About the Editor

Wei Zhang
School of Electrical Engineering and Telecommunications
The University of New South Wales
Sydney, NSW, Australia

Wei Zhang is a Professor at the University of New South Wales, Sydney, Australia. His current research interests include UAV communications, millimeter-wave communications, space information networks, and massive MIMO. He is the Editor-in-Chief of *IEEE Wireless Communications Letters* and Editor-in-Chief of *Journal of Communications and Information Networks* (JCIN). He is a TPC Co-Chair of IEEE/CIC ICCC 2019, Changchun, China. He also serves as Chair for IEEE Wireless Communications Technical Committee and Vice Director of IEEE Communications Society Asia Pacific Board. He is a member of Board of Governors of IEEE Communications Society. He is an IEEE fellow.

Part I
Cognitive Radio Communications

Multiple Antenna Spectrum Sensing in Colored Noise

1

Jitendra K. Tugnait

Contents

Abstract

The problem of multiple antenna spectrum sensing is addressed where the receiver noise is allowed to be temporally colored with unknown power spectral density, but must be spatially uncorrelated. The signal is received over a possibly frequency-selective, unknown channel. A comprehensive overview of spectrum sensing approaches under colored noise is presented. Both time-domain and frequency-domain approaches exploiting stationarity are presented. Cyclostationarity-based spectrum sensing methods are also reviewed.

W. Zhang (ed.), *Handbook of Cognitive Radio*,
https://doi.org/10.1007/978-981-10-1394-2_1

Introduction

Cognitive radio (CR) allows for usage of licensed frequency bands (rights held by primary users) by unlicensed users (secondary or cognitive users) when the licensed spectrum bands are unoccupied (a function of time and location). Therefore, one of the first steps to be accomplished by a cognitive user is *spectrum sensing*: analysis of the received electromagnetic transmissions to search for unoccupied spectrum bands (*spectrum holes*). Based on the received signal $x(t)$, the cognitive user's spectrum sensing problem is to decide if the primary user (PU) is present or not. This may be formulated as a binary hypothesis testing problem:

$$x(t) = \begin{cases} n(t) & : \mathscr{H}_0 \\ s(t) + n(t) & : \mathscr{H}_1 \end{cases} \tag{1}$$

where $\mathscr{H}_0$ is the null hypothesis that cognitive user is receiving just noise $n(t)$ and $\mathscr{H}_1$ is the alternative that PU signal $s(t)$ is also present. A popular approach is that of energy detection; see [8, 15] and references therein. One designs a CFAR (constant false alarm rate) test requiring prior knowledge of some of the signal statistics under $\mathscr{H}_0$. For instance, $n(t)$ is taken to be thermal noise with known variance.

Quite often, as a result of receive filters at the cognitive user's receiver, the filtered thermal noise will not be white. Most existing approaches assume white noise sequences at the receiver. The goal of this chapter is to present a comprehensive overview of spectrum sensing approaches when noise is colored. Emphasis is on multiple antenna receivers which rely on the fact that noise is spatially (across antennas) independent and PU signals are spatially dependent while temporal properties of signal and noise become "irrelevant."

Notation: Notations $|\mathbf{D}|$ and $\text{tr}(\mathbf{D})$ stand for the determinant and trace of square matrix $\mathbf{D}$, respectively, $\text{etr}(\mathbf{D}) = \exp(\text{tr}(\mathbf{D}))$, $\mathbf{D}_{ij}$ is the ijth element of $\mathbf{D}$, $\mathbf{I}$ is the identity matrix and superscripts $*$ and H denote the complex conjugate and the conjugate transpose (Hermitian) operations, respectively. The notation $y = \mathscr{O}(g(x))$ means that there exists some finite real number $b > 0$ such that $\lim_{x\to\infty} |y/g(x)| \leq b$. Given a column vector $\mathbf{y}$, $\text{diag}\{\mathbf{y}\}$ denotes a square matrix with elements of $\mathbf{y}$ along its main diagonal and zeros everywhere else. Covariance $\text{cov}(\mathbf{x}, \mathbf{y}^*) := E\{\mathbf{x}\mathbf{y}^H\} - E\{\mathbf{x}\}E\{\mathbf{y}^H\}$ where E denotes expectation, and let $\text{cum}_4(x_1, x_2, x_3, x_4)$ denote the joint fourth cumulant of random variables x_i ($i = 1, 2, 3, 4$). Note that $\text{cum}_4(x_1, x_2, x_3, x_4) = E\{x_1x_2x_3x_4\} - E\{x_1x_2\}E\{x_3x_4\} - E\{x_1x_3\}E\{x_2x_4\} - E\{x_1x_4\}E\{x_2x_3\}$ when all x_i's are zero mean. The function $\delta_{i,j}$ denotes the Kronecker delta function, i.e., $\delta_{i,j} = 1$ if $i = j$, 0 otherwise. The abbreviations i.i.d. and w.r.t. stand for "independent and identically distributed" and "with respect to," respectively.

Colored Noise

An irreducible source of noise at the receiver is thermal noise which is zero-mean white Gaussian and whose baseband-equivalent model is that of a zero-mean, white, circularly symmetric complex Gaussian random process $v(t)$. Before processing the (continuous-time) received noisy signal, at the receiver front-end, the noisy (baseband-equivalent) signal is passed through a receive filter $g_r(t)$. Let $\tilde{v}(t)$ denote the filtered noise:

$$\tilde{v}(t) = v(t) \circledast g_r(t) = \int v(t-\lambda) g_r(\lambda)\, d\lambda$$

where $\circledast$ denotes convolution. The autocorrelation function of $\tilde{v}(t)$ is

$$R_{\tilde{v}\tilde{v}}(\tau) = E\{\tilde{v}(t)\tilde{v}^*(t-\tau)\} = \frac{N_0}{2} \int g_r(t) g_r^*(t-\tau)\, dt$$

where $R_{vv}(\tau) = \frac{N_0}{2}\delta(\tau)$. If $g_r(t)$ is a square-root raised cosine filter with bandwidth $(1+\alpha)/(2T_s)$, $0 \le \alpha \le 1$, where T_s is the symbol interval, then $R_{\tilde{v}\tilde{v}}(nT_s) = 0$ for $n = \pm 1, \pm 2, \cdots$. That is, $\{\tilde{v}(t)\big|_{t=nT_s}\}_n$ is white Gaussian sample sequence when $\tilde{v}(t)$ is sampled at the symbol rate. But if one oversamples (more than one sample in T_s sec, called fractional sampling), then $\{\tilde{v}(t)\big|_{t=nT}\}_n$, $T < T_s$, is colored.

Thus, if the filters are not necessarily the ones that yield white noise at symbol rate sampling, or the sampling rate exceeds the symbol rate, the sampled filtered thermal noise will be a colored random sequence. For CR applications, active RC filters with tunable cutoff frequencies have been proposed in the literature [23, 32]. Sampling of the filtered thermal noise using such RC filters will invariably result in colored noise. The effect of noise correlation on spectrum sensing performance for a class of spectrum sensing algorithms has been analyzed in [22].

Spectral Sensing Models

Assume that there are p antennas at the cognitive user. Then the hypothesis testing problem (1) is reformulated as

$$\mathbf{x}(t) = \begin{cases} \mathbf{n}(t) & : \mathscr{H}_0 \\ \underbrace{\sum_{l=0}^{L} \mathbf{h}(l) s_{pu}(t-l)}_{=\mathbf{s}(t)} + \mathbf{n}(t) & : \mathscr{H}_1 \end{cases} \tag{2}$$

where under $\mathscr{H}_0$, cognitive user is receiving just noise $\mathbf{n}(t)$ (assumed to be zero-mean, complex-valued, possibly colored, Gaussian, and spatially uncorrelated),

and under $\mathscr{H}_1$, (scalar) PU signal $s_{pu}(t)$ is also present where p-column $\mathbf{h}(l)$ is the complex channel impulse response and $s_{pu}(t)$ is the scalar (non-Gaussian) complex-valued proper i.i.d. information sequence with zero mean and variance $E\{|s_{pu}(t)|^2\} = \sigma_s^2$.

Spectrum sensing methods considered here include time-domain approaches that exploit either stationarity or cyclostationarity properties of the received noisy signals and also include frequency-domain approaches based on multivariate spectral analysis that exploit stationarity properties of the received noisy signals. To this end, first some of these properties are briefly reviewed.

Large Sample Statistics of Sample Correlation

In (2), $\mathbf{n}(t)$ is complex (proper) possibly colored Gaussian with

$$E\{\mathbf{n}(t)\mathbf{n}^H(t+\tau)\} = \text{diag}\left\{R_{11,n}(\tau),\ R_{22,n}(\tau),\ \cdots,\ R_{pp,n}(\tau)\right\}. \tag{3}$$

Given an observation length of N samples of $\mathbf{x}(t)$ in (2), estimate the correlation function $\mathbf{R}_{xx}(\tau) = E\{\mathbf{x}(t)\mathbf{x}^H(t-\tau)\}$ as

$$\hat{\mathbf{R}}_{xx}(\tau) = \frac{1}{N}\sum_{t=1}^{N}\mathbf{x}(t)\mathbf{x}^H(t-\tau). \tag{4}$$

It is easy to see that $E\{\hat{\mathbf{R}}_{xx}(\tau)\} = \mathbf{R}_{xx}(\tau)$. With $R_{ij,xx}(\tau)$ denoting the ijth element of matrix $\mathbf{R}_{xx}(\tau)$, one has

$$\begin{aligned}
&E\{x_i(t_1)x_j^*(t_1-\tau_1)x_k^*(t_2)x_l(t_2-\tau_2)\}\\
&\quad= \text{cum}_4\left(x_i(t_1), x_j^*(t_1-\tau_1), x_k^*(t_2), x_l(t_2-\tau_2)\right) + R_{ij,xx}(\tau_1)R_{kl,xx}^*(\tau_2)\\
&\qquad+R_{ik,xx}(t_1-t_2)R_{lj,xx}(t_2-t_1-\tau_2+\tau_1).
\end{aligned} \tag{5}$$

Hence,

$$\begin{aligned}
&\text{cov}\left(\hat{R}_{ij,xx}(\tau_1), \hat{R}_{kl,xx}^*(\tau_2)\right)\\
&\quad= \frac{1}{N^2}\sum_{t_1=1}^{N}\sum_{t_2=1}^{N}\left[R_{ik,xx}(t_1-t_2)R_{lj,xx}^*(t_1-t_2+\tau_2-\tau_1) + A_2\right]
\end{aligned} \tag{6}$$

where

$$A_2 := \text{cum}_4\left(x_i(t_1), x_j^*(t_1-\tau_1), x_k^*(t_2), x_l(t_2-\tau_2)\right). \tag{7}$$

Denote the first double summation term in (6) by B_1 and set $t_1 - t_2 = m$ therein to obtain

$$B_1 = \frac{1}{N^2} \sum_{t_1=1,\, t_1-t_2=m}^{N} \sum_{t_2=1}^{N} R_{ik,xx}(m) R^*_{lj,xx}(m + \tau_2 - \tau_1)$$

$$= \frac{1}{N^2} \sum_{m=-(N-1)}^{N-1} (N - |m|) R_{ik,xx}(m) R^*_{lj,xx}(m + \tau_2 - \tau_1), \tag{8}$$

leading to

$$\lim_{N\to\infty} NB_1 = \sum_{m=-\infty}^{\infty} R_{ik,xx}(m) R^*_{lj,xx}(m + \tau_2 - \tau_1). \tag{9}$$

It then follows that ($\gamma_{4s} := \mathrm{cum}_4(s(t), s^*(t), s(t), s^*(t))$)

$$A_2 = \gamma_{4s} \sum_{m=-\infty}^{\infty} h_i(m+\tau_1) h^*_j(m) h^*_k(t_2 - t_1 + m + \tau_1) h_l(t_2 - t_1 + m + \tau_1 - \tau_2). \tag{10}$$

Using $R^{(s)}_{ij,ss}(\tau) = E\{[x_i(t) - n_i(t)][x_i(t-\tau) - n_i(t-\tau)]^*\} = \sigma_s^2 \sum_{l=-\infty}^{\infty} h_i(l) h^*_j(l - \tau)$ and mimicking (8) and (9), one obtains

$$\lim_{N\to\infty} \frac{1}{N} \sum_{t_1=1}^{N} \sum_{t_2=1}^{N} A_2 = \frac{\gamma_{4s}}{\sigma_s^4} R_{ij,ss}(\tau_1) R^*_{kl,ss}(\tau_2). \tag{11}$$

From (6), (9), and (11), one has

$$\lim_{N\to\infty} N \mathrm{cov}\left(\hat{R}_{ij,xx}(\tau_1), \hat{R}^*_{kl,xx}(\tau_2)\right)$$

$$= \frac{\gamma_{4s}}{\sigma_s^4} R_{ij,ss}(\tau_1) R^{(*}_{kl,ss}(\tau_2) + \sum_{m=-\infty}^{\infty} R_{ik,xx}(m) R^*_{lj,xx}(m + \tau_2 - \tau_1). \tag{12}$$

Spatially Uncorrelated, Temporally Colored Noise

If $\mathbf{x}(t)$ is Gaussian, then

$$\lim_{N\to\infty} N \mathrm{cov}\left(\hat{R}_{ij,xx}(\tau_1), \hat{R}^*_{kl,xx}(\tau_2)\right) = \sum_{m=-\infty}^{\infty} R_{ik,xx}(m) R^*_{lj,xx}(m + \tau_2 - \tau_1). \tag{13}$$

If $\mathbf{x}(t) = \mathbf{n}(t)$, then

$$\lim_{N\to\infty} N \mathrm{cov}\left(\hat{R}_{ij,nn}(\tau_1), \hat{R}^*_{kl,nn}(\tau_2)\right) = \delta_{i,k}\delta_{j,l} \sum_{m=-\infty}^{\infty} R_{ii,nn}(m) R^*_{jj,nn}(m + \tau_2 - \tau_1). \tag{14}$$

In particular, with $\tau_1 = \tau_2 = 0$, one obtains

$$\lim_{N\to\infty} N\mathrm{cov}\left(\hat{R}_{ij,nn}(0), \hat{R}^*_{kl,nn}(0)\right) = \delta_{i,k}\delta_{j,l} \sum_{m=-\infty}^{\infty} R_{ii,nn}(m) R^*_{jj,nn}(m) \tag{15}$$

and

$$\begin{aligned}\lim_{N\to\infty} N\mathrm{cov}\left(\hat{R}_{ij,nn}(0), \hat{R}_{kl,nn}(0)\right) &= \lim_{N\to\infty} N\mathrm{cov}\left(\hat{R}_{ij,nn}(0), \hat{R}^*_{lk,nn}(0)\right) \\ &= \delta_{i,l}\delta_{j,k} \sum_{m=-\infty}^{\infty} R_{ii,nn}(m) R^*_{jj,nn}(m)\end{aligned} \tag{16}$$

It is assumed that $R_{ij,nn}(\tau) = 0$ for $|\tau| > L_n$ for some L_n (finite memory). Invoking the central limit theorem, it is seen that for $i \neq j$,

$$\lim_{N\to\infty} \sqrt{N}\,\hat{R}_{ij,nn}(0) \sim \mathcal{N}_c\left(0, \sum_{m=-\infty}^{\infty} R_{ii,nn}(m) R^*_{jj,nn}(m)\right) \tag{17}$$

where $\mathcal{N}_c(\boldsymbol{\mu}, \Sigma)$ denotes a complex (proper) Gaussian (vector) distribution with mean $\boldsymbol{\mu}$ and covariance matrix Σ. Furthermore, by the central limit theorem and (14), (15), and (16), the upper (lower) triangular off-diagonal elements of $\hat{\mathbf{R}}_{nn}(0)$ are asymptotically independent of the other upper (lower) triangular off-diagonal elements.

Spectral Analysis Background

Suppose that $\mathbf{x}(t)$, $t = 0, 1, \cdots, N-1$, has zero mean and $p \times p$ power spectral density (PSD) matrix $\mathbf{S}(f)$. Numerous approaches are available [3, 19] to estimate $\mathbf{S}(f)$ on a grid $f_n := n/N$, $n = 0, 1, \cdots, N-1$. Consider the Daniell method (unweighted frequency-domain averaging) to estimate PSD. Given $p \times 1$ time series $\mathbf{x}(t)$, $t = 0, 1, \cdots, N-1$, first the periodogram estimator of the $\mathbf{S}(f)$ is calculated as

$$\hat{\mathbf{S}}_p(f) = N^{-1}\mathbf{I}(f)\mathbf{I}^H(f), \quad \mathbf{I}(f) := \sum_{t=0}^{N-1} \mathbf{x}(t) e^{-j2\pi ft}. \tag{18}$$

In the Daniell method, the periodogram is averaged over $K = 2m_t + 1$ nonoverlapping frequency bins:

$$\hat{\mathbf{S}}(f_n) = \frac{1}{K} \sum_{l=-m_t}^{m_t} \hat{\mathbf{S}}_p(f_{n+l}) \tag{19}$$

where $f_n := n/N, n = 0, 1, \cdots, N-1$ and there are N data observation samples. A key fact is that at any frequency f (on the appropriate FFT grid in the interval $(0, 2\pi) \equiv (0, 1.0)$), the PSD estimator $\hat{\mathbf{S}}(f)$ of the true $p \times p$ PSD matrix $\mathbf{S}(f)$ has the (asymptotic: N "large") distribution

$$\hat{\mathbf{S}}(f) \sim (1/K) W_C(p, K, \mathbf{S}(f)) \tag{20}$$

where $W_C(p, K, \mathbf{S}(f))$ denotes the complex Wishart distribution of dimension p and degrees of freedom K. These results follow from [3] (and others). It has been shown in [19, Sec. 6.19] that for circularly symmetric complex-valued time series, the spectral estimators are (asymptotically) statistically independent on an appropriate discrete grid on $(0, 2\pi)$, in contrast to the case of real-valued time series where this property holds true on just $(0, \pi)$.

If $\mathbf{X} \sim W_C(p, K, \mathbf{S}(f))$, then by [3, Sec. 4.2], $E\{\mathbf{X}\} = K\mathbf{S}(f)$, $\text{cov}\{\mathbf{X}_{jk}, \mathbf{X}_{lm}\} = K\mathbf{S}_{jl}(f)\mathbf{S}^*_{km}(f)$, and the probability density function (pdf) of $\mathbf{X}$ is given by

$$f_{\mathbf{X}}(\mathbf{X}) = \frac{1}{\Gamma_p(K)} \frac{1}{|\mathbf{S}(f)|^K} |\mathbf{X}|^{K-p} \,\text{etr}\{-\mathbf{S}^{-1}(f)\mathbf{X}\} \tag{21}$$

where (21) is defined for positive-definite Hermitian $\mathbf{X}$ and is otherwise zero, and

$$\Gamma_p(K) := \pi^{p(p-1)/2} \prod_{j=1}^{p} \Gamma(K - j + 1)$$

where $\Gamma(n)$ denotes the (complete) gamma function $\Gamma(z) := \int_0^\infty t^{z-1} e^{-t}\, dt$. Applying [16, Thm. 3.2.5] to complex-valued random vectors, if $\mathbf{X} \sim W_C(p, K, \mathbf{S}(f))$, then $\mathbf{AXA}^H \sim W_C\left(m, K, \mathbf{AS}(f)\mathbf{A}^H\right)$ for any $m \times p$ matrix $\mathbf{A}$ of rank m. It then follows that $\mathbf{Y} = \hat{\mathbf{S}}(f_k) = (1/K)\mathbf{X}$ and the pdf of $\mathbf{Y}$ is given by

$$f_{\mathbf{Y}}(\mathbf{Y}) = \frac{1}{\Gamma_p(K)} \frac{K^{pK}}{|\mathbf{S}(f_k)|^K} |\mathbf{Y}|^{K-p} \,\text{etr}\{-K(\mathbf{S}(f_k))^{-1}\mathbf{Y}\}. \tag{22}$$

Cyclostationarity Background

First consider scalar signals to fix notation and concepts.

Scalar Processes

A discrete-time, zero-mean, scalar complex-valued cyclostationary signal $x(t)$ is characterized by a time-varying autocorrelation function $R_{xx}(t, t+\tau) := E\{x(t)x^*(t+\tau)\}$ which has a Fourier series representation [4, 17]

$$R_{xx}(t, t+\tau) = \sum_{\alpha \in \mathscr{A}} R_{xx}(\alpha; \tau) e^{j2\pi\alpha t} \tag{23}$$

where given $x(t)$ for $t = 1, 2, \cdots, M$, the *cyclic autocorrelation function* (CAF) $R_{xx}(\alpha;\tau)$ at cycle frequency $\alpha \in \mathscr{A}$ is given by

$$R_{xx}(\alpha;\tau) = \lim_{M\to\infty} \frac{1}{M} \sum_{t=1}^{M} R_{xx}(t, t+\tau) e^{-j2\pi\alpha t} \tag{24}$$

and $\mathscr{A}$ is the set of cycle frequencies [4]

$$\mathscr{A} := \{\alpha \,|\, 0 \le \alpha < 1,\ R_{xx}(\alpha;\tau) \not\equiv 0\}\,. \tag{25}$$

A conjugate CAF is defined as

$$R_{xx(*)}(\alpha;\tau) = \lim_{M\to\infty} \frac{1}{M} \sum_{t=1}^{M} R_{xx^*}(t, t+\tau) e^{-j2\pi\alpha t} \tag{26}$$

where $R_{xx^*}(t, t+\tau) := E\{x(t)x(t+\tau)\}$. Reference [4] considers conjugate CAFs whereas [14, 17] consider both types of CAFs. For wide-sense stationary (WSS) signals, $R_{xx}(\alpha;\tau) = 0$ as well as $R_{xx(*)}(\alpha;\tau) = 0$ for any $\alpha \neq 0$.

OFDM Signals

As shown in [17] and [18], an OFDM signal exhibits nonconjugate cyclostationarity with cycle frequencies $\alpha = kF_s$, $k = \pm1, \pm2, \cdots$ and lags $\tau = \pm T_u$ where the OFDM symbol duration is $T_s = T_u + T_c = (1/F_s)$, T_c is the duration of the cyclic prefix, and T_u is the useful symbol duration. Consider a (continuous-time) baseband OFDM signal with N_c subcarriers given by

$$s(t) = \sum_{n=-\infty}^{\infty} \sum_{i=0}^{N_c-1} d_{n,i}\, g(t - nT_s) e^{-j2\pi(i-\frac{N_c-1}{2})(t-nT_s)/T_u} \tag{27}$$

where $d_{n,i}$ is the complex nth information symbol modulating the ith subcarrier, T_u^{-1} is the subcarrier separation, and $g(t)$ is the rectangular pulse of duration T_s centered at 0. If $E\{d_{n,i}d_{m,k}\} = 0$ (as for M-PSK ($M \neq 2$) or QAM modulation), then the OFDM signal does not exhibit conjugate cyclostationarity. The continuous-time nonconjugate CAF of (27) is given by [18]

$$R_{ss}(\alpha;\tau) = \begin{cases} \sigma_d^2 \frac{\sin(\pi N_c \tau/T_u)\sin(\pi k F_s(T_s - |\tau|))}{\pi k \sin(\pi\tau/T_u)}, & \alpha = kF_s,\ \ k = \pm1, \pm2, \cdots,\ \ |\tau| < T_s \\ 0, & \text{otherwise}\,, \end{cases} \tag{28}$$

where $\sigma_d^2 = E\{|d_{n,i}|^2\}$. As noted in [17, 18], the CAF (28) exhibits discrete cyclic autocorrelation surfaces for $\alpha = kF_s$ ($k = \pm1, \pm2, \cdots$), which peak at $\tau = \pm T_u$. If one samples $s(t)$ in (27) with $N = N_c + N_{cp}$ samples every T_s sec with N_c samples in useful symbol duration T_u and N_{cp} samples in cyclic prefix duration T_c, then,

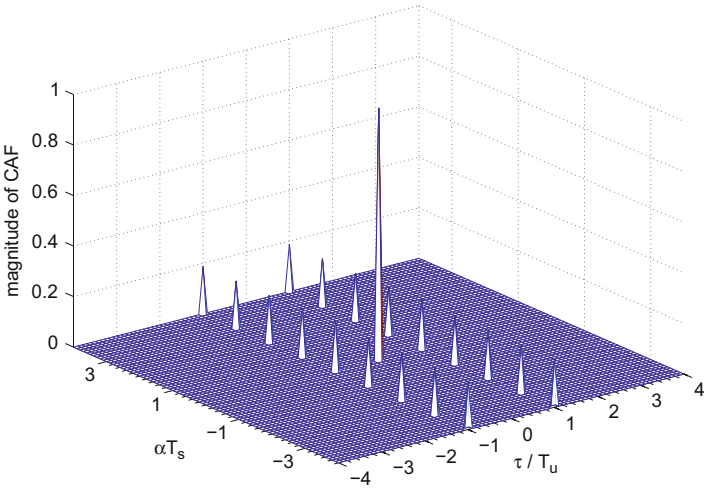

Fig. 1 CAF magnitude for an OFDM signal with $N_c = 32$, $N_{cp} = 8$

in terms of normalized frequency and sampled signal, the discrete-time sampled OFDM signal has normalized cyclic frequencies $\alpha = k/N$ ($k = \pm 1, \pm 2, \cdots$), and the nonconjugate CAF peaks at $\tau = \pm N_c$. Thus the set $\mathscr{A}$ in (25) for sampled OFDM signals is $\mathscr{A} = \{\frac{k}{N},\ k = 0, 1, 2, \cdots, N-1\}$.

Figure 1 shows the magnitude of $R_{ss}(\alpha; \tau)$ when $N_c = 32$, $N_{cp} = 8$, and $\sigma_d^2 = 1$.

GMSK signals

Using a linearization approximation, it has been shown in [17] and [18] that a GMSK (Gaussian Minimum Shift Keying) signal with symbol rate F_s exhibits conjugate cyclostationarity with cycle frequencies of $\alpha = \pm k F_s/2$, k odd, and the conjugate CAF for $k = 1$ peaks at $\tau = 0$. It is also shown in [18] that for GMSK-based GSM signals, nonconjugate cyclostationarity can be quite weak. For further details, one is referred to [17] and [18]. If there are N (even) samples per GMSK symbols, then in terms of normalized frequency, $\mathscr{A} = \{\frac{k}{2N},\ k = 1, 3, \cdots, 2N-1\}$.

Multivariate Processes

One has a vector random process arising due to a multiple antenna receiver with $p \geq 1$ antennas. Therefore, consider a $p \times 1$ discrete-time zero-mean complex-valued cyclostationary signal $\mathbf{x}(t)$ with time-varying autocorrelation function $\mathbf{R}_{xx}(t, t+\tau) := E\{\mathbf{x}(t)\mathbf{x}^H(t+\tau)\}$ which has a Fourier series representation [4, 17]

$$\mathbf{R}_{xx}(t, t+\tau) = \sum_{\alpha \in \mathscr{A}} \mathbf{R}_{xx}(\alpha; \tau) e^{j 2\pi \alpha t} \tag{29}$$

where the nonconjugate *cyclic autocorrelation function* (CAF) $\mathbf{R}_{xx}(\alpha;\tau)$ at cycle frequency $\alpha \in \mathscr{A}$ is given by

$$\mathbf{R}_{xx}(\alpha;\tau) = \lim_{M\to\infty} \frac{1}{M} \sum_{t=1}^{M} \mathbf{R}_{xx}(t, t+\tau) e^{-j2\pi\alpha t}. \tag{30}$$

Similar comments apply to conjugate CAFs.

Tests Using Stationarity

The spectrum sensing tests considered here assume that the noisy signal is stationary during the time interval over which the measurements are collected and processed at the cognitive receiver.

Correlation-Based Approaches

Consider the binary hypothesis testing problem (2). The PU channel impulse response and the noise correlation are unknown. It is known that noise is zero-mean complex (proper) Gaussian, spatially uncorrelated and temporally possibly colored. Assume further that correlation function of noise is "effectively" zero for lags $> L_n$ where L_n is known, i.e.,

$$\mathbf{R}_{nn}(\tau) = 0 \text{ for } |\tau| > L_n. \tag{31}$$

The binary hypothesis testing problem in this case is formulated as

$$\begin{aligned} &\mathscr{H}_0 : \mathbf{R}_{ij,xx}(0) = 0 \ \text{ for } i \neq j, \ \ i,j = 1,2,\cdots,p \\ &\mathscr{H}_1 : \mathbf{R}_{ij,xx}(0) \not\equiv 0 \ \text{ for some } i \neq j, \ \ i,j = 1,2,\cdots,p \end{aligned} \tag{32}$$

In view of the earlier results of section "Large Sample Statistics of Sample Correlation", consider the following ad hoc test statistic

$$\mathscr{T} := 2N \sum_{i=1}^{p-1} \sum_{j=i+1}^{p} \frac{|\hat{R}_{ij,xx}(0)|^2}{\sum_{m=-M}^{M} \hat{R}_{ii,xx}(m)\hat{R}^*_{jj,xx}(m)} \tag{33}$$

where $M \ll N$ is an upperbound on "effective" memory of the colored noise sequence. Under $\mathscr{H}_0$, $\hat{R}_{ij,xx}(0)$ has zero mean for every $i \neq j$, and under $\mathscr{H}_1$, it has nonzero mean for some $i \neq j$. This motivates the (ad hoc) CFAR (constant false alarm rate) test

$$\mathscr{T} \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \eta \tag{34}$$

where the threshold η is picked to achieve a specified probability of false alarm $P_{fa} = P\{\mathscr{T} \geq \eta \,|\, \mathscr{H}_0\}$. By the results of section "Large Sample Statistics of Sample Correlation", asymptotic distribution of $\mathscr{T}$ under $\mathscr{H}_0$ can be found to enable design of a CFAR test. Such CFAR tests are not optimal in any sense but do yield a constant false alarm rate, a desirable property, under model parameter uncertainties. CFAR tests have been used in radar and other problems under parameter uncertainty [9, Sec. 8.1].

The threshold η is calculated based on asymptotic considerations as follows. It follows from (17) that asymptotically (as $N \to \infty$),

$$2N \frac{|\hat{R}_{ij,xx}(0)|^2}{\sum_{m=-M}^{M} R_{ii,xx}(m) R^*_{jj,xx}(m)} \overset{\mathscr{H}_0}{\sim} \chi^2_2 \tag{35}$$

where χ^2_n denotes the central chi-square distribution with n degrees of freedom (dof). Equation (13) applied to finite-memory sequences also implies that as $N \to \infty$, $\hat{R}_{ii,xx}(0)$ converges in the mean-square sense, hence in probability (i.p.), to $R_{ii,xx}(0)$. Together with (35) this result implies that asymptotically

$$2N \frac{|\hat{R}_{ij,xx}(0)|^2}{\sum_{m=-M}^{M} \hat{R}_{ii,xx}(m) \hat{R}^*_{jj,xx}(m)} \overset{\mathscr{H}_0}{\sim} \chi^2_2. \tag{36}$$

As noted earlier, the upper (lower) triangular off-diagonal elements of $\hat{\mathbf{R}}_{nn}(0)$ are asymptotically independent of the other upper (lower) triangular off-diagonal elements; therefore, for distinct ij pairs with $i \neq j$, the left side of (35) results in mutually independent random variables for distinct ij pairs. Therefore, since there are $p(p-1)/2$ such terms in $\mathscr{T}$, asymptotically

$$\mathscr{T} \overset{\mathscr{H}_0}{\sim} \chi^2_{p(p-1)}. \tag{37}$$

This allows one to pick the test threshold for a given P_{fa}.

PSD Based Approaches

Here the generalized likelihood ratio test (GLRT) proposed in [27] is summarized. Denote the spectral estimator at the k-th frequency bin f_k as $\mathbf{X}_k$ with its true value denoted as $\mathbf{S}(f_k)$. Thus, $\mathbf{X}_k \sim (1/K) W_C(p, K, \mathbf{S}(f_k))$. Attention is confined to the frequency points over which the spectral estimators are independent. If one uses the Daniell method, then the frequencies over which the estimators are (asymptotically) independent, given by $f_k = (kK + \lceil (K/2) \rceil)/N$, $k \in [0, \lfloor$

$(N-(K/2)-1)/K\rfloor]$. After reindexing the frequency subscripts to run from 1 through M, let $\mathscr{M} := \{f_k : 1 \le k \le M\}$ denote the set of M frequency bins under consideration.

The binary hypothesis testing problem under consideration is

$$\begin{aligned} &\mathscr{H}_0 : \mathbf{S}(f_k) = \text{diag}\left\{\mathbf{S}_{11}(f_k), \cdots, \mathbf{S}_{pp}(f_k)\right\} \ \forall f_k \in \mathscr{M} \\ &\mathscr{H}_1 : \mathscr{H}_0^c, \text{ i.e., } \mathbf{S}_{lm}(f_k) \not\equiv 0 \text{ for some } l \ne m \end{aligned} \tag{38}$$

given the "data" $\mathbf{X}_k$. Under $\mathscr{H}_0$ noise is spatially uncorrelated, while under $\mathscr{H}_1$, spatially correlated signal may also be present; no assumptions are made regarding temporal correlations. Under $\mathscr{H}_0$, the joint pdf of $\mathbf{X}_k$ for $k \in \mathscr{M}$ is maximized w.r.t. $\mathbf{S}_{ii}(f_k)$ for $\widehat{\mathbf{S}}_{ii}(f_k) = (\mathbf{X}_k)_{ii}$, $i = 1, 2, \cdots, p$. Under $\mathscr{H}_1$, the joint pdf of $\mathbf{X}_k$ for $k \in \mathscr{M}$ is maximized w.r.t. the Hermitian matrix $\mathbf{S}(f_k)$ for $\hat{\mathbf{S}}(f_k) = \mathbf{X}_k$. Then one gets the GLRT

$$\begin{aligned} \mathscr{L} &:= \frac{f\left(\mathbf{X}_k,\ 1 \le k \le M | \mathscr{H}_1, \hat{\mathbf{S}}(f_k),\right)}{f\left(\mathbf{X}_k,\ 1 \le k \le M | \mathscr{H}_0, \widehat{\mathbf{S}}_{ii}(f_k), i = 1, 2, \cdots, p,\ \ 1 \le k \le M\right)} \\ &= \prod_{k=1}^{M} \frac{\prod_{i=1}^{p} \left[(\mathbf{X}_k)_{ii}\right]^K}{|\mathbf{X}_k|^K} \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \tau \end{aligned} \tag{39}$$

where the threshold τ is picked to achieve a prespecified probability of false alarm $P_{fa} = P\{\mathscr{L} \ge \tau \,|\, \mathscr{H}_0\}$. This requires pdf of $\mathscr{L}$ under $\mathscr{H}_0$. This problem is addressed in [27] which is reviewed next after introducing some notation.

Let $B_r(n)$ denote the Bernoulli polynomial of degree r and order unity. The first five Bernoulli polynomials are $(B_0(n) = 1)$ [1]:

$$\begin{aligned} &B_1(n) = n - \frac{1}{2},\ B_2(n) = n^2 - n + \frac{1}{6}, \\ &B_3(n) = n^3 - \frac{3}{2}n^2 + \frac{1}{2}n,\ B_4(n) = n^4 - 2n^3 + n^2 - \frac{1}{30}, \\ &B_5(n) = n^5 - \frac{5}{2}n^4 + \frac{5}{3}n^3 - \frac{1}{6}n. \end{aligned}$$

Let

$$\nu = Mp^2 - Mp,\ \ \rho = 1 - \frac{1}{\nu}\left[\frac{Mp(p^2-1)}{3K}\right], \tag{40}$$

and for $r = 1, 2, \cdots$

$$\omega_r = \frac{(-1)^{r+1}M}{r(r+1)(\rho K)^r}\left[\left\{\sum_{l=1}^{p} B_{r+1}((1-\rho)K+1-l)\right\} - pB_{r+1}((1-\rho)K)\right]. \tag{41}$$

Theorem 1 ([27]). *The GLRT for the binary hypothesis testing problem (38) is given by*

$$2\rho\ \ln(\mathscr{L}) \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \tau \tag{42}$$

where ρ is given by (40) and

$$\ln(\mathscr{L}) = K\left\{\sum_{k=1}^{M}\left(\left[\sum_{i=1}^{p}\ln\left(\mathbf{X}_k\right)_{ii}\right] - \ln(|\mathbf{X}_k|)\right)\right\}. \tag{43}$$

The threshold τ is picked to achieve a specified probability of false alarm $P_{fa} = P\{2\rho\ \ln(\mathscr{L}) > \tau \,|\, \mathscr{H}_0\} = 1 - P\{2\rho\ \ln(\mathscr{L}) \leq \tau \,|\, \mathscr{H}_0\}$. The probability $P\{2\rho\ \ln(\mathscr{L}) \leq \tau \,|\, \mathscr{H}_0\}$ is given by

$$\begin{aligned} P\{2\rho\ \ln(\mathscr{L}) \leq \tau \,|\, \mathscr{H}_0\} = {} & P\{\chi_\nu^2 \leq \tau\} + \omega_2\big[P\{\chi_{\nu+4}^2 \leq \tau\} \\ & - P\{\chi_\nu^2 \leq \tau\}\big] + \omega_3\big[P\{\chi_{\nu+6}^2 \leq \tau\} - P\{\chi_\nu^2 \leq \tau\}\big] \\ & + \Big\{\omega_4\big[P\{\chi_{\nu+8}^2 \leq \tau\} - P\{\chi_\nu^2 \leq \tau\}\big] \\ & + \frac{1}{2}\omega_2^2\big[P\{\chi_{\nu+8}^2 \leq \tau\} - 2P\{\chi_{\nu+4}^2 \leq \tau\} + P\{\chi_\nu^2 \leq \tau\}\big]\Big\} \\ & + \mathscr{O}(K^{-5}) \end{aligned} \tag{44}$$

where χ_n^2 denotes a random variable with central chi-square distribution with n degrees of freedom (as well as the distribution itself), and ω_r's are given by (41).

