells that takes account of the actual user demand without affecting the macro network. A prime requisite for such a scenario is that the license from the operator is flexible enough and technology neutral.

CR technology can also be used to pool spectrum between unlicensed applications. Knowledge of the radio environment is in this case used to realize a fair distribution of access to spectrum between an undefined number of devices.

A very promising application for a true commons whereby unlicensed devices dynamically pool their spectrum is in-house networking. An in-house network is an ad hoc network by its very nature. No two in-house networks are exactly alike and devices are turned on and off during the day, new devices are brought in, devices leave the house, and the neighboring houses have the same ad hoc way of working. The number of wireless devices in a household is rising while the users want to have new equipment that is "plug and play." A new device that is put into service should be able to find its own possibilities to communicate within the in-house network.

A second example of ad hoc networking is the radio network between vehicles as part of intelligent transportation systems (ITS). Restricting access to the pool for certain applications with a polite cognitive protocol may alleviate the tragedy of the commons. In that case, the number of devices outnumbers the available spectrum in such amount that the spectrum is of no use to all. However, even if a polite cognitive protocol is used and the band is restricted to a certain type of applications, the amount of spectrum that is made available must be enough to cater for the intended business case.

Table 2 Impact of the regulatory regime for spectrum access on the business case for CR applications

	Horizontal sharing (Spectrum pooling)	Vertical sharing (white space access)
Unlicensed acces (spectrum commons)	• Sharing between an undefined number of devices	
	Fair distribution of spectrum access between the devices	No guarantees for spectrum access, i.e., less suitable for time critical applications
Licensed access	• Restricted group of users • Increased level of trust • More certainty about access to spectrum • Better suited for infrastructure based service offerings	
	CR user groups not in direct competition with each other	Possibility for active coordination. More guarantees for spectrum access

Impact Assessment of Spectrum Access on the Business Case

The regulatory regime has a huge impact on the business case for cognitive radio. Each regulatory regime will facilitate a different kind of CR applications and/or service offerings. A mixture of these regimes will be necessary to unlock the full potential of CR technology in increased spectrum efficiency. The impact on the business case of the regulatory regime under which the CR application will operate is summarized in Table 2.

Especially the use of CR technology for a restricted group of users can help to bring this technology further for two reasons. First, restricting access to a controlled group may increase the level of trust between the users who share the spectrum. Second, restricted access can provide certainty about access to spectrum over a longer period of time needed to recover the investments to be made in CR technology.

The Impact of Cognitive Radio Capabilities on the Business Case

The fundamental difference between a cognitive radio and a conventional radio is that a cognitive radio uses information of the radio environment to select and deploy the most appropriate communications profile, such as frequency band, access technique, and modulation method. There are various techniques possible to obtain information about the radio environment. Each of them will have different implications for potential CR applications and the magnitude of the required investments.

Sensing

In its basic form a cognitive radio senses the radio environment to acquire information on the local usage. The CR device relies thereby on its own judgment of the local use of the spectrum to transmit over sections of the spectrum that are considered free. No matter how good the sensing technology is, a system that only relies on its own judgment to obtain information about spectrum usage might come in a situation where it inadvertently is not able to detect usage of a radio channel. This means that with a cognitive radio based on sensing alone, there is always the possibility of interference to the conventional users of the band. To limit this risk, restrictions on the output power of the CR devices will have to be set. As a consequence, the CR can only be used for applications which use low power in relation to the incumbent usage.

Sensing can be used without the need for coordination with the "outside world." Sensing can be used by stand-alone applications, whereby there is no need for investments in the rollout of associated infrastructure. However, there is always the possibility that the device is not able to detect a white space. Hence, dynamic spectrum access based on sensing is expected to be restricted to low-end applications involving low power devices.

Sensing is also of interest to military users. Since the radio only relies on its own judgement, it makes it possible to communicate without making the whereabouts and communication needs of the military radios known to others. This will make their communications less vulnerable.

The probability of finding a white space that can be utilized depends on the activities of the incumbent user(s), the range of frequencies which is sensed, and the number of active white space devices. Sensing will have to take place over a sufficiently large frequency range to support the capacity needed by the CR application. Sensing becomes more challenging, and more expensive, when a wider range of frequencies and/or a wider range of conventional user applications are to be taken into account. At the current state of technology and field experience on sensing, a case-by-case approach will be required which takes into consideration the existing spectrum usage. Hence, for new CR regulations to be meaningfully applied, i.e., before making available a band for white space devices, an assessment should be made of the amount of white spaces that can be made available against the capacity needed for the introduction of the application that uses these white spaces.

A possibility to ease the problem of the (un)reliability of sensing is to focus sensing in a band that is not too wide in a completely unlicensed environment to create a true commons for short-range devices. The regulator should pinpoint a band for dynamic spectrum access in cooperation with industry. To reach economies of scale, this band could be designated on a regional level, for example, on a European level.

An obvious example is the earlier mentioned in-house network. Sensing can be used to realize that devices pool the spectrum available for in-house network in a "plug and play" manner. A new device senses its environment and coordinates its use within the local in-house network. A possible band to start is, e.g., the 60 GHz band.

Sensing can be made more reliable by cooperation between the sensing devices [12]. Cooperation can improve the probability of detection and reduces the detection time and thus increase the overall agility of the system. Drawbacks are the need for a common signaling channel between the devices and the additional overhead needed to exchange sensing information over this channel.

Especially the need for a signaling channel makes this coordinated approach complex. The cognitive devices become part of a network. This makes this coordinated approach especially feasible in applications where the CR device is already part of a (local) network, e.g., in-house networks. Coordination is a less attractive option for stand-alone CR applications.

Another possibility is to use sensing in a more controlled environment between licensed users. This will give more control over the environment, because the users are known. This type of sharing could be used to broaden the amount of accessible spectrum for temporarily users who need a guaranteed quality of service. This makes this type of sharing a perfect fit for, e.g., electronic news gathering and other programme making and special events services. Electronic news gathering only requires spectrum for short periods of time and for a restricted local area, but it requires guaranteed access during the operation.

Geolocation Database

Since sensing is in its present form is not reliable enough, regulators around the world have turned their focus from sensing toward a geolocation database. This will require investments in a database and related infrastructure that need to be recouped. Entrepreneurs will only invest in this infrastructure if there is long-term assurance for access to spectrum and willingness to pay from customers. This shifts the orientation from a device centric approach to a service centric approach. Such a business case is better supported by a regulatory regime based on licensed access.

The database should contain the relevant information on the frequencies that can be used at a certain location as well as the applicable restrictions. The database will have to be kept up to date, which makes this option especially suitable in cases where spectrum usage of the conventional user(s) does not change frequently, e.g., in a broadcasting band or a band for fixed satellite communications.

The restrictions for the CR application imposed by the use of a geolocation database are twofold. First of all, the CR device needs to be (made) aware of its geographical location. This information can be programmed in the device during the installation of the CR device for fixed applications. Mobile CR devices will need a means to acquire that information, for instance, by incorporating radio navigation in the terminal. However, the use of radio navigation will be difficult for indoor applications.

Secondly, the CR device will need to have access to this database on a regular basis. Access to the database is easier to arrange if the CR device is already part of a network than for stand-alone CR applications. The rate at which the CR devices have to obtain updated information on the local radio environment depends on the

rate at which the information on the incumbent user may change and on the degree of mobility of the CR device.

The use of a geolocation database is proposed to enable mobile broadband communications in the 2300–2400 MHz band. Licensed Shared Access based on a geolocation database is the recognized approach in Europe for the introduction of mobile communications in the band while maintaining the current incumbent use. Among the incumbent users to protect are programme making and special events (PMSE) applications (wireless video camera's). Although the concept of LSA with a geolocation database was originally developed for the introduction of mobile communications in the band, it could also be used to enhance efficient use of the band by the wireless camera's themselves. In the latter case, the database is used to electronically assign a license to a wireless camera, but only for the time duration and the location it is actually needed.

Cognitive Pilot Channel

Coordination between CR devices can be realized through a so-called cognitive pilot channel (CPC). A CPC is a dedicated carrier providing information about the availability of spectrum and possibly usage restrictions to the CR devices in a certain area. The CPC can be used to (1) give general –local– information on the availability of white spaces in relation to the service to be protected or (2) to coordinate the use of the spectrum resources by the CR devices competing for spectrum access or (3) a combination of both [4, 5].

The first option requires that the CPC broadcasts information on channels that are available and possibly the associated use restrictions, unless these restrictions are already known beforehand by the CR device. The second option is more complex because there is also a need for the network to know which channels are actually used by the CR devices, and therefore there is a need for a feedback channel.

Implementation of a CPC will require a radio-infrastructure to support the CPC. The CPC can be provided by a dedicated, autonomous network, but this will require substantial investments. The necessary investments can be lowered if the CPC uses a logical channel within an existing network, e.g., within a mobile network.

Because a CPC can provide real-time information, a CPC is highly suitable in cases where spectrum usage of the user(s) with which the band has to be shared is more dynamic. In this case, the network will need to have up-to-date information of the spectrum usage of all user(s) at all times.

Impact Assessment of CR Technology on the Business Case

The means a CR uses to acquire information on the radio environment has a significant impact on the business case for CR applications. An outline of the main conclusions of the impact of the CR technology on the CR application, and thereby on restrictions for a viable business case, is given in Table 3.

Table 3 The impact of the CR technology on the CR application

	Implication to potential CR applications	Remarks
Sensing	Low power in relation to the primary user Sensing over a relatively small band sets limits to the data transfer capacity available. Wide band sensing increases the capacity available, but is more complex and expensive. Can be used for stand-alone applications	There remains a potential for interference to the conventional user.
Geolocation database	Can be used for applications which need a higher power. The location of the CR device needs to be known. Application needs a connection to the database on a regular basis	Only useful in bands with relatively static conventional users Costs of database service will have to be recovered
Cognitive pilot channel	Can be used for applications which need a higher power. Need for a radio-infrastructure to support the CPC. Large-scale deployment more expensive than a database	Can also be used in case conventional use varies

An apparent difference between sensing on the one hand and a geolocation database or Cognitive Pilot Channel on the other hand is that the latter two will require investments in infrastructure. This means that sensing can be used for stand-alone applications, while the other options are better suited for the delivery of services with an associated infrastructure rollout, i.e., sensing can be used in a business case based on the sales of equipment, whereas the database and CPC are better suited for a service provider-driven business case based on the sales of a service. In that case, there will be a direct relationship between the service provider and the customer. This relationship is necessary to recoup the investments in infrastructure.

Of course, it is always possible to use a combination of techniques. Especially a combination of database access and sensing seems promising. The database can be used to protect existing services with which the band is shared, and sensing can be used to assess whether the opportunity is really available or already in use by another CR device.

Another possibility is the use of a local CPC (or so-called beacon) to reduce some of the drawbacks of sensing, especially the complexity and associated costs of sensing devices. A relatively complex master device can be used to process the sensing results of a range of locally connected devices. The master device decides

based on this information on what channel the connected devices may operate and sends this information to these devices over a local beacon. This solution can only be used if these devices form a local network. The relatively expensive master device acts as an intelligent central node for the relatively cheap connected devices. A good example is a local area network, whereby the router can serve as a master to provide information to the wireless devices that are active in the network. This configuration provides possibilities to open bands for additional use that were closed otherwise, such as the earlier mentioned 5 GHz band.

Two Levels of Alignment

While alignment between new technologies, such as CR, and the associated regulations is an important prerequisite, it is not enough to assure a successful introduction of this new technology. There are numerous examples on the introduction of new technologies where the necessary alignment between the technology and the regulations was in place but the market for the provisioning of products and services based on this new technology did not mature.

Our analysis of the underlying causes is that firms will only decide to invest in new products and/or services if they can expect a future return. These investment decisions are driven by three major considerations: (1) the prospective demand and willingness to pay for new products and/or services, (2) the magnitude of the investments required, and (3) the degree of risk or uncertainty involved.

The profile of the business case, in terms of depth of investment and the recovery period required, will influence the ability to obtain the necessary (external) funding. As such the business case is especially challenging for service provisioning that requires a huge, up-front investment, e.g., an infrastructure rollout to provide mobile telephony. In these cases, the right to exploit the radio spectrum or any other infrastructure over a significant period of time and on an exclusive basis will contribute to the willingness of firms to invest as it reduces the uncertainty, which may make the business case more viable [11].

Although the regulator can't do much about technological and market uncertainties as such, the regulator plays a crucial role. The regulator should create a regulatory environment in which these uncertainties are lowered to an acceptable level for commercial applications to emerge. This environment should, among other things, give clear directions on the expectations of CR technology [1].

However, in setting up institutional arrangements, governments will steer technology and possible business cases in a certain direction. Ostrom [14] showed that the specificities of the entry and authority rules will favor certain types of usage over other types of use. This is also true the other way around; certain types of perceived usage will require particular entries and authority rules. Although Ostrom made this observation in the investigation of common pool resources, the problems associated to the provisioning of telecommunication services are quite similar as shown by Künneke and Finger [9]. They argue that infrastructures (including energy,

communication, transport, and postal services) can be perceived as common pool resources providing essential services to society.

Hence, decisions made by governments on the market design and associated regulations will have an influence on the viability of possible business cases. For example, decisions made in spectrum policy on the amount of spectrum allocated, whether the spectrum is made available on a license exempt basis or not, the number of licenses issued, the rollout and other obligations attached to the licenses, and the award mechanism for the licenses (e.g., an auction or a beauty contest), will all influence the required investments and the possibilities to exploit a certain business case. This is quite well demonstrated by mobile communications (GSM) which could flourish under a strict licensing regime and Wi-Fi that could develop under a license exempt regime.

Governments will need to be very well informed to make the right decision in order to let the intended business case flourish. Lessons learned from the past seem to suggest that a too "pushy" approach from governments may be counterproductive and retard or stall technological development [8]. Governments will need to take decisions that are not only in line with their own goal(s) but also make it possible for entrepreneurs to realize their goals. After all, it is through the actions of the firms, individually and collectively, that the governmental goals will be realized. This is illustrated in Fig. 1 [3].

The government and the entrepreneurial firm have different objectives, in a somewhat simplistic view of the world, since the liberalization governments have, above all, an objective of economic efficient use of spectrum. This is accompanied

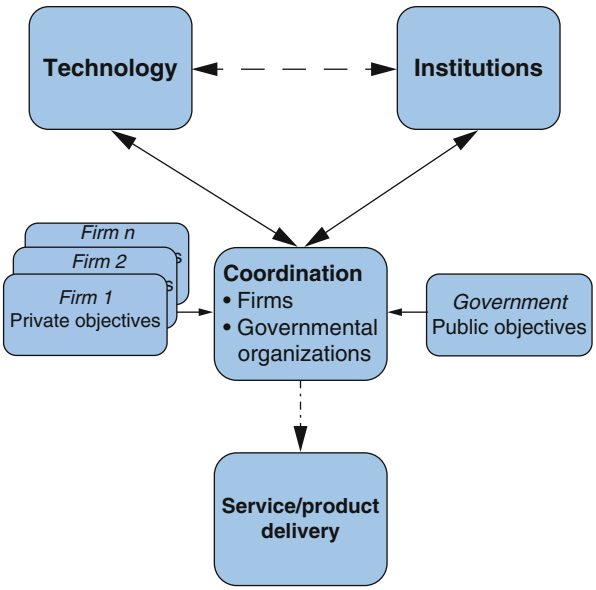

Fig. 1 Two levels of alignment

by societal objectives, such as universal service delivery, and in some cases also by industry policy. Governments rely on a market design and associated regulations to serve this mixture of economic and societal objectives. In the case of mobile communications, radio spectrum policy is used to create a market for mobile telephony. Specific auction rules may be used to allow new entrants and to influence the number of players on the market. Specific obligations are attached to the licenses to serve societal objectives, e.g., a coverage obligation.

Firms, on the other hand, have a completely different objective. They want to invest in (new) technology to develop products and services with the aim to maximize profit. The government and the firm are highly interdependent in the realization of their objectives. The institutional arrangements that are set up will have to provide certainty to entrepreneurial firms to invest in new technology and the exploitation thereof. If, as a result of profit maximization considerations, firms decide not to use the system as intended, the government fails in realizing its governance objectives.

Use of the new technology in such a way that both the government and the entrepreneurs can realize their objectives is what we call a "sweet spot." A sweet spot is only possible if the use of certain technology and the associated institutional arrangements are aligned in such a way that both the intended business opportunity and the public objectives can be realized [3].

Analyzing the Case of White Space Access in the Television Broadcasting Band

Having established this actor-centric perspective, we will now apply this perspective to a case of which its resolution lies in the future. It concerns one of the first applications for CR that was put forward: the introduction of cognitive radiotechnology in the so-called white spaces in TV bands. The US Federal Communication Commission (FCC) made these white spaces available for unlicensed broadband Internet. Its intended use is, above all, to provide more affordable broadband deployment in rural areas [6, 7].

In this case CR technology is intended to share the TV band with the legitimate primary users, the TV broadcasting stations, and low power auxiliary service stations (notably wireless microphones). Given the latter, it is understandable that the FCC removed sensing from the original requirements and took alternative measures to guarantee access to spectrum for wireless microphones and to prevent wireless microphones from being subjected to interference from CR devices. First of all, at the current state of technology, sensing is not sufficiently reliable. More importantly, to prevent interference to the primary user, the output power of the CR device should be low relative to the primary users (see section "Sensing"). These primary users are not only TV broadcasting stations but also these low power wireless microphones. Restriction of the output power of CR devices to a level that is low compared to the wireless microphones would have been detrimental for the business case of rural broadband access.

In taking the perspective of the private actor, the first question to be asked is as follows: Why is there no service provided at the moment? There certainly is no scarcity of radio spectrum; the 2G/3G bands are underutilized in these rural areas. The main reason appears to be that the costs to provide the service are too high in relation to the willingness to pay for the provided service.

The second question to be asked is as follows: How will the business case for CR improve the situation? For the business case to become viable, either the willingness to pay for the CR enabled services has to become higher or the cost reduction needs to be greater than the additional costs associated with the new (more capable and sophisticated) cognitive technology. Combined they need to bridge the gap between the provision of services based on the current technology and the current willingness to pay.

Under the FCC white space ruling, rural broadband access is made more feasible due to the fact that a lower frequency range is made available, which extends the coverage area of a base station, compared to the existing alternatives to provide the service. However, existing mobile networks operate at frequencies that are just above the television band. This means that the gains of using a lower frequency are very limited. (As the use of white spaces is considered to be free of charge, this represents a benefit compared to the business case for existing 2G/3G deployments, which may be subject to the recovery of a hefty auction fee. However, in serving the rural areas, economists will consider the auction fee as sunk costs and will calculate the business case on marginal costs.) Therefore, the business case for deployment of a wide area network in rural areas based on white space access remains highly questionable. It is much more likely that white space access will be used to provide localized access to the Internet at specific backbone nodes. This is a business case that is comparable to Wi-Fi hot space access, although over larger distances.

The next question is whether the capacity that can be supported by white space access is high enough to support the demand from users. In areas where the required demand for capacity is bigger, the coverage area of the base station may have to be made smaller. This conflicts with the reasoning to make these lower frequencies available. This means that the business case will be restricted to areas with a population density below a certain limit. This limit will be lower if the demand per customer is higher. It remains to be seen whether the assigned band will have enough white space capacity available for the intended application – broadband Internet access – to support a successful business case. Moreover, the already limited capacity that is available for white space access is under pressure, because the FCC decided in 2012 to auction off part of the TV band (the so-called 600 MHz band) for use by public mobile operators, based on a preceding incentive auction for TV licensees to give up their licenses. This limits the available white space capacity even further.

The final question is if there are private actors that are willing to provide the intended business case. When the FCC proposed to make use of a geolocation database instead of relying on sensing, a shift was made from a device-oriented business case toward a business case where there is a need to invest in infrastructure to build the database and to provide access to this database. However, the FCC

retained the institutional setting of unlicensed access to white spaces. Given the fact that there is limited capacity available and there are no guarantees to spectrum access in an unlicensed access regime will reduce incentives for private actors to invest in the infrastructure. This would explain why the intended service providers are relatively absent in the standardization activities and other discussions around white space access in the UHF TV band and why the number of TV white space devices deployed is still limited although the FCC has allowed access to TV white space since February 2009 and a commercial service offering was made possible after the FCC permitted white space database administration to provide the necessary database services. In the Third Memorandum Opinion and Order of 2012, the FCC made some changes to the rules mainly to lower the cost for WISPs to provide broadband access in rural areas. However, the white spaces do not seem to attract WISPs to provide their service in rural areas. Moreover, in this institutional setting ,it is also not very clear what the business model for commercial operation of the database should be.

To conclude, the white space access regulations appear to be a technological fit instead of a business case fit, driven by the regulator to realize a societal objective. The FCC took a very careful step by step approach to implement regulations that are aligned with the current state of technology. However, whether there is alignment between the public objective of the FCC to provide broadband access in rural areas with the objectives of the private actors remains to be seen. It is highly questionable whether the intended social objective will materialize in a viable business opportunity to provide wireless broadband access in rural areas and for the exploitation of the associated database.. It would explain why the intended service providers are relatively absent in the standardization activities and other discussions around white space access in the TV band. Moreover, it may explain why there is, as yet, no viable business model for the commercial operation of a database in support of sharing the spectrum with wireless microphones.

Next Steps: Finding a Sweet Spot for Cognitive Radio

Although there are possibilities to use cognitive radio under the current radio spectrum management regime, there is still no compelling business case. To assure development and deployment of CR technologies, it is worthwhile to review potential product-market combinations where CR functionality provides a “value add” and determine whether these cases are attractive enough to be taken up by the industry as first applications of CR, as first steps on the road toward broader deployment of CR technologies.

The government can facilitate this process through the initiation of a platform in which the equipment industry, the service providers, and the government itself closely cooperate with the aim to find a sweet spot. This sweet spot serves as a catalyst to both the private sector and the government, for the private sector to develop products and services based on cognitive technology and for the government to realize the ultimate goal of more efficient use of spectrum.

The RSPG (Radio Spectrum Policy Group) has already recommended creating a platform to allow researchers, academia, manufacturers, operators, service providers, and regulators to coordinate research activities. According to the RSPG, this platform could build upon already existing platforms with comparable purposes, notably COST-TERRA [16]. This notion of the RSPG on COST-TERRA is quite relevant. The discussions within COST-TERRA were very fruitful, but were rather academic in nature.

As the discussion within COST-TERRA were too academic, discussions will benefit from a new extended platform that serves as a community of practice that involves all stakeholders. In order to do so, participation should be widened in two directions. Firstly, participation should be extended to service providers and users of spectrum. This may strengthen the discussions on the incentives for primary users and possible business cases for the primary and secondary users. Secondly, participation should be widened to industry players to incorporate the ideas and solutions in the development of new technology and technology standards.

In this platform, all participants should work together with the national spectrum regulators to find and enable a sweet spot. A sweet spot needs a fit between a specific CR technology, an initial business opportunity and an associated regulatory regime. The regulators can enable this sweet spot on a European level by specifying the necessary and specific regulatory regime in a European decision and/or European recommendation.

This requires participation at the working level. Intended participation is largely the same as those of the workshops that were organized by ERO, the national spectrum regulators as organized within the ECC, in association with COST-TERRA, and the industry actors as organized within ETSI.

There is already some experience with a community of practice related to CR in the Netherlands (CRplatform.NL). This community of practice aims to identify the uncertainties surrounding potential deployment areas of CR and through discussion among stakeholders to find ways and means of addressing and reducing these uncertainties, thereby facilitating the successful deployment of CR-based products and services. This initiative evolved from the regular interaction between representatives of the Ministry of Economic Affairs, responsible for radio spectrum policy and the industry.

The platform organizes meetings and workshops and has a repository on the Internet with information considered useful for the participants. The main focus of the workshops is to explore potential application areas of cognitive radio, so-called use cases. Some of the workshops are dedicated to the state of the art of the technology and to the theoretical framing of sharing spectrum through cognitive radiotechnology. Each workshop brought together potential users, industry, service providers, policy makers, and regulators, as well as academic researchers.

The workshops on the use cases take the perspective of the user itself. The use case is introduced by the case owner. A presentation is given of the use case centered around the communication needs. The discussion that follows is centered around solutions to these communication needs and the question whether the use of cognitive radio has added value. The following application areas have been among

the topics of a use case workshop during the first two years: container terminals in the Rotterdam harbor; special events captured by broadcasting organizations; public safety communications by the police force; high-intensity communications at airports; and domotica. Moreover, manufacturers of cognitive radio and related shared access products and technology have had an opportunity to present their solutions, such as hybrid radio, professional wireless audio equipment, and high-density Wi-Fi solutions.

In these explorations, one of the first questions to be asked is what are the gains from the use of this new technology, and are these gains high enough to cover the increased cost of the use of this technology compared to the alternatives? The use cases as discussed suggest that cognitive radio functionality adds most value in situations that are typically niche applications or are a small segment of the overall market for wireless technologies. One of the reasons is the fact that cognitive radiotechnology is basically a technology to (more efficiently) share the radio spectrum. As cognitive radio provides additional functionality compared to current radiotechnology, this will come at increased costs, at least initially. Situations of high-intensity demand are expected to provide the highest willingness to pay by the end users.

Each use case discussed so far addressed a specific market segment, or even a market niche. Hence, potential market volumes are (relatively) low to moderate, which impacts the viability of the cognitive radio business case. Nonetheless, the use cases also show similarities, in particular if cognitive radio-based solutions are considered as variants of a more generic cognitive radio-platform solution. Especially the combined business case of the communication needs of the public safety services in case of an emergency and the registration of this emergency and other news gathering seems to be logical and promising. This became apparent during the Use Case Workshop on Special Events, as during (ad hoc) events, the needs of public safety and broadcasting converge at the same place and time. The type of communication needs to show a strong parallel. Hence, pursuing solutions for one group of actors (broadcasters) should best be done cognizant of the needs of the other group of actors (public safety).

This example shows that finding a sweet spot for cognitive radio might be easier if the solutions for one group are similar to the solutions for the other group, at least on the platform level. This increases the addressable market and hence the viability of the business case. The unresolved issue is the capacity issue. How much capacity is available for cognitive radio use and is there enough capacity available to support the (combined) business case?

The use cases further show that a viable business case for cognitive radio will require economies of scale. This extends the need for coordination to the European Union level, if not at the global level. Such coordination may still be left to be organized by the industry actors. However, the use case experience suggests that lacking a very compelling business case, the likelihood that industry actors will take the lead is expected to be low. This ties in with the fact that discussions within the community of practice confirmed the role of the regulator to facilitate this search for a sweet spot [3].

Conclusions and Recommendations

For successful introduction of cognitive radio, it is necessary but not enough to align the specific CR technology with the regulatory environment that is chosen. Next to it, the business opportunities that are enabled by specific choices should serve the objectives of both the entrepreneur and the government. In other words, the regulations and the technology should be carefully chosen such that both the private objectives of the entrepreneur and the public objectives can be realized.

Exploring use cases can be a good instrument to bring all interested parties together and to find and enable a "sweet spot" for the use of new technology in an explorative modus. A sweet spot is enabled if the institutional arrangements and the characteristics of the new technology are aligned in such a way that both the intended business opportunity and the public objectives can be realized.

This exploration can take place in a community of practice. An initial exploration of possible business cases revealed that the type of CR technology to be used and the appropriate regulatory regime to support it depend on the specifics of the intended business case and the specifics of the users with which the bands will be shared. When a viable combination is found, the spectrum regulator should set up the specific regulations to facilitate the CR deployment and thereby make an important step toward a more efficient utilization of the radio spectrum.

It is recommended to introduce this community of practice for cognitive radio on a European level. Such a community could make use of, and build upon, the experiences of COST-TERRA. In order to encompass all interested stakeholders, this platform should be broader than the COST-TERRA participation. It should include representatives of service providers, user communities, industry players, academia, and national regulators.

Spectrum Sharing Policy at Global Level

48

Marja Matinmikko and Miia Mustonen

Contents

Abstract

Spectrum sharing developments exploiting cognitive radio technology will change the traditional spectrum management models, which calls for discussions and decisions in the policy making domain. Efficient governance of natural resources such as the radio spectrum requires actions in different policy making levels ranging from national level all the way to the international level. This chapter will introduce spectrum sharing related policy making activities in the

global level presenting the actions taken at the International Telecommunication Union Radiocommunication (ITU-R) sector. We will introduce the groups within ITU-R and their related activities and introduce cognitive radio and spectrum sharing related terminology developed at the ITU-R. Special emphasis is put to the ITU-R studies on cognitive radio systems (CRS) with a set of capabilities for obtaining knowledge, decision-making and adjustment, and learning, to enhance the efficiency of spectrum use. We will introduce the CRS capabilities and present scenarios and applications where vertical and horizontal spectrum sharing using CRS capabilities could take place. Other sharing related activities at the ITU-R are also presented including spectrum management, spectrum monitoring and spectrum occupancy measurement studies, as well as more general ongoing work on regulatory tools to enable spectrum sharing and CRS from the point view of spectrum management. Finally, a future outlook is given for spectrum sharing policy developments toward the fifth generation (5G) networks.

Introduction

Research community has made extensive studies on cognitive radio techniques for spectrum sharing to enable several radio systems to operate in the same frequency band on a shared basis. In the early cognitive radio research studies, the focus was on technical approaches to detect users with higher priority of spectrum access rights by using spectrum sensing techniques [1] and to select operational channels according to some optimization criteria such as interference minimization and throughput maximization [2]. While the early studies on cognitive radio work were about new spectrum management techniques, the link between the cognitive radio techniques developed in the research domain and the actual spectrum management principles adopted in the spectrum regulatory domain remained loose. Thus, the criteria for the development of cognitive radio techniques in the research domain did not thoroughly address the real requirements set for spectrum policy by the regulators and the concerns of involved stakeholders in terms of, e.g., interference issues.

As the term "cognitive radio" very rapidly became commonly used in the research domain in the beginning of the century with various definitions and interpretations, there was a need for a global spectrum policy making body to give guidance on the definition itself and the evolution of the entire cognitive radio topic. While spectrum management and development of spectrum sharing methods and models are a national matter, decided by the local regulatory authorities in the regulatory domain, there is a strong need for coordination between neighboring countries and for harmonization to achieve economies of scale. Therefore, regional and international levels need to develop and promote feasible solutions with potential for widespread adoption. The United Nations based International Telecommunication Union Radiocommunication (ITU-R) sector [3–5] plays the key role in spectrum policy making as the truly global body where relevant stakeholders are represented to take decisions on spectrum matters. ITU-R conducts studies on technical and

spectrum management aspects and provides a global forum for discussions and disseminating best practices [3–5].

Since the cognitive radio topics studied and developed in the research domain introduced a novel way of spectrum sharing and coexistence using technical advances to detect other spectrum users and to coordinate interference between different wireless systems in a more dynamic way, there was a need to investigate at the ITU-R whether changes are required in the traditional spectrum management and allocation principles due to the introduction of the cognitive radio concept. This process resulted in a number of studies conducted at the ITU-R and outputs published in several ITU-R documents.

This chapter will discuss cognitive radio and the related spectrum sharing policy activities at the global level by introducing the relevant activities at the ITU-R and their link to the research domain. By starting with the basic requirements for efficient governance models for natural resources, spectrum sharing related governance principles are first discussed in a high level. Then, the different groups at the ITU-R with activities on cognitive radio and spectrum sharing topics are then summarized including their activities around spectrum sharing and especially cognitive radio systems (CRS) as called by the ITU-R. Finally, a future outlook for the spectrum sharing policy developments are given depicting directions for 5G.

Spectrum Sharing in Governance Framework

Management of the radio spectrum belongs to the broader framework of governance of natural resources that have been extensively studied in many fields [6]. The development of effective governance mechanisms is at the heart of managing the precious resources. Efficient management of natural resources requires governance models at different levels ranging from the local level all the way to the global level [6]. Management of the radio spectrum is about defining bundles of property rights over the radio spectrum, and spectrum sharing introduces new bundles of rights that vary with the sharing model [7]. More specifically, the radio spectrum can be seen as a common pool resource (CPR) that is characterized by difficulty to exclude and high subtractability of use [7]. Difficulty to exclude refers to how complicated it is to prevent others from using the same resource. Subtractability of use indicates whether one person's use of the resources diminishes someone else's ability to use the same resources which takes place in the case of the radio spectrum. The guidelines from the management of CPR can provide useful insight into the development of spectrum management and particularly spectrum sharing models.

General principles for robust governance of environmental resources introduce several requirements including providing information, dealing with conflict, inducing rule compliance, providing infrastructure, and being prepared for change [6]. Promising strategies to meet these requirements include dialogue among interested parties; layered institutions including a mix of institutional types; and designs that facilitate experimentation, learning, and change and rules that evolve [6]. Best governance systems in fact are polycentric indicating that there are several points

of decision-making control that may partially overlap in scope and hierarchy and interact with each other in complex ways that evolve over time [7].

In terms of management of the radio spectrum and particularly introducing dynamic spectrum sharing, *efficient governance highlights the different levels of governance* for providing information, dealing with conflict, inducing rule compliance, and providing infrastructure and readiness for change. Different radio systems that want to use spectrum such as broadcasting, mobile communications, satellite, and fixed and the specific systems within these services need to be coordinated by mechanisms at various levels to manage the complicated interference scenarios. Thus, spectrum policy discussion and spectrum sharing related activities take place at several levels in the policy making. While the actual awarding of spectrum access rights is done at the national level, spectrum sharing related developments exploiting cognitive radio technologies need international-level activities. In the following, we will focus on the global level for spectrum sharing by presenting spectrum sharing developments within the spectrum governance framework at the international level.

Role of ITU-R

For spectrum sharing policy making at the global level, the ITU-R plays the key role in the governance framework regarding the global harmonization on spectrum matters. The role of ITU-R is "to ensure the rational, equitable, efficient and economical use of the radio-frequency spectrum by all radiocommunication services, including those using satellite orbits, and to carry out studies and approve Recommendations on radiocommunication matters" [5]. The activities taken at the ITU-R aim at providing an environment that enables the sustainable development of radio communications. In practice, this means ensuring interference-free operation of the different radio applications to guarantee quality and reliability of services, harmonization of frequency usage, promotion of new technologies while protecting existing users, and ensuring efficient spectrum utilization. One particularly important part of the ITU-R work is to create conditions for harmonized development and efficient operation of existing and new systems while taking into account the different stakeholders' often conflicting concerns. This becomes a highly complicated task as the ITU-R brings together approximately 40 different radio services that compete for the spectrum allocations. This results in a complex environment for coordinating the various interference scenarios between different services with different technical and operational characteristics.

As being the global body in spectrum policy making, the specific role of the ITU-R is to maintain and extend international cooperation between different countries for the improvement and rational use of telecommunications [3–5]. With this respect, the detailed roles taken by the ITU-R as described in [3–5] are to:

- effect allocation of bands of the radio frequency spectrum, the allotment of radio frequencies, and the registration of radio frequency assignments and of associated

orbital positions in the geostationary satellite orbit in order to avoid harmful interference between radio stations of different countries;
- coordinate efforts to eliminate harmful interference between radio stations of different countries and to improve the use made of radio frequencies and of the geostationary-satellite orbit for radiocommunication services.
- create the regulatory and technical basis for the development and effective operation of satellite and terrestrial climate monitoring and data systems.

Avoidance of harmful interference is a key principle in the above roles of the ITU-R, and there are several mechanisms to attain that goal. The global use and management of the radio spectrum requires a high level of international cooperation, and an important task of the ITU-R is thus to facilitate the intergovernmental negotiations to develop legally binding agreements between different countries. To ensure interference-free operations of the different radio systems, the key tool of the ITU-R is the Radio Regulations (RR) that is the international treaty governing the use of the radio frequency spectrum and satellite orbits. The RR is reviewed and revised regularly through the World Radiocommunication Conferences (WRC) arranged by the ITU-R [8] as shown in Fig. 1. The RR defines the recommended allocations of frequency bands to the different radio services and their related technical parameters and procedures for coordination. In preparation for WRCs, the ITU-R conducts detailed studies in order to improve the international spectrum

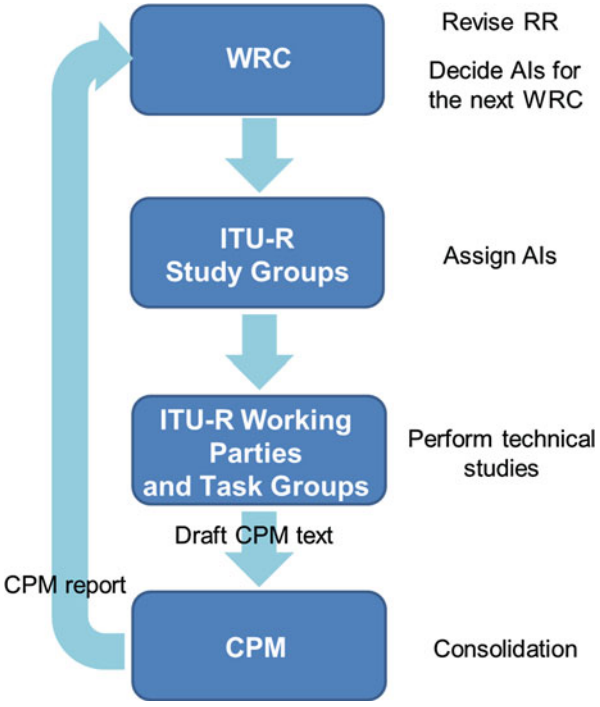

Fig. 1 The ITU-R process for revision of RR

regulatory framework with respect to the evolution of existing, emerging, and future applications, systems, and technologies. The WRC is organized to deal with topics covered by different agenda items (AI), and the previous WRC specifies the AIs for the next WRC. These AIs are assigned to different working parties (WP) or task groups (TG) by study groups (SG) where the actual preparatory work is carried out. WPs and TGs are responsible for technical studies for the AIs, such as sharing and coexistence studies between different radiocommunication services when preparing for new spectrum allocations. Detailed sharing considerations related to the specific implementation of the bands are left to the regional and national regulatory bodies. The results of the WRC preparatory studies from the various WPs and TGs are provided to the Conference Preparatory Meeting (CPM) prior to the WRC in the form of draft CPM text. The CPM then prepares a consolidated report on the ITU-R preparatory studies and possible solutions to the WRC AIs.

In addition to maintaining and revising process of RR through the WRCs, ITU-R promotes the development of radio systems and their new technologies to ensure the efficient use of the radio spectrum by studying technical and spectrum management related aspects in various SGs. The results of these studies are published in reports, handbooks, and recommendations. Best practices of spectrum usage are collected and disseminated in workshops, seminars, and publications. The current study groups of the ITU-R are [4]:

- SG1: Spectrum management,
- SG3: Radiowave propagation,
- SG4: Satellite services,
- SG5: Terrestrial services,
- SG6: Broadcasting service,
- SG7: Science services.

The study groups are presented in more detail in [4]. The key tool for the organization of these studies at the ITU-R is the Radiocommunication Assembly (RA) that is responsible for the structure, program, and approval of radiocommunication studies. RAs are normally convened held every four years and often associated in time and place with WRCs. The RAs determine the questions to be studied in detail in the different study groups of the ITU-R, assign WRC conference preparatory work and other questions to the study groups, and respond to other requests. RAs also acts as the forum to approve and issue ITU-R recommendations and questions developed by the study groups, to set the program for study groups, and to reshape the study group structure.

The ITU-R has developed its terminology for the global governance of the radio spectrum to fulfill policy making goals which can differ from the terminology defined and used in the research domain. For example, the ITU-R terminology on spectrum allocations in terms primary and secondary differs from those that were commonly used in the wireless communications research literature on cognitive radios. According to the ITU-R terminology used in the RR [8], “stations of

secondary service shall not cause harmful interference to stations of primary services to which frequencies are already assigned or to which frequencies may be assigned at a later date." In addition, they "cannot claim protection from harmful interference from stations of a primary service to which frequencies are already assigned or may be assigned at a later stage". However, "stations of a secondary service can claim protection from harmful interference from stations of the same or other secondary service(s) to which frequencies may be assigned at a later date" [8].

Interference is defined in RR [8] as "the effect of unwanted energy due to one or a combination of emissions, radiations, or inductions upon reception in a radiocommunication system, manifested by any performance degradation, misinterpretation, or loss of information which could be extracted in the absence of such unwanted energy". Harmful interference is interference "which endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs, or repeatedly interrupts a radiocommunication service operating in accordance with Radio Regulations" [8].

The dynamic spectrum sharing work in the form of cognitive radio technology development originally initiated in the research domain has been vetted into the ITU-R process of going through studies to become part of the global spectrum regulatory framework. In fact several of the study groups within the ITU-R and the key events (WRC and RA) have been involved in this process. In particular, spectrum sharing using cognitive radio system (CRS) technologies has been studied at the ITU-R in several groups from different perspectives. In the following, we present these groups and their activities describing their activities around CRS and dynamic spectrum sharing.

Overview of Dynamic Spectrum Sharing Related Studies at ITU-R

Cognitive radio research has considered new innovative ways of accessing the radio spectrum to improve the spectrum utilization efficiency. In the early cognitive radio studies, the system models assumed that the wireless devices themselves could decide on starting to transmit in a frequency channel based on observing the status of the outside world [9]. More specifically, the devices could dynamically share the spectrum by opportunistically accessing channels with the aid of spectrum sensing techniques to protect incumbent primary users by avoiding occupied channels. These approaches made the inherent assumption on the use of spectrum sensing techniques as the mechanism for the protection of incumbent systems from harmful interference. However, the link between what harmful interference meant in the technical studies in the research domain and in the regulatory domain was vague. Thus, early on for promoting real-life deployment of the cognitive radio technology, there was the need to introduce the cognitive radio principles developed in the research domain into the spectrum regulatory process in the global level.

As a concrete step, the ITU-R decided at its WRC in 2007 (WRC-07) to address the topic of cognitive radio at the following WRC in 2012 (WRC-12). The agenda item 1.19 of WRC-12 was *to consider regulatory measures and their relevance, in order to enable the introduction of software-defined radio and cognitive radio systems, based on the results of ITU R studies, in accordance with Resolution 956 (WRC 07)*. WRC-07 adopted Resolution 956 [10] that invited the ITU-R to study the need for regulatory measures for cognitive radio system (CRS) and software-defined radio (SDR). The responsibility on the spectrum management related aspects of CRS was assigned to SG1 and specifically its working party 1B (ITU-R WP1B), while the technical studies on its use particularly in the land mobile service were to be conducted in SG5 by its working party 5A (ITU-R WP5A).

Prior to WRC-07, the RA in 2007 (RA-07) issued Question ITU-R 241 [11] on studies of cognitive radio systems in the mobile service. This question seek to obtain answers to ITU definition of cognitive radio systems; closely related radio technologies and their functionalities; key technical characteristics, requirements, performance, and benefits; and potential applications of cognitive radio systems and their impact on spectrum management, operational implications, and cognitive capabilities that could facilitate coexistence. As the ITU-R Question 241 [11] was specifically focused on the use of cognitive radio systems within the mobile service, it was the topic of SG5 and particularly its working party ITU-R WP5A and ITU-R WP5D regarding the land mobile service and IMT systems, respectively.

As a starting point for the preparations for WRC-12, the ITU-R WP1B defined cognitive radio system (CRS) in 2009 in [12] as "A radio system employing technology that allows the system to obtain knowledge of its operational and geographical environment, established policies and its internal state; to dynamically and autonomously adjust its operational parameters and protocols according to its obtained knowledge in order to achieve predefined objectives; and to learn from the results obtained." [12] Technical studies used as a basis for the AI on CRS were conducted in ITU-R WP5A and WP5D, and the results of these studies were contained in reports [13] and [14], respectively. These reports included deployment scenarios, capabilities, as well as potential challenges and benefits arising from the cognitive technologies. These three ITU-R reports formed the basis for CPM text for the AI on cognitive radio for WRC-12.

As a result, the WRC-12 concluded that the introduction of CRSs does not require any changes to the RR and developed a WRC recommendation on the deployment and use of CRSs [15]. In fact, it was clarified that a CRS is not a radiocommunication service, but rather a system that employs technology that in the future may be implemented in a wide range of applications in the land mobile service. The WRC-12 concluded that any radio system implementing CRS technology needs to operate in accordance with the RR and that the obligations on the protection of stations of other administrations operating in accordance with the RR still hold.

However, it was determined that further studies would be required to explore the potential of cognitive radios. As a result, RA-12 developed Resolution

ITU-R 58 [16] regarding further studies on the implementation and use of cognitive radio systems which instructed the ITU-R to continue with the CRS studies. It urged the ITU-R to study operational and technical requirements, characteristics, performance, and possible benefits associated with the implementation and use of CRS in relevant radiocommunication services and related frequency bands and to give particular attention to enhancing coexistence and sharing among radiocommunication services [16]. The need for the further studies on CRS presented in ITU-R Resolution 58 [16] was further confirmed at the WRC in the development of WRC recommendation [15] that recommended administrations to actively participate in the studies. In fact, the resolution triggered a number of studies that are described in more detail in this chapter. The resolution was further updated in 2015.

To conclude, the studies on CRS at the ITU-R were based on responding to the topics raised in ITU-Resolution 58 [16] and ITU-R Question 241 [11]. In the course of work, ITU-R Resolution 58 [16] was updated in 2015 after its initial launch in 2012, and ITU-R Question 241 [11] was updated in 2012 and 2015 after its launch in 2007. The spectrum management related work is conducted in SG1 and particularly ITU-R WP1B. While the scope of ITU-R Resolution 58 [16] was more generic on the implementation and use of CRS in different radiocommunication services, the focus of Question ITU-R 241 [11] was specific to the mobile service. In fact the technical CRS related work within the ITU-R was mainly focused on the land mobile service while applications to other radiocommunication services are also possible. Thus, the technical work was mainly done in SG5. In particular, the ITU-R WP5A developed two reports on CRS in the land mobile service [13, 17], and ITU-R WP5D one report on CRS specific to IMT systems [14]. Moreover, other ITU-R study groups started to address the topic of CRS from the perspective of being impacted by CRS. For example, ITU-R WP5C studied the impact of CRS on the fixed service and started to prepare a report on it. In SG6, ITU-R WP6A started to study potential interference into broadcasting from CRS devices in the 470–790 MHz band and prepare a report on it but later ended the work.

The cognitive radio studies in the research domain were often motivated by measurements on the spectrum occupancy in different frequency bands in different countries [18]. The spectrum measurement and monitoring related activities within the ITU-R are dealt within ITU-R WP1C. In fact there were ITU-R studies that are directly related to the measurements conducted by the researchers providing guidelines responding to two ITU-R questions [19, 20]. ITU-R Question 233 [19] was originally assigned in 2007 and updated in 2011 and extended in 2015 on the measurement of spectrum occupancy. ITU-R Question ITU-R 235 [20] from 2011 and extended in 2015 dealt with spectrum monitoring evolution. It specifically addresses monitoring from the administrations' perspective regarding new considerations for monitoring of radiocommunication systems based on new technologies.

In the following sections, we will describe the studies related to CRSs in the mobile service and other related spectrum management studies in more detail.

CRS in Land Mobile Service

The technical studies on CRS at the ITU-R have focused on the use of CRS technology within the mobile service in response to ITU-R Question 241 [11]. This section reviews the work done at the ITU-R WP5A that resulted in two published reports on CRS in the land mobile service [13, 17]. The first report ITU-R Report M.2225 [13] was published in 2011, and it addressed a subset of the questions of the first version of ITU-R Question 241 [11] and provided technical features and capabilities, potential benefits, technical challenges, and deployment scenarios for CRS. The second report ITU-R Report M.2330 [17] addressed the updated questions in Question ITU-R 241 [11] from 2012 that asked the ITU-R to study closely related radio technologies and their functionalities; key technical characteristics, requirements, performance improvements, and/or other benefits; potential applications of CRS and their impact on spectrum management; how CRS promote efficient use of spectrum; operational implications (including privacy and authentication); CRS cognitive capabilities and CRS technologies that could facilitate sharing and coexistence between the mobile service and other services; and factors to be considered for the introduction of CRS technologies in the land mobile service.

As the starting point for the studies, ITU-R WP5A used the ITU-R definition for CRS [12] that identified three key CRS capabilities: (1) obtaining knowledge, (2) decision-making and adjustment, and (3) learning. These general capabilities could be applied to different systems in different bands on a case-by-case basis, and within these capabilities, there are several individual techniques. For example, knowledge of spectrum availability for sharing could be obtained via control channels, databases, or spectrum sensing techniques. Decision-making can take centralized or distributed forms, and the parameter to be decided can include frequency channels or power levels for operations among others.

The initial benefits of CRS to operators and end users were depicted in Report ITU-R M.2225 [13]. They include improvements in the efficiency of spectrum use; increased flexibility, self-correction, and fault tolerance; resilience in disaster or emergency situation; improved power efficiency; and potential for new mobile communication applications. The report [13] further identified four CRS deployment scenarios:

1. Use of CRS technology to guide reconfiguration of connections between terminals and multiple radio systems,
2. Use of CRS technology by an operator of a radiocommunication system to improve the management of its assigned spectrum resource,
3. Use of CRS technology as an enabler of cooperative spectrum access,
4. Use of CRS technology as an enabler for opportunistic spectrum access in bands shared with other systems and services.

The first two scenarios address an intra-system situation where an operator can use CRS technology to obtain more efficient use of resources within its networks.

The latter two are intersystem scenarios that involve spectrum sharing between different operators and systems. In the third scenario, wireless systems collaborate and exchange information about their spectrum use in order to avoid mutual interference. In the fourth scenario, CRSs may access unused spectrum band on a shared basis without causing harmful interference to other systems which resembles the traditional cognitive radio use cases extensively considered in the research domain. Scenarios are also discussed in [21, 22].

ITU-R WP5A continued the work in ITU-R Report M.2330 [17] that was published in 2014 providing answers to the remaining topics of the updated ITU-R Question 241 [11]. The report [17] introduced applications of CRS, details of CRS capabilities and enabling technologies, high-level characteristics, high-level technical and operational requirements, aspects related to CRS performance, potential benefits, factors related to introduction of CRS, and migration issues.

CRS Applications

ITU-R Report M.2330 [17] specifically addressed spectrum sharing where two or more radio systems operate in the same frequency band as well as coexistence where two or more radio systems operate in adjacent frequency bands. Noting that CRSs could share spectrum with other radio systems that are not necessarily CRSs, as well as with other CRSs, the report introduced two general level spectrum sharing cases:

- *Vertical spectrum sharing*: The case where one or more radio systems with CRS capabilities share the band of another radio system that does not necessarily have CRS capabilities. The radio systems with CRS capabilities are only allowed to utilize frequencies within the band as long as the other radio system is not affected by harmful interference from the CRSs;
- *Horizontal spectrum sharing*: The case where multiple radio systems with CRS capabilities are accessing the same shared spectrum band.

Figure 2 illustrates vertical and horizontal spectrum sharing cases where horizontal spectrum sharing refers to systems operating with the same level of access rights, while vertical spectrum sharing introduces sharing between systems with different levels of spectrum access rights. Horizontal and vertical spectrum sharing are not mutually existing, and both of them can be simultaneously present in various forms in practical applications. Report ITU-R M.2330 [17] identified the following benefits related to vertical and horizontal spectrum sharing:

- Interference minimization: The CRS capability of obtaining knowledge, for example, using databases can give information on the current protection requirements thus allowing the radio systems to adapt their operations in accordance within the given rules and policies.
- Efficient spectrum use: Additional spectrum can be made available by allowing radio systems to share spectrum with other radio systems leading to increase

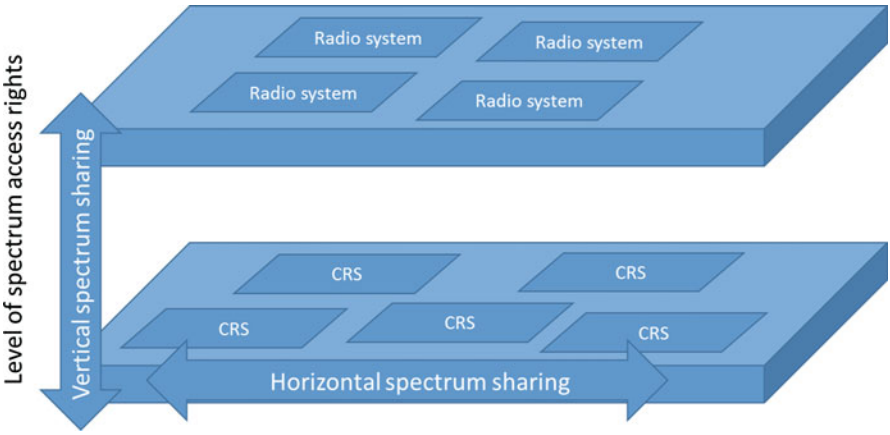

Fig. 2 Horizontal and vertical spectrum sharing in the context of CRSs

efficiency of spectrum use which can lead to capacity enhancements for the systems employing CRS technologies.

– Flexible operations: In sharing and coexistence situation, CRS system is flexible and could operate over various system configurations, and information shared between the involved CRS nodes would ensure that the relevant nodes have the most accurate information of available spectrum in a timely manner.

The Report ITU-R M.2330 [17] introduced a collection of CRS applications including existing, emerging, and potential applications. An existing application is the radio local area network (RLAN) system operating in the 5250–5350 MHz and 5470–5725 MHz bands on a co-primary basis with radiolocation systems and radar utilizing dynamic frequency selection (DFS) protocol to avoid harmful interference. The RLAN is required to use DFS to ensure by sensing/detection techniques that radiolocation systems are not operating in the same channels and vacate the channels when they appear as described in [23].

An emerging application is the use of TV white space which according to [13] refers to "A portion of spectrum in a band allocated to the broadcasting service and used for television broadcasting that is identified by an administration as available for wireless communication at a given time in a given geographical area on a non-interfering and non-protected basis with regard to other services with a higher priority on a national basis." Some administrations are allowing license-exempt devices to operate on a non-interfering basis in these TV white spaces with the help of CRS capability of geolocation with database access.

Examples of potential CRS applications identified in [17] include cognitive networks exploiting reconfigurable nodes, cognitive mesh networks, heterogeneous system operation using CRS capabilities, intra-system inter-RAT handover, inter-system handover, coordinated spectrum access in heterogeneous radio environment, and vertical and horizontal spectrum sharing enabled by CRS technologies. Several

examples of the last application are under study by several administrations to allow additional users to access spectrum with existing incumbent usage with the help of CRS to provide appropriate protection of other radio systems. These examples include Licensed Shared Access (LSA) in Europe and Citizens Broadband Service (CBRS) in the USA.

CRS Capabilities

Report ITU-R M.2330 [17] also elaborated the CRS capabilities identified in [12,13] and provided detailed descriptions of the three key capabilities and their enabling technologies which are depicted in Fig. 3. For obtaining knowledge of its operational and geographical environment, established policies, and its internal state, the CRS can listen to wireless control channels, use spectrum sensing techniques, and/or access databases. Examples of wireless control channels include cognitive control channel (CCC) and cognitive pilot channel (CPC). CCC aims at enhancing coordination between the CRS devices by providing real-time communication channel between distributed CRS nodes within a specific geographic area. CPC is a pilot channel that broadcasts radio environment information to CRS devices. Challenges of using wireless control channels for obtaining knowledge of the operational environment include power consumption, synchronization between nodes, contention resolution mechanisms, reliability of information, and strict requirements for timeliness of the data.

Spectrum sensing is another enabling technique identified in [17] for obtaining knowledge and has been widely studied in the cognitive radio research [1, 2, 9]. Spectrum sensing is the capability to detect other signals around the CRS node. There are different sensing techniques with varying sensing capabilities, requirements for a priori information, and degrees of complexity. Moreover, the use of sensing techniques can be with single or multiple devices and by CRS nodes themselves or by dedicated listening devices or community sensor networks. There are several challenges related to the use of spectrum sensing for obtaining knowledge or the operational environment including hidden node problem, reliability of sensing, implementation of particularly wideband sensing, power and processing consumption, signaling cost, performance in realistic settings, and detection of receive-only nodes. The report discussed that the implementation of opportunistic spectrum access could not rely solely on spectrum sensing techniques but would additionally require alternative methods.

The third technique for obtaining knowledge in [17] is the use of databases often combined with geolocation capability where the CRS node knows its location. CRS nodes can access a database that provides information about the locally usable frequencies ensuring that incumbent services remain protected from harmful interference. Databases can provide information of vacant frequency channels as well as the rules related to the use of the channels in certain locations. Many of the CRS applications introduced previously such as TV white space, LSA, and CBRS have taken the database approach. The implementation can take various forms such

as single open database, multiple open databases, proprietary close databases, or clearinghouse that aggregates and host raw data from multiple providers. Definition of open interfaces and protocols is important for allowing different types of CRS nodes to access different databases. Challenges for the database approach with geolocation include, e.g., timely update of data, availability of information about the stations to be protected, and security and privacy aspects.

The CRS capability of decision-making and adjustment of operational parameters and protocols (see Fig. 3) discussed in Report ITU-R M.2330 [17] involves the CRSs to take actions in link level and network level that take into account underlying policies in the dynamic operational environment. The report identifies centralized and distributed decision-making techniques and provides examples of channel selection and cognitive network management for CRS in the land mobile service. Centralized decision-making assumes a centralized entity for decision-making that informs the CRS nodes about adaptations of operational parameters such as spectrum resources. Distributed decision-making is based on localized decisions of distributed CRS nodes which can involve coordination between nodes. In the case of spectrum sharing, decision-making can involve the selection of channels for operation. Moreover, for dynamic adjustment of reconfigurable nodes in a network, cognitive network management functions are needed.

Finally, learning as a CRS capability can enable performance improvement by allowing the CRS to use stored information of its own actions and other's actions and the results of the actions to help in the decision-making process. Learning can make the operations of the CRS more efficient by, e.g., improving fault tolerance,

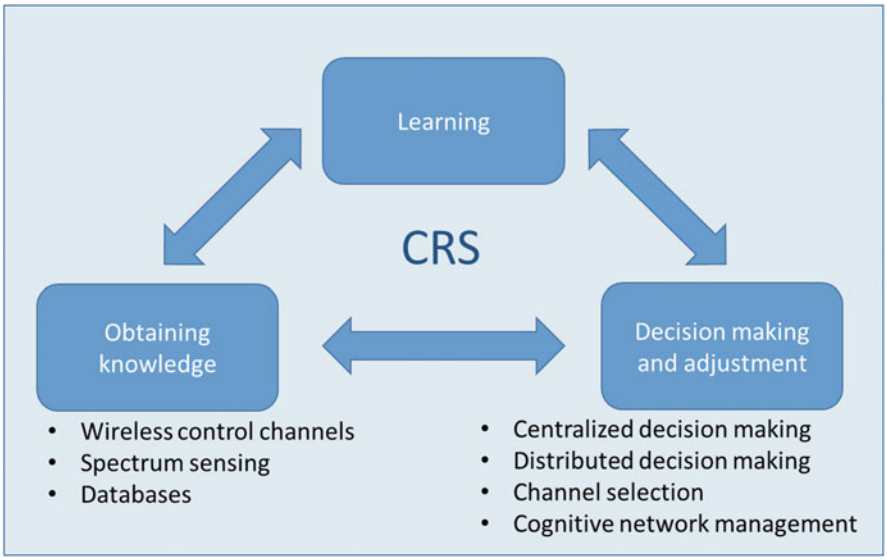

Fig. 3 CRS capabilities and enabling technologies

learning traffic patterns in different frequency channels for channel selection, and enhancing network management to adjust to different requirements.

CRS Characteristics, Requirements, and Performance Aspects

CRS introduces new high-level characteristics over conventional radio systems including aspects related to flexible spectrum management in temporal, frequency, and geographical domains to improve spectrum efficiency and dynamic coordination among radio systems to facilitate spectrum sharing and coexistence [17]. More accurate knowledge of the characteristics and operations of other systems combined with dynamic interference management could help the CRSs to avoid causing harmful interference and share the spectrum more efficiently in horizontal and vertical spectrum sharing cases.

New requirements for CRSs over traditional radio systems arise from CRS internal operations as well as from interactions with other systems operating in the same channel or adjacent channel in spectrum sharing and coexistence cases, respectively. Horizontal and vertical spectrum sharing and coexistence with other systems set requirements on the CRSs requesting them to support specific technical features and functionalities to avoid harmful interference to other radio systems with same level or higher level of spectrum usage rights in dynamic conditions where the spectrum use of the channels changes.

CRSs that introduce radio operations with dynamic availability of spectrum call for new metrics to characterize the system internal performance, interference considerations in spectrum sharing and coexistence between radio systems, and overall spectrum usage efficiency. Initial benefits from [13] are expanded in [17] specifically to vertical and horizontal spectrum sharing cases which were discussed above. In addition, CRS can provide benefits for operators by introducing dynamic spectrum reconfiguration, radio resource optimization, and dynamic device context provision. Finally, introduction of CRS capabilities into the land mobile service introduces migration aspects which were also discussed in [17] including inclusion of information exchange between different systems to facilitate spectrum sharing.

CRS for IMT Systems

The International Mobile Telecommunications (IMT) systems, the ITU-R terminology encompassing the mobile communication networks from 3G to upcoming 5G, are addressed in ITU-R WP5D. While majority of the studies on cognitive radio techniques at the ITU-R was focused on mobile communication systems in response to ITU-R Question 241 [11] encompassing both IMT and non-IMT systems, the IMT specific work on spectrum sharing and CRS remained limited. In fact in the research domain, a lot of effort was put on developing cognitive radio techniques for cellular systems where spectrum sharing was assumed between operators or between cellular systems and other systems. However, the work at the ITU-R on

CRS specific for IMT systems resulted in only one report ITU-R M.2242 developed by the ITU-R WP5D in 2011 [14]. The report studied the impact of adding CRS capabilities to existing IMT systems, and analyzed the benefits, challenges and impacts of CRSs in IMT, particularly regarding the impact on the use of IMT spectrum. The report emphasized that an IMT system employing CRS technology should still meet the minimum requirements for IMT systems and that the existing IMT systems should not suffer from harmful interference and quality-of-service (QoS) degradation from the introduction of CRS technology.

The report [14] took a very cautious view on what CRS could mean for IMT systems and only focused on single-operator scenarios where an operator would use CRS technology to enhance its own performance as the exclusive owner of the spectrum. The report preferred the operator centric intra-operator approach as the scenario for IMT to benefit from some CRS capabilities. It is restricted to improvement in the spectrum usage efficiency by accessing spectrum resources from one IMT system for other IMT systems inside the domain of a single operator. The report [14] identified the following scenarios for CRS in IMT systems:

1. Update of a network for optimized radio resource usage,
2. Upgrade of an existing radio interface or a network with a new radio interface,
3. In-band coverage/capacity improvement by relays,
4. Self-configuration and self-optimization of femtocells,
5. Multimode coexistence and simultaneous transmission.

The intra-operator scenarios involved cases where an operator who is the exclusive owner of the spectrum may use cognitive radio features to better manage its heterogeneous radio access networks. CRS scenarios for IMT are also discussed in [24].

The report identified benefits from CRS in IMT in the intra-operator case and in terms of overall spectrum efficiency and capacity improvement, radio resources utilization flexibility, and interference mitigation. The report concluded that the introduction of CRS in IMT systems in intra-operator case is the preferred scenario which did not include vertical or horizontal spectrum sharing. Even in that case, a concern is to ensure that existing radio systems do not suffer from harmful interference or QoS degradation from CRS technology, which shows the caution of the operators about the topic.

There has been a lot of work at the ITU-R on sharing and compatibility studies between IMT systems and other radiocommunication systems for the potential use of IMT systems in the bands currently used by other services. These studies take into account the characteristics of the IMT systems and the other systems to identify the potential interferences between the systems. They typically identify for protection criteria in terms of, e.g., separation distance, transmission power limit, interference mitigation techniques, and feasibility of sharing. These studies typically characterize the static situations without the use of CRS capabilities and dynamic spectrum sharing as such. To some extent, they have taken into account the use of interference mitigation techniques which has seen to reduce the protection

distances. In fact the CRS capabilities could help in the sharing studies to relax the conditions and improve opportunities for sharing and coexistence between different radio systems.

The most recent IMT developments are now focusing on the fifth generation (5G) of mobile communication systems denoted as IMT-2020 at the ITU-R. The IMT the work at the ITU-R is specifically addressing the preparations for WRC-19 AI 1.13 about the possible new spectrum allocations for IMT systems in the frequency range between 24 and 86 GHz.

Spectrum Management Related Studies at ITU-R

While the technical studies on CRS were conducted in SG5 of the ITU-R, spectrum management related aspects of CRS belong to SG1. The CRS related spectrum measurement studies and new spectrum management principles studied at SG1 are reviewed next.

Spectrum Measurements and Occupancy Studies

Many of the cognitive radio studies in the research domain were motivated by spectrum measurement studies conducted by research people where the spectrum occupancies of different frequency bands were analyzed as summarized in [18]. In fact a number of spectrum measurement campaigns were conducted around the world to quantify the percentage of time that the received signal levels exceed some threshold giving an indication of the channel occupancies. The main findings from the research studies indicated very low levels of spectrum occupancy in many bands which gave motivation for the studies to introduce dynamic spectrum sharing in bands with low occupancy levels. While these measurements were mainly done by the research community, spectrum measurement and monitoring had been a standard tool in the spectrum regulatory domain for a long time. However, the basic guidelines developed in the regulatory domain were not applied to a large extent in the research domain.

At the same time, as the CRS studies were conducted at the ITU-R, there were studies about the measurement of spectrum occupancy and spectrum monitoring that took place in SG1. In fact, studies addressed two ITU-R questions, ITU-R Question 233 [19] about measurement of spectrum occupancy and ITU-R Question ITU-R 235 [20] on spectrum monitoring evolution. ITU-R Question 233 [19] originated from RA-07 and was updated in 2011 and expanded in 2015. It called for identifying techniques to perform frequency channel and frequency band occupancy measurements including processing and presentation methods. It also seek to define the term "occupancy" for frequency channel and frequency band measurements and define and apply threshold levels in practical situations. Question ITU-R 235 [20] initiated in 2011 was extended in 2015 and focused on spectrum monitoring evolution with the advent of new technologies. It looked for

new considerations for monitoring of radiocommunication systems including new approaches in terms of organization, procedures, and equipment to monitor systems based on future radiocommunication technologies. It is particularly concerned with the administrations' positions and seeks for the needs for administrations in order to implement the new approaches to monitor systems based on future radiocommunication technologies.

The studies have resulted in several reports and recommendations published by the ITU-R [25–28]. Recommendation ITU-R SM.2039 [25] on spectrum monitoring evolution published in 2013 provides answers to Question ITU-R 235 [20] and recommends new technologies to be used in spectrum monitoring evolution to extend monitoring coverage including detection of weak signals, co-frequency signal separation, and multimode location based on a combination of techniques. Report ITU-R SM.2355 [26] published in 2015 highlights the role of spectrum monitoring as an important tool in the management of radio spectrum by providing monitoring data, including spectrum occupancy and characteristic of signal, such as field strength, bandwidth, modulation type, location of emitter, etc. The report addresses the challenges of future spectrum monitoring systems that should have the capability for monitoring new radiocommunication technologies and systems including those with CRS capabilities, such as detection of weak signal, co-frequency signal separation, and multimode location based on digital signal processing and network. The report also provides examples of advanced monitoring techniques.

Recommendation ITU-R SM.1880 [27] on spectrum occupancy measurement and evaluation originally published in 2011 and revised in 2015 specifies the measurement procedures and techniques in response to Question ITU-R 233 [19]. It recommends the use of Report ITU-R SM.2256 [28] and ITU-R Handbook on spectrum monitoring [29] to be used as guidance and equipment that should fulfill the requirements set in those documents. Report ITU-R SM.2256 [28] on spectrum occupancy measurement and evaluation was published in 2012 and further updated in 2016. The report provides a comprehensive description of spectrum occupancy measurement terminology and methodology and acts as the guideline for conducting spectrum occupancy measurements. The report includes relevant terminology, measurement parameters, measurement procedure, calculation of occupancy, presentation of results, as well as interpretation and use of results. Finally, the ITU-R Handbook on spectrum monitoring [29] whose latest edition is from 2011 contains ITU-R guidelines for monitoring.

New Spectrum Management Principles

In ITU-R, the nontechnical spectrum management related issues are handled in the WP 1B "Spectrum management methodologies and economic strategies" of SG1. The WP1B considers, for example, spectrum management fundamentals, methodologies, as well as both national and international regulatory frameworks. The studies performed in this WP are done in a technology and service neutral

manner. After completing of the preparatory work for WRC-12 on CRS, the WP1B is currently working on two reports regarding more dynamic spectrum use. Similarly to prior studies on the CRS, the first report is being developed in response to ITU-R Resolution 58 [16]. This current working document toward a preliminary draft new (PDN) report on spectrum management challenges [30] is addressing spectrum management principles and spectrum engineering techniques for the dynamic access to spectrum by radio system employing CRS capabilities. Whereas the previous CRS reports were service specific and concentrated on the technical aspects of CRS developed in ITU-R WP5A and ITU-R WP5D, the focus of this report is to study general framework and highlight some challenges related to CRS techniques including the means to ensure the protection of incumbent services sharing the same band or operating in the adjacent bands.

The second working document toward a PDN report on innovative regulatory tools [31] is being developed within the framework of an ITU-R Question 208-1/1 [32] "Alternative methods of national spectrum management." This report aims to provide a collection of regulatory mechanisms which may be implemented on a national basis that have been experimented and are recognized as best practices in terms of spectrum management solutions by administrations. Currently, the draft report includes the European LSA approach and an approach to share spectrum between multiple mobile operators.

Conclusions and Future Outlook

At the international level, the ITU-R has developed general guidelines for dynamic spectrum sharing using the CRS technology. These guidelines form the ground for spectrum sharing in the global scale. The main conclusions of the CRS work for WRC-12 was that the introduction of CRS does not require any changes to the RR and that a system employing CRS technology needs to operate in accordance with the RR.

As defined by the ITU-R, the CRS is a set of capabilities for obtaining knowledge, decision-making and adjustment, and learning, which can be applied to different radiocommunication services. The CRS work within the ITU-R mainly focused on the land mobile service while applications to other radiocommunication services are also seen possible. The ITU-R introduced vertical and horizontal spectrum sharing applications where the distinction comes from the different levels of spectrum usage rights between the wireless systems operating in the same spectrum band.

In fact the ITU-R guidelines for CRS have been there for a few years now. ITU-R studies on CRS capabilities expanded the considerations from pure spectrum sensing techniques to wireless control channels and databases. In the research domain, the interest in pure cognitive radio technology has shifted to the development of specific spectrum sharing models that exploit CRS capabilities. At the same time, these sharing models have been introduced at the ITU-R level to exchange information about new spectrum management approaches. The role of the ITU-R

continues to be the global forum for gathering and disseminating best practices, providing place for discussions by all stakeholders, and conducting studies of technical and spectrum management aspects.

The development of fifth generation (5G) networks is a major ongoing effort in research, industry, and regulatory domains regarding future mobile communication systems. While the prior work carried out in the scope of CRS specific to the IMT systems at the ITU-R remained limited and focused only on intra-operator scenarios, spectrum sharing will have a more prominent role in 5G. In the future, spectrum sharing will find new application areas in the development and deployment of 5G networks. 5G networks are envisaged to be deployed in a wide variety of frequency bands ranging from the existing bands with mobile allocation toward higher frequency range between 24 and 86 GHz studied for WRC-19. In the context of 5G, spectrum sharing in vertical and horizontal dimensions will play an increasingly important role to allow efficient utilization of the spectrum for the different stakeholders. Operations in these higher frequencies will call for new models and techniques for both horizontal and vertical spectrum sharing to allow local deployments and to protect possible incumbents, respectively.

ETSI-RRS Reconfigurable Radio Systems Standards

49

Markus Mueck

Contents

Abstract

The evolution of classical, static Radio Systems toward Reconfigurable Radio Systems is a clear trend in the industry for several reasons – first, the lack of spectral resources forces manufacturer to exploit novel technological trends in order to meet 5G-related promises in terms of quality of service, latency,

reliability, etc. Second, the fast evolution and heterogeneous nature of the radio environment combined with an ever-increasing computation power in mobile devices call for new ways of ensuring that the diverse environment is exploited in the best possible way; software reconfigurability is the key to dynamically adapt any target device to the specific needs of its owner through installation of tailored and targeted software components. All this flexibility, however, is useless without access to real-time, reliable context information which feeds decision-making entities in the network and in the mobile device or implemented in a distributed way such that the network and mobile devices participate in the decision-making process. The European Commission has recognized this trend in an early stage and acted correspondingly. ETSI received EC Mandate M/512 "Standardisation Mandate to CEN, CENELEC and ETSI for Reconfigurable Radio Systems" which has led to the development of the Licensed Shared Access Spectrum Sharing solution in ETSI's Technical Committee Reconfigurable Radio Systems (TC RRS). Furthermore, the new Radio Equipment Directive creates a clear framework for Software Reconfigurable Radio Equipment in Europe. This section details the respective technical solutions and trends as they are currently being developed in ETSI standards.

Keywords
Cognitive radio systems · ETSI · Reconfigurable radio systems · Software reconfiguration · Spectrum sharing

Introduction

Within the European Telecommunications Standards Institute (ETSI), the Reconfigurable Radio Systems (RRS) Technical Committee (TC) is focusing on standardization activities in all relevant areas of Reconfigurable Radio Systems encompassing system solutions related to software-defined radio (SDR) and cognitive radio (CR). TC RRS is therefore the center of competence within ETSI for cognitive radio and Reconfigurable Radio Systems standards development. Still, TC RRS sees its activities to be horizontal across ETSI and thus interacts with other TCs as required in order to ensure the proliferation of RRS and CR technology.

This section summarizes available standards and ETSI activities in the space of RRS and CR technology. The key focus is in particular on:

- Reconfigurable Radio Systems and cognitive radio on a political, regulation, and standards level;
- Spectrum sharing, in particular Licensed Shared Access (LSA) and TV White Space (TVWS) access, as an enabler for future 5G capacity;
- Software reconfigurability of radio equipment, including mobile terminals as well as network equipment, in order to enable a dynamic adaptation to an ever-changing heterogeneous system environment.

Reconfigurable Radio Systems and Cognitive Radio on a Political, Regulation, and Standards Level

On a political and regulation level, a number of steps have been undertaken in order to accelerate the adoption of RRS and related technology in the European market. In the sequel, the following specific steps will be further outlined and commented:

- Through the publication of a novel *Radio Equipment Directive* [6], the European Commission has created an official framework for RRS and related technology. The conditions for granting access to the single European market are clearly defined and outlined.
- In *EC M/512 Standardisation Mandate To CEN, CENELEC and ETSI For Reconfigurable Radio Systems* [41], the European Commission has furthermore addressed all European Standards Organizations (ESOs), i.e., CEN, CENELEC, and ETSI, to develop Reconfigurable Radio Systems-related standards. In particular ETSI has answered to this request and has developed a series of standards in the field.
- The European Conference of Postal and Telecommunications Administrations (CEPT) has furthermore developed a regulation framework where required – this was in particular the case for Licensed Shared Access (LSA) and TV White Space (TVWS)-based spectrum sharing technology for which a number of *recommendations* and *decisions* were developed.
- The UK regulator, OFCOM UK, has taken the initiative within Europe to drive the adoption of TVWS technology [39, 48].
- The US Federal Communications Commission (FCC) has furthermore issued a series of rulings related to the usage of so-called TV White Space (TVWS) bands and related requirements, including the usage of TVWS databases [42].

As stated above, the European Commission has revised the *Radio and Telecommunication Terminal Equipment (R&TTE) Directive* [5] for the first time since 1999. It was replaced by the novel Radio Equipment Directive [6] which specifically includes provisions to enable the introduction of RRS technology onto the single European market. Note in particular articles (3)(3)(i) and 4 which address requirements related to software reconfiguration:

> *Article 3:* **Essential requirements**
>
> . . .
>
> *3. Radio equipment within certain categories or classes shall be so constructed that it complies with the following essential requirements:*
>
> . . .
>
> *(i) radio equipment supports certain features in order to ensure that* ***software can only be loaded*** *into the radio equipment where the* ***compliance of the combination of the radio equipment and software has been demonstrated***

Article 4: **Provision of information on the compliance of combinations of radio equipment and software**

1. Manufacturers of radio equipment and of software allowing radio equipment to be used as intended shall provide the Member States and the Commission with information on the ***compliance of intended combinations of radio equipment and software*** *with the essential requirements set out in Article 3. Such information shall result from a conformity assessment carried out in accordance with Article 17, and shall be given in the form of a statement of compliance which includes the elements set out in Annex VI. Depending on the specific combinations of radio equipment and software, the information shall precisely identify the radio equipment and the software which have been assessed, and it shall be continuously updated.*

. . .

The upper text gives legal clarity on the requirements to be met in order to introduce corresponding equipment into the single European market. To have it finally implemented, however, so-called delegated act and implementing act need to be triggered. The European Commission is currently working on these requirements which will finally *activate* the corresponding articles. As it will be outlined in the sequel, ETSI has developed a number of *European norms* which provide a technical, security, and regulation solution for software reconfiguration [11,15–18]. ETSI furthermore analyzed key software reconfiguration use cases from a feasibility and regulation perspective in ETSI TR 102 967 [22]. The latter document in particular outlines how the requirements of the Radio Equipment Directive [6] may translate into technical solutions. Finally, ETSI has considered security channels and introduces a corresponding security framework in [21,22,33].

Concerning EC Mandate M/512 [41], ETSI and CEPT interacted closely in order to develop/ensure consistency between the available regulation framework and ETSI standards in the field of TWS and LSA technology in particular. CEPT has developed a number of recommendations and decisions [4,7,38] enabling the usage of LSA in the 2300–2400 MHz band in Europe. ETSI, on the other hand, has developed in its Technical Committee (TC) Reconfigurable Radio Systems (RRS) the required standards [30–32] based on an initial System Reference document (SRdoc) related to LSA [26], which is the official way for ETSI to inform CEPT about the intended definition and deployment of new radio technologies. Note that ETSI is in close contact with 3GPP – a split of responsibilities has been agreed with 3GPP defining the technology required within the 3GPP network; a corresponding has started in 3GPP [1].

In terms of TVWS technology, CEPT has issued a number of reports [3,37,47]. ETSI has considered the problem from various angles. In order to enable an immediate deployment of related systems, typically under the applicable UK framework [39, 48], a so-called harmonised standard [9] was issued which comprises all technical requirements to be met in order to introduce corresponding products to the single European market. Further, ETSI considered a possible evolution, in particular

in terms of spectrum access coordination among secondary devices themselves (in order to increase quality-of-service (QoS) levels for secondary devices by reducing mutual interference) and by introducing advanced solutions for database management and inter-database coordination [12–14, 19, 21, 23, 28].

Spectrum Sharing

Spectrum sharing technology will be one of the key ingredients for future 5G systems. It is indeed expected that 5G systems will require between 1000× and 10,000× the capacity of legacy 4G systems. As illustrated in Fig. 1, major analysts expect a growth by a factor of 6×–10× by 2019 – and the full-fledged 5G rollout will only begin in 2020! Over the lifetime of the 5G system, massive capacity requirements are thus obvious and lead to expected factors up to 10,000× as mentioned above.

In this context, it is fair to ask the question which main enabler will be available to achieve the capacity objectives. In the opinion of the author of this section, there are four key vectors which are mutually exclusive (at least to some extend) as illustrated in Fig. 2: spectrum sharing, higher frequencies, spectrum efficiency, and densification. Very roughly speaking, it will be required to achieve a 10× capacity for each of those vectors in order to achieve the 10,000× target.

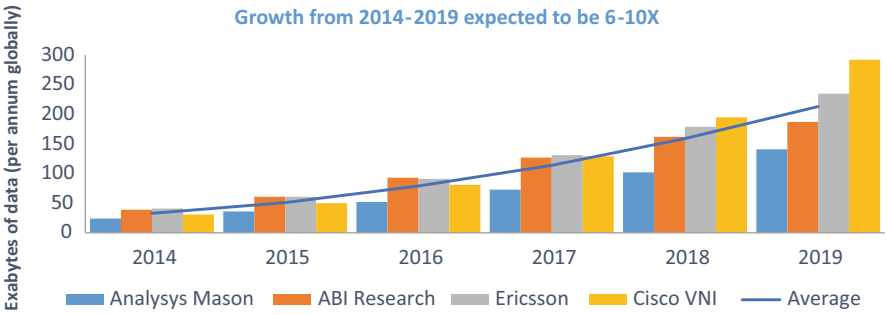

Fig. 1 Wireless traffic growth predictions until 2019

Fig. 2 Key enablers for 5G capacity growth

Note that the FCC has already acted and made approx. 11 GHz of spectrum available in the mmWave bands [36]. Previously, approx. 1.2 GHz were available for licensed and unlicensed commercial services taken together, so this corresponds to the 10× expectations for the corresponding "higher frequencies" vector in Fig. 2. Similar decisions are expected for Europe.

The "densification" vector is addressed in the current trend to move toward small cells in frequency ranges such as 3.5–6 GHz. The "spectrum efficiency" vector should not be understood as a required capacity increase in terms of Shannon capacity of a single link but rather as a requirement to work toward a better integration of heterogeneous radio systems, reduce signaling overhead, etc.

The "spectrum sharing" vector is orthogonal to the "higher frequencies" vector in some sense, since spectrum sharing can be applied independently to classical frequency bands below 6 GHz as well as to higher mmWave bands. The importance of spectrum sharing will furthermore depend on the availability of robust and reliable solutions of mmWave communication in commercial user equipment. It is currently unclear whether such solutions will be available in a reasonable time frame and at a reasonable cost for all user scenarios. In particular, medium to high mobility scenarios are an obvious challenge. If this "source of capacity" will not be available in some scenarios, the importance of spectrum sharing technology will grow even beyond the current level of critical need for it.

Currently, the following spectrum sharing technologies are considered to be candidates for future 5G systems:

- TV White Space usage
  - The technology has been extensively investigated, and a database-based usage approach was defined in the USA [42] and Europe [9]. OFCOM UK has implemented the corresponding regulation framework, while other European countries are currently hesitant. The commercial success of TVWS technology for wireless broadband applications is still limited. In the opinion of the author of this section, the main reasons lie in (i) the unclear business model (there is no interaction between spectrum owners and secondary users), (ii) the lack of QoS guarantees for secondary users, and (iii) the lack of certainty that TVWS spectrum will be available in the future for a given geographic area. The adoption rate may increase with the proliferation of 5G where a strong need for additional spectral resources may arise. The corresponding ETSI solutions are detailed in the sequel.
- Licensed Shared Access (LSA) and Spectrum Access System (SAS)
  - Following the experience from TVWS-based spectrum sharing technology, regulation administrations have further evolved the concept with the objective to address the shortcomings addressed above. This has finally led to the creation of the Licensed Shared Access (LSA) technologies in Europe and Spectrum Access System (SAS) in the USA. In the sequel, both technologies are briefly introduced, and then a more detailed description is given on ETSI's work focusing on LSA. SAS-related activities are mainly done in the Wireless Innovation Forum [49].

– Licensed Shared Access (LSA)
  The main use case for LSA technology relates to the extension of cellular capacity below 6 GHz in Europe. LSA specifically enables a 3GPP LTE network to be operated on licensed shared basis in the 2.3–2.4 GHz frequency band, which corresponds to 3GPP LTE band 40. It is expected that LTE mobile network operators (MNOs) will engage in a multiyear sharing contract with incumbents such as military stakeholders, professional video camera services, and others. Sharing contracts are typically 10 years or more in length. This long-term certainty is a key requirement for justifying large-scale investments into cellular network infrastructure. Still, the incumbent (tier-1) user is prioritized over the licensee (tier-2), i.e., the concerned MNO (or other LSA licensee) is required to vacate the LSA band for the given geographic area, the given frequency range, and the given period of time for which the incumbent is requiring access to the resource.
  Typically, the LSA band is combined with LTE operation in dedicated licensed spectrum through suitable carrier aggregation mechanisms. Because legacy LTE systems in Europe are mainly employing frequency division duplex (FDD) technology, the 3GPP Release-12 FDD/TDD carrier aggregation feature is required for a suitable combination of existing deployments with LTE LSA modes. The basic principle is illustrated in Fig. 3.
– Spectrum Access System (SAS)
  The main use case for SAS technology is similar to the LSA case above but currently defined for usage in the US market – as illustrated by Fig. 4.

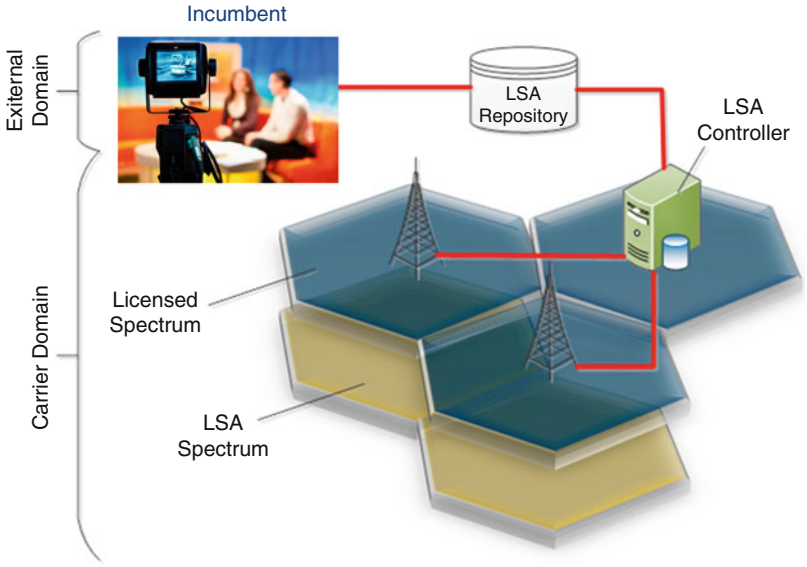

Fig. 3 The Licensed Shared Access (LSA) system approach

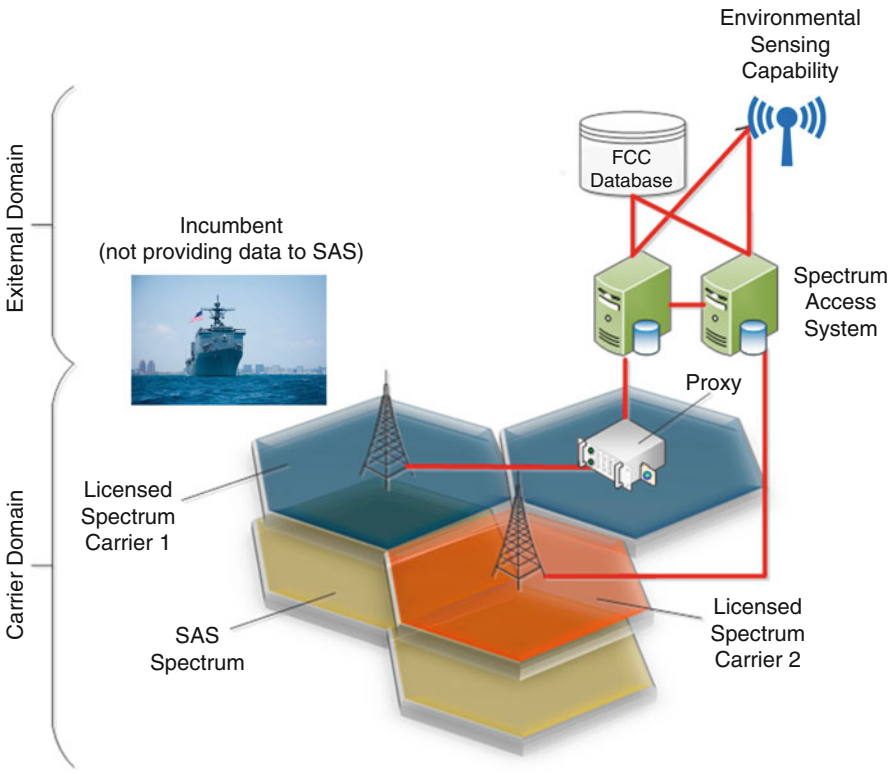

Fig. 4 The Spectrum Access System (SAS) approach

A so-called Citizens Broadband Radio Service (CBRS) network, such as a 3GPP LTE network, is operated on licensed shared basis in the 3.55–3.7 GHz frequency band, i.e., 3GPP LTE TDD bands 42 and 43. A major difference to LSA consists in the fact that licensed shared spectrum slots are only available in parts of the entire SAS band (up to 70 MHz) for so-called Priority Access License (PAL) tier-2 users. The remaining part of the spectrum and unused portions of the PAL spectrum ("use-it-or-share-it" rule) are available to a new user class called General Authorized Access (GAA) tier-3 users. This tier-3 class does not exist in the LSA system definition. GAA users may typically operate systems which have originally been defined for industrial, scientific, and medical (ISM) radio bands, such as LTE License-Assisted Access (LAA)-type systems or similar, including modifications in order to be adapted to the SAS requirements imposed by the FCC [43] (employing a "license-by-rule" framework).

– Comparison of Licensed Shared Access (LSA) vs Spectrum Access System (SAS)
  It should be noted that both systems – LSA and SAS – are currently defined for usage in a specific frequency band. The basic operational principles of

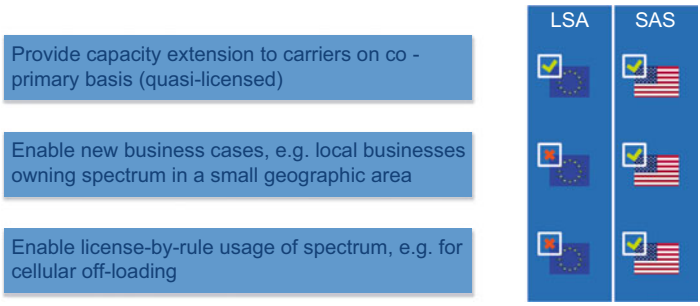

Fig. 5 Comparison of the Licensed Shared Access and Spectrum Access System (SAS) approaches

those systems, however, are frequency agnostic and can be applied to other bands. NRAs will be able to utilize the technologies as a new tool in the frequency management toolbox in order to allocate suitable bandwidth to wireless broadband systems.

A high-level overview on the difference is given in Fig. 5.

The LSA system is based on two tiers: incumbents and LSA licensees which each gets exclusive access right to the spectrum while they are using it. Furthermore, the incumbent populates a database indicating when the LSA licensee can access the spectrum in a given geographic area, a given frequency band, and a given period of time. The 3.5 GHz spectrum has three tiers with a tier-3 component to it (requiring communication capabilities with the SAS entities for interference mitigation, etc.) which closely relates to unlicensed operation and does not exist in the LSA system. However the most notable difference is the fact that the federal SAS incumbents (in particular the DoD) will not populate any databases giving usage information and it has to be entirely determined by sensing. It puts accurate and reliable sensing technologies in the forefront unlike LSA, where sensing could be used to improve network performance but is not essential for accessing the band.

The interference mitigation problem is also enhanced in the 3.5 GHz system for two reasons. First, the size of a census tract (i.e., the minimum geographic area which can be auctioned/used independently for each 10 MHz band) is based on population and not area. As a result, in densely populated urban areas, these census tracts could be as small as a few blocks and greatly increases the coordination needed for interference mitigation along each of these boundaries. Second, the GAA users need to be actively managed to prevent interference to the PAL users, something that is not needed in LSA. Finally, SAS expects to make the system attractive to new stakeholder and user groups who can acquire spectrum over a single census tract only, e.g., for providing access to a local business or similar. LSA, on the other hand, is rather designed for providing additional spectral resources to major MNOs over a large geographic area, such as an entire country.

Fig. 6 Mid-/long-range wireless access, no mobility

TV White Space

TV White Space Use Cases

A cognitive radio vision has been published by ETSI in ETSI TR 102 802 [20], and a number of active working items are currently dealing with (TV) White Space-related standardization. In this chapter, selected key use cases and scenarios are presented as they have been derived by ETSI TR 102 907 [21] – the below presented selection among available use cases was done with a focus on opportunistic sharing applications.

Use Case: Mid-/Long-Range Wireless Access over (TV) White Space Frequency Bands

A base station is providing Internet access to the end users by utilizing (TV) White Space frequency bands over ranges comparable to today's cellular systems, e.g., in the range of 0–10 km.

This use case is considered in further detail in the following scenarios:

- **Mid-/long range, no mobility**

In this scenario, a base station is providing wireless access toward fixed devices, e.g., a nonmobile home base station/access point. The geo-location of both the base station and from the fixed device is well known (Fig. 6).

- **Mid-/long range, low mobility**

In this scenario, a base station is providing wireless access toward mobile devices where the users have low mobility, e.g., they are staying at their location or are moving at walking speed. In that respect, the mobility of the user does not lead to invalid sensing results for primary users retrieved for the current location. The geo-location of the base station is well known. The geo-location of the mobile device must be determined during operation, e.g., via GPS, GLONASS, Galileo or BeiDou system, or cellular positioning systems.

- **Mid-/long range, high mobility**

In this scenario, a base station is providing wireless access toward mobile devices, and the concerned mobile devices may move at high speed, e.g., because a user is in a car or a train. In that respect, sensing results for primary users retrieved for the current location may get invalid quickly due to the mobility of the user. Thus, this use case leads to challenging constraints for the detection of primary users, and it needs to be evaluated if high mobility can be suitably supported in (TV) White Spaces at all.

Use Case: Short-Range Wireless Access Over (TV) White Space Frequency Bands

An access point or a base station is providing Internet access to the end users via short-range wireless communication (e.g., in the range of 0–50 m) by utilizing (TV) White Space frequency bands.

This use case is considered in further detail in the following scenarios:

- **Networks without coexistence management**

In this scenario one or more independent networks access (TV) White Space frequency bands. The access points require knowledge on the incumbent users of the spectrum (e.g., via (TV) White Space incumbent geo-location databases, sensing, etc.). However, in this first scenario, the different networks are uncoordinated, and thus they have no knowledge on other secondary networks and other users operating in the (TV) White Space bands.

- **Networks with distributed coexistence management**

In this scenario multiple networks access (TV) White Space frequency bands. The different networks are independent, and different network operators provide the backbone connectivity. Such a scenario can be envisaged, e.g., in an apartment building, where residents independently acquire their own local area access points operating in (TV) White Space frequency bands. Typically, the concerned access points can be operated and maintained by the residents themselves or the Internet service providers.

In order to work properly, effective coexistence mechanisms are required for (TV) White Space frequency access (Fig. 7).

- **Networks with centralized coexistence management**

In this case a (TV) White Space operator operates the (TV) White Space networks in the proximity in coordinated manner. Examples of this kind of usage can be small-scale corporate networks, networks for academic institutions, etc. (Fig. 8).

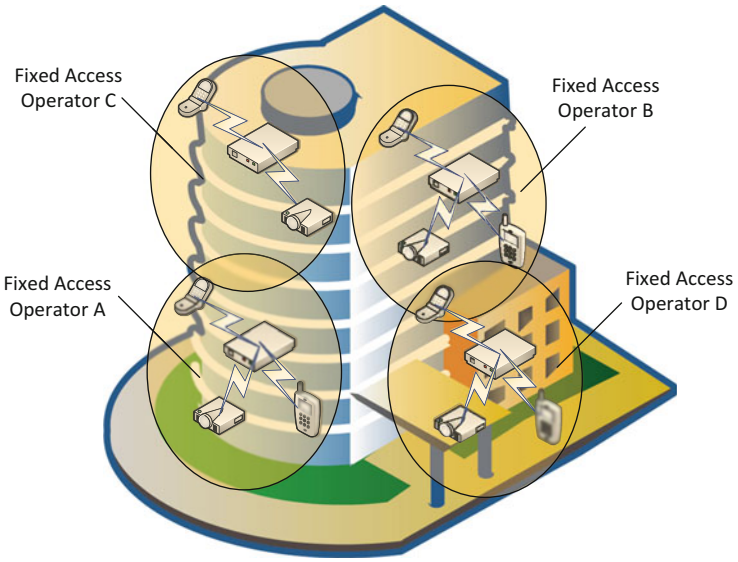

Fig. 7 Use case scenario of internet access by networks with distributed coexistence management on (TV) White Space frequency bands

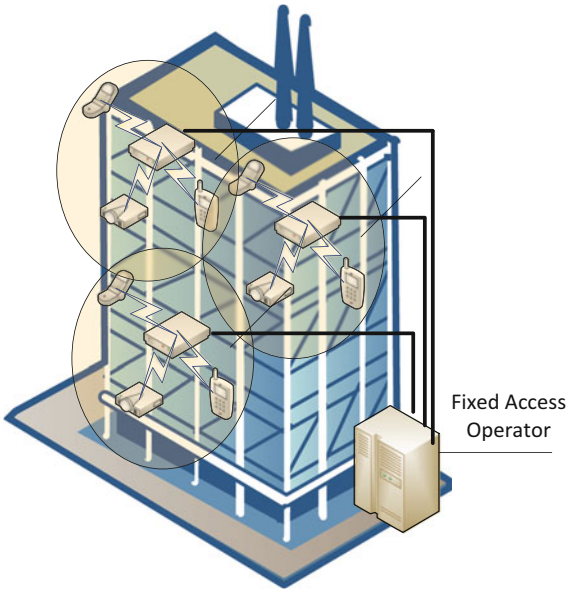
Fig. 8 Short-range wireless access, coordinated networks



- **Hybrid of networks with distributed and centralized coexistence management**

This scenario combines the above two scenarios, i.e., in the same geographic area, there are centralized coexistence management and distributed coexistence management applied. Such setup typically occurs in combinations of public and private places, like campus areas and shopping malls, where, e.g., the "official" local area networks, operating under centralized coexistence management, are complemented by independent access points set up independently by some individuals.

The overall coexistence management in this scenario is distributed, due to the existence of the independent networks (Fig. 9).

Use Case: Sporadic Use of (TV) White Space Frequency Bands

In this use case, (TV) White Space resources are only available sporadically for secondary users, such as multimode user terminals being able to operate, among

Fig. 9 Use case scenario of internet access by hybrid of networks with distributed and centralized coexistence managements on (TV) White Space frequency bands

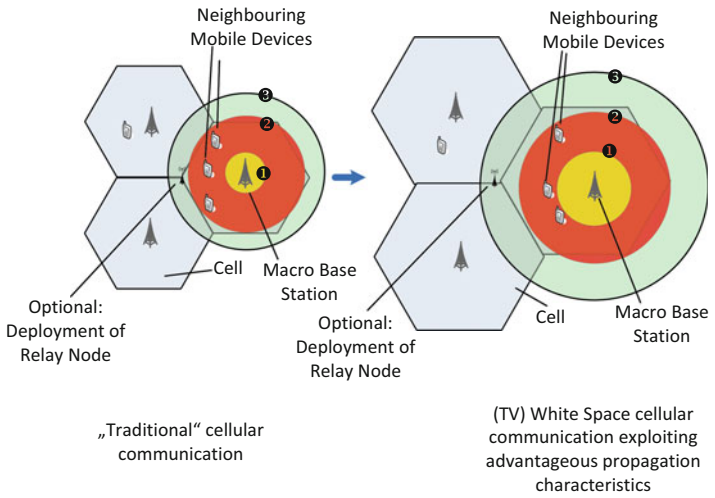


Fig. 10 Reduced propagation loss in (TV) White Spaces and thus improved coverage (the symbols ❶, ❷, ❸ indicate decreasing throughput levels, QoS, etc.)

other systems, cellular systems in licensed and unlicensed spectrum. The supported unlicensed spectrum is assumed to include (TV) White Spaces, i.e., the 470–790 MHz range in Europe/Region 1 (Fig. 10).

TVWS Medium Access Control Standards: A Coordinated and an Uncoordinated Approach

First-generation TVWS systems will focus on the protection of incumbent system, since this is a key regulation requirement. For an efficient usage of the technology, however, it is important to consider the resource sharing among multiple TVWS systems themselves. Otherwise, a chaotic and uncontrolled access to the resource will make the system hard to handle – in particular in dense environments. For this purpose, [29] introduce a system architecture and corresponding procedures for coordinated and uncoordinated use of TVWS.

The proposed approach builds on three entities as introduced in [29]: the cognitive radio system (CRS), the spectrum coordinator (SC), and the geo-location database (GLDB)) as shown in Fig. 11. The use of SC is specific to coordinated approach (Fig. 11).

The cognitive radio system (CRS) consists of a TVWS device (WSD) or network of WSDs (i.e., a master WSD and some slave WSDs). The CRS uses available TVWS resources which are identified with the help of geo-location database (GLDB), and/or the CRS uses available TVWS resources by exploiting the GLDB and with additional knowledge of spectrum usage by its neighbor CRSs by the spectrum coordinator (SC).

The operation of a GLDB is mandated or authorized by a regulatory authority and that provides a WSD in a CRS with location-specific information on the

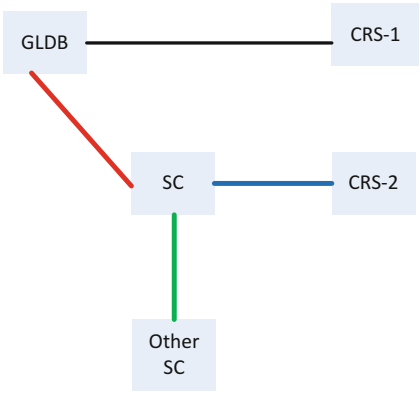

Fig. 11 Overview of TVWS system

available frequencies and associated maximum EIRP values. The concerned WSD is permitted to use the service which allows for protection of the incumbent service.

The SC is coordinating spectrum usage of CRSs. For this purpose, information is requested from GLDB and is communicated to CRSs, as well as supplemental spectrum usage data from different CRSs using its service. Different SCs are capable of communicating with each other.

Coordinated Usage of TVWS

In this section, it is outlined how several (distinct) CRSs can be coordinated among themselves in order to ensure access to required amount of spectrum and protection from harmful interference for secondary systems.

Spectrum Coordination

A SC uses spectrum coordination to serve CRSs such that they can operate in available spectrum resources of TVWS without causing harmful interference to each other and having a predictable access to the spectrum resources. The SC coordinates the management of radio resources among a set of CRSs that are potentially interfering with each other (coexistence) and allows for channel assignment requested by a CRS that requests guaranteed access to full capacity of a channel and with priority over other CRSs (priority-based channel assignment). The priority-based channel assignment is managed by the SC based on some minimum protection requirements requested by the CRS, which includes minimum bandwidth, minimum SINR (or maximum allowable interference), and some guaranteed minimum availability time. There are two basic approaches on how to implement priority access: (i) In the first approach, the SC translates these requirements into protection criteria, which are used by the GLDB to ensure that the priority-based channel assignment is maintained in the presence of other WSDs not using the SC; (ii) In the second approach, the SC stores the spectrum usage of the priority access, and the GLDB checks with the SC before providing available channels to other CRSs not using SC. From the perspective of the CRSs, coexistence and priority-based channel

assignments are provided as a set of two available SC services: the information service (for coexistence only) and the management service (for both coexistence and priority-based channel assignment). Each SC provides at least an information service or a management service for CRSs or provides both services.

Information Service

CRSs can be subscribed to an information service. In this case, a SC provides information about selected operational parameters (e.g., the operational parameters of other CRS in the available spectrum resources). In the information service, a SC does not make decision on the operational parameters to be used by those CRSs, but rather, all decisions are made by the CRS itself. However, the SC may process information about the current usage of spectrum to provide it to the CRS in order to support the CRS decision-making processes (such as ranking the potential operational parameters according to the resulting expected performance).

Management Service

For CRSs that are subscribed to the management service, a SC provides the operational parameters to be used by a CRS based on its requests and, if requested, certain QoS and usage time requirements. A CRS will not make any decision for its operational parameters (e.g., channel and transmit power) that are determined by the SC.

High-Level Operation Sequence

An overview of coordinated usage of TVWS is shown in Fig. 12. A CRS consists of a master WSD and one or more slave WSDs. The master WSD sends device parameters to a GLDB via the SC. The SC typically acts as relay and can also store the device parameters of the master WSD. The SC, during the process, maintains additional data about spectrum usage of the different CRSs using its service. This additional data contains information on the current state of spectrum usage, including spectrum measurement data from WSDs, and usage maps or areas of occupancy of the different CRSs. It also contains information related to the Radio Access Technology of each CRS that facilitates coexistence. A GLDB receives

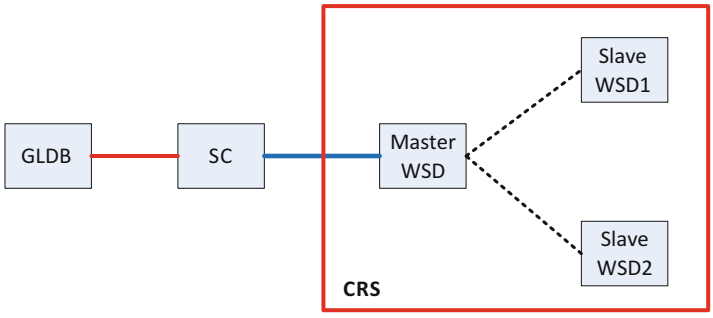

Fig. 12 Overview of coordinated usage of TVWS system

information from the master WSD about the characteristics of that WSD in order to generate operational parameters for that WSD. The GLDB provides operational parameters to the master WSD via the SC. During this process, the SC determines the operational parameters using the information obtained from the GLDB as well as the additional data about spectrum usage provided by the different CRSs and sends these operational parameters to the master WSD in response to the request for TVWS access. The operational parameters determined by the SC will not violate the protection criteria of the incumbent and are therefore compliant with the information obtained from the GLDB. The master WSD then sends the selected channel usage parameter to the GLDB via the SC. The SC will also update its additional spectrum usage data based on information sent by the WSD. At any time in the process of assigning channels to the CRSs, the SC could reconfigure the channel usage of the CRSs to ensure an efficient use of spectrum, such as reducing fragmentation in the available spectrum. The GLDB can either access SC or use channel usage parameters sent by the SC to ensure that WSDs can operate in the presence of other WSDs not using the SC (Fig. 12).

Uncoordinated Usage of TVWS

While the upper approach introduces coordination among CRSs, the uncoordinated usage of TVWS spectrum ensures a protection of the incumbents without providing specific protection for interference between the secondary users themselves (Fig. 13).

An overview of uncoordinated usage of TVWS is shown in Fig. 13. A CRS consists of a master WSD and one or more slave WSDs. The master WSD communicates with a GLDB to obtain its operational parameters in TVWS. A GLDB receives information from a WSD about the characteristics of that WSD in order to generate operational parameter for that WSD. A GLDB maintains a record of the actual usage of the TVWS. This information could be used to enable offending WSDs to be readily identified if interference to incumbent users were to occur and to allow the GLDB to know the extent to which available TVWS are being used.

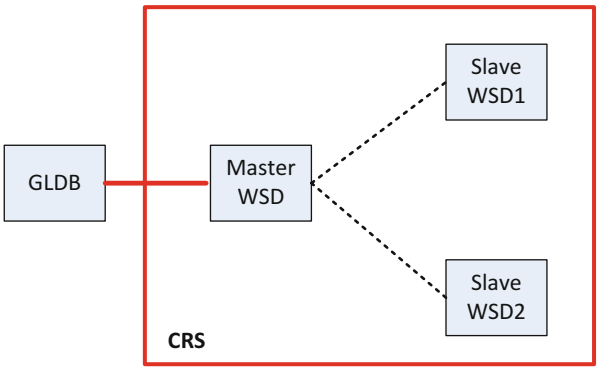

Fig. 13 Overview of uncoordinated usage of TVWS system

Licensed Shared Access (LSA)

In the sequel, a detailed overview on ETSI's solution for LSA is given.

System Design

The LSA system will address the needs of the following stakeholders:

- Incumbent user(s), i.e., primary users who may sublicense spectrum to LSA licensees under certain conditions;
- LSA licensee(s) operating a wireless system under a sharing agreement, typically a MNO providing 3GPP LTE services;
- NRA(s), which will monitor spectrum sharing activities.

Note that the upper guidelines imply a substantial change over legacy spectrum sharing technology, overcoming in particular the insufficiencies of the TVWS communication system approach. The LSA scheme provides a clear business case in which a long-term rental relationship between incumbents and LSA licensees leads to a defined money flow with LSA licensees obtaining guaranteed quality-of-service (QoS) conditions in a given geographic area, frequency band, and time period. TVWS neither offer such a clear business model for all stakeholders nor a guaranteed level of QoS, which may at least partly explain the technology's lack of commercial success. Further, the LSA approach is supported by major stakeholders, which is a key advantage for LSA in gaining marketplace acceptance.

In Europe, the 2.3–2.4 GHz band has been identified for an initial deployment of LSA [26]. This band corresponds to LTE TDD band 40 and is used in other regions as dedicated licensed LTE spectrum. ETSI's Reconfigurable Radio Systems (RRS) Technical Committee has developed corresponding system requirements [30] and system architecture [31] documents, defining the key building blocks and interfaces related to the upper framework.

The LSA repository (LR) is an entity providing database and other functionalities as it will be detailed below. In the European LSA context, the LSA repository plays a key role because relevant information related to spectrum occupancy is provided by the incumbent(s) to the database. The US model follows a different strategy for users entering (coastal) protection zones: all such information needs to be derived by an ESC and must comply with strict confidentiality requirements, as detailed further on in this in paper. The LSA controller features processing and decision-making capabilities building on the data elements provided by the LSA srepository. The LSA controller will interact with an MNO's (or other LSA licensee's) operations, administration, and management (OA&M) framework in order to indicate spectrum availability and request short-term vacating of the spectrum and other functions as illustrated in Fig. 14.

In accordance to the definitions in [31], the LSA repository and LSA controller components are illustrated by Fig. 15:

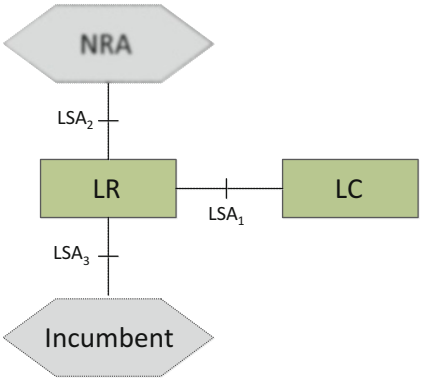

Fig. 14 LSA architecture reference model

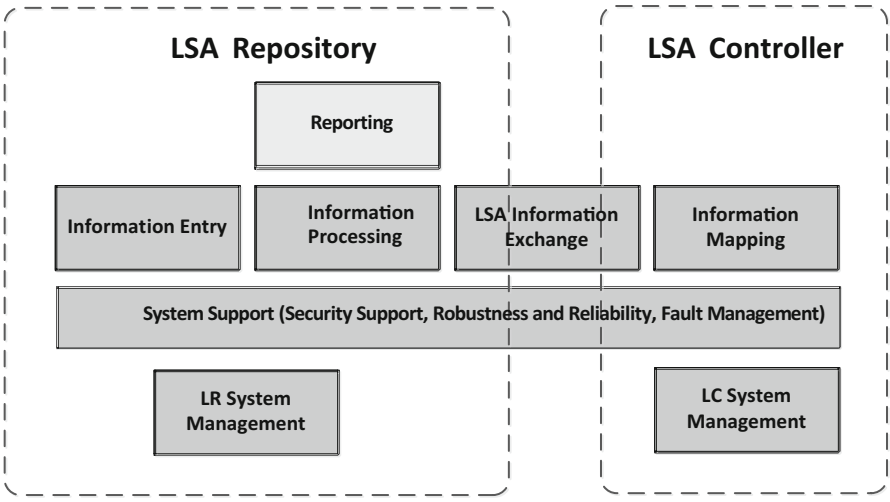

Fig. 15 Mapping of high-level functions and function groups to logical elements

The high-level functions introduced in Fig. 15 are derived from the ETSI requirement document [30], and they are further detailed below:

- The information entry function enables the entry and storage of information which is required for the operation of the LSA system and is comprised of the following:

  (i) Information on the sharing of framework between incumbent(s) and LSA licensee(s) indicating mutually agreed sharing conditions for the concerned band(s);
  (ii) LSA licensee information such as its identity;
  (iii) Information on the incumbents' LSA spectrum resource usage and protection requirements.

- The information processing function supports the derivation of LSA spectrum resource availability information for each licensee, to be provided to the information exchange function for forwarding to the respective Information Mapping function of the LSA licensee. This function uses data provided through the information entry function. It also includes support for multiple incumbents and multiple LSA licensees, scheduled and on-demand modes of operation, and logging of processing information.
- The information mapping function receives LSA spectrum resource availability information, confirms reception, and initiates respective operations in the MFCN. Furthermore, it provides acknowledgments to the information exchange function (for forwarding to the information processing function) when changes in the MFCN are processed.
- The reporting function is responsible for creating and providing reports regarding the LSA system operation to administration/NRA, incumbent(s), and/or LSA licensee(s) on an on-demand or scheduled basis.
- The LSA information exchange function supports communication mechanisms, internal to the LSA system, to exchange LSA spectrum resource availability information, and related acknowledgment information.
- The system support function group is comprised of the following elements:

  (i) Security support function for support of authentication and authorization as well as services to support integrity and confidentiality of data;
  (ii) Robustness and reliability function for support of mechanisms to maintain robustness and reliability against failures and malicious attacks;
  (iii) Fault management function for support of failure detection in the LSA system, subsequent generation and delivery of respective failure notification(s) to LSA licensee(s) and incumbent(s), and initiation of respective operations in the LSA system.

- The system management function group includes:

  (i) Operation, administration, and maintenance tasks in the LSA system,
  (ii) Identity management (comprising user identity and authentication management and user authorization profiles)
  (iii) System management is separate for LR and LC since these logical entities belong to different operation domains.

It is expected that the upper system approach is able to satisfy the needs of all stakeholders, including incumbents, LSA licensees, NRAs, and others such that:

(i) The incumbent(s) will be able to monetize spectrum which is underused in a given geographic area, a given frequency band, and a given time;
(ii) The LSA licensee will be able to access additional spectrum enjoying guaranteed QoS conditions and
(iii) The NRAs ensure the best possible usage of already allocated spectrum.

Standards and Regulation Framework

LSA and SAS-related standard (system definitions) activities are currently ongoing in the ETSI Reconfigurable Radio Systems (RRS) Technical Committee with a focus on LSA, in the Wireless Innovation Forum (WInnForum) with a focus on SAS, and in 3GPP targeting a global solution.

Thus far, the ETSI work has mainly produced documents [26, 30], and [31] and currently finalizes stage-3 interface definitions in [32] which are outside of the 3GPP system, such as the definition of the LSA1 Interface as illustrated in Fig. 14.

3GPP is discussing the integration and linkage of the LSA and SAS components into the 3GPP architecture. Document [40] proposes one possible option on how to include both sides under a common umbrella as it is illustrated in Fig. 16. As defined in [2], the corresponding entities provide the following functionalities:

- A network manager (NM) provides a package of end-user functions with the responsibility for the management of a network, mainly as supported by the EM(s), but it may also involve direct access to the network elements. All communication with the network is based on open and well-standardized interfaces supporting management of multi-vendor and multi-technology network elements;
- A domain manager (DM) provides element management functions and domain management functions for a subnetwork. Interworking domain managers provide multi-vendor and multi-technology network management functions;
- An element manager (EM) provides a package of end-user functions for management of a set of closely related types of network elements. These functions

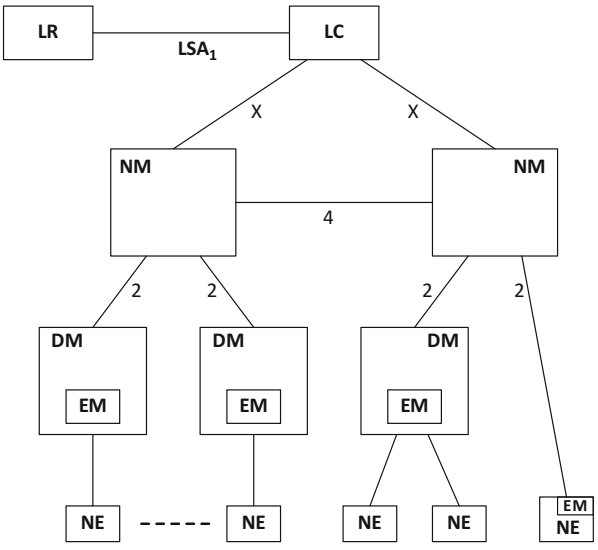

Fig. 16 Integration and linkage of LSA components to 3GPP SA5 architecture

can be divided into two main categories: element management functions and subnetwork management functions;
- A network element (NE) corresponds to a discrete telecommunications entity, which can be managed over a specific interface, e.g., the RNC.

The WInnForum leverages its long-term relationship with the US Department of Defense (DoD) in order to define a SAS system approach compatible with the needs of the US incumbents, which include in particular naval shipborne radar and satellite services. Protection of satellite services is a key aspect of the FCC's second further notice of proposed rulemaking [43].

From a regulatory perspective, the European CEPT organization has acted following investigations and a corresponding mandate by the European Commission [35, 44, 45]. CEPT has produced a number of reports, recommendations, and decisions [4, 7, 38] and has finally closed the corresponding working groups. From a CEPT perspective, the work is complete, and the actual usage of the LSA band in Europe now depends on NRAs to enable the usage of spectrum sharing in the national territories.

Protection of Incumbents and Neighboring Licensees

The current usage of the 2.3–2.4 GHz LSA band varies over the European Countries. While professional video camera services represent the main incumbents for some countries, others have allocated the spectrum also to (military) aircraft telemetry services, amateur radio, police wireless communication, and others. Detailed information for each country is available in the ECO Frequency Information System [8]. Based on information where corresponding incumbent systems are operated and which level of protection they require, the maximum LSA output power levels can be derived as shown in Fig. 17, which illustrates France as an example. Note that in this example, major parts of the country are available without major restrictions, including the capital of France: Paris.

Traditionally, incumbent systems are protected by so-called exclusion zones which prohibit the usage of interfering equipment within a given zone. In order to ensure a sufficient level of protection, corresponding zones are typically defined for a geographic area of substantial size, since the interfering system can operate without restrictions starting from the boundaries of the exclusion zone. In order to maximize the geographic area in which the operation of LSA is possible, the standards committee ETSI RRS has identified further zone types to reduce the constraints on the LSA system [30]:

- **LSA exclusion zone**: geographical area within which LSA licensees are not allowed to have active radio transmitters. Note: An exclusion zone is normally applicable for a defined frequency range and time period.
- **LSA restriction zone**: geographical area within which LSA licensees are allowed to operate radio transmitters, under certain restrictive conditions (e.g., maximum EIRP limits and/or constraints on antenna parameters). Note: A

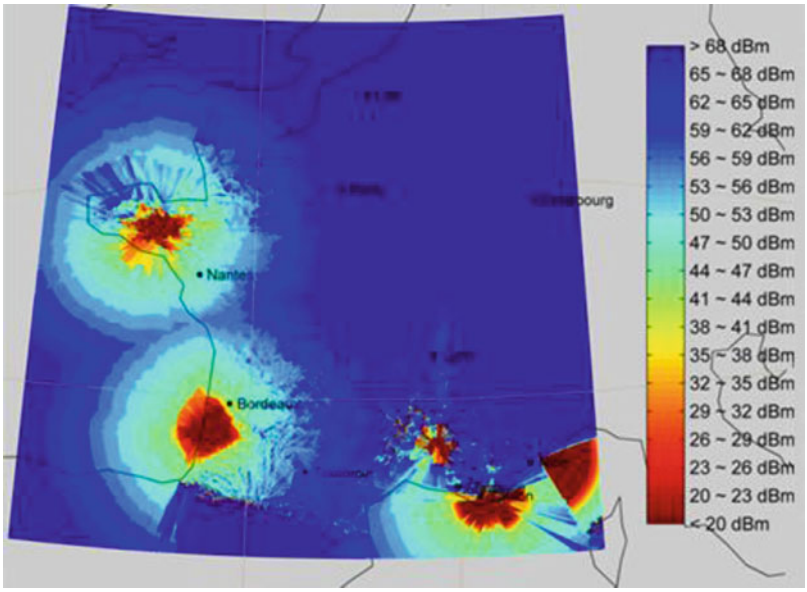

Fig. 17 LSA spectrum availability in France [46]

restriction zone is normally applicable for a defined frequency range and time period.

- **LSA protection zone**: geographical area within which incumbent receivers will not be subject to harmful interference caused by LSA licensees' transmissions. Note: A protection zone is defined using specific measurement quantities and thresholds (e.g., a mean field strength that does not exceed a defined value in dBμV/m/MHz at a defined receiver antenna height above ground level). A protection zone is normally applicable for a defined frequency range and time period.

Concerning requirements on protection of neighboring (LSA) systems operated by distinct MNOs (or other LSA licensees), mainly cross-border issues need to be considered for an efficient operation close to national country borders. Note that complex interference mitigation between distinct licensees is not required for LSA across small geographic areas – it is assumed that an LSA license is allocated to an MNO (or other LSA licensee) across an entire country or at least for a large geographic area (with the inherent limitations for exclusion, restriction, and protection zones). This is in contrast to the FCC SAS concept, where interference mitigation is required between neighboring Census Tracts which may be of small geographic size in particular in densely populated areas. Intra-MNO (or other intra-licensee) interference mitigation, on the other hand, may be employed as it is detailed in the next section.

Intra-MNO-System Interference Mitigation Through LSA

Future 5G network deployments will provide increased energy efficiency and spatial utilization of the licensed spectrum, but such a diverse and heterogeneous cell deployment will create some important technical challenges that need to be overcome first. One of the critical aspects in such high dense heterogeneous networks is a rich and uncoordinated inter-cell interference within the system of a given MNO (or other LSA licensee). LSA is expected to provide a new tool in order to address at least some of the interference cases.

While LSA spectrum can straightforwardly be used as additional spectrum for voice and data communication, the available LSA spectrum can be also exploited for inter-cell interference coordination. As LSA provides additional spectral resources over a given geographic area, for a given time interval, and a given frequency band, depending on interference levels and the need for interference mitigation, a trade-off can be made between LSA resources assigned for voice and data and LSA resources assigned for inter-cell interference coordination. Introducing collaborative spectrum sensing and more flexibility in spectrum sharing, the licensed users can dynamically access and share spectrum without causing interference to primary users. By intelligently allocating LSA spectrum to center and cell-edge cells in a network, interference can be reduced significantly, and implementation of complex and high-cost interference mitigation techniques in the user equipment receiver chain can be avoided.

Challenges and Next Steps

The regulatory circumstances related to LSA have been developed by CEPT, and the corresponding work is complete. The standards work is in an advanced stage in ETSI's RRS Technical Committee, while 3GPP's activities have only recently been initiated for Release 13. The technology is likely to further evolve in 3GPP Release 14 and beyond. A commercial availability, however, can be envisaged before the standards work is finally achieved. Thus, the main challenge relates to the possibility for the NRAs to finally enable the usage of the target 2.3–2.4 GHz band and possibly other bands in the future. Corresponding trials are ongoing in France and Italy, and additional countries are expected to follow. Once LSA has been proven to operate efficiently, it is expected that NRAs will open the 2.3–2.4 GHz band for licensed shared cellular usage under the LSA framework and to start identifying additional target bands. It is expected that LSA will become a key tool in the regulation toolbox in order to provide spectrum resources for 5G systems and beyond in order to meet the target 1000× to 10,000× capacity requirements.

Software Reconfigurability

ETSI TC RRS has developed a set of six European norms detailing a software reconfiguration framework for mobile device reconfigurability [10, 11, 15–18]:

- [10] Introduces the related system requirements;
- [11] Defines the system architecture;

- [15] Details the Multiradio Interface (MURI) which introduces in particular functions to (un)install radio applications packages (RAPs), to select suitable operational modes (e.g., simultaneous operation of multiple RATs), to access to the data pipes of the active RATs, and to access to radio parameter measurements.
- [16] Introduces Reconfigurable Radio Frequency Interface (RRFI), which complements existing Radio Interfaces, such as DigRF and others. It enables RAPs to access radio parameters and introduces the concept of Radio Protection Classes. These protection classes allow a (third party) software developer to choose a trade-off between the level of the mobile device "openness" to developers (e.g., access to Application Programming Interfaces (APIs)) and the required recertification complexity (and thus cost) of the platform.
- [17] Finally defines the Radio Programming Interface (RPI). The key novel concept consists of the Radio Virtual Machine (RVM) which is an abstract machine capable of executing Configcodes independent of the available hardware on the target platform. Its particularity is that it does not require a middleware for execution and thus lead to a far more efficient device reconfigurability compared to state-of-the-art approaches.

This set of European norms is complemented by a study on use cases for dynamic equipment reconfiguration [22]. This study introduces the following five basic use cases:

(1) OEM establishing initial conformity of reconfigurable equipment platform.
(2) DoC/StoC (Declaration of Conformity/Statement of Conformity) verification of reconfigurable equipment
(3) OEM upgrade of reconfigurable equipment (individual or en masse).
(4) Third-party upgrade of reconfigurable equipment (individual or en masse).
(5) Configuration enforcement of reconfigurable equipment.

Finally, security solutions are outlined in [24, 25, 27, 34].

Reconfiguration Capabilities: Mobile Device Reconfiguration Classes

As it is expected that the reconfiguration capabilities of a mobile device will evolve over time, mobile device reconfiguration classes (MDRC) are introduced. As shown in Fig. 18, seven different classes of reconfigurable MD are introduced (MDRC-0 corresponds to a non-reconfigurable device).

A reconfigurable MD belongs to a defined class according to the reconfiguration capabilities, which are determined by the type of resource requirements and the form of the Radio Application Package. Reconfigurable MD classes are defined as follows (see also Fig. 2):

- **MDRC-0:** No MD reconfiguration is possible; MDRC-0 represents legacy radio implementations and does not allow for MD reconfiguration (except for bug fixing and release updates through firmware updates) or exploitation of cognitive

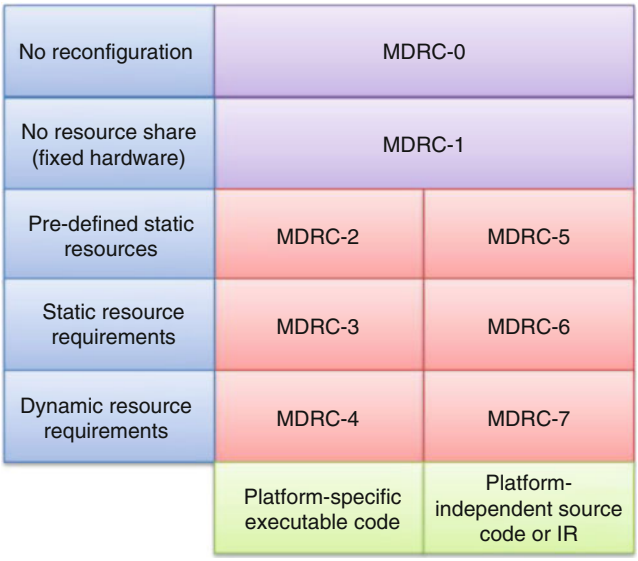

Fig. 18 Definition of MDRCs according to reconfiguration capabilities [10]

radio (CR) features. MDRC-0 represents legacy radio implementations and does not allow for MD reconfiguration.