Remark 1. Under some very general conditions, the following results hold ([7] and [6, Chapter 22]) asymptotically (as $N \to \infty$ with $K \to \infty$, $M \to \infty$ and $M/K \to 0$) for the problem under consideration

$$2\ \ln(\mathscr{L}) \sim \begin{cases} \chi^2_{M(p^2-p)} & : \mathscr{H}_0 \\ \chi^2_{M(p^2-p)}(\lambda) & : \mathscr{H}_1 \end{cases} \tag{45}$$

for some $\lambda > 0$ where $\chi_n^2(\lambda)$ denotes the noncentral chi-square distribution with n degrees of freedom and non-centrality parameter λ. As pointed out in [1, 2, 16],

under $\mathscr{H}_0$, the distribution $\chi^2_{M(p^2-p)}$ is often not accurate unless N is quite large, hence the extra terms and the Bartlett scale factor ρ in Theorem 1. As $N \to \infty$, $\rho \to 1$ and $\omega_r \to 0$ for $r = 2, 3, \cdots$. □

Performance: Probability of Detection

Under "local" alternatives, using [7] and [6, Chapter 22] (see also Remark 1), it follows that asymptotically, under $\mathscr{H}_1$, $2\ln(\mathscr{L}) \sim \chi^2_{M(p^2-p)}(\lambda)$. Typically (see, for instance, [7], [6, Chapter 22] and [33]) one calculates first- and second-order derivatives of the log-likelihood ratio and then takes their expectation (essentially one needs the Fisher information matrix [33]) in order to compute λ. Alternatively, an indirect approach to compute λ can be used. Under $\mathscr{H}_1$, one must have $E\{2\ln(\mathscr{L})\} = M(p^2-p) + \lambda$. In [29] an asymptotic expression ("large" K) for the non-centrality parameter λ via $E\{2\ln(\mathscr{L})\}$ has been derived as

$$\lambda = 2K \sum_{k=1}^{M} \left[\sum_{i=1}^{p} \ln(\mathbf{S}(f_k))_{ii} - \ln|\mathbf{S}(f_k)| \right]. \tag{46}$$

Remark 2. As noted in Remark 1, under $\mathscr{H}_0$, the distribution $\chi^2_{M(p^2-p)}$ is often not accurate unless N is "quite large," hence the extra terms and the Bartlett scale factor ρ in Theorem 1. Just as Theorem 1 accounts for "smaller" data sizes and modifies the distribution $\chi^2_{M(p^2-p)}$ under $\mathscr{H}_0$, one may follow (45) to modify the distribution $\chi^2_{M(p^2-p)}(\lambda)$ under $\mathscr{H}_1$ exploiting Theorem 1. That is, [29] proposes to use the distributions

$$\begin{aligned}
&P\{2\rho\ln(\mathscr{L}) \le \tau \mid \mathscr{H}_0\} \text{ is given by (44)},\\
&P\{2\rho\ln(\mathscr{L}) \le \tau \mid \mathscr{H}_1\} = P\{\chi^2_\nu(\lambda) \le \tau\}\\
&\qquad + \omega_2\big[P\{\chi^2_{\nu+4}(\lambda) \le \tau\} - P\{\chi^2_\nu(\lambda) \le \tau\}\big]\\
&\qquad + \omega_3\big[P\{\chi^2_{\nu+6}(\lambda) \le \tau\} - P\{\chi^2_\nu(\lambda) \le \tau\}\big]\\
&\qquad + \Big\{\omega_4\big[P\{\chi^2_{\nu+8}(\lambda) \le \tau\} - P\{\chi^2_\nu(\lambda) \le \tau\}\big]\\
&\qquad + \frac{1}{2}\omega_2^2\big[P\{\chi^2_{\nu+8}(\lambda) \le \tau\} - 2P\{\chi^2_{\nu+4}(\lambda) \le \tau\}\\
&\qquad + P\{\chi^2_\nu(\lambda) \le \tau\}\big]\Big\} + \mathscr{O}(K^{-5})
\end{aligned} \tag{47}$$

where $f = M(p^2-p)$ and λ is given by (46). Under $\mathscr{H}_0$, $\lambda = 0$ and under $\mathscr{H}_1$, as signal gets weaker, $\lambda \to 0$; under both these cases, (44) and (47) become the same. Also, as $N \to \infty$, we have $\rho \to 1$ and $\omega_r \to 0$ for $r = 2, 3, \cdots$, and we get (45). Thus use of (47) is well justified. □

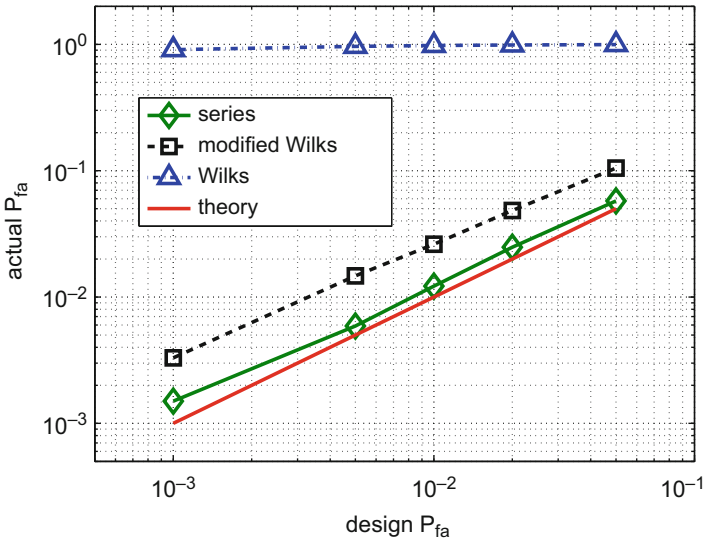

Fig. 2 Actual P_{fa} versus design P_{fa} based on 10,000 runs, $p = 4$, N=256, $K = 7$, $M = 36$.

Analytical Threshold Calculation Verification Example

This example is taken from [27] where efficacy of Theorem 1 in analytically computing the GLRT threshold for a given P_{fa} is investigated. There are four antennas (p=4) with independent complex Gaussian noise. First generate i.i.d. noise sequences at the antennas with variances σ_n^2, $2\sigma_n^2$, $0.75\sigma_n^2$, and $0.25\sigma_n^2$ with $\sigma_n^2 = 0.01$, and then filter each of them through the same linear filter with impulse response $\{0.3, 1.0, 0.3\}$. For $N = 256$, $m_t = 3$ was picked in (19) for spectral estimation, leading to $K = 7$ and $M = 36$. In Fig. 2 actual P_{fa} and design P_{fa} based on 10,000 runs are compared for N=256. It is seen that calculation of the test threshold via Theorem 1 is effective. In Fig. 2, "Wilks" refers to the test (42) with $\rho = 1$ and $2\ln(\mathscr{L}) \sim \chi^2_\nu$ under $\mathscr{H}_0$, and "modified Wilks" (more generally known as Bartlett's correction [2]) refers to the test (42) with $2\rho\ln(\mathscr{L}) \sim \chi^2_\nu$. It is seen that both Wilks approximation and Bartlett's correction for threshold calculation are ineffective.

Performance Analysis Verification Example

Here comparison of theoretical performance as predicted by the results of section "Performance: Probability of Detection" (in particular Remark 2) with the simulations-based performance for the proposed detector is presented when $N = 256$. Detection simulation results based on 5000 runs are shown. The noise sequences are as in the previous example. The signal is scalar QPSK filtered through impulse response $\{0.227, -0.460, 0.688, -0.460, 0.227\}$ and then passed through a flat-fading channel with random gain $\mathbf{h}$ (4×1) having mutually independent components, zero-mean proper complex-Gaussian with unit variance. The information

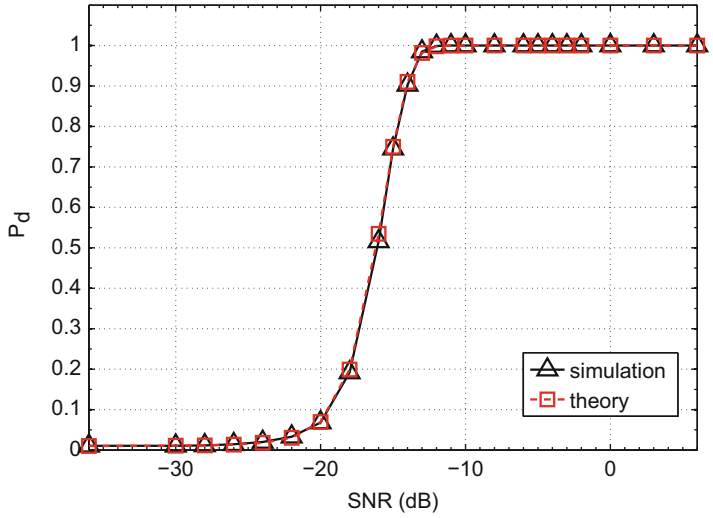

Fig. 3 Verification of theoretical performance analysis: N=256, $p = 4$, $P_{fa} = 0.01$

sequence variance σ_s^2 is scaled to achieve the desired SNR across antennas, defined as ratio of the sum of signal powers at the antennas to the sum of noise powers. Figure 3 shows the probability of detection ($P_d = P\{2\rho \ln(\mathscr{L}) > \tau \,|\, \mathscr{H}_1\}$ computed using (47)) versus average SNR results based on 5000 runs for $P_{fa} = 0.01$ and $p = 4$ for a randomly generated PU channel response which was then kept fixed for all Monte Carlo runs, only the noise sequence realization varied from run to run. It is seen from Fig. 3 that the theoretical- and simulation-based results are in excellent agreement.

Other Approaches

Several time-domain approaches relying on the generalized likelihood ratio test (GLRT) paradigm have been proposed for multiple antenna spectrum sensing in cognitive radios [24, 33, 35]. These approaches are suitable for flat-fading signals in white noise. They can obviate the need for the precise knowledge of the noise variance, but they do assume that noise variance is the same at all antennas. In sections "Correlation-Based Approaches" and "PSD Based Approaches", noise is allowed to be colored, and its variances can be different at different antennas without requiring knowledge of their spectra. In [13] various approaches are discussed to handle unequal noise variances across sensors. However, [13] (also [12]) assumes that noise is white and the primary user's signal is temporally white Gaussian, whereas in sections "Correlation-Based Approaches" and "PSD Based Approaches", one only requires it to be ergodic (it can be non-Gaussian). In [11] a spectral covariance sensing approach has been discussed where one

first computes the spectrogram of downconverted baseband signal. For analysis [11] also assumes both signal and noise samples to be temporally independent and identically distributed, and only a single antenna has been considered. In [26] an autocorrelation-based multiantenna spectrum sensing approach in white Gaussian noise is presented, and an extension of this approach to colored Gaussian noise is in [28]. There exist other non-GLRT approaches to the problem under consideration; see, for instance, [34] and references therein. In [34] two sample covariance-based test statistics have been proposed and analyzed for multi-antenna real-valued colored signals in real-valued white noise. Colored (complex) signals have been considered within the GLRT paradigm in [21] assuming multiple records (snapshots) and Gaussian PU signals; the results of sections "Correlation-Based Approaches" and "PSD Based Approaches" are based on a single observation record (snapshot).

A PSD-based GLRT approach was recently proposed in [27]. Except for [27] (and [28]), the PU signal is always assumed to be Gaussian in existing approaches, and most often noise is assumed to be white, and when handling colored noise/signal, both [20] and [21] (others consider white signal in white noise) require multiple independent data realizations (measurements) whereas only one data realization is needed in [27]. In [20] the test threshold is selected via simulations whereas [27] provides an analytical formulation. In [20] a frequency-domain test statistic (see (2) therein) similar to [27, Eqn. (6)] is derived via a time-domain formulation under the Gaussian assumption and some asymptotic considerations.

Tests Using Cyclostationarity

The problem under consideration is as in (2) except that now $s_{pu}(t)$ is a scalar cyclostationary signal (emitted by a primary user) with at least one known cycle frequency α and at least one known lag τ such that $R_{s_{pu}s_{pu}}(\alpha;\tau) \neq 0$. The approach taken here is similar to section "Correlation-Based Approaches" except that one uses estimated CAFs. To this end, first the large sample statistics of sample CAF are discussed.

Large Sample Statistics of Sample CAF

We are interested only in nonzero cycle frequencies.

Nonconjugate CAF

These results are appropriate for OFDM signals.

Spatially White and Temporally Correlated Gaussian Noise

Consider a $p \times 1$ WSS proper (circularly symmetric) complex-valued zero-mean colored Gaussian sequence $\mathbf{x}(t) = \mathbf{n}(t)$ with correlation function $\mathbf{R}_{xx}(t, t+\tau) =$

$\mathbf{R}_{nn}(t, t+\tau) = \mathbf{R}_{nn}(\tau) = \text{diag}\{R_{ii,n}(\tau),\ 1 \le i \le p\}$. Also, $E\{\mathbf{n}(t)\mathbf{n}^T(t+\tau)\} \equiv 0$ since $\mathbf{n}(t)$ is proper. Given an observation length of M samples, one can estimate the (nonconjugate) CAF $\mathbf{R}_{xx}(\alpha;\tau)$ as

$$\hat{\mathbf{R}}_{xx}(\alpha;\tau) = \frac{1}{M}\sum_{t=1}^{M} \mathbf{x}(t)\mathbf{x}^H(t+\tau)e^{-j2\pi\alpha t}. \tag{48}$$

It is easy to see that $\lim_{M\to\infty} E\{\hat{\mathbf{R}}_{xx}(\alpha;\tau)\} = \mathbf{R}_{xx}(\alpha;\tau)$. Let ($x_i$ is the i-th component of $\mathbf{x}$)

$$\hat{R}_{ik,x}(\alpha;\tau) := \frac{1}{M}\sum_{t=1}^{M} x_i(t)x_k^*(t+\tau)e^{-j2\pi\alpha t}. \tag{49}$$

Then

$$E\{\hat{R}_{ik,x}(\alpha;\tau)\} = R_{ik,x}(\tau)\left[\frac{1}{M}\sum_{t=1}^{M} e^{-j2\pi\alpha t}\right] \tag{50}$$

where $R_{ik,x}(\tau) := E\{x_i(t)x_k^*(t+\tau)\}$. It follows that

$$\begin{aligned} &E\{x_i(t_1)x_j^*(t_1+\tau_1)e^{-j2\pi\alpha t_1}x_k^*(t_2)x_l(t_2+\tau_2)e^{j2\pi\beta t_2}\} \\ &\quad= \text{cum}_4\left(x_i(t_1), x_j^*(t_1+\tau_1), x_k^*(t_2), x_l(t_2+\tau_2)\right)e^{-j2\pi(\alpha t_1-\beta t_2)} \\ &\qquad+R_{ij,x}(\tau_1)R_{kl,x}^*(\tau_2)e^{-j2\pi(\alpha t_1-\beta t_2)} \\ &\qquad+R_{ik,x}(t_2-t_1)R_{lj,x}(t_1-t_2-\tau_2+\tau_1)e^{-j2\pi(\alpha t_1-\beta t_2)}. \end{aligned} \tag{51}$$

For Gaussian sequences, the fourth cumulants are identically zero. Hence,

$$\begin{aligned} &\text{cov}\left(\hat{R}_{ij,x}(\alpha;\tau_1), \hat{R}_{kl,x}^*(\beta;\tau_2)\right) \\ &\quad= E\left\{\hat{R}_{ij,x}(\alpha;\tau_1)\hat{R}_{kl,x}^*(\beta;\tau_2)\right\} - E\left\{\hat{R}_{ij,x}(\alpha;\tau_1)\right\}E\left\{\hat{R}_{kl,x}^*(\beta;\tau_2)\right\} \\ &\quad= \frac{1}{M^2}\sum_{t_1=1}^{M}\sum_{t_2=1}^{M}\left[R_{ik,x}(t_2-t_1)R_{lj,x}(t_1-t_2-\tau_2+\tau_1)e^{-j2\pi(\alpha t_1-\beta t_2)}\right] =: A. \end{aligned} \tag{52}$$

Setting $t_1 - t_2 = m$ in (52) and with $\mathbf{x}(t) = \mathbf{n}(t)$, one obtains

$$A = \frac{1}{M^2}\sum_{m=-(M-1)}^{M-1} e^{-j2\pi\beta m}R_{ik,n}(-m)R_{lj,n}(m+\tau_1-\tau_2)\left[\sum_{t_1=|m|+1}^{M} e^{-j2\pi(\alpha-\beta)t_1}\right]. \tag{53}$$

It follows that

$$\frac{1}{M}\sum_{t=1}^{M} e^{-j2\pi(\alpha-\beta)t} = \begin{cases} 1 & \text{for } \alpha = \beta \in \mathscr{A} \\ \frac{e^{-j\pi(\alpha-\beta)(M+1)}}{M}\frac{\sin(\pi(\alpha-\beta)M)}{\sin(\pi(\alpha-\beta))} & \text{for } \alpha \neq \beta,\ \alpha,\beta \in \mathscr{A}. \end{cases} \tag{54}$$

It then follows that for any fixed m,

$$\begin{aligned} \lim_{M\to\infty}\frac{1}{M}\sum_{t=|m|+1}^{M} e^{-j2\pi(\alpha-\beta)t} &= \lim_{M\to\infty}\frac{1}{M}\left[\sum_{t=1}^{M} e^{-j2\pi(\alpha-\beta)t} - \sum_{t=1}^{|m|} e^{-j2\pi(\alpha-\beta)t}\right] \\ &= \delta_{\alpha,\beta}. \end{aligned} \tag{55}$$

Using (52), (53), and (55) and the fact that $\mathbf{n}(t)$ is spatially uncorrelated, one has

$$\lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{ij,n}(\alpha;\tau_1), \hat{R}^*_{kl,n}(\beta;\tau_2)\right) = \tilde{\gamma}_{ij,n}(\alpha;\tau_1-\tau_2)\delta_{i,k}\delta_{j,l}\delta_{\alpha,\beta} \tag{56}$$

where

$$\tilde{\gamma}_{ij,n}(\alpha;\tau_1-\tau_2) := \sum_{m=-\infty}^{\infty} R_{ii,n}(-m)R_{jj,n}(m+\tau_1-\tau_2)e^{-j2\pi\alpha m}. \tag{57}$$

Using (49) it follows that

$$\hat{R}^*_{ik,x}(\alpha;\tau) = \hat{R}_{ki,x}(-\alpha;-\tau) = \hat{R}_{ki,x}(1-\alpha;-\tau). \tag{58}$$

Therefore, from (56) and (58), one obtains

$$\begin{aligned} &\lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{ij,n}(\alpha;\tau_1), \hat{R}_{kl,n}(\beta;\tau_2)\right) \\ &\quad= \lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{ij,n}(\alpha;\tau_1), \hat{R}^*_{lk,n}(-\beta;-\tau_2)\right) \\ &\quad= \tilde{\gamma}_{ij,n}(\alpha;\tau_1+\tau_2)\delta_{i,l}\delta_{j,k}\delta_{\alpha,-\beta}. \end{aligned} \tag{59}$$

Finite-Memory Colored Gaussian Noise

It is analytically convenient to make a further assumption that correlation function of noise is "effectively" zero for lags $> L_n$ where L_n is known, i.e.,

$$\mathbf{R}_{nn}(\tau) = 0 \text{ for } |\tau| > L_n. \tag{60}$$

By (56), (59), and (60), for $\alpha, \beta \in \mathscr{A}$, we have

$$\begin{aligned} &\lim_{M\to\infty} M\,\mathrm{cov}\big(\hat{R}_{ij,n}(\alpha;\tau_1), \hat{R}^*_{kl,n}(\beta;\tau_2)\big) \\ &\quad= \tilde{\gamma}_{ij,n}(\alpha;0)\delta_{i,k}\delta_{j,l}\delta_{\tau_1,\tau_2}\delta_{\alpha,\beta} \text{ for } |\tau_1-\tau_2| > L_n, \end{aligned} \tag{61}$$

$$\lim_{M\to\infty} M \operatorname{cov}\left(\hat{R}_{ij,n}(\alpha;\tau_1), \hat{R}_{kl,n}(\beta;\tau_2)\right) = 0. \tag{62}$$

Also, by [4, 14, 17], asymptotically (as $M \to \infty$), $\hat{R}_{ik,x}(\alpha;\tau)$ is a Gaussian random variable (complex-valued but not necessarily circularly symmetric), and "vectorized" matrix $\hat{\mathbf{R}}_{xx}(\alpha;\tau)$ is a Gaussian random vector for any α and τ, for $\mathbf{x}(t)$ under either $\mathscr{H}_0$ or $\mathscr{H}_1$ and whether $\mathbf{x}(t)$ is finite memory or not. Invoking asymptotic Gaussianity, it then follows that

$$\lim_{M\to\infty} \sqrt{M}\,\hat{R}_{ij,n}(\alpha;\tau) \sim \mathscr{N}_c\left(0, \tilde{\gamma}_{ij,n}(\alpha;0)\right) \quad \forall i, j \tag{63}$$

where $\mathscr{N}_c(\mathbf{m}, \Sigma)$ denotes a circularly symmetric (proper) complex Gaussian (vector) distribution with mean $\mathbf{m}$ and covariance matrix Σ. Furthermore, $\hat{R}_{ij,x}(\alpha;\tau)$ is asymptotically independent of $\hat{R}_{kl,x}(\alpha;\tau)$ if $i \neq k$ or $j \neq l$. Moreover, $\hat{R}_{ij,x}(\alpha;\tau_1)$ is asymptotically independent of $\hat{R}_{kl,x}(\beta;\tau_2)$ if $\alpha \neq \beta$ ($\alpha, \beta \in \mathscr{A}$) or $\tau_1 \neq \tau_2$, for any i, j, k, l.

As discussed in section "OFDM Signals", for OFDM signals, the nonconjugate CAF peaks at $\tau = \pm N_c$ (N_c = number of subcarriers). If $\tau_1 = N_c$ and $\tau_2 = -N_c$, then one must have $L_n < 2N_c$ for (61) to hold true.

Conjugate CAF

These results are appropriate for GMSK signals. Given an observation length of M samples, one can estimate the conjugate CAF

$$\mathbf{R}_{xx(*)}(\alpha;\tau) := \lim_{M\to\infty} \frac{1}{M} \sum_{t=1}^{M} E\{\mathbf{x}(t)\mathbf{x}^T(t+\tau)\} e^{-j2\pi\alpha t} \tag{64}$$

as

$$\hat{\mathbf{R}}_{xx(*)}(\alpha;\tau) = \frac{1}{M} \sum_{t=1}^{M} \mathbf{x}(t)\mathbf{x}^T(t+\tau) e^{-j2\pi\alpha t}. \tag{65}$$

Spatially White and Temporally Correlated Gaussian Noise

When $\mathbf{n}(t)$ is proper and $\mathbf{x}(t) = \mathbf{n}(t)$, it follows easily that $E\{\hat{\mathbf{R}}_{nn(*)}(\alpha;\tau)\} = 0$ and

$$\operatorname{cov}\left(\hat{R}_{(*)ij,n}(\alpha;\tau_1), \hat{R}_{(*)kl,n}(\beta;\tau_2)\right) = E\{\hat{R}_{(*)ij,n}(\alpha;\tau_1)\hat{R}_{(*)kl,n}(\beta;\tau_2)\} = 0 \tag{66}$$

where $R_{(*)ik,x}(\tau) := E\{x_i(t)x_k(t+\tau)\}$. Mimicking section "Spatially White and Temporally Correlated Gaussian Noise" one has

$$\operatorname{cov}\left(\hat{R}_{(*)ij,n}(\alpha;\tau_1), \hat{R}^*_{(*)kl,n}(\beta;\tau_2)\right) = E\{\hat{R}_{(*)ij,n}(\alpha;\tau_1)\hat{R}^*_{(*)kl,n}(\beta;\tau_2)\}$$

$$= \frac{1}{M^2}\sum_{t_1=1}^{M}\sum_{t_2=1}^{M}\Big[R_{ik,n}(t_2-t_1)R_{jl,n}(t_2-t_1+\tau_2-\tau_1)$$
$$+R_{il,n}(t_2-t_1+\tau_2)R_{jk,n}(t_2-t_1-\tau_1)\Big]e^{-j2\pi(\alpha t_1-\beta t_2)}$$
$$= \frac{1}{M^2}\sum_{m=-(M-1)}^{M-1} e^{j2\pi\alpha m}\Big[R_{ik,n}(m)R_{jl,n}(m+\tau_2-\tau_1)$$
$$+R_{il,n}(m+\tau_2)R_{jk,n}(m-\tau_1)\Big]\left[\sum_{t_2=|m|+1}^{M} e^{-j2\pi(\alpha-\beta)t_2}\right]. \tag{67}$$

It then follows that

$$\lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{(*)ij,n}(\alpha;\tau_1),\hat{R}^*_{(*)kl,n}(\beta;\tau_2)\right)$$
$$= \sum_{m=-\infty}^{\infty}\left[R_{ik,n}(m)R_{jl,n}(m+\tau_2-\tau_1)+R_{il,n}(m+\tau_2)R_{jk,n}(m-\tau_1)\right]e^{j2\pi\alpha m}\delta_{\alpha,\beta}. \tag{68}$$

For GMSK signals, the nonconjugate CAF peaks at $\tau = 0$. Confining one's attention to $\tau_1 = \tau_2 = 0$, for finite-memory, spatially uncorrelated, colored Gaussian noise, one obtains

$$\lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{(*)ij,n}(\alpha;0),\hat{R}^*_{(*)kl,n}(\beta;0)\right)$$
$$= \begin{cases} 2\sum_{m=-L_n}^{L_n} R^2_{ii}(n)e^{j2\pi\alpha m}\delta_{\alpha,\beta} & \text{if } i=k=l=j \\ \sum_{m=-L_n}^{L_n} R_{ii,n}(m)R_{jj,n}(m)e^{j2\pi\alpha m}\delta_{\alpha,\beta} & \text{if } (i,j)=(k,l) \text{ but } i\neq j, \\ & \quad \text{or } (i,j)=(l,k) \\ 0 & \text{otherwise.} \end{cases} \tag{69}$$

Specializing (68) to white, spatially uncorrelated, Gaussian noise with $\tau_1 = \tau_2 = \tau$, it follows that

$$\lim_{M\to\infty} M\,\mathrm{cov}\left(\hat{R}_{(*)ij,n}(\alpha;\tau),\hat{R}^*_{(*)kl,n}(\beta;\tau)\right)$$
$$= \begin{cases} 2R_{ii,n}(0)R_{jj,n}(0)\delta_{\alpha,\beta} & \text{if } i=k=l=j \text{ and } \tau=0 \\ R_{ii,n}(0)R_{jj,n}(0)\delta_{\alpha,\beta} & \text{if } (i,j)=(k,l) \text{ but } i\neq j, \text{ or } (i,j)=(l,k) \text{ and } \tau=0 \\ 0 & \text{otherwise.} \end{cases} \tag{70}$$

Invoking asymptotic Gaussianity, it then follows that for finite-memory colored Gaussian noise

$$\lim_{M\to\infty} \sqrt{M}\,\hat{R}_{(*)ij,n}(\alpha;0) \sim \mathcal{N}_c\left(0,\ \sum_{m=-L_n}^{L_n} (1+\delta_{i,j})R_{ii,n}(m)R_{jj,n}(m)e^{j2\pi\alpha m}\right) \quad \forall i,j. \tag{71}$$

Similarly for white Gaussian noise, one has

$$\lim_{M\to\infty} \sqrt{M}\,\hat{R}_{(*)ij,n}(\alpha;0) \sim \mathcal{N}_c\left(0,(1+\delta_{\tau,0}\delta_{i,j})R_{ii,n}(0)R_{jj,n}(0)\right) \quad \forall i,j. \tag{72}$$

Noting that since $\lim_{M\to\infty} \hat{R}_{(*)ij,x}(\alpha;\tau) = \lim_{M\to\infty} \hat{R}_{(*)ji,x}(\alpha;\tau)$ and $\hat{R}_{(*)ij,x}(\alpha;0) = \hat{R}_{(*)ji,x}(\alpha;0)$, unlike nonconjugate CAFs, in case of conjugate CAFs, $\hat{R}_{(*)ij,x}(\alpha;\tau)$ is asymptotically independent of $\hat{R}_{(*)kl,x}(\alpha;\tau)$ for $i \neq k$ or $j \neq l$ if $i \geq j$ and $k \geq l$ (or if $i \leq j$ and $k \leq l$).

Test Statistics

Based on the large sample statistics of CAFs of colored Gaussian noise discussed in section "Large Sample Statistics of Sample CAF", one can devise ad hoc CFAR (constant false alarm rate) detectors for detection of nonzero nonconjugate as well as conjugate CAFs. They are ad hoc as they do not follow any optimality criterion. Since no knowledge is assumed about the structure of the colored noise (its variance or correlation function) or the underlying channel (flat or frequency selective), an optimal detector based on the likelihood ratio or generalized likelihood ratio test does not appear to be possible. It is assumed that the finite-memory assumption (60) holds true. The desired PU signals are assumed to have nonzero CAF at certain known nonzero cycle frequencies and lags, whereas CAF of colored noise is zero at all lags and nonzero cycle frequencies. The considered tests exploit the large sample statistics of the estimated CAF to yield CFAR detectors.

Nonconjugate CAF: OFDM Signals

Consider the binary hypothesis testing problem (2). The PU channel impulse response and the noise correlation function are unknown. Also, $s_{pu}(t)$ is a scalar cyclostationary signal (emitted by PUs) with $K \geq 1$ known cycle frequency and lag pairs (α_k, τ_k), $k = 1, 2, \cdots, K$, such that $R_{s_{pu}s_{pu}}(\alpha_k;\tau_k) \neq 0$ and $|\tau_1 - \tau_2| > L_n$ so that (61) holds true. The binary hypothesis testing problem in this case can be formulated as

$$\begin{aligned} \mathcal{H}_0 &: R_{ij,x}(\alpha_k;\tau_k) = 0 \ \ \forall\, i,j,k \\ \mathcal{H}_1 &: R_{ij,x}(\alpha_k;\tau_k) \not\equiv 0 \ \ \text{for some } i,j,k. \end{aligned} \tag{73}$$

Under both hypotheses, $\lim_{M\to\infty} E\{\hat{\mathbf{R}}(\alpha;\tau)\} = \mathbf{R}(\alpha;\tau)$. Under $\mathcal{H}_0$, by the results of section "Spatially Uncorrelated, Temporally Colored Noise", $\hat{R}_{ij}(\alpha_k;\tau_k)$ has zero-mean $\forall\, i,j,k$, and under $\mathcal{H}_1$, it has nonzero mean for some i,j,k; therefore, $|R_{ij}(\alpha_k;\tau_k)| > 0$ for some i,j,k. Define (see also (57))

$$\bar{\gamma}_{ij,n}(\alpha_k) := \sum_{m=-L_n}^{L_n} R_{ii,n}(-m) R_{jj,n}(m) e^{-j2\pi\alpha_k m} \tag{74}$$

and let $\tilde{\mathbf{r}}$ denote the $Kp^2 \times 1$ vector composed of elements $\hat{R}_{ij,x}(\alpha_k;\tau_k)/\sqrt{\bar{\gamma}_{ij,x}(\alpha_k)}$ for all distinct triplets (i,j,k). Then by (63), one has $\lim_{M\to\infty} \sqrt{M}\tilde{\mathbf{r}} \overset{\mathscr{H}_0}{\sim} \mathcal{N}_c(0,\mathbf{I})$ leading to $2M\tilde{\mathbf{r}}^H\tilde{\mathbf{r}} \overset{\mathscr{H}_0}{\sim} \chi^2_{2Kp^2}$ where χ^2_n denotes the central chi-square distribution with n degrees of freedom (dof). Since $|R_{ij}(\alpha_k;\tau_k)| > 0$ for some i,j,k, it follows that $E\{\tilde{\mathbf{r}}^H\tilde{\mathbf{r}} \,|\, \mathscr{H}_1\} > E\{\tilde{\mathbf{r}}^H\tilde{\mathbf{r}} \,|\, \mathscr{H}_0\}$. Furthermore, since the true values $\bar{\gamma}_{ij,n}(\alpha_k)$, $(k = 1,2,\cdots,K)$, are not available, they are replaced with estimates $\hat{\gamma}_{ij,x}(\alpha_k)$, and consider the following ad hoc test motivated by $2M\tilde{\mathbf{r}}^H\tilde{\mathbf{r}}$ and $E\{\tilde{\mathbf{r}}^H\tilde{\mathbf{r}} \,|\, \mathscr{H}_1\} > E\{\tilde{\mathbf{r}}^H\tilde{\mathbf{r}} \,|\, \mathscr{H}_0\}$:

$$\mathscr{T} := 2M \sum_{k=1}^{K} \sum_{i=1}^{p} \sum_{j=1}^{p} \frac{|\hat{R}_{ij,x}(\alpha_k;\tau_k)|^2}{\hat{\gamma}_{ij,x}(\alpha_k)} \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \eta \tag{75}$$

where

$$\hat{\gamma}_{ij,x}(\alpha_k) := \sum_{m=-L_n}^{L_n} \hat{R}_{ii,x}(-m) \hat{R}_{jj,x}(m) e^{-j2\pi\alpha_k m}, \tag{76}$$

$$\hat{R}_{ii,x}(m) := \frac{1}{M-m} \sum_{k=1}^{M-m} x_i(k) x_i^*(k+m), \quad m \geq 0, \tag{77}$$

$\hat{R}_{ii,x}(-m) = \hat{R}^*_{ii,x}(m)$, and the threshold η is picked to achieve a specified probability of false alarm $P_{fa} = P\{\mathscr{T} \geq \eta \,|\, \mathscr{H}_0\}$. By the results of section "Spatially Uncorrelated, Temporally Colored Noise", one can find asymptotic distribution of $\mathscr{T}$ under $\mathscr{H}_0$ and design a CFAR test. Such CFAR tests are not optimal in any sense but do yield a constant false alarm rate, a desirable property, under model parameter uncertainties.

How does one calculate η? It follows from (63) that asymptotically (as $M \to \infty$),

$$2M \frac{|\hat{R}_{ij,x}(\alpha_k;\tau_k)|^2}{\bar{\gamma}_{ij,x}(\alpha_k)} \overset{\mathscr{H}_0}{\sim} \chi^2_2. \tag{78}$$

Equation (61) applied to finite-memory colored Gaussian noise also implies that as $M \to \infty$, under $\mathscr{H}_0$, $\hat{R}_{ii,x}(m)$ converges in the mean-square sense, hence in probability (i.p.), to $R_{ii,x}(m)$. Together with (78) this result implies that asymptotically

$$2M \frac{|\hat{R}_{ij,x}(\alpha;\tau)|^2}{\hat{\gamma}_{ij,x}(\alpha_k)} \overset{\mathscr{H}_0}{\sim} \chi^2_2. \tag{79}$$

As noted in section "Spatially Uncorrelated, Temporally Colored Noise", any element of $\hat{\mathbf{R}}_{xx}(\alpha_k;\tau_k)$ is asymptotically independent of all other elements, and the same holds true for distinct cycle frequencies; therefore, in (75) one has (asymptotically) mutually independent random variables for distinct (i,j,k) triples. Since there are Kp^2 such terms in $\mathscr{T}$, asymptotically

$$\mathscr{T} \overset{\mathscr{H}_0}{\sim} \chi^2_{2Kp^2}. \tag{80}$$

Conjugate CAF: GMSK Signals

In this case too, the binary hypothesis testing problem is formulated as (73) except that one uses $R_{(*)ij,x}(\alpha_k;\tau_k)$ instead of $R_{ij,x}(\alpha_k;\tau_k)$, and one should take $\tau_k = 0\ \forall k$ since that is where the GMSK CAF is the strongest [18]. Following sections "Conjugate CAF" and "Nonconjugate CAF: OFDM Signals", consider the test statistic

$$\mathscr{T}_{conj} := 2M \sum_{k=1}^{K} \sum_{i=1}^{p} \sum_{j=i}^{p} \frac{|\hat{R}_{(*)ij,x}(\alpha_k;0)|^2}{\sum_{m=-L_n}^{L_n}(1+\delta_{i,j})\hat{R}_{ii,x}(m)\hat{R}_{jj,x}(m)e^{j2\pi\alpha_k m}} \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \eta_{conj}. \tag{81}$$

Using the results of section "Conjugate CAF" and noting that there are $K(p^2+p)/2$ terms in the double summation in (81), it follows that

$$\mathscr{T}_{conj} \overset{\mathscr{H}_0}{\sim} \chi^2_{K(p^2+p)} \tag{82}$$

which allows for calculation of the test threshold η_{conj} corresponding to a specified P_{fa}.

Single Antenna Case: Nonconjugate CAF

Here some existing tests for $p = 1$ are briefly discussed and compared.

Test of [10]

For $p = 1$ (single antenna), the considered nonconjugate CAF test reduces to

$$2M \sum_{k=1}^{K} \frac{|\hat{R}_{11,x}(\alpha_k;\tau_k)|^2}{\sum_{m=-L_n}^{L_n}|\hat{R}_{11,x}(m)|^2 e^{-j2\pi\alpha_k m}} \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \eta. \tag{83}$$

Dandawate-Giannakis and Related Tests [4, 14, 17]

It is interesting to compare the above test with the corresponding tests in [4, 14]. Define

$$\hat{\mathbf{c}}(\alpha;\tau) := \begin{bmatrix} \mathrm{Re}\left\{\hat{R}_{11,x}(\alpha;\tau)\right\} \\ \mathrm{Im}\left\{\hat{R}_{11,x}(\alpha;\tau)\right\} \end{bmatrix},$$

$$F(f) := \sum_{t=1}^{M} x(t)x^*(t+\tau)e^{-j2\pi ft}, \tag{84}$$

$$\hat{S} := \frac{1}{ML_w} \sum_{s=-(L_w-1)/2}^{s=(L_w-1)/2} W(s)F(\alpha - \frac{s}{M})F(\alpha + \frac{s}{M}), \tag{85}$$

$$\hat{S}^{(*)} := \frac{1}{ML_w} \sum_{s=-(L_w-1)/2}^{s=(L_w-1)/2} W(s)F^*(\alpha + \frac{s}{M})F(\alpha + \frac{s}{M}), \tag{86}$$

$$\hat{\Gamma}(\alpha;\tau) := \begin{bmatrix} \text{Re}\left\{\frac{\hat{S}+\hat{S}^{(*)}}{2}\right\} & \text{Im}\left\{\frac{\hat{S}-\hat{S}^{(*)}}{2}\right\} \\ \text{Im}\left\{\frac{\hat{S}+\hat{S}^{(*)}}{2}\right\} & \text{Re}\left\{\frac{\hat{S}^{(*)}-\hat{S}}{2}\right\} \end{bmatrix} \tag{87}$$

where $W(s)$ is a spectral smoothing window of odd length L_w. The test of [4] is given by

$$\mathscr{T}_{2c}(\alpha;\tau) := M\hat{\mathbf{c}}^T(\alpha;\tau)\hat{\Gamma}^{-1}(\alpha;\tau)\hat{\mathbf{c}}(\alpha;\tau) \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \gamma \tag{88}$$

where $\mathscr{T}_{2c}(\alpha;\tau) \overset{\mathscr{H}_0}{\sim} \chi^2_2$. A multi-antenna version of this test for conjugate CAFs may be found in [36]. A Kaiser window function has been used for $W(s)$ in [4, 14, 17, 18, 36]. It is given by

$$W(s) = \begin{cases} I_0\left(\beta\sqrt{1-(\frac{s}{L_w/2})^2}\right), -\frac{L_w-1}{2} \le s \le \frac{L_w+1}{2} \\ 0 \text{ elsewhere} \end{cases} \tag{89}$$

where I_0 is zero-order modified Bessel function of the first kind and β and L_w are parameters to be selected. In [14] a multifrequency-multilag version has been proposed as

$$\sum_{k=1}^{K} \mathscr{T}_{2c}(\alpha_k;\tau_k) \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \gamma_K \text{ where } \sum_{k=1}^{K} \mathscr{T}_{2c}(\alpha_k;\tau_k) \overset{\mathscr{H}_0}{\sim} \chi^2_{2K}. \tag{90}$$

Computational requirements for these tests are discussed in [10]. In (85) and (86), $\hat{S}$ and $\hat{S}^{(*)}$ are estimates of nonconjugate and conjugate cyclic spectra of $f(t,\tau) = x(t)x(t+\tau)$, respectively [4, 14, 17]. Thus, while in [4, 14, 17] cyclic spectra of $x(t)x(t+\tau)$ are used in the test statistic; in [10], one only needs the autocorrelation (equivalently power spectral density) of $x(t)$.

It should be pointed out that the tests of [4, 14, 17, 18, 36] are not generalized likelihood ratio tests (GLRTs), contrary to the claims made therein. It is more appropriate to view $\mathscr{T}_{2c}$ in (88) as an ad hoc test statistic resulting in a CFAR test; same remark applies to [14, 17, 18, 36] (all based on [4]).

Tani-Fantacci Test [25]
This test applies to OFDM signals only. Given an OFDM signal as discussed in section "OFDM Signals", the test statistic of [25, Sec. IV.A] is given by

$$T_\alpha := \left| \frac{\hat{R}^{\alpha}_{11}(N_c)}{\hat{R}^{\alpha+S}_{11}(N_c)} \right| \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \eta_T, \tag{91}$$

where

$$\alpha = \frac{1}{N_c + N_{cp}} = \frac{1}{N}, \tag{92}$$

$$\hat{R}^{\alpha}_{11}(\tau) := \frac{1}{M} \sum_{n=1}^{M} \left(\frac{1}{L} \sum_{k=n}^{n+L-1} x(k) x^*(k+\tau) \right) e^{-j2\pi\alpha n} \tag{93}$$

and L is picked to be shorter than the OFDM symbol duration. One picks the (fundamental) cycle frequency $\alpha = \alpha_0 = \frac{1}{N}$ (for sampled OFDM signal), and S is an arbitrary integer value that does not belong to the set of cycle frequencies $\{\frac{k}{T_s},\ k = 1, 2, \cdots\}$ for continuous-time OFDM signal. For sampled signals, [25] suggests choosing $S = S_{bin}/M$ where S_{bin} is the "frequency bin number." It is established in [25] that under $\mathscr{H}_0$, asymptotically T_α follows a Cauchy distribution.