- **MDRC-1:** Radio applications use different fixed resources; in this scenario, at least some of the radios are implemented with non-software-defined radio (SDR) technology, e.g., with dedicated Application-Specific Integrated Circuits (ASICs), and are resource-wise independent of each other. Simple CR functionality may be supported through radio parameter management to the extent which the radio implementations allow.
  MDRC-1 implements multiple radio applications with fixed resources allocation and no resource sharing.
- **MDRC-2:** Radio applications use predefined static resources; MDRC-2 implements multiple radio applications, but no dynamic resource management is available. The radio applications for MDRC-2 come from a single Radio Application Package which is normally provided by a reconfigurable MD vendor or SDR chipset manufacturer. In this scenario, we assume that software radio components in the Radio Application Package are provided in platform-specific executable code.
- **MDRC-3:** Radio applications have static resource requirements; for MDRC-3, a resource budget is defined for each radio application. This budget contains a static resource measure that represents the worst-case resource usage of the application, generated at radio application compile time. If an application is being started, the resource manager installed in a reconfigurable MD of MDRC-3 checks its resource budget and the sum of all resource budgets of already running

applications and admits the new application only if the resources can still be guaranteed for all running applications. In this scenario, we assume that software radio components in the Radio Application Package are provided in platform-specific executable code.

- **MDRC-4:** Radio applications have dynamic resource requirements; this scenario assumes a similar resource manager in a reconfigurable MD as for MDRC-3, but in addition, radio applications have now varying resource demands based on their current type of activity. Applications have separate operational states for different types of activity, and a resource budget is assigned to each operational state. In this scenario, we assume that software radio components in the Radio Application Package are provided in platform-specific executable code.
- **MDRC-5:** Radio applications use predefined static resources, on-device compilation of software radio components. This class corresponds to MDRC-2 with the difference that all or part of the software radio components are provided in the Radio Application Package as platform-independent source code or platform-independent intermediate representation (IR), which is compiled on the reconfigurable MD itself. It particularly means that the reconfigurable MD should include a proper compiler in order to convert the source code or IR of the software radio components into an executable code that runs on a given modem chip of a reconfigurable MD. It is assumed that the methods of radio programming and the tools to support this category have become sufficiently standardized so that third-party vendors may create radio applications and activate them to different platforms with relative ease. The formal description of the resource management is the same as for MDRC-2.
- **MDRC-6:** Radio applications have static resource requirements, on-device compilation of software radio components. This class corresponds to MDRC-3 with the difference that all or part of the software radio components are provided in the Radio Application Package as platform-independent source code or platform-independent IR, which is compiled on the reconfigurable MD itself. As in the case of MDRC-5, it particularly means that the reconfigurable MD should include a proper compiler in order to convert the source code or IR of the software radio components into an executable code that runs on a given modem chip of a reconfigurable MD. As in the case of MDRC-5, it is assumed that the methods of radio programming and the tools to support this category have become sufficiently standardized so that third-party vendors may create radio applications and activate them to different platforms with relative ease. The formal description of the resource management is the same as for MDRC-3.
- **MDRC-7:** Radio applications have dynamic resource requirements, on-device compilation of software radio components. This class corresponds to MDRC-4 with the difference that all or part of the software radio components are provided in the Radio Application Package as platform-independent source code or platform-independent IR, which is compiled on the reconfigurable MD itself. As in the case of MDRC-5 or MDRC-6, it particularly means that the reconfigurable MD should include a proper compiler in order to convert the source code or IR of the software radio components into an executable code that

Table 1 Summary of MDRCs

	Multi-radio system	Resource share (among Radio applications)	Resource manager	Multitasking	Resource measurement	Resource allocation
MDRC-0	No	No	No	no	Design time	Design time
MDRC-1	Yes	No	No	no	Design time	Design time
MDRC-2 MDRC-5	Yes	No[a]	Yes[b]	Yes[c]	Design time	Design time
					Design time/install time	Design time/install time
MDRC-3 MDRC-6	Yes	yes	Yes	yes	Design time	Run time
					Design time/install time	
MDRC-4 MDRC-7	Yes	yes	Yes	yes	Design-time	Run time
					Design time/install time	

[a]Resource share can exist among Radio Access Technologies (RATs) in a given Radio Application.
[b]This is for a fixed resource allocation only. Resource management and resource allocation among RATs (in a single RA) are predetermined in a static manner by Radio Application provider.
[c]Multitasking in this case is for multiple RATs within a single radio application.

runs on a given modem chip of a reconfigurable MD. As in the case of MDRC-5 or MDRC-6, it is assumed that the methods of radio programming and the tools to support this category have become sufficiently standardized so that third-party vendors may create radio applications and activate them to different platforms with relative ease. The formal description of the resource management is the same as for MDRC-4.

The definition of MDRCs described above can be summarized as shown in Table 1.

Note that radio conformance tests are mandatory for MDRC-1 to MDRC-7 in order to ensure that the joint operation of (dynamically) reconfigured base bands and RF front ends is in compliance with the relevant conformance requirements before the device is introduced into the market.

The Basic Technical Approach for Software Reconfiguration

The ETSI RRS approach for software reconfiguration introduces a complex tool set enabling an end-to-end ecosystem for software reconfiguration taking technical, security, and certification solutions into account. This section explains how a subset of the entire framework can be used to introduce a simple software reconfiguration framework offering the basic functionalities independent of the underlying target hardware platform (Fig. 19).

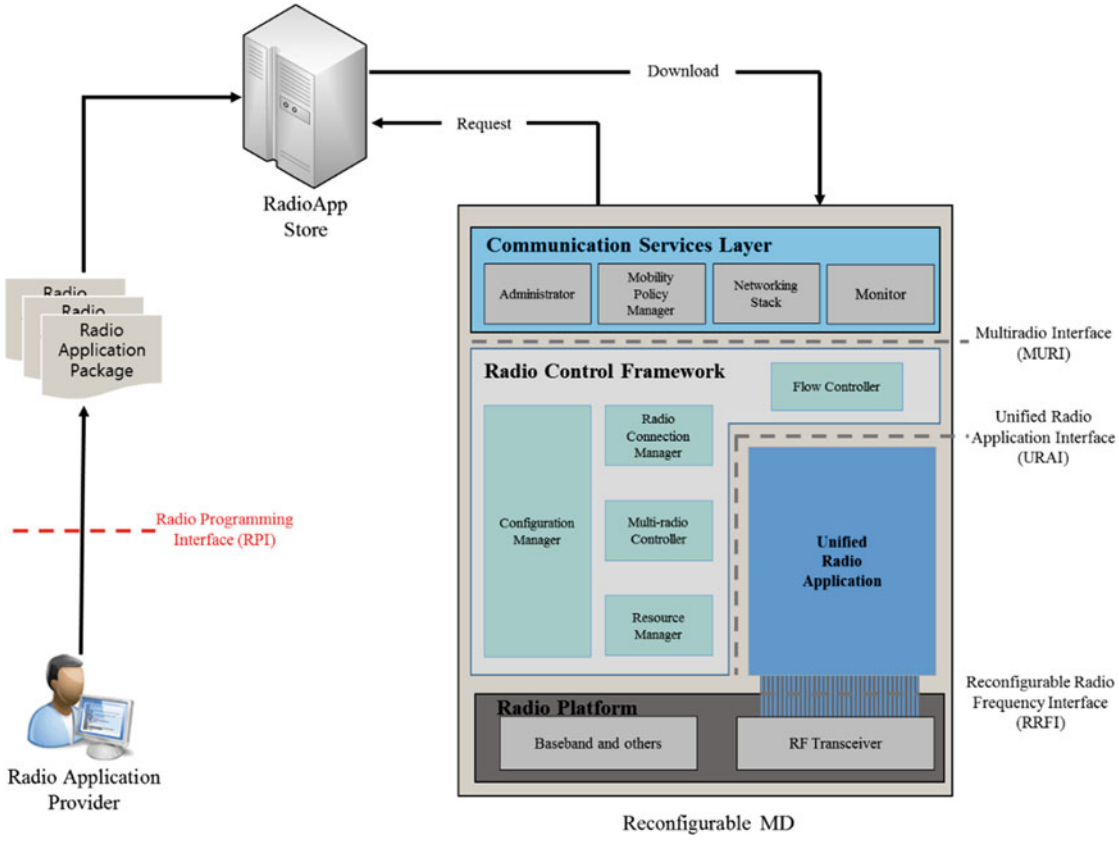

Fig. 19 The reconfigurable mobile device architecture and four sets of interfaces for reconfigurable MD introduced in [11]

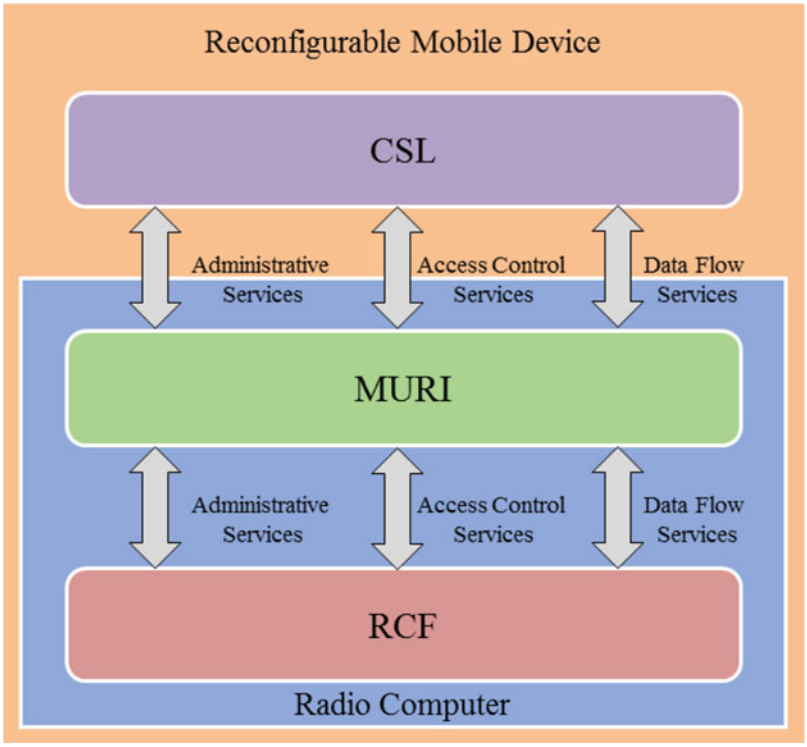

Fig. 20 Interconnection between CSL and RCF using MURI for reconfigurable MD [15]

A basic implementation of the framework may comprise the communication services layer (CSL) and the Multiradio Interface (MURI) to be complemented by the minimum set of required functions in the Radio Control Framework.

As shown in Fig. 20, MURI supports three kinds of services:

- **Administrative Services:** These services are used by some device configuration application, i.e., administrator which is included in the CSL, to (un)install a new unified radio application (URA) into the reconfigurable MD and create/delete an instance of the URA. Installation and loading may take place both at device start-up time to set up the network connection and during run time, whenever reconfiguration of available URAs is needed. MURI does not make any assumption on how and when the mobile device will detect the need of the reconfiguration.
- **Access Control Services:** These services are used by the MPM to maintain the user policies and preferences related to the usage of different RATs and to make a selection between them. Modeling of such preferences and selection algorithms is not in the scope of the present document; however, the MURI specification covers the information exchange of RAT selection decisions between CSL and

RCF. The preferences themselves may originate either locally from applications or end-user settings as well as in a distributed manner from network operator or from a cognitive radio management framework.

- **Data Flow Services:** These services are used by the networking stack of the reconfigurable MD, such as the TCP/IP stack. Therefore data flow services represent the set of (logical) link layer services, which are provided in a uniform manner regardless of which URAs are active.

With these basic features, it is possible to:

- Enable the installation and activation of a unified radio application;
- Parameterize the configuration, e.g., select a number of RATs to be operated simultaneously;
- Access to data flow services
- Perform the deactivation and uninstallation of a Unified Radio Application

Regulation Considerations

With the development of a unified radio application, the radio behavior of the target devices typically changes, and the conformity to the application regulation must be (re)validated. In Europe, annex VII of the Radio Equipment Directive [6] introduce a useful tool in order to update the applicable Declaration of Conformity of a radio equipment. In this context, Radio Virtual Machine (protection) classes are introduced in order to find a trade-off between (re)certification effort and base-band code development flexibility [10].

At one extreme of RVM class, a high-level RVM class corresponds to full reconfigurability of the low-level parameters of an RVM and accordingly necessitates a relatively more extensive certification testing process after the RVM has been reconfigured. At the other extreme of RVM class, a low-level RVM class corresponds to a limited reconfigurability of the low-level parameters of an RVM. As the reconfigurability of the low-level parameters of this particular class of RVM is limited, a relatively less extensive certification testing process is necessitated after the RVM has been reconfigured. Moreover, an RVM can have different RVM classes associated with different components of the RVM that relates to the reconfigurability of the low-level parameters of the respective components of the RVM.

Reconfiguration of an RVM of the highest-level RVM class may necessitate that the overall certification testing process focuses on the certification of each reconfigured software components of the RVM. In such a situation, each respective reconfigured software component may need to be separately certified before one or more sets of reconfigured software components are certified together. For example, a reconfigured RVM software component “A” (e.g., Wi-Fi) may need to be separately certified from a reconfigured and certified RVM software component “B” (e.g., LTE). The certification process may then be such that the joint operation of separately certified reconfigured RVM software components “A” and “B” may then take place jointly.

At the other extreme of RVM classes, the lowest-level RVM class corresponds to a restricted reconfigurability of the low-level parameters of an RVM. For such a restricted level of reconfigurability, a developer of radio applications would only have limited access to the low-level parameters of an RVM. For example, the lowest-level RVM class would permit a radio application developer to have access to only the low-level parameters of the receive chain of an RVM. Accordingly, the lowest-level of RVM class would not need to utilize a corresponding detailed and thorough certification testing process because, for example, a radio platform operating a malfunctioning reconfigured RVM would not interfere with other radio platforms. Thus, level of certification testing for the lowest RVM class would be less extensive certification testing process than that used for the highest RVM class.

One or more medium- or intermediate-level RVM classes may also be established between the two extreme RVM classes that correspond to intermediate levels of reconfigurability of the low-level parameters of an RVM. An intermediate-level RVM class, for example, would allow more flexibility for reconfiguring low-level parameters of an RVM than the lowest-level RVM class but would not permit the degree of reconfigurability that would be associated with the highest-level RVM class. Depending on the level of reconfigurability to the low-level parameters of an RVM, an intermediate-level RVM class may necessitate a certification testing process for a compiled reconfigured RVM and underlying hardware that is more extensive than that corresponding to the lowest-level RVM class but less extensive than that corresponding to the highest-level RVM class. For example, a certification based on the intermediate-level RVM software component might be obtained by contacting an authorized notified body and providing only a serial number for the RVM software component and an identification of the target device type on which the compiled reconfigured RVM would operate. In another example, there could be no requirement for a joint certification based on an RVM software component for a simultaneous operation with other RVM software components. That is, a certificate based on an RVM software component "A" (e.g., Wi-Fi) and a separate certificate based on another RVM software component "B" (e.g., LTE) would allow for a simultaneous operation of reconfigured components "A" (e.g., Wi-Fi) and "B" (e.g., LTE).

Another exemplary situation that may necessitate a relatively less extensive certification testing process would be a Radio Application developer that only reconfigures non-transmission-related low-level parameters, for example, low-level parameters relating to a data interleaver and/or a channel coder in the transmit/receive (TX/RX) chain of an RVM that otherwise has been defined to be of the highest-level RVM class. As nothing related to the spectral shaping of a transmitted signal is reconfigured by the reconfiguration of the data interleaver and/or channel coder, a relatively less extensive certification testing process could be used. Another exemplary situation that may necessitate a less extensive certification testing process would be a reconfiguration that involves changes targeting predefined frequency bands and/or bandwidths. In still other exemplary situations, there may be reconfigurations for which a certification testing process may not be necessary.

The Radio Virtual Machine

The Radio Virtual Machine usage is defined in [18]. It introduces highly efficient software reconfigurability without requiring the usage of a (inefficient) middleware while still enabling code portability.

It is typically up to the manufacture to decide which components of a target platform may be made available to a (third party) software developer. In the past, it has proven difficult to fully open up a highly complex hardware environment, so at least in a first time it may be preferable to enable such third parties to replace one or multiple of selected components by novel software components. Figure 21 illustrates the replacement of an abstract component B through a novel implementation by (third party) software developers.

The Radio Virtual Machine (RVM) is an abstract machine which is capable of executing Configcodes, and it is independent of the hardware. The implementation of a RVM is target radio computer specific, and it has access to the back-end compiler (on the platform itself or externally) for just-in-time (JIT) or ahead-of-time (AOT) compilation of Configcodes.

The RVM executes a particular algorithm presented as a data flowchart. In other words, the RVM is the result of replacing all operators and tokens in the particular data flowchart with abstract processing elements (APEs) and data objects (DOs), respectively. Each APE executes computations marked by the replaced operator identifier. These computations are taken from the Radio Library.

Figure 21 illustrates a conceptual view of RVM processing. This process requires APE, DO, and Radio Library, of which the definitions are as follows:

- APE abstracts a computational resource corresponding to the operation in a particular data flow chart;

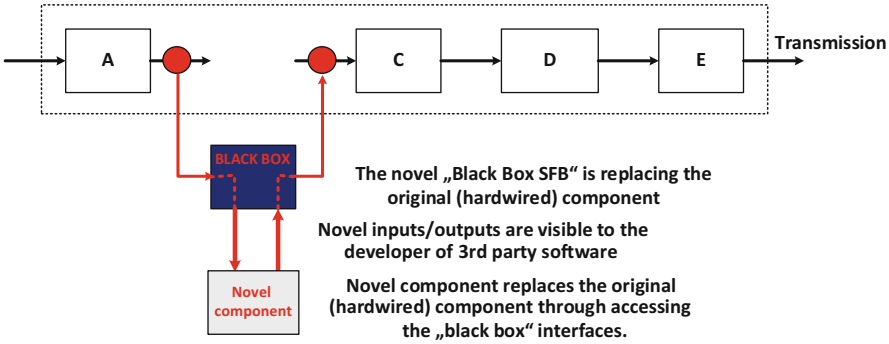

Fig. 21 Example replacement of a component through interfacing with novel SFB provided by a (third party) software provider [18]

- DO abstracts a memory resource. In other words, DO is an abstracted memory for storing data used during the procedure of radio processing;
- Reference/Native Radio Library includes normative definitions/native implementation of all Standard Functional Blocks (SFBs) for front-end/back-end compilation. Note that the computations included in the Radio Library are represented in terms of normative definitions or native implementations of SFBs depending upon whether the Radio Library is used for front-end or back-end compilation, respectively.

Note: User-defined function blocks (UDFBs) will be created through combination of SFBs and represented as a data flowchart to be executed in the RVM. Alternatively, a UDFB is implemented as a stand-alone module/function which can be mapped (i) into one APE (i.e., this UDFB can be considered atomic) or (ii) into an eRVM/RVM (i.e., not atomic). UDFBs are not in general included into the Radio Library, but they are part of the Radio Application Package.

The RVM begins to work immediately after some DO initialization. All APEs execute computations asynchronously and concurrently. An individual APE executes the allocated operator if all the corresponding input DOs are full. APEs access DOs with operations "read," "read-erase," or "write." After reading input data from DOs, the APE executes the allocated operator, and, if output DOs are empty, then the APE writes processed data. Any full output DO blocks the corresponding writing operation. The RVM executes computations until reaching the state when all APEs become inactive. In this state, there are not enough full DOs, which can activate the

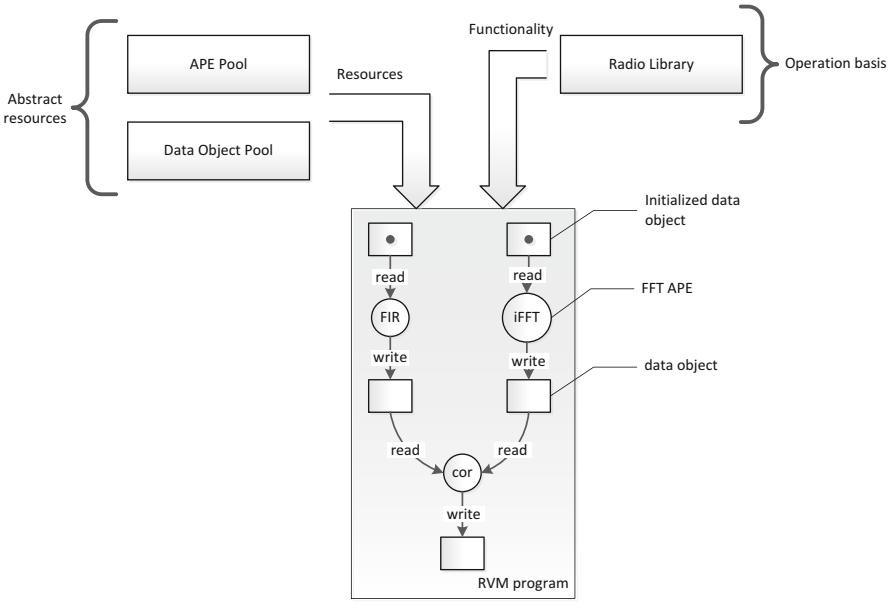

Fig. 22 Conceptual diagram of radio virtual machine processing [18]

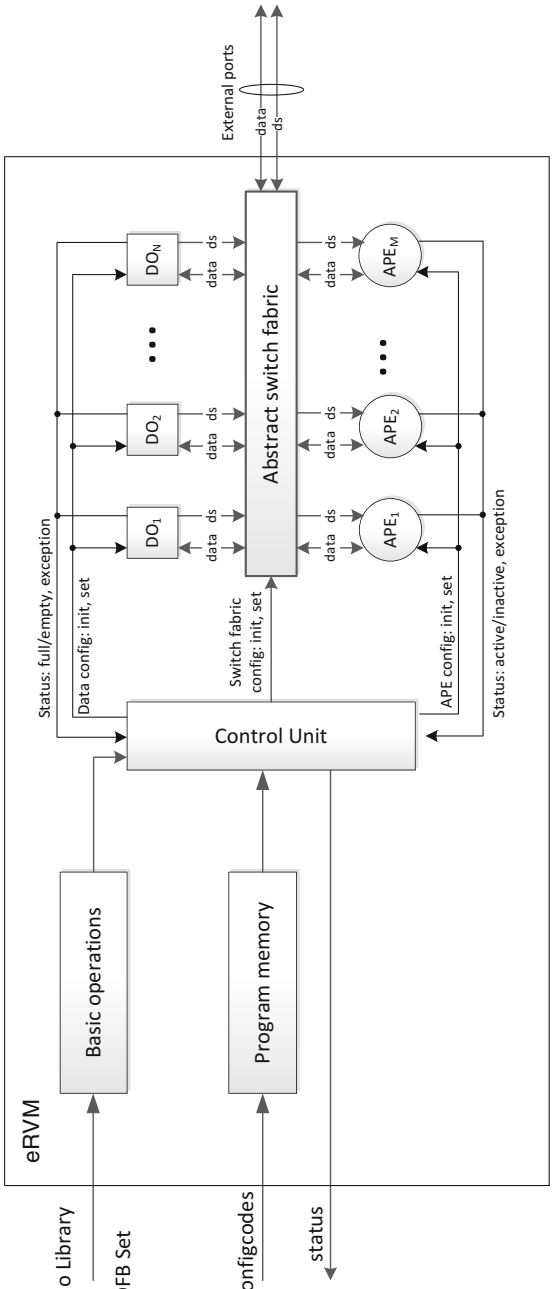

Fig. 23 Elementary RVM [18]

inactive operators. The result of computations is full DOs, which cannot activate the inactive operators.

Note: An output DO can become an input DO for a subsequent operator. Then, this input DO can activate the subsequent operator. Furthermore, the state or operation of a given APE is independent on the state of other APEs, i.e., each APE is atomic (Fig. 22).

In the sequel, the elementary RVM (eRVM) approach is described. An eRVM consists of components of basic operations, program memory, control unit (CU), abstract switch fabric (ASF), as well as APEs and DOs, of which the definitions are as follows. eRVM does not contain another eRVM or RVM.

Basic operations include operators either provided (i) from Radio Library as SFBs and/or (ii) from UDFB set as UDFBs, each of which is mapped onto one single APE.

Note: Since UDFBs might be implemented as a stand-alone module/function which can be mapped into one APE, in this case, basic operations include operators provided by UDFB set as well as by Radio Library as SFBs. Note that those UDFBs are atomic.

Note: For a RVM, the SFB or UDFB can be mapped onto an APE or RVM or eRVM. In the eRVM case, the mapping to RVM or eRVM is not possible since it is the lowest level of hierarchy. Furthermore, from an execution perspective, there is no difference between SFBs and UDFBs.

The program memory is provided with Configcodes which determine the eRVM configuration.

The CU generates initialization and setup instructions for APEs, DOs, and ASF based on decoding Configcodes stored in the program memory.

The ASF connects APEs and DOs in accordance with CU signals. One DO can be connected with multiple APEs. One APE can be connected with multiple DOs. DO from other eRVMs can be connected with ASF through external data ports.

Figure 21 illustrates a block diagram of eRVM. Basic Operations in eRVM consist of operations provided by the Radio Library and/or UDFB set.

Note: A target platform may or may not provide accelerators for some/all SFBs and/or UDFBs. Furthermore, three cases can be considered: (i) RAP includes only SFBs, (ii) RAP includes only UDFBs, and (iii) RAP includes SFBs and UDFBs. Finally, and independent of the upper note, basic operations may include (i) SFBs only, (ii) UDFBs only, or (iii) SFBs and UDFBs (Fig. 23).

Conclusion

In future 5G communication systems, the usage of hardware and spectrum resources will be dramatically different from previous generations. ETSI RRS deliverables will help to provide an efficient spectrum sharing framework based on Licensed Shared Access technology, which will lead to an overall higher spectrum usage efficiency and thus better QoS for the single end user. Software Reconfigurability solutions will allow chipset manufacturers to develop generic solutions which

can then be tailored to a multitude of vertical applications, including medical, automotive, industrial, mass market commercial, etc. ETSI RRS has developed an entire reconfiguration ecosystem which provides solutions for technical, security, and conformity needs. The underlying solution is different from existing state-of-the-art software reconfiguration approaches in the sense that (i) the manufacturer can choose any appropriate level of "openness" of the underlying platform (allowing for the replacement of an entire RAT or only specific components) and (ii) the Radio Virtual Machine approach ensures a highly efficient approach that allows code portability without requiring the usage of an (inefficient) middleware.

activities are important to bridge the gap between these two levels. This chapter introduces the spectrum management framework and spectrum sharing initiatives in the regional level in Europe. The roles of major European regulation and standardization authorities are outlined as well as the cooperation framework between these entities. Additionally, the activities promoting spectrum sharing in Europe is discussed. These European spectrum sharing policy developments have addressed the introduction of additional users in a spectrum band considering both individual usage rights and general authorization by developing specifically licensed shared access and TV white space sharing concepts. These sharing concept are introduced on general level as well as on the basis of introducing the underlying regional regulatory and standardization activities that have led to harmonized overall framework, leaving national administrations the freedom to decide on details of the implementation of the concept.

Introduction

The current spectrum regulatory framework consists of three levels: the international, regional, and national level. The role of the ITU-R at international level has been discussed in ▸ Chap. 48, "Spectrum Sharing Policy at Global Level" as the global forum for spectrum harmonization. The purpose of regional regulation is to harmonize ITU-R spectrum allocations at the regional level. This is especially critical in Europe with small countries with multiple borders and limited national markets. Harmonization in the regional level brings industry confidence on the continuity of spectrum availability, QoS guarantees, and scale of the solutions developed for spectrum management and spectrum sharing to guarantee return of investment and helps the regulators in coordination of spectrum between different radiocommunication services.

The use of mobile data has increased rapidly in the last few years as the increased amount of smartphones, tablets, and other devices has changed the usage patterns of users [1]. Meanwhile, regulatory authorities are struggling to find solutions to guarantee spectrum resources required to support this trend, as the regulatory process for traditional spectrum allocation is becoming too time-consuming and complex. In addition, finding harmonized spectrum for exclusive mobile use is getting increasingly difficult due to existing usage. This has motivated regulatory authorities to consider new concepts and tools to allow more flexibility in spectrum management and enable spectrum sharing.

There are several forums influencing spectrum management and particularly the spectrum sharing policy in Europe including the European Commission (EC), the Electronic Communications Committee (ECC) of European Conference of Postal and Telecommunications Administrations (CEPT), and the European Telecommunications Standards Institute (ETSI). These bodies have established close collaboration framework to promote new technology and services in order to guarantee compatibility of solutions leading to maximal benefit for the society. The European spectrum management framework and spectrum sharing-related activities have also been discussed previously in [2, 3] and [4].

The rest of this chapter is organized as follows. First, the European spectrum regulatory framework is introduced including the introduction of the relevant forums and description of the cooperation framework between them. Second, European activities to promote shared use of spectrum are introduced. Third, activities to develop the licensed shared access (LSA) concept are reviewed followed by sharing initiatives in the ultrahigh frequency (UHF) band. The chapter considers only sharing concepts that are based on individual licensing, leaving out the activities based on general authorization. Finally, conclusions are drawn.

European Regulatory Framework for Spectrum Management

European regional regulatory authorities regarding spectrum issues are the European Commission (EC) and the Electronic Communications Committee (ECC) of European Conference of Postal and Telecommunications Administrations (CEPT). The European Telecommunications Standards Institute (ETSI) is the European standardization organization. In the following sections, the roles of each of these entities as well as the means of cooperation between them are discussed.

The European Commission

The member states (MSs) of the European Union (EU) manage the radio spectrum at the national level in line with the EU level legislation. The MSs need to implement the EU level decisions and supply information on the status of national implementations such as on frequency allocations when requested by the EC. Thus, the EU level decisions on spectrum matters shape the spectrum sharing policy in the MSs. The EC is divided into directorate-generals (DGs). The DGs dealing with spectrum related issues are Communications Networks, Content and Technology (CNECT) and Mobility and Transport (MOVE). DG CNECT is the main DG dealing with mobile communications. It considers aspects such as digitization, regulatory environment for electronic communications, future internet, cyber security, digital privacy, and digital trust policy [5]. The aim of the DG MOVE is to promote efficient, safe, secure, and environmentally friendly mobility and to create the conditions for a competitive industry. Regarding mobile communications, for example, intelligent transport systems and plain and train-related communication issues fall under jurisdiction of DG MOVE.

The Radio Spectrum Policy Group (RSPG) is a high-level advisory group consisting of senior representatives of the MSs and the official representative of the EC. These include representatives from both the regulatory authorities and the ministries having responsibility for radio spectrum-related matters in each MS. The RSPG assists the EC in the development of radio spectrum policy by giving advice on radio spectrum policy issues, coordination of policy approaches, and harmonized conditions, where appropriate, with regard to the availability and efficient use of radio spectrum necessary for the establishment and functioning of the internal market [6]. This is illustrated in Fig. 1. The RSPG can also be requested by the

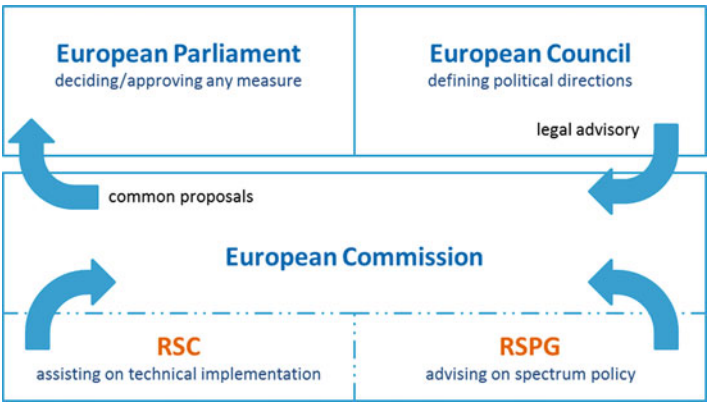

Fig. 1 Roles of different groups of the European Commission and cooperation

European Parliament and/or the Council to issue an opinion or produce a report on specific radio spectrum policy issues relating to electronic communications [7]. The RSPG consults all relevant stakeholders on a variety of technological, market, and regulatory developments relating to the use of radio spectrum. These include both commercial and noncommercial radio spectrum users as well as any other interested party. The Radio Spectrum Committee (RSC) assists EC on the development of technical implementing decisions to ensure harmonized conditions across Europe for the use of radio spectrum. The RSC is composed of MS representatives and is chaired by the EC [8]. EC discusses its proposals with national administrations before implementation in order to ensure that any measure is optimized to the various national situations.

Body of European Regulators for Electronic Communications (BEREC) was established by the European Parliament in 2009 to promote competition, contribute to the development of the internal market, and promote the interests of EU citizens. BEREC has recognized the radio spectrum to be essential to the development of the market and of innovative products and services and supports the study of innovative sharing mechanisms as means to optimize spectral efficiency.

ECC of CEPT

The CEPT is a recognized regional organization representing 48 European national regulatory administrations in the field of posts and telecommunications. Thus, it spans over a wider area than the EC. The goal of Electronic Communications Committee (ECC) of CEPT is to develop common policies and nonbinding regulations in electronic communications and related applications in order to harmonize the use of the radio spectrum across Europe [9]. European proposals developed in ECC represent European interests in the ITU and other international organizations.

The ECC undertakes compatibility studies and establishes conditions and parameters for sharing between different spectrum users. Results of ECC studies are reported to public in the form of ECC Decisions, ECC Recommendations, ECC Reports, and CEPT Reports. ECC Decisions are measures to harmonize the use of spectrum and numbering across the CEPT membership. ECC Recommendations describe measures that national administrations are encouraged to apply. ECC Reports support ECC Recommendations and ECC Decisions by describing results of studies conducted by the ECC. CEPT Reports describe technical studies carried out by in response to mandates from the EC. Results of ECC studies are based on consensus between the member countries.

ETSI

ETSI is officially recognized European Standards Organization which produces standards for information and communication technologies (ICT), including fixed, mobile, radio, converged, broadcast, and internet technologies [10]. ETSI is an independent, nonprofit association; members include national administrations, companies, and international organizations. ETSI produces and maintains technical standards and other deliverables. In accordance to the EC standardization mandate M/536 [11], ETSI develops their part of harmonized standards for radio equipment under the Radio Equipment Directive (RED) [12]. This Directive covers products, including unlicensed devices, which use spectrum. Applying harmonized standards enable manufacturers and service providers to sell, deploy, and put into service the radio equipment within the whole EU. Additionally, ETSI develops technical reports, so-called system reference documents, SRdocs, which provide technical, legal, and economic background on new radio systems under standardization.

Cooperation Framework

The relationship between the EC, ECC, and ETSI is illustrated in Fig. 2 [13]. Partnership between these three aims to facilitate the delivery of technologies and services for the benefit of society. EC may issue study mandates to ECC of CEPT

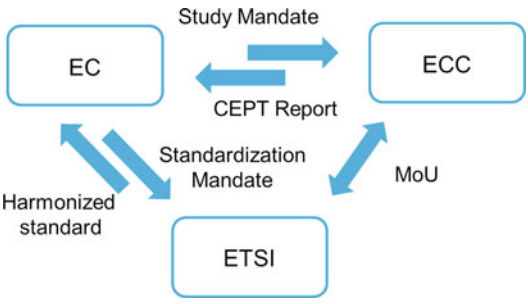

Fig. 2 Cooperation between European regulatory and standardization entities

for the development of technical implementing measures to ensure harmonized conditions for the use of radio spectrum. These mandates specify the task to be undertaken and the timeframe in which they should be achieved. ECC of CEPT communicates technical implementation measures to the EC in the form of CEPT Reports.

The EC submits standardization mandates to ETSI, which responses to these mandates via harmonized standards. Those CEPT Reports that are adopted as EC Decisions by the EC become mandatory for all MSs of the EU [13]. The cooperation agreement between ECC of CEPT and ETSI, so-called memorandum of understanding (MoU), ensures, for example, that deliverables from these parties do not contradict each other and the results from sharing studies are mutually acceptable and implemented consistently by both parties. A MoU has been established also between the CEPT and the EC to support activities on harmonization of radio spectrum.

Promoting Shared Use of Spectrum in Europe

Meeting the growing demand for wireless connectivity with traditional spectrum regulation based on exclusive usage or license-exempt usage is becoming increasingly difficult in the absence of vacant spectrum. In addition, making existing bands available for new type of usage is often expensive, involves delays, and runs the occasional risk of having to "switch off" existing users. Advances in technologies, for example, cognitive radio technology, make it possible for different types of wireless systems with different technologies to operate in the same frequency band. To make shared use of spectrum reality, there is a need to promote such new technologies and make shared use of spectrum easier in the regional level in Europe. Common European framework is needed to achieve economies of scale.

As the early steps to promote shared use of spectrum in 2008, the ECC published a CEPT report that identified white space as a part of the spectrum, which is available for a radiocommunication application (service, system) at a given time in a given geographical area on a non-interfering/non-protected basis with regard to primary services and other services with a higher priority on a national basis [14]. The report discussed cognitive techniques for white space applications in ultrahigh frequency (UHF) band including spectrum sensing, geolocation, and local beacons.

Further to promote shared use of spectrum, the EC has published a report on cognitive radio technologies in 2010 [15]. The purpose of the report was to clarify the concepts and the terminology used as well as to provide an overview of various enabling technologies for cognitive radio, for example, sensing, databases, cognitive pilot channels, and learning. It also provided an overview on various experiences with precognitive technologies and considered regulatory frameworks. Based on their study, the RSPG concluded that more efforts are needed to study the subject to provide adequate confidence on all stakeholders [15]. In 2011 RSPG together with Body of European Regulators for Electronic Communications (BEREC) published a report on infrastructure and spectrum sharing in mobile networks. The report

defined spectrum sharing as the simultaneous usage of a specific radio frequency band in a specific geographical area by a number of independent entities, leveraged through mechanisms other than traditional multiple- and random-access techniques. The report specifically denoted spectrum sharing to consist of common exploitation of frequencies among several operators [16].

As a continuation the EC published a communication to promote shared use of spectrum and highlighted the importance of identifying beneficial sharing opportunities in both licensed and license-exempt frequency bands [12]. These approaches could be based on national administrations granting shared spectrum access rights. The main drivers and enablers identified by the EC for spectrum sharing in Europe were (1) wireless broadband, (2) wireless-connected society, and (3) research and innovative technologies. The main benefits identified by the EC were cost savings for mobile network operators, affordable Internet connectivity, and infrastructure sharing possibilities as well as increased innovation potential arising from lowered spectrum access barrier. The greatest challenges were considered to arise from interference management, incentivizing and safeguarding all stakeholders and capacity of license-exempt bands.

In relation to the mission of the EC to set up annual and multiannual work programs for the European Union in the various economic fields, regarding spectrum management, the EC proposed in 2012 the Radio Spectrum Policy Program (RSPP) [17]. Core mission of the RSPP is to facilitate a strategy toward a digital agenda for Europe leading to a common digital market, part of which should be the efficient use of the spectrum by introducing more reliable approaches to share the resources. In this regard, the RSPP highlights considerations, for example, on the following topics:

- Innovative types of authorization
- CRS as a means to facilitate spectrum sharing based on geolocation
- A spectrum inventory to benefit spectrum sharing opportunities
- Harmonized standards for efficient use of spectrum and spectrum sharing

These considerations lead to decisions related to:

- The identification and sharing of best practices on authorization conditions and procedures
- Establishing a spectrum inventory, which could help to identify the bands suitable for reallocation and spectrum sharing
- The exploration of new ways of spectrum sharing

Regarding the spectrum inventory, the RSPG proposed a three-phased spectrum review process [18]. In the first phase, the demand for spectrum is assessed by collecting and analyzing information on the current and future demands for spectrum using, for example, trends in technology development, surveys, and forecasts of demand in relevant markets. In the second phase, the supply of spectrum is quantified based on the information about the actual use of the frequency bands.

In the third phase, the demand and supply of spectrum is analyzed to determine whether current allocations are adequate to meet the future demand and, if not, identify technically suitable bands to meet the increased demand.

Regarding the spectrum sharing, the EC has identified two dynamic sharing approaches that relate spectrum availability into time and geographical area:

- Collective use of spectrum (CUS): "*Collective Use of Spectrum allows an unlimited number of independent users and/or devices to access spectrum in the same range of designated CUS frequencies at the same time and in a particular geographic area under a well-defined set of conditions*" [19].
- Licensed shared access (LSA): "*A regulatory approach aiming to facilitate the introduction of radio communication systems operated by a limited number of licensees under an individual licensing regime in a frequency band already assigned or expected to be assigned to one or more incumbent users. Under the LSA framework, the additional users are allowed to use the spectrum (or part of the spectrum) in accordance with sharing rules included in their rights of use of spectrum, thereby allowing all the authorized users, including incumbents, to provide a certain QoS*" [20].

CUS concept is based on general authorization without any control on the number of users sharing the band [19]. A device is allowed to use spectrum that it finds unused through its capabilities. This type of usage is generally considered irreversible, and it may make the band unusable for other applications due the potential interference. Interference may be mitigated with power limits, duty cycle limits, or coordination between users. Alternatively, introduction on the higher-frequency ranges could be considered. Without any control mechanism, QoS offered for users depends on the amount of other traffic.

In the LSA concept, an incumbent user is able to share the spectrum assigned to it with one or several new users (so-called LSA licensees) in accordance with a set of conditions negotiated between the primary user and the LSA licensee and implemented under the direction of the NRA [19]. Since the incumbent user continues the use of spectrum while enabling the use of the same spectrum by other users, the efficiency of spectrum use is improved. The LSA concept allows the LSA licensee a faster access to a spectrum band in comparison to a lengthy repurposing process. Both the incumbent user and the LSA licensee are guaranteed protection from harmful interference and predictable QoS. A reliable sharing agreement and a database (or another system for updating the conditions of spectrum access) were considered as critical items for success of LSA by the RSPG. In its opinion on June 2013, the RSPG stated that [21] "To meet the growing demand for spectrum the industry and administrations are under pressure to introduce new technologies and regulatory mechanisms to optimise the use of the limited frequency resources. In this context, the promotion of the shared use of radio spectrum resources is a valuable means to offer additional spectrum access to broadband communications, for licence exempt but also licensed usage, which is a new paradigm referred to as Licensed Shared Access."

The development on the LSA concept has been continued by CEPT and ETSI as well as by Administrations in terms of live experimentation as will be discussed in the following section. It could be concluded that the EC values and supports the development of new concepts, related technologies, and authorization conditions for sharing the scarce spectrum resources in future. In the Digital Single Market (DSM) initiative of the EC [22], one of the key actions as announced by the EC is to *present an ambitious overhaul of EU telecoms rules. This includes more effective spectrum coordination and common EU-wide criteria for spectrum assignment at national level, creating incentives for investment in high-speed broadband; ensuring a level playing field for all market players, traditional and new; and creating an effective institutional framework* [23].

There are new activities in the development of next-generation mobile communication networks known as 5G. These efforts are specifically addressing new spectrum for the mobile service in preparation for WRC-19 in the frequency range between 24 and 86 GHz. In these discussions, spectrum sharing will play an increasingly important role. The 5G Action plan for Europe published by the EC in 2016 states that the potential for spectrum sharing, including under license-exempt use, should be maximized as it generally supports innovation and market entry [24]. RSPG published an early opinion on spectrum aspects for 5G in 2016 providing a strategic roadmap toward 5G for Europe [25]. As a specific point, the RSPG was requested to identify and analyze spectrum-related challenges, such as spectrum sharing, usage, and license conditions, which will be addressed in a subsequent detailed opinion. A communication from the EC in 2016 toward a gigabit society promotes shared use of spectrum, either on the basis of general authorization or individual rights of use, as it can enable more efficient and intensive exploitation of spectrum especially in the new millimeter spectrum bands foreseen for 5G communications [26]. CEPT roadmap for 5G published in 2016 urges to investigate new sharing opportunities and challenges that new technologies (e.g., MIMO) can bring [27].

Licensed Shared Access

The development of the LSA concept was initiated by industry with their concept of providing mobile industry means to access spectrum that was occupied by other services. Based on this initiative, the LSA at its current form was introduced by the EC as a general concept to facilitate controlled sharing between any two systems in such way that predictable QoS is provided [19]. Thus, the entrant user, so-called LSA licensee, may present any industry field. The incumbent user will maintain higher spectrum usage rights and is allowed to reclaim spectrum when needed. This will increase the efficiency of spectrum use considerably, especially when considering sporadic or spatially restricted incumbent usage.

In LSA, access to the shared band is based on licensing regime and a sharing framework. Depending on the national approach and incumbent usage, the LSA license may be limited in time or geographical area. The sharing framework defines

the set of conditions for shared access, and it is negotiated between the incumbent user, the LSA licensee, and the NRA. The conditions should be defined in reasonable accuracy to provide enough predictability toward the future access to spectrum for the LSA licensee, to invest in equipment and network.

The first use case of LSA considered in the standardization and regulation in Europe has been the application to the 2.3–2.4 GHz band to enable mobile operations on the band [28–31], and [32]. This band has been allocated to mobile service and identified for international mobile telecommunications (IMT) by the WRC-2007 of the ITU-R on a globally harmonized manner. However, due to the incumbent usage on the band, it is not available for mobile use on an exclusive basis globally or even in all European countries. The incumbent use on the band includes Programme Making and Special Events (PMSE), wireless cameras, telemetry, fixed service, unmanned aircraft systems, and amateur service depending on the country [28]. The amateur service, however, is on the secondary basis and therefore has no protection from LSA usage. Tools for LSA need to be flexible enough to function regardless of the difference characteristics of the incumbent usage. Task of the European regulatory and standardization activities is to develop harmonized solutions for LSA in order to create a European internal market. The activities of ECC of CEPT and ETSI on LSA are explained below and summarized in Fig. 3.

The first report from ECC of CEPT on LSA was aimed at providing a description of the general LSA framework that could be applied to enable sharing between any two services in accordance to the definition of RSPG [33]. Studies were made on the compatibility of the LSA framework with the current regulatory framework on the use of spectrum, current spectrum management, and management of frequency authorizations. Additionally, some general guidelines were given on the applicability criteria of LSA when applied to the mobile communications. Regarding the application of the LSA concept to the 2.3–2.4 GHz band, the work was initiated by the EC by sending a study mandate to CEPT on harmonized conditions for mobile use on the band [34]. As a response, ECC of CEPT developed guidelines for the application of LSA into this band and communicated them to EC in the form of two CEPT Reports. In the first report, technological and regulatory options for sharing between mobile broadband and the relevant incumbent services were identified [28]. The report included an overview of different incumbent services on the band in the European countries as well as options for sharing for these services. In the second report, focus was on the technical sharing solutions between the mobile broadband and PMSE, which is the most common incumbent usage on the band [29]. The report included a step-by-step approach for the implementation of an LSA sharing framework. The following steps were identified: determining the extent and type of incumbent use, calculating the protection criteria for the incumbent, and identifying operational conditions for sharing, such as implications on the mobile network.

The use case considered for LSA in ETSI RRS is bandwidth expansion to an existing MNO [30]. In practice this means additional bandwidth to an MNO that is already operating LTE in a licensed band in that given area. This can be used either for macro- or small cell deployment. The first system reference document from ETSI provided an overview of the LSA concept, including aspects such

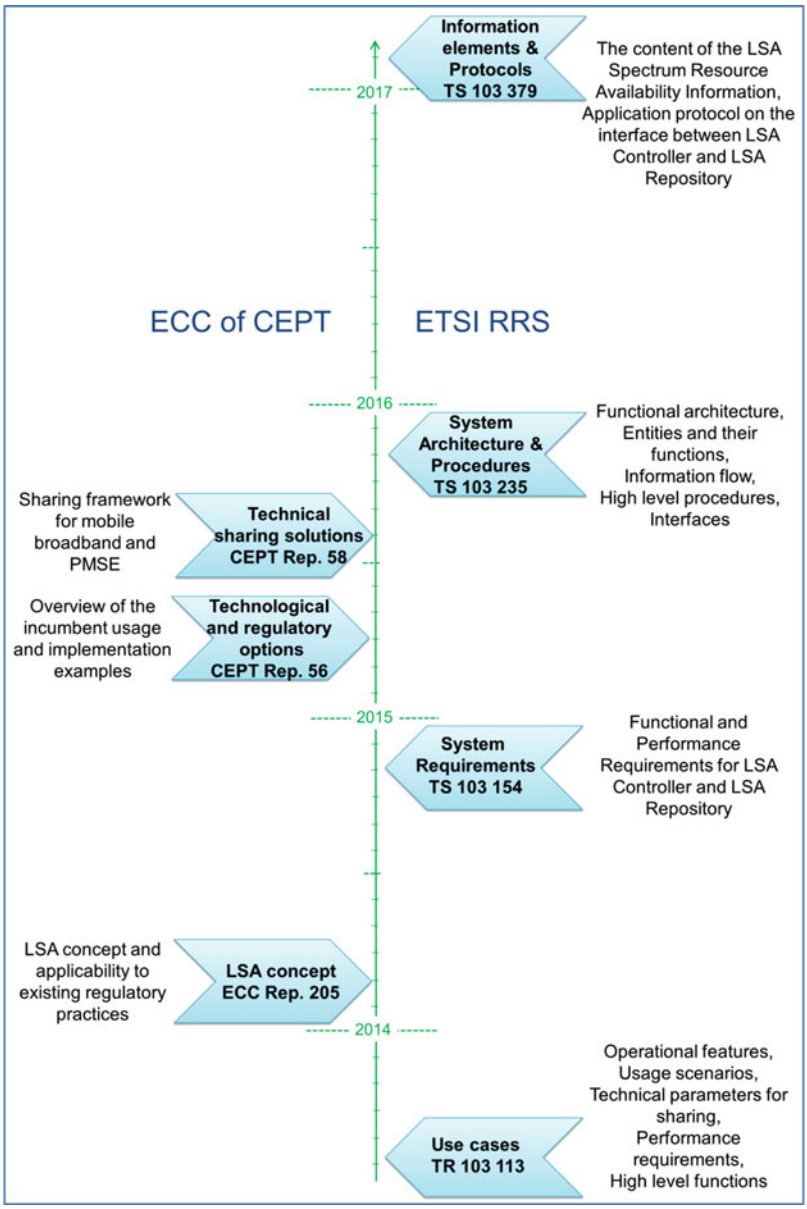

Fig. 3 Activities on LSA in ECC of CEPT and ETSI RRS

as operational features, performance requirements, and high-level functions [30]. At this point, it was outlined that the LSA architecture would be based on two functional units on top of the existing cellular network: LSA controller (LC) and LSA repository (LR). This is illustrated in Fig. 4 [30]. In this initial report, the

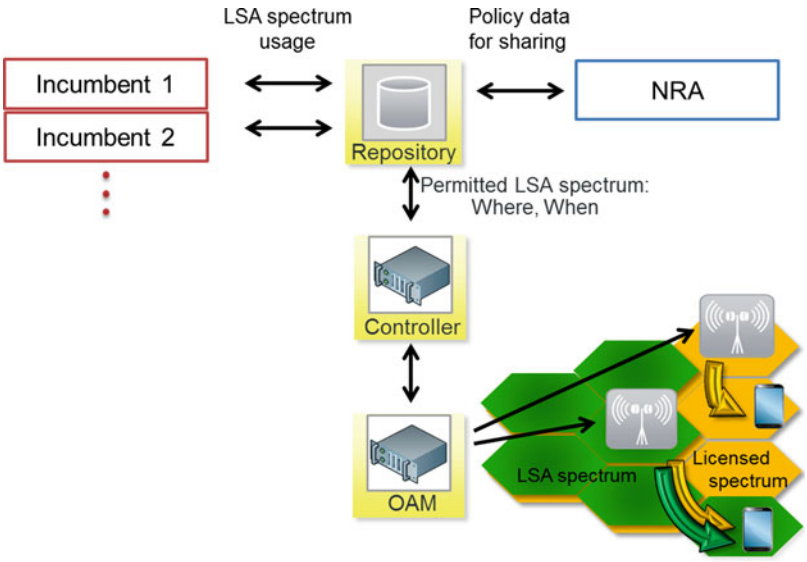

Fig. 4 An example architecture for LSA according to ETSI RRS

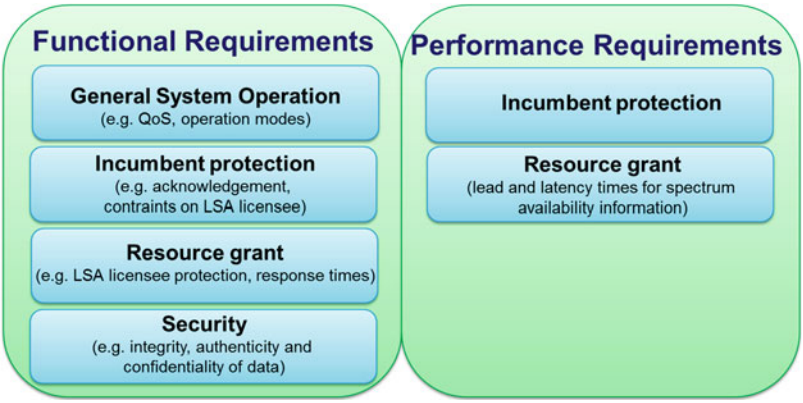

Fig. 5 Requirements for the LSA system defined by ETSI RRS

LR was defined as a database that contains information on the incumbent spectrum usage and LC as a control unit that uses this information together with additional information on, e.g., access rules to compute the spectrum availability information. This initial definition was then complemented in the second report which provided a full list of functional and performance requirements for the LSA system, consisting of LC and LR, that would enable mobile broadband access to the band [31]. These requirements were categorized as shown in Fig. 5. Functional requirements relate to the general system operations, to the protection of the incumbent user, to the

process of granting the rights of use of LSA spectrum resource to the LSA licensee, and to security. Performance requirements relate to the timescales required by the LSA system for delivering spectrum usage information. Third report defined high-level functions and mapped them into the two logical elements, LC and LR [32]. It also defined high-level procedures, messaging, and information exchange between these elements. The last report defined the application protocol LC and LR, and the content of the LSA spectrum resource availability information (LSRAI) conveyed by this protocol [35].

One of the major benefits of the LSA is that it requires no changes to internal procedures or air interfaces of the mobile network or to the user equipment. Therefore, there is no need to change the mobile network internal procedures or protocols defined by the 3rd Generation Partnership Project (3GPP) standardization. This reduces the time required for implementation considerably. The fact that LSA can be implemented using additional logical units on top of the cellular architecture also means that the MNO can continue using the existing equipment regardless of whether it needs to implement LSA or not. However, on an architecture level, 3GPP is working on defining a harmonized LSA solution supported by the 3GPP network management architecture and internal interfaces [36].

Sharing Concepts Targeted for the UHF Band

For several decades the ultrahigh frequency (UHF) band has been used for broadcasting linear over-the-air TV services in Europe, but the broadcasting sector received pressure particularly from the mobile communication sector to give up parts of its traditional UHF broadcasting spectrum to be used by the mobile service. As a consequence, almost half of the original UHF broadcasting band (470–862 MHz) has been or is being cleared from broadcasting service and repurposed for mobile use in Europe (694–862 MHz). In addition, there are spectrum sharing initiatives specifically addressing the UHF band which are discussed next.

TV WS

The CEPT defines a white space (WS) as a part of the spectrum, which is available for a radiocommunication application (service, system) at a given time in a given geographical area on a non-interfering/non-protected basis with regard to primary services and other services with a higher priority on a national basis [14]. The European regulatory activities on TV WSs were initiated in ECC of CEPT within Working Group (WG) Spectrum Engineering (SE) in May 2009. A dedicated Project Team (PT) SE43 "*White Spaces-cognitive radio systems*" began its work by defining technical and operational requirements for the possible operation of cognitive radio systems in the white space of the frequency band 470–790 MHz. Terms of reference to SE43 was to (1) define technical and operational requirements for the operation of cognitive radio systems in the white spaces of the UHF broadcasting band

(470–790 MHz) to ensure the protection of incumbent radio services/systems and investigate the consequential amount of spectrum potentially available as white space; (2) provide, if required, technical assistance on further issues related to white spaces and cognitive radio systems that ECC may identify in the future; and (3) liaise directly with relevant groups within ECC and ETSI as necessary [37].

The first report from SE43 addressed technical and operational requirements for the possible operation of cognitive radio systems in the white spaces needed to ensure the protection of the incumbent radio services [38]. The report identified a range of possible deployment scenarios as well as set up some key working assumptions and protection criteria to be used in sharing studies for different incumbent services existing on the band. In the second report, additional technical investigations to facilitate development of the regulation for white space devices (WSDs) were performed [39]. The report described the protection of incumbents, digital terrestrial television (DTT) broadcasting and PMSE wireless microphones, protection of services on the bands adjacent to UHF TV band, and the classification and technical characteristics of WSDs. It also included measurement campaigns which detailed DTT and PMSE protection ratios tests with example WSD technologies. The third report described the use of information in a centralized manner from a geolocation database to guarantee the protection of the incumbent services [40]. The report provided detailed framework proposal based on new modeling techniques and a range of measurement campaigns as well assessed the appropriateness of the geolocation technique for protecting incumbent services coexisting and adjacent bands. The report also provided more detailed guidance on general principles and basic requirements for WSDs operating under the geolocation database.

The work of SE43 was later on complemented by the work of ECC WG Frequency Management (FM) PT 53 group [41]. In this group, a report was developed for describing overall framework for TV WSD using geolocation databases and for providing guidance for national implementation [42]. Additionally, the report described options for database policy and provision. Annex 2 of the report contained a high-level description of an example of national implementation of TVWS framework and calculation of operational parameters from Ofcom UK.

The standardization for TVWS has been performed in ETSI RRS. ETSI has carried out extensive standardization efforts for operation in TV white spaces by defining and publishing technical specifications for use cases [43], system architecture and high-level procedures [44], and system architecture for information exchange between different geolocation databases [45]. The European standard for TV white space devices was published in [46]. Harmonized standard covering the essential requirements of article 3.2 of the Radio and Telecommunication Terminal Equipment (R&TTE) Directive [47], which includes WSD radio frequency (RF) requirements to prevent harmful interference to DTT incumbents by setting specific limits for the radiated power in the assigned and adjacent channels of the WSD. In addition, ETSI has published an European standard on parameters and procedures for information exchange between different geolocation databases (GLDBs) in [48] and signaling protocols and information exchange for coordinated use of TV White Spaces in [49].

Flexible Use of UHF Band

The flexible use of UHF band has been under active discussion in the last few years as the media convergence has inspired a lot of investigations on the broadcast broadband converge and its impact on spectrum and network [50]. In Europe, the high-level group (HLG), comprised of nineteen executive-level representatives from the mobile and broadcasting sectors, was convened by the EC in 2013 to deliver strategic advice to the EC for developing a European strategy on the future use of the UHF band. The results of the 6-month long debate in the group were reported by one of the group members [51]. In parallel, the regulatory group ECC of CEPT TG6 "long-term vision UHF" prepared a report, long-term vision for the UHF broadcasting band, identifying and analyzing possible scenarios for the development of the UHF band in the long term [52].

RSPG of the EC issued a draft opinion on the future use of the UHF band 470–790 MHz supporting the provisioning of wireless broadband services in the 700 MHz band [53]. In the opinion, RSPG recommended that the frequency band 470–694 MHz will remain available for broadcasting in the future. However, it also encouraged flexibility for countries to use the band for wireless broadband in downlink. In line with the RSPG view, the EC published a draft decision to allow mobile downlink use on the band [54]. This would allow member states of the EU to introduce mobile use on the band on a national basis in accordance to the current regulatory boundary conditions, without causing interference or claiming protection from broadcasting in the neighboring countries. In practice the availability of the spectrum would vary within country. The shared use with broadcasting and variable availability of the spectrum may motivate the implementation and further development of spectrum sharing concepts such as LSA.

Conclusion and Future Directions

The regional-level regulatory activities on spectrum matters aim to bridge the gap between the international harmonization and governance of spectrum by national administrations. Regional harmonization plays a critical role especially in Europe with small national markets for countries. The purpose of the harmonization at the regional level is to provide industry confidence and visibility to the future opportunities as well as to guarantee economies of scale for the sharing solutions to guarantee return of investment. It also aids European administrations to manage spectrum in their country in an efficient manner as well as to coordinate between the neighboring countries.

In the last few years, extensive efforts have been taken at the European level to develop new spectrum sharing concepts that introduce additional users in a frequency band on a shared basis while protecting the incumbent users. This has led to considerations on concepts targeted for specific bands (e.g., UHF band) as well as development of more general sharing frameworks such as LSA. In addition

to currently considered use case of mobile broadband, LSA has potential not only for mobile as currently considered but also to enable sharing between any two radio systems.

Importance of spectrum sharing will significantly grow in the development of 5G systems that will operate in a wide range of frequency bands. In particular, the operation in higher-frequency bands will require sharing with incumbents as well as between 5G networks where the development of European level harmonization will be important. Spectrum sharing becomes more relevant to all future use cases for 5G, and it is therefore essential to understand how to develop the frameworks within which different technologies and services can coexist in the same frequency band.

Abstract

The regulation of spectrum in the United States is managed by two independent agencies: the National Telecommunications and Information Administration, who is responsible for spectrum used by US government agencies such as the Department of Defense and the National Weather Service, and the Federal Communications Commission, who is responsible for all nonfederal spectrum. Both agencies are mandated by law to maximize the efficient use of spectrum, and toward that end, both agencies are working to share underutilized spectrum to the greatest extent possible. This chapter will explore various initiatives by these two agencies to achieve this objective, both independently and in cooperation.

Introduction

Regulation of spectrum sharing in the United States is oftentimes more complex than in other countries because spectrum is managed by multiple regulatory agencies (see Fig. 1) [1]. Through the Communication Act of 1934, the US Congress established the Federal Communications Commission (the FCC or "Commission") as an independent body with broad powers to regulate both wireline and wireless communications for nonfederal use including commercial, private, and state and local government use. Through the same act, Congress reserved for the President of the United States the authority to assign operating frequencies for federal government use. In 1978, the President issued an executive order effectively delegating these powers to the newly established National Telecommunications and Information Administration (NTIA) operating within the Department of Commerce and led by the Assistant Secretary of Commerce for Communications and Information. Congress later codified the functions defined in this order in the National Telecommunications and Information Administration Organization Act, making the delegation permanent.

The regulation of spectrum is managed differently by the FCC and NTIA. Regulations from the FCC are largely created through a rulemaking process [2]. For each new rule, a docket is opened to act as an electronic file for all the rulemaking documents issued. Once a docket is opened, a notice of public rulemaking (NPRM) can be released, defining the need for and the text of the proposed rule to allow for public comment. Comments and reply comments (comments about the comments) are reviewed, and the Commission can then choose to leave the docket open, issue a further notice of proposed rulemaking with an amended proposal, or issue a final rule, or Order. The Commission may also release a notice of inquiry or other public notice in support of the rulemaking process. The FCC's rules and regulations are in Title 47 of the Code of Federal Regulations (CFR), which are published and maintained by the Government Printing Office. Parties disagreeing with the final rules may issue a petition for reconsideration or seek court review of the decision. The FCC is supported in this rulemaking process through a Technological Advisory Council (TAC), which is comprised of leading experts and is chartered to

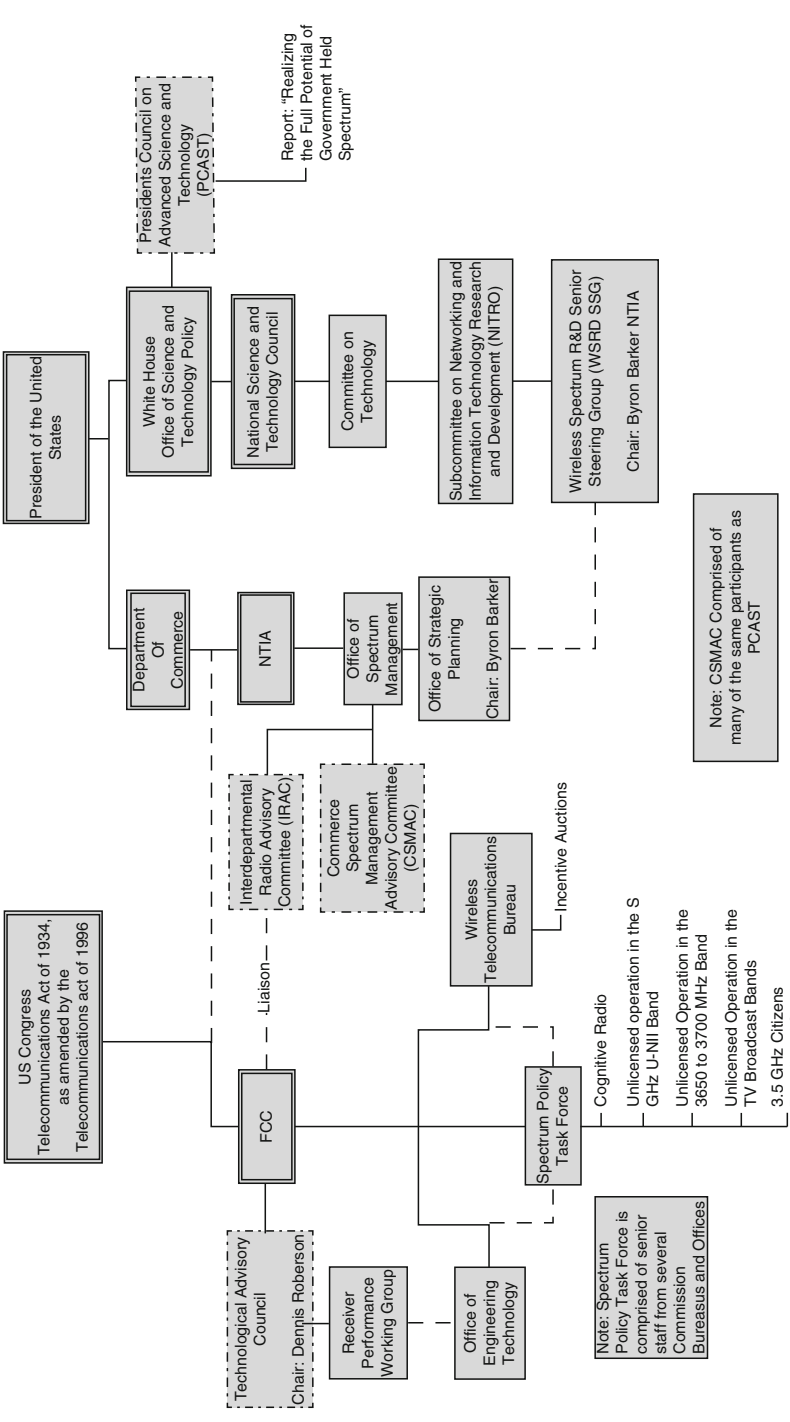

Fig. 1 Relationships between organizations regulating and managing spectrum in the United States

help the Commission keep abreast of current innovations and understand relevant technologies [3].

Spectrum management at NTIA follows a different model. Policies and procedures for assigning federal spectrum within the United States are established by NTIA's Office of Spectrum Management (OSM) [4]. To help facilitate this task, OSM chairs the Interdepartmental Radio Advisory Committee (IRAC) consisting of representatives from 19 federal government agencies who advise the NTIA on policies and regulations for the use of federal spectrum [5]. OSM coordinates with the IRAC to set policy for the assignment of spectrum, the results of which are published in the NTIA "Manual of Regulations and Procedures for Federal Radio Frequency Management," also known as the "Red Book" [6]. In addition to the IRAC, OSM receives support in this area from the Commerce Spectrum Management Advisory Committee (CSMAC), comprised of government and industry experts chartered to advise NTIA on spectrum management policy [7].

The Communications Act of 1934 does not allocate exclusive use of specific bands for federal and nonfederal use, so all allocations stem from coordination and agreement between the FCC and NTIA. To help in this process, the FCC appoints a representative to act as a liaison between the IRAC and the Commission. Through this coordination, 54.2% of spectrum below 3.1 GHz in the United States is already shared, with 31.7% and 14.1% allocated, respectively, to the private sector and government on an exclusive basis [8]. Until recently, most sharing has been through static allocations; however, this is changing, and new regulations are being looked at for federal and nonfederal use to utilize more dynamic sharing to improve efficiency to free spectrum for new applications. The remainder of this chapter will explore existing and emerging regulations related to these new dynamic spectrum sharing regulations, with a focus on the technical details of the defined policies and rules.

Managing Spectrum Sharing Among Federal Users

Frequency sharing is assumed for federal users, and the Red Book specifically states:

> Sharing of frequencies is necessary for the fullest utilization of the radio spectrum. This may entail the acceptance of some interference but does not contemplate requiring the acceptance of harmful interference.

With that in mind, Chapter 8 of the Redbook defines the specific procedures followed for the coordination and assignment of frequencies [9]. In summary:

- Each federal agency evaluates telecommunications needs on a mission-by-mission basis. As a part of this evaluation, agencies perform technical studies, select potential frequencies for each mission, and coordinate with other agencies as necessary, with a requirement to neither cause harmful interference to nor receive harmful interference from other authorized users, as outlined in Red Book Chapter 10 [10].

- Once this evaluation is complete, the agency files an application with the NTIA Office of Spectrum Management for consideration of the Frequency Assignment Subcommittee (FAS) of the IRAC. Preparation of these applications is outlined in Chapter 9 of the Redbook [11] and includes requirements for technical data on transmit and receive equipment, geolocation information, application descriptions, and other usage information. Applications can request a regular or permanent assignment, a temporary assignment, a trial assignment, or a group assignment.
- The FAS considers applications and takes action within the established policy guidelines. Principles followed by the FAS in frequency assignment include frequency sharing, planned frequency utilization, and the justification for frequency assignments.

Frequency assignments are made with a specific geographic location, a specific service area, and performance requirements levied against stations in a close geographic proximity. If multiple assignments are made in the same area, Priority Access is generally given to the assignment made first. Other frequency assignment regulations defined in the Red Book take into account the type of service and band of operation. Under these rules, OSM processes between 8000 and 10,000 assignment actions each month while maintaining a database of over 400,000 assignment entries [12]. On 11 April 2014, the NTIA published a new online resource detailing these assignments and use [13].

One important item to note: the sharing of spectrum between federal and nonfederal users discussed later in this chapter is facilitated through this same process. The FCC, through their IRAC liaison, files frequency assignment applications for nonfederal use of shared bands and in cases where operation in nonfederal bands may impact federal spectrum use. Processing of the application then follows the standard course.

Early Regulations Supporting Nonfederal Spectrum Sharing

A key element of the Act of 1934, as amended, directs the Commission to "generally encourage the larger and more effective use of radio in the public interest" and to seek to promote "efficient and intensive use of the radio spectrum" [14]. In 2000, the FCC began looking at new models to achieve these objectives with a move toward higher levels of spectrum sharing for nonfederal users through two early rulemakings: one on software-defined radio and the other on secondary markets. In 2002, the Commission took these actions a step further in forming the Spectrum Policy Task Force. This task force was made up of senior staff and chartered to "provide specific recommendations to the Commission for ways in which to evolve the current "command and control" approach to spectrum policy into a more integrated, market-oriented approach that provides greater regulatory certainty, while minimizing regulatory intervention" and "assist the Commission in addressing ubiquitous spectrum issues, including, interference protection, spectral

efficiency, effective public safety communications, and implications of international spectrum policies" [15]. Through this task force, a host of other proceedings advanced spectrum sharing, including an early proceeding on smart radio systems. This section will explore these early regulations.

FCC Rulemaking on Software-Defined Radio (Docket 00-47)

In March of 2000, the FCC issued a notice of inquiry seeking comment on a variety of issues related to software-defined radios (SDR) [16]. A key element of this notice was an exploration of several spectrum sharing scenarios that could be enabled by SDR, allowing a lessee to reconfigure a radio to meet with the requirements of a specific band manager at a specific moment in time. Twenty-four parties filed comment on this NOI, and in December of 2000, the FCC followed with a Notice of Proposed Rulemaking. The NPRM proposed a regulatory definition of SDR and rules for SDR equipment authorization. Through the NPRM, the Commission recognized the potential for SDR to increase spectrum efficiency, but concluded that no additional rules were required at that time with respect to this capability. The Commission later went on to issue a Report and Order, building on the 14 comments and 8 reply comments to modify the proposed SDR definition and to finalize voluntary authorization requirements (Table 1).

Table 1 Timeline for early regulations

	2000	2001	2002	2003	2004	2005
Early regulations Report and Order on SDR	Notice of inquiry on SDR			NPRM on employing cognitive radio technologies		Report and Order on cognitive radio technologies
	NPRM on eliminating barriers to the development of secondary markets			Report and Order and further NPRM on eliminating barriers to the development of secondary markets	Second Report and Order and further NPRM on eliminating barriers to the development of secondary markets	
			Spectrum policy task force formed			

Elimination of Barriers to the Development of Secondary Markets (Docket 00-230)

In November of 2000, the FCC issued a Notice of Proposed Rulemaking on "Promoting the Efficient Use of Spectrum through Elimination of Barriers to the Development of Secondary Markets" [17]. Through this NPRM, the Commission recognized that spectrum may be being used inefficiently, especially in rural areas, and, given the increased demand for spectrum, sought ways to encourage license holders to lease underutilized spectrum on a temporary basis. Concurrent with this NPRM, the Commission also issued a policy statement outlining its long-term principles for encouraging the development of such secondary markets.

A key issue that the NPRM tried to address was clearly defining who was responsible should harmful interference occur under the defined scenarios. In addressing this issue, the NPRM introduced the concept of a "band manager," which is a class of licensee specifically authorized to lease unused spectrum. The NPRM also proposed a database approach for band managers to utilize in managing secondary users, concluding that "the private sector is better suited both to determine what types of information parties might demand, and to develop and maintain information on the licensed spectrum that might be available for use by third parties."

Thirty seven parties commented on this NPRM and 21 filed reply comments. Based on these comments, in 2003 the FCC issued a Report and Order and Further Notice of Proposed Rulemaking. The Order established two options for use in secondary markets:

- A spectrum license holder may enter into an agreement with an entity wishing to lease spectrum without Commission interaction. In doing so, the licensee must maintain legal responsibility for the leased spectrum. The licensee acts as the "spectrum manager" in this option and may lease any or all of their licensed spectrum in any geographic area for any length of time they wish. Technical and interference-related rules associated with the license still apply, and the licensee is liable for any violations.
- A streamlined process for a licensee to transfer control to an entity wishing to lease the spectrum. Referred to as de facto transfer leasing, the lease can apply to any amount of spectrum in any geographic area and for any period of time. All the original service rules and policies apply; however for the period of the lease, the leasing entity is the responsible party and is liable for any violation.

In addition, the Commission issued a second NPRM seeking comment on issues fundamental to the development of secondary markets. Questions contained in this NPRM included what additional steps the Commission needed to take, whether there would need to be a clearing house mechanism to provide real-time information for "opportunistic" devices, and what role the Commissions should take, if any, in regulating such a clearing house.

The Commission received five petitions for reconsideration on the order, along with 21 comments and 10 reply comments on the NPRM. In July of 2004, the Commission responded with a Second Report and Order, Order on Reconsideration, and Second Further Notice of Proposed Rulemaking (NPRM). In summary, the order:

- Adopted immediate approval procedures for certain categories of de facto transfer leasing agreements and streamlined the procedures for establishing a short term de facto lease
- Clarified policies related to "smart" or "opportunistic" use technologies, including reinforcing that the rules allow for dynamic forms of spectrum leasing and that licensees and those entities that are leasing their spectrum may share use of the same spectrum on a nonexclusive basis for the term of the lease
- Established a new type of secondary market that facilitates the development of a private commons in licensed spectrum, allowing groups of licensees or lessee to make spectrum available to a group of users that do not use the licenses or lessees network infrastructure

The second further NPRM sought comment on ways in which new technologies could make opportunistic use of licensed spectrum, including types of uses of opportunistic spectrum and examples of private commons and ways to improve the private commons model. Only three comments were received, and so in April 2007, the Commission issued a third Report and Order that reaffirmed the existing Report and Order without change.

FCC Rulemaking on "Smart Radio" Systems (Docket 03-108)

In May of 2003, the FCC Office of Engineering and Technology (OET) hosted a workshop exploring the use of cognitive radiotechnologies to enable more efficient use of spectrum [18]. In December 2003, the FCC followed up on this workshop by launching a Notice of Public Rulemaking on "Facilitating Opportunities for Flexible, Efficient, and Reliable Spectrum Use Employing Cognitive Radio Technologies." Through this NPRM, the Commission sought comment on all issues related to cognitive radio technology, with a specific focus on:

(1) Allowing unlicensed devices to operate in higher power levels in rural areas
(2) Allowing unlicensed devices to operate at higher power levels in bands with limited spectrum use
(3) Enabling spectrum leasing, including:
    a. The ability of cognitive radio to support/enable for interruptible spectrum leasing, allowing a lessor to take back spectrum from a lessee,
    b. Applicability of interruptible spectrum leasing models to allow secondary commercial use of public safety spectrum
(4) Dynamically coordinating spectrum sharing, allowing ad hoc sharing of licensed spectrum

(5) Facilitating interoperability between communications systems, especially first responder public safety communications systems
(6) Forming ad hoc or mesh networks with the ability to self-heal

The NPRM also sought comment on proposed rule changes allowing automated frequency selection for unlicensed devices, allowing manufacturers to build devices that can operate worldwide when unlicensed frequency bands are not harmonized.

Through the associated Order, Docket 00-47 was closed, with the further evolution of the regulation of SDR now falling under a combined SDR/CR docket. The NPRM also revisited equipment authorization for SDRs, noting that in the 2 years since the rules were passed, no manufacturers had filed applications to certify an SDR, even though many of the devices certified by the FCC met the Commission's broad definition of SDR. With this in mind, the NPRM sought comment on whether it should become mandatory for manufacturers to declare certain types of equipment as SDR, rules on the types of security features that SDR must incorporate, and the approval process for SDR contained within modular transmitters.

The Commission received 56 comments and 14 reply comments to this NPRM and based on this issued a Report and Order in March 2005. The report covered a wide range of cognitive radio topics, recognizing that both software-defined radio and cognitive radio will continue to evolve over time. The report also described the technical requirements for interruptible spectrum leasing as follows:

(1) The licensee must have positive control as to when the lessee can access the spectrum.
(2) The licensee must have positive control to terminate the use of the spectrum by the lessee so it can revert back to the licensee's use.
(3) Reversion must occur immediately upon action by the licensee unless that licensee has made specific provisions for a slower reversion time.
(4) The equipment used by the licensee and the lessee must perform access and reversion functions with an extremely high degree of reliability.
(5) The equipment used by the licensee and the lessee must incorporate security features to prevent inadvertent misuse of, and to thwart malicious misuse of, the licensee's spectrum

The Commission did not adopt any particular technical model in this area, stating that this was best left to the licensee to be satisfied that the technical mechanism implemented meets with their requirements for reclaiming leased spectrum.

Through the associated Order, the Commission broadened the definition of software-defined radio to include changes in software that could make a transmitter noncompliant with Commission emission rules. They also changed the equipment authorization rules to require that equipment in which the software controlling the radio-frequency operating parameters is expected to be modified by a party other than the manufacturer must be certified as an SDR. Certification as an SDR remains optional for equipment that is not expected to be modified by a third

party. In addition, the Order allowed certification of unlicensed transmitters that are capable of operating outside of US unlicensed frequency bands, provided that they incorporate automatic frequency selection mechanisms to ensure they operate only on allowed frequencies inside the United States.

Results from Early Regulations for Nonfederal Spectrum Sharing

The market success of these early proceedings, in and of themselves, has been limited. A search of the FCC's license database shows that there are only 92 active leases [19]. Although the exact reason for this low number is unknown, if one believes the published studies showing that commercial spectrum is largely underutilized (e.g., [20,21]), it must be assumed that the business case for spectrum leasing does not surpass the business case for not leasing. One can speculate that this is because holding unused spectrum versus leasing creates a barrier to entry for potentially competing services. Likewise, while a review of the licensing database showed that there was significant early activity in licensing software-defined radios, that activity declined following the publication of the revised rules. Industry continued to advance SDR technology, however, and the Wireless Innovation Forum now estimates that roughly 95% of defense, public safety, and cellular infrastructure radios are now software defined [22]. All this said, even though these proceedings, taken individually, have not been considered business successes, the proceedings provided significant data to the Commission and provided an important basis for future proceedings.

Early Regulation to Facilitate Spectrum Sharing Between Federal and Nonfederal Users

Building on these earlier rulings, the FCC began initiating proceedings in 2004 to enable spectrum sharing between federal and nonfederal users. Two rulings are of significant interest: the 5 GHz U-NII ruling and the 3650 to 3700 MHz band ruling. Regulations from these proceedings are addressed below (Table 2).

FCC 5 GHz U-NII Rulemaking (Docket 03-122)

Prior to 2002, Unlicensed National Information Infrastructure (U-NII) devices were permitted to operate in the United States over a total of 300 megahertz of spectrum spread across the 5 GHz band [23]. The majority of U-NII devices operating in this band supported the IEEE 802.11a standard, and in January of 2002, the Wireless Ethernet Compatibility Alliance (WECA, now the Wi-Fi Alliance) petitioned for rulemaking to provide an additional 255 MHz of spectrum for use by these types of devices in the 5470 to 5725 MHz band. In response to this petition, 17 comments

Table 2 Timeline for initial regulations for sharing between federal and nonfederal users

	2002	2003	2004	2005	2006	2007	. . .	2013	2014
Federal and nonfederal spectrum sharing		NPRM on 5 GHz U-NII Report and Order on 5 GHz U-NII			Memorandum Opinion and Order on 5 GHz U-NII			NPRM Extending 5 GHz U-NII band	Report and Order Extending 5 GHz U-NII band
	Unlicensed Spectrum Notice of Inquiry		NPRM on Unlicensed Spectrum in the 3650 Band	Report and Order on 3650 band		Memorandum Opinion and Order on 3650 band			

and 10 reply comments were filed, and upon reviewing these comments, the FCC issued a Notice of Public Rulemaking in May of 2003.

In the NPRM, the FCC agreed with WECA that current allocation was insufficient for growth. However, the 5350 to 5650 band was currently allocated to radiolocation and used by the US Department of Defense (DoD) for a number of radar systems, including systems used for national security. The DoD was concerned that U-NII devices would cause interference to its radar systems and therefore asked that if this petition were granted, its radiolocation services be upgraded from secondary to primary status in this band.

In addition, NTIA working with the FCC, NASA, and the DoD reached the following agreement on International Telecommunications Union World Radiocommunications Conference 2003 (WRC-03) Agenda Item 15 to establish an international recommendation that:

(1) Radiolocation service in the 5350 to 5650 MHz band be upgraded to primary status
(2) An allocation be added in the 5305 to 5460 MHz band for Space Research Services (SRS) and in the 5460 to 5560 for SRS and the Earth Exploration Satellite Service (EESS)
(3) A mobile allocation be added to the 5150 to 5350 MHz and 5470 to 5725 MHz bands
(4) U-NII or HiperLAN users in the 5250 to 5350 MHz and 5470 to 5725 MHz bands be required to employ dynamic frequency selection (DFS) using a listen-before-transmit mechanism with the following detection thresholds: −64 dBm for devices that operate with an Effective Isotropic Radiated Power (EIRP) of between 200 mW and 1 W and −62 dBm for devices that operate with an EIRP of less than 200 mW.

Based on this agreement, through the NPRM the Commission sought comment on proposals to upgrade affected federal government radiolocation service to primary status; to upgrade the affected nonfederal government radiolocation services, primarily used for weather radar, to co-primary status; to add primary federal Government and secondary nonfederal government allocations for SRS and EESS; and to allow U-NII devices to operate as per the WECA petition on a noninterference basis.

Technical requirements for unlicensed operation proposed in the NPRM were as follows:

- 1 watt EIRP peak
- Devices operating in the 5250 to 5350 MHz and 5470 to 5725 MHz bands employ DFS to monitor spectrum and determine if radar signals are present (listen before talk) with detection thresholds as per the WRC-03 agreement. In addition, the Commission sought comment on:
  - A proposed correction factor for devices with under 1 MHz BW
  - The minimum number of radar pulses and observation time for reliable detection

- A proposal that devices operating under control of a central controller or master not be required to have DFS, proposing that only the master be required to have DFS capability
- As U-NII devices in the 5250 to 5350 MHz band currently operate without DFS capability, the Commission proposed establishing a transition period

The Commission also sought comment on a proposal to require devices operating in the 5470 to 5725 MHz band employ Transmit Power Control (TPC) to further protect EESS and SRS operations. The Commission's proposal was that the power level be reduced by 6 dB when triggered and requested comment on a suitable trigger. The Commission also requested comment on whether TPC should be required for devices that operate at less than 500 mW EIRP. Finally, the Commission requested comments on test procedures necessary to ensure compliance with the DFS and TPC requirements.

Twenty-nine comments and 12 reply comments were filed in response to this NPRM, and the Commission quickly followed up to issue a Report and Order in November of 2003. Through this Order, the Commission established rules to make the 255 MHz requested by the WECA available in the 5470 to 5725 MHz band for Unlicensed National Information Infrastructure (U-NII) devices. As a part of this ruling, the FCC upgraded federal and nonfederal radiolocation services to primary status as proposed and added primary federal and secondary nonfederal government allocations for SRS and EESS. The Commission declined to adopt a specific mobile allocation and instead chose to treat devices equally as unlicensed intentional radiators, allowing to operate on a noninterfering basis.

On the technical side, the Report and Order adopted the power requirements and DFS requirements as proposed. The order exempted remote devices under control of a central controller from the DFS requirement, but did not exempt controller or master devices. The Order required Transmit Power Control for devices operating at power levels of greater than 500 mW. In doing so, the Commission declined to provide a triggering mechanism but rather asked that applicants seeking equipment authorization for U-NII devices provide a statement in the certification application explaining how they comply. Finally, the Order provided an interim test procedure to allow immediate certification.

This Order was followed in June of 2006 with a Memorandum Opinion and Order clarifying the rules for TPC and providing a revised test procedure for determining DFS compliance. Then, in 2013, the Commission issued a new NPRM (Docket 13-49) proposing an additional 100 MHz bandwidth in the 5 GHz band for U-NII devices [24]. This was followed by an Order in April of 2014 allocating this new bandwidth as a part of the regulations.

FCC 3650 MHz Rulemaking (Docket 04-151)

The Omnibus Budget Reconciliation Act passed by the US Congress in 1993 required the US Secretary of Commerce to identify at least 200 MHz of spectrum allocated for use by the federal government agencies to be transferred to the private

sector [25]. NTIA released a final report on reallocation in 1995, identifying the 3650 MHz band for transfer on the condition that government radiolocation stations in two locations continue to operate in that band and that spectrum in the adjacent 3600 to 3650 MHz band continue to be used for high-power radar. In 1998, the Commission issued an NPRM (Docket 98-237) proposing to allocate the 3650 band for nongovernment fixed service on a primary basis. In 2000, the FCC issued an associated Report and Order that allocated the 3650 MHz band to fixed and mobile terrestrial services on a co-primary basis but to protect grandfathered fixed satellite service (FSS) earth stations and radiolocation operations operating on a primary basis. This order limited mobile service allocation to base station use only and established that new FSS earth stations were only allowed to operate in the band on a secondary basis. The Commission received four petitions for reconsideration, requesting that FSS be returned to full allocation and deleting the fixed service and mobile service allocations. Concurrent with the issue of 3650 MHz allocation Report and Order, the Commission issued a 3650 Service Rules Second NPRM. In response to this NPRM, the FCC received 17 comments and 7 reply comments. Comments submitted on behalf of telecommunications providers serving rural areas and Internet service providers who provide wireless internet to their customers were interested in licensed terrestrial services. FSS providers submitted comments that licensed fixed and mobile services would cause interference.

Later, in December 2002, the Commission issued an Unlicensed Spectrum Notice of Inquiry (Docket 02-380). This inquiry sought to assess the feasibility of releasing additional spectrum for unlicensed use below 900 MHz (TV bands) and in the 3 GHz band. The inquiry specifically sought comment on whether unlicensed devices could operate in these bands at higher power levels than was previously allowed and asked whether licensed and unlicensed devices should be allowed to operate in unused portions of the spectrum on a noninterfering basis.

A number of commenters supported the ideas proposed by the Commission; however, numerous comments were also received from those incumbent licensed users in these bands with mixed opinions on whether such operation would cause interference, especially when operating in band adjacent to those supporting licensed operation (adjacent band interference).

With this as background, in April of 2004, the FCC issued a Notice of Public Rulemaking. Through this NPRM, the Commission deferred comment on petitions for reconsideration defined above and instead sought comment on whether new FSS stations could operate in band on a co-primary basis using smart/cognitive radio technologies. The Commission also sought comment on a proposal to delete fixed service and mobile service allocations in favor of unlicensed operation and sought comment on proposed fixed and non-fixed unlicensed operation as follows:

- Fixed operation
  - Primary use will be to provide wireless broadband connectivity by wireless Internet service providers (WISPs) in rural areas
  - A certified professional installer would be required to ensure fixed unlicensed devices operate in a manner that will avoid causing interference with FSS earth stations

  - Maximum allowed EIRP of 25 watts, with comment sought on the proposed use of sectorized or scanning spot beam antennas
  - Fixed devices would be prohibited from operating within protection zones defined as 180 km within +/−15 degrees of the FSS antenna main-beam azimuth and 25 km otherwise
- Non-fixed operation
  - Maximum allowed EIRP of 1 W
  - DFS like listen before talk function required, with power to be adjusted based on detected FSS receiver signal strength.
  - Device prohibited from transmitting if detects an uplink signal greater than −76 dBm in a 1 MHz bandwidth.
  - Device must lower EIRP to 500 mW if FSS signal strength of between −79 and −82 dBm is detected
  - Device must lower EIRP to 250 mW if FSS signal strength of −76 and −79 dBm is detected

The NPRM also proposed to prohibit operation by unlicensed devices within 8 km of the US/Mexico border and proposed to require all unlicensed devices to broadcast identification information at regular intervals. Through the NPRM, the Commission also sought comment on the use of geolocation or a dedicated FSS beacon signal to protect incumbents and sought comment on options for licensed use or combinations of licensed and unlicensed use.

The Commission received responses to this NPRM from over 100 parties. In March of 2005, they followed up with a Report and Order and Memorandum Opinion and Order. Through this Order, the FCC maintained the existing FSS and fixed service allocations established in the 2000 Order and removed the base station-only restriction on the mobile service allocations. The Order established that the fixed service and mobile service access would be through nonexclusive nationwide licensing in lieu of the unlicensed scheme discussed in the NPRM. The Order also allowed new FSS earth stations but limited them to secondary status.

The Order required that licensees cooperate to avoid generating harmful interference and to facilitate this required that they register their fixed and base stations in a common database. The Order further required a contention-based protocol to manage interference in the shared spectrum, but did not specify the protocol, and left this to industry standards bodies. Fixed station power was limited to 25 W EIRP in any 25 MHz band, and mobile station power was limited to 1 W EIRP over the same bandwidth.

In response to this Order, the Commission received eight petitions for reconsideration, with 160 oppositions, replies, or comments to those petitions. After consideration, in June of 2007, the FCC issued another Memorandum Opinion and Order reaffirming the nonexclusive licensing and retaining the requirement for contention-based protocols but clarified that the rules allow for the certification of a variety of different protocols and contention avoidance mechanisms [26]. This included unrestricted protocols such as listen before talk or restricted protocols which can only prevent interference from other devices utilizing the same protocol. To avoid contention between these types of devices, the Order limited devices using

restricted protocols to the lower 25 MHz of the band. No other reconsideration of power levels or other petition items occurred.

Results from Early Regulations to Facilitate Spectrum Sharing Between Federal and Nonfederal Users

Through these proceedings, the Commission made over 400 MHz of spectrum available for shared use, and from a business perspective, the proceedings can be considered a success. The U-NII band is broadly used to support the millions of wireless local area network and broadband access devices. There are currently 78 protected sites in the 3650 rulemaking, and a search of the FCC license database shows that there are 2608 active licenses operating in that band [27]. The success of these can be attributed to the amount of available spectrum and the ease in meeting the license requirements.

Unlicensed Operation in the TV Broadcast Bands (Docket 04-186)

As part of the Docket 02-380 Notice of Inquiry, the FCC also asked questions concerning the unlicensed use of unused spectrum below 900 MHz [28]. Comments received from wireless technology suppliers and wireless Internet service providers generally support the concept; however, television broadcasters expressed concerns that the technology to determine if a television station is active in a specific location and the ability to quickly change frequency is unproven. Based on these comments, in May of 2004, the FCC issued a Notice of Public Rulemaking with a stated goal to enable wireless Internet service providers to offer expanded services by allowing unlicensed operation in the broadcast television spectrum at locations where that spectrum is not being used. The hope was that such operation would also provide synergy between WISPs and traditional broadcast operations to offer broadcasters the opportunity to provide additional services.

Initial Regulations for TV Band Operations

The approach taken by the FCC through the NPRM was to ensure no harmful interference to authorized users of spectrum by requiring that "smart radio" technology be used to identify unused TV channels in a specific geographic area. Two types of operation were proposed by the FCC:

(1) *Personal/portable devices.* Personal/portable devices were envisioned by the FCC to be used as Wi-Fi-like cards in home computers and for in-home local area networks. For these types of devices, the Commission proposed that interference could be prevented through the use of a control signal sent by TV transmitters in the vertical blanking interval of a standard TV signal.

Transmission of this control signal was voluntary, and parties could receive compensation for transmitting. The control signal would be current on a 24 h cycle.

For personal/portable devices, a TV channel would only be considered vacant if no portion of the service area of an authorized station assigned to use that channel was within the service area of the station transmitting the control signal.

(2) *Fixed access devices.* Fixed access devices were envisioned by the FCC to be used for commercial service. The Commission proposed that for these devices, interference would be prevented through the use of geolocation information. The location of the device would be set with 10 m accuracy using a GPS or certified professional installer to establish and set the location. Once the location was set, the device would access a database, provide its location, and retrieve information to calculate what channels are available in its area. Once a frequency of operation was selected by a device, the Commission proposed that the device register with a separate database indicating its operating frequency and location.

The Commission received numerous comments and reply comments to this NPRM. WISPs, manufacturers of unlicensed TV band devices (TVBDs), and potential users of TVBDs all expressed support for the proposals. Broadcasters and other licensed incumbents expressed strong concerns as to whether unlicensed devices could in fact operate without causing interference. Several comments were also received from several parties who felt that the operations of TVBDs should be licensed.

Upon reviewing these comments, the Commission issued a First Report and Order and Further Notice of Proposed Rulemaking in October of 2006. Through this Order, the Commission concluded that allowing low-power devices to operate in the TV band in frequencies that are not used could have significant benefits for the public by enabling the development of new wireless devices, systems, and services. The Commission also reiterated its belief that properly regulated devices could operate in the TV bands without causing interference; however based on comments received, the Commission concluded that it needed more data to set those regulations, including in the area of spectrum sensing.

Sensing Versus Geolocation Databases

The original NPRM made no specific proposals on spectrum sensing to detect active TV signals, but sought comment on spectrum sensing technologies, including levels that must be detected and ways of dealing with the hidden node problem that occurs when the TV signal is blocked from the sensing device but not from a TV receiver in range of the unlicensed wireless transmitter. The Commission noted that in the comments to this NPRM, no party provided sufficient technical information on the use of spectrum sensing for rules to be established. As such, in the further NPRM, the Commission reiterated that technical rules are necessary if sensing devices are

to be used to ensure that such devices adequately sense incumbents and sought comment on the following proposal for sensing TV band signals, modified from the radar signal sensing rules adopted for the 5 GHz U-NII band:

- Detection threshold of −116 dBm (based on work of 802.22) as well as factors that may affect this threshold such as number of false positives and antenna height, addressing the hidden node problem through technologies such as distributed sensing or sensing in combination with geolocation information.
- Devices will sense before occupying a channel and then periodically recheck the channel, with a proposed recheck period of every 10 s, with sensing only required in the adjacent channels during recheck

The Commission also raised a number of questions on which it sought comment such as whether the sensing bandwidth should be regulated and whether antenna gain should be limited to 0 dBi as proposed by 802.22

In response to requirement for data to set regulations established in the Report and Order, FCC Office of Engineering and Technology invited submittal of prototype devices for initial testing in December of 2006. Two prototype devices were provided for testing, which focused on "detect and avoid" or "listen before talk" strategies using spectrum sensing. The test results from this initial testing were released in July of 2007, concluding that:

> . . . sample prototype White Space Devices submitted to the Commission for initial evaluation do not consistently sense or detect TV broadcast or wireless microphone signals. Our tests also found that the transmitter in the prototype device is capable of causing interference to TV broadcasting and wireless microphones.

In August of 2007, OET held a meeting with interested parties to review the test results and define a way forward. Based on the outcome of this meeting, the Commission announced a second phase of testing beginning in January of 2008 following a revised test procedure. In July of 2008, the Commission also initiated filed trials of TV White Space devices. Results of the Phase II Testing were published in October 2008, with conclusions summarized as follows:

(1) All devices were able to reliably detect a clean DTV signal on a single channel; however, results varied in a noisy real-world environment.
(2) Signals in adjacent channels degraded detection capability in channel
(3) All devices were able to detect wireless microphones when no other signals were present. TV signals in adjacent channels degraded performance in detecting wireless microphones to the point that it was no longer reliable.
(4) In most cases, devices correctly reported occupied channels in field tests, but there were some errors and high false alarm rates
(5) The use of a geolocation database in combination with sensing was 100% reliable in detecting DTV
(6) Wireless microphone field tests failed in that false alarms eliminated all bands or when sensitivity was adjusted indicating channels were available when in fact they were not.
(7) Under certain conditions, direct pickup was possible

Based on these results, in November of 2008, the Commission issued a Second Report and Order and Memorandum Opinion and Order. Through this Order, the Commission continued to allow for both fixed and personal/portable devices; however, they modified the original proposed rules to require that devices, except personal/portable devices operating in client mode, access a geolocation database over the Internet. The rules also required that all devices employ spectrum sensing as a further means of minimizing potential interference, but the database will be the controlling mechanism as test results showed that more developmental work was needed before spectrum sensing can be the principal means of identifying unoccupied channels. The rules also established that fixed devices were prohibited from operating in adjacent channels; fixed devices must register with the database to provide FCC ID, location, and responsible party info and that wireless microphones could be registered in the database for protection. Through this order, the Commission eliminated the control signal option for determining available channels but agreed to revisit if economics or other circumstances make it more favorable. No regulation was established for coexistence of TVBDs.

The Commission received 17 petitions for reconsideration in response to this First Memorandum and Order and following review and analysis issued a Second Memorandum Opinion and Order in September of 2010. Among changes to the rules made by the Commission in addressing the petitions was the elimination of the requirement that TVBDs support sensing and allowed database-only solutions. In doing so, the Commission stated that they continue to believe that sensing will evolve, that sensing has promise, and left open the possibility of sensing-only devices. The Commission also allowed sensing to be used on a voluntary basis (Table 3).

Table 3 Timeline for TV White Space regulations

Other Technical Rules and Other Requirements

The rules established by the FCC through these proceedings allowed for operation of TVBDs in all channels except:

- Channels 4
- Channel 37, which was being used for radio astronomy
- Channels 52 to 69, which were being reallocated in the digital TV transition

Operation was allowed in channels 14 to 20 but must avoid interference with PLMRS/CMRS and offshore radio telephone service. For all devices, out-of-band emissions in the first adjacent channel are limited to a level of 55 dB below the power in the channel they occupy and measured in a 100 kHz bandwidth.

Technical criteria for determining when a TV channel would be considered vacant were established through the use of protected contours defining service areas based on service types (digital TV, low-power TV, etc.) with defined propagation curves. The rules established desired to undesired signal protection ratios based again on service type, channel separation (co-channel or adjacent channel), and propagation curves. The rules required that calculations would be made to determine if operation within a specific location would create an undesired signal strength from the unlicensed device within the service area that is too high.

Other technical requirements established for fixed and personal portable devices are summarized as follows:

- Fixed devices
  - Maximum transmit power of 1 W, with 4 W maximum EIRP. For antennas with gains above 6 dBi, the transmit power must be reduced so that EIRP does not exceed 4 W
  - Power spectral density limits on conducted output power of 16.7 mW (12.2 dBm) when measured in a 100 kHz bandwidth
  - Should use Transmit Power Control to limit maximum power where possible
  - Allowed to communicate with other fixed devices and personal portable devices
  - Must incorporate geolocation capability or have location set by professional installer
  - Must transmit identifying information, following a standard to be established by the industry
  - Restricted fixed devices from operating in locations where the ground HAAT is greater than 250 m. The Commission established that HAAT would be calculated by the database provider.
- Personal portable devices
  - 100 mW maximum EIRP, except when operating adjacent to a TV station or licensed station within the protected coverage area, in which case limited to 40 mW. Power should typically be adjusted to less than the maximum permitted power when possible

- Power spectral density limits on conducted output power of 1.67 mW (2.2 dBm) for personal/portable devices and 0.7 mW (−1.8 dBm) for personal portable in adjacent channels when measured in a 100 kHz bandwidth
- Two modes
  - Mode I – client that is controlled by a fixed device or a personal portable device operating in mode II
  - Mode II – determines available channels from internal geolocation/database access. Can act as a master to a mode I device in a master client link
- Both modes must establish location each time they are activated and must reverify their location each time they detect they have moved. Mode II devices must not transmit if location is unknown

The order also established a fixed adjacent channel emission limit of 72.8 dB below the maximum power limit for each type of device.

The Order established that all fixed devices and mode II personal portable devices are allowed to operate in master mode. Each network would have at least one master, and a master is allowed to transmit without receiving an enabling signal from any other device. A personal portable device communicating with a fixed master is required to use channels and frequencies as directed by the fixed device. If a fixed device does not have direct connection to the Internet, and has not initialized and registered with the database system, then it can communicate to another TVBD that does have a connection and is registered over a channel that device is using. That link must then be used to register with the database and receive a list of channels for use. Mode I devices must either receive a current list of available channels from a mode II or fixed device once per minute or must contact the mode II or fixed device once per minute to reverify/reestablish channel availability. Finally, a mode I personal portable device that does not have geolocation capability can listen for and then communicate with a mode II or fixed device over a channel that device has already used. The mode II device must then immediately obtain a list of channels.

The Order also established that the database system for fixed stations and mode II personal portable devices would be managed by database administrators selected by OET. The database requirements established are summarized as follows:

- Databases will be privately owned and operated service, with database service providers allowed to charge fees for registration of fixed devices and to provide available channels to all devices
- More than one entity may be authorized to operate as a TV band database provider, with final decision based on expressions of interest
- Database providers must share registration information with each other and with the Commission
- Fixed and mode II TVBDs must re-sync with the database at least once per day and, after a 1-day grace period, must stop transmitting
- Database administrators are not required to resolve claims of interference by TVBDs

- Services must be made available by database providers to all TVBDs on a nondiscriminatory basis
- TVBDs shall only be capable of contacting databases operated by administrators designated by the Commission, the database must not provide channel information to uncertified TVBDs, and communication between TVBDs and database be secure. The Commission did not require specific technologies to meet these requirements.
- All database information required by the Commission be publicly available. In doing so, the Commission stated that public disclosure was not required and that data not required by the Commission does not have to be disclosed by a database administrator
- Information on TV stations in Canada and Mexico border areas be included in the database

The rules also established that two channels between 14 and 51 would be reserved in all markets nationwide for wireless microphones and disallowed unlicensed wireless microphone and other low-power auxiliary devices operating without a license to be registered in the database, stating that these devices will not be afforded protection from interference from TV band devices on channels were TV band devices are allowed to operate. Established that operators of licensed low-power auxiliary stations including wireless microphone may register their site directly with one of the designated database administrators. Established that entities operating or otherwise responsible for the audio systems of major events where large numbers of wireless microphones will be used may request a registration of the event.

Finally, rules established that the FCC would be the certifying authority for TVBDs and databases and establish a proof of performance standard to allow certification of sensing-only devices that demonstrate the capability to detect protected services with a high level of accuracy.

In compliance with these orders, the FCC OET began accepting applications for White Space database administrators. To date, ten organizations have been designated as database administrators, and four have databases that have been approved for operation:

Organization	Status
Google	Designated Database Administrator, Database Approved
Keybridge Global	Designated Database Administrator, Database Approved
Spectrum Bridge	Designated Database Administrator, Database Approved
iconectiv	Designated Database Administrator, Database Approved
Comsearch	Designated Database Administrator, Database Approval Pending
LS Telecom	Designated Database Administrator, Database Approval Pending
Microsoft	Designated Database Administrator, Database Approval Pending
Airity	Designated Database Administrator
Frequency Finder	Designated Database Administrator
Neustar	Designated Database Administrator

The Commission has also published a compliance guide for TV band devices and a guide for database administrators.

Standards for Unlicensed Operation in TV Bands

Standard development in support of TV band device regulations has been somewhat scattered. Pre-standard development for database to device communications began in the Wireless Innovation Forum. At the same time, the White Space database administrators formed a closed group to do pre-standard development of a database-to-database interoperability specification. Both of these efforts fed into the Protocol to Access White Space Database (PAWS) Effort of the Internet Engineering Task Force (IETF) [29].

Results from Unlicensed Operation in TV Bands

The potential success of this proceeding is still unknown. While there have been some initial trials and early deployments across the United States, there has not been a large commercial investment in this band to date. The reason for this is likely tied to the regulatory uncertainty surrounding the TV band spectrum. In February 2012, Congress directed the FCC to hold a reverse auction, or incentive auction, which freed up broadcast spectrum for use by cellular operators "by encouraging <broadcasters> to voluntarily relinquish spectrum usage rights in exchange for a share of the proceeds from an auction of new licenses to use the repurposed spectrum" [30]. If successful, these incentive auctions, which are currently scheduled for 2015, will necessarily reduce the amount of White Space that is available in the TV broadcast bands. The uncertainty in the amount of White Space spectrum that will be available following these auctions has effectively frozen the market by delaying investment.

The impact of these regulations outside of the United States, however, has been more positive. In 2014, Ofcom, the UK regulator, launched a White Space pilot program that eventually led to the TVWS regulations in the United Kingdom. These regulations specifically referenced the European Telecommunications Standards Institute (ETSI) harmonized requirement standard, which mirrors the technical requirements outlined in the US regulatory proceeding in many areas, including defining multiple device types and master-slave operation. Canada, Singapore, and a host of other countries also followed suit implementing TVWS test beds and field trials, which often have resulted in follow-up regulatory actions. As a result of this activity, Markets and Markets anticipates that:

> The global TV white space spectrum market . . . is expected to reach USD 53.1 Million (approximately) by 2022, at a CAGR of 74.30% during the forecast period. [31]

Without the United States leading the way in the development of TV White Space regulations, it is reasonable to conclude that many of these efforts would have been, at the very least, delayed.

Citizens Broadband Radio Service (Docket 12-354)

In June of 2010, the President of the United States issued an executive memorandum on "Unleashing the Wireless Broadband Revolution" [32, 33]. This memorandum recognized that "America's future competitiveness and global technology leadership depend, in part, upon the availability of additional spectrum" and that "We can also unlock the value of otherwise underutilized spectrum and open new avenues for spectrum users to derive value through the development of advanced, situation-aware spectrum sharing technologies." Through this memorandum, the President directed the Secretary of Commerce, working through the NTIA, to collaborate with the FCC and other federal agencies to make 500 MHz of federal spectrum available for nonfederal use within a 10 year time frame. In support of this initiative, NTIA undertook a fast-track review of the 1675 to 1710 MHz band, 1755 to 1780 MHz band, 3500 to 3650 MHz band, 4200 to 4220 MHz band, and 4380 to 4400 MHz band to determine the near-term viability of nonfederal broadband access within the 10 year time frame [34]. Through this study, NTIA identified the 1675 to 1710 MHz bands and the 3550 to 3650 MHz bands as early candidates for commercial use. They also identified several additional bands that may be viable but required further study. In response to this report, in March of 2011, the FCC issued a Notice of Inquiry under Docket 10-123 seeking comment on the proposed bands, noting that the 3550 to 3650 MHz band was already shared for WiMAX as federal operations were geographically limited [35]. In November of 2010, the FCC also issued a Notice of Inquiry on Dynamic Spectrum Access Technologies (Docket 10-237), as a means of building a record on current state of dynamic spectrum sharing technologies [36].

In the meantime, the President's Council of Advisors on Science and Technology (PCAST) was preparing a report on "Realizing the Full Potential of Government-Held Spectrum to Spur Economic Growth" [37]. This report, published in 2012, had a number of key findings related to the 500 MHz Initiative, the first of which was that "clearing and reallocating Federal spectrum is not a sustainable basis for spectrum policy." The report cited as an example the March 2012 report by NTIA entitled "An Assessment of the Viability of Accommodating Wireless Broadband in the 1755 to 1850 MHz Band" [38]. The report indicates that this band is currently used for fixed point-to-point microwave systems, military tactical radio relay, air combat training systems, precision-guided munitions, tracking and telemetry, video surveillance, and UAVs. Moving these systems to other spectrum to allow dedicated use by nonfederal users is estimated to cost approximately $18 billion over 10 years. The PCAST reports that the last successful auction of 90 MHz in 2006 yielded only 13.7 billion in revenue, bringing into question the business case for clearing the 1755 MHz band.

The PCAST report offered an alternative view instead, recommending a federal spectrum architecture where "the norm for spectrum use should be sharing, not exclusivity." The report urged the President to issue a new memorandum directing the Secretary of Commerce to find 1000 MHz for sharing, building on a number of elements including the following:

(1) Spectrum should not be fragmented for use, but allocated in as large of frequency bands as possible. These bands should not be allocated for the use of specific technologies, but rather be technology neutral allowing the greatest possible flexibility in use.
(2) Spectrum should be managed via a Spectrum Access System (SAS), similar to the White Space database but with additional features and capabilities
(3) Access to shared spectrum should take a three-tier approach:
    a. Protected nonexclusive use by primary users.
    b. Protected, nonexclusive access for certain priority secondary users so long as they do not interfere with primary users.
    c. General authorized access for all other devices. Such access is not protected and must not interfere with primary users or priority secondary users.
(4) Spectrum management should include not only transmission characteristics but also receiver characteristics, recognizing that receiver performance will increasingly impact the ability of spectrum to be shared as poor receiver design will increase the likelihood that the receiver will receive harmful interference from adjacent channel or co-channel transmitters.

Building on this report and in support of the President's initiative, the FCC opened a new docket (12-354) and issued a Notice of Proposed Rulemaking in January 2013 proposing the creation of a Citizens Broadband Radio Service (CBRS) in the 3550 to 3650 MHz band. The Commission positioned this spectrum as an innovation band, allowing the exploration of new spectrum sharing paradigms and providing low barriers to entry to emerging small cell technologies.

Evolution of the CBRS Regulations

In the initial Notice of Proposed Rulemaking, the Commission proposed a three-tier access model as per the PCAST report, with the Priority Access tier limited to critical users under the defined model. Through the Notice, the Commission sought comment as follows:

- *Design of the Spectrum Access System*. Building from the TV White Space proceedings, the Commission sought comment on whether the government, a commercial entity, or a public private partnership should manage the SAS and, if a commercial entity was used, whether the Commission should select a single database administrator or allow multiple administrators. The Commission also sought comment on the requirements for registration with the database and on a number of security issues including the management of classified and unclassified data, cross-domain access, and techniques to manage sensitive but unclassified federal information. Finally, the Commission sought comment on whether data within the database be available for public inspection.
- *CBRS devices.* The Commission sought comment on the proposal that all CBRS devices include geolocation technology, on power levels for Priority Access

and GAA devices for fixed base station and mobile station operation, and whether lower power should be allowed near or within an exclusion zone versus outside of an exclusion zone. The Commission also sought comment on HAAT and minimum/maximum emission bandwidth and allowances for out-of-band emissions.

- *Geographic area exclusion.* The Commission sought comment on the geographic exclusion area defined in the NTIA fast-track report based on high-power WiMAX models.
- *Other related items.* The Commission also sought comment on a whole host of other items, including equipment authorization, receiver protection, spectrum sensing, and indoor use-only models. The Commission also sought comment on whether the proposal should be extended to the 3.65 to 3.70 GHz band and alternative two-tier schemes based on the European Authorized Shared Access/Licensed Shared Access models. Public notice seeking comment on licensing models and technical requirements.

In a follow-up to this NPRM, the FCC Wireless Telecommunications Bureau and Office of Engineering Technology hosted a workshop on the proposed SAS in January of 2014. In parallel with this activity and based on a review of the record from the NPRM, the Commission issued a Public Notice soliciting further comment on alternative licensing proposals inspired by suggestions made by the commenters to the original NPRM. Through this Public Notice, the Commission sought to explore whether Priority Access should be made open to a broader class of users, including commercial users, allowing some level of assured access beyond the critical access users defined in the NPRM. Expanding on this, the Commission sought comment on licensing Priority Access by auction, to include proposed licensing term as well as the geographic, temporal, and frequency dimensions associated with such licenses. The Notice also sought comment on a defined floor proposed for GAA spectrum availability, allowing GAA access to unused Priority Access bandwidth, managed by the SAS, to maximize dynamic use of unutilized spectrum, and a proposal to allocate a portion of the Priority Access bandwidth for the critical users defined in original NPRM. Through the Notice, the Commission sought comment on technical implementation issues, including limiting the maximum power to 24 dBm with maximum antenna gain of 6 dBi for a composite 30 dBm EIRP, and how to facilitate coexistence. Finally, the Commission sought comment on whether the formation of one or more stakeholder groups, as defined under Docket 13-101, should be encouraged to study receiver standards.

The Commission received extensive comments on both the NPRM and the Public Notice and, based on an analysis of these comments and the outputs from the workshops held, issued a Further Notice of Proposed Rulemaking in April of 2014. Through this new NPRM, the Commission proposed to increase the band for consideration to include the 3650 to 3700 MHz band, and confirmed the three-tier licensing model across, but established open eligibility for Priority Access as per the Public Notice.

Since Priority Access will no longer be limited to critical users under the defined model, the Commission proposed accommodating these users by setting aside 20 MHz of GAA spectrum with protection similar to Priority Access users inside the confines of their facility, such as a hospital. This effectively created a fourth tier referred to as Contained Access Users.

The Notice proposed to allow users at the PA or GAA tiers to select whether to provide access under common carrier or non-common carrier basis and sought comment on whether a SAS could effectively coordinate to allow GAA users to provide common carrier services. The Notice also proposed that there would be no fixed channel assignments. Instead, the SAS will manage assignments within each geographic area and can reassign channels from time to time as required, indicating that SAS providers are free to agree upon a convention for reassignment, but such convention will not be in the rules. The NPRM also proposed that GAA devices can use PAL spectrum that is not used at a given location and time, again with the SAS to coordinate.

In April of 2015, the FCC issued a Report and Order amending the Commission's rules with regard to the 3550 to 3650 MHz band (Docket 12-354). The Report and Order is established in Part 96 of the regulations and largely aligned with the rules outlined in the related Notice of Proposed Rulemaking and Further Notice of Proposed Rulemaking. In conjunction with the Report and Order, the Commission also released a Second Further Notice of Proposed Rulemaking, the Commission. In the FNPRM, the Commission explored three questions:

(1) Defining the use of PAL frequencies. The Report and Order allowed GAA use of PAL spectrum when not in active use by a Priority Access licensee. The FCC proposed an engineering, economic, and hybrid definition of what constitutes "not in active use" and proposed and sought comment on the proposed definitions.
(2) Implementing Secondary Markets in Priority Access Licenses. The Commission sought comment on changes required in the rules to facilitate the establishment of a secondary market for PALs, including allowing partitioning and disaggregation of PALs in terms of frequency and location.
(3) Optimizing protections for FSS. The Commission sought comment on proposals for both in-band and out-of-band protection of FSS. For in-band protection, five topics were presented:
    a. Calculation methodology
    b. Propagation modeling
    c. Interference protection criteria (IPC)
    d. Avoiding policy concerns related to aggregate IPC
    e. End user devices

    In terms of out-of-band protections for C-Band FSS Earth Stations, the Commission sought comment on whether the proposed in-band IPC was sufficient to address out-of-band protection or if other criteria should be applied.

In October 2015, the FCC released a Public Notice seeking comment on a proposed two-prong approach for determining a grandfathered wireless protection zone:

(1) Protection is provided for unregistered customer premise equipment (CPE) by establishing a protection radius of 4.4 km around each base station.
(2) Protection is provided for registered CPEs by establishing a protection sector determined by the azimuth and beamwidth of the registered base station antenna and a radius determined by the location of the furthest CPE (normally not more than 18 km).

In May 2016, the Commission released an Order on Reconsideration and Second Report and Order addressing the eight petitions for reconsideration received for the First Report and Order and the second Further Notice of Proposed Rulemaking. Through this Order, the Commission addressed the eight petitions for reconsideration received on the First Report and Order covering areas that included PAL License Terms and Renewability, PAL Auctions, SAS and CBSD Response Time, CBSD Power Limits, Out-of-Band Emission and Adjacent Channel Emission Limits, Emission Power Measurements and Testing Methodology, Device Geolocation, PAL Protection Criteria, and FSS Protection. In addition the Second Report and Order addressed the three issues raised in the second Further Notice of Proposed Rule Making. In August of 2016, the Commission extended these rules further in defining the methodology for determining the Grandfathered Wireless Protection Zones in the 3650 to 3700 MHz band based on the inputs received from the October 2015 Public Notice (Table 4).

Table 4 Timeline for CBRS regulations

	2013	2014	2015	2016
CBRS	Notice of Public Rulemaking	Further Notice of Proposed Rulemaking	Report and Order and Second Further Notice of Proposed Rulemaking	Order on Reconsideration and Second Report and Order
	3.5 GHz Workshop		Public Notice on Protection of Grandfathered 3650 to 3700 MHz Licensees	Methodology Adopted on Protection of Grandfathered 3650 to 3700 MHz Band Licensees
	Public Notice on 3.5 GHz Licensing Framework		First Wave Applications for SAS Administrators and ESC Operators	Conditional Approval of SAS Administrators

Technical Rules and Other Requirements

The rules in Part 97 define a three-tier structure as follows:

- Tier 1: Incumbents. This tier includes:
  - Military shipborne radars on 17 ships with current-generation radar, about 75% of which are homeported in Norfolk, VA; San Diego, CA; and Seattle, WA
  - Military ground-based radars with occasional in-band operations in 3650–3700 MHz at three sites: St. Inigoes, MD; Pensacola, FL; and Pascagoula, MS, and below 3500 MHz radar operations at isolated military bases spread around the United States.
  - Receive-only fixed satellite service (FSS) earth stations operating in band in 35 sites around the United States (mostly coastal sites, limited to inter-continental international satellites) and in the adjacent band 3700 to 4200 (thousands of sites around the United States).
  - Wireless broadband services (Part 90 services) operating in the 3650 to 3700 MHz band. In extending the regulations to include the 3650 to 3700 band, the Commission "grandfathered" existing license holders in this band for 5 years.
- Tier 2: Priority Access License (PAL). PALs are licensed by auction for a 3 year term, with license areas defined by the approximately 74,000 census tracts in the United States, each supporting a population of approximately 4000 people. Each PAL license will define a single 10 MHz channel in a single census tract, and each census tract will have from zero to seven PALs. PALs will be limited to the lower 3550 to 3650 MHz portion of the band. Anticipated use cases for PALs include:
  - Capacity/offload networks for established wireless service providers
  - QoS-managed enterprise networks
  - Utility networks
  - Backhaul
  - Wireless broadband service (after 5-year sunset on Part 90 3650–3700 MHz operations)
- Tier 3: General authorized access (GAA). GAA licenses allow the use of ANY frequency in any location in the 3550 to 3700 MHz band not being used at a given time by a higher tier licensee. The definition of unused is yet to be defined beyond the explicit statement that must not interfere with incumbents and PALs. GAA licensees are afforded no interference protection. GAA is licensed by rule, with no a priori bandwidth limit or license area. The regulations require that a minimum of 80 MHz and a maximum of 150 MHz be reserved for GAA in each census tract, subject to incumbent activity. Anticipated use cases for GAA include (Fig. 2):
  - Personal & small business hot spots
  - Campus hot spots

- PAL offload during periods of incumbent activity interrupting PAL spectrum
- Unprotected capacity/offload for established wireless providers
- Wireless broadband services
- Backhaul

Access to spectrum in Tiers 2 and 3 is facilitated through the use of Citizens Broadband Radio Service Devices (CBSDs) acting as fixed base station/access points for end user devices (EUDs). CBSDs can only operate under the authority and management of a centralized Spectrum Access System (SAS), which manages interference to incumbents by Tiers 2 and 3, interference among Tier 2 devices, and interference from Tier 3 into Tier 2 (see Fig. 3). To support this function, each CBSD wishing a spectrum grant must register with a SAS and provide its location

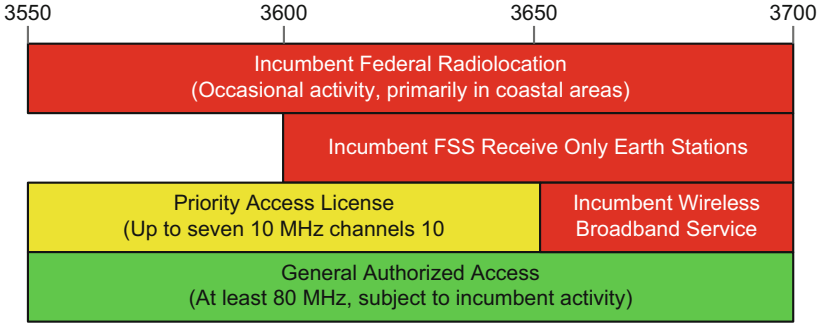

Fig. 2 3.5 GHz Band Overview

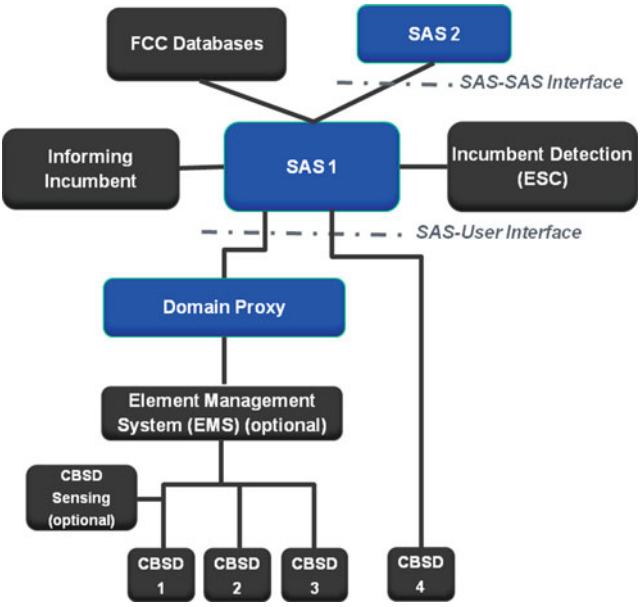

Fig. 3 SAS functional architecture [39]

and other information [40]. The SAS then determines and provides to the CBSD the permissible channels or frequencies and the maximum permissible transmission power level available at its location. Aggregate interference to protected users from all CBSDs is calculated by each SAS, and SAS share information as required to resolve conflicting uses of the band while maintaining, as much as possible, a stable radio-frequency environment.

Within Part 96, CBSDs are broken into two categories: Category A and Category B. Category A devices are envisioned primarily for indoor use as access points, femtocells, etc. Category A devices are limited to 30 dBm Effective Isotropic Radiated Power (EIRP), and if used outdoors, Category A devices are limited to 6 m height above average terrain (HAAT). Conversely, Category B devices are only allowed to operate outdoors with a 47 dBm maximum EIRP. Category B devices must be professionally installed and allow for both point-to-point and point-to-multipoint operation. The location of both Category A and Category B devices is required by the regulations to be accurate to $+/-50$ m horizontal and $+/-3$ m vertical, and CBSDs are required to report to the SAS within 60 s if their location changes.

End user devices in the CBRS system communicate exclusively with CBSDs: peer-to-peer communication is prohibited. The EIRP for end user devices is limited to 23 dBm.

Incumbent Protection

Protection for incumbent radar under Part 96 is initially provided through exclusion zones which effectively define keep out areas for CBSDs. The regulations also allow, however, the use of an environmental sensing capability (ESC) in lieu of exclusion zones to monitor for incumbent radar activity in coastal areas and near inland military bases. When incumbent activity is detected, and ESC communicates that information to a SAS, and the SAS or SASs will reconfigure local devices within 300 s to avoid interfering with incumbent radars, current incumbent radar will impact at most two channels in one area, and while the specific area of impact is to be determined, these radars operate infrequently, and so the use of a ESC will significantly improve access to spectrum over the defined exclusion zones.

Protection for PAL holders under Part 96 is established through the use of PAL Protection Areas (PPAs). The PPA defines a protection contour surrounding the CBSDs associated with a PAL holder that are in use in a specific location. A PPA may cross census track boundaries and therefore may be associated with multiple Priority Access licenses. PPAs are determined by a default protection contour based on a signal strength of -96 dBm/10 MHz around each CBSD or alternatively are self-reported by the PAL holder so long as they do not exceed the default contour. Areas outside the PPA are available for GAA use so long as the aggregate interference generated by CBSDs does not exceed -80 dBm/10 MHz within or at the PPA boundary.

Protection of legacy fixed satellite service providers was defined separately in the Report and Order for in-band and out-of-band services. For fixed satellite services operating in the 3550 to 3700 MHz band, the SAS shall ensure that the aggregate passband power spectral density at the location of the FSS earth station operating

in the 3600 to 3700 produced by emissions of co-channel CBSDs within 150 km operating in the Citizens Band Radio Service do not exceed a median RMS value of −129 dBm/MHz. In addition, the aggregate RF power at the location of the FSS earth station operating in the 3600 to 3700 produced by emissions of ALL CBSDs within 40 km operating in the Citizens Band Radio Service do not exceed a median RMS value of −60 dBm. Similarly, the SAS shall ensure that the aggregate passband power spectral density at the location of the FSS earth station operating in the adjacent 3700 to 4200 MHz band by emissions of CBSDs within 40 km operating in the Citizens Band Radio Service do not exceed a median RMS value of −129 dBm/MHz. The aggregate RF power at the location of the FSS earth station operating in the 3700 to 4100 MHz band produced by emissions of ALL CBSDs within 40 km operating in the Citizens Band Radio Service does not exceed a median RMS value of −60 dBm.

This level of protection is only afforded to those FSS earth stations that are registered annually, and such registration must provide detailed information on technical and operational characteristics, including antenna characteristics. If any information changes, the FSS operator has an obligation to update the SAS with the new information. CBSDs may operate within areas that may cause interference to FSS earth stations, in excess of the levels described so long as the licensee of the FSS earth station and the authorized user of the CBSD mutually agree on such operation and the terms of any such agreement are provided to an SAS Administrator that agrees to enforce them. In addition, the SAS must be capable of receiving and responding to complaints of interference from FSS operators.

In terms of protection for grandfathered broadband wireless service providers, protection is provided through use of a protection zone established in one of two ways:

- For sectors encompassing unregistered customer premises equipment (CPE), a 5.3 km radius sector from each registered base station based on the azimuth and beamwidth registered for that base station;
- For sectors encompassing registered CPE, a sector centered on each base station with the registered azimuth and beamwidth covering all registered subscriber stations within that sector.

The Commission established that aggregate power of co-channel CBSDs must be no greater than −80 dBm/10 MHz at any point inside these protection zones.

Standard Development

In its Report and Order establishing rules for the Citizens Broadband Radio Service ("CBRS") in the 3550 MHz band, the Commission observed that "a multi-stakeholder group focused on the complex technical issues raised by this proceeding could provide us with a wealth of valuable insights and useful information." In response to this need, in January of 2015, the Wireless Innovation Forum stood up a Spectrum Sharing Committee (SSC) to serve as a common industry

and government standard body to support the development and advancement of spectrum sharing technologies based on the three-tier architecture proposed for the 3.55 GHz rulemaking activities [41]. This Committee is intended to facilitate the interpretation and implementation of FCC rulemaking to a level that allows industry and government parties to collaborate on implementation of a common, efficient, well-functioning ecosystem around this technology.

The participants of this Committee include:

- Developers and operators of SAS, wireless equipment and devices, and sensor systems
- Operators and service providers interested in deploying in the spectrum
- Suppliers of systems and components operating on this spectrum
- Representatives of incumbent users including DoD/DISA, satellite operators, and utilities
- General users of spectrum outside of main providers
- Policy makers, academics, and researchers
- Representatives from other standard groups where interfaces or joint work is desired or necessary

These participants are organized into five work groups that work collaboratively to develop the reports, recommendations, and standards necessary to establish a commercial CBRS ecosystem (Fig. 4).

In the Report and Order, the Commission proposed a number of areas where a multistakeholder group would take action in supporting the band. The SSC Steering Group has reviewed these "callouts" and assigned them to the committee work groups as follows (Table 5):

Thus far, the Wireless Innovation Forum Spectrum Sharing Committee balloted, approved, and released three technical reports in support of this mandate:

- Technical reports
  - WINNF-15-P-0051-V1.0.0 Interim SAS to SAS Protocol Technical Report-A
  - WINNF-15-P-0023-V1.0.0 Interim SAS to CBSD Protocol Technical Report-A
  - WINNF-15-P-0060-V1.0.0 SSC WG4 Certification Process
  - WINNF-15-P-0047-V1.0.0 SAS Functional Architecture
  - WINNF-15-P-0062-V1.0.0 Interim SAS to CBSD Protocol Technical Report B
  - WINNF-16-P-0063-V1.0.0 Interim SAS to SAS Protocol Technical Report B
  - WINNF-16-P-0089-V1.0.0 CBRS Threat Model
- Recommendations
  - WINNF-15-R-0200-V1.0.0 WInnForum Comments on 3650 Protection Contours
  - WINNF-15-R-0092-V1.0.0 Emission Measurement Ex Parte
  - WINNF-15-R-0058/0059-V1.0.0 Reply Comments on the Second FNPRM
  - WINNF-15-R-0045-V1.0.0 WInnForum Comments on the Report and Order

  - WINNF-16-S-0096-V1.0.0 SAS to SAS Technical Specification

Table 5 SSC work group assignments for Report and Order multistakeholder group callouts

Paragraph	Callout	Work Group
59	We acknowledge that SAS Administrators, potential licensees, and other industry stakeholders will need to develop various implementation details to facilitate development of the Citizens Broadband Radio Service. As described elsewhere in this *Report and Order*, we believe that many of these issues can be addressed during the SAS Approval Process and through the efforts of a multistakeholder group	WG1
195	We recognize that ensuring compliance with this limit at the boundary is likely challenging on a real-time basis and there are legitimate questions relative to how to develop appropriate predictive models. We also recognize that the use of an aggregate metric could be challenging in a multi-user environment. We encourage any multistakeholder group formed to address technical issues raised by this proceeding to consider how this limit should be applied	WG1
214	For example, it might be possible that instead of the bright-line urban/rural distinction implemented in these initial rules, industry stakeholders (perhaps working through a multistakeholder forum) could agree on a "congestion metric" and associated methodology for SASs to reduce CBSD power levels in high-demand areas. We intend to continue an informal dialog with stakeholders on this topic and welcome the submission of additional technical analysis or reports of technological developments that can inform us going forward	WG1
222	Given the importance of accurate reporting by professional installers, we strongly encourage the SAS and user community, through multistakeholder fora or industry associations, to develop programs for accrediting professional installers who receive training in the relevant Part 96 rules and associated technical best practices	WG4 in partnership with another organization TBD
234	We encourage multistakeholder groups to consider the issues raised by the registration rules described in this section, including acceptable contact intervals between CBSDs and SASs, and to suggest appropriate operational parameters.	WG1
237	We encourage industry to develop detailed metrics regarding issues like received signal strength, packet error rate, and technology specific parameters of signal and interference metrics. These metrics could be developed by an industry multistakeholder group. Such guidance could be incorporated in the SAS Approval process described in section IIIH)(3)(b) or incorporated independently by authorized SAS Administrators, subject to Commission review	WG3

(*continued*)

Table 5 (continued)

Paragraph	Callout	Work Group
240	We encourage the industry to develop best practices for end-to-end security that can be validated in the equipment and SAS certification processes	WG2
268	We also require SAS Administrators to implement protocols to respond to directions from the President of the United States or another designated federal entity to manually discontinue operations of its associated CBSDs in a given area pursuant to 47 U.S.C. §606. SAS Administrators must also implement protocols to manually discontinue operations of their associated CBSDs in response to enforcement actions taken by the Commission	WG3
289	We agree with Federated Wireless, Google, Motorola Solutions, SIA, the Wireless Innovation Forum, and others, that a multistakeholder process could provide insight into the technical factors and interference limits between coexisting services in the 3.5 GHz Band	WG1
319	We continue to believe that a "light touch" regulatory approach is appropriate for this band and that the rules should include only the high-level requirements necessary to ensure the effective development and operation of fully functional SASs. We agree with commenters that support collaborative, industry-wide efforts to create standards and best practices governing SAS operations. The Commission will assist these efforts through the SAS Administrator approval process, as set forth in III(H)(3)(b). We also believe that an active multistakeholder group could help develop industry consensus around the best methods of meeting the SAS requirements	All
346	We require potential SAS Administrators to develop and demonstrate that their systems include robust communications and information security features during the SAS Approval process.745 CBSDs shall demonstrate compliant security features during the equipment authorization process. These security protocols will be subject to the Commission's review and approval, with input from NTIA and DoD. We anticipate that given the immense value of industry-wide interoperability, groups – such as the types of multistakeholder groups discussed in section III(K) – will develop security models that SAS Administrators may consider, subject to Commission review	WG2
438	We seek comment on what propagation model(s) are best suited for SAS-based protections of FSS. We solicit measurement results that validate model parameters for combined short range and long range propagation scenarios, involving indoor and outdoor propagation channels. What model(s) are the most accurate in accounting for urban clutter and other environmental factors such as rain attenuation, ducting, etc., and most suitable for modeling statistical variations to support analysis – including possible Monte-Carlo analysis – of many potential interfering sources? In order to generate the same exclusion distances between CBSDs and any individual FSS earth stations in 3650–3700 MHz, we expect each SAS to enforce the same minimum separation distance and we tentatively conclude that each SAS must use the same propagation model. We seek comment and objective analysis from anyone who believes otherwise	WG1

(*continued*)

Table 5 (continued)

Paragraph	Callout	Work Group
440	We also invite comment as to whether we can establish a default earth station protection area based on an assumed minimum earth station receiving system gain-to-temperature ratio (G/T) and minimum antenna elevation angle, and what the assumed values of the G/T and elevation angle should be. CBSD operation outside of such a default protection area would be assumed not to cause interference to earth stations receiving in the 3700–4200 MHz band. Such a default protection area would be adjusted by the SAS to accommodate the actual operating characteristics of earth stations that are registered in order to achieve additional protection	WG1

SAS Administrators and ESC Operators (Docket 15-319)

In December of 2015, the FCC opened a new docket allowing "First Wave" applications for SAS administrators and ESC operators [42]. Seven organizations applied to be SAS administrators and six applied to be ESC operators:

SAS administrator applicants	ESC operator applicants
Amdoc	
Comsearch	Comsearch
CTIA	CTIA
Federated Wireless	Federated Wireless
Google	Google
Keybridge Global	iPosi
Sony	Keybridge Global

In December of 2016, the Commission conditionally approved all seven SAS administrator applicants, based upon a review of the proposals submitted and subsequent amendments.

Current Status and Future Plans

The next step in the evolution of the CBRS band is the certification of SAS for commercial use, followed by certification of ESC and CBSD products. Such testing is expected to occur in the first half of 2017, with commercial deployments expected later that same year. In anticipation of this, the CBRS ecosystem has undertaken a number of activities:

- 3GPP has approved "Band 48" for LTE operation in the CBRS
- Google and Federated Wireless have both announced trials involving multiple operators and equipment manufacturers in the United States [43].

- Google and Federated Wireless have validated the SAS to SAS interface protocol standard through an interoperability demonstration [44].

While not conclusive, this level of activity indicates significant interest by the industry in the success of this new band.

Many of the SAS administrators are also seeking to extend elements of the CBRS framework to other bands. Google, for example, has publicly announced support for Part 96 rules in 5G [45], and the University of Oulu has led an effort to field trial CBRS as a part of the Finnish Spectrum Sharing Trial [46]. Keybridge Global has signed a contract with more immediate impact. In November of 2013, the US DoD and the Broadcasting Industry agreed to relocate DoD operations in the 1755 to 1780 MHz spectrum to the 2025 to 2110 MHz band, currently used by broadcasters for remote news gathering operations [47]. Doing so allows the 1755 to 1780 MHz band to be paired with the 2155 to 2180 MHz band as a part of the AWS-3 auction. DoD use of the 2025 to 2110 spectrum would be on a co-primary shared basis with nonfederal users. Nonfederal operation will have priority over DoD operations in this band, with the fixed and mobile military stations operating in the band incorporating frequency agile technology to ensure they shall not cause harmful interference to nonfederal users. In October 2016, Keybridge Global signed a contract to become the SAS administrator for the 2025 to 2110 MHz band [48].

Conclusion

Through the regulatory activities highlighted in this chapter, the FCC working in cooperation with NTIA have made hundreds of megahertz of spectrum available for sharing at various different levels. The results of these activities to date have been mixed. Spectrum sharing regulations appear to be successful when the amount of available spectrum is relatively well known, and the mechanism for obtaining a license is relatively straightforward. Where the regulations are less successful from a business perspective, the hurdles to success are generally not technical. Instead, regulatory uncertainty has limited investment, or a failure to overcome business disincentives to share has limited the actual availability of spectrum. Open proceedings in the 500 MHz initiative and in other initiatives ongoing in this area indicate that the FCC and NTIA are learning from these proceedings in their efforts to better facilitate the effective use of spectrum in serving the public interest.

Abstract

More than half (58%) of the spectrum in the UK is shared between different classes of users. Typically, this has been enabled by authorizing individual applications to use specific frequencies at specific locations on a first-come-first-served basis.

But technological developments, the focus of this book, have presented Ofcom with promising opportunities to share spectrum more effectively. Ofcom has taken advantage of these technologies within the UHF band (470–790 MHz) in the context of the digitization of terrestrial television. More recently, Ofcom has focused on establishing a systematic way of enabling spectrum sharing in general and has taken preliminary steps in exploring how to share the 3.8–4.2 GHz band.

Introduction

Spectrum Regulation in the UK

Ofcom was established in late 2003 in anticipation of convergence in communications. It has a mandate to regulate (among other things) telecommunications, broadcasting, and radio spectrum in the UK.

Its work regarding radio spectrum is driven by two pieces of legislation, the Communications Act 2003 [1] and the Wireless Telegraphy Act 2006 [2]. Broadly speaking, the former sets out the high-level objectives that Ofcom must work to, and the latter provides Ofcom with the authority to authorize access to radio spectrum in the service of those objectives, as well as further guidance. European law is embedded in both Acts. In particular, through its regulation of spectrum, Ofcom must always apply objective, transparent, nondiscriminatory, and proportionate regulatory principles.

Section 3 of the Communications Act provides that Ofcom's principal duty is to further the interests of citizens in relation to communication matters and to further the interests of consumers in relevant markets, where appropriate, by promoting competition.

In carrying out these functions, section 3(2) provides that Ofcom is required, among other things, to secure the optimal use for wireless telegraphy of the electromagnetic spectrum and the availability throughout the UK of a wide range of electronic communication services.

It follows that when considering spectrum policy in the UK, Ofcom always keeps in mind its requirement to "secure the optimal use for wireless telegraphy of the electromagnetic spectrum." This provokes Ofcom to consider cognitive radio and/or spectrum sharing if it is thought that it would make the use of the spectrum more "optimal."

The Wireless Telegraphy Act 2006 confers on Ofcom the authority to fulfill its statutory duties by authorizing access to spectrum. It also imposes a number of further obligations regarding how it carries out these duties. Specifically, section 3(2) requires Ofcom to have regard to (among other things) the desirability of promoting the efficient management and use of the spectrum, the economic and other benefits that may arise from the use of wireless telegraphy, and the development of innovative services and competition in the provision of electronic communications services. When taking into account the desirability of those things, Ofcom must have regard to the extent to which the spectrum is available for use and to the demand, both current and future, for use of the spectrum.

Clearly, making a judgment on what use of spectrum would comprise a given frequency's "optimal" use for wireless telegraphy (any form of wireless communication) is a difficult task. This is only partially mitigated against by the guidance articulated through additional duties set out in the Wireless Telegraphy Act, especially when there could be a tension between these objectives.

For example, taking into account the desirability of the development of innovative services means that for a given part of the spectrum, Ofcom should look to encourage technical innovation, including cognitive radio and spectrum sharing. At the same time, a given policy that would enable spectrum sharing might not be thought by some to deliver, for example, the greatest economic benefits from the use of (a hypothetical) part of the spectrum.

Altogether, the duty to secure the optimal use of radio spectrum, and to also have regard to the desirability of developing innovative technologies when authorizing access to spectrum, means that the preconditions are in place to allow Ofcom to enable cognitive radio and spectrum sharing.

Sharing Within the UK Legal Framework

The Wireless Telegraphy Act empowers Ofcom to authorize transmissions under two circumstances:

- A licensee has obtained a Wireless Telegraphy Act license and transmits according to the conditions specified in the license. These conditions will typically be (where possible) technology neutral and could be focused on avoiding undue interference into adjacent channels. For example, a mobile network operator (MNO) may have a WT Act license that gives it permission to transmit within a certain assignment within a given band. The MNO may have obtained the license through an auction mechanism, and transmissions will have to follow certain parameters referred to in the license, alternatively.
- A stakeholder is exempted from requiring a license in order to transmit under certain circumstances and in certain spectrum bands that have been defined by Ofcom. Section 8(5) of the WT Act sets down a series of conditions that have to be met for Ofcom to establish such rules, including that license-exempt use may not cause undue interference to wireless telegraphy (as additionally set down in WT Act Section 55).

The use of spectrum to receive signals is exempted from licensing under the Wireless Telegraphy Apparatus (Receivers) (Exemption) Regulations 1989 [3]. Ofcom does not "protect" receivers from undue interference. Nonetheless, some of its policies have a similar effect in that they allow a stakeholder to benefit from "benchmark spectrum quality," which may be defined as a particular interference level at a given site. When doing so, Ofcom sometimes makes grants of Recognised Spectrum Access available to stakeholders. These grants allow Ofcom to take a certain usage into account when regulating spectrum access, even though Ofcom does not directly license its transmission. For example, the transmitter may be a "Crown" user (the UK Government) or could be a naturally occurring phenomenon in outer space that radio astronomers wish to be able to receive in the UK.

This framework enables spectrum sharing because license-exemption and WT Act licenses only authorize transmissions and in principle do not comprise "exclusive" use of a given spectrum band. This means that there is no legal barrier preventing another stakeholder from using spectrum (for transmitting and/or receiving) that is already assigned to another stakeholder through a WT Act license.

One way of achieving spectrum access could be for the new entrant to enter into a commercial arrangement with the licensee (e.g., leasing), if permitted under the terms of the relevant license. Alternatively, the new entrant could obtain a WT Act license where it would be up to Ofcom to decide whether or not to allow such spectrum sharing by issuing such a new license.

In an international context, in particular in the Radio Regulations [4], spectrum managers typically discuss a hierarchy of spectrum rights based on the concept of primary and secondary users of spectrum. According to this understanding, the primary user can transmit and receive without undue interference. This means that the secondary user must not cause undue interference to primary services and cannot claim protection from undue interference from the primary service, even if a specific deployment of a primary service was established after the secondary service. In some frequency bands, particularly those designated for industrial, scientific, and medical applications (ISM bands), all spectrum users are secondary and cannot claim protection against each other regarding undue interference.

In this context, cognitive radio and spectrum sharing could depend on secondary spectrum access, where a secondary user can "borrow" spectrum already assigned to another (often primary) user.

In the UK context, however, because of the legal framework described above, Ofcom is not able to issue licenses that provide explicitly "primary" or "secondary" spectrum access rights; rather, any distinction between primary and secondary users may only exist when they are embedded in the conditions set down within authorizations or the processes that Ofcom itself undertakes when authorizing spectrum access.

In some bands, Ofcom authorizes spectrum access on a site-by-site or area-defined basis where a hierarchy is established on the basis of when an authorization has been issued. In these bands, sometimes referred to as "Ofcom Managed Bands," Ofcom issues WT Act licenses, or grants of Recognised Spectrum Access on a first-come-first-served basis subject to Ofcom coordination and Ofcom technical

frequency assignment criteria. The conditions in each new WT Act license will be designed to avoid interference to already-existing users. For example, a fixed link license might be issued with quite detailed technical specifications that Ofcom has found to be necessary to protect nearby satellite Earth stations with a grant of Recognised Spectrum Access for a given band. Altogether, these bands comprise around half of the radio spectrum in the UK [5].

Seeing as spectrum sharing is already so widespread in the UK, it is more appropriate to discuss innovative forms of spectrum sharing, potentially enabled by cognitive radio, as "enhanced spectrum sharing."

In sum, in pursuing its general duties, Ofcom has sought to enable the development of cognitive radio and spectrum sharing, working with the authorization tools at its disposal. Secondary spectrum access, which might enable cognitive radio and spectrum sharing, can only exist in the UK when embedded in the conditions of access authorizations or through Ofcom's internal processes. Ofcom can enable new entrants to access spectrum even though there may already be a licensee because Ofcom does not in principle issue "exclusive" licenses.

The rest of this chapter considers two examples of this, one where spectrum sharing is now authorized on a license-exempt basis (or in some cases WT Act licenses) and one where Ofcom's policy is still in development.

TV White Space

Introduction

Terrestrial broadcasting has traditionally been a cornerstone of economic and cultural activity in the UK, and it has long been a policy objective to ensure near-universal access to the service. The 470–790 MHz band has been used to achieve this because it is considered to comprise the "sweet spot" where high-capacity signals can be transmitted over a very wide area.

Partly because the infrastructure predates the concept of "spectrum scarcity" (and market-based spectrum fees), the network is based on high-power high-tower transmitters that require relatively few sites to provide universal coverage. The disadvantage of this is that interference can only be prevented by using different frequencies in different areas for the same multiplexes.

This legacy requirement for geographical separation of broadcasting transmitters (as shown in an early illustration made by Ofcom given in Fig. 1) [6] means that in most places, most of this spectrum is theoretically available for alternative use. The presence of unused UHF spectrum at a given location is referred to as interleaved spectrum or TV White Space.

Programme Making and Special Events (PMSE) applications already use TV White Spaces (TVWS), where Ofcom issues licenses to PMSE users that provide a degree of protection against undue interference from a third party, such as another PMSE user. PMSE licenses are only issued to frequencies that are not issued to DTT at a particular location or where its use will not cause undue interference to DTT

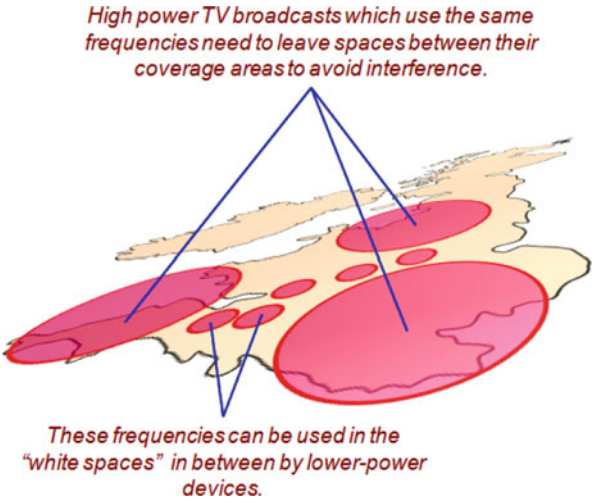

Fig. 1 Geographical separation of broadcasting transmitters (Source: Ofcom (2012) TV White Space: a consultation on white space device requirements. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0022/40477/condoc.pdf)

(such as in an indoor environment). These licenses can be conceived of as operating on a second tier to DTT as practically speaking a license would not be issued to PMSE where undue interference would be caused to the primary tier (DTT).

Ofcom has now established a framework whereby a new class of radios, known as white space devices (WSDs), can also access these TV White Spaces on a license-exempt basis or on an interim basis through a WT Act license. Effectively this establishes a third tier for where use is permitted as long as it does not cause undue interference to any licensed user.

It should be noted that the concept of a first, second, and third tier does not correspond to primary and secondary spectrum access, which as described in the introduction does not exist in Ofcom's authorizations.

The Scale of the Opportunity

Digital terrestrial television (DTT) is based upon six national multiplexes, each of which carries eight to 13 channels. Three of these (used for public service broadcasting) provide coverage to around 98.5% of the UK population, while the other three provide coverage to 90% of the population. There are also local multiplexes in some areas. Additionally, there are interim multiplexes that can operate until 2020, or beyond albeit with diminished rights, and are intended to promote the adoption of more advanced digital terrestrial television technology (DVB-T2).

Each multiplex uses a single 8 MHz block of spectrum, meaning that only a fraction of the 320 MHz allocated to the broadcasting service is required in any particular location in the UK for the reception of DTT.

It is worth noting that this conception of TV White Space is different than the one used in the USA. In the UK, the "white spaces" refer to the channels that are not in

use at a particular place taking into account any nearby viewer antenna locations and the relevant transmitters, whereas in the USA white space refers to the geographical areas between TV coverage areas that are not used in a particular channel. The difference in conception is a function of the fact that the DTT offering in the UK is almost universal, whereas in the USA there are some areas with relatively little DTT usage, as well Ofcom's policy to only protect DTT antennas that are actually in use.

Notwithstanding the more limited conception of TVWS in the UK, spectrum is still abundantly available.

In preparation for the TVWS Framework Statement [7], Ofcom calculated the availability of spectrum for different types of devices operating at different power levels at different locations.

It found that if one assumes a geographically fixed WSD transmitting at 23 dBm within a strict emissions class at a height of 10 m (e.g., as part of a municipal Wi-Fi network), then there would be 14 channels (112 MHz) available at 85% of locations in London. The graph below demonstrates how the availability of spectrum would differ according to power limit and number of locations (Fig. 2).

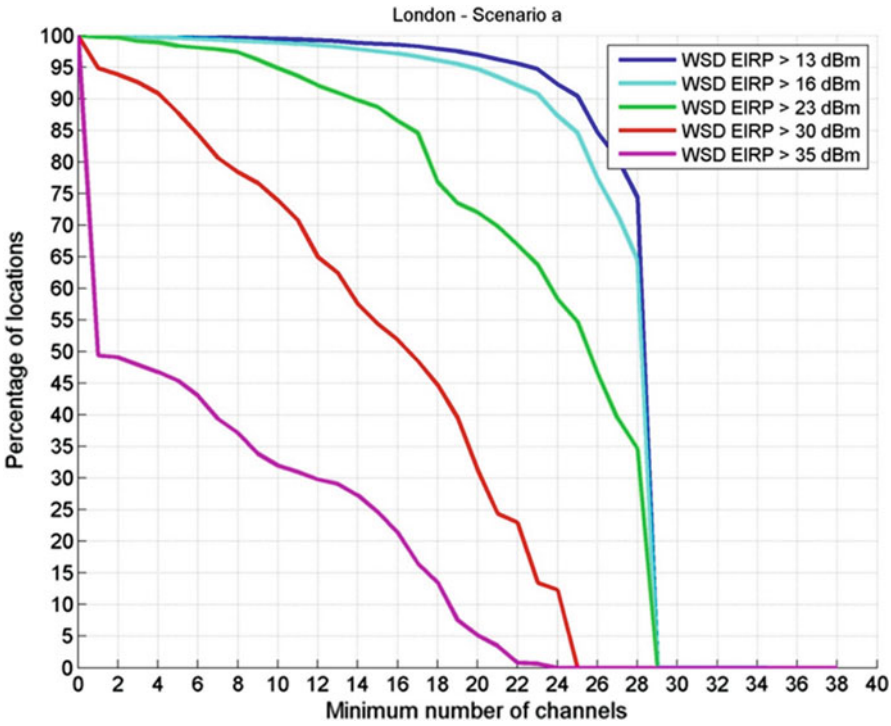

Fig. 2 Availability of TV White Space in central London (Source: Ofcom (2015) Implementing TV White Spaces. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0034/68668/tvws-statement.pdf)

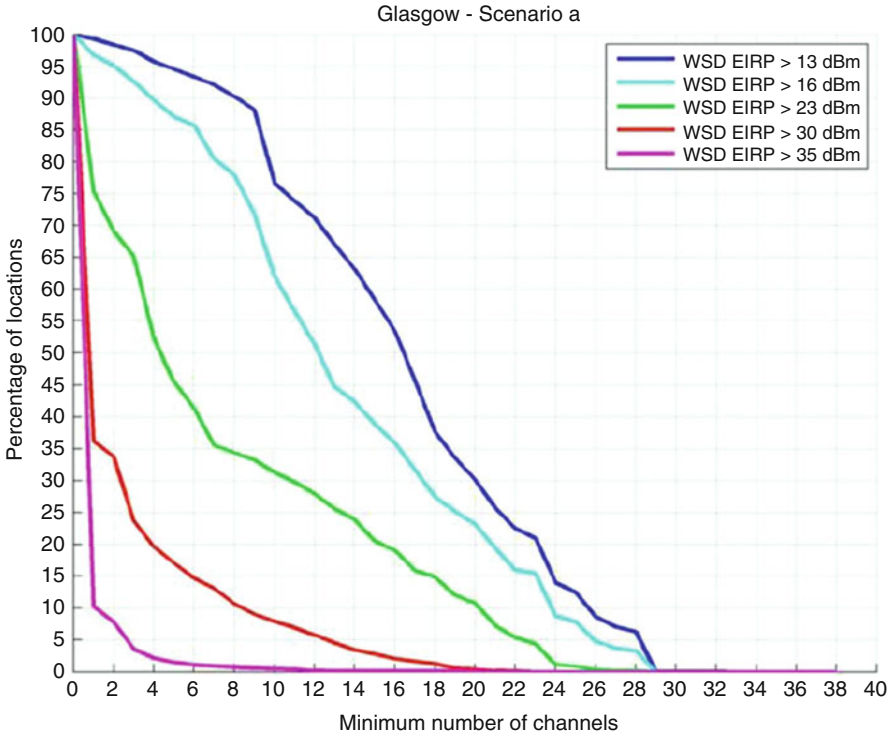

Fig. 3 Availability of TV White Space in Glasgow (Source: Ofcom (2015) Implementing TV White Spaces. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0034/68668/tvws-statement.pdf)

However, the London case is favorable for TVWS availability because it is dominated by a single high-tower high-power transmitter (Crystal Palace). In other areas, there is a significant overlap between the different transmitters, resulting in less TVWS available. For example, in Glasgow there would be no channels available under the circumstances described above. Instead, power would have to be reduced to 13 dBm, and even then only 9 channels (72 MHz) would be available, as shown below (Fig. 3).

In general, the opportunity to use this spectrum more intensively has long been perceived and exploited by services auxiliary to broadcasting, now known as Programme Making and Special Events (PMSE) applications. These devices, such as wireless microphones and in ear monitors, typically use 200 kHz channels at low power. Additionally, other applications such as audio links and video links use different bandwidths and are planned on the basis of an 8 MHz channel, although the user can often plan many devices in one channel. PMSE users currently obtain time- and location-specific licenses to access TV White Spaces from Ofcom or can alternatively obtain from Ofcom a license for Channel 38 (606–614 MHz), which is uncoordinated and typically used for news-gathering.

PMSE equipment is typically used in venues such as theaters, studios, or churches on a regular basis. Peak demand comes from special events such Formula One or music festivals.

Permitting Cognitive Radio in Principle

Terrestrial broadcasting's digitization in the last decades both enhanced the capabilities of the platform and allowed Ofcom to reuse parts of the spectrum for mobile, eventually comprising the 800 MHz mobile band. It also prompted Ofcom to review its policy toward the band as part of its Digital Dividend Review [8].

As discussed in the introduction, Ofcom's principal duty is to secure the optimal use of spectrum. A prevalent interpretation of this is that it should seek to ensure that the radio spectrum is being used as intensively as possible. Ofcom's additional duty to consider future requirements also requires Ofcom to monitor the opportunities presented by new technologies.

These duties indicated to Ofcom when it was undertaking its Digital Dividend Review that it should consider allowing cognitive radios to use this band.

One could argue that the most effective way to promote innovation would have been to set spectrum aside for cognitive radios operating on a license-exempt basis, thus creating a "sandpit" for innovation. In the absence of spectrum licenses, this would have required devices to find their own technical solutions to undue interference arising from the use of radios by third parties. This approach has been praised for fostering technologies such as Wi-Fi and Bluetooth in the 2.4 GHz band. However, there are plenty of other sandpits across the radio spectrum, and Ofcom felt that the loss of benefits (the opportunity cost) arising from not allowing licensed services (in this case DTT, PMSE, or Mobile) to use these bands were seen to be greater than the potential benefits of allowing only licence-exempt users access to a portion of the band.

Bearing in mind the large amount of spectrum available within TV White Spaces, as explained above, there remained ample opportunities for cognitive radio to access spectrum without reserving spectrum. Doing so would allow the spectrum to be used more "optimally," as it would otherwise probably be unused.

It therefore decided in 2008 to allow the interleaved parts of the band to be used by cognitive devices on a license-exempt basis, providing Ofcom was satisfied that licensed users of the band (DTT and PMSE) would be protected from undue interference.

Authorizing Access to Spectrum

Typically under license exemption, the regulator shifts the responsibility to protect a user from undue interference from the regulator to the user itself. To do this, a device needs to know whether or not its transmissions will be able to be received by the

intended receiver using information about the interference environment. This could be done through the use of beacons, sensing technology, or geolocation databases.

Beacons could theoretically use the same sites used for DTT multiplexes to transmit information about available spectrum within the reception area of a given transmitter. If a WSD could not receive signals from a beacon, then the WSD would not be permitted to transmit within TV White Spaces at all. A principle advantage of this approach is that it would be effective in preventing the emergence of scenarios where a WSD would cause undue interference to another spectrum user.

However, the infrastructure necessary for this was deemed to be expensive to construct and maintain, and it was not clear who would be responsible for creating standards for this technology and who would maintain it. Additionally, it was also anticipated at the time that this approach would be inherently too conservative as the beacons would need to transmit at a lower power than that of the multiplexes so that the beacon signal could not be received outside of the geographic area where DTT transmission was intended to be received. The consequence of this is that WSDs would not be able to receive the signal from the beacon, even though it may be safe to transmit. This would not result in the optimal use of spectrum.

Sensing, where a device itself would detect whether or not spectrum was available to use would be much less conservative. An added advantage would be that no infrastructure would need to be constructed. However, sensing also generated challenges. For example, a White Space Device (WSD) might not be able to detect a weak signal in a given channel from a distant transmitter and may begin transmissions that would cause interference to a nearby DTT receiver.

Additionally, a reliance on sensing would create the hidden node problem, whereby the transmitter path remains blocked but the interference path remains open. The image below, created by Ofcom as part of a policy statement it made on the subject [9], demonstrates how this might occur in the context of WSDs. Here, it is imagined that a cognitive WSD may not be able to detect a DTT transmission because of an obstacle so would start to use a given frequency. However, these transmissions would cause undue interference to a DTT receiver that is reliant on the frequency for its DTT reception (Fig. 4).

Seeing as Ofcom had sought to be satisfied that there was a low probability of undue interference *to* the licensed users of the band *from* the license-exempt device, this was not seen as a viable solution for the time being.

Alternatively, a WSD may be able to obtain information about the spectrum environment at its particular geolocation from a database that can compute this information based on its knowledge of DTT transmitters, PMSE licenses, and (in some cases) other WSD deployments. The use of geolocation was judged to be able to provide a good balance between optimizing the use of spectrum (allowing as much WSD use of the spectrum as possible), while satisfying Ofcom that undue interference to licensed users would be unlikely [10]. An additional advantage of this approach is that it allows Ofcom to retain control on WSDs' access to spectrum. For example, if interference were to be found to be occurring at a particular location due to changes in the performance of a DTT transmitter, then the databases could be updated to take account of this.

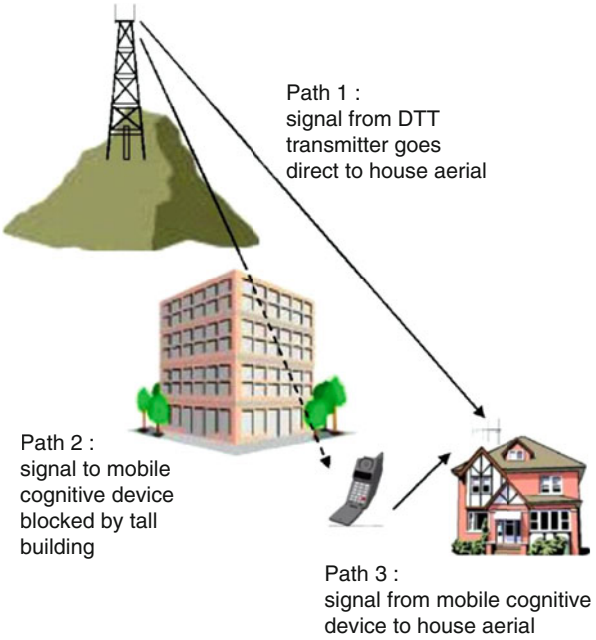

Fig. 4 The hidden-terminal issue (Source: Ofcom (2009) Digital dividend: cognitive access. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0023/40838/statement.pdf)

Seeing as WSDs in the UK depend on geolocation databases, it is not strictly accurate to describe the devices as cognitive radios. As explained later, the cognition required for an effective deployment of dynamic spectrum access is undertaken by the geolocation database.

Geolocation databases could theoretically have been provided by Ofcom itself, or by a third party on its behalf. However, in order to keep costs to a minimum, and to allow the development of white space services to develop without regulatory constraints, it was felt that geolocation databases should be provided by third parties according to their own business models. In this scenario, white space service providers negotiate with geolocation database providers on a commercial basis for use of the database.

A disadvantage of allowing third parties to operate geolocation databases is that Ofcom needed to create an overall framework that would ensure that databases would work correctly (as it would not have direct control).

An additional problem is that the UK's legal framework concerning spectrum does not currently allow for such geolocation databases to be registered through Ofcom. To overcome this problem, Ofcom has entered into contractual arrangements with geolocation providers. In the interests of simplicity and clarity, it is proposed as part of the Digital Economy Bill 2016/17 that geolocation databases may be registered by Ofcom. At the time of writing, this bill is being considered in the UK Parliament and may become an Act in the future.

The Database Approach

An overview of the database approach to TV White Space in the UK is given in the diagram below. This was created by Ofcom as part of its *Implementing TV White Spaces* statement in 2015 [11] (Fig. 5).

The database approach establishes two types of WSDs:

- **Master WSDs**. These devices are able to communicate with a White Space Database (WSDB) without using TV White Space spectrum. They provide information about their own characteristics and the characteristics of their slave WSDs to the database. These characteristics are known as device parameters.
- **Slave WSDs**. These devices must be under the control of a master WSD and are not allowed to communicate with a WSDB directly.

Before communicating with a WSDB, the master WSD must regularly interrogate a machine-readable page on Ofcom's website to find out which WSDBs are registered with Ofcom. Once it has obtained a list of WSDBs, the master WSD sends information about its device parameters to its chosen WSDB, including device parameters concerning slave WSDs.

The WSDB then performs calculations using the device parameters and provides the master WSD with information on which frequencies can be used by the master WSD and slave WSD and at what power level. These are referred to as operational parameters.

The master WSD chooses which frequencies to use at what power and informs the WSDB of its channel usage parameters (the lower- and upper-frequency

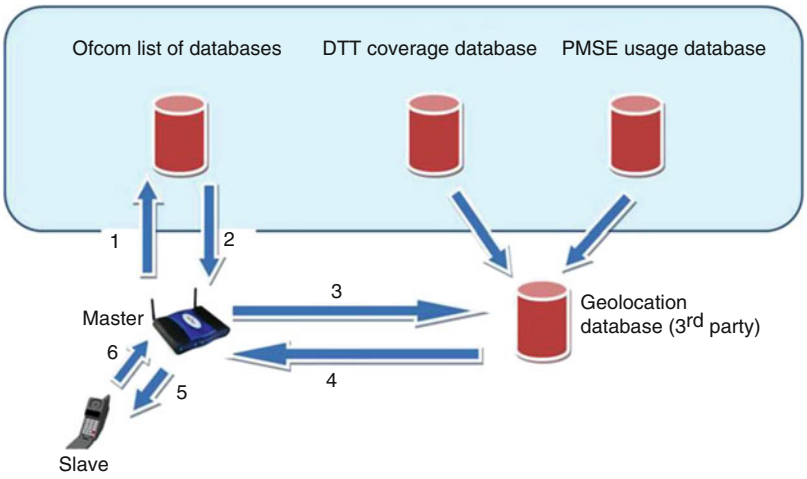

Fig. 5 Overview of TV White Spaces framework (Source: Ofcom (2015) Implementing TV White Spaces. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0034/68668/tvws-statement.pdf)

boundaries within which the WSD will transmit and the maximum in-block EIRP spectral density).

Ofcom has chosen to adopt a more complex form of TV White Space access than other countries (notably the USA) so as to allow for the optimal use of spectrum. For example:

- The operating parameters generated by WSDBs will vary the power levels permitted by WSDs based on the specific location of WSDs. Conversely, in the USA a WSD may either operate at full power or not at all, depending on whether or not transmission in a certain frequency and place risks causing undue interference to a licensed user. The UK approach means it is possible for a WSD to transmit at a greater proximity to licensed receivers, as long as the power levels are appropriately moderated. This is designed to take into account the fact that the UK's DTT network is near-universal, resulting in a different conception of TV White Space, as explained above;
- *Specific operating parameters* are generated by databases in order to allow high-performing WSDs to transmit at a higher power in some cases (although never higher than 36 dBm/8 MHz). More information about specific operating parameters in provided below.

Specific Operating Parameters

Once a connection is established between the master and slave WSDs, the master WSD may update the WSDB with device parameters concerning a specific slave WSD.

These parameters include:

– Device category (master or slave)
– Device type (fixed or non-fixed)
– Geolocation and geolocation uncertainty
– A unique identifier
– Device emission class (nonmandatory)
– Technology identifier (nonmandatory)
– Spectral mask improvement and reverse intermodulation attenuation improvement (nonmandatory)

This will allow the WSDB to generate specific operational parameters for the slave WSD. These are likely to be much less restrictive for the WSD. For example, the WSDB will initially assume that the slave could be in any 100×100 m pixel within a given radius of the master WSD and will generate generic operational parameters that take into account the powers in the most restrictive pixel within that area for each channel. Once a more specific location is known, then fewer pixels will be taken into account, and it is likely that higher powers will be permissible.

Additionally, generic operational parameters assume that the performance of WSDs is the minimum permitted under the ETSI standard (EN 301 598) [12], which is known as Class 5. WSDs conforming to higher classes have lower out of block emissions, meaning that its transmissions have a lower impact on adjacent channels. The effect of this is that when the WSDB calculates the permitted power levels across the available channels, there is likely to be greater availability and, at higher power, for better performing WSDs. These can only be taken advantage of if specific operational parameters have been obtained.

The master WSD will always need to inform the WSDB of the channel usage parameters of each WSD under its control, regardless of whether it is using generic operating parameters or specific operating parameters.

Data Used by the Geolocation Databases

In line with equipment used for TVWS access in the USA, the maximum power level of any WSD is 36 dBm. In many cases, the permissible power level will be lower than this, depending on the result of calculations undertaken by the database.

The algorithms have been defined by Ofcom, and database operators have had to demonstrate that they are able to carry these out before they are qualified by Ofcom.

When calculating the operating parameters that master WSDs (Master OPs) must use when communicating with their slave WSDs, the databases use four datasets provided by Ofcom. This is shown in the diagram below, which was created by Ofcom as part of its *Implementing TV White Spaces* statement:

(1) **PMSE data**. Ofcom provides information on licensed PMSE use, which must be used by WSDBs according to algorithms designed to ensure adequate separation in frequency between WSDs and PMSE devices for a given location.
(2) **Location agnostic data**. Ofcom provides general power limits applicable to WSDs operating in channels 34–41 in order to protect PMSE use of Channel 38 from undue interference & users in adjacent bands & international users. WSDs cannot operate in channel 38.
(3) **DTT coexistence data**. Ofcom provides for WSDBs information about the permissible power level for a WSD in each 100 × 100 m pixel in the UK taking into account the need to ensure a low probability of undue interference.
These calculations are based on the DTT planning model (UKPM), which has information on the predicted wanted signal level, taking into account receiver characteristics and interference from other DTT transmitters, at each 100 × 100 m pixel in the UK for each channel. Ofcom then adds statistics about the potential additional interference caused by a WSD, taking into account factors such as how far away the WSD would be from the nearest DTT receiver in terms of geography and frequency.

These calculations take into account both in-band emissions and out-of-band emissions from the WSD.
This calculation is repeated for each channel and for each pixel in the relevant area.
These calculations are complex and many (although not all) of the assumptions adopted are designed to be conservative.
These calculations are based on the assumption that households receive only intended DTT transmissions (i.e., that the aerial is pointing the right way).
In line with Ofcom's general policy, indoor aerials are not protected from interference from WSDs. Nevertheless, Ofcom believes that if the risk of interference to an outdoor aerial is low, then the risk to the indoor aerial is likely to be low too, as long as the WSD is located outside the building because the path loss generated by the building is likely to have a similar effect on both DTT and WSD signals.
The DTT coexistence data also takes into account the UK's international obligations concerning protecting DTT reception in neighboring countries.

(4) **Unscheduled adjustments data**. These are revised power limits that may need to be introduced into a particular geographic area on an ad hoc basis (Fig. 6).

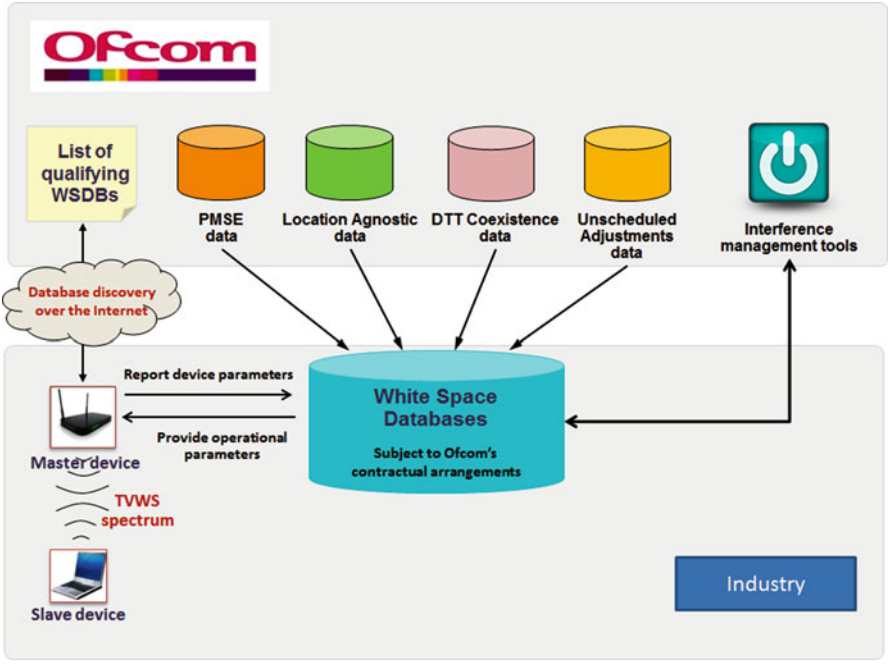

Fig. 6 Framework for authorising the use of TVWS including the interactions between WSDs and white space databases (WSDBs) (Source: Ofcom (2015) Implementing TV White Spaces. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0034/68668/tvws-statement.pdf)

Interference Management Tools

Ofcom has also established several safeguards against undue interference:

- **White Space Information Platform**. This is a single interface where Ofcom can request information about active WSDs from all WSDBs simultaneously through a single API. During the pilot, Ofcom had relied on a White Space Devices Information System based on multiple WSDB interfaces, but this was demonstrated to be impracticable in the event of an interference case.
- **Requirements to cease transmissions**. WSDs must re-query a database for their operational parameters at least every 15 min. Should a device be suspected of causing interference Ofcom are able to instruct a database to cease providing selected master devices with operational parameters. This instruction must be relayed to the selected master devices at the next re-query following the instruction. Ofcom recognize that such a "cease transmission" instruction is a fairly blunt instrument insofar as it has the potential to impact an entire network of master and its slave nodes (which are dependent on the master for their operational parameters). Partly for this reason Ofcom has developed other interference management options that they are able to apply using the WSIP.
- **Adjustments to the maximum power at which WSDs can operate**. Contrary to its original intentions, Ofcom retains control over the calculations concerning DTT reception. This gives Ofcom the ability to revise the results it gives taking into account new evidence it may receive where, for example, the UKPM may be found to be inaccurate regarding the signal levels delivered to particular 100 $\times$ 100 m pixels.
- **Requirements to cease providing WSDB services**. WSDBs are subject to a process of qualification, which includes testing whether or not a database is capable of implementing Ofcom's coexistence framework. Ofcom retains the ability to instruct WSDBs to stop providing certain services, potentially for a specific timeframe. Ultimately, Ofcom may remove a WSDB from the list of qualifying WSDBs on its website if there are found to be repeated breaches.

The License-Exempt Approach

Most mass market devices using radio spectrum do so on a license-exempt basis as this approach minimizes the costs related to intrusive regulation. However, Ofcom has been careful in implementing its TVWS framework to only allow devices to be available on a license-exempt basis if they can demonstrate automatic geolocation.

It was found during Ofcom's pilot of TV White Space spectrum access that none of the WSDs being trialed were able to demonstrate an automatic geolocation capability. To get around this problem, researchers typically manually configured the devices so that they could report their geolocation to a WSDB.

Manual configuration was permitted during the pilot as the researchers were operating under nonoperational licenses (previously known as test and development Licenses). However, allowing this approach to continue indefinitely would introduce conditions where undue interference could theoretically be caused.

For example, it is possible to imagine a scenario where a master WSD inaccurately reports that its slave WSD is at a suburban location and receives permission to transmit on several channels that are to be used in theaters at that time. If the slave WSD were in front of a theater and started to transmit, then there would be a high risk of undue interference to PMSE devices used in that production. Clearly this would not comprise the optimal use of this spectrum.

To address this problem, equipment adhering to the relevant ETSI standard (EN 301 598) specifies that the device must be able to geolocate automatically (i.e., it cannot be manually configured).

Under EU law, radio transmissions can only be performed by devices adhering to the Radio Equipment Directive [13]. The simplest way for manufacturers to achieve this is to self-declare that their device complies with the specifications cited in a European Telecommunications Standards Institute (ETSI) standard. It is also possible to obtain type approval from a notified body.

Under the TVWS framework, which has been operational since the end of 2015, license exemption is only permitted for devices that comply with the ETSI standard.

However, recognizing that it may be some years before devices adhering to the ETSI specifications become mass produced, Ofcom has set up a transitional arrangement whereby manually configurable WSDs may operate under a standard Ofcom license (under the terms of the Wireless Telegraphy Act) [14]. These licenses cover an unlimited number of manually configured WSDs, but the licensees must keep comprehensive and accurate installation records and make them available to Ofcom through a web tool.

Ofcom hopes this can allow benefits to be generated to UK citizens and consumers through the use of WSDs in the interim period before devices adhering to the ETSI standard are easily available.

Ofcom issued a statutory instrument [15] in December 2015 authorizing license-exempt use of TVWS by cognitive radios, providing they comply with the ETSI standard.

The Spectrum Sharing Framework and the 3.8–4.2 GHz Band

The Spectrum Sharing Framework

Ofcom's *Spectrum Management Strategy* [16] published in 2013 observed that the demand for spectrum was continuing to grow rapidly. In the past, Ofcom would typically address this by creating conditions where the spectrum can be used by the entity that values it the most. This could include clearing users out of a given spectrum band, meaning that often alternative solutions would need to be identified for those users, and then auctioning the spectrum to the highest bidder. This complex

process typically takes years and is often delayed further due to litigation regarding one or more of the many difficult policy decisions required in this process.

Bearing in mind improvements in the efficient use of spectrum over the last decades, the Strategy acknowledged that fewer and fewer spectrum bands are left where current users can be "cleared" so that new entities can start using the spectrum. Notwithstanding the fact that the same document found that 58% of the spectrum was shared (Ofcom Managed and license-exempt bands), Ofcom found that there should be more spectrum sharing in order to address growing demands.

This insight demanded Ofcom allow for new thinking to flow through its decision-making process. To enable this, Ofcom published a series of documents culminating in a *framework for spectrum sharing* [17].

A Framework for Spectrum Sharing

The *framework for spectrum sharing* establishes a systematic approach that Ofcom takes when it appears that an opportunity for spectrum sharing could arise or when it appears that spectrum sharing could be a solution for future spectrum demand.

This could take place, for example, when stakeholders' demand for spectrum cannot be met through existing authorization products. Alternatively, Ofcom may become aware of new developments, for example, advances in technology, that could comprise a tool or enabler for spectrum sharing. These circumstances are illustrated in Fig. 7, which was provided as part of Ofcom's statement on its *framework for spectrum sharing*

Under these circumstances, Ofcom would arrive at potential sharing proposals by considering the relevant *high-level characteristics of use*, *barriers*, *tools and enablers*. These concepts are defined below.

High-level characteristics of use allow Ofcom to make sure it is asking the right questions when it is analyzing potential, or current, users of spectrum. Ofcom has identified eight of these and has set out the thinking that would be employed when defining a given application's characteristics of use:

- **Time and duration**. What are the temporal requirements of the service – is it always-on, a set time, or unpredictable? Does the service require spectrum for long-term use or temporarily? What are the temporal requirements of the individual transmissions? What duty cycle do these use?
- **Geography and coverage**. Will the service cover the whole UK or be restricted to certain areas? Will it be ground based; will it be used outdoors or indoors? Is the location predictable – is the service in a fixed location or mobile? If it has control over end users, does the user know where its end users are?
- **Quality of service**. What type of reliability does the service require – guaranteed availability vs. best effort? What level of interference is acceptable? Is the service critical, e.g., used for critical national infrastructure?

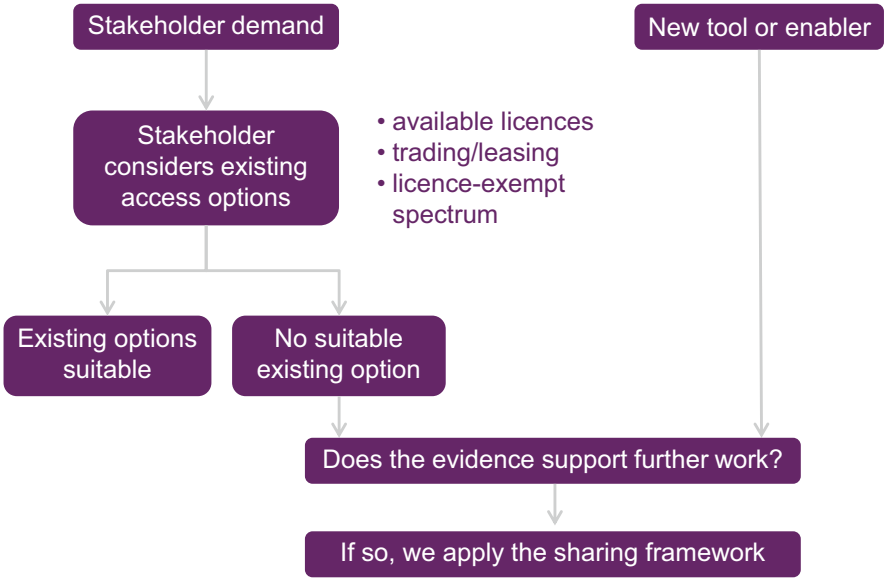

Fig. 7 Use of the spectrum sharing framework (Source: Ofcom (2016) A framework for spectrum sharing. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0028/68239/statement.pdf)

- **High-level technical characteristics**. EIRP (power), typical transmitter height and location (i.e., urban, rural, on hills, etc.) and antenna characteristics (beam widths directionality), typical receiver sensitivity (minimum receivable signal), and receiver locations and antenna characteristics.
- **Capacity requirement**. How much capacity is needed for each device and for the whole service? Is this a core capacity requirement or for additional capacity, e.g., for occasional overflow?
- **Density of use**. What is the approximate number of devices in use, i.e., whether a mass market consumer use or a limited number of terminals?
- **Evolution of characteristics over the life of an authorization**. How will each of these characteristics evolve over the term of the authorizations involved? What is the best way of approaching the uncertainty over longer timeframes? What is the payback period on the investment?
- **Harmonization required [for potential new applications]**. How essential are the benefits from international harmonization? What extent of economies of scale is necessary (e.g., one or several world regions or just UK specific)? What is essential to securing sufficient harmonization?

Having established the relevant characteristics of use, Ofcom then identifies the *barriers* and *tools and enablers* that flow from this analysis. According to the framework, *tools and enablers* are introduced to address the *barriers*. These aspects relate to information, the market, technology, and authorization conditions.

How these concepts relate to each other is shown in the following table:

	Barrier	Tool/Enabler
Information	Lack of information prevents identification of opportunities	Provision of information about spectrum assignment and use
Market	Transaction costs, concerns about impact on spectrum value, uncertainty about constraints on future use	Spectrum trading and leasing, spectrum pricing, auctions and awards (such as the DECT guard band concurrent license awards)
Authorization conditions	Terms of authorization can limit flexible use; Ofcom's commitment to sharing and regulatory timescales	Information requirements, tiered authorization approach;
Technology	Coexistence adds complexity and cost	Protocols for accessing shared spectrum (such as CSMA used in Wi-Fi), geolocation database technologies, sensing, automatic reporting of interference, frequency and band agile equipment

These *barriers* and *tools and enablers* are anticipated to change over time. For example, as Ofcom found during its work in TVWS, it is not clear that sensing can currently be considered to be an effective tool for sharing, but this may change as technologies evolve with time. After analyzing the appropriate tools and enablers, Ofcom may be in a position to make proposals related to spectrum sharing

Ofcom decided to use the proposed sharing approach identified in the framework for the first time on the 3.8–4.2 GHz band. These insights fed in to a Call for Input (CFI), which was published in April 2016 [18]

Opportunities for Innovation at 3.8–4.2 GHz

Ofcom's policy development regarding TVWS was in part driven by the insight that the UHF band comprises a "sweet spot" where large amounts of data can be transmitted over relatively large distances. Technological advances, and more investment in infrastructure, have arguably extended this "sweet spot" into higher frequencies.

The 3.8–4.2 GHz band is one of the "Ofcom Managed Bands" that comprise around half of radio frequencies in the UK.

The entire band is currently shared by the fixed and fixed-satellite services, while an 84 MHz block (3925–4009 MHz) of it is also used by UK Broadband. Ofcom authorizes point-to-point fixed links on a first-come-first-services basis, subject to Ofcom coordination and Ofcom technical frequency assignment criteria. These links are coordinated by Ofcom so that there is no undue interference caused to the assignments to the fixed-satellite service that are taken into account on Ofcom's

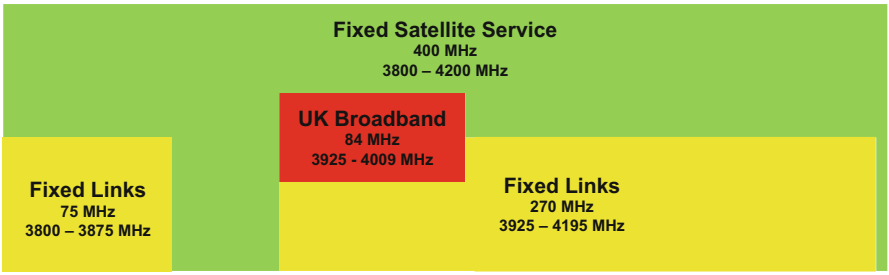

Fig. 8 The 3.8–4.2 GHz band (Source: Ofcom (2016) 3.8–4.2 GHz band: opportunities for innovation. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0031/79564/3.8-GHz-to-4.2-GHz-band-Opportunities-for-Innovation.pdf)

planning tool. A stakeholder is taken into account when it has a permanent Earth station license or grant of Recognised Spectrum Access that includes reception of space-to-Earth transmissions in the 3.8–4.2 GHz band at a particular satellite Earth station. UK Broadband has a nationwide spectrum access license, but its deployments also have to be coordinated through Ofcom so as to avoid interference with the other services. The frequency allocations of this band are shown in Fig. 8, which Ofcom created as part of its Call for Input to demonstrate how the band is used.

Much like the UHF bands, there appears to be scope to enhance the current sharing of the band. For the UHF bands, this is because at most locations there are many unused frequencies. This is also the case for the 3.8–4.2 GHz band, but additionally for much of the band, the spectrum is only being used in a few dozen locations at most.

For example, while the band is available for space-to-Earth transmissions anywhere in the UK, in reality its use is confined to 28 sites with satellite Earth stations (not including links operated by foreign governments). Further, these satellite Earth stations tend to be clustered in relatively small portions of the UK. Aside from a handful of important facilities such as Goonhilly in Cornwall and the Meteorological Office at Exeter, the use of the band is focused on Aberdeen and the home counties. Fixed links also tend to be concentrated geographically. All of the locations of these applications are shown in Fig. 9 (not taking into account UK Broadband's use of the 3925–4009 MHz range), which was created by Ofcom as part of its April 2016 Call for Input.

Further, each satellite Earth station will have several assignments authorized to it by Ofcom related to discrete blocks of spectrum and orbital positions. This means that not all of the spectrum will be used at each satellite Earth station. Similarly, each fixed link uses a 2×30 MHz block of spectrum, meaning that of the 65 fixed links in this band, only a few of these would be used in any particular part of the spectrum.

The way that their duplex channel plan is arranged (2×270 MHz within the 3.6–4.2 GHz band) additionally allows for a 50 MHz gap (3875–3925 MHz) where use is confined to the satellite Earth stations.

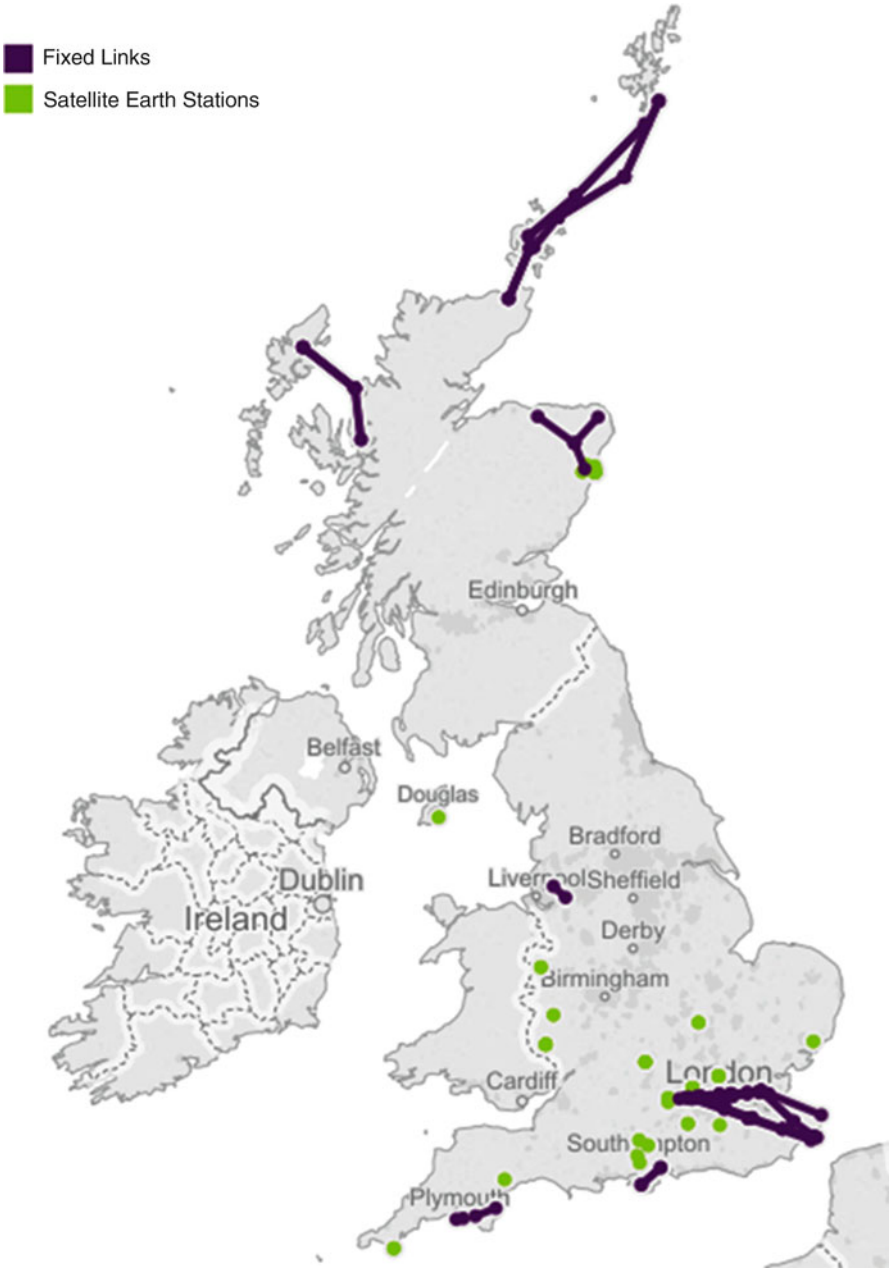

Fig. 9 Current users of the 3.8–4.2 GHz band (Source: Ofcom (2016) 3.8–4.2 GHz band: opportunities for innovation. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0031/79564/3.8-GHz-to-4.2-GHz-band-Opportunities-for-Innovation.pdf)

Characteristics of Use

To take the language of the Framework, the scale of the opportunity for sharing in this band derives from the current users' characteristics of use. The following table compares these high-level characteristics of use for major users in the UHF and 3.8–4.2 GHz band. WSDs are not included in this table as their use cases are varied.

	470–790 MHz		3.8–4.2 GHz	
	Digital terrestrial television	Audio Programme Making and Special Events	Fixed links	Satellite Earth stations
Time	Continuous	Variable	Continuous	
Geography/Coverage	Near-universal coverage required	Concentrated around a few locations at any given time, apart from channel 38, which could be needed anywhere	Concentrated around specific locations	Concentrated in certain regions
Quality of service	High levels of availability		High levels of availability	
Capacity requirement	High	Low for individual devices, but many devices may be required	Variable	
Density of use	Millions of TV receivers at UK premises	Many hundreds of thousands	Several dozen in the UK	Dozens in the UK
Evolution of these criteria	Stable for the medium to long term	Stable for the medium to long term. Growth in demand could be partly mitigated against by new band availability	Some change possible in medium term for some channels due to mobile data strategy at 3.6–3.8 GHz [20]	Stable, although some change possible in medium term due to mobile data strategy at 3.6–3.8 GHz band

One can observe that a major difference between these bands is that the use of the UHF band is much more "dynamic," because PMSE assignments change on a regular basis whereas current users of the 3.8–4.2 GHz band operate on indefinite licenses and have usage requirements that do not change substantially year by year. This makes sharing by time difficult, but also means that sharing may not be dependent on complex technologies, as is required for the Citizen Broadband Radio Service [19] in the USA at 3550–3700 MHz. It should be noted that, as explained earlier, even in geographic areas containing current users there are

typically frequencies that are not being used due to the channeling arrangements in this band.

It is also clear that there are fewer current users of the 3.8–4.2 GHz band than in the UHF band and that the usage tends to be concentrated in fewer areas than in those bands. As set out in the section above, this indicates that a more optimal use of this spectrum could involve finding a way of allowing spectrum access for additional applications in more areas of the UK, seeing as in many areas of the UK there is no current use of the spectrum.

As explained in the section above, it is the geography and coverage, density of use, and (relatively little) evolution of these characteristics of use that make the 3.8–4.2 GHz band a good opportunity for innovation in terms of securing a more optimal use of the spectrum.

Barriers and Enablers

Bearing in mind the high-level characteristics of use defined above, one could identify the following as potential barriers/enablers:

- **Information**. An absence of accurate information concerning current use of the band would prevent stakeholders from sharing this band as they would not understand its users' characteristics of use. However, in this case, Ofcom makes available high-level information on all fixed link deployments and the majority of satellite Earth stations (excluding those operated by foreign governments) on the Wireless Telegraphy Register.
- **Market**. In principle, some stakeholders have an incentive to prevent sharing, for example, from uncertainty about constraints on future use. In this case, regarding fixed links and satellite Earth stations, it is not clear that any market mechanism could enable sharing, seeing as the authorizations refer to specific applications at specific locations (i.e., they are not technology neutral), and are assumed to be required at all times. Spectrum assigned to UK Broadband (3925–4009 MHz) could in principle be shared through spectrum leasing (which is permitted under its licence for this band), and it is possible that fees could produce incentives for this outcome.
- **Technology**. Ofcom manages authorizations in this band because the coexistence challenges arising from the wide diversity of relevant equipment (i.e., highly sensitive receivers used in satellite Earth stations and high-power fixed link transmitters) are significant. Any technological innovation that can ensure that Ofcom does not need to directly coordinate spectrum authorizations in this band would need to be sophisticated enough to take into account the fact that satellite Earth stations operate on a receive-only basis in this band. For this reason, sensing or the use of protocols for accessing shared spectrum is not likely to be appropriate.
- **Authorisation**. Arguably, a significant barrier to enhanced sharing of the 3.8–4.2 GHz band is the absence of appropriate regulatory tools. For example, a

new user wishing to deploy a local fixed wireless access service could not use this band as a fixed link license would only allow transmissions under certain circumstances, and licenses for satellite Earth stations would not authorize any sort of transmissions within this band. The exception to this is UK Broadband (in the 3925–4009 MHz band only), which is able to use this band but only if Ofcom is satisfied that other users of the band will not suffer undue interference from a particular deployment.

A Potential Tool: The Tiered Approach

One could argue that one of the barriers to enhanced sharing in this band is the lack of an authorization mechanism for additional users.

A potential enabler to overcome this could be to introduce new licensing products that would support an overall tiered access model for spectrum access.

Ofcom imagined one scenario how this might be enabled in the future. A map generated by Ofcom to demonstrate this scenario is shown in Fig. 10, which shows how a given range of spectrum might be authorized across the UK.

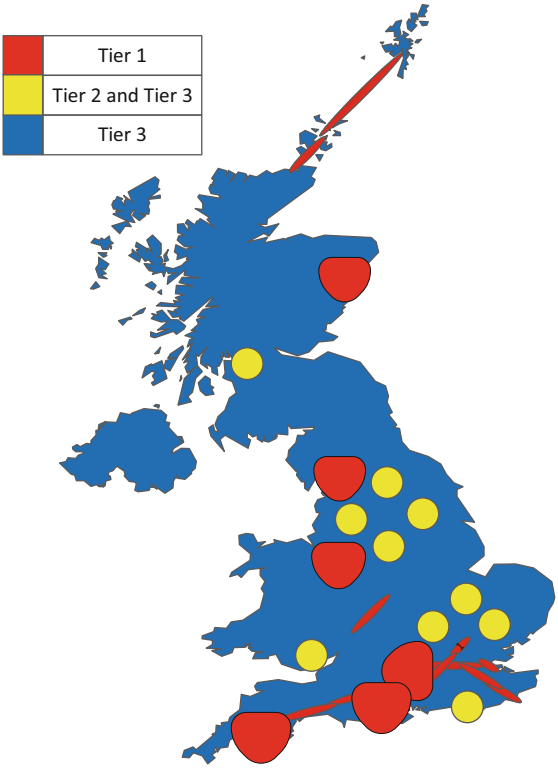

Fig. 10 A potential tiered approach to the 3.8–4.2 GHz band (Source: Ofcom (2016) 3.8–4.2 GHz band: opportunities for innovation. Available online at https://www.ofcom.org.uk/__data/assets/pdf_file/0031/79564/3.8-GHz-to-4.2-GHz-band-Opportunities-for-Innovation.pdf)

The scenario speculated on how much of the spectrum (the 316 MHz not assigned to UK Broadband) could be used more effectively.

In the imagined scenario, "Tier 1" would comprise the current point-to-point terrestrial links licenses, permanent Earth station licenses, and grants of Recognised Spectrum Access that are made available by Ofcom on a first-come-first-served basis. The majority of stakeholders responding to the Call for Input expressed the view that any changes in this band should allow for the continued further availability of these products.

Additionally, Ofcom could issue regional licenses for spectrum access as part of a "Tier 2." As an example, these could comprise a 10 MHz block for a local mobile service provided in areas where mobile network operators have not built a network. These licenses could be issued for areas at a large distance away from Tier 1 deployments, in order to minimize the risk of interference.

Ofcom did not consider the authorization mechanism for such a tier; nor did it consider how geographic areas would be defined (e.g., by Ofcom dividing up the country or by specific requests from stakeholders).

The third tier could comprise "opportunistic" spectrum access, which would be akin to a "secondary" service. While holders of Tier 2 license products could be granted some form of certainty of spectrum access (arising from the way Ofcom could issue authorizations), users in this layer would have no such guarantees. As with TVWS, the successful operation of this layer might require some mechanism by which users in other tiers could be sure that they would not suffer undue interference from Tier 3 users. As a preliminary suggestion, Ofcom raised the possibility of using databases as a means of giving such assurances. Databases have the advantage of being a proven and demonstrated concept during the TVWS pilot.

In the UHF band, the only incumbent user of the spectrum whose deployments frequently change is PMSE. In the 3.8–4.2 GHz band, current use (Tier 1) is assumed to be static seeing as current authorization products in this band are indefinite. Some potential future use of the band (Tier 2) is assumed to be relatively static, although the Call for Input did not include any discussion of whether or not Tier 2 licenses would be time limited.

Opportunistic spectrum users, however, are often assumed to have dynamic characteristics of use, so the deployment of databases could also ensure that there is minimal undue interference caused between these users, notwithstanding the fact that they would all operate on a "secondary" basis. An additional potential advantage of databases is that they could also in principle allow opportunistic spectrum users to access spectrum assigned to a Tier 2 users, if information about Tier 2 use was also included in the database. As discussed at the beginning of this chapter, the WT Act licenses granted by Ofcom allow Ofcom to authorize additional use in the band. However, the extent to which a database might control users has not been discussed in the Call for Input.

Responses to the Call for Input were in general supportive of Ofcom's analysis and overall intentions. Many respondents advocated two-tier sharing where, for example, current licensees would share with mobile, which may correspond to the

form of Licensed Shared Access envisaged in some European countries for the 3.6–3.8 GHz band.

In August 2016 Ofcom published an update. In general, Ofcom confirmed its interest in enhanced sharing for (nonspecific) authorizations that, according to Ofcom's preliminary analysis, should be geographically defined. Geographically defined means that authorizations could be, for example, based on regional licenses and/or for a specific geographic point plus an area around it based on a given radius, defined as pixels, as is authorized under TV White Space spectrum access.

Conclusions and Future Directions

This chapter explained how the legal framework in the UK has provoked Ofcom to exploring novel regulatory solutions for spectrum sharing.

Its Spectrum Management Strategy and subsequent Framework for Spectrum Sharing have underlined that it considers spectrum sharing to be a priority going forward.

A test-bed for this new approach has been the 3.8–4.2 GHz band, where it has demonstrated an interest in finding novel regulatory solutions for spectrum sharing in service of Ofcom's principal duty, to secure the optimal use of the radio spectrum in the UK.

In the short term, it seems possible that industry focus on spectrum sharing is likely to be on TV White Space. The last words of this chapter reflect on the future directions for this form of spectrum access.

As previously noted, terrestrial broadcasting plays a very important role in public life in the UK. Bearing this in mind, Ofcom has in general taken a conservative approach in ensuring that there will be an adequately low probability of interference to these users.

It is possible that the combined effect of these conservative assumptions has resulted in an overall over-restrictive approach to TV White Space, and Ofcom may in the future review these assumptions. Equally, it may consider that these assumptions are not conservative enough. For example, it does not currently consider the effect of an aggregation of WSDs being authorized to transmit on the same frequency from different databases. While the probability of this is deemed low in the initial stages, this may require attention in the future. This could, for example, be resolved through the sharing of information between WSDBs, seeing as WSDBs are not aware of the channel usage parameters being reported to other WSDBs.

Future change to Ofcom's framework for TV White Space is likely to be dependent on market developments, not least the proliferation and performance of WSDs using this spectrum. It is true that the adoption of cognitive radio in TVWS has been slower than predicted by some, although the pilot saw interesting use cases that had not originally been anticipated, such as digital signage and webcam backhaul. In turn manufacturers are likely to closely monitor changes to the use of the band by the broadcasting service internationally.

At the World Radiocommunication Conference in 2012 (WRC-12), the countries in ITU Region 1 (Africa, the Middle East, Europe, and the former Soviet Union) agreed to allocate the 700 MHz band (694–790 MHz) for mobile services from 2015, bringing its spectrum allocations more in line with the rest of the world. This agreement was confirmed at WRC-15. The introduction of mobile into the 700 MHz band could in some cases reduce the amount of TV White Spaces available for cognitive radio. In the UK, this change of use could begin from 2020 [21], which is when the spectrum is expected to be auctioned for mobile services.

This will partly be enabled by reducing use of the interim multiplexes, which may somewhat mitigate against the loss of spectrum available for cognitive radios.

Another mitigation is that Ofcom has made the 960–1164 MHz band available for low-power audio PMSE applications on a shared basis with [21] aeronautical radionavigation services.

In the very long run, the future of the DTT platform itself will have to be considered. The issue will be considered again in the run-up to WRC-2023 (23), although the consensus within EU member states is to retain the platform until at least 2030, revisiting the issue again from 2025.

Therefore, the future availability of the UHF band for cognitive radio might in the long run be to some extent dependent on society's idea of what broadcasting services should be made available universally and what platform can best deliver that. These considerations might take into account the proliferation (or nonproliferation) of alternative broadcasting platforms (including IPTV) among the population at large, including the most vulnerable members of society.

Additionally, although by definition license-exempt applications are not in general directly protected from undue interference by regulators, it is possible that the benefits that cognitive radio may deliver to citizens and consumers could also be taken into account in such discussions.

Contents

Abstract

In this chapter, we investigate the spectrum measurement results in Asia-Pacific region. Then the spectrum sharing policy in Asia-Pacific region is reviewed in details, where the national projects and strategies on spectrum sharing in China, Japan, Singapore, India, Korea, and Australia are Investigated. Then, we

W. Zhang (ed.), *Handbook of Cognitive Radio*,
https://doi.org/10.1007/978-981-10-1394-2_52

introduce the spectrum sharing test-bed developed in China, which is a cognitive radio-enabled TD-LTE test-bed utilizing TV white space (TVWS). This chapter provides a brief introduction to the spectrum sharing mechanism and policy in Asia-Pacific region.

Radio spectrum resources play a fundamental role in wireless communication systems. The fast-growing demand for wireless communication services and the inefficient spectrum allocation methods result in the scarcity of spectrum resources, greatly hindering the development of future wireless communication systems [6,27].

For example, in China, the state radio regulatory commission of China (SRRC) divides the entire available spectrum resources into multiple frequency bands and assigns them to different license services such as broadcast TVs and cellular networks for exclusive use. Such fixed spectrum allocation approach ensures that wireless applications and devices dont cause harmful interference with each other. However, it will result in inefficient use of current radio spectrum. Some bands are heavily occupied by busy radio services, while other bands are rarely used. There exist great difficulties to find unassigned spectrum for new broadband wireless communication systems such as time division long-term evolution (TD-LTE).

One of the most promising solutions to overcome this problem is cognitive radio (CR). A CR device has the ability to identify and access an unoccupied spectrum band for temporary usage. Therefore, CR is viewed as a technology to overcome the current inefficient use of radio spectrum resources [32,55].

Due to its importance, a lot of research funds have been invested in developing cognitive radio technology. National research programs have already been founded to support CR technology in China such as the Major State Basic Research Development Program (973 Program), the National High Technology Research, the Development Program of China (863 Program), and the National Natural Science Foundation of China. Government policy regulators such as SRRC are now considering modifying the current spectrum allocation policies in order to enable dynamic spectrum access technologies. However, if they fail to fully understand the current spectrum occupancy patterns, the investments and efforts may not produce expected accomplishments.

In the rest of this chapter, we first introduce the spectrum measurement in Asia-Pacific region and then describe the spectrum sharing policies. In addition, the main spectrum sharing technologies such as spectrum sensing and geo-location database-based spectrum sharing schemes are introduced. Finally, we give a brief introduction to the spectrum sharing test-bed in China.

Spectrum Measurement in Asia-Pacific Region

Spectrum occupancy survey is essential for spectrum management and provides policy makers with necessary information on the frequency usage pattern of different services in different frequency bands. Until now, several measurement

campaigns have already been conducted in the United States, Singapore, Vietnam, and Germany [2, 20, 31, 52]. All these studies show a common discovery that a large portion of assigned spectrum resources are seldom used, while some particular spectrum bands are overcrowded. In this chapter, we make a brief survey on the spectrum occupancies in Asia-Pacific region.

China

The spectrum occupancies in Beijing are measured by our team [4, 51]. We have measured the spectrum band from 440 to 2700 MHz for 2 weeks in Beijing. This measurement not only fills the gap of the current lack of knowledge on the radio spectrum usage pattern in Beijing but also finds out the frequency bands suitable for future dynamic spectrum access products like CR devices. Our measurement consists of two parts, the fixed measurement and the mobile measurement, which are introduced in the following sections.

Spectrum measurement

Fixed measurement

The fixed measurement was adopted to measure the spectrum band from 440 to 2700 MHz. Our fixed measurement was taken on the roof top of a 30-story building near the central business district (CBD) in Beijing. Without any higher buildings surrounding the measurement site, it ensures us to measure the radio activities accurately. The equipment includes omnidirectional broadband antenna BOGER DA753G that has a frequency range of 75 MHz∼3 GHz, Agilent high-performance spectrum analyzer N9030A with a dynamic range from −154 to 30 dBm, and a computer. As illustrated in Fig. 1 (left), the antenna was installed on the roof top and connected to the spectrum analyzer by a low-loss cable. The spectrum analyzer was controlled by a computer which was used for parameters setting and data saving. Both the spectrum analyzer and the computer were kept in an indoor metal box as shown in Fig. 1 (right). The resolution bandwidth (RBW) of the spectrum analyzer was set to be 200 kHz. The measurement started in June 2012 and lasted for seven consecutive days. In total, around 100 billion data samples were collected.

Mobile Measurement

As illustrated in Fig. 2 (left), the instruments utilized in the mobile measurement and their connections are mostly the same as the fixed measurement. It is worthwhile to mention that a GPS is connected to the computer in order to record the geographical coordinates of data samples. The GPS we used is Garmin 72HGPS with a location precision of 5 m. To ensure that the mobile measurement captures the actual spectrum occupancies in Beijing, a proper route is crucial. Therefore, the following three principles are adopted for the selection of measurement route.

Fig. 1 Equipment and measurement environment of fixed measurement

Fig. 2 Equipment and route of mobile measurement

(1) The route should be a helix circling the TV transmitters. The distance from the TV transmitter changes gradually, such that the relationship between signal strength and distance can be captured.
(2) To avoid the distortion caused by Doppler effect, the speed of the vehicle must be kept low. In addition, the performance of the instruments may be affected by the turbulence at high speed. So we maintained a speed around 20 Km/h in the measurement.
(3) To make the measurement convincing, the route should cover all typical places including business district, residents living quarters, open outdoor areas, etc.

The selected measurement route is plotted in Fig. 2 (right). Here different colors denote different kinds of places. In this map, yellow stands for residential areas, purple for business districts, and white marks the open areas with sparse buildings. The measurement was conducted from 9 a.m. to 5 p.m. each weekday.

The Measurement Results

Spectrum Measurement of 440–2700 –MHz

The spectrum band from 450 to 470 MHz is authorized for radio navigation, radio localization, and land mobile services such as interphone. The average spectrum occupancy is observed as 18%. A temporary usage pattern can be observed for part of frequency channels in this band, which mainly are interphone services resulting in relatively low spectrum occupancy. The spectrum measurement results in Beijing are shown in Fig. 3.

The spectrum band from 470 to 806 MHz is allocated for the broadcasting services, which are Chinese analog TV service PAL-DK and Chinese digital TV service "Digital Television Terrestrial Multimedia Broadcasting (DTMB)." The average spectrum occupancy of spectrum band from 470 to 806 MHz is about 42%. However, not all TV stations work for 24 h each day. Some TV channels are closed between 00:10 a.m. and 5:50 a.m.

The spectrum band from 880 to 960 MHz is assigned to the mobile cellular services (GSM900). The average spectrum occupancy of this spectrum band is 45.52%. Note that the spectrum occupancy patterns of uplink and downlink of GSM900 are quite different. Similar signal occupancy pattern is observed in the GSM1800 and 3G services. This may result from that the transmit power of uplink of the cellular systems is relatively lower than the transmit power of downlink. And the uplinks are silent when there are no active communication sessions. The

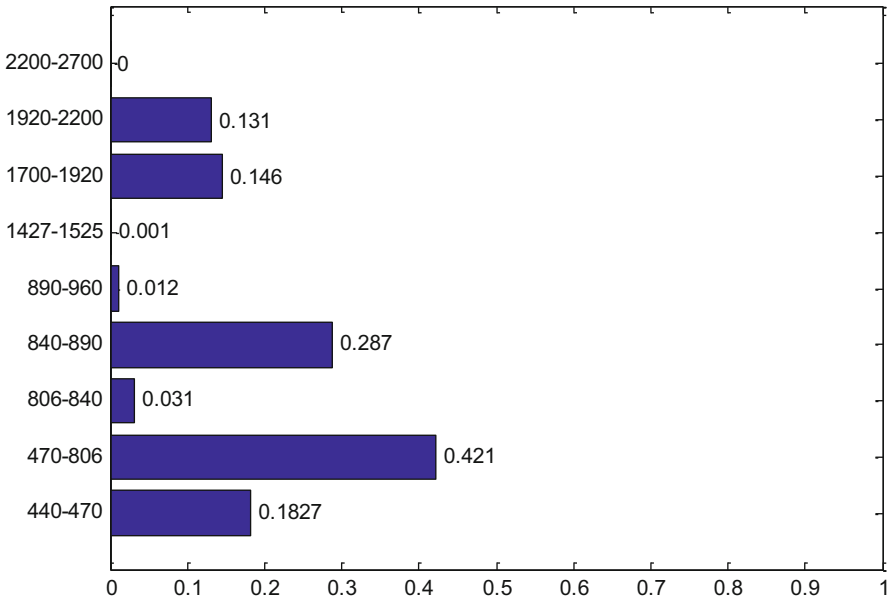

Fig. 3 Spectrum occupancy in Beijing

TD-SCDMA band A (1880∼1900 MHz) was not detected in our experiment, and its service only existed in band B (2010∼2025 MHz). CDMA2000 signals were not detected during the 2-week period. The average spectrum occupancy of 1700-1920 MHz is about 14.6%, and the average spectrum occupancy of 1920-2200 MHz is about 13.1%.

The spectrum occupancy of the industrial, scientific, and medical band (ISM band), ranging from 2400 to 2500 MHz, appears to be completely unused during 2-week observation. High-likelihood signal occupancy pattern is found in the radar spectrum band from 2500 to 2700 MHz, TD-SCDMA candidate band C 2300∼2400 MHz, and 1427∼1525 MHz band for pointing to multipoint microwave communication system, which is currently utilized by military services. The occupancy estimations of ISM and radar bands may not be the real situation of the systems such as WLAN and Bluetooth. Since the measurement site is on the roof top of a 30-story (115-m-high) building, the ISM signals may not reach the measurement point. Besides, ISM signals may not penetrate through walls. Radar signals may need special detection methods and equipment, since its pulse is too short to be detected and may result in a very low probability to be captured.

The summary of average spectrum occupancy in Beijing city is presented in Fig. 3. The results indicate the sparse usage characteristics both in time and frequency domains. The spectrum occupancy rate in average is 13.5% in Beijing for 450∼2700-MHz frequency band. Therefore, nearly 86.5% of allocated spectrum is unused.

Spectrum Measurement of TV Band

We conducted fixed and mobile measurement of the 470∼806 MHz spectrum band in Beijing. The frequency, time, and space domain [18] and the specific TV standards are all considered in our analysis. Similar to previous measurements, the fixed measurement and mobile measurement are both conducted.

In China, the spectrum band originally allocated for terrestrial TV broadcasting service is between 470 and 806 MHz. Due to historical reasons, 566∼606 MHz band is reallocated to trunking communication service, which is omitted in our analysis. Thus the TV band takes up to 296 MHz bandwidth. Currently, both analog television (ATV) and digital television (DTV) are utilized in Beijing. The channel bandwidth is 8 MHz for both DTV and ATV. Therefore, TV band contains 37 channels. Their transmit power is very high, which means that these channels are occupied almost all the time, like 750∼758 MHz. In the second case, both the maximum and the average transmit powers are high. However, a certain difference exists between them, which suggests that these frequency bands are only partially used, like 478∼486 MHz. In the last case, the maximum power is high, while the average power is close to the noise floor, like 700∼730 MHz. Since TV broadcasting system usually works stably over a long period of time, these channels may be utilized by wireless microphones or interphones.

The water fall map of the spectrum band is depicted in the lower subfigure of Fig. 4. It can be observed that some spectrum bands are not utilized during the time interval 00:00∼06:00. To show whether the spectrum utilization has periodicity over

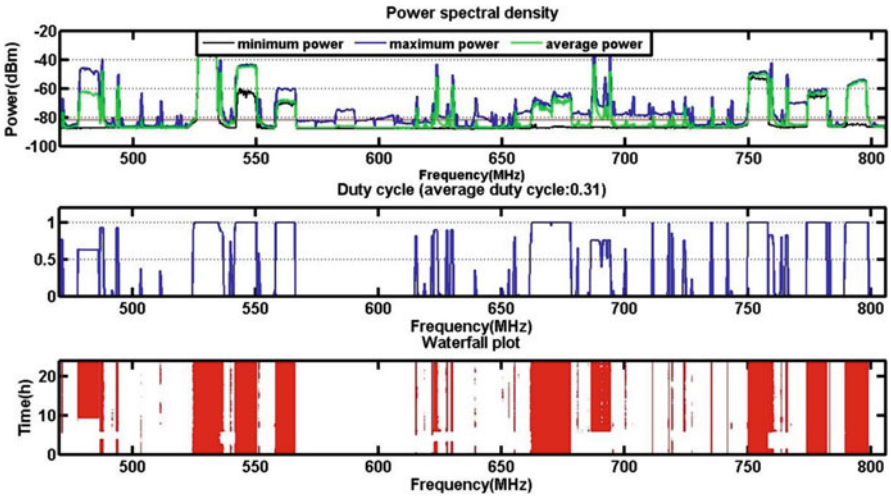

Fig. 4 The utilization of TV band

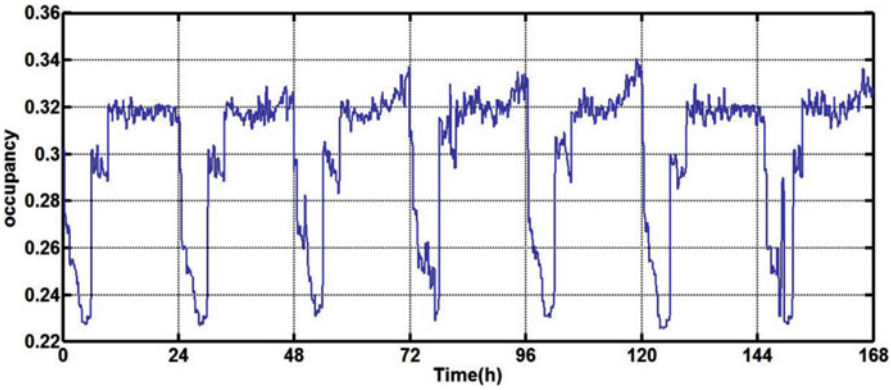

Fig. 5 Spectrum occupancy versus time in the 7-day measurement

time, the spectrum occupancy versus time in the 7-day measurement is plotted in Fig. 5.

It is obvious that the entire spectrum band occupancy shows strong periodicity with 1-day period. As illustrated in Fig. 5, the lowest occupancy appears in 00:00∼06:00, which can be explained by the fact that some TV transmitters are shut down at midnight due to the small number of audiences. The occupancy is almost identical for each day during a week, which depicts the static feature of the TV channels. Ripples in the occupancy curve can be explained by measurement errors and illegal usage. Notice that the high utilization period of TV band coincides with the busy period of the public communication systems such as CDMA and WLAN.

An interesting paradox is that even though spectrum opportunity in the time domain is sufficient in 00:00∼06:00, the spectrum demand may not exist in this period.

Suggestions on Spectrum Innovation in TV Band of China

Based on the analysis of both fixed and mobile measurement above, we would like to provide our suggestions on spectrum innovation for the TV band of China.

Our first suggestion is that China should accelerate the transition from ATV to DTV. The advantages of DTV are obvious. Firstly, the DTMB standard developed by China can provide a data rate as high as 30 Mbps via OFDM, which is sufficient for HDTV. So the experience of the audiences will be greatly enhanced. Secondly, the receiver design and out-of-band performance of DTMB are better than PAL-DK and make DTMB robust to adjacent channel interference. The replacement of ATV with DTV will eliminate the hidden occupancy problem, resulting in fewer requirements on the device using this band. Thirdly, Chinese DTV standard has its unique single-frequency network (SFN) technology. To cover a huge area, the same TV program is traditionally broadcasted using different channels to avoid the interference among transmitters. However, in SFN, a TV program can be synchronously broadcasted across the entire area via only one channel. Thus spectrum efficiency can be improved, and more channels can be relieved for reallocation. Finally, multiple TV programs can be carried by a DTV channel, and the channels needed for TV broadcasting can be further reduced. The transition to DTV is an international trend which has been accomplished in many countries. China began the transition from 2008 and is more likely to accomplish in 2020.

We believe spectrum reallocation should be the main spectrum innovation strategy in the TV band of China. As the measurement indicates, the overall occupancy of TV band is merely 38%, which is very low. Thus, the vacant band can be reallocated to other services. However, the spectrum allocation for TV band varies in the different areas of the country. To leave a universal band for other services, national-wide adjustment of TV spectrum band may be required. Moreover, the spectrum occupancies show that there exist the time domain spectrum opportunity in the midnight and space domain spectrum opportunity in the suburb of city. However, there are difficulties to use these spectrum opportunities. Besides, indoor spectrum opportunities exist for short-distance communication technologies like femtocell. However, a further measurement is needed to justify the possibility to implement femtocell in TV white space.

Other Countries and Regions

Contreras et al. in [5] carried out the spectrum occupancy measurements in three locations of Kanto area in Japan. The spectrum band from 90 MHz to 3 GHz is measured. It has been found that only 6.9% of the spectrum between 90 MHz and 3 GHz is used for more than 10% of time, which indicates the great potential for deploying spectrum sharing systems in Japan.

Table 1 Spectrum occupancies in Japan [5]

Subband	Bandwidth	Occupancy	Services
90∼108 MHz	18 MHz	23.58%	TV broadcast (until 07/11)
108∼170 MHz	62 MHz	12.91%	Miscellaneous communications
170∼222 MHz	52 MHz	17.46%	TV broadcast (until 07/11)
222∼470 MHz	248 MHz	0.63%	Miscellaneous communications
470∼810 MHz	340 MHz	13.9%	TV (until 07/12), radio microphones
810∼958 MHz	148 MHz	28.55%	Cellular networks, disaster prevention, RFID
958∼1710 MHz	752 MHz	0.09%	Miscellaneous services
1710∼2300 MHz	590 MHz	5.9%	IMT 2K, spatial applications
2300∼3000 MHz	700 MHz	0.018%	Radar, IMT 2K, ISM, public communications

Table 2 Spectrum occupancies in Malaysia [21]

Service	Frequency range (MHz)	Bandwidth (MHz)	Average duty cycle (%)
GSM 900	880∼960	80	35.31
GSM 1800	1710∼1880	170	9.59
3G (IMT-2000)	1885∼2200	315	26.08
VHF TV	174∼230	56	10.92
UHF TV	470∼798	328	13.36

The spectrum occupancies of different sub-bands are provided by [5], which is presented in Table 1. It is noted that the highest spectrum occupancy is 810∼958 MHz, which is occupied by cellular networks. On the other hand, the spectrum bands which are occupied by radar, TV broadcasting system, etc. are relatively idle. Overall, the spectrum measurement in Japan has demonstrated the great potential for deploying spectrum sharing systems in Japan all along the evaluated spectrum from 90 MHz to 3 GHz [5].

Jayavalan et al. in [21] investigated the spectrum occupancy of cellular and TV broadcasting spectrum bands in Malaysia, as shown in Table 2. Malaysia is closely located with Singapore, Thailand, and Indonesia, so some of the TV spectrum bands are not utilized in this country due to cross-border spectrum coordination. Specifically, TV broadcasting in VHF and UHF bands has the average duty cycles of 11% and 13%, respectively [21]. Besides, Jayavalan et al. found that the utilization of most allocated TV spectrum bands is below 15%. Thus their work provides the motivation for spectrum sharing in Malaysia and can bring economic and social welfare to this country.

Spectrum Sharing Policy in the Asia-Pacific Region

China

According to the prediction of ITU, the spectrum demand of international mobile telecommunications (IMT) in 2020 will be 1340∼1960 MHz. SRRC estimates that

spectrum demand in 2020 will be 1490∼1810 MHz. However, there is still around 1000 MHz shortage of spectrum for China [53].

In this situation, the spectrum refarming, spectrum sharing, etc. are proposed to improve the spectrum utilization. In China, government policy regulators such as the ministry of industry and information technology (MIIT), SRRC, etc. are considering modifying current spectrum allocation policies in order to enable dynamic spectrum access technologies. The Chinese government has already released the regulations that allow the spectrum sharing among the radio access technologies (RATs) within an operator. In 2016, MIIT of China firstly carried out spectrum audit, which aims to evaluate the spectrum usage to enhance the radio spectrum resource regulation. Through this work, Chinese government obtains the actual use of key spectrum bands of 7 public mobile communication systems consisting of 25 spectrum bands. Thus Chinese government has enhanced the monitoring level of the spectrum, which paves the road for spectrum refarming and spectrum sharing.

Moreover, in order to satisfy the requirements of future mobile broadband systems in 5G, such as ultrahigh traffic and ultrahigh data rates, more spectrum and wider bandwidth are needed to improve the performance. Therefore, the innovative spectrum utilization methods should be further investigated to discover the available spectrum of IMT under horizontal or vertical spectrum sharing systems. Spectrum sharing is a dynamic and optimized allocation of multi-RAT spectrum resources, which involves some key factors such as deployment scenario, network load, and user experience. Spectrum efficiency improvement and interference control are benefited from the optimized dynamic spectrum allocation and management among different networks or systems. Besides, self-adaption functions of autonomous access networks and handover between networks can be realized. Furthermore, air interface efficiency and coverage are enhanced for the efficient, dynamic, and flexible spectrum utilization. Therefore, the utilization efficiency of spectrum can rise.

Spectrum sharing technologies can be classified by the application scenarios, including intra-operator inter-RAT spectrum sharing, inter-operator spectrum sharing, spectrum sharing in the unlicensed band, and spectrum sharing in secondary access. There are various implementation choices for spectrum sharing such as independent control node, database-based control, etc. The specific functionalities of spectrum sharing contain multiple priority spectrum allocation, interference coordination, and so on. In the following sections, we will introduce the development of spectrum sharing technologies in China.

Spectrum Refarming

In the United States, Finland, etc., the spectrum bands of 2G mobile communication systems are reallocated to the 4G mobile communication systems. In China, there are also some cases of spectrum refarming. In 1998, the personal handy-phone system (PHS) entered into China market. Until October 2006, the number of the users of PHS system in China is 93 million. However, in October 2008, MIIT of China announced that the spectrum band of PHS (1900∼1920 MHz) was planned to be reallocated to time division-synchronous code division multiple access

(TD-SCDMA) system, a third-generation mobile communication system proposed by China. In January 2011, PHS system began to be officially withdrawn from the market of China. In October 2014, the base stations of PHS were completely closed in China.

TD-SCDMA has inherited the spectrum band of PHS system in China. However, when the TD-SCDMA began its commercial operation, the 4G mobile communication system has been already on the way. Besides, the time division long-term evolution (TD-LTE) and TD-SCDMA are both operated by China Mobile Communications Corporation (China Mobile). Hence TD-SCDMA fell in an awkward situation. In 2013, China Mobile determined that the voice service of 4G will fall back to GSM system rather than TD-SCDMA system. In 2014, China Mobile announced that the investment to TD-SCDMA had been stopped. And the users of TD-SCDMA will be moved to TD-LTE, which means that TD-SCDMA network will be naturally withdrawn in the future. Actually, China Mobile has already started some trials to refarm the spectrum of TD-SCDMA. In 2015, China Mobile allocated the spectrum band A (1880∼1920 MHz) of TD-SCDMA to TD-LTE, such that the data rate of TD-LTE can be improved to 79.8 Mbps. Besides, China Telecom and China Unicom started to refarm the spectrum of CDMA 800 MHz and GSM 900 MHz [53].

Spectrum Sharing

In China, the mobile Internet plays an important role in economic development and everyone's life. Driven by the devices such as smartphones and tablet PCs and the services, such as social networking, streaming media, and online game, the amount of mobile traffic dramatically increases, which gives birth to the fifth-generation (5G) mobile networks. One of the quality of service (QoS) requirements of 5G is the 1000× capacity improvement compared to 4G. With such large capacity demand in the future mobile communication system, the spectrum refarming cannot totally solve the shortage of spectrum. Hence the spectrum sharing is regarded as the long-term solution in the 5G era.

Recently, with the emergence of sharing economy or collaborative consumption, the spectrum sharing becomes more and more popular. Similar as the business model of Uber and Didi, the government believes that spectrum sharing can stimulate the economy. In 2013, the Broadband China Strategy was proposed by China government, where optimized spectrum planning was initialized as one of the strategies.

In the spectrum planning of Broadband China Strategy, the government of China regarded the dynamic spectrum allocation as a promising approach to improve the utilization of spectrum resources. To achieve this goal, the interference mitigation technology and equipment are required to be addressed to enable the spectrum sharing among various wireless services. Meanwhile, the spectrum regulation for multiple wireless devices operating on the public spectrum is essential, which aims to maintain the order of spectrum utilization among the spectrum sharing wireless networks and devices.

The TV white spaces (TVWSs), 2.3 and 3.5 GHz, etc. are widely regarded as the promising spectrum bands that can be shared with other wireless systems. In the Broadband China Strategy, the spectrum band of 2300∼2400 MHz, which was originally allocated to the radar system, was planned to be shared with wireless communication systems. The spectrum bands that are utilized locally, such as spectrum bands of TV and radar, are commonly regarded as the ideal candidate spectrum sharing bands. However, the TV white spaces in China are difficult to be shared because of the policy issues, although the sharing of TV white spaces has been already deeply studied in China's academia.

National projects of Cognitive Radio

The government of China has supported a lot of national projects to study the cognitive radio and spectrum sharing, etc. In 2005, the National High-Tech R&D Program (863 Program) began to support the research on cognitive radio. In 2008, the National Natural Science Foundation of China established a group of the projects on cognitive radio. The Beijing University of Posts and Telecommunications (BUPT), Tsinghua University, PLA University of Science and Technology, etc. were all supported by this group.

Specifically, in 2008, BUPT was supported by the Major State Basic Research Development Program of China (973 Program) to study the architecture of cognitive radio networks, multi-domain cognition theory and method, autonomous resource management and control schemes of cognitive radio networks, etc. The proposed architecture of cognitive radio network was illustrated in Fig. 6, which consists of four modules.

(1) End-to-end goal management: This module consists of two aspects: the end-to-end goals and cognitive specification language. The cognitive information collection and autonomous resource management module are guided by the end-to-end goals. The cognitive specification language maintains the connection among different modules.
(2) Cognition coordinator: Cognition coordinator is mainly used to set the filter to obtain cognitive information from multi-domain environment. Then cognition coordinator establishes the precise mapping between multi-domain environment and cognitive information. Finally, cognition coordinator extracts the relevant cognitive information.
(3) Self-organization coordinator: With the goals of end-to-end utility, the autonomous resource management module generates the optimization strategy based on the collected cognitive information.
(4) Reconfiguration management: Based on the optimization decision, the related reconfiguration model is established to execute the reconfiguration command and reconstruct the network parameters.

In the architecture of cognitive network, the entire architecture is driven by end-to-end performance. And the learning function is realized through the interaction between the theoretical model and the modules. As illustrated in Fig. 7, the

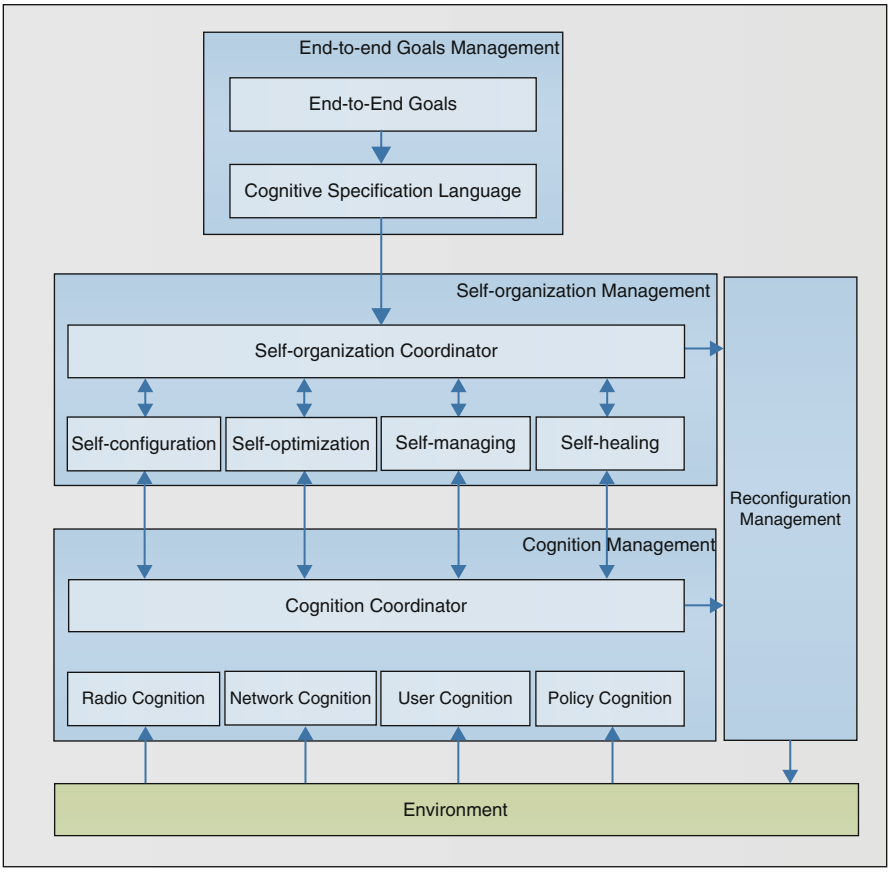

Fig. 6 The architecture of cognitive radio proposed by China

cognitive information flows from the cognitive management module to the end-to-end module, the self-organization module, and the reconfiguration module.

Apart from BUPT, the University of Electronic Science and Technology of China (UESTC) was also supported by the 863 Program. UESTC designed the architecture of cognitive radio networks and developed the test-bed of cognitive radio networks with the support of 863 program.

Cognitive Radio Networks in China

It is noted that in China, the cognitive TD-LTE system was proposed by BUPT, which can be regarded as one of the precursors of LTE-U. In LTE-U, LTE system shares the unlicensed band. The cellular network is the pillar of telecommunication industry. Thus utilizing cognitive technology to solve spectrum usage in cellular network is of great importance. To improve the spectrum efficiency of cellular system, the following requirements must be satisfied.

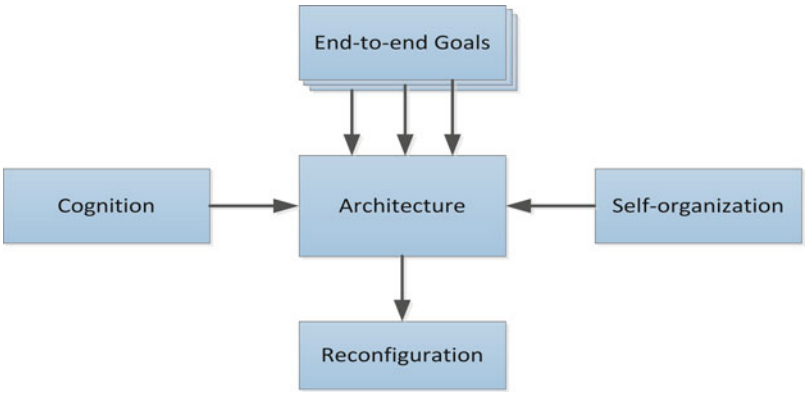

Fig. 7 The main modules in the architecture of cognitive radio

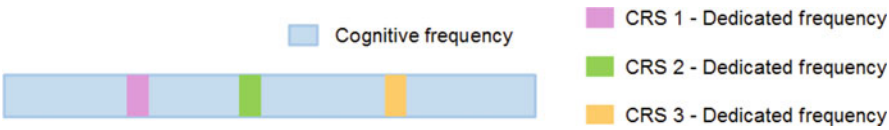

Fig. 8 The spectrum allocation in cognitive radio

(1) Accurate and efficient vacant spectrum awareness.
(2) Dynamic spectrum management.
(3) Flexible and adaptive transmission and dynamic spectrum utilization.

Notice that time division duplex (TDD) mode can be operated in unpaired spectrums, whereas frequency division duplex (FDD) requires paired spectrums. Thus TDD offers more flexibility in spectrum allocation. The capacity of TD-LTE system can be improved with the assistance of cognitive radio.

The cognitive TD-LTE system coexisting with TV broadcast services enables high efficiency of spectrum utilization. Based on the field test of the spectrum band allocated to broadcast TV services, the band 698∼806 MHz is selected for the cognitive TD-LTE system. However, the dedicated spectrum is also necessary to guarantee the control signaling and basic data transmission. The dedicated spectrum is allocated to a certain cognitive cellular system to guarantee cognitive information transmission and basic data transmission. Different dedicated spectrum bands are allocated to multiple cognitive cellular systems to work together without any interference to each other, as shown in Fig. 8. Hence it is challenging to design the dynamic spectrum management for the cognitive cellular system with statically utilized dedicated frequency and dynamically utilized cognitive frequency.

Besides, as illustrated in Fig. 9, two-level spectrum management architecture is proposed to enable the spectrum regulation among TD-LTE and TV broadcast services, consisting of global layer and local layer [7, 8].

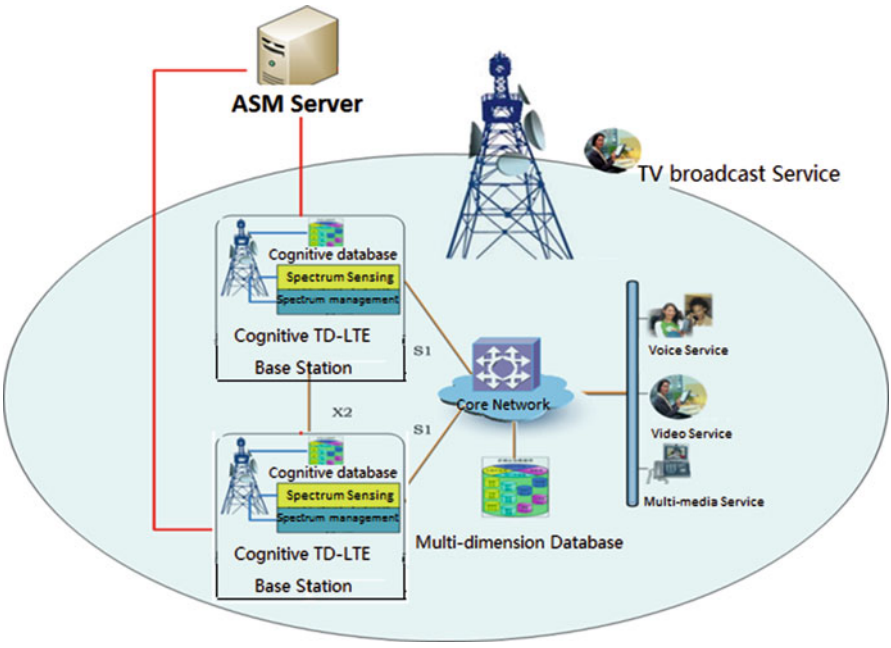

Fig. 9 The two-level spectrum management architecture

(1) Global layer: The advanced spectrum management (ASM) server is operated in the global layer and is responsible for the inter-cell spectrum management, which is a large time granularity spectrum planning.
(2) Local layer: In practice, the spectrum occupancies vary in the space and time dimensions. Hence the local layer spectrum management is also necessary. In the local layer spectrum management, the combination of cognitive database and spectrum sensing is essential to capture the spatial and temporal spectrum fluctuations and coordinate the possible interference between TD-LTE and TV broadcasting networks.

Policy and Regulation Challenges of Spectrum Sharing in China

The major difference between the spectrum policy of China and that of western countries is that spectrum bands are not allocated by auction. Thus the operators in China, like China Mobile, China Unicom, and China Telecom, do not need to pay for the dedicated spectrum. In the United States, Britain, Germany, etc., the spectrum is always billion dollar asset. Hence in these countries, the spectrum sharing is highly motivated to improve the spectrum efficiency. When Qualcomm proposed the LTE-U and LAA technologies, the motivation was due to the expensive spectrum. When the operators try to improve the network capacity, the unlicensed spectrum is one of reasonable choices. Hence in China, from the operators' point of view, the motivation of spectrum sharing is not strong enough compared to other countries.

Meanwhile, the sharing of TV white spaces is not well developed owing to the policy issues.

However, on the other hand, Chinese government has strong incentive to push spectrum sharing forward because the spectrum sharing can stimulate the industry innovation and boost the economic development. The spectrum regulation entities like MIIT and SRRC have launched a large number of regulations and projects to study the possibility to share the spectrum bands of TV and radar. The sharing of infrastructures and spectrum can save public resources and avoid the waste of resources, such as reputably building the base stations and low spectrum utilization. Hence Chinese government has promoted to establish the China Tower company, which aims to share the base stations among the operators. From the vision of development, the spectrum sharing in China is challenging while on the way.

Japan

The spectrum policy of Japan is administrated by the Radio Regulatory Commission, which is an independent agency under Japan government [47]. The Ministry of Internal Communications (MIC) of Japan established a committee in 2004 to formulate the policies on spectrum regulation. The telecommunications policy functions of the Ministry of Posts and Telecommunications (MPT) moved to the Ministry of Internal Communications (MIC) in 2001 [30]. MIC releases the radio legislation, the spectrum rules and the spectrum allocation table [30].

In Japan, with the innovation of wireless technologies such as small cells, code division multiple access (CDMA), and high-speed packet access/evolution-data only (HSPA/EVDO) [41], the spectrum utilization is significantly improved compared to traditional spectrum usage. However, the spectrum in Japan has been nearly exhausted. Hence the emerging wireless technologies have great difficulties in finding new spectrum bands, similarly in China. With the severe spectrum usage, the development of mobile Internet faces great challenges. However, the economy is boosted by the information and communication technology (ICT), where the mobile communication plays an important role. With the upgrade of the different generations of wireless communication systems, the ideal frequency bands are allocated to the prior wireless communication system, which makes the spectrum resources to be scarce. In addition, the mobile communication operators need to provide new services to attract consumers. Therefore the spectrum resource is also in shortage supply. Hence the mobile communication operators need to find an approach to efficiently use spectrum. In this situation, spectrum sharing is one of the promising technologies to efficiently improve the spectrum efficiently [41].

Cognitive Radio Architecture Proposed by Japan

Spectrum sharing aims to use the vacant spectrum bands. In spectrum sharing, the vacant spectrum bands and vacant time slots of primary users can be exploited by secondary users. By sensing and accessing the vacant spectrum in spatial and temporal dimensions, secondary users can use adequate spectrum bands to improve

the capacity of cognitive radio networks. In the implementation of spectrum sharing in cognitive radios, the cooperation among heterogeneous wireless networks is essential to coexist among them and improve the spectrum utilization.

In Japan, the cognitive wireless cloud (CWC), a kind of architecture of cognitive radio network was proposed by NICT [15]. The cognitive radio systems cooperated with primary networks are called dynamic spectrum access network or cognitive wireless clouds [15]. In CWC, a network reconfiguration manager (NRM) installed in secondary networks collects the sensing data of secondary users. The sensing data includes data rate, delay, throughput and signal strength, and so on. The NRM analyzes the collected sensing data and feedbacks the controlling information to secondary users, such that secondary users can access to the most appropriate wireless networks.

White Space Sharing in Japan

It is worth noting that Japan is a small island country with population of 126.81 million and is close to Busan, one of South Korea's major cities. Therefore the geographic features of Japan are different compared to many other countries that have multiple land borders with neighboring countries. Large population and small area make Japan's spectrum resources particularly scarce. The government of Japan attaches great importance to the efficient use of spectrum.

To solve the shortage of spectrum resources, MIC released a series of the related policies to improve spectrum utilization. The exploitation of white space is an important part. MIC announced the action plan for spectrum reuse in 2004, with the latest revision accomplished in October 2015 [11]. For the implementation of the plan, the government of Japan conducts annual audits for spectrum. Through the investigation and evaluation of specific spectrum bands, they developed spectrum recovery programs and use the frequency compensation mechanism to promote spectrum migration.

In July 2011, Japan finished the transition from ATV to DTV. Spectrum band of 710∼722 MHz was released on July 24, 2006. Spectrum band 722∼770 MHz was released in July 24, 2012, which was no longer used for the broadcasting service [43]. The spectrum band 90 $\sim$ 108 MHz and 170 $\sim$ 222 MHz cannot be used for TV broadcasting after July 25, 2011 [43]. As illustrated in Fig. 10, TV white space (TVWS) devices must be separated from the protected area of TV channel within a distance based on their transmission power and antenna height. Typically, the protected area of TV channel is the area where the corresponding transmitter provides the required signal strength for acceptable TV service. According to [34], there were more than 20 available TVWS channels in central Tokyo in 2012. There are many wireless systems aiming to be operated in TVWS, such as sensor networks, wireless microphones, and public safety communication systems. The possibility of adopting geo-location database in spectrum sharing is under the investigation by the TVWS working group established by MIC, which has so far investigated the feasibility of allowing small-area broadcasting systems, wireless microphones, sensor networks, and public safety communication systems to access TVWSs [34].

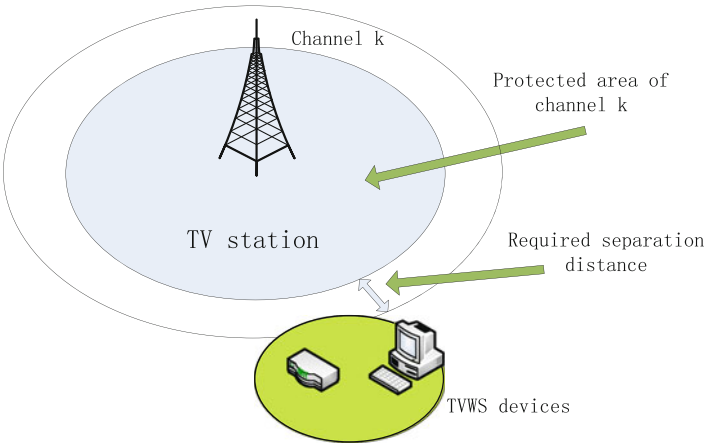

Fig. 10 Basic concept of TVWS device regulations [34]

In Japan, the spectrum has already been allocated to a variety of services. Spectrum sharing also faces the political barrier, which is not purely a technical problem. Hence, the realization of spectrum sharing will still have a long way to go.

Singapore

White Space Sharing in Singapore

Due to its restricted area and large population similarly as Japan, the government of Singapore is highly concerned about the efficient use of spectrum. There are also many trial experiences to investigate the possibility to use spectrum efficiently. ATV to DTV transition produces a large number of idle spectrum bands, and the new spectrum utilization method, namely, spectrum sharing, is proposed to improve the spectrum efficiency [45].

TVWS is a good choice to be utilized to enrich the available spectrum. The VHF spectrum (174 and 230 MHz) and the UHF spectrum (470 and 806 MHz) for TVWS operations were not fully utilized [38]. Such spectrum bands could potentially be redeployed for other wireless services. Info-communications Development Authority in Singapore (IDA) has the authority to plan the spectrum bands. The white space equipment operates without permission as long as it complies with IDA's technical specifications. The license-free approach allows the users to explore a range of business models, which reduces user's costs and stimulate innovative services.

As early as 2006, the Singapore Institute of Information and Communications (I2R) participated in the standardization of TVWS in IEEE [17]. In 2008, I2R proposed an experimental prototype exploiting TVWS to the Federal Communications Commission (FCC), which is the original development of the spectrum sharing in

Singapore. In 2009, IDA completed Singapore's regulatory framework for TVWS deployment [36]. In 2011, IDA carried out the spectrum planning in white spaces and development of relevant regulatory framework. In 2012, Singapore set up a TVWS test working group. More than 40 locations were tested within 2 years, and it is found that the use of TVWS has many obvious advantages.

The use of TVWS has been found to have many obvious advantages. It is estimated that Singapore has TVWS of up to 180 MHz [39]. Once the TVWS is open to use, the capacity of wireless networks can be boosted. IDA has developed a regulatory framework in November 2014 to allocate the 180 MHz TVWS to unlicensed users. In 2015, TVWS regulatory framework was further pushed forward. It allows other wireless networks to use TVWS to increase capacity and create broadband wireless networks. Singapore is the second country in the world after the United States who agrees to access TVWS for unlicensed users [39]. The concept of dynamic spectrum access can optimize and enable the access to underutilized spectrum, which can be used in many areas such as smart grid, wireless broadband, and machine-to-machine communication. Moreover, the geo-location database approach will be a practical method for white space devices to access TVWS. Allowing unlicensed users accessing TVWS will motivate potential new technologies and business models, which will bring opportunities for small- and medium-sized enterprises. Although the companies wish to use TVWS without license, they need to comply with the technical regulations proposed by IDA. Manufacturers and suppliers of TVWS equipment must register their devices in IDA, similarly for the manufacturers and suppliers of mobile phones and communication equipment [40].

Furthermore, the Minister of Communications and Public Information in Singapore announced the latest development blueprint, namely, Master Plan 2025, to tackle the shortage of the spectrum facing the great spectrum demand of mobile Internet [42].

National Projects of Cognitive Radio in Singapore

Singapore has developed a white space test-bed cognitive radio venue (CRAVE) to evaluate the promising technologies to improve spectrum utilization. The test locations of CRAVE are Malaysian coast, Indonesia coast, near broadcast tower, dense urban environment, and in-building environment [28]. The performance of WSD devices is evaluated by this program.

Policy and Regulation Challenges of Spectrum Sharing in Singapore

Singapore is a country with small area and limited natural resources. Facing the grow of elderly population and the process of urbanization, the high-tech products such as sensors, robots, and wireless networks are widely deployed to build a smart nation that improves people's life quality. It is also the common aspiration of Singapore government and the people. Spectrum-related policies are important for the construction of smart country.

The realization of spectrum sharing faces many open and critical challenges, for example, is low-power transmission of secondary user able to meet the transmission requirements, what transmit power level should be adopted and how to control it, how to effectively estimate the users interference [29], etc. All these questions need to be addressed in the policy design.

India

White Space Sharing in India

Unlike the developed countries, India has a lot of licensed but unutilized TV spectrum band [33], namely, TVWS. Since the UHF television band has ideal radio propagation characteristics, Indian authorities plan to use this spectrum band and fiber-based point of presence (POP) connections to cover the 250,000 rural offices. Since most of the Indian citizens live in rural areas, the communications engineers of India addressed the possibility to use TVWSs as the broadband access in rural areas [35]. Some researchers in India proposed to create a geo-location database that can broadcast TVWS information on rate constrained channels, such that multi-hop mesh network can operate in TV UHF band [14]. With this solution, the TV UHF band is used to provide seamless connectivity between the gram panchayat and village users [26]. The network can coexist with TV broadcasts through a licensed shared access mechanism.

National Projects of Cognitive Radio in India

India government has launched some projects on cognitive radio. Among them, an emergency network based on cognitive radio was proposed in Adaptive Ad hoc Free (AAF) Band Project [54]. Besides, the authorities of India approved the spectrum sharing, which allows the operators to share the spectrum of a particular band to improve spectrum utilization.

Policy and Regulation Challenges of Spectrum Sharing in India

The authorities in India are determined to change the situation that many citizens cannot access to broadband Internet. Spectrum sharing is a promising answer to solve this problem. Therefore, the government of India approved the operators to share a specific spectrum band within the service area to improve spectrum utilization, which is regarded as a big step toward spectrum sharing.

Korea

White Space Sharing in Korea

The South Korea government has recently proposed a TVWS field demonstration system that meets the requirements of the Federal Communications Commission (FCC). The measurements of TV band device (TVBD) networks have been

conducted in Jeju, South Korea. The measurement results show that the service's coverage of mobile network can be extended to more than 2 km when TVBD operates on the available TV spectrum bands [24]. The primary service in TV band is the digital television (DTV) [23]. With the DTV service, both the co-channel and adjacent channel deployment scenarios of TVBD network are investigated in Korea.

Policy and Regulation Challenges of Spectrum Sharing in Korea

The government of Korea has launched some projects on cognitive radio. The service coverage measurements on TVBD networks were implemented in Jeju, Korea [24]. Besides, the Korea Communications Commission (KCC) has proposed a new spectrum strategy based on dynamic spectrum access technologies, such as LBT universal spectrum for RFID, UWB-DAA, and flexible access (FACS) [25]. The KCC also considers spectrum sharing for TVWS after the transition from ATV to DTV and pays much attention to the improvement of spectrum efficiency [25].

Australia

Australia is a large continental country with population of 23.8 million. However, the distribution of populations in Australia is highly inhomogeneous. Australia is highly urbanized, and nearly half of the populations live in the two largest cities: Sydney and Melbourne. Most people in Australia live in the big cities near the coastline. About 70% of Australia's land is arid or semiarid, and most of the central area is not suitable for human habitation. Hence in the central area or rural area of Australia, the distribution of the people is very sparse.

According to Prof. Y. Jay Guo's report, the Federal Government of Australia has started a 43 billion dollar project to build a national broadband network (NBN) [22]. NBN will deliver 100 Mbps broadband services to 90% of the population. The rest of the populations, which mainly live in rural area, will be served by wireless and satellite communications networks [22]. In this situation, the TVWSs are proposed as the suitable spectrum bands to provide coverage for rural area.

In Australia, with the process of switching off ATV beginning in 2010 and completing at the end of 2013, the UHF spectrum allocated to broadcasting in Australia shrinks from 300 (520∼820 MHz) to 174 MHz (520∼694 MHz) [10]. Thus there are considerable TVWSs emerging in Australia. To provide wireless services to rural area of Australia, CSIRO has developed cognitive radio technologies to dynamically access the TVWSs. These technologies include reconfigurable antennas, reconfigurable active devices, out-of-band interference suppression techniques, and adaptive and reconfigurable multiple input and multiple output (MIMO) systems [22]. Hence, due to the special geographical feature and population distribution, Australia has great motivation to perform spectrum sharing and has already obtained some achievements in spectrum sharing.

Spectrum Sharing Test-Bed in China

The explosive growth of mobile Internet has led to a surge of data traffic. Hence, the next-generation cellular network is facing both opportunity and challenge. Under this background, the new unlicensed spectrum widely known as TVWS offers new opportunities to improve spectrum efficiency [49]. The 4G cellular networks adopt long-term evolution (LTE) technology based on all-IP network architecture and significantly improve area spectrum efficiency [1]. LTE can support both frequency division duplex (FDD) and time division duplex (TDD) operations over a variety of allocated frequency bands. In Asia, typically 1800, 1900, 2100, 2300, and 2500 MHz are often utilized [19]. To meet the requirement of high data rate services, TDD LTE (TD-LTE) with flexible downlink and uplink time slot ratio without stringent requirements for paired uplink and downlink frequencies can better utilize fragmented TVWS.

However, the available licensed spectrum bands for 4G cellular networks using LTE technology in Asia are around 2 GHz and above, which may increase the network cost for large area coverage. According to spectrum occupancy measurements in Beijing, significant white space opportunities exist in TV broadcasting bands around 700 MHz [55]. Hence, the 4G cellular networks can be operated in TVWS. Such opportunistic operation will require dynamic spectrum access (DSA), which is based on effective cognitive radio principles. Compared to the strict requirements of the paired downlink and uplink spectrum bands with appropriate spectrum separation in FDD LTE, the TD-LTE system with multiplexed downlink and uplink in the same spectrum band can fully utilize the fragmented TVWS. In addition, to meet the service demands in hot spots, multi-tier heterogeneous radio access networks are deployed with overlapped coverage areas, which will bring much challenge for spectrum allocation and interference coordination among multi-tier heterogeneous networks. Therefore DSA and efficient spectrum management technologies should be applied in heterogeneous radio access networks.

Standardization activities on TVWS utilization include IEEE 802.22 [16] for wireless regional area networks (WRAN), European computer manufacturers association (ECMA) 392 [48] for wireless personal area network (WPAN), and IEEE 802.11af task group [13] for wireless local area network (WLAN). Generally speaking, the above standards consist of the mechanisms for coexistence between the secondary and primary networks, where a variety of use cases are addressed such as long-range outdoor services for 802.22 and short-range indoor services for ECMA-392 and 802.11. With respect to spectrum sensing, these standards mostly advocate a quiet period for spectrum sensing by interrupting an existing communication session. This is not appropriate for TD-LTE system which has strict QoS requirements for latency in the voice service and precludes interrupting a communication session [3]. Therefore, some new and simple modifications to the existing TD-LTE protocol stack are needed to exploit TVWS.

In this section, a cognitive radio-enabled TD-LTE test-bed that operates in TVWS is proposed [9]. It supports multi-tier heterogeneous radio access networks. Specifically, an efficient feature detection-based spectrum sensing method is proposed for TD-LTE which can achieve 99.9% detection probability and 1% false alarm probability. The proposed cognitive radio-enabled TD-LTE frame structure utilizes the guard period and adjacent vacant uplink subframe for spectrum sensing by the cognitive eNodeB (CeNB), which requires the minimum protocol stack modifications. In particular, cognitive control channel (CogCCH) is proposed in medium access control (MAC) layer to transmit CR-related radio resource control (RRC) information. Physical cognitive channel (PCogCH) is also proposed in physical (PHY) layer to broadcast the spectrum decision information to CR user. To mitigate the potential adjacent channel interference between the TD-LTE system and the TV broadcasting system, appropriate guard bands between these two systems are needed. The width of guard bands is determined through the simulations and field experiments. To the best of our knowledge, our proposed test-bed is the first CR-enabled TD-LTE system operating in TVWS.