Two-Window Approaches

Suppose the model (1) is changed to the following

$$x(t) = \begin{cases} i(t) + n(t) & : \mathscr{H}_0 \\ s(t) + i(t) + n(t) & : \mathscr{H}_1 \end{cases} \tag{94}$$

where now one includes interference $i(t)$. In all of the approaches discussed thus far, under $\mathscr{H}_0$, $i(t)$ is assumed to be absent and $n(t)$ represents thermal noise or filtered thermal noise. One designs a CFAR test requiring prior knowledge of some of the signal statistics under $\mathscr{H}_0$. For instance, for spectrum sensing one needs to know the PSD under $\mathscr{H}_0$ to design the CFAR test. Typically, $i(t)$ is ignored and $n(t)$ is taken to be thermal noise with known white PSD. An interesting approach not requiring any prior knowledge of the PSD under $\mathscr{H}_0$ was proposed in [5]. Reference [5] assumes that a PU-free data record is available in an *assessment window* of observations which allows one to acquire signal statistics of interest under $\mathscr{H}_0$. Then the PSD of the current observations segment (*evaluation window*) is estimated and compared with the PSD of the assessment window "bin by bin" on the frequency grid to test for the presence/absence of the PU. Reference [5] uses a single antenna receiver. The approaches of [30, 31] proposed in the context of wireless user authentication and comparison of random processes can be exploited for spectrum sensing based on two windows.

Reference [30] analyzes a single antenna receiver whereas [31] discusses multiple antenna receivers. Following [5] two nonoverlapping time windows, each of N samples, are considered, where the first window (occurring earlier in time) is called the *assessment window* and the second window is called the *evaluation window*. As in [5], a key assumption is that the time location of *assessment window* is such that the measurements made during this window consist of just noise and interference (i.e., it is free of the primary user signal). The PSD estimated from the *assessment window* serves a reference against which the PSD obtained from the *evaluation window* is compared. If there is a statistically significant deviation between the two estimated PSDs, one declares presence of PU over a particular frequency bin or over a particular frequency band. Thus, prior knowledge of noise and interference spectrum is not needed. On the other hand, a PU-free set of measurements must be available. Note that the time interval within which the two windows reside must be less than the channel coherence time for the procedure to work.

Summary

Quite often, as a result of receive filters at the cognitive user's receiver, the filtered thermal noise will not be white. Most existing approaches assume white noise sequences at the receiver. The goal of this chapter was to present a comprehensive overview of spectrum sensing approaches when noise is colored. Emphasis was on multiple antenna receivers which rely on the fact that noise is spatially (across antennas) independent, and PU signals are spatially dependent, while temporal properties of signal and noise become irrelevant to design of the PU signal detector. Both time-domain and frequency-domain approaches exploiting stationarity were presented. Cyclostationarity-based spectrum sensing methods were also reviewed. Enough details were presented to allow the reader to understand the underlying model assumptions and their consequences. There is no single best approach, and the detection results will depend upon the prior knowledge about the sensing environment.

Abstract

Markovian models, as well as other statistical models, have been applied in the context of cognitive radio communications to characterize user activity in a given spectrum band and to develop algorithms for temporal spectrum sensing. In this chapter, we discuss spectrum sensing based on Markovian models. We provide an overview of the related literature and then discuss the application of discrete-time Markov chain models to spectrum sensing, in particular the hidden bivariate Markov chain. We focus on the modeling of cognitive radio channels using Markov chains, spectrum detection, and parameter estimation. We then discuss various spectrum sensing scenarios in which the Markovian models are used. Finally, we discuss open problems and topics for further research related to spectrum sensing using Markovian models.

Introduction

The conventional approach to spectrum management is to partition the spectrum into bands and issue licenses for spectrum usage in those bands. Studies of spectrum usage have shown that this spectrum allocation paradigm often results in severe underutilization of the spectrum; see, e.g., [22, 45]. In opportunistic or dynamic spectrum access, a band of licensed spectrum can be used by unlicensed users whenever it is not being used by licensed users. The licensed user is often referred to as the primary user, whereas the unlicensed user is called the secondary user. To take advantage of the portions of the spectrum unused by the primary users, also known as spectrum holes, the secondary users must be capable of dynamically switching their transmissions among different frequency bands, i.e., they must be frequency agile. In addition, the secondary users must be capable of sensing the radio environment to determine the spectrum hole opportunities for dynamic spectrum access. Such capabilities are realized in cognitive radio technologies [26]. A group of communicating secondary users equipped with cognitive radios forms a cognitive radio network. In the context of dynamic spectrum access, the goal of the cognitive radio network is to maximize spectrum utilization while avoiding harmful interference to the primary users.

Dynamic spectrum access can be seen as a "fix" to the problem over spectrum underutilization caused by static allocation of spectrum to licensed users. The primary users maintain strict priority over the secondary users with respect to access to the licensed spectrum. The onus is on the secondary users to identify spectrum holes and transmit in such a way as to avoid harmful interference to the primary users. In a more general dynamic spectrum *sharing* framework, a given spectrum band may be shared among different groups of users rather than being licensed to a certain group of primary users. The spectrum may be shared according to some criterion of fairness, and the different groups of users may collaborate with each other to maximize overall spectrum efficiency while achieving their own individual communication goals. As in dynamic spectrum access, the users in a dynamic

spectrum sharing network must be capable of sensing the radio environment to determine spectrum holes and be frequency agile.

In this chapter, we focus on the problem of spectrum sensing, specifically the temporal aspect of identifying when spectrum holes occur in time. Our treatment of temporal spectrum sensing is based on Markovian models of user activity. To simplify the discussion, we will use the terminology of primary users and secondary users associated with the dynamic spectrum access paradigm, but the same principles of spectrum sensing will be applicable in a more general dynamic spectrum sharing setting. We will mainly look at applying Markovian models to characterize spectrum usage, detection of spectrum activity, and parameter estimation. For a given user, there is an important trade-off between devoting resources toward spectrum sensing vs. actually using spectrum for transmission. In the terminology of multiarmed bandit problems, this is the trade-off between "exploration" and "exploitation." To limit the scope of this chapter, we shall focus almost exclusively on the exploration aspect and consider only discrete-time models in detail. The spectrum sensing techniques discussed here could be applied in a dedicated spectrum monitoring infrastructure independently from the users. In this setting, the users would consult the spectrum monitoring system to determine spectrum availability, rather than perform the spectrum sensing themselves. Nevertheless, we will touch upon some of the related work in the literature that deals with both the exploration and exploitation aspects of spectrum sensing.

The remainder of this book chapter is organized as follows. In section "Background and Overview of Related Work," we provide an overview of the literature related to spectrum sensing using Markovian models. In section "Markovian Models," we introduce some terminology and notation for Markovian models as they are applied to temporal spectrum sensing. We focus on the hidden bivariate Markov chain and discuss the associated problems of spectrum detection and parameter estimation. In section "Spectrum Sensing Scenarios," we discuss various spectrum sensing scenarios in which the Markovian models can be applied. In section "Research Challenges and Open Problems," we consider some future challenges and areas of further research involving spectrum sensing via Markovian models. A brief summary and concluding remarks are given in section "Conclusion."

Background and Overview of Related Work

In this section, we provide background on applications of Markovian models to spectrum sensing and an overview of the related work in the literature. Some of the material discussed at a high level in this section is treated in greater detail in subsequent sections.

Applications of Markovian Models

Markovian models have been applied in many different areas, including network traffic modeling [23], speech processing [17], and ion channel current modeling [4], just to name a few. In such applications, some aspect of the system or signal of interest is represented by a Markov process either in discrete time or continuous time. Depending on the application, a discrete-time or a continuous-time model may be preferred for various reasons such as model fidelity, mathematical tractability, or computational complexity. Typically, the number of states of the Markov process is assumed to be finite. In general, Markovian models are attractive because of their mathematical tractability relative to other statistical models and their wide applicability. The fidelity of the Markovian model representation can sometimes be improved by increasing the number of states of the Markov process, but often at the expense of higher computational complexity and the need for a larger training set for parameter estimation.

In some applications, the purpose of the Markovian model is to represent the system or signal as closely as possible in a statistical sense. In other applications, the Markovian model may be only a means to an end, and accuracy of the model itself is of less importance than that of the final result, though the two are obviously closely related. In queueing applications, for instance, the arrival process may not need to be modeled with high accuracy if only the mean queue length is desired. For such a situation, a Poisson arrival process may be sufficient. If the queue length distribution is desired, a more sophisticated model such as the Markov-modulated Poisson process (MMPP) may be necessary. In teletraffic applications, the Poisson process has been found to be sufficiently accurate for modeling call arrivals, but does not provide a good model for bursty packet traffic. The MMPP model can represent the burstiness in packet arrivals [27], but may not be sufficiently rich to represent other phenomena such as long-range dependence or self-similarity, which have been observed in empirical studies of packetized traffic. Modeling of such phenomena takes us outside the realm of Markovian models, so some authors have devised approaches to approximate, in a local sense, characteristics such as long-range dependence using Markovian models.

Markovian Models in Cognitive Radio Systems

In a cognitive radio system, where the secondary user must vacate a channel before a primary user accesses it, statistical prediction of the future primary user state can reduce the probability of interference. Therefore, a Markovian model of the primary user can be used for state prediction, which in turn can prevent unintended collisions. Several cognitive radio media access control methods have been developed which model the primary user as a Markovian process. In [58], the primary user is modeled as a discrete-time partially observable Markov decision process (POMDP), where only part of the state of the system is observed. The

system consists of a set of independent channels, each occupied by a primary user that is modeled as a two-state discrete-time Markov chain. At a given time slot, the states of only a small subset of the total set of channels can be observed. Based on the partially observed state, the secondary user makes a decision on which channel or channels to sense or access in the next time slot. The Markov chain parameters for the primary users on the channels are assumed to be known. The basic POMDP model is augmented to account for errors in observing the partial system state.

Markovian models have been used to model primary users in optimization of exploration/exploitation of channels in cognitive radio systems. In [39, 59], a restless multiarmed bandit model is used to model dynamic spectrum access in the presence of multiple primary users on different channels. Solutions are presented to determine how much time should be spent sensing each channel with the objective of maximizing system throughput. In these works, the primary users are modeled by two-state discrete-time Markov chains, but estimation of the Markov chain parameters is not performed explicitly. In [39], estimation of the stationary distribution in the formulation of the reward function is performed.

Hidden Markov Models

In cognitive radio applications, the state of the primary user must be inferred by observing the signal through a noisy channel. When the primary user is modeled as a Markov chain, and the process is observed through a memoryless channel, the resulting model is a hidden Markov process. The bivariate process which comprises the Markovian primary user chain and the observations from the channel observations is a Markov process. The observable process alone is not Markov. The hidden Markov process is a natural model, which allows for inference of the underlying state, while still allowing for prediction of future states. A hidden Markov model consists of the underlying or hidden state process, together with an observable process that is conditionally dependent on the underlying state. The joint bivariate process retains the Markov property, so HMMs fall under the purview of Markovian models. As an additional benefit, HMMs allow for smoothing of decisions by performing maximum likelihood sequence estimation with the Viterbi algorithm, which can reduce the probability of detection error [20]. The HMM has been applied in many different fields including speech and image processing. A comprehensive review of HMMs is given in [20].

HMMs were first introduced as a model for spectrum sensing in cognitive radio networks independently in [1] and [40]. Although an HMM may use any conditional distribution to model signal impairments, the conditional normal distribution is of particular interest for its ability to model additive white Gaussian noise, Rayleigh fading [7], and lognormal shadowing [38].

Parameter Estimation for Markovian Models

Much of the research regarding cognitive radio media access using Markovian models relies on knowledge of the Markov chain parameters, either the state transition rates for continuous-time Markov chains or the state transition probabilities for discrete-time Markov chains. In practice, these parameters are unlikely to be known a priori, so a secondary user would have to perform parameter estimation as part of its spectrum sensing process. In [50], multichannel Markov parameter estimation for cognitive radio is considered. Multiple channels, each containing a single primary user, are observed by the secondary user. The primary user is modeled as a continuous-time Markov chain, and each channel is sensed sequentially using a maximum likelihood estimator [2]. Per-channel sensing times are allocated such that the total variance across all channels is minimized.

For HMMs, additional parameters of the conditional distributions must be estimated with the Markov chain parameter. The Baum algorithm (Also known as the Baum-Welch algorithm.), described in detail in [20], is used to estimate the Markov chain transition matrix and the conditional distribution. The Baum algorithm is a specific realization of the expectation-maximization algorithm [15]. An initial parameter is specified, and the algorithm alternates between computing the state probability distribution for each data point and reestimating the parameters.

The Baum algorithm is considered an *offline* parameter estimation algorithm because it requires a relatively large record of sample data. Reestimation of parameters if new data is received would require iterating again over the entire data set. In [44] and [46], recursive HMM parameter estimators were proposed. Recursive parameter estimation allows for *online* processing of data, where single samples or small blocks of samples may be used to update the HMM parameter estimates, rather than a large block of sample data.

Multivariate Markovian Models

As discussed above, the HMM is an example of a bivariate Markovian model. The underlying Markov chain of an HMM has geometrically distributed so journ times in each state. In many applications, including spectrum sensing, the state sojourn times may have non-geometric distributions such that the HMM is not a suitable model. A more general model that has been proposed is the hidden semi-Markov model [55], in which the sojourn time distributions are explicitly represented in the parameter of the model. The hidden semi-Markov model, however, is not Markovian. Consequently, parameter estimation for the hidden semi-Markov model has significantly higher computational complexity.

As an alternative to the semi-Markov model, a bivariate Markov chain can be used to model the underlying state. The bivariate Markov chain consists of two processes: one represents the observed state and the other represents phases during which the first process remains in a given state. This gives rise to discrete phase-type

state sojourn time distributions. By observing a bivariate Markov chain through a channel, we obtain a hidden bivariate Markov chain, which generalizes the HMM, but remains within the realm of Markovian models, i.e., the hidden bivariate Markov chain is a trivariate Markov process. A review of bivariate and multivariate Markov processes is given in [18].

The hidden bivariate Markov chain enjoys many of the same properties of an HMM. For example, the Baum algorithm can be used to perform parameter estimation for the hidden bivariate Markov chain. The hidden bivariate Markov chain may be considered a special case of a hidden semi-Markov model, in which the sojourn time distributions are of discrete-phase type. Unlike the hidden semi-Markov model, however, the sojourn time distribution is implicit in the model, rather than specified as a separate component of the model parameter. With a single underlying state, the bivariate Markov chain is equivalent to a standard univariate Markov chain. Increasing the number of phases or order of the bivariate Markov chain allows for modeling the state sojourn time distributions with more general phase-type distributions. On the other hand, the parameter estimation becomes more computationally complex, and more observation data is required to avoid overfitting the model.

In [38], hidden bivariate Markov chains were applied to spectrum sensing, and it was shown that when predicting many steps in the future, the bivariate Markov process was substantially more accurate. In [48], the work in [38] was extended using a recursive parameter estimation algorithm to perform online spectrum sensing. The algorithm from [44] was extended to perform parameter estimation of hidden bivariate Markov processes.

Markovian Models

Markov Chains

A Markov chain is a discrete-time random process with finite or countably infinite alphabet. Each letter of the alphabet is commonly referred to as a *state*, and the collection of states, i.e., the alphabet, is commonly referred to as the *state space*. The Markov chain may start from one of the states and subsequently visits any state that is reachable from the present state. A state is reachable if the probability of jumping to that state in one or more steps is positive. Self-transitions are allowed. In a Markov chain, future states are conditionally independent of past states given the current state. Thus, a Markov chain is characterized by the initial distribution which represents the probability of the chain to start from any given state and by the transition matrix which contains all conditional probabilities of the chain to visit any state given any current state. Each such conditional probability is referred to as the *transition probability*.

A discrete-time memoryless random process with finite alphabet is a particular Markov chain. Markov chains enable dependence of the process at various times and thus are more suitable for many applications. Furthermore, since their mathematical

structure is relatively simple, they are amenable to mathematical analysis, and they are well understood.

We denote the Markov chain by $X = \{X_0, X_1, \ldots, X_t, \ldots\}$ where $X_t \in \mathbb{X}$ and $\mathbb{X} = \{0, 1, \ldots, d\}$ denotes the state space for some finite integer d. In cognitive radio applications, the process X represents the status of the primary user at any given moment. Thus, $X_t = 0$ when the primary user is idle at time t and $X_t = 1$ when the primary user is active. Clearly, in that case $d = 1$. It is possible to choose $d > 1$ to refine the description of the status of the primary user. For example, various states may represent different levels of transmission power by the primary user. We assume that the Markov chain is homogeneous and irreducible. Homogeneity means that transition probabilities are independent of time. Irreducibility means that each state may be reached from any other state, that is, $\mathbf{P}(X_{t+k} = j \,|\, X_t = i) > 0$ for any $i, j \in \mathbb{X}$, any $t \geq 0$, and some $k > 0$. We use the row vector $\pi = \text{row}(\pi_0, \pi_1, \ldots, \pi_d)$ to denote the initial distribution of the process X and $A = \{a_{ij}, i, j = 0, 1, \ldots, d\}$ to denote the *transition matrix* of X. For given (i, j), π_i is the probability of $X_0 = i$, and a_{ij} represents the conditional probability of $X_t = j$ given $X_{t-1} = i$ for any $t \geq 1$. From the Chapman-Kolmogorov theorem, A^k represents the k-step transition matrix. That is, $A^k(i, j) = \mathbf{P}(X_{t+k} = j \mid X_t = i)$ for any positive integer k and any $t \geq 0$. The Markov chain is a stationary process if and only if its initial distribution π satisfies $\pi = \pi A$. In that case, π is called the stationary distribution of X, and $\pi_i = \mathbf{P}(X_t = i)$ for any $t \geq 0$. By the Perron-Frobenius theorem [29, p. 536], a sufficient condition for a finite state Markov chain to have a unique stationary distribution is that the chain be irreducible. A well-known result for an irreducible aperiodic finite state Markov chain is

$$\lim_{k \to \infty} A^k = \Pi \tag{1}$$

where Π is a matrix with identical rows each equal to the stationary distribution π. A Markov chain is *aperiodic* if the greatest common divisor of its returning epochs to a given state is one. This result shows that for sufficiently large t, $\mathbf{P}(X_t = j \mid X_{t-1} = i) = \pi_j$, $j = 1, \ldots, d$, regardless of i, where π is the stationary distribution of the chain.

There are many excellent books on Markov chains. The book by [5] contains an elementary chapter on finite-state Markov chains. The book by Kemeny and Snell [28] is very accessible, and there is the classic and more advanced book by Çinlar [11].

Hidden Markov Models

Normally, the process X cannot be observed directly. When the channel is sensed, noise is inevitably present at the cognitive radio receiver. A Markov chain observed through noisy memoryless channel is commonly referred to as a hidden Markov

model (HMM). An HMM is not a Markov chain, and its analysis is far more complex. HMMs, however, have numerous applications, and their statistical theory is very well understood. A review of HMMs may be found in [20]. Let $Y = \{Y_0, Y_1, \ldots, Y_t, \ldots\}$ denote the received signal by the cognitive radio receiver. The HMM is characterized by (π, A) as well as by the transition density of the channel. This is the conditional density of Y_t given X_t. We denote this conditional density by $b(y_t \mid x_t)$. The density $b(y_t \mid x_t)$ could be normal, exponential, Poisson, Gamma, etc. Let $B = \{b(y_t \mid x_t), x_t = 0, 1, \ldots, d\}$ denote the collection of all possible densities associated with the various states. In cognitive radio applications, when $x_t = 0$, $b(y_t \mid x_t)$ represents the density of the received signal when the primary user is idle, and when $x_t = 1$, $b(y_t \mid x_t)$ represents the density of the received signal when the primary user is active. Motivated by a central limit theorem, the density $b(y_t \mid x_t)$ is usually assumed normal with mean and variance dependent on the value of x_t. If we denote the mean and variance by μ_{x_t} and $\sigma^2_{x_t}$, respectively, then the parameter of the HMM is given by $\phi = \left(\pi, A, \{(\mu_i, \sigma_i^2), i = 0, \ldots, d\}\right)$. Hidden Markov models in the forms of a Markov chain observed through a channel with memory are also possible.

Let y^n denote a realization of the observation sequence $Y^n = \{Y_0, Y_1, \ldots, Y_n\}$ at the input of the cognitive radio receiver. The density of y^n is then given by

$$p(y^n; \phi) = \sum_{x_0, \ldots, x_n} \pi_{x_0} \prod_{t=1}^{n} a_{x_{t-1} x_t} b(y_t \mid x_t) \tag{2}$$

The parameter ϕ of the HMM may be estimated in an unsupervised offline manner from some training data. This is usually done by the Baum algorithm which is the earliest form of the expectation-maximization (EM) algorithm. The Baum algorithm is an iterative approach for generating a sequence of parameter estimates with increasing likelihood values unless a fixed point in the parameter space is reached. In the latter case, the algorithm is terminated, and the fixed point is a stationary point of the likelihood function. The algorithm is not guaranteed to reach a fixed point and hence is practically terminated when the relative likelihood values in two consecutive iterations fall below a preset threshold. Conditions for convergence of the sequence of estimates generated by the EM algorithm were given by Wu [54].

Given a value ϕ_κ of the true parameter of the HMM at the conclusion of the κth iteration, a new estimate is obtained as

$$\begin{aligned} \phi_{\kappa+1} &= \arg\max_\phi E\{\log p(x^n, y^n; \phi) \mid y^n; \phi_\kappa\} \\ &= \arg\max_\phi \sum_{x^n} p(x^n \mid y^n; \phi_\kappa) \log p(x^n, y^n; \phi). \end{aligned} \tag{3}$$

The density $p(x^n, y^n; \phi)$ is given by the summand of (2). Implementation of the Baum algorithm requires the density $p(x_t \mid y^n; \phi_\kappa)$, $t = 1, 2, \ldots, n$, which is

efficiently calculated using the so-called forward-backward algorithm. The forward density is given by $p(x_t, y^t; \phi_\kappa)$, $t = 0, 1, \ldots, n$, and the backward density is given by $p(y_{t+1}^n \mid x_t; \phi_\kappa)$, $t = n, n-1, \ldots, 0$, where $p(y_{n+1}^n) = 1$ and $y_{t+1}^n = \{y_{t+1}, \ldots, y_n\}$. Both densities are calculated recursively in forward and backward modes, respectively. Progressive scaling is required for better numerical stability. Scaling of the forward density, for example, results in recursive evaluation of $p(x_t \mid y^t; \phi_\kappa)$. We demonstrate the recursive calculation of the forward-backward formulas and the scaling procedure in section "Forward-Backward Matrix Recursions." The Baum algorithm is well known for its slow convergence which cannot be controlled by a choice of a step size as in Newton's methods for maximizing a function.

In cognitive radio applications, a fading channel with thermal additive noise is assumed. The measurements $\{Y_t\}$ constitute the logarithm of the power of the signal in a given narrowband portion of the available spectrum. When the state of the primary user is $X_t = a$, then Y_t is assumed normal with mean μ_a and variance σ_a^2. The samples $\{Y_t\}$ are assumed statistically independent. This model is motivated by a central limit theorem developed in [21]. The relation between $\{\mu_a, \sigma_a^2\}$ and the parameters of the fading additive noise channel is nontrivial. In [21, Corollary 5.6.3], the statistics of the logarithm of the smoothed periodogram of a stationary process with small dependence span were studied. The power of each narrowband signal may be seen as a value of the smoothed periodogram of a broadband process measured at a particular frequency. It was shown in [21] that the log-smoothed periodogram at a given frequency is asymptotically normal with mean that depends on the underlying power spectral density and a constant variance that is independent of the underlying power spectral density. In the proposed model, we allow both the mean and variance of each Y_t to depend on the state of the primary user, and hence on the underlying power of the received signal, in order to accommodate possible deviations from the model of [21]. If the variance of Y_t is somewhat independent of the underlying hypothesis, then that should be reflected in its estimated values.

When the active/idle process of the primary user in cognitive radio is represented by a Markov chain as described in this article, the sojourn time of the primary user in each of the two states has a geometric distribution with parameter that depends on the present state. The geometric distribution presents an unrealistic restriction since it does not conform with the typical sojourn time distributions of the primary user. That well-known fact in cognitive radio applications, as well as in other applications such as speech recognition, has led to the use of semi-Markov models [10,11,55]. In these models, which are not Markov processes, a desired sojourn time distribution is imposed. A semi-Markov process may be seen as a pair of processes comprising a Markov jump process for the states and a sequence of conditionally independent sojourn times given the sequence of states. Estimation of the parameter of a semi-Markov process is far more complicated than that of an HMM. This difficulty may be circumvented by substituting the Markov chain of the HMM by a bivariate Markov chain.

Bivariate Markov Chains

A bivariate Markov chain is a pair of discrete-time finite state random processes that are jointly Markov. Each of the individual processes is not necessarily Markov. When a bivariate Markov chain is used in cognitive radio sensing, one of the two processes represents the state process of the primary user while the other is an auxiliary process which endows the primary process with some desired statistical properties. A particularly useful property is a new distribution of the sojourn time of the primary process in each of its state. This distribution is phase type and is far more general than the geometric sojourn time distribution of the univariate Markov chain. The set of discrete phase-type distributions is dense in the set of distributions on $0, 1, 2, \ldots$. This means that every distribution in that family is either a phase type or it can be approximated arbitrarily well by a phase-type distribution. The family of phase-type distributions includes mixtures of convolutions of geometric distributions. Intuitively, either a jump of the two processes comprising the bivariate Markov chain or a joint jump of the two processes constitutes a jump of the bivariate Markov chain. The sojourn time in each pair of states of the bivariate Markov chain has geometric distribution like in any other Markov chain. Consecutive jumps of the primary process may occur while the secondary process has undergone several jumps along some path in the state space. Thus, the sojourn time of the primary process in each of its states is the sum of multiple independent geometric random variables. Considering different paths, we see that the sojourn time in each state of the primary process could have a mixture of convolutions of geometric distributions. A review of bivariate Markov chains may be found in [18].

Let $Z = \{Z_t = (X_t, S_t), t = 0, 1, \ldots\}$ denote a bivariate Markov chain where $X = \{X_t, t = 0, 1, \ldots\}$ represents the primary process and $S = \{S_t, t = 0, 1, \ldots\}$ represents the auxiliary process. We assume that X takes values in the state space $\mathbb{X} = \{0, 1, \ldots, d\}$, S takes values in the state space $\mathbb{S} = \{0, 1, \ldots, r\}$, and Z takes values in the state space $\mathbb{Z} = \mathbb{X} \times \mathbb{S}$. The state pairs $\{(a, i) \in \mathbb{Z}\}$ are assumed to be ordered lexicographically, and the transition probability of Z is given by

$$h_{ab}(ij) = P_\phi(Z_{t+1} = (b, j) \mid Z_t = (a, i)) \tag{4}$$

where ϕ is the parameter of the process, that is, ϕ comprises the set of independent entries of initial distribution and transition matrix of the bivariate Markov chain. The transition matrix $H = \{h_{ab}(ij)\}$ is written as a block matrix $H = \{H_{ab}; a, b \in \mathbb{X}\}$, where $H_{ab} = \{h_{ab}(ij); i, j \in \mathbb{S}\}$ is an $r \times r$ matrix. The underlying chain S is Markov with transition matrix Q if and only if the equation $\sum_{b \in \mathbb{X}} H_{ab} = Q$ holds independently of a. A similar condition can be given for the observable chain X to be Markov. When H is irreducible, it has a unique stationary distribution $\pi = \text{row}\{\pi_{ai}, a \in \mathbb{X}, i \in \mathbb{S}\}$ satisfying $\pi = \pi H$. The process $\{Z_t\}$ is stationary if and only if $P_\phi(Z_0 = (a, i)) = \pi_{a,i}$ for all $(a, i) \in \mathbb{Z}$.

The probability mass function of the sojourn time of the primary process in each state in $\mathbb{X}$ is given by [38]

$$p_\phi(l \mid a) = \bar{\nu}_a(\phi) H_{aa}^{l-1}(I - H_{aa})\mathbf{1} \tag{5}$$

for $l = 1, 2, \ldots$, where $\mathbf{1}$ is a column vector of all ones of suitable dimension, and $\bar{\nu}_a$ is defined as follows. Let $\nu_{a,i}(\phi) = P_\phi(Z_0 = (a, i))$ denote the initial probability of the bivariate Markov chain to be in state (a, i) at time $t = 0$, and let

$$\nu_a(\phi) = (\nu_{a,1}(\phi), \nu_{a,2}(\phi), \ldots, \nu_{a,r}(\phi)). \tag{6}$$

Then, $\bar{\nu}_a(\phi) = \nu_a(\phi)/(\nu_a(\phi)\mathbf{1})$ is a normalized version of $\nu_a(\phi)$. Equation (5) provides the *discrete-time phase-type* probability mass function with parameter $(\bar{\nu}_a(\phi), H_{aa})$ [37, p. 46]. This probability mass function is derived under the assumptions that the matrices H and $\{H_{aa}, a \in \mathbb{X}\}$ are irreducible and that the diagonal elements of H are positive.

Consider now substitution of the univariate Markov chain of an HMM with the bivariate Markov chain described above. The bivariate Markov chain is now observed through a memoryless channel with output denoted by $Y = \{Y_0, Y_1, \ldots, Y_t, \ldots\}$ as before. The resulting process (Y, X, S) is an HMM with a bivariate Markov chain $Z = (X, S)$ rather than the univariate Markov chain X. The sojourn time in each pair of states of the bivariate Markov chain is geometrically distributed. Assume now that the triplet process (Y, X, S) possesses a Markov property such that the processes Y and S are conditionally independent given the process X. With this assumption, the observable process Y inherits its sojourn time from the non-Markovian process X, rather than from the Markovian process Z, and hence, the sojourn time distribution of Y in each state of X is discrete phase-type rather than geometric [38], [18, Eq. 8.7]. The process (Y, X, S) with the Markovian property provides a realistic model for the received signal in a cognitive radio receiver [38]. We refer to the model that incorporates the above Markovian property as a *hidden bivariate Markov chain*.

Likelihood of Observable Process

Proceeding with the Markovian assumption, for each time instant t, Y_t is independent of S_t given X_t. That is, $b(y_t \mid z_t) = b(y_t \mid x_t)$. We next develop expressions for the likelihood function of the observable process and for the forward-backward formulas for both the HMM and the hidden bivariate Markov chain.

Define the conditional distribution

$$F_{ij}^{ab}(y) := P_\phi(Y_t \le y_t, Z_t = (b, j) \mid Z_{t-1} = (a, i)) \tag{7}$$

and the corresponding transition density

$$f_{ij}^{ab}(y_t) = \frac{\partial}{\partial y_t} F_{ij}^{ab}(y_t) = p_\phi(y_t, z_t = (b, j) \mid z_{t-1} = (a, i)). \tag{8}$$

Recall that the states (X, S) are ordered lexicographically. Define the $dr \times dr$ *transition density matrix* by

$$f(y_t) = \left\{ f_{ij}^{ab}(y_t); (a,i),(b,j) \in \mathbb{Z} \right\}. \tag{9}$$

The transition density matrix for the HMM where Y_t depends on Z_t is given in terms of the transition matrix H from (4) and the density which corresponds to $P_\phi(Y_t \leq y_t \mid Z_t = (b,j))$. We denote that density by $g_{\theta_{bj}}(y_t)$ where θ_{bj} is its parameter. This density is determined by the channel. For memoryless Gaussian channel as is assumed here, the parameter $\theta_{bj} = (\mu_{bj}, \sigma_{bj}^2)$, where μ_{bj} denotes the mean and σ_{bj}^2 denotes the variance. For the hidden bivariate Markov chain where Y_t given X_t is independent of S_t, the density $g_{\theta_{bj}}(y_t)$ is independent of j and is given by $g_{\theta_b}(y_t)$. In either case,

$$f(y_t) = HG(y_t) \tag{10}$$

where for the HMM,

$$G(y_t) = \text{diag}(g_{\theta_{bj}}(y_t), (b,j) \in \mathbb{Z}), \tag{11}$$

and for the hidden bivariate Markov chain,

$$G(y_t) = \text{diag}(g_{\theta_b}(y_t) I, b = 1, \ldots, d) \tag{12}$$

where I is an $r \times r$ identity matrix. Define the $1 \times dr$ row vector $\zeta_{y_0} = \left\{ p_\phi(y_0, z_0); z_0 \in \mathbb{Z} \right\}$ representing the initial density of (Y_0, Z_0). Then, the likelihood function of the hidden bivariate Markov chain is given by

$$p_\phi(y_0^n) = \zeta_{y_0} \prod_{t=1}^{n} f(y_t) \mathbf{1}. \tag{13}$$

The likelihood function of the HMM is given by a similar expression. The parameter ϕ of the HMM comprises the independent components of the initial distribution π and of the transition matrix H and $\{\theta_{bj}, (b,j) \in \mathbb{Z}\}$. For the hidden bivariate Markov chain, the relevant entries of π and H are the same as for the HMM, but the parameter of the channel densities is given by $\{\theta_b, b \in \mathbb{X}\}$. The difference is due to the Markovian assumption making Y and S conditionally independent given X.

Forward-Backward Matrix Recursions

Evaluation of the likelihood function of the hidden bivariate Markov chain, as well as iterative estimation of its parameter using the EM algorithm, is facilitated by the use of the forward-backward recursions. We present here a slightly more general

form of the standard recursions for HMMs due to Stiller and Radons [46]. This version is useful in recursive estimation of the parameter of the model [19]. Define

$$R(k,m) := \prod_{t=k}^{m} f(y_t) \tag{14}$$

where $1 \leq k \leq m \leq n$. For fixed k, we have the forward recursion (in m) on the backward density as follows:

$$\begin{aligned} R(m,m-1) &:= I \\ R(k,m) &= R(k,m-1)\, f(y_m) \end{aligned} \tag{15}$$

where I is an identity matrix. For fixed $m = n$, the backward recursion (in k) on the backward density is given as follows:

$$\begin{aligned} R(n+1,n) &:= I \\ R(k,n) &= R(k+1,n)\, f(y_k) \end{aligned} \tag{16}$$

for $k = n, n-1, \ldots, 0$. The forward recursion for the forward density is given by

$$L(m) = L(m-1)\, f(y_m) \tag{17}$$

where $m = 1, 2, \ldots, n$ and $L(m) = \nu_{y_0} R(1,m)$, and let $L(0) = \nu_{y_0}$. Note that for a given parameter ϕ and observation sequence $Y_0^n = y_0^n$, the $((a,i),(b,j))$ element of $R(k,m)$ is given by

$$R_{ai,bj}(k,m) = p_\phi(y_k^m, z_m = (b,j) \mid z_{k-1} = (a,i)), \tag{18}$$

and the (b,j) element of $L(m)$ is given by

$$L_{bj}(m) = p_\phi(y_0^m, z_m = (b,j)). \tag{19}$$

Numerical stability of the recursions in (15) and (17) is improved when scaling is introduced in each iteration. It is instructive to start with the description of the scaled version of $L(m)$, which we denote by $\tilde{L}(m)$. Let $c_0 = \nu_{y_0}\mathbf{1}$, and let $\tilde{L}(0) = \nu_{y_0}/c_0$. The scaled version of (17) is given by

$$\tilde{L}(m) = \frac{1}{c_m} \tilde{L}(m-1)\, f(y_m) \tag{20}$$

where

$$c_m = \tilde{L}(m-1)\, f(y_m)\mathbf{1}. \tag{21}$$

It follows that

$$\tilde{L}(m) = \frac{1}{\prod_{t=0}^{m} c_t} L(m), \tag{22}$$

$p_\phi(y_0^m) = \prod_{t=0}^{m} c_t$, $c_t = p_\phi(y_t \mid y_0^{t-1})$ for $t \geq 1$, and the (b, j) component of $\tilde{L}(m)$ is given by $\tilde{L}_{bj}(m) = P_\phi(Z_m = (b, j) \mid y_0^m)$. The scaled version of forward recursion on $R(k, m)$ is given by

$$\begin{aligned} \tilde{R}(k, m) &= \frac{1}{\prod_{t=k}^{m} c_t} R(k, m) \\ &= \tilde{R}(k, m-1) \frac{f(y_m)}{c_m}. \end{aligned} \tag{23}$$

where c_m is given in (21). The recursion $\tilde{R}(k, m)$ does not enjoy an appealing probabilistic interpretation as $\tilde{L}(m)$. A similar scaled backward recursion on $R(k, n)$ can be written.

The parameter of the hidden bivariate Markov chain may essentially be estimated as the parameter of an HMM using the Baum or the EM algorithm as is demonstrated in the next section "Estimation of the Bivariate Markov Chain Parameter." Batch estimation of the parameter from a given training sequence was detailed in [19, 38]. Sequential estimation of the parameter using an EM iterate was described in [19].

Estimation of the Bivariate Markov Chain Parameter

In this section we demonstrate how the parameter of the hidden bivariate Markov chain can be estimated from a sequence of observations y_0^n using the batch EM algorithm. Our presentation follows that in [19]. A sequential estimation approach which is based on the EM iteration may also be found in [19]. It turns out that the estimation procedure can be described simultaneously for an HMM as well as for a hidden bivariate Markov chain. We shall thus start with estimation of the HMM parameter and then infer about estimation of the hidden bivariate Markov chain.

Assume that ϕ_κ is the parameter estimate at the end of the κth iteration. At the conclusion of the $(\kappa + 1)$th iteration, the new estimate of the initial distribution π_{bj} is given by

$$\hat{\pi}_{bj}(n) = P_{\phi_\kappa}(Z_0 = (b, j) \mid y_0^n), \tag{24}$$

and the new estimate of $h_{ab}(ij)$ is given by

$$\hat{h}_{ab}(ij) = \frac{\hat{M}_{ij}^{ab}(n)}{\sum_{(\beta,l)} \hat{M}_{il}^{a\beta}(n)} \tag{25}$$

where $\hat{M}_{ij}^{ab}(n)$ denotes the conditional mean estimate given y_0^n of the number of transitions of Z from (a, i) to (b, j) in $[0, n]$. This number includes self-transitions.

Using the indicator function

$$\varphi_{bj}(t) = \begin{cases} 1, & Z_t = (b, j) \\ 0, & \text{otherwise,} \end{cases} \tag{26}$$

the number of transitions is given by

$$M_{ij}^{ab}(n) = \sum_{t=1}^{n} \varphi_{ai}(t-1)\varphi_{bj}(t), \tag{27}$$

and

$$\begin{aligned} \hat{M}_{ij}^{ab}(n) &= E_{\phi_\kappa}\left\{ M_{ij}^{ab}(n) \mid y_0^n \right\} \\ &= \sum_{t=1}^{n} P_{\phi_\kappa}\left(Z_{t-1} = (a, i), Z_t = (b, j) \mid y_0^n \right). \end{aligned} \tag{28}$$

For an HMM with normal densities, $\{b_{\phi_\kappa}(y_t \mid z_t), z_t \in \mathbb{Z}\}$, with mean μ_{bj} and variance σ_{bj}^2 when $z_t = (b, j)$, define

$$N_j^b(n; \lambda) = \sum_{t=0}^{n} y_t^\lambda \varphi_{bj}(t) \tag{29}$$

for $\lambda \in \{0, 1, 2\}$. Note, for example, that if the observations $\{y_t\}$ are clustered into the various states of the HMM, then $N_j^b(n; 1)$ is the sum of the observations associated with state (b, j). Let

$$\begin{aligned} \hat{N}_j^b(n; \lambda) &= E_{\phi_\kappa}\left\{ N_j^b(n; \lambda) \mid y_0^n \right\} \\ &= \sum_{t=0}^{n} y_t^\lambda P_{\phi_\kappa}(Z_t = (b, j) \mid y_0^n). \end{aligned} \tag{30}$$

The new estimates of the mean and variance at the conclusion of the $(\kappa + 1)$th iteration are, respectively, given by

$$\hat{\mu}_{bj}(n) = \frac{\hat{N}_j^b(n; 1)}{\hat{N}_j^b(n; 0)}, \tag{31}$$

$$\widehat{\sigma_{bj}^2}(n) = \frac{\hat{N}_j^b(n; 2)}{\hat{N}_j^b(n; 0)} - \hat{\mu}_{bj}^2(n). \tag{32}$$

For a hidden bivariate Markov chain, μ_{bj} and σ_{bj}^2 are reduced to μ_b and σ_b^2, respectively. Thus, $P_{\phi_\kappa}(Z_t = (b, j) \mid y_0^n)$ in (31) and (32) should be substituted

by $P_{\phi_\kappa}(X_t = b \mid y_0^n)$. It is well known that the conditional probability in (28), and hence in (24) and (30), may be efficiently implemented using forward-backward recursions.

Spectrum Sensing Scenarios

In this section, we shall discuss the application of spectrum sensing techniques based on Markovian models to a variety of scenarios. Temporal spectrum sensing scenarios can be organized into three basic categories [47]:

1. *Narrowband:* The secondary user senses a single channel that is clearly defined in terms of center frequency and bandwidth.
2. *Multiband:* The secondary user senses multiple independent narrowband channels.
3. *Wideband:* The secondary user senses a spectrum band with no prior knowledge of channel boundaries or channel occupancy.

In the descriptions of the above categories, we "the secondary user" may refer to a group of several secondary users collaboratively sensing the given spectrum band. Spectrum sensing performance can be significantly enhanced by employing collaborative sensing among a group of several secondary users [30]. Multiband temporal sensing techniques are useful for applications such as TV whitespace where multiple independent primary users operate on clearly defined channels. To simplify our discussion, we shall assume that only a single primary user occupies a given narrowband channel. The wideband temporal sensing problem can be transformed into a multiband sensing problem by first identifying the channel boundaries [6].

Narrowband Sensing

Well-known signal detection algorithms for a narrowband channel include energy detection, cyclostationary feature detection, and matched filter detection [56]. The energy detector is the simplest of the narrowband detectors and requires no a priori knowledge of the channel, but performs poorly in low signal-to-noise ratio (SNR) conditions. The matched filter detector can detect primary user activity at very low SNR, but requires a priori knowledge of the primary user waveform. Cyclostationary feature detection lies between the matched filter and energy detector with respect to performance at low SNR, but requires significant computation times and long integration windows. The performance of all three signal detection methods can be degraded by low primary user duty cycle. By characterizing the primary user signal using a Markovian model, the temporal dynamics of primary user activity on the channel can be taken into account in detecting the signal. Spectrum sensing

based on a Markovian model can lead to better detection performance in lower SNR scenarios, since the past history of primary user activity is incorporated into the detection process. Moreover, use of a Markovian model can provide predictive information that can be applied to achieve more effective dynamic spectrum access.

In [38], the hidden bivariate Markov chain model discussed in section "Bivariate Markov Chains" was proposed as a model for the received primary user signal in a narrowband channel. Consider a system consisting of one primary user transmitting on the narrowband channel. The primary user alternates between an active state, in which a signal of fixed power is transmitted over the narrowband channel, and an idle state, in which no signal is transmitted. We denote the idle state of the primary user at time $t\Delta$ by $X_t = 0$ and the active state by $X_t = 1$, where Δ is a sampling period. The process $X = \{X_t\}$, taking values in the set $\mathbb{X} \in \{0, 1\}$, models the directly observed state of the primary user.

The wireless propagation environment is assumed to be governed by a standard path loss with lognormal shadowing model [35, pp. 40–41]. We ignore fast fading since it can be reduced effectively by an averaging filter (cf. [34]). Let $u(t)$ denote the complex baseband demodulated primary user signal. For a particular secondary user, let $c(t)$ denote a random process representing the fading, and let $w(t)$ denote the additive thermal noise of the channel. The signal received by the secondary user is given by $y(t) = c(t)u(t) + w(t)$. The received baseband signal may be envisioned as a phasor perturbed by the additive noise. The received signal is sampled every Δ seconds, and each sample is represented by the logarithm of its power.

Let Y_t denote the logarithm of the power of the tth sample of the received signal of the secondary user. Given the state $X_t = a$ of the primary user, the samples $\{Y_t\}$ are assumed statistically independent, and each Y_t is assumed normally distributed with some mean μ_a and variance σ_a^2. The process $Y = \{Y_t\}$ represents the received primary user signal, which can be interpreted as the primary user state observed through the narrowband channel. Further motivation and discussion of this model for the cognitive radio channel is given in section "Hidden Markov Models."

If the primary user state process X is modeled as a Markov chain, the joint process (Y, X) is an HMM. In this case, the primary user sojourn times in the active and idle states are given by geometric distributions. We now introduce an underlying process S, taking values in $\mathbb{S} = \{0, 1, \ldots, r\}$, such that $Z = (X, S)$ is a bivariate Markov chain. In this case, the sojourn time of the process X in each state $a \in \{0, 1\}$ takes on a discrete-time phase-type distribution with r phases [38]. The trivariate process (Y, X, S) is then a hidden bivariate Markov chain. In the nomenclature of section "Bivariate Markov Chains," the conditional density of Y given $X = a$ is denoted by $g_{\theta_a}(y) = \mathcal{N}(\mu_a, \sigma_a^2)$, where $\mathcal{N}(\mu, \sigma^2)$ is the normal density with mean μ and variance σ^2. The parameter ϕ of the hidden bivariate Markov chain consists of the initial distribution of Z, denoted by $\boldsymbol{\pi}$, and the independent components of the generator of Z, denoted by H and $\{\theta_a; a \in \mathbb{X}\}$.

Assume that the parameter ϕ of the hidden bivariate Markov chain is given. The conditional probability of the bivariate state at time $t + \tau$ given the observations up

to and including time t can then be computed as follows (cf. [38, Eq. (22)]):

$$p_\phi(z_{t+\tau} \mid y^t) = \sum_{z_t \in \mathbb{Z}} p_\phi(z_k \mid y^t)\; p_\phi(z_{t+\tau} \mid z_t)$$
$$= \sum_{z_t \in \mathbb{Z}} \tilde{L}_{z_t}(t)\, [H^\tau]_{z_t, z_{t+\tau}}\,, \tag{33}$$

where $[H^\tau]_{ai,bj}$ denotes the $((a,i);(b,j))$ entry of the generator matrix given by H^τ. A detection scheme for the state of the primary user at time $t+\tau$ given the received signal power y^t is specified by (cf. [38, Eq. (23)]):

$$\hat{X}_{t+\tau|t} = \begin{cases} 0, \sum_s p_\phi(z_{t+\tau} = (0,s) \mid y^t) \geq \eta, \\ 1, \text{ otherwise}, \end{cases} \tag{34}$$

for $t = 0, 1, \ldots$, where η is a decision threshold, $0 < \eta < 1$. The detection scheme is a maximum a posteriori detector when $\eta = 0.5$. When $\tau = 0$, $\hat{X}_{t+\tau|t} = \hat{X}_{t|t}$ is an estimate of the current state X_t. When $\tau = 1, 2, \ldots$, $\hat{X}_{t+\tau|t}$ is the τ-step predicted estimate of the state $X_{t+\tau}$. The current and predicted state estimates $\hat{X}_{t+\tau|t}$ can be directly applied to make dynamic spectrum access decisions.

The parameter ϕ of the hidden bivariate Markov chain can be estimated offline from training data using the EM algorithm described in section "Estimation of the Bivariate Markov Chain Parameter"; see also [38]. A major advantage of online parameter estimation is that it can adapt to changes in the behavior of the primary user or the channel. An online approach to estimating the parameter, based on Rydén's recursive algorithm HMM parameter estimation, is developed in [48]. An alternative approach to online parameter estimation, based on the EM iteration discussed in section "Estimation of the Bivariate Markov Chain Parameter," is discussed in [19].

Collaborative Sensing

In radio environments with severe shadowing and fading effects, spectrum sensing by a single secondary user can lead to hidden terminal effects and other errors which can result in harmful interference to the primary users. Collaborative spectrum sensing techniques leverage multiuser diversity to improve sensing performance, particularly in severely shadowed environments with hidden terminals. Collaborative sensing involves multiple secondary users in a joint decision-making process to determine when a given channel is idle or active [30, 57]. Collaborative sensing schemes can be categorized into two main types: hard fusion and soft fusion. In this discussion, we review hard and soft fusion collaborative sensing and summarize the collaborative sensing schemes based on hidden bivariate Markov chain modeling developed in [49].

Hard Fusion

In a hard fusion scheme, at each time t, each secondary user q makes an independent decision, $X_{t|t}^{(q)}$, on the primary user state based on the observations $Y_1^{(q)}, \ldots, Y_t^{(q)}$. The 1-bit secondary user hard decisions are transmitted to the fusion center, which computes a final decision, denoted by $\hat{X}_{t|t}$, according to a hard fusion rule. For example, the "OR" rule decides that the primary user is active, i.e., state 1, if at least one of the secondary user hard decisions has the value 1. The "majority voting" rule decides that the primary user is active if more than half of the Q secondary user hard decisions have value 1. The OR rule and majority voting rule are special cases of the q-out-of-Q rule, where $1 \leq q \leq Q$ is an integer constant. Here, the primary user state is determined to be active if q or more of the individual hard decisions are "active"; otherwise, the primary user state is determined to be idle. The OR and majority voting rules are equivalent to the q-out-of-Q rule when $q = 1$ and $q = \lfloor Q/2 \rfloor$, respectively. The q-out-of-Q fusion rule is in turn a special case of linear hard fusion (cf. [41]). Under linear combining, the decision variable is computed as $V_t = \sum_{q=1}^{Q} w_q \hat{X}_{t|t}^{(q)}$, where the w_q are predetermined weights. The decision variable V_t is then compared to a threshold ψ to obtain the final decision $\hat{X}_{t|t}$. The q-out-of-Q fusion rule is a special case of linear hard fusion.

In conventional hard fusion schemes, each secondary user employs an energy detector to obtain a hard decision at each time t. Typically, a majority voting rule is applied at the fusion center. In the hard fusion scheme proposed in [49], each secondary user independently estimates the parameter of a hidden bivariate Markov chain to characterize the observed primary user signal on the channel. An estimator of the form (34) is employed to obtain a hard decision at the secondary user. The hard decisions are combined at the fusion center using a linear fusion rule proposed in [42] based on maximizing a so-called modified deflection coefficient.

Soft Fusion

In soft fusion, at each time t, the secondary users transmit quantized versions of their received signals $Y_t^{(1)}, \ldots, Y_t^{(q)}$, to the fusion center, where they are collectively used to predict the state of the primary user at time $t + \tau$ for some nonnegative integer τ. The state estimator is denoted by $\hat{X}_{t+\tau|t}$. For conventional fusion schemes that do not have predictive capability, $\tau = 0$. In a *linear* soft fusion scheme, a weighted sum, $V_t = \sum_{q=1}^{Q} w_q Y_t^{(q)}$, of the observations at time k is computed and compared to a threshold ψ as follows [33,41,42]:

$$\hat{X}_{t|t} = \begin{cases} 0, & V_t < \psi, \\ 1, & V_t \geq \psi, \end{cases} \tag{35}$$

where $w_1, \ldots, w_Q$ are the weights. Typically, the threshold and weights for soft fusion are computed offline [33,42].

In [48], at each time t, the observation sample $Y_t^{(q)}$ from each secondary user q is transmitted directly to the fusion center, which forms the vector observation sample $\boldsymbol{Y}_t = (Y_t^{(1)}, \ldots, Y_t^{(Q)})$. The soft fusion scheme is based on hidden bivariate Markov chain modeling of the *vector* observation sequence $\boldsymbol{Y} = \{\boldsymbol{Y}_t; t = 0, 1, \ldots\}$ generated by the Q secondary users. Here, the conditional output density parameter is given by $\boldsymbol{\theta} = (\boldsymbol{\theta}_a : a \in \mathbb{X})$, where $\boldsymbol{\theta}_a = (\theta_a^{(1)}, \ldots, \theta_a^{(Q)})$, and $\theta_a^{(q)}$ is the conditional output density parameter of each secondary user q when the primary user is in state a. With this definition of $\boldsymbol{\theta}$, the parameter ϕ of the hidden bivariate Markov chain is given by the independent elements of $(\pi, \boldsymbol{\theta}, H)$, where π is the initial state probability distribution and H is the generator of the underlying bivariate Markov chain.

Parameter estimation of the hidden bivariate Markov chain with vector observation input $\boldsymbol{Y}$ can be carried out at the fusion center using the EM approach discussed in section "Estimation of the Bivariate Markov Chain Parameter" by replacing the scalar sequence y^t with the vector sequence $\boldsymbol{y}^t$ and interpreting the parameter ϕ as discussed above. Similarly, state estimation can be performed via (34). The online parameter estimation approach in [48] can be extended to handle vector observation input, as described in [49].

Performance Comparison

Receiver operating characteristic (ROC) curves presented in [49] show a significant improvement in detection performance of collaborative sensing schemes based on the hidden bivariate Markov chain compared to conventional hard and soft fusion schemes based on energy detectors. In particular, the Markovian model-based soft fusion scheme performs markedly better than the linear soft fusion-based scheme proposed in [42]. Linear soft fusion performs better than the hard fusion scheme based on hidden bivariate Markov chain modeling, which in turn performs substantially better than conventional hard fusion based on energy detection. A disadvantage of soft fusion schemes is that they incur substantially higher communication overhead than the hard fusion schemes. This overhead can be reduced by quantizing the received signal strength values using a smaller number of bits at the expense of poorer detection accuracy, as proposed in [49]. Using a simple uniform quantization scheme, soft fusion based on the hidden bivariate Markov chain with 4-bit observation samples was shown to outperform linear soft fusion with 8-bit samples.

Multiband Sensing

In multiband spectrum sensing, the secondary user tracks the states of primary users operating on a given set of channels to determine spectrum access opportunities. The center frequency and bandwidth of each channel are assumed known. In a given sensing interval, the secondary user must allocate time for sensing each of

the channels. A Markovian model for multiband sensing was proposed by [50], in which each primary user on a given channel is modeled as a two-state homogeneous continuous-time Markov chain. Hence, the state of the primary user on each channel is assumed to be observable directly, or at least the signal-to-noise ratio is sufficiently high that sensing errors are negligible. The Markov chains corresponding to different primary users are assumed statistically independent. One of the basic issues in multiband sensing involves how much time should be allocated to sensing each channel.

To discuss this model further, let us assume there are M independent channels, each having the same bandwidth, but the primary user model parameters for the channels may be different. The parameter of each Markov chain is not known in advance and hence is estimated from observations of the state processes. In a given sensing interval of length T seconds, the secondary user senses each channel i for T_i seconds, where $\sum_{i=1}^{M} T_i = T$. In [50], the sensing times $\{T_i\}$ are determined by minimizing the Cramer-Rao lower bound on the minimum mean squared error in estimating the parameters of *all* M channels. An approximation for the inverse Fisher information matrix, asymptotic in the sensing interval length T, is used to obtain closed-form formulas for the MMSE sensing time allocations.

Since not all M channels may provide equally *good* secondary user spectrum access opportunities, allocating channel sensing times with the objective of minimizing the overall estimation error may not be optimal for dynamic spectrum access. In [8], a preprocessing step to determine the *best* $N < M$ channels, with respect to a criterion related to the spectrum opportunity on the channel, is performed first. The criterion used in [8] was based on the mean idle time on the channel. Then the approach of [50] is applied to the remaining N channels from the first step. The preprocessing step in [8] is based on the optimal computing budget allocation (OCBA) methodology [12] from the field of simulation optimization. The OCBA approach was originally developed to test multiple designs through simulation by allocating simulation time to the designs with the objective of maximizing the probability that the best design is selected according to a given cost function under a Gaussian model [13]. The technique was subsequently extended to determine the best $N > 1$ designs among a given set of M designs [14]. In the context of multichannel parameter estimation, sensing times are allocated rather than simulation times, and the multiple designs correspond to the multiple channels in multiband sensing.

A number of articles on multiband spectrum sensing have approached the problem as a type of multiarmed bandit problem [3,39,53,59] or the related partially observable Markov decision process (POMDP) [58]. Several assume knowledge of the parameters of the underlying Markov chains, but do not address the important issue of parameter estimation [3, 53, 58]. The multichannel parameter estimation algorithm proposed in [8] obtains estimates of this parameter and thus could, in principle, be used in conjunction with these approaches. Knowledge of the model parameter can be used to improve spectrum detection performance and allows the prediction of future primary user state, which provides clear advantages for spectrum sensing [38, 53].

Wideband Sensing

In the wideband spectrum sensing scenario, a secondary user must sense an entire band and determine channel boundaries. The bandwidth that must be sensed can vary from the order of 1 MHz to 1 GHz. This is required if the secondary user cannot leverage any external information about channel allocation. A secondary user need only perform wideband sensing during initialization and may then revert to multiband or narrowband sensing during normal operation. In general, primary user signals may be heterogeneous in frequency, bandwidth, and power, so robust wideband sensing algorithms must be developed to detect all primary user activity within the spectrum band.

State-of-the-art techniques for wideband sensing include wideband energy detection [9] and frequency-domain edge detection [51]. The wideband energy detector is a very simple wideband sensing technique in which the secondary user estimates the power spectral density over the entire band and applies an energy threshold to determine primary user activity [9,25]. Many power spectral density frames may be averaged to increase reliability. This simple algorithm has several limitations. Like all energy detectors in additive white Gaussian noise (AWGN), this technique has limited sensitivity, and performance is severely degraded at low SNR. Furthermore, this technique operates on a snapshot in time, and dynamic behavior of the primary user will degrade performance, since both the on and off cycles will be averaged into the power spectral density estimate.

Edge detectors can offer an improvement over energy detection in terms of SNR threshold, but they can also perform relatively poorly on signals with gradual roll-offs in their band edges. An alternative wideband spectrum sensing technique that has been studied in the literature employs frequency-domain edge detection to determine channel boundaries. A popular edge detection technique uses the continuous wavelet transform to decompose the edge detector into multiple resolutions and multiplies the resolutions together, which has a beneficial effect of reducing the noise [51]. While the edge detectors do offer an improvement over energy detectors in terms of SNR threshold, they come with several limitations. Most importantly, the edge detectors require that primary user signals have sharp transitions in the frequency domain. This allows them to work well with the rectangular spectra of OFDM and quadrature amplitude modulation (QAM) with low excess bandwidth, but edge detectors tend to fail on signals with gradual roll-offs on their band edges, such as QAM with large excess bandwidth and GMSK.

Neither energy detection nor edge detection alone takes into account the temporal dynamics of primary user signals and consequently can perform rather poorly when primary user signals have low duty cycles. In [6], a framework for wideband temporal spectrum sensing is proposed in which a given spectrum band is divided into smaller channels and modeled as a balanced binary tree. In [6], a sensing framework for reliable wideband detection of primary users with low duty cycle was developed. The approach, referred to as wideband temporal sensing, involves partitioning the given spectrum band into smaller subchannels. The energy in each subchannel is measured and an HMM-based spectrum sensing approach is applied

to each subchannel. A recursive tree search is performed to aggregate correlated subchannels into a set of independent narrowband channels, which effectively reduces the sensing task to the multiband case. The wideband temporal sensing approach developed in [6] allows primary user signals with low duty cycle to be detected accurately at high to moderate SNR. This approach was demonstrated to outperform both wideband energy and edge detection techniques particularly in the presence of dynamic primary user signals. In principle, the recursive tree search could be based on a hidden bivariate Markov chain in lieu of the HMM to provide more accurate modeling of the state sojourn times.

In [7], the wideband temporal sensing approach of [6] is extended to incorporate edge detection. In particular, the wavelet-based edge detection algorithm in [51] is incorporated into the wideband temporal sensing framework of [6]. The use of edge detection avoids the need for the recursive tree search used in the wideband temporal energy detector, resulting in a computationally more efficient spectrum sensing scheme. Moreover, the wideband temporal edge detector was shown to perform better in low SNR scenarios in the presence of primary user signals with sharp band edges, i.e., OFDM signals.

Research Challenges and Open Problems

In this section, we discuss future challenges and open research problems related to spectrum sensing using Markovian models.

Signal Feature vs. Energy Detection

In the Markovian model-based spectrum sensing techniques discussed in section "Spectrum Sensing Scenarios," the front end for spectrum sensing was assumed to be similar to that of an energy detector. The energy of the received signal samples was measured and used to perform parameter estimation of a hidden bivariate Markov chain, as well as detection and prediction of primary user spectrum usage. The energy-based front end could, in principle, be replaced by a front end that extracts certain features of the received signal. This could potentially improve the performance of Markovian-based spectrum sensing in low SNR scenarios.

Cyclic feature detection, for example, is based on computing the cyclic or cyclostationary spectrum of the received signal. Modulated signals are often readily identifiable based on their cyclic spectra. Therefore, cyclic feature detection has been proposed as an approach to spectrum sensing that has the potential to perform much better than energy detection or edge detection in low SNR scenarios [16, 31, 32]. A drawback of cyclic feature detection is the usual requirement to sample above the Nyquist rate to recover the cyclic spectrum. Furthermore, long sensing periods are typically required to obtain a statistically reliable estimate of the cyclic spectrum [24]. A cyclic feature detector also has much higher computational complexity compared to an energy detector. Nevertheless, practical implementation

of cyclic feature detection for spectrum sensing is the subject of ongoing research. Aside from the cyclic spectrum, other features of the received signal could be used to perform spectrum sensing based on Markovian models. For example, the cepstrum has been used successfully in speech recognition in conjunction with HMMs [21,43].

Multiband Sensing with Channel Impairments

Multiband sensing was discussed in section "Multiband Sensing" mainly in the context of determining appropriate sensing intervals for each channel, based on the framework of [50]. In [8,50], the primary user activity on each channel is modeled by a two-state continuous-time Markov chain in which the primary user state was assumed to be observed directly. In practice, the primary user state is observed only through the received signal, which is subject to channel impairments such as fading, shadowing, and additive white Gaussian noise. Therefore, it would be of interest to extend the approach to incorporate channel impairments. Some form of noise could be incorporated into the continuous-time Markov primary user state model. Alternatively, a multiband sensing approach based on the HMM or hidden bivariate Markov model in discrete time could be developed.

Multiuser Channels

In the temporal spectrum sensing scenarios discussed in section "Spectrum Sensing Scenarios," a single primary user was assumed to occupy a given narrowband channel. More generally, multiple primary users could share a given channel in a dynamic spectrum sensing scenario. In this case, the two-state Markov model discussed previously would not be sufficient to characterize the channel. One approach is to increase the number of states in the model. For example, if there were N distinct primary users sharing a channel, with different received signal characteristics, an $(N+1)$-state Markov channel could be used to model the channel. An alternative approach is to introduce a Gaussian mixture model for the primary user state. In this case, the Markov model would still consist of two states, i.e., an active and an idle state, but the conditional distribution in the active state would be governed by a mixture of N Gaussian random variables.

Wideband Sensing

The wideband temporal spectrum sensing approach discussed in section "Wideband Sensing" has limitations with respect to the spectrum bandwidth that can be sensed in a practical implementation. This approach could be extended to cover larger spectrum bands by partitioning the spectrum into smaller chunks and then employing high-performance hardware to implement wideband temporal sensing in

parallel over the spectrum chunks. However, for very wide spectrum bands, e.g., on the order of tens or hundreds of GHz, the required hardware may be too expensive in terms of actual cost and/or power consumption.

Detection of temporal spectrum hole opportunities over a wide spectrum band remains an open problem. In general, spectrum sensing over very wide spectrum bands requires prohibitively high sampling rates for current analog to digital converters. A drawback of cyclic feature detection is the usual requirement to sample above the Nyquist rate to recover the cyclic spectrum. Compressive sensing has been proposed as a technique to exploit the sparsity of primary user signal occupancy within a wide spectrum band. In [52], the inherent sparsity in the two-dimensional cyclic spectrum of communication signals is leveraged, and compressive sensing and sparse signal techniques are developed to recover the desired cyclic statistics with sub-Nyquist samples in a robust manner. Related work along these lines is reported in [36].

Wideband spectrum sensing techniques based on compressive sensing do not take into account the bursting nature of primary user signals, which may result in false detection of spectrum holes in the spectrum band. Moreover, compressive sensing techniques provide only a snapshot of primary user activity over the given spectrum and do not provide a mean of exploiting temporal spectrum hole opportunities. In principle, the primary user activity over the spectrum band during a given time slot could be characterized by a state, and the temporal dynamics could then be modeled using a Markov chain. Unfortunately, the number of states required for such a Markovian model would be infeasible for practical implementation.

A possible solution may involve a two-stage approach in which wideband sensing techniques such as those based on compressive sensing may be applied in the first stage to provide a rough picture of the spectrum occupancy at a given epoch. Portions of the spectrum may then be characterized as being idle, fully occupied, or partially occupied. In the second stage, the Markovian-based wideband temporal sensing approach may be applied to the portions of the spectrum deemed partially occupied based on the results of the first stage. A partially occupied spectrum band may be classified as such because of bursting primary user signal activity, or simply because of a weak primary user signal. In the former case, temporal spectrum hole opportunities may exist, whereas in the latter case, a spatial spectrum hole opportunity may exist. Clearly, these cases must be treated differently in a dynamic spectrum access or dynamic spectrum sharing systems.

Resource Allocation

In this chapter, we have focused on Markovian-based spectrum sensing methods to detect and predict spectrum hole opportunities in the settings of a narrowband channel, a multiband scenario, and a wideband scenario. Emphasis has been placed on estimating the parameter of a Markovian model to characterize primary user occupancy in a given spectrum band. Given an estimate of the model parameter, detection and prediction of the primary user state for spectrum sensing follows

from the Markovian model. On the other hand, we have not discussed the important issue of how to allocate harvested spectrum resources to the secondary users. In the language of multiarmed bandit problems, our focus has been on *exploration* rather than *exploitation* of the spectrum.

The spectrum sensing techniques we have discussed may be employed by a spectrum monitoring service. In this scenario, the secondary users may contribute observation data to the spectrum monitoring service, but they do not make the spectrum sensing decisions per se. The secondary users access the spectrum holes by making requests to the spectrum monitoring service. In this way, exploration of the spectrum is decoupled from its exploitation by secondary users. In this setting, the spectrum monitoring service is responsible both for making spectrum sensing decisions and spectrum allocation decisions to the secondary users. An interesting problem requiring further research is how the Markovian characterization of primary user spectrum occupancy can be leveraged to perform spectrum allocation to secondary users in an efficient manner. In the multiband scenario, for example, when multiple channels are detected to be idle, a secondary user requesting a channel for dynamic spectrum access may be assigned the best channel with respect to some criterion such as the expected sojourn time in the idle state. Such resource allocation could also depend on further information provided by the secondary user, for example, the expected length of time that the channel would be needed. Furthermore, the transmission requirements of secondary users may play a role in which portions of the spectrum are sensed by the spectrum monitoring service.

The presence of a spectrum monitoring service effectively decouples the exploration task from the exploitation task in dynamic spectrum access or sharing. When the secondary users are responsible for both tasks, an important trade-off between exploration and exploitation arises. As discussed in section "Background and Overview of Related Work," several works in the literature have addressed this issue by modeling the dynamic spectrum access problem as POMDP or multiarmed bandit problem. These problems are formulated in a multiband setting in which the the underlying model of primary user activity for a given channel is assumed to be Markovian. A given secondary user must decide, in a given time slot, whether to perform sensing, i.e., explore, or to access a channel, i.e., exploit. If it decides to explore, the secondary user must further decide which channel or channels to sense. Similarly, if it decides to exploit, the secondary user must decide which channel or channels to exploit. In the POMDP formulations, the parameter of the underlying Markov process is assumed to be known either a prior or via parameter estimation. In the multiarmed bandit formulations, usually full knowledge of the parameter is not needed.

In the OCBA-based approach to multiband sensing proposed in [8], the N *best* channels out of a total M channels is selected, based on a parameter estimation process. In the context of a secondary user implementing a POMDP or multiarmed bandit approach to joint sensing and resource allocation, this approach is particularly beneficial when $N \ll M$. Reducing the number of channels under consideration from N to M can have a significant impact on the computational burden. Moreover, the parameter estimates for the M channels can be used in both the POMDP and

multiarmed bandit approaches. It would be of interest to investigate further the role that parameter estimation could play with respect to the exploration/exploitation trade-off in the multiband setting.

Conclusion

In this chapter, we have discussed the application of Markovian models to spectrum sensing in cognitive radio networks. The focus of the chapter has been on the formulation of the Markovian models, parameter estimation, and detection/prediction of primary user activity in a given spectrum band based on knowledge of the model parameter. We provided an overview of background material and related work on spectrum sensing using Markovian models. We reviewed relevant Markovian models for spectrum sensing, primarily in discrete time, including Markov chains, hidden Markov models, and multivariate Markov chains. We also reviewed parameter estimation techniques for these models, particularly the Baum algorithm. We then discussed the application of Markovian-based spectrum sensing in the three progressively more difficult settings of narrowband, multiband, and wideband sensing. Finally, we discussed some interesting issues and open problems for further research on spectrum sensing using Markovian models.

paradigm for the wireless communications systems in the past decades. Besides that, different communications systems and wireless communications channels require different waveform designs and radio access technologies. In this study, a general design and evaluation procedure for the new waveform techniques are presented based on cognitive radio and dynamic spectrum access requirements. Radio access technology researches for the future-generation cellular systems and cognitive radio systems intersect to each other. Therefore, some of the future waveform designs and related modifications are analyzed under the cognitive radio perspective. Several waveforms which have various trade-off situations are discussed from a general perspective and an adaptivity/flexibility perspective.

Introduction

Cellular communications systems have seen a huge growth of data usage in the past decades. In parallel, cognitive radio (CR) and dynamic spectrum access (DSA) systems are developed to create alternative ways of using radio spectrum efficiently for the wireless communications systems. CR and DSA systems provide spectrally efficient solutions by exploiting the unused but licensed radio spectrum, while primary users (licensed users, LUs) are not using the same frequency bands because the radio spectrum is generally underutilized [1]. By this way, frequency spectrum can be utilized efficiently. CR and DSA applications changed the paradigm in the wireless communications system development.

The performance of a wireless communications system depends on the radio access technology (RAT). Different parameters such as the compactness of symbols (localization) which are in time-frequency plane and the robustness issues against channel impairments are determined by the RAT. Also, it has to overcome the new challenges and problems which come with the new-generation systems including decreasing the out-of-band (OOB) emission, increasing spectral efficiency, enabling asynchronous communications, decreasing latency, and decreasing complexity. Different communications systems and wireless channels require different waveform designs and different RATs [2, 3].

Orthogonal Frequency Division Multiplexing (OFDM) has been popularly used in broadband wireless and wired communications systems, but it suffers from several limitations such as high spectral leakage, large peak-to-average power ratio (PAPR), and strict synchronization requirements and is not considered a strong waveform candidate to be used in future communications systems [2, 4]. Generally, existing new waveform designs aim to decrease OOB leakage and increase spectral efficiency compared to OFDM technique which is taken as a reference waveform in most of the waveform studies. However, computational complexity is an important problem for most of the new waveforms. Because of that, modified OFDM methods are also very important in new waveform researches because their complexities are generally low. Today, RAT researches for the future-generation cellular systems and CR systems can intersect to each other. Hence, the future waveform designs need to be analyzed also for CR and DSA systems.

The main goal of this chapter is to provide a general design and evaluation procedure that allows the reader to tailor new waveform techniques based on CR and DSA requirements.

This book chapter is organized as follows: Requirements for CR and DSA systems are given in section "Requirements for Cognitive Radio and Dynamic Spectrum Access". Advantages and disadvantages of OFDM for the CR and DSA applications are presented in section "OFDM for Cognitive Radio". New waveforms beyond OFDM from the general and adaptivity perspectives are explained in sections "Beyond OFDM from Dynamic Spectrum Access Perspectives" and "Beyond OFDM for Adaptation and Flexible Utilization of Various Resources". Finally, in section "Conclusion and Future Directions", future work and concluding remarks are given.

Requirements for Cognitive Radio and Dynamic Spectrum Access

CR and DSA systems need flexible and adaptable physical layer design to provide spectrally efficient solutions. By this perspective, requirements for the opportunistic usage of the underutilized spectrum by CR and DSA applications are given in this section to understand the relationship between the relevant requirements and waveform design parameters better.

As a fundamental requirement, CR systems need to have the ability to utilize scattered and narrow spectrum opportunities. Available signal bandwidth which is a very broadband is divided into smaller bands to exploit the narrow spectrum opportunities for the multiband signaling approach, and it enables better spectrum allocation. On the contrary, the single broadband signaling approach is not preferred for the CR and DSA systems because it is not a spectrally efficient solution. If single broadband signaling approach is employed, fractional frequency usage cannot be maintained and many subcarriers might be deactivated. Hence, single-carrier waveform designs do not fulfill the fundamental requirement of CR and DSA systems. When the multiband signaling approach is considered, the portion of the time and spectrum resources need to be dynamically turned on and off. Multicarrier waveform signals can be shaped adaptively in time and frequency by deactivating a set of subcarriers where primary users exist. To activate/deactivate the subcarriers dynamically, suitable algorithms need to be employed like FFT/IFFT to provide a flexible waveform design.

Spectrum powers of subcarriers leak to adjacent nulled subcarriers especially while activating/deactivating the subcarriers dynamically. This type of situations causes mutual interference to LUs, and it is desired to provide minimal OOB leakage to prevent the interference. There are many techniques to minimize OOB emission in the literature given in the next sections of this chapter. Additionally, orthogonality between subcarriers and user synchronization to the receiver are also important concepts for the CR waveform design.

As another requirement, parameters of the waveform need to be changed on the fly in real time. Waveform parameters such as center frequency, signal bandwidth,

power levels of subcarriers, FFT size, subcarrier spacing, cyclic prefix (CP) size, modulation type and order, coding, etc. should be adaptable and controllable for different wireless channel environments and user requirements. Therefore, CR and DSA systems need highly flexible waveform designs. They need to sense the opportunity in frequency domain while utilizing the spectrum. Actually, CR must sense and exploit the spectrum holes very fast and efficiently. Because of that, awareness of the radio channel characteristics is a critical issue. Besides, the computational complexity of the sensing algorithms should be reduced to provide this awareness. Computationally efficient FFT/IFFT operations are very helpful for the spectrum sensing algorithms in the frequency domain. Simple one-tap frequency domain equalizers are more suitable for the CR and DSA applications in respect to computational complexity requirements. Additionally, minimal latency is another requirement for the CR waveform designs because transmission parameters need to be changed very fast.

In section "OFDM for Cognitive Radio", all requirements given in this section are analyzed considering the OFDM technique as a CR and DSA waveform.

OFDM for Cognitive Radio

OFDM can be thought of as a candidate for the physical layer transmission technology in CR because of its flexibility and adaptivity aspects [1]. OFDM has its wide range of pros and some cons that should be taken into account. In this section, a brief summary of the pros and cons when using OFDM as a physical layer technology for CR systems is provided. The pros of using OFDM as the physical layer technology in CR can be described as follows:

- The process of sensing the spectrum can be done quickly and efficiently using OFDM as the physical layer for CR. OFDM inherently uses the IFFT block to perform the conversion from the frequency domain to the time domain. Therefore, the process of scanning the time-frequency grids, looking for untapped resources, can be done by just reusing the IFFT block at the transmitter, without the need of any supplementary hardware or computation.
- CR shares the system bandwidth with LUs of narrowband. The LUs can operate on a predefined bands or operate at any location of the bands that CR could be operating on causing an interference from and to the LUs. OFDM can avoid this problem by enabling the fractional bandwidth (FBW) mode, where it can deactivate some of the subcarrier by transmitting zeros at that portion of the IFFT block.
- OFDM can adaptively shape its spectrum to fit within the required spectrum mask by simply turning off some of the subcarrier from the IFFT block.
- OFDM provides a high degree of flexibility through the wide range of parameters it has, which can be adjusted accordingly to adapt its waveform to different situations [5]. It can adaptively change the modulation order, the power transmitted for each subcarrier, and the coding according to the channel quality and the user's

need [6]. This adaptation can be performed to serve different design targets, such as lowering the bit error rate (BER), enhancing the system's throughput, controlling the interference, extending the user's battery life or increasing the coverage. OFDM systems also have the flexibility to adaptively change the subcarrier spacing to maintain it less than the coherence bandwidth; thus, the equalization process at the receiver can be done by simple one-tap equalizer. Furthermore, the subcarrier spacing can be adaptively adjusted to reduce the inter-carrier interference (ICI) caused by Doppler spread [7]. Also, OFDM systems deal elegantly with the inter-symbol interference (ISI) caused by the multipath channel effect by appending a CP to each OFDM symbol, the CP duration needs to be larger than maximum channel delay spread to eliminate any ISI that could happen. In OFDM, the CP duration can also be adaptively adjusted according to each user's channel to cope with the amount of ISI observed by each user's channel and maximize the total system throughput.

- In multiuser CR radio scenario, the resources need to be shared and accessed by different users. There are many access technologies that can perform this task in different ways. OFDM supports many access technologies such as Frequency Division Multiple Access (FDMA), Time Division Multiple Access (TDMA) and Carrier Sense Multiple Access (CSMA). Also, OFDM can be combined with Code Division Multiple Access (CDMA) technology, where this transmission is called Multicarrier Code Division Multiple Access (MC-CDMA) or multicarrier Direct Spread Code Division Multiple Access (DS-CDMA). OFDMA, which is an extension of FDM for the multiuser case, is also considered as flexible access technique that can be used for CR. In Orthogonal Frequency Division Multiple Access (OFDMA), the subcarrier of each user (unlicensed user or renter) can either be grouped into a cluster of adjacent subcarriers or to be interleaved among other user's subcarrier according to the availability of free spectrum.
- Since OFDM has been implemented in many of the standards such as WLAN (IEEE 208.11), WMAN (IEEE 802.16), WRAN (IEEE 802.22), and WPAN (IEEE 802.15.3a). This brings another key advantage which is referred to as the interoperability.

On the other hand, OFDM has some limitation when it is considered as the physical layer for CR. OFDM cons can be described as follows:

- The OFDM modulated subcarriers have the sinc shape that is considered to have large sidelobes in both sides. The presence of the large sidelobes of the OFDM signal results in an interference in the adjacent subcarrier. Many techniques have been proposed to lower the power leakage to enable the coexistence of CR-OFDM systems with the primary users.
- In single band CR-OFDM systems, after searching for an available free portion of the spectrum, one OFDM signal can be transmitted over the available free parts of the spectrum. Then by shaping the OFDM spectrum, CR can avoid interfering with the LUs operating on the same band because OFDM is a multiband approach. Although using single broadband transmission approach facilities the

system design, it requires high-speed analog to digital converter (ADC) to be able to sample the wide band signal. On the other hand, the implementation of wideband multiband OFDM system includes the need for a wide range of frequency synthesizer, broadband TX/RX switch at the antenna and fast band hopping to avoid interference to the occupied bands.

- Synchronization is one of the fatal issues that should be taken care of when designing any OFDM system. In CR, a narrow band interference (NBI) can interfere with the preamble sequence causing a synchronization problem [8]. Also, pilots could fall into the place of the unused subcarriers which can also cause a synchronization problem. Therefore, to keep the orthogonality between subcarrier and to avoid the ICI, all users should be synchronized to the receiver. Adding longer preambles to CR-OFDM compared to conventional systems is proposed as a solution [8].

Beyond OFDM from Dynamic Spectrum Access Perspectives

In the previous sections, it is mentioned about that the future-generation cellular system and CR requirements can intersect to each other. Existing new waveform designs generally aim to decrease OOB leakage and increase spectral efficiency compared to OFDM technique which is taken as a reference waveform in most of the studies. However, computational complexity is an important problem for most of the new waveforms. Because of that, modified OFDM methods are also very important in fifth-generation (5G) waveform researches as analyzed in section "Sidelobe Suppression Techniques". And, new multicarrier waveforms beyond OFDM are discussed from a general perspective under two main groups: Orthogonal waveforms in section "New Waveforms" and non-orthogonal waveforms section "Non-orthogonal Waveforms".