CR-Enabled TD-LTE Test-Bed Utilizing TVWS

The TD-LTE-based spectrum sharing test-bed is developed by the Beijing University of Posts and Telecommunications (BUPT) [9, 56]. To solve the challenges of deploying CR-enabled TD-LTE system operating in TVWS, both solutions and analysis are proposed, including an efficient spectrum sensing method for TV signal detection, interference analysis, and the CR-enabled TD-LTE protocol stack to support the efficient utilization of TVWS, which will be introduced in the following sections.

Spectrum Sensing in TVWS

The cognitive eNodeB (CeNB)-based spectrum sensing method is proposed for spectrum sensing in TVWS with two advantages. Firstly, the spectrum occupied and signaling overhead for information exchange between CR users and CeNBs can be minimized. Secondly, the energy consumption for spectrum sensing by CR users can be saved.

Unlike the United States where TVWS exists among digital TV signals, analog TV signals will be the dominant primary users in China for years. Therefore, we propose a feature detection-based spectrum sensing method exploring the specific characteristic of the analog TV signals. According to the spectral characteristics of analog TV signals (PAL-D) in China [2], the energy of the baseband TV signals is mostly concentrated on 1.25 MHz, chroma vice carrier on 5.68 MHz and audio FM carrier on 7.75 MHz as illustrated in Fig. 11. The procedure of the proposed feature detection method for analog TV signals is shown in Fig. 12. The TV RF signal is digitized directly via fast ADC, which is then down-converted to a baseband signal.

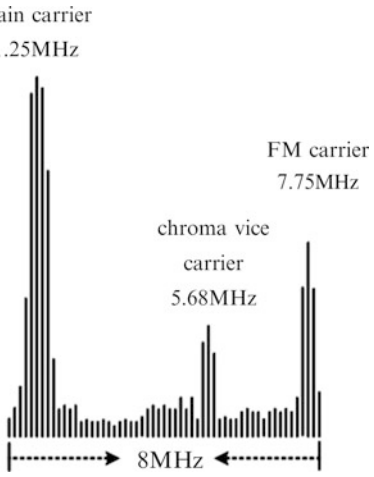

Fig. 11 Spectrum characteristics of analog TV signals

If there are narrow band signals existing on 1.25, 5.68, and 7.75 MHz, and the signal waveform is similar to the analog TV signals, the analog TV signal is then detected. Otherwise, the spectrum is assumed to be unoccupied by the TV signal. Because the detection bandwidth is only 200 kHz compared to 8 MHz for each TV channel, it can increase the spectrum sensing speed for each TV channel with an improvement of 16 dB. The proposed feature detection method can also reduce the noise and the sampling time, which has a good performance under the low signal-to-noise ratio (SNR) condition.

The field experiments are implemented to test the performance of the proposed feature detection method, which is programmed into a baseband signal process board of the spectrum sensing modules. The Agilent N5182A MXG signal generator is used to generate analog TV signals. Spectrum sensing module receives analog TV signals through a cable and reports the detection results to the computer. The detection probability and false alarm probability can be determined by the experiment in Fig. 13, which shows that the detection probability can be 99.9% with at most 1% false alarm probability. Besides, the proposed feature detection method improves the weak signal detection capability significantly with the TV signal power level of −120 dBm.

Furthermore, in order to utilize the vacant spectrum in time-frequency-space multi-domains in TVWS, an efficient spectrum utilization scheme called three regions is proposed in [50], which applies the joint geo-location database and spectrum sensing scheme in order to reduce the complexity and cost of traditional spectrum sensing. Firstly, CeNBs of the TD-LTE system access to the geo-location database to find their locations and decide their specific regions, i.e., the black region, gray region, and white region. Geo-location database is a database system that maintains the records of all authorized services in TV frequency bands and is capable of determining vacant channels at a specific location based on the

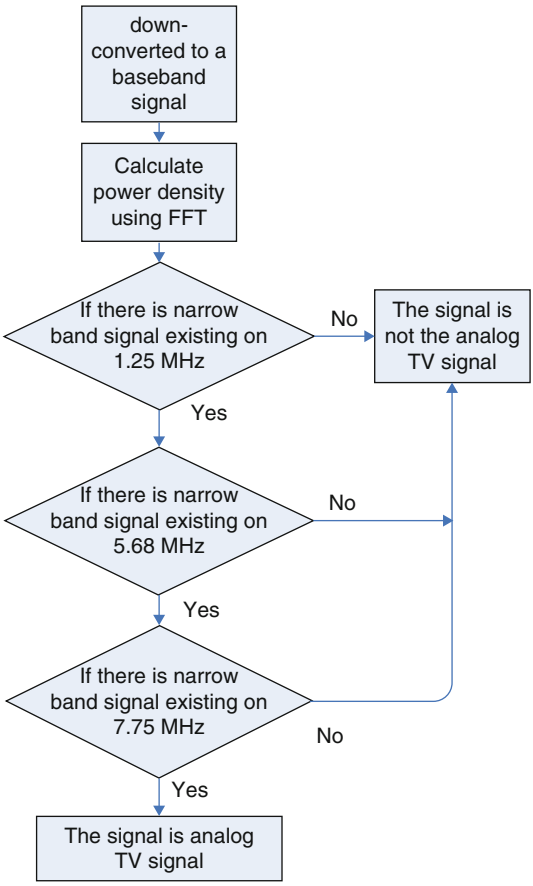

Fig. 12 Procedure of the feature detection method for analog TV signals

interference protection requirements. Black region is defined as the region where the CeNB within it cannot reuse the spectrum of TV broadcasting system. Gray region is a region where the CeNB should apply the spectrum sensing to utilize TVWS. White region is defined as a region where the CeNB can reuse the spectrum of the TV broadcasting system freely without implementing the spectrum sensing procedure. Therefore, by checking the position information in the geo-location database, the CeNB can decide its specific region and make an appropriate decision on whether to apply the spectrum sensing. The scheme of three regions can improve the efficiency and reduce the cost of spectrum utilization.

Interference Analysis

One approach to the reduction of the adjacent channel interference (ACI) between the TD-LTE system and TV broadcasting system is reconfiguring the central frequency of the TD-LTE system and setting the appropriate guard bands between two systems, which will reduce available spectrum resources. Another approach is

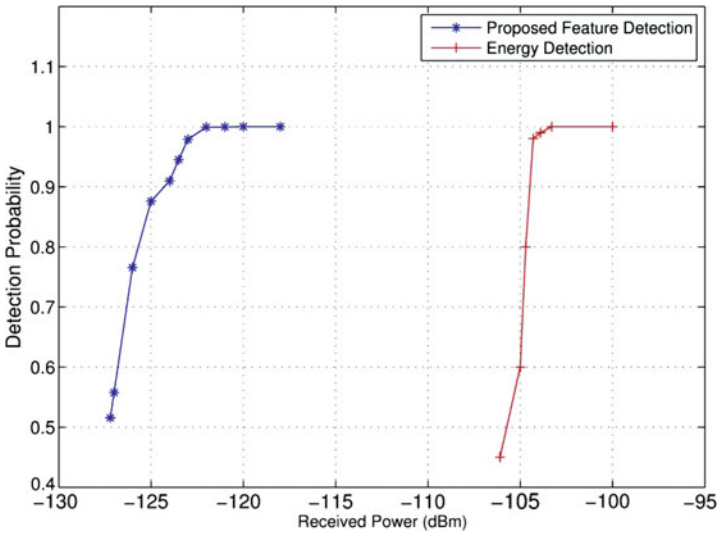

Fig. 13 Detection probability against the received power level of TV signals

to use power control scheme to transmit with a lower power on adjacent channels close to the active TV channels. Based on the geo-database approach, if the TD-LTE system is close to TV receivers, it can use the spectrum bands far from the active TV channels to reduce the interference.

Firstly, we conduct simulation experiments to analyze the interference between two systems. We establish the TV circle-shaped system and TD-LTE honeycomb-shaped network topology (19 CeNBs and 57 sectors) and then assign TV receivers and TD-LTE users, configure transmitter/receiver and channel models, and upload resource scheduling and user mobility schemes to simulate the real system operation states. Moreover, TV receivers and TD-LTE users are assumed to be uniformly distributed. During the simulations, system configurations are the category B in [44]. The left part of Fig. 14 shows the interference probability of the TV broadcasting system versus ACIR, where interference probability is defined as the percentage of TV users that cannot receive signals normally due to the interference. It denotes that the interference decreases as ACIR becomes larger. It also depicts that the interference from CeNB is bigger than that from CR users, which is caused by a much higher CeNB transmit power compared to CR users. The right part of Fig. 14 depicts the interference from the TV broadcasting system to the TD-LTE system. Similarly, we define the percentage of interference-caused capacity decline as the capacity loss, and the larger ACIR leads to a less capacity loss of the TD-LTE system, and the uplink capacity is prone to be decreased compared to the downlink capacity. In general, from the engineering point of view, 5% system performance loss is acceptable for the TD-LTE system. Thus 75/30 dB ACIR (TV interfered by TD-LTE downlink/uplink) and 27/78 dB ACIR (TD-LTE downlink/uplink interfered

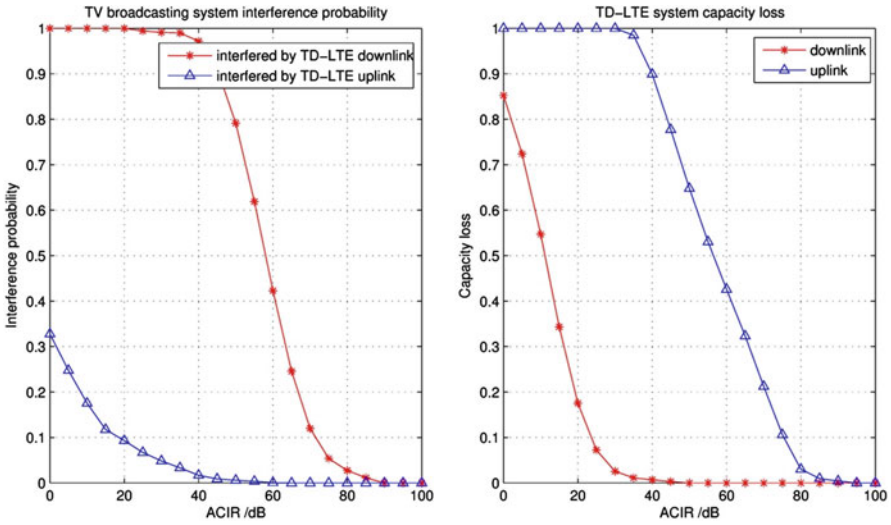

Fig. 14 Performance of the TV broadcasting system and the TD-LTE system against ACIR

by TV) are acceptable for the TV broadcasting system and the TD-LTE system, respectively. Based on the mapping relationship between ACIR and the width of guard bands [44], the frequency separation bandwidth of 7 MHz is appropriate to enable the coexistence of two systems.

Secondly, further field experiments are performed to find the width of the guard bands. The Agilent E4438C signal generator and Agilent N5182A MXG signal generator are applied to generate downlink TD-LTE and TV broadcasting signals, respectively, which go through the signal emulator (EB propsim F8) to emulate different indoor and outdoor channel environments. Then an R&S ETL TV broadcasting signal analyzer acts as a TV receiver to measure the quality of received TV signals with the interference from TD-LTE signals. The central frequency of both TD-LTE and the TV signals is set to be 700 MHz at first, and then the central frequency of the TD-LTE system increases until the TV signal analyzer indicates that the received TV signal quality reaches the normal standard [12]. Then, the separation bandwidth between two signals is the width of the guard bands. The results show that a frequency separation of 6 MHz between TD-LTE and TV signals is an appropriate value, which will not cause harmful interference between them. Therefore, 7 MHz guard band can be used for the coexistence between two systems.

The CR-enabled TD-LTE protocol stack

The protocol stack of the TD-LTE system should be designed with the minimum modifications in order to support CR functions. In addition, the spectrum sensing results and network information exchange among the CeNBs should be supported.

As illustrated in Fig. 15, the modifications to the TD-LTE protocol stack for both the CeNBs and the CR users are designed to support CR functions.

In the RRC layer, the spectrum decision management module in CeNB is introduced to make spectrum decision according to the spectrum sensing information received from the spectrum sensing module. Two main spectrum management functions are proposed for RRC. The first is called the long-term spectrum management among the different CeNBs for the efficient allocation and utilization of TVWS. The second is called the short-term spectrum management within CeNB.

The MAC layer provides different types of data transmission on different types of logic channels such that the types of logical channels are determined by data types. To accomplish the interaction of the CR-related information, a new logic channel called CogCCH is proposed both in CeNBs and CR users to transmit CR-related RRC messages.

In the PHY layer, a physical channel named PCogCH is proposed both in CeNB and CR users to carry the spectrum decision information on the transport channel called cognitive channel (CogCH) and broadcast the spectrum decision information to CR users through the special subframes. The CR users execute the spectrum decision after receiving the broadcast information. To reduce the power consumption and signaling overhead for the CR users, the spectrum sensing module is only added in CeNB to perform the spectrum sensing and report the spectrum sensing results to RRC layer. Meanwhile, through the X2 interface among CeNBs, cooperative spectrum sensing can be performed accordingly and will be used between the adjacent CeNBs for spectrum sensing, information exchange, and long-term spectrum management.

Furthermore, the TD-LTE frame structure is modified to enable CR functions, as demonstrated in the lower part of Fig. 15. Within 10 ms TD-LTE frame, the guard period (GP) in the special subframe #1 is used for spectrum sensing, which will not disrupt the communication between CeNBs and CR users. Moreover, the adjacent vacant uplink subframe #2 is also used for spectrum sensing when the candidate TVWS is too wide. Thus, the TD-LTE system performs the spectrum sensing within 2 ms within each 10 ms frame period. In the meantime, the spectrum sensing module will perform spectrum sensing and deliver the results to the RRC layer. The DwPTS in the special subframe is chosen to transfer both spectrum sensing and spectrum decision information of the previous frame.

Test-Bed and results

Considering the industrial trend of future telecommunication networks in China, a CR-enabled TD-LTE test-bed has been designed and developed in the Beijing University of Posts and Telecommunications (BUPT) with two CeNBs and eight CR users. Both CeNBs and CR users are implemented with a unified hardware platform [46], where the baseband signal processing functions are implemented on TI C6487 DSP. For the three-core DSP, one core is used for downlink signal processing, another is used for uplink signal processing, and a third is for scheduling. AD/DA operation is implemented in Xilinx FPGA, with the AURORA interface to DSP. In

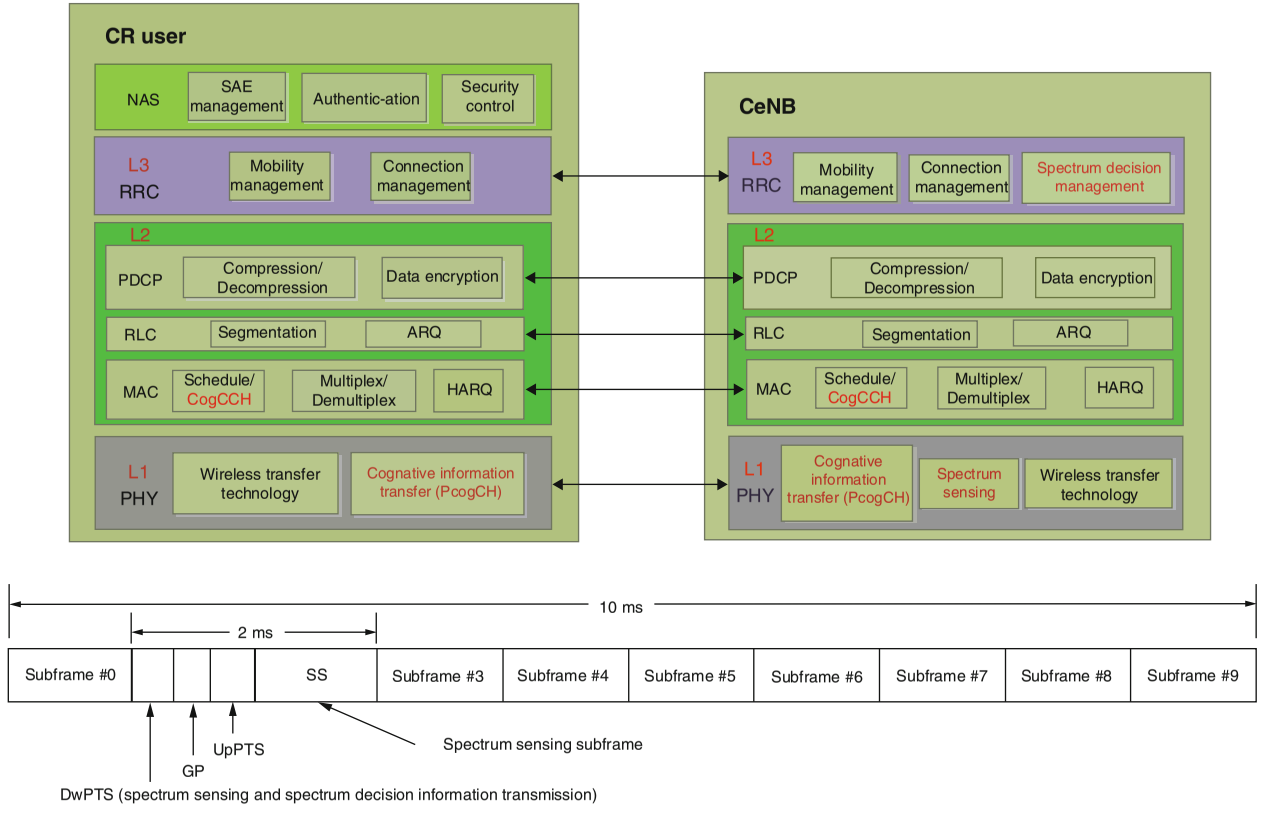

Fig. 15 Proposed CR-enabled TD-LTE protocol stack and frame structure

addition, the platform can also download different protocols from DSP dynamically and be capable of reconfiguring its work mode and parameters intelligently to utilize TVWSs efficiently.

Each TV channel occupies a frequency of 8 MHz in China; thus the TD-LTE system can be implemented with 20 MHz system bandwidth when three continuous TV channels (24 MHz) are all vacant. After the CeNB detects the TV signal, it will execute spectrum handover and switch to another vacant spectrum band accordingly. Furthermore, the spectrum sensing results will also be sent to the TVWS database for vacant spectrum information update, which is used for vacant spectrum information coordination and synchronization among CeNBs. In addition, considering the scenario that continuous TV channels are less than three, the test-bed can apply the dynamic system bandwidth adjustment technology, which means that 15 MHz bandwidth is used when two continuous TV channels are both vacant, while 5 MHz bandwidth is used if only one TV channel is available. Therefore, the test-bed can dynamically change its system bandwidth to adapt the different vacant spectrum conditions in practical scenarios.

The proposed CR-enabled TD-LTE test-bed has both the outdoor and indoor scenarios. In the outdoor scenario, CeNB is deployed on the roof of a building with two mobile CR users. In the indoor scenario, the trial of the test-bed is illustrated in Fig. 16 with three analog TV signal transmitters deployed as the primary TV broadcasting system. The CeNB and CR users are placed inside a room with a light-of-sight (LOS) propagation. The antennas for both CeNB and CR users are 6 dBi rod-antenna. The transmit power of the CeNB is 20 dBm. In addition, the CeNBs are connected to the TVWS database and advanced spectrum management (ASM) subsystem. The TVWS database will collect and update the crude data of spectrum sensing results from different CeNBs, the database of the mobile network, TV broadcasting operators, and the database of state spectrum regulators, in order to draw the global spectrum occupancy graph. Moreover, based on the global spectrum occupancy graph from the TVWS database, the ASM subsystem is responsible for an efficient spectrum management and coordination among different CeNBs by making decisions on the efficient vacant spectrum allocation.

Fig. 16 CR-enabled TD-LTE test-bed

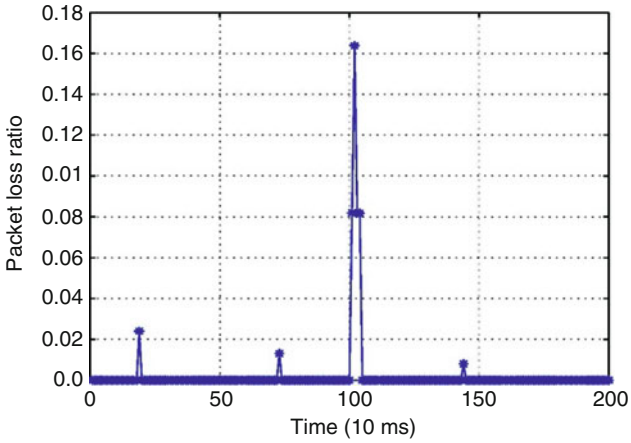

Fig. 17 Packet loss ratio during spectrum handover

In Fig. 17, the packet loss ratio of the CR-enabled TD-LTE system is plotted during a period of 2 s by 200 samples with 10 ms for each sample. During the experiment, the TV transmitter is turned on at 1 s, and the packet loss ratio of the CR-enabled TD-LTE system is fairly steady before 1 s and increases significantly after 1 s as depicted by the surge at the point of 100 samples. This indicates that the interference from TV signals is fairly strong and results in a tremendous packet loss. However, due to the accurate and timely TV signal detection and spectrum handover, the packet loss ratio of the CR-based TD-LTE system can be quickly restored within a short time of 50 ms, as shown in Fig. 5. In contrast to the silence period applied by IEEE 802.22 standard in [6], the proposed CR-enabled TD-LTE test-bed can achieve the spectrum handover within 50 ms on average without severe performance deterioration or service dropout, which significantly outperforms the avoiding time of 2 s in [6].

Abstract

In an earlier book chapter published in the Book titled Opportunistic Spectrum Sharing and White Space Access: The Practical Reality, First Edition (Holland et al., 1st edn. Wiley, 2015), we provided an in-depth overview of the IEEE 802.22 standard for cognitive wireless regional area networks. The discussion featured the motivation and the need for that standard, white space regulations around the world, in-depth analysis of the IEEE 802.22-2011 standard along with a brief overview of the new features present in the amendment to the IEEE 802.22 standard.

IEEE 802.22 standard for wireless regional area networks (WRANs), also known as Wi-FAR® (IEEE Std 802.22-2011) proposes to use the unused television band channels (the so called white spaces) in the VHF and the UHF bands to provide fixed and nomadic, high-throughput, long-range communications. Applications of this standard include remote and rural broadband Internet access, Frugal 5G for e-Education, e-Health, e-Banking, e-Payments, ship to shore communications, homeland security, border protection and surveillance, environment monitoring, smart grid applications such as supervisory control and data acquisition (SCADA), as well as low latency applications such as protective relaying at a future date. The IEEE Std. 802.22-2011 has been approved by ISO, and its interoperability testing is being carried out by the WhiteSpace Alliance under the commercial brand name of Wi-FAR®.

In this book chapter, we focus on an early implementation of the IEEE 802.22 standard. We also focus on the emerging IEEE 802.22.3 Standard on Spectrum Characterization and Occupancy Sensing and the implementation challenges based on software defined radio platforms. It would be nice if the readers have some basic understanding of the IEEE 802.22 standard, but as such, this book

chapter is self-contained for the new readers. The readers wanting to go deeper into the IEEE 802.22 spec may get the IEEE 802.22-2011standard at no cost using the following URL: http://standards.ieee.org/about/get/802/802.22.html

Introduction

While the wireless technologies have moved to 3G/4G and now even 5G, the connectivity to rural parts of the world, as well as developing countries has severely lagged behind. There are many technologies that can bring broadband internet connectivity. While developed economies can afford the price of bringing cable or optical fibre to the curb, Satellite Communications (SATCOM) or advanced cellular services, these are not viable options in rural areas and developing economies due to their hight cost. In case of 3G/4G cellular services, the higher cost comes from spectrum that needs to be licensed through auctions process, and deployment of many cellular towers or satellites. This is a costly process, where the cost that is incurred, is passed down to the consumers. Hence, the traditional wireless carriers have focused on urban areas with high population density which typically results in faster Return on Investment (RoI). Another problem for rural areas and developing countries are the distances. Distances between homes could span anywhere from few meters to a few kilometers (km). Traditional technologies have been unable to provide large area wireless coverage under Non-Line-of-Sight (NLoS) conditions present in rural area to build successful and viable business models. This has resulted in a digital divide and this situation tends to be worse in developing and under-developed countries.

Figure below shows a recent statistics on the percentage of households that have broadband Internet connectivity in developed, developing, and least developed countries. The statistics are truly alarming (Fig. 1).

The table below further shows the distribution of the affordable monthly communications expenditure as we traverse through the seven billion people around the world. In his analysis, Richard Thanki [13] shows why tackling the global connectivity problem is a challenging one (Table 1).

One of the core issues facing the digital divide that exists today is a lack of cost-effective middle-mile solution. Middle-mile solution refers to the gap between some optical fiber, wired or wireless backhaul connection at the edge of the regional area, and the last-mile solution which may use technologies such as Wi-Fi® or LTE. The middle-mile range requirement map spans between a few kilometers (km) to tens of km. In many areas of the world, such middle-mile gaps have uneven terrains, requiring NLoS solutions, and in many cases there is an absence of electric power which means that the wireless connectivity needs to be powered using solar cells. Hence, every joule of energy must be consumed in a "Frugal" manner, technology should be able to overcome foliage and terrain issues, and spectrum should be such, so that a little transmit power can go very far.

The use of Television (TV) Band WhiteSpaces can alleviate the digital divide that exists today. This has been enabled by analog to digital TV transition where

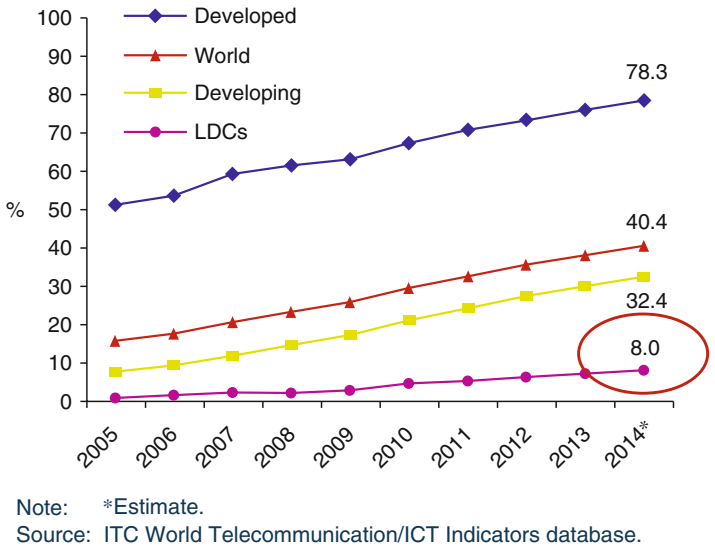

Fig. 1 International telecommunications union broadband Internet penetration statistics

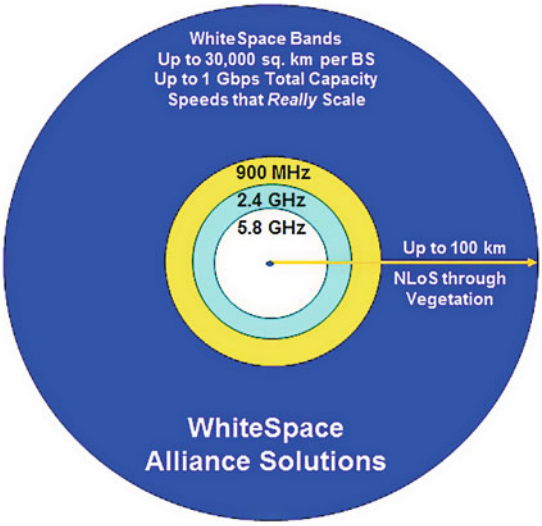
Table 1 Reality of Internet Affordability: Providing Internet Connectivity to the Remaining Three Billion People is Going to Require Low-Cost Long Range Communications Solutions

Billions of people on the Earth	Average annual income per annum	Affordable monthly communications spend
1st Billion	$29,206	$205
2nd Billion	$12,722	$53
3rd Billion	$5,540	$23
4th Billion	$2,987	$12
5th Billion	$1,771	$7
6th Billion	$1,065	$4.4
7th Billion	$540	$2.25

one digital TV station can potentially transmit 5 standard definition signals on the same channel. As such, in many countries around the world, not all the TV channels are being used by the broadcasters. In urban areas, more TV transmitters operate as compared to the rural areas. So you can envision the spectrum occupancy in every country by the region to be like swiss cheese, where large swathes of channel by the region are un-occupied or un-used. These channels are termed as White Spaces TV Channels in very high frequency - ultra high frequency (VHF/UHF) bands and have highly favorable propagation characteristics for long-distance reach.

In addition, many administrations are moving towards establishing regulations that allow opportunistic license-exempt usage of the spectrum on a non-interfering basis with the TV receivers using cognitive radio techniques.

Fig. 2 WRAN coverage



Favorable propagation characteristic of TV channels combined with opportunistic license-exempt use of spectrum creates a synergy that is perfect to provide middle-mile broadband connectivity to rural areas and developing countries in a cost-effective manner. When this is combined with favorable technologies, it can result in communications ranges of nearly 30 km as shown in Fig. 2. Hence it has a great promise to bridge the digital divide that exists today.

After the 2004 Federal Communications Commission (FCC)' s Notice of Inquiry (NoI) to open up TV WhiteSpaces for communications, the Institute of Electrical and Electronics Engineers (IEEE) Local Area Networks Metropolitan Area Networks (LAN/MAN) Standards Committee initiated the IEEE 802.22 Project on Cognitive Radio (CR) enabled Wireless Regional Area Networks (WRANs). The work resulted in a standard that was approved in 2011 for wireless access in the TV white space spectrum using cognitive radio techniques. The resulting type of wireless networks are referred to as wireless regional area networks (WRAN) which was later given a trade name of Wi-FAR® by the industry alliance called the WhiteSpace Alliance® [16]. In this book chapter, the terms WRAN, Wi-FAR™ or IEEE Std. 802.22™-2011 or IEEE 802.22 will be inter-changeably used.

Other similar activities of the IEEE 802 Standards Committee include the IEEE Std. 802.11af™-2013 amendment that specifies wireless local area networks (WLAN) operation, the IEEE Std. 802.15.4m™-2013 amendment that specifies the wireless personal area networks (WPAN), and the IEEE Std. 802.19.1™-2014 that specifies co-existence between various systems in the TV Band white spaces respectively. Similarly the internet engineering task force (IETF) has completed its protocol to access white spaces (PAWS) specification for the geolocation database access.

Since 2011, the IEEE 802.22-2011 standard has had two amendments. The 802.22a-2014 Amendment on Management Information Base (MIB)s and the

IEEE 802.22b-2015 Amendment on Enhancements for Broadband Servies and Monitoring Applications. Currently IEEE 802.22 Group is working on revising this standard, which will fold in these amendments, provide support for new frequency bands where spectrum sharing is allowed, and also new technologies such as Full Duplex Communications, also known as Simultaneous Transmit and Receive (STAR).

The IEEE 802.22 Spec uses orthogonal frequency division multiple access (OFDMA) physical layer. This OFDMA implementation supports long range operation by accommodating long signal turn-around times by providing sufficient cyclic prefixes to absorb long excess delay multipath. The medium access control (MAC) layer includes the traditional MAC layer features as well as support for various cognitive radio capabilities. These include management messages for the Base Stations (BS) to control spectrum sensing carried out at the Customer Premises Equipment (CPEs) and to query for various results, and for the CPEs to signal Urgent Coexistence Situation (UCS) to the BS. The MAC layer implementation is described in section "MAC Layer Architecture".

IEEE Std 802.22 allows geolocation of the devices by providing an interface to the Global Positioning System (GPS) receiver interface. Geolocation may also be enabled using on-line database of licensed services that compiles the location and radio frequency characteristics of these licensed services, whether they are permanent or temporary services, and when they are in operation. This geo-location and database access capability is fundamental in determining which TV channels are vacant of licensed services (e.g., TV white space) and hence are available for use by a WRAN. A description of these two capabilities is provided in section "Geolocation and Database".

The WRAN Base Station (BS) determines which channel to be utilized. The entity that makes the final decision on which channel the WRAN should use is called the *Spectrum Manager*. This entity can utilize the geo-location information of the base station and of each associated Customer Premises Equipment (CPE), the database of licensed services and optionally the Spectrum Sensing reports from the base station and the CPEs to decide which channel is to be used by the WRAN.

The TV WhiteSpaces regulatory rules are more elaborate than the rules for most other unlicensed devices, like the rules for operation in the 2.4 GHz industrial scientific and medical (ISM) band. A summary and analysis of the FCC rules for operation in the TV white space spectrum is given in section "Summary of FCC Rules on Operation in the TV White Space".

IEEE Std 802.22 also includes spectrum sensing which enables the devices to make observations of the radio frequency spectrum and deduces from those observations whether a channel is occupied by a licensed transmitter or if the channel is vacant and hence can be used by a WRAN. Spectrum sensing is performed at both the base station and the CPEs. The IEEE 802.22 has provided primitives that allow the spectrum sensing to be performed at the CPEs and transmitted to the BS, or the sensing to be performed at the BS itself.

In 2014, the IEEE 802.22 working group formed the IEEE 802.22.3 task group on Spectrum Characterization and Occupancy Sensing (SCOS) to create standards

and protocols to enable distributed spectrum monitoring. More information on this standard may be found in section "Distributed Spectrum Monitoring: IEEE 802.22.3 Standard on Spectrum Characterization and Occupancy Sensing".

WRAN System Overview

The Wi-FAR network consists of a base station and a set of fixed and portable client devices, called CPE. CPEs are typically installed with directional antennas. CPE may be connected to a Wi-Fi router for last mile connectivity. IEEE 802.22 supports 6, 7 and 8 MHz bandwidth operation which corresponds to the channel width in various countries. These channels are in both the very high frequency (VHF) and ultra high frequency (UHF) bands. In the United States, for example, the VHF band consists of channels 2–13 while the UHF band consists of channels 14–51.

The Wi-FAR technology specifically focuses on regional and rural broadband access. Also it is the first standard that embeds many cognitive radio features to avoid interference to the primary users. FCC and other regulations require that wireless networks support several cognitive radio features such as geo-location and access to a regulatory approved database and optionally spectrum sensing. In order to operate properly, these WRANs may also include additional features such as adaptation to regulatory dependent policies, channel set management, spectrum etiquette and self coexistence mechanisms.

Summary of FCC Rules on Operation in the TV White Space

Many administrations, such as Canada, United Kingdom, Colombia, India, European Union, Japan, Singapore, Botswana, South Africa, Malawi etc. have issued or are expected to issue rules for operation in TVWS. United States has been the first administration to initiate development of the regulatory rules for TVWS. Organizations such as the WhiteSpace Alliance urged FCC to use the spectrum in the most efficient way possible. Based on the recommendations of WhiteSpace Alliance, FCC has started doctrines such as use it or share it. The FCC has issued more recent additions to the rules on TVWS that allow for more efficient use of spectrum. For example, previous rules did not allow that adjacent channels to TV stations within the protected contour to be used by the whitespace devices (WSDs). This meant that three channels had to be available for one in the middle to be used. This was relaxed by the FCC, where they allowed WSD operation even when two consecutive channels were available, by letting the WSDs be operating in the middle of the two available channels. This section provides an overview of the FCC R&O [12], the second MO&O [11], and the third MO&O [14] on operation in the TV white space. The FCC refers to the devices that use the TV white space as TV band devices (TVBDs).

Classes of TV Band Devices

TV band devices are divided into two categories: fixed devices and personal/portable devices. Personal/portable devices can operate in one of two modes: Mode I and Mode II. Mode I devices can only operate in TV channels identified as an *available channel* by either a fixed or a personal/portable Mode II device to which they are usually associated. Mode I operation does not require geo-location capability nor access to the *TV band database* since it is assumed that such Mode I devices will be in the vicinity of the Mode II or fixed devices. Geo-location and TV bands databases are described below. Mode II personal/portable operation does require both geo-location capability and access to the TV bands database.

IEEE 802.22 devices can be fixed devices or Mode II devices: usually organized as a fixed BS and a set of fixed and/or Mode II CPEs. A fixed WSD transmits from a fixed location while a personal/portable device transmits either from an unknown location or while in motion (e,g., nomadic).

Permissible TV Channels

The FCC specifies a set of permissible channels, not occupied by licensed services, in which fixed and personal/portable devices may be permitted to transmit. There are a few channels that are excluded from use by TV band devices (i.e., channels 3, 4 and 37). Channels 36 and 38 are also excluded since they would require excessive adjacent channel emission rejection, being adjacent to Channel 37 that is reserved for use for medical telemetry. These two channels are reserved for wireless microphone operation. If channels 36 and/or 37 are used by local TV stations, the reserve channels would then become 35 and 38. Some channels may only be used by fixed devices (i.e., channels 2–20), whereas other channels may be used by both fixed and personal/portable devices (i.e., 21–51).

In thirteen metropolitan areas, some channels out of Channels 14–20 are used for public land mobile radio systems (LMRS). In those metropolitan areas, fixed TVBD may not operate co-channel or adjacent channel to the channels used by any PLMRS. Which channels are used for PLMRS in each of those metropolitan areas is specified by the FCC.

A summary of permissible channels for fixed and personal/portable, along with the frequencies of operation, are provided in Table 2.

Transmission Power Limits

Fixed devices have a maximum transmit power of 30 dBm (1 watt) with up to 6 dBi antenna gain, resulting in a maximum effective isotropic radiated power (EIRP) of 36 dBm. It is allowed to transmit lower power and have higher antenna gain as long as the maximum EIRP does not exceed 36 dBm. IEEE 802.22 standard uses this

Table 2 Permissibility of TV Channels usage by TV band devices

TV channel	Frequency (MHz)	Fixed permitted	Personal/Portable permitted
2	54–60	Yes	No
3–4	60–72	No	No
5–6	76–88	Yes	No
7–13	174–216	Yes	No
14–20	470–512	Yes	No
21–35	512–602	Yes	Yes
36	602–608	No	Yes
37	608–614	No	No
38	614–620	No	Yes
39–51	620–698	Yes	Yes

option to increase the antenna gain for the CPEs for the fixed devices. Antenna gain increase is normally less easily applicable in the case of the BS since its coverage needs to be broader to reach all CPEs.

Personal/portable devices have a maximum transmit power of 20 dBm (100 mW) with a 0 dBi antenna gain resulting in a maximum EIRP of 20 dBm. It is allowed to lower the transmit power and increase the antenna gain as long as the maximum EIRP does not exceed 20 dBm. Personal/portable devices operating on an adjacent channel to a TV broadcast within the protected contour are allowed a maximum EIRP of 16 dBm (40 mW).

TV band devices must incorporate transmit power control (TPC) to limit their transmit power to the minimum necessary for successful communication.

Antenna Requirements

For fixed TV band devices, the transmit antenna is allowed to be no more than 30 meters above ground. The receive antenna used for sensing has to be mounted outdoors at least 10 meters above ground and should be capable of receiving equally in all directions and on all polarization orientations. The IEEE 802.22 CPE transmit receive (TX/RX) antenna is used for communication between the BS and a fixed CPE is directional and points towards the BS. When RF sensing is performed, there is a need for a separate omnidirectional sensing antenna mounted at least 10 m above ground and not lower than the CPE transmit antenna. Antennas on personal/portable TV band devices have to be permanently attached.

Out of Band Emissions

There are three out-of-band emission (OOBE) requirements specified by the FCC for TV band devices. The first requirement specifies the power density in an adjacent

Table 3 PSD and Adjacent Channel Emission Limits

Type of TV bands device	Power limit (6 MHz)	PSD limit (100 kHz)	Adjacent channel limit (100 kHz)
Fixed	30 dBm (1 W)	12.6 dBm	−42.8 dBm
Personal/portable (adj. channel)	16 dBm (40 mW)	−1.4 dBm	−56.8 dBm
Sensing only	17 dBm (50 mW)	−0.4 dBm	−55.8 dBm
Other personal/portable	20 dBm (100 mW)	2.6 dBm	−52.8 dBm

TV channel relative to the total power in the band of operation. The second is the requirement to meet FCC Section 15.209(a) requirement beyond the two adjacent channels. And the third requirement is the emissions in Channel 37, and its two adjacent channels (Channels 36 and 38).

In each of the two TV channels adjacent to the channel being used by the TV band device, the maximum in-channel power spectrum density and adjacent channel emission limits in a measurement bandwidth of 100 kHz shall be as indicated in Table 3.

Outside the channel of operation and the two TV channels adjacent to the channel of operation, the out-of-band emissions shall meet FCC Section 15.209(a) requirement. That is, in the band 216–960 MHz, the electromagnetic field strength measured at 3 meters from the radiating source must not exceed 200 microvolts/meter, when measured in a 120 kHz bandwidth. In order to appreciate this requirement we must understand the relationship between transmit power and electromagnetic field strength measured at a specified distance from the transmitter.

This corresponds to a differential of 55.4 dB between the maximum PSD level within the channel for the maximum rated transmission power in each category to the maximum allowable PSD in the first adjacent channels for all four cases indicated in Table 3. This is much more demanding than in the case of other similar wireless systems such as Wi-Fi (20–28 dB) and WiMax (25–32 dB).

For all four cases indicated in Table 3, this corresponds to a differential of 55.4 dB between the maximum PSD level within the channel for the maximum rated transmission power in each category to the maximum allowable PSD in the first adjacent channels. This is much more demanding than in the case of other similar wireless systems such as Wi-Fi (20–28 dB) and WiMax (25–32 dB).

From [9] we have that for free space propagation,

$$\frac{PG}{4\pi d^2} = \frac{E^2}{R_{FS}} \tag{1}$$

where P is the transmit power, G is the transmit antenna gain, d is the distance in meters, E is the electric field strength, and R_{RS} is impedance of free space and is given by $R_{FS} = 120\pi$. Solving for the field strength, we get

$$E^2 = \frac{30PG}{d^2} \tag{2}$$

Taking logarithms and multiplying by 10, we have

$$20\log(|E|) = 10\log(P) + 10\log(G) + 10\log(30) - 20\log(d) \tag{3}$$

We would like to represent the field strength in dBu (microvolts/meter) and the transmit power in dBm. To make these conversions, we let

$$FS_{dBu} = 20\log(|E|) + 120 \tag{4}$$

$$P_{dBm} = 10\log(P) + 30 \tag{5}$$

This gives the following formula for the electromagnetic field strength in dBu for free space propagation,

$$FS_{dBu} = P_{dBm} + 10\log(G) + 10\log(30) + 90 - 20\log(d) \tag{6}$$

After simplification we get

$$FS_{dBu} = P_{dBm} + 10\log(G) + 104.77 - 20\log(d) \tag{7}$$

Now this formula gives us the field strength for free space propagation. We would like to convert back from field strength to transmit power. To be more specific, since in the IEEE 802.22 standard it is expected that the in-band transmissions will be more accurately specified by the EIRP, we can combine the transmit power and antenna gain into the EIRP though the following formula, $EIRP_{dBm} = P_{dBm} + 10\log(G)$. Utilizing this in the formula for the field strength and solving for EIRP in terms of the resulting field strength, we get

$$EIRP_{dBm} = FS_{dBu} - 104.77 + 20\log(d) \tag{8}$$

We can then determine the permitted out-of-band emission EIRP beyond the second adjacent channel, when measured in 120 kHz bandwidth. As we recall, the field strength must be below 200 μv/m. When converted to dBu, this is 23.01 dBu. Since this is measured at 3 m, we have $d = 3$. Therefore, the maximum EIRP measured in 120 kHz beyond the second adjacent channel is

$$EIRP_{dBm} = 46.02 - 104.77 + 9.54 = -49.21\,\text{dBm} \tag{9}$$

In order to relate this to our in-band emission, we must calculate the corresponding EIRP in 100 kHz bandwidth as used to define the rejection in the first adjacent channel,

$$EIRP_{dBm} = -49.21 + 10\log\left(\frac{100}{120}\right) = -50.02\,\text{dBm} \tag{10}$$

The maximum allowed EIRP in 100 kHz in the second channel and beyond, relative to the total 36 dBm transmitted in-channel EIRP from fixed devices, is therefore

$$\Delta EIRP_{dBm} = 36 - (-50.02) = 86.02\,\text{dB} \tag{11}$$

This corresponds to a differential in power spectrum density between in band and out of band in the second adjacent channel and beyond, for the IEEE 802.22 standard with an occupied bandwidth of 5.625 MHz of

$$\text{Relative OOBE} = 36 - 10\log\left(\frac{5.625}{0.1}\right) - (-50.02) = 68.52\,\text{dB} \tag{12}$$

The same calculations can be done for the personal/portable devices with their maximum EIRP of 20 dBm, and this will result in

$$\Delta EIRP_{dBm} = 20 - 50.02 = 70.02\,\text{dB} \tag{13}$$

$$\text{Relative OOBE} = 20 - 10\log\left(\frac{5.625}{0.1}\right) - (-50.02) = 52.52\,\text{dB} \tag{14}$$

If the EIRP of the fixed and/or personal/portable devices is not at the stated maximum but less by some dBs, the OOBE requirement becomes less stringent by this amount of dBs.

Interference Avoidance Mechanisms

Protection of licensed systems shall be provided by a combination of geolocation with database access and spectrum sensing.

Geolocation and Database Access

Fixed TV band devices shall have a known location to within ±50 m, through either an integrated geolocation capability (e.g., GPS) or through a professional installation, as defined in the IEEE standard and later by the FCC. A Mode II portable device shall incorporate a geolocation capability with an accuracy of ±50 m. A Mode II device is required to reestablish its location after power cycling.

Fixed devices must access a TV band database prior to initial transmission and may only operate on TV channels indicated as available at that location. Fixed devices must subsequently access the database at least once a day.

Mode II portable devices must access the TV band database prior to initial transmission. Mode II devices must also access the database after every power cycle. It must also access the database at least every 60 s.

Mode I portable devices shall obtain a list of available channels from a master device. A master device can transmit without receiving an enabling signal. Fixed and Mode II portable devices can both be master devices for Mode I devices.

Spectrum Sensing

If protection of TV band incumbents is to be achieved through RF sensing, all TV band devices, both fixed and portable, must be capable of detecting ATSC (Advanced Television Systems Committee) and NTSC (National Television System Committee) signals down to −114 dBm and wireless microphone signals down to −107 dBm. These detection levels are referenced to a 0 dBi sensing antenna with no coupling or cable loss. If the minimum antenna gain is less than 0 dBi and/or there is coupling or cable loss present, then the detection level shall be reduced by the difference between a 0 dBi antenna gain and the minimum antenna gain and the eventual amount of coupling or cable loss.

A TV band device must determine that the TV channel is unoccupied by either a TV signal or a wireless microphone signal above the detection threshold for 30 s before it can utilize the TV channel. If a TV signal is detected above the detection threshold on a channel indicated as available by the TV database, the TV band device will notify the base station so that it may optionally remove the channel from the local list of available channels. The base station may also indicate the presence of such signal to the database service.

A TV band device must check the availability of the channel in use at least every 60 s.

If a wireless microphone is detected on the operating channel, the TV band device must cease transmissions within 2 s.

The IEEE 802.22 working group carried out a thorough evaluation of the spectrum sensing techniques by providing over-the-air-collected ATSC and NTSC signal samples to various participants. As a result of this evaluation, many sensing techniques were accepted to be incorporated into an informative annex of the standard. These techniques range from simple energy detector, to time and/or frequency domain matched filters, to covariance, higher-order statistics (HOS), or cyclostationary processing approaches. Typically, more complex techniques such as the ones based on cyclostationary processing provide better sensitivity at an increased cost in complexity.

Since the FCC Second and Third MO&O encourages the use of spectrum sensing, but does not require it, the IEEE 802.22 working group decided to provide a regulatory domain-dependent switch which can be turned off if spectrum sensing operation is not required or not desired.

Additional Requirements

A TV band device must display available channels and its operating channel. In IEEE 802.22 systems, this will correspond to the operating channels and the list of backup channels provided by the base station.

A fixed TV band device must transmit identifying information that conforms to a standard format recognized by an industry standards setting organization. For IEEE 802.22 systems, a set of primitives has been included in the standard that can be used by the base station to communicate with the database. A standard protocol is being defined by the Internet Engineering Task Force IETF-PAWS Working Group [6]. The IEEE 802.22 working group members have also been in touch with several database service providers to make sure that adequate interfaces are defined.

A fixed TV band device without database access can transmit on channels indicated from another fixed TV band device to register its location and receive a list of channels that are available for it to use. This slave fixed device corresponds to a CPE in IEEE 802.22 systems, whereas the master fixed device corresponds to the base station.

A Mode I portable device may only transmit on channels indicated as being available by a fixed or Mode II portable device.

Protection Contours

The FCC rules provide a table of protection contours for analog and digital TV in the lower VHF, upper VHF, and UHF bands. While Fixed devices are permitted in both VHF and UHF bands, portable devices are only permitted in the UHF band. In the UHF band, the protection contour is defined at 41 dBu reception signal level for ATSC and 64 dBu for NTSC.

The devices must be outside these contours by a specified distance depending on their antenna height as indicated in the following Table 4.

Table 4 Required minimum separation distance from TV broadcast contours as a function of the TVBD antenna height

Antenna height above average terrain of unlicensed device	Required separation (km) from digital or analog TV (full service or low power) protected contour	
	Co-Channel (km)	Adjacent channel (km)
$h < 3$ m	4.0	0.4
$3 \leq h < 10$ m	7.3	0.7
$10 \leq h < 30$ m	11.1	1.2
$30 \leq h < 50$ m	14.3	1.8
$50 \leq h < 75$ m	18.0	2.0
$75 \leq h < 100$ m	21.1	2.1
$100 \leq h < 150$ m	25.3	2.2
$150 \leq h < 200$ m	28.5	2.3
$200 \leq h \leq 250$ m	31.2	2.4

The rules also provide detailed requirements regarding operation near the cable head-ends, fixed broadcast auxiliary services, and portable land mobile radio systems (PLMRS). See [12] for all the details.

Fixed TV band devices are not permitted to operate within 1 km of registered wireless microphones, and this distance is reduced to 400 m for portable TV band devices.

Implementation of the IEEE 802.22 Standard Using a Software-Defined Radio Chip

In this section, we provide some insights into the implementation of the IEEE 802.22 standard based on a Software-defined radio (SDR) architecture. The implementation as described in this section is based on one SDR architecture based on customized system on a chip (SoC) digital signal processing (DSP) from one of the vendors [10]. Later in this section, we also provide some insights on another implementation.

The predominant difference between a white space band receiver and a regular Wi-Fi receiver is the dynamic range (DR) of signals that the white space receivers may experience. For example, the receiver operator may want to receive a distant and weak white space signal from a 4 watt base station while being in an environment where one or many high-power TV transmitter is present in the same band. Such a situation imposes stringent requirements on the receiver design and can only be solved by careful and experienced analog front design.

A second difference is that Wi-Fi devices are designed to communicate over short distances. The 802.11 standard compliant devices typically communicate of distances of a few meters up to a maximum of 100 m. They operate in radio bands where the wavelength is in the order of few centimeters. This is very useful for indoor and portable devices, as small antennas can be used in these bands. However, it has a drawback when longer range communications may require the signal to go through vegetation. When such a signal encounters the leave of a tree, the signal bounces off the leaf in an arbitrary direction. It may then bounce of yet another leaf and finally reach the receiver. However, because of the jagged path it has followed, it has traveled a longer distance than a signal that would not have encountered leaves. This causes the received signal to disperse as it crossed vegetated areas, which can muddle up the signal to the point it becomes unintelligible.

The Wi-FAR spec has been designed to circumvent this problem by really stretching out the signal and coding it in such a fashion that it is more intelligible, even in the presence of such dispersion. The industry refers to this a NLoS transmission. Radio signals do not go through rock but do go through vegetation. Signals coded following the Wi-FAR coding are up to 100 times more intelligible after dispersion, in comparison to Wi-Fi signals. Moreover, due to their much longer wavelengths, they are less affected by leaves. To be an efficient reflector, the size of a leaf has to be at least 10% of the size of the wavelength. In the VHF and UHF television bands, wavelengths begin in the order of meters instead of a few centimeters, and hence, the dispersion is reduced. Hardened coding in

conjunction with reduced dispersion yields a signal that is far more tolerant of vegetation impairments. This can be observed by the fact that ADSL TV signals, which were designed with the same impairments in mind, quite easily penetrate through vegetation and provide an excellent user experience.

An additional difficulty in designing a white space device is in the fact that the signal of such a transmitter must not interfere with adjacent TV transmissions. As the white space networks have to coexist with regular TV broadcasts, the signal purity needed is very high. TV broadcasters can achieve such signal purity by placing expensive cavity filters designed to pass their specific frequency and sharply reject splatter in adjacent bands.

Contrary to a TV broadcaster which operates on a specific frequency, the TV band white space regulations call for frequency agile transmitter, able to operate on any given channel and quickly hop to another channel upon demand. This renders impossible the use of the fixed frequency filters typically used by TV broadcasters. Regular Wi-Fi devices are allowed to splatter many MHz away from their frequency of operation with as little as 30 dB suppression, allowing for a lowest possible cost design. On the other hand, white space transmitters must drop their out-of-band emission by 55 dB and do so within 200 kHz of their intended transmission channel.

The IEEE 802.22 WRAN system is a cognitive radio-based network but has similarities to modern-day cellular networks. A typical Wi-FAR system uses the time division duplex (TDD) mode of operation. TDD provides larger range compared to FDD for the same transmitter power, due to lack of self-interference. For the same reason, TDD also reduces the system complexity, especially for the RF front end. A frequency division duplex FDD) system needs duplexers which could become expensive especially if the band separation is not high and higher rejections become necessary. For the Wi-FAR operation, CPEs are likely to be stationary, and issues related to mobility like handoff do not exist. In a typical deployment, the average distance supported between the base station and the CPE is determined by a link budget analysis. The link budget analysis considers aspects of transmitter and receiver like frequency of operation, transmit power, receiver sensitivity, the respective antenna gains, heights of antenna above sea level, and Fresnel zone clearance. Depending on the desirable robustness, appropriate fading margin also needs to be considered.

The BS is the central controller within a WRAN cell responsible for managing the traffic flow to the different CPE endpoints. The base station is connected to a backhaul network of relatively higher throughput. Typically this backhaul network may terminate in an Internet service provider (ISP) gateway. The different base stations are expected to communicate among each other via the backhaul network.

A base station can service a cell using either an omnidirectional antenna or several sectored antennas depending on the relative CPE distribution around it. The CPE is a device which resides with the user or group of users who are receiving the network service. The CPE can be connected to a wired network interface like Ethernet or a wireless access point which enables a group of users to share the service.

Architecture of the Signal Chain for Downlink and Uplink Paths

The BS performs the functions of downlink (DL) transmit to various CPEs and uplink (UL) receive from various CPEs in the WRAN cell. A typical signal chain for the operations performed in the physical layer or Layer 1 (L1) including the base station transmit and CPE receive operation is shown in Fig. 3.

On the downlink transmit side, the data packets received from the medium access control (MAC) Layer 2 (L2) are randomized using the scrambler and encoded using convolutional code as per the desired code rates and undergo bit interleaving using the desired turbo interleaver parameters. The interleaved data passes through the mapper, and frequency interleaving operations, the required pilots, and frame preambles are added and converted to time domain using the IFFT operation. The time domain signal is passed through a spectral mask filter to ensure that the output signal adheres to the desired transmit spectral mask. The time domain analog signal finally obtained is up-converted in the desired frequency band of operation and transmitted.

On the DL receive side, the signal passes through the RF tuner. The receiver synchronizes to the DL frame and subsequently demodulates the OFDM symbols. The soft decision bits from the demapper undergo bit deinterleaving and subsequently decoded using tail-biting Viterbi decoder. The decoded bits are descrambled and passed on to the MAC/L2 for further processing.

The various CPEs perform the functions of UL transmit to the BS and DL receive from the BS in the WRAN cell. Once the CPE powers up and achieves DL synchronization, it registers to the BS using the process of initial ranging. Ranging is the process of estimating and adjusting the delays, transmitting power and frequency offsets of various CPEs with respect to the references fixed at the BS. Once initial ranging is successful, the CPEs are time aligned to BS. From this point on, the UL transmit and DL receive process is similar to equivalent processes described earlier.

The BS typically consists of three significant components – RF unit, baseband unit, and protocol stack unit as shown in Fig. 4.Typically one RF unit serves as sector and connects to a sector antenna. Based on the processing capability, there could be one or multiple baseband units which interface to one of the RF units serving a single sector. Each baseband unit consists of multiple cards of baseband

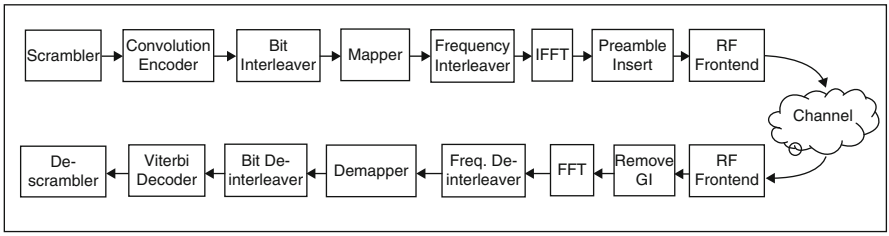


Fig. 3 Downlink signal flow from base station to CPE

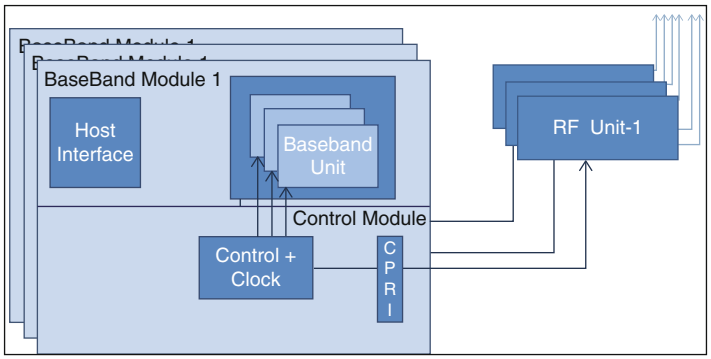

Fig. 4 Base station unit architecture

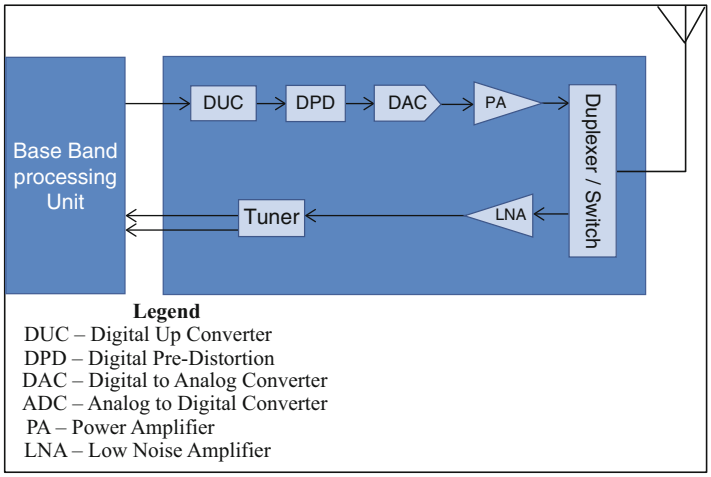

Fig. 5 Baseband and RF unit architecture

unit serving a set of users. Typically a single host processor interfaces to all the baseband units. The block diagram of the combined baseband and RF unit is shown in Figs. 4 and 5. The protocol stack unit is responsible for performing the L2 (MAC) and L3 functions.

Baseband and RF Module Architecture

The baseband module is based on software-defined radio (SDR) platform architecture which performs OFDMA processing for both uplink receive and downlink transmit processing. The baseband SoC is a SDR capable of supporting multiple radio technologies including custom waveforms. This is described in detail in the section on SDR platform. The RF unit interfaces to the sectored antenna via a TDD

RF switch. The input path from the TDD switch goes to a high gain LNA and a tuner having the ability to receive VHF-UHF bands of interest. The tuner typically generates a differential low-IF or zero-IF signal which connects to the receive SDR SoC for performing uplink receive functions. It is important to note that base station receives a signal which is a sum total of all the uplink waveforms transmitted by the CPEs. Hence the input DR of BS receiver needs to be carefully chosen and gain control loops appropriately handled.

MAC Layer Architecture

The protocol stack will have an abstraction layer that will make the PHY design compatible to that of 802.22 WRAN stack model. The abstraction layer will map all MAC messages to the PHY layer. The MAC provides mechanisms for flexible and efficient data transmission. In the downstream direction, data are scheduled over consecutive MAC slots, while in the upstream direction, the channel capacity is shared by the CPE units based on a demand-assigned multiple access (DAMA) scheduling scheme. The concept of a connection plays a key role in the MAC. The mapping of all services to connections, as performed in the convergence sub-layer, facilitates bandwidth allocation, quality of service (QoS) and traffic parameter association, and data delivery between the corresponding convergence sub-layer. The MAC employs a superframe structure in order to efficiently manage data communication and facilitate WRAN synchronization. Each MAC frame, with a 10 ms frame size, comprises a DL subframe and an UL subframe with an adaptive boundary in between as shown in Fig. 6. While the DL subframe only contains a single PHY protocol data unit (PDU), the UL subframe may have a number of PHY PDUs scheduled from different CPE units, as well as contention intervals for initialization and bandwidth request. Because the DL traffic for CPE located far from the BS can be scheduled early in the DL subframe, such a data layout allows the MAC to absorb the round-trip delay for large distances. In addition to these functions, the MAC also controls the network entry and initialization procedures which are accomplished using several processes such as synchronization, ranging, capacity negotiation, authorization, registration, and connection setup. In a typical base station, the protocol stack and MAC functions are handled using a high-performance reduced instruction set computing (RISC) processor (like dual-core ARM-9-based SoC).

Customer Premise Equipment (CPE)

The customer premise equipment housed at the user end consists of a similar subsystem as present on the base station side with much lower processing capabilities as shown in Fig. 7. The CPE unit typically consists of three significant components – RF unit, baseband unit, and protocol stack unit (similar to base station). The RF unit connects to a directional antenna with its main lobe pointing

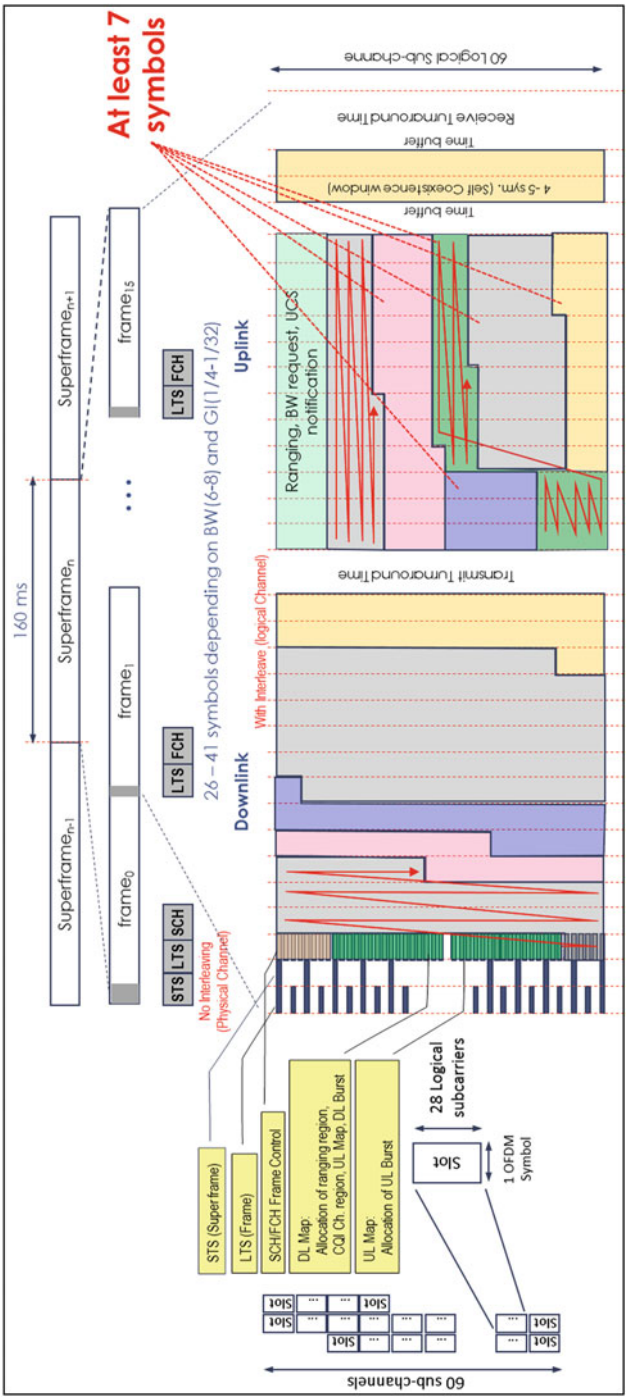

Fig. 6 IEEE 802.22 Frame Structure

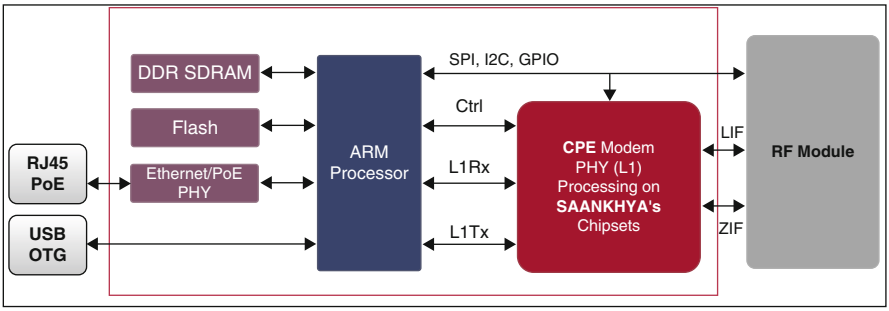

Fig. 7 Customer premise equipment unit

toward the base station. A single or dual baseband unit based on the SDR architecture performs the uplink transmit and downlink receive functions. In addition to this, the protocol stack unit typically consisting of an ARM-based SoC is responsible for performing the L2 (MAC) and L3 functions (Fig. 7).

The RF front end consists of both transmit and receive paths. The front end contains the following functionality low noise amplifier (LNA), receive/transmit (Rx/Tx) mixers, RX/TX filters, synthesizers, Rx gain control and required Rx variable gain amplifier (VGA), Tx power control, power amplifier (PA) driver, and the PA. The RF front end is expected to cover the UHF-VHF frequency range as intended. The functional block diagram of the RF unit is shown in Fig. 8.

On the transmit side, the RF front end interfaces to a differential real and imaginary (IQ) digital-to-analog converter (DAC) outputs from the baseband device. The DAC outputs are filtered using on-board DAC image rejection filters. The output of the filters passes through a stage of VGA and then is fed to an IQ up-converter mixer. The IQ-mixer and up-converter output is fed to a PA driver. The PA driver is finally connected to an external power amplifier which drives an output. The power amplifier is designed to meet the adjacent channel leakage ratio (ACLR) requirements of 55dBr for N+/− 1 channel. Additional power amplifiers can be connected to increase the final transmit power based on requirements.

On the receive side, the RF front end interfaces to a zero-intermediate frequency (IF) or low-IF analog to digital converter (ADC) interface with differential inputs. The received input from the antenna is fed to a combination of LNA, complex mixer and gain stages, and a baseband filter. Alternately this signal chain can be replaced with a tuner which operates in the desirable RF band.

SDR Platform

Platform Description

The architecture of the software-defined radio (SDR) subsystem for communication processing is shown in Fig. 9.

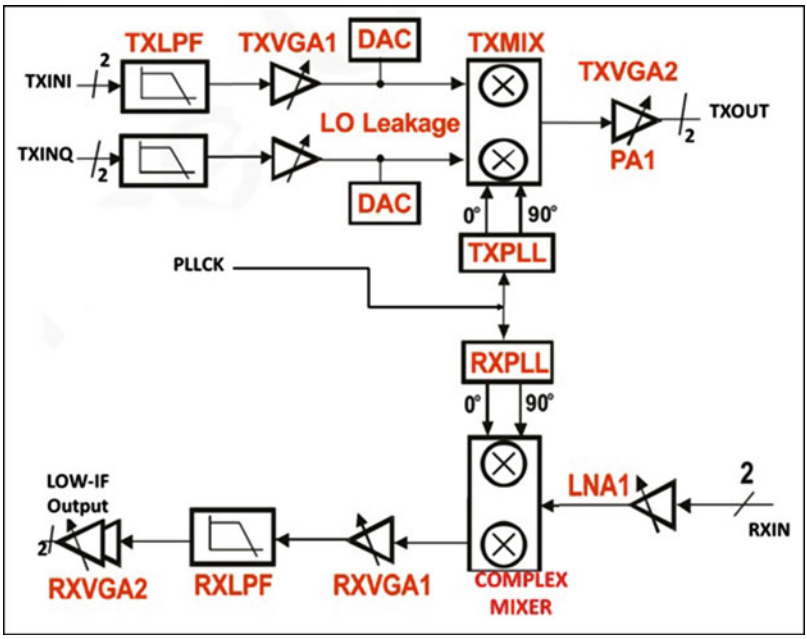

Fig. 8 Functional blocks of the radio frequency unit

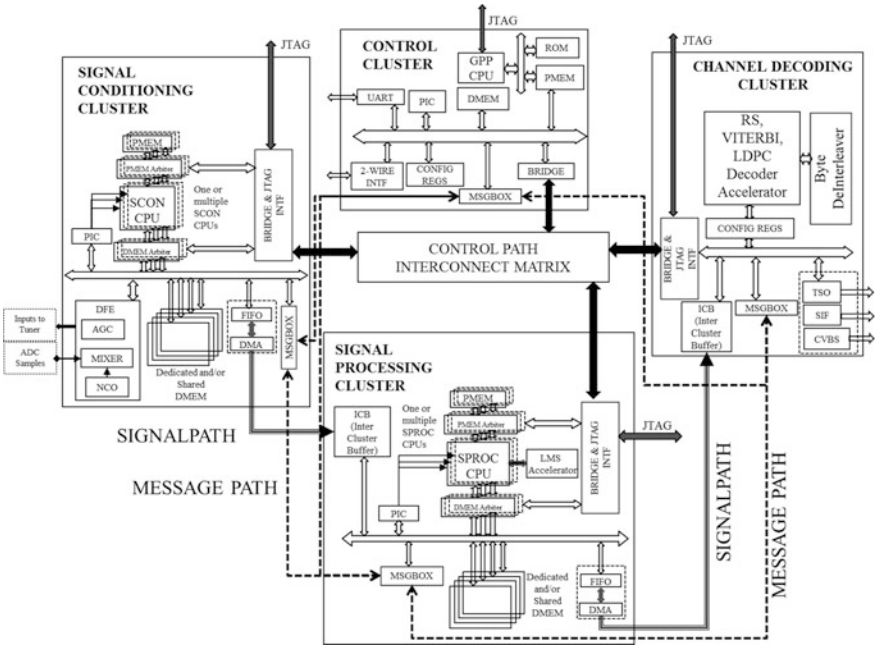

Fig. 9 Architecture of SDR Platform for demodulation

The architecture consists of signal conditioning cluster, signal processing cluster, and channel decoding cluster. The channel decoding cluster performs the tasks of Viterbi, Reed-Solomon, LDPC decoding along with bit/byte deinterleaver. The decoded data is packetized and exported out through a FIFO-like interface or to an on-chip/off-chip DAC. The overall scheduling and control of the entire SDR subsystem is performed by a control cluster which consists of a RISC processor with some general purpose peripherals. The control cluster accesses all individual clusters via the bridge. The signal conditioning cluster (SCC) consists of the following key components:

- One or multiple signal conditioning (SCON) CPUs.
- Digital front end (DFE),
- SCC-FIFO and SCC-DMA blocks.

The SCC cluster is responsible for digital down-conversion from intermediate frequency (IF) rate samples to symbol-rate samples. The associated peripheral block, namely, message box (MSG), is used to interact with other CPU clusters, while programmable interrupt controller (PIC) is used to interface to interrupts generated on chip from same or different clusters. The SCC cluster interfaces to control cluster via the bridge and to the intercluster buffer (ICB) memory of SPC cluster via DMA.

The digital front end (DFE) receives samples obtained by digitizing the incoming intermediate frequency (IF) signal from ADC. The DFE has a numerically controlled oscillator (NCO) operating at sample-rate frequency and a mixer. The mixer obtains a digitally synthesized waveform and is responsible for down-conversion of signal from IF to base band. In addition an AGC circuitry is also present which helps in ensuring that the full-scale range of ADC is used effectively. In addition to this the DFE has an internal FIFO using which incoming samples converted to baseband are stored. These samples are transferred in blocks of samples to SCON CPU. The DFE interfaces with the SCON CPU as a memory-mapped device on the DMEM data bus.

Signal Conditioning (SCON) CPU

The SCON CPU is a VLIW vector CPU with Wide multiply-accumulate units as shown in Fig. 10. This can interface to high-speed streaming input samples and implement finite impulse response (FIR), infinite impulse response (IIR), and sample-rate conversion filters. In addition it also performs carrier synchronization by implementing PLL's in software. In cases when input samples are obtained from IQ ADC, this CPU also performs the task of IQ imbalance correction. The CPU has four execution slots, namely, vector MAC slot, load-store broadcast slot, arithmetic slot, and logical slot. The SCON CPU has a dedicated program memory which interfaces via the program memory interface. SCON CPU interfaces to its dedicated data memory (SCC Data Memory), DFE, FIFO, and DMA using the DMEM interface. The salient features of the different execution units are as follows:

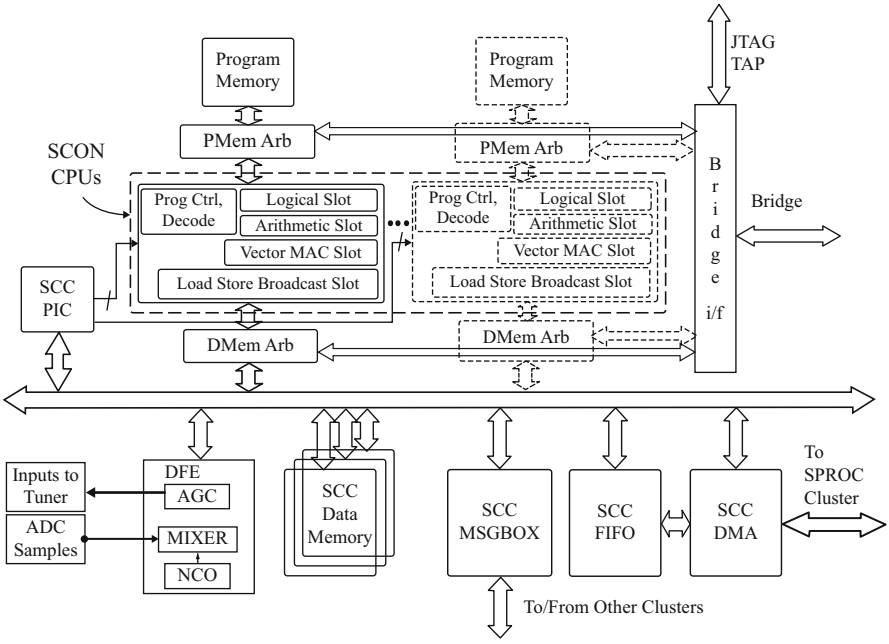

Fig. 10 Details of signal conditioning cluster

- Vector Slot with Real Multiply and Real MAC Capability with Wide MACs: This is capable of doing high sample-rate FIR and IIR filtering, decimation, interpolation, down-sampling, and up-sampling.
- Load-Store Broadcast Slot: This unit is capable of quad-word-sized load-store operations. The broadcast load capability is used to replicate a wide bit-width sample to the vector slot in single cycle.
- Arithmetic Slot: This unit is capable of basic arithmetic functions like add, subtract, absolute finding, exponent calculation, and swapping of IQ pair of complex signals. In addition this unit also does processing of accumulator values by doing summation with post-scaling.
- Logical Slot: This unit is capable of supporting basic logical operations like Boolean operations and compare operations.

The bridge interface is used for transferring control information from the control CPU (in control cluster) to the SCON cluster. The SCON data memory bus is a wide bit-width bus internal to the SCON cluster through which the SCON CPU and bridge can access slaves on data memory bus. The SCON program memory bus is of wide bit-width. The bridge is used at boot-up time to download each CPU code into its program memory. After completion of processing by the SCON CPU, the data is written by the SCON CPU over DMEM bus to the SCC FIFO. The SCC FIFO serves either as store and forward or cut-through buffer. The attached DMA

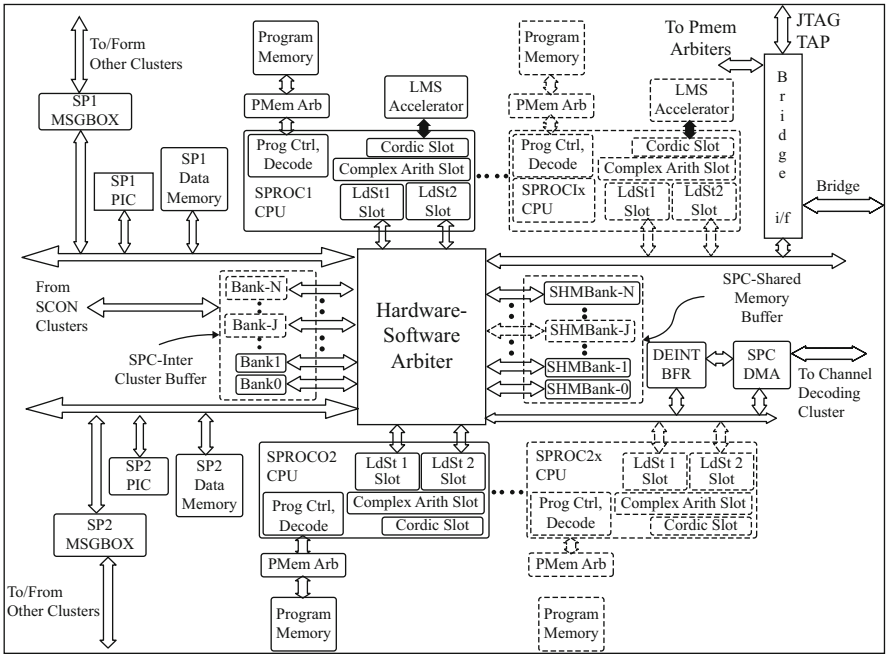

Fig. 11 Details of signal processing cluster

engine (SCC-DMA) moves the data from the FIFO through a dedicated interface independent of data memory bus, once the programmed threshold is reached. The SCC-DMA moves the data from FIFO and transfers it out of the SCC cluster to the intercluster buffer (ICB) of SPROC cluster. Associated with SCON CPU is a message box (SCC MSGBOX) which allows the CPU to exchange messages with each of the other CPU's in different clusters. It receives messages in its inbox from all other CPU's and sends messages to other CPU's via outbox. SCON cluster has a programmable interrupt controller (SCC PIC) which aggregates multiple source events into two levels of interrupts (INT1, INT2) and an exception (EXCP) for SCON CPU.

The signal processing cluster (SPC) as shown in Fig. 11 consists of the following key components:

- One or multiple SPROC CPUs (SP1, SP2,... SPx...),
- Least mean squares (LMS) coprocessor,
- Intercluster buffer (SPC-ICB),
- Shared memory buffer (SPC-SHMB),
- Packing buffer (DEINT BFR) and SPC-DMA blocks.

The signal processing cluster (SPC) performs the bulk of tasks comprising of symbol synchronization, channel estimation, channel correction, and demapping to

bits. It contains one or more SPROC CPUs (e.g., in case of a need of 2 CPUs, we name them SPROC1 and SPROC2) which does most of these tasks. An LMS coprocessor is tightly coupled to one SPROC CPU and designed to handle high sample-rate adaptive filtering required for time domain equalization. The SPC intercluster buffer (SPC-ICB) is used to receive inputs for processing from the previous signal conditioning cluster. The SPC shared memory buffer (SHMBank) is organized to effectively be used across the multiple CPUs in this cluster. A packing buffer (DEINT BFR) and a DMA are present to send processed data to the channel decoding cluster in the signal chain. Each SPROC CPU comes with its associated blocks, namely, message box (SPx-MSGBOX where x = 1, 2) and a programmable interrupt controller (SPx-PIC where x = 1, 2).

Signal Processing (SPROC) CPUs

This cluster contains one of multiple identical SPROC CPUs. The SPROC CPU is a VLIW core optimized for signal processing of complex signals. It is capable of handling complex arithmetic computations like complex MACs and complex multiply and is also capable of handling large (8192-, 4096-, or 2048-point) FFTs including non-power of 2, prime factor DFT computation. In OFDM-like standards, these CPUs are used for symbol synchronization, channel impulse response interpolation, and symbol deinterleaving and demapping. It has four execution slots, which consist of a complex arithmetic slot, a cordic slot (capable of twiddle factor generation and Arc-tan computation), and two wide bit-width slots. Special instructions for dividing complex signal by a real signal and single depth trace-back for Viterbi decoding are provided for channel estimation.

The salient features of the signal processing execution slots are as follows:

- 2× wide bit-width Load-Store Slots: This unit is capable of load and store operations. It supports linear, circular, and bit-reverse addressing. Some registers are marked in the register file as address pointers. In addition to load-store operations, this unit is also capable of performing Boolean, compare, and extract operations.
- Complex Arithmetic Slot: This unit is capable of performing operations on complex signals. It supports complex multiply and division, complex MAC, real multiply, and real MAC operations. It also supports efficient FFT butterfly operations which enable low cycle count FFT operations.
- Cordic Slot: This unit is capable of generating twiddle factors (sine and cosine operations) as well as non-normalized magnitude and phases of complex signals. This unit has a tight coupling with the LMS coprocessor which enables fast equalizer operations.

Each SPROC CPU has a dedicated program memory to which it interfaces via the PMEM interface. Each SPROC CPU interfaces to its dedicated data memory over the exclusive DMEM interface. The message box and PIC peripherals also interface using this data memory interface.

SPC Cluster Access Paths

The SPC cluster access paths are as follows. The access to SPC intercluster banks is arbitrated between different SPROC CPUs (SPROC1, SPROC2,..,SPROC1x, SPROC2x). This could be either priority based or round-robin based. Since the access paths to bridge are also required, they could also have similar types of access schemes.

There are specific registers for programming SPC-DMA and DEINT BFR to select between different SPROC CPUs, to ensure that only one CPU has exclusive access. The access to shared memory banks (SHM) and CPU-exclusive slaves (PIC, MSGBOX) is arbitrated between the SPROC CPU and bridge either using priority based or round-robin algorithm.

SPC Intercluster Buffer (SPC ICB)

SPC intercluster buffer is a bank-based memory with wide data width meant for continuous transfer of processed signal from SCON cluster to be consumed by SPROC cluster. The SPC ICB can be written by SCC DMA (one bank at a time) and can be read (multiple banks at a time) by one of the SPROC CPUs. Banks are contiguous in address space and are used in a circular mode by SCC DMA because it is provided for transferring continuous signal data.

SPC Shared Memory Buffer (SHMBank)

SPC Shared Memory (SPC SHM) is a bank-based buffer with wide datapath meant for storage and exchange of computed results between SPROC CPUs (this could be between SPROC1, SPROC2, SPROC1x, and SPROC2x CPUs). Each bank can be accessed by either of the two load-store ports of SPROC1, SPROC2, and so on. Bridge access is shared with any of the above ports. Either CPU is guaranteed fixed-latency access if it is the owner of a given bank. If nonowner accesses a bank, it will be allowed only on cycles where owner is not accessing that bank.

SPx-Data Memory and SPx-Program Memory

There is a dedicated data memory for each CPU, and it can be accessed by both load-store units of that CPU provided they are not in the same cycle. Both memories can also be accessed by bridge. In addition each SPROC CPU also has its dedicated program memory. The control cluster writes into program memory during boot-up time to download each CPU code.

Packing Buffer (DEINT BFR) and SPC-DMA Operation

The Packing buffer (SPC DEINT BFR) assists in data packing operation to be performed on data written by SPx CPU before it is transferred by SPC-DMA to channel decoding cluster. The packing buffer accepts data of a certain programmed data width from SPx CPU in nonsequential order. The SPC-DMA waits for an indication that data block is ready along with the block size from DEINT BFR after which it transfers data to intercluster buffer of channel decoding cluster.

Channel Decoding Operation and Generation of Payload Data

The SPC-DMA pushes the data into ICB of the channel decoding cluster. Here the channel decoding cluster consists of accelerators performing the tasks of Viterbi and TCM decoder, Reed-Solomon decoder, and LDPC decoder. In addition the byte deinterleaver is also present in this cluster. These processes act on the data in various phases as inner decoder and outer decoder. Additional processes like inner deinterleaver, outer deinterleaver and derandomizer, etc. are also taken care in the channel decoding cluster. The decoded data is finally collected via a ping-pong buffer that accepts packets and sends them out in 8-bit parallel or serial mode outputs. In certain cases the processed data from the SPROC cluster is bypassed through the channel decoding cluster and routed to the IQ-DAC.

Suitability of the Platform for 802.22 Implementation

SDR Partitioning for Demodulation

Figure 12 shows how the various OFDM demodulation processes are partitioned across the different clusters. The numerically controlled oscillator (NCO) and mixer followed by IF to baseband converter, down-sampler, adjacent channel filtering, and sample-rate convertor are performed on the SCON cluster. The time domain synchronization, fast Fourier transform (FFT), frequency domain synchronization, pilot processing, fine symbol synchronization, frame sync detection, channel estimation and correction, symbol demapping, and bit interleaving are performed on the SPROC cluster using one or multiple CPUs. The LMS equalizer is optionally used for long echo channel shortening. The remaining processes constituting Viterbi decoding, outer deinterleaver, Reed-Solomon decoder, and derandomizer are expected to be done in the channel decoding cluster. This final output from channel decoding cluster is the transport stream packet.

The proposed SDR subsystem consisting of signal processing clusters and signal conditioning cluster can be used along with an additional channel encoding cluster to implement a transmit path function as shown in Fig. 13. In such a case, the channel encoding cluster performs the tasks of RS encode, convolution encode, LDPC encoding, and interleaving functions by collecting the required payload data. The data from the channel decoding cluster is passed to the signal processing cluster and from signal processing cluster to signal conditioning cluster. This is done by interchanging the components of FIFO, DMA, and intercluster buffer as compared to the previous configurations across the clusters. Once this configuration change is done, the signal path traverses from channel encoding to signal processing and finally to signal conditioning.

The signal processing cluster does the function of mapping the bits to waveform and performing IFFT for the case of OFDM-based standards or performing the required modulation as per the communication standard of choice. Once the signal is modulated, it is transferred to the signal conditioning cluster for spectrum shaping and filtering. The spectrum-shaped signal is transmitted out either by optionally

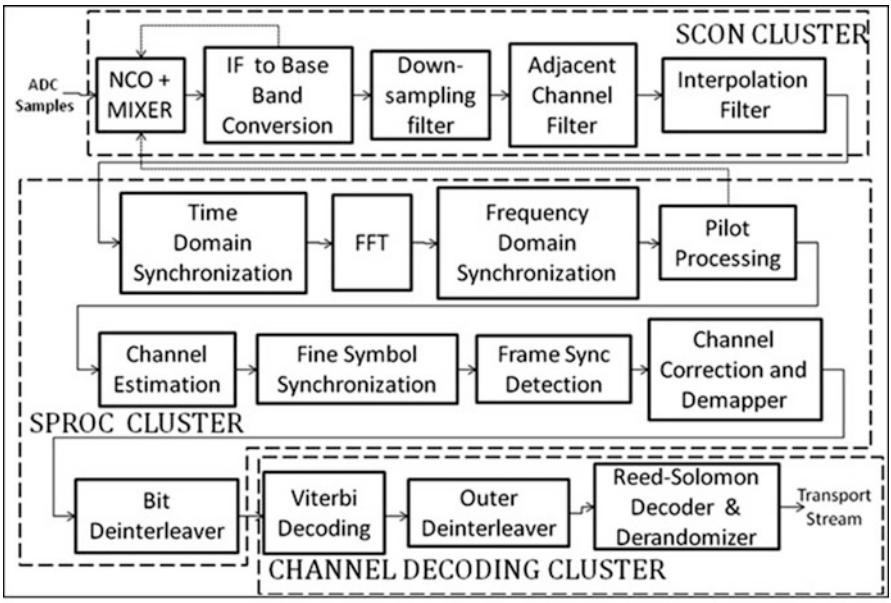

Fig. 12 OFDM demodulation on the SDR chip

up-converting using a mixer and NCO combination or could be send out as is at baseband from the DFE sub-module of signal conditioning cluster. In case a baseband signal is send out, the up-conversion can be performed externally before transmitting it. This data is passed through a digital-to-analog converter (DAC) to transmit a baseband signal or an IF signal. In a similar manner, the transmitter path of other digital communication standards can also be mapped and implemented using the SDR subsystem.

The proposed SDR subsystem consisting of signal processing (SPROC) clusters and signal conditioning (SCON) cluster can be used along with an additional channel encoding cluster and channel decoding clusters to implement universal modulator and demodulator (MODEM) functionality. A scheme to implement this is shown in Fig. 14.

In this scheme we have shown the transmit path (TX-SDR) and receive path (RX-SDR). The transmit path consists of outgoing data being processed via channel encoding cluster (as explained earlier), followed by signal processing (SPROC) cluster and finally to be send out after being processed by the signal conditioning (SCON) cluster. This outgoing signal is fed to a digital-to-analog converter which is up-converted and sent via the transmit antenna. The receive path consists of incoming signals from the receive antenna which pass through the tuner to get intermediate frequency or zero IF signals. These signals are digitized using an analog to digital (ADC) converter to generate real or complex samples. As explained in the previous sections, the real or complex signals are processed by signal

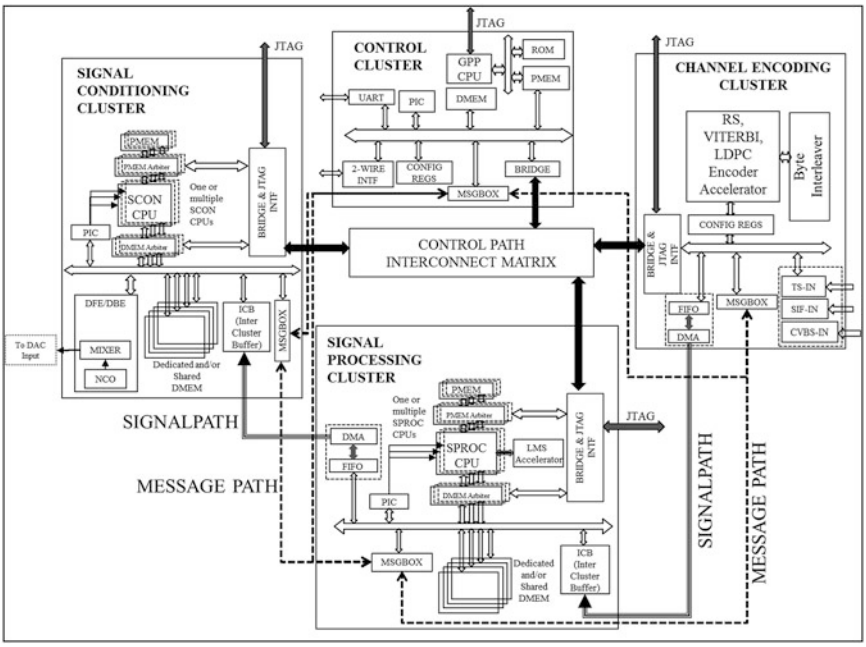

Fig. 13 SDR Platform for Modulator function

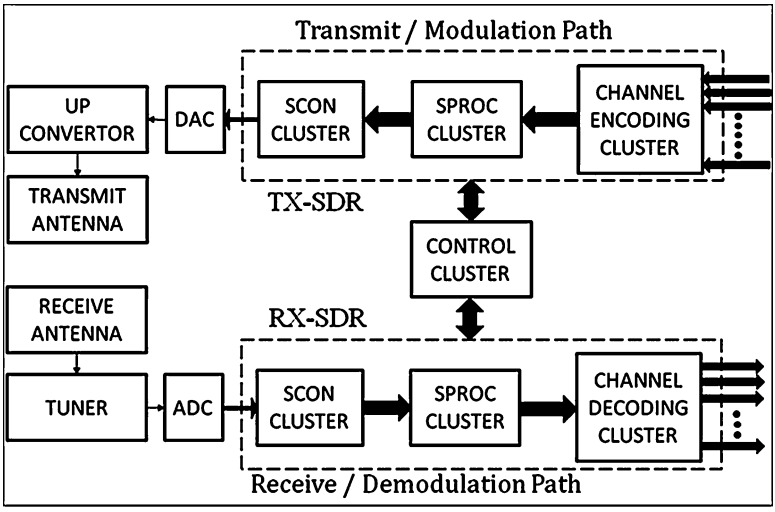

Fig. 14 Usage of SDR systems for implementing modem functionality

conditioning (SCON) cluster for sample processing followed by signal processing (SPROC) cluster for symbol processing and finally demapped to generate bits. The generated bits are passed through the channel decoder to remove errors and get a final data bits. Figure 14 also shows a control cluster which will interact with the transmit and receive SDR paths for performing control and supervisory functions. Thus the proposed SDR subsystem is versatile and can be reused as a basic building block for implementing a universal modem.

802.22 WRAN PHY Implementation on SDR Platform

This section describes how the 802.22 WRAN physical layer is implemented on the SDR platform described in the previous section for the base station as well as the CPE. Base Station (BS). The base station performs the functions of downlink transmit and uplink receive to and from all the CPEs.

Downlink Transmit Processing

The downlink transmit processing chain is shown in Fig. 15. The data obtained from the MAC layer is packetized, randomized using the scrambling sequence in the channel encoding cluster. The payload contains bits which needs to be transmitted to different users. The scrambled packet is convolutional encoded and punctured appropriately, following which it undergoes bit interleaving using the turbo interleaver. The interleaved bits intended for multiple users are combined and sent to the SPROC cluster where it undergoes the process of mapping to different OFDM carriers. The pilots transmitted in the frame are also boosted here. These carriers are interleaved in frequency domain, and pilots are added as desired for the different frames. Superframe preamble and preamble generations happen in this cluster based on the type of frame to be transmitted. The mapped carriers are converted to time domain via process of IFFT and sent to the SCON cluster. The SCON cluster performs the tasks of up-sampling and adherence to spectral mask using filtering operations. The up-sampled and filtered signal is eventually converted to baseband analog waveform using IQ-DACs.

Uplink Receive Processing

The uplink receive processing chain is shown in Fig. 16. The base station RF front end receives signals from different CPEs which are sampled by the ADC. The ADC samples are filtered to remove the effects of adjacent channel interference, in the SCON cluster. The filtered samples are transferred to SPROC cluster where they are aligned on proper boundary and FFT is performed to get frequency domain samples. The frequency domain samples are subsequently deinterleaved, and further processes of channel estimation, equalization, and demapping are performed after removing the CDMA pilot carriers. The demapped soft bits are segregated on a user-specific basis and then undergo the processes of bit deinterleaving, Viterbi decoding, and descrambling. The user-specific payloads are passed to the MAC layer.

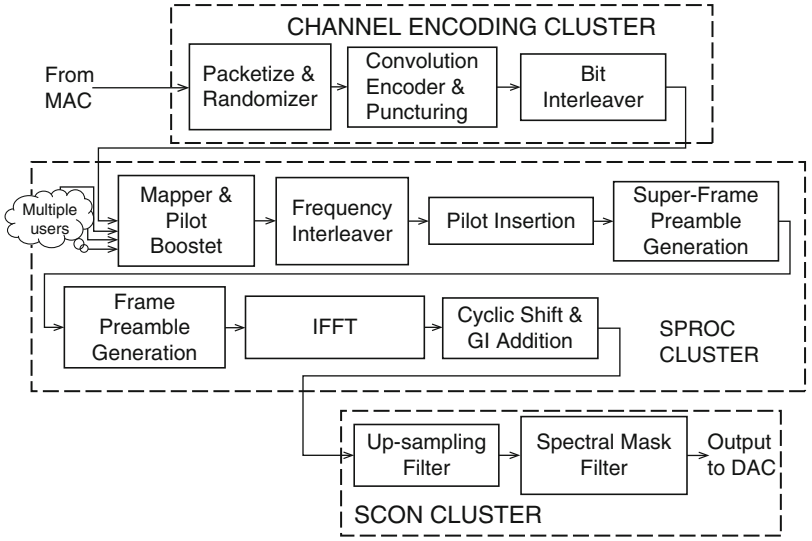

Fig. 15 Downlink transmit task partitioning on the SDR platform

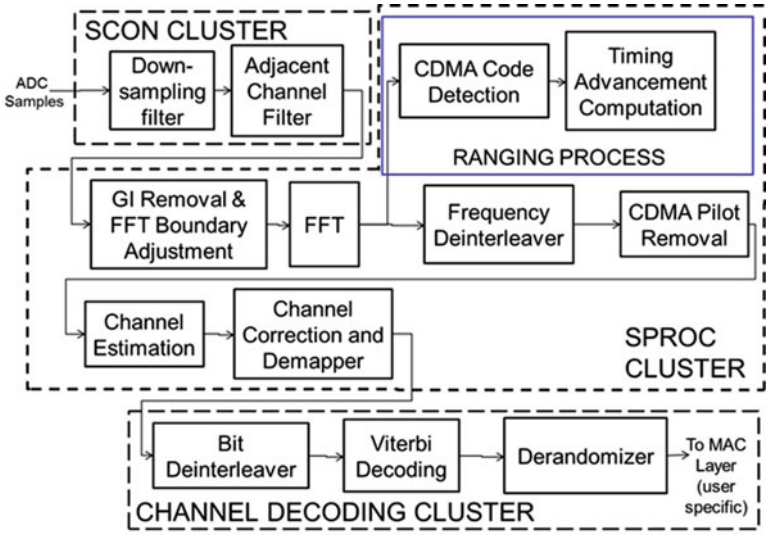

Fig. 16 Uplink receive task partitioning on the SDR platform

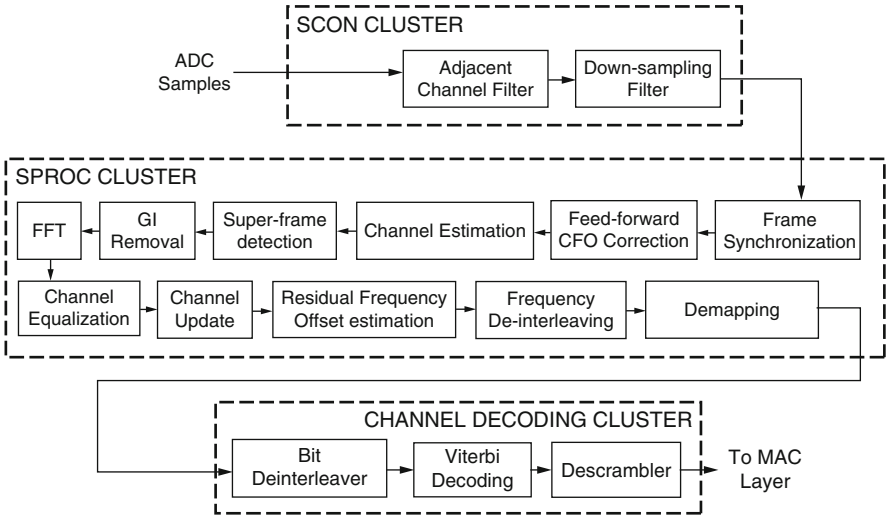

Fig. 17 Downlink receive task partitioning on the SDR platform

Customer Premise Equipment (CPE)

The customer premise equipment performs the functions of downlink receive and uplink transmit from and to the base stations.

The downlink receive processing chain is shown in Fig. 17. The signals received by the RF front end are sampled by the ADC and then filtered to remove the effects of adjacent channel interference in the SCON cluster.

The filtered samples are subsequently processed in the SPROC cluster for frame synchronization and carrier-frequency offset correction. Subsequently the tasks of channel estimation, superframe detection, and frequency domain conversion via FFT are performed. This is followed by channel equalization, channel update, residual frequency offset estimation, frequency deinterleaving, and demapping in the SPROC cluster. The soft-bits are deinterleaved and undergo Viterbi decoding and descrambling in the channel decoding cluster. The final bits obtained are packetized as payload and passed to the MAC layer.

The uplink transmit processing chain is shown in Fig. 18. The channel encoding cluster receives the payload bits from MAC layer, scrambles, and packetizes it. The scrambled payload undergoes convolutional encoding and bit interleaving and is transferred to SPROC cluster. The SPROC cluster further performs the tasks of mapping data to the OFDM carriers and symbol-wise frequency interleaving (characteristic of 802.22 uplink frames) before insertion of CDMA carriers required for ranging. The frequency domain data is converted to time domain via IFFT, and any frequency offset introduced in the CPE is compensated. An additional task of timing advance correction is performed on the uplink side from all CPEs to ensure that all waveforms from different CPEs arrive at the same time at the base station. The time domain data subjected to timing advance correction is subjected to spectral

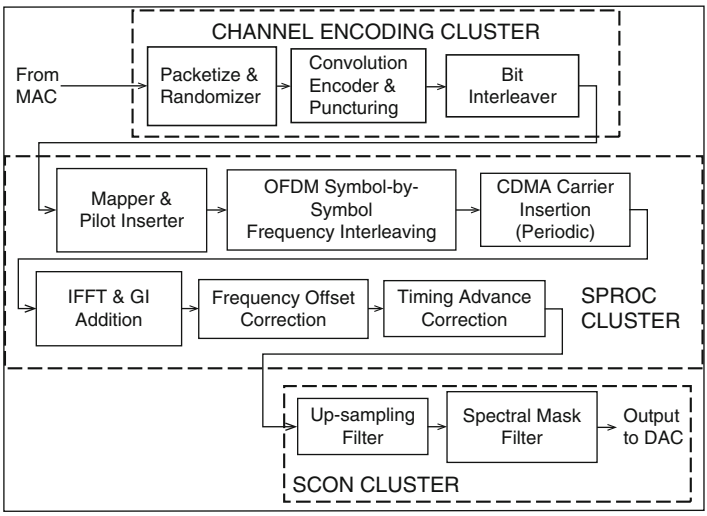

Fig. 18 Uplink transmit task partitioning on the SDR platform

mask filtering in the SCON cluster to be exported to the DAC which generated the baseband analog waveform.

MAC Layer Implementation

The 802.22 MAC primarily consists of the convergence sublayer and common part sublayer on both the CPE and base station side. The different components of the MAC are detailed in Fig. 19.

Each module is expected to be implemented such that it can execute as a thread, task, and function or even be located in a different processor.

Test Methodology for the IEEE 802.22 and Results

The setup shown in Fig. 20 is used to inject different kinds of impairments between the transmit and receive chains for validating the correctness of IEEE 802.22 WRAN system.

This setup enables testing and performance benchmarking of the TVWS (IEEE 802.22) modem implementation for different impairments, viz., additive white Gaussian noise (AWGN), multipath, phase noise, carrier-frequency offset, sampling frequency offset, etc. The unique frame structure specific to 802.22 consisting of superframes and frames is verified using correlation techniques.

The correlation plots shown in the following Fig. 21 help us identify the superframe and frame boundary detection.

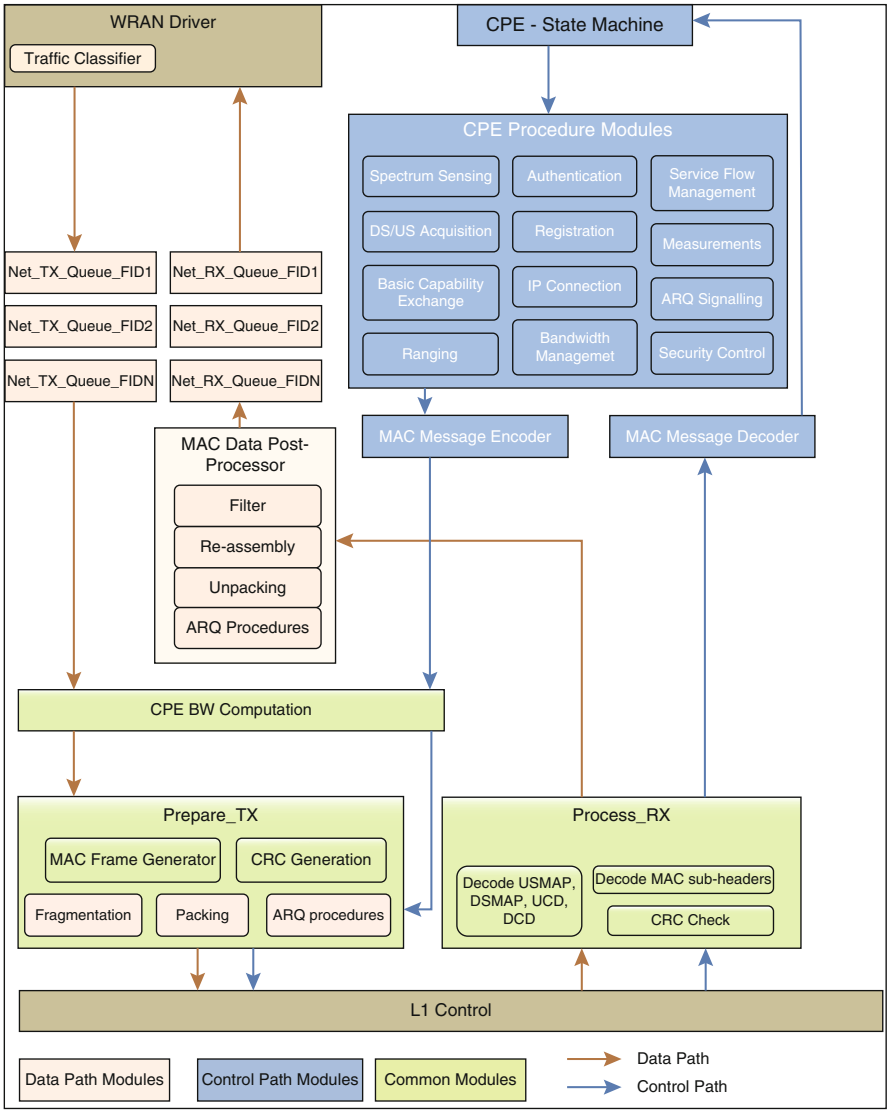

Fig. 19 MAC functional architecture

Figure 22 shows the channel path delay profiles used for verification of the IEEE 802.22 implementation. Red components indicate that the channel profile falls outside 1/32 guard interval (GI) window.

These channel models have been defined based on extensive work carried out over many years by the IEEE 802.22 working group. Some of these models have been derived directly from over the air measurements that have been carried out by the broadcasters as shown in Table 5.

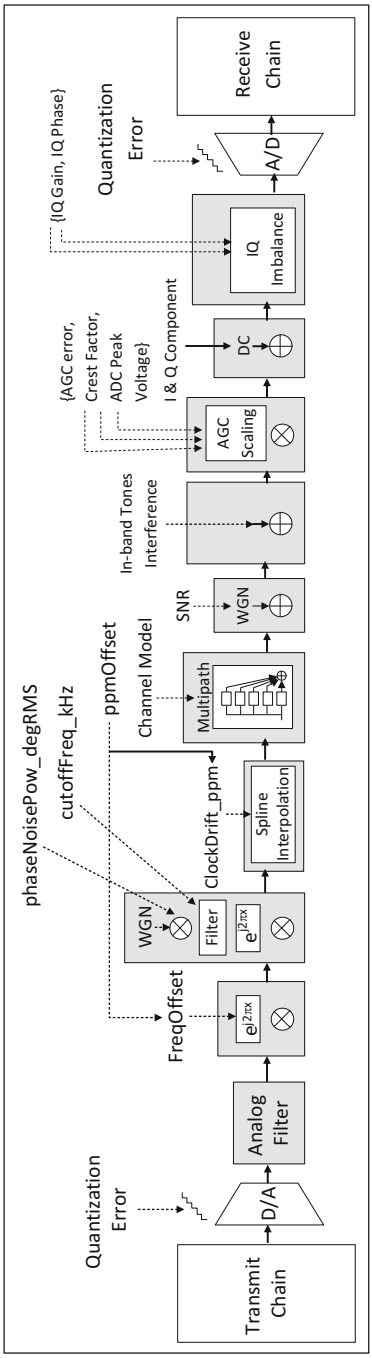

Fig. 20 Simulation setup for 802.22 modem

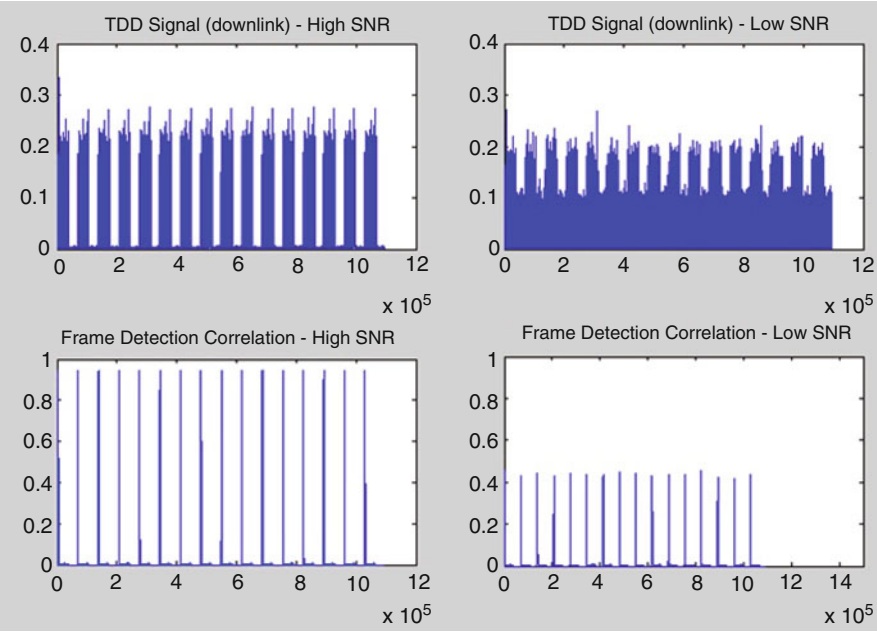

Fig. 21 Correlation plots of packet detection and initial symbol timing

Spectrum Mask

Fig. 23 shows the typical output spectrum obtained at the power amplifier output at base station/CPE side. As can be seen, the spectrum mask complies with the FCC regulations. This is one of the most challenging aspects of the white space device implementation, and based on the techniques described earlier, one can comply with the regulations.

Effect of Carrier-Frequency Offset and Sampling Frequency Offset

Figure 24 describes the constellation in the presence of residual frequency offset and sampling frequency offset. As can be seen, all these offsets need to be taken care of and equalized in order to recover the bits contained in the signal.

Over-the-Air Tests of the IEEE 802.22 Device

This section describes over-the-air tests performed in India for the 802.22 WRAN systems. These tests were done as a technology demonstrator and proof of

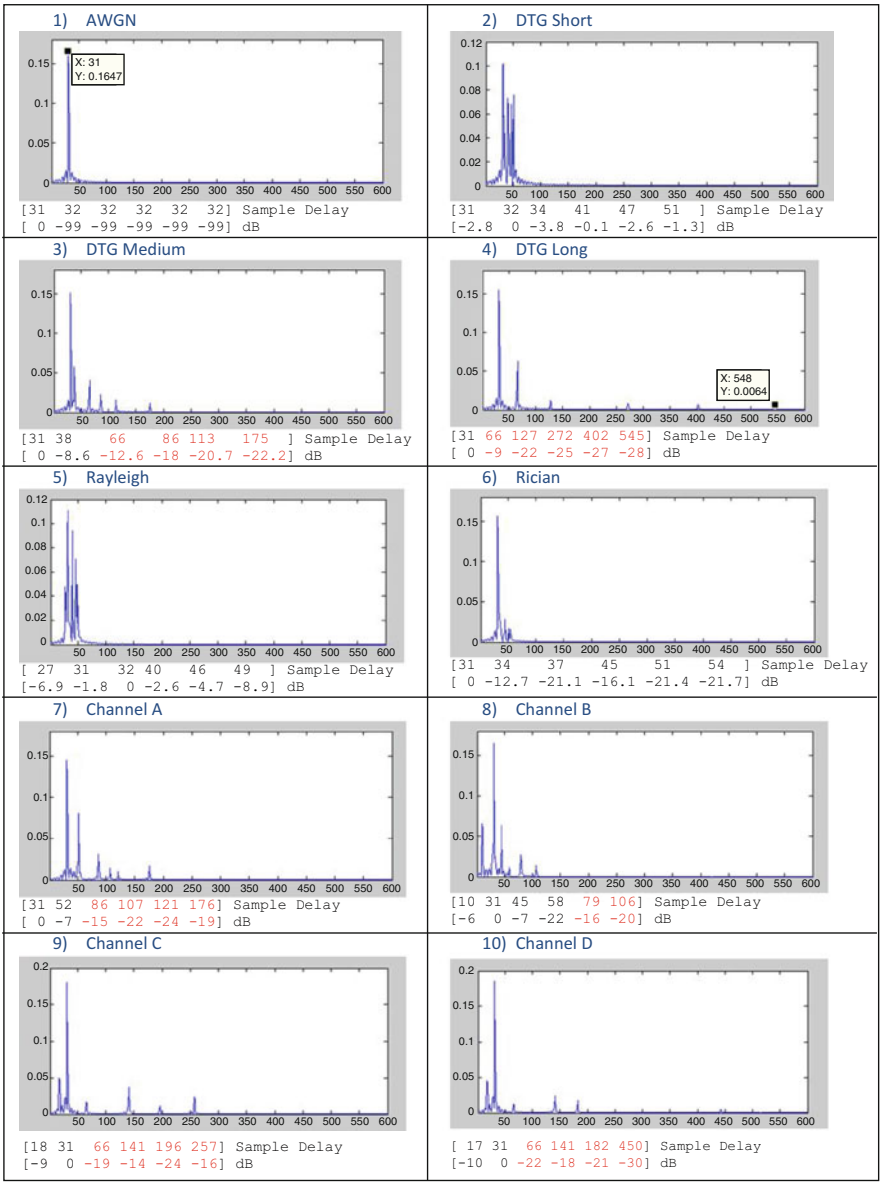

Fig. 22 Channel type for performance verification (Red components indicate, they fall outside 1/32 GI window)

Table 5 Channel types used to conduct the IEEE 802.22 performance evaluation

Channel type	Sample delay and power delay profile
AWGN	[31 32 32 32 32 32] [0 −99 −99 −99 −99 −99] dB
DTG short	[31 32 34 41 47 51] [−2.8 0 −3.8 −0.1 −2.6 −1.3] dB
DTG medium	[31 38 66 86 113 175] [0 −8.6 −12.6 −18 −20.7 −22.2] dB
DTG long	[31 66 127 272 402 545] [0 −9 −22 −25 −27 −28] dB
Rayleigh	[27 31 32 40 46 49] [−6.9 −1.8 0 −2.6 −4.7 −8.9] dB

Channel B	[10 31 45 58 79 106] [−6 0 −7 −22 −16 −20] dB
Channel C	[18 31 66 141 196 257] [−9 0 −19 −14 −24 −16] dB
Channel D	[17 31 66 141 182 450] [−10 0 −22 −18 −21 −30] dB

concept in collaboration with Education and Research Network (ERNET) in India.

ERNET India is the National Research and Education Network dedicated to support the needs of the research and education community within the country. It was established in 1998 as an autonomous scientific society under the Ministry of Electronics and Information Technology (MeitY), Government of India. It operates ERNET network – a pan-Indian terrestrial and satellite network with 15 points of presence at premier research and academic institutions [1].

The main objectives were as follows:

- Test point-to-point and point-to-multipoint link scenarios.
- Test for long-, mid-, and short-distance ranges
- Measure data rates with iperf benchmarks.
- Video conference using Internet backhaul

Srikakulam district of Andhra Pradesh was chosen for one of the trials. This is a typical rural scenario where the base station was installed at Voppangi (on an existing BSNL tower) and connectivity was demonstrated with 2 schools located at Ponnada (located 6.5 km from Voppangi) and Dharmavaram (located 10.6 km from Voppangi).

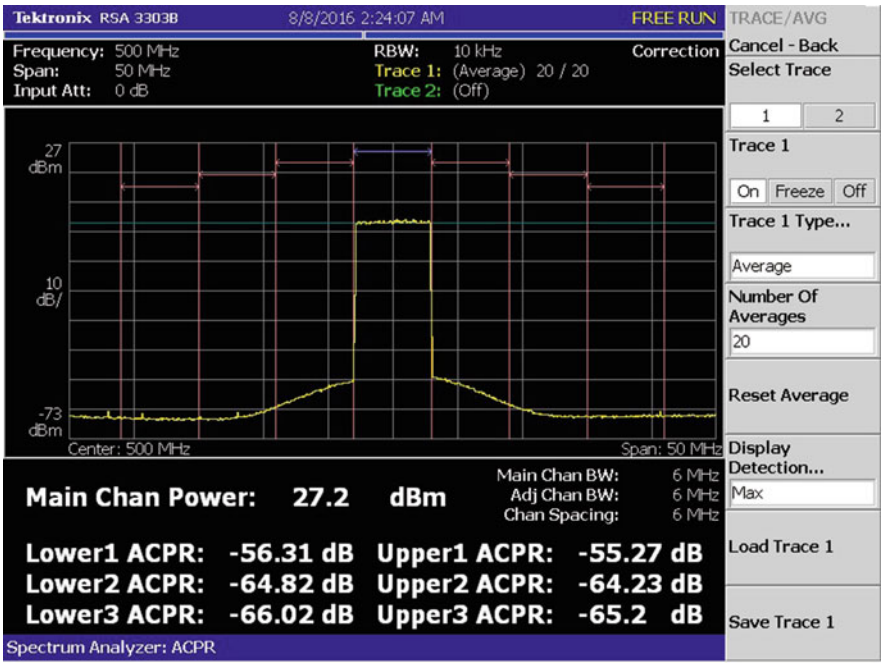

Fig. 23 802.22 implementation spectrum mask

Base station characteristics (Voppangi)

- Configuration:
  Mode: FDD
  Band width: 6 Mhz
  Frequency Band: Down link: 647 MHz, Up Link: 695 MHz
- Antenna
  Gain: 9 dBi
  Height above ground level: 58 ft
- EIRP
  32 dBm
- Back haul (Courtesy: BSNL broadband)
  Downlink: 9.45 Mbps
  Uplink:5.6 Mbps

The directional antennas at the CPE locations were oriented toward the base station for getting the best signal strength.

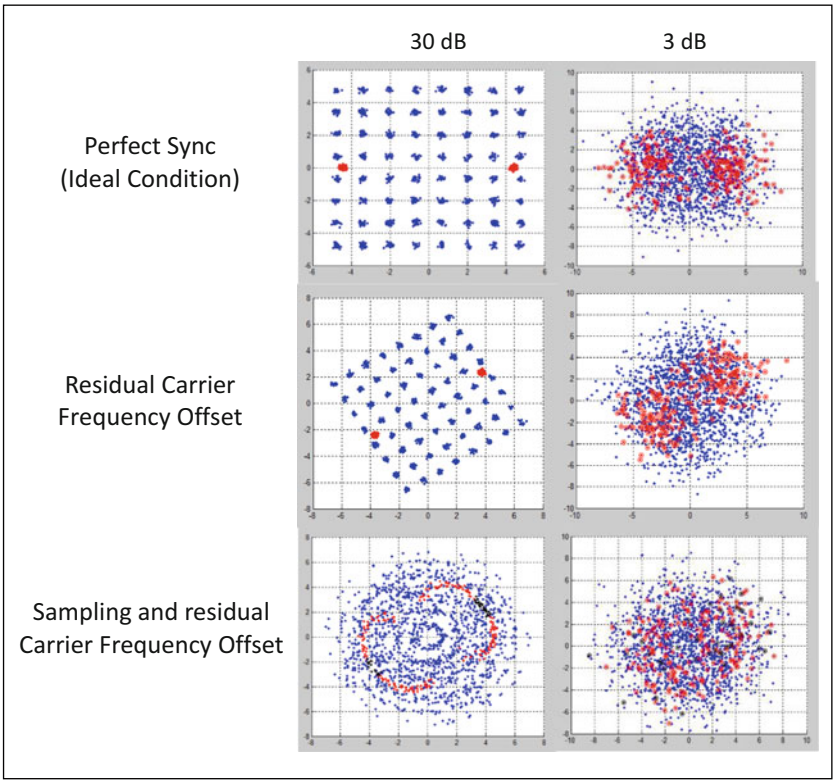

Fig. 24 Constellation in presence of residual frequency offset and sampling frequency offset

CPE location 1 (Z.P.H School, Ponnada)

- Configuration:
  Distance from Voppangi:6.5 KMS
  Frequency band: Downlink: 647 MHz, Up Link: 695 MHz
- Antenna:
  Gain: 9 dBi
  Height: 40 ft
- EIRP
  32 dBm
- Results:
  Point-to-point configuration
  Iperf
  Downlink: 6.95 Mbps (16-QAM, 2/3 code rate).
  Uplink: 4.56 Mbps (QPSK, 3/4 code rate).

Point-to-multipoint(2 Cpe) configuration
Iperf
Downlink: 3.4 Mbps (16-QAM, 2/3 code rate).
Uplink: 1.4 Mbps (QPSK, 1/2 code rate).

CPE location 2 (Z.P.H School, Dharmavaram)

- Configuration
  Distance from Voppangi: 10.6 KMS
  Frequency band: Downlink: 647 MHz, Up Link: 695 MHz
- Antenna:
  Gain: 9 dBi
  Height: 30 ft
- EIRP
  32 dBm
- Results: Point-to-point configuration
  Downlink: 3.89 Mbps (QPSK, 3/4 code rate).
  Uplink: 2.94 Mbps (QPSK, 1/2 code rate)
- Point-to-multipoint (2 Cpe) configuration
  Downlink: 1.76 Mbps (QPSK, 3/4 code rate).
  Uplink: 0.84 Mbps (QPSK, 1/2 code rate)

Another case study for over-the-air trials was the trials done in conjunction with IIT-Hyderabad. In these trials the base station was mounted on top of academic building, and several CPEs were mounted at the following locations:

- CPE1 at Main Gate, IIT Hyderabad: The aerial distance from base station: 1.3 Kms
- CPE2 at Utharpalle School: The aerial distance from base station: 7.5 Kms
- CPE3 at Mallepalle School: The aerial distance from base station: 8.5 Kms
- CPE4 at Terpole School: The aerial distance from base station: 11.8 Kms

The goal of this project was to provide Internet connectivity to students in villages in and around IIT-Hyderabad Campus. The typical configurations used for the base station and CPE equipment are as follows:

- Base station configuration
  Band width: 6 MHz
  FDD: Downlink frequency: 502–508 MHz, Uplink Frequency: 514–520 MHz
  BS antenna type/gain: Sectoral/7 dBi
  BS antenna height(m):20
- Total EIRP @ BS: 31 dBm(1.25 W)
- CPE configuration
  Band width: 6 MHz
  FDD: Downlink frequency: 502–508 MHz, uplink frequency: 514–520 MHz

Table 6 Results of some of the initial field tests for the IEEE 802.22 Wi-FAR Technology

CPE	Distance from the Base station (km)	CPE antenna Height (m)	Downlink (Mbps)	Uplink (Mbps)	Total throughput (Mbps)
CPE1: IIT Main Gate	0.3	1.8	10	12	22
CPE2: Uttarpally	7.5	6	10	12	22
CPE3: Mallepalle	8.5	6	4.74	1	5.74
CPE4: Terpole	11.8	0.6	0.9	1.5	1.4

CPE antenna type/gain: Directional/6 dBi
Total EIRP @ CPE: 30 dBm(1 W)

The summary of the results obtained from point-to-point links is summarized in the following Table 6.

Implementation Challenges of the IEEE 802.22 Standard

Several challenges exist in the design of customer premise equipment and Base Station compliant to the 802.22 standard using SDR approach.

AGC Response Time

The receiver RF chain used in 802.22 mostly makes use of existing TV tuners, since they operate in the band of interest. However, the drawback posed due to the usage of TV tuners is that they have long AGC response times. However, if we consider the frame durations of 802.22 system, they are much lesser in comparison to these response times. This poses a challenge in terms of AGC loops not being able to completely settle. Consequently, the task of gain control cannot be left to RF tuner completely under such circumstances. The SDR architecture as explained earlier also participates in signal normalization and gain control to some extent.

Turbo-Like Interleaver Implementation on SDR

Turbo-like interleavers (TLI) used for frequency interleaving and bit interleaving pose a significant challenge in SDR platforms because of their pattern computation incorporating a modulo operation. If we consider the scenario when extremely high data rates need to be supported, the rate of bit interleaving computation required also becomes significant. Such type of complexities forced two different types of TLI implementation, one for frequency interleaving where the compute requirements are significantly lower and the other (bit interleaving) which needs

much higher compute capability. Hence these types of disparate requirements force the programmer to give up on a modular approach to programming.

Compliance to 802.22 Spectrum Mask

The 802.22 emission mask is very stringent because it is a secondary mode of transmission. The requirement is to have a rejection of 55dBr in N+1 and N-1 channels and 69dBr in N+2 and N−2 channels. These stringent mask requirements become difficult to meet especially because the noise floor in the transmit RF chain also gets amplified by the gain stages when we want to transmit at a certain required power level. To ensure that the spectrum mask is adhered to it is important to pay attention to the noise floor starting from the DAC which converts the digital baseband signal to analog. The designer can choose the DAC with the appropriate noise floor or somehow ensure that in the stages following the DAC (i.e., the post-DAC filters), the noise floor is appropriately shaped and suppressed so that at the power amplifier output, the mask is met. In addition to noise floor shaping, it is also observed that the power amplifier needs to operate mostly in Class A or linear region so that the contribution of nonlinear components is kept to a minimum. It is for reasons of compliance to the tight spectrum mask are why we find the power amplifier having poor efficiency. There are certain implementations which have overcome this deficiency and adopted power amplifier linearizers in the transmit chain to meet the spectrum mask as well as have better power amplifier efficiency.

Alternate Implementation of the IEEE 802.22 Spec

Another manufacturer of the IEEE 802.22 equipment uses advanced, state-of-the-art digital filters coupled with high-resolution digital-to-analog converters, essentially synthesizing on the fly a signal that meets all these requirements. This is then followed by analog antialiasing filters before the complex signal is modulated, amplified, and finally transmitted. Such digitally controlled transmissions have been found to truly mimic simulation predictions in compliance with all of the above requirements.

The received design begins with a gallium arsenide front end, providing an exceptionally low noise figure and a large dynamic range. The signal is then demodulated and passed through a first analog filter. This filter ensures the signal can then be sampled with minimal aliasing, further filtered by a state-of-the-art digital filter, decimated, and further filtered before it is digitally processed to extract every ounce of intelligibility it may contain. The net result is an exquisite sensitivity and an excellent performance in the presence of dispersion, out of band TV transmitter signals, instabilities caused by vegetation shimmering in the wind, etc.

With a useful range of 100 km, the IEEE 802.22 line of radios can provide up to 22 Mbps of robust transmission to areas where other technologies such as LTE, 4G, WiFi, and WiMax fall short. As such, it is not positioned as a replacement for these

technologies but rather as a complement, expanding the service area beyond what more traditional or legacy technologies can provide.