Sidelobe Suppression Techniques

Based on the advantages and disadvantages of OFDM, which are given in section "OFDM for Cognitive Radio", there are various modification methods to overcome some drawbacks of OFDM. The most important and widely used modifications are related to the sidelobe suppression techniques. OFDM can be employed in a better way especially for CR applications by using these sidelobe suppression methods. In this subsection, various sidelobe suppression techniques are presented under a common umbrella.

There are too many different sidelobe suppression approaches in the literature. Their performances change according to the various trade-off situations which are generally originated from the amount of spectral leakage, computational complexity performance, and BER performance. Among these performance metrics, if the spectral leakage is not handled, the high spectral sidelobes can create severe adjacent

channel interference (ACI) problems. Superiorities and drawbacks of these sidelobe suppression techniques differ.

Time windowing techniques are known as the computationally efficient way for the sidelobe suppression [9–11]. They modify the shape of OFDM symbols to suppress sidelobes. Generally, the guard interval is increased while windowing the time domain OFDM symbols and spectral efficiency is decreased because of these guard intervals. In one similar time domain approach called as adaptive symbol transition (AST) [12], the OFDM symbols are extended in time like in the windowing technique, but the transition signal is optimized adaptively to minimize ACI. By this way, spectral efficiency can be increased in exchange for the computational complexity. Rather than windowing techniques, there are also some filtering methods in the literature; however, they usually increase the computational complexity and cause long delays while employing filtering operations [12].

For the frequency domain approaches, active interference cancellation (AIC) [13] and cancellation carriers (CC) [14] are two techniques which smooth the sharp transitions between OFDM symbols. They reduce interference to white spaces and provide high spectral efficiency. However, these methods are known as computationally complex techniques. For example, calculation of cancellation carrier values increases the complexity. Subcarrier weighting (SW) [15], constellation adjustment (CA) [16], and constellation expansion [17] are other schemes which include an extension for the OFDM symbols in time. SW technique multiplies all subcarriers in specific weights to reduce the sidelobe powers.

A precoder for shaping the spectrum of OFDM is given under mask compliant precoder (MCP) technique [18] which aims to control the OOB emission levels without impacting the BER performance. There are also different precoder methods like N-continuous precoder (NCP) [19], least square notch precoder (LSNP) [20], and orthogonal precoder (OP) [21]. For NCP technique, OFDM signals are constructed by precoder that renders the phase and amplitude of the emitted signal and this method leaves the effective length of the CP unchanged. BER performance of the NCP method is low compared to conventional OFDM. Generalization of the N-continuous method with using more degrees of freedom is achieved by enabling disturbance-free data subcarriers at the receiver [22]. LNSP scheme is introduced as a spectrum-sculpting and linear precoder that suppresses the power in predefined parts of the related spectrum flexibly. The computational complexity of this method is low because of the notching process. In OP technique, N-continuous OFDM signals are realized as an orthogonal multiplex to increase BER performance compared to other precoder methods.

One of the low-complexity techniques is sidelobe suppression with orthogonal projection (SSOP) which is based on orthogonal projection matrix and uses one reserved subcarrier for recovering the distorted signal in the receiver [23]. In this method, ISI between the symbols can be removed in the absence of noise by using the reserved subcarriers. Another sidelobe suppression method is multiple choice sequences (MCS), and it is based on the idea that transforming the original transmit sequence into a set of sequences [24]. After that, the sequence with the lowest sidelobe power is chosen.

There are also various joint PAPR and OOBE reduction methods in the literature [25, 26]. And, instead of the sidelobe suppression techniques, there are also new waveform designs which can be considered as waveform candidates of 5G and beyond cellular systems. In sections "New Waveforms" and "Non-orthogonal Waveforms", some of these approaches are analyzed from a general perspective.

New Waveforms

Current waveforms all have various positive and negative properties which push the research for new waveforms [27]. Optimization of any parameter results in losses in other parameters. This game of trade-offs has not converged to a fully optimal solution yet [2]. The proposed waveforms are usually benchmarked against OFDM.

As mentioned in section "OFDM for Cognitive Radio", OFDM has the following advantages: It has low computational complexity due to the FFT algorithms, adjustable bandwidth, simple equalization, and good coupling with multi-input multi-output (MIMO) systems. The disadvantages of OFDM are high PAPR, synchronization requirement between users, sensitivity against time and frequency shifts, and high level of OOBE.

The high OOBE problem limits the OFDM in the framework of new cognitive radio systems. Most of the new waveforms are generally better than OFDM with respect to their OOB leakage amounts. However, they generally have some computational complexity problems compared to OFDM or modified OFDM methods.

Some of the new waveforms proposed to address challenges associated with 5G and beyond include filtered OFDM (f-OFDM) [28], universal filtered multicarrier (UFMC) (aka universal filtered OFDM, UF-OFDM) [29], and unique word OFDM (UW-OFDM) [30]. These waveform designs are backward compatible because the main structure of the OFDM frame is maintained. However, some other waveform designs do not have the same frame structure such as FBMC [31,32] and generalized frequency division multiplexing (GFDM) [33]. FBMC and GFDM are analyzed under non-orthogonal waveforms in section "Non-orthogonal Waveforms". Additionally, some waveform techniques are analyzed from an adaptivity perspective in section "Beyond OFDM for Adaptation and Flexible Utilization of Various Resources".

As mentioned previously, filtering and windowing methods can be used to suppress the sidelobes after pulse shaping. At the transmitter, the OOB emission levels are suppressed when the windowing technique is applied. Suppressing the OOB emission levels reduces the interference among adjacent channels and provides better adjacent channel leakage power ratio. Alternatively, different-length filters can be applied either to a group of subcarriers or to all the subcarriers for one OFDM frame in f-OFDM and UF-OFDM techniques. Besides, the windowing technique helps to reduce the interference between the users within one band by lowering the in-band emissions at the receiver.

In f-OFDM, a different number of subcarriers are grouped into subbands for different users and applications. Based on these subbands, the appropriate IFFT, different length CP addition and filtering operations are performed [28]. Filters are designed to reduce OOBE. However, these operations destroy the orthogonality between the subbands and may cause inter-user interference. Some other details related with the adaptivity of f-OFDM are presented in section "Filtered OFDM with an Adaptivity Perspective".

In UFMC, subcarriers are grouped in subbands, and these subbands are filtered with either the same filter or different filter functions. IFFT is performed to each subband separately and zero guard (ZG) is added afterward in place of CP [29]. UFMC has less OOBE and higher spectral efficiency when compared to CP-OFDM due to the filtering performed.

Conventional pulse shaping and filtering may not be sufficient to meet the needs of a wide range of transmitted and received signals. Additional processing on top of grid design, filtering, and pulse shaping can be used to modify the signal and its structure to optimize the waveform design. For example, unique word (UW) [30] and zero tail (ZT) [34] have been proposed for future-generation wireless communications systems which can be considered as pre/post processes. These techniques aim to deal with disadvantages of the hard-coded CP.

The pre- and post-processing techniques may have purposes such as easing the equalization [34,35], reducing spectral leakage emission [18], reducing PAPR [36], improving physical layer security [37], and even joint goals [38]. Structural or adaptive processing techniques are used to improve different aspects of the wireless communications system that cannot be solved only by filtering and lattice design. They can be gathered under the pre- and post-processing at transmitter and receiver, respectively.

In CP-OFDM, CP is used to prevent ISI between consecutive symbols and eases the frequency domain equalization by transforming the linear convolution of transmitted OFDM symbols to a circular convolution. In UW-OFDM, the UW process improves the aforementioned gains by placing the same known sequence between all consecutive symbols [30]. Since the sequence is known, it can be used for the synchronization, and channel estimation can be done at the receiver. Also, it eliminates the need for dedicated pilot subcarriers used in CP-OFDM. Compared to CP-OFDM, UW-OFDM trades off a gain in OOBE with increased computational complexity.

The inflexibility of the duration of hard-coded CP is another disadvantage of CP-OFDM. If CP length is longer than required duration, resources are not used efficiently. Otherwise, it causes an insufficient mitigation against ISI. In zero-tail DFT-spread OFDM (ZT DFT-s OFDM), the ZT procedure generates low power samples, which are called as tails, inside the FFT duration, and they are adjusted according to different channel delay spreads to increase spectral efficiency [34]. This conserves the same total symbol duration even with different guard durations. For 5G heterogeneous networks operating over different frame structures and different symbol lengths, the usage of flexible guard time becomes a promising

feature, making ZT DFT-s OFDM a candidate. The drawback is the uncontrollable ISI in the case of unusually long delay spreads.

By the way, from the CR design perspectives, multicarrier waveform methods need to be discussed rather than single-carrier methods. There are various single-carrier waveform methods especially for the 5G uplink systems. However, they are not suitable for the CR applications because it is a need for more carriers to switch on and switch off between these carriers. At this point, DFT-s techniques can be thought as mixed waveform types of multicarrier and single-carrier methods according to the number of subcarrier groups. If there are fewer subcarrier groups, DFT-s method behaves like a single-carrier method. On the contrary, DFT-s method can be analyzed like a multicarrier waveform technique. DFT-s OFDM techniques and their variations introduce flexible physical layer for the future-generation cellular systems and CR applications.

There are also some other DFT-s OFDM-based waveform suggestions in various publications. These suggestions include some modifications to the new waveforms which are given in this subsection. UW DFT-s OFDM method modifies ZT DFT-s OFDM and UW-OFDM techniques by removing the impact of symbols on the tail of the transmitted signal [39]. In another study of the same authors, UW DFT-s Windowed OFDM is proposed which uses a frequency domain windowing technique as in GFDM to suppress the leakage to the tail of the DFT-s OFDM symbols [40]. Guard interval (GI) DFT-s OFDM scheme uses an adaptive GI of variable size to decrease PAPR while providing similar OOBE compared to DFT-s OFDM and CP-OFDM techniques [41]. Another paper introduces generalized DFT-s OFDM which replaces the CP with a sequence having a tunable length to provide more flexibility [42]. Some other details related with the adaptivity of DFT-s OFDM methods are presented in section "New Adaptive Waveforms".

A generic block diagram of the transmitter and receiver designs for major waveforms developed for 5G can be seen in Tables 1 and 2, respectively. Some basic differences between these waveform designs are given in these tables. For ZT DFT-s OFDM method, M is less than N.

Non-orthogonal Waveforms

There are also new non-orthogonal waveforms which ignore the assumption of strict synchronization and orthogonality in the wireless network systems. For example, different non-orthogonal waveform designs were studied in some EU projects like PHYDYAS (Physical Layer for Dynamic Access and Cognitive Radio) and 5GNOW (5th Generation Non-Orthogonal Waveforms for Asynchronous Signalling). FBMC and GFDM are two techniques analyzed in these EU projects. Generally, these methods may need interference suppression techniques on the receiver side of the transceiver systems.

In FBMC, a different filter is used for each subcarrier and these filters are not orthogonal in the complex plane. Polyphase network (PPN) approaches are taken for better performance [43]. To achieve better filtering performance, symbols are

FBMC	Yes		FFT		
GFDM		Yes			GFDM demodulator

modulated using offset QAM (OQAM) [32]. FBMC has extremely low OOBE due to the utilization of very long filters. However, these long filters increase the computational complexity and decrease the spectral efficiency with their tails. FBMC is not well suitable for MIMO since the filters span a few symbols [44].

Comparing UFMC to FBMC, the shorter filters utilized in UFMC decrease the access delays introduced by the waveform. The same reason makes UFMC less computationally complex compared to FBMC, but UFMC is still more computationally complex than CP-OFDM.

In GFDM, time blocks are divided into shorter duration symbols, which results in wider band subcarriers compared to CP-OFDM [33]. The cyclic filters used for each subsymbol adds CP before GFDM blocks. Filtering is performed per subcarrier as in FBMC. Different than FBMC, the subcarriers are upsampled before filtering is performed, resulting in shorter access delays. ICI introduced by the non-orthogonality requires utilization of cyclostationarity-based interference suppression techniques at the receiver, which greatly increases receiver complexity. Some other details related with the adaptivity of GFDM are presented in section "Generalized Frequency Division Multiplexing with an Adaptivity Perspective".

For the beyond of 5G, more adaptive, flexible, and hybrid systems with mixed numerology structures are needed. In section "Beyond OFDM for Adaptation and Flexible Utilization of Various Resources", this type of systems is explained in more details, and new waveforms beyond OFDM are discussed from an adaptivity perspective.

Beyond OFDM for Adaptation and Flexible Utilization of Various Resources

From the adaptivitiy perspective, OFDM is a multicarrier modulation scheme that has the potentials that makes it suitable for CR. OFDM provides a high degree of adaptation in many aspects which are described in section "OFDM from the Adaptivity Perspective". There are also other new adaptive waveforms like DFT-s methods which are explained in section "New Adaptive Waveforms".

OFDM from the Adaptivity Perspective

Adaptive CP

In a multipath environment, the transmitted symbol reaches the receiver from different propagation paths with different time delays. Therefore, the duration of the received symbol is stretched causing some overlapping with the previously received symbols. This overlapping caused by the multipath propagation is usually referred to as ISI. Also, there is another kind of interference called ICI that arises with the ISI when there is no guard time between the consecutive OFDM symbols or when the guard time is insufficient. The integer number of cycles for each subcarrier within the FFT interval is no longer maintained due to the phase transition introduced by the previous symbol. A zero guard time that has a length greater than or equal to the maximum excess delay can be used to accommodate the spreading of the previous symbol and eliminate the ISI. At the receiver, the guard time including the interfering parts is discarded before the FFT operation. Although the guard time can be sufficient to cope with the ISI between the adjacent received OFDM symbols, OFDM symbol still suffers from a self-interference caused by the delayed replicas arriving from different propagation paths as shown in Fig. 1. The orthogonality of subcarriers is lost due to the multipath propagations. The reason is that there is no longer an integer number of cycle's difference between the subcarrier within the FFT interval. Alternatively, CP that is a guard time inserted between consecutive OFDM symbols, can restore the orthogonality by converting the linear convolution channel into a circular convolution channel. It is done by copying enough number of time samples from the end of the OFDM symbol and appending them into the front.

In order to handle with this distortion, a one-tap channel equalizer can be used for each subcarrier. In the receiver, the output samples of the FFT is multiplied by the corresponding channel equalizer coefficient. On the other hand, using CP

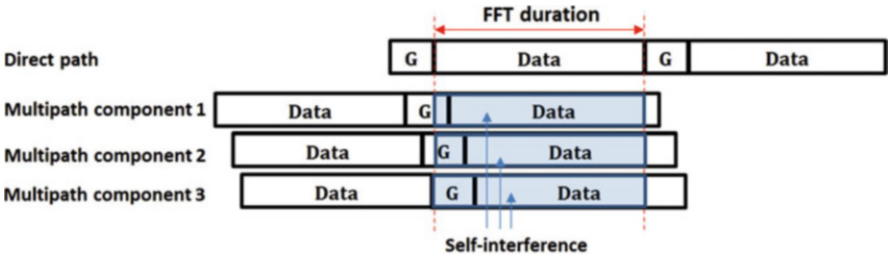

Fig. 1 Guard interval solves ISI, but does not solve the self-interference due to multipath propagation

results in energy waste by transmitting redundant OFDM samples that are used to mitigate ICI and ISI. Also, ICI occurs in the time-varying multipath channels, where the Doppler shifts cause frequency offset on the subcarriers, then ICI and a loss of orthogonality. For large Doppler frequency, f_d, values, the channel varies faster relatively to the OFDM symbol duration resulting in ICI and a degradation in the BER performance. While, for small Doppler frequency values, the channel varies slowly relative to OFDM symbol duration yielding to performance that is close to the flat fading channel.

As not having a sufficient CP length can cause interference problems and degradation on the quality of communication, also having unnecessary long CP causes a waste of resources and degradation in the throughput. CP contains a redundant data that is not being processed and discarded at the receiver prior to demodulation. Therefore, CR needs to adaptively change CP duration after estimating the channel in order to maintain ISI and ICI-free signal while achieving the maximum throughput possible. As discussed previously, the amount of effect that ISI causes can be reduced by increasing the OFDM symbol duration. And the symbol duration is proportional to the number of subcarriers for a given bandwidth. Therefore, it shows that a small number of subcarriers is better than a large number of subcarriers for ISI. Long OFDM symbols are more immune to frequency-selective fading channels. However, they are more sensitive to time-selective fading channels. Time selectivity causes the loss of orthogonality. Therefore, in doubly dispersive channels an optimum combination of CP and number of subcarriers should be selected depending on the required BER performance, available bandwidth, and the available transmitted power.

Adaptive Modulation and Subcarrier Allocation

Adaptive modulation is one of the techniques used to enhance the performance of an OFDM system. Assuming all subcarriers transmit at the same power level. If the transmitter knows the instantaneous channel transfer function, then the subcarriers with large channel gains can transmit more bits per OFDM symbol using higher order modulations, while the subcarrier that suffers from low channel gains "deep fading" can carry less number of bits or no bits per OFDM symbol to enhance the

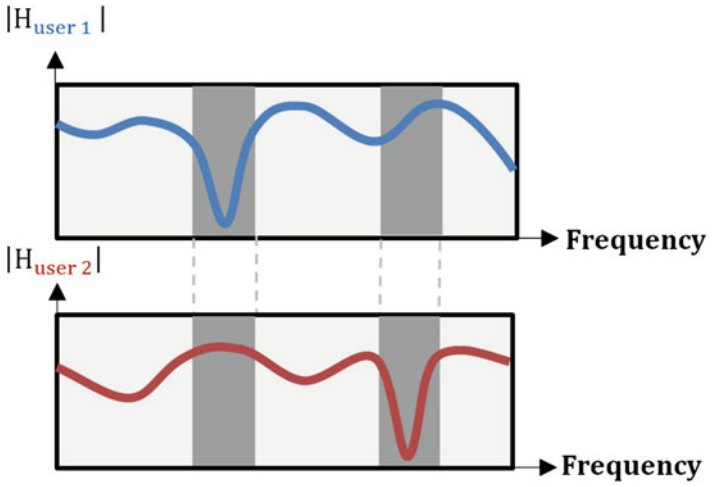

Fig. 2 Low channel gains at the locations of the subcarriers of the first user corresponds to high channel gains for the same group of subcarrier of the second user

BER performance. Since different subcarriers suffer from different channel gains and transmit at different rates "bits per OFDM symbol," then the transmit power level of each subcarrier should be changed accordingly. In frequency-selective channels, some subcarriers suffer from deep fades, as a result, a large number of subcarriers could be left without being utilized causing waste of resources. In a multiuser scenario, the deep fading affecting portion of the subcarriers of one user might not also be affecting the same portion of subcarriers of other users, as illustrated in Fig. 2. In static resource allocation such as TDMA and FDMA, users are allocated to predetermined time slots or frequency bands, the unused subcarriers in the time slots or frequency bands of one user cannot be used by the other users. Figure 3 shows the differences between the three static resource allocation schemes. In OFDM-TDMA, the subcarriers are not shared with other user(s) during a predetermined TDMA time slot. Each user is assigned in a predetermined time slot to use the subcarriers in that time slot separately. While in OFDM-FDMA, each user is assigned a predetermined group of subcarriers to be used at all times by single users. Another version of OFDM-FDMA is referred to as OFDM-interleaved-FDMA, which is similar to OFDM-FDMA, except that the subcarriers assigned to each user are not consecutive, the subcarriers of one user are merged within the other user's subcarriers. Therefore, multiuser adaptive subcarrier allocation, depending on the instantaneous channel response of the users, allows better utilization of the resources since there is a benefit of the subcarriers that suffers from deep fade at one user by other users.

One of the objectives in an adaptive multiuser subcarrier, bit, and power allocation system is to minimize the overall transmit power [45]. At the transmitter, the total number of bits that need to be transmitted from K users are fed to subcarrier and bit allocation block that allocates the bits from different users to

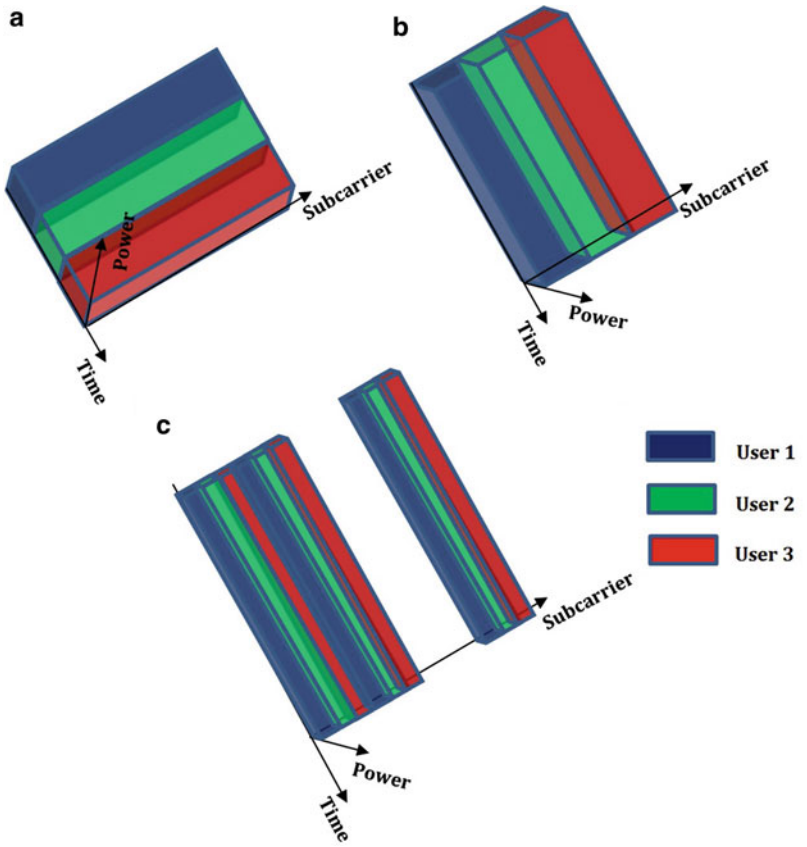

Fig. 3 (**a**) OFDM-TDMA, (**b**) OFDM-FDMA, (**c**) OFDM-interleaved-FDMA

different subcarriers. The transmitter is aware of the instantaneous channel gains from the K users on all the subcarriers. The transmitter exploits the extracted channel information by applying them to a subcarrier, bit, and power allocation algorithm which assigns different subcarriers to different users. And, the adaptive modulator chooses a modulation scheme and the transmit power level depending on the number of bits assigned on each subcarrier.

Adaptive OFDMA Frame Structure: "Adaptive Lattice"

The frame consists of multiple OFDMA symbols that have a structure in time and frequency referred to as lattice. The structure of all the OFDMA symbols within the frame defines the structure of the whole frame. The structure of OFDMA symbols in time and frequency domains is determined by different parameters, but the fundamental parameters are mainly the subcarrier spacing (Δ_f) and the cyclic prefix duration (T_{cp}). In conventional OFDMA systems, the frame structure is fixed, meaning that the design parameters chosen (T_{cp} and Δ_f) for all the OFDM symbols within the frame are set to a fixed value that is chosen considering the worst

case communication channel to guarantee to maintain the orthogonality between the subcarriers within one OFDM frame. The interference is composed of ISI in doubly dispersive channels. It is caused by the time dispersion due to the multipath propagation and ICI. The motion of the transmitter, the receiver, or the objects in between causes a frequency spreading which is also the reason of ICI. Depending on the channel characteristics of the users, the time and frequency dimensions might be exposed to different time and frequency responses at the same. Although the conventional approach in designing the frame structure provides an immunity to different channel conditions, it ignores the fact that not all the users within the frame undergoes to the worst channel condition in time and frequency at all times. For example, the conventional approach does not consider the user with a less maximum excess delay than the worst maximum excess delay spread as the users close to the base station; also it doesn't consider stationary users with narrower subcarrier spacing. Other approaches follow different strategies by treating the user's communication channels fairly rather than equally when designing the frame structure. The new approach in [46] aims to improve the spectral efficiency while maintaining the frequency spread immunity by classifying the OFDMA symbols within the frame into different cases according to the user's channel response in doubly dispersive channel as shown in Fig. 4. Having multiple users with different doubly dispersive channels is exploited by adapting the time-frequency structure of OFDMA scheme. Having large subcarrier spacing provides immunity to ICI, but on the other hand, smaller subcarrier spacing improves the spectral efficiency. Also, the subcarrier spacing is related to delay spread characteristics of the channel by the relation that connects the subcarrier spacing and the symbol duration T_s by:

$$T_s = \frac{1}{\Delta_f} \tag{1}$$

Additionally, the subcarrier spacing indirectly impacts T_{cp}, which depends on the delay spread characteristics of the channel. Longer T_{cp} is desirable to avoid ISI between OFDMA symbols, while shorter T_{cp} increases the spectral efficiency. This approach is based on prior knowledge of the channel statistic that the frame structure is designed base upon it. Prior knowledge of channel statistics is used to reduce feedback requirements.

New Adaptive Waveforms

Zero-Tail DFT-s OFDM with an Adaptivity Perspective

As being mentioned previously, in OFDM and DFT-spread-OFDM, the problem of ISI that is caused by the multipath channel effect is being taken care of by copying the last part of the time domain signal and appending it at the beginning before the transmission which is referred to as CP. Then at the receiver, the effect of ISI is being removed by discarding the CP part and applying single tap equalizer after the IFFT process to get rid of the ICI caused by the multipath effect [47].

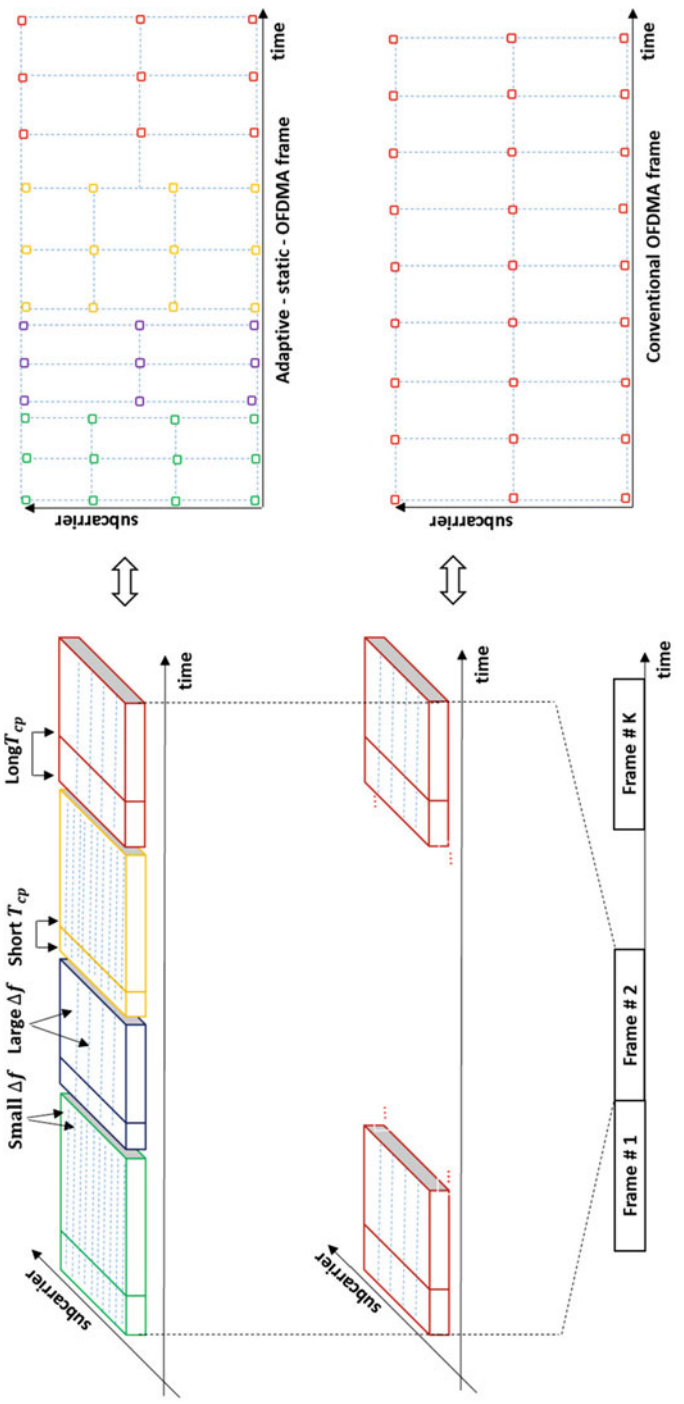

Fig. 4 Adaptive OFDMA frame structure [46]

Although CP approach has a great role in protecting the signal against the multipath channel effect, it still suffers from some limitation in terms of its flexibility. Since, CP duration is agreed on in prior according to the channel characteristics, e.g., maximum channel delay spread, it becomes not feasible to change the CP duration while maintaining their fit in one millisecond subframe duration. Also, since the CP is pre-agreed on prior to channel delay spread then this either results in and excessive CP duration for the users who observe less channel delay spread, or it can result in insufficient CP duration for user who observe high channel delay spread, allowing some leakage from the previous symbols which result in degradation in the system performance. While ZT DFT-s OFDM is a new approach which generates an internal GI between the consecutive symbols by adding zero tail at the beginning of the DFT process after the data symbols [34]. Thus, even if the guard interval changes, the complete symbol duration remains the same. Also, it is worth mentioning that this GI that appears after the IFFT process; it does not have a zero power; however, it has a low-power samples at the tail due to the spreading that happens after the DFT and IDFT processes. Furthermore, adding some zero before the data symbols (at the header of the data symbols) to the input of DFT block enhances the OOB emission by making the smooth transition between the consecutive symbols. The basic structure for the ZT DFT-s OFDM is shown in Fig. 5.

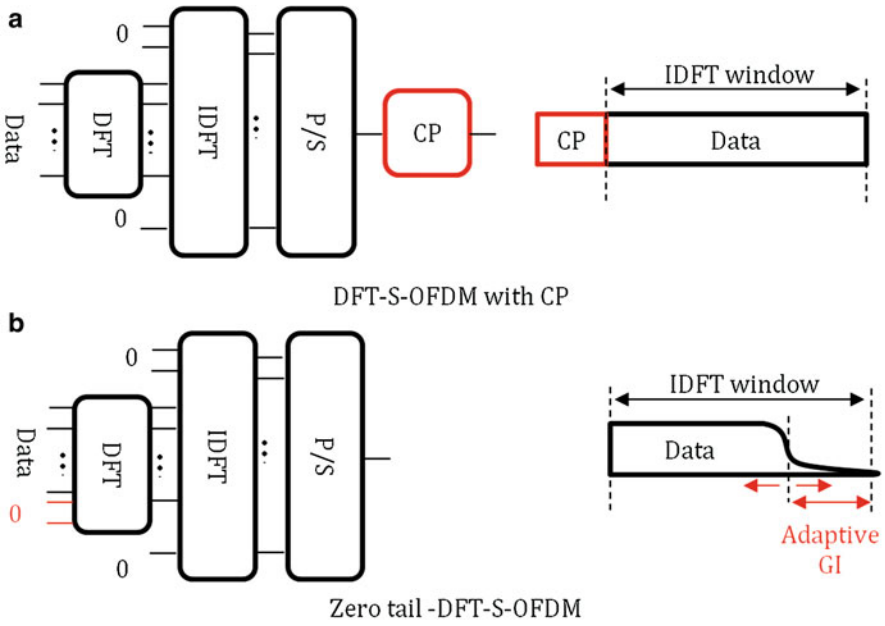

Fig. 5 ZT DFT-s OFDM structure

Unique Word DFT-s OFDM

UW DFT-s OFDM can be seen as a general case which ZT DFT-s OFDM have flowed from it. Instead of generating a zero (or low-power) time domain samples at the beginning and at the end of the DFT-s OFDM symbol, UW DFT-s OFDM generates a non-zero fixed samples at the end and the beginning of the DFT-s OFDM symbol. This non-zero-sample can be generated by adding a signal which is referred to as UW. This UW signal can either be added in time domain with two steps, or in the frequency domain in one step [30]. The two-step approach is done be firstly generating a ZT DFT-s OFDM symbol by inserting zeros at the head and tail of the data symbols before the DFT process. Then add the UW signal in time domain after the IDFT process. This two-step approach is used, then the UW should be generated within the transmission bandwidth. Additionally, any interference that could occur due to the addition of the UW signal should be handled at the receiver. Alternatively, the second approach which is a one-step approach maintains the orthogonally between the UW signal and the DFT-s OFDM signal by replacing the zeros added at the beginning of DFT block by a unique fixed sequence to generate the unique word at the output of the IDFT block. Thus, the UW signal and the DFT-s OFDM signal are orthogonal since they use different input signals at the DFT block. Additionally, it worth to mention that the since the UW is generated by a fixed sequence, it can be used in the estimation of noise variance and tracking [48] and also in phase tracking algorithms [49]. General solutions and challenges for the flexible DFT-s OFDM techniques are analyzed in [40]. The basic structure for the UW DFT-s OFDM is given in Fig. 6.

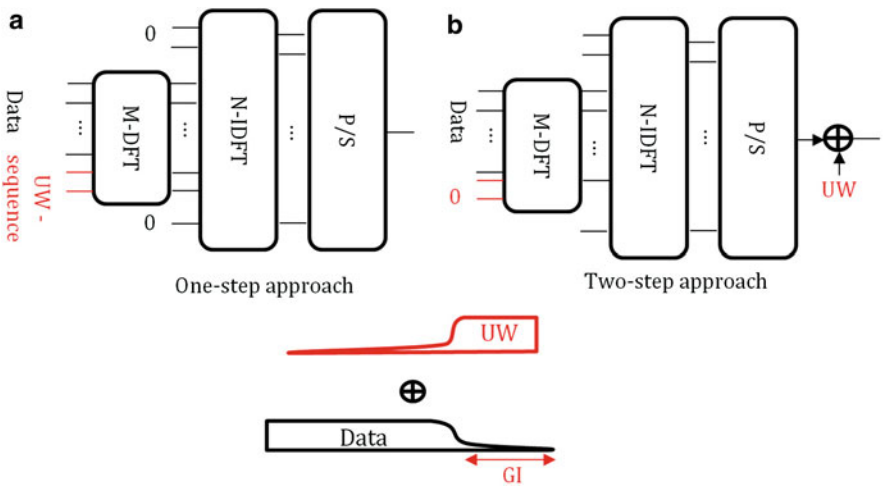

Fig. 6 UW DFT-s OFDM structure

Filtered OFDM with an Adaptivity Perspective

OFDM signal is not well localized in frequency due to the presence of the large sidelobes. Therefore, at least 10% guard band is required to meet the OOB leakage rejection requirements. Also, OFDM is not a flexible waveform with fixed subcarrier spacing and have limited options in CP. Also, OFDM is not suitable for asynchronous transmission across different subbands do to the high OOB emission. And most importantly, conventional OFDM does not allow using different configurations (e.g., subcarrier spacing, CP duration, etc.) across different subbands. f-OFDM enables the use of different waveforms with different configurations. While the conventional OFDM makes the whole frequency band as one block with the same subcarrier spacing and the same CP. While in f-OFDM the whole frequency band is divided into smaller subbands with different bandwidths and different subcarrier spacing and each subband can have different CP duration, this provides the flexibility in both frequency (subcarrier spacing and subband bandwidth) and in time (symbol duration, CP duration). Then after each subband has its own filter that is applied to it. f-OFDM allows the support of asynchronous transmission across the subbands and the support of mixed numerologies due to better OOBE at the expense of a lower number of guard tones between neighboring subbands.

The filters considered in f-OFDM is designed by multiplying a sinc function in time domain, which has an ideal response in the frequency domain, by a time domain window function (e.g., Hanning, root-raised cosine (RRC)), which is well localized in time, to produce a filter which has better localization in time and frequency domains for better ICI and ISI. Frequency domain filtering is preferred for simple implementation via an overlap-save algorithm [50]. The basic structure of f-OFDM is given in Fig. 7.

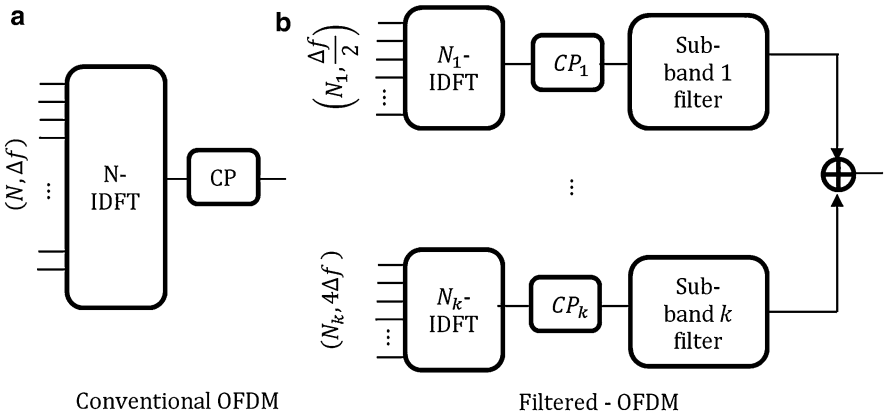

Fig. 7 f-OFDM structure

Generalized Frequency Division Multiplexing with an Adaptivity Perspective

In the literature, GFDM is presented as a flexible waveform that can be customized to correspond to either OFDM or DFT-s OFDM as two extreme cases of GFDM. Also, GFDM can be customized by adjusting some of its parameters to be able to adapt to different requirements and channel conditions. Moreover, GFDM has shown enhancement in lowering the OOB radiation when it is compared with OFDM. However, even a lower OOB can be achieved by applying windowing to GFDM as an additional process at the expense of increasing the complexity.

These features of flexibility and lowering the OOB are achieved by changing the building unit of the system which is the pulse shape. Unlike OFDM which uses a rectangular pulse shape in time domain that extends to only one OFDM symbol, GFDM uses a pulse shape that spreads to multiple subsymbols. In GFDM, the pulse shapes are overlapped in time domain by circularly shifting the pulse shape across all the subsymbols within one GFDM symbol. GFDM, like some other waveforms, works on enhancing the OOB emission by filtering each subcarrier, leading to better immunity against ICI and relaxing synchronization requirements. As illustrated in Fig. 8, GFDM can be converted to DFT-s OFDM by setting $K = 1$; thus, the number of subsymbols increases $M = N$. On the other hand, GFDM can correspond

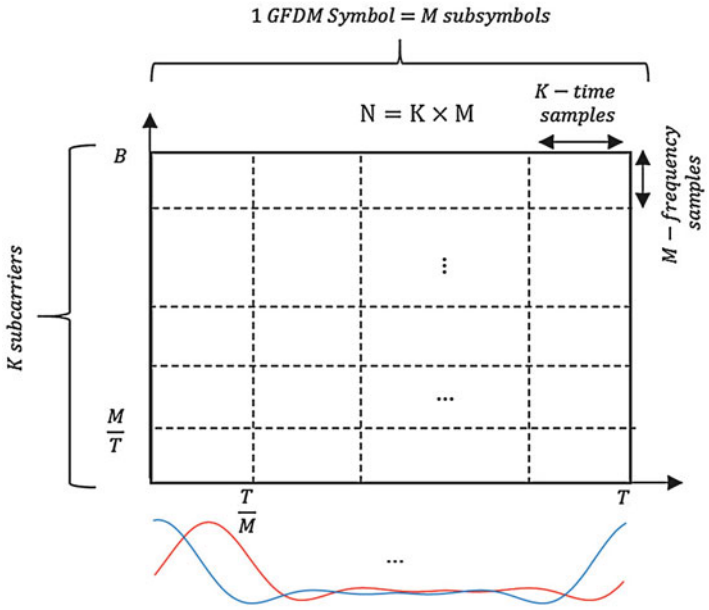

Fig. 8 GFDM structure

to OFDM waveform by elegantly setting $M = 1$ and increasing the number of subcarriers to $K = N$.

Conclusion and Future Directions

As it is discussed, OFDM is seen as a promising physical layer candidate for CR. It has high level of flexibility and high level of adaptation to the open opportunities in the spectrum and to different conditions. However, OFDM still suffers from limitation such as high OOBE, requiring strict synchronization, and some other drawbacks. Some of those problems have been solved with some additional processing done on the OFDM signal. On the other hand, other waveforms that have better characteristics than OFDM can be thought of as a good alternative for CR physical layer. Those waveforms have a wide range of adjustable parameters that grants them a high level of flexibility and adaptivity which are important aspects of the CR physical layer. Moreover, adaptive waveform designs can be multiplexed in a hybrid structure to provide more flexible and adaptive solutions. In hybrid structures, different waveforms may be employed under the same cell. Thus, hybrid structure designs can let the future communications systems benefit from different techniques and choices for different times and conditions.

Abstract

A cognitive radio (CR) system aims at an efficient utilization of the spectrum below 6 GHz – suitable for mobile communications – by enabling a secondary access to the licensed spectrum while ensuring a sufficient protection to the licensed users. Despite the fact that an extensive amount of literature has been dedicated to the field of CR, its performance analysis has been dealt inadequately from a deployment perspective, therefore making it difficult to understand the extent of vulnerability caused to the primary system. Following a deployment perspective, it has been identified that the involved channels' knowledge is pivotal for the realization of CR techniques. However, the aspect of channel knowledge in context of CR systems, particularly its detrimental effect on the performance, has not been clearly understood. With the purpose of curtailing this gap, this chapter proposes a successful integration of this knowledge by carrying out estimation of the involved channels within a CR system. More specifically, this chapter outlines the following two aspects: first, this chapter establishes an analytical framework to characterize the degradation in the performance due to effects such as time allocation and variation, arising due to imperfect channel knowledge. Second, this chapter features performance tradeoffs that determine the maximum achievable throughput of the CR systems while satisfying the interference constraint.

Introduction

Since the invention of smart devices, the mobile traffic has been increasing tremendously over the last decade. According to the recent surveys on mobile traffic by prominent market leaders (Cisco [15] and Ericsson [20]), the existing mobile traffic is expected to increase 11-fold by 2021. The wireless community including the standardization bodies (3GPP) believe that the state-of-the-art standards (fourth-generation (4G) – LTE, WiMAX) are not capable of sustaining these ever-increasing demands in the upcoming decade. With this situation in hand, the standardization bodies are currently in the phase of conceptualizing the requirements of the fifth generation (5G) of mobile wireless systems. Some of these major requirements are (i) areal capacity in bits/sec/m^2 must increase by a factor of 1000 compared to 4G, (ii) low latency of approximately 1 ms, and (iii) energy- and cost-efficient deployment [3].

The feasibility of these requirements can be envisaged through the application of promising approaches such as maximization of the spatial degrees of freedom (using techniques like massive MIMO [50] and 3D-beamforming [33]), in-band full duplex communications [64], small cell densification [2, 24], alternatives to the already allocated spectrum – such as millimeter-wave technology (mmW) [62], visible light communications [76], and cognitive radio (CR) communications – and waveform design [65]. A classification of these approaches is described in Fig. 1. In order to narrow down the perspective, in this chapter, a deployment scenario that lays

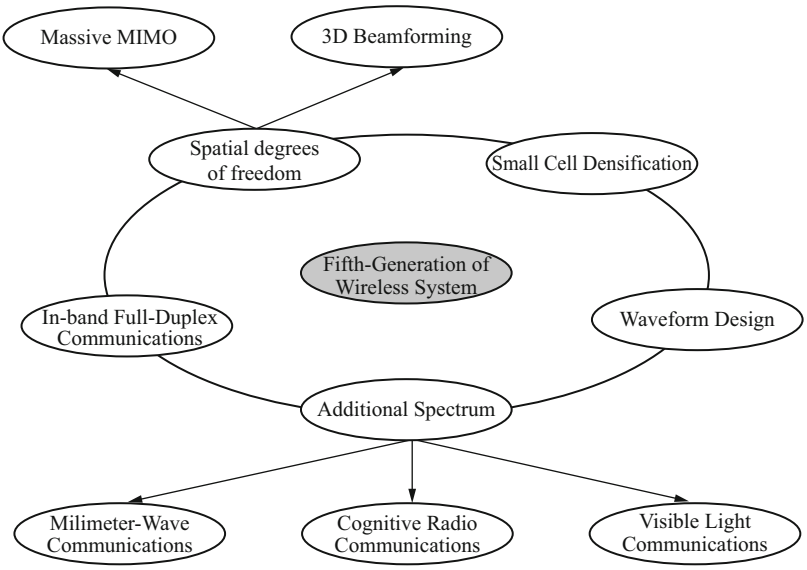

Fig. 1 An illustration of the potential approaches considered under the 5G framework

emphasis on the small cell densification and the implementation of CR is proposed. Before proceeding further, it is essential to briefly discuss some of the prerequisites that render small cell densification and CR communication approaches, particularly their combination, a suitable candidate for a 5G network.

Small Cell Densification

In the recent past, small cells (SCs) have emerged as a potential solution for coverage and capacity enhancements inside a wireless network. An SC represents a low-power station that ranges from 10 to 100 m. The reduced transmit distance accomplished with the deployment of SCs enhances the link quality and aids spatial reuse [13]. As a result, small cell densification can leverage the areal capacity of a 5G network [3]. Because the capacity increases linearly with the number of SCs, it is infeasible to procure the factor of 1000 in the areal capacity with densification alone. In addition, the operation and the integration of these substantial number of SCs to the backhaul network are cost- and energy-intensive for the mobile operator. Therefore, the degree to which the densification can be achieved by a wireless network is rather limited.

Additional Spectrum

Complementing the SCs, an additional spectrum is envisioned as a power source that is capable of sustaining the desired areal capacity for 5G. In consideration to the present allocation of the spectrum below 6 Hz to different wireless services, it is difficult to procure an extension to the already available spectrum to the mobile

communication. Before investigating the potential candidates for the spectrum extension, it is necessary to consider the following classification of the spectrum: (i) $>$ 6 GHz; (ii) $\leq$ 6 GHz. This sort of classification allows us to focus on the feasibility characteristics and the issues thereof.

The spectrum beyond 6 GHz largely entails the mmW, which is well known for point-to-point communications. Recently, it is envisaged as a powerful source of spectrum for 5G wireless systems. However, the mmW technology is still in its initial stage, and along with complex regulatory requirements in this regime, it has to address several challenges like propagation loss, low efficiency of radio-frequency components such as power amplifiers, small size of the antenna, and link acquisition [62]. Therefore, in order to capture a deeper insight of its feasibility in 5G, it is essential to overcome the aforementioned challenges in the near future.

In contrast to the spectrum beyond 6 GHz, an efficient utilization of the spectrum below 6 GHz presents an alternative solution. The use of the spectrum in this regime (below 6 GHz) is fragmented and statically allocated [56, 57], leading to inefficiencies and the shortage in the availability of the spectrum for new services. A glimpse of the measurement campaign demonstrating the underutilized spectrum is presented in Fig. 2. The measurements, acquired during the peak hours, illustrate the spectrum occupancy for the GSM 1800 MHz downlink sub-channels. The low spectrum occupancy for most of the sub-channels clearly signifies the fact that the demand for the additional spectrum can be fulfilled only by managing the utilization of the available spectrum efficiently.

In this perspective, CR is foreseen as one of the potential contenders that addresses the spectrum scarcity problem. Since its origin by Mitola et al. in 1999 [58], this notion has evolved at a significant pace and consequently has acquired certain maturity. Despite the existence of the theoretical analysis, from a deployment perspective, this technology is still in its preliminary phase [60]. In order to curtail the gap between the theoretical models and the practical implementations, recently, the wireless community has started to show an inclination toward models and/or techniques as indicated by the increased promotion of hardware implementation/demonstration or the events such as spectrum challenge [44] in conferences like IEEE DySPAN. Hence, facilitating a hardware implementation of this concept in a way encourages the disposition of CR systems in the upcoming 5G wireless systems. Motivated by this fact, this chapter focuses on the performance analysis of CR systems from a deployment perspective.

In contrast to the radio-frequency (RF) spectrum, visible light communication (VLC) has started to gain extensive attention for 5G wireless communication and hence deserves consideration in context to spectrum extension. Despite the fact that VLC offers some attractive characteristics like spatial, spectrum reuse, high-energy efficiency, and security, it has to overcome certain challenges such as mobility and adverse effect of atmospheric conditions while operating outdoor [76].

In order to enhance the readability, this chapter is organized as follows: section "Cognitive Radio Systems " features different CR systems. Next, to illustrate a successful incorporation of the CR in a 5G network, a specific use-case (deployment

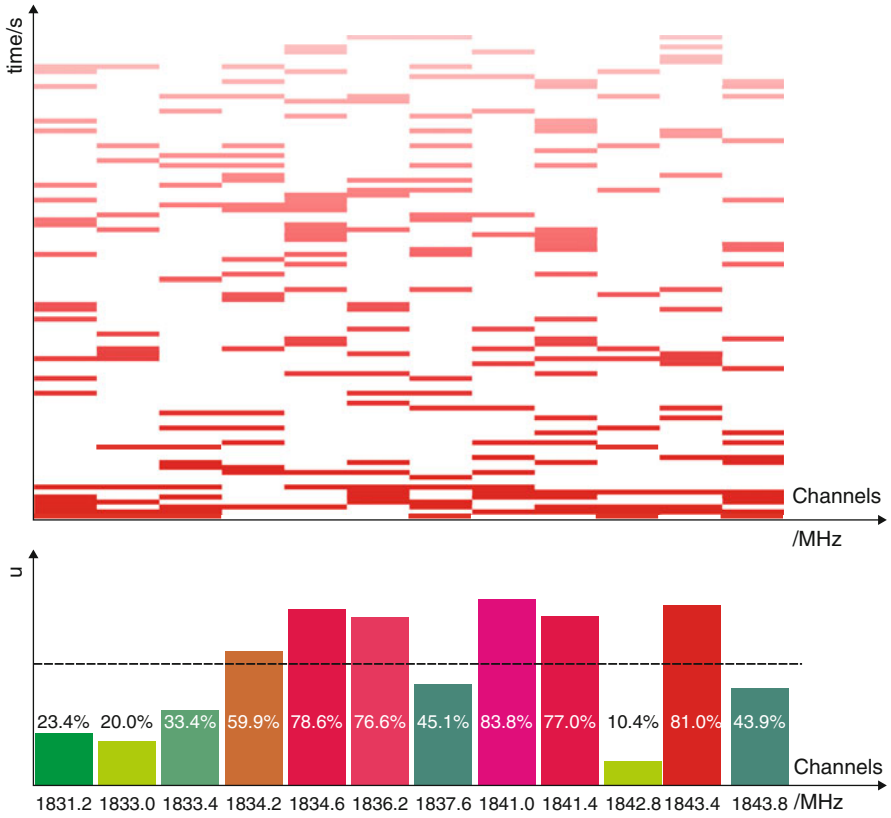

Fig. 2 A snapshot of a hardware demonstrator that measures the spectral occupancy in GSM 1800 MHz downlink channels, whereby the red slices represent the spectrum occupancy (1 or 0) corresponding to a single measurement at a given time instant. The bar plots illustrate the spectrum occupancy (u) for each channel with a history of 500 measurements [40]

scenario) is presented subsequently in section "Cognitive Small Cell: A Prominent Use-Case". Section "Performance Analysis of CR Systems: A Challenging Task" brings out the key aspects that are pivotal to performance analysis of a CR system. Subsection "Imperfect Channel Knowledge" underlines the significance channel knowledge with regard to the realization of CR techniques on a hardware platform. It also describes the harmful effects arising due to the imperfect channel knowledge, leading to performance degradation. In order to justify this argument, section "Interweave System: A Case Study" presents a case study that incorporates channel estimation to characterize the performance of CR as interweave system. Thus, the indoor deployment scenario is transformed into an interweave scenario, whereby a spectrum sensing mechanism is employed at the CR, enabling a secondary access to the licensed spectrum. In addition, this section establishes an analytical framework to capture the effect of imperfect channel knowledge on the

Table 1 Definitions of acronyms and notations used

Acronyms and notations	Definitions
AC, OC	Average Constraint, Outage Constraint
CR	Cognitive Radio
CSC, CSC-BS, MC-BS, MS	Cognitive Small Cell, Cognitive Small Cell-Base Station, Macro Cell-Base Station, Mobile Station
IM, EM	Ideal Model, Estimation Model
IS	Interweave System
PU – PT, PR	Primary User – Primary Transmitter, Primary Receiver
SU – ST, SR	Secondary User – Secondary Transmitter, Secondary Receiver
$\mathscr{H}_1, \mathscr{H}_0$	Signal plus noise hypothesis, noise only hypothesis
f_s	Sampling frequency
τ_{est}, τ_{sen}	Estimation time, sensing time interval
T	Frame duration
P_d, P_{fa}	Detection probability, false alarm probability
$\bar{P}_d$	Target detection probability
ρ_d	Outage constraint over detection probability
$h_{p,1}, h_{p,2}, h_s$	Channel coefficient for the link PT-ST, PT-SR, ST-SR
$\gamma_{p,1}, \gamma_s$	Signal to noise ratio for the link PT-ST, ST-SR
$\gamma_{p,2}$	Interference (from PT) to noise ratio for the link PT-SR
R_s	Throughput at SR
C_0, C_1	Date rate at SR without and with interference from PT
μ	Threshold for the energy detector
$F_{(\cdot)}$	Cumulative distribution function of random variable $(\cdot)$
$f_{(\cdot)}$	Probability density function of random variable $(\cdot)$
$\widehat{(\cdot)}$	Estimated value of $(\cdot)$
$\widetilde{(\cdot)}$	Suitable value of the parameter $(\cdot)$ that achieves maximum performance
$\mathbb{E}_{(\cdot)}$	Expectation with respect to $(\cdot)$
$\mathbb{P}$	Probability measure
$\mathbf{T}(\cdot)$	Test statistics
σ_s^2, σ_w^2	Signal variance at PT, noise variance at ST and SR

performance. Section "Research Directions" presents some possible direction for further research. Finally, section "Conclusion" concludes this chapter. Table 1 lists the definitions of acronyms and important mathematical notations used throughout this chapter.

Cognitive Radio Systems

In order to proceed further, it is essential to understand the classification of different CR systems described in the literature. An access to the licensed spectrum is an outcome of the paradigm employed by a secondary user (SU). In this context, all CR

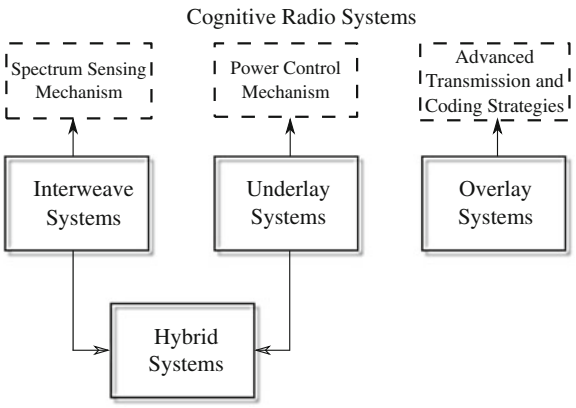

Fig. 3 A classification of different CR systems and some specific CR techniques that allow shared access to the licensed spectrum

systems that provide shared access (used interchangeably with secondary access) to the spectrum mainly fall under the following categories [30]; please consider Fig. 3 for a graphical illustration of different CR systems, including some specific CR techniques:

- According to interweave system (IS) , the SUs render an interference-free access to the licensed spectrum by exploiting spectral holes in different domains such as time, frequency, space, and polarization.
- An underlay system (US) enables an interference-tolerant access, according to which the SUs are allowed to use the licensed spectrum (e.g., ultra-wide band (UWB)) as long as they respect the interference constraints of the primary receivers (PRs).
- A hybrid system (HS) combines the benefits of the IS (agility to detect spectrum holes in different domains) and the US (interference-tolerant capability) so that the spectrum available for performing secondary access can be used efficiently.
- An overlay system considers advanced transmission and coding strategies, which include the participation of higher layers for enabling the spectral coexistence between two or more wireless networks.

The IS, the US, and the HS are closely associated with the physical layer; hence, these systems are mostly considered not only for the theoretical analysis but for practical implementations as well [6, 9, 10, 40, 41, 44, 47, 63]. Underlying this fact, this chapter establishes a deployment-centric viewpoint toward these CR systems. In order to illustrate a successful incorporation of the CR in a 5G network, a specific use-case (deployment scenario) is presented subsequently.

Cognitive Small Cell: A Prominent Use-Case

It is evident from the previous discussion in section "Introduction" that the spectrum extension via CR systems and SC densification is significant to the 5G system.

Based on this, a preliminary concept of cognitive small cell (CSC), a promising application that combines the benefits from the SC deployment and the efficient usage of the spectrum below 6 GHz, by realizing CR, is presented. A typical scenario where the CSC finds its application would be the coexistence of Wi-Fi or unlicensed small cell and wireless cellular systems [7]. The notion of CSC has been previously investigated by Elsawy et al. [19], where the authors primarily emphasized on the modeling techniques that depict the positioning of several CSCs inside the network. The modeling is based on stochastic geometry, which allows a spatial averaging over multiple network geometries [32]. Due to this, the performance analysis of the CSC has been limited mainly to network abstraction. In contrast, this chapter examines the fundamental aspects encountered while deploying a CSC, which otherwise could forbid its realization of this concept over the hardware. A comprehensive incorporation of CSC in a preliminary 5G architecture is illustrated in Fig. 4. In order to enhance the viability of the proposed network architecture, it is reasonable to highlight some of the essential ingredients pertaining to the deployment of the CSC.

Network Elements

In order to propose a successful integration of CSC in a 5G network, the following key elements are essential: a CSC-base station (CSC-BS), a macro-cell-base station (MC-BS), and mobile stations (MSs), cf. Fig. 4. MSs are the devices either served

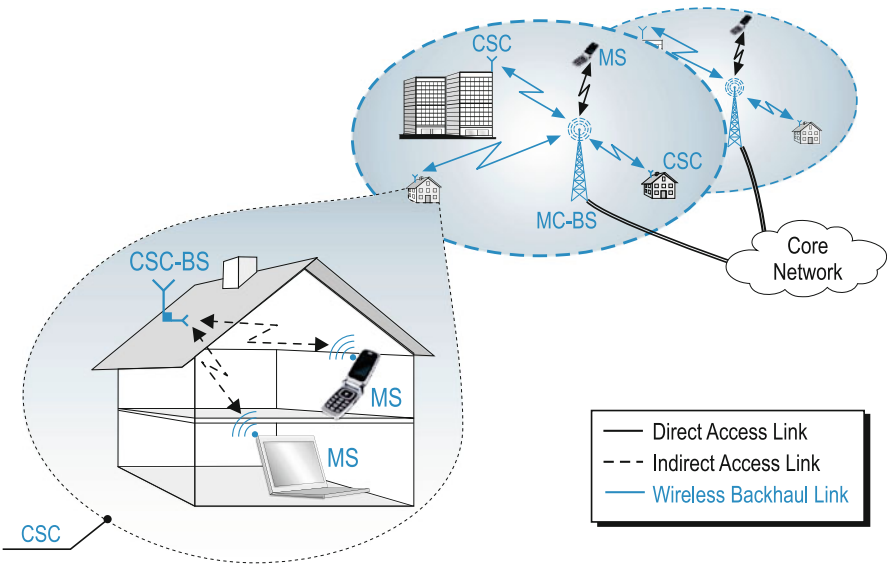

Fig. 4 An illustration of the CSC deployment in a 5G network

by the MC-BS over a *direct access* link or the CSC-BS over an *indirect access* link. The direct access and the indirect access are the nomenclature used to distinguish a state-of-the-art (spectrum) access between the MC-BS and the MS from an access between the CSC-BS and the MS representing a CR communication, respectively. Furthermore, the MC-BS is connected to several CSC-BSs over a *wireless backhaul* link. Although the MC-BS and the MS already exist in the conventional cellular architecture, to incorporate the opportunistic access inside the CSC, it is necessary to consider a functionality upgrade.

Spectrum Access

In the proposed network architecture, the access to the spectrum is realized over the wireless backhaul, the direct access, and the indirect access links, cf. Fig. 4.

1. A wireless backhaul is a point-to-point wireless link between the CSC-BS and the MC-BS that relays the traffic generated from the CSC to the core network. With regard to the densification of the CSC in 5G network, the wireless backhaul link, in contrast to the optical fiber link, presents a cost-effective and energy-efficient alternative to the mobile operator. With limited infrastructure required for the deployment, wireless backhauling accelerates the installation process and promotes scalability of the network. For the wireless backhaul link, considering that it is utilized for a longer time duration, an exclusive spectrum represents a viable option. In this context, it is sensible to nominate a mmW band; alternatively, an exclusive band below 6 GHz can be acquired using the principles of licensed shared access (LSA) [21].
2. A direct access link represents a direct access of the MS at the MC-BS over the allocated spectrum. Consequently, the spectrum access for this link is analogous to the one existing in the state-of-the-art wireless standards.
3. The CSC elements (the CSC-BS and the MS) are responsible for executing the secondary access to the licensed spectrum. The additional spectrum, acquired through the realization of CR techniques, including spectrum sensing and power control, at the CSC-BS, is used for the communication between the CSC-BS and the MS over the indirect access link.

Hardware Feasibility

Along with other ingredients, it is essential to outline certain aspects that pertain to the hardware realizability of the CSC. For the CSC-BS, an antenna mount system consisting of an indoor and an outdoor antenna is proposed. The indoor antenna exploits the walls of the building to physically separate the indoor transmissions over the indirect access link. In this way, the CSC is able to mitigate the interference to the primary system and to the neighboring CSCs and vice versa. However, the outdoor antenna secures a narrow beam transmission to enhance the link quality for the wireless backhaul link. Besides this, it is a well-known fact that software-

defined radio (SDR) has played an important role in the genesis of the CR [37]. This means that the SDR can serve as a suitable platform for executing CR techniques, accomplishing rapid prototyping for the CR systems. Taking this into account, the SDR platform is utilized for realizing (or demonstrating) the CR functionality pursued by the CSC-BS over a hardware.

Indoor Deployment

From a market survey, it has been depicted that 70% of the mobile traffic is originated from indoor locations [13]. Another survey of the leading WiMAX operators revealed that 80% of their subscribers will be connected indoors [59]. In addition, a new range of wireless services, categorized as Internet of things (IoT), will operate indoors. Following these facts, it is clear that the performance gains in terms of spectrum reuse will be far more consequential if we manage to consolidate these sources of traffic by means of SCs deployment. In order to capture the indoor-originated traffic, it is sensible to consider the residential and enterprise as the main deployment scenarios for the CSC, cf. Fig. 4. Except for a different coverage regime, the operating principles of these scenarios are analogous. Besides, in context with the CR, where the interference mitigation between the primary and the secondary systems is a significant aspect, a CR communication within walls (which attributes to an indoor deployment) provides a spatial separation between the two systems. This, however, does not indicate that CR communication is limited to indoor scenarios. As the matter of fact, the indoor deployment is opted to:

- Exploit the behavioral dimension of the traffic source (traffic management) and
- Mitigate the interference between the two systems

so that coexistence with the licensed users is encouraged. In this regard, an indoor scenario is considered for the deployment of the CSC, cf. Fig. 4. Besides employing such interference mitigation approach, an effective control over the interference is essential for a successful operation of the CR systems. Therefore, the next section extensively discusses the performance of the CR systems.

Performance Analysis of CR Systems: A Challenging Task

Since the evolution of wireless systems, understanding the performance of novel algorithms/techniques related to the wireless systems has always been a challenging task. With regard to this, for a CR system, because of the involvement of two different systems, namely, primary and secondary systems, this task is even more difficult. On one end, it has been engaging a large number of researchers that are eager to find solutions for the new set of problems that are emerging from an interplay between these two systems, leading them to develop theoretical models (system models). As a result, these models allow us to determine the performance

limits of the CR system. However, to sustain analytical tractability, they tend to consider assumptions that in most situations are unrealistic for a hardware deployment.

On the other end, due to the coexistence of the two systems sharing the same spectrum, the performance of a CR system is critical to the regulatory bodies and the mobile operators, responsible for managing the spectrum. These operators are the ones who are willing to share their license (as primary system) or the ones who are willing to access the licensed spectrum (as secondary system). In this regard, despite the numerous theoretical models that exist in the literature, when it comes to judging the performance of a CR system, the regulatory bodies give more preference to the hardware implementations.

These different mindsets and the lack of proper guidelines ultimately slow down the evolution of the CR in realistic scenarios. Under this situation, it is advisable to merge these mindsets and establish a deployment-centric viewpoint toward the CR systems, according to which the upcoming models and/or techniques not only associate themselves to the performance characterization but also eligible for practical implementations.

The coexistence between the primary and the secondary systems can be accomplished only through a detailed analysis of the performance of these systems. To address this issue, the researchers have made an intensive effort to develop system models [38, 39, 52] that characterize the performance of the CR systems. The performed analysis boils down to the fact that the CR systems are allowed to successfully coexist with the primary system only if they respect the interference power (or interference) at the primary system caused due to an access to the licensed spectrum. In other words, imposing an interference constraint ensures a sufficient protection to the primary systems and enables the CR system to perform secondary access.

With regard to the aforementioned constraint, the CR system also intends to deliver a certain quality of service/quality of experience (QoS/QoE) in the form of throughput to its corresponding secondary receiver (SR), defined as *secondary throughput*. Such a QoS/QoE provisioning helps us to determine the potential applications or prominent use-cases for the CR system. For instance, the secondary throughput's knowledge over the access link enables the CR to execute a band allocation policy, based on which the CR can relinquish those channels that ineffectively contribute to the secondary throughput, and/or are responsible for causing interference at the primary system. As a result, the performance of a CR system can be jointly characterized in terms of the harmful interference received at the primary system and the throughput achieved by the secondary system.

The fact is that the derived expressions depicting the performance of the CR systems are rarely examined over the hardware, mainly because of the complicated deployment scenario or the computational complexity of the employed CR techniques, leaving the validity of the existing theoretical analysis questionable. Because of this, we tend to overlook certain imperfections (or uncertainties) inherent to the CR systems, including noise uncertainty, channel imperfections, signal uncertainty, noise/channel correlation, hardware imperfections, and modeling imperfections

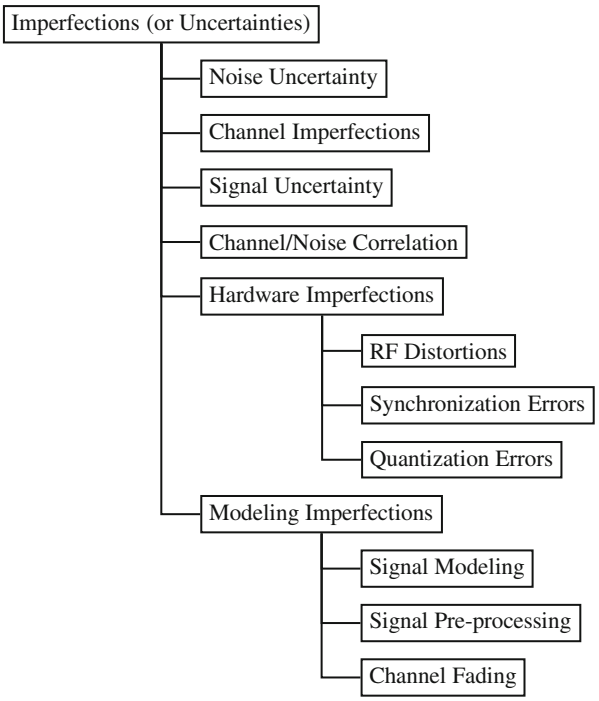

Fig. 5 An illustration of major imperfections (or uncertainties) in CR systems [68]

[68], which may be responsible for degrading the performance of CR systems; refer to Fig. 5. In other words, by neglecting these imperfections in the system model, the performance of a CR system is overestimated. To narrow down the perspective, this chapter considers the effect on performance of CR systems due to imperfect channel while putting emphasis on the fact that the performed analysis can be easily validated through a hardware implementation.

Imperfect Channel Knowledge

In a nutshell, *a CR is an agile system that possesses the ability to adapt to the changes in the environment*. From a physical layer perspective, this corresponds to the response to the changes incurred within the system or from the outside environment, which in a way leads to a performance enhancement. Inherent to the wireless systems, these changes may arise due to the variations in the signal caused by the presence of the thermal noise at the receiver and the fading in the channel. It is well known from the textbooks, related to wireless communications [29, 74], that the channel fading, in particular, is critical for wireless systems. As a matter of fact, channel knowledge – in the form of channel state information at the transmitter (CSIT) available through a feedback from the receiver – has rendered a substantial

improvement in the performance in terms of data rate, for instance, multiplexing gains for a MIMO system [55].

In context with a CR system, the channel knowledge, unlike the conventional or state-of-the-art wireless systems, is not confined to a single transmitter-receiver link. It rather includes all the related channels that exist within as well as across the primary and the secondary systems. Therefore, at this stage, it is worth understanding the fact that channel knowledge is paramount for the hardware implementation of the CR systems. This knowledge allows them to exercise CR techniques and to respect the desired interference constraints, which are necessary for their coexistence with the primary systems. Besides, from a theoretical perspective, the channel knowledge is required for the performance characterization. The absence of this knowledge, especially of those channels that are related to the interference at the primary systems, renders the performance characterization of a CR system inadequate for the practical implementations.

Despite the existence of multitude of analytical models in the literature [25, 52, 67] that consider with the performance analysis of a CR system, its performance with regard to the channel estimation, due to the complexity of the underlying problem, has never been completely understood. In order to curtail this gap, this chapter capitalizes on the estimation of the involved channels in a CR system. In this sense, the accessibility of the channel knowledge at the CSC-BS facilitates the implementation of the CR techniques at the CSC-BS, establishing a CR communication link with the MS over the acquired spectrum. More importantly, this knowledge allows us to regulate the interference at the PR below a desired level.

Certainly, an access to the channel knowledge comes at a certain cost. Firstly, the inclusion of channel estimation demands an allocation of a certain time interval by the CSC-BS. In consideration to the time allocation, a certain degradation in the performance in terms of the throughput is obvious. Secondly, the variations introduced due to the estimation process, also treated as imperfect channel knowledge, lead to an uncertainty in the interference, defined as *uncertain interference*, to the primary systems. The uncertain here specifically symbolizes the variations in the interference power received at the PR that exists because of the imperfect channel knowledge. If not considered, this uncertain interference may severely degrade the performance of the CR systems. In order to approach a successful integration of channel estimation into the CR system, it is essential to consider the performance degradation arising due to the time allocation and the uncertain interference in the system model. These effects concerning the performance degradation have been completely left aside in the existing models that consider the perfect channel knowledge. Section "Interweave System: A Case Study" takes these effects into account to establish analytical frameworks that allow us to understand the behavior of the CR systems as interweave systems under those situations that are close to realistic scenarios.

Shifting the focus back to the deployment, it is worthy to understand that the channel estimation, facilitating shared access to the licensed spectrum, is viable only if the CR system is equipped with the knowledge about the primary system. This implies that in order to perform channel estimation based on conventional

techniques – such as training-based [70], pilot-based [27, 28], and signal to noise ratio-based [14, 66] channel estimation, which already exist in the literature – a preliminary processing in the form of synchronization and demodulation of the baseband signal received from the primary system is necessary. The existence of multiple wireless standards and their complexity preclude us from deploying a dedicated circuitry corresponding to each primary system [26]. The fact is, these conventional channel estimation techniques are well known for delivering accurate channel estimates, which is employed in state-of-the-art wireless standards. However, in context of the CR systems, these techniques

- Increase the complexity related to the channel estimation, evaluated in terms of the mathematical operations,
- Demand the demodulation of the primary user (PU) signal.

Under these circumstances, it is advisable to consider only those solutions that offer low complexity and show versatility toward different PU signals. Generally speaking, such solutions will not only ease the deployment process but also have a large acceptance among the CR community. For instance, energy-based detection (or energy detection) has been a popular choice compared to its counterparts such as matched filtering-based and cyclostationary-based detection for detecting a PU signal, required for performing spectrum sensing for the interweave systems (discussed later in section "Interweave System: A Case Study"). A direct comparison of these techniques by simply counting their implementations for hardware demonstration has been done in [60].

On similar grounds as energy detection, in order to approach the channel estimation for the CR system, particularly for the channels that involve the primary systems, a *received power-based* channel estimation technique is proposed as a part of the analytical framework. It is worthy to understand that the received power refers to the signal power measured after analog to digital conversion; hence, it consists of the signal and the noise power. Traditionally, received signal strength is a metric used for measuring signal quality to perform tasks such as cell association and handover [8]. This channel estimation technique is introduced to substitute the conventional techniques because, like energy detection, employing received power-based estimation assures the low complexity and the versatility toward unknown PU signal requirements of the CR system, and consequently facilitates its deployment. Besides, the channel within the secondary framework, treated as a conventional transmitter-receiver link, does not fall in the aforementioned category. Therefore, its knowledge is procured by employing a pilot-based channel estimation technique.

Modeling Imperfections

Besides imperfect channel knowledge, this section briefly discusses some key issues that are necessary from a deployment perspective but left aside while establishing the system model.

Signal Modeling

The Gaussian and the constant power signals are generally used for modeling the PU signals, which correspond to orthogonal frequency-division multiplexing (OFDM) and phase-shift keying (PSK) modulated signals, respectively. In practice, this modeling can be employed only if the sampling point is selected appropriately, hence resulting in i.i.d. samples. In other situations, the samples are correlated. This correlation is not considered while modeling the system, hence leading to deviation of the performance parameters (false alarm probability and detection probability) obtained theoretically from the ones obtained by performing the measurements. In order to resolve this issue, the OFDM and PSK-modulated signals can be replaced with their mathematical counterparts for signal transmission; these include a Gaussian and a sinusoidal signal, respectively. By doing this, we are able to avoid the correlation between the samples that are used for computing the energy.

Signal Preprocessing

Generally, ST is emulated using an SDR platform (for instance, Universal Software Radio Peripheral (USRP) B210, an SDR from Ettus Research [22]). Such low-cost hardwares are associated with a direct downconversion of the bandpass to the baseband signal – a homodyne receiver. Spurious effects such as DC offset, flicker noise $(1/f)$, and I/Q imbalance arising from the analog front-end can affect the accuracy of the analytical expressions. These spurious effects, particularly the DC offset and the flicker noise, become significant at low signal to noise ratio. In order to retrieve the complex samples close to the one obtained while characterizing the system model that do not take such spurious effects into account, the following signal processing (referred as preprocessing) is proposed; please consider Fig. 6:

- The received PU signal (a complex sinusoid) is oversampled with sampling frequency of 200 kHz. In order to filter out the spurious effects, the local oscillator is tuned at a certain offset frequency defined as $f_{\text{LO-Offset}} = 50\,\text{kHz}$, refer to Fig. 6a.
- Subsequently, a bandpass filter with bandwidth = 50 kHz, corresponding to an oversampling factor = 4, is employed to obtain the desired bandpass signal at the $f_{\text{LO-Offset}}$. This filters out the DC offset and the flicker noise present at low frequencies, cf. Fig. 6b.
- In order to obtain the lowpass equivalent of the desired signal, a digital down-conversion (i.e., multiplying with a complex sinusoid with frequency $f_{\text{LO-Offset}} = 50\,\text{kHz}$) of the bandpass filtered signal is performed, cf. Fig. 6c.
- Lastly, a decimation filter (with decimation factor = 4) over the downconverted signal is applied, cf. Fig. 6d, to reduce the correlation between the samples, arising due to oversampling.

Channel Fading

Channel fading is essential to establish a macroscopic view toward the performance of a CR system. With regard to this, Rayleigh block fading is mostly preferred for modeling channel fading. However, block fading considers uncorrelated over the

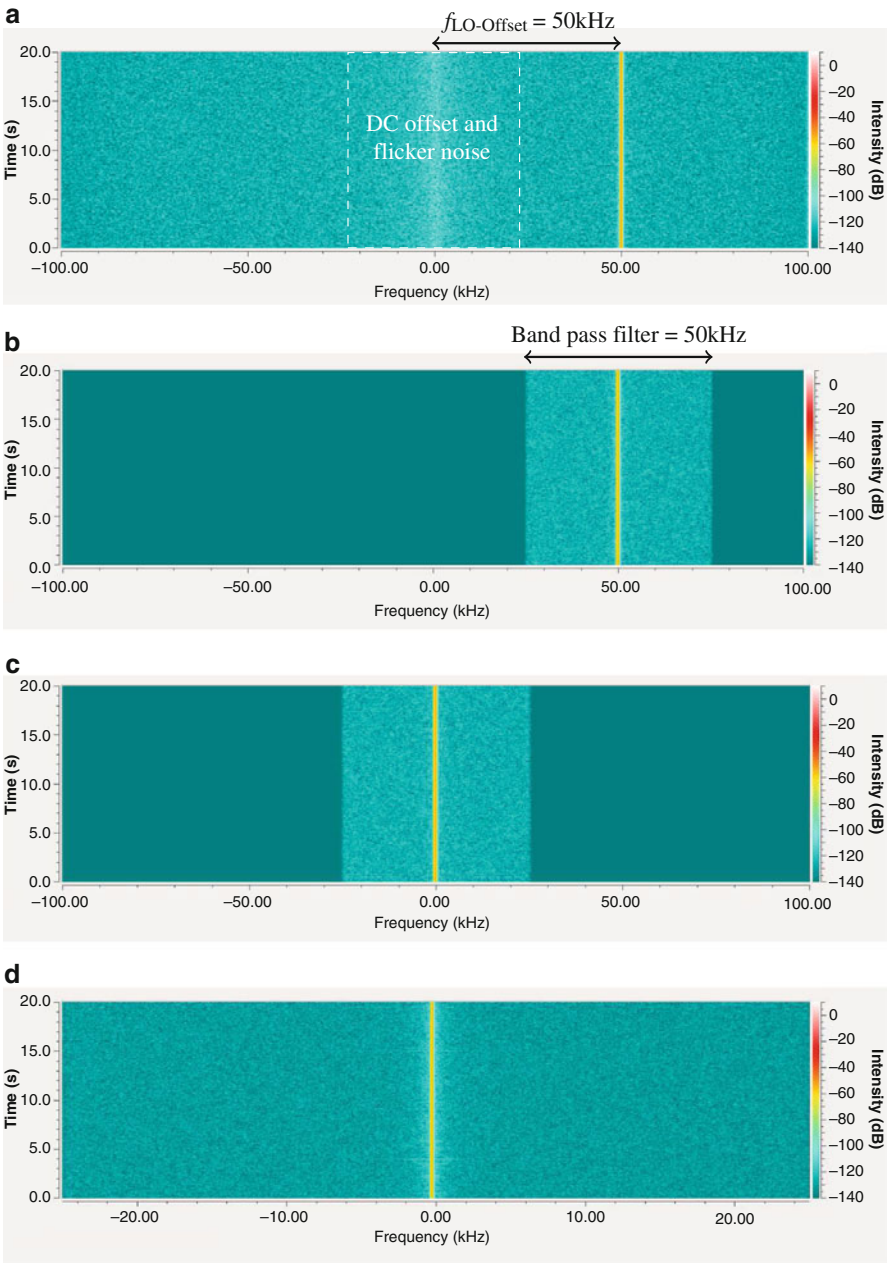

Fig. 6 An illustration of the signal processing steps carried out at the host computer to preclude the spurious effects such as the DC offset and the flicker noise on the signal received at the ST. (**a**) Signal with oversampling, where the local oscillator is tuned at $f_{\text{LO-Offset}} = 50\,\text{kHz}$. (**b**) Signal after bandpass filtering, filter bandwidth $= 50\,\text{kHz}$. (**c**) Signal after digital downconversion. (**d**) Signal after decimation

different energy measurements. However, in practice, either uncorrelated fading is not encountered or the measurements may converge to a different fading model such as Nakagami-*m* fading model [41]. Due to this issue, hardware validation of the analytical expressions that incorporates channel fading models is rarely considered.