The manufacturer also uses an open-source Linux operating system. Proprietary drivers interface the open-source code to the radio board, the latter ensuring that FCC compliance is achieved despite changes the operator may do at the operating system level. Since the radio uses well-known Linux distributions, there are plenty of experienced personnel available and a plethora of documentation for any operator who would like to use the radio in a customized fashion, all the while knowing that the transmitter/receiver continues to operate in compliance with standards and country-specific regulations.

Rather than relying on global positioning system (GPS) receivers, radios provide exquisite location capabilities, as they implement standardized terrestrial fine ranging, as described in the 802.22 standard. Therefore, this implementation of the radios can operate under adverse conditions where GPS signaling may fail. They are therefore less susceptible to weather and are immune to GPS jamming. With the proper software, these radios can actually map an entire area, acting as a superb swarm of highly precise OFDMA 3D radars. After a natural disaster, all these attributes may be of vital importance in an emergency deployment of these devices to reconstruct a basic telecommunications infrastructure.

Geolocation and Database

Protection of licensed incumbent systems in the TV bands can be provided by either geolocation and access to an incumbent database over the Internet, or spectrum sensing or a combination thereof. This section deals with the first means, whereas spectrum sensing is dealt with in section "Distributed Spectrum Monitoring: IEEE 802.22.3 Standard on Spectrum Characterization and Occupancy Sensing".

Two modes of geolocation can be used with the IEEE 802.22 WRAN technology and satellite-based and terrestrially based geolocation. The satellite-based mode relies on global navigation systems such as GPS, Glonass, and Galileo. The WRAN BS will use its satellite-based geolocation capability to determine the latitude and longitude of its transmitting antenna as well as its altitude above mean sea level from a geolocation receiver installed on the antenna. Each CPE also needs a geolocation receiver to acquire its geolocation and transmit it to the BS using a standard NMEA string at the time of association. The BS can also query the CPE for its geolocation at any time to verify that it is always at the same place.

The terrestrially based geolocation mode relies on the inherent transmission capabilities of the IEEE 802.22 WRAN system. Terrestrial geolocation is based on the time of arrival (ToA) ranging technique which relies on the propagation time on the round trip between the BS and its CPE obtained by the normal ranging process of the wireless system but with an augmented accuracy resulting from the consideration of the relative phase of the frame preamble carriers as received at the CPE on the downstream and the relative phase of dedicated CDMA ranging carriers as received at the BS on the upstream. This information is extracted through the

normal OFDM signal processing of the WRAN system and can be made available to the BS. It is also based on the range between CPEs obtained by the propagation time of the CBP bursts from one CPE to another. Again, the accuracy is augmented by the consideration of the relative phase of the carriers contained in the CBP burst preamble as it is received by the second CPE which, meanwhile, keeps its synchronization with the BS.

A geolocator is used at the BS to initiate the ranging requests on which the BS will act by querying the CPE for the differential carrier phase information and requesting a CDMA ranging burst to be transmitted by the selected CPE to carry out the precise BS-CPE-BS ranging and by requesting specific CPEs to send their CBP bursts and other CPEs to capture these bursts and send the resulting differential carrier phase information to the BS. The geolocator will then compute the distance between the BS and each of its CPEs as well as the distance between the selected CPEs and establish their geolocation by triangulation based on a number of reference WRAN devices for which the precise geolocation is known. Upon completion of the triangulation calculations, the geolocator will return a NMEA longitude-latitude string to the BS for each CPE that it has successfully triangulated.

Once the BS has acquired the geolocation of its CPEs, it can register these geolocations with the incumbent database using standardized primitives through the higher layers of the backhaul transmission so that the database sends back the list of TV channels available at the specific CPE location or the maximum EIRP that the CPE can use at that specific location on each available channel to avoid interference to incumbents.

Both options on the type of information to be provided by the database have been considered and included in the IEEE 802.22 standard since these are the two main ways by which the various databases in the different countries may specify the constraints on TVBD operation, i.e., list of available channels or maximum EIRP that can be used by the TVBD at its location on each channel of interest. The second option includes the first since the indication of the protected channels can be signaled by a much-reduced EIRP level that would not allow WRAN operation on a specific channel. However, this second option would allow operation with reduced EIRP in some instances where a communication link between the BS and the CPE can still be established, resulting in a tapering-off of the EIRP when the BSs and CPEs get close to a protected contour rather than an abrupt transition from full EIRP operation to disallowed operation. Since the BS fully controls the EIRP of its CPEs through the transmit power control (TPC), interference control is centralized at the base station.

However, means had to be developed at the CPE to make sure that the BS actually controls the maximum EIRP and not only the conducted power going to the antenna. The IEEE 802.22 standard includes the requirement that unless an integrated CPE/antenna is used where conformance testing can be done on the entire unit, the antenna will have to indicate its on-axis gain on all the TV channels on which it can operate once it is connected to the CPE (e.g., a PROM in the antenna readable from the CPE). A special signaling interface has been included in the IEEE 802.22 standard for this antenna-to-CPE data communication so that

the BS can securely control the EIRP of the CPE even if the attached antenna can be changed.

A standardized set of primitives to support the interface between the BS and the database has been developed and included in the IEEE 802.22-2011 [5]. This set of primitives should constitute the basis of a communication protocol between the database and the various TV white space unlicensed devices. This set of primitives was presented to the IETF-PAWS which has taken the task of developing such protocol.

IEEE 802.22 Future Enhancements and Other Activities

Many enhancements to the IEEE 802.22 standard are under way in form of amendments or revisions. The IEEE 802.22 working group is working on the IEEE 802.22b amendment on enhancements for broadband services and monitoring applications [8]. The IEEE 802.22b has currently recommended ten new usage cases [15]. The usage cases can be categorized as smart grid and monitoring, broadband service extension, and combined services. The smart grid and monitoring applications include regional area smart grid/metering, agriculture/farm house monitoring, critical infrastructure/hazard monitoring, environment monitoring, homeland security/monitoring, and smart traffic management and communications, which have properties of low capacity/complexity CPEs, very large number of monitoring CPEs, real-time monitoring, low duty cycle, high reliability and security, etc. The broadband service extension applications, on the other hand, including temporary broadband infrastructure such as emergency broadband infrastructure, remote medical service, and archipelago/marine broadband service, have properties of relatively high capacity CPEs; high QoS, reliability, and security; high data rate; and easy network setup.

Based on the above use cases and the functional requirements [2], the IEEE 802.22b amendment and the proposed revision to the IEEE 802.22 standard will provide the following additional features:

- Operation of the IEEE 802.22 beyond TV band white spaces, including new bands of operation. These bands include 1300 to 1750 MHz, 2700 to 3700 MHz and the VHF/UHF TV broadcast bands between 54 and 862 MHz.
- Aggregated throughput of 802.22b to be at least two times the maximum throughput supported by the IEEE Std. 802.22-2011 and in some cases four times the maximum throughput as a result of channel aggregation, channel bonding, and multiple input multiple output (MIMO) operation.
- Support for two new classes of CPEs for different service applications of broadband services and monitoring applications and shall support at least 2048 CPEs to cover a regional area network for monitoring applications.
- The amendment may provide mechanisms to meet the regulatory requirements on spectrum mask,
- Support for multi-hop connections,

- Support for QoS mechanisms for real-time monitoring applications.
- This amendment will provide enhancement to existing or alternate security mechanisms, provide a means for alternative channelization, and provide methods for cost-effective compliance with regulatory spectral mask.

The 802.22 WRAN standard uses the features of cognitive radio primarily for spectrum sensing. In future we envision that most of the CPE and base stations will be based on SDRs. This has the potential of converting modern-day cellular networks into a cognitive RAN (CRAN) network. A CRAN network will learn constantly and update itself in real time. It does so by sensing the current environment and learning from past data. This will lead to hyper-personalization for all devices that operate in the network. Some of the salient characteristics of such devices will be the following:

- All devices will operate at their optimal performance level for all users in the network.
- The modulation (and demodulation) schemes will be designed based on real-time inputs – almost on the fly.
- Devices and the infrastructure elements will apply deep learning to figure out the optimal use of compute resources.
- In such a network, each end point of the network will be a virtual machine, thus leading to virtualization of the interface between different RAN components.

Such a network will marry the concepts of big data, cognitive radio, and machine learning to generate a self-organizing network which updates itself based on environment, device capabilities, and past data. [7]

Distributed Spectrum Monitoring: IEEE 802.22.3 Standard on Spectrum Characterization and Occupancy Sensing

In 2014, the IEEE 802.22 working group formed a task group to commence activities on the IEEE P802.22.3 standard on spectrum characterization and occupancy sensing.

The IEEE 802.22.3 standard will help solve the urgent need for issues such as on-demand spectrum survey and reporting; collaborative spectrum measurement and calibration; labeling of systems using the spectrum; spectrum planning; spectrum mapping; coverage analysis for wireless deployment; terrain and topology – shadowing and fading analysis; quantification of the available spectrum through spectrum observatories; complementing the database access for spectrum sharing by adding in situ awareness and faster decision-making; space-time-frequency spectrum hole identification and prediction where non-time-sensitive tasks can be performed at certain times and at certain locations, when the spectrum use is sparse or nonexistent; as well as identification and geolocation of interference

sources. We will devote some time to this new upcoming standard and some SDR implementations of the distributed spectrum monitoring systems, as well as interference mitigation in cellular networks.

The large amount of wireless services and the consequent growth in terms of request for new allocation in terms of spectrum bands are leading toward a fast saturation of spectrum resources. On the other hand, several studies [4] on the actual occupation status of the allocated bands show how spectrum channels are idle most of the time, and the percentage of average usage in under 30%, on a daily basis. A CR system is an intelligent wireless communication system that is aware of its surrounding environment and uses the methodology of understanding by building to learn from the environment and adapt its internal states to statistical variations in the incoming RF stimuli by making corresponding changes in certain operating parameters (transmit-power, carrier-frequency, and modulation strategy) in real time [13]. Such a definition implies two needed capabilities: the first one is the awareness of the surrounding environment in terms of spectrum occupancy status. This piece of knowledge is the input for the intelligent access to the wireless medium. The second capability is the intelligence, i.e., the radio cannot work in a standard way, but needs to have some processing capabilities and choose the best parameters for each environmental condition. To achieve these goals, the spectrum sensing task is a crucial phase of the cognitive communication. In particular, a cognitive device has two opportunities to be aware of the surrounding electromagnetic environment: the first is to perform spectrum sensing locally and thrust on the output of the sensing method to access idle channels and the second is to query a geolocation database, where sensing outputs are stored by other distributed systems.

Sensing Engines: Spectrum Analyzer, Low-Cost Solutions, and SDR

A sensing engine [3] can be defined as a device, or a part of it, which is able to perform sensing task, composed of two subtasks: sampling phase and processing phase. In particular, a good sensing engine should have some peculiarities, such as efficiency, flexibility, reliability, and capability of continuous recording. The first one, efficiency, is defined as the ratio between the sampling time and the total time (sampling + processing) needed to perform sensing. It approaches 100% if the processing time is negligible with respect to the sampling time. It is very important that the processing time is minimized, since during this period the sensing cannot acquire, in normal single radio operations, new samples and so it becomes blind to the changes of the spectrum occupancy status.

Several sensing devices are available today on the market. They can be coarsely divided into three categories: spectrum analyzers, low-cost USB devices, and SDR. Devices belonging to the first category are able to scan very wide frequency ranges, but they are extremely costly and they are usually not customized to perform channel assessment. They can acquire spectrum records just for a few seconds, due to

the high-frequency resolution they need to apply for good visualization. Further processing is still needed to run more complex outcomes.

We will provide further insights on the IEEE 802.22.3 standard during future revisions of this book chapter.

Conclusions

In this chapter we provided insights on the implementation of the IEEE 802.22 (Wi-FAR) standard for wireless regional area networks. The IEEE 802.22 standard is the first standard that specifically focuses on regional and rural broadband access. Also it is the first standard that embeds many cognitive radio features to avoid interference to the primary users as a result of license-exempt operation. The regional and rural broadband wireless access is enabled as a result of using empty or vacant channels in the TV band frequencies which have exceptional propagation characteristics. Although the population density may be limited in rural areas, this allows deployment of such large regional area networks that can typically cover 300 sq. km with a single BS, or 30,000 sq. kms when exceptional propagation conditions are available. This allows adequate customer base per cell, thus making the rural area network business model viable. The PHY layer is based on orthogonal frequency division multiple access, to counter potentially harsh multipath environments. The MAC layer incorporates a number of features to support the cognitive radio capabilities. Geolocation, incumbent database, and spectrum sensing are utilized to provide protection for the incumbent services in the TV bands. The spectrum manager combines the geolocation, spectrum sensing information, regulatory-dependent policies, and channel set management to decide on the choice of TV channel to be utilized.

In this chapter we also discussed trials, certification, and interoperability testing of the IEEE 802.22-based Wi-FAR^{TM} systems.

Abstract

In this chapter, spectrum management technologies based on a spectrum database are introduced. Statistical spectrum maps and spectrum databases are important components for understanding a spectrum environment that has locality due to geolocation, surrounding structures, frequency, and so on. The typical spectrum database provides spectrum information according to a radio propagation model for estimating the unused spectrum for spectrum sharing. However, the original geolocation spectrum database does not consider the site-specific environment because a statistical radio propagation model is used. Here, in order to improve the accuracy of the spectrum database, the measurement-based spectrum database is considered. The highly accurate spectrum database can improve spectrum-sharing performance and spectrum efficiency. Finally, a future spectrum management concept, called a smart spectrum, is introduced to open up the possibility for a new wireless world.

Introduction

In order to share the spectrum in cognitive radio, the detection of a primary user (PU) and protection from interference from the secondary users (SUs) to the PU are important. Spectrum sensing and geolocation databases are considered for comprehension of the existence of the PU. Although spectrum sensing can check the current status of the PU by detecting the PU signal, misdetection generates interference toward the PU, and a false alarm may eliminate the opportunity to transmit the signal from SUs. These errors degrade the reliability of spectrum sharing. On the other hand, the geolocation database stores the available frequency for SUs without creating interference toward the PUs. Therefore, the SU can know the available frequency of a certain location by checking the data stored in the database. However, the real-time PU status cannot be understood from the database because the available frequency is usually calculated by conservative radio propagation model for avoiding the interference toward the PU.

Because spectrum sensing cannot guarantee the protection of PUs, the current practical discussion on spectrum sharing for TV white space is based on geolocation databases, like the Federal Communications Commission (FCC)-defined spectrum database and Office of Communications (Ofcom)-defined spectrum database [1, 2]. The geolocation database stores and provides geographical radio information and is expected to achieve interference avoidance influenced by the probabilistic behavior of wireless channels. The database stores radio environment information, such as the transmitter position and the received signal power from each transmitter to any location in each channel. The main information consists of the propagation loss and the transmitter and receiver locations. This empirical propagation model is derived from the enormous amount of propagation data collected from urban, suburban, and rural environments.

However, the propagation model-based geolocation database cannot support the locality of radio propagation, like shadowing, and a conservative spectrum-sharing design is required for protecting PUs. In order to improve the accuracy of the database considering the locality of propagation, spectrum databases generated by measurement results, called measurement-based spectrum databases, are considered [3, 4]. The measurement-based spectrum database gathers the measurement results from mobile terminals with their location information, and the spatial spectrum map is generated by statistically processing the gathered datasets. The typical registered information is the average received power with a mesh-divided area, which can be used to estimate the propagation of the PU and SU signals. In order to make a highly accurate and wide-coverage measurement-based spectrum database, spatial interpolation is an important technique that does not require high-density measurement data. In this chapter, we introduce the statistical interpolation techniques for measurement-based spectrum databases, and the effectiveness of such techniques on spectrum sharing is discussed.

Finally, we consider a future wireless world with dynamic spectrum use based on spectrum measurement, modeling, database, and management, which are collectively referred to as the smart spectrum [5]. The current spectrum allocation policy is based on exclusive spectrum use by a primary system determined by the regulator in each county. However, exclusive spectrum use reduces the efficiency of the spectrum, because flexible spectrum use according to user demand is difficult and a large spatial margin is required to avoid interference. In order to improve spectrum efficiency, a smart spectrum has been proposed for future wireless networks. In this chapter, we introduce the smart spectrum, and future spectrum policy is discussed with a hierarchical spectrum database and spectrum manager.

Throughout this chapter, we would like to open a future wireless world with flexible spectrum use based on user demand.

Geolocation Database

At the beginning of spectrum sharing, harmful interference toward license services is to be avoided using spectrum sensing with a white-space device. In this case, the white-space device can only transmit its own signal on the license band if the result of spectrum sensing is idle; collision avoidance between the licensed system and white-space device can subsequently be achieved in the temporal, spatial, and/or spectral domains. This concept is device-driven with respect to interference avoidance; therefore, it is important to detect the idle channel with high accuracy for the protection of licensed services. However, the radio regulations defined by organizations such as the FCC and Ofcom set a spectrum-sharing policy independent of spectrum sensing, caused by poor performance of spectrum sensing in low-SNR regions. In other words, it is difficult to protect the licensed service with satisfactory accuracy using spectrum sensing. The FCC and Ofcom offer an outline for a possible alternative, interference management by geolocation database [1, 2]. The geolocation database stores and relays geographical radio information and is

expected to achieve interference avoidance influenced by probabilistic behavior of the wireless channel. Database-driven spectrum sharing has attracted attention as an alternative solution with satisfactory accuracy.

In spectrum sharing assisted by geolocation database, a white-space device queries the database with its own parameters and current location to determine the availability of communication over the licensed band. The geolocation database responds with the allowable transmission parameters, such as the available channel list in the FCC rule or the maximum transmit power in the Ofcom rule. This response is derived from the database information and the specified parameter of the white-space device based on the utilization rule. The white-space device begins transmitting signals over the licensed band according to the database response. In other words, the interference toward licensed system is managed by the database response. The rules for management of harmful interference is divided into two categories: channel allocation and power allocation. The FCC rule is a channel-allocation type, in which white-space devices coexist with Digital TV systems and other white-space devices by utilizing the channel provided by database response. On the other hand, the Ofcom rule is a power-allocation type. Critical interference can be avoided by suppression of the maximum transmit power. The major difference between the FCC and Ofcom rules is the design of the database response as a policy for interference avoidance.

This section summarizes the concept of the geolocation database required by FCC and Ofcom rules, for clarity of the measurement-based spectrum database.

Radio Propagation Prediction from Empirical Model

A common feature of geolocation and measurement-based spectrum databases is the storage of radio environment information such as the transmitter position and received signal power from each transmitter to any location within each channel. The main information consists of the propagation loss and the transmitter and receiver locations. In other words, the performance of the geolocation database is dependent on the accuracy of the propagation loss prediction. In traditional wireless communications, channel prediction is a major topic for system design in terms of transmitter geometry, coverage size, and system capacity under performance constraints. Various empirical propagation models have been proposed, for example, the Okumura model [6], Hata model [7], and COST Hata model [8]. These empirical models are derived from enormous propagation data collected from urban, suburban, and rural areas.

The main purpose of deriving empirical models is to construct a versatile model with low error from the actual values in a real environment. In order to achieve a versatile model, measurement data is obtained from a wide area, and the impact of a site's specific character is suppressed by mean reversion. However, measurement data from an oversized area leads to an increase in the error between the predicted and actual values. The radio environment, as typified by propagation loss, is referenced from surrounding environments, such as geography and aboveground

structures. The empirical model predicts the relationship among the received signal power and the typical feature quantities in urban, suburban, and rural areas. The predicted value from the above empirical model is different from the actual value averaged over a short term. This residual error is called the shadowing factor and also indicates a unique characteristic at the specific location. With regard to accuracy, it is better to confine the measurement area to model the propagation loss, although collection and utilization of small measurements or specific area data cause a lack of versatility of the propagation model. Therefore, the empirical propagation model creates a dilemma for versatile prediction with high accuracy.

The geolocation database utilizes one of the above types of empirical propagation model for signal prediction. However, this does not mean that the geolocation database provides the licensed signal power at every location. Generally, the edge of service coverage for each transmitter is calculated in the geolocation database, as illustrated in Fig. 1. Nevertheless, it is not always possible to predict every location with high accuracy using the geolocation database. In order to avoid harmful interference due to prediction error, a protective margin is added to the calculated service coverage.

Protection of the licensed system often requires maintaining a signal-to-interference ratio (SIR) of the licensed receiver above the threshold demanded by the licensed system. In spectrum sharing, there could be two causes of situations in which there is harmful interference toward the licensed system. The first is the overestimation of the licensed signal power at the coverage edge. The other is the underestimation of the interference from the white-space device. To mitigate the former risk, licensed signal prediction must avoid overestimation by setting a protective margin. In particular, service coverage is extended from the estimated edge by the margin distance. This is expected to prevent regional overestimation of the weak signal area due to the shadowing effect and to attenuate harmful interference received within the true service coverage. However, the prediction error of the regional area in the geolocation database leads to the degradation of spectral efficiency in the spatial domain.

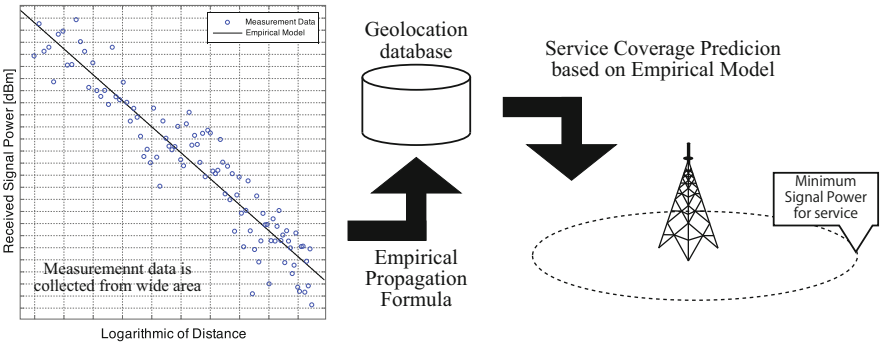

Fig. 1 Signal prediction from empirical propagation formula

Available White Space

As mentioned in section "Radio Propagation Prediction from Empirical Model", the licensed signal is predicted based on the empirical model. Similarly, the transmitted signal from the white-space device, or the harmful interference, is predicted through the empirical model. In fact, different empirical propagation models of the licensed system are often used for white-space devices because of the different system parameters. In the geolocation database, the boundaries of two kinds of wireless signal are obtained through prediction of the signal. The response of the geolocation database is also obtained from these prediction results.

In order to find the available white space, the transmit parameters that satisfy the relative position of the two boundaries are calculated. The relationship between the two boundaries is divided into two cases: overlapping and non-overlapping. As shown Fig. 2a, two boundaries are crossed, and the white-space device interferes with the receiver of the licensed system. If the SIR at the edge of licensed coverage exceeds the lower limit of the SIR requirement, then the white-space device cannot transmit its own signal. In other words, there is no available white space for spectrum sharing in Fig. 2a. The geolocation database derives the transmit parameters of the white-space device from these geographical results.

Because Ofcom's database is power-allocation type, the maximum transmit power of the white-space device is decreased from Fig. 2a. With decreasing transmit power, the interference area decreases to eliminate overlap with the service coverage of the licensed system, as shown in Fig. 2b. On the other hand, the FCC uses a channel-allocation database. This database searches the channels that satisfy the non-overlap condition between the licensed coverage and interference area by changing the channel, as shown in Fig. 2c. After that, the database responds with the solution parameters under the geographical constraint, which is the non-overlapping case with the white-space device. The FCC database responds with the available channel list, and the Ofcom database responds with the maximum transmit power of the white-space device.

Measurement-Based Spectrum Database

The spectrum database facilitates users to acquire global knowledge of surrounding radio environment. However, many databases that are under consideration for practical use including FCC-defined spectrum database are constructed based on a path loss model. Such a path loss model cannot take into account the effect of shadowing sufficiently, often a large estimation error occurs in the path loss-based spectrum database. Therefore, SUs is required to set a large interference margin. In addition, although there are complex models that consider a larger number of variables (i.e., terrain models), these models do not necessarily make better predictions [9].

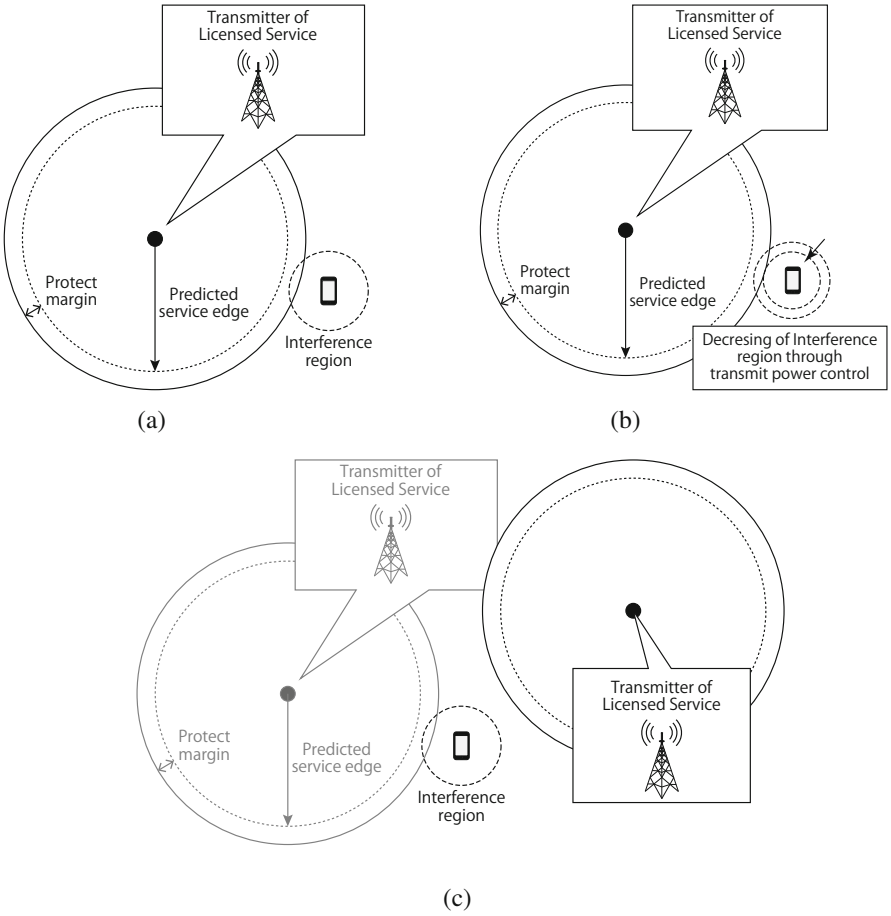

Fig. 2 Relationship between licensed system and white-space device. (**a**) Interfering case. (**b**) Availability case by controlling transmit power. (**c**) Availability case by changing channel

On the other hand, the accuracy of the spectrum database can be improved via actually measured information of the radio environment. Figure 3 shows a concept of measurement-based spectrum database. The database is a hybrid system, combining spectrum sensing and a spectrum database. The spectrum database consists of radio environment information that is measured by SUs (e.g., highly accurate spectrum analyzer, smartphones, and vehicles). The collected dataset is related to the measurement location and is reported to the database. After enough data are gathered, the database estimates the radio environment characteristics of the PUs by statistical processing with the large created dataset. Because the data include actual propagation losses and shadowing effects, accurate channel statuses can be determined.

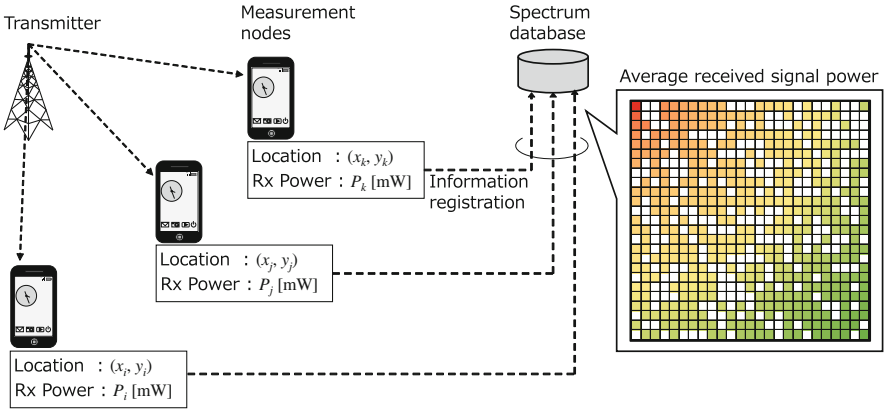

Fig. 3 Measurement-based spectrum database

In this section, we summarize basics of statistical analysis of radio environment based on the actual observation. We especially focus on the map of average received signal power, often called *Radio Environment Map* (REM), for a fixed transmitter such as TV broadcaster and cellular base station.

Geostatistics for Radio Environment Analysis

Overview of Spatial Interpolation in Wireless Communications

In the frequency reuse over the spatial domain, such as in cellular systems and spectrum sharing over TVWS, the average received signal power and communication coverage are important factors for appropriate interference management between transmitters. The measurement-based spectrum database can accurately estimate the information via the map of the average received signal power, often called REM. In this section, we introduce the fundamentals of map cartography.

In wireless communications, the instantaneous received signal power from a transmitter is often modeled as

$$\begin{aligned} P_{\mathrm{Rx}}(\boldsymbol{x}) &= P_{\mathrm{Tx}} - 10\eta \log_{10} ||\boldsymbol{x}_{\mathrm{Tx}} - \boldsymbol{x}|| + W(\boldsymbol{x}) + F \quad [\mathrm{dBm}] \\ &= \overline{P}_{\mathrm{Rx}}(\boldsymbol{x}) + F, \end{aligned} \tag{1}$$

where $\boldsymbol{x}$ is the receiver location, $\boldsymbol{x}_{\mathrm{Tx}}$ is the transmitter location, P_{Tx} [dBm] is the transmission power, η is the path loss index, W [dB] is the log-normal shadowing with zero mean and standard deviation σ [dB], and F [dB] is the effect of multipath fading. Because the communication coverage depends on $\overline{P}_{\mathrm{Rx}}(\boldsymbol{x})$ and the value is uniquely determined by the receiver location, the main task of the map is to provide $\overline{P}_{\mathrm{Rx}}(\boldsymbol{x})$ accurately.

When the database collects radio environment information measured by mobile terminals, as shown in Fig. 3, the database consists of instantaneous received signal power, including the multipath fading factor F. In order to obtain $\overline{P}_{\mathrm{Rx}}$, the measurement area is divided into a square grid with a side length of a few meters, and the instantaneous information is averaged in each grid. Here, by only averaging such datasets, the tooth missing map can be obtained, as shown on the right side of Fig. 3. Therefore, after averaging, we need to consider the interpolation of the tooth missing information.

The spatial interpolation can be implemented by considering the spatial correlation of shadowing. It is empirically known that shadowing has a spatial correlation that follows the function [10]

$$\begin{aligned}\rho_{i,j} &= \frac{\mathrm{E}\left[W(\boldsymbol{x}_i)W(\boldsymbol{x}_j)\right]}{\sigma_i \sigma_j} \\ &\approx \exp\left(-\frac{||\boldsymbol{x}_i - \boldsymbol{x}_j||}{d_{\mathrm{cor}}}\ln 2\right),\end{aligned} \tag{2}$$

where d_{cor} [m] is the correlation distance. Therefore, by taking the weighted average shown in the following equation and assigning suitable weight factors, we can implement a highly accurate spatial interpolation:

$$\hat{Z}(\boldsymbol{x}_0) = \sum_{i=1}^{N} \omega_i Z(\boldsymbol{x}_i), \tag{3}$$

where Z is a random variable, N is the number of datasets, $\boldsymbol{x}_0$ is the interpolated location, $\boldsymbol{x}_i$ is the measured location, and ω_i is the weight factor multiplied to $Z(\boldsymbol{x}_i)$. Intuitively, by assigning a high weight factor for nearby datasets and a small weight factor for distant datasets, an accurate interpolation will be performed. Estimation problems for such spatially random variables have been established in the field of geostatistics (see [11, 12]), and recent works show the effects in the field of wireless communications [3].

Inverse distance weighting (IDW) is the simplest technique for spatial interpolation. This method designs ω_i according to the inverse of the distance from the interpolation point to the pth power, and ω_i is calculated by the following equation:

$$\omega_i = \frac{1}{\sum_{j=1}^{N} ||\boldsymbol{x}_0 - \boldsymbol{x}_j||^p} \cdot \frac{1}{||\boldsymbol{x}_0 - \boldsymbol{x}_i||^p}. \tag{4}$$

Generally, a value of about 1–2 is set for p. However, because IDW produces a constant weight factor for a certain distance regardless of the spatial correlation characteristics of the random variable, its guideline leaves room for consideration.

On the other hand, *Kriging* determines the optimum weights that minimize the variance of the estimation error.

$$\sigma_k^2 = \mathrm{Var}\left[\hat{Z}(\boldsymbol{x}_0) - Z(\boldsymbol{x}_0)\right] \tag{5}$$

In the following section, we describe the procedure of the Kriging interpolation. After semivariogram modeling and ordinary Kriging are explained for a general random variable Z, we show the procedure for map cartography in wireless systems.

Semivariogram

Kriging methods are subdivided on the basis of the decision rule of ω_i and assumptions about Z, but all the methods must preliminarily estimate the spatial-covariance structure of the random process from the datasets.

In the field of geostatistics, the semivariogram is used for the analysis of the spatial-covariance structure, which is the semivariance of the difference of all pairs of points $Z(\boldsymbol{x}_i)$ and $Z(\boldsymbol{x}_j)$ at distance $\boldsymbol{h} \triangleq ||\boldsymbol{x}_i - \boldsymbol{x}_j||$,

$$\gamma(\boldsymbol{h}) = \frac{1}{2}\mathrm{Var}[Z(\boldsymbol{x}_i) - Z(\boldsymbol{x}_j)]. \tag{6}$$

The semivariogram allows the influence of a spatially varying mean to be filtered for sufficient small distances and does not depend on the mean of the field when the mean is constant:

$$\mathrm{Var}\left[Z(\boldsymbol{x}_i) - Z(\boldsymbol{x}_j)\right] = \mathrm{E}\left[\left(Z(\boldsymbol{x}_i) - Z(\boldsymbol{x}_j)\right)^2\right]. \tag{7}$$

To obtain the semivariogram in the measurement area, it is necessary to estimate the empirical semivariogram from the available data. Under the assumption of a constant mean, a natural estimator based on the method of moments can be written as

$$\hat{\gamma}(\boldsymbol{h}) = \frac{1}{2|N(\boldsymbol{h})|}\sum_{N(\boldsymbol{h})}\left\{Z(\boldsymbol{x}_i) - Z(\boldsymbol{x}_j)\right\}^2, \tag{8}$$

where $N(\boldsymbol{h})$ denotes the set of nodes that are separated by a distance $\boldsymbol{h}$. Note that this averaging procedure is called *binning*. Once $\hat{\gamma}(\cdot)$ has been estimated, it must be fitted into a theoretical semivariogram model. Table 1 summarizes the major theoretical semivariogram models. Here, τ^2, $\tau^2+\sigma^2$, σ^2, and $1/\phi$ are called *nugget*, *sill*, *partial-sill*, and *range*, respectively. Examples of the theoretical semivariogram models are shown in Fig. 4. In wireless communications, because the shadowing correlation follows the exponential function shown in Eq. (2), the exponential model is often chosen as the theoretical model.

Figure 5 draws an example of semivariogram modeling. All of $\{Z(\boldsymbol{x}_i) - Z(\boldsymbol{x}_j)\}^2/2$, called *variogram cloud*, are plotted in Fig. 5a. As shown in Fig. 5b, after the semivariograms are averaged over a given interval, the theoretical semivariogram can be fitted. Here, because $N(\boldsymbol{h})$ becomes smaller as $||\boldsymbol{h}||$ becomes larger, there is a problem in which the averaged semivariogram is used for curve fitting. This is generally determined by trial and error, and Cressie introduces a practical

Table 1 Examples of theoretical semivariogram models

Model	Equation
Linear	$\gamma(\boldsymbol{h}) = \begin{cases} \tau^2 + \sigma^2 \|\|\boldsymbol{h}\|\| & \text{if } \|\|\boldsymbol{h}\|\| > 0 \\ 0 & \text{otherwise} \end{cases}$
Spherical	$\gamma(\boldsymbol{h}) = \begin{cases} \tau^2 + \sigma^2 & \text{if } \|\|\boldsymbol{h}\|\| > 1/\phi \\ \tau^2 + \sigma^2 \left\{ \frac{3}{2}\phi \|\|\boldsymbol{h}\|\| - \frac{1}{2} (\phi \|\|\boldsymbol{h}\|\|)^3 \right\} & \text{if } 0 < \|\|\boldsymbol{h}\|\| < 1/\phi \\ 0 & \text{otherwise} \end{cases}$
Exponential	$\gamma(\boldsymbol{h}) = \begin{cases} \tau^2 + \sigma^2 \{1 - \exp(-\phi \|\|\boldsymbol{h}\|\|)\} & \text{if } \|\|\boldsymbol{h}\|\| > 0 \\ 0 & \text{otherwise} \end{cases}$
Gaussian	$\gamma(\boldsymbol{h}) = \begin{cases} \tau^2 + \sigma^2 \{1 - \exp(-\phi^2 \|\|\boldsymbol{h}^2\|\|)\} & \text{if } \|\|\boldsymbol{h}\|\| > 0 \\ 0 & \text{otherwise} \end{cases}$

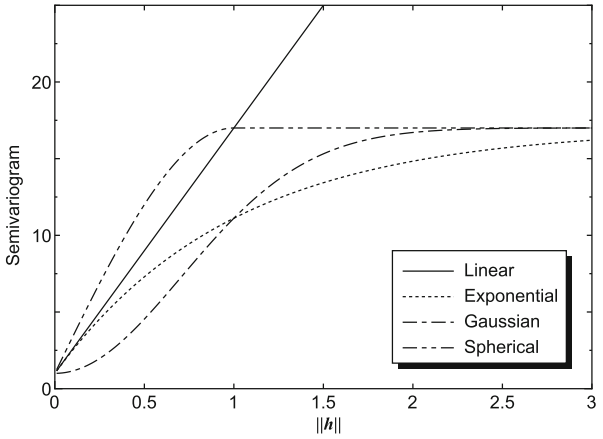

Fig. 4 Examples of theoretical semivariogram where $\tau = 1.0$, $\sigma = 4.0$ and $\phi = 1.0$

rule: the averaged semivariogram, in which $N(\boldsymbol{h}) > 30$ and $||\boldsymbol{h}||$ are smaller than the maximum $||\boldsymbol{h}||$, is used for curve fitting, as a guideline [13].

Ordinary Kriging

Ordinary Kriging is assumed to be constrained in the local neighborhood of each estimation point, i.e., $\mathrm{E}[Z(\boldsymbol{x})] = const.$ for each nearby data value. In order to achieve the best linear unbiased estimator (BLUE), this method determines the weights that minimize the variance of the estimation error $\sigma_k^2 = \mathrm{E}[\{\hat{Z}(\boldsymbol{x}_0) - Z(\boldsymbol{x}_0)\}^2]$ under the condition

$$\sum_{i=1}^{N} \omega_i = 1. \tag{9}$$

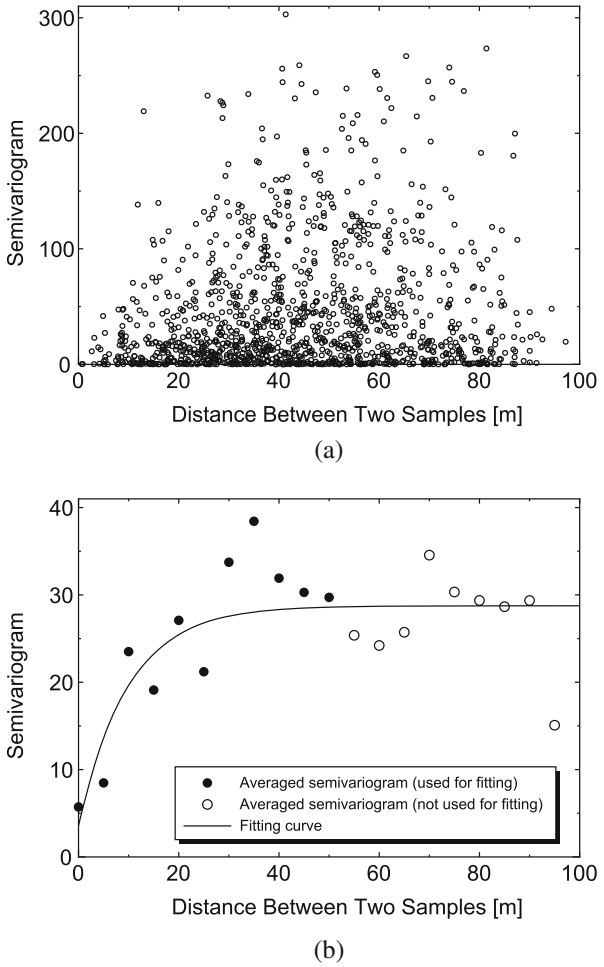

Fig. 5 Example of semivariogram modeling. (**a**) Variogram cloud. (**b**) Averaged variogram and estimated curve

This constraint can be derived from the condition of unbiased estimation,

$$\mathrm{E}\left[\hat{Z}(\boldsymbol{x}_0) - Z(\boldsymbol{x}_0)\right] = 0. \tag{10}$$

Using the Lagrange multiplier method, the objective function $\phi(\omega_i, \mu)$ can be written as

$$\phi(\omega_i, \mu) = \sigma_k^2 - 2\mu\left(\sum_{i=1}^{N}\omega_i - 1\right), \tag{11}$$

where μ is the Lagrange multiplier. Here, σ_k^2 can be written as the following equation:

$$\sigma_k^2 = -\gamma(d_{0,0}) - \sum_{i=1}^{N}\sum_{j=1}^{N}\omega_i\omega_j\gamma(d_{i,j}) + 2\sum_{i=1}^{N}\omega_i\gamma(d_{i,0}), \tag{12}$$

where $d_{i,j} \triangleq ||\boldsymbol{x}_i - \boldsymbol{x}_j||$.

From the partial derivatives in Eq. (12), we can obtain $N + 1$ simultaneous equations

$$\begin{pmatrix} \gamma(d_{1,1}) & \cdots & \gamma(d_{1,N}) & 1 \\ \gamma(d_{2,1}) & \cdots & \gamma(d_{2,N}) & 1 \\ \vdots & \vdots & \vdots & \vdots \\ \gamma(d_{N,1}) & \cdots & \gamma(d_{N,N}) & 1 \\ 1 & \cdots & 1 & 0 \end{pmatrix} \begin{pmatrix} \omega_1 \\ \omega_2 \\ \vdots \\ \omega_N \\ \mu \end{pmatrix} = \begin{pmatrix} \gamma(d_{1,0}) \\ \gamma(d_{2,0}) \\ \vdots \\ \gamma(d_{N,0}) \\ 1 \end{pmatrix}. \tag{13}$$

From the above simultaneous equations, the weights that minimize σ_k^2 can be derived. Here, the minimized σ_k^2 is called the *Kriging variance*, and σ_k is called the *Kriging standard deviation*.

Procedure for Received Signal Power Estimation

Both semivariogram modeling and ordinary Kriging shown above assume $\mathrm{E}[Z(\boldsymbol{x})] = const.$ for each nearby data value. On the other hand, $\mathrm{E}[P_{\mathrm{Rx}}(\boldsymbol{x})]$ is not constant because of the effect of path loss $10\eta\log_{10}||\boldsymbol{x}_{\mathrm{Tx}} - \boldsymbol{x}||$: such a location dependence is called a *trend* in the geostatistics. A way to consider the dependence is the use of *universal Kriging* (see [11]). If we apply ordinary Kriging for the map cartography, in a precise sense, the path loss modeling and the shadowing estimation should be separated as follows.

1. Path loss factor η and transmission power P_{Tx} are estimated from the dataset with a traditional method for path loss modeling such as the least squares (LS) method. Then, each shadowing factor is extracted via

$$\hat{W}(\boldsymbol{x}_i) = P_{\mathrm{Rx}}(\boldsymbol{x}_i) - \hat{P}_{\mathrm{Tx}} - 10\hat{\eta}\log_{10}||\boldsymbol{x}_{\mathrm{Tx}} - \boldsymbol{x}_i||, \tag{14}$$

   where $\hat{\eta}$ is the estimated path loss factor and $\hat{P}_{\mathrm{Tx}}$ is the estimated transmission power.
2. The variogram cloud between $\hat{W}(\boldsymbol{x}_i)$ is generated.
3. The theoretical semivariogram is fitted to the variogram cloud.

4. The weight factor ω_i is calculated via ordinary Kriging.
5. $P_{\mathrm{Rx}}(\boldsymbol{x}_0)$ is interpolated by

$$\hat{P}_{\mathrm{Rx}}(\boldsymbol{x}_0) = \hat{P}_{\mathrm{Tx}} - 10\hat{\eta}\log_{10}||\boldsymbol{x}_{\mathrm{Tx}} - \boldsymbol{x}_0|| + \sum_{i=1}^{N} \omega_i \hat{W}(\boldsymbol{x}_i). \tag{15}$$

Note that some works show that we can perform an accurate interpolation even when the semivariogram analysis and ordinary Kriging are applied directly to $P_{\mathrm{Rx}}(\boldsymbol{x}_i)$ [3, 14]. This is because the fluctuation of the path loss is gradual in the area away from the transmitter.

Here, Kriging has a powerful property: the statistical performance of the estimation error $\{\hat{Z}(\boldsymbol{x}_0) - Z(\boldsymbol{x}_0)\}$ can be roughly estimated via the Kriging standard deviation σ_k. If the random variable Z spatially fluctuates with a Gaussian process, the estimation error follows a Gaussian distribution. This behavior can be applied to typical radio propagation because the shadowing follows a logarithmic Gaussian process. Because this interpolation procedure achieves unbiased estimation, we can estimate that the error $\hat{P}_{\mathrm{Rx}}(\boldsymbol{x}_0) - P_{\mathrm{Rx}}(\boldsymbol{x}_0)$ nearly follows a log-normal distribution with mean 0 [dB] and standard deviation σ_k [dB] (Kriging standard deviation means the standard deviation of the estimation error under the perfect semivariogram modeling. Because the semivariogram is modeled from datasets, the true estimation error exceeds σ_k. Therefore, the upper bound of $\mathrm{E}[\sigma_k]$ is equal to the standard deviation of the estimation error [11]).

Effect of Measurement-Based Spectrum Database on Spectrum Sharing

Let us discuss the effect of the knowledge of radio propagation information on spectrum sharing from a theoretical perspective. Now, we consider a typical spectrum-sharing environment in which a secondary transmitter shares a spectrum with a primary link, as shown in Fig. 6. To evaluate the spectrum-sharing efficiency, we calculate the allowable transmission power at the secondary transmitter under given channel information. Note that the following discussion does not consider the knowledge of instantaneous multipath fading gain: the SU only knows the path loss gain and shadowing gain. This is because the acquisition of the instantaneous factor requires some feedback from the primary receiver. On the other hand, in spectrum sharing with legacy wireless systems, such feedback is *not* a realistic

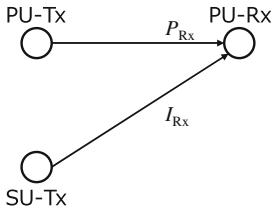

Fig. 6 Spectrum-sharing model

assumption. Aiming for the improvement of spectrum-sharing efficiency in the legacy systems, this section considers the case with no instantaneous feedback from the PUs.

Spectrum-Sharing Model

First, P_{Rx} [dBm] is defined as the received signal power at the primary receiver PU-Rx from the primary transmitter PU-Tx. We assume the value fluctuates according to the path loss and the log-normal shadowing, as follows:

$$P_{\mathrm{Rx}} = P_{\mathrm{P,\,Tx}} - L_{\mathrm{P}} + W_{\mathrm{P}} \quad [\mathrm{dBm}] \tag{16}$$

$$\triangleq \overline{P}_{\mathrm{Rx}} + W_{\mathrm{P}}, \tag{17}$$

where $P_{\mathrm{P,\,Tx}}$ [dBm] is the transmission power at PU-Tx, L_{P} [dB] is the path loss in the primary link, and W_{P} [dBm] is the shadowing gain following an i.i.d. log-normal distribution with zero mean and standard deviation σ_{P} [dB].

Next, we assume that SU-Tx interferes with PU-Rx with the following power:

$$I_{\mathrm{Rx}} = P_{\mathrm{S,\,Tx}} - L_{\mathrm{S}} + W_{\mathrm{S}} \quad [\mathrm{dBm}] \tag{18}$$

$$\triangleq \overline{I}_{\mathrm{Rx}} + W_{\mathrm{S}}, \tag{19}$$

where $P_{\mathrm{S,\,Tx}}$ is the transmission power at SU-Tx, L_{S} is the path loss in the interference link, and W_{S} is the shadowing gain. W_{S} follows an i.i.d. normal distribution with zero mean and standard deviation σ_{S} [dB] and is statistically independent from W_{P}. Under the above conditions, we utilize the SIR as the protection criterion for primary communication according to a typical rule of spectrum sharing. Here, the SIR at PU-Rx can be written as

$$\Gamma = P_{\mathrm{Rx}} - I_{\mathrm{Rx}} \quad [\mathrm{dB}]. \tag{20}$$

If the PU determines the desired SIR as Γ_{d} [dB], the outage event can be formulated as $\Gamma_{\mathrm{d}} > \Gamma$. Thus, considering the desired protection probability $1 - p_{\mathrm{out}}$, the SU must satisfy the protection probability at PU-Rx, given by the following equation:

$$\Pr[\Gamma \geq \Gamma_{\mathrm{d}}] \geq 1 - p_{\mathrm{out}}. \tag{21}$$

Using the channel information in both the primary link and the interference link, SU-Tx estimates the maximum transmission power

$$\max P_{\mathrm{S,\,Tx}} \triangleq P_{\mathrm{S,\,max}} \quad [\mathrm{dBm}], \tag{22}$$

which is subject to Eq. (21). We analyze the performance of the maximum transmission power under two conditions: P_{Rx} can be estimated via the measurement-based

spectrum database, and only $\overline{P}_{\mathrm{Rx}}$ and σ_{P} can be estimated. For simplicity, we assume that both of the conditions only include information on L_{S} and σ_{S} for the interference link.

Error Characteristics of Geostatistics-Assisted Radio Propagation Estimation

Before discussing the performance of the database-assisted spectrum sharing, we model the error characteristics of the geostatistical radio propagation estimation. Let us define $\hat{P}_{\mathrm{Rx}}$ [dBm] as the estimated values for P_{Rx}. By introducing the error factor ε_{P} [dB], the relationship between the estimated and true values can be written as

$$\begin{aligned}\hat{P}_{\mathrm{Rx}} &= P_{\mathrm{Rx}} - \varepsilon_{\mathrm{P}} \\ &= \left(\overline{P}_{\mathrm{Rx}} + W_{\mathrm{P}}\right) - \varepsilon_{\mathrm{P}}.\end{aligned} \tag{23}$$

We assume that $\hat{P}_{\mathrm{Rx}}$ is estimated by the Kriging-based database construction. As mentioned in section "Procedure for Received Signal Power Estimation", if the received signal power follows a log-normal distribution, the estimation error follows a log-normal distribution with median zero [dB]. Because the estimated and true values are highly correlated in the log domain, P_{Rx} and $\hat{P}_{\mathrm{Rx}}$ follow a bivariate normal distribution with median $\overline{P}_{\mathrm{Rx}}$ and covariance matrix

$$\begin{pmatrix} \sigma_{\mathrm{P}}^2 & \rho_{\mathrm{P}}\sigma_{\mathrm{P}}\sigma_{\hat{P}_{\mathrm{Rx}}} \\ \rho_{\mathrm{P}}\sigma_{\hat{P}_{\mathrm{Rx}}}\sigma_{\mathrm{P}} & \sigma_{\hat{P}_{\mathrm{Rx}}}^2 \end{pmatrix}, \tag{24}$$

where σ_{P} [dB] is the standard deviation of W_{P}, $\sigma_{\hat{P}_{\mathrm{Rx}}}$ is the standard deviation of $\hat{P}_{\mathrm{Rx}}$, and ρ_{P} is the correlation coefficient between P_{Rx} and $\hat{P}_{\mathrm{Rx}}$. The PDF of $\varepsilon_{\mathrm{P}} = P_{\mathrm{Rx}} - \hat{P}_{\mathrm{Rx}}$ can be derived from the bivariate normal distribution. Because ε_{P} consists of the difference between two variables following a bivariate normal distribution and Kriging can perform unbiased estimation, ε_{P} also follows a log-normal distribution with median zero. In addition, its variance can be calculated by

$$\sigma_{\varepsilon_{\mathrm{P}}}^2 = \sigma_{\mathrm{P}}^2 + \sigma_{\hat{P}_{\mathrm{Rx}}}^2 - 2\rho_{\mathrm{P}}\sigma_{\mathrm{P}}\sigma_{\hat{P}_{\mathrm{Rx}}}. \tag{25}$$

For simplicity, we approximate $\sigma_{\hat{P}_{\mathrm{Rx}}}$ by σ_{P}. From this relationship, $\sigma_{\varepsilon_{\mathrm{P}}}^2$ can be derived as

$$\sigma_{\varepsilon_{\mathrm{P}}}^2 \approx 2\sigma_{\mathrm{P}}^2\left(1 - \rho_{\mathrm{P}}\right). \tag{26}$$

Using these characteristics, we can easily emulate the Kriging-based radio propagation estimation by σ_{P} and ρ_{P}. Note that ρ_{P} strongly depends on the estimation conditions, such as the number of datasets and the correlation distance of the shadowing. In addition, $\sigma_{\varepsilon_{\mathrm{P}}}^2$ can be directly estimated from the Kriging variance σ_k^2.

Performance of Spectrum-Sharing Capability

According to the error characteristics mentioned above, we derive the allowable transmission power of SU-Tx $P_{\mathrm{S,max}}$ that satisfies the interference constraint defined in Eq. (21).

First, for the comparison, we derive the allowed transmission power when the SU-Tx only knows $\overline{P}_{\mathrm{Rx}}$ and σ_{P}. In this situation, the SIR follows a log-normal distribution with a median $\overline{P}_{\mathrm{Rx}}-\overline{I}_{\mathrm{Rx}}$ and a standard deviation $\sqrt{\sigma_{\mathrm{P}}^2+\sigma_{\mathrm{S}}^2}$. Therefore, its cumulative distribution function (CDF) can be formulated as

$$F_{\Gamma}(\Gamma_{\mathrm{d}}|\overline{P}_{\mathrm{Rx}},L_{\mathrm{S}}) = \frac{1}{2}\left\{1+\mathrm{erf}\left(\frac{\Gamma_{\mathrm{d}}-\left(\overline{P}_{\mathrm{Rx}}-\overline{I}_{\mathrm{max}}\right)}{\sqrt{2\left(\sigma_{\mathrm{P}}^2+\sigma_{\mathrm{S}}^2\right)}}\right)\right\} \tag{27}$$

$$= p_{\mathrm{out}}, \tag{28}$$

where $\mathrm{erf}(\cdot)$ is the error function and $\overline{I}_{\mathrm{max}} \triangleq P_{\mathrm{S,\,max}} - L_{\mathrm{S}}$ is the median of the allowed interference power. Therefore, the allowed transmission power can be determined by

$$\begin{aligned} P_{\mathrm{S,\,max}} &= L_{\mathrm{S}} + \overline{I}_{\mathrm{max}} \\ &= L_{\mathrm{S}} + \overline{P}_{\mathrm{Rx}} - \Gamma_{\mathrm{d}} - \sqrt{2(\sigma_{\mathrm{P}}^2+\sigma_{\mathrm{S}}^2)}\mathrm{erf}^{-1}(1-2p_{\mathrm{out}}), \end{aligned} \tag{29}$$

where $\mathrm{erf}^{-1}(\cdot)$ is the inverse error function.

Next, we evaluate the performance in which the SU-Tx can estimate the signal power P_{Rx} via the measurement-based spectrum database. Because the SU-Tx knows $\hat{P}_{\mathrm{Rx}}$ and $\overline{I}_{\mathrm{Rx}}$, the SIR $\Gamma = (\hat{P}_{\mathrm{Rx}}+\varepsilon_{\mathrm{P}})-I_{\mathrm{Rx}}$ follows a log-normal distribution with median $\hat{P}_{\mathrm{Rx}} - \overline{I}_{\mathrm{Rx}}$ and standard deviation $\sqrt{\sigma_{\varepsilon_{\mathrm{P}}}^2+\sigma_{\mathrm{S}}^2}$. Thus, based on the condition of $P_{\mathrm{S,\,max}}$, we can formulate the CDF of the SIR as

$$F_{\Gamma}(\Gamma_{\mathrm{d}}|\hat{P}_{\mathrm{Rx}},L_{\mathrm{S}}) = \frac{1}{2}\left\{1+\mathrm{erf}\left(\frac{\Gamma_{\mathrm{d}}-\left(\hat{P}_{\mathrm{Rx}}-\overline{I}_{\mathrm{max}}\right)}{\sqrt{2\left(\sigma_{\varepsilon_{\mathrm{P}}}^2+\sigma_{\mathrm{S}}^2\right)}}\right)\right\} \tag{30}$$

$$= p_{\mathrm{out}}. \tag{31}$$

Therefore, $\overline{I}_{\mathrm{max}}$ can be formulated as

$$P_{\mathrm{S,\,max}} = L_{\mathrm{S}} + \hat{P}_{\mathrm{Rx}} - \Gamma_{\mathrm{d}} - \sqrt{2\left(\sigma_{\varepsilon_{\mathrm{P}}}^2+\sigma_{\mathrm{S}}^2\right)}\mathrm{erf}^{-1}(1-2p_{\mathrm{out}}). \tag{32}$$

A numerical example is shown in Fig. 7. If the SU-Tx only knows $\overline{P}_{\mathrm{Rx}}$ and σ_{P}, the spectrum-sharing opportunity decreases in proportion to the intensity of the shadowing variation. The measurement-based spectrum database can improve performance, although $\hat{P}_{\mathrm{Rx}}$ has an estimation error.

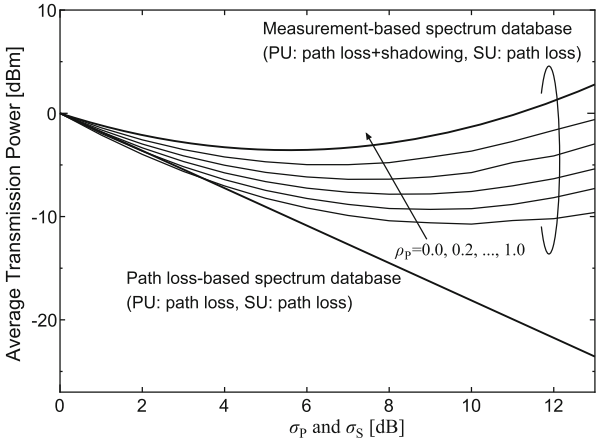

Fig. 7 Effects of channel state information on average transmission power where $p_{\text{out}} = 0.10$, $\Gamma_{\text{d}} = 10$ [dB], $L_{\text{S}} = 100.0$ [dB], and $\overline{P}_{\text{Rx}} = -90.0$ [dBm]

Future Smart Spectrum World

Spectrum Allocation Policy and Smart Spectrum

In the current spectrum allocation policy, International Telecommunication Union Radiocommunication Sector (ITU-R) decides the global spectrum allocation policy, and the detailed spectrum utilization is allocated in each country by a spectrum regulator, such as the FCC in the USA, Ofcom in the UK, and the Ministry of Internal Affairs and Communications (MIC) in Japan. Roughly speaking, spectrum allocation policies can be categorized into two types. One is "Command and Control," and the other is "Spectrum Commons." "Command and Control" is the spectrum management policy in which the regulator centrally allocates the spectrum to systems with the usage of the spectrum. Therefore, the spectrum is allocated to systems without duplication. On the other hand, "Spectrum Commons" is the spectrum-sharing method in which the users access the spectrum in a distributed manner. The Industry, Science, and Medical radio (ISM) band is a spectrum managed by a "Spectrum Commons" policy. "Command and Control" can exclusively allocate the spectrum to a certain system to avoid intersystem interference. Currently, almost all licensed spectra are exclusively allocated to the system. However, exclusive allocation may reduce the spectrum efficiency because it is required to give a spatial margin for sharing multiple systems in the same spectrum. Moreover, even if the system does not continuously transmit radio waves due to the various traffic, such as in a public safety system, the spectrum is occupied by the primary licensed systems. Therefore, spectrum redundancy over the spatial and time domains becomes a serious problem. On the other hand, "Spectrum Commons" can utilize the spectrum based on user demand.

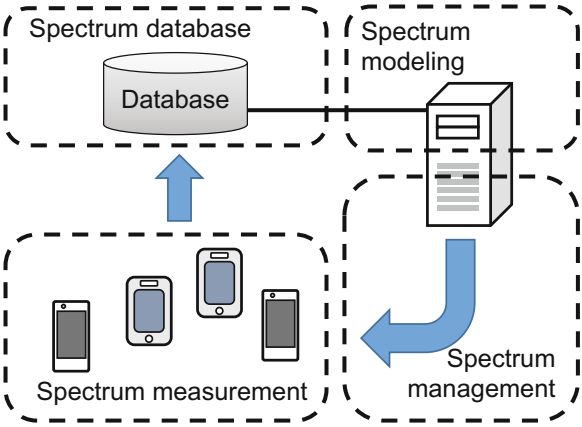

Fig. 8 Concept of smart spectrum

Currently, the listen-before-talk technique based on carrier sense function is used for wireless LANs and wireless sensor networks. However, because of its distributed control based on carrier sensing, the reliability of communication is not high. The hidden node problem and dense installed access points in the crowded area deteriorate the quality and throughput of distributed networks. In order to improve the spectrum utilization in future wireless networks, a smart-spectrum concept has been proposed [5]. The smart spectrum is a dynamic spectrum-utilization scheme based on measurement and modeling, in which on-demand spectrum allocation is applied for spectrum management. The basic issues of smart spectrum comprise four categories: spectrum measurement, modeling, database, and management, as shown in Fig. 8. The spectrum database is a key component of the smart spectrum, and the physical radio spectrum environment is projected into the spectrum database. In order to generate the spectrum database, the spectrum is modeled by gathering the results of the spectrum measurement at mobile terminals and/or measurement equipment. The spectrum allocation is managed by the spectrum manager in cooperation with the spectrum database. Therefore, the smart spectrum can utilize the spectrum according to the demand of the users by considering the exact radio environment based on spectrum efficiency and user demand.

Hierarchical Spectrum Database

The spectrum database can be used for managing the spectrum utilization of wireless systems. In a spectrum database defined by the FCC for TV white space, a simple database storing the spectrum availability according to location is installed in a large area. However, if we consider the measurement-based spectrum database, a large amount of spectrum data with locality must be registered in the database. In order to support the spectrum data with different granularities and supporting areas, the spectrum database with a hierarchical structure is considered, as shown

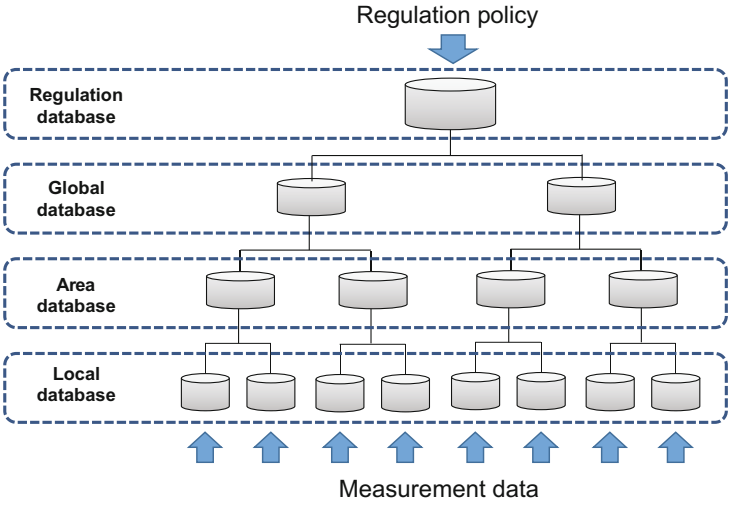

Fig. 9 Example hierarchical spectrum database

in Fig. 9 [5]. The upper layer of the hierarchical spectrum database can be used to define the spectrum regulation policy. For example, the data in this database can be registered and updated by the radio regulators of each country, like the FCC, Ofcom, and MIC. A small number of databases are prepared in each country. However, the lower layer of the hierarchical spectrum database supports a small area, and the measurement data generated by local mobile terminals can be registered. The spectrum environment of each location is managed in a distributed manner. The measurement results are statistically processed, and a self-organizing spectrum allocation according to user demand can be supported. The middle-layer databases can be used for coordinating (1) the upper layer spectrum policy and the lower-layer measurement-based spectrum environment and (2) the adjacent databases belonging to the lower layer for smooth spectrum allocation beyond the supporting area of each local database. The lowest-layer spectrum database may be located in each mobile terminal, and the spectrum database in the second-lowest layer may be located in the access point of wireless LAN systems or the base station of cellular networks.

The spectrum database can manage the spectrum of its supporting area in conjunction with spectrum servers. An example of spectrum management using the spectrum server and the spectrum database is shown in Fig. 10. The users request the spectrum by a demand of communication, such as data rate, error rate, throughput, stability, and reliability, and the available spectrum is allocated to the users with consideration for the spectrum efficiency by the spectrum manager with the spectrum database. The spectrum efficiency can be improved compared with the current fixed-allocated spectrum because on-demand spectrum allocation can be realized. In particular, the real-time spectrum status can be recognized by the measurement results, on-demand spectrum assignment with efficient spectrum-

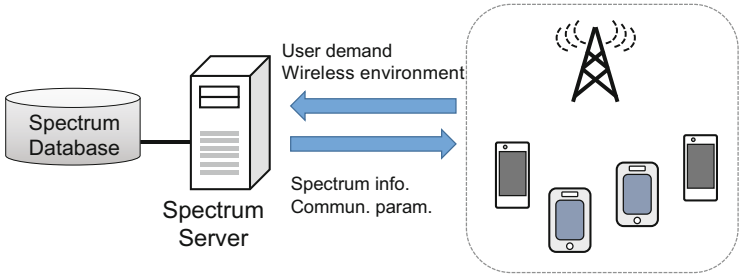

Fig. 10 Spectrum management server

sharing performance, and guaranteeing the user demand. Therefore, it can be considered that the hierarchical spectrum database with measurement results can change the current fixed-spectrum allocation policy.

In order to obtain the measurement results of the spectrum, wireless measurement equipment, like a spectrum analyzer, can be used. However, measurement equipment to gather the measurement results in every location is expensive. In order to solve the cost of measurement, crowd-sensing techniques using mobile terminals, such as smart phones, can be used. Today, the computational availability of mobile terminals increases, and multiple frequencies and systems are supported. Therefore, these terminals can be used for spectrum environment in a large area with low cost. Crowd sensing is a low-cost measurement technique and is already used for estimating the cellular performance by telecom operators [15].

Components of Smart Spectrum

Smart spectrum is a concept of dynamic spectrum management based on the measurement results from multiple terminals and statistical modeling for a future wireless world. The smart spectrum is realized by a cycle of components, which are spectrum measurement, modeling, database, and management, as shown in Fig. 8.

"Spectrum measurement" is the first step for obtaining the surrounding wireless environment. The typical measurement data is the received power of radio signals corresponding to the radio frequency. The basic technique is similar to spectrum sensing, and the following soft information is the basic measurement information for the smart spectrum.

$$P_r = \frac{1}{N} \sum_{n=1}^{N-1} |h[n]s[n] + w[n]|^2, \tag{33}$$

where $h[n]$ is the channel coefficient, $s[n]$ is the signal component, and $w[n]$ is the noise. N is the number of samples and n is the sample index. These sensed data are measured at each terminal and gathered in the spectrum database. The measurement

data can be expanded to other physical data, like angle of arrival, Doppler shift, delay spread, as well as network information, such as the number of active mobile terminals, throughput, and the location of mobile terminals.

"Spectrum modeling" is the statistical model of the measurement results for easy utilization of spectrum-sharing and reliable wireless communications. The typical statistical models are the averaged received power and the channel occupancy ratio. The averaged received power can be used for creating a spectrum map of the primary system. The channel occupancy ratio is useful for providing ON/OFF characteristics of wireless systems, like wireless LAN and other unlicensed systems. As these systems share the spectrum of the time domain, the channel occupancy ratio can be used for the basis of channel congestion for time-division spectrum sharing. In addition, the channel transition rate and the channel occupancy duration can be used for similar statistical information.

"Spectrum database" is used for storing the spectrum measurement data and modeling data for on-demand spectrum utilization. The hierarchical structure supports regulatory issues and local radio environments observed by the measurement results. The detailed structure is explained in the previous subsection.

Finally, "smart-spectrum management" is a dynamic spectrum management system according to the spectrum environment data stored in the spectrum database. On-demand spectrum allocation considering the user demand and current spectrum environment, considering spectrum efficiency, is the ultimate spectrum utilization for future wireless systems.

Case and Future Spectrum Policy Based on Smart Spectrum

Here, cases of a measurement-based spectrum database and its applications are introduced. Several reports of spectrum databases for TV white space (TVWS) have been published for estimating the area of TV broadcasting based on the measurement results [3,4]. The reference paper [3] discussed the linear interpolation technique for estimating the area of TV broadcasting by using the results of the measurement campaign in the UK. The reference paper [4] discussed the comparison with the current propagation model-based spectrum database and the measurement-based spectrum database by using the results of the measurement campaign in Japan. The accurate received power estimation performance by using the measurement-based spectrum database is confirmed. The similar idea has been considered in cellular networks for minimizing the drive test to check the communication quality in the support area using user equipment measurement logging in the 3GPP standard [15]. These cases assume that the transmitter is fixed like a TV broadcasting station and cellular base station. The measurement-based spectrum database for the distributed system has been reported for vehicle-to-vehicle (V2V) communication [16]. This database can be used for predicting the communication reliability of the intersection with many buildings in advance, and the usual broadcast-based V2V packets like IEEE 802.11p can be used as the dataset storing in the database, as shown in Fig. 11. The issue with this database is that

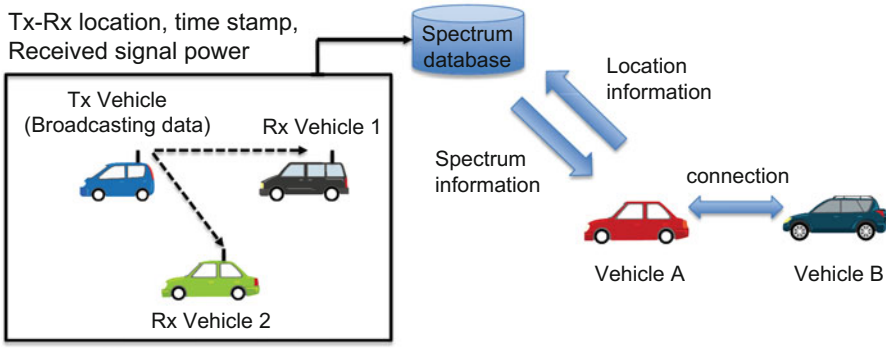

Fig. 11 Sepctrum database for V2V communication

the registered data becomes large because the database must be prepared for each transmit position. The appropriate mesh size and the database support area are important practical databases. It can be used for automated and connected vehicles with highly reliable wireless communications according to the demand.

As seen in this section, the smart spectrum can be used for smart dynamic spectrum utilization considering the local wireless environments and user demand as well as the radio regulation policy. The smart spectrum can be used not only to improve spectrum-sharing performance but also to guarantee reliable communication because the exact spectrum environment can be known at communication terminals. As a result, the current spectrum allocation policy can be changed by using smart spectrum, and a new wireless world with highly efficient spectrum use can be realized in the future.

Conclusion and Future Directions

More than 100 years, spectrum allocation regulation policy has been based on exclusive spectrum use by a primary system determined by the regulator in each country. However, exclusive spectrum use degrades the spectrum utilization efficiency due to inflexible spectrum use without considering demands of users. Cognitive radio and software defined radio technologies have possibility to change this regulation policy to more flexible spectrum use according to the demand of users. The most important issue for launching the new dynamic spectrum allocation is to recognize the exact wireless environment. Recognizing the accurate wireless environment can avoid intersystem interference with minimum spatial separation. In this chapter, we have introduced spectrum databases for providing wireless environment information to users. We have shown that the measurement-based spectrum database can improve the accuracy of the wireless environment recognition. We have also introduced the concept of smart spectrum which is a future spectrum management based on spectrum measurement, spectrum modeling,

spectrum database and smart spectrum management. By using the smart spectrum, the current exclusive spectrum allocation can be changed to on-demand spectrum allocation with highly efficient spectrum use in the future.

Contents

Abstract

Cognitive radio can be applied to a multitude of domains, one of which is M2M communication. Specifically, M2M communication refers to communication between devices without human intervention. Hence, devices should be able to organize themselves and run the communication protocol autonomously. If cognitive radio is used, tasks such as dynamic spectrum access (DSA), spectrum sensing, and alike present additional challenges compared to traditional network, as all the decision framework should be implemented and automatized in the

devices. In this chapter, we focus on DSA techniques for M2M. The main difference from other kinds of communication is relative both to the energy efficiency and to the low protocol overhead, as devices should run for long periods of time and run without human intervention. At first we present related work from literature, categorizing the different tasks devices which want to leverage DSA on M2M have to perform. At the end of the chapter, we present a proof of concept of a general framework, which can be applied to different scenario concerning M2M, encompassing all the spectrum management and measurement tasks M2M devices should generally perform. Finally, we derive open challenges and future research directions concerning this scenario.

Introduction

Machine to machine (M2M) communication refers to interactions which occur between devices with no human intervention. M2M has gained attention mostly thanks to the Internet of things (IoT) paradigm, where a multitude of devices communicate together with little to no human intervention. M2M communication inherently has such unique characteristics which differ from standard communication and is typically used on resource limited devices, hence posing additional constraints on the communication.

Over the years, many proposals, technologies, and standards have been proposed and are used to realize the M2M paradigm. However, such a plethora of different technologies also raises challenges on the interoperability and ability to communicate. The risk is to create the so-called intranet of things, or islands of things, meaning that devices are able to communicate only within the same ecosystems.

This heterogeneous scenario, in which different manufacturers and consortiums develop different technologies, is due to the extreme diverse scenario in which M2M communication can take place. These can span from healthcare scenarios, in which M2M technologies should provide reliability in the first place, to video surveillance installation, in which also the data rate is an important aspect. Productive scenario, such as predictive maintenance, often requires long operational times; hence, energy efficiency is key. All of the above has contributed in creating a vast ecosystem, in which different technologies share some characteristics and differ in other.

Besides the aforementioned scenarios, also cognitive M2M technologies can play an important role. Basically, cognitive networks sense the environment and reconfigure their communication parameters in order to better adapt to the scenario and possibly communicate. Among all the facets of cognitive networks, one of the most studied and investigated is certainly dynamic spectrum access (DSA), through which cognitive networks can transmit in the so-called spectrum holes, that is, part of the spectrum which are currently free and not occupied by others. Clearly, DSA requires extra computation on the device side, hence requiring more performing hardware and possibly reducing the energy efficiency.

In this chapter we present the different technologies, standards, and applications of M2M technologies. We also derive potential challenges and future research work on the topic.

Use Cases

In this section we review the applications that would benefit from cognitive M2M communication. In general, cognitive M2M communication helps deploying services in specific scenarios. For instance, M2M communication deployed in TVWS is beneficial for applications requiring an extended range compared to classical wireless solutions and for applications requiring good propagation through obstacles like building walls. This is especially interesting for indoor/outdoor networks, in which nodes are placed inside homes and need to communicate between each other as well as with other buildings. For instance, the new smart grid network is certainly a good representative of this category, as nodes should gather the consumptions of the home and balance the load of the network by aggregating the data coming from different sources.

Smart Grid Communication

One of the most prominent and most investigated topics regarding M2M communication in general, and specifically with TVWS, is certainly smart grid communication. Nowadays, and with a foreseen increase in presence over the next years, utility meters will be deployed in homes to report consumptions and balance the load. The scenario is that of multiple sensor devices deployed in homes, which monitor and report loads either to an in-home aggregator or to the utility operator. The former is for automatic balance of the consumptions locally; the latter is to enable the operator to balance the network.

As said, TVWS have been widely studied specifically for this scenario, due to their characteristics which make them appealing for such a deployment. The possibility to cover large distances, even if the meters are located in the basement [4], and the reduced energy consumptions to send data locally [3] are just two of the characteristics of TVWS that are interesting for this specific scenario.

Specifically in [59] it has been firstly seen in the term cognitive M2M (CM2M), to enhance the flexibility and the reliability of M2M communication.

There is a natural bind between devices needed in a smart utility network (SUN) like the smart grid and the TVWS device classes. In [49] it is highlighted this, which candidates TVWS as one of the most prominent technologies to realize these kind of networks. They identify four classes of devices needed in SUNs, namely: – Utility provider base station – Data collector – Utility meter – Mobile data collector They bind to the different classes of TVWS devices foreseen by regulations. The base station is clearly the static device, which is able to transmit at high power (up to 4 W) and thus covers larger distances. The data collector and

the utility meter are, respectively, Mode II and Mode I devices. They do not need sensing capabilities, which are instead required by the mobile data collector, carried by operators to gather data from meters. TVWS would be beneficial for SUNs thanks to the larger coverage range, which make them attractive particularly in rural areas.

This is also the path taken by [10], which present a test-bed deployed in Scotland specifically focused on smart grid communication. The motivation leading to the use of TVWS is mainly economical: more expensive systems such as fiber optic or DSL are not economically viable in rural areas, where few people live. Instead, TVWS are more economic and explored for this deployment, following results in [46]. The underlying protocol for this network test-bed is 802.11, which runs in the UHF bands instead of ISM bands over channel 57 (758–766 MHz). Another interesting feature, going toward the energy efficiency required by M2M communication, is that of a wind turbine for power supply mounted on top of the base station, making it autonomous from an energy supply. Wind power is an attractive option for Scotland, and clearly other options should be explored in other countries and environments, where wind may not be the most efficient method of energy production. The work presented in [10] is one of the first aimed at deploying an M2M network directly on the field.

Another work which studies the deployment of smart grid communication in TVWS is [4], which presents both a measurement study to deploy smart grid networks in TVWS and TV gray space and field results on the indoor propagation of narrowband signals in the TVWS. What emerges from the study is that the superior propagation characteristics of UHF bands are able to deliver the signal much farther compared to classical ISM bands. Moreover, it is interesting to note that if deployed indoors and at a low floor such as in the basements, the DVB-T receiver can easily compensate possible interference coming from the smart meters, thanks to the high directionality of its antenna.

The battery savings are presented in [3], where the authors foresee clusters of smart meters that communicate together through TVWS and one of them eventually reports the load measurements to the remote utility aggregator. Here the main advantage of TVWS networks relies in its duality: it can be used as a local communication technology, using low power but still penetrating obstacles better than technologies in higher-frequency bands. When needed, for instance, when the meter has to report the data to the aggregator, it can increase its transmitting power to cover a larger range.

Sensor Networks

Apart from the specific case of smart grid communication, as we already mentioned, M2M networks can also be built with the focus on energy efficiency. This allows building sensor networks in general with battery-powered devices, for a range of possible applications:

- Environmental monitoring: through TVWS networks it is easier to build large-scale networks for battery-powered devices, which by transmitting in narrowband channels can reduce their power consumption keeping a satisfactory transmission range.
- Industrial monitoring: wireless sensor networks have been deployed in several machines and automated tools, mainly for machinery condition-based maintenance. The use of M2M in this domain would help reduce the problems when machines are placed in hard-to-reach places, and thus shadowing effects could reduce the signal to undetectable levels.
- eHealth: in eHealth, devices could be either implanted in patients or deployed as wearable computing devices. They report the patient health with important parameters such as the heart rate or the blood oxygen level. Doctors can then monitor the patient remotely and be alarmed whenever health parameters fall below or rise above a predefined threshold.

ITS

Another interesting application of M2M communication is related to intelligent transportation systems (ITS). Here, cars report their state and gather information about the road situation, to possibly inform the driver of alternate paths in presence of road works or accidents. An important aspect is that vehicular communication happens at the ground level, and thus possible interference to the primary receiver is naturally mitigated.

Messages in safety VANETS are typically of two kinds: Emergency safety messages (ESM) and periodic beacon messages (PBM) [37]. The aim of the work is to show how to deliver ESM messages faster than classical dedicated short-range communication (DSRC), thanks to better propagation and penetration into other cars and buildings. Examples of ESM messages are stopped cars on blind turns, cars driving in the opposite way, or cars approaching too fast. Given their nature, it is straightforward to understand how reliable and fast the communication has to be. The classical approach for DSRC communication would be multihop, with vehicles relaying the message to eventually reach farther drivers. Although it is possible to enhance the IEEE 802.11p to meet stringent delivery requirements [17], it would still be challenging to guarantee the reception of the message to all the interested cars with such a congested network. Moreover, multihop communication raises the well-known problem of the broadcast storm, in which too many relays could interfere with each other and reduce the communication performance. Thus, the benefits for V2V are mainly in the longer transmission range, which make them ideal to deliver safety messages. At the same time, the challenges reside in the spectrum availability. ESM messages cannot depend solely on opportunistic communication, since in areas with scarcity of spectrum, or when the licensee is using its spectrum band, the ESM messages should still be delivered. So the main idea is to use opportunistic communication when available, but switch back to classical DSRC when this is not possible. Another issue to consider is about the

time needed to get the available channels on which the message should be delivered. For classic DSA protocols, the key challenge is to achieve this information rapidly, as the ESM message cannot be delayed. For the case of TVWS, the car should get the list of available channels from the remote spectrum database in advance, since this cannot be done when the emergency occur, so that the client already have to send the message; otherwise, it would incur in too much delay. So clients should ask in advance to the database or other clients what are the channels available on the road they are traveling [16]. This would reduce the time needed to send the ESM, as the car already has the channel list in which it can transmit when needed.

Studies in literature have also demonstrated the feasibility of the aforementioned approaches, like [2] and [29]. In [2] the test-bed is built in Massachusetts, while [29] is deployed in Japan. Both are realized thanks to the GNU radio platform and show in practice how it is possible to build VANETs using TVWS.

When we consider M2M communication for cars, it is also important to commonly agree on the protocol to be used. For vehicular communication, the IEEE standardized the well-known IEEE 802.11p protocol, in which are foreseen two periods of time: one is used to transmit safety messages over a common control channel (CCC) and the other one to offer services such as infotainment. One of the issues with 802.11p, analyzed in [17], is about the timely delivery of messages, particularly those containing safety information. A possible solution is to rely on licensed communication for mission critical messages and rely on DSA for all the other messages, such as control information. This also goes in the direction foreseen by [37], which proposes to use TVWS to transmit safety messages which could then reach farther cars and possibly use DSRC communication for critical information. Another possible protocol proposed for V2V communication is 802.11af, studied in this particular scenario in [60]. 802.11af for V2V is certainly feasible and an interesting option, which could also be used together as 802.11p, by using DSRC and 802.11af together, as we already stated before.

Industry 4.0 and IoT

An area which is not much explored but that can certainly represent one peculiar application scenario for M2M in TVWS is certainly the upcoming Industry 4.0. In this environment, machines and devices are able to talk without human intervention, to offer new and enhanced services, ranging from predictive analytics to enhanced services for the end users.

Industry 4.0 refers to the plethora of tools, technologies, and methodologies needed to revolutionize normal industries with enhanced technologies, such as wireless sensor network and big data, which will open up services which would had never been possible. For instance, wireless technologies should be adapted to this changing environment, which will likely have multiple devices running different standards, which need not to prevent others from working [53]. Here, multiple gateways, able to speak different wireless protocols, are envisioned, so that they can bring messages from one network to the other [15]. For instance, access to

users can be provided either through Ethernet or WiFi; however, this is not feasible for battery-powered devices, which might also be located in hard-to-reach places [42].

Another scenario which hugely benefits from M2M communication is predictive analytics [34], defined as the ability for a system to monitor its assets and forecast the remaining life of each one, hence optimizing maintenance and reducing downtimes. This is done by monitoring components and through big data analysis and machine learning techniques recognizes unusual behaviors, such as never seen before vibrations, exceeding threshold values, and so on. Then, maintenance may be performed to multiple components at once, reducing the costs and arguably maintaining machines in better health. In fact, the cost of replacing a component before its end of life is generally much lower than having the machine to stop for a period of time, waiting for that component to be replaced.

To realize the IoT vision, it needs a technology that glues together different networks together, like the TVWS, as IoT networks can be locally sparse. For example, smart crossing lights can broadcast their status to nearby cars, which in turn could dynamically update the travel time, to proactively activate smart objects at homes. What typically happen is that these communication links can be realized through different technologies. In the previous example, the crossing light might transmit locally using WiFi, the car could use the cellular connection, and the messages are delivered in the smart home through a DSL connection or fiber optic. In this heterogeneous scenario, TVWS is one of the candidate technologies to possibly offer a bridge to all these devices, since they could propagate the messages farther than other technologies and can thus deliver the messages to more devices. Crossing lights would then be able to talk between each other and disseminate locally not only their status but also on the crossroads, so cars can infer more information.

Even if this is only an example, it exemplifies the potential of M2M communication in TVWS. Longer range means potentially more devices to be connected and from which obtain and give data.

eHealth

Another interesting domain for TVWS M2M is that of eHealth services, in which patients are monitored through wireless devices, and enhanced medical services can be provided also in hard-to-reach areas. TVWS network can provide useful services such as patient monitoring and locate them in the premises of a hospital. In addition, TVWS networks can also realize the remote patient monitoring, so that people can still be monitored at home, by constantly communicating with the doctor, without the need for human intervention, which can be warned only when needed, by setting for instance appropriate triggers. Moreover, many medical devices rely on the wireless medical telemetry system (WMTS), which operates in similar bands of TVWS. Therefore, they would need little intervention to be adapted to also use a larger spectrum band. However, there are several interference issues that need to be

carefully studied, since medical devices would compete also with other, consumer-like devices in the same bands.

It is worth noting the ongoing development of an eHealth test-bed in the Philippines [27], aimed at connecting 100 sites in rural areas of Philippines. The goal/plan initially is to use TVWS as a public service allowing for connectivity for education, eHealth, eGovernment services, environmental sensor networks such as those used by PAGASA and DOSTs Project NOAH, as well as Internet access in public places such as halls and town plazas. The trial is ongoing, proceeding slowly, mostly due to a precise policy missing.

A similar trial is ongoing also in Africa [29], where Microsoft is partnering with the Botswana-University of Pennsylvania, to provide medical services in poorly connected regions. They selected TVWS since it represents a less costly, faster, and farther-reaching Internet connection that is a promising option for connecting the previously unconnected populations of remote and underserved areas." Thus, TVWS are again selected as a candidate technology to practically realize services where the communication range is an issue and also because they represent a cheaper technology, compared to other well-known wireless standards. In addition, it is worth to note that once TVWS will roll out, the economy of scale might decrease even more the price of the devices, as more TVWS chips will be produced. Also in Bhutan TVWS are currently investigated to provide last mile connectivity, particularly for eHealth services, as patients incur in high costs to reach healthcare centers.

Apart from human medicine, TVWS networks are also currently investigated for animal treatment and monitoring. In particular, recently the London Zoo partnered with Google [38] to monitor endangered species through the use of a TVWS network. Moreover, animals can also be viewed online through video streaming by people through the Internet. TVWS have been selected as the ideal technology as animals can be hidden behind trees or in caves, and therefore the carrier wireless technology in use should be resilient to environmental obstacles. In areas such as rainforests and deserts, where animals can travel long distances and where therefore it is difficult to monitor animals for long period of times, TVWS can definitely fill the technology gap by meeting these needs. The test-bed has been rolled out in the London ZOO, and it is planned to extend it also to wider areas. Apart from wild animals, there is also an interest in TVWS for livestock monitoring [51] through the use of smart geofences, which can monitor animals inside a huge area, thanks to the propagation characteristics of TV bands.

M2M Operational Characteristics

In this section we present the details of M2M characteristics and how these are tackled by cognitive networks.

Generally speaking, M2M communications are typically referred to small and battery-powered devices, although this is not always true. For instance, video surveillance cameras where it is also performed image recognition, either on the

edge or on the cloud, can be still seen as M2M, as no human intervention is performed in the middle of the communication. However, it is also true to say that most of the M2M deployed scenario envision small, battery-powered devices which report different kind of data to a central entity, in charge of analyzing them and inform the users. Clearly, the number of intermediate levels can change, as intermediate computation may be performed to achieve network optimization.

Focusing only on the communication slice of the picture, we define the following operational characteristics of M2M communication:

- **Self-instantiated**: no human intervention should be envisioned, like checking connectivity or acknowledging any sort of data in order to establish a new M2M connection.
- **Self-healing**: in case of network disruption, such as nodes that depart the network either voluntarily or because they have run out of batteries, the network should be able to heal itself.
- **Battery efficient**: although we mentioned that M2M communication can be in main powered devices, M2M communication should be designed to be energy efficient. Hence, M2M devices are typically sleeping and wake up only upon certain events. Hence, it should not be assumed that they can receive a message, and optional device configuration should be performed by the device station in reply to events on which M2M devices wake up.
- **Lightweight**: M2M protocol should also be designed to carry the minimum amount of protocol overhead possible, as this would require additional time and computation to be achieved, such as CRC an alike.
- **Multiple transmissions**: unlike human communication, M2M may perform many, simultaneous connections. Coupled with the battery efficiency requirement, this involves developing novel techniques to access the channel by M2M devices. Imagine the Industry 4.0 scenario, in which thousands of tiny devices installed report sensed data to a central entity. Clearly, these devices should access the channel fast, and the high number of them poses technical challenges on how this should be performed.
- **Heterogeneous kind of traffic**: M2M traffic can be characterized in two different shapes: `bursty` or `sporadic`. `Bursty` traffic refers to devices which typically sleep and when they wake up send a large amount of information. This may be surveillance cameras which perform image recognition locally and, only when something which requires additional analysis has to performed, send that information to a central entity. `Sporadic` refers to anything which is not bursty and comprises periodic beaconing of information to a central station.
- **Security**: although not a specific requirement of M2M communication, security can take a dual meaning in M2M communication. At first, there is the communication security, which may mean encryption. However, this should also be tailored to battery-powered devices; hence, it should not require excessive computation power. There is also the security of the device itself, since they can be stolen, and hence they should be able to sense unusual behaviors and events and report those to the central entity.

- **Latency**: depending on the scenario, latency may be or not a constraint. For critical scenario, such as eHealth, clearly latency becomes a more severe constraint. However, it is also worth to mention the latency when data has to be synchronized through different M2M devices, for instance, for predictive analytics, when considering Industry 4.0 scenarios or of building structure monitoring. There, latency becomes of paramount importance, to determine the sequence of events reported by different devices.

It is also worth to say that cognitive networks should be carefully tailored to meet M2M communication. For instance, tasks such as spectrum sensing and spectrum decision, which are normally battery consuming, have to be reengineered to meet the constraints this scenario poses. For this reason, among others, dynamic spectrum access and cognitive networks have a narrow area of application for M2M. In fact, the overhead needed by cognitive networks is not particularly suitable for battery-powered devices, which may waste considerable amount of energy to perform network maintenance and access tasks. In fact, in the M2M domain, typically network operations are performed vastly on a remote central unit, and less consuming tasks are left to the edge of the network, formed by the end nodes.

A fundamental difference which has to be made between different M2M scenarios is about the operational range. M2M scenarios can be built either for short-range or long-range communication, and several technologies and protocols have been proposed for both. In the following, we outline some of the major differences between the two and protocols and standards which have been proposed.

M2M Range

Short-Range M2M

Short-range M2M technologies are historically used to build wireless sensor networks (WSN), due to their ability to form networks of devices in close to each other. Certainly, one of the most adopted technologies in this field is IEEE 802.15.4, although more recently also IEEE 802.15.1 (Bluetooth Low Energy) has gained interest.

Among the IEEE 802.15.4 family, it is interesting to discuss the IEEE 802.15.4m amendment, which is the use of IEEE 802.15.4 on the TV white space (TVWS) bands.

TVWS are frequency bands which are progressively becoming available for secondary user operations, thanks to the digital TV switchover. Basically, thanks to the transition from analog to digital TV, several channels are not used anymore and can possibly be exploited for other use cases. TVWS have already shown interesting performance in scenario such as communication in rural areas, thanks to the low-frequency band used which helps in achieving a large communication range. Many standards have been proposed to work in TVWS, like IEEE 802.22 for regional networks, IEEE 802.11af for indoor, WiFi like deployments, and IEEE 802.15.4m for M2M communication and more oriented to IoT and WSN.

At the moment of writing, not all the countries in the world have regulations to transmit in TVWS. It is worth mentioning the US case, in which the FCC already published the rules to access TVWS, and the UK case, where Ofcom followed a similar path. Although they differ in details, they share the fundamental building block of the TVWS architecture, which is the remote spectrum database. Basically, it contains the positions of the TV transmitter, and through path loss models, it determines in which areas a given channel is free or occupied. Devices which need to access the TVWS should firstly query the remote spectrum database and ask for free channels, by providing their position. The remote spectrum database will eventually reply with a list of available channels on which the device can transmit, since they are free at that moment.

IEEE 802.15.4m has been proposed in 2014 [7, 28], and the major differences over the standard IEEE 802.15.4 standard are devoted to the physical layer, with the IEEE 802.15.4m defining three novel PHY layers, an FSK PHY, an OFDM PHY, and a narrowband OFDM PHY (NB-OFDM). They are designed to operate on TVWS frequency bands, up to 862 MHz.

The OFDM layer, which is the one which offers the highest data rate among the available ones, offers six different modulation and coding schemes (MCS), ranging from around 390 kb/s with a BPSK modulation to a maximum of 1562.5 kb/s, when using a 16-QAM. Note that these values can be increased up to four times when using channel bonding. The study in [7] summarizes the practical use of IEEE 802.15.4m, finding that in practical scenarios free of noise, the highest throughput can reach around 30 m, with a transmitting power of 20 dBm. Clearly, this can be increased if higher transmission powers are allowed or when using stronger MCS which require lower link budget.

Concerning dynamic spectrum access, IEEE 802.15.4m should ask to the remote spectrum database the available channels. However, [32] finds that when using bursty transmissions, which are typical of M2M scenarios, TV receivers better compensate for interference. Hence, [7] shows that it is possible to transmit small packets even on occupied channels, without causing interference to the primary user of the channel.

Long-Range M2M

While short-range M2M achieves a maximum transmission range of tenths of meters, long-range M2M foresees to connect devices which are located several kilometers away. This is generally done either by increasing the transmitting power or by reducing the communicating band. Recently, a lot of standards have been proposed and are now used in different scenarios. These include LoRa, LTE-M, and Weightless.

LoRa is a technology developed by the LoRa alliance and is rapidly becoming one of the most used standards in the M2M and IoT world. Its network topology is a star of stars, which means that each device is directly connected to a LoRa gateway, which can communicate to the central entity, called the LoRa NetServer, which also handles the authentication and association of the devices. Basically, the LoRa gateway is simple, acting mostly as a relay, since the complexity is

moved to the LoRa NetServer. Hence, features such as mobility and information redundancy elimination are inherently supported, as the NetServer manages them all. Concerning the data rate, LoRa devices can reach a peak of 50 kbps, transmitting at a maximum power of 24 dBm.

LTE-M is an LTE version which enables machine type communication, particularly for constrained devices. This technology has the clear advantage of relying on a vastly deployed technology such as LTE, and transmitting in smaller bands enables longer range and battery savings when reducing the transmission power. This would also enable hybrid devices, which might leverage on the full LTE stack when needing bandwidth hungry data transfer and switch to the more efficient LTE-M for smaller communication. The 3GPP studied LTE-M in the area of Washington [1], achieving a maximum of more than 10 km. NB-LTE-M further improves the capabilities of LTE-M, by reducing the bandwidth to 200 kHz and allowing a maximum transmitting power of 23 dBm instead of 20 dBm like in LTE-M.

Finally, Weightless is a set of technologies originally proposed by Neul and now developed by the Weightless Special Interest Group (SIG). It is composed basically of three different technologies, namely, Weightless-N, which uses a narrowband transmission scheme, achieving a maximum range of 5 km. For bi-directional communication there is Weightless-P, although this reduces the maximum transmission range from 5 to 2 km. Finally, Weightless-W is based on TVWS, which tops the other two in terms of communication range, achieving a maximum of 10 km.

Dynamic Spectrum Access for M2M

The need for dynamic spectrum access (DSA) comes from the scarcity of the spectrum resources, which is also the basis for the birth of cognitive networks in general. Basically, we are living in a world where almost all the spectrum are statically allocated to different services. In [21] the FCC shows the current allocation of frequency spectrum up to 3000 GHz, and it is possible to note how little space is left for new services. Apart from the ISM bands such as the 868/915 MHz, 2.4 GHz, and 5.8 GHz where different services take place, it is challenging to license new bands for other purposes. However, a lot of studies have shown how little licensed space is used. We mention [39, 44, 55] for the European-related measurement studies, [14,41,50] for the USA, [30,56,57], for Asia, and [40] for Africa. Clearly, measurement bands differ, and also the purpose of the study varies. However, there is a global consensus that some licensed bands are heavily underutilized. As new services are deployed, which build upon new technologies, spectrum is a scarce hence valuable resource. With these premises, cognitive networks are born, and more specifically the building block which takes into account the so-called spectrum holes is named DSA [36].

DSA can be mainly implemented through two different architectures: centralized DSA or distributed DSA. In the centralized DSA architecture, it is foreseen as a server which allocates the radio resources to clients, while in distributed DSA the

devices compete or cooperate together to access the spectrum. Contention can occur, for instance, through a control channel, where devices declare their willingness to transmit and reach agreement together.

Certainly, one of the major challenges to tackle is the fairness between clients. While such achievement might be easy to obtain in centralized DSA, as the remote server has a global view of all the clients and the air time allocated to them, achieving fairness in distributed DSA is more challenging. One possible solution would be to gain access to the spectrum proportionally to the sensing time [35]. If a client senses the spectrum more, hence gives to the neighboring devices more information about the spectrum state, it should be given more opportunities to communicate. However, in the domain of M2M communication, where devices are typically on batteries and with low duty cycle, this technique is clearly inefficient. This can be mitigated using solutions like the one presented in [26], where forced vacation periods for devices must take place; hence, sooner or later a device will have the opportunity to transmit. However, for M2M communication distributed DSA solution requires energy hungry operations such as sensing and requires to wait some time to understand the state of neighboring devices, hence which are not suitable for battery operated devices.

Cognitive networks are realized through different modules, in charge of performing tasks related to recognize, access, and efficiently use the spectrum. For the purpose of M2M, we will look at spectrum sensing, spectrum sharing, and spectrum management. Spectrum sensing is the ability for a device to sense the spectrum and identify potential spectrum holes, which are portion of the spectrum band at a given time and frequency which are not utilized by anyone. Spectrum sharing is performed across multiple devices, which share the resources to gain access to it. Finally, Spectrum management relates to all the operations needed to grant access to the spectrum and manage the resource between the clients. In other words, it is the overarching architecture composed of other submodules, in charge of executing different tasks.

Spectrum Sensing

As we already introduced, spectrum sensing is the ability for a device to sense the environment and acquire information about the spectrum occupancy, on a given frequency band. This is generally done by listening to the channel and analyzes the signals received. The spectrum detection, which is the task of determining whether a channel is occupied or not, can be done with different degrees of complexity, which clearly lead to different results.

In general, we can divide spectrum sensing in two broad categories, namely, energy detection spectrum sensing and cyclostationary spectrum sensing. Energy detection has the advantage of being simpler; hence, they require less resources to be run. Moreover, they do not need any information on the nature of the signal they are sensing. However, they are generally less accurate than other techniques, and they cannot distinguish between primary signals and secondary signals. More

accurate techniques, such as the cyclostationary one, analyze the signal to determine whether a primary user is present or not. Generally speaking, they are more accurate, at the cost of a higher computation power required, and knowing the nature of the primary signal. At the same time, they may also distinguish between primary signal and secondary signal, opposite to the energy detection systems which only sense an occupied channel.

In [45] the authors proposed a compressive spectrum sensing algorithm, designed specifically for M2M communication. Specifically, the design is for UHF TV, thanks to TVWS technology. TVWS have been targeted as highly interesting for M2M [58], as they have favorable characteristics that bind well with M2M. The main idea behind the proposed solution is to sense only a part of the spectrum, instead of a wider band. Instead of sampling the whole band with fast update rates, the spectrum is sampled at sub-Nyquist rates, and only specific portions of the spectrum are further evaluated, thus reducing the overall complexity of the algorithm. Clearly, knowing which part of the spectrum needs further analysis has multiple benefits:

- If information is shared among M2M devices, it could reduce the complexity also for other devices, at the cost of adding further overhead both on the management part and on the battery consumed to transmit the information.
- If the device can make a decision without involving complex techniques, it saves battery. Clearly, this cannot come at the cost of potentially interfering with the primary user.
- Through cooperative sensing, devices may share the computation costs, so that the energy required for each one is lower.

Energy detection, although fascinating for M2M communication, thanks to its simplicity, presents other drawbacks that need to be tackled [12]. For instance, it is difficult to set an appropriate threshold for the sensing, as setting a too low threshold may lead to missed communication opportunities due to environmental, and a high threshold may result in being too conservative. In fact, carefully setting the threshold is certainly the most challenging part in designing an efficient spectrum sensing algorithm, and this has been the main focus of several works which can be found in literature [19, 52]. While [52] provides general considerations and boundaries for energy detectors, [19] proposes a novel spectrum sensing algorithm, which involves cooperation between the nodes. In particular, they communicate to reach a consensus on the optimal energy threshold to be used. Even though this comes at the cost of involving additional communication, [19] shows that the gains are in favor of their solution.

Cooperative spectrum sensing uses shared knowledge among the nodes to reach a decision about the spectrum occupancy. A major challenge which arises with other techniques is related to the well-known hidden node problem, that is, nodes which might be sensed by some devices and not by others. In cooperative spectrum sensing, the hidden node problem is tackled by sharing the channel occupancy by nodes placed in different positions, hence reducing the probability that the hidden node is not sensed by anyone.

In cooperative spectrum sensing, we may have three different architectures:

- **Centralized Cooperative Sensing**, in which nodes report spectrum measurements to a central entity, usually main powered, which analyzes the results and reports either hard or soft decisions to the clients.
- **Distributed Cooperative Sensing**, in which there is not a central entity, but spectrum measurements are shared among nodes in a distributed way. Clearly, synchronization challenges have to be tackled.
- **Relay Cooperative Sensing**, in which nodes send their measurements to other devices, which relay them to a central entity. The closer to the central entity, the higher the energy consumption, since a higher number of measurements should be reported.

Regardless of the specific architecture used, cooperative spectrum sensing also carries the problem of user selection, which is the subset of devices chosen for the next round of sensing. These devices should be representatives (i.e., cover the area of interests) and possibly be independent (i.e., in different positions, to limit the hidden node problem) [47].

Spectrum Sharing

Spectrum sharing refers to the techniques needed in order to share the spectrum resource between devices. Techniques vary, but the underlying idea is that devices could either compete for the spectrum, such as through auctions [20,54], or through cooperative schemes [11, 23, 25, 59]. In particular, [25] is focused specifically on M2M communication, and by exploiting some of the M2M constraints, such as a small packet length, it shows how it is possible to transmit leveraging WiFi whitetimes, which is the inter-time between subsequent WiFi transmissions. In other words, in [25] vision M2M communication, thanks to its bursty nature and small packet lengths, can coexist with other transmissions by using period of non-transmissions in normally occupied channels.

Moreover, we can also distinguish between two different architectures of spectrum sharing:

- **Centralized Spectrum Sharing**, in which the access to the spectrum is managed by a central entity, which is often named as **Spectrum Coordinator**. It can lease the spectrum in a competitive way, sending the same information to all the devices which eventually compete to access to it, or controlled, in which it decides which portion of spectrum should be leased to a given device.
- **Distributed Spectrum Sharing**, in which devices take decision locally, based on the information they have, which could also be obtained through cooperation with other nodes. Again, cooperation improves the overall performances of the spectrum sharing, at the cost of an increased overhead and energy consumption.

Much work has been done on spectrum sharing architectures. Many works explore the possibilities offered by game theory, modeling games in which the objective of the client is accessing the spectrum [24,31,43].

Southwell et al. [48] focuses on quality of service games for spectrum sharing. Their solutions are totally distributed, and they also show the overarching benefits of a distributed solution over a centralized one.

A novel paradigm of spectrum sharing also exploits the height of the devices, as a countermeasure to reduce interference between devices accessing the spectrum, named 3D spectrum sharing, proposed in [5,8]. The idea is that generally spectrum is considered free or occupied at a certain location, without considering the height of the buildings which may have been constructed there. For specific M2M use cases such as smart metering [4], this may significantly help in finding spectrum opportunities, as spectrum sharing is considered on a per-floor basis.

More formally, we can define the spectrum occupancy at a given location $\mathscr{L}$ as

$$S_{\mathscr{L}} = \mathscr{O} \tag{1}$$

where $S_{\mathscr{L}}$ is the spectrum information regarding location $\mathscr{L}$ and $\mathscr{O}$ is the result obtained through a given technique of spectrum sharing. Since $\mathscr{L}$ is a location, it is generally defined as

$$\mathscr{L} =< Lat, Lng >$$

where Lat and Lng represent the latitude and the longitude, respectively. Most notably, this is the definition used by the TVWS spectrum database [9], which has been shown to offer less communication opportunities than those which may be used without interfering with the primary users. 3D spectrum sharing modifies the definition of $\mathscr{L}$, changing it into

$$\mathscr{L}_{3D} =< Lat, Lng, \mathscr{H} >$$

where $\mathscr{H}$ is defined as the height from ground floor. In tall buildings, or in the case of specific networks such as TVWS, 3D spectrum sharing has shown good results in finding additional spectrum sharing opportunities, compared to other techniques. Of course, this comes at an additional cost and with additional constraints. At first, devices should know which are their $\mathscr{H}$. This can be either manually defined when the device is installed, or it can be determined by the device during its operations. If manual configuration is used, the spectrum occupancy estimation may become inaccurate, due to the fact that devices may be moved or substituted. In case of the device determining its $\mathscr{H}$, additional costs for building it should be accounted for, due to the need of a barometric sensor. Moreover, pressure value changes during the day, due to natural events such as thunderstorms or clouds, which should be again detected and properly managed [6].

An additional aspect crucial to M2M communication is related to the energy consumption. Switching from a 2D to a 3D space may involve additional

computation costs, as more complex spectrum propagation and detection techniques should be used. However, this may be solved by using a spectrum manager which is in charge of handling all the spectrum information of a building. Again, this is not straightforward to implement, due to devices which may not be in the range of the spectrum manager and should then use relays to reach it in order to report measurements or to obtain information about the free channels.

Spectrum Management

Spectrum management comprises different tasks to be achieved, to efficiently utilize the available spectrum. This does not involve only spectrum sensing or spectrum sharing, as they may be relative to a specific frequency band. In fact, in spectrum management it is also foreseen that clients may have access to multiple bands, which may be exploited for specific needs. This may include multiband devices, able to utilize both WiFi channels and others, depending on the scenario and on the instant needs, like [22], where the authors design a system which leverages both cellular technologies such as LTE-A, to other opportunistic technologies like TVWS. The underlying idea is to utilize LTE-A to perform spectrum management tasks and also to query the remote spectrum database for TVWS availability.

Other solutions leverage TVWS to overcome other technology limitations in specific scenarios, such as video streaming [7]. Here, the scenario of interest is different from M2M, but the general architecture presents many similarities, like the use of a technology to query the database like WiFi and occasionally TVWS if WiFi performance is not enough to support the video streaming.

We can characterize multiband solutions, based on the spectrum availability and on the technologies characteristics overlapping, into the following categories:

- Two technologies, both always available, similar characteristics: this is the case, for instance, of technologies such as WiFi and Bluetooth, which do not have to rely on other entities to assess the spectrum availability, as they use the ISM bands. They share similar characteristics; hence, their use together is limited.
- Two technologies, both always available, different characteristics: this is the case, for instance, of WiFi and LTE, assuming coverage. In this scenario, typically technologies complement each other: for instance, modern smartphones have the possibility to switch to LTE should the WiFi connection presents low performance.
- Two technologies, one always available: this is the case of TVWS, in which another technology such as LTE or WiFi is used to gain access to the TVWS network, by asking to the remote spectrum database the list of channels available at a given location.

Concerning M2M communication, most notably here is the work presented in [13], which compares LTE-Direct and WiFi-Direct over classical LTE communication, in the specific scenario of M2M. Cellular communication has been extensively

looked at as one of the most prominent candidates for M2M, as they have a large coverage and present characteristics favorable for this kind of communication, like a longer range of communication over other technologies. However, they should be optimized to fully unleash the potential of M2M, like optimizing them for bursty transmissions or a better energy efficiency for battery-powered devices.

In [13] the authors show that both LTE-Direct and WiFi-Direct outperform classical LTE, mostly thanks to a specific design targeted at M2M communication. However, no clear winner arises, as LTE offers the best energy efficiency, particularly with a high number of devices, while WiFi has an advantage when considering small packets.

Other proposals do not focus on different access technologies but rather use M2M to enhance the main network basically by providing enhanced coverage, by using M2M devices which act as relay [33]. Even though this kind of communication has to be considered M2M, as no human intervention is foreseen in between, it is hard to think at those devices as battery powered and only communication to other devices. In fact, they can be devices which offer different services, one of which is M2M communication to extend the transmission range.

Spectrum management can thus be considered both a solution which enhances and optimizes the performance of M2M device. At the same time, it requires additional computation resources which eventually lead to increased battery consumption and reduced device life. Hence, there is a trade-off between using specific technologies, which may not be well suited for a specific scenario, even though they are simple to be managed, and to a more complex spectrum management which involves different bands and requires algorithms to successfully exploit additional technologies. Needless to say, also the cost of the device increases, and possibly the size of it, as different technologies may require different antennas and transceivers to operate.

Case Study: Cooperative M2M for Smart Metering

In this section we describe in detail a specific use case for M2M, related to smart metering applications. The scenario we model is depicted in Fig. 1, where multiple devices need to report their data to a central aggregator. Devices can have different capabilities and different residual energy; hence, algorithms which make them cooperate can significantly extend their battery life.

System Model

We model a generic network scenario S, composed by $\mathcal{N}$ secondary devices (SUs), operating in the same area. In other words, we assume they are able to sense the same signals. Each SU operates a DSA-enabled device, able to sense signals over

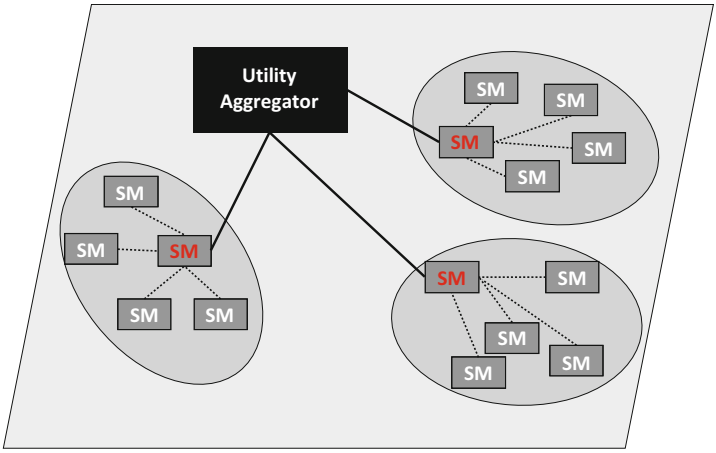

Fig. 1 Scenario for M2M smart metering communication. Multiple heterogeneous devices need all to report their data to a central aggregator, which is in charge of merging them. Devices can either report the measurements alone, hence consuming a considerable amount of battery, or they can form clusters, in which only one of them sends the measurements to the aggregator, and information about the other measurements is shared within the cluster. In this picture, we picture in red smart meters which report information of all the smart meters in the cluster, and in white those smart meters which only transmit intra-cluster. Clearly, the device which reports the data to the utility aggregator may change in time

all the frequencies of interest. We study the use case for the specific frequency band of TV white space (TVWS), although it can be easily extended to other frequency bands as well.

In TVWS, devices should query the remote spectrum database to obtain access to the list of channels available on a given area. This can be done by a device to obtain the list for its own purposes or to share the list to other devices which may not have access to the remote spectrum database. Hence, we also assume that devices also have an interface such as WiFi, through which they can access the remote spectrum database.

As the devices are close to each other, we can also assume that they are at most at one hop from the device which executes the query to the remote spectrum database. Hence, we call the querying device `master device` (MD) and all the other $\mathcal{N}-1$ as `slave devices` (SDs). Energy smart meters may be main powered, but for other kind of smart meters, such as those measuring gas, it is not possible to assume main power, but battery power is viable, and eventually energy efficiency has to be accounted for.

The set of activities $\mathcal{S}$ MD i has to perform through the day can be summarized as:

- **Sense**: based on the measure and on regulations, the device has to acquire the measure of interest and store it locally.

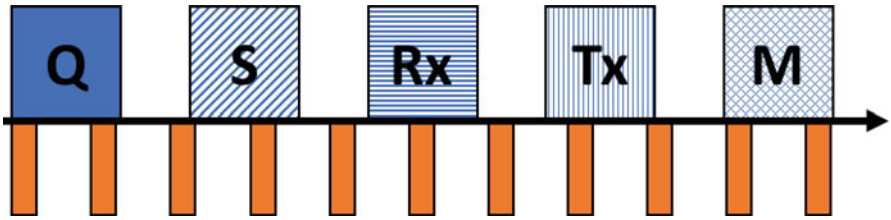

Fig. 2 The daily schedule of an MD. Below the lines there are the `Sense` operations, while on the upper line, we show the communication operation, starting from **Q**, which is relative to the `Query` operation. After getting the channel information, the MD can `Share` it through the **S** operation. Then the MD is ready to receive data from the SDs through the **Rx** operation and transmit it to the utility aggregator in the **Tx** phase. Finally, `Maintenance` operation can be performed through the **M** phase

- **Query**: this task has to be done to acquire access to the spectrum. Depending on the network, it can vary.
- **Share**: in this task, the MD and SD share information about the available channels.
- **Rx**: the MD, which should reports all the measurements of the SDs, receives measurement updates by them, which transmit their data to it.
- **Tx**: the MD eventually sends its measurements and those received by the SDs to the utility aggregator.
- **Maintenance**: based on its residual energy, the MD decides whether to drop its role to another device, which in this case should be informed.

Clearly, an SD performs a subset $\int \in \mathscr{S}$ of activities, where

$$\int =< Sense, Share, Rx, Maintenance >$$

We depict the typical day routine of smart meters in Fig. 2.
To model the energy consumption of the MD, we define the following Equation:

$$E_{MD} = E_{\text{sense}} + E_q + E^{MD}_{\text{share}} + E^{MD}_{rx} + E_{tx} + E^{MD}_{m}, \tag{2}$$

where E_{sense} is the energy consumed by the sensing operation, common to both the MD and SDs, E_q is the energy needed to query the remote spectrum database, E^{MD}_{share} is the energy consumed by sharing the measurements from the MD perspective, E^{MD}_{rx} accounts for the energy spent receiving measurements from SDs, E_{tx} is relative to the energy needed to transmit the measurements to the utility aggregator, and E^{MD}_{m} accounts for the maintenance costs, in terms of energy, from the MD perspective.

Table 1 Symbols table

Symbol	Description
E_r	Energy per reading
$\mathscr{F}$	Number of readings per day
γ	Energy needed to transmit locally
ϵ	Sleep energy
α	Energy while in Rx
t_α^{MD}	Time in which the MD listens for SD data
t_β^{SD}	Time in which the SD listens for MD data
$\mathscr{N}$	Number of nodes
E_i^{start}	Starting energy

Clearly, each SD has a similar behavior, more precisely as follows:

$$E_{SD} = E_{\text{sense}} + E_{\text{share}}^{SD} + E_{rx}^{SD} + E_m^{SD},$$

where $E_{\text{share}}^{S} D$ accounts for the energy spent to acquire the list of channels available, E_{rx}^{SD} is relative to SDs sending their measurements to the MD, and finally E_m^{SD} is relative to management operations.

The general model we just presented can be tailored to meet specific needs, depending on the scenario and on the target objective. For instance, if all the devices have to query the spectrum database, then E_q has to be counted also for SD. Another case would be the use of a fixed MD: this case can be modeled by putting $E_m^{MD} = E_m^{SD} = 0$.

To compute each term, we refer to Table 1, where we report all the symbols used to model the scenario.

In detail, we obtain

$$E_{\text{sense}} = E_r \cdot \mathscr{F} \tag{3}$$

$$E_{\text{share}}^{MD} = \gamma \cdot (\mathscr{N} - 1) \tag{4}$$

$$E_{rx}^{MD} = \alpha \cdot t_\alpha^{MD} \tag{5}$$

$$E_m^{MD} = \mathscr{H} \cdot \gamma \cdot (N - 1) \tag{6}$$

where $\mathscr{H}$ is a 0−1 variable indicating whether management has to be performed or not, depending on the policy used.

Concerning the SDs, the following equations are then defined:

$$E_{\text{share}}^{SD} = \gamma + t_\beta^{SD} \cdot \alpha \tag{7}$$

$$E_{rx}^{SD} = \gamma \tag{8}$$

$$E_m^{SD} = t_\beta^{SD} \cdot \alpha \tag{9}$$

Based on the above model, and having all the data about the devices, it is then possible to compute the devices lifetime. Moreover, it is also possible to design specific algorithms which manage the cluster, such as the one defined in [3], where the authors also define the cluster goal, which is the minimum lifetime the cluster should be able to achieve. Since devices are heterogeneous, achieving a higher goal requires that some devices never become an MD, in order to save battery, while others will have a higher probability of being the MD.

Here we present three different algorithms, derived from [3], which are summarized as follows:

- **Greedy**: a device remains as MD as much as it can, before reaching a point where it must save battery to reach the final lifetime goal.
- **Highest**: at the end of each day, the MD drops its role to the device having the highest residual energy. This can be realized with different techniques, and here we leverage on the dynamic backoff. Basically, when the MD advertises, it wants to change its role to SD; each SD computes a backoff to reply to the election proportional to its residual energy. The higher the residual energy, the shorter the backoff time. If a device hears a reply from another SD, it cancels its transmission, since a new MD has been found. This solution has also been used in other scenarios, such as vehicular communication [18].
- **Cost Aware**: since devices can be heterogeneous, this algorithm updates periodically the actual costs of being an SD or an MD, and during the `Maintenance` slot, it selects the client which has done less for the cluster. In other words, the device which has been less days an MD compared to others will be elected.

In this domain, several metrics of interest exist. Within the scope of this analysis, we consider the following:

- **Lifetime**: defined as the time from the start till the first device runs out of battery.
- **Elections**: this is the number of times an MD changes its role. It gives an idea of the overhead involved in each protocol, hence the additional energy used to perform the `Maintenance`.
- **Fairness**: the fairness of the system $\in [0, 1]$. A higher value means that clients shared the workload based on their capabilities, while a low value indicates that there is a considerable variation in the workload between them. More precisely, the fairness is computed as

$$F = 1 - \left(\max_{i \in [0,n[} \left(\frac{D_i}{MD_i} \right) - \min_{i \in [0,n[} \left(\frac{D_i}{MD_i} \right) \right), \tag{10}$$

  where D_i is the amount of time device i has been MD, and MD_i is the maximum time device i can be an MD to keep its lifetime goal.

Figure 3 shows the overhead needed by the three protocols. In Fig. 3a we show the number of elections per day, when considering a cluster of 500 nodes. Setting

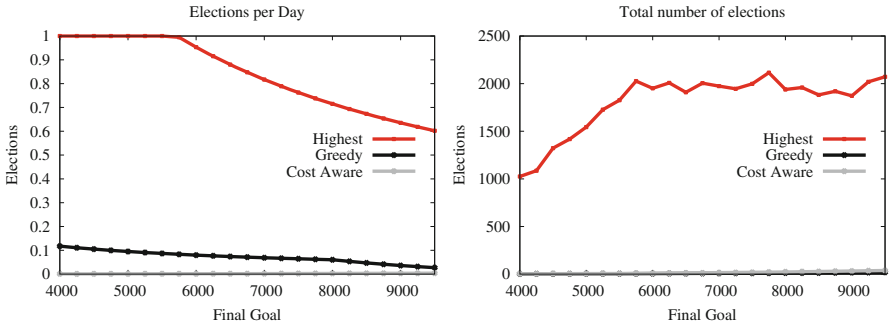

Fig. 3 Analysis on the elections, which translates to the algorithm overhead. A higher number of elections translate into a higher consumption by the devices, which need to send several messages to reach a consensus on the MD. (**a**) Elections per day. (**b**) Total number of elections

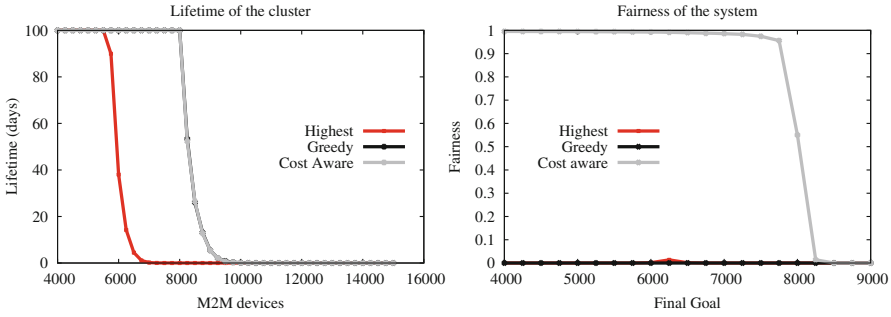

Fig. 4 Lifetime and fairness of the cluster. Setting a higher minimum goal may result in an unfeasible scenario, as the client cannot reach the goal, hence a lower average cluster lifetime. The fairness of the system is achieved only when using the **Cost Aware** protocol, as the other two do not share the load among the devices but only select those which better suit the MD role at the moment. (**a**) Lifetime of the cluster. (**b**) Fairness of the cluster

a higher minimum goal to reach for the devices increases the performance of the system, and the number of elections per day decreases, as devices tend to keep the MD role for a longer time and save battery. This is also confirmed by Fig. 3b, where it is straightforward to note that the total number of elections remains stable after a certain point, which is clearly dependent on the initial configuration of the nodes.

Figure 4 shows the cluster lifetime, along with the fairness. A higher minimum goal for the cluster pushes the capabilities of the devices, and some may not be able to support such high demands. Hence, on the average the cluster lifetime may be reduced. Figure 4a shows the percentage of cluster which are able to reach the goal, which obviously decreases as the minimum goal is increased. These results should only be regarded as qualitative, as precise quantitative results can be obtained only by setting appropriate parameters on the framework, depending on the specific scenario and on the characteristics of the devices.

The fairness of the system is an important parameter, as it shows the workload share. This is of paramount importance when performing maintenance operations, as having only one device which runs out of battery, while all the others still have energy remaining, raises the maintenance costs for such device. On the other hand, achieving a discharge which goes at the same pace for each one, depending on the different capabilities, can end up in having all the cluster to have similar energy remaining, hence perform maintenance operations on all the devices at once, thus decreasing the maintenance cost per single device.

Conclusion and Future Directions

In this chapter we presented the benefits and the challenges of DSA for M2M communication. M2M communication should be performed by devices without or with little human intervention. Thus, they should encompass self-healing and self-configuring capabilities. Cognitive network, hence DSA, is a technology that could help to overcome some of the challenges that M2M networks face, such as the energy constraints and the possible long range of the communication. Several experiments, both theoretic as well as simulative and with test-beds, have demonstrated both the benefits and the limits of M2M communication when considering DSA. In particular, energy efficiency should be taken into account when deploying M2M networks, and it becomes even more constrained when using spectrum agile techniques such as spectrum sensing and DSA.

Clearly, there is a plethora of topics which can be explored and further analyzed, which we have identified and commented in this chapter, and which we summarize here:

- **Energy efficiency**: even though we stated that M2M device may not be battery powered, it is also straightforward to understand that in a vast set of scenarios, they will be. Energy efficiency can be optimized in several parts of the device, either on the computation, on the transmission, or on the architecture level, where improvements are obtained through device collaboration.
- **Spectrum sensing**: it can be expensive both in terms of computation cost and also simply on the energy needed to listen to the channels, even more depending if a large spectrum is considered. Different techniques can be applied, such as cooperative spectrum sensing, in which devices organize and divide the tasks so that the energy consumption per single device is reduced. Other solutions involve identifying smaller portions of spectrum so that the task of sensing becomes more feasible. Regardless of the technique used, spectrum sensing is vital for DSA, and it is also an operation which needs to be repeated multiple times, as spectrum utilization may change suddenly.
- **Test-beds**: most of the presented results have been studied through simulations or with devices which implement only some of the tasks a cognitive M2M device should utilize. Hence, it is challenging to find wider analysis, which take

into account M2M communication and DSA accounting for realistic scenarios. In particular, primary user activity on the spectrum may be challenging to understand in real scenarios, rather than simulations where it can be controlled.

tal and application requirements, is considered as important as the hardware components which enable the dynamic spectrum access (DSA) capabilities. To this purpose, several machine learning (ML) techniques have been applied on CR spectrum and network management issues, including spectrum sensing, spectrum selection, and routing. In this paper, we focus on reinforcement learning (RL), an online ML paradigm where an agent discovers the optimal sequence of actions required to perform a task via trial-end-error interactions with the environment. Our study provides both a survey and a proof of concept of RL applications in CR networking. As a survey, we discuss pros and cons of the RL framework compared to other ML techniques, and we provide an exhaustive review of the RL-CR literature, by considering a twofold perspective, i.e., an application-driven taxonomy and a learning methodology-driven taxonomy. As a proof of concept, we investigate the application of RL techniques on joint spectrum sensing and decision problems, by comparing different algorithms and learning strategies and by further analyzing the impact of information sharing techniques in purely cooperative or mixed cooperative/competitive tasks.

Introduction

A cognitive radio (CR) can be defined as a wireless device that is able to autonomously control its configuration based on the environmental conditions and on the quality of service (QoS) requirements of the applications [1]. Since its original proposal in 1999 [2], the node architecture has been considered the core novelty of a CR device, being the fusion of advanced dynamic spectrum access (DSA) functionalities at the radio level and of intelligent decision-making provided by a cognition module (CM) at the software level. Through the DSA, a CR is able to observe the network environment and to dynamically adjust transmission parameters like the operative frequency, the modulation and coding scheme, or the power level. To this purpose, the dynamic reuse of vacant portion of the licensed spectrum, in overlay or underlay mode, has emerged as the prominent use-case of the CR technology: CR devices, also known as secondary users (SUs), aim to maximally exploit all the available spectrum frequencies, including both licensed and unlicensed ones, without affecting the performance of the frequency owners, also known as primary users (PUs) [1]. The research literature on channel sensing techniques, required to detect PU-free transmission opportunities on the frequency and time domains, is vast [3, 4], as well as the number of proposed network architecture and standards regulating the operations of the SUs [5, 6]. On top of the DSA module, the CM leverages the perceptions and measurements gathered during the sensing phase for the decision-making process, i.e., to properly adjust the radio configuration and plan the network operations, by means of advanced learning and reasoning functionalities [7]. For this reason, a significant portion of the literature on CR networking is investigating the utilization of machine learning (ML) techniques [8] for the device and network configuration, optimization, and planning; the ML approaches adopted so far are extremely heterogeneous and include supervised

learning techniques (e.g., neural networks and Bayesian classifiers), unsupervised learning techniques, and dynamic games [9–11].