One possible way of resolving this issue is to emulate fading at the ST, according to which the transmit signal is modulated with channel gains at the PT using software [63]. This allows us to establish a close relation between the analytical model and the acquired energy measurements, which consequently enhances the validation of a CR system that incorporates channel fading for the performance analysis. However, to proceed with the hardware validation pertaining to scenarios that involve channel fading, in the future, it is essential to incorporate correlated fading model into the system and estimate the related parameters [41].

Interweave System: A Case Study

At this stage, it is well-understood that the knowledge of the related channels is crucial for the application of CR techniques in the practical scenarios. This section capitalizes on the successful integration of this knowledge on interweave system. In this context, the indoor deployment scenario is transformed into an interweave scenario, whereby a spectrum sensing mechanism is employed at the CSC-BS enabling a secondary access to the licensed spectrum. Section "Theoretical Analysis" derives the theoretical expressions to capture the effect of imperfect channel knowledge on the performance of an IS. Further, section "Numerical Results" establishes an estimation-sensing-throughput tradeoff that depicts the suitable estimation and the suitable sensing time intervals at which the maximum secondary throughput is achieved by an IS. Please note that this section contains material from the following publication [45].

For detecting a PU signal, several techniques such as energy-based detection (or energy detection), matched filtering-based, cyclostationary-based, and feature-based detection exist [5]. Because of its versatility toward unknown PU signals and its low computational complexity, energy detection has been extensively investigated in the literature [34,75]. In this technique, the decision is accomplished by comparing the power received at the ST to a decision threshold. In reality, the ST encounters variations in the received power due to the existence of thermal noise at the receiver and fading in the channel. Subsequently, these variations lead to sensing errors described as misdetection and false alarm, which limit the performance of the IS. In order to determine the performance of a detector, it is essential to obtain the expressions of detection probability and false alarm probability.

In particular, detection probability is critical for IS because it protects the PR from the interference induced by the ST. As a result, the IS has to ensure that they operate above a target detection probability [61]. Therefore, the characterization of the detection probability becomes absolutely necessary for the performance analysis of the IS. In this context, Urkowitz [75] introduced a probabilistic framework for characterizing the sensing errors; however, the characterization accounts only for the noise in the system.

To encounter the variation caused by channel fading, a frame structure has been introduced in [52], assuming that the channel remains constant over the frame duration (corresponds to a quasi-static block fading). Upon exceeding the frame duration, the system may observe a different realization of the channel. Based on this frame structure, the performance of the IS has been investigated in terms of a deterministic (corresponding to a nonrandom behavior) channel [52, 67] and a random channel [16, 34]. These deterministic and random behaviors of the channel illustrate a microscopic and a macroscopic view toward the performance characterization, respectively, of a CR system. In this chapter, the former approach is considered; hence, the performance is analyzed for a specific frame, i.e., for a certain (unknown) realization of the channel.

Besides the detection probability, false alarm probability has a large influence on the throughput achieved by the secondary system. Recently, the performance characterization of CR systems in terms of a sensing-throughput tradeoff has received significant attention [12, 52]. According to Liang et al. [52], the ST assures a reliable detection of a PU signal by retaining the detection probability above a desired level with an objective of maximizing the throughput at the SR. In this way, the sensing-throughput tradeoff depicts a suitable sensing time interval that achieves a maximum secondary throughput. To characterize the detection probability and the secondary throughput, the system requires the knowledge of interacting channels, namely, a *sensing* channel, an *access* channel, and an *interference* channel; refer to Fig. 7. Since the interference to the PR is controlled by a regulatory constraint over the detection probability, in this view, the interaction with the PR is excluded in the considered scenario [52]. The baseline models, investigated in the literature, assume the knowledge of these channels to be available at the ST. However, in practice, this knowledge is not available; thus, it needs to be estimated by the secondary system. As a result, the existing solutions for the IS are considered inadequate from a practical viewpoint.

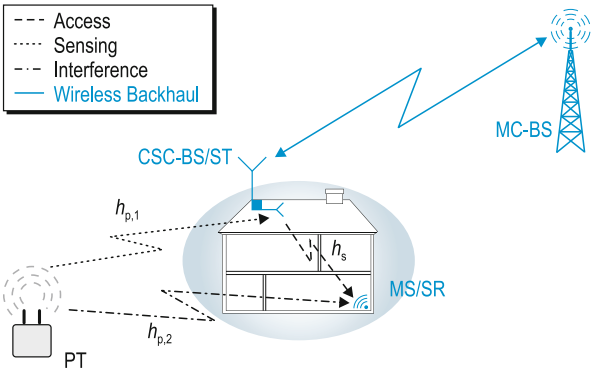

Fig. 7 A cognitive small cell scenario demonstrating: (i) the interweave paradigm, (ii) the associated network elements, which constitute cognitive small cell-base station/secondary transmitter (CSC-BS/ST), mobile station/secondary receiver (MS/SR), macro cell-base station (MC-BS) and primary transmitter (PT), (iii) the interacting channels: sensing ($h_{p,1}$), access (h_s) and interference ($h_{p,2}$)

As a matter of fact, the sensing and the interference channels related to the CR system (refer to Fig. 7) represent the channels between two different (primary and secondary) systems. In this context, it becomes challenging to select the estimation methods in such a way that low complexity and versatility (towards different PU signals) requirements are satisfied. These issues, discussed later in section "Proposed Approach", render the existing estimation techniques [14, 27, 28, 66, 70] unsuitable for hardware implementations. To tackle the issue related to the channel estimation, as discussed previously in section "Imperfect Channel Knowledge", a received power-based estimation at the ST and at the SR for the sensing and the interference channels is employed, respectively. Considering the fact that the access channel corresponds to the link between the ST and the SR, conventional channel estimation techniques such as pilot-based channel estimation at the ST is employed.

Inherent to the estimation process, the variations due to the channel estimation translate to the variations in the performance parameters, namely, detection probability and secondary throughput. In particular, the variations induced in the detection probability cause uncertain interference at the PR, which may severely degrade the performance of a CR system. The detrimental effect due to the time allocation for the channel estimation and the uncertain interference due to imperfect channel knowledge have not been considered in [12, 52] or studied partially in [11, 14]. In this context, the performance characterization of an IS with imperfect channel knowledge remains an open problem. Motivated by this fact, this section focuses on the performance characterization of the IS in terms of sensing-throughput tradeoff taking these aforementioned aspects into account.

System Model

Interweave Scenario

To consider the applicability of IS, the CSC, a CR application illustrated previously in Fig. 4 is transformed into an interweave scenario. Considering the fact that the IS is employed at the CSC-BS, the CSC-BS and the MS represent the ST and the SR, respectively. A hardware prototype of the CSC-BS operating as IS was presented in [40]. For simplification, a PU constraint based on false alarm probability (Neyman-Pearson criterion) was considered in [40]. With the purpose of improving system's reliability, the analysis is extended to employ a PU constraint on the detection probability.

Signal Model

Subject to the underlying hypothesis that illustrates the presence ($\mathscr{H}_1$) or the absence ($\mathscr{H}_0$) of a PU signal, the discrete and complex signal received at the ST is given by

$$y_{\mathrm{ST}}[n] = \begin{cases} h_{\mathrm{p},1} \cdot x_{\mathrm{PT}}[n] + w_{\mathrm{ST}}[n] & : \mathscr{H}_1 \\ w_{\mathrm{ST}}[n] & : \mathscr{H}_0 \end{cases}, \tag{1}$$

The signal $x_{\mathrm{PT}}[n]$ transmitted by the PUs can be modeled as (i) a PSK modulated signal or (ii) a Gaussian signal. The signals that are prone to high inter-symbol interference or entail precoding, for instance, OFDM signal with linear precoding, can be modeled as Gaussian signals [52]. In this chapter, the analysis is focused on the latter case, i.e., the primary and the secondary systems employ OFDM to carry out their transmission. As a result, the mean and the variance for the signal and the noise are determined as $\mathbb{E}\left[x_{\mathrm{PT}}[n]\right] = 0$, $\mathbb{E}\left[w_{\mathrm{ST}}[n]\right] = 0$, $\mathbb{E}\left[|x_{\mathrm{PT}}[n]|^2\right] = \sigma_{\mathrm{s}}^2$ ($= P_{\mathrm{Tx,PT}}$) and $\mathbb{E}\left[|w_{\mathrm{ST}}[n]|^2\right] = \sigma_{\mathrm{w}}^2$. The channel $h_{\mathrm{p},1}$ is considered to be independent of $x_{\mathrm{PT}}[n]$ and $w_{\mathrm{ST}}[n]$. Thus, $y_{\mathrm{ST}}[n]$ is also an independent and identically distributed (i.i.d.) random process.

Similar to (1), during data transmission, the discrete and complex received signal at the SR conditioned on the detection probability ($\mathrm{P_d}$) and the false alarm probability ($\mathrm{P_{fa}}$) is given by

$$y_{\mathrm{SR}}[n] = \begin{cases} h_{\mathrm{s}} \cdot x_{\mathrm{ST}}[n] + h_{\mathrm{p},2} \cdot x_{\mathrm{PT}}[n] + w_{\mathrm{SR}}[n] & : 1 - \mathrm{P_d} \\ h_{\mathrm{s}} \cdot x_{\mathrm{ST}}[n] + w_{\mathrm{SR}}[n] & : 1 - \mathrm{P_{fa}} \end{cases}, \tag{2}$$

where $x_{\mathrm{ST}}[n]$ corresponds to discrete and complex sample transmitted by the ST and $w_{\mathrm{SR}}[n]$ is the AWGN at the SR with $\mathscr{CN}(0, \sigma_{\mathrm{w}}^2)$. In practice, the noise power at different network nodes (the ST, the SR, and the PR) has different values. The fact is, only the signal to noise ratios received at these nodes are affected due to these different values, which are already included in the performance analysis. For the brevity of the exposition, the noise powers at these nodes are expressed using a single notation (σ_{w}^2). Further, $|h_{\mathrm{s}}|^2$ and $|h_{\mathrm{p},2}|^2$ represent the power gains for the access and the interference channels, refer to Fig. 7.

Problem Description

In accordance with the conventional frame structure, the ST performs sensing for a duration of τ_{sen}. The test statistics at the ST is evaluated as

$$\mathrm{T}(\mathbf{y}) = \frac{1}{\tau_{\mathrm{sen}} f_{\mathrm{s}}} \sum_{n=1}^{\tau_{\mathrm{sen}} f_{\mathrm{s}}} |y_{\mathrm{ST}}[n]|^2 \underset{\mathscr{H}_0}{\overset{\mathscr{H}_1}{\gtrless}} \mu, \tag{3}$$

where μ is the decision threshold, f_{s} represents the sampling frequency, and $\mathbf{y}$ is a vector with $\tau_{\mathrm{sen}} f_{\mathrm{s}}$ samples. $\mathrm{T}(\mathbf{y})$ represents a random variable, whereby the characterization of the cdf depends on the underlying hypothesis. With regard to the Gaussian signal model, which corresponds to the OFDM signal transmitted by the PU, $\mathrm{T}(\mathbf{y})$ follows a central chi-squared ($\mathscr{X}^2$) distribution for both hypotheses $\mathscr{H}_0$ and $\mathscr{H}_1$ [46]. It is worthy to mention here that the Gaussian approximation that exists due to application of central limit theorem – confining the applicability of the considered analysis to large samples only – is avoided. in this context, an effort has been made to derive the theoretical expressions so that the performance analysis is valid for all sample sizes.

As a result, the detection probability ($\mathrm{P_d}$) and the false alarm probability ($\mathrm{P_{fa}}$) corresponding to (3) are determined as [73]

$$\mathrm{P_d} = \Gamma\left(\frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}} \mu}{2 P_{\mathrm{Rx,ST},h_{\mathrm{p,1}}}}\right), \tag{4}$$

$$\mathrm{P_{fa}} = \Gamma\left(\frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}} \mu}{2\sigma_{\mathrm{w}}^2}\right), \tag{5}$$

where $P_{\mathrm{Rx,ST},h_{\mathrm{p,1}}}$ is the power received over the sensing channel and $\Gamma(\cdot,\cdot)$ represents a regularized upper-incomplete Gamma function [31].

Following the characterization of $\mathrm{P_{fa}}$ and $\mathrm{P_d}$, Liang et al. [52] established a tradeoff between the sensing time and the secondary throughput (R_{s}) subject to a target detection probability ($\bar{\mathrm{P}}_{\mathrm{d}}$). This tradeoff is represented as

$$\begin{aligned} R_{\mathrm{s}}(\tilde{\tau}_{\mathrm{sen}}) &= \max_{\tau_{\mathrm{sen}}} R_{\mathrm{s}}(\tau_{\mathrm{sen}}) \\ &= \frac{T - \tau_{\mathrm{sen}}}{T}\Big[\mathrm{C_0}(1-\mathrm{P_{fa}})\mathbb{P}(\mathscr{H}_0) + \mathrm{C_1}(1-\mathrm{P_d})\mathbb{P}(\mathscr{H}_1)\Big], \end{aligned} \tag{6}$$

$$\text{s.t. } \mathrm{P_d} \geq \bar{\mathrm{P}}_{\mathrm{d}}, \tag{7}$$

$$\text{where } \mathrm{C_0} = \log_2\left(1 + |h_{\mathrm{s}}|^2 \frac{P_{\mathrm{Tx,ST}}}{\sigma_{\mathrm{w}}^2}\right) = \log_2\left(1+\gamma_{\mathrm{s}}\right), \tag{8}$$

$$\begin{aligned} \mathrm{C_1} &= \log_2\left(1 + \frac{|h_{\mathrm{s}}|^2 P_{\mathrm{Tx,ST}}}{|h_{\mathrm{p,2}}|^2 P_{\mathrm{Tx,PT}} + \sigma_{\mathrm{w}}^2}\right) \\ &= \log_2\left(1 + \frac{|h_{\mathrm{s}}|^2 P_{\mathrm{Tx,ST}}}{P_{\mathrm{Rx,SR}}}\right) = \log_2\left(1 + \frac{\gamma_{\mathrm{s}}}{\gamma_{\mathrm{p,2}}+1}\right), \end{aligned} \tag{9}$$

where $\mathbb{P}(\mathscr{H}_0)$ and $\mathbb{P}(\mathscr{H}_1)$ are the occurrence probabilities for the respective hypothesis, whereas $\gamma_{\mathrm{p,1}}$ and γ_{s} represent the signal to noise ratios for the links PT-ST and ST-SR, respectively, and $\gamma_{\mathrm{p,2}}$ corresponds to interference (from the PT) to noise ratio for the link PT-SR. Moreover, $P_{\mathrm{Tx,PT}}$ and $P_{\mathrm{Tx,ST}}$ represent the transmit power at the PT and the ST, whereas $P_{\mathrm{Rx,SR}}$ corresponds to the received power (which includes the interference power from the PT and the noise power) at the SR. In addition, $\mathrm{C_0}$ and $\mathrm{C_1}$ represent the data rate without and with the interference from the PT. Please note that the following terms the data rate $\mathrm{C_0}$, $\mathrm{C_1}$ and the throughput R_{s} have been introduced to make a clear distinction between the instantaneous data rate and its average value over the frame duration. Also, the use of the term "capacity" is avoided for representing $\mathrm{C_0}$ and $\mathrm{C_1}$, since it implies the optimization of the mutual information over the cognitive channel.

In other words, using (6), the ST determines a suitable sensing time $\tau_{\text{sen}} = \tilde{\tau}_{\text{sen}}$, such that the secondary throughput is maximized subject to a target detection probability; refer to (7). From the deployment perspective, the tradeoff depicted above has the following fundamental issues:

- Without the knowledge of the received power $P_{\text{Rx,ST},h_{\text{p,I}}}$ over the sensing channel, it is not feasible to characterize P_d, refer to (4). This renders the characterization of the secondary throughput (6) impossible and the constraint defined in (7) inappropriate.
- Moreover, the knowledge of the interference and the access channels is required at the ST; refer to (8) and (9) for characterizing the throughput in terms of C_0 and C_1 at the SR.

Proposed Approach

In order to overcome the difficulties discussed in section "Problem Description", the following strategy is proposed:

1. As a first step, the estimation of the involved channels is considered. In order to characterize the detection probability, a received power-based estimation at the ST for the sensing channel is employed. This is done to ensure that the detection probability remains above a desired level. Further, a pilot-based estimation and a received power-based estimation for the access channel and the interference channel are employed at the ST and the SR, respectively, to characterize the secondary throughput.
2. Next, the variations due to channel estimation in the estimated parameters, namely, received power (for the sensing and the interference channels) and the power gain (for the access channel) are characterized in terms of their cdfs.
3. In order to investigate the performance of the IS subject to the channel estimation, these variations in the performance parameters, which include the detection probability and the secondary throughput, are characterized in terms of their cdfs.
4. Finally, the derived cdfs are utilized to obtain the expressions of sensing-throughput tradeoff. Hence, based on these expressions, the impact of imperfect channel knowledge on the performance of the ISs is qualified, and subsequently the achievable secondary throughput at a suitable sensing time is determined.

Considering the channel estimation, it is well known that systems with transmitter information (which includes the filter parameters, pilot symbols, modulation type, and time-frequency synchronization) at the receiver acquire the channel knowledge by listening to the pilot data sent by the ST [4, 23, 27, 28]. Other systems, where the receiver possesses either no access to this information or is limited by hardware complexity, procure channel knowledge indirectly by estimating a different parameter that entails the channel knowledge, for instance, received signal power [43] or received signal to noise ratio [14,66]. Recently, estimation techniques such as pilot-based estimation [48, 71] and received power-based estimation [42] have been applied to obtain channel knowledge for the CR systems. However, the

performance analysis has been limited to the underlay systems, where the emphasis has been given on modeling the interference at the PR.

Since the pilot-based estimation requires the knowledge of the PU signal at the secondary system, the versatility (in terms of PU signals) of the secondary system is compromised. On the other side, for the estimation of the received signal to noise ratio, Eigenvalue (which involves matrix operations)-based approach [66] or iterative approaches such as expectation-maximization have been proposed [14]. Due to the complicated mathematical operations or the complexity of the iterative algorithms, such approaches tend to increase the hardware complexity of the ISs. In order to resolve these issues, a received power-based estimation for the sensing and the interference channels and a pilot-based estimation for the access channel are employed. Similar to the energy-based detection, since the received power-based estimation involves simple operations on the obtained samples such as magnitude squared followed by summation, the proposed estimation provides a reasonable tradeoff between complexity and versatility.

Frame Structure

In order to include channel estimation, a frame structure that constitutes estimation τ_{est}, sensing τ_{sen} and data transmission $T - \tau_{\text{sen}}$ is proposed, where τ_{est} and τ_{sen} correspond to time intervals and $0 < \tau_{\text{est}} \leq \tau_{\text{sen}} < T$; refer to Fig. 8. Since the estimated values of the interacting channels are required for determining the suitable sensing time (the duration of the sensing phase), the sequence depicted in Fig. 8 is reasonable for the hardware deployment, whereby estimation is followed by sensing. Particularly for the sensing channel, it is worthy to note that the samples used for estimation can be combined with the samples acquired for sensing

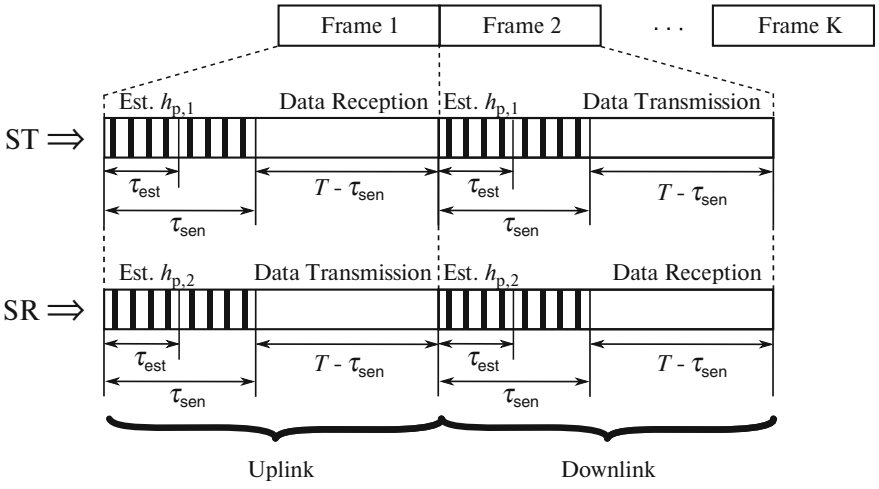

Fig. 8 Frame structure of the IS illustrating the time allocation of the channel estimation, sensing, and data transmission from the perspective of the ST and the SR

(therefore, the sensing phase incorporates the estimation phase, see Fig. 8) such that the time resources within the frame duration can be utilized efficiently, as shown in the frame structure in Fig. 8. Considering the fact that the number of pilot symbols is relatively small in comparison to the samples used for performing received power-based channel estimation, the time allocation of the pilot symbols does not affect the overall performance of the ISs. Hence, no time resources are allocated for the estimation of the access channel in the frame structure. In the following paragraphs, the estimation of the involved channels is considered.

Estimation of Sensing Channel ($h_{\mathrm{p},1}$)

Following the previous discussions, the ST acquires the knowledge of $|h_{\mathrm{p},1}|^2$ (included in $P_{\mathrm{Rx,ST},h_{\mathrm{p},1}}$, cf. (4)) to characterize $\mathrm{P_d}$ and to further evaluate the detector's performance. This knowledge is acquired by estimating the power received at the ST over the sensing channel.

Under $\mathscr{H}_1$, the received power-based estimated during the estimation phase at the ST is given as [75]

$$\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}} = \frac{1}{\tau_{\mathrm{est}} f_{\mathrm{s}}} \sum_{n=1}^{\tau_{\mathrm{est}} f_{\mathrm{s}}} |y_{\mathrm{ST}}[n]|^2. \tag{10}$$

$\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}$ determined in (10) using $\tau_{\mathrm{est}} f_{\mathrm{s}}$ samples follows a central chi-squared distribution $\mathscr{X}^2$ [46]. f_{s} and τ_{est} are such that the number of samples $\tau_{\mathrm{est}} f_{\mathrm{s}}$ is an integer. The cdf of $\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}$ is given by

$$F_{\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}}(x) = 1 - \Gamma\left(\frac{\tau_{\mathrm{est}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{est}} f_{\mathrm{s}} x}{2 P_{\mathrm{Rx,ST},h_{\mathrm{p},1}}}\right). \tag{11}$$

Estimation of Access Channel (h_{s})

The signal received from the SR undergoes matched filtering and demodulation at the ST; hence, it is reasonable to employ pilot-based estimation for h_{s}. Unlike received power-based estimation, pilot-based estimation renders a direct estimation of the channel. Now, to accomplish pilot-based estimation, the ST aligns itself to the pilot symbols transmitted by the SR.

Under $\mathscr{H}_0$, the discrete and complex pilot symbol at the output of the demodulator is given by [28]

$$p[n] = \sqrt{E_{\mathrm{s}}} h_{\mathrm{s}} + w_{\mathrm{ST}}[n], \tag{12}$$

where E_{s} denotes the pilot energy. Without loss of generality, the pilot symbols are considered to be +1. The maximum likelihood estimate, representing a sample average of N_{s} pilot symbols, is given by [27]

$$\widehat{h}_{\mathrm{s}} = h_{\mathrm{s}} + \underbrace{\frac{\sum_{n=1}^{N_{\mathrm{s}}} w_{\mathrm{ST}}[n]}{N_{\mathrm{s}}}}_{\epsilon}, \tag{13}$$

where ϵ denotes the estimation error. The estimate $\widehat{h}_{\mathrm{s}}$ is unbiased, is efficient, and achieves a Cramér-Rao bound with equality, with variance $\mathbb{E}\left[|h_{\mathrm{s}} - \widehat{h}_{\mathrm{s}}|^2\right] = \sigma_{\mathrm{w}}^2/N_{\mathrm{s}}$ [28].

Consequently, $\widehat{h}_{\mathrm{s}}$ conditioned on h_{s} follows a circularly symmetric Gaussian distribution:

$$\widehat{h}_{\mathrm{s}}|h_{\mathrm{s}} \sim \mathscr{CN}\left(h_{\mathrm{s}}, \frac{\sigma_{\mathrm{w}}^2}{N_{\mathrm{s}}}\right). \tag{14}$$

As a result, the power gain $|\widehat{h}_{\mathrm{s}}|^2$ follows a noncentral chi-squared $\left(\mathscr{X}'^2\right)$ distribution with two degrees of freedom and noncentrality parameter $\lambda_{\mathrm{s}} = \frac{N_{\mathrm{s}}|h_{\mathrm{s}}|^2}{\sigma_{\mathrm{w}}^2}$.

Estimation of Interference Channel ($h_{\mathrm{p,2}}$)

The knowledge of $|h_{\mathrm{p,2}}|^2$ is required to characterize the interference from the PT. Analog to the sensing channel, the SR performs received power-based estimation by listening to the signal transmitted by the PT.

Under $\mathscr{H}_1$, in the estimation phase (which implies ST is not transmitting, please consider Fig. 8), the discrete and complex signal received at the SR is given as

$$y_{\mathrm{SR}}[n] = h_{\mathrm{p,2}} \cdot x_{\mathrm{PT}}[n] + w_{\mathrm{SR}}[n]. \tag{15}$$

As a result, the estimated power at the SR, from the signal transmitted by the PT, is given by

$$\widehat{P}_{\mathrm{Rx,SR}} = \frac{1}{\tau_{\mathrm{est}} f_{\mathrm{s}}} \sum_{n=1}^{\tau_{\mathrm{est}} f_{\mathrm{s}}} |y_{\mathrm{SR}}[n]|^2, \tag{16}$$

where $\widehat{P}_{\mathrm{Rx,SR}}$ follows a $\mathscr{X}^2$ distribution.

Validation

At this stage, it is clear that the estimates $\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p,1}}}$, $|\widehat{h}_{\mathrm{s}}|^2$ and $\widehat{P}_{\mathrm{Rx,SR}}$ exhibit the knowledge corresponding to the involved channels; however, it is essential to validate them, mainly $\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p,1}}}$ and $\widehat{P}_{\mathrm{Rx,SR}}$. In this context, it is necessary to ensure the presence of the PU signal ($\mathscr{H}_1$) for that particular frame. In this direction, Chavali et al. [14] recently proposed a detection followed by the estimation of the signal to noise ratio, while [11] implemented a blind technique for estimating the signal power of noncoherent PU signals.

Here, a different methodology is proposed, according to which a coarse detection on the estimates $\left(\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p,l}}}, \widehat{P}_{\mathrm{Rx,SR}}\right)$ at the end of the estimation phase τ_{est} is applied. For the coarse detection, an energy detection is employed whose threshold can be determined by means of Neyman-Pearson criterion. Through an appropriate selection of the time interval τ_{est} (for instance, $\tau_{\mathrm{est}} \in [1, 10]$ms) during the system design, the reliability of the coarse detection can be ensured. With the existence of a separate control channel such as cognitive pilot channel, the reliability of the coarse detection can be further enhanced by exchanging the detection results between the ST and the SR.

The estimation and the coarse detection processes in the proposed method are equivalent in terms of their mathematical operations, consisting of magnitude squared and summation. In this regard, the validity of the channel estimates with certain reliability and without comprising the complexity of the estimators, employed by the secondary system, is considered. Moreover, by performing a joint estimation and (coarse) detection, an efficient way of utilizing the time resources within the frame duration is proposed. The ST considers these estimates to determine a suitable sensing time based on the sensing-throughput tradeoff such that the desired detector's performance is ensured. At the end of the detection phase, a fine detection of the PU signals is carried out, thereby improving the performance of the detector. In accordance with the proposed frame structure in Fig. 8, fine detection represents the main detection, which also includes the samples acquired during the estimation phase.

Assumptions and Approximation

To simplify the analysis and sustain analytical tractability for the proposed approach, several assumptions, considered in this section, are summarized as follows:

- All transmitted signals are subjected to distance-dependent path loss and small-scale fading gain. With no loss of generality, it is considered that the channel gains include distance-dependent path loss and small-scale gain. Moreover, the coherence time for the channel gain is considered to be greater than the frame duration. In scenarios, where the coherence time exceeds the frame duration, the proposed characterization depicts a lower performance bound.
- Perfect knowledge of the noise power is assumed in the system; however, the uncertainty in noise power can be captured as a bounded interval [73]. Inserting this interval in the derived expressions, refer to subsection "Theoretical Analysis", the performance of the IS can be expressed in terms of the upper and the lower bounds.

For analytical tractability, the following approximation is considered.

Approximation 1. *For all degrees of freedom, $\mathscr{X}'^2$ distribution can be approximated by a gamma distribution [1]. The parameters of the gamma distribution are obtained by matching the first two central moments to those of $\mathscr{X}'^2$.*

Theoretical Analysis

At this stage, it is evident that the variation due to the imperfect channel knowledge translates to the variations in the performance parameters:

$$\widehat{\mathrm{P}}_{\mathrm{d}} = \Gamma\left(\frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}} \mu}{2\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}}\right), \tag{17}$$

$$\widehat{\mathrm{C}}_0 = \log_2\left(1 + |\widehat{h}_{\mathrm{s}}|^2 \frac{P_{\mathrm{Tx,ST}}}{\sigma_{\mathrm{w}}^2}\right), \tag{18}$$

and

$$\widehat{\mathrm{C}}_1 = \log_2\left(1 + \frac{|\widehat{h}_{\mathrm{s}}|^2 P_{\mathrm{Tx,ST}}}{\widehat{P}_{\mathrm{Rx,SR}}}\right), \tag{19}$$

which are fundamental to sensing-throughput tradeoff. It is worth noticing the fact (17), (18) and (19) are determined using the estimated parameters, which include $\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}$, $|\widehat{h}_{\mathrm{s}}|^2$ and $\widehat{P}_{\mathrm{Rx,SR}}$, determined in previous section. Below, the variations in these performance parameters are characterized in terms of their cdfs: $F_{\widehat{\mathrm{P}}_{\mathrm{d}}}(\cdot)$, $F_{\widehat{\mathrm{C}}_0}(\cdot)$ and $F_{\widehat{\mathrm{C}}_1}(\cdot)$.

Lemma 1. The cdf of $\widehat{\mathrm{P}}_{\mathrm{d}}$ is characterized as

$$F_{\widehat{\mathrm{P}}_{\mathrm{d}}}(x) = 1 - \Gamma\left(\frac{\tau_{\mathrm{est}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{est}} \tau_{\mathrm{sen}} f_{\mathrm{s}}^2 \mu}{4P_{\mathrm{Rx,ST},h_{\mathrm{p},1}} \Gamma^{-1}(x, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2})}\right), \tag{20}$$

where $\Gamma^{-1}(\cdot,\cdot)$ is the inverse of the regularized upper-incomplete gamma function [31].

Solution 1. The cdf of $\widehat{\mathrm{P}}_{\mathrm{d}}$ is defined as

$$F_{\widehat{\mathrm{P}}_{\mathrm{d}}}(x) = \mathbb{P}(\widehat{\mathrm{P}}_{\mathrm{d}} \leq x). \tag{21}$$

Using (17)

$$= \mathbb{P}\left(\Gamma\left(\frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2}, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}} \mu}{2\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}}\right) \leq x\right), \tag{22}$$

$$= 1 - \mathbb{P}\left(\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}} \geq \frac{\mu \tau_{\mathrm{sen}} f_{\mathrm{s}}}{2\Gamma^{-1}\left(x, \frac{\tau_{\mathrm{sen}} f_{\mathrm{s}}}{2}\right)}\right). \tag{23}$$

Replacing the cdf of $\widehat{P}_{\mathrm{Rx,ST},h_{\mathrm{p},1}}$ in (23), an expression of $F_{\widehat{\mathrm{P}}_{\mathrm{d}}}(\cdot)$ is obtained.

Lemma 2. *The cdf of $\widehat{C}_0$ is defined as*

$$F_{\widehat{C}_0}(x) = \int_0^x f_{\widehat{C}_0}(t)dt, \tag{24}$$

where

$$f_{\widehat{C}_0}(x) = 2^x \ln 2 \frac{(2^x-1)^{a_s-1}}{\Gamma(a_s)b_s^{a_s}} \exp\left(-\frac{2^x-1}{b_s}\right), \tag{25}$$

and

$$a_s = \frac{(2+\lambda_s)^2}{(4+4\lambda_s)} \text{ and } b_s = \sigma_w^2 \frac{(4+4\lambda_s)}{(2+\lambda_s)}. \tag{26}$$

Solution 2. See [45, Section IV, Lemma 2].

Lemma 3. *The cdf of $\widehat{C}_1$ is given by*

$$F_{\widehat{C}_1}(x) = \int_0^x f_{\widehat{C}_1}(t)dt, \tag{27}$$

where

$$f_{\widehat{C}_1}(x) = 2^x \ln 2 \frac{(2^x-1)^{a_s-1}\Gamma(a_s+a_p)}{\Gamma(a_s)\Gamma(a_p)b_s^{a_s}b_p^{a_p}} \left(\frac{1}{b_p} + \frac{2^x-1}{b_s}\right)^{(a_s+a_p)}, \tag{28}$$

and

$$a_p = \frac{\tau_{\text{sen}} f_s}{2} \text{ and } b_p = \frac{2P_{Rx,SR}}{\sigma_w^2 \tau_{\text{sen}} f_s}. \tag{29}$$

where a_s and b_s are defined in (26).

Solution 3. See [45, Appendix A].

Next, a sensing-throughput tradeoff for the estimation model is established that includes the estimation time and incorporates the variations in the performance parameter. Most importantly, to restrain the harmful effect of the uncertain interference at the PR due to the variations in the detection probability, two new PU constraints at the PR, namely, an average constraint (AC) and an outage constraint (OC) on the detection probability are proposed. Based on these constraints, the sensing-throughput tradeoff for the IS is characterized.

Problem 1. The achievable expected secondary throughput subject to an average constraint on $\widehat{\mathrm{P}}_{\mathrm{d}}$ that employs channel estimation corresponding to the deterministic behavior of the interacting channels is given by

$$\begin{aligned} R_{\mathrm{s}}(\tilde{\tau}_{\mathrm{est}}, \tilde{\tau}_{\mathrm{sen}}) &= \max_{\tau_{\mathrm{est}}, \tau_{\mathrm{sen}}} \mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}, \widehat{\mathrm{C}}_0, \widehat{\mathrm{C}}_1} \left[R_{\mathrm{s}}(\tau_{\mathrm{est}}, \tau_{\mathrm{sen}}) \right] \\ &= \frac{T - \tau_{\mathrm{sen}}}{T} \Bigg[\mathbb{E}_{\widehat{\mathrm{C}}_0} \left[\widehat{\mathrm{C}}_0 \right] (1 - \mathrm{P}_{\mathrm{fa}}) \mathbb{P}(\mathscr{H}_0) + \\ &\quad \mathbb{E}_{\widehat{\mathrm{C}}_1} \left[\widehat{\mathrm{C}}_1 \right] \left(1 - \mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}} \left[\widehat{\mathrm{P}}_{\mathrm{d}} \right] \right) \mathbb{P}(\mathscr{H}_1) \Bigg], \qquad (30) \\ &\text{s.t. } \mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}} \left[\widehat{\mathrm{P}}_{\mathrm{d}} \right] \geq \bar{\mathrm{P}}_{\mathrm{d}}, \qquad (31) \\ &\text{s.t. } 0 < \tau_{\mathrm{est}} \leq \tau_{\mathrm{sen}} \leq T, \end{aligned}$$

where $\mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}} [\cdot]$ represents the expectation with respect to $\widehat{\mathrm{P}}_{\mathrm{d}}$, $\mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}, \widehat{\mathrm{C}}_0, \widehat{\mathrm{C}}_1} [\cdot]$ denotes the expectation with respect to $\widehat{\mathrm{P}}_{\mathrm{d}}$, $\widehat{\mathrm{C}}_0$ and $\widehat{\mathrm{C}}_1$. Unlike (7), $\bar{\mathrm{P}}_{\mathrm{d}}$ in (30) represents the constraint on expected detection probability.

Solution 4. See [45, Appendix B].

Problem 2. The achievable expected secondary throughput subject to an outage constraint on $\widehat{\mathrm{P}}_{\mathrm{d}}$ that employs channel estimation corresponding to the deterministic behavior of the interacting channels is given by

$$\begin{aligned} R_{\mathrm{s}}(\tilde{\tau}_{\mathrm{est}}, \tilde{\tau}_{\mathrm{sen}}) &= \max_{\tau_{\mathrm{est}}, \tau_{\mathrm{sen}}} \mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}, \widehat{\mathrm{C}}_0, \widehat{\mathrm{C}}_1} \left[R_{\mathrm{s}}(\tau_{\mathrm{est}}, \tau_{\mathrm{sen}}) \right] \\ &= \frac{T - \tau_{\mathrm{sen}}}{T} \Bigg[\mathbb{E}_{\widehat{\mathrm{C}}_0} \left[\widehat{\mathrm{C}}_0 \right] (1 - \mathrm{P}_{\mathrm{fa}}) \mathbb{P}(\mathscr{H}_0) + \\ &\quad \mathbb{E}_{\widehat{\mathrm{C}}_1} \left[\widehat{\mathrm{C}}_1 \right] \left(1 - \mathbb{E}_{\widehat{\mathrm{P}}_{\mathrm{d}}} \left[\widehat{\mathrm{P}}_{\mathrm{d}} \right] \right) \mathbb{P}(\mathscr{H}_1) \Bigg], \qquad (32) \\ &\text{s.t. } \mathbb{P}(\widehat{\mathrm{P}}_{\mathrm{d}} \leq \bar{\mathrm{P}}_{\mathrm{d}}) \leq \rho_{\mathrm{d}}, \qquad (33) \\ &\text{s.t. } 0 < \tau_{\mathrm{est}} \leq \tau_{\mathrm{sen}} \leq T, \end{aligned}$$

where ρ_{d} represents the outage constraint.

Solution 5. See [45, Appendix B].
In contrast to the ideal model, the sensing-throughput tradeoff investigated by the estimation model (refer to Problems 1 and 2) incorporates the imperfect channel knowledge. In this context, the performance characterization considered by the proposed framework is closer to the realistic situations. Herein, based on the

estimation model, a fundamental relation between estimation time (which regulates the variation in the detection probability according to the PU constraint), sensing time (which represents the detector performance) and achievable throughput is established. This relationship is characterized as estimation-sensing-throughput tradeoff. Based on this tradeoff, a suitable estimation time $\tau_{\text{est}} = \tilde{\tau}_{\text{est}}$ and a suitable sensing time $\tau_{\text{sen}} = \tilde{\tau}_{\text{sen}}$ that attains a maximum achievable throughput $R_{\text{s}}(\tilde{\tau}_{\text{est}}, \tilde{\tau}_{\text{sen}})$ for the IS are determined.