In this paper, we focus on reinforcement learning (RL) [12, 13], a well-known ML paradigm where the agent learns the optimal sequence of actions in order to fulfill a specific task via trial-and-error interactions with a dynamic environment; at each action performed, the agent observes its current state and receives a numeric reward, which quantifies the effectiveness of the action. The agent behavior, also known as the *policy*, should choose actions that tend to increase the long-term sum of rewards [13]. The literature on RL dates back to the 1960s [12] and comprises several different techniques and variants [14–17]. The online nature of the learning process fits well the architecture of a CR device: the DSA module provides context-awareness via explicit feedbacks and channel measurements, and based on such rewards, the RL-CM is able to learn the optimal state-action mapping. Differently from supervised learning [8], RL algorithms might work without assuming any previous knowledge of the environment and of the reward function [11]. At the same time, a RL agent continuously adjusts its current policy based on the interactions with the environment: hence, policy adaptiveness is implicitly addressed also in dynamic and nonstationary environments.

This property is particularly interesting in CR networking scenarios, which are dynamic by nature due to the mobility of the SU devices, the PU activity patterns, and the likely varying propagation and traffic load conditions, and constitutes another significant advantage compared to traditional optimization approaches. Thanks to these benefits, several recent works have demonstrated that RL techniques can be applied on spectrum management issues [18–20], including channel sensing, channel selection, or power control problems, as well as on many CR network management issues, including routing, cooperation control, and security [21, 22]. At the same time, the application of RL techniques in CR scenarios hides a number of technical challenges, like the impact of exploration phase on the system performance Ozekin et al. [23, 24] and the convergence in distributed environments characterized by the presence of SUs that compete for shared resources (e.g., channel frequency) while cooperating on keeping the aggregated interference below a predefined QoS threshold [25, 26].

This paper investigates the application of RL techniques on CR networking by providing two kinds of scientific contributions, i.e., (i) a survey of the RL-CR-related literature, which can serve also as a tutorial for readers approaching the topic for the first time, and (ii) a proof of concepts of RL techniques on novel CR use-cases. Regarding the survey/tutorial, after a brief presentation of the RL theory and of the main algorithms, we discuss advantages and drawbacks of the RL framework for CR networking, and we compare it against other ML approaches. We then provide an up-to-date and exhaustive review of the RL-CR-related literature through a twofold taxonomy. The first taxonomy is based on the CR application domains, focusing on spectrum management and network configuration issues (i.e., spectrum sensing, decision, power allocation, and routing); on each category, we further classify the studies according to the proposed goal being addressed. The second taxonomy is learning methodology-driven, i.e., we review

the literature according to specific RL modeling features which are orthogonal to the application domain, like the modeling of the environment and of the reward function. Regarding the proof of concepts, we describe a novel application of RL techniques on joint channel sensing and decision problems (hence, combining two research issues which are treated separately in the survey): more specifically, we show how the SUs can autonomously learn the optimal channel allocation, as well as the optimal balance of sensing/transmitting actions on each channel, so that the secondary network performance are maximized, while the harmful interference to PU receivers are kept below a QoS threshold. We formulate the problem as an instance of a Markov decision process (MDP) [12, 13], and we tested different algorithms (Q-Learning and Sarsa) and learning models, on two different task goals: independent learning and collaborative agents on a fully cooperative task (e.g., PU-SU interference minimization) and distributed coordinating agents on a mixed cooperative/competitive task (e.g., SU-SU and PU-SU interference minimization). The experimental results show that RL-based solutions can greatly enhance the performance in dynamic CR environments compared to non-learning-based solutions; at the same time, they unveil the impact of RL parameter tuning, knowledge sharing techniques, and algorithm selection, hence paving the way to further researches on the topic.

The rest of the paper is structured as follows. Section "Related Works" reviews the existing surveys addressing ML and RL applications in CR networks and points out the novelties of this paper. Section "Overview of Reinforcement Learning" provides an overview of the RL theory, by introducing a taxonomy of the existing techniques and by also summarizing the operations of the most popular RL algorithms. Advantages and drawbacks of RL-CR approaches are discussed in section "Reinforcement Learning in Cognitive Radio Scenarios: Pros and Cons". Section "Reinforcement Learning in Cognitive Radio Scenarios: Applications-Driven Taxonomy" reviews the existing RL-CR studies according to an application-driven taxonomy. The existing works are further classified by means of a learning methodology-driven taxonomy in section "Reinforcement Learning in Cognitive Radio Scenarios: Learning Methodology-Driven Taxonomy". The case study is presented in section "Case Study: RL-Based Joint Spectrum Sensing/Selection Scheme for CR Networks", together with the RL formulation, proposed algorithms and performance evaluation results. Conclusions are drawn in section "Conclusions and Open Issues".

Related Works

The most comprehensive surveys investigating the applications of ML techniques on CR networking are probably [9, 10], and [11]. More specifically, [10] describes the existing applications of ML techniques on CR networking, considering both supervised and unsupervised learning techniques and including also the RL-based approaches. Moreover, the authors investigate the learning challenges in non-Markovian environments and discuss policy-gradient algorithms. An impressive

review of model-free learning-based solutions in CR networks is presented in [11], where the existing works are grouped in three main categories, i.e.: (i) strategy-learning schemes based on single-agent systems, (ii) strategy-learning schemes based on loosely coupled multi-agent systems, and (iii) strategy-learning schemes in the context of games. In [9], the authors survey the ML-CR literature by considering an interesting distinction between learning aspects of cognition – which include RL and dynamic games – and reasoning aspects. These latter are in charge of applying inference on the acquired and the learned knowledge, hence enriching the current knowledge base; applications of policy-based reasoning to predict spectrum handover operations or to enhance spectrum opportunity detections are evaluated in a test-bed [9]. The strict relationship occurring between learning and reasoning in CR networks is also investigated in [7]. By focusing on the RL-CR literature, the authors of [20] demonstrate how the RL framework, and in particular the Q-routing algorithm, can be utilized as modeling tool in four different problems, regarding dynamic channel selection (DCS), DCS and route selection, DCS and congestion control, and packet scheduling in QoS environments. Similarly, the authors of [18] show how three different CR problems (routing, channel sensing, and decision) can be modeled via the Markov decision process (MDP) introduced by the RL framework. Applications, implementations, and open issues of RL techniques in CR networks are extensively discussed in [19], which is the work most similar to our paper. Our paper provides two additional contributions compared to [19]: (i) it provides an up-to-date review of the RL-CR literature from two different perspective, i.e., a CR networking perspective and a learning perspective, and (ii) it evaluates gains and drawbacks of the RL framework on a realistic CR use-case, addressing joint spectrum sensing, and selection.

Overview of Reinforcement Learning

Reinforcement learning (RL) constitutes an area of machine learning (ML) [8] addressing the problem of an agent that must determine the optimal sequence of actions to perform over time, so that a predefined goal is achieved [12, 13]. Differently from supervised techniques, the learning process is based on trial-error interactions with the environment, i.e., at each action, the agent receives a numeric reward which is a proxy for its optimality (see Fig. 1). The optimal sequence is the

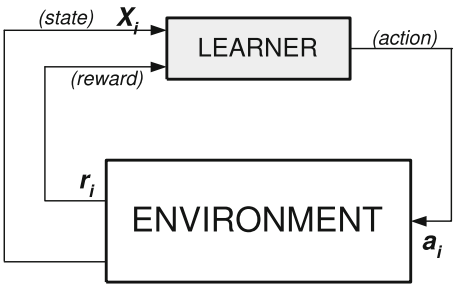

Fig. 1 The reinforcement learning (RL) model

one maximizing the summation of the expected rewards received by the agent over time.

More formally, the RL problem can be modeled by using a discrete Markov decision process (MDP), represented by the tuple $< S, A, R, ST >$, where:

- S is the (discrete) set of *available States*; let s_t denote the current state of the agent at time t.
- A is the (discrete) set of *Actions*; let $A(s_t)$ denote the set of actions available in state s_t.
- $R : S \times A \rightarrow \Re$ is the *Reward* function indicating the numeric reward received at each state/action; more specifically, let r_t indicate the reward received by the agent while being in state s_t and executing action $a_t \in A(s_t)$.
- $ST : S \times A \rightarrow S$ is the *State Transition* function, which indicates the next state s'_{t+1} after executing action $a_t \in A(s_t)$ from state s_t; in case of nondeterministic environments, the ST function is a probabilistic distribution over the set of actions and states, i.e., $ST : S \times A \times S \rightarrow [0 : 1]$.

Another component of the RL framework is the policy function $\pi : S \rightarrow A$, which indicates, for each state s_t, the proper action a_t to execute. Similarly to the state transition function, also the policy function can be modeled as a probabilistic distribution over the set of actions and states, i.e., $\pi : S \times A \rightarrow [0 : 1]$. The goal of the agent is to discover the optimal policy π^* which maximizes a specific function of the received rewards over time. In the infinite-horizon discount model [13], the policy aims to maximize the long-run expected reward; however, it discounts the rewards received in the future, i.e.:

$$goal \rightarrow maximize\ E\left(\sum_{t=0}^{\infty} \gamma^t \cdot r_t\right) \tag{1}$$

where $0 \leq \gamma \leq 1$ is a factor discounting the future rewards. If $\gamma = 0$, the agent aims to maximize the immediate rewards.

In order to compute the optimal policy, several RL algorithms employ two additional data structures: the state-value function (V^π) and the state-action function (Q^π) [12, 13]. For each state $s \in S$, the state-value function $V^\pi(s_t)$ represents the expected reward when following policy π from state s_t. The $V^\pi(s_t)$ value can be computed as follows:

$$V^\pi(s_t) = \sum_{a_t \in A(s_t)} \pi(s_t, a_t) \cdot \sum_{s' \in S} ST(s_t, a_t, s') \cdot \left(R(s_t, a_t) + \gamma \cdot V^\pi(s')\right) \tag{2}$$

Analogously, the state-action function $Q^\pi(s_t, a_t)$ represents the expected reward when the agent is in state s_t, executes action a_t, and then follows the policy π. More formally:

$$Q^\pi(s_t, a_t) = \sum_{s' \in S} ST(s_t, a_t, s') \cdot \left(R(s_t, a_t) + \gamma \cdot V^\pi(s')\right) \tag{3}$$

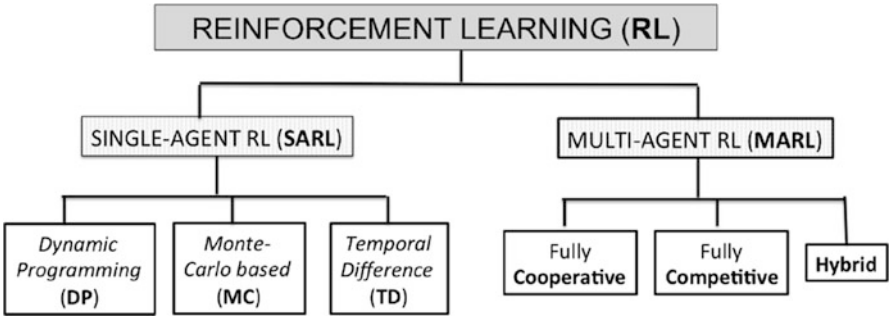

Fig. 2 Taxonomy of reinforcement learning (RL) algorithms

RL techniques can be classified into single-agent RL (SARL) and multi-agents RL (MARL) (see Fig. 2); the main characteristics of each approach are illustrated in the following section.

SARL Algorithms

In a SARL framework, each agent acts independently and aims to maximize its long-run expected reward (Eq. 1). Different techniques have been proposed in order to determine the optimal policy π^*, including dynamic programming (DP), Monte Carlo-based, and temporal-difference (TD) learning algorithms. DP techniques assume a perfect knowledge of the environment, i.e., of the reward (R) and of the state transition (ST) functions; hence, the exact value of $V^{\pi}(\cdot)$ can be computed by solving Eq. 2. The DP algorithms alternate between a policy-evaluation phase, during which the value of the current policy $V^{\pi}(s)$ is determined for each state $s \in S$, and a policy improvement phase, where the current policy π is modified into π' so that $\pi'(s) = \text{argmax}_{a \in A} Q^{\pi}(s, a)$ [12]. Monte Carlo methods do not assume the knowledge of the environment, but they are mainly used on episodic tasks [12]. Vice versa, TD methods implement an online, step-by-step learning process without assuming a model of the environmental dynamics. Among the several existing TD-based solutions, we cite the popular Sarsa and Q-learning algorithms [16, 17]: they both update the Q-table after each received reward, till converging to the optimal Q^* values. More specifically, each time the agent chooses action a_t from state s_t (receiving reward r_t), and action a_{t+1} from next state s_{t+1}, the Sarsa algorithm [17] updates the $Q(s_t, a_t)$ entry as follows:

$$Q(s_t, a_t) = Q(s_t, a_t) + \alpha \cdot [r_t + \gamma \cdot Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)] \tag{4}$$

where α is a learning rate factor. The Q-learning algorithm [16] employs a slightly different update rule, since it is independent from the policy being followed (offline policy learning), i.e.:

$$Q(s_t, a_t) = Q(s_t, a_t) + \alpha \cdot \left[r_t + \gamma \cdot \max_{a_{t+1} \in A(s_{t+1})} Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t) \right] \tag{5}$$

Both Sarsa and Q-learning algorithms are guaranteed to converge to the optimal Q^* values, under the assumption that all state-action pairs are visited an infinite number of times, and proper tuning of the α factor [16, 17]. This poses a challenging trade-off between exploration and exploitation actions, i.e.: (i) insufficient exploration might affect the convergence to the optimal Q^* values, while (ii) excessive exploration might determine performance fluctuations caused by the selection of random actions. A well-known approach to balance exploration and exploitation actions is via the Boltzmann Equation [12], which assigns a probability to each action and state as a graded function of the estimated $Q(s, a)$ value:

$$p(s, a) = \frac{e^{Q(s,a)/TE}}{\sum_{a' \in A(s)} e^{Q(s,a')/TE}} \tag{6}$$

where $TE > 0$ is the temperature parameter and controls the exploration/exploitation phases. Indeed, high temperature values cause the actions to be all equiprobable, while, if $TE \to 0$, the greedy action a^* associated to the highest $Q(s, a^*)$ value is always selected, for each state $s \in S$.

MARL Algorithms

The MARL framework generalizes the MDP to the case of a multi-agent environment. Let N be the number of learning agents and S^i and A^i be the state and action sets for agent i. The state of the MARL at time t, $\widehat{s_t}$, is then defined as the combination of the individual states of the agents, i.e., $\widehat{s_t} = \{s_t^1, s_t^2, \ldots s_t^N\}$. Similarly, the system action $\widehat{a_t}$ is defined as the combination of the individual actions performed by the agents, i.e., $\widehat{a_t} = \{a_t^1, a_t^2, \ldots a_t^N\}$; based on $\widehat{a_t}$ and $\widehat{s_t}$, a vector of rewards is produced, i.e., $\widehat{r_t} = \{r_t^1, r_t^2, \ldots r_t^N\}$. According to the way such rewards are computed, and to the interactions among the agents, [14, 15] further classify MARL techniques as *fully cooperative*, *fully competitive*, or *hybrid*. In the first case, all the agents receive the same reward, i.e., $r_t^1 = \ldots = r_t^N$, and the goal is to determine the optimal joint policy maximizing a common discounted return; although such policy could be also determined via SARL techniques assuming that all the agents keep the full Q-table of $\widehat{s}$ and $\widehat{a}$ values, most of the MARL algorithms work by decomposing the Q-table and introducing indirect coordination mechanisms [27]. In fully competitive MARL frameworks, a min-max principle can be applied, for instance, when $N = 2$, $r_t^1 = +\zeta$ and $r_t^1 = -\zeta$ [14]. Finally, hybrid MARL techniques apply on not fully cooperative nor fully competitive problems, where the reward function might assume a complex shape depending on the joint action being implemented by the agents; this is the case, for instance, of agents competing for a shared resource, like SUs determining the optimal channels

where to transmit and taking into account the interference caused by other players (we further investigate such use-case in section "Case Study: RL-Based Joint Spectrum Sensing/Selection Scheme for CR Networks"). Hybrid MARL frameworks usually employ distributed coordination techniques derived from the game theory. We do not further elaborate on MARL techniques; interested readers can refer to [14] and [15] for a detailed illustration.

Reinforcement Learning in Cognitive Radio Scenarios: Pros and Cons

In CR networking, the cognition cycle, i.e., the ability of wireless transceivers to learn the optimal configuration meeting the characteristics of the environment and the QoS requirements of the applications, is considered as important as the hardware components which enable the spectrum reconfiguration capabilities. To this purpose, several ML techniques have been applied on CR-related use-cases [10], like spectrum sensing, spectrum selection, or routing; beside the RL techniques, which are the main topic of the paper, we cite approaches based on the game theory (GT), neural networks (NN), or Bayesian classifier (BC). On the SCOPUS database, we counted around 400 scientific papers addressing ML-based approaches in CR networks[1]: 23% of them are based on RL schemes, more than the supervised learning schemes but still less than GT-based approaches. In any case, Fig. 3 shows that there is no ML solution fitting all the solutions. This is because RL techniques provide clear advantages but also formidable drawbacks when applied on CR-related use-cases. About the advantages, RL techniques can considered highly suitable for CR applications because of these characteristics:

1. *Experience-based Learning*. In supervised learning, a cognitive agent must be instructed on how to perform a classification task by means of a knowledge base containing both positive and negative instances. In CR-related applications, building the knowledge base from real experiments can pose practical issues in terms of scalability and costs. Another issue pertains to the generalization of the learning process, i.e., to the problem of classifying novel instances which are considerably different from those occurring in the knowledge base. This aspect is particularly critic in CR environments, since the network performance is affected by a high number of parameters and by environmental conditions (like the PU activity model, the SU traffic load, the channel error rate, etc.); as a result, a transmitting policy learnt by a CR agent via supervised techniques might not be effective on a different network scenarios or even on the same scenario in presence of dynamic changes of environmental conditions. Vice versa, RL techniques do not require the creation of a knowledge base, rather they leverage on trial-and-error interactions with the environments. In addition, some

[1]The classification rule is based on the occurrence of specific keywords in the paper title.

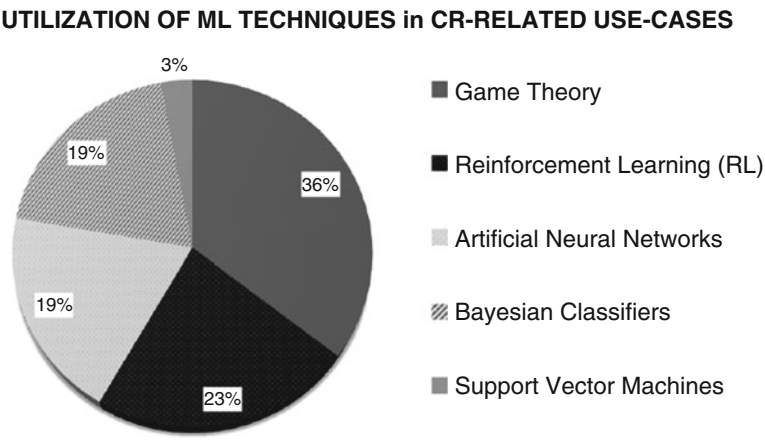

Fig. 3 Machine learning (ML) techniques utilized in the RL literature

model-free algorithms like Sarsa and Q-learning [11, 16, 17] do not assume an a priori knowledge of the environmental dynamics (i.e., of the reward and state transition functions); as a result, the same learning algorithm deployed on different network scenarios can automatically discover differentiated transmitting policies, without any need of adaptation or tuning of the RL algorithm.

2. *Context adaptiveness*. Through the concepts of rewards and Q-values, the RL framework provides effective building blocks in order to implement adaptive, spectrum-aware solutions. Indeed, since any RL agent continuously evaluates its current policy and improves it, any change in the received reward might cause a policy switch, or it might trigger new exploration actions, hence leading to the discovery of better actions to perform in some states. Moreover, the presence of aggregated rewards can indirectly boost the context-awareness in another way. As already said, performance of CR networks can be affected by multiple factors, whose interactions might be difficult to model analytically. Instead of addressing a single factor at a time, a RL agent can observe all the factors as a state, receive an aggregate feedback (e.g., the cost of each transmission), and optimize a general goal as a whole, e.g. throughput [28].
3. *Reduced complexity*. In most cases, RL techniques provide a simple yet effective modeling approach [12]. Model-free RL algorithms like Q-learning or Sarsa require only the storing of the Q-table. The number of state-action values can be further reduced via function approximation techniques; an example related to CR spectrum management can be found in [29]. In addition, it is worth remarking that the update rule of Q-learning or Sarsa algorithms can be implemented in few lines of codes. This feature makes RL techniques suitable also in resource-constrained environments, like CR-based sensor networks [30], where the wireless devices must face severe energy issues.

These advantages are counterbalanced by formidable drawbacks, which should be taken into account when working on CR networks, i.e.:

1. *Continuous Discovery.* Properly balancing the exploitation/exploration phase is a unique challenge of the RL framework [23]. On the one side, RL agents are required to perform random actions in order to explore the state-action space and then compute the optimal policy. In dynamic environments, the exploration phase cannot be ended after the boot phase; rather it must be continuously performed over time. This is the case, for instance, of SUs aimed to learn the available spectrum opportunities in a multiband scenario; while transmitting on a PU-free channel, the SU should also keep track of the opportunities on other channels, so that a spectrum handoff can be quickly performed in case of PU appearance [31]. On the other hand, a random selection might translate into suboptimal actions being executed, e.g., into the selection of low-quality or PU-busy channels, and hence lead to temporary performance degradation. Permanent performance degradation can occur when the exploration phase has been too short, or too long; hence, the optimal trade-off between exploration and exploitation can be complex to achieve, as investigated in section "Case Study: RL-Based Joint Spectrum Sensing/Selection Scheme for CR Networks".
2. *Convergence Speed.* Many RL techniques (specially time discounted methods [12]) guarantee convergence to the optimal policy only if each action is executed in each state an infinite number of times. This is clearly not realistic for most of CR applications; moreover, the fact that environmental conditions can quickly change over time can pose additional requirements on the speed of convergence. The issue is further exacerbated in MARL scenarios, where the optimal joint action must be determined, e.g., in spectrum selection or power adaptation problems [32, 33] where the SUs should maximize their own performance while collectively mitigating the interference to PUs. For these reasons, MARL-based algorithms are often enhanced with GT mechanisms which guarantee the emergence of a Nash equilibrium under specific assumptions [25, 26].

Reinforcement Learning in Cognitive Radio Scenarios: Applications-Driven Taxonomy

In this section, we describe the applications of RL techniques in four different CR use-cases, e.g., spectrum sensing, power allocation, spectrum decision, and routing. For each use-case, we provide a taxonomy of the existing works, and we briefly discuss their technical contributions, by mainly focusing on the problem formulation through the MDP. Figure 4 depicts the classification adopted throughout this section.

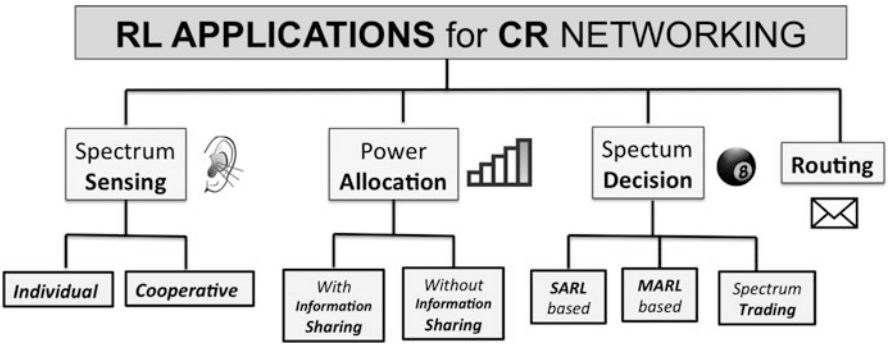

Fig. 4 Applications-driven taxonomy of the RL-CR literature

Spectrum Sensing

In CR, spectrum sensing techniques play the crucial role to identify the available spectrum resources for the SUs [1]. As a result, most of research is focused on advanced signal processing schemes aimed to achieve robust PU detection under different signal-to-noise ratio (SNR) conditions [3]. Beside this, the scheduling of sensing actions is also a crucial task affecting the performance of the SUs [34], mainly due to the fact that half-duplex radios cannot transmit on a channel while listening to it. The optimal sensing schedule can be determined via experiments and analytical models [4] or dynamically learnt via trial-and-error interactions with the environment [35]. About this latter, existing RL-based sensing schemes can be further classified into *individual* or *cooperative* approaches. We discuss them separately in the following.

Individual Sensing Scheduling

Frequency and duration of the sensing phase constitute a challenging trade-off between PU detection accuracy and throughput of the secondary network: too long sensing intervals might cause buffer overflow and/or TCP time-outs, while too short sensing intervals might lead to poor throughput due to SU-PU collisions [34]. Moreover, SUs should periodically explore all the available channels in order to detect spectrum opportunities over time. For these reasons, recent studies like [36, 37] and [38] investigate the problem on how to optimally balance sensing, transmission, and exploration actions, so that the performance of SU networks are maximized, while the PU detection accuracy is always kept higher than a safety threshold. More specifically, the authors of [36] formulate the problem via a MDP defined as follows: the set of states $S = \{s_1, s_2, ..s_{|S|}\}$ represents the available (licensed) resources. On each channel s, a SU can perform three actions:

- a_1: sense channel s and transmit in case the channel is found idle (*exploitation*).
- a_2: sense channel $s' \neq s$ (*exploration*).
- a_3: switch to channel $s' \neq s$ (*exploitation*).

For actions a_1 and a_2, the reward is expressed by the number of PU-free subcarriers detected on the sensed channel; vice versa, for action a_3 the reward is always equal to zero. The study in [37] extends such formulation, by taking into account the channel switching delay in the reward of action a_3 and by decoupling the transmit action from the sensing action; for sensing actions, the reward is equal to 1 in case of PU detection, 0 otherwise. Vice versa, the reward of transmit actions is computed as the average number of MAC retransmissions for each successful data transmission. The simulation results in [37] show that the proposed RL-based scheme is able to dynamically adjust the sensing frequency according to the perceived PU activity on each channel. Similarly, in [38], the authors aim to balance transmission and sensing actions on each channel; a cost function $C_s(\tau)$ is decreased each time a sensing action is performed on channel s, and this latter is found idle. When $C_s(\tau)$ is lower than a threshold Γ, then the SU can perform a transmission attempt; vice versa, if $C_s(\tau) > \Gamma$, then SU defers its attempt and keeps sensing the channel. When the channel is found occupied by a PU, the cost function $C_s(\tau)$ is reset to a maximum value. In [39], the problem of determining the optimal sequence of channels sensed by each SU is formulated through the RL framework; here, a state is defined as an ordered couple $< o_k, f_j >$, where o_k is the current position at the sensing order and f_j is the k-th channel sensed in the current slot. At each state $< o_k, f_j >$, the list of available actions will include all the channels (not visited yet) which could be sensed at the next position of the sensing order (o_{k+1}). The reward function for a specific sensing order action takes into account the time spent sensing the channels and the transmission rate experienced by the SU on the selected channels [39].

Cooperative Sensing Scheduling

Sensing techniques can be prone to errors in presence of shadowing or multipath fading conditions on the current licensed channel. For this reason, cooperative sensing techniques [3] aim to enhance the PU detection by aggregating channel measurements from multiple SUs and by averaging the gathered results. However, the network overhead might limit the cooperative gain: for instance, the transmission delay might be higher in presence of cooperative sensing, since each SU should gather the measurements from other peers before taking a decision about the spectrum availability. For this reason, studies like [40,41] and [42] employ the RL framework in order to determine the optimal set of cooperating neighbors for each SU; the goal is to maximize the PU detection accuracy while avoiding unnecessary measurements sharing among correlated SUs. In [40], the set of states S for SU i coincides with the list of neighbors, plus one start and one end state. There is an action which allows to move from any couple of states; the sequence of actions correspond to the list of cooperative sensing neighbors, i.e., neighbors to query in order to get channel measurements. The reward function combines the amount of correlation among the gathered sensing samples plus the total reporting delay. In [42], the authors investigate how to coordinate the sensing actions of a secondary network, in order to meet the optimal trade-off between two goals: (i) the maximum number of spectrum opportunities is detected, and (ii) the probability of missed detection on each channel is kept below a safety threshold. Such probability is

estimated based on the number of SUs currently sensing the channel. Since the SUs cannot directly observe the PU state on each channel, the sensing problem is formulated via a partially observable MDP (POMDP).

Power Allocation

In both underlay and overlay CR spectrum paradigms, the SUs should properly tune their transmitting power levels so that the probability of generating harmful interference to any active PU is minimized. Differently from spectrum sensing, which can be considered an individual or, in presence of knowledge sharing, a fully cooperative task, power allocation is a natively hybrid competitive/collaborative task, since the reward function, i.e., the aggregated interference perceived by PU receivers, depends on the joint action performed by the SUs, i.e., on the selected transmitting power level of each SU. For this reason, power allocation can be easily modeled via a MARL framework (see section "Overview of Reinforcement Learning"). A straightforward approach in order to determine the optimal power allocation consists in storing the complete MARL Q-table for each state/action/learning agent and by computing the optimal $\widehat{a}_t$ through Eq. 4. This methodology is employed in [43], assuming a centralized CR network with a single learning agent, i.e., the cognitive base station, which is charge of determining the optimal power level of each SU, based on the cumulative interference caused to the PUs. In distributed deployments, storing and updating the complete MARL Q-table at each SU might not be practical especially when the number of learning agents (i.e., the SUs) increases. For this reason, most of recent works employ decentralized MARL with two different approaches. In the first case (described in section "RL-Based Power Allocation Based on Information Sharing"), the SUs share rewards or rows of their Q-table after each local action, so that the interference caused by the joint action $\widehat{a}_t$ can be computed. In the other case (described in section "RL-Based Power Allocation Without Information Sharing"), each SU acts according to the local information only, but the secondary network still aims to achieve a global coordination, often expressed by the notion of Nash equilibrium (NE).

RL-Based Power Allocation Based on Information Sharing

In decentralized MARL frameworks, information sharing can be used for two different objectives: (i) speedup the learning process of the individual agents, by reducing the amount of exploration needed; or (ii) favor the identification of joint optimal actions at each learning agent. The docitive paradigm discussed in [44,45] is an example of the first use-case; here, the learning agents are secondary base stations (femtocells) which must determine the optimal transmitting profile so that the aggregated interference at the primary receivers is kept below a specific threshold ($SINR_{Th}$). The problem is modeled through the MDP defined as follows:

- The state set is defined as the set of couples $\{I_t^i, d_t^i\}$, where $I_t^i \in \{0; 1\}$ is a binary indicator specifying whether the CR base station i is generating an aggregated

interference above or below the $SINR_{Th}$ threshold, and d_t^i is the approximated distance between i and the protection contour region of the primary system.
- The action set coincides with the discrete set of power levels which can be assigned to each CR base station.
- The reward function $R(i) = (SINR_t^i - SINR_{Th})^2$ expresses the difference between the SINR value measured by SU i and the expected threshold.

In addition, docitive SUs can teach the discovered policies to other peers, by sharing parts of the local Q-table. In [44] , three different information-sharing techniques are evaluated, namely, start-up docition, adaptive docition, and iterative docition. This latter (involving continuous sharing of the Q-table entries) maximizes the system performance, although introducing the highest network overhead. In [45], the docitive scheme is extended for the case of partially observable environments, i.e., when the SUs lack of complete information about aggregated interference at the protection contour regions. A similar learning-from-experts MARL approach is followed in [46] and [47] but also introducing expertness measures which estimate the amount of knowledge which can be transferred between each couple of SUs. More specifically, the authors of [47] address a generic power-spectrum selection problem; at each step, an agent can decide whether to stay idle, to switch to a different channel, or to increase/decrease the current transmitting power. The current state reflects the buffer occupancy of each SU, while the reward function is related to the energy efficiency of each action. Periodically, all the SUs update their Q-entries by considering a weighted combination of location information and received Q-values, i.e., $Q_i^{\text{new}} = \sum_j W_{i,j} \cdot Q_j^{\text{old}}$, where $W_{i,j}$ is a measure on how much SU i relies on knowledge produced by SU j. The scheme in [47] employs information sharing in order to speed up the individual learning process; however, there is no guarantee that the optimal joint action will be determined. In order to fulfill this second requirement, the authors of [48] propose a cooperative RL-based power allocation scheme aimed to control the aggregated interference generated by SU femtocells. The MDP model is similar to [44, 45]; however , each SU shares only a row of its Q-table. At each time-slot, a SU chooses action a_i maximizing the summation of the Q-values considering the current states of all the N neighbors, i.e.:

$$a_i = \text{argmax}_a \left(\sum_{i \le j \le N} Q_j(s_j, a) \right) \tag{7}$$

RL-Based Power Allocation Without Information Sharing

Differently from the previous works, studies like [32] and [33] address the power selection problem without assuming information sharing among the SUs; each SU tunes its transmitting power based on local (possibly inaccurate) interference measurements, but at the same time, it observes or makes conjectures about the behavior of other SUs. Based on such estimations, each SU adjusts its transmitting

power so that a global NE is achieved, i.e., no SU can experience better rewards by following a different policy. The MDP is formulated as follows:

- The state set is defined as the set of couples $\{I_i, p_i(a_i)\}$, where $I_i \in \{0; 1\}$ is a binary indicator specifying whether the SINR of SU i is higher or lower than a predefined safety threshold and $p_i(a_i)$ denotes the current power level.
- The action set coincides with the discrete set of power levels which can be assigned to each SU.
- The reward function R is a proxy for the energy efficiency of the transmission attempt, i.e., of the average number per bits received per unit of energy consumption; if I_i=1, the reward is set to zero.

Differently from [44, 45], each SU keeps internal conjunctures about how the other SUs will react to their current action. More specifically, at each action performed in state s_t, SU i updates its Q-table as follows:

$$Q^{t+1}(s_i, a_i) = (1-\alpha) \cdot Q^t(s_i, a_i) + \alpha \cdot \left(\sum_{a_{-i}} \overrightarrow{c}^t(s_i, a_{-i}) \cdot r_t + \beta \max_{b_i} Q(s_i', b_i) \right) \tag{8}$$

where $\overrightarrow{c}^t(s_i, a_{-i})$ denotes the conjecture of SU i regarding the behavior of the other players and is updated as follows:

$$\overrightarrow{c}^{t+1}(s_i, a_{-i}) = \overrightarrow{c}^t(s_i, a_{-i}) - \omega_i^{s_i, a_{-i}} \cdot \left[\pi_i^{t+1}(s_i, a_i) - \pi_i^t(s_i, a_i) \right] \tag{9}$$

Spectrum Selection

Dynamic channel selection (DCS) constitutes the most investigated RL application in the field of wireless networking [20, 49–53]. In overlay RL networks, each SU must select the proper channel where to transmit in order to fulfill two main requirements: (i) minimize the interference caused to PU receivers tuned on the same or adjacent spectrum bands (G_0) and (ii) maximize its own performance, by taking into account the channel contention and the MAC collisions caused by other SUs operating on the same band (G_1). Moreover, the SUs should continuously execute channel selection in order to adapt to dynamic changes of the PU activities, to the traffic loads generated by the SUs, and to varying propagation and channel state conditions. It is easy to notice that the RL framework fits well the requirements of adaptive protocol design. G_0 is usually addressed via the SARL techniques presented in section "SARL-Based DCS". Vice versa, meeting both G_0 and G_1 requires some form of coordination among the SUs: for this reason, the DCS problem is modeled via MARL techniques enhanced with game theory concepts, so that a stable channel allocation is achieved (details are provided in section "MARL-Based DCS"). Another way of classifying the existing RL-DCS schemes proposed in the literature is by focusing on the learning

agent, i.e., on where the RL framework is implemented. The solutions presented in sections "SARL-Based DCS" and "MARL-Based DCS" refer to a scenario where channel selection is performed by each SU, and the PU is unaware about the presence of opportunistic users. Vice versa, in spectrum trading models, the PUs borrow portions of its spectrum to the SUs, receiving in return a monetary revenue; the problem formulation through the RL framework allows determining the optimal portion of spectrum band which can be leased to the SUs without compromising the QoS requirements of the primary network. Details about RL-based spectrum trading schemes are provided in section "RL-Based Spectrum Trading".

SARL-Based DCS

This subcategory includes all the works where a SU learns in isolation the optimal sequence of channels where to transmit, without receiving any explicit feedback from other SUs and without keeping any implicit model of the opponents behaviors. At the same time, the reward function is often modeled in order to reflect some network performance (e.g., throughput or delay metrics) which are also affected by the joint strategy, i.e., by the channel selection performed by the other SUs. While this approach greatly simplifies the problem formulation, it might introduce some oscillating behaviors when also goal G_1 is taken into account: a SU might keep adjusting its operating channel as a consequence of channel selection performed by the other SUs. SARL-based DCS schemes can be further classified as *state-full* or *stateless* approaches. In the first case, the RL framework contains both actions and states, hence following the traditional structure discussed so far. Examples of state-full SARL-based DCS schemes are presented in [20] and [49]. More specifically, in [49] the authors propose an opportunistic spectrum model, in which each SU is associated to a home band (where it has the right to transmit), but it may also seek for spectrum opportunities in the licensed bands (at condition of minimizing the interference caused to the licensed users). The DCS problem is modeled through the following MDP:

- The state set $S = \{s_0^i, s_1^i, \ldots, s_M^i\}$ coincides with the list of available channels; s_0^i corresponds to the home channel of the SU, while $s_1^i, \ldots, s_M^i$ are the licensed channels.
- The action set $A = a_0, a_1, \ldots a_P$ indicates the output of the channel selection process; a_0 is the action of transmitting on the home channel, while action $a_i, i > 0$ perform explorations, i.e., the SU will transmit on the M licensed frequency by following a specific channel sequence.
- The reward R is a function of the quality communication level, which can be determined via link-metrics (e.g., SNR or packet success rate).

The simulation results in [49] show that the RL-based DCS scheme can greatly enhance the performance compared to random access schemes, also in presence of PU load variability. In [20], the authors propose a joint RL-based DCS and congestion control scheme, which performs channel selection by taking into account the traffic load produced by each SU and the amount of PU activity on each band.

This is achieved by enriching the definition of states of the RL framework; each state is a combination of four variables, which models, respectively , the amount of required bandwidth, the current data packet dropping probability, the amount of good white space in the current channel, and the amount of good white space across the various channels.
Stateless SARL-based DCS schemes simplify the RL framework, by eliding the states, and considering only the action set A which often coincides with the list of available channels; executing action a_i corresponds to switching to frequency f_i, sensing it, and transmitting in case no PU activity is detected. In [51], the Q-learning update rule of Eq. 4 is simplified to:

$$Q^i_{t+1}(a) = (1-\alpha) \cdot Q^i_t(a) + \alpha \cdot r^i_t \tag{10}$$

Here, the reward r^i_t is the throughput experienced by SU i at time-slot t. In order to avoid oscillations in the learning process, sequential exploration is employed, i.e., a single SU can undergo exploration within a neighborhood. In [30], the authors propose three different RL-based DCS schemes, all based on the update rule of Eq. 10 but adopting three different formulation of the reward function, i.e.: the transmission successful rate in each epoch (named Q-learning+ scheme), the SINR metric (named Q-Noise scheme), and the SINR plus the historical behavior of the SUs (named Q-Noise+). A similar approach is also followed in [54], where the SUs aim to learn the optimal channel selection probability and the amount of PU activity on each channel. It is also worth noting that stateless RL frameworks can be considered instances of the multiarmed bandit (MAB) problem [55]. Several MAB-based DCS algorithms have been proposed in the literature. We cite, among others, the study in [56], where the authors compare two popular MAB schemes, named the UCB and the WD techniques, to the DCS problem in RL scenarios, assuming error-free sensing and that the temporal occupation of each channel follows a Bernoulli distribution. The output of the learning process is hence to learn the PU channel occupation probability of each channel, limiting the summation of regret[2] over time. The MAB framework of [56] is extended in [57] by considering cooperation techniques, aimed to improve the sensing accuracy, and coordination techniques, aimed to mitigate the impact of secondary interference.

MARL-Based DCS

In [52] and [53], the authors formulate the DCS problem through a MARL framework, by extending the previous SARL formulation [51]; the goal of the SUs is to discover the optimal joint action addressing both G_0 and G_1 requirements. This is performed via a payoff propagation mechanism, i.e., each SU i maintains – in addition to the Q table – a μ-table with size $|\Gamma(i) \times A|$ where $\Gamma(i)$ denotes its set of neighbors and A is the set of actions, which coincides with the channel list. Each

[2] In MAB theory [55], the regret is defined as the expected difference between the reward sum associated with an optimal strategy and the sum of the collected rewards of the actual strategy.

time SU plays action a_k (i.e., switches to channel a_k), it transmits a payoff message including its $Q^i_{t+1}(a_k)$ value, while all the other SUs $j \in \Gamma(i)$ will store such value in their μ-table. When selecting the next channel $\widehat{a}_{t+1}$, SU i will take into account both the local Q-table as well as the payoff table, i.e.:

$$\widehat{a}_{t+1} = \text{argmax}_{a \in A} | Q^i_t(a) + \sum_{j \in \Gamma(i)} \mu_{ji}(a) | \tag{11}$$

The simulation results show that the MARL-based and SARL-based DCS schemes provide similar level of throughput, although the MARL-based scheme greatly reduces the number of channel switching operations. The converge of MARL-based DCS schemes to a Nash equilibrium (NE) is investigated in [25] and [58]. More specifically, in [58] the authors consider a simplified SU interference model where maximum one SU can operate on each channel and demonstrate that a Q-learning-based DCS scheme without any SU cooperation and regardless of the initial allocation can converge to a stationary channel allocation. The result holds only under the assumption that all the SUs have perfect knowledge of the complete system state, i.e., of the PU occupancy of all the available channels. In [25], the authors remove such assumption and propose a probabilistic DCS scheme which is demonstrated to converge to a NE. To this purpose, each SU updates the selection probability $p_{t+1}(k)$ at each transmission attempt on channel k according to a linear reward-inaction model, i.e.:

$$p_{t+1}(k) = p_t(i) + r_t \cdot (e_k - p_t(k)) \tag{12}$$

where r_t is a function of the SINR metric perceived by the SU receiver, and e_k is the unit vector [25].

RL-Based Spectrum Trading

Spectrum trading can be considered as a variant of DCS problems where spectrum operations involve both the PU, who is in charge of deciding the amount of frequencies to borrow to the SUs, and SUs, who can request specific portions of the spectrum. In [59], the authors propose a RL-based scheme which helps a PU in deciding which requests to accept and which to reject, assuming that SUs belong to different classes, mapped on different QoS requirements. The MDP formulation is as follows:

- the state set S coincides with the number of SU traffic classes; the value of s_i is the number of SU requests accepted belonging to class i.
- the action set $A = \{0, 1\}$ includes only two choices, corresponding to the option of accepting a new incoming request or to refuse it.
- the reward function $R = P - C$ combines the expected monetary profit (P) that should be paid by the SU with the cost C, which is proportional to the number of already leased channels.

In addition, the authors of [59] show how to dynamically adjust the spectrum price and the size of the spectrum leased over time, based on the dynamic SU traffic load conditions. In [60], the RL-based spectrum leasing problem is inverted, i.e., the SUs learn to improve the bidding policy in the spectrum auction game, by using the transmission capability of each channel as immediate reward.

Spectrum-Aware Routing

In multi-hop wireless networks, routing protocols are in charge of discovering a feasible path between any source and a destination nodes; the path creation is performed through a distributed node selection process guided by end-to-end/global (e.g., delay) or link-by-link/local (e.g., SNR) metrics. In CR networks, routing protocols must address additional challenges caused by the dynamic variation of spectrum opportunities, like (i) the need of selecting forwarding nodes, so that the interference caused to PU receivers is minimized; (ii) the need of fast rerouting mechanisms, so that alternative, back-up paths can be used when the main path is invalidated due to the appearance of a PU [61]. For this reason, several existing routing schemes for CR networks address joint node and frequency selection [61, 62]. The routing problem can be easily modeled in the RL framework: each CR node must learn the optimal next-hop toward the destination via trial-and-error interaction. At each data transmission, the SU receives a reward which is a proxy for the forwarding cost, like the mean-access delay or the amount of energy consumed. Changes in the environment, like the appearance of a PU or the SUs mobility, are reflected in changes of the received feedbacks, which in turn translate into the selection of an alternative path. The MDP process for a generic RL-enabled routing protocol can be described as follows:

- The state set S coincides with the set of SU nodes N_{SU} in the network.
- The action set A_i is defined for each node $i \in N_{SU}$; more specifically, $a_j^{(s,d)} \in A_i$ denotes the action of forwarding data toward next-hop j, where s and d are, respectively, the source and destination communication end-points.
- The reward $R(i, a_j^{(s,d)})$ is a network metric reflecting the effectiveness for node i of using j as next-hop node toward the destination d.

The above model has been implemented by Q-routing [63], which is a popular routing protocol for dynamically changing networks, also applied over generic multi-hop wireless ad hoc networks [64]. In Q-routing, each node i maintains a *table* of Q-entries for each destination d; the entry $Q_i(j, d)$ is the *expected delivery time* toward destination d when using next-hop node j. After forwarding a packet via node j toward destination d, node i updates its Q-Table as follows [63]:

$$Q_i(j, d) = q_i + \delta + min_z Q_d(y, z) \tag{13}$$

where q_i is the time spent by the packet in the queue of node i, δ is the transmission delay on the $i-j$ link, and $\min_z Q_j(z,d)$ is the best delivery time at node j and for destination d. The same learning framework than Q-routing has also been adopted by several CR routing protocols, like [21, 65] and [66] although properly adapting the reward function to the CR scenario. In [65], the reward $R(i, a_j^{(s,d)})$ is the per-link delay, which also takes into account the retransmissions caused by SU-PU collisions. In [21], the reward function is an estimation of the average channel available time, i.e., average OFF period of PUs interfering over the bottleneck link along the route from j to d. In addition, the authors of [21] investigate the performance of the proposed RL routing protocol on a real test-bed environment using USRP platforms; the experimental result demonstrates that the RL scheme provides better result than a greedy approach in terms of end-to-end metrics (i.e., throughput and packet delivery ratio). A multi-objective Q-routing scheme for CR networks is discussed in [66]; more specifically, the proposed algorithm aims to minimize the packet loss rate under desired constraint of transmission delay. The multi-objective is implemented by employing two rewards for each successful transmission (e.g., loss rate and delay) and by storing two separate Q-values at each node. The authors of [28] propose two RL-based spectrum-aware routing protocols for CR networks. Here, the $Q_i(j,d)$ value denotes the number of available PU-free channels on the route from SU i to SU d via SU j; the SU j providing the highest Q-value is the preferred next-hop candidate. The Q-values are updated after each successful transmission, using a dual RL algorithm. In [67], the RL framework is used in order to properly tune the transmitting parameters of the popular AODV routing protocol. A different RL formulation for CR routing is proposed in [68], considering both the delay minimization requirement of each SU-SU flow and the interference minimization requirement of each SU-PU link and assuming no cooperation occurs among the SUs. The MDP is defined as follows:

- The state set of SU i is defined as the tuple: $< \eta_i(t), \lambda_1(t), \lambda_2(t), \ldots, \lambda_{|PU|}(t) >$, where $\eta_i(t)$ is the packet arrival rate of SU i and $\lambda_x(t)$ is the packet transmission rate of PU x at time t.
- The action set of SU $iA = \{a_0, NH_i^1, NH_i^2, .., NH_i^k, \}$ includes the no-forwarding action a_0 and the transmission toward next-hop node NH_i^j.
- The reward function is equal to the delay experienced by packets flowing from SU i to the destination node, in case the interference caused to PUs is kept below a safety threshold; it is set to a large value in case the no-forwarding action is selected or in case the interference caused to the PUs is higher than the threshold.

Since no information sharing is assumed, each SU forms conjectures on the other SUs routing strategies by using local observations of the environment; the convergence to proposed routing protocol is also investigated in [68] through an analytical framework and network simulations.

Reinforcement Learning in Cognitive Radio Scenarios: Learning Methodology-Driven Taxonomy

While the aim of the previous section was to analyze the existing literature from a networking perspective, in this section we provide an alternative review from the learning perspective, i.e., on the way different components of the RL framework are modeled for CR-related issues and on the overall evaluation method adopted. To this purpose, we decompose the learning process into six steps, which are depicted in Fig. 5 and discussed separately in the following:

- *State representation*. The state of SUs is often modeled through a single discrete variable or a combination of discrete variables. However, the reviewed RL-CR studies differentiate on whether the state variables are *fully observable* by the SU or are only *partially observable*. In the first case, the state variable is expressed by parameters which are internal to the SU or by network conditions which can be measured by the DSA without perception errors. This is the case, for instance, of the MDP model proposed in [44], where each state takes into account both internal (i.e., the current distance from the PU) and network metrics (i.e., the aggregated interference caused by the secondary network). Vice versa, a minority of the cited studies takes into account the impact of perception errors on the network observation: we cite, for instance, the MDP proposed in [41] and [42] where the SU state is the belief that a given frequency is vacant, hence subject to the accuracy of the sensing scheme.
- *Model representation*. Almost the totality of the proposed RL-CR solutions employs *model-free* strategies with very few exceptions [68, 69], i.e., the agent does not keep any representation/estimation of the state transition and of the reward functions (the T and R functions in section "Overview of Reinforcement Learning"); rather, it updates the Q-table after each immediate reward through the popular Q-learning or Sarsa algorithms. This choice can be justified since, on several use-cases like DSA problems, the reward values are associated to network metrics (e.g., the actual throughput or the SNR) which are stochastically by nature and whose trends are hard to predict without having full knowledge of the network and channel conditions; moreover, both the state transition and the reward functions can dynamically vary in nonstationary environments

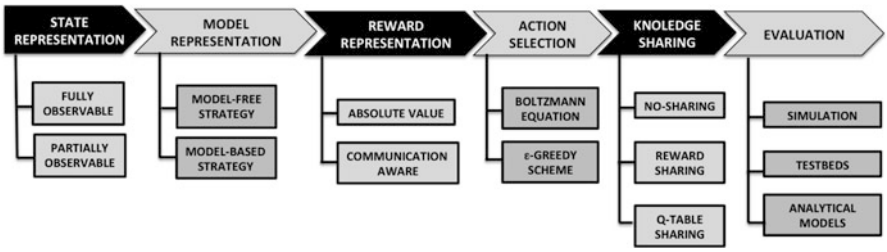

Fig. 5 Application-driven taxonomy of the existing RL-CR literature

due, e.g., to SU or PU mobility. For this reason, most of the works prefer to adjust the policy as a blind consequence of the received reward, instead of attempting to unveil the rules behind it. Some foundational results on this topic are provided in [70], where the authors investigate the relationship between the learning capabilities of the SUs in RL-DCS applications and the complexity of the PU pattern activity, measured through the Ziv-Lempel complexity metric. The experimental results demonstrate that, for specific levels of Ziv-Lempel complexity, the PU spectrum occupancy pattern can be learnt in an effective way by the SUs, hence justifying the utilization of model-based solutions.

- *Reward representation*. The modeling of the reward function clearly depends on the specific CR use-case. However, we can distinguish between two main approaches: *absolute* representation and *communication-aware* representation. In the first case, the reward is a scalar value, which can assume positive or negative values in order to encourage good actions or to penalize bad actions, but it is not related to any network metric. This is the case, for instance, of the RL-DCS scheme proposed in [29], where different rewards are introduced according to the outcome of each SU-SU transmission (i.e., successful, failed due to CRPU interference, failed due to CR-CR interference, failed due to channel errors). Vice versa, in communication-aware scheme, the reward takes into account node-related (e.g., the energy efficiency in [47]), link-related (e.g. the SNR in [43]) or network-related (e.g., the throughput in [20]) metrics. The clear advantage of this second approach is that the Q-table will converge over time to the actual system performance for the selected metric; at the same time, this might introduce additional protocol complexity, especially in presence of aggregated or cumulative metrics (e.g., the end-to-end path delay in Q-routing [63]).
- *Action Selection*. Strategies for action selection play a crucial role since they are in charge of balancing the exploration/exploitation phases, which in turn affect the performance of the RL-based solutions. Two main strategies have been employed in the RL-CR literature reviewed so far: the *Boltzmann rule*, which is based on Eq. 6 and relies on the temperature parameter TE in order to balance the exploration/exploitation phases, or the ε-*greedy rule*, which selects the optimal action with ε probability, while it performs random actions with $1-\varepsilon$ probability. Both such strategies might guarantee adaptiveness to nonstationary environments; however, the way the TE and ε parameters are set and discounted over time is barely addressed, except for [23, 24]. More in details, [24] proposes an interesting self-evaluation mechanism which is added to a basic RL-DSA framework: each time the SU receives a predecided number of negative rewards in exploitation mode, it assumes that there has been a change in the environment and reacts by forcing an aggressive channel exploration phase.
- *Knowledge Sharing*. In several CR use-cases modeled through a MARL, the SUs can share learnt information in order to speed up the exploration phase or to implement distributed coordination mechanisms. From the analysis presented in section "Reinforcement Learning in Cognitive Radio Scenarios: Applications-Driven Taxonomy", we can further classify the existing MARL-

CR works in three major families: (i) *no-sharing*, (ii) *reward-based*, or (iii) *Q-table-based*. The first category includes all works where the SUs update their Q-table independently and without receiving any feedback from the other peers, although the instantaneous reward might depend from the joint action executed by the secondary network (e.g., the throughput in [30]). We include in this group also centralized approaches, where the global Q-table is managed by a network coordinator (e.g., the cognitive base station in [43]), or solutions where each SU keeps conjectures about the future behavior of the other SUs [32,68]. The second category includes approaches like the docitive [44, 45] or payoff propagation paradigms [52, 52] where the SUs share the immediate rewards or rows of the Q-table. The received data are then merged with the local data, by using expertness measures controlling the knowledge transfer [46, 47] or action selection methods for achieving distributed coordination [48]. The impact of knowledge sharing on MARL-DCS problems is further investigated in section "Case Study: RL-Based Joint Spectrum Sensing/Selection Scheme for CR Networks".

- *Evaluation method*. Performance of RL-based solutions can be investigated through *simulation* studies, *testbeds*, or *analytical* models. The first two methods allow understanding the network performance gain introduced by RL techniques compared to non-learning approaches: at the best of our knowledge, [21, 71] and [72] are the only experimental studies in the literature. More specifically, [21] investigates the ability of a RL-enhanced routing protocol to select PU-free routes on a network environment consisting of ten USRP SU nodes, while [71] and [72] implement a RL-based DCS algorithm, respectively, over GNU-radio and USRP N210 platforms, and evaluate the way CR devices are able to learn the PU spectrum occupancy patterns. Both [21] and [71] confirm the effectiveness of RL-based solutions compared to state-of-the-art (non-ML-based) approaches. Analytical studies like [58] investigate the convergence of proposed RL algorithms to the optimal solution. Such theoretical results can be considered highly relevant from a pure scientific perspective but less practical in real-world network deployments, since the convergence property is assumed asymptotic and without accounting for the impact of exploration phase on the short-term system performance.

Case Study: RL-Based Joint Spectrum Sensing/Selection Scheme for CR Networks

In this section, we describe an application of RL techniques to CR networks, in order to highlight gains and drawbacks of different RL algorithms and also to investigate the impact of learning parameters on the system performance. By referring to the taxonomy presented in section "Reinforcement Learning in Cognitive Radio Scenarios:
Applications-Driven Taxonomy", we consider here a joint spectrum sensing/selection (JSS) problem, in which a SU must learn the optimal channel where

to transmit among the available frequencies and also the optimal balance between sensing and transmit actions on each channel. In section "System Model", we introduce the system model and the problem goals. The problem is formulated by using the RL framework in section "RL-Based Problem Formulation". Then, we evaluate the performance of RL-based solutions by neglecting the impact of secondary interference (section "Analysis I: SU-PU Interference Only"). Such assumption is removed in section "Analysis II: SU-PU and SU-SU Interference".

System Model

We model a generic network scenario composed by N couples of SUs operating within the same sensing domain. Each SU is equipped with a DSA transceiver, able to switch over K frequencies of the licensed band, and over a common control channel (CCC) implemented in the unlicensed band. Each couple i is formed of one SU transmitter (SU_i^{tx}) and one SU receiver (SU_i^{rx}). Data packets are transmitted over a licensed channel, while the signaling traffic is transmitted over the CCC. On each frequency f_j, there is an active PU which transmits according to an exponential ON/OFF distribution with parameters $< \alpha_j, \beta_j >$. Hence, frequency j is vacant with a posteriori probability equal to $\frac{\alpha_j}{\alpha_j+\beta_j}$, while it is occupied by the PU with probability equal to $\frac{\beta_j}{\alpha_j+\beta_j}$. In addition, we model the packet error rate (PER) on each channel; let φ_j be the PER of channel f_j. Each SU_i^{tx} can implement three different time-slots:

- *Sensing* slot, i.e., SU_i^{tx} senses the frequency to which it is currently tuned, in order to determine the PU presence. The sensing length is equal to t_{slot}. We assume a default energy-detection sensing scheme [3]: let p_D indicate the probability of correct detection and $1 - p_D$ the probability of sensing errors (including both false-positive and true negative instances).
- *Transmit* slot, i.e., SU_i^{tx} attempts transmitting exactly one packet to SU_i^{rx} by using a CSMA MAC scheme. In case the MAC ACK frame is not received, SU_i^{tx} retransmits the packet till a maximum number of attempts equal to $MAX\_ATTEMPTS$. Otherwise, the packet is discarded.
- *Switch* slot, i.e., SU_i^{tx} switches to a different licensed frequency and communicates the new channel to the SU_i^{rx} on the CCC. Let t_{switch} represent the time overhead required for the handover.

Figure 6 shows an example of the time-slot sequences for three different SU transmitters. We indicate with τ_i^k the type of k-th time-slot implemented by SU i, where $\tau_i^k = \{\texttt{SENSE}, \texttt{TRANSMIT}, \texttt{SWITCH}\}$ and with $T_i = \{\tau_i^0, \tau_i^1, \ldots\}$ the slot schedule of SU i. Each SU i can decide its own schedule T_i, but subject to these constraints: (i) if τ_i^k=SENSE, and the channel is found busy, then τ_i^{k+1}=SENSE or τ_i^{k+1}=SWITCH, i.e., the SU can keep sensing or switching to a different channel, but it cannot perform a transmission and (ii) if τ_i^k=SWITCH, then τ_i^{k+1}=SENSE,

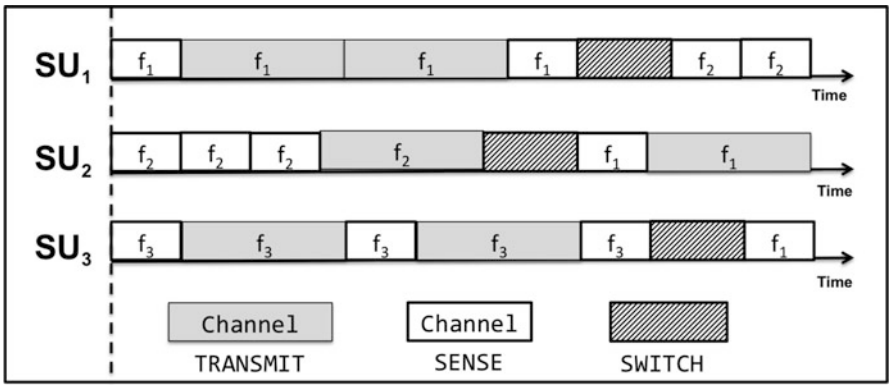

Fig. 6 Example of time-slot sequences for three different SU transmitters

i.e., the SU must sense the new channel in order to discover its availability.
Similarly, let NTX_i be the total number of transmissions performed by SU i (including the retransmissions). We denote with $STX_i(l)$ the outcome of the $l-$th transmission (with $0 \leq l < NTX_i$) performed by SU i. Based on the channel conditions, and on the SUs and PUs activities, the $STX_i(l)$ variable can assume one of these four values: (i) $STX_i(l)$=`OK` if the transmission has been acknowledged by SU_i^{rx}, (ii) $STX_i(l)$=`FAIL-PU-COLLISION` if the transmission has failed due to collision with an active PU (i.e., PU is ON during the SU transmission); (iii) $STX_i(l)$=`FAIL-SU-COLLISION` if the transmission has failed due to collision with other SU transmissions on the same channel; and (iv) $STX_i(l)$=`FAIL-CHERROR` if the transmission has failed due to channel errors.
The JSS problem can be formulated as the problem of determining the optimal schedule T_i of each SU i, $0 \leq i < N$, so that the total number of successful transmissions is maximized, while the probability to interfere with the PUs is kept below a predefined threshold (ψ). More formally:

(**JSS Problem**) Determine the optimal schedule T_i $\forall i, 0 \leq i < N$, so that:

- $\sum_{0 \leq i < N, 0 \leq l < NTX(i)} I(STX_i(l) =$`OK`$)$ is maximized;
- $\frac{\sum_{0 \leq i < N, 0 \leq l < NTX(i)} I(STX_i(l)=\texttt{FAIL-PU-COLLISION})}{\sum_{0 \leq i < N} NTX(i)} > \psi$, where $I(\cdot)$ is the identity function.

RL-Based Problem Formulation

We model the JSS Problem via a SARL model; each SU_i^{tx} is a learning agent. Figure 7 depicts the corresponding MDP for the case of K=2. More in details:

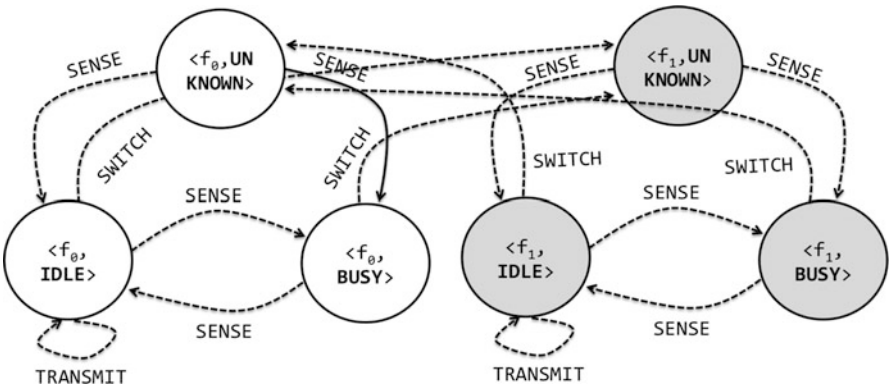

Fig. 7 The Markov decision process (MDP) for the JSS problem

- The set of states S is the set of couples $< f_j, \{\texttt{IDLE, BUSY, UNKNOWN}\} >$ where the first field is the frequency $f_j \in K$ and the second field is the estimated availability of frequency f_j, based on the output of the sensing action.
- The set of actions $A = \{\texttt{SENSE}, \texttt{TRANSMIT}, \texttt{SWITCH}\}$ coincides with the slot types previously introduced.
- The reward function $R : S \times A \rightarrow [0 : 1]$ is defined in different ways according to the action implemented by SU_i^{tx}. More specifically, $R(< f_j, \cdot >, \texttt{SENSE})$ is set to 1 whether channel f_j is found BUSY, 0 otherwise. In case of transmit action, $R(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT})$ is set as follows:

$$R(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT}) = 1 - \frac{\#Retransmissions}{\texttt{MAX\_ATTEMPTS}} \tag{14}$$

  where $\#Retransmissions$ denotes the number of retransmissions performed. Hence, the reward is set to 1 whether the packet is acknowledged without any retransmission. Vice versa, it is set to 0 whether the packet is discarded since the maximum number of retransmission attempts has been reached. Finally, in case of channel switch, the reward $R(< f_j, \texttt{UNKNOWN} >, \texttt{SWITCH})$ is set to zero.
- The transition function $T : S \times A \times S \rightarrow [0 : 1]$ is defined as follows, i.e.:

$$T(< f_j, \cdot >, \texttt{SENSE}, < f_j, \texttt{IDLE} >) = \frac{\beta_j}{\alpha_j + \beta_j}$$

$$T(< f_j, \cdot >, \texttt{SENSE}, < f_j, \texttt{BUSY} >) = \frac{\alpha_j}{\alpha_j + \beta_j}$$

$$T(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT}, < f_j, \texttt{TRANSMIT} >) = 1$$

$$T(< f_j, \cdot >, \texttt{SWITCH}, < f_k, \texttt{UNKNOWN} >) = 1$$

$$T(< f_j, \texttt{UNKNOWN} >, \texttt{SENSE}, < f_j, \texttt{IDLE} >) = \frac{\beta_j}{\alpha_j + \beta_j}$$

$$T(< f_j, \texttt{UNKNOWN} >, \texttt{SENSE}, < f_j, \texttt{BUSY} >) = \frac{\alpha_j}{\alpha_j + \beta_j}$$

For all the other input values, the transition function assumes output value equal to 0. In the equations above, we neglect the impact of channel sensing errors, and we assume that the next channel f_k has already been determined. In any case, the T matrix is interesting only from the theoretical side, since in practice we assume that the SUs do not know its values.

We consider three RL-based learning algorithms addressing the JSS problem, i.e.:

- **Q-Learning based**: each SU_i^{tx} stores a Q-table for each state/action and updates it after each `TRANSMIT` or `SENSE` action through Eq. 4. Moreover, at the end of slot k, SU_i^{tx} decides the next action through a probabilistic scheme. The probability of `TRANSMIT` or `SENSE` actions is set through Eq. 6, while the probability of a `SWITCH` action is computed as follows:

$$p(< f_j, \cdot >, \texttt{SWITCH}) = \max\{\max_{0 \leq v < K, v \neq j} Q(< f_v, \texttt{IDLE} >, \texttt{TRANSMIT}) - Q(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT}), \theta\} \quad (15)$$

  Here, the first term of the max operator denotes the maximum gain achievable when switching to a channel different from the current one (f_j), while the $0 \leq \theta \leq 1$ parameter indicates the probability of spectrum exploration. In case a `SWITCH` action is implemented, another probabilistic step is executed in order to select the channel: with probability θ, a random value is selected in range $\{0 \ldots K\}$; otherwise, the best channel is selected (the one equal to $\text{argmax}_{0 \leq v < K, v \neq j} Q(< f_v, \texttt{IDLE} >, \texttt{TRANSMIT}) - Q(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT})$. The values of the temperature TE (see Eq. 6) and of γ are set to a large initial value, and then progressively discounted at each slot in order to ensure convergence, but they cannot decrease below predefined minimum $TE_{\min}$ and $\theta_{\min}$ values. We investigate the impact of the initial temperature value TE in section "Analysis I: SU-PU Interference Only".
- **Sarsa based**: the scheme works similarly to the Q-learning except for the update rule of the `TRANSMIT` and `SENSE` actions, which is based on Eq. 5.
- **Information Dissemination Q-Learning based** (IDQ-Learning): the scheme works similarly to the Q-learning. In addition, each SU_i^{tx} shares the information about its state, action, and received reward, at each slot. All the SU_j^{tx}, $j \neq i$ update their Q-values consequently as if the action was performed locally.

Analysis I: SU-PU Interference Only

We modeled the CR network scenario and the RL-based algorithms through the NS2-CRAHN simulator described in [34]. Unless stated otherwise, we considered a scenario composed of 20 SU couples (i.e., N=20) and K= 6 licensed channels. The other parameters are p_D=10%, $MAX\_ATTEMPTS$=7, TE_{ini}=50, $TE_{\min}$=5,

$\theta_{\text{ini}} = 80\%$, and $\theta_{\text{min}} = 10\%$. Each of the six channels exhibits different PU activity levels (PUL) and PER values, as reported in the table below.

We consider a constant bit rate (CBR) application; each SU_i^{tx} generates a new packet destined to SU_i^{rx} every 0.005 seconds. The packet length is 1000 bytes.

In this analysis, we assume that each SU does not interfere with other SUs tuned to the same channel. Hence, the goal of the learning algorithm is to identify vacant spectrum opportunities over the K channels. We compare the performance of the three RL-based schemes described in section "RL-Based Problem Formulation" with those of a non-learning scheme, named *Sequential* in the following. The protocol operations of the sequential scheme are straightforward: each SU senses the channel before any transmission attempt; in case the current channel f_j is detected as busy, the SU switches to channel $f_{(j+1)\%K}$; otherwise, it transmits one packet and then senses the channel again.

Figure 8a shows the system throughput when varying the number of transmitting SUs (N) on the x-axis. It is easy to notice that all the RL-based algorithms greatly outperform the sequential scheme. No significant differences can be appreciated between Q-learning and Sarsa. Vice versa, IDQ-learning provides the highest throughput, and the gain produced by the cooperation becomes more evident when increasing the number of involved SUs. This result can be justified as follows: (i) the RL-based schemes estimate the quality of each channel and then concentrate most of the SU transmissions on channels 5, 2, and 4 characterized by favorable PUL and PER values and (ii) on these channels, the RL-based schemes reduce the amount of sensing actions while still guaranteeing satisfactory PU detection (see next results). In addition, compared to Q-learning and Sarsa, IDQ-learning guarantees better exploration and quicker convergence of all the SUs to the optimal state-action policy (which is equal for all the SUs). This is made evident in Fig. 8b, which shows the throughout over time, for a network scenario with N=20. Till second 100, both Q-learning and Sarsa perform poorly because they are performing exploration, caused by the high values of the TE and θ parameters. After second 100, the throughput of both schemes sharply increases because they exploit more aggressively the learnt policy. In IDQ-learning, the impact of random actions is greatly mitigated since the exploration phase is shorter: at each round, each SU can receive N different rewards and hence discounts more quickly the TE and θ parameters. At the same time, the exploration phase is more effective since all the SUs converge to the same policy guaranteeing the highest throughput. Figure 8c confirms the same trend of Fig. 8a, by showing the packet delivery ratio (PDR) of the four schemes for different values of N. The PDR of the sequential, Q-learning and Sarsa schemes are not affected by N since – in this analysis – we are neglecting the impact of SU channel contention. The PDR of the IDQ-learning increases with N, again due to the positive impact of the SU cooperation.

Figure 9a reveals that the PDR and throughput enhancements do not come at the expense of increased interference caused to the PUs. On the y axis, we show the PU interference probability, defined as the rate of SU transmissions ending in state `FAIL-PU-COLLISION` over the total number of transmissions performed by the SUs. The Q-learning and Sarsa schemes guarantee a value which is comparable

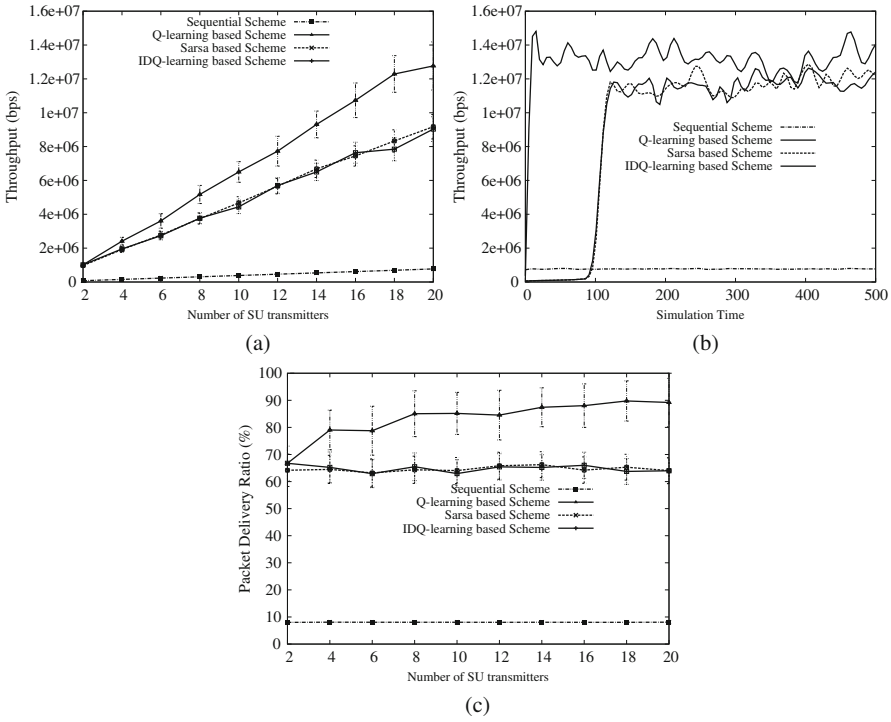

Fig. 8 The throughput and packet delivery ratio (PDR) of the sequential and of the RL-based schemes are shown in (**a**) and (**c**), respectively. The throughput over simulation time for N=20 is shown in (**b**)

with the performance of the sequential scheme and in any case lower than 2%. The IDQ-learning exhibits a counterintuitive behavior: the risk of interference with PUs even reduces when increasing the number of potential interferers (i.e., the SUs), again thanks to the reward dissemination mechanisms, through which all the SUs converge to the optimal channel sequence and to the optimal balance between `SENSE` and `TRANSMIT` actions on each channel. To this purpose, Fig. 9b shows the average frequency rate of each action (different color bars) and on each channel (on the x axis), experienced by the IDQ-learning (N=20). It is easy to notice that our learning scheme (i) concentrates most of transmissions on channels 5 and 2 (which are the one most favorable toward the PUs in terms of PUL and PER values) and (ii) significantly reduces the frequency of sensing actions on channel 5, while it maximizes sensing on channels 0 and 3 (characterized by high PU activity). Hence, the graph confirms the ability of the IDQ-learning scheme to learn the optimal sequence of spectrum opportunities, and the amount of sensing on each channel, without knowing in advance the PER and PUL values. Finally, in Fig. 9c we investigate the impact of the initial temperature value (TE_{ini}) on the throughput (on the $y1$ axis) and on the number of channel switches (on the $y2$ axis). Again,

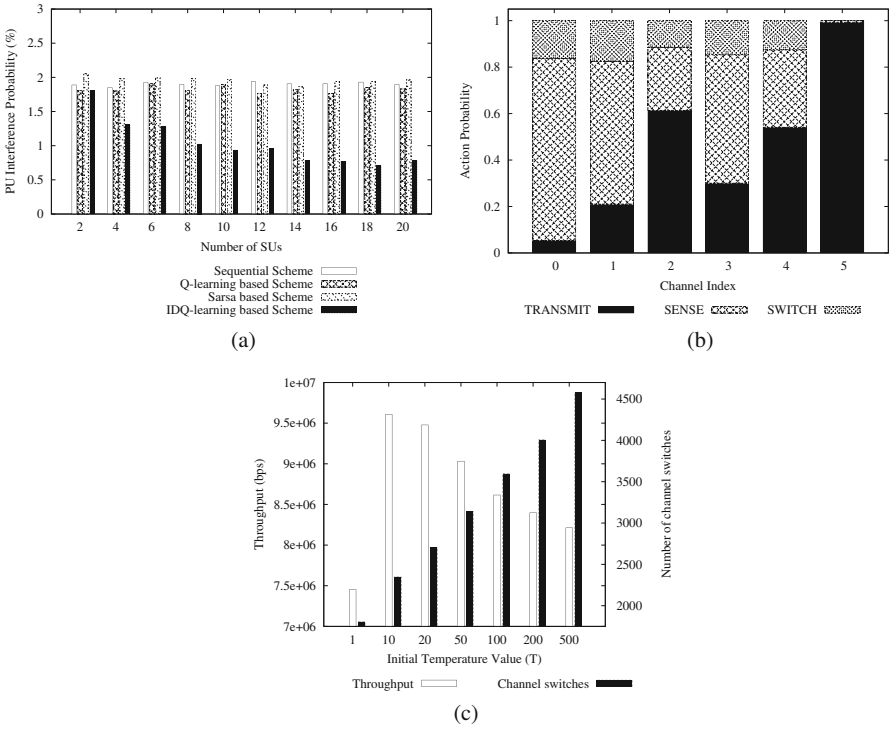

Fig. 9 The PU interference probability over N is shown in (**a**). The selection rate of the three actions (`TRANSMIT`, `SENSE`, and `SWITCH`) on each of the K channels and for the IDQ-learning scheme is depicted in (**b**). The impact of the initial temperature value (TE_{ini}) on the throughput and on the number of channel switches is shown in (**c**)

we evaluate the IDQ-learning scheme with $N = 20$. We can notice that there is an optimal TE_{ini} value (equal to 10 in our case) maximizing the throughput: when $TE_{\text{ini}} < 10$, the exploration phase is too short and hence the optimal policy cannot be discovered, vice versa when $TE_{\text{ini}} \gg 10$, the impact of suboptimal actions during exploration becomes significant. On the other side, the number of channel switches increases proportionally with TE_{ini}.

Analysis II: SU-PU and SU-SU Interference

In this section, we complete the analysis by considering also the impact of SU-SU interference on the system performance. In addition to the channel model presented so far, a SU transmission might result in state `FAIL-SU-COLLISION`, i.e., it can fail due to collisions with other SU transmissions operating on the same channel. Such collisions can occur despite the utilization of a MAC protocol providing distributed channel contention orchestration mechanisms (we assume all the SUs

follow a CSMA/CA protocol). As a result, SUs cannot merely implement all the same policy; besides determining the optimal balance of sensing actions, SUs must also learn the optimal coordinated action, which leads to the optimal allocation of the SUs to the available frequency. The goal is a hybrid collaborative/competitive MARL problem; no solutions could be found in the literature for this specific JSS problem instance, although close problems have been modeled via game theory-based approaches and distributed collaboration techniques (e.g., the payoff propagation mechanism described in [52, 53]). Far from determining the optimal solution, we introduce here an addition RL-based scheme, named distributed Q-learning, which is based on the frequency maximum Q-value (FMQ) heuristic [27]. This latter attempts to achieve SU coordination without any explicit policy exchange and also with minimal extra-storage requirements compared to the basic SARL techniques. We present the protocol operations in brief:

- **Distributed Q-Learning** (DistQ-Learning): the protocol works similarly to the Q-learning scheme described in section "RL-Based Problem Formulation", with two significant differences. First, each time SU_i^{tx} performs a `TRANSMIT` action on a given channel; it computes a local reward $r_i^L = 1 - \frac{\#Retransmissions}{\texttt{MAX\_ATTEMPTS}}$ and shares it with all the other SUs. By averaging the received r_j^L values, $j \neq i$, each SU_i^{tx} computes the average network reward $r^G = \frac{\sum_{0 \leq i < N} r_i^L}{N}$, which is a proxy for the network throughput. Second, once computing the r^G value, each SU_i^{tx} updates the Q-table for the `TRANSMIT` action on channel f_j by following the FMQ rule [27], i.e.:

$$Q(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT}) = Q(< f_j, \texttt{IDLE} >, \texttt{TRANSMIT}) + \frac{C^i_{\max}(r^G_{\max}, f_j)}{C^i(f_j)} \cdot r^G_{\max}(f_j) \tag{16}$$

  where $r^G_{\max}(f_j)$ is the maximum global reward observed when SU_i^{tx} is tuned to channel f_j, $C^i_{\max}(r^G_{\max}, f_j)$ is the number of times such values has been observed, and $C^i(f_j)$ is the total number of transmission attempts on frequency f_j. As a result, each SUs pushes its policy toward channels where an optimal network reward r^G is achieved, although no SU keeps track on the global MARL Q-table nor it makes conjectures about the opponents' behaviors; the r^G value reflects indirectly the optimality of the joint action performed by the other SUs, and based on it each SU adjusts its own policy.

In Fig. 10a, b, and c, we compare the performance of the DistQ-learning scheme against the sequential and the IDQ-learning algorithms previously introduced in section "Analysis I: SU-PU Interference Only". We consider the same network environment of the previous analysis, except for the number of licensed frequencies (K= 9 instead of $K = 6$); the channels 7-8-9 have the same PUL-PER profiles of channels 3-4-5 (see Table 1). Figure 10a shows the network throughput when

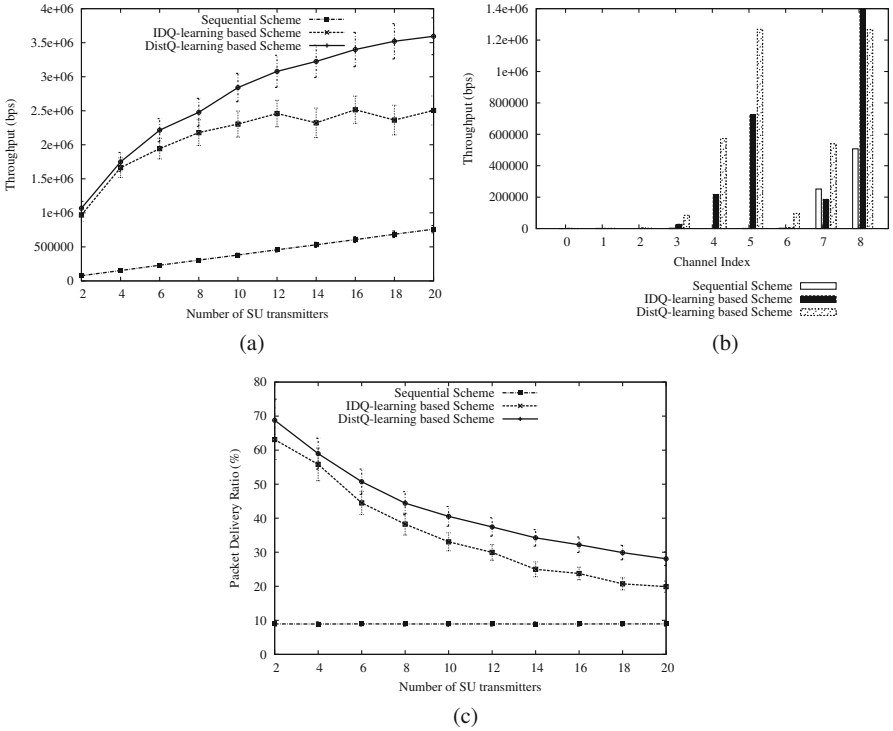

Fig. 10 The throughput and packet delivery ratio (PDR) of the sequential and of the RL-based schemes are shown in (**a**) and (**c**), respectively. The throughput on each of the $K = 9$ channel, for N=20, is shown in (**b**)

Table 1 PUL/PER profiles of the $K = 5$ licensed channels

Channel index	PUL	PER	PUL profile: $< \alpha, \beta >$	PER
0	High	Medium	<10,2>	50%
1	Medium	Medium	<5,5>	50%
2	Low	Medium	<2,10>	50%
3	High	Low	<10,2>	10%
4	Medium	Low	<5,5>	10%
5	Low	Low	<2,10>	10%

varying the number of transmitting SUs (N). The throughput values are lower than Fig. 8a and also decrease with N as a consequence of the SU contention on each channel. We can notice that the DistQ-learning scheme provides significantly better performance than the sequential scheme but also than the IDQ-learning scheme. Using this latter, all the SUs attempt to discover the same policy, i.e., they transmit on the same channels and balance `TRANSMIT` and `SENSE` actions in the same way. Vice versa, the DistQ-learning aim at achieving implicit coordination among

SUs through Eq. 16; the SUs learn differentiated policies – at least regarding the Q-value of the TRANSMIT action on each channel – so that the maximum, network-wide reward can be achieved. This is also visible in Fig. 10b which shows the network throughput on each of the K channels, for the three different algorithms and $N = 20$. The IDQ-learning scheme concentrates most of the SU transmissions on channel 8 and 4 (which are the most favorable to SUs for PUL/PER profiles) but clearly increasing the contention level on those frequencies and hence the risk of packet losses due to SU-SU collisions. Vice versa, the DistQ-learning scheme achieves better distribution of the SUs over the available spectrum opportunities, which also translates into enhancements in terms of PDR, as depicted in Fig. 10c.

Conclusions and Open Issues

In this paper, we have addressed the utilization of reinforcement learning (RL) techniques in cognitive radio (CR) networks. A twofold taxonomy of the existing RL-CR studies has been proposed, from a networking perspective and a learning perspective. The review of the literature has confirmed that RL techniques are quite popular in RL networking and that they have been applied on several different use-cases and on dynamic network scenarios, often enhancing the performance of non-learning-based solutions. At the same time, despite the number of published papers, we believe there is great room for improvement, since some RL-CR issues have been only superficially addressed by the academic research. We focus here on three main research issues:

- *Accurate performance evaluation in real-world CR network scenarios*. Despite few experimental works [68, 71, 72], the evaluation of RL-based solutions have been mainly conducted through simulation studies, in which the spectrum occupancy pattern is modeled by using well-known probability distribution (like the exponential [4] or the Bernoulli [56] distributions). However, spectrum bands might exhibit different complexity of the PU occupancy pattern, based the signal waveform and regulations of licensed users transmitting on those frequency [70]. Hence, differentiated RL learning algorithms (e.g., by considering model-free or model-based approaches, MDP or POMDP frameworks) can be tested and deployed on different frequencies, also based on the predictability of the spectrum availability. Additional works based on real-world spectrum traces are required in order to address this issue.
- *Analysis of RL techniques for CR applications with strict QoS network requirements*. Several multimedia applications pose strict QoS requirements (e.g., the maximum packet drop rate or jitter for video-streaming services) that must be continuously met by the network, in order not to affect negatively the users' experience. In RL-CR solutions, the SUs must continuously balance the exploitation and exploration phases during the system lifetime: when the SU selects random, possibly suboptimal actions, the QoS requirements of the CR multimedia applications are not guaranteed. Proper techniques that provide effec-

tive state-action exploration without causing detectable performance degradation for CR applications with strict QoS network requirements have not designed so far.

- *Enhancement of the learning framework*. Most of the reviewed works in the RL-CR literature provide an accurate modeling of the CR network scenario, including the operations of the main actors (PUs and SUs); the same level of complexity cannot be found on the learning part, since in most cases, the RL framework consists in a straightforward application of model-free algorithms (Q-learning or Sarsa algorithms overall). However, the RL theory is vast and is not limited to such results [12]; moreover, it is continuously extended by novel contributions coming from an active research community [73]. CR networking can benefit from the novel RL architectures introduced so far: we cite, among others, the utilization of deep RL techniques (i.e., RL framework enhanced with artificial neural networks for state-action representation) for better coordination in distributed scenarios [74] or for more efficient exploration [75].

About the second contribution of this paper, i.e., the application of RL techniques on joint spectrum sensing and selection problems, the evaluation results have revealed that the information-sharing schemes can considerably enhance the performance of RL-based schemes in fully cooperative tasks, like SUs seeking for PU-vacant channels. Vice versa, in mixed cooperative/competitive tasks, like SUs seeking for PU-vacant channels and also minimizing their mutual interference, information-sharing schemes can be counterproductive unless enhanced with distributed coordination strategies. Current and future research activities on the case study include the convergence analysis in multi-agent scenarios, the implementation of proposed RL schemes on a small-case test-bed, and the extension of the proposed modeling approach for the case of partially observable environments.

Overview of Recent Applications of Cognitive Radio in Wireless Communication Systems

58

Miguel López-Benítez

Contents

Abstract

Cognitive radio (CR) is one of the most intensively researched paradigms in recent wireless communication systems. The great deal of attention that CR has attracted can be ascribed to its demonstrated capability to increase spectrum efficiency and overall network capacity through interference-free spectrum sharing among several wireless communication systems. CR provides intelligence to wireless networks, enabling users to access multiple air interfaces and select the most appropriate alternative under varying communication needs and operation conditions. The potential benefits of CR have not gone unnoticed to many wireless communication systems, which nowadays have effectively benefited

from the adoption of CR techniques and operating principles. This chapter provides an overview on the introduction of CR principles into two prominent wireless communication systems, namely, mobile and satellite communication networks. A detailed discussion is provided on the background and motivation for the adoption of the CR technology and how CR techniques have been introduced in these two systems. A brief discussion is also provided on the adoption of the CR technology in other wireless communication systems, including military communications, public safety and emergency networks, aeronautical communications, and wireless-based Internet of Things. This chapter is aimed at illustrating the practical implementation of the theoretical CR principles widely discussed in the literature.

Cognitive radio · Dynamic spectrum access · Mobile communications · Satellite communications

Introduction

While the concept of cognitive radio (CR) [39] in its broadest sense can find a wide range of applications in wireless communications, dynamic spectrum access (DSA) [3] is certainly the most popular one (as a matter of fact, the term CR is often used to refer to DSA). The main motivation for the development of DSA/CR is to overcome the conflicts between spectrum demand growth and spectrum underutilization arising from legacy static spectrum allocation policies. This spectrum access paradigm allows several wireless communication systems to coexist in the same region of the spectrum, thus enabling a more efficient exploitation of the available spectrum resources. The potential benefits that the CR technology can bring into a broad variety of wireless communication systems have not gone unnoticed by academia, industry, and regulatory bodies, which over the last years have constantly explored new ways to introduce the principles of CR and DSA into existing wireless communication networks. This chapter provides an overview of how CR principles and techniques have been adopted in wireless communication systems. Two prominent examples have been selected to this end, namely, mobile communication networks (section "Mobile Communication Networks") and satellite communication networks (section "Satellite Communication Networks"). This chapter discusses the background and motivation for the introduction of CR in these systems and how CR techniques have been adopted by different standardized technologies, which illustrates the practical implementation in real deployments of the theoretical CR principles widely discussed in the literature [34]. The adoption of the CR technology in other wireless communication systems is briefly discussed as well (section "Cognitive Radio in Other Wireless Communication Systems").

Mobile Communication Networks

Mobile communication systems have always experienced an ever-increasing capacity demand since the early days [30]. The replacement of the first generation (1G) of analogic devices with digital handsets based on the second-generation (2G) global system for mobile communication (GSM) standard [15] unleashed a worldwide expansion of mobile communications to the general public and the creation of a mass market for mobile communications. The decade following the deployment of GSM networks witnessed an astonishing increase in the number of subscribers to the mobile service that has never decreased. The third-generation (3G) universal mobile telecommunications service (UMTS) standard [16] introduced true data services in mobile networks for the first time and represented the beginning of a race to increase the network capacity in response to the sustained increase in the number of subscribers as well as the introduction of more demanding data-hungry services. This trend can be clearly appreciated by comparing the requirements set for the fourth-generation (4G) long-term evolution (LTE) standard [17] and the fifth-generation (5G) systems: while 4G radio requirements [10] were set at peak data rates of 100 Mbit/s in downlink and 50 Mbit/s in uplink in a 20 MHz bandwidth (which required a spectral efficiency of up to 5 bit/s/Hz, i.e., 2–4 times greater than that of UMTS Release 6), the 5G radio requirements [13] have been set at peak data rates of 1 Gbit/s in downlink and 500 Mbit/s in uplink (for indoor hot spots) and 50 Mbit/s in downlink and 25 Mbit/s in uplink (for outdoor macro-environments), with prospective field (i.e., not theoretical maximum) peak data rates of up to 10 Gbit/s being widely accepted in the industry community. This continuous increase in traffic demand has strained mobile operators, which have been forced to find new ways to increase the network capacity.

The capacity of a wireless communication system can be increased by achieving higher spectrum efficiency, denser network deployments, and obtaining more spectrum resources. All three approaches have been exploited in different ways by mobile network operators, some of which are summarized below.

- *More spectrum efficiency.* This approach is aimed at increasing the number of bits transmitted per time and spectrum unit (i.e., bit/s/Hz) by means of innovative physical layer solutions. This includes new modulation and coding schemes such as orthogonal frequency-division multiplexing (OFDM) or filter bank multicarrier (FBMC) which can reduce the space between modulated subcarriers [9, 38], multiple antenna techniques such as massive MIMO (multiple-input multiple-output) [22], full-duplex radios [32,41] which can transmit and receive simultaneously in the same time and frequency thus potentially enabling (in theory) an increase in the spectrum efficiency by a factor of 2, non-orthogonal multiple access techniques [7] which use the power domain to separate signals from each other (high-power signals can be isolated to be detected and then cancelled out to leave the low-power signals), or orthogonal polarizations used to transmit different data streams (however, the radio propagation environment can

modify the polarization of the signal components and cause mutual interference). Research in this area has been intensive, and the current state of the art has closely approached the well-known Shannon limit [43], which represents an upper bound on the maximum attainable spectrum efficiency. This suggests that this approach has almost hit the performance wall and the room for further improvements appears to be limited [8].

- *More dense network deployments.* This approach is aimed at increasing the spatial reutilization of spectrum resources by means of network densification. A basic method to increase the capacity of a cellular network is to reduce the radius of coverage (size) of each cell [30], since a more dense reuse of the available frequencies over shorter distances enables a higher density of subscribers. While the 2G GSM system was designed for macro-cell radii of up to 35 km, subsequent generations have targeted progressively smaller coverage areas such as microcells (few kilometers), picocells (few hundreds of meters), and femtocells (few tens of meters) [35]. This trend has led to heterogeneous scenarios with overlaying cells of different sizes, which has made necessary the development of more complex inter-cell interference coordination (ICIC) mechanisms [25], in particular with the introduction of more aggressive frequency reuse patterns (e.g., fractional frequency reuse and single-frequency networks). The extent to which a network can be densified is theoretically upper bounded [14]; however, such limitation can be overcome with the introduction of beamforming techniques, which can reconfigure the antenna radiation pattern in order to target specific user locations and minimize interference in other directions.
- *More spectrum resources.* This approach provides more network capacity by making new spectrum available. The amount of additional spectrum that can be gained at higher frequencies is virtually unlimited and only constrained by the ability of the available technology to efficiently transmit and receive signals at such high frequencies. One option to realize this approach is the exploitation of new high-frequency bands in the region of millimeter waves (typically 10 GHz and above) [33]. These bands can provide unprecedented large amounts of spectrum and therefore offer the potential to achieve extremely high network capacity. However, several important challenges need to be overcome. Propagation characteristics at such high frequencies not only limit the application of these bands to short-range communications but also pose new challenges for the design of network protocols and radio resource management methods to cope with unreliable links that can drop frequently and unexpectedly. Moreover, the equipment for use at these high frequencies is typically more expensive. As a result, in parallel with this alternative, the idea of opportunistically exploiting unused spectrum at lower frequencies with better radio propagation conditions (below 6 GHz) has recently gained interest from both industry and academia. The principle of DSA based on the CR paradigm in the context of mobile communication systems has led to several initiatives, which are presented in the following sections.

Spectrum Coexistence in Licensed Bands

The main initiatives for spectrum coexistence of mobile communication systems in licensed bands are the licensed shared access (LSA), which is focused on the sharing of the 2.3 GHz band in Europe, and the spectrum access system (SAS), which is focused on the sharing of the 3.5 GHz band in the USA [40]. These initiatives allow licensed spectrum to be used by more than one entity and provide the means for mobile networks to increase their capacity through additional spectrum in bands originally licensed to other systems. Mobile network operators can combine the new spectrum obtained from these bands with their own licensed spectrum by means of carrier aggregation techniques [57].

LSA was envisaged as a means to provide access to licensed spectrum bands that otherwise would not be possible in some European countries [29]. LSA defines a framework to enable (rather than enforce) spectrum sharing between a license holder or incumbent (tier 1) and an LSA licensee (tier 2) whereby the license holder agrees to grant exclusive use of part of its licensed spectrum at a given time and location (likely on a long-term basis, typically 10 years or more). The key features of LSA are that it is voluntary (this framework enables but does not enforce spectrum sharing), licensed (spectrum sharing takes places under an agreed license), and exclusive (the licensee is guaranteed exclusive access to the new spectrum). The LSA framework also guarantees the protection of the incumbent system and its use of the spectrum. A particular case of LSA is authorized shared access (ASA), which refers to spectrum sharing between an incumbent system (other than a mobile communication system) and a mobile communication system. As a matter of fact, the main use case for the LSA technology is the extension of the capacity of cellular mobile communication systems in the sub-6 GHz band in Europe. LSA allows 3GPP LTE mobile networks to be operated on a licensed shared basis in the 2300–2400 MHz band (3GPP LTE band 40) along with incumbents such as military stakeholders or professional video camera services, among others [40].

The SAS technology relies on the same principle as LSA but refers to the use case in the US market, where the so-called citizens broadband radio service (CBRS) network, such as an LTE network, is operated on a licensed shared basis in the 3550–3700 MHz band (3GPP LTE bands 42–43). The main difference with respect to LSA relies on the available spectrum slots based on a three-tier hierarchy (as opposed to the two-tier hierarchy of LSA). Licensed 10 MHz spectrum slots (up to 70 MHz) are only available in parts of the entire band (3550–3650 MHz) for the second tier priority access license (PAL) users, while the third tier general authorized access (GAA) users are guaranteed at least 80 MHz of spectrum throughout the 3550–3700 MHz band. The third tier (GAA), which does not exist in LSA, is intended for "Wi-Fi-type systems" and therefore not protected from interference; the second tier (PAL) is protected from GAA, and the first tier (incumbents) is protected from all users.

While LSA and SAS share some common features, there are differences as well. LSA relies on a central database that is populated by incumbents with accurate

Table 1 Comparison between LSA and SAS

	LSA	SAS
Geographic domain	Europe	United States
Frequency band	2.3 GHz (2300–2400 MHz) 3GPP LTE band 40	3.5 GHz (3550–3700 MHz) 3GPP LTE bands 42–43
Spectrum awareness	Central database populated by incumbents	Spectrum sensing plus exclusion/ protection zones
Tiers	Tier 1: Incumbent Tier 2: LSA licensee	Tier 1: Incumbent Tier 2: PAL Tier 3: GAA
Incumbents	Country-dependent (e.g., military stakeholders, professional video cameras)	Military services (e.g., radars) around coastal areas

information on spectrum usage over space and time. This database is used to either grant access to an LTE network or request to vacate specific bands through an LSA controller. On the other hand, SAS relies on spectrum occupancy information obtained from spectrum sensing combined with the definition of exclusion and protection zones around coastal areas, where SAS incumbents (mostly military services) are operated. It is worth noting that both systems (LSA and SAS) are defined for specific frequency bands but can be applied to other bands as well. Table 1 summarizes the main features of both systems.

Spectrum Coexistence in Unlicensed Bands

The most popular initiatives for spectrum coexistence of mobile communication systems in unlicensed bands are LTE unlicensed (LTE-U), licensed assisted access (LAA), and MuLTEfire [26, 27, 49, 59]. These initiatives are designed to operate in the unlicensed 5 GHz band (5150–5925 MHz), which is also known as the unlicensed national information infrastructure (U-NII) band (3GPP LTE bands 46–47) and is mostly utilized by radar systems and wireless local area networks (WLAN) based on IEEE 802.11a/g/n/ac (*WiFi* networks). Both LTE-U and LAA operators will typically employ the dedicated licensed spectrum as the primary carrier for signalling traffic (i.e., control channels) and provide data services with high QoS requirements, while a secondary set of carriers in the unlicensed spectrum will be added by means of carrier aggregation techniques to provide data services with less demanding QoS requirements.

LTE-U (standardised in 3GPP LTE Releases 10/11/12) was designed for quick launch and deployment in countries that do not require the implementation of the listen-before-talk (LBT) technique (e.g., USA, South Korea, India, and China). This allowed existing LTE systems to operate in unlicensed spectrum with no changes to the air interface protocol by simply exploiting mechanisms provided by the standard. LAA (standardised in 3GPP LTE Release 13) was introduced to allow

spectrum coexistence in unlicensed bands in countries where the implementation of the LBT protocol is required (e.g., Europe and Japan). The third variant of LTE in unlicensed bands, MuLTEfire, was designed as a stand-alone version of LTE for small cells relying exclusively on unlicensed spectrum as the primary and only carrier.

LTE-U was developed by the LTE Forum (established in 2014) with the aim to exploit the latest 3GPP LTE features to enable operation in unlicensed frequency bands. The approach of LTE-U was not to introduce changes to the standard, which would have required a long development time, but instead adapt the existing features provided by the standard so that operation in unlicensed bands could be enabled within a short time frame. Three main simple mechanisms are exploited by LTE-U to operate in unlicensed bands (see Fig. 1):

- On-off switching: In order to minimize interference to other users within the unlicensed band, transmissions in the unlicensed spectrum are performed only when needed. If the LTE traffic load exceeds a certain threshold and there exist active users within the unlicensed spectrum band, then the carrier in the unlicensed band is turned on to offload LTE traffic. On the other hand, when the main (licensed) carrier of the LTE network operator is sufficient to manage the traffic demand (or when there is no active user within the unlicensed band), then the carrier in the unlicensed band is turned off. This mechanism is referred to as

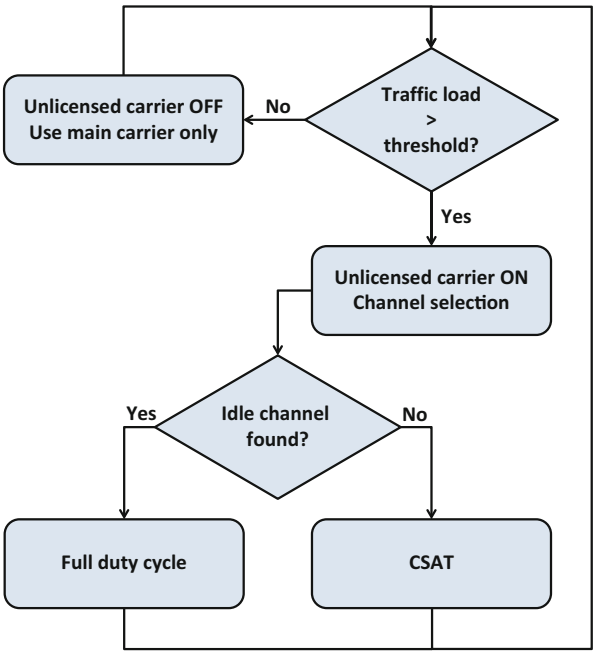

Fig. 1 LTE-U operation

opportunistic supplementary downlink (SDL) since LTE-U only uses unlicensed spectrum for additional downlink capacity.

- Carrier selection: The LTE base station scans the unlicensed spectrum and monitors the power level in each available channel. An unused channel will eventually lead to a low measured power and therefore to a low prospective interference if the LTE network operates in that channel. Based on this premise, the channel with the lowest detected signal power is selected. Since the sources and types of interference in an open unlicensed band are unknown, the power level is measured based on energy detection. Power measurements are usually performed both at the beginning power-up stage and later on periodically during active transmission (typically every 10 s). If interference is detected, LTE-U will attempt to switch to other channels with lower interference levels.
- Carrier-sensing adaptive transmission (CSAT): When no unused channel is found within the unlicensed spectrum, an active channel is selected. The CSAT mechanism allows LTE systems to share an active channel with other users on a time-division multiplex (TDM) basis as illustrated in Fig. 2. The LTE base station senses periodically the channel (for a relatively long period that can be anywhere between 0.5 and 200 ms) to determine if a signal is present (typically using an energy detection principle with a decision threshold of −62 dBm). Based on the detection result, CSAT will adjust the transmission duty cycle by deciding for how many frames the LTE system will transmit or remain quiet. If low channel activity is detected during LTE off periods, the duty cycle will be increased and vice versa (within some constraints of minimum and maximum durations for LTE on/off periods). During the LTE transmission periods, LTE accesses the channel without performing sensing; however, it regularly leaves some short transmission gaps to allow for latency-sensitive Wi-Fi services.

The distributed coordination function (DCF) used by Wi-Fi devices to access the channel includes a clear channel assessment (CCA) mechanism which dictates that the channel can only be accessed if it has been idle for a certain period. Moreover, Wi-Fi devices will vacate the channel if a collision is detected during the transmission, after which they will enter a back-off mode where they will wait for a random time before a new transmission is attempted. As a result of this channel

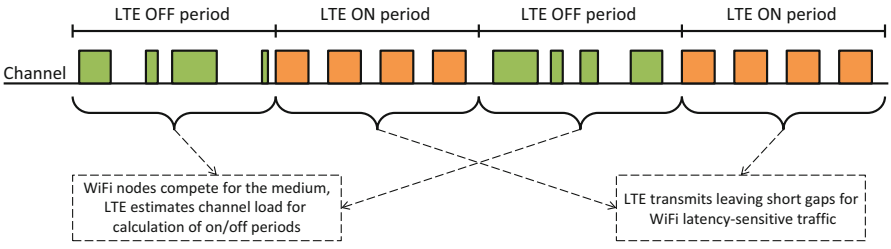

Fig. 2 Example of coexistence between LTE-U and WiFi [36]

access protocol, the performance of Wi-Fi users can be severely degraded by the presence of LTE-U users monopolizing the unlicensed spectrum.

LAA was developed and standardized by 3GPP in Release 13 with the aim to enable a fair coexistence between LTE and Wi-Fi. Fairness is defined as the capability of LTE "to not impact WiFi services more than an additional WiFi network on the same carrier, with respect to throughput and latency" [11]. An LBT mechanism with random back-off and a variable contention window size, similar to that of Wi-Fi, was introduced as the main means to enable such fair coexistence. The main idea to prevent LTE users from monopolizing the spectrum is to first sense the channel (based on energy detection) and transmit only if the medium is sensed to be idle for a minimum period of time. This process is referred to as clear channel assessment (CCA), and the LBT mechanism includes both initial and extended CCA (see Fig. 3). The back-off mechanism is designed to avoid collisions when two or more nodes sense the channel as idle and transmit at the same time. The back-off counter N is randomly drawn from a uniform distribution within a dynamic contention window (CW), which is increased exponentially (up to a predefined maximum value) when a collision is detected (typically when at least 80% of the HARQ reports indicate erroneous transmission) and reset (to a predefined minimum value) when the transmission is successfully completed. The required N idle slots do not need to be contiguous; however, when a busy slot is detected, the back-off process is suspended until the channel has been idle for at least a predefined extended defer period, after which the counter can be decreased again with each idle slot. As a result of this channel access protocol, LTE behaves similarly to Wi-Fi as illustrated in Fig. 4, which leads to a *fair coexistence* as defined in [11].

In 3GPP LTE Release 13, where the use of unlicensed spectrum is supported for downlink only, the eNodeB follows the procedure shown in Fig. 3 for transmission in the physical downlink shared channel (PDSCH). An enhanced-LAA (eLAA) version that supports transmission in the uplink, via the physical uplink shared channel (PUSCH), was introduced in 3GPP LTE Release 14, which enables the user equipment to access the unlicensed spectrum following a largely similar procedure.

There exist specific regulations in many countries that prevent from continuous transmission. As a result, LTE operators cannot transmit in unlicensed spectrum for unlimited periods of time. When a transmission opportunity arises, LTE can transmit for a predefined amount of time, after which the channel has to be vacated even if there are more data to transmit. This resembles the behavior of Wi-Fi nodes, which utilize the channel for a limited time to allow for medium access competition. 3GPP introduced four different priority classes for LAA (the smaller the priority class number, the higher the priority). The maximum channel occupancy time for the commonly used category 4 LBT is typically 10 ms. Certain countries may have additional requirements (e.g., for LAA operation in Japan, the eNodeB should sense the channel to be idle after every 4 ms of transmission). To allow for a more flexible access to the unlicensed spectrum, LAA has a slightly different frame structure (Type 3). This frame is also based on ten 1 ms subframes; however, transmissions do not necessarily start or end at the boundary of a subframe [12].

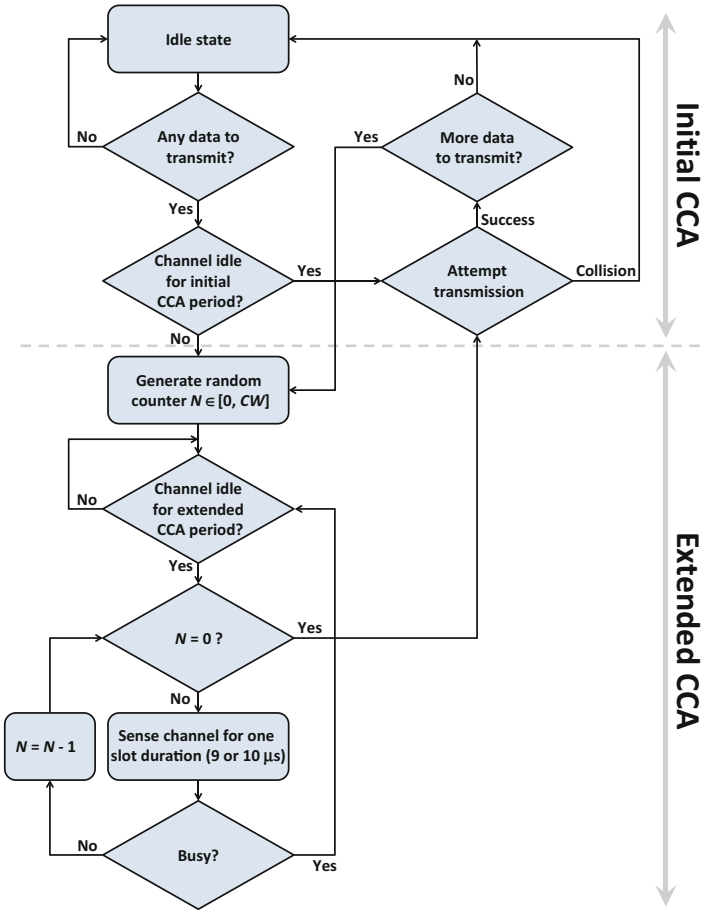

Fig. 3 LAA operation [11]

Table 2 summarizes the main features of LTE-U and LAA. A related technology is LTE-WLAN aggregation (LWA), introduced in 3GPP LTE Release 13 to enable mobile terminals equipped with LTE and Wi-Fi employ both links simultaneously through the LTE dual connectivity architecture introduced in Release 12 (but using a Wi-Fi access point instead of an LTE secondary base station) and aggregate the data traffic of both links at the radio access network level (instead of aggregating the traffic at the core network level through the interfaces introduced in Release 8). Unlike LTE-U and LAA, in LWA, there is no spectrum coexistence between LTE (operating in licensed spectrum) and Wi-Fi (operating in unlicensed spectrum), and CR techniques are therefore not applicable in this case. In general, LWA provides a performance comparable to that of LAA (which outperforms LTE-U as a result of the fair coexistence with Wi-Fi networks enabled by the LBT mechanism).

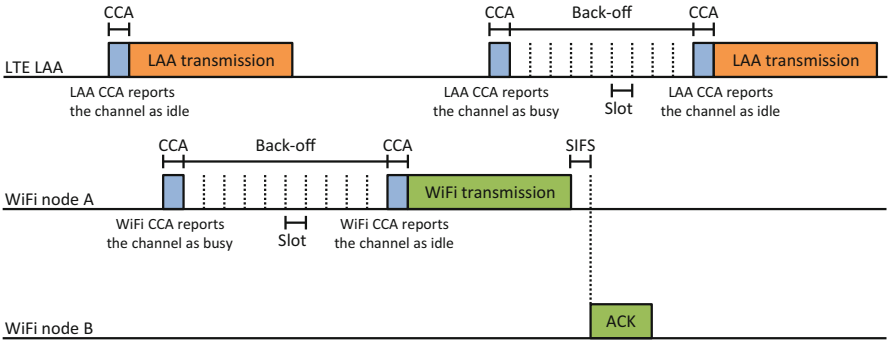

Fig. 4 Example of coexistence between LAA and WiFi [36]

Table 2 Comparison between LTE-U and LAA

	LTE-U	LAA

[a]Both use the licensed spectrum as the primary carrier and are backward-compatible with Rel. 9

Other Applications in Mobile Communication Networks

The increase of the mobile network capacity by exploiting unused spectrum in other (licensed and unlicensed) bands is not the only application of CR techniques in the context of mobile communications. CR principles can be exploited in other contexts and scenarios as well. CR has the potential to provide simple solutions to overcome some of the challenges faced by mobile communication networks and improve the effectiveness and efficiency of already existing solutions [20].

The trend of network densification (i.e., the deployment of cells with smaller coverage areas as a means to increase network capacity) has resulted in heterogeneous network scenarios where macro-, micro-, pico-, and/or femtocells coexist in the same area and typically in the same spectrum as well. The application of CR principles in the context of femtocells has led to the concept of *cognitive femtocells*, which has received significant attention. Femtocells are consumer-deployed access points designed to provide low-power short-range broadband

coverage at homes, offices, public hotspots (e.g., airports, malls), and other indoor scenarios. Femtocell access points (FAPs) are connected to the operator's network through broadband wired connections or wireless backhaul links and can therefore be seen as gateways for indoor terminals. The deployment of FAPs is carried out by the customer and is therefore uncoordinated (i.e., without network planning), which usually leads to potential cross-layer interference with the macrocell as well as co-layer interference with other femtocells. Traditional solutions include the use of coordinated resource allocation schemes (which is in general challenging due to the lack of a direct communication interface defined between the femtocell and macrocell access points) and static or dynamic frequency reuse schemes (where different portions of spectrum are allocated to macro-/femtocells, which usually results in sub-optimum exploitation of the spectrum resources). The limitations of both approaches can be overcome with the adoption of CR techniques in the FAPs, thus leading to a dynamic spectrum coexistence scenario where the femtocell plays the role of a cognitive (secondary) system accessing opportunistically the spectrum of the incumbent (primary) macrocell without generating harmful interference. This approach results in a more efficient exploitation of the spectrum than frequency partitioning methods, without the need of direct coordination mechanisms between femtocells and macrocells or other femtocells. The femtocell can sense the spectrum to detect free channels not used by the macrocell or another femtocell (which can be performed by the FAP to remove the need of additional infrastructure as well as battery life issues in mobile terminals), select the carrier frequency that best suits the requirements of the femtocell users, and exploit the free carrier using either interweave or underlay techniques, depending on the detected spectrum activity, tolerable interference levels, and user traffic requirements [54]. Cognitive femtocells can observe the surrounding radio environment and adapt dynamically to exploit spectrum opportunities and avoid co-layer and cross-layer interference in a manner that is transparent to the macrocell. This approach enables an uncoordinated deployment of femtocells while allowing an efficient exploitation of the spectrum allocated to the mobile communication network, without having to resort to additional spectrum bands. Alternatively, under high traffic demands, femtocells can exploit the cognitive capabilities to access other spectrum bands (e.g., Wi-Fi bands using LTE-U/LAA techniques).

Another area of application of CR in mobile communications is in device-to-device (D2D) communications. D2D was introduced in 3GPP LTE Release 12 to enable nearby mobile terminals establish a direct communication link, bypassing their corresponding cellular base station. By enabling a low-power direct D2D link instead of a higher-power dual-hop link through the base station (uplink/downlink), the D2D concept can reduce congestion and improve radio resource utilization and spectral efficiency at the base station, reduce interference at the macrocell, and improve latency and power consumption at mobile terminals. While the network may be aware (even take control) of D2D links, it is in network-unaware D2D links where CR can unleash its full potential by allowing mobile terminals detect the proximity of the other terminals, sense the spectrum to find suitable frequencies for the establishment of D2D links, and reconfigure the operation parameters to allow

opportunistic use of the spectrum [42]. Cognitive D2D communications can enable efficient radio resource utilization and interference management among coexisting cellular and D2D users with limited or no intervention from the cellular base station.

With the advent of the Internet of Things (IoT), mobile communication networks have emerged as one of the main connectivity technologies. In this context, the narrowband IoT (NB-IoT) was standardized by 3GPP in Release 13 to enable a wide range of IoT devices to be connected using LTE networks. The NB-IoT technology has been designed to coexist with standard LTE users in the spectrum allocated to LTE (using the same radio resource block bandwidth of 180 kHz) where LTE used to operate exclusively. This can lead to interference problems between LTE and NB-IoT carriers when only some base stations are NB-IoT-capable. While the adjacent channel interference may be negligible [53], low-power NB-IoT devices may be affected by strong co-channel interference from base stations that are LTE-capable only. CR techniques can also be exploited in this context to mitigate this harmful interference (e.g., by means of selective LTE resource blanking [37]).

Satellite Communication Networks

Satellite communication networks are nowadays fundamental to meet the challenging objectives of future fast broadband access for everyone. Their inherently large coverage footprint makes them the ideal candidate to reach areas where the deployment of wired and wireless networks is not economically feasible. While satellite communications may be better known to the general public for direct-to-home (DTH) interactive video broadcasting services, they have certainly found a broader range of applications in market niches such as land mobile, aeronautical, maritime, transports, military, and rescue and disaster relief.

Similar to the evolution of mobile communication networks, satellite communications have also suffered a substantial increase in traffic and capacity demands over recent years. This has historically been addressed with the gradual optimization of the single-user satellite link by means of more spectrum-efficient technologies, for instance, the different families of the digital video broadcasting (DVB) standard (DVB-S, DVB-SH and DVB-RCS). This process is well documented in the existing literature. Given that the current state of the art has closely approached the well-known Shannon limit [43] and further improvements usually provide incremental performance enhancements, satellite communication research has recently shifted toward multiuser communication techniques, many of which have already demonstrated great potentials for performance improvements in the context of terrestrial communications. In line with this trend, the introduction of CR techniques is currently inspiring the next generation of satellite communication systems.

While the application of CR principles to terrestrial communication networks has been investigated for over a decade, it has not been until more recently that the potential benefits that CR techniques may bring into satellite communications have started to be explored. Flexible spectrum utilization is a cornerstone for the efficient exploitation of the scarce spectrum resources, and CR techniques have broadly

demonstrated their potential benefits in the context of terrestrial communication networks (e.g., more efficient exploitation of the scarce spectrum resources, rollout of new and optimized services at lower costs for the end user, or new revenue streams for operators from secondary services). Future satellite communication systems may also benefit from the capability to access spectrum opportunities in frequency bands other than the dedicated licensed spectrum. CR techniques can be implemented in satellite communications to enable spectrum sharing and provide its associated benefits by effectively managing interference.

Long-term persistent interference from terrestrial or other satellite systems pose a major challenge to satellite operators as interference has a significant impact on the obtained revenues. In this context, CR techniques can help relieve interference. Certain types of interference may be difficult to mitigate by the introduction of CR techniques. This is the case of cross-polarization interference, which is typically caused by misaligned antennas, incompatible modulation types in opposite polarizations, or sometimes inappropriate training of the operators. Given its inherent nature, CR techniques can provide limited benefits in the relief of cross-polarization interference, which is solved by addressing the source of interference (usually a time-consuming and labor-intensive task). However, CR techniques can help relieve interference in scenarios of spectrum coexistence. This interference can occur from or to terrestrial fixed or mobile services and other satellites or satellite constellations in both geostationary and non-geostationary orbits (GSO/NGSO). Adjacent satellite interference is usually accidental and caused by inadequate coordination between systems. While this type of interference can be solved between satellite operators, CR techniques can be introduced as a countermeasure to mitigate its consequences. Interference between terrestrial and satellite services can be more severe and depends on the considered frequency band, geographic region, and enforced regulatory framework. For example, interference is in general lower in DTH markets in developed countries than in very small aperture terminal (VSAT)-oriented markets, while it is currently low (but increasing) in the Ka band and higher in the Ku and C bands. An interesting and useful application of CR solutions in this context is the use of dynamic adaptation methods for interference-free dynamic spectrum sharing in order to exploit unused or underused frequency bands assigned to other (satellite or terrestrial) services on an incumbent/primary or secondary basis.

Satellite Bands of Interest for Cognitive Radio

Satellite communication systems operate over a wide range of spectrum bands. Several beneficial applications of CR principles have been identified in the Ka (27–40 GHz), Ku (12–18 GHz), C (4–8 GHz), and S (2–4 GHz) bands [4, ch. 10]. Some characteristics as well as the motivation for introducing CR techniques for spectrum sharing in these bands are reviewed in this section. The exploration of the potential applications and benefits of CR techniques at higher frequencies such as the Q (35–50 GHz), V (40–75 GHz), and W (75–110 GHz) bands has

Table 3 Satellite bands of interest for cognitive radio

IEEE designation[a]	Frequency range	Motivation for the introduction of CR
Ka band	27–40 GHz	Capacity extension through secondary cognitive access to adjacent spectrum
Ku band	12–18 GHz	Capacity extension and exploitation of fragmented spectrum
C band	4–8 GHz	Capacity extension and mitigation of interference from LTE/WiMAX
S band	2–4 GHz	Capacity improvement through mitigation of intra-system (satellite/ground segments) and inter-system (UMTS) interferences

[a]IEEE Standard Letter Designations for Radar-Frequency Bands (IEEE Std 521-2002)

been suggested as well; however, most of the interest has mainly focused on lower frequencies, and these are therefore the bands considered in this section (see Table 3).

As a result of the long-standing demand of broadband via satellite from users out of reach to high-speed terrestrial networks, a general trend in the evolution of satellite communications has been the migration of systems and services to higher-frequency bands, where larger portions of contiguous spectrum can be found, in order to deploy the so-called high-throughput satellite (HTS) systems (communication satellites that can provide at least twice the total throughput of a classic FSS satellite for the same allocated spectrum, although in practice, this is typically exceeded by a factor of 20 or more). One advantage of the Ka band over lower-frequency bands (Ku, C, S) is the possibility to exploit higher-frequency bands with smaller spot beam cell sizes and higher degrees of frequency reuse (i.e., reuse of the allocated frequency band several times over the coverage area, similar to cellular networks in the terrestrial domain), which enables a more efficient exploitation of the available frequency resources and therefore an increase of the overall system capacity and a reduction of the cost per bit per second per Hertz. Consequently, the use of the Ka band has been targeted by the majority of satellite operators as a technical pathway to deliver high capacity services at economically affordable and sustainable rates. The Ka band is nowadays populated by HTS able to deliver maximum throughput rates typically between 70 and 100 Gbit/s over contiguous coverage areas ranging from small to regional and even continental scales. The increasing attention received by the Ka band and the perspective of broadband satellite applications motivate the additional use of some adjacent spectrum in the Ka band as a means to extend the overall satellite capacity in this band and further drive down the cost per bit per second per Hertz. This adjacent spectrum may be accessed on a cognitive/opportunistic basis through the adoption of CR techniques.

The Ku band is used extensively for DTH applications (in particular the downlink), and the current trend is an increase in the capacity demand (by a factor of around 1000 transponder equivalents over a 10-year period) mainly driven by DTH and VSAT services, followed by mobility and video distribution services.

Within the heavily exploited Ku spectrum, an additional issue is the fragmented use due to interference or other reasons. CR techniques are well suited to exploit and share non-contiguous regions of the spectrum and therefore become a natural (and promising) candidate to cater for the increasing capacity demand in Ku band.

The C band is significantly less affected by rain and humidity than the Ka and Ku bands, which results in better radio propagation conditions. The atmospheric fading conditions are excellent for highly reliable, weather-independent links over very large coverage areas (at continental and intercontinental scales) with very high availability rates. This band has traditionally been used by satellite communication systems extensively and is still appreciated for satellite service deployments, which include mainly point-to-point and point-to-multipoint links for IP backbone connections. The bandwidth required for backhaul, trunking and professional services, and the continuously increasing bit rates of digital video distribution services provided in the C band are expected to push the required capacity in this band. This challenge has traditionally been addressed by means of new combinations of wide beams, spot beams, and frequency reuse patterns along with enhanced connectivity options between beams and new improvements of antenna technologies. In this context, the adoption of CR principles can provide a new dimension for further capacity enhancements. However, it is in the management of interference in the C band where the introduction of CR techniques can unleash its full potential and provide the most significant improvements. Despite the robustness under all atmospheric conditions, the current deployments found in the C band are very sensitive to interference and, as a result, are facing numerous challenges to provide reliable and efficient services to the standard required by the customers. Given the high imbalance of power levels between satellite and terrestrial signals, any terrestrial interference toward satellite systems has a strong negative impact on the satellite signal quality and the resulting end-user QoS. The relatively recent deployment of LTE cellular services and broadband wireless access (BWA) systems such as WiMAX in the so-called *extended* C band (3.4–3.6 GHz) has led to severe interference problems on C band satellite systems. The extended C band was globally allocated to IMT-2000 cellular services on an incumbent basis with no real system impact considerations (or insufficient analysis) and without protection to satellite communications, which has led to numerous interference concerns for satellite operators as well as reported coexistence problems with LTE, in particular for transmissions into low elevation angles for GSO satellite links. Moreover, the presence of WiMAX signals, which typically operate at power levels approximately 40 dB higher than satellite signals, has resulted in problems of obliterating in-band interference, harmful interference from out-of-band emissions, and blocking of signals resulting from saturation of the low-noise amplifiers used by satellite receivers. Typical countermeasures employed to date in order to mitigate the negative impact of terrestrial interference include the increase of separation distances, use of larger dishes (antennas) at the receivers, and deployment of new expensive filters or other hardware upgrades of the end-user equipment. Unfortunately, the technology available today may not be able, in some cases, to mitigate completely the interference, in particular when it comes to high data rate services requiring very high signal-to-noise ratios. In exceptional cases,

this has required spectrum refarming from regulators and price reductions from operators given the inability to provide suitable levels of service to the customers. Such interference problems (mainly in the reception of digital TV) led some Asian countries (Philippines, Indonesia, Malaysia, Vietnam) to refuse or withdraw WiMAX licenses in the extended C band, while European regulatory regimes have started to review more strictly licenses in the lower part of the C band. However, with LTE and WiMAX services already deployed in the extended C band, the damage has already been caused, which claims for novel technological solutions to mitigate the existing interference problems. In this context, CR emerges as a promising solution given its demonstrated ability to manage and control interference through several techniques, mechanisms, and protocols. The introduction of CR techniques is expected to significantly relieve interference problems in the C band and relax the demanding requirements currently imposed on other interference-mitigating techniques. An adequate interference mitigation in C band is relevant not only for the coexistence of satellite systems in this band with LTE/WiMAX terrestrial systems but also for many other satellites that today operate in other higher-frequency bands but carry out telemetry, tracking, and control (TTC) operations in C band.

The S band is typically populated by hybrid networks composed of a satellite segment and a complementary ground segment, both of which may be integrated and coordinated by the same operator to provide holistic service coverage and delivery over urban, suburban, and rural areas but may utilize potentially different broadcast and interactive technologies in the space and terrestrial segments. The frequency planning of these networks is quite complex and requires a careful consideration not only of the potential intra-system interference between satellite and ground segments (a problem usually worsen by the presence of mobile user terminals in the ground segment) but also the potential inter-system interference arising from 3G UMTS cellular deployments in adjacent spectrum allocations, which are heavily used in Europe and other regions. CR techniques can find several useful applications in this context as a tool to mitigate both intra- and inter-system interferences and increase the overall system throughput. Either the satellite or complementary ground segment can be the primary/incumbent part of the integrated network, while the other segment plays the role of a secondary/cognitive network, or the fixed part of the network acts as primary/incumbent, while the mobile terminals dynamically adapt the forward and return links to the changing interference scenario on a secondary/cognitive basis.

Spectrum Coexistence Scenarios

Several scenarios in satellite communications offer the potential for flexible spectrum sharing and interference mitigation through the adoption of CR techniques. Some possible application areas include the secondary use of satellite spectrum by terrestrial systems, satellite systems as cognitive secondary users of the terrestrial spectrum, extension of terrestrial networks using satellite networks, and wider

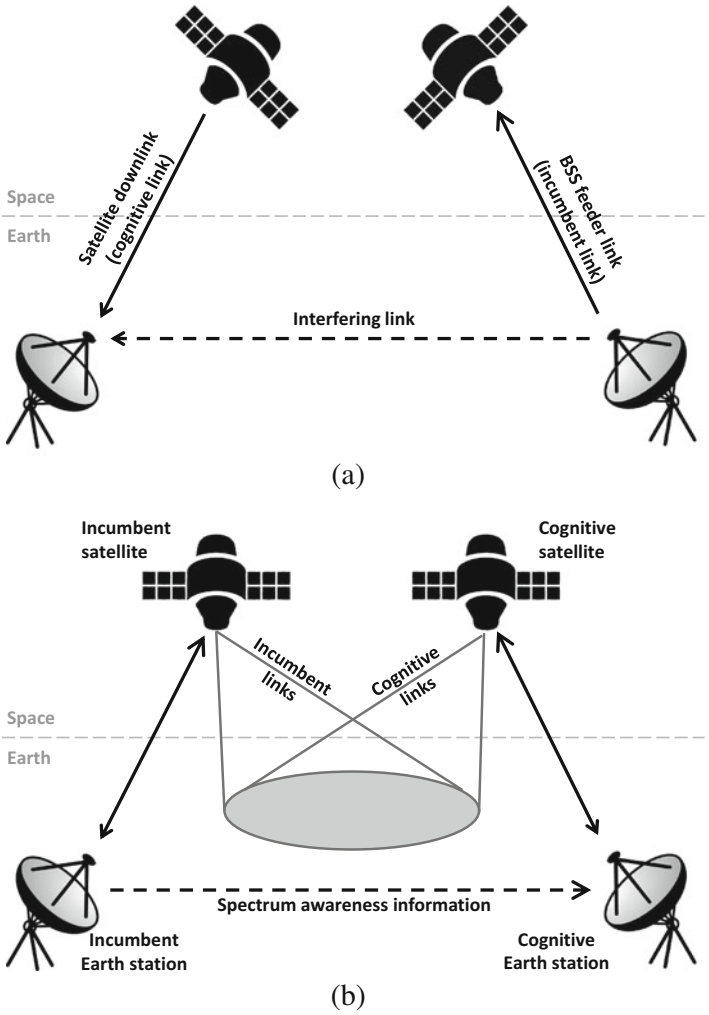

Fig. 5 Spectrum sharing scenarios in satellite communications (satellite-satellite) [4, ch. 10]

cognition for more efficient use of resources in the satellite network (with or without involvement of a terrestrial network) [19]. Figures 5 and 6 illustrate some representative scenarios of satellite-satellite and satellite-terrestrial spectrum coexistence, respectively. Each scenario is defined by the frequency band of operation, the provided services, and the enforced regulatory framework, which are discussed in more detail in the following.

The scenario shown in Fig. 5a is applicable to the downlink of GSO satellites in Ka band (17.3–17.7 GHz). The 17.3–17.7 GHz band is mainly allocated to satellite systems (with the exception of some particular countries where this band may

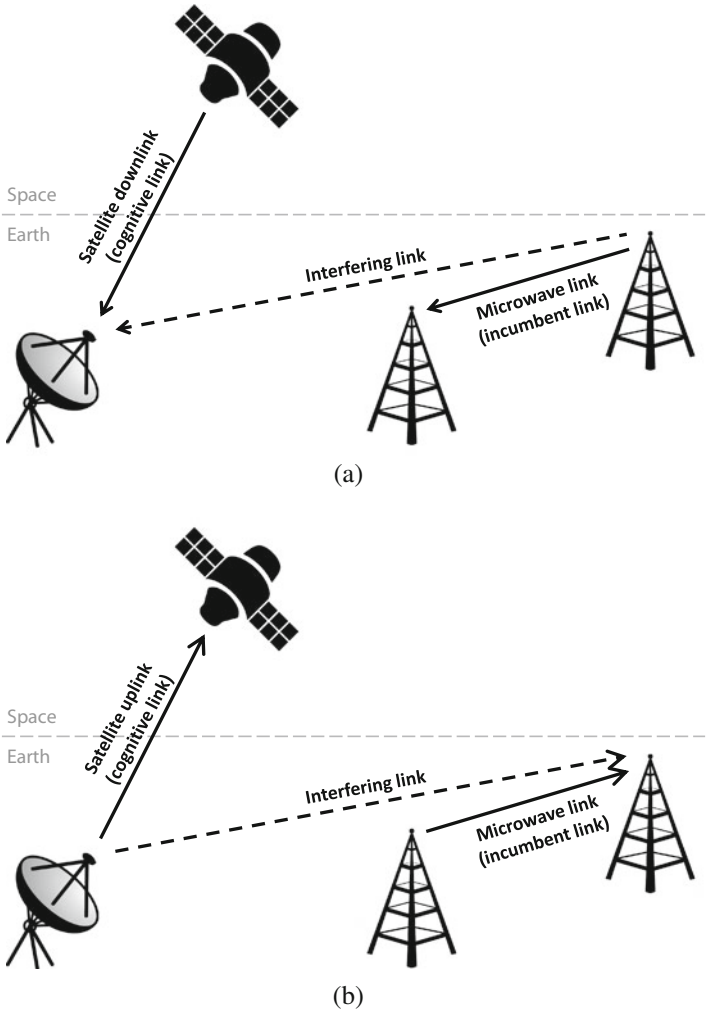

Fig. 6 Spectrum sharing scenarios in satellite communications (satellite-terrestrial) [4, ch. 10]

also be allocated to some terrestrial services on an incumbent basis). This band is typically allocated to high-density applications in the fixed satellite service (HDFSS), without prejudice to its use by GSO broadcasting satellite service (BSS) feeder uplinks. Spectrum regulations also allow the deployment in this band of uncoordinated fixed satellite service (FSS) Earth stations and contemplate the harmonized use of Earth stations on mobile platforms (ESOMP). The deployment of uncoordinated FSS Earth stations may eventually take place in locations subject to long-term interference from BSS feeder uplinks as well as temporary, short-term interference from satellite terminals on mobile platforms. In this context, the

adoption of CR techniques can provide the means required for an interference-free coexistence among the involved parties and an increased frequency exploitation by means of flexible spectrum usage.

The scenario shown in Fig. 5b is applicable to the uplink and downlink of GSO satellites in Ku band (10.7–12.75, 12.75–13.25 and 13.75–14.5 GHz). These bands are allocated to GSO satellite systems, which use these regions of the spectrum on a primary/incumbent basis. However, an additional (secondary/cognitive) GSO satellite system may be overlaid, thus leading to a dual GSO satellite system. In this scenario, the cognitive GSO satellite system can adopt the use of CR techniques in both uplink (12.75–13.25 GHz and 13.75–14.5) and downlink (10.7–12.75 GHz) to dynamically adapt to the interference environment of the incumbent GSO satellite system and exploit the available spectrum opportunities in order to achieve a more efficient exploitation of these bands. A detailed discussion of this scenario can be found in [4, ch. 12].

The scenario shown in Fig. 6a is applicable to the downlink of GSO satellites in Ka band (17.7–17.9 GHz) and C band (3.4–3.8 GHz). The 17.7–17.9 GHz band can be used by FSS and terrestrial fixed services (FS) such as microwave links. In this band, FSS Earth stations can be deployed anywhere, however without the right of protection from interference from the FS transmitters. CR techniques can be adopted to provide such protection and enable the FSS to reuse the spectrum in this band in the vicinity of terrestrial FS transmitters. Satellite operators can exploit this to gain significant user capacity by extending the 19.7–20.2 GHz band (exclusive for wideband downlink FSS) with additional contiguous spectrum in the 17.7–19.7 GHz band. The presence of ESOMP in this band needs to be taken into account as well. In the 3.4–3.8 GHz band, which is also shared between terrestrial FS and satellite services, the incumbent system can be either the satellite or terrestrial service. In this context, CR techniques can be exploited to enable a more intense use of the spectrum by allowing satellite systems adapt their frequency usage in the downlink according to the interference environment generated by the incumbent satellite and terrestrial FS. Information on the FS frequency assignment would enable the local selection of suitable frequencies that would enable satellite operation while avoiding interference from microwave links.

The scenario shown in Fig. 6b is applicable to the uplink of GSO satellites in Ka band (27.5–29.5 GHz). The 27.5–29.5 GHz band is segmented between FS and uncoordinated FSS Earth stations. The FS segment is typically subject to a low level of utilization (in particular through Europe), which motivates the flexible reuse of the FS segment by FSS stations through the adoption (in the satellite uplink) of CR techniques able to dynamically control the potential interference to FS stations.

The scenarios in Fig. 6a, b are also applicable to the downlink and uplink, respectively, of NGSO satellites in Ka band (17.7–19.7, 27.8285–28.4445 and 28.9485–29.4525 GHz), where similar coexistence and interference issues can be found and similar solutions through the adoption of CR techniques can be applied.

It is worth noting that in some scenarios, in particular those shown in Figs. 5a and 6a, the relevant interference is from the incumbent system to the cognitive

system. This is a distinguishing feature of satellite communications with respect to terrestrial scenarios where this type of interference is irrelevant and the focus typically is on avoiding interference in the reverse direction (i.e., from the cognitive system to the incumbent system). On the other hand, in the scenarios shown in Figs. 5b and 6b, the relevant interference is from the cognitive system to the incumbent system, which resembles the traditional scenarios typically found in terrestrial CR networks. There exist some additional interference relations besides those shown in Figs. 5 and 6; however, these typically correspond to *weak interference* and can be considered negligible in practice. This is usually the case of interference links between Earth and space stations, where the long distances along with the use of directional antennas lead to very low (negligible) levels of interference, or between Earth-Earth and space-space stations where interference occurs through side or back lobes of the antennas and is negligible in practice as well. The interference links shown in Figs. 5 and 6 correspond to *strong interference* that determines the performance limits of spectrum coexistence between services.

Cognitive Radio in Satellite Communications

Spectrum exploitation in satellite communications has traditionally relied on static approaches such as separation of frequency bands on the basis of geographical service areas, service types, or angle of the satellite signals. While these traditional static approaches have provided effective mechanisms for interference-free operation of satellite communication systems, they do not allow for dynamic adaptation to the evolving conditions of traffic demand, geographical mobility, or temporal and spatial interference. They introduce significant inefficiencies that leave a substantial margin for improvement in the exploitation of the allocated spectrum and are currently regarded as suboptimal. Most (if not all) existing CR techniques have been inspired by terrestrial scenarios, and their applicability to satellite communication systems is not always straightforward, thus requiring an exhaustive revision and potential redesign of the existing CR technology taking into account the specific features of satellite communication systems (e.g., much lower received signal levels, much larger coverage areas, much longer delays, or very limited ability to update in-orbit infrastructures).

This section presents an overview of some of the main CR techniques of interest for application in satellite communications, with discussions on specific particularities of satellite scenarios and differences with respect to their terrestrial counterparts. These techniques can be classified into *spectrum awareness* solutions used to obtain relevant information and knowledge of the surrounding radio environment (spectrum sensing and geolocation databases) and solutions for *spectrum utilization* aimed at enabling interference-free coexistence between incumbent and cognitive systems (cognitive zone, power control, carrier allocation, beamforming).

Spectrum sensing is one of the simplest forms of spectrum awareness in CR-based systems and, with some special considerations, may be applicable to satellite communications. Spectrum sensing aims at detecting the presence of

incumbent user signals by scanning some selected frequency bands and processing the captured samples with advanced signal processing methods. The signal to be detected may be fully known, partially known, or unknown, and this determines the range of spectrum sensing methods that can be applied as well as their performance [58]. One of the main limitations of spectrum sensing as a spectrum awareness technique is its detection reliability. The unavoidable presence of errors in the idle/busy decisions of spectrum sensing methods leads to interference and efficiency problems. This problem is accentuated in satellite communications, where received signal levels are significantly lower than in terrestrial scenarios as a result of the limited transmission power of satellite stations along with substantial signal attenuation due to cloud, rain, and other atmospheric effects, which can deteriorate significantly the quality of incumbent signals received at cognitive sensors. Devices based on energy detection methods may need to employ highly directed antennas toward the satellite, which may require the deployment of separate stations with parabolic antennas for the task of spectrum sensing [18]. Other detection methods such as matched filter or feature detection can provide better detection performance by exploiting signal inherent features such as cyclo-stationarity, specific autocorrelation, pilot symbols (e.g., in DVB-S2 signals typically used in satellite communications), or signal polarization [44,46]; however, these techniques require a priori information on the signal to be detected and its properties. Cooperation among spectrum sensors is a well-known approach to improve the overall detection performance while reducing the sensitivity requirements imposed on individual sensors. The existence of multiple users that belong to the same network (and can therefore communicate among them) exploiting the same band can be exploited to use cooperative spectrum sensing techniques. However, this approach faces additional problems in satellite communications: firstly, finding another sensor with better channel conditions for cooperation may sometimes mean finding a sensor hundreds of kilometers away given the large coverage areas of satellite communications; secondly, the design of an efficient means for intercommunication among cooperative users spread over large geographical areas is an additional issue to be addressed; and thirdly, the heterogeneity of satellite communications scenarios (satellite/terrestrial stations, uplink/downlink, incumbent/cognitive roles) requires a case-by-case analysis and design of cooperative spectrum sensing. In addition to the challenge of providing a reliable incumbent signal detection, satellite communications also face the problem of having to deal with channel bandwidths significantly larger than those usually found in terrestrial communications, which require the use of more powerful analog-to-digital converters (ADC). The use of sub-Nyquist sampling techniques such as sparse power spectrum estimation or compressive wideband spectrum sensing may help relieve the problem [2,50,56]; however, this still remains an important challenge, in particular in certain cases such as low Earth orbit (LEO) constellations, which are affected by mobility and frequency issues [31].

A popular alternative to spectrum sensing is the use of geolocation databases, which has also been considered in the context of satellite communications [18,23] [4, ch. 14]. Secondary nodes are required to implement the means to know their

own location (e.g., GPS receiver), which is sent to a centralized database in order to produce a report with the relevant spectrum awareness information for that location. A database for CR applications in satellite communications will typically contain information on geographic characteristics (coverage, service, and capture areas of space and terrestrial stations), incumbent and cognitive devices present in the area of interest and their characteristics (location, elevation and azimuth angles, coverage footprint, device type, height and altitude, antenna type, and directivity), and the surrounding radio environment (incumbent available frequencies, power levels and polarizations, spectrum masks). This rich set of data can be exploited to produce spectrum awareness information that would be difficult to acquire by individual spectrum sensors. This, along with the reliability problems associated with spectrum sensing, makes databases the most favored approach for spectrum awareness.

Spectrum sensing and databases have their specific advantages and limitations and provide different tradeoffs among performance, accuracy, complexity/cost of terminals and infrastructure, reliability, and legacy compatibility (see [34] for a detailed discussion). These approaches provide complimentary characteristics in terms of spectrum dynamism. In general, geolocation databases are not well suited for operation in spectrum bands with highly dynamic spectrum occupancy patterns. The procedure for determining the location of a cognitive node, sending a request to a database, and producing a report on the available spectrum and exploitation constraints is a time-consuming process. In highly dynamic bands, this may result in a cognitive node retrieving outdated information that does not reflect the current spectrum use scenario by the time it is received. On the other hand, spectrum sensing is well suited to obtain instantaneous spectrum awareness information even in highly dynamic, fast-changing bands. In general, geolocation databases are suitable for static scenarios where the transmitter characteristics (location, frequency, power, etc.) are stable or change very infrequently, such as geostationary Earth orbit (GEO) satellites (where the coverage and visibility of the satellite are almost fixed) or FS terrestrial stations (which are deployed at geographically fixed locations and with fixed frequency plans, similar to TV bands where databases are a popular approach as well). Databases may also be suitable for scenarios where spectrum occupancy patterns vary over relatively long time scales, such as medium Earth orbit (MEO) satellites (with altitudes of 10,000–20,000 km and pass times of 130–300 min) and even low Earth orbit (LEO) satellites (with altitudes of 200–1400 km and pass times of 7–2 min) [4, ch. 14]. On the other hand, the use of spectrum sensing may be necessary in bands where mobile terminals are present (e.g., ESOMPs) or a database is not available at all. Ideally, spectrum awareness information would be obtained by the joint use of a centralized database and the local spectrum usage detection of cognitive sensors; spectrum sensing can be used to support the database-based access; however, it should not be used as a stand-alone method in satellite bands.

Once the cognitive system has obtained adequate spectrum awareness information about the incumbent system, it can exploit that information to access spectrum opportunities by means of appropriate spectrum utilization techniques that can guarantee interference-free operation. One simple technique for interference

protection is the definition of a *cognitive zone*, which is a geographical region around a potentially interfered receiver where prospective interferers are not allowed to transmit unless they implement appropriate CR techniques that can mitigate interference to acceptable levels, which will be discussed later on. Interference outside this region is considered to be below the acceptable interference threshold, and transmission is allowed in a non-cognitive manner (i.e., without CR techniques). In terrestrial scenarios, where interference occurs from cognitive to incumbent users, the cognitive zone is typically defined around incumbent receivers. However, in satellite scenarios, where interference may occur in both directions (i.e., from cognitive to incumbent users and vice versa), the cognitive zone may need to be defined around either incumbent or cognitive users. For example, in Figs. 5a and 6a, the cognitive zones would be calculated around the satellite cognitive receiver, while in Fig. 6b, it would be calculated around the terrestrial incumbent receiver. Sometimes the cognitive zone may need to be defined around both, and the most restrictive one needs to be applied in order to guarantee that both systems can coexist simultaneously in the same region of the spectrum (e.g,, if bidirectional communication is assumed in the scenarios of Fig. 6). The cognitive zone can be defined around one or more individual stations or sometimes may need to be defined around a whole satellite spot beam or coverage area (e.g., in Fig. 5b). Cognitive zones are typically computed based on information from satellite and terrestrial databases along with interference modelling techniques that take into account the interferer's transmission power, the amount of aggregated interference tolerated by the interfered receiver, and the propagation channel between both including a range of propagation mechanisms such as line of sight, diffraction, tropospheric scattering, surface ducting, and anomalous propagation (ducting and layer reflection/refraction) as well as environmental factors such as frequency of operation, climate, distance, and path topography. If an accurate and complete database is not available, cognitive zones may then be designed based on spectrum sensing measurements, but worst-case designs should be adopted, which may result in loose zones. In any case, the use of cognitive zones has been proven to be effective for interference protection in satellite communications [45].

Within the cognitive zone, several spectrum utilization techniques can be employed. The most popular CR techniques proposed for satellite communications are based on underlay and interweave spectrum access approaches, while overlay-based solutions are less popular due to their inherent complexities and practical issues [45]. A typical underlay CR technique is the traditional location-aware power control [52], while a widely explored interweave CR technique is carrier allocation (other dynamic radio resource methods such as channel selection, admission control, and user scheduling have also been explored in the context of satellite communications [4, ch. 10] [5]). Carrier allocation techniques proposed for satellite communications are typically aimed at maximizing either the total overall throughput or the fairness (i.e., availability of carriers to as many users as possible according to their data rate requirements) [28] and can be combined with carrier aggregation techniques, which are popular in the context of LTE mobile communication networks and very appealing for the exploitation of the fragmented

spectrum in Ku band. Carrier allocation techniques have been proposed for the dynamic allocation of both incumbent and cognitive carrier frequencies to the users, not only in specific time and/or geographical locations but also exploiting additional degrees of freedom available in satellite communications such as polarization and angular direction (since satellites are seen at high elevation angles, depending on the latitude, an adequate design of antenna radiation diagrams can help reduce mutual interference and enable cognitive frequency reuse [23]).

Specific antenna radiation diagrams can be achieved by means of beamforming, a multiple-antenna signal processing technique that operates separately the individual elements of an antenna array in such a way that the combined radiations form a desired overall radiation (beam) pattern. Beamforming enables transmission/reception along certain spatial directions of interest while cancelling or mitigating signal components along non-desired directions. The spatial discrimination and filtering provided by beamforming can be exploited to enable spectral coexistence of two systems in the angular domain [47] and can be combined with resource allocation methods for a more efficient use of the spectrum [48]. Beamforming can be applied both in reception (e.g., in the cognitive satellite receiver of Figs. 5a and 6a) and transmission (e.g., in the cognitive satellite transmitter of Figs. 5b and 6b) as a passive/active interference mitigation technique, respectively. The introduction of beamforming techniques may very likely require significant upgrades in current satellite communication systems, both in the terminal and satellite sides, such as the introduction of multiple radiation elements (e.g., multi-LNB receivers) in order to create the desired beam patterns (which can be challenging in scenarios with high density of desired and/or interfering links) as well as modifications to enable full frequency reuse and perform the advanced signal processing required by beamforming. Moreover, in addition to the channel state information at the transmitter, which is crucial to design suitable beamforming techniques, location information of the terminals is required as well. If databases of both interfering and interfered systems are available and the interference links are fixed (e.g., fixed FSS or FS links), the direction of interference links can be calculated from the available database information; otherwise, spectrum sensing can be combined with beamforming to detect the direction of arrival (DoA) of interfering signal components. In practice, the DoA of the desired and interfering signals are not perfectly known, and the use of some DoA estimation algorithm is required, which not only provides more accurate estimations of the DoA but also has the advantage of compensating for antenna array imperfections and multipath signals. A more detailed discussion on cognitive beamforming for satellite communications can be found in [4, ch. 13].

Given the large variety of scenarios, services, users, potential interferences, and alternatives for the adoption of primary/secondary roles, a detailed discussion of the possibilities for the application of CR techniques in satellite communications is beyond the scope of the overview provided in this section; however, the interested reader can refer to the literature where a rich set of solutions specifically designed for dual satellite scenarios, hybrid satellite-terrestrial scenarios, or both can be found (see [4, ch. 10] [5] and references therein).

Cognitive Radio in Other Wireless Communication Systems

The two wireless communication systems reviewed in this chapter are some examples of prominent use cases of the CR technology in established systems but are certainly not the only possible application scenarios. The principles of the CR paradigm are helpful not only to increase spectrum usage efficiency and enhance network capacity but also to improve many aspects of wireless communications, providing intelligence to wireless communication networks and enabling users to access multiple air interfaces under varying communication needs and conditions. A detailed discussion is beyond the scope of this chapter, but the application of CR in some other scenarios is briefly mentioned in this section.

One of the early developments of the CR technology was in the context of military communications, where CR can be used to automatically find spectrum opportunities in regions with different frequency allocations or when communications are jammed by an enemy. Public safety and emergency networks can also benefit from the adoption of CR to provide reliable and flexible communications in disaster scenarios where the network infrastructure is partially damaged or completely destroyed [51]. CR-enabled devices can spontaneously configure new communication links among surviving nodes and communicate on an ad hoc basis. The infrastructureless, distributed, self-configuring multi-hop features of ad hoc networks are well suited for the implementation of the CR principles. Cognitive ad hoc networks involve challenging practical problems that have attracted significant research efforts for generic ad hoc networks [1] as well as particular types thereof, such as vehicular ad hoc networks [6]. The potential applications of CR techniques in the context of aeronautical communication systems have been considered as well [21]. The growth of the aviation industry and steady rise in air traffic have led to the depletion of aeronautical radio channels, which has worsen in recent years with the widespread deployment of unmanned aerial systems needing a vast amount of spectrum for remote real-time operation. CR techniques can be introduced to provide a more efficient exploitation of the aeronautical spectrum and mitigate interference in the broad range of systems and technologies involved in aeronautical communications, which includes air-ground systems, air-air systems, satellite-based communications, in-flight information and entertainment (infotainment) systems, and LTE air-ground (LTE A/G) links, among others (see [21] for a detailed discussion).

Table 4 shows some wireless communication systems where CR principles have been adopted. The adoption of CR in wireless communication systems has not only led to the definition of new standards but also the extension of existing ones to incorporate CR-based techniques:

- IEEE: In addition to the creation of new specific CR standards such as the IEEE 802.22 standard for WRANs in TVWS and the IEEE 1900 series of standards for dynamic spectrum access networks, IEEE has also extended some of its existing standards for WLANs (e.g., 802.11af for operation in TVWS, 802.11 h for dynamic frequency sharing and transmit power control extensions in the 5 GHz

Table 4 Adoption of the CR technology in some wireless communication systems

Body/group	Standard/document	Description
IEEE	802.11 [af/h/y]	Wireless local area networks (WLANs)
	802.15 [.2]	Wireless personal area networks (WPANs)
	802.16 [a/h/m]	Wireless metropolitan area networks (WMANs)
	802.19	Coexistence between unlicensed wireless standards
	802.22 [a/b/.1/.2/.3]	Wireless regional area networks (WRANs)
	SCC41/1900 [.1-7]	Dynamic spectrum access networks
3GPP	23.402, 24.302	Non-3GPP network access
	24.312	Access network discovery and selection function (ANDSF)
ECMA	ECMA-392	In-home HD video streaming, interactive TV broadcasting
ITU-R	M.2225	CR systems in the land mobile service
	M.2242	CR systems in the IMT service
ETSI	Technical reports	Feasibility studies and standardisation needs/opportunities
WINNF	Technical reports	Definitions, benefits, use cases in public safety

band in Europe, and 802.11y for operation in the 3650–3700 MHz band in the USA), WPANs (e.g., 802.15.2 for coexistence with other devices in unlicensed bands), and WMANs (e.g., 802.16a for operation in the 2–11 GHz band, 802.16 h for improved license-exempt coexistence, and 802.16 m for coexistence of fixed and mobile broadband wireless systems) and existing IEEE 802.19 standards for the coexistence among wireless standards for unlicensed devices.

- 3GPP: Besides the accommodation of features required for operation of mobile communication networks in licensed and unlicensed bands, 3GPP standards also include CR-like capabilities to enable integration for inter-system mobility between 3GPP and non-3GPP networks (e.g., WLAN or WiMAX) by means of modifications in the network architecture (3GPP TS 23.402) and the definition of access approaches (3GPP TS 24.302) as well as an access network discovery and selection function (3GPP TS 24.312).
- ECMA: The European Computer Manufacturers Association (ECMA) released ECMA-392, the first standard for personal/portable devices operating in TVWS [55], designed for applications such as in-home high-definition video streaming and interactive TV broadcasting services. The standard defines the PHY and MAC layers of a CR system with flexible network formation, mechanisms for protection of primary users, adaptation to different regulatory requirements, and support for real-time multimedia traffic.

Other important organizations have published technical reports and other documents addressing specific aspects of CR-enabled systems, including, for example:

- ITU-R: The International Telecommunication Union (ITU) has published reports addressing aspects of CR systems specific to the land mobile

(ITU-R M.2225) and international mobile telecommunication (ITU-R M.2242) services (LMS/IMT) such as technical features and capabilities, potential benefits, and deployment scenarios.

- ETSI: The European Telecommunications Standards Institute (ETSI) Technical Committee for Reconfigurable Radio Systems (RRS) has published a series of technical reports (TR 102 838) summarizing various feasibility studies on topics such as control channels for CR systems (TR 102 684), performance of CR systems operating in UHF TVWS (TR 103 067), and coexistence between CR systems operating in TVWS and existing radio frequency cable networks (TR 101 571). Other reports examine standardization needs and opportunities, including functional (TR 102 682) and coexistence (TR 102 908) architectures, system requirements for operation in TVWS (TR 102 946), network-aided spectrum awareness methods such as the cognitive pilot concept (TR 102 683), and use cases (TR 102 907).
- WINNF: The Wireless Innovation Forum (WINNF) has published a number of reports on CR deployments in TVWS, including potential benefits (WINNF-09-P-0012) and use cases for CR application in public safety networks (WINNF-09-P-0015) and LTE in white spaces (WINNF-12-P-0003), among others.

As new radio technologies and wireless communication paradigms appear, CR consistently continues to be an important candidate taken into account. The recent popularity of the IoT paradigm has opened new research directions in CR. The IoT concept involves a rich variety of interconnected smart devices that enable remote collection and exchange of data (with little or no human intervention) across existing network infrastructure, creating unlimited opportunities for the integration of the physical world into communication networks. While the Internet has historically been a wired network, wireless technologies are gaining popularity for the delivery of IoT services due to their flexibility and ability to provide connectivity anytime, anywhere, with anyone and anything. Traffic forecasts predict tens of billions of IoT devices in the foreseeable future, a significant part of which will be connected to the IoT through wireless links. This poses unprecedented challenges to network operators and claims not only for the utmost efficient exploitation of the already allocated spectrum but also the urgent need to gain additional capacity at much faster pace than spectrum regulations and allocations typically evolve. Relying on the already demonstrated benefits brought into legacy and modern wireless communication systems, CR emerges in this context as a promising concept to also increase the spectrum efficiency and network capacity of future IoT systems [24].

Conclusion and Future Directions

The CR paradigm has deeply impacted the way spectrum is accessed, shared, and exploited in modern (and will be in the future) wireless communication systems. CR provides wireless communication systems with an effective and elegant way

to overcome the challenge of increasing traffic demands, by opportunistically accessing and sharing spectrum bands that are not efficiently exploited. An increasing number of spectrum bands are being targeted by multiple wireless technologies to gain additional network capacity. However, besides the common vision of CR as a DSA method to increase the amount of spectrum available to a wireless network, CR can actually enhance many aspects of wireless communications through a more efficient exploitation of the allocated radio resources and mitigation of interference. This chapter has provided an overview on how CR techniques have been adopted by some prominent wireless communication systems (taking into account system-specific aspects and features) in order to gain additional network capacity, efficiently manage radio resources, mitigate interferences, or a combination thereof. CR has demonstrated its potentials in legacy and modern wireless communications and will, with no doubt, contribute to the evolution of the future radio technologies to come.

Abstract

The UK has long held a reputation for innovation in the TV bands. This chapter explains how the UK regulator's (Ofcom) openness to innovation, together with long established TV industry collaboration, enabled a robust regulatory framework for TV white spaces to be put in place. This chapter considers how the UK broadcasting heritage led up to this point and shapes the TV white spaces capacity availability. It also considers how industry cooperation in substantive trials produced results that encouraged the regulator to finalise its framework development and enact the required regulation, by the start of 2016.

Summary

The UK has embraced the principle of opening access to the TV white spaces (TVWS) and is applying the dynamic spectrum access mechanisms to enable more efficient sharing of other parts of spectrum, in the future.

Due to the established place of terrestrial broadcasting in UK domestic life, Ofcom, the UK's communications regulator, took considerable care in evaluating the effectiveness of cognitive sharing techniques. As in the USA, the regulator favored license-exempt access to the TV white spaces and found that the use of geolocation databases was the only practical approach which provided sufficient security for the licensed spectrum users – broadcasters and PMSE applications.

Development and evaluation of the regulatory approach to TV white spaces involved considerable cooperation between the regulator and industry – and between existing spectrum users and those who advocated dynamic spectrum access.

Ofcom needed to see strong industry interest, in order to justify the considerable effort needed to develop the regulations in full. This interest was demonstrated in two substantive TVWS trials – one in Cambridge and the other on the Isle of Bute. The trials demonstrated that the technology worked to deliver new applications and did not disrupt existing spectrum users.

When the regulatory framework had been worked up in detail, Ofcom invited participants from across the UK to participate in a pilot of the new framework. This attracted a diverse range of applications and enabled Ofcom to confirm and finalize its approach – albeit with more cautious parameters than it had initially proposed. Finally, the new UK regulation entered into force at the start of 2016.

Although the UK invested in laying the foundations for Europe-wide TV white space access, it still remains the only European country to have enacted the enabling regulations. Others have considered license-shared access to higher frequency bands, but the UHF bands used for broadcasting have proved more politically

complex to share. This has been compounded by the recent clearances of the 800 and 700 MHz bands, for reallocation to mobile broadband.

In implementing TV white spaces regulation, the UK has shown itself to be open to innovation. This openness, together with the cooperative approach taken by incumbents and newcomers, has enabled more efficient use of spectrum, without compromising existing services.

Introduction/Background

Political interest in improving Internet connectivity is as strong in the UK as anywhere else in the world. Policy makers have been considering a range of spectrum options to enhance Internet access performance – particularly in rural areas, where sub-megabit speeds have been a common frustration.

The UK Government has attempted to find mechanisms to encourage major operators to fill in the rural gaps, but with mixed success to date, as the commercial justification is weak.

An alternative approach for regulators is to make spectrum available in such a way that local operators or individuals can access it – either free or at low cost. License-exempt access is the main way to achieve this – since there are no fees for spectrum and the technical conditions on spectrum use are met by the equipment, without requiring any special skills or knowledge of the end user.

Wireless technology has the potential to improve rural connectivity rapidly, flexibly, and cost-effectively, but the lack of available spectrum for new networks has hindered its application.

Regulators have made cleared spectrum available for new wireless applications but mostly through national auctions. The inevitable winners are the mobile network operators (MNOs), which are prepared to spend large sums of money on securing exclusive access to spectrum and as well on network rollout. Given their commercial nature, the MNOs have tended to favor more densely populated areas. Many rural areas have been left with significant holes in network coverage.

Wireless Access Technology Is a Good Fit with Improving Rural Broadband Connectivity

In the early 2000s, the rapid growth in Internet use had started to reveal a stark rural/urban difference. In urban areas, residents and business generally had a way to get a reasonable (broadband) Internet connection. However, because its means of delivery was predominantly wired (either via a telephone wire or a cable TV system coaxial cable), homes in rural areas were at a real disadvantage.

This problem had already been seen in the USA, where typical telephone line lengths are much longer than in Europe, reflecting lower housing densities in urban areas.

- Wired cable TV systems are not widely deployed in rural areas
- The typically longer length of telephone wire connections in rural areas does not work well with the default broadband-over-telephone distribution technology (DSL)

License-Exempt Access Is a Key Tool in Community Service Provision

The license-exempt model has proved highly successful with Wi-Fi, Bluetooth, and other wireless communication technologies, but given the relatively high frequency of the available bands and the low transmission power limits, the range that could be achieved was quite limited.

The Attraction of Spare Frequencies in the TV Band

Wireless technology, on the other hand, was eminently suitable for filling coverage gaps – especially when using cost-effective Wi-Fi hardware. The problem was that the only frequencies available with sufficient bandwidth, on a license-exempt basis, were too high to achieve wide area coverage needed for serving rural communities (with the transmission power restrictions imposed by a regulation). The answer was to look for lower frequencies, under 1 GHz, but there was little or no spare spectrum available. Or at least the frequencies had already been assigned.

On closer inspection, however, it is clear that not all of the allocated frequencies are in use all the time in all places. This creates opportunities for sharing. In particular, the terrestrial TV bands (UHF IV and V) tend to have many, quite stable, white spaces. The beauty of spare capacity in the TV bands is that terrestrial television broadcasting uses UHF spectrum in all countries around the world, so there is great scope for harmonizing technology to harness capacity in this band – with the result that equipment cost can be much lower than it would if different hardware was needed for each market.

However, although there are overlaps in the frequency bands assigned for broadcasting, regulatory approaches for allowing access to the white spaces have differed, with the UK adopting a more cautious and complex framework than was used in the USA, where the first TVWS rules emerged, back in 2008.

Part of the reason for the additional caution, on the part of the UK, is the popularity and political importance of terrestrial TV broadcasting.

A Brief History of UK TVWS

UK TVWS interest can be traced back to the desire of the US IT players, Microsoft, Intel, and Compaq to inject IT technology into consumer electronics and realization that Internet connectivity was key. The industry's interest was articulated in 1997 at the NAB conference in Las Vegas where Craig Mundie, from Microsoft, presented

his vision for the future of television [1]. It came soon after the company's acquisition of WebTV, whose business was based on a merger of the Internet and television.

This vision of the TV, the Internet, and the PC coming together was shared by Intel and Compaq, among others.

Concerns Over Poor Connectivity Drove Interest in the TV White Spaces

Recognition of the need for Internet connectivity led the IT majors to look at how to extend the reach of Wi-Fi, beyond the home, office, and coffee shop.

In the UK, the planned switchover from analogue to digital TV provided a major opportunity to secure more efficient use of the spectrum that was to be retained for broadcasting.

Nature of TV White Spaces in the UK

Essentially white spaces are unused spectrum, but their exact capacity and location are, at least partly, a matter of definition. The national regulator has ultimate control of this, determining the areas where services do not need to be protected (even if they happen to be receivable – e.g., with high-gain antennas).

Development of the UK TVWS Rules

Ofcom has generally welcomed innovation and has sought to enable spectrum access to facilitate it. This was one of the key motivations for digital TV switchover, which started in 2005. The main objective at the time was to clear 112 MHz of UHF spectrum which could then be offered for new applications (mobile broadband being the most likely, especially given the bidding resources of the major UK mobile operators).

Television Broadcasting in the UK

Television (TV) broadcasting started back in the late 1920s, building on the early success of radio broadcasting. The British Broadcasting Corporation (BBC) was set up by the radio manufacturers to stimulate demand for new receivers, by providing suitably attractive content. Early experiments with TV began in 1928 using a system devised by John Logie Baird, transmitted in the VHF band. This rudimentary service progressed to a 405-line (vertical dimension) monochrome picture service, in 1936. At this stage, there was a single BBC TV channel to be broadcast, with relatively few transmitter stations, operating in a high-power, high-tower, transmitter network.

Over the following decades, TV's popularity grew, as receivers became more affordable. There were also steady improvements in the production and distribution technology. In the 1960s broadcasters wanted to increase the picture resolution and introduce a color service. The VHF bands lacked capacity, so some UHF bands (IV and V) were cleared of defense applications and made available for terrestrial TV broadcasting. The allocated frequency range was 470–860 MHz, providing 48 possible broadcast channels (each 8 MHz wide) – each could carry a single analogue TV signal – comprising picture and sound components. However, at that stage only three channels were needed at any given transmitter site – for BBC1, BBC2, and ITV.

National/Regional Coverage Approach Has Created more Openings for TVWS

Due to the national and regional nature of public service broadcasting in the UK and other parts of Europe and the limited scope of UHF transmissions, it was necessary to construct networks with multiple transmitters (in rural and suburban locations) – to ensure contiguous coverage. This contrasts with the pattern in the USA and other countries where private broadcasters drive the show and city-based broadcasting is the norm.

- National/regional coverage in the UK is provided by a network of main transmitter stations and linked (lower-power) relay stations. In the UK, there are 50 main stations and around 1100 relay (lower-power) stations. The top 80 stations (50 main + 30 relays) cover around 95% of the population (around half of the land area), and the remaining 1070 or so, added over a number of decades, provide coverage for an additional 3% to 4% of the population
- Currently each transmitter can (in the latest digital television configuration) carry up to nine multiplexes (groups of TV channels) – each multiplex requiring its own frequency. Frequencies used by adjacent transmitters need to be avoided, so that terrestrial networks resemble a "patchwork quilt" of frequencies where frequencies can only be reused at a certain transmitter spacing. The large capacity available in the broadcast band is traded off against nation- or region-wide coverage
- Television white spaces (TVWS) are the unused frequencies in each coverage area. In remote rural areas, they can approach 100% of the frequencies in the broadcast band range.

Future DTT Planning Evolution Squeezes White Spaces

Across the world, regulators continue their search for harmonizable spectrum bands which can be released to enhance mobile broadband capacity (and coverage in some

cases). This has included significant rollback of spectrum allocated for broadcasting in the UHF bands.

More efficient modulation schemes together with the increasing use of single-frequency network configurations will allow broadcasters to pack more TV channels in and/or move more services to higher definition. In principle, this means that white spaces capacity would reduce, over time. However, broadcasting regulations and business models will ultimately determine how much of the effective capacity is actually taken up by broadcast services.

Single-Frequency Networks

UK broadcast network planners achieved wide national regional/coverage through the reuse of frequencies in a "patchwork quilt" (multifrequency) pattern – so that adjacent transmitters do not disrupt each other's coverage. However, the digital terrestrial technology can be configured to allow adjacent transmitters on the same frequency – provided that key parameters (such as the distance between them) stay within certain ranges. This mode of operation is referred to as "single-frequency" network, since only one frequency is used for a given TV station, across an entire region. This works well when the content to be delivered across the region is the same, but it doesn't support local inserts, e.g., for advertising. Content boundaries therefore define the limits to single-frequency network size and the spectrum usage efficiency that can be gained.

White Space Pioneers: Program Making and Special Events

Broadcasting was not the only user of the broadcast bands. With many channels remaining unused in any given location, broadcasters and event/performance producers found that this spectrum provided a convenient way to accommodate short-distance wireless links – especially from microphones. Each microphone channel can take around 200 kHz, and with many tens of microphones in use during performances at some of the major shows in London, for example, this use can be quite intensive – albeit within a limited geographic scope.

A Cooperative Approach Toward Establishing TVWS Regulations

The UK terrestrial TV market has been largely cooperative – necessitated by the separation between (often publicly funded) broadcasters and private-sector receiver manufacturers. The BBC was originally founded by radio manufacturers, who were trying to create a market for the new devices. The separation between content providers and receiver manufacturers has enabled choice and value for consumers, in receiving systems. However, it has been necessary for the two sides to cooperate so that technology advances can be introduced smoothly. This contrasts with the

UK Pay TV industry – which was confined to cable and satellite platforms until 1998, when digital terrestrial TV was launched. In the Pay TV market, proprietary delivery solutions have favored integrated service provider and device provision.

The spirit of cooperation in the UK TV industry remains strong and is needed more than ever as distribution technology keeps advancing rapidly and choice offered to viewers multiplies. The growth of mobile broadband has led to more intensive sharing of spectrum, which has also required coordination between regulators, broadcasters, and TV device manufacturers, to ensure that disruption to television services is minimized.

Ofcom Working Group

To support a decision announced at the end of 2007, Ofcom formed a working group to look at the regulatory options for enabling access to the TV white spaces. The group was chaired by the then Head of Technology Research at Ofcom – Professor William Webb. It comprised members of industry as well as the regulator. Existing UHF users, including the broadcasters and PMSE industry, were well represented – together with a representative from Microsoft and occasionally from others advocating license-exempt access to the TV white spaces.

The working group's output fed into Ofcom consultations and statements.

After looking at the spectrum sensing and beacon models for facilitating spectrum access, it became clear that the combination of device geolocation and spectrum databases (dubbed geolocation database for short) was the only option which was both sufficient to meet the concerns of incumbents and practical to implement.

Ofcom consulted on this conclusion in November 2010 and then developed more detailed proposals, which were published in September 2011 [6].

TV White Spaces Advantages for Applications

TVWS technology was seen as a powerful tool for filling rural broadband gaps, due to the improved coverage that lower frequencies bring. The relatively broad channels into which UHF (and therefore TVWS) is partitioned (8 MHz wide in ITU Region 1) are well suited to broadband applications – including high-quality video and audio streaming, as well as aggregating narrowband network traffic. The flexibility afforded by dynamic spectrum access also seemed to lend itself to the as yet little known requirements of the emerging "Internet of Things."

First UK TV White Spaces Trials: Cambridge and Isle of Bute

UK industry interest in applying TV white spaces grew with development of the enabling regulations. This, together with the availability of prototype TVWS

equipment, led to trials of the new technology. The trials, in turn, encouraged Ofcom to invest in detailing and finalizing its TVWS regulations.
Two sites emerged for the earliest TV white spaces trials in the UK:

- On the Isle of Bute, in Scotland,
- In and around the City of Cambridge
- Both venues offered the chance to illustrate the coverage potential of TV white spaces, though the Scottish Island was the more representative of the remote rural coverage challenges and a closer approximation to a consumer broadband service.

Wireless connectivity can support a very wide range of applications, with diverse spectrum access needs. Some applications, such as video streaming, require wide-band continuous access. Others are more modest in their capacity requirements and may function quite effectively with even intermittent access to spectrum.

The Isle of Bute Trial

The Isle of Bute is located in the Firth of Clyde, in South West Scotland. It provided more evident terrain challenges than Cambridge – with hills and adjacent marine areas.

It also had a severe connectivity deficit, with many residents having had little or no broadband access.

The newly formed Centre for White Space Communications, at the University of Strathclyde, pulled together a consortium of key industry players (including the BBC and BT), supported by the UK Government's Technology Strategy Board to trial the application of TV white space technology, to the delivery of broadband to a number of residential properties in the south end of Bute.

The details of the deployment, operation, and results of the trial are reported in [2].

The Cambridge Trial

Cambridge is a well-established technology innovation hub, with the research centers of many leading technology companies located there, next to the renowned university. Microsoft's Research Centre, was the focus hub for the organization of the trial. Cambridge proved to be an excellent location to hold a TV white spaces trial, given the skills and resources available to deploy and maintain the emerging technology.

At the time the trial was staged, it was the largest TV white spaces trial, and its results [3] were influential beyond its target UK and European markets. By the time the trial concluded, the following organizations were involved: Adaptrum, Alcatel Lucent, Arqiva, BAE Systems, BBC, BT, Cambridge Consultants, Cambridge

Silicon Radio, CRFS, Digital Television Group, Jaguar Land Rover, Microsoft, Neul, Nokia, Samsung, Sky, Spectrum Bridge, TTP, and Virgin Media.

Preparations

A consortium was created to assist Ofcom in its regulatory work on TVWS and enable industry members to better understand TVWS' potential impact on their businesses. The members included a broadcaster, a broadcaster network operator, and technology vendors (including manufacturers of operator equipment and mobile devices).

A number of sites around the city were evaluated; for ease of installation and potential network coverage, Ofcom provided a test license to cover all of the likely sites for TV white spaces access points. To ensure compliance with the test license, Arqiva, the UK broadcast network operator, conducted a thorough survey – pre- and post-commissioning of each site. This was to check, for example, the proximity of DTT reception antennas and thus avoid the risk of disrupting neighbors' TV reception.

Hardware for deployment was sourced from a locally based start-up, called Neul, which had identified the TV white spaces as a key enabler for the emerging Internet of Things. Neul had designed its own radios from scratch, and it provided the radios for installation at sites around Cambridge as well as technical support to the trial operations. Silicon valley-based TVWS pioneer Adaptrum made available its prototype radio hardware to assist with the demonstration and measurements of TVWS coverage and link performance.

Cambridge Trial Applications

A prime application was rural broadband – given the poor broadband availability/performance experienced by many living and working in areas outside the main conurbations.

Other applications could be grouped under:

- Local area communications and content distribution
- Internet of Things applications – where devices, sensors, etc. can use wireless connections to form intelligent systems

Rural Broadband

As discussed earlier, lack of connectivity is a significant problem for many rural and some urban residents and businesses. This applied to villages around Cambridge as well as remote rural communities in Scotland.

TV white spaces technology, at the time of the trials (2011), offered connections with around 10 megabits/second (Mbps), using a single UHF channel (8 MHz wide). This was considered a reasonable broadband performance at the time and a great step-up from what many rural dwellers could access – even today (2018). The use of UHF spectrum enabled longer link lengths (for a given transmission power and receiver sensitivity) and less impairment due to intervening trees and hills than is experienced with fixed wireless access technology – using higher frequency

bands (2.4 and 5 GHz). The white spaces link provided backhaul to a Wi-Fi access point in single residential property. Conventional Wi-Fi then enabled end users to benefit from the broadband connection using existing devices – laptops, tablets, and smartphones.

Local Content Distribution

The combination of range and potentially high capacity offered by TV white spaces enables a convenient mechanism for local content distribution. A single access point could be used to drive display boards across a community. For example, such a board it might be used to provide news, information, and entertainment content.

Location-Based Content

The propagation range of TVWS can be used effectively to deliver content to individual users within a local area (such as a campus or retail center).

TV white spaces technology was coupled with a mobile device and exhibits at the Duxford Air Museum (part of the Imperial War Museum). As the mobile device user approached an "active" exhibit, interesting content relating to that exhibit could be presented to the user. For example, text summaries, photographs, and video clips are all helpful for understanding of the importance of a particular exhibit and give the visitor a sense of what it might have been like in operation.

Pop-Up Wi-Fi Hotspots

Cambridge offers a number of green open spaces amid its historic and more recent buildings. The open spaces are valued for leisure in general and also host major public events – such as summer festivals.

Users would benefit from connectivity, but the limited range of traditional Wi-Fi hotspots means that open spaces are largely out of reach.

Links from TVWS base stations around the city could be used to create temporary Wi-Fi hotspots – using a portable equipment set (e.g., carried in a backpack), consisting of a battery power supply and TVWS client connected to a Wi-Fi access point. At an event, this configuration could be hosted in a refreshments tent, ice cream stall, etc.

Internet of Things: Waste Management

With an increasing use of cloud-based services to manage a widening array of aspects of modern life, it is important to enable wireless cloud access from devices of all kinds.

Local authorities face a range of challenges to delivery high-quality public services with increasingly constrained budgets.

One such service is waste collection – which involves trucks circulating around the city streets through the week, to empty household and business bins. This provides a consistent service, but not all bins need emptying when the truck calls.

With a small amount of embedded hardware, it is possible to determine how full a bin is. The challenge was to read the level remotely, to determine which bins really need to be emptied and how the truck route could therefore be optimized.

In the trial, a link from an intelligent bin to the cloud via white spaces was demonstrated, allowing immediate indication of its current loading. The use of TV white spaces would enable relatively few access points to provide sufficient coverage across the city. Given the low data rate needed by this application – the 8 MHz TV white spaces channel could be used with a robust modulation to allow even greater coverage to be achieved from a base station.

Trial Measurements: Proving the Rules

Trials/pilots played a key role in building industry confidence in the application of the TV white spaces and shaping the regulatory approach to managing coexistence with licensed services sharing the band. The Cambridge white spaces trial was the largest of its time 2011/2012 and was a watershed moment in UK TVWS developments – with influence far beyond the UK.

Measurements made during the trial included:

- The data link capacity of wireless links into rural village locations
- Coverage and capacity achieved around TV white spaces access points – external and within buildings
- Spectrum usage around the city

The results of the measurements are summarized in the Cambridge TVWS Trial Technical Findings report [4]. They were fed into the Ofcom working group on the TV white space regulations and into the European regional spectrum regulatory working group CEPT SE43, where they helped in establishing recommendations for coexistence between TVWS applications and existing spectrum users.

Ofcom's UK TVWS Pilot

Following the Cambridge and Bute trials, Ofcom decided to complete the required regulations to enable access to the TV white spaces. It made use of an open working group – with participants from companies across the world – to help it develop the required approach to coexistence with established services.

Ofcom piloted the draft regulations before finalizing the details. This evaluation ran over the period 2013 to 2014.

Applications were invited from across the UK, and a number of groups applied for a TVWS pilot license. Among these were:

- a cooperation between Google and London Zoo to create a video link from animal cages, to allow remote viewing
- a project to extend Internet connectivity to the ferries that travel between the islands in Orkney.
- a flood monitoring network, around Oxford

The Centre for White Space Communications (CWSC), at the University of Strathclyde, ran a pilot in Glasgow, with support from the Scottish Government, Microsoft, Sky, 6Harmonics, and MediaTek. The project was aimed at assisting Ofcom in its efforts to progress toward finalizing the regulations and assisting the industry to evaluate potential benefits and opportunities associated with enabling access to the TV white spaces (UHF spectrum).

UK TVWS Pilot: Glasgow Tri-band Wi-Fi

The application chosen by CWSC was wireless home networking, in which "standard" Wi-Fi in the 2.4 GHz ISM band and the 5 GHz UNII bands was augmented with the use of spectrum in the UHF band (suing TVWS technology). Earlier results from Ofcom research had indicated that UHF frequencies would provide coverage benefits within buildings, complementing what the established Wi-Fi bands could deliver [5].

The IEEE had recently ratified the IEEE 802.11af standard, which added TVWS features to the IEEE 802.11 family of specifications, opening the possibility of mass market adoption. This was significant for Internet service providers (ISP), which could potentially benefit from the improved range and bandwidth that might be expected from using TVWS. With ISP requirements in mind, CWSC investigated the performance of IEEE 802.11af in a number of homes around Glasgow and carried out a comparison of IEEE 802.11af (TVWS), with Wi-Fi at 2.4 GHz and Wi-Fi at 5 GHz. CWSC worked with MediaTek and 6Harmonics, who agreed to provide access to their prototype IEEE 802.11af radios, along with engineering support. It also worked with broadcaster and communications service provider, Sky, which offered practical assistance with test locations.

The test results indicated that the IEEE 802.11af radios had the potential to significantly increase Wi-Fi coverage over that of IEEE 802.11n systems (using the 2.4 and 5 GHz bands). Quantifying the amount by which coverage might be improved was difficult, but it was particularly noticeable from the results of tests described in *the final report* [5] that IEEE 802.11af was able to provide coverage throughout the older homes of sandstone and brick construction (and outside), while an IEEE 802.11n network operating at 5 GHz struggled to penetrate beyond the room in which the access point was located.

Finalizing the Regulation

The pilot projects yielded a considerable wealth of data, enabling Ofcom to adjust the draft regulations. In general, its adjustments were toward greater caution – protecting existing users more and hence reducing the TV white space capacity available.

The regulatory framework was divided into two parts:

- The statutory instrument – which license-exempted TV white space access devices meeting suitable technical requirements. The requirements are laid down in ETSI 301 598
- Geolocation databases – validated by Ofcom, holding information on which channels are available in each possible location. Around eight companies applied for validation and there are now two providers in operation: Nominet and FairSpectrum.

The statutory instrument was in place by the start of 2016, and the first databases had already been validated by that point.

Into Commercial Service

With the TVWS regulations in place, it became possible to start commercial network deployments. A UK company called Broadway Partners recognized the opportunity to use the new technology to fill gaps in rural broadband provision, around a new model in community service provision. Broadway identified an initial opportunity to apply the technology on the Isle of Arran, in Scotland, and worked with the local community to define the requirements. It enlisted the help of a database partner and Microsoft to deploy the UK's commercial service using TV white space technology. Arran's rugged and rolling topography provides a representative challenge to network provision and much has been learned about how best to use TVWS to illuminate the least reachable locations.

Arran Broadband continues its rollout around the island, reaching out to the unconnected (or under-connected). Meanwhile Broadway has gone on to tackle broadband challenges facing other remote communities in Scotland and Wales.
Other companies applying TV white space technology, that we know of, are:

- *Cloudnet* in Orkney, which has been providing Internet connectivity on the inter-island ferries and support adjacent rural applications
- New entrant *Whitespace UK*, which has been rolling out rural broadband networks in Dumfries and Galloway, as well as the beautiful, but remote highland village called Balquhidder.

Abstract

As more user applications emerge for wireless devices, the corresponding amount of traffic is rapidly expanding, with the corollary that ever-greater spectrum capacity is required. Service providers are experiencing deployment blockages due to insufficient bandwidth being available to accommodate such devices. *TV White Space* (TVWS) represents an opportunity to supplement existing licensed spectrum by exploiting unlicensed resources. TVWS spectrum has materialized from the unused TV channels in the switchover from analogue to digital platforms. The main obstacles to TVWS adoption are reliable detection of *primary users* (PU) i.e., TV operators and consumers, allied with specifically, the *hidden node* problem. This chapter presents a new *generalized enhanced detection algorithm* (GEDA) that exploits the unique way *digital terrestrial TV* (DTT) channels are deployed in different geographical areas. GEDA effectively transforms an energy detector into a feature sensor to achieve significant improvements in detection probability of a DTT PU. Furthermore, by framing a novel margin strategy utilizing a *keep-out contour*, the hidden node issue is resolved and a viable secondary user sensing solution formulated. Experimental results for a cognitive radio TVWS model have formalized both the bandwidth and throughput gains secured by TVWS users with this new paradigm.

Introduction

Mobile communications have become integral to our daily lives with the mobile phone now having developed into a smart device that is able to interact with its user. Commensurately, mobile data traffic has grown exponentially due to a vast array of services and applications for smartphones including interactive gaming, video and music streaming, web browsing, and e-mail [1,2].

In many countries, terrestrial TV broadcast networks are changing from analogue to digital delivery platforms, a process already completed in North America, the UK, and Europe [3,4]. This switchover process has continued apace because during migration, maintenance updates were necessary to channel allocations, with the most recent, respectively, being in 2016 and 2015 for the UK [5] and USA [6]. The switchover released valuable spectrum in the UHF band which was subsequently split into two categories. The first, known as the *digital dividend*, denoted spectrum no longer used by terrestrial TV broadcast networks. This was auctioned for mobile operators to develop application technologies like *Long-Term Evolution* (LTE) [3,4]. The second, known as *TV White Space* (TVWS) or interleaved spectrum, relates to unused spectrum within given geographical locations that avoids adjacent and co-channel interference with *digital terrestrial TV* (DTT) transmitters. Since the *digital*

dividend spectrum has already been sold off, TVWS has come to be the primary spectrum for *cognitive radio network* (CRN) services and applications.

With 5G mobile technology evolving, there are two nascent views for how it will be successfully realized: (i) a focus on greater coverage [7–9] and (ii) increasing throughput and lower latency [7–9]. The emergence of CRN technology [2, 10, 11] and TVWS provides new access opportunities for unlicensed *secondary users* (SU), and since TVWS exists in the low UHF band, it offers greater coverage and increased throughput so satisfying a major 5G requirement. This chapter presents a framework for how TVWS can effectively fulfill the aforementioned 5G criteria allowing services to not only exploit the increased spectrum released by TVWS but also ensure long-term SU access benefits, especially as bandwidth scarcity is still a major 5G issue [5, 6].

Sensing Strategies

CRN offers an efficient and autonomous TVWS solution to facilitate SU access by sensing the RF environment within licensed *primary user* (PU) spectrum [12, 13]. Since TVWS is static spectrum, channels do not change in a particular location, so relaxing the need for efficient PU updates as channels varies only on a spatial and not temporal basis [12, 14]. To access unused TVWS, *spectral holes* [10, 11] must be identified using *dynamic spectrum access* (DSA) techniques [10, 14) which enable the CRN to learn about its neighboring RF environment and make access decisions accordingly. DSA techniques for TVWS are generally classified into three categories: beacons, sensing, and static databases [12, 13].

Beacons are dedicated in-band signals that advertise for SU access in the licensed spectrum, though since the PU must administer this process, it is not practical for DTT broadcasters due to the prohibitive overheads incurred.

Sensing techniques in contrast automatically update a PU static database to reduce operational costs, though the ubiquitous *hidden node* problem [4] must be overcome for them to be viable.

Static databases require manual upkeep, but as interference margins for PU protection are theoretically calculated rather than based on actual measurements, system accuracy can be compromised. This approach offers greater flexibility in embracing scenarios where sensing is not feasible, such as *program making and special event* (PMSE) radio microphones.

The principal requirement for TVWS access is reliable PU detection to avoid interference to local DTT users. Both Ofcom and FCC favor the geo-location database approach [12], though this entails expense to implement and maintain the database infrastructure. It is for these reasons that alternative sensing mechanisms are considered in this chapter. Another key sensing issue to resolve is the *hidden node* problem [11, 15, 16], where a SU sensing receiver is obstructed from a

PU transmitter, so a spectral hole is falsely detected, potentially causing major PU disruption. This is especially critical at the cell edge where signal strength is generally low.

While assorted cooperative sensing solutions exist [17] to overcome hidden nodes, the novel GEDA solution presented in this chapter does not rely on either cooperative mechanisms or compromises SU bandwidth availability. It exploits the unique deployment pattern of DTT frequencies to determine if a PU channel is occupied, applying an energy detector for local real-time measurements in the decision-making, so effectively turning it into a feature detector. We will now investigate in greater depth the rich opportunity TVWS spectrum affords for providing extra bandwidth for SU access.

TV White Space (TVWS)

The DTT switchover from analogue TV reduced the number of TV channels, with some being released for auction, while the remainder were allocated as DTT channels. Unused DTT channels in a particular geographic area are TVWS (interleaved spectrum) and in the most recent standards [5, 6] are assigned to CRN applications. The UK 8 MHz DTT channels are shown in Fig. 1, with TVWS channels being the unused (interleaved) spectrum in any location. The purple channels are DTT, green channels have been auctioned, and the pink channel is for PMSE applications.

In [3], it was noted that in the UK, 50% of locations can release 150 MHz of spectrum and from 90% of locations, 100 MHz of TVWS. The key issue distilled from this analysis is that for a CRN to utilize TVWS, it must be able to allocate non-contiguous channels to all its SU. Figure 2 shows the non-contiguous nature

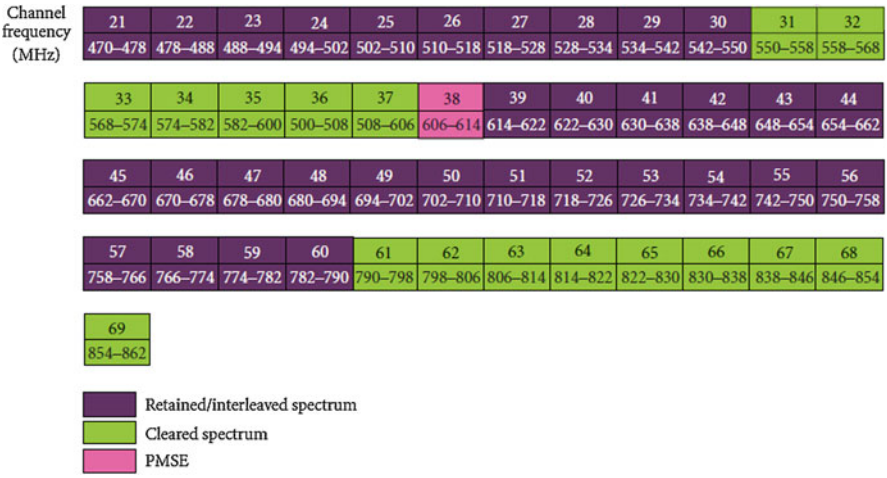

Fig. 1 Channel allocation after DTT conversion in the UK [5]

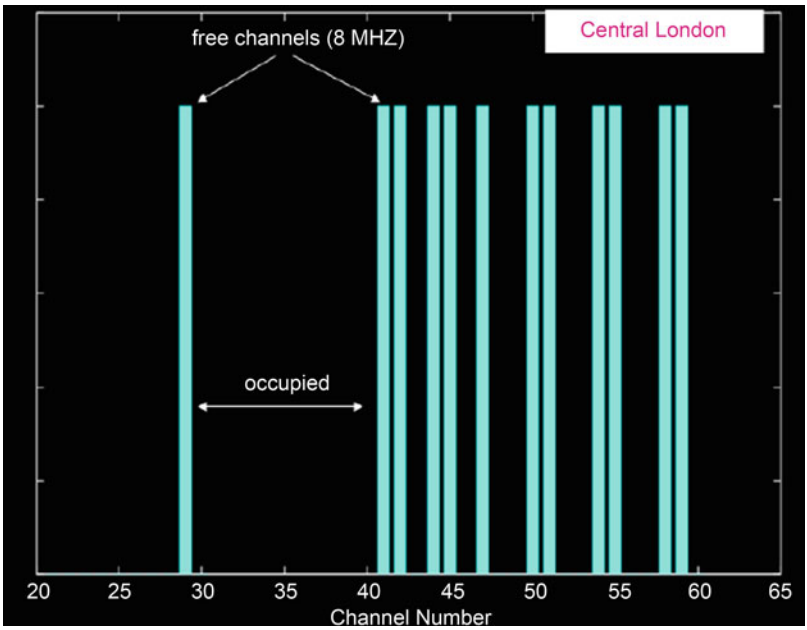

Fig. 2 Contiguous TVWS Channels in Central London [3]

of channels allocated in London, where each cyan bar represents a free 8 MHz channel. It is evident the maximum contiguous channel capacity is 16 MHz, i.e., two adjacent cyan bars, so to achieve greater capacity, non-contiguous techniques such as assembly and disassembly of non-contiguous OFDM channels must be employed.

Figure 3 provides some examples of contiguous channel capacities for other UK locations.

As evidenced in [18], the minimum number of TVWS channels available in the UK for a SU using a 10 m antenna and transmitting at 15 dBm yielded an extra 80 MHz of bandwidth for 90% of households and 184 MHz for 50% of households, so confirming there are significant gains to be leveraged on available SU bandwidth within the TVWS band. The next section briefly reviews the regulatory steps to enable this unlicensed bandwidth to be exploited. It is interesting to note both Ofcom and FCC [18, 19] have opened a TVWS band for industry proposals, while recently the use of TVWS for autonomous vehicles has been proposed [20].

Regulatory Standards

The adopted Ofcom and FCC standards permit CRN broadband devices to operate in TVWS [12,13,21,22]; with the main TVWS engagement parameters specified by both regulators alongside the corresponding IEEE 802.22 standard [13, 15], values

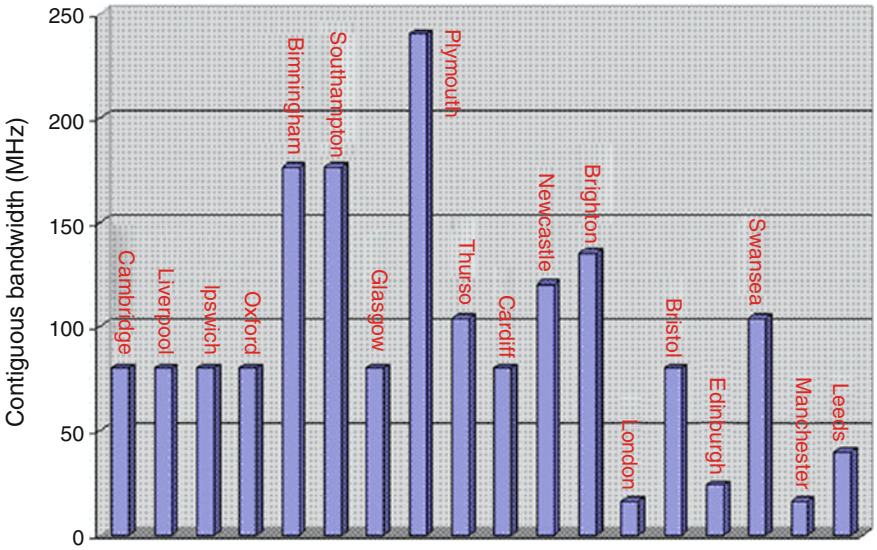

Fig. 3 Maximum Contiguous capacity values for UK [3]

Table 1 Regulatory TVWS engagement parameters [13, 15]

Rule	Parameter	OFCOM	FCC	IEEE802.22
1	DTT sensing threshold	−120 dBm	−114 dBm	−114 dBm
2	Wireless microphone threshold	−126 dBm	−114 dBm	−114 dBm
3	SU transmit power fixed network node 1st adjacent Ch - $P_{BS(N+1)}$	4 dBm	16 dBm	–
4	SU transmit power fixed network node 2nd adjacent Ch - $P_{BS(N+2)}$	17 dBm	30 dBm	36 dBm
5	SU transmit power mobile network node 1st adjacent Ch - $P_{M(N+1)}$	4 dBm	16 dBm	–
6	SU transmit power mobile network node 2nd adjacent Ch - $P_{M(N+2)}$	17 dBm	20 dBm	–
7	Out-of-Band powers	<−46 dBm	−55 dBc	–
8	DTT bandwidth	8 MHz	6 MHz	6 MHz
9	Probability of detection P_d	1	1	0.9
10	Probability of false detection P_f	–	–	0.1

are defined in Table 1. These include the respective probabilities of PU detection (P_d) and false detection (P_f), the DTT sensing noise floor, SU transmit RF power for a *base station* (BS) node in the presence of PU adjacent channels, and SU transmit RF power for a mobile node in the presence of PU adjacent channel.

The Ofcom and FCC settings in Table 1 are committed to PU protection in their respective countries. Conversely, IEEE802.22 is a SU-focused standard, with the

specified parameters being the maximum allowable transmit-power requirements, while corresponding PU protection is the responsibility of the respective country regulators. While sensing has been considered by the regulators, Ofcom currently has only proposed a geo-location database solution for industry consultation, while FCC is focusing on the database solution, with any sensing proposal having to undergo stringent certification with reduced radiating power [23].

The IEEE802.11af wireless networking standard [23], which is also known as White Space Wi-Fi (White-Fi) and Super Wi-Fi, permits WLAN operation in TVWS in both the VHF and UHF bands between 54 and 790 MHz. CRN technology can transmit on unused DTT channels, with crucially this particular standard stipulating PU interference bounds.

Enabling Technologies for Spectral Sensing

Historically the *Open Systems Interconnection* (OSI) communication stack has been used to communicate information between layers; however, for CRN applications this is limited by both parameter availability and acquisition time scales. Once the parameters have been acquired, some analysis is required to interpret an unpredictable RF environment. In the regulatory parameter settings in Table 1, the RF transmit power can vary between a fixed SU BS and a mobile SU user. Furthermore, the mobile SU uses minimum RF power in order to minimize the local noise temperature outside the coverage area of the SU BS which can occur if the mobile SU is at the edge of the BS coverage area. To achieve the coverage area of a fixed SU BS, the mobile SU uplink must employ ad hoc routing [24, 25]. The following sections detail some of the supporting technologies for CRN access of TVWS.

Cross-Layer Processing

Cross-layer processing (CLP) design strategies attempt to optimize key parameters by using information from other OSI layers, allied with information not readily available within the OSI communication stack. Unlike normal OSI stack information exchange, CLP is not constrained to information that is of necessity, contained within adjacent layers. This enables faster information retrieval because the information does not have to be transferred through several layers before reaching the requisite layer. Furthermore, not all information required within a layer to perform its function is passed to other layers, so CLP permits information to be utilized by any OSI layer.

The benefits of CLP are that it reduces the overhead within the protocol stack, lowering the time to acquire information and configure parameters. In [10], it was shown that if CR routing in the network layer uses information from the spectrum management block, then enhanced routing performance can be achieved.

There are two drawbacks of CLP. Firstly, proprietary information models must be implemented across the cross-layer block which will vary between implementations. Standards can be formulated between all stakeholders to frame a rigid information model for interoperability; however, this requires considerable time overhead to establish such a standard. The second limitation is that a higher computational cost is incurred in implementing a CLP block with an associated increase in power resources.

To date, this has not been an issue in CRN research [10,11], because the focus has largely been on the physical layer. Now, however, the emphasis has shifted toward optimizing resources to improve the *quality-of-service* (QoS) provision for the SU, so the CRN needs to simultaneously influence parameters in the significant OSI layers. Examples include optimizing the RF power for routing to spectrum access decisions which are tailored to the application layer (Layer 7) requirements, which directly relate to the QoS user experience.

This chapter also introduces a novel cross-layer mechanism called the *cross-layer cognitive engine* (CLCE) which shares information between the *medium access control* (MAC) and physical layers, so sensing measurements can readily influence spectrum access decisions. Some of the challenges in successfully implementing the CLCE [2, 15, 26] include:

- **Modularity** – The OSI layers are designed to be modular so they operate independently of each other. CLP design can compromise this property, so avoiding technology-specific parameters being passed to the CLCE by abstraction alleviates the need for a bespoke solution in different cross-layer blocks.
  - **Information interpretability** – Choosing a knowledge representation base which is able to accommodate different implementations of the layer modules is vital.
  - **Imprecision and uncertainty –** Since parameters to be exported can contain measurement inaccuracies, cross-layer blocks must be able to manage imprecision which makes incorporating a fuzzy capability an attractive option**.**
  - **Complexity and scalability –** CRN must operate with different wireless configurations to be able to be scalable, so to optimize the wireless link to user requirements, the cross-layer block can become complex because of the number of possible parameters to be exported.

A number of cross-layer block implementations currently exist, with the most prominent being considered below [26–29]:

- **Radio Knowledge Representation Language** [28, 29] – Each micro-world represents a specific wireless technology which implies the CLCE needs explicit knowledge about these technologies. This is contrary to the aforementioned modularity and scalability features.

- **Artificial intelligence (AI)** [2, 27, 30] – Solutions such as neural networks and genetic algorithms are well suited to handling large datasets, but they concomitantly require long training periods to be effective which is not practical in most wireless applications.
- **Fuzzy logic controllers** [2, 26, 27] – These are modular, so technology-specific information is retained in the layers with more generic information used in the cross-layer block. Improved information interpretability is achieved using linguistic attributes for each defined membership function. Precision and accuracy issues are avoided by using an imprecise knowledge representation base. The complexity of the cross-layer block is also lower than other proposals.

Ad Hoc Routing

Section "Regulatory Standards" stressed that regulatory requirements mean the RF transmit power of both fixed and mobile SU nodes can vary up to the maximum values in Table 1, and because of the fixed node antenna height being higher than the mobile node, greater coverage is achieved. To compensate for this asymmetrical coverage in the down and uplink directions, ad hoc routing can be innovatively applied in the uplink direction (mobile to fixed node) to achieve the same coverage in both directions.

To enable frequency reuse and thus increase spectral efficiency, low RF power needs to be used, though a corollary of this is that ad hoc routing must be employed to ensure CR messages reach their destination via other CR nodes. To minimize latency in time-sensitive applications, consideration must be paid to how the message is routed through the CRN to their destination [2, 15].

Routing protocols for *mobile ad hoc networks* (MANET) [2, 15, 24, 25] are well established, though CRN introduce some new challenges which need to be solved. These include:

i. Link availability – In the example in Fig. 4, there is a short spectral hole for the CRN to exploit; however, unlike in a MANET, the availability window is measured in milliseconds rather than seconds, except in the case of TVWS.
ii. Unidirectional links – Typical wireless networks use bi-directional links though this is questionable for CRN for the above reason. Also, in TVWS scenarios, due to the regulatory SU unidirectional power allocation, pragmatically there is only the prospect of unidirectional links which imposes a specific design constraint on the network layer.
iii. Heterogeneous wireless networks – Normal wireless networks are structured, while CRN have a more ad hoc, heterogeneous node structure. This means CRN require inter-system handover but with very short duration links routing relying on cooperative relaying. Such heterogeneous networks pose a security risk because the link duration is so small; there is insufficient time to authenticate any security certificate.

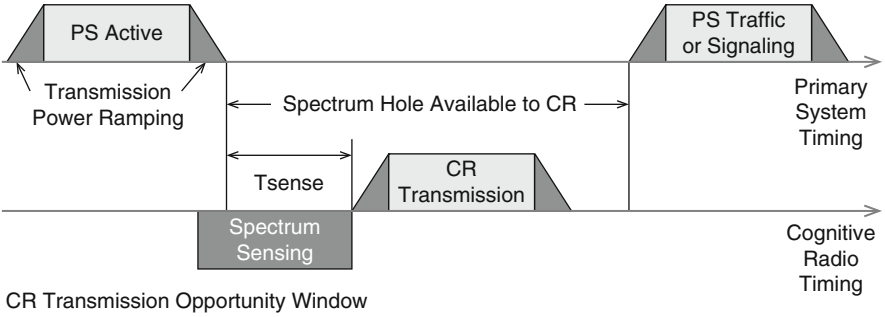

Fig. 4 CRN transmission opportunity window [15]

Reactive protocols devised for typical wireless networks can be adopted for CRN to overcome some of the above issues. The two most common routing protocols are *Dynamic Source Routing* (DSR) [24] and *Ad Hoc On Demand Distance Vector* (AODV) [25].

The DSR protocol is based on source routing whereby all the routing information is maintained by the mobile nodes. It is a simple and efficient routing protocol designed specifically for use in multi-hop links for mobile nodes. DSR allows the network to be completely self-organizing, without the need for any existing network administration. The protocol is composed of two main phases, namely, "Route Discovery" and "Route Maintenance," which work together to allow nodes to discover and maintain routes to destinations in the ad hoc network. All aspects of the protocol operate entirely on demand, allowing the routing packet overhead of DSR to scale automatically, since only after a route to the destination node has been identified does packet transmission occur.

In contrast, the AODV routing protocol is intended solely for use by mobile nodes in ad hoc networks. It offers quick adaptation to dynamic link conditions, low processing and memory overheads, and low network utilization and determines unicast routes to destinations within the network. AODV route table entries are dynamically set up at each intermediate node as the packet is transmitted toward the destination, reducing the traffic overhead.

Existing Sensing Techniques

The regulatory framework in Table 1 has formed the basis for a variety of spectrum sensing proposals including noncooperative feature sensing and cooperative sensing using a non-Gaussian noise covariance Rao test. This section critically analyses these sensing solutions within a regulatory context.

Noncooperative Feature Sensing

In [21, 22], an autocorrelation algorithm for spectrum sensing was developed based upon the correlation of the frame headers and synchronization blocks which are a form of matched filter feature detection. Spectrum sensing is explored in the context of the three main TV standards deployed in China, namely, Digital Terrestrial Multimedia Broadcast (DTMB), China Multimedia Mobile Broadcasting (CMMB), and Phase Alternating Line – D/K (PAL-D/PAL-K). For comparative purposes, only DTMB is considered in this discussion because it is the standard that most closely resembles the UK DVB-T standard in term of frame structure and transmission bandwidth. In [21], a simulation platform was constructed along with a prototype model with the detection results being displayed in Fig. 5.

Figure 5 shows both the simulation and laboratory prototypes at *false detection rates*, $P_f = 0.1$ and $P_f = 0.001$. The *detection rate* (P_d) for the prototype is generally 3–4 dB lower compared to the simulation results which is explained by the simulation not including analogue RF stage impairments like frequency offsets and amplifier nonlinearity. Interestingly, by comparing the detection and false detection probabilities for the IEEE 802.22 standard, $P_d = 0.9$, $P_f = 0.1$ at a signal strength of -114 dBm (Table 1), while the corresponding simulation results for $P_f = 0.1$ in Fig. 5 reveal only a $P_d = 0.7$ at -114 dBm, so this sensing solution fails to comply with the IEEE 802.22, Ofcom or FCC requirements defined in Table 1.

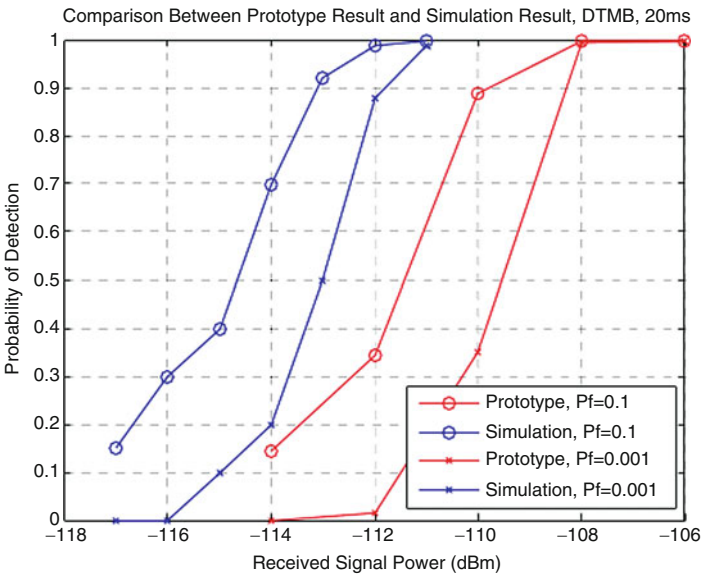

Fig. 5 Simulation and laboratory results for DTMB detection [21]

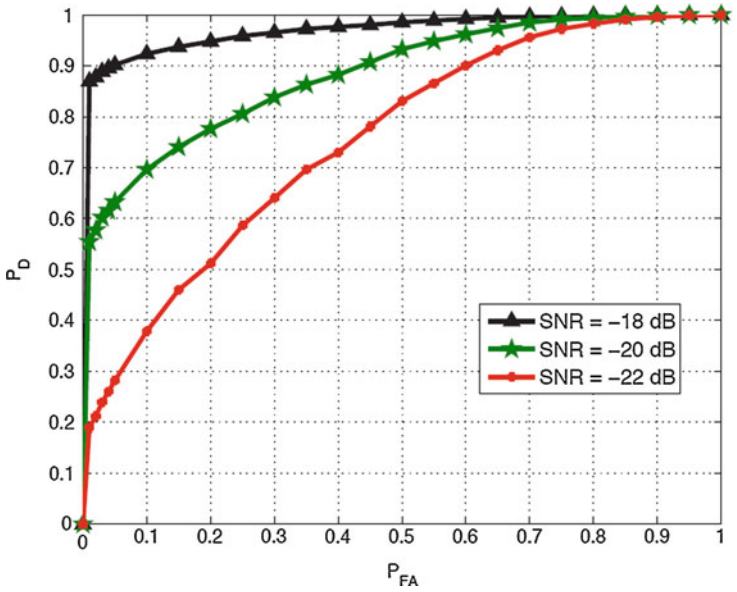

Fig. 6 Probability curves for ATSC DTT Signals at different levels of SNR [22]

The North American approach [22] examined the development of spectrum sensing algorithms for *Advanced Television Systems Committee* (ATSC), *National Television System Committee* (NTSC), and radio microphones. Sensing for both ATSC and NTSC involves a unified signature-based, spectrum sensing algorithm, which, in the case of the US DTT standard ATSC, is the autocorrelation of the SYNC segment of the frame.

ATSC results are plotted in Fig. 6, which shows detection probability (P_d) against the probability of false detection P_f at different SNR values.

If a noise floor of -100 dBm is assumed within a 6 MHz bandwidth, which is the TVWS bandwidth in the USA, then a SNR $= -18$dB is represented by a signal of -118 dBm which is below the sensing threshold of -114 dBm for both IEEE 802.22 and FCC (Table 1). From Fig. 6, at SNR $= -18$ dB, $P_d = 0.9$ and $P_f = 0.05$ which is the only SNR value which upholds IEEE 802.22, though it still does not comply with the FCC detection probability requirement in Table 1. The other SNR values (-20 and -22 dB) do not comply with IEEE 802.22 and FCC sensing thresholds.

Cooperative Sensing Using a Non-Gaussian Noise Covariance Test Rao [31]

Spectrum sensing for CRN in the presence of non-Gaussian noise is challenging due the CR having to have knowledge of both the PU and SU. To overcome

this limitation, the *generalized likelihood ratio test* (GLRT) can be applied which combines unknown parameter estimation with a likelihood ratio test. While GLRT is an optimal detector, it must compute a maximum likelihood estimation (MLE) for the received signal power of the desired signal, the noise variance, and the unwanted signal and so consequently incurs a large computational burden. The Rao test is an approximate form of the GLRT which only estimates system model parameters for unwanted signal conditions. This simplifies the Rao structure and [31] examined its use in the cooperative mode, which is a commonly used technique in spectrum sensing since it overcomes the harmful effects of fading and shadowing by taking advantage of spatial diversity. It thus offers a solution to PU sensing for non-Gaussian noise conditions. Cooperative spectrum sensing is a viable solution for a CR sub-network comprising one SU BS and multiple SU mobiles, which collectively detect the presence/absence of a PU within a given frequency band. Each SU employs a Rao detector to independently sense the PU signal in the presence of non-Gaussian noise, with local SU decisions then forwarded to the BS which makes a final access decision.

The cooperative spectrum sensing system in [31] is an IEEE 802.22-based solution that uses the Rao test to measure the non-Gaussian noise level to improve the energy detection performance and includes a multiuser extension where β defines the noise model used. Figure 7 shows the results for four SU sensors at differing β settings which represent various noise profiles ranging from Gaussian ($\beta = 2$) to Laplacian ($\beta = 1$). Also, the results evaluate four strategies for

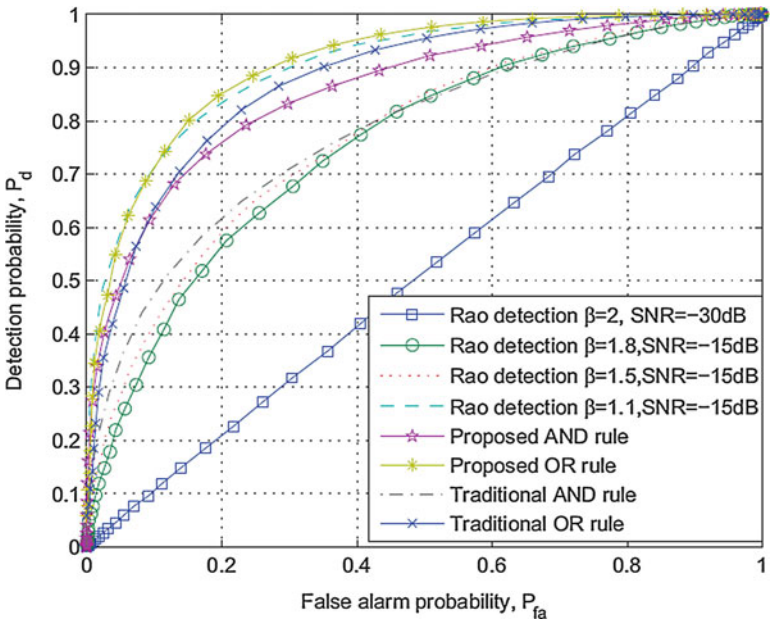

Fig. 7 Family of ROC curves of cooperative for different values of β [31]

cooperative sensing. The first is the traditional cooperative sensing technologies (OR, AND) where the proposed solution uses the cooperative technologies coupled with the Rao test measure.

In summary, the results for both noncooperative sensing in [21, 22] and cooperative sensing [31] corroborate that the requisite detection and false detection rates specified in Table 1 are not upheld. This provided the motivation to investigate new sensing strategies which are able to fulfil the strict sensing regulatory requirements of OFCOM and FCC, with one innovative solution being detailed in the following sections.

Enhanced Detection Algorithm (EDA)

This PU detection technique [17, 32, 33] was introduced to specifically facilitate access to TVWS channels by employing the *cross-layer cognitive engine* mechanism introduced in section "Cross-Layer Processing". This shares information between the MAC and physical layers, so energy sensing measurements can dynamically influence the DSA decisions [10, 17]. EDA exploits inherent patterns in the DTT frequency deployment to determine whether a PU occupies a particular DTT channel using a fuzzy logic model to make channel occupancy decisions. By scanning adjacent frequencies on either side of the channel under investigation, this effectively turns the energy detector into a feature detector, with a *scan range* parameter B determining the number of channels to be sequentially scanned. Hence, if *Ch_A* is the DTT channel under review, EDA symmetrically scans *Ch_A*$\pm$ 1, *Ch_A*$\pm$ 2...up to *Ch_A*$\pm$ B. Symmetrical scanning is used due to the equiprobability of a neighboring DTT channel being either below or above the channel of interest.

EDA affords a unique sensing option for DTT transmitters because regional DTT frequencies are deployed in clusters of 6 channels in the UK, and due to DTT domestic receiver antennae groupings [34], these 6 channels can only lie within a possible bandwidth of 16 DTT channels. The corollary is that by scanning B channels either side of the channel of interest, the majority of occupied DTT channels in a region are detected, with crucially, low false detection probabilities being achieved by maintaining a low B value. Selecting the best choice of B will be discussed shortly. EDA uses the sensed energy values in the scanned channels to resolve whether the DTT channel is occupied. This approach allied together with a geo-location database means EDA generates an accurate map of PU channel usage. The advantage of EDA, when coupled with a geo-location database, is that an accurate mapping of PU channel usage is obtained. PMSE devices can also be included in the database so reducing PU interference and increasing the available bandwidth for SU.

The next section introduces the design principles underpinning EDA.

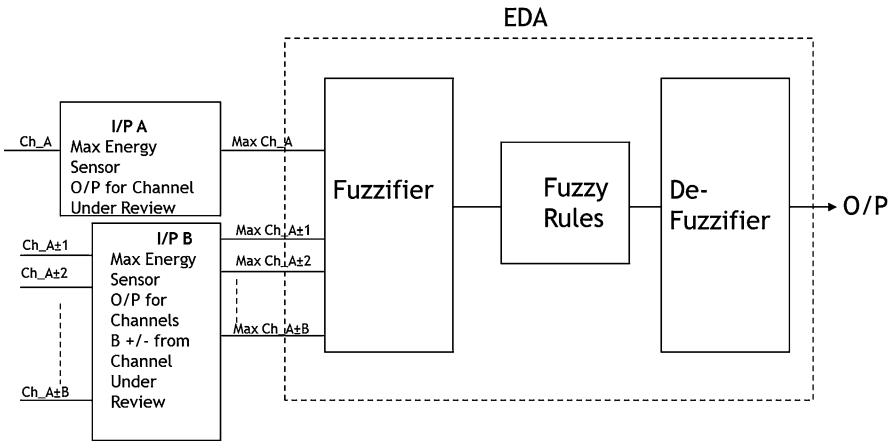

Fig. 8 EDA block diagram [17, 32, 34]

EDA Design

Figure 8 shows a block diagram of the EDA [17, 32, 33], with fuzzy logic inference model employing a classical fuzzy logic framework [26], so I/P (input) A is the sensor output for the channel under investigation, while I/P B is the maximum sensor output for 1 to B channels either up or down from the channel under investigation.

The role of the fuzzifier is to translate the input into a fuzzy set which is allocated a membership function. This follows a normal (Gaussian) probability function used for RF detection. The fuzzy rule block defines how EDA behaves under practical conditions, while the de-fuzzifier produces a final crisp output using the *centre of area* method [26].

B Parameter Selection

The choice of B is critical to EDA detection performance as it scans channels up and down from the channel under investigation to B, where B is the integer number of channels to be scanned. Three membership functions *Lo*, *Med*, and *Hi* are used to assess the occupancy status of a specific channel. If a particular channel lies within the *Med* probability range and another channel which is either within B up or down and also lies within either the *Med* or *Hi* probability detection ranges, then the outcome is weighted according to a set of fuzzy rules [34] which is defined above and a crisp occupied or unoccupied result is returned. This reflects the phenomena that DTT channels in a local area are generally deployed in a cluster configuration due to DTT antenna groupings [34] in which another DTT channel either B channels up or down can be located. EDA detection/false detection response against B for

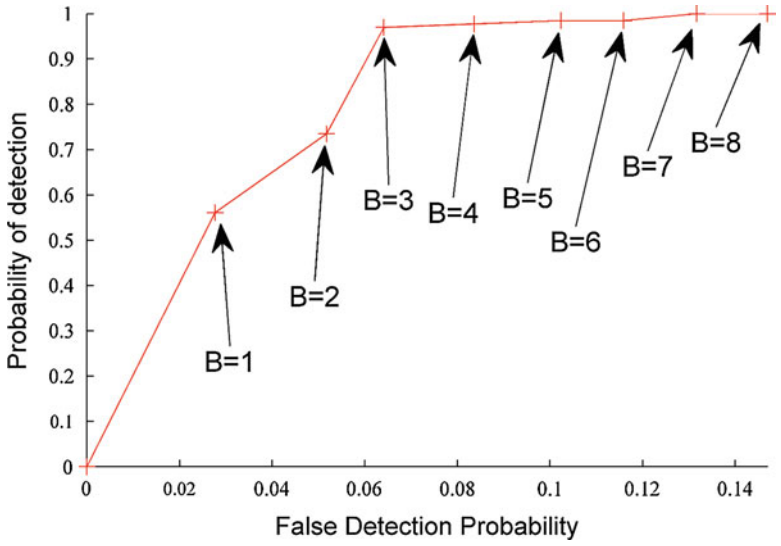

Fig. 9 B Response for the UK

signal strength of −120 dBm and averaged over 22 major DTT transmitter sites in the UK is shown in Fig. 9, with B dynamically determined. Note, B will always be bespoke to the country of the DTT channel deployment.

The corollary from Fig. 9 is that by scanning B channels either side of a channel of interest, the majority of occupied DTT channels in a region are detected with crucially, low false detection probabilities P_f achieved by maintaining a low B value. EDA then uses the sensed energy values in the scanned channels to determine whether the DTT channel is occupied.

EDA Performance

The detection performance of EDA is shown in Fig. 10 in comparison with [21]. This reveals EDA consistently out performs existing PU detection algorithm by up to 9 dB when applying the IEEE 802.22 standard detection thresholds of $P_d = 0.9$ and $P_f = 0.1$, though importantly both techniques fail the stringent Ofcom requirement of $P_d = 1.0$ at a signal strength of −120 dBm.

Despite its performance limitations, EDA demonstrated that a sensing strategy for TVWS applications was feasible, and consequently it became an integral constituent block in a novel adaptive-based sensing framework known as *Generalized EDA* (GEDA) [17], which achieves 100% PU detection under for all regulatory scenarios. GEDA will now be reviewed.

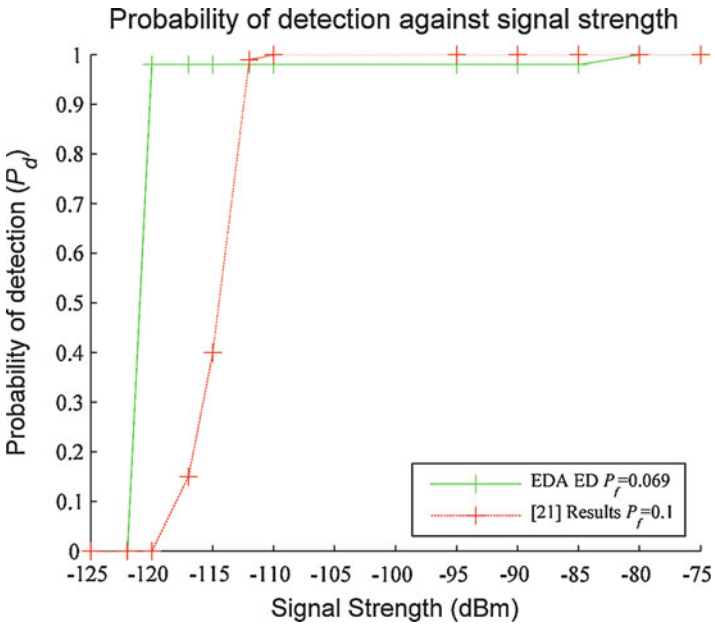

Fig. 10 Detection probabilities versus signal strength

Generalized EDA (GEDA)

Introduction

As highlighted in section "Enhanced Detection Algorithm (EDA)", while EDA upholds the $P_f = 0.1$ requirement of IEEE 802.22 [22], it failed to achieve $P_d = 1.0$ for the DTT sensing threshold in Table 1. This provided the motivation for the development of the GEDA paradigm, which reuses key EDA components, while crucially integrating a new adaptive mechanism for selecting the B parameter to secure significant performance improvements.

GEDA Design

Figure 11 shows the block diagram of the GEDA model which reveals the key role EDA plays. In comparison with EDA, GEDA introduces three new system parameters, namely, B_{Pri}, B_{Sec} and a *scaling factor* (*SF*). B_{Pri} is the initial scan range value of B used to evaluate channel occupancy in accordance with the IEEE 802.22 standard, i.e., $P_d = 0.9$ and $P_f = 0.1$, while B_{Sec} is a higher B value, if required, which ensures an overall $P_d = 1$ once the first frequency scan using B_{Pri} has been completed. It is important to stress that B_{Sec} cannot be directly used at

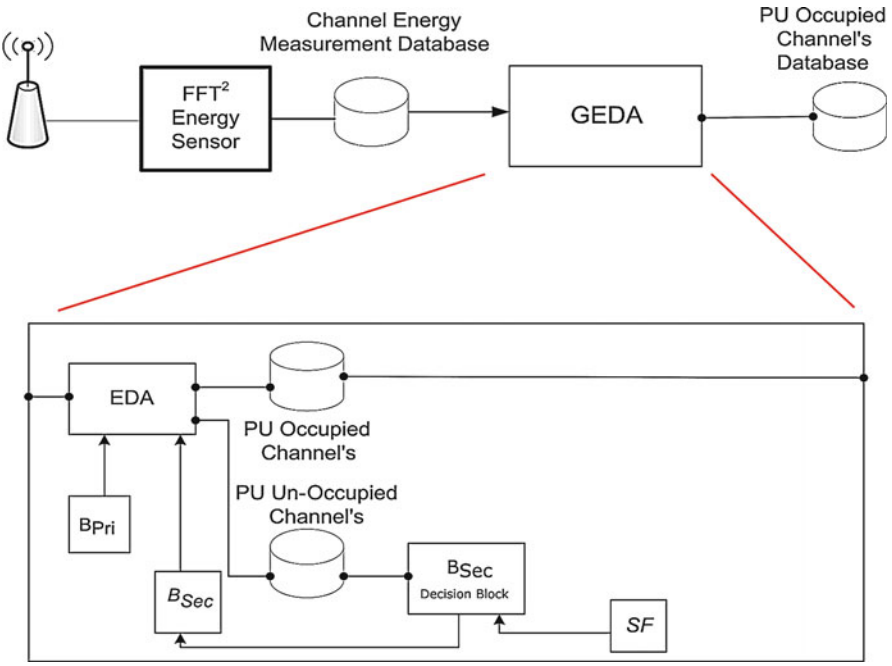

Fig. 11 GEDA block diagram

the outset of sensing by GEDA because its higher value increases the likelihood of false detections which compromises detection performance. It is, thus, only used on occupied DTT channels that B_{Pri} cannot detect. Both B_{Pri} and B_{Sec} are country-specific and are determined applying EDA using the corresponding B value that yields the respective P_d and P_f values.

GEDA detection can thus use either B_{Pri} or B_{Sec} for its DTT scanning range. The former is the initial scan range B value, and, in many cases, this is the only value required. In a few cases, however, B_{Sec} has to be used to achieve $P_d = 1$. Whether B_{Sec} is used is governed by the *SF*, which is the ratio of the highest to the lowest DTT frequency energy values, both of which are stipulated by the relevant regulatory authority [13, 34]. The role of *SF* will now be further investigated.

Scaling Factor (SF)

Using this highest frequency (lowest RF energy) to the lowest frequency (highest RF energy) ratio enables a window of energy measurements to be defined within which it is feasible that a PU DTT channel may trigger using B_{Sec}, provided the channel is in the unoccupied channel database. Thus, by scaling the lowest-frequency energy measurement in the DTT channel occupied database obtained using B_{Pri}, a threshold for using B_{Sec} on an unoccupied DTT channel is established. SF is formally expressed as:

$$SF = \frac{\left|\mathcal{F}\left(RSS_{Hi\_DTTFreq}\right)\right|^2}{\left|\mathcal{F}\left(RSS_{Lo\_DTTFreq}\right)\right|^2} \quad (1)$$

where $RSS_{Hi\_DTTFreq}$ and $RSS_{Lo\_DTTFreq}$ are the respective *received signal strength* (RSS) measurements for the highest and lowest DTT frequencies for a preset distance between the DTT transmitter and receiver.

GEDA Mechanism

Using B_{Pri}, the initial PU sensing results are determined using EDA, from which a PU unoccupied list is compiled. If the criteria in Eq. (2) is upheld, EDA is reapplied, but this time the DTT channel scanning is performed using B_{Sec} to assemble the final PU DTT channel occupied list [17] with y being the energy measurement of the lowest occupied DTT channel.

$$IF\ unoccupied\ DTT\ channel\ energy \geq y \cdot SF \quad THEN\ B = B_{Sec} \quad (2)$$

Numerical Evaluation of the GEDA Mechanism

To demonstrate how GEDA resolves undetected PU channels which are outside the B_{Pri} capture range, we shall examine the Yorkshire-Belmont UK scenario. To illustrate how GEDA is easily transferrable to other countries, the Washington DC FCC (6) scenario is also examined.

Yorkshire-Belmont: UK Channel Deployment GEDA Analysis

The first part of the analysis is where the B_{Pri} value is calculated for the UK DTT channel deployment plan using the algorithm in section "GEDA Design". From this analysis, $B_{Pri} = 4$ which gives a P_d of 0.98 and P_f of 0.0692.

From this DTT channel deployment, the B_{Sec} parameter will be invoked for two transmitter sites, namely, Yorkshire Belmont and Central-Waltham. For the latter case, only one channel is not detected by B_{Pri}; however, using B_{Sec} in the same transmitter region resolves this channel. Yorkshire-Belmont is chosen as the most challenging case study due to having two PU channels not detected, while Scunthorpe is the location for the SU BS, since it is at the edge of the DTT transmission area. The two channels which are not resolved to be occupied are DTT channels 53 and 60, and the way GEDA effectively resolves these channels for the Yorkshire-Belmont DTT transmitter is detailed in [5] and is summarized here.

Firstly, the *SF* for the UK is calculated from (1). The lowest DTT frequency in the UK is 474 MHz and the highest is 786 MHz, and the energy references were 60 km away from a 100 KW DTT transmitter. The DTT propagation model is used to obtain the two energy values below from the sensor with stated parameters:

$$SF = 3.4482118 \times 10^4 / 1.4930635 \times 10^5 = 0.23$$

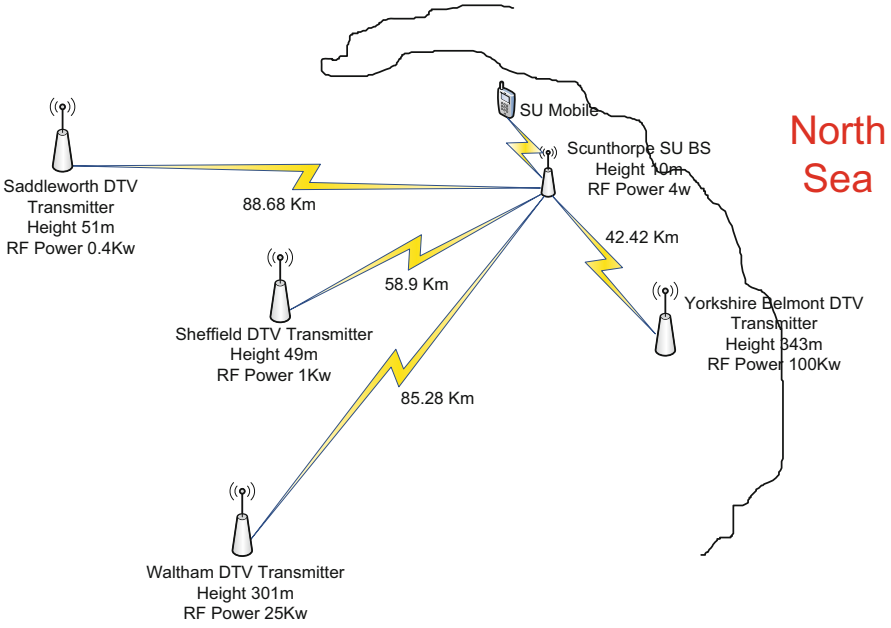

Fig. 12 Yorkshire-Belmont Analysis

Table 2 Energy responses for the Yorkshire-Belmont transmitter area to a Scunthorpe SU BS

Transmitter site and channel	Sensor measurement at SU BS in Scunthorpe
Saddleworth Ch 39	6.0904529×10^{1}
Sheffield Ch 21	6.2628017×10^{1}
Waltham Ch 29	6.3129225×10^{1}
Yorkshire Belmont Ch 53	2.5336327×10^{5}
Yorkshire Belmont Ch 60	2.0449943×10^{5}
Yorkshire Belmont Ch 22 lowest channel detected by GEDA using B_{Pri}	8.4410224×10^{5}

The next step is to map the Yorkshire-Belmont scenario which is shown in Fig. 12, where Yorkshire-Belmont is the primary DTT transmitter and Saddleworth, Sheffield, and Waltham are, respectively, the adjacent region transmitters.

The energy responses for each DTT transmitter is calculated to a SU BS in Scunthorpe by the DTT distance model using the SU BS antenna height (10 m). The corresponding sensor results are shown in Table 2.

The next step is to calculate the trigger for expediting a scan for a channel using B_{Sec}. This is calculated from taking the lowest-frequency channel sensor measurement which is detected by the GEDA using B_{Pri} which in this case is channel 22 and multiplying by SF (0.23) to obtain the trigger point. From Table 2, this will be $8.4410224 \times 10^5 \times 0.23 = 1.94143 \times 10^5$.

Now applying GEDA, the unoccupied channel scan using $B_{Sec} = 7$ is conducted, and if the channel sensor output is $\geq 1.94143 \times 10^5$, which means from Table 2, the Yorkshire-Belmont DTT channels 53 and 60, then the B_{Sec} parameter is triggered. This means when applying $B_{Sec} = 7$, both these DTT channels are detected.

The GEDA mechanism has been fully validated for all UK scenarios though not all countries follow the same channel deployment rules. Hence in order to demonstrate the agility of this novel sensing algorithm, an alternative North American scenario is now presented to exhibit this flexibility.

Washington DC: North American Channel Deployment GEDA Numerical Analysis

The major differences between the North American and UK scenarios are:

1. The DTT channel bandwidth utilized in North America is 6 MHz as opposed to 8 MHz in the UK.
2. The modulation scheme utilized in North America is 8 *Vestigial Sideband* (VSB) modulation where in the UK both 64 and 256 *Quadrature Amplitude Modulation* (QAM) are used.
3. The way the DTT channels are distributed is quite different and mainly driven by geography. In the North American case, distributed transmitter sites [6] are used to service a region because real estate is not a driving factor, with the number of channels varying between 3 and 21 depending on terrain and size of region.

For this analysis, data is required upon channel and RF parameters for the DTT deployment which is generally available from the relevant regulator (6). Using the channel deployment in [6], P_d was calculated using $B_{Pri} = 4$ giving a $P_d = 0.9016$ and $P_f = 0.053$, which conforms to the IEEE 802.22 P_d and P_f criteria. The channel deployment matrix is converted into a detection matrix by using the previously mentioned *detection probability* algorithm.

From the detection matrix, it was noted that channel 15 for Washington DC was not detected when using $B_{Pri} = 4$. Figure 13 shows the Washington DC DTT transmitter model along with a SU BS in the center of Washington in which this forms the basis of the analysis, with ten DTT channels allocated to the Washington DC region, supported by six transmitter sites. Each transmitter is identified by a four-letter call sign, with the particular transmitter of interest being WFDC, which is the channel which cannot be detected. WNVC is the transmitter whose channel is the lowest frequency detected using B_{Pri}, while WMPB is in the adjacent region to Washington DC.

Channel 15 cannot be detected using B_{Pri}, and the lowest frequency which can be detected using B_{Pri} is channel 24. Figure 14 shows the model for these two transmitters WNVC (Channel 24) and WFDC (Channel 15). WMPB (Channel 29), which is a channel servicing Baltimore which is an adjacent region to Washington DC, is also included to demonstrate that false triggering of B_{Sec} will not be caused

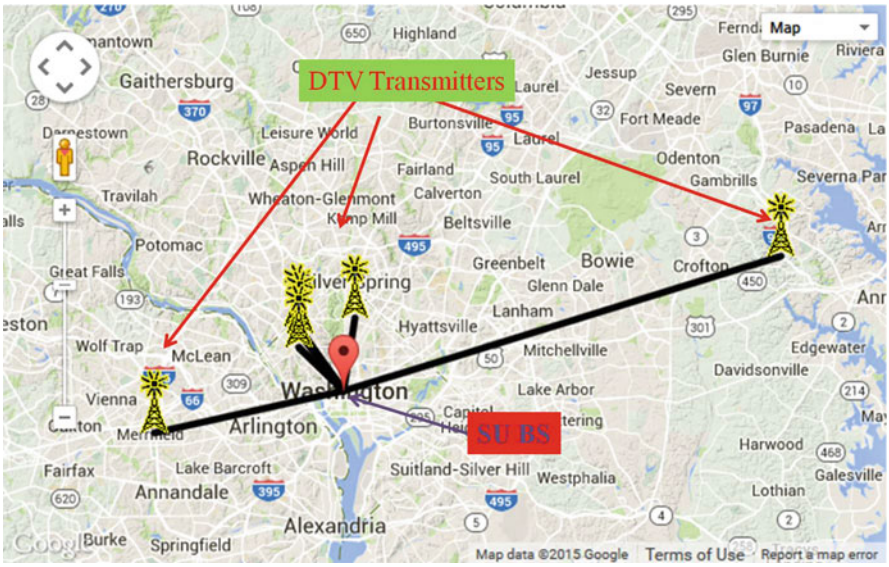

Fig. 13 Washington DC DTT Model [6]

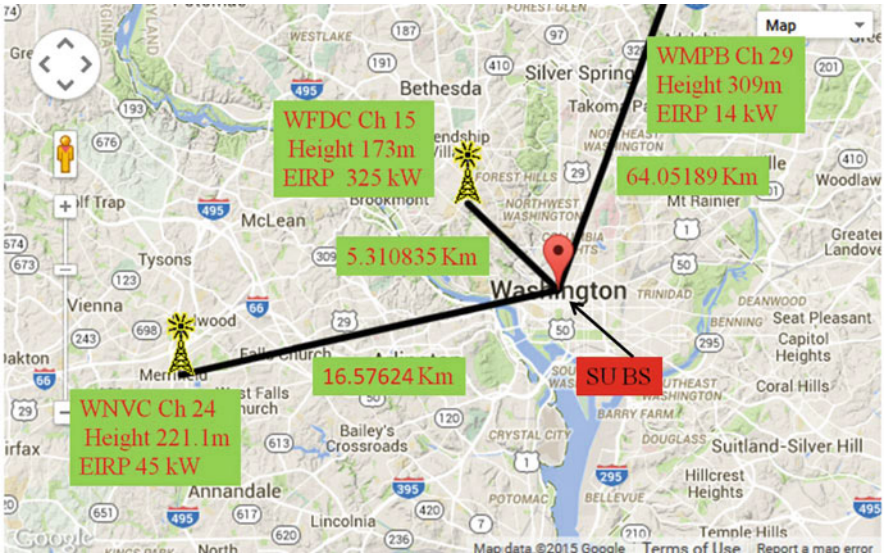

Fig. 14 Washington DC – WNVC, WFDC, and WMPB DTT Model [6]

by any adjacent region, as this would have the effect of increasing the probability P_f , thereby unnecessarily triggering B_{Sec}.

WFDC (channel 15) is not detected using B_{Pri} and WNVC, which is the lowest frequency detected in the Washington DC region thus defines the value at which

Table 3 Washington Model sensor measurements

Transmitter site and channel	Sensor measurement at SU BS in Washington
WFDC Ch 15	1.1846454×10^{10}
WMPB Ch 29 adjacent region	4.9109495×10^{4}
WNVC Ch 24 lowest channel detected by GEDA using B_{Pri}	2.0910753×10^{7}

B_{Sec} is to be used in conjunction with *SF*. Again using (1), the *SF* is calculated using the lowest and highest DTT frequencies in the USA, which are 473 and 887 MHz, respectively.

$$SF = 1360281/7907096.5 = 0.172033$$

This value is now used to calculate the sensor outputs for the three transmitters in Fig. 14 to the SU BS in Table 3.

As with the UK scenario, the next step is to determine the trigger for advancing the scan for a channel using B_{Sec}. This is calculated by taking the lowest-frequency sensor measurement detected by GEDA using B_{Pri}, which in this case is channel 24 and multiplying it by *SF* (0.172033) to give the trigger point. Using Table 3, this is $2.0910753 \times 10^7 \times 0.172033 = 3.597339 \times 10^6$. Now applying GEDA, the unoccupied channel scan using B_{Sec} is conducted, and if the channel sensor measurement is $\geq 3.597339 \times 10^6$, then this means for WFDC (channel 15) B_{Sec} is triggered. Thus, by using $B_{Sec} = 9$ in both the detection and false detection algorithms, this channel is successfully detected.

GEDA Results

The sensing performance of GEDA has been critically compared with two disparate DTT datasets. The first is DTMB which is the DTT standard in China (21), while the other is a North American study [22]. Both results were generated from a DTT deployment matrix of 22 sites. Given the Chinese scenario closely follows the UK in terms of DTT bandwidth and modulation schemes, this was compared to GEDA in a UK scenario using the same channel bandwidths and modulation schemes.

UK GEDA Results Compared to DTMB Standard [21]

DTMB channels have a bandwidth of 8 MHz and employ five modulation constellations, namely, 4-QAM NR, 4-QAM, 16-QAM, 32-QAM, and 64-QAM. The UK DTT standard DVB-T also has eight MHz channels but only two modulation constellations, which are 64-QAM and 256-QAM. To ensure the worst-case UK scenario is evaluated for GEDA, the latter is used because 64 QAM will display a greater energy level than 256 QAM, i.e., higher signal bit energy per noise energy

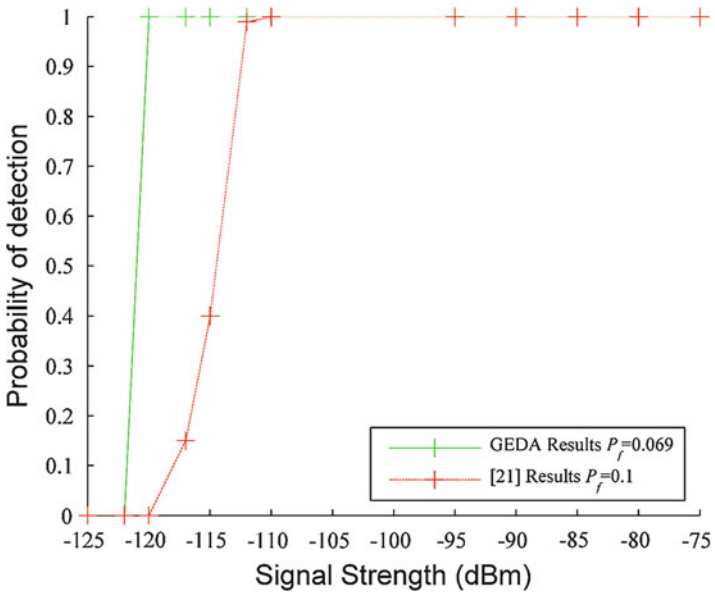

Fig. 15 Comparative detection results for GEDA and DTMB standard

(E_b/N_o) is required to decode 256 QAM signals for the same throughput as per Shannon's law [35].

The B_{Pri} and B_{Sec} values are calculated using the detection and false detection probability algorithms for compliance to $P_d = 1$ and found to be $B_{Pri} = 4$ and $B_{Sec} = 7$ for the UK scenario. The GEDA results are displayed in Fig. 15 along with the corresponding Chinese detection rates [21] at a $P_f = 0.1$. The results confirm that unlike DTMB, GEDA achieves $P_d = 1$ at a signal strength of -120 dBm in accordance with Ofcom requirements (Table 1) and overall produces a 9 dB improvement over [21]. It also achieves a lower comparative $P_{fd} = 0.069$ compared to 0.1 in [24].

US GEDA Results

The next set of results in Fig. 16 show how GEDA performs against the associated North American scenario in [22]. For FCC channel deployment, $B_{Pri} = 4$ and $B_{Sec} = 9$, however, to have an equitable comparison, both B_{Pri} and B_{Sec} values were varied between 1 and 9, so a wide range of P_f values were analyzed.

The results clearly demonstrate GEDA superior robustness across the range of SNR values. The reason for this is that the comparators in [21] and [22] depend on the detection of frame headers, which requires a certain SNR to exist. In contrast, GEDA energy measurements are combined with DTT channel deployment patterns, which effectively becomes a feature detector that is not dependent on demodulating the frame and is thus autonomous of the prevailing noise environment.

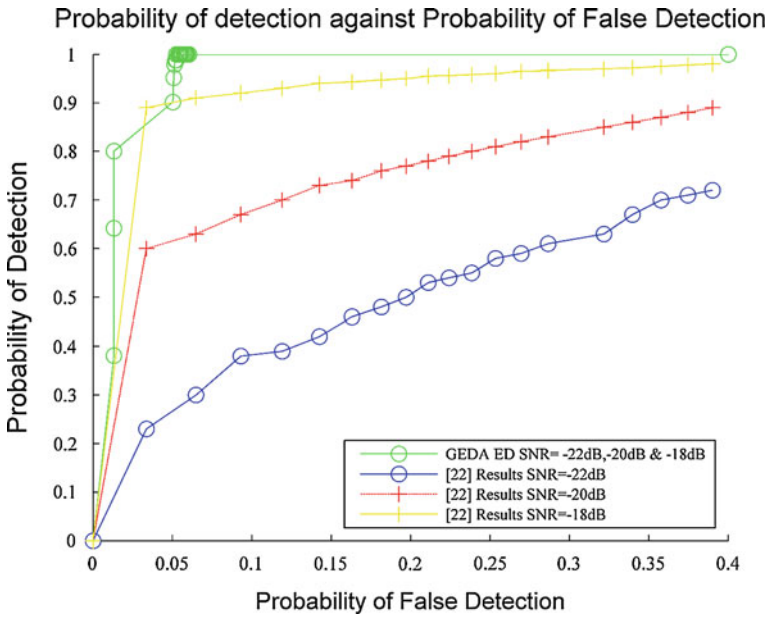

Fig. 16 FCC SNR GEDA results

Comparison of GEDA Results for UK and US

In Figs. 15 and 16, GEDA has been evaluated against other sensing solutions deployed in the UK and USA; however, GEDA was not compared using the same criteria. This section analyzes GEDA performance for both countries using SNR, and the detection and false detection metrics, with Fig. 17 displaying their comparative performance.

The graphs show the US sensing results attain a $P_d = 1$ before GEDA, though both sets of results secure a $P_d = 1$ and $P_f = 0.1$ to uphold both regulatory and IEEE 802.22 requirements. The difference is attributable to the diverse DTT channel deployment patterns between the UK and USA (demonstrated by different the B values used) for the same sensing threshold $= -120$ dBm.

Bandwidth Available for TVWS Devices

This section critically evaluates the potential of TVWS to make available extra bandwidth for SU cognitive devices. Two key concepts are firstly introduced.

(i) The *Protection contour* [34], which is a function of the DTT receiver being able to decode a DTT picture signal, even at the edge of a reception area, without incurring co-channel interference

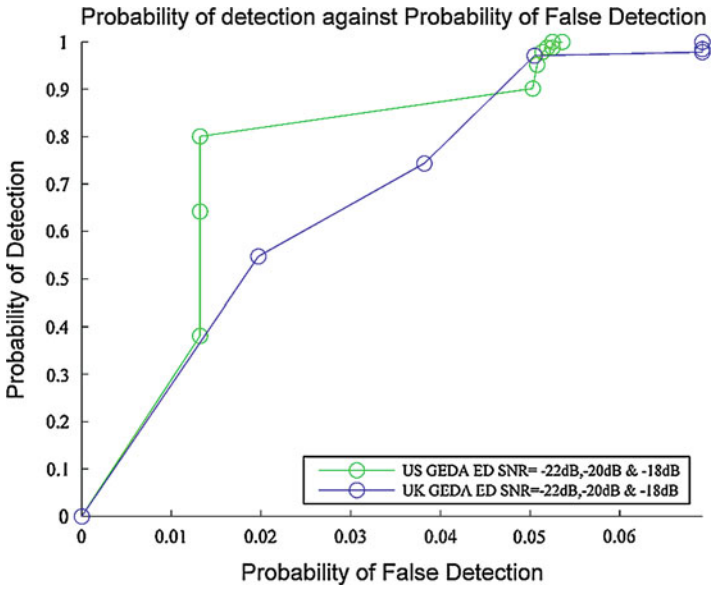

Fig. 17 Comparison between GEDA UK and US results

(ii) The *keep-out contour* which combines the protection contour and hidden node issue to establish a dedicated sterilization zone for each specific DTT channel

To consider how real DTT systems operate in the UK, both the average coverage distance from the transmitter for the Mendip area [17, 34] and the matching Egli terrain factor were calculated. Using the Mendip DTT area as the case study [34], without loss of generality, the Egli terrain value was empirically found to be 97%. It will now be shown how the concepts of a *protection contour* and *keep-out contour* can be innovatively coupled to define how much bandwidth is available for SU TVWS cognitive devices to access. Each will be now individually considered.

Protection Contour and Interference Management

This contour [34] crucially depends upon the RSS at the edge of the Mendip DTT area, which is the worst-case scenario for a PU where no co-channel interference occurs. The related protection contour geometry is shown in Fig. 18.

The *protection contour distance* ($Dist_{PC}$) [34] at the edge of the receivable DTT signal (BER $= 2 \times 10^{-6}$) for the Mendip area is 54.023 km for Channel 54. This $Dist_{PC}$ value does not, however, take account of two different sources of interference:

(i) *Co-channel* – interferers on the same channel
(ii) *Adjacent channel* – interferers on channels adjacent to the PU

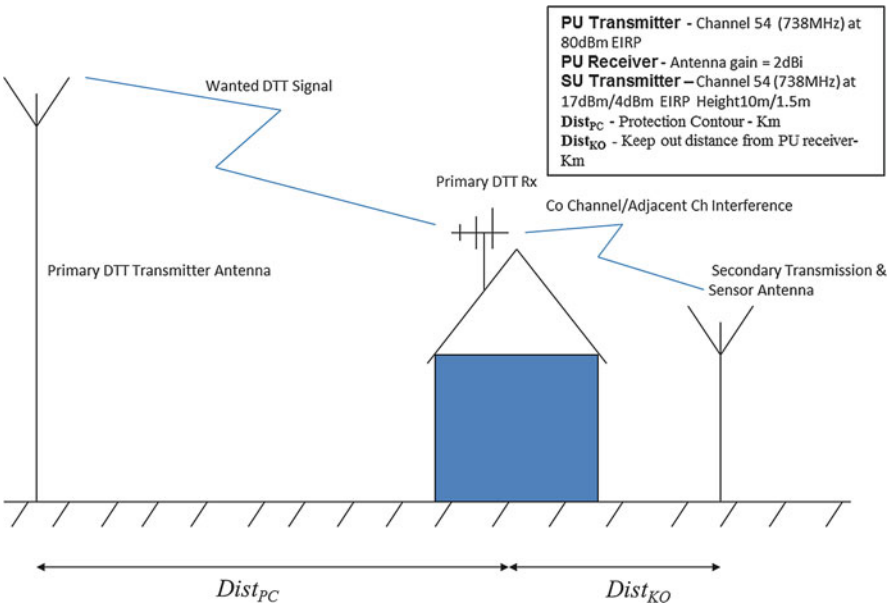

Fig. 18 Protection contour geometry for the Mendip DTT area

For (i), the DTT receiver is located on the protection contour, which for the Mendip area means $RSS_{PC} = -86.2429$ dBm. The co-channel interference signal is now increased until the BER exceeds the 2×10^{-6} threshold, which occurs at $RSS = -131.9$ dBm. Using this value, a model was developed to determine the distance from the protection contour that would generate an interference of -131.9 dBm at the DTT receiver. It was assumed SU BS transmit *effective isotropic radiated powers* (EIRP) of 17 and 4 dBm [12] are used along with the TVWS parameters defined in Table 1, 16 QAM at 32Mbps raw data (user application data together with IP and MAC overheads), and an 8 MHz DTT bandwidth. This equates to a minimum keep-out distance ($Dist_{KO}$) of 3.75 km from the DTT receiver on the protection contour for the 17 dBm SU while $Dist_{KO} = 1.77$ km for the 4 dBm SU. Both $Dist_{KO}$ distances crucially assume no margin for a hidden node.

For adjacent channel interference, the adjacent channel interference signal (N+1) was increased on the DTT receiver at the protection contour until the BER exceeded the 2×10^{-6} limit, which occurred when $RSS = -47.77$ dBm. This is the maximum allowable SU signal strength in this adjacent channel. Undertaking the same analysis for the $(N + 2)$ adjacent channel gave a maximum $RSS = 196.4$ dBm for a SU.

To critically evaluate whether the OFCOM SU maximum transmit EIRP of 4 dBm for $(N + 1)$ and 17 dBm for the $(N + 2)$ adjacent channel interference provides sufficient DTT PU defense against interference, the SU BS and mobile scenarios where the interfering RSS is calculated for both 4 and 17 dBm SU transmit EIRP on $(N + 1)$, 14 m away from a DTT receiver which is assumed to be the

minimum separation of a SU BS from a PU receive antenna. The respective $(N+1)$ BS results were -47.78 and -34.78 dBm, which endorse the Ofcom decision to limit the $(N+1)$ transmit EIRP to only 4 dBm, as this is lower than -47.77 dBm, so it will not generate interference from 14 m unlike the 17 dBm SU BS. The SU mobile scenario for $(N+1)$ using 4 dBm SU transmit EIRP gives protection to the PU receiver up to 5.4 m away from the PU receiver. In contrast, for the $(N+2)$ channel case, the -13 dBm RSS caused by a 17 dBm SU BS at 4 m from the PU receiver is much lower than 196.4 dBm, so no interference is generated. In the 17 dBm SU mobile case, a $RSS = -5.4$ dBm is generated when 1 m away from the PU receiver which again is much lower than 196.4 dBm, so no interference is produced to any PU.

While these co-channel results demonstrate the minimum distance away from the protection contour a SU can reliably transmit on the same channel, the *hidden node* issue [17, 34] is not reflected. It is clear from the above discussion that no interference is generated provided the Ofcom settings (Table 1) on the $(N+1)$ and $(N+2)$ SU power restrictions are upheld.

So far, the *hidden node* effect has been only considered in sensing a PU very close to an obstacle, i.e., 10 and 20 m away. The graph in Fig. 19 shows the sensor output at distances more than 55 km away from a DTT transmitter, for differing obstacle heights in the range 15-90 m [32–34]. The graph reveals that while the distance to the *keep-out contour* distance varies between points (2), which are the minimum, and points (3), the maximum, depending on the obstacle height, the keep-out margin X_{KO} remains constant.

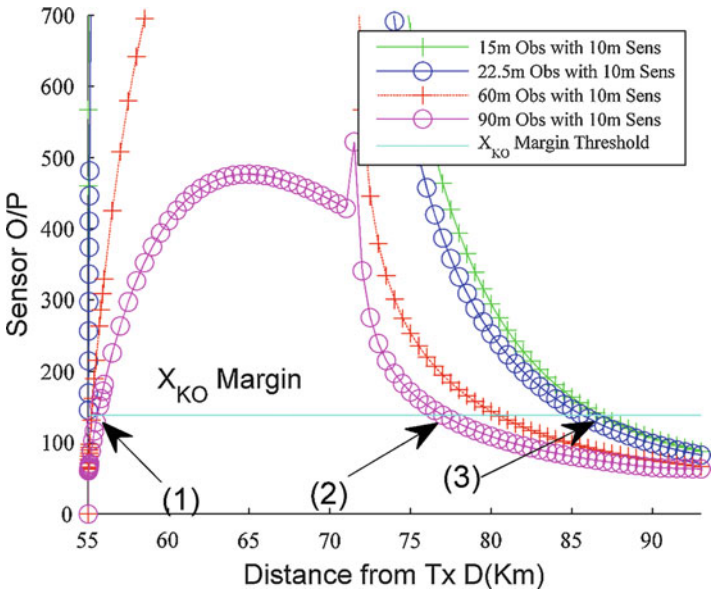

Fig. 19 Mendip keep-out contour at 738 MHz

At point (2), the minimum distance at 76.89 is 22.87 km from the nearest DTT receiver ($Dist_{KO}$) on the protection contour. This means from Table 1 where the maximum allowed Ofcom transmit power is 17 dBm, a minimum distance of 3.75 km is required to avoid co-channel interference. It can then be assumed that by using the *keep-out margin* X_{KO}, no interference is caused by a SU transmitter with an obstacle height of 90 m. For a typical residential scenario and a 15 m obstruction, the maximum *keep-out contour* distance is 86.69 km at point (3), which is the value used in channel reuse calculations. Note, the distance from the obstruction to point (1) is just 0.58 km which represents a special case where PU detection is only achievable using either a cooperative sensing strategy or special sensor heights as discussed in [33] and needs to be within 1 km of the obstruction.

Keep-Out Contour

This contour defines the exclusion zone around the DTT transmitter which protects the PU receiver by applying the *protection contour* even when there is a hidden node present. It also provides sufficient bandwidth to TVWS devices to ensure their users receive the best *QoS*. The difference between the protection and keep-out contours is that the latter includes a margin loss alongside the protection contour to permit prescribed interference RSS in the presence of hidden nodes as illustrated in Fig. 20.

In the *keep-out contour* geometry of Fig. 20, the main parameters are:

$Dist_{PC}$ = *Protection contour* for the lowest modulation scheme in the DTT deployment
$Dist_{KO}$ = Distance from the *protection contour* to *keep-out contour*

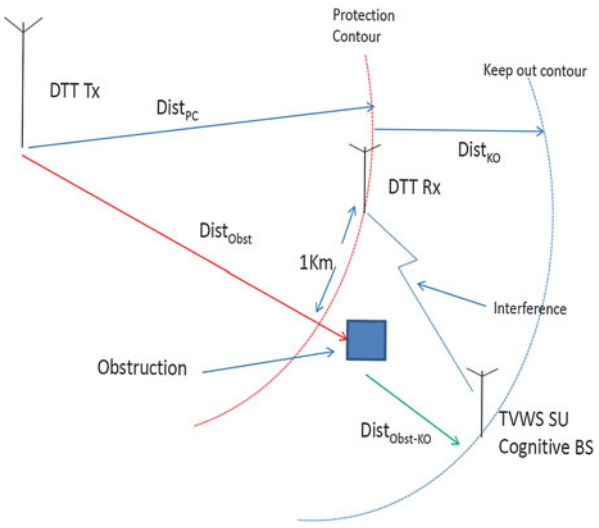

Fig. 20 Keep-out contour geometry

Table 4 Power control parameters

X_{KO}	Keep-out contour energy (section "Ad Hoc Routing")
$P_{BS(N+1)}$	Regulatory definition for base station EIRP for adjacent channel (Table 1)
$P_{BS(N+2)}$	Regulatory definition for base station EIRP (Table 1)
$P_{M(N+1)}$	Regulatory definition for mobile EIRP for adjacent channel (Table 1)
$P_{M(N+2)}$	Regulatory definition for mobile EIRP (Table 1)
DB_{PU}	GEDA identified PU channel database
DB_{DTT}	DTT channel database containing channel numbers and energy measurements
$DB_{DTT}^{(Ch)}$	DTT channel database channel number
$DB_{PU}^{(Ch)}$	GEDA identified PU Channel database channel number
$DB_{DTT}^{(E)}$	DTT channel database energy measurement

$Dist_{Obst}$ = Distance between an obstruction and DTT transmitter
$Dist_{Obst-KO}$ = Distance from an obstruction to the *keep-out contour*

To define the *keep-out contour*, the distance from the *protection contour* in the worst-case scenario must be determined, namely, a 36 dBm SU BS (maximum RF power in Table 1) producing an interference signal strength of −120.8 dBm plus a margin for the hidden node. This margin is derived from the mid-variation point of the 90 m obstacle diffraction loss at distances up to 400 m away from an obstacle, where the most significant changes occur at 41.33 dB. Using the interference models, the corresponding distance $Dist_{KO}$ for this margin in the Mendip DTT region is 47 km. Distance $Dist_{KO} + Dist_{PC}$ now determines the minimum sensor threshold X_{KO} for the *keep-out contour*. For the Mendip DTT area, this is 138.73, which means any sensor output value lower than 138.73 will trigger the *keep-out contour* to enable the SU to access that particular channel as shown in Fig. 19.

Figure 19 reveals that while the distance to the *keep-out contour* varies between the highlighted points (2) and (3), depending on the obstacle height, X_{KO} remains constant. For the most typical residential scenario and a 15 m obstruction, it can be assumed the maximum *keep-out contour* distance is 86.69 km, which is the value used in channel reuse calculations. Note, the distance from the obstruction to point (1) is just 0.58 km which represents a special case where PU detection is only achievable using either a cooperative sensing strategy or special sensor heights [33, 34].

The GEDA model employs the *keep-out contour* to both determine active PU channels and to govern whether these channels can be accessed by a SU. The complete adjacent and co-channel interference management process is presented in pseudo-code form in [17], with Table 4 defining the key parameters.

The interference management algorithm [17] checks every DTT channel in the PU database, which is created during the GEDA process, against the current channel under review. If the sensor output of the DTT under review is greater than (X_{KO}) and the channel number is specified in the PU database, i.e., it is a co-channel, then a SU cannot access this particular channel. However, if the channel under review does

not reside in the PU database or the sensor output is less than X_{KO}, then a SU may access the channel using RF powers of $P_{M(N+2)}$ and $P_{M(N+2)}$, respectively. Finally, if the channel under review lies in an adjacent channel $N + 1$ or $N + 2$, then the SU may use RF powers; $P_{M(N+1)}$, $P_{M(N+2)}$, $P_{BS(N+1)}$, or $P_{BS(N+2)}$, respectively, without crucially impacting upon the PU.

In [14] and [36], the available TVWS bandwidth calculation at any location was determined from physical RF surveys, which incurred extensive resources, so instead GEDA adopted the innovative strategy to assess the amount of SU bandwidth available using the *keep-out contour* and *sterilization index* (SI) [33].

The UK DTT network consists of major regions, with each having minor transmitters operating within their boundaries to overcome local propagation issues so ensuring populated areas have service coverage. The USA DTT deployment in contrast has distributed major transmitter sites covering a region, though notably the *SI* concept is still applicable.

Let the *keep-out contour* area of adjacent main DTT transmitters transmitting intersecting a major DTT area be F km^2 per DTT channel per transmitter. If Y km^2 is the area covered by the furthest *keep-out contour* of a major transmitter serving a UK DTT region, then for a distributed deployment like the US, this will represent the area covered by the radius of the furthest- away transmitter *keep-out contour*, added to the distance from the transmitter to the center of the region under analysis. *SI* is thus formally expressed as:

$$SI = \frac{F}{Y} \tag{3}$$

where the *SI* is calculated on per channel (n), per transmitter (m) basis, with each individual si_{mn} value used to construct a primary area SI' matrix.

$$SI' = \begin{pmatrix} si_{11} & \cdots & si_{1n} \\ \vdots & \ddots & \vdots \\ si_{m1} & \cdots & si_{mn} \end{pmatrix} \tag{4}$$

where the number of DTT channels $n = 32$ in the UK and m the number of transmitters radiating into area Y. If two different transmitters use the same channel, with one *keep-out contour* area nested within another, then the lower si_{mn} value is set to zero.

The final step is to sum all columns and resulting rows in Eq. (4) to form a final *SI* value.

$$SI = \sum_{i=1}^{n} \sum_{j=1}^{m} SI'_{ij} \tag{5}$$

The *SI* determines the available bandwidth in the DTT area under investigation by (*N*-*SI*) x *BW* MHz, where N DTT channels of bandwidth of *BW* MHz area assumed

in the country of interest. The next section investigates how the *SI* can be applied to determine the number of TVWS channels available in the specific case study area of the Mendip region.

UK Case Study for TVWS in the Mendip DTT Transmitter Area

All the major, adjacent, and minor transmitters of either 50 W or more (5) in the Mendip DTT transmitter area, together with their corresponding *SI* values, are given in Table 5.

Using the individual *SI* values in Table 5, the overall *SI* in (5) is 15.1194 which equates to an available bandwidth of 135 MHz for TVWS SU devices, when considering all transmitters of either 50 W or greater. However, there are 60 minor DTT transmitters operating below 50 W that must also be taken into account. To do this efficiently, the average antennae heights and EIRP values are used to determine the *SI*. The *SI* for each channel was found to be 0.0133, and since three channels are allocated to each minor transmitter, $SI = 2.4$. This is now added to (5) giving a total $SI = 17.5194$, so the average available bandwidth for TVWS over the entire Mendip area is 115.85 MHz. While this represents the average available bandwidth for the Mendip DTT region, this value will vary according to locality. In heavily populated areas, it will reduce while in rural areas it will increase. This corroborates the findings in [13], which, based on measured availability and geo-location database access, showed that in the largest city (Bristol) in the Mendip DTT region, 104 MHz of bandwidth was available for TVWS devices.

Other Ofcom studies [13] suggest that over 90% of the population can access at least 100 MHz, aggregated across the interleaved spectrum. They also estimated that $\approx$50% of the population could have access to 150 MHz or greater and some rural communities could enjoy more over 200 MHz of this spare capacity [17]. These findings underscore the importance the *keep-out contour* threshold and *SI* play in

Table 5 Corresponding SI values for the DTT major, adjacent, and minor transmitters of 50 W or over

Salisbury	0.6
Bristol IC	0

releasing valuable bandwidth for SU TVWS exploitation while upholding the *QoS* provision for PU DTT users. As an illustration, the SU gains secured for the Mendip region using the *SI* is approximately 6×20 MHz LTE RF bearers per location. This translates to an increase in the number of active data users in a LTE cell location from 800 to 4600, if a TVWS access node is used in conjunction with an LTE eNodeB, i.e., an improvement of more than a factor of 5.

Future Research Challenges in TVWS and 5G

Emerging 5G technologies [7–9] recognize that coverage, throughput, and latency are the overarching objectives in both framing and advancing any new wireless standard. This chapter has presented a flexible framework for how TVWS can effectively fulfill some of these aims by enabling 5G services to not only utilize the increased spectrum released by TVWS but also safeguard long-term access benefits for unlicensed SU.

Central to this novel TVWS access framework is the GEDA model which uniquely depends on the DTT channel deployment patterns. It is thus motivated by the narrowband nature of DTT UHF receiver antenna, which means only a narrowband of channels are allocated to a specific region. To exploit the SU access benefits of GEDA in other spectrum opportunities such has the millimeter spectrum, it will need to be modified to be able to detect other patterns, such as timing of the PU signals, or when new spectrum is allocated to a PU by administrators, such patterns are factored into the allocation.

Another key challenge is to improve the SU transport QoS metrics of *packet error rate* (PER) and latency when accessing TVWS. Existing TVWS regulatory requirements [13] mean SU BS transmits at far higher RF power compared to SU mobile units, so to achieve adequate SU coverage, the uplink signal from the mobile device to BS needs to employ newly developed innovative routing models to achieve the additional coverage through multi-hop network arrangements.

Furthermore, heterogeneous network environments have been introduced to access different technologies to meet user requirements. An underlying assumption of this development is that TVWS spectrum would be shared between multiple mobile operators, with each setting up a separate WLAN. An interesting alternative strategy would be to critically investigate open WLAN arrangements, involving some commercial agreements between operators for resource sharing [37]. Multi-operator heterogeneous networks have the advantage that any mobile operator can route packets so increasing the number of mobiles in a routing area because it is not restricted to one operator. This will increase the mobile routing population in an area so reducing the PER. A major research question for such an environment, however, would be how best to create a cross-operator heterogeneous implementation framework on existing platforms, including the cognitive TVWS access framework presented in this chapter.

Conclusion

This chapter has investigated how *cognitive radio* (CR) technologies can address the scarcity of spectrum for the increasing demands made by today's wireless applications. It, in particular, explores how *TV White Space* (TVWS) offers a unique, low-risk option to enhance existing licensed spectrum by exploiting unlicensed resources due to the static temporal characteristics of the *primary user* (PU) spectrum. The key hurdles to TVWS adoption are reliable PU detection allied with resolving the *hidden node* issue. A review of existing TVWS regulatory standards has been presented with the PU-centric country-related requirements detailed together with the SU-centric requirements. A key conclusion is that any proposed sensing solution needs to robustly demonstrate resilience to the omnipresent *hidden node* problem.

Supporting technologies which facilitated the introduction of CRN including cross-layer processing and ad hoc routing were also reviewed to address the challenges of both supporting SU access to TVWS and overcoming latency issues of ensuring the correct information is delivered to the required OSI layers in a timely fashion. Ad hoc routing has been highlighted as the favored solution for ensuring the unidirectional transmission caused by the SU RF power differentials, which do not negatively impact on user QoS.

Finally, PU interference management has been analyzed with a novel *generalized enhanced detection algorithm* (GEDA) detailed which exploits the unique way *digital terrestrial TV* (DTT) channels are deployed in different geographical areas. GEDA transforms an energy detector into a feature sensor to achieve significant sensing improvements compared to existing detection solutions. By applying a *keep-out contour* together with a novel *sterilization index*, the *hidden node* problem is resolved and a practical SU sensing solution is formulated. GEDA and the *keep-out contour* interference management paradigm leverages extra bandwidth for SU in TVWS to achieve notably enhanced QoS provision as demonstrated in a UK DTT transmitter case study. The advantages of GEDA has also been shown to be equally effective in DTT deployments in other countries.

Abstract

In this paper an overview is given of the current status of 5G industry standards, spectrum allocation, and use cases, followed by initial investigations of new opportunities for spectrum sharing in 5G and the underlying technologies to enable efficient sharing, considering both licensed and unlicensed scenarios and spectrum both below 6 GHz and in the millimeter-wave frequency range.

What Is 5G?

5G is the next generation of mobile communications technology and is being designed to provide (in comparison with 4G) greater capacity and faster data speeds and offer very low latency and very high reliability, enabling innovative new services across different industry sectors. The first wave of 5G commercial products is expected to be available in 2020 although some "pre-5G" deployments are already expected in 2018. 5G technology standards are currently under development and will include both an evolution of existing (4G) and new radio technologies (5G NR).

5G Use Cases

According to the International Telecommunication Union ITU [4] who has defined the vision and requirements of IMT2020 [1], potential 5G services and applications can be grouped into three different classes:

- Enhanced Mobile Broadband. Together with an evolution of the services already provided by 4G, 5G is expected to provide much faster and more reliable mobile broadband, offering a richer experience to consumers for application such a virtual reality (VR) and augmented reality (AR) as well as cloud-based services. The specific requirements are a minimum of 100 Mbps user-experience data rates and 20 Gbps peak data rate.
- Massive Machine-Type Communications. The Internet of Things (IoT) – where sensors, actuators, consumer electronics appliances, street lighting, etc. wirelessly connect to the Internet and each other. This is already happening on existing 4G networks, and the technology is being used in everything from smart homes to wearables. 5G should help the evolution of IoT services and applications and improve the interaction between different platforms as well as enable the vision of 50 billion devices becoming connected by 2030. Possible future applications could include real-time health monitoring of patients, optimization of street lighting to suit the weather or traffic, and environmental monitoring and smart agriculture. Data security and privacy issues will need to be considered given huge amounts of data could be transferred over a public network. We note that many IoT services are already being offered or will be offered in the next few years over existing and evolved 4G networks, e.g., using narrowband IoT (NB-IOT), LTE-M, or NB-LTE-M technologies. 5G, in this area, is likely to kick in by about 20205 where we expect to see through the explosion of new IoT services for which the evolution of LTE is unable to address the required scalability requirements.
- Ultrareliable and low-latency communications. This class is likely to rely on the new radio developments and includes services requiring a very high

Fig. 1 Exemplar use cases of 5G and their requirements

reliability and/or a very low latency. Possible applications include connected and autonomous cars and aerial vehicles, remote control of robots in extreme conditions and hazardous situations and for industry automation (Industry 4.0), remote surgery, and the so-called tactile Internet as well as some of the applications in the context of smart grids.

These different services have different requirements in terms of speed, coverage, latency, and reliability, which will demand different network solutions (the evolution of existing network and potentially new networks) and different deployment models (including many small cells), an appropriate network infrastructure (which will include both fiber and wireless connectivity to the core network), and access to different spectrum bands. Therefore, the concept of network slicing is being put forward, where different slices of the overall 5G network infrastructure (including spectrum) may be allocated to different types of services to end users (Fig. 1).

We note that in addition to the above three categories of 5G use cases, perhaps surprising a new use case for 5G, the so-called fixed wireless access (FWA) or fiber-like wireless, has recently emerged [2,3]. FWA refers to the provision of high-data-rate (>100 Mbps) broadband wireless access to residential customers and enterprise premises using pre-5G/5G access technologies, including full-dimensional MIMO (FD-MIMO), massive MIMO, and millimeter-wave radio access technologies. The FWA concept has been around for quite a long time (being known also as wireless local loop), but only with 5G the techno-economic case for this use case has become a compelling alternative to wired solutions, such as next-generation cable, copper-based G-fast, and Fiber-to-the-Premises (FTTP) (Fig. 2).

Fig. 2 5G fixed wireless access architecture

Radio Access Technologies for 5G

Different from previous generations, where a new radio access technology replaced the old one, 5G will integrate different radio technologies. Some of these will be the evolution of already existing radio access technologies; some will be new. Different service classes could rely on different radio interfaces. Evolutions of the latest version of the 4G radio interface (LTE-Advanced Pro) are likely to be used to provide a coverage layer via macro cells. A new cellular radio interface (being developed in 3GPP under the name "New Radio" or "NR") operating in frequencies up to 50 GHZ will be used to provide very high data rates and ultralow latencies and to serve a very large number of devices via a large number of small cells. Low-cost, low-battery consumption IoT services are likely to be delivered initially using evolved 4G technologies, as described in the Introduction, with a gradual transition/phaseout to 5G by 2025. Wi-Fi evolutions will also play an important role for consumers, in particular to provide 5G services within homes or offices. In addition it is also expected that satellite technologies also play a role in 5G, in particular for wide area coverage in IoT application space (e.g., tracking of goods and vehicles) and also as a mechanism to off-load broadcast and multicast linear TV traffic from 5G cellular networks.

5G Standards Timelines

Figure 3 shows the latest (as of 25/06/2017) timeline of 3GPP (Third Generation Partnership Project), which is responsible for developing a global industry standard for 5G mobile communication technologies. As can be seen from this figure, 5G phase 1 standards, which are mainly focusing on enhanced mobile broadband (eMBB) with some element of ultralow latency included, are expected to be ready mid-2018, with an initial "non-stand-alone" version of the standard to be released already by the end of 2017. The second phase of 5G technology, which encompasses massive machine-type communications and ULL, is expected to be ready by the end

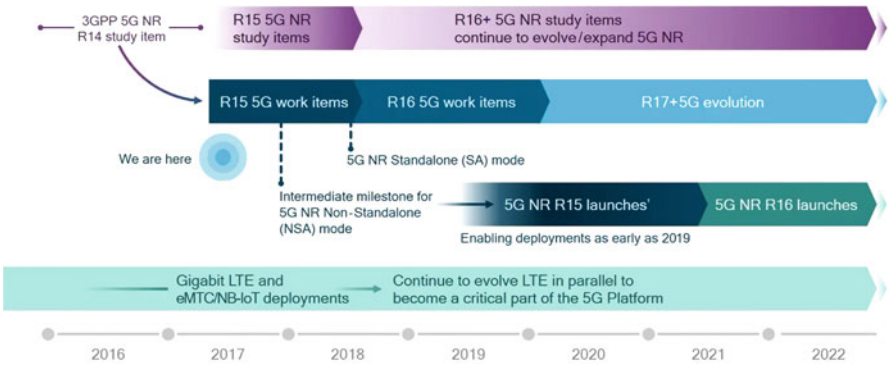

Fig. 3 5G standardization timeline according to 3GPP

of 2019, in time for the standard to be proposed to ITU as a candidate technology which fulfils the IMT 2020 requirements.

Spectrum for 5G

Spectrum is a critical component of wireless networks. It makes up the "airwaves" that underpin the communication services we use every day, such as mobile, Wi-Fi, and TV. The diverse set of 5G services and applications, described above, will require a diverse set of spectrum bands, with different characteristics, addressing different requirements and combining both low and high frequencies:

- Spectrum at lower frequencies, and in particular below 1 GHz, to enable 5G coverage to wide areas;
- Spectrum at higher frequencies with relatively large bandwidths below 6 GHz, to provide the necessary capacity to support a very high number of connected devices and to enable higher speeds to concurrently connected devices; and
- Spectrum at very high frequencies above 24 GHz (e.g., millimeter wave) with very large bandwidths, providing ultrahigh capacity and very low latency. Cells at these frequencies will have smaller coverage (between 50 and 200 m), and it is likely that build-out of 5G networks in millimeter wave bands will initially be focused on areas of high traffic demand or to specific locations or premises requiring services with very high capacity and/or peak data rates (Gbps) (Fig. 4).

5G Spectrum Allocation

The 2015 World Radio Congress (WRC-15) agreed on a WRC-19 agenda item (1.13) to consider the identification of frequency bands for the future development of International Mobile Telecommunications (IMT), including possible additional

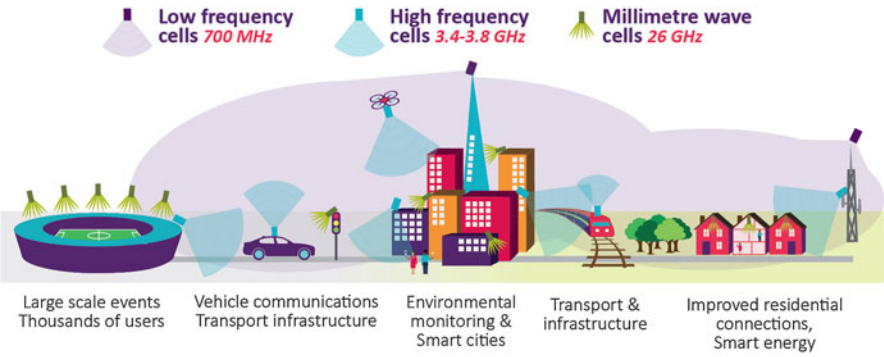

Fig. 4 Radio spectrum for 5G and its uses [Ofcom]

allocations to the mobile service on a primary basis, in accordance with Resolution 238 (WRC-15). This involves conducting and completing the appropriate sharing and compatibility studies for a number of bands between 24 and 86 GHz in time for WRC-19. The compatibility and sharing studies for these bands are being carried out in ITU-R Task Group 5/1 until 2018. This follows work in ITU-R on spectrum needs, deployment scenarios, sharing parameters, and propagation models which were completed in March 2017.

Candidate bands identified for further study in WRC-15 are shown in Fig. 5. It can be seen that there are regional differences, and in particular in the 20–30 GHz range, it can be expected that the 27.5–29.5 band will be only available in Americas, while other regions, including Europe, are likely to converge around the 24.25–27.5 range.

In parallel on the European level, Radio Spectrum Policy Group (RSPG) has developed in 2016 a strategic road map for 5G in Europe. In particular, the road map identified the following building blocks for 5G:

- Low-bandwidth spectrum at **700 MHz**; Medium-bandwidth spectrum at **3.4–3.8 GHz** as a "primary" band, which will provide capacity for new 5G services; and
- High-bandwidth spectrum at **24.25–27.5 GHz** as the "pioneer" millimeter wave band to give ultra-high capacity for innovative new services, enabling new business models and sectors of the economy to benefit from 5G. In addition, a European Commission Mandate to CEPT was approved by member states with regard to the development of harmonized technical conditions in two "pioneer" bands: 3.4–3.8 GHz and the 26 GHz band.

5G Spectrum Sharing

Sharing Below 6 GHz Spectrum

While above 6 GHz large chunks of spectrum are expected to become available for 5G systems, the amount of spectrum the sub-GHz and below 6 GHz range is far more limited. The sub-6GHz band is expected to support important applications of 5G, such a machine-type communications due to excellent propagation and indoor penetration characteristics, while the first wave of 5G mobile communication systems are expected to be deployed in 3.6 GHz frequency range, where in conjunction with the use of massive MIMO and full-dimensional MIMO (FD-MIMO) technologies 100Mbps+ data rates could be supported while also keeping cell sizes sufficiently large for viable deployment. It is, therefore, of great importance to explore options for the sharing of these very precious portions of 5G spectrum.

Due to quality of service requirement of 5G use cases that are expected to be supported, a very important option for the sharing of these bands is the evolution of Licensed Shared Access (LSA) [5]. In this approach licensed users, called LSA licensees, can access underutilized licensed spectrum on an exclusive basis, thus enjoying predictable QoS, when it is not being used by the incumbent, hence protecting it from harmful interference.

In 2017, the Federal Communications Commission (FCC) opened up 150 MHz of spectrum in the USA around 3.5 GHz that it named *Citizens Broadband Radio Service (CBRS)* [12]. Similar to the LSA approach, CBRS enables others to use the spectrum while it is still being used by existing incumbents, such as the military or satellite communication (see Fig. 6). However, in addition to sharing with incumbents – CBRS adds a "third tier" of general usage. In this third tier, anyone can use the spectrum when it is not used by the higher tiers (the incumbents or users that paid for a license) (see Fig. 2). Of course, if there are multiple third-tier users in the same area, then they will share the available spectrum with each other in a fair manner. The complexity of managing three tiers will require some additional control. To this effect, the FCC has defined a Spectrum Access System (SAS) – a type of database, in effect – and the *Wireless Innovation Forum* is helping to specify the details to ensure that it all works in accordance with the FCC rules.

CBBS can be used by existing mobile operators to offer Gigabit LTE in more places by making more spectrum available. One can also use this spectrum for small-cell deployments to extend coverage and add capacity indoors. Another foreseen

Fig. 6 CBBS spectrum sharing scenario in 3.5 GHZ between an incumbent system (in this case Navy radar) and secondary users

use is the so-called neutral host, which is a LTE deployment that can be used by subscribers irrespective of their service provider.

Sharing mm-Wave Spectrum

Millimeter-wave (mm-wave) communications have emerged as a key disruptive technology for both cellular networks (5G and beyond) [6] and wireless local area networks (802.11ad and beyond). While spectrum availability is limited in traditional bands below 6 GHz, mm-wave frequencies offer order of magnitude greater bandwidths. In addition, mm-wave communication is typically characterized by transmissions with very narrow beams, enabling further gains from directional isolation between mobiles. This combination of massive bandwidth and spatial degrees of freedom may make it possible for mm wave to meet some of the boldest 5G requirements, including higher peak per user data rate, high traffic density, and very low latency. The use of mm-wave bands for 5G presents a number unique features not present at lower frequencies:

- **Beamforming as a mandatory requirement**: A common characteristic of all systems operating in mm-wave frequencies is that beamforming is mandatory to compensate for the significantly higher path loss in these frequencies. For example, the IEEE 802.11ad standard supports up to 4 transmitter antennas, 4 receiver antennas, and 128 sectors. Beamforming is mandatory in802.11ad, and both transmitter-side and receiver-side beamforming are supported. Furthermore specification of beamforming for 5G is expected to be finalized by 3GPP, as part of 5G New Radio (NR) work item. Consequently, beams provide a common new dimension for the sharing of spectrum among multiple access technologies.
- **Potential for "infinite" spatial reuse:** Wireless communications systems already rely on spatial sharing of spectrum in two dimensions, and the entire concept of cellular communications relies on spatial reuse of radio spectrum. In mm-wave systems with the use of transmit-side and receive-side beamforming, spatial spectrum reuse can be pushed even further down close to one dimension, which the footprint of interference from each transmission link becoming very close to the line, rather than an area, in two dimensions. In the idealized case of ultra-narrow beams, this would allow infinite spatial reuse of spectrum.

Sharing with Satellite Services

FSS (Fixed Satellite Service) is the official classification for geostationary communications satellites that provide, for instance, broadcast feeds to television stations, radio stations, and broadcast networks. The FSS uplink (from FSS to satellite) is allocated in the band from 27.5 to 30 GHz, which is adjacent to the 24.25–27.5 GHz band identified for 5G. Therefore, there could be potential issues with the

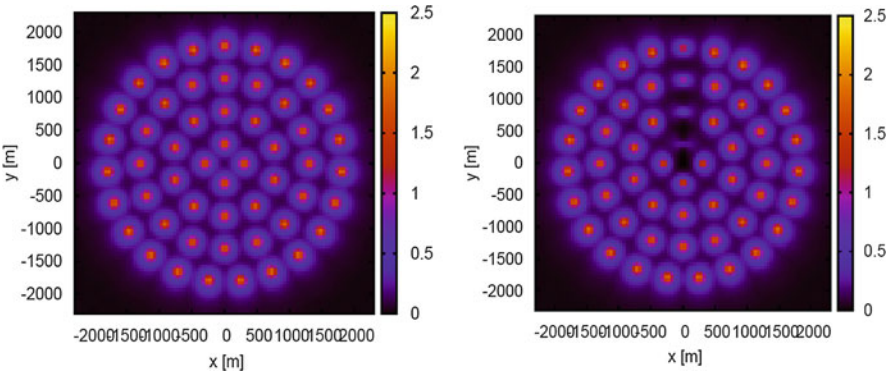

Fig. 7 Impact of FSS uplink transmission on the coverage of a mm-wave 5G network in the worse-case co-channel sharing of 28 GHz spectrum. Coverage maps are shown in the absence (left panel) and presence (right panel) of a FSS's highly directional transmitter positioned at the center of the area

sharing between 5G and FSS due to adjacent channel interference. Several cognitive techniques can be applied to mitigate and improve the 5G-FSS coexistence.

The coexistence between FSSs and mobile cellular BSs in the mm-wave bands has been the subject of only few, and mainly theoretical, studies. Important new parameters that need to be considered are how the interference levels could be reduced by exploiting multiple antenna configurations by 5G mm-wave systems as well as investigating the aggregate interference resulting from massive deployment of 5G systems on uplink FSS. The studies in [7, 8], performed in the worse-case scenario of co-channel sharing, have indicated that due to the use of a beamforming technology, combined with the relatively short range of communications in mm-wave frequencies, spatial sharing is much more feasible than in the case of IMT-advanced systems. In particular, even in this worse-case scenario, the required protection distance around FSS is much smaller (~1 km as opposed to hundreds of km) than those recommended previously. Furthermore, by using coordination among multiple 5G BS, further gains in spectrum sharing can be achieved. These studies also indicate that the presence of highly directional FSS transmission can cause outage in the coverage of 5G mm-wave network. However, due to the highly directional FSS transmission, the outage region is well-confined, and its impact could be mitigated using a combination of null forming at 5G UEs and cooperation by multiple BS to boast signal strengths at the victim UE (Fig. 7).

Sharing Between Access and Backhaul (Fixed) Links

The 26 GHz frequency range is used in many countries for 4G backhaul links, also known as fixed links (FL). Therefore it is of prominent importance to investigate the compatibility of using the 24.25–27.5 GHz for 5G access. A recent study of coexistence between FL and 5G access links has been performed by Ofcom [ofcom]. The study considered the deployment of 5G mm-wave base stations (BS) in London

overlaid on the existing FS deployment. It was assumed that, to avoid harmful interference to FS links, 5G BS can only operate if they are outside the denial area of FS links. Denial areas where assumed to be circular and were derived from interference analysis of a single 5G BS on a single FS link (Fig. 8).

The analysis shows that, in the non-LoS case, 5G BS would not be able to be rolled out within 0.5 km of a typical FL without a 20% probability of causing unacceptable levels of interference in all directions. This probability significantly increases in the pointing direction of the FL, while the distance at which a 20% probability of causing unacceptable levels of interference increases to 1.2 km. Therefore, to ensure that unacceptable interference was not caused to this incumbent FL, this area would have to be denied to IMT-2020 BSs. In fact, dependent on the requirements of the incumbent FL and what probability of interference they were willing to accept, this denial area may need to be significantly larger.

Figure 9 shows what impact this denial area would have on a mobile operator wanting to deploy 5G BSs in an urban conurbation, provided they were willing to ensure that their 5G BS did not have LoS to any FL. In this figure a denial area of 1.2 km is placed over all FLs in London which overlap with the block of 400 MHz of spectrum from 24.5 to 24.9 GHz (shown in red).

Sharing Unlicensed mm-Wave Spectrum

A recent trend in cellular communication is to utilize both the licensed and unlicensed spectrum simultaneously for extending available system bandwidth. In this context, LTE in unlicensed spectrum, referred to as LTE-U, is proposed to enable mobile operators to off-load data traffic onto unlicensed frequencies more efficiently and effectively and provides high performance and seamless user experience. Integration of unlicensed bands is also considered as one of the key enablers for 5G cellular systems. However, unlike the typical operation in licensed bands, where operating base stations (BS) have exclusive access to spectrum and therefore are able to coordinate by exchanging of signalling to mitigate mutual interference, such a multi-standard and multi-operator spectrum-sharing scenario (as shown in Fig. 4), this imposes significant challenges on coexistence in terms of interference mitigation. Licensed Assisted Access (LAA) with listen-before-talk (LBT) protocol has been proposed for the current coexistence mechanism of LTE-U. In case of mm-wave unlicensed sharing, a major issue is that the use of highly directional antennas as one of the key enablers for 5G networks becomes problematic for the current coexistence mechanisms where omnidirectional antennas were mostly assumed. For example, as shown in Fig. 10, transmission by a different nearby 5G BS or WiGig access point (AP) may not be detected due to the narrow beam that has been used, resulting in "beam collision" which can cause even more excessive interference than in conventional systems (Fig. 10).

We note that such beam-collision interference scenarios can also occur in exclusively used mm-wave spectrum as well. However in such scenarios, centralized resource allocation algorithms from 4G can be extended to include beam scheduling among multiple base stations to avoid such excessive interference scenarios. In the case of unlicensed sharing of mm-wave spectrum, centralized coordination is

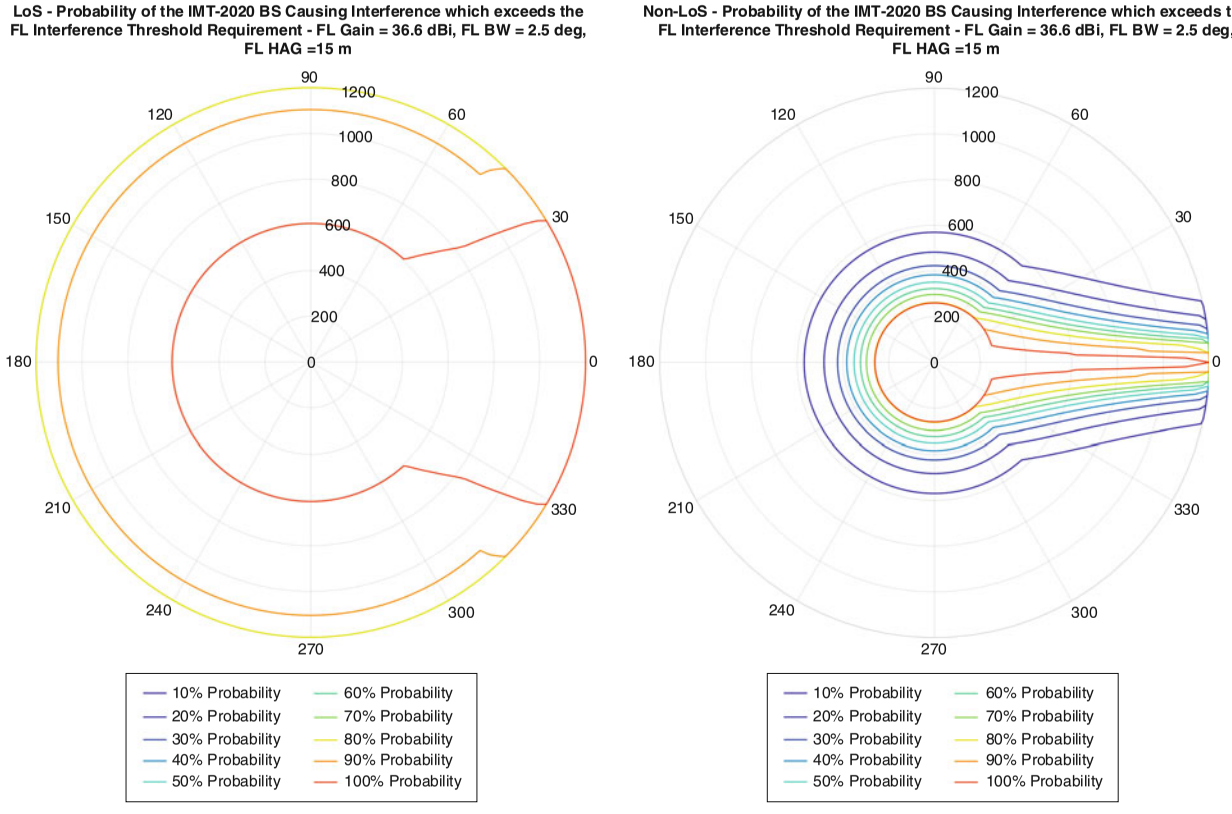

Fig. 8 Contour plots showing the probability of a 5G base station causing harmful interference to a fixed link operating in 26 GHz assuming line-of-sight (left panel) and non-line-of-sight (right panel) results [11]

Fig. 9 Denial area within 1.2 km of all backhaul links in London operating in the 24.9 GHz [11]

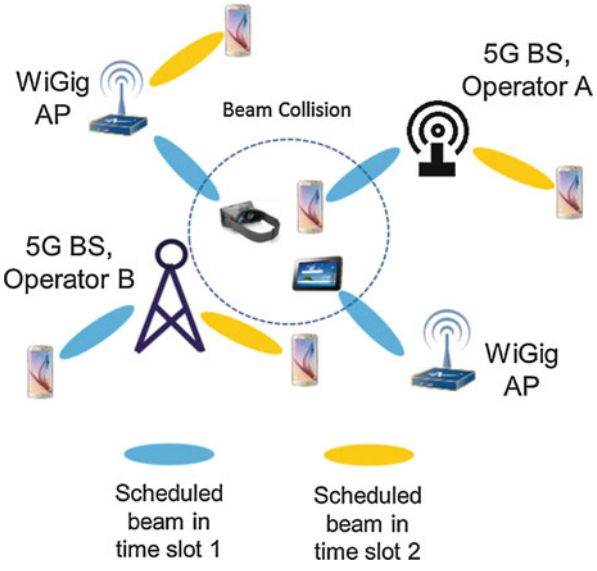

Fig. 10 Multi-standard and multi-operator sharing of unlicensed mm-wave bands in future 5G systems, showing also a beam-collision interference scenario [9]

not possible, and novel mechanisms need to be developed. Work in this direction has only recently being started as part of a new study item in 3GPP 5G-NR which is expected to be completed in 2018 [10]. Various mechanisms for sharing are being proposed, including distributed and self-organized mechanism for beam coordination [9], and approaches based on spectrum pooling [13].

Conclusion

With industry standards for 5G cellular systems rapidly progressing and firming up, issues and challenges related to future sharing and coexistence of spectrum are starting to take a center stage. Furthermore, there is a strong desire from governments and regulators for efficient allocation and use of 5G spectrum. Therefore, given the maturity of technologies such as LSA, LLA, cognitive radio, and mm-wave communications, we can expect that spectrum sharing will be a very prominent area for innovation, standardization, and spectrum regulation in the next few years. Finally beyond 5G mm-wave frequencies, the World Radio Congress in 2019 is expected to consider new spectrum beyond 300 GHz [14], where new opportunities for spectrum sharing can be expected.

Abstract

Cognitive radio (CR) integrates results from software-defined radio (SDR), machine learning (ML), and neuroscience for smart radio transmission devices. SDR enables devices to be digitally and dynamically configured in online applications; methodologies and techniques developed to introduce self-awareness in existing systems can be based on ML. Specifically, CR can adaptively regulate its internal parameters in response to the changes in the surrounding environment. New physical layer security issues are also emerging, for example, smart jamming attacks aim to reduce the quality of service or to disrupt legitimate communications. In this context, the electromagnetic spectrum represents the environment, while signals inside it are the individual entities. A CR-to-spectrum interaction consists of a dynamic process that can be driven by a CR device. Learning dynamic and measurement models from spectrum data is the main objective in CR applications.

To learn a model, statistical signal processing techniques can be used. Such models can be considered as parametric Bayesian filters that allow a CR to estimate current state of observed entities (including CR itself) and to predict their actions in the near future. Adaptive hierarchical Bayesian filters able to cover nonstationary entity behaviors can be described through probabilistic graphical models (PGM). *Interacting entities* can be modelled by coupling multiple PGMs related to different entities.

In this chapter, state-of-the-art on representation and learning of dynamic models for physical layer security is introduced along with some future directions. An experimental framework is then presented with two currently investigated applications: *Spectrum Intelligence* and *TV White Spaces (TVWS)*.

Introduction

An *Interactive and Cognitive Environment (ICE)* [17] can be defined as a physical environment with artificially extended capabilities obtained through digital artificial cognition based on information and communication technologies (ICT). An ICE

requires the capability to understand and to actively modulate human-machine interactions by learning from experiences.

A CR device can be seen as an actor of an ICE. In particular, the physical nature of the appropriate environment for a CR is the electromagnetic (EM) spectrum. Considering that, since a CR is equipped with antennas to send signals on the spectrum as well as to sense the frequency content in the same spectrum, it can perform a cognitive cycle and, consequently, becomes progressively smarter provided that it can learn models from experiences that associate the signal that the CR can sense to signals it can send. In other words, the CR becomes smarter if it can learn models that are able to adapt the cognitive cycles applied to maintain a dynamic equilibrium with the external environment. Recent advances in both SDR and ML can make this possible. SDR is a paradigm which enables a full software implementation of radio devices making them general purpose and dynamically reconfigurable devices (even in online applications). This means that internal parameters can be regulated and controlled by software according to some internal and/or external state. Implementation of real-time adaptive systems is then feasible. By employing ML, a paradigm is available consisting of methodologies and techniques developed to translate big amounts of sensed data into classification and generative models that can be used to detect and predict situations. Self-awareness can be introduced in existing systems (such as radar, robots, and wireless equipments) that can enable radios to become more adaptive, cognitive, and interactive. The success encountered in this field has resulted in innovative techniques in radio communications like *dynamic spectrum access* (DSA) which enables opportunistic transmission on shared spectrum and *defense against jamming attacks* to address the physical layer (PHY-layer) security problem. *Spectrum Intelligence (SI)* and *TVWS* are two current applications of Interactive and Cognitive devices as described in this chapter.

Since the environment is assumed to be dynamic, *time information* is a decisive factor when analyzing and processing signals. To this end, *time-frequency analysis* is the tool which retains both frequency and time information of signals, namely, not only where signals are inside the spectrum of interest but also when they are in specific bands that represent the contextual spectrum environment. Specifically, dynamic features can be extracted from the two-dimensional representations (such as bandwidth, central frequency, transmitting power, and shape) of each signal. These features constitute a way to indirectly observe the state (hidden or non-observable) in the dynamical model for each entity. The spectrum of interest is the dynamic environment, while signals inside it represent the observations by which the hidden state of the entities can be measured. Once the problem is described, signal representation is the framework which enables entities and interactions modelling. There are several techniques to perform signal representation, namely, modelling entities in the specific environment. Basically, dynamic systems are used in which the state is observed through noisy measurements. They consist of both a *dynamic model* of the state and a *measurement model*. Transition probabilities of the state refer to the probabilities of changing from an initial state to a new state. In an

ICE scenario, single entities are described by stand-alone models, while interacting (multiple) entities are described by linked coupled models.

In this chapter, different features and signal representations are presented along with probabilistic models. This is necessary to go through the learning process in order to estimate and predict state and transitions for each single entity as well as interactions for multiple interacting entities.

The remainder of the chapter is organized as follows: firstly, PHY-layer security is introduced in section "PHY-Layer Security" with particular emphasis to jamming attacks and intelligent jammers. Afterwards, in section "Dynamic Signal Representation" different representations for dynamic signals are described from conventional features, including time-frequency representation, to probabilistic graphical models to represent single entity state and interacting entities situation assessment. Learning dynamic Bayesian representations is then presented in detail in section "Learning Dynamic Bayesian Representations" including techniques in the state-of-the-art employed to learn dynamic models for both single and interacting entities. To this end, several current techniques and algorithms, with some probable future work, are discussed in this context. Subsequently, *Spectrum Intelligence* and *TV White Spaces*, two currently investigated applications, are included in the experimental framework in section "Experimental Framework and Results", and some preliminary results are shown. A discussion about cognitive dynamic jamming can be found in section "A Discussion of Application Directions of ML Techniques to Cognitive Dynamic Jamming". Finally, some future directions are introduced in the conclusion of the chapter.

PHY-Layer Security

Signals can be transmitted in the shared spectrum with different objectives which means that legitimate users occupy the spectrum in a licit way complying with the security requirements and avoiding interference to other users, while malicious signals are transmitted to produce interference or disrupt legitimate communications. Indeed, radio communications in wireless environments introduce security issues due to external attacks from malicious devices. In particular, the PHY-layer is extremely vulnerable to *jamming attacks*. A malicious node in wireless networks can readily generate intentional interference for disrupting the data communications between legitimate users, which is referred to as a jamming attack (also known as denial of service – DoS – attack) [48]. In addition, the jammer may prevent authorized users from accessing wireless network resources by, for example, continuously transmitting a signal over a shared wireless channel so that legitimate nodes always find the channel busy and keep deferring their data transmissions. This impairs the network availability for the legitimate users.

Due to the recent developments in SDR and ML, both legitimate users and smart (or intelligent) jammers can quickly learn the transmission parameters of the other users in the spectrum of interest and adaptively adjust its transmission parameters to maximize the utility function and the damaging effect, respectively [47].

Recently, in addition to *SI* and *TVWS* discussed in the experimental framework of this chapter, substantial efforts have also been devoted to the research and development of the fifth-generation (5G) mobile systems. Indeed, strict security requirement is desired for the 5G systems, since more and more sensitive information will be transmitted wirelessly. To this end, physical layer security will be a beneficial complement to conventional security mechanisms [48].

In this context, *spectrum sensing (SS)* is the fundamental method which provides radio devices with information about the wireless spectrum in the surrounding environment in which signals with different characteristics, such as different modulation schemes, different communication standards, or different objectives, are transmitted taking into account spectrum sharing techniques. In literature, various SS techniques have been proposed for CRs, such as energy detection [9], matched filtering detection [46], cyclostationary feature detection (CFD) [34], and wavelet transform [42].

Dynamic Signal Representation

The first step toward learning dynamic models is signal representation through feature-based, graphical, and probabilistic methods. This is a decisive step because the performance of the learning process is strongly influenced by the chosen signal representation. Consequently, features representing the signal of interest, the corresponding model, and the necessary parameters should be selected carefully since a sensible choice of them may produce better learning accuracy.

Features are extracted from the signal and represented in the corresponding feature space. Some of the extracted features can provide information about the state variable of the entity whose state needs to be dynamically estimated. They could be, e.g., central frequency, bandwidth, transmitting power, shape, and other more complex entity state descriptors (of analog and digital modulated signals) as presented in this section.

Consequently, probabilistic representation of random variables related to the signal as random process can be obtained by using the extracted features. Specifically, dynamic models (which include the state variable and its noisy observations) are described by PGMs such as DBNs from Bayesian theory.

In this section, after discussing conventional features and algorithms to extract them, time-frequency analysis is introduced, and then, probabilistic models corresponding to both single and interacting entities are discussed.

Conventional Features and Detectors

In the CR framework, there are many SS schemes such as energy detector, matched filter detector, cyclostationary feature detector, and wavelet-based SS.

– *Energy detector (ED)*: this process formally corresponds to solving the decision problem between the following two hypotheses [12]:

$$Z(n) = \begin{cases} \eta(n), & H_0 \\ S(n) + \eta(n), & H_1 \end{cases}; \quad n = 1, ..., N_S \tag{1}$$

where $Z(n)$, $S(n)$, and $\eta(n)$ are the received signal, the transmitted signal, and the noise samples, respectively. H_0 is the *null hypothesis* corresponding to the absence of the signal (in this case, received signal consists of only noise), and H_1 is the *alternative hypothesis* corresponding to the presence of the signal, while N_S is the number of samples acquired during the sampling process.

Finding the appropriate threshold is the principal challenge of any energy detection scheme. The most common approaches are the constant detection rate (CDR) and constant false alarm rate (CFAR) detectors. Energy detection is easy to implement and does not require prior signal parameters, but its performances are highly dependent on noise levels and interference.

– *Matched filter detector (MFD)*: the received signal is convolved with a conjugated time-reverse version of the transmitted signal and then compared with a particular threshold level to recover the transmitted signal without any error. MFD is the optimal linear filter for maximizing the signal-to-noise ratio (SNR) in the presence of additive stochastic noise. Although in general this requires a non-flat frequency response, the associated distortion is not significant in situations such as radar and digital communications, where the original waveform is known and the objective is to detect the presence of this signal against the background noise.

The main advantage of the matched filter detector is that it achieves both high processing gain due to coherency and good robustness to noise uncertainty with moderate computational complexity. On the other hand, it requires a priori knowledge of the primary user signal such as the modulation type and order, the pulse shape, and the packet format. If this information is not accurate, the matched filter performs poorly [28]. In addition, matched filtering detector requires a dedicated receiver structure which may not be possible in a practical CR terminal.

– *Cyclostationary feature detector (CFD)*: it exploits the cyclostationarity of modulated signals by detecting spectral peaks in spectral correlation function (SCF) [34]. Major advantage of CFD-based detector lies on its abilities to perform better than energy detector at low signal-to-noise ratio (SNR) values and to distinguish different modulated signals. Furthermore, the cyclic spectral analysis has been used as a robust tool for signal classification when the carrier frequency and bandwidth information is unavailable. This performance is achieved at the cost of increased implementation complexity.

A process $x(t)$ is said to be wide-sense cyclostationary with period T_0 if its mean $E[x(t)] = \mu_x(t)$ and autocorrelation $E[x(t)x^*(t+\tau)] = R_x(t,\tau)$ are both periodic with period T_0; in such case, they can be defined, respectively, as $\mu_x(t+T_0) = \mu_x(t)$ and $R_x(t+T_0,\tau) = R_x(t,\tau)$. The major benefit of spectral correlation is its insensitivity to background noise. Furthermore, different types of modulated signals (BPSK, AM, FSK, MSK, QAM, PAM) with overlapping power spectral densities have highly distinct SCFs.

– *Wavelet-based detector*: wavelet transform (WT) is employed to characterize singularities and edges exhibited in the local singular structure of the PSD of a wideband signal $r(t)$, denoted by $S_r(f)$ in frequency. Edges in the spectrum correspond to the locations of frequency discontinuities $\{f_i\}_{i=1}^{N-1}$ to be identified.

WT provides good precision to detect the occupied spectrum and to identify and locate spectrum holes in the signal spectrum even for faded signals [42].

Formally, $\Psi(f)$ is a wavelet smoothing function with a compact support, m vanishing moments, and m times continuously differentiable. Widely used examples for $\Psi(f)$ include the Gaussian function and the perfect reconstruction filter bank (PRFB). The dilation of $\Psi(f)$ by a scale factor s is given by

$$\Psi_s(f) = \frac{1}{s}\Psi\left(\frac{f}{s}\right) \tag{2}$$

where s takes values from powers of 2, i.e., $s = 2^j$, $j = 1, 2, \cdots, J$. Letting $*$ denote convolution, the continuous wavelet transform (CWT) of $S_r(f)$ is given by $\mathscr{W}_s S_r(f) = S_r * \Psi_s(f)$. It has been shown that the local extrema of the first derivative and the zero-crossings of the second derivative characterize the signal irregularities.

The first-order and second-order derivatives of $S_r(f)$ smoothed by the scaled wavelet $\Psi_s(f)$ are derived in [42].

Time-Frequency Analysis and Features

The capability of describing the frequency content of a signal is a critical objective in diverse fields of science. Although the conventional Fourier transform (FT) is an extremely important signal and image analysis tool, it assumes that a signal is stationary, i.e., that the frequency content is constant at all times in a signal or at all locations in an image. However, in real applications like speech processing, geology, astronomy, or medicine, signals are nonstationary and frequency changes over time or space [5]. Consequently a series of techniques have been developed which analyze dynamic signals and extract time information about their spectral content by representing a signal as a function of both time and frequency. These methodologies are the foundation of time-frequency analysis, and the corresponding signal representations are commonly referred to as time-frequency distributions (TFDs). Cohen showed that these distributions are related to each other and provided a generalized equation for (TFDs) in [10].

Since TF operates in two-dimensional space, both time and frequency resolutions have to be considered, and such resolutions depend on the window choice. Time and frequency resolutions cannot be improved simultaneously: when the frequency resolution increases, the time resolution decreases, as a consequence of the time-frequency uncertainty principle [33]. Several TF approaches are here described.

– *Short-time Fourier transform (STFT)*: it is the most basic form of linear time-frequency transform [1] and defined as follows:

$$STFT\,(t,\omega) = \int x\,(\tau)\,h\,(\tau - t)\,e^{-j\omega\tau}d\,\tau \tag{3}$$

where $x\,(t)$ is the signal to be analyzed and $h\,(t)$ is the window function which is a symmetric function and is utilized to select a certain time interval of the signal. Changes in frequency over time are captured by sliding the window function to provide time localization. Due to the aforementioned time-frequency uncertainty principle, high frequency resolution is obtained with the window function as long as possible, which contradicts the time domain resolution. The commonly used window functions include rectangular window, triangular window, Hanning window, Hamming window, and Gauss window (in Gabor transform).

The discrete version of the STFT distribution can be found in [26]:

$$X\,(n,k) = \sum_{m=-\infty}^{+\infty} x\,[m]\,w\,[n-m]\exp^{-j2\pi km/N}\,R_N\,[k] \tag{4}$$

where $R_N\,[k] = u\,(k) - u\,(k - N + 1)$.

– *Wigner-Ville Transform (WVT)*: another fundamental distribution in the TF analysis is the Wigner-Ville distribution [3]. It is defined as the Fourier transform of the bilinear product (indeed, unlike linear time-frequency transform, the signal appears twice in bilinear time-frequency transform):

$$WVT\,(t,\omega) = \int x\left(t + \frac{\tau}{2}\right)x^*\left(t - \frac{\tau}{2}\right)e^{-j\omega\tau}d\,\tau \tag{5}$$

where $x^*\,(t)$ is the conjugate of the signal $x\,(t)$.

Even though this distribution provides improved resolution over a single-window spectrogram, it suffers from cross-terms due to its bilinear nature which can clutter the corresponding TF signature [27]. Indeed, for multicomponent signals, cross-terms are introduced, and the SNR is reduced. The more the multicomponents are, the more the cross-terms are generated. To reduce the cross-terms, the Cohen distribution introduced a kernel function $g\,(\theta,\tau)$ to perform as a two-dimensional low-pass filter. There are many kernel functions, including Born-Jordan, Choi-Williams, etc.

The discrete WVD of the time series $x\,(n)$ is given by:

$$DWVT\,(n,k) = \sum_{m=0}^{N-1} x\,(n+m)\,x^*\,(n-m)\,e^{-j2\pi mk/N} \tag{6}$$

where n and m are time indexes, while k denotes the frequency index, and N is the number of samples in the discrete time series.

– *Wavelet transform (WT)*: it improves on the STFT by introducing the concept of progressive resolution [14]. Transforms that incorporate progressive resolution are known to provide better, more consistent time-frequency representations across

the entire spectrum. The WT provides the equivalent of finer time resolution at high frequencies and finer frequency resolution at low frequencies. However, the WT does not measure frequency but only an analogue, called scale. Additionally, the WT provides either no phase information or phase measurements which are all relative to different local references. This is in contrast to the conventional concept of phase, as provided by the FT, where all phase measurements are relative to a global reference.

Wavelet is a waveform function $\Psi(t)$ with limited support in time and zero average which indicates that it is an oscillating function. Wavelets are not periodic and may have discontinuous derivatives; signals with rapid changes are analyzed better with the nonperiodic wavelets. The WT is defined as the projection of the time signal $f(t)$ onto a set of functions $\Psi_{s,d}(t)$ (daughter wavelets) obtained by translating and scaling the original wavelet $\Psi(t)$ (mother wavelet). They determined as:

$$\Psi_{s,d}(t) = \frac{1}{\sqrt{s}}\Psi\left(\frac{t-d}{s}\right) \tag{7}$$

where s is the positive adimensional scale parameter and d is the delay. The scale parameter stretches or compresses the mother wavelet and is connected to the frequency (low scale gives compressed wavelet and thus it can better analyze rapidly changing features which means high frequency components of a signal and vice versa). The delay parameter shifts the wavelet along the time axis and is connected to the time. Both parameters vary continuously. The WT of the signal is then:

$$W^f(s,d) = \int_{-\infty}^{+\infty} f(t)\,\Psi^*_{s,d}(t)\,dt = \int_{-\infty}^{+\infty} f(t)\,\frac{1}{\sqrt{s}}\Psi^*_{s,d}\left(\frac{t-d}{s}\right)dt \tag{8}$$

where wavelet coefficients $W^f(s,d)$ are functions of scale and delay. The basis of WT is not unique and should be chosen according to the characteristics of the signal. Time and frequency resolutions depend on the wavelet choice. There are a number of mother wavelets that can be used for analysis such as Gabor mother wavelet which has the best time-frequency resolution.

The discrete version of the wavelet transform can be found in [18].

– *Stockwell transform (ST)*: developed by Stockwell et al. [40] and based on a sliding Gaussian window distribution. It exhibits globally referenced phase and frequency measurements similar to those of the STFT, as well as the progressive resolution of the WT. This combination of desirable features makes ST particularly suitable in several fields, such as biomedical signal and image analysis applications, and has shown promise in one of the most recent applications which has been employing the ST extensively, namely, the automatic modulation recognition (AMR) [39], although the computational demands of the ST, due to redundant representation of time-frequency, in some cases limit its utility and prevent more widespread usage.

The ST of a nonstationary time signal is defined as

$$S(\tau, v) = \int_{-\infty}^{+\infty} g(t) \frac{|v|}{\sqrt{2\pi}} e^{-\frac{(\tau-t)^2 v^2}{2}} e^{-i2\pi vt} dt \tag{9}$$

where τ and v are the transform time and frequency coordinates. This equation has the same form as that of the FT but adds a normalized-area Gaussian window for time localization. The center of the window is τ, and the variance of the window is $1/v^2$; consequently the width of the window decreases with increasing frequency. This automatically adjusts the ST window to provide progressive resolution.

The ST of a discrete time series $r[p]$ is given by [2]:

$$S_T[m,n] = \sum_{p=0}^{P-1} r[p] \frac{|n|}{\sqrt{2\pi} kN} e^{-\left(n^2(m-p)^2/2k^2N^2 + j2\pi pn/N\right)} \tag{10}$$

when $m = 0, \cdots, M-1$; $n = 1, \cdots, N-1$; and by

$$S_T[m,0] = \frac{1}{P} \sum_{p=0}^{P-1} r[p] \tag{11}$$

when $n = 0$; m is the time delay of the sliding window, n denotes the index of frequency range, p denotes the time index, and k is a scaling factor that controls the time-frequency resolution. When k increases, the frequency resolution increases, with a corresponding loss of time resolution.

– *Hilbert-Huang transform (HHT)*: a multicomponent nonstationary signal is decomposed by using the empirical mode decomposition (EMD) technique [25], and then, the Hilbert transform (HT) is applied to the obtained components known as intrinsic mode functions (IMFs). Although the decomposition is adaptive and therefore highly efficient, IMFs suffer from mode mixing issue that result in an improper time-frequency representation.

From time-frequency analysis described in this section, features for each signal such as the central frequency, bandwidth, and transmitting power can be extracted and used as input dataset for the learning step to estimate model parameters for each signal, transition probability, and interaction as discussed in section "A Discussion of Application Directions of ML Techniques to Cognitive Dynamic Jamming".

Single Entity State

To represent the state of each entity, *probabilistic graphical models (PGMs)* provide a graph-based representation as in [30]. The main idea is to encode complex distributions over high-dimensional spaces where causality links are defined among model components. In the basic graphical representation depicted in Fig. 1a, random variables of the system model such as state and observables are represented by

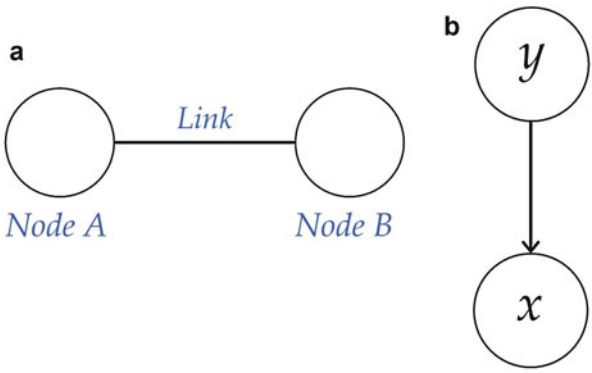

Fig. 1 (**a**) Basic probabilistic graphical model structure consisting of two nodes connected through a link, (**b**) graphical representation of the conditional probability $f_{\mathbf{X}|\mathbf{Y}}(\mathbf{x}|\mathbf{y})$

nodes, while edges (or links) express direct probabilistic relationships between them. Temporal dependencies among nodes can also be represented (often by horizontal edges) as can be seen later in this section. Furthermore, graphical models also introduce a compact representation for independencies among variables in the distribution described by corresponding graph. Considering that, probability distribution functions (PDFs) are often in the form of some parametric functions; the probabilistic relationship described by $p(\mathbf{x}|\mathbf{y}) = f(\mathbf{x}, \mathbf{y}, \theta)$ is represented as in Fig. 1b where $\mathbf{x}$ could be the state (hidden variable) of a dynamic system, $\mathbf{y}$ the corresponding observable, and θ the unknown parameter.

PGMs provide a statistical framework to model interactions and cause-effect relationships like in interaction analysis and enable formalizing and handling the uncertainties. The basic idea is to provide a graphical tool to decompose a multivariate probability distribution into a factored form by providing an intuitive and manageable visual description.

– *Dynamic Bayesian Networks (DBNs)* are based on Bayesian network (BN) approach which is a graph model describing the statistical relationships among a group of n random variables $\mathbf{X} = \{X_i\}_{i=1,2,\ldots,n}$. A BN is determined by its graph structure G and distribution parameter Θ. A variable X_i is independent of its non-descendants given all its parents $Pa(X_i)$ in G. Therefore, the joint probability distribution over $\mathbf{X}$ can be decomposed by:

$$Pr(\mathbf{X}) = \prod_{i=1}^{n} Pr(X_i | Pa(X_i)). \tag{12}$$

The parameter set $\Theta = \{\theta_i\}_{i=1,2,\cdots,n}$ specifies the parameters of each conditional distribution in (12). A Dynamic Bayesian Network (DBN) is the extension of a BN to model temporal processes. In DBN, a set of random processes is represented by the $\mathbf{X}(k) = \{X_i(k)\}_{i=1,2,\cdots,n}$, and $X_i(k)$ is the random variable of process at discrete time k. The network structure G now defines the dependency among variables over a period of time as well as those within the same time epoch. Assuming Markovian and causal processes, a node in graph G is only linked from the other nodes in the same or previous epoch [31]. Thus

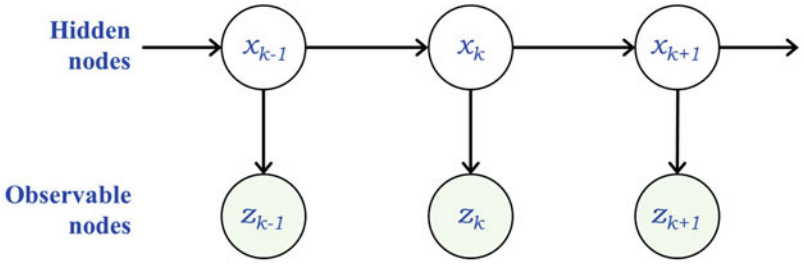

Fig. 2 Hidden Markov Model representation: **x**'s is latent variables, and **z**'s is the observable variables, while the horizontal arrows describe temporal dependencies

$$Pr\left(\mathbf{X}\left(k+1\right)|\mathbf{X}\left(0:k\right)\right) = Pr\left(\mathbf{X}\left(k+1\right)|\mathbf{X}\left(k\right)\right), \quad k = 0, 1, 2, ... \tag{13}$$

Several basic dynamic models which can be represented by DBNs are now introduced.

– a *Hidden Markov Model (HMM)* is a tool for representing probability distributions over sequences of observations and is in fact a special case of the more general DBNs [22]. In Markov models, the state is directly visible to the observer, and therefore, the state transition probabilities are the only parameters to be considered, whereas, in a HMM, the state is not directly visible, but only outputs, dependent on the state, are visible.

The HMM assumes that the observation at time k was generated by some process whose state $\mathbf{x}_k$ is hidden from the observer. It also assumes that the state of this hidden process satisfies the Markov property, which is, given the value of $\mathbf{x}_{k-1}$, the current state $\mathbf{x}_k$ is independent of all the states prior to $k-1$. Graphically we can explain it as shown in Fig. 2. The graph shows the dependencies between the variable of the model. $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \cdots, \mathbf{x}_k\}$ is a sequence of unobservable states and $\mathbf{Z} = \{\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3, \cdots, \mathbf{z}_k\}$ is a sequence of observable emissions. Considering that the probability of being in a particular state at step i is known once the state at step $i-1$ is known and that the probability of seeing a particular emission at step i is known once the state step i is known, the joint distribution of a sequence of states and observations can be factored in the following way:

$$P\left(\mathbf{x}_{1:k}, \mathbf{z}_{1:k}\right) = P\left(\mathbf{x}_1\right) P\left(\mathbf{z}_1|\mathbf{x}_1\right) \prod_{i=2}^{k} P\left(\mathbf{x}_i|\mathbf{x}_{i-1}\right) P\left(\mathbf{z}_i|\mathbf{x}_i\right) \tag{14}$$

– a *Switching linear dynamical system (SLDS)* is defined in [20] by:

$$\begin{cases} \mathbf{x}_k = \mathbf{A}^{(a_k)}\mathbf{x}_{k-1} + \mathbf{v}_k^{(a_k)} \\ \mathbf{z}_k = \mathbf{C}\mathbf{x}_k + \mathbf{w}_k \end{cases} \tag{15}$$

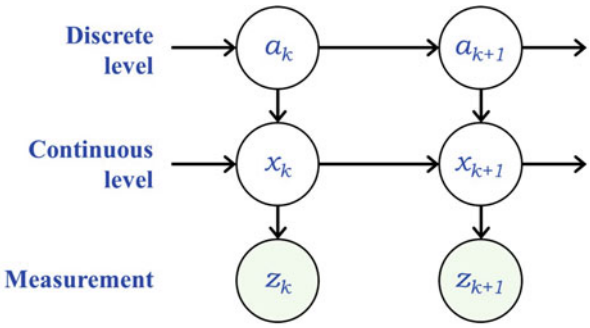

Fig. 3 A SLDS representation in which ¸'s are the categorical variables

with $a_k|a_{k-1} \sim \pi_{a_{k-1}}$. a_k belongs to a set $S \triangleq \{1, 2, \cdots, s\}$ consisting of a finite number of modes (i.e., categorical variable). When a discrete first-order Markov chain a_k with transition probabilities $\{\pi_{ij}\}$, $i, j \in S$, indexes the mode-specific linear dynamic system at time index k driven by Gaussian noise $\mathbf{v}_k^{(a_k)} \sim \mathcal{N}\left(0, \Sigma^{(a_k)}\right)$, it is called Jump Markov Linear System (JMLS). A JMLS can be seen as an extension of the (HMM), which has the same mode evolution, but conditionally independent observations. The corresponding probabilistic graphical representation is shown in Fig. 3. *Rao-Blackwellized particle filter* is an example of a commonly used filter associated with a switching model.

In general, the filtering process is performed to filter (estimate) and predict variables belonging to the dynamic models including nodes and links. Common filters also include:

– *Kalman filter* provides optimal finite-dimensional algorithm for recursive Bayesian state estimation in linear-Gaussian cases. A linear dynamic system is described by the following state-space equations:

$$\mathbf{x}_k = \mathbf{F}_{k-1}\mathbf{x}_{k-1} + \mathbf{n}_{k-1} \tag{16}$$

$$\mathbf{z}_k = \mathbf{H}_k\mathbf{x}_k + \mathbf{w}_k \tag{17}$$

Equation (16) represents the *process model*, while Eq. (17) represents the *measurement model*. Kalman filter assumes that the posterior pdf $p(\mathbf{x}_k|\mathbf{z}_k)$ at every step is Gaussian and then it can be completely characterized by the mean and the covariance. These assumptions hold if $\mathbf{n}_{k-1}$ and $\mathbf{w}_k$ are drawn from Gaussian density, and the dynamic system is linear.

The matrices $\mathbf{F}_k$ and $\mathbf{H}_k$ define the linear functions in the dynamic system. Random sequences $\mathbf{n}_k$ and $\mathbf{w}_k$ are mutually independent zero-mean white Gaussian with covariance $\mathbf{Q}_k$ and $\mathbf{R}_k$, respectively. Mean and covariance predictions are given by:

$$\hat{\mathbf{x}}_{k|k-1} = \mathbf{F}_{k-1}\hat{\mathbf{x}}_{k-1|k-1} \tag{18}$$

$$\mathbf{P}_{k|k-1} = \mathbf{Q}_{k-1} + \mathbf{F}_{k-1}\mathbf{P}_{k-1|k-1}\mathbf{F}_{k-1}^T \tag{19}$$

respectively. In the update process, the prediction is compared to the observation which results in the estimated mean and covariance are as follows:

$$\hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \mathbf{K}_k \left(\mathbf{z}_k - \mathbf{H}_k \hat{\mathbf{x}}_{k|k-1}\right) \tag{20}$$

$$\mathbf{P}_{k|k} = \mathbf{P}_{k|k-1} - \mathbf{K}_k \mathbf{S}_k \mathbf{K}_k^T = \left[\mathbf{I} - \mathbf{K}_k \mathbf{H}_k\right] \mathbf{P}_{k|k-1} \tag{21}$$

where $\mathbf{z}_k - \mathbf{H}_k \hat{\mathbf{x}}_{k|k-1}$ is called innovation and denoted as $\mathbf{v}_k$, $\mathbf{S}_k$ is its covariance, and $\mathbf{K}_k$ is the Kalman gain. In presence of high Kalman gain, i.e., when the $\mathbf{P}_{k|k-1}$ is large or the $\mathbf{S}_k$ is small, the innovation is considered as reliable. A large Kalman gain value occurs when the prediction is not consistent and/or the innovation is trustworthy, and it implies that the estimate $\mathbf{x}_{k|k}$ relies more on the innovation than on prediction.

– the *Extended Kalman filter (EKF)* is a suboptimal solution of the Bayesian filtering problem for nonlinear systems with additive noise

$$\mathbf{x}_k = \mathbf{f}_{k-1}\left(\mathbf{x}_{k-1}\right) + \mathbf{n}_{k-1} \tag{22}$$

$$\mathbf{z}_k = \mathbf{h}_k\left(\mathbf{x}_k\right) + \mathbf{w}_k \tag{23}$$

The basic idea is to linearize the nonlinear functions by the first term in the Taylor series expansion. Prediction and innovation are computed using, respectively, nonlinear functions $\mathbf{f}_{k-1}$ and $\mathbf{h}_k$.

By substituting $\mathbf{f}_{k-1}$ and $\mathbf{h}_k$ with their local linearization (first-order Taylor approximation):

$$\hat{\mathbf{F}}_k = \left[\nabla_{\mathbf{x}_{k-1}} \mathbf{f}_k^T\left(\mathbf{x}_{k-1}\right)\right]^T \Big|_{\mathbf{x}_{k-1}=\hat{\mathbf{x}}_{k-1|k-1}} \tag{24}$$

$$\hat{\mathbf{H}}_k = \left[\nabla_{\mathbf{x}_k} \mathbf{h}_k^T\left(\mathbf{x}_k\right)\right]^T \Big|_{\mathbf{x}_k=\hat{\mathbf{x}}_{k|k-1}} \tag{25}$$

where

$$\nabla_{\mathbf{x}_k} = \left[\frac{d}{d\mathbf{x}_k\left[1\right]} \cdots \frac{d}{d\mathbf{x}_k\left[n_x\right]}\right]^T \tag{26}$$

and $\mathbf{x}_k\left[i\right]$ is the i-th component of the state vector, a linearized Kalman filter is obtained as in Eqs. (16), (17), (18), (19), (20), (21).

Unscented Kalman filter (UKF), cubature Kalman filter (CKF), and Gauss-Hermite Kalman filter (GHKF) are also variations of KF which handle the nonlinear Gaussian problem. Furthermore, nonlinear filtering also includes *particle filter and its variants*.

Interacting Entities Situation Assessment

The previous section investigated single entity representation through PGMs which well-capture dependencies of variables. More specifically, *temporal dependencies* (dynamics of the system) and *entity-to-entity dependencies* (interactions among objects) can be represented in graphical models.

To introduce entity-to-entity dependencies, interaction-oriented DBN structures can be employed with linked nodes belonging to different entities (interacting entities). Specifically, the DBN structure corresponding to a system consisting of two interacting objects described through a SLDS model (introduced in the previous section) is shown in Fig. 4.

Such kind of links defines the probability that a random variable of an entity influences (or is influenced by) one or more random variables of a different entity. Interactions may also happen among three or more objects; each of them can be represented through PGMs.

From neuroscience, cognition and interaction are two interrelated functionalities of biological systems. A *bio-inspired* approach is the main idea toward the concept of cognitive dynamic systems (CDSs) and the development of interactive

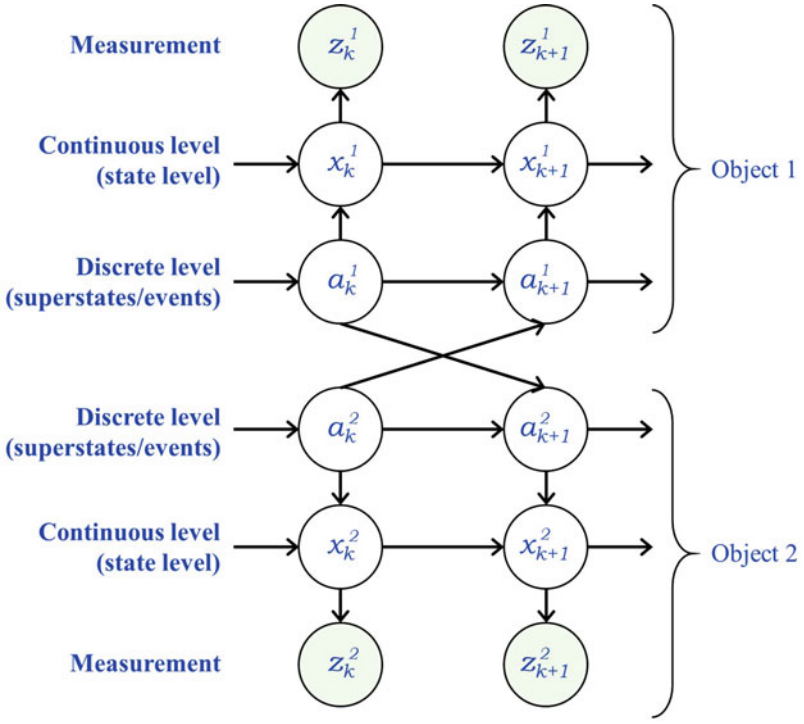

Fig. 4 Interaction-oriented SLDS structure with linked nodes belonging to two interacting objects

systems [17]. Dynamic systems take into account embodied and situated cognition by adaptively changing their state. The goal of dynamic systems is to maintain stability of the equilibrium between the object and the environment (i.e., maintenance of the proper level of security and/or safety). CDSs build up rules of behavior over time through learning from continuous experiential interactions with the environment and thereby deal with environmental uncertainties.

Specifically, a CDS can be described as a system whose design closely mimics the human brain and is motivated by human cognition. Cognitive reasoning is based on dynamical dispositional representations of the interactions between an object in contextual scenario and the changed organism state it causes [13]. Such dispositional representation of external objects with respect to a self-object is the key aspect of the knowledge embedded on bio-inspired CDSs. The capability of *learning from experience* and the idea of *autobiographical memory (AM)* are drawn from the bio-inspired approach of the interactions occurring between the system and the user. Indeed, this concept is based on neurophysiological observations of human brain structure for modelling and learning interactions between the user and the system and provides engineering implications in the development of context-aware learning and predicting strategies.

Self-awareness plays a key role in the development of *self-adaptation* techniques. In particular, self-adaptation based on self-awareness at the individual level means that one single entity receives inputs both from itself or some of its components and from the external environment and uses the input to adjust to the current conditions [32]. *Multiple entity adaptation* is then obtained by introducing the interaction of different self-adaptation techniques at the level of the single individual.

Learning Dynamic Bayesian Representations

Learning *dynamic models* can be considered a main objective in CR applications where the spectrum of interest hosts several signals whose parameters (such as central frequency, transmit power, modulation scheme, and so forth) may change across the measurement time. To this end, *learning from available data* (current and past data) should in perspective become a major approach used in this framework. Basically, in order to learn a model which describes a *single entity*, parameters are estimated and predicted by using statistical signal processing techniques and Bayesian filters. The cycle observation-update-prediction performs learning of parameters and dynamic models at successive time instants. In other words, when the system collects a new observation of the state, both the predicted transition probability of the state and the predicted measurements (obtained at the previous step) are updated with the new data, and their predictions for the subsequent time instant are also computed, as introduced in the KF description, for example. Again, when a new observation is collected, a new cycle observation-update-prediction is performed.

In this section, after introducing the basic concepts of learning, several techniques employed to learn causal conditioned probabilities, dynamic models, and

interactions are described along with some current work and probable future directions in the field of learning dynamic models.

Learning Vocabulary, State, and State Changes

A learning approach in a Bayesian framework starts with some a priori knowledge about both probabilistic distributions of the model structure (namely, edges in the graphical model) and the model parameters. A prior probability distributions over model structures and model parameters represent this initial knowledge which is then updated using the data to obtain the corresponding posterior probability distribution over models and parameters [21]. Denoting the prior distribution over model structures with $P(\mathbf{M})$, the priori distribution over parameters for each model structure with $P(\theta|\mathbf{M})$, and the dataset as $\mathbf{Y} = \{\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_t\}$, the posterior distribution over models can be obtained through Bayes rule as follows:

$$P(\mathbf{M}|\mathbf{Y}) = \frac{\int P(\mathbf{Y}|\theta, \mathbf{M})\, P(\theta|\mathbf{M})\, d\theta\, P(\mathbf{M})}{P(\mathbf{Y})} \tag{27}$$

which takes into account the uncertainty in the parameters. The posterior distribution over the parameters, for a given model structure, can be obtained through:

$$P(\theta|\mathbf{M}, \mathbf{Y}) = \frac{P(\mathbf{Y}|\theta, \mathbf{M})\, P(\theta|\mathbf{M})}{P(\mathbf{Y}|\mathbf{M})} \tag{28}$$

Now, based on available data and models, the next observation $\mathbf{y}_{t+1}$ can be computed by Bayesian prediction as:

$$P(\mathbf{y}_{t+1}|\mathbf{Y}) = \int P(\mathbf{y}_{t+1}|\theta, \mathbf{M}, \mathbf{Y})\, P(\theta|\mathbf{M}, \mathbf{Y})\, P(\mathbf{M}|\mathbf{Y})\, d\theta d\mathbf{M} \tag{29}$$

based on averages over both the uncertainty in the model structure and in the parameters. This is known as *predictive distribution* for each model.

Typically, the state-space model (SSM) of a *dynamic system* consists of three random processes, namely, *state model*, *process model* of the state of a signal (or entity) which describes the transition of the state, and *measurement model* which describes observations of the state:

$$\begin{aligned} \mathbf{x}_0 &\sim p_0(\mathbf{x}_0) \\ \mathbf{x}_t|\mathbf{x}_{t-1} &\sim p_f(\mathbf{x}_t|\mathbf{x}_{t-1}) \\ \mathbf{z}_t|\mathbf{x}_t &\sim p_g(\mathbf{z}_t|\mathbf{x}_t) \end{aligned} \tag{30}$$

where $\mathbf{x}_t$ and $\mathbf{z}_t$ are the state and measurement vectors at time t, p_0 is the initial state probability distribution function (PDF), p_f is a conditional probability

density function (CPDF) representing the dynamics of the state, and p_g is a CPDF representing the measurement process. Interaction-oriented models include linked dynamic systems, as described in the previous section, to represent *interacting entities* in an ICE scenario.

Changes in the state of a dynamic system, described by the corresponding transition probability, are referred to as *trajectories*. Each entity adopts a strategy inside the spectrum of interest, which defines its behavior. *Normal behavior* means that it is predictable because already observed, and consequently the implemented model is capable of obtaining accurate estimates (and predictions) of the parameters and model by using learned information gathered from past experience. When the hypothesized model does not produce the estimates (and predictions) accurately, the behavior is said to be *abnormal*. This happens when the strategy has not been observed in past experiences or from a security point of view, that behavior is different (or not allowed) from legitimate behavior.

Learning Causal Conditioned Distributions

Learning techniques can be classified in *supervised learning* based on labelled data, but it is always an expensive training algorithm and difficult to obtain, and *unsupervised learning* which does not need the labelled data making it a better training algorithm. On the other hand, *semi-supervised learning* is a class of ML techniques which is receiving increasing interest in the last decade. These techniques combine both labelled and unlabelled data items in their training process. Therefore, they are usually applied in datasets in which only a small subset of data items may be effectively labelled, due to the high costs and time required in the labelling process [4]. In this section, some methods used in the literature to learn model parameters are introduced.

– *HMMs* are one of the most important techniques to model and classify sequential data with several applications in sequence modelling problems like speech recognition, human activity recognition (HAR), or time series analysis [35]. The Expectation-Maximization (EM) algorithm is the classical method used to learn the parameters of HMMs. However, it exhibits two main problems: (1) the likelihood is multimodal so the EM is guaranteed to converge only to local maxima, and (2) the multiple initializations required for minimizing the effects of the local convergence and the more than quadratic growth with the number of hidden states make EM computationally heavy with large training dataset. Bayesian inference methods including Gibbs sampling, variational optimization, or Bayesian non-parametric methods are even computationally heavier, and global convergence is still not guaranteed. A spectral algorithm for learning HMMs with discrete observations is proposed in [24]. This method adjusts the model by moment matching instead of maximizing the likelihood, and it relies on the use of the observable operators view of the HMM [35].

Learning of SLDSs is introduced in the practical example of section "A Discussion of Application Directions of ML Techniques to Cognitive Dynamic

Jamming". Now, two supervised learning methods are briefly described, while some unsupervised techniques are discussed in section "Some Current Learning Techniques and Probable Future Directions".

– *Support vector machines (SVMs)* are supervised learning models with associated learning algorithms that analyze data used for classification and regression analysis. In this chapter, SVD for regression is presented. The support vector method for regression is formulated in solving a convex optimization problem, more specifically a quadratic programming (QP) problem [15].

In SVM for nonlinear function regression, the main idea is to approximate the dataset

$$D = \{(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_k, y_k), \cdots, (\mathbf{x}_N, y_N)\}, \quad \mathbf{x}_k \in R^n, \quad y_k \in R \tag{31}$$

with a nonlinear function

$$f(\mathbf{x}) = < \boldsymbol{\omega}, \phi(\mathbf{x}) > + b \tag{32}$$

where $< \cdot, \cdot >$ denotes the dot product, $\boldsymbol{\omega} \in R^{n_h}$ is the weight vector in primal weight space, $\phi(\cdot) : R^n \rightarrow R^{n_h}$ is the nonlinear function that maps the input space to a high dimensional feature space where linear regression is performed, and b is the bias term. The optimization problem is given by:

$$\min \frac{1}{2}\|\boldsymbol{\omega}\|^2 + C\sum_{k=1}^{N}\left(\xi_k + \xi_k^*\right) \quad s.t. \quad \begin{cases} y_k - < \boldsymbol{\omega}, \phi(\mathbf{x}) > -b \leq \varepsilon + \xi_k \\ < \boldsymbol{\omega}, \phi(\mathbf{x}) > + b - y_k \leq \varepsilon + \xi_k^* \\ \xi_k, \xi_k^* \geq 0 \end{cases} \tag{33}$$

where ε is the approximation accuracy that can be violated by means of the slack variables ξ, ξ^* for the non-feasible case. The constant $C > 0$ determines a trade-off between flatness of f and the amount up to which deviations larger than ε are tolerated. A smaller value of C tolerated a larger deviation. From the constrained optimization problem in Eq. 33, the Lagrange function can be written as in [44] with multipliers α and α^*. Consequently, the resulting SVM takes the form:

$$f(\mathbf{x}) = \sum_{k-1}^{N}\left(\alpha_k - \alpha_k^*\right) < \phi(\mathbf{x}), \phi(\mathbf{x})_k > + b \tag{34}$$

where the inner product $< \phi(\mathbf{x}), \phi(\mathbf{x})_k >$ can be defined through a kernel $K(\mathbf{x}, \mathbf{x}_k)$.

However, the major drawback of SVM is its higher computational burden because of the required constrained optimization programming. Major breakthrough has been obtained at this point with a least squares version of SVM, called LS-SVM.

– *Gaussian processes (GPs) for regression* are a powerful supervised learning algorithm well-suited to high dimensional data analysis and nonlinear estimation problems [6]. Basically, given the covariance function, it provides an analytical

solution to any regression estimation problem. It does not only provide point estimates but it also gives confidence intervals for them. In GPs for regression, the optimization step to set the hyperparameters of the covariance function is performed by maximum likelihood. GPs method assumes a zero-mean GP prior over the space of possible functions and a Gaussian likelihood model. The posterior can be analytically computed; it is a Gaussian density function as well as the predictions given by the model.

Given a labelled training dataset ($D = \{\mathbf{x}_i, y_i\}_{i=l}^{n}$, where the input $\mathbf{x}_i \in \mathscr{R}^{d\times 1}$ and the output $y_i \in \mathscr{R}$) and a new input location $\mathbf{x}^*$, the probability distribution for its output y^*, i.e., $p(y^*|\mathbf{x}^*, D)$, can be predicted. Assuming a Gaussian linear prediction model for $y_i : p(y_i|\mathbf{x}_i, \mathbf{w}) = \mathscr{N}\left(y_i; \mathbf{w}^T\phi(\mathbf{x}_i), \sigma_v^2\right)$, where $\phi(\cdot)$ defines a transformation of the input space and a zero-mean Gaussian prior over $\mathbf{w}$, $p(\mathbf{w}) = \mathscr{N}\left(\mathbf{w}; \mathbf{0}, \sigma_{\mathbf{w}}^2\mathbf{I}\right)$, the posterior for the weight vector w using Bayes theorem is given by:

$$p(\mathbf{w}|D) = \frac{p(y_i|\mathbf{X}, \mathbf{w})\, p(\mathbf{w})}{p(y_i|\mathbf{X})} = \mathscr{N}(\mathbf{w}; \mu_{\mathbf{w}}, \Sigma_{\mathbf{w}}) \tag{35}$$

where $\mu_{\mathbf{w}} = \Phi^T\Phi/\sigma_v^2 + \mathbf{I}/\sigma_{\mathbf{w}}^2$, $\mathbf{y} = [y_1, \cdots, y_n]^T$, $\Phi = [\phi(\mathbf{x}_1), \cdots, \phi(\mathbf{x}_n)]^T$, and $\mathbf{X} = [\mathbf{x}_1, \cdots, \mathbf{x}_n]^T$. The prediction for y^* is obtained integrating out the posterior over $\mathbf{w}$ times its likelihood:

$$p\left(y^*|\mathbf{x}^*, D\right) = \int p\left(y^*|\mathbf{x}^*, \mathbf{w}\right) p(\mathbf{w}, D)\, d\mathbf{w} = \mathscr{N}\left(y; \mu_{y^*}, \sigma_{y^*}\right) \tag{36}$$

where

$$\mu_{y^*} = \phi^T\left(\mathbf{x}^*\right)\mu_{\mathbf{w}} = \mathbf{k}^T\mathbf{C}^{-1}\mathbf{y} \tag{37}$$

$$\sigma_{y^*}^2 = \phi^T\left(\mathbf{x}^*\right)\Sigma\mathbf{w}\phi\left(\mathbf{x}^*\right) = k\left(\mathbf{x}^*, \mathbf{x}^*\right) + \mathbf{k}^T\mathbf{C}^{-1}\mathbf{k} \tag{38}$$

being $k\left(\mathbf{x}_i, \mathbf{x}_j\right) = \phi^T(\mathbf{x}_i)\phi^T\left(\mathbf{x}_j\right)$, $(\mathbf{C})_{ij} = k\left(\mathbf{x}_i, \mathbf{x}_j\right) + \frac{\sigma_\mu^2}{\sigma_w^2}\delta_{ij}$, and $\mathbf{k} = [k(\mathbf{x}^*, \mathbf{x}_1), \cdots, k(\mathbf{x}^*, \mathbf{x}_n)]$. To obtain the estimation given by a GP model for regression, it is necessary only to specify its covariance function $k(\cdot, \cdot)$.

Learning Interactions

A decision support-based system should be capable of inferring on occurring behaviors and interactions of each entity in the corresponding environment. Behaviors are the specific activities defined as actions of each individual object without any external influence, while interactions are the actions inducted by pairwise exchanges of influences between the objects [7].

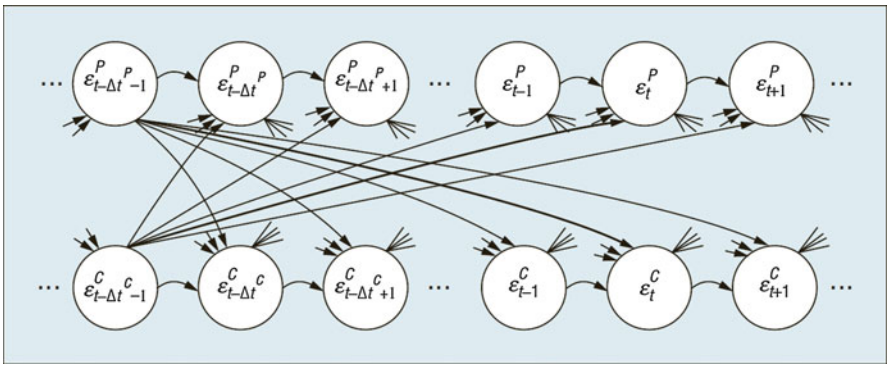

Fig. 5 Dynamic Bayesian Network (DBN) model representing bio-inspired interactions in [16] with linked proto- and core-self nodes

Basically, coupled DBNs are introduced as appropriate models to represent interactions between the entities [8]. Indeed, probabilistic processes and graphical models are characterized by their capability of working in the presence of uncertainty and noise in the environment of interest as well as with a large number of interrelated variables. In addition to these intrinsic capabilities of DBNs, the computational load is kept to a manageable level even with coexistence of many entities and models.

A probabilistic model based on a specific type of event takes inspiration from a bio-inspired approach and the concept of AM as described in section "Interacting Entities Situation Assessment". Damasio describes the cognitive entities as complex systems with incremental learning capabilities based on experience of the interactions between themselves and the external world [13]. Two specific brain processes can be defined to formalize the above concept called proto-self and core-self.

The DBN model proposed in [16] (Fig. 5) takes into account the conditioned probability densities (CPDs) given by $p\left(x_t^P | x_{t-1}^P\right)$ and $p\left(x_t^C | x_{t-1}^C\right)$ relative to the state of each individual object in the environment, denoted through the random variables x_t^P and x_t^C, regardless of the presence of other objects, while the interactions between two objects are defined in terms of casual events ε^P and ε^C through the CPDs:

$$p\left(x_t^P | x_{t-t^C}^C\right) \quad \text{and} \quad p\left(x_t^C | x_{t-t^P}^P\right) \tag{39}$$

In particular, the two conditioned probabilities in Eq. (39) describe the probability that the event ε^C, which occurred at time t^C, provokes the event ε^P in the proto node and the probability that the event ε^P, which occurred at time t^P, provokes the event ε^C in the core node, respectively. Causal relationships between the two entities are then described by the following two CPDs:

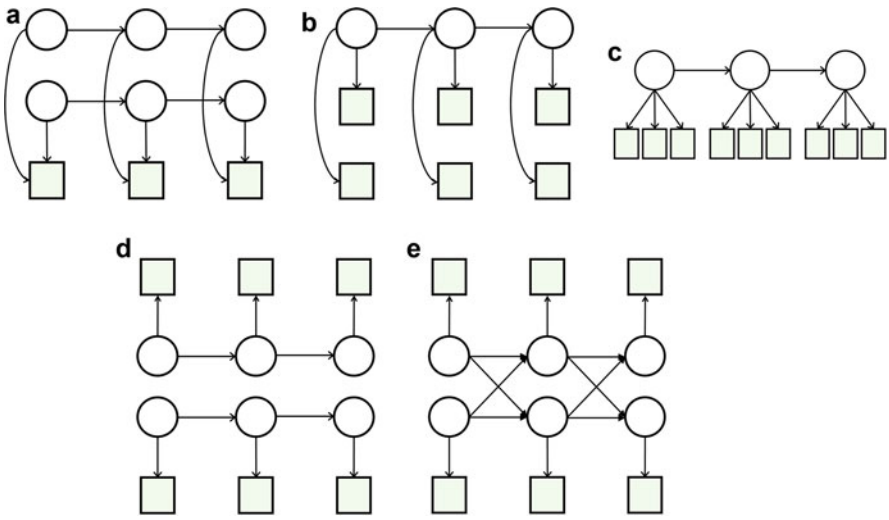

Fig. 6 Graphical representation of five different dynamic models [41]: (**a**) Factorial HMMs (FHMMs), (**b**) Observation Decomposed HMMs (ODHMMs), (**c**) Multiple Observation HMMs (MOHMMs), (**d**) Parallel HMMs (PaHMMs), and (**e**) Coupled HMMs (CHMMs)

$$p\left(x_t^P | x_{t-t^C}^C, x_{t-t^P}^P\right) \quad \text{and} \quad p\left(x_t^C | x_{t-t^P}^P, x_{t-t^C}^C\right) \tag{40}$$

which consider both the interactions in Eq. (39) and the initial situation given by $x_{t-t^P}^P$ and $x_{t-t^C}^C$. In other words, the entity's initial state, an external stimulus (the cause) and its consequence on the behavior of the entity (the effect) can learn an entity's most frequent reaction to the action of another element in the scene.

Several widely used dynamic probabilistic methods in the literature are shown in Fig. 6.

Some Current Learning Techniques and Probable Future Directions

– *Deep learning* has dramatically improved the state-of-the-art in many different ML topics like object detection, speech recognition, and machine translation. Following the initial development of neural networks, the recent success of deep learning is due to its deep architecture based on the idea of a system that simulates human brain [45]; this allows deep learning to solve many more complicated tasks.

The main objective is now to maintain the strength of neural networks while reducing the number of computation units (or neurons). Indeed, it has been shown that the representation of a $(k-1)$-layer neural network with exponentially many neurons is equivalent to a k-layer structure with polynomial many neurons.

In the framework of deep generative models, two examples that have been proposed recently are generative adversarial networks (GANs) and variational autoencoders (VAEs), discussed later in this section. Typically, learning the underly-

ing data distribution of unlabelled signals or images can be highly challenging, and inference on such distributions is highly computationally expensive or intractable. GANs and VAEs provide efficient approximations, making it possible to learn tractable generative models of unlabelled data [43]. Recent works have also extended the VAE and the GAN from unsupervised to semi-supervised settings.

– *Variational autoencoders* consider a dataset $\mathbf{X} = \{\mathbf{x}^{(i)}\}_{i=1}^{N}$ consisting of N i.i.d. samples of observed variables $\mathbf{x}$ [29]. The data are assumed to be generated from some random process that involves latent variables $\mathbf{z}$ as follows: (1) a value $\mathbf{z}^{(i)}$ is drawn from a prior distribution $p_\theta(\mathbf{z})$, and (2) a value $\mathbf{x}^{(i)}$ is drawn from a conditional distribution $p_\theta(\mathbf{x}|\mathbf{z})$ where θ is the true parameter. Both $p_\theta(z)$ and $p_\theta(\mathbf{x}|\mathbf{z})$ are assumed to come from some distribution family parametrized by θ. To learn this generative process with the presence of only observed data, it is often required to estimate the posterior distribution $p_\theta(\mathbf{x}|\mathbf{z})$; however, with moderately complex conditional distributions $p_\theta(\mathbf{x}|\mathbf{z})$, true posterior distributions are generally intractable. A variational autoencoder addresses this issue by introducing an encoder and a decoder. The probabilistic decoder maps the latent variable $\mathbf{z}$ to the conditional distribution $p_\theta(\mathbf{x}|\mathbf{z})$, while the probabilistic encoder maps the observed variable $\mathbf{x}$ to the approximated posterior distribution $q_\phi(\mathbf{x}|\mathbf{z})$, also called recognition model, an approximation of the true posterior $p_\theta(\mathbf{x}|\mathbf{z})$.

– *Generative adversarial networks* have been proposed in [23] to sidestep difficulties in deep generative models of approximating many intractable probabilistic computations and of leveraging the benefits of piecewise linear units in the generative context.

In the adversarial nets framework, the generative model is pitted against an adversary: a discriminative model that learns to determine whether a sample is from the model distribution or the data distribution. The generative model can be thought of as analogous to a team of counterfeiters, trying to produce fake currency and use it without detection, while the discriminative model is analogous to the police, trying to detect the counterfeit currency. Competition in this game drives both teams to improve their methods until the counterfeits are indistinguishable from the genuine articles. This framework can yield specific training algorithms for many kinds of model and optimization algorithm. In [23], the generative model generates samples by passing random noise through a multilayer perceptron, and the discriminative model is also a multilayer perceptron. To learn the generators distribution p_g over data $\mathbf{x}$, a prior on input noise variables $p_{\mathbf{z}}(\mathbf{z})$ is defined, and then, a mapping to data space as $G\left(\mathbf{z}; \theta_g\right)$ is represented, where G is a differentiable function represented by a multilayer perceptron with parameters θ_g, while a second multilayer perceptron $D(\mathbf{x}; \theta_d)$ outputs a single scalar. $D(\mathbf{x})$ represents the probability that $\mathbf{x}$ came from the data rather than p_g. D is trained to maximize the probability of assigning the correct label to both training examples and samples from G, while G is trained to minimize $\log(1 - D(G(\mathbf{z})))$. D and G play the following two-player minimax game with value function $V(G, D)$:

$$\min_G \max_D V(D, G) = \mathscr{E}_{\mathbf{x}\sim p_{\text{data}}(\mathbf{x})}[\log D(\mathbf{x})] + \mathscr{E}_{\mathbf{z}\sim p_z(\mathbf{z})}[\log(1 - D(G(\mathbf{z})))]. \tag{41}$$

Other learning techniques could be considered from the *Game theory* framework such as *Pursuit evasion game* and *Multi-armed bandit*.

Experimental Framework and Results

Research in CR and PHY-layer security has been carried on in different fields for both civil and military purposes. In this section, two current applications are introduced: the *SHIELD project* along with *SPD-Driven Smart Transmission layer* which implement Spectrum Intelligence for security against jamming attacks and *TVWS* to mitigate the shortage of wireless bands. Recent research in TVWS also addresses the problem of jamming attacks in the digital TV band. Some results are then described for future developments in learning dynamic jamming models.

The SHIELD Project and Smart SPD-Driven Transmission Layer

Nowadays, cyber-physical systems (CPSs) and Internet of Things (IoT) are rapidly expanding [19], and new business opportunities are being developed thanks to the dynamic interaction between the entities involved in the business. Indeed, dynamic interactions between entities represent the recent evolution of collaborations between entities for Internet-based services. In this context, autonomous decisions are enabled by dynamic modelling, but the lack of a measurable security makes information exchanges one of the big challenges. Current research on security in CPSs is far less intensive than research on security in computing and networking leaving many devices vulnerable to attacks.

The need for measurable security in the context of interoperating services, applications, systems, and devices in a CPS framework requires the development of an appropriate paradigm. A step forward in that direction is made by *SHIELD* which consists of methodologies for building secure embedded systems. Specifically, the basic approach specifies security through the terms security (S), privacy (P), and dependability (D).

The test-bed, shown in Fig. 7, is a SDR platform which consists of two SWAVE HHs (Secure Wideband Multi-role–Single-Channel Handheld Radios) connected through a dual directional coupler with 20dB nominal coupling (Agilent 778D 100 MHz–2 GHz) [12]. Because of the high output power of the radios, one programmable attenuator is included in the communication path and programmed to their maximum attenuation value – 30dB. The SWAVE HH radio terminal is capable of generating the digital SelfNET Soldier Broadband Waveform (SBW) waveform with bandwidth up to 5 MHz and provides operability in both very high frequency band, VHF (30–88 MHz), and ultrahigh frequency band, UHF (225–512 MHz). Every 3 s, a burst of 8192 consecutive complex samples of the spectrum of interest is outputted over the RS-485 serial port. The bandwidth of the spectrum is 120 MHz. Additional equipment can be connected to the dual directional coupler

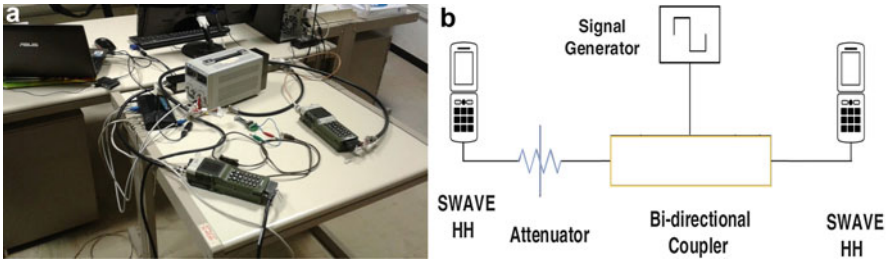

Fig. 7 SDR test-bed in the SHIELD project utilized to generate dynamic signals in the 0–120 MHz spectrum including the SBW signal: (**a**) hardware platform, (**b**) diagram of the main components of the test-bed and their connections

such as a signal generator to inject further modulated signals into the spectrum of interest. Full details on the test-bed architecture may be found in [11].

In order to comply with the minimum requirements for smart and secure data transmission in shared spectrum, SDR-capable devices are based on a set of services implemented at the network level to form a *smart SPD-driven transmission layer* [19]. This is made possible thanks to both the SDR technology with its reconfigurability properties and the CR technology with its learning and self-adaptive capabilities. Cognitive functionalities include self-awareness, spectrum awareness, spectrum intelligence, jamming detection and counteraction, and self-protection.

SPD-driven smart transmission layer addresses the problem of jamming attacks to PHY-layer by providing safe and reliable communication in wireless environments. Anti-jamming methodologies include retroactive frequency hopping (namely, channel surfing), transmission power changing, modifying the modulation of the transmitted waveform, as well as spread spectrum techniques. In particular, when channel surfing is applied, the operating frequency of the radio is changed whenever a strong interfering signal is detected. The probability of detection and reconstruction of a signal may be enhanced by increasing the transmission power and/or gain. Modulation altering may also be decisive in alleviating RF jamming interference, provided that the radios are equipped with automatic modulation recognition capabilities, allowing them to detect and classify the modulation-related features of jamming waveforms.

Research in TVWS

In recent years, the rapid development of wireless devices and wireless services resulted in an ever-growing demand and shortage of the wireless spectrum [36]. For this reason, CR was proposed to efficiently utilize spectrum resources by allowing unlicensed usage of vacant spectrum. Indeed, as reported by the Federal Commu-

nications Commission (FCC) and the UK Office of Communications (Ofcom), a large percentage of spectrum resources is underutilized. This has encouraged the governments to take critical steps toward releasing multiple bands for dynamic spectrum sharing. Consequently, spectrum holes in the licensed spectrum can now be used by secondary users (SUs) without causing any interference to primary users (PUs). In particular, TV White Spaces (TVWS) is one of the most promising paradigms for dynamic spectrum sharing in the digital TV band.

The experimental test-bed in [37] employed for TVWS research consists of a RFeye node, an antenna in the digital TV band [470–790 MHz], and a processing unit (Fig. 8a). The corresponding RF spectrum is shown in Fig. 8b in which there are I = 40 channels over TVWS spectrum (each of them with bandwidth of 8 MHz) ranging from 470 to 790 MHz. Among these TVWS channels, channel 27 is generally vacant, whose frequency ranges from 518 to 526 MHz. During the measurement, channel 27 was randomly corrupted by Digital Video Broadcasting-Terrestrial (DVB-T) signals in order to mimic a malicious user.

To this end, SS is a promising solution to identify potential spectral holes and is one of the most challenging tasks in CR networks [37]. Cooperative SS (CSS) is an effective approach to offer significant performance gain in detecting spectrum holes, by exploiting the spatial diversity of collaborative secondary users (SUs). However, due to the openness of low-layer protocol stacks, CSS networks are vulnerable to attacks from SS data falsification (SSDF). The main goals of malicious attacks come from two aspects: decreasing detection probability for disturbing the normal operation of PUs and increasing false alarm probability to deprive access opportunities for honest SUs. In decentralized CSS networks, sensing results are exchanged between neighboring SUs to improve the network reliability to link failure. However, this characteristic makes decentralized CSS more vulnerable to malicious attacks, as the observations at honest SUs are also available to malicious users during the information exchanging and convergence process. Furthermore, corrupted data can be integrated into the decisions of honest neighbor SUs, which eventually brings significant performance degradation to the whole CSS network.

Dual Resolution ST Approach

As mentioned in the previous section, SS is a challenging task in CR devices. In an ICE context, dynamic signal should be processed through time-frequency techniques such as the ST whose complexity often limits its applicability to wideband (i.e., high sampling rate) signals. In the Stockwell transform framework, the dual resolution (DR) technique is conceived to exploit learning mechanisms to adaptively learn the ST parameters for a better trade-off between time resolution and computational time in future work. The DR greatly reduces the computational time of the conventional ST by increasing time delay of the sliding window. Specifically, the signal vector is divided up into sub-blocks in which the wideband signal is assumed to be locally stationary and the sliding window is moved on the first sample of each sub-block. This technique has been validated in a dynamic scenario consisting of real data collected through a SDR test-bed.

Specifically, let $r[p]$, $p = 0, 1, \cdots, P-1$ denote the discrete time series corresponding to a continuous signal $r(t)$ with a time sampling interval T. The corresponding discrete ST is given in Eqs. (10), (11). Considering that the time index m in the discrete ST is the time delay of the sliding window over the signal $r[p]$ and assuming that the signal is locally stationary within the time corresponding to several time delays m, a different approach is proposed in this paper which reduces the computational load of the discrete ST.

From Fig. 9, the P samples of the locally stationary signal are divided into s sub-blocks consisting of P/s samples. This approach computes the ST on s equally spaced values for m belonging to the set $\{0, \cdots, P-1\}$, while $n = 0, \cdots, P-1$ remains as before. Indeed, since in this way the time delay of the sliding window is increased, all the values of m in each sub-block (unless the first one) are not directly included in the computation of the ST (it is sufficient to increase the sliding window length, by increasing k, to also cover the discarded samples). This is based on the consideration that the signal is locally stationary over P/s m's or (P/s)-stationary, namely, variations of the parameters happen no faster than the time

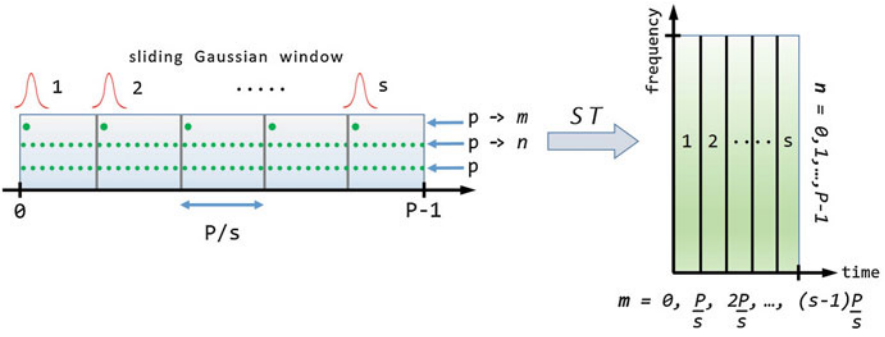

Fig. 9 The dual resolution ST technique for high sampling rate signals

corresponding to P/s samples and not necessarily at the boundary between two consecutive sub-windows. For quicker changes, the length of the sub-blocks can be reduced by increasing s accordingly. This introduces a new capability of the ST, namely, a trade-off between time resolution and computational time that can be adaptively controlled through s, P, and k. The frequency resolution can be changed by regulating P or k (or both).

The (m, n) element in the transformation matrix $\mathbf{T}$ can be written in a vectorial form as follows:

$$S_T[m, n] = \mathbf{T}_{mn}\mathbf{r} \tag{42}$$

where the $P \times 1$ vector $\mathbf{r} = [\, r[0], r[1], \cdots, r[P-1] \,]^T$ is the discrete series, while the following $1 \times P$ vector

$$\mathbf{T}_{mn} = \left[\, T_{mn,0}, T_{mn,1}, \cdots, T_{mn,(P-1)} \,\right]$$

consists of elements given by [2]:

$$T_{mn,p} = \frac{|n|}{\sqrt{2\pi}kN} e^{-\left(n^2(m-p)^2/2k^2N^2 + j2\pi pn/N\right)} \tag{43}$$

$p = 0, \cdots, P-1$. By using the $sN \times P$ transform matrix

$$\mathbf{T} = \left[\, \mathbf{T}_{00}^T, \cdots, \mathbf{T}_{0(N-1)}^T, \mathbf{T}_{\frac{P}{s}0}^T, \cdots, \mathbf{T}_{\frac{P}{s}(N-1)}^T, \cdots, \mathbf{T}_{\frac{P(s-1)}{s}0}^T, \cdots, \mathbf{T}_{\frac{P(s-1)}{s}(N-1)}^T \,\right]^T \tag{44}$$

the discrete ST can be modelled as a linear vectorial equation:

$$\mathbf{s} = \mathbf{T}\mathbf{r} \tag{45}$$

in which the $sN \times 1$ vector $\mathbf{s}$ consists of elements s_{mn} corresponding to $S_T[m, n]$. The dimensionality of Eq. (45) is drastically reduced because $m = m_s P/s$ where $m_s = 0, \cdots, s-1$ is the delay index, instead of $m = 0, 1, 2, \cdots, P-1$.

To validate the proposed dual resolution approach, the discrete ST has been applied to real data in the 0–120 MHz band which includes the VHF band, as described in section "The SHIELD Project and Smart SPD-Driven Transmission Layer". Specifically, at four different time instants, the carrier frequency of the transmitted SBW signal assumes sequentially the values 41 - 51 - 61 - 71 [MHz], while the transmit power is 7dBm. The other waveforms extracted from the spectrum of interest include four sub-signals close to one other (spacing about 0.5–1 MHz) at low frequencies, two interference signals at 20 and 80 MHz, respectively, and three sub-signals in the FM band (spacing about 2.5 and 7 MHz). The carrier frequency of each of these waveforms is fixed over the measurement time.

According to Table 1, the analyzed parameters are P (number of samples in the signal to be S-transformed), s (number of sub-blocks), and the scaling factor k

Table 1 Parameters used to validate the dual resolution ST

P				s			k		
256	512	640	1024	16	32	64	5	17.5	25

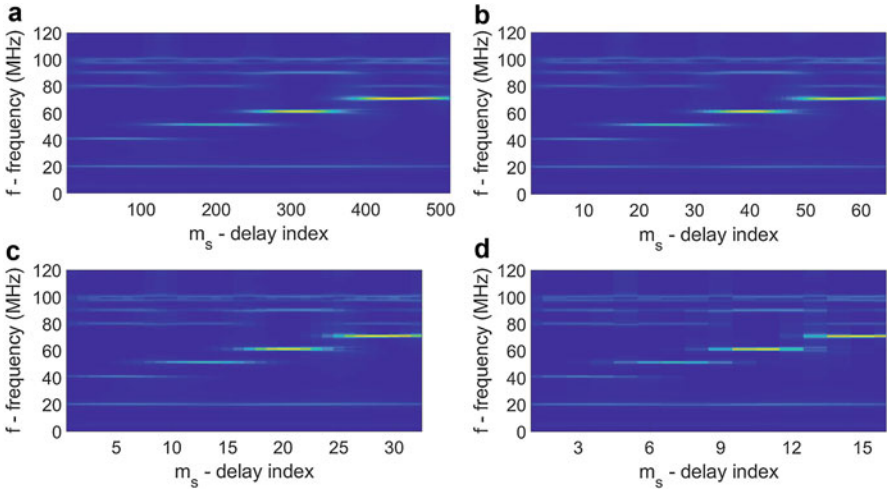

Fig. 10 ST representation of the wideband signal with $P = 512$ and $k = 17.5$: (**a**) without DR; and with dual resolution where (**b**) $s = 64$, (**c**) $s = 32$, and (**d**) $s = 16$. The SBW jumps among 41-51-61-71 MHz at different time instants

described in section "Time-Frequency Analysis and Features". The SBW signal is at least (P/s)-stationary in each configuration.

Figure 10a is the conventional ST, obtained with $k = 17.5$ and without DR, of a signal which consists of $P = 512$ samples. m_s is the delay index, namely, the time variable after ST. The waveforms in the spectrum can be clearly distinguished. In particular, the SWB signal in the middle of the figure jumps sequentially to the four different frequencies at four consecutive time instants. In the bottom, there are the BB peaks (they are very close to each other; the progressive resolution of ST produces fine frequency resolution at low frequencies [5]). Just above them, there is the interference at 20 MHz. Beyond the SBW signal, the interference at 80 MHz and the three FM sub-signals can be seen (the progressive resolution of ST produces low frequency resolution at high frequencies [5]). In this case, the amount of frequency-time samples is $P \cdot P$. The dual resolution algorithm produces the ST in Fig. 10b–d in which s is 64, 32, and 16, respectively. Although the time resolution gets worse by reducing the number of sub-blocks, the signals in the spectrum remain clear. In particular, the dynamic hopping of the SWB signal can be still observed. The main advantage is that the amount of frequency-time samples is reduced to $P \cdot s$, with $s \ll P$.

To show the effective benefits obtained with the proposed algorithm, Fig. 11 illustrates three different indicators: the time to create the $\mathbf{T}$ matrix, the time to compute the ST through Eq. (45), and the $L2$-norm error which illustrates the

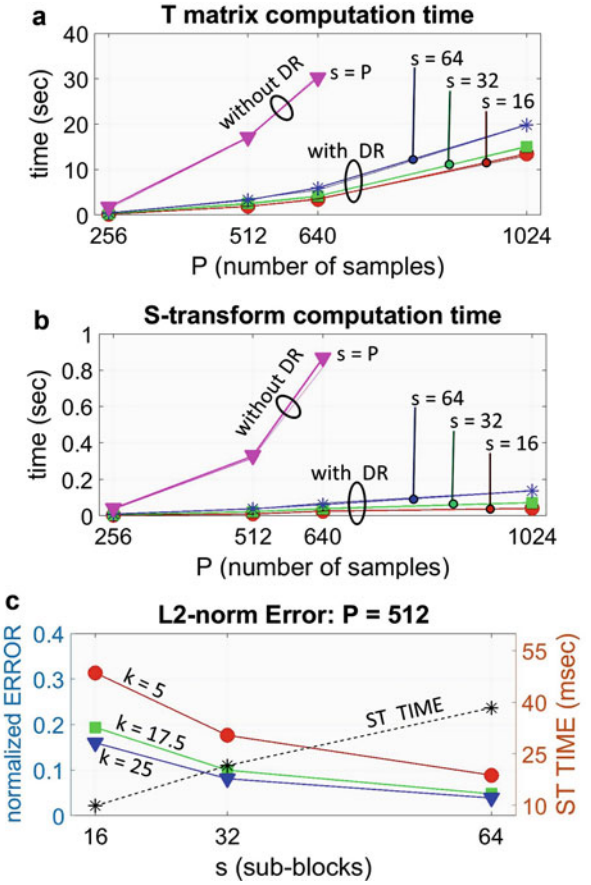

Fig. 11 Performance indicators: (**a**) time to generate **T**, (**b**) ST computation time, (**c**) normalized $L2$-norm error

difference between the 2D TF representation without DR and the corresponding representation with DR ($s = 64, 32, 16$). Specifically, let ε_n be the normalized $L2$-norm error defined as $\frac{\|\mathbf{X}_s - \mathbf{X}_P\|_2}{\|\mathbf{X}_P\|_2}$, where the matrix $\mathbf{X}_s$ is the expanded ST representation with DR, obtained through P/s replicas of each column, the matrix $\mathbf{X}_P$ is the ST representation without DR, and $\|\cdot\|_2$ is the $L2$-norm function.

Figure 11a, b show that in the conventional ST without DR the computational time to both generate the **T** matrix and perform the ST increases sharply when P is increased from 256 to 640. With $P = 1024$, Matlab is no longer capable of generating **T** because of its large dimensions ($P \cdot P$ rows and P columns), while the dual resolution approach reduces dramatically the computational time, and $P = 1024$ is also feasible. This means that the frequency resolution can be improved. Basically, k does not influence the computational time which is through increased by s.

Figure 11c, where $P = 512$, shows that both s and k influence ε_n. As expected, the error (mostly related to the time resolution) increases when at least one between

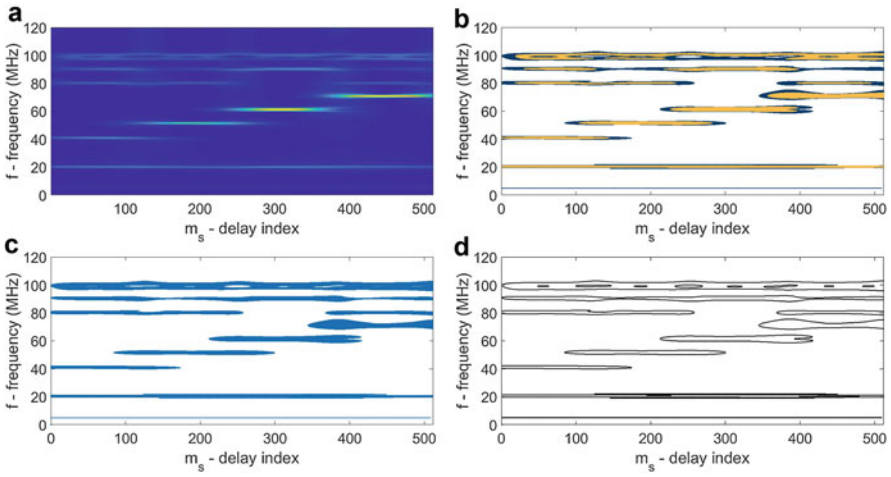

Fig. 12 (**a**) ST representation of the observed 0–120 MHz spectrum with $P = 512$ and $k = 17.5$ and without DR ($s = P$), (**b**) energy locations with threshold = $2\mu_{ST}$ (external dark-blue areas) and with threshold = $4\mu_{ST}$ (internal light-orange areas), (**c**) energy locations with threshold = $2\mu_{ST}$, (**d**) contours of the energy locations with threshold = $2\mu_{ST}$

s and k decreases, and it can be reduced by increasing k when s is small. In Fig. 11c, the corresponding ST computation time is also included which is inversely proportional to the error. The same results hold when a different value for P is considered.

As shown in Fig. 12, contours for each signal in the observation spectrum can be extracted from the time-frequency representations of the wideband signal:

(i) ST representation of the observed 0–120 MHz spectrum is in Fig. 12a;
(ii) energy locations obtained with threshold = $2\mu_{ST}$ and with threshold = $4\mu_{ST}$ are in Fig. 12b–c; μ_{ST} is the mean value of the ST representation;
(iii) contours of the occupied regions detected with threshold = $2\mu_{ST}$ are in Fig. 12d.

Dynamic features can be extracted from the two-dimensional contours of each signal such as bandwidth, central frequency, transmitting power, and shape.

A Discussion of Application Directions of ML Techniques to Cognitive Dynamic Jamming

A possible shared radio environment, as basis for future ICE, is depicted in Fig. 13 in which there are several interacting agents such as a jammer, which aims to "catch" legitimate signals and a user whose objective is to avoid the jammer. In addition, a network manager (NM) is an external observer of the spectrum, e.g., a primary

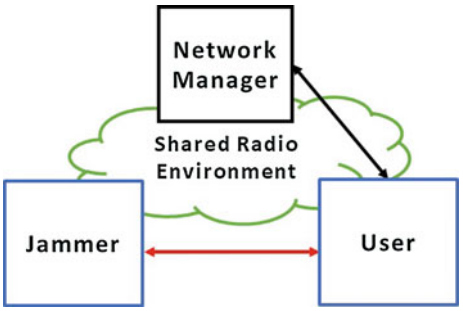

Fig. 13 A practical example in a shared radio environment consisting of two interacting agents, a jammer and a user, with opposite objectives and a network manager. The NM interacts with the user

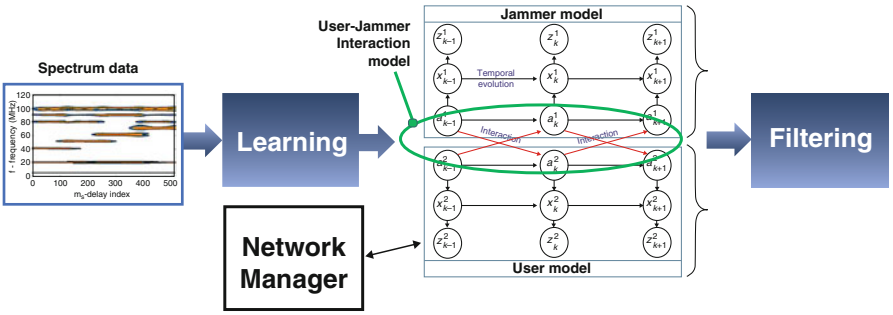

Fig. 14 The proposed example in which jammer, user, and their interactions are modelled through JMSs. The NM observes the spectrum and interacts with the user. Learning and filtering blocks are also shown in the picture

base station, that monitors dynamical spectrum joint situations generated by actions of both the jammer and the user. Such a station can interact with the user and could be either a human operator or an ICE system. The NM can be useful, for example, in case the spectrum sensing computational resources are too intensive to be implemented directly in the user device and the spectrum monitoring facility is shared among many users of the network. Furthermore, in case the NM is the only CDS, it can be in charge to continuously check the normality of an observed situation, namely, to predict if the user behavior is in line with avoiding the jammer.

In general, each of the three radios representing the user, the jammer, or the NM can be a cognitive radio that can be modelled as a CDS. In this example, the NM is assumed to be a CDS that use two JMSs to model the observed interaction between user and jammer as in Fig. 14. The goal is to provide a discussion on how this model can be learned from observed spectrum behaviors where the user successfully avoids the jammer. Such data series correspond to normality patterns that can be used as examples from which to train NM's CDS. First of all, features coming from spectrum monitoring methods are extracted, e.g., by using the time-frequency representation of the spectrum of interest as described at the end of section "Dual Resolution ST Approach". Such spectrum data can be used by the *learning* algorithm to estimate parameters of the switching models. In other words,

normality models are learned corresponding to models where rules that allow the user to avoid the jammer are estimated from the data series examples where this is known to have happened successfully. Such rules describe a dynamic equilibrium condition that should be verified according to previous experiences recorded in such data series if a normal situation occurs. Normal training samples are much easier to collect than abnormality samples whose dataset could be insufficient or unavailable [38]. After having trained the switching models using only normal data in order to learn a representation of the normal spectrum activities, the *filtering* phase produces predictions of the corresponding hidden variables and observation at each time instant. Filtering can be also thought as a generative block for abnormality detection; indeed, since the JMSs are not able to generate abnormal events at testing time because trained with normal data only, a normality condition is said to be probabilistically verified if updates and related predictions are consistent, while excess of deviations of updated observations from predictions corresponds to abnormalities where the jammer's behavior is different from the patterns observed during the training and the user is no longer capable of avoiding it.

From Eq. (15), the state vector $\mathbf{x}_k^i$ for the i-th entity can be augmented into $\tilde{\mathbf{x}}_k^{i\,T} = \left[\mathbf{x}_k^{i\,T}, \mathbf{a}_k^{i\,T}\right]$, where $i = \{1, 2\}$; then the corresponding nonlinear state-space model (NLSSM) is given by:

$$\begin{cases} \tilde{\mathbf{x}}_k^i = f\left(\tilde{\mathbf{x}}_{k-1}^i, \mathbf{v}_k^i\right) \\ \mathbf{z}_k^i = h\left(\tilde{\mathbf{x}}_k^i, \mathbf{w}_k^i\right) \end{cases} \tag{46}$$

The NLSSM for interactive entities evolves according to

$$\Pi\left(\mathbf{a}_k^i|\mathbf{a}_{k-1}^i\right), \quad p\left(\mathbf{x}_k^i|\mathbf{x}_{k-1}^i, \mathbf{a}_k^i, \mathbf{a}_{k-1}^j\right), \quad p\left(\mathbf{z}_k^i|\mathbf{x}_k^i, \mathbf{a}_k^i, \mathbf{a}_{k-1}^j\right); \quad i, j = \{1, 2\}, \; i \neq j \tag{47}$$

and [16]

$$\Pi\left(\mathbf{a}_k^1|\mathbf{a}_{k-1}^2\right), \quad \Pi\left(\mathbf{a}_k^2|\mathbf{a}_{k-1}^1\right) \tag{48}$$

Specifically, in this example *learning* aims to estimate (from available data) model parameters, continuous- and discrete-valued states, and transition and interaction probability distributions in nonlinear state-space models with Markovian switching structure. Discrete switching variables (a's), probabilistic distributions described by links between the discrete nodes (namely, Π matrices) including entity-to-entity interactions, and probabilistic distributions described by links between discrete variables and continuous state variables (x's) can be learnt through unsupervised clustering techniques such as *Dirichlet process mixture (DPM)* model, while continuous state variables, transition models between the state at time k and its value at time $k-1$, and likelihood models between observations (z's) and state variables can be learnt through techniques like *Gaussian process (GP) regression* or *GaNs*.

The *filtering* block estimates and predicts sequentially the latent states $\{\mathbf{x}_k^i, \mathbf{a}_k^i\}$ given the densities for the initial state $\{\mathbf{x}_0^i, \mathbf{a}_0^i\}$ and the measurements up to time k ($\mathbf{z}_{1:k}^i$). For this purpose, *particle filtering*-based methods can be used such as *Markov Jump Particle Filter* (MJPF) or *Rao-Blackwellized Particle Filter* (RBPF).

Conclusion and Future Directions

This chapter addresses the application of learning techniques to dynamic models for wireless communications. Indeed, PHY-layer security is gathering ever-growing interest in the research world due to the high vulnerability of wireless communications to external attacks such as jamming attacks. This is the main objective for which a detailed discussion of selected techniques and scientific results in the current state-of-the-art is provided throughout the above sections. Some probable and interesting future directions in this framework are also introduced in order to show the evolution of CR, which has been conceived to overcome the shortage of available bands in the wireless spectrum, toward a wider paradigm designed for interactive and cognitive environments. Considering that, *dynamic* is a decisive concept to enable cognition and interactions which are on the basis of self-aware and self-adaptive devices. To this end, time information seems to be a key component in processing dynamic signals. For this reason, time-frequency analysis is included in this chapter as a first step to detect signals in the spectrum of interest and to extract both time and frequency information. Afterward, several statistical models are described; most of them are based on a Bayesian approach and represented through probabilistic graphical models which highlight both temporal dependencies, namely, dynamic of the system, and entity-to-entity dependencies, namely, interactions. In this framework, the concepts of *learning*, *cognition*, and *interactions* come from recent results obtained in computational neuroscience. Specifically, autobiographical memory results from a bio-inspired approach which enables cognition and interactions with external entities. To this end, several techniques from ML and data mining are described which are employed to learn parameters, models, and interactions.

A more practical point of view is described in the experimental framework section which includes two applications in dynamic environments: TVWS to overcome the shortage of spectrum availability, which can be vulnerable to jamming attacks, and the SHIELD project which aims to implement measurable security, privacy, and dependability (SPD) in cyber-physical systems. A time-frequency analysis is also introduced which extracts both time and frequency information from real dynamic signals with controllable resolution in both the domains. The corresponding contours are then extracted for future work. In addition, a practical example about application directions of ML techniques for cognitive dynamic jamming lays the foundations toward complex CDSs to make ICEs become a reality.

In particular, probable future directions include employing techniques and algorithms used for data analysis, image and video processing, robotics, and so

forth, in wireless communications. Indeed, general concepts such as entity, state, and trajectory can be specified to CR as signal, central frequency and bandwidth, and time-frequency information, respectively. Specifically, representation of wireless signals (including jammers) through, for example, multilayer perceptron, variational autoencoders, or HMMs are not found in the current state-of-the-art, and, consequently, learning techniques to learn such kind of dynamic models in a jamming context are not either.

In addition, a bio-inspired approach, as described in this chapter, could enhance the learning process by combining cognition with self-awareness and self-adaptation in CR devices for future PHY-layer security.