Corollary 1. *Problems 1 and 2 consider the optimization of the expected secondary throughput to incorporate the effect of variations due to the channel estimation and subsequently determine the suitable sensing and the suitable estimation time. Here, an alternative approach to the optimization problem that captures the effect of imperfect channel knowledge is investigated. According to which, the suitable sensing time for a certain value of estimation time, subject to the average constraint, is determined as*

$$\begin{aligned}
\tilde{\tau}_{\text{sen}} &= \underset{\tau_{\text{sen}}}{\text{argmax}}\ R_s(\tau_{\text{est}}, \tau_{\text{sen}}) \\
&= \frac{T - \tau_{\text{sen}}}{T}\left[\widehat{C}_0(1 - P_{fa})\mathbb{P}(\mathscr{H}_0) + \widehat{C}_1(1 - \widehat{P}_d)\mathbb{P}(\mathscr{H}_1)\right], \\
&\text{s.t. } \mathbb{E}_{\widehat{P}_d}\left[\widehat{P}_d\right] \geq \bar{P}_d, \\
&\text{s.t. } 0 < \tau_{\text{est}} \leq \tau_{\text{sen}} \leq T.
\end{aligned} \tag{34}$$

Similarly, the suitable sensing time for a certain value of estimation time, subject to the outage constraint, is determined as

$$\begin{aligned}
\tilde{\tau}_{\text{sen}} &= \underset{\tau_{\text{sen}}}{\text{argmax}}\ R_s(\tau_{\text{est}}, \tau_{\text{sen}}) \\
&= \frac{T - \tau_{\text{sen}}}{T}\left[\widehat{C}_0(1 - P_{fa})\mathbb{P}(\mathscr{H}_0) + \widehat{C}_1(1 - \widehat{P}_d)\mathbb{P}(\mathscr{H}_1)\right], \\
&\text{s.t. } \mathbb{P}(\widehat{P}_d \leq \bar{P}_d) \leq \rho_d, \\
&\text{s.t. } 0 < \tau_{\text{est}} \leq \tau_{\text{sen}} \leq T.
\end{aligned} \tag{35}$$

In contrast to (30) and (32), the suitable sensing time evaluated in (34) and (35) entails the variations due to the channel estimation from the performance parameters $(\widehat{P}_d, \widehat{C}_0, \widehat{C}_1)$. Hence, the expected secondary throughput subject to the average and the outage constraints that captures the variations in the suitable sensing time and the performance parameters is determined as

$$\mathbb{E}_{\widehat{P}_d, \widehat{C}_0, \widehat{C}_1, \tilde{\tau}_{\text{sen}}}\left[R_s(\tau_{\text{est}}, \tilde{\tau}_{\text{sen}})\right], \tag{36}$$

where $\mathbb{E}_{\widehat{P}_d, \widehat{C}_0, \widehat{C}_1, \tilde{\tau}_{\text{sen}}}[\cdot]$ corresponds to an expectation over $\widehat{P}_d, \widehat{C}_0, \widehat{C}_1, \tilde{\tau}_{\text{sen}}$.

In accordance with the Problems 1 and 2, the expected secondary throughput, defined in (36), is further optimized over the estimation time to yield the achievable expected secondary throughput:

$$R_s(\tilde{\tau}_{\text{est}}, \tilde{\tau}_{\text{sen}}) = \max_{\tau_{\text{est}}} \mathbb{E}_{\widehat{P}_d, \widehat{C}_0, \widehat{C}_1, \tilde{\tau}_{\text{sen}}} \left[R_s(\tau_{\text{est}}, \tilde{\tau}_{\text{sen}}) \right]. \tag{37}$$

In this way, an estimation-sensing-throughput tradeoff for the alternative approach is established that determines the suitable estimation and the suitable sensing time intervals.

Remark 1. Complementing the analysis in [52], it is complicated to obtain a closed-form expression of $\tilde{\tau}_{\text{sen}}$, thereby rendering the analytical tractability of its cdf difficult. In this view, the performance of the alternative approach is captured by means of simulations.

Numerical Results

Here, the performance of the IS based on the proposed approach is investigated. In this regard, (i) the simulations are performed to validate the expressions obtained, and (ii) the performance degradation incurred due to the channel estimation is analyzed. In this regard, the ideal model is considered to benchmark and to evaluate the performance loss; (iii) the mathematical justification to the considered approximations is established. Although the derived expressions, depicting the performance analysis, are general and applicable to all CR systems, the parameters are selected in such a way that they closely relate to the deployment scenario described in Fig. 7. Unless stated explicitly, the choice of the parameters given in Table 2 is considered for the analysis.

At first, the performance of the IS in terms of sensing-throughput tradeoff corresponding to the ideal model (IM) and estimation model (EM) for a fixed $\tau_{\text{est}} = 5$ ms is analyzed; refer to Fig. 9. In contrast to constraint on P_d for the ideal model, the average constraint (EM-AC) and the outage constraint (EM-OC) for the proposed estimation model are employed. With the inclusion of received power-based estimation in the frame structure, the ST achieves no throughput at the SR for the interval τ_{est}. For the given cases, namely, IM, EM-AC, and EM-OC, a suitable sensing time that results in a maximum secondary throughput $R_\text{s}(\tau_{\text{est}} = 5\,\text{ms}, \tilde{\tau}_{\text{sen}})$ is determined. Apart from that, a performance degradation is depicted in terms of the achievable throughput; refer to Fig. 9. For $\rho_\text{d} = 0.05$, it is observed that the outage constraint is more sensitive to the performance loss in comparison to the average constraint. It is clear that the analysis, illustrated in Fig. 9, is obtained for a certain choice of system parameters, particularly $\gamma_{\text{p},1} = -10\,\text{dB}$, $\tau_{\text{est}} = 5\,\text{ms}$, and $\rho_\text{d} = 0.05$. To acquire more insights, the effect of these variations on the performance parameters is considered, subsequently.

Table 2 Parameters for numerical analysis

Parameter	Value
f_s	1 MHz
$\lvert h_{p,1}\rvert^2$	-100 dB
$\lvert h_{p,2}\rvert^2$	-100 dB
$\lvert h_s\rvert^2$	-80 dB
T	100 ms
$\bar{P}_d$	0.9
ρ_d	0.05
σ_w^2	-100 dBm
$\gamma_{p,1}$	-10 dB
$\gamma_{p,2}$	-10 dB
γ_s	10 dB
$\sigma_s^2 = P_{Tx,PT}$	-10 dBm
$P_{Tx,ST}$	-10 dBm
$\mathbb{P}(\mathscr{H}_1) = 1 - \mathbb{P}(\mathscr{H}_0)$	0.2
τ_{est}	5 ms
N_s	10

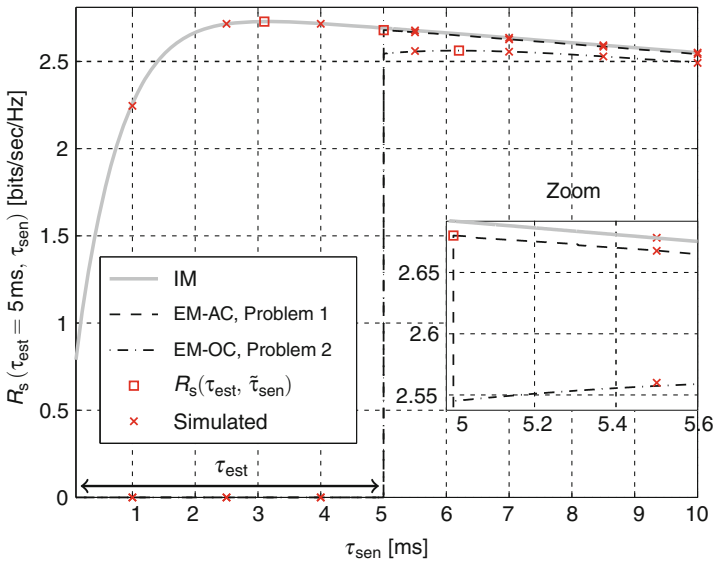

Fig. 9 Sensing-throughput tradeoff for the ideal model (IM) and estimation model (EM), $\gamma_{p,1} = -10$ dB, $\tau_{est} = 5$ ms and $\rho_d = 0.05$

Hereafter, the theoretical expressions are considered for the analysis; in addition, the IS is operated at the suitable sensing time. Next, the variation in the achievable throughput $R_s(\tau_{est}, \tilde{\tau}_{sen})$ against the received signal to noise ratio $\gamma_{p,1}$ at the ST with $\tau_{est} = 5$ ms is considered; refer to Fig. 10. For $\gamma_{p,1} < -10$ dB, the estimation model incurs a significant performance loss. This clearly reveals that the ideal

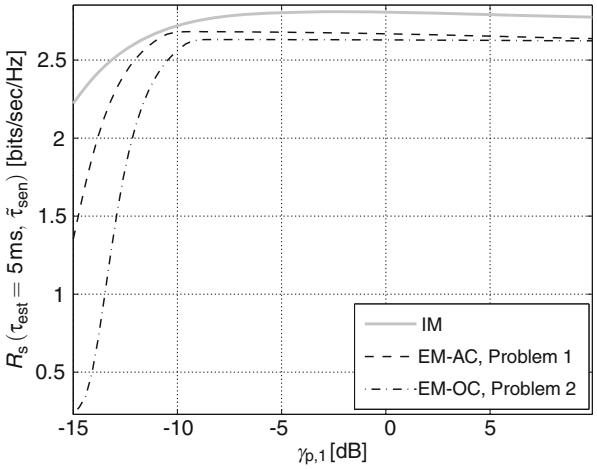

Fig. 10 Secondary throughput versus $\gamma_{p,1}$ with $\tau_{est} = 5$ ms for the deterministic channel

model overestimates the performance of the IS. From the previous discussion, it is concluded that the inclusion of the average and the outage constraints (depicted by the proposed framework) precisely tackles the uncertainty in the interference at the PR, arising due to channel estimation, without considerably degrading the performance of the IS.

Upon maximizing the secondary throughput, it is interesting to analyze the variation of the secondary throughput with the estimation time. Corresponding to the estimation model, Fig. 11 illustrates a tradeoff among the estimation time, the sensing time, and the secondary throughput. From Fig. 11, it can be noticed that the function $R_s(\tau_{est}, \tau_{sen})$ is well behaved in the region $0 < \tau_{est} \leq \tau_{sen} \leq T$ and consists of a global maximum, yielding the achievable secondary throughput.

This tradeoff depicted by the proposed framework can be explained from the fact that low values of the estimation time result in large variations in $\widehat{P}_d$. To counteract and satisfy the average and the outage constraints, the corresponding thresholds shift to a lower value. This causes an increase in P_{fa}, thereby increasing the sensing-throughput curvature. As a result, the suitable sensing time is obtained at a higher value. However, beyond a certain value ($\tilde{\tau}_{est}$), a further increase in the estimation time slightly contributes to the performance improvement and largely consumes the time resources. As a consequence to the estimation-sensing-throughput tradeoff, the suitable estimation time that yields an achievable throughput $R_s(\tilde{\tau}_{est}, \tilde{\tau}_{sen})$ is determined.

To procure further insights, the variations of expected $\widehat{P}_d$ and P_{fa} with the estimation time are studied. From Fig. 12, it is observed that the expected $\widehat{P}_d$ corresponding to the outage constraint is strictly above the desired level $\bar{P}_d$ for all values of the estimation time. However, for lower values of the estimation time, this margin reduces. This is based on the fact that lower estimation time shifts the probability mass of P_d to a lower value.

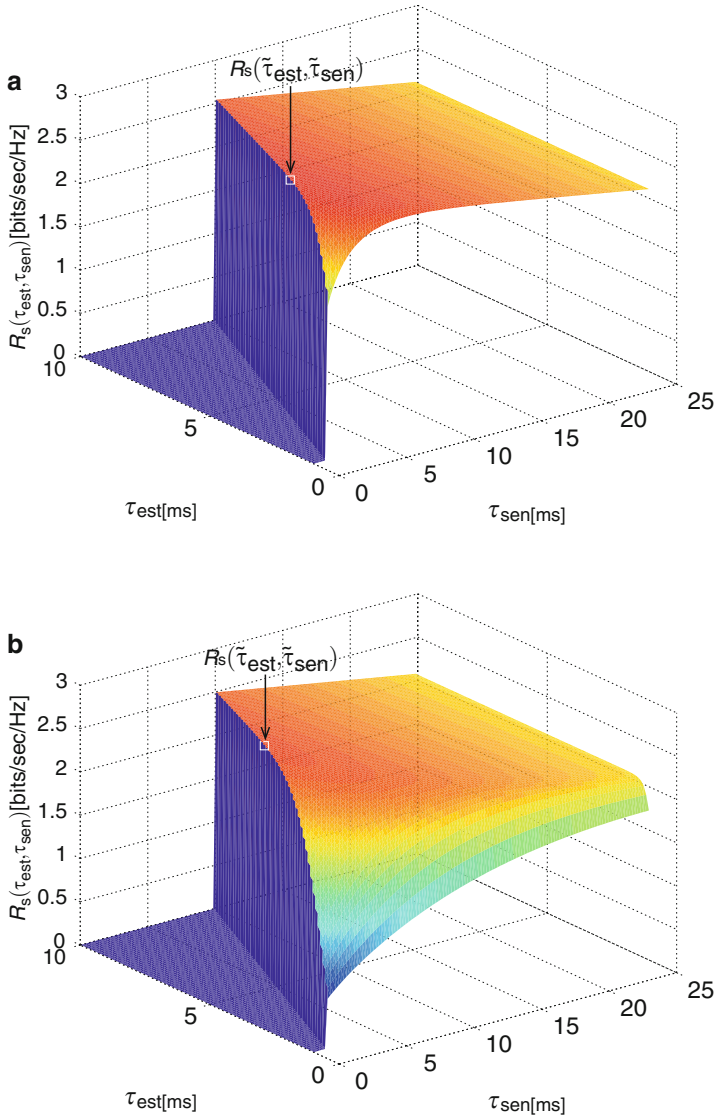

Fig. 11 Estimation-sensing-throughput tradeoff for the estimation model for (**a**) average constraint and (**b**) outage constraint with $\rho_d = 0.05$

According to Fig. 13, the system notices a considerable improvement in P_{fa} at small values of τ_{est}, which saturates for a certain period and falls drastically beyond a certain value. To understand this, it is important to study the dynamics between the estimation and the sensing time. Low τ_{est} increases the variations in the detection probability, these variations are compensated by an increase in the suitable sensing time, and vice versa. The performance improves until a maximum ($\tilde{\tau}_{est}$, $\tilde{\tau}_{sen}$) is

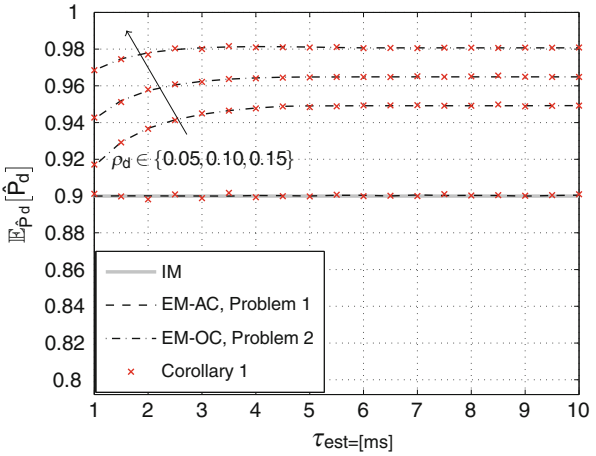

Fig. 12 Variation of $\mathbb{E}_{\widehat{P_d}}\left[\widehat{P}_d\right]$ versus the τ_{est}, where the secondary throughput is maximized over the sensing time, $R_s(\tau_{est}, \tilde{\tau}_{sen})$

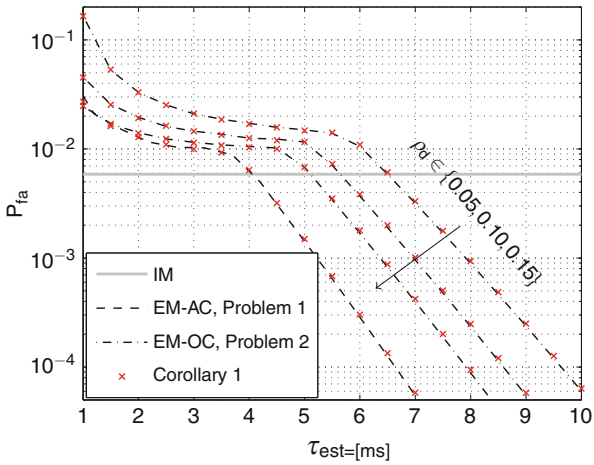

Fig. 13 Variation of P_{fa} versus the τ_{est}, where the secondary throughput is maximized over the sensing time, $R_s(\tau_{est}, \tilde{\tau}_{sen})$

reached, beyond this, the time resources (allocated in terms of the sensing and the estimation time) contribute more in improving the detector's performance (in terms of P_{fa} as P_d is already constrained) and less in reducing the variations due to the channel estimation.

Summary

This section investigated the performance of cognitive radio as an interweave system from a deployment perspective. It has been argued that the knowledge of the

interacting channels is a key aspect that enables the performance characterization of the interweave system. In this regard, a novel framework that facilitates channel estimation and captures the effect of channel estimation in the system model has been proposed. As a major outcome of the analysis, it has been justified that the existing model, illustrating an ideal scenario, disregards the effects such as time allocation and imperfect channel knowledge encountered by the IS due to the inclusion of channel estimation. In this context, the existing model overestimates the performance of the interweave system and, hence, is less suitable for deployment.

Moreover, it has been clearly identified that the variations induced in the system, specially in the detection probability, cause uncertain interference. Unless controlled, this uncertain interference may severely degrade the performance of the primary system. To overcome this situation, average and outage constraints as primary user constraints have been employed. As a consequence, for the proposed estimation model, novel expressions for the sensing-throughput tradeoff based on the mentioned constraints have been established. More importantly, by analyzing the estimation-sensing-throughput tradeoff, the suitable estimation time and the suitable sensing time that maximize the secondary throughput have been determined.

Research Directions

With regard to the performance analysis and the deployment-centric viewpoint toward CR systems emphasized in this chapter, the following extensions or considerations to the proposed framework could be of great interest for future investigations.

In-Band Full-Duplex

For instance, this chapter focused only on a half duplex CR communication, i.e., the CR techniques (which include spectrum sensing and power control) are time-interlaced with the data transmission. Recently, there has been significant advancement concerning the feasibility of in-band full duplex communication; for a detailed discussion over in-band full duplex communication, please consider [54, 64] and the references therein. In this context, the CR communication can be transformed into the in-band full duplex, whereby the CR techniques and the data transmission occur simultaneously in time and over the same frequency channel. The design challenges and the corresponding performance tradeoffs related to the in-band full duplex CR communication are precisely dealt within [49, 53].

Multiple Antennas at ST

In addition, the performed analysis considers that the ST and the SR are installed with single antenna. As a matter of fact, state-of-the-art standards are mostly equipped with multiple antennas. With an intention of establishing a preliminary analysis involving channel estimation in context of the CR systems, the performance enhancement procured by upgrading the existing spectrum sensing (detector performance) due to the deployment of multiple antennas [17, 72], has been completely neglected in the chapter. Based on a hardware deployment, the authors in [63]

argued that the hardware complexity in context with the CR system escalates with the deployment of multiple antennas, prohibiting the usage of well-known combining techniques such as equal-gain combining and maximum-ratio combining [16]. In this regard, nonconventional techniques, such as square-law selector and square-law combiner (following the principle of energy detection) are able to reduce complexity, thereby promoting the feasibility of multiple antennas.

Asynchronous Access

Given the complexity of the underlying problem, impairments due to the asynchronous (in time domain) access by the secondary system to the licensed spectrum is left aside throughout the chapter. The asynchronous access is due to the unknown (which can be random also) behavior of PU traffic. In these circumstances, the assumption concerning the synchronous access (i.e., perfect alignment to the primary system's medium access) becomes invalid. As a consequence, this asynchronous access certainly has an impact on the performance of the CR systems. A careful integration of the asynchronous access to the proposed analysis presents a promising research direction. To tackle this problem, the reader is encouraged to consult the references [35, 36].

Network-Wide Perspective

Finally, the performance analysis in this chapter has been confined to a single of PT, PR, ST, and SR, a classical way of illustrating a node-wide perspective of a CR system. The effect of the presence of other PTs and other STs in the network on the performance – evaluated using parameters such as spatial interference at the PR and spatial throughput at the SR, illustrating a network-wide perspective – has not been treated in the chapter. The concept of stochastic geometry, widely accepted for modeling the wireless networks, has been recently applied to the perform analysis for the cognitive radio networks. In order to establish an in-depth understanding of this concept, it is advisable to consult the references [18, 51, 69].

Conclusion

Despite its huge popularity and in-depth knowledge acquired on this topic, an autonomous as well as exhaustive implementation of such a concept is underdeveloped. One main reason behind this is the fact that the existing models (developed for the performance characterization) have focused more on theoretical analysis and less on the hardware deployment. In this regard, due to the complexity of the underlying problem, these models tend to overlook certain aspects such as noise uncertainty, channel knowledge, signal uncertainty, and hardware and model imperfections that are fundamental to a hardware implementation. The lack of such imperfections in the system model renders the performance analysis of the CR system incomplete.

The knowledge of the involved channels residing within a CR system is one of such aspects dealt in this chapter. From a physical layer perspective, it has been

identified that the channel knowledge is extremely necessary for the realization of the CR techniques on a hardware, thus allowing a CR system to control the interference accumulated by the primary system. In this chapter, this notion has been extensively justified and resolved through adequate analysis while considering a hardware deployment.

Above all, the inclusion of the channel estimation requires a proper allocation of time resources in the frame structure and appropriate measures to counter variations due to the estimation error induced in the system. Surely, these factors have a detrimental effect on the performance of a CR system, leading to the performance degradation. These channel estimation-related issues have been carefully identified and characterized, which ultimately allows us to depict the performance of the CR systems in a fairly realistic scenario. Besides, following the deployment perspective, a received power-based channel estimation technique is proposed for the estimation, particularly, for the channels that exist between the two systems.

Briefly, the analysis performed in this chapter does not only provide answers to specific questions related to imperfect channel knowledge, including:

1. How to counter the uncertain interference induced in different CR systems?
2. How to evaluate the performance degradation?
3. How to determine the suitable estimation time and suitable sensing time that yields the maximum throughput achieved?

but also promotes techniques such as:

1. implementation of the channel estimation at the secondary system
2. energy-based detection and
3. received power-based channel estimation

that ultimately encourage hardware feasibility of CR systems.

As a closing remark, spectrum is a precious component that can enable wireless connectivity to the billions of devices residing inside a 5G network. To meet this escalating demand of more spectrum, cognitive radio, competing with technologies such as the millimeter-wave technology and the visible light communication, represents a viable option. Having said that, there exist certain scenarios, including the one considered in this chapter (refer to section "Cognitive Small Cell: A Prominent Use-Case") that facilitate the coexistence of these technologies within a 5G system.

Abstract

Modeling spectrum sensing is a critical step that paves the way to (i) identify the key impairments that affect the detection performance and (ii) help develop algorithms and receiver architectures that mitigate these impairments. In this chapter, realistic and practical sensing models are presented beyond those

developed for classical detection theory. These models capture the impact of different sensing receiver impairments on several detectors such as the energy, the pilot, and the cyclostationarity detectors. Several receiver nonidealities are investigated, including noise uncertainty, imperfect synchronization, and cyclic frequency offsets. In addition, challenges and impairments pertaining to wideband sensing are analyzed, including the presence of strong adjacent interferers as well as the nonlinearities of the receiver RF front-end. From these models, several mitigation techniques are developed to compensate for the presence of the different sensing receiver impairments. Measurements and simulation results are presented throughout the chapter to show the negative impact of such impairments and validate that the developed mitigation techniques provide tangible performance gains.

Introduction

A standard cognitive radio (CR) system seeks to identify channels that are not occupied by primary systems so it can access them. Such cognitive and dynamic approach promises to enhance spectrum utilization. For this reason, the CR receiver must be equipped with a spectrum sensor that helps scan a single (in case of narrowband) or multiple (in case of wideband) spectrum bands. The objective of the spectrum sensing receiver is to employ detection algorithms to quickly and reliably detect primary systems and identify available spectral resources.

Among the most popular spectrum sensing techniques proposed in the literature are the energy, pilot, and cyclostationarity detectors. The theoretical detection performance of these detectors has been thoroughly investigated in the literature, yet the derived expressions are assumed to hold under ideal assumptions irrespective of the signal-to-noise ratio (SNR) at the sensing receiver front-end, as will be discussed in section "Spectrum Sensing Techniques". Indeed, measurements have verified that in negative SNR regimes, many of these assumptions do not hold. In this chapter, more accurate spectrum sensing models are presented, where several receiver impairments are included to better capture the performance attained via experimental studies. Specifically, the energy detector requires noise power estimation, which is commonly assumed to be perfect. Such assumption is dropped, and the detection performance is analyzed in the presence of noise uncertainty. Similarly, pilot and cyclostationarity detectors require tight synchronization to reap the coherent gains achieved via signal feature exploitation. This synchronization is difficult to attain in practice, where frequency, cyclic frequency, and sampling clock offsets are inevitable. Modeling these impairments and studying their impact on energy detection, pilot detection, and cyclostationarity detection will be discussed in details in sections "Energy Detection Under Noise Uncertainty," "Pilot Detection Under Frequency Offsets," and "Cyclostationarity Detection Under Imperfect Synchronization", respectively. Several mitigation algorithms are also presented in their corresponding sections.

While narrowband sensing is fundamental, wideband sensing is a highly desirable feature since it enables the CR receiver to explore more spectral resources and switch between different channels in case some of them become occupied by primary systems. To this end, modeling the wideband sensing problem has been reduced to modeling several narrowband sensing problems by dividing the wideband into many narrowbands. Such approach typically assumes an ideal channelization process, which is infeasible in practice. Indeed, two major bottlenecks arise in wideband sensing. First, a band that is adjacent to other bands with strong signals can suffer from high interference due to the nonideal filter mask in practice, which is commonly assumed to be a brick wall in theory. In addition, strong signals can saturate the RF front-end components such as the low-power amplifier (LNA). This pushes the LNA to operate in a nonlinear region, introducing spurious terms that can affect the detection performance. These two challenges and the mitigation techniques to overcome them will be presented in section "Wideband Sensing: Challenges and Solutions".

The different sensing impairments require revisiting the sensing models for two reasons. First, it is important to understand how the presence of these impairments affects the performance. Second, by identifying the key parameters that affect the performance, it becomes feasible to develop compensation algorithms and architectures to mitigate these impairments. The design procedure, which will be followed throughout this chapter, is summarized below:

1. Include the impairment in the sensing model. Such impairment may be identified through measurements or more practical modeling.
2. For a given detection algorithm, derive the detection performance in the presence of the impairment. The theoretical derivations help identify the key parameters that affect the detection performance.
3. Develop a compensation algorithm that mitigates the issues introduced by the impairment.

Spectrum Sensing Techniques

The CR receiver must have sensing capabilities to decide whether a channel is occupied by other users or not. Generally, physical layer sensing relies on estimating parameters that convey information about the channel such as the signal energy in that channel or the presence of signal features or pilots. In essence, the spectrum sensing problem can be viewed as a classical binary hypothesis test, where H_0 stands for the absence of primary user signals, i.e., noise-only samples, and H_1 stands for the presence of users, i.e., both noise and signal samples are present. This is a digital implementation, where a test statistic, Λ, is used to process N samples and estimate a desired parameter. Then, the statistic is compared to a predetermined decision threshold. Mathematically, this is expressed as

$$\Lambda \underset{H_0}{\overset{H_1}{\gtrless}} \lambda, \tag{1}$$

where λ is a threshold that can be optimized to attain a certain objective, e.g., meet a false alarm constraint.

There are a plethora of spectrum sensing techniques [2, 11, 23, 28], but the most prominent candidates for practical implementation are the energy detector, the pilot detector, and the cyclostationarity detector, which will be reviewed next.

Energy Detection

This is one of the simplest forms of detection because the CR receiver does not require any knowledge about the received samples beforehand. Specifically, the objective is to process the received samples to compute the energy level in the channel. Let $r(n)$ denote the n-th sample of the received signal; then the energy detector is expressed as

$$\Lambda_E = \frac{1}{N} \sum_{n=0}^{N-1} |r(n)|^2. \tag{2}$$

The detection performance of this test statistic is well-investigated in the literature for different signal and noise models. For instance, it can be shown that under the additive white Gaussian noise (AWGN) channel, the receiver operating characteristic (ROC) performance is expressed as [24]

$$P_d = Q\left(\frac{1}{1+\text{SNR}}\left[Q^{-1}(P_f) - \sqrt{N}\,\text{SNR}\right]\right), \tag{3}$$

where P_d is the probability of detection, P_f is the probability of false alarm, $Q(\cdot)$ is the Q-function, and $Q^{-1}(\cdot)$ is the inverse Q-function. It can be observed that the performance improves for higher SNR or longer sensing times, i.e., larger N. Note that this expression is assumed to be valid for any SNR value.

Pilot Detection

While the energy detector is a *universal* detector, since it does not need any specific signal structure, some practical communication systems deliberately embed signal features to either perform synchronization and acquisition or help improve signal decoding. For instance, in some broadcast communication systems, e.g., digital television, sinewave pilot tones are transmitted for data frame synchronization. Mathematically, the transmitted primary signal can be expressed as [10, 24]

$$x(n) = \sqrt{\varepsilon} x_p(n) + \sqrt{1-\varepsilon} x_d(n), \tag{4}$$

where $x_p(n)$ is a known pilot tone, $x_d(n)$ is the data-carrying signal, and ε is the pilot power factor, i.e., the fraction of the total power allocated to the pilot tone. For example, pilots in digital TV signals are 11 dB weaker than the average signal power, i.e., $\varepsilon \approx 0.1$ [1].

Pilot detection infers the occupancy of a channel by utilizing prior knowledge about pilots embedded in transmitted signals. One common approach for pilot detection is the following test statistic [5, 24]

$$\Lambda_P = \frac{1}{N} \sum_{n=0}^{N-1} \hat{x}_p^*(n) r(n), \tag{5}$$

where $\hat{\mathbf{x}}_p = [\hat{x}_p(1), \hat{x}_p(2), \cdots, \hat{x}_p(N)]^T$ is a unit vector in the direction of the pilot tone. The ROC performance of this statistic in an AWGN channel can be shown to be [10]

$$P_d = Q\left(Q^{-1}(P_f) - \sqrt{N\varepsilon\,\mathrm{SNR}}\right). \tag{6}$$

It can be observed that the performance depends on the power allocated to the pilot tone.

Cyclostationarity Detection

In the absence of deterministic pilot tones, the CR receiver can instead utilize the inherit features of modulated signals, which exhibit periodic statistical properties [7, 8]. Specifically, many of the modulated signals are second-order *cyclostationary*, i.e., their means and autocorrelation functions are periodic, where the period depends on the symbol period and the carrier frequency of the signal [21].

Cyclostationarity properties can be observed via the spectral correlation function, a two-dimensional complex transform [8]. This transform is actually a generalization of the power spectral density function, and it maintains several key advantages. First, it preserves phase and frequency information related to certain parameters in modulated signals. Second, features that overlap in the power spectrum are nonoverlapping features in the spectral correlation domain, making it easier to detect them. Third, different modulation schemes, e.g., BPSK and QPSK, have identical power spectral density functions, yet they can have highly distinct spectral correlation functions [4]. Last, noise samples are typically uncorrelated, and hence noise does not exhibit any cyclic features, making the detection in low SNR regime robust. Indeed, the measured spectral correlation of a receiver sensing noise-only samples is illustrated in Fig. 1, which confirms that noise does not have any peaks in the spectral correlation function except at zero cyclic frequencies.

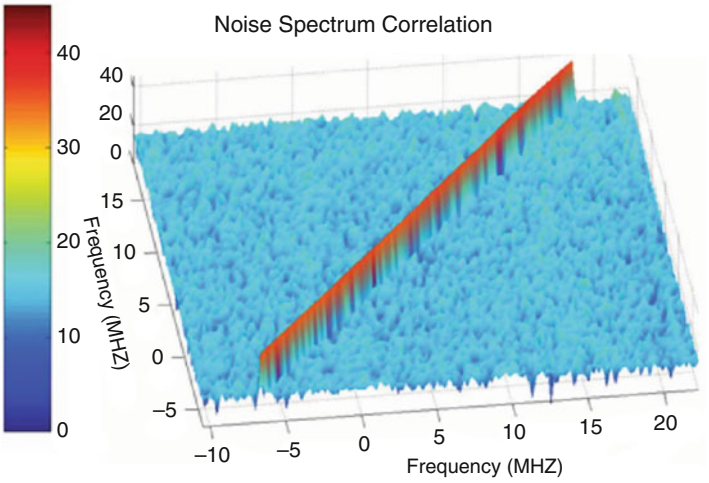

Fig. 1 Measured spectral correlation function of the noise at the 2.4 GHz receiver

The detection of cyclic features in the received signal is typically done by computing the *cyclic autocorrelation function* (CAF), where the received signal is correlated with a frequency-shifted version of itself [7]. More formally, the CAF can be estimated using N samples as follows [14, 21]

$$R_r^{\alpha}(\tau) = \frac{1}{N} \sum_{n=0}^{N-1} r(n) r^*(n-\tau) e^{-j2\pi\alpha n T_s}, \tag{7}$$

where α is the cyclic frequency and T_s is the sampling period. Once the CAF is computed at the CR receiver, the following test statistic can be performed:

$$\Lambda_{\alpha} = |R_r^{\alpha}(\tau)|. \tag{8}$$

As stated, different modulation schemes have peaks at different cyclic frequencies, and hence by varying α, it can be possible to not only detect signals but also classify them [9, 22].

Beyond Classical Detection Theory

Modeling the binary hypothesis testing problem in classical detection theory generally includes many ideal assumptions. For instance, it is commonly assumed that noise samples are generated from a white Gaussian wide-stationary process with a noise variance that is precisely known. This means that the threshold used for the energy detector can be accurately optimized to achieve any desired detection performance. Similarly, for pilot detection, tight synchronization is assumed between

the transmitter and the sensing receiver to properly correlate the received signal with a replica of the pilot tone, whereas frequency and clock offsets are neglected in the analysis of cyclostationarity detection.

Such ideal assumptions can be warranted if detection is done in good SNR conditions, where noise estimation and receiver synchronization are more reliable. However, primary user systems require protection even in the worst-case scenarios when the received signal at a CR receiver could be far below noise floor. For example, for a cognitive radio operation in licensed TV bands, IEEE 802.22 working group defined required SNR sensitivities for primary user signals to be -22 dB for DTV signals and -10 dB for wireless microphones [6]. Hence, spectrum sensing must be reliable in negative SNR regimes.

In addition to the reliable operation under stringent SNR requirements, the CR receiver must seek spectral opportunities over a wide swath of the spectrum, elevating the need for wideband spectrum sensing. The problem of wideband sensing has been typically approached by breaking the spectrum into many narrowband channels, and hence the problem is converted into several binary hypotheses tests, one per channel [11, 12, 16–18]. Such simplification, however, neglects many design challenges inherited with wideband sensing, including the impact of strong interferers in some channels [26, 27], spectral leakage due to nonideal filters [26], or the presence of spurious harmonics generated from nonlinearities in the receiver front-end [19].

The aforementioned design challenges require revisiting the sensing models for two reasons. First, it is important to accurately understand the impact of operating in negative SNR regions with nonideal wideband receiver front-ends on the detection performance. Second, by identifying the key parameters that affect the detection performance, the sensing algorithms can be enhanced to compensate for the different impairments that affect the detection reliability.

Energy Detection Under Noise Uncertainty

In an unoccupied channel, the CR receiver collects noise-only samples. From these samples, the noise variance can be estimated using the energy detector to optimize the detection threshold λ in order to achieve *any* desired probability of detection. Indeed, it can be observed from the ROC performance of the energy detector in (3) that controlling the sensing time N can help meet any specified (P_d, P_f) pair. Specifically, the following relation holds

$$N = \frac{\left[Q^{-1}(P_f) - Q^{-1}(P_d)(1 + \text{SNR})\right]^2}{\text{SNR}^2}. \tag{9}$$

In other words, the theoretical analysis shows that the number of samples asymptotically scales as $1/\text{SNR}^2$, which follows using the approximation $1 + \text{SNR} \approx 1$ in negative SNR regimes. To verify this scaling law, an experimental study is

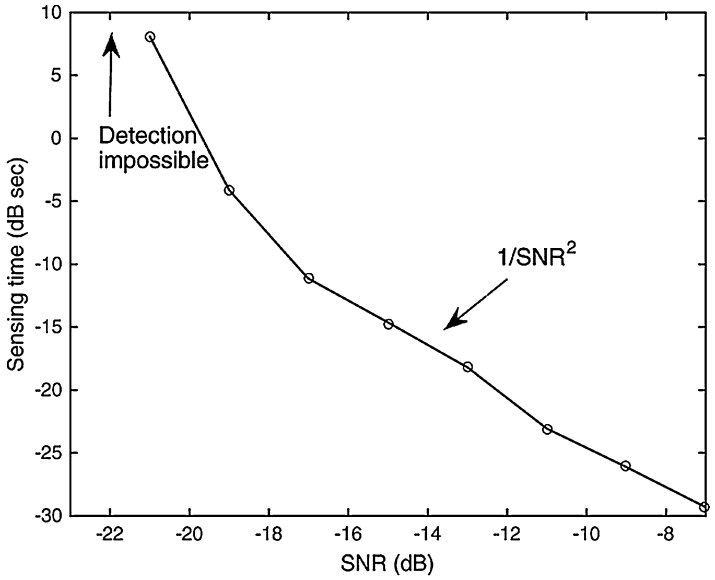

Fig. 2 Measured sensing time versus SNR for energy detector

performed using a real CR test bed [3]. In this study, the objective is to detect a QPSK signal under different SNR values. For each value, two different sets of energy values are collected: one in the absence of the signal and one in its presence. When the signal is absent, the noise-only samples are used to estimate the detection threshold λ that achieves a false alarm of $P_f = 0.05$. The threshold is then applied to compute P_d. From these measurements, the sensing time for a given SNR is derived to achieve a detection performance of $P_d = 0.9$ as shown in Fig. 2. It can be observed that the theoretical scaling law holds for SNR values above -20 dB. However, as the signal becomes weaker, detection becomes progressively harder, and when the signal is below -23 dB, the detector cannot sense the signal irrespective of the sensing time, leading to a phenomenon known as the *SNR wall* [24]. Such deviation illustrates that the energy detector lacks robustness in negative SNR regimes. In addition, the measurements show that the existing sensing model must be revisited to accurately capture the SNR wall phenomenon.

To understand the deviation of the measured sensing time curve from the predicted one, it is imperative to address the assumptions used in the existing sensing model. Specifically, there are two strong assumptions used here. First, noise is assumed to be an additive white Gaussian wide-sense stationary process with zero-mean and known variance. However, noise is an aggregation of various sources including not only thermal noise at the receiver and underlined circuits but also interference due to nearby unintended emissions, weak signals from transmitters very far away, etc. Second, by assuming that the noise variance is perfectly known, the detection threshold can be optimized with infinite precision. However, in the

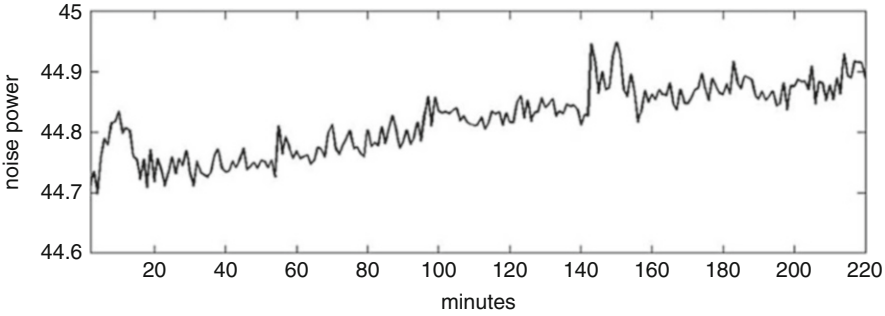

Fig. 3 Measured noise power at the CR receiver

actual implementation, this is practically impossible as noise could vary over time due to temperature change, ambient interference, filtering, etc. Indeed, Fig. 3 shows that the measured noise power level in the receiver used for testing of energy detection varies over time. The impact of the time-varying nature of the noise process on detection becomes tangible when the signal strength is below the estimation error of the noise variance. Hence, these temporal changes must be captured in the sensing model, particularly when the receiver operates in negative SNR regimes.

Modeling Noise Uncertainty

In a standard sensing model, it is common to model the noise-only samples as $w(n) \sim \mathcal{N}(0, \sigma_w^2)$, i.e., a Gaussian random variable with zero-mean and perfectly known variance σ_w^2. However, it is more accurate to assume that such noise samples are instead generated from $\tilde{w}(n) \sim \mathcal{N}(0, \tilde{\sigma}_w^2)$ such that

$$\tilde{\sigma}_w^2 \in \left[\frac{1}{\rho}\sigma_w^2, \rho\sigma_w^2\right], \tag{10}$$

where $\rho \geq 1$ is a parameter that quantifies the noise uncertainty. Note that $\rho = 1$ implies perfect knowledge of the noise variance. In other words, the CR receiver estimates that the noise variance is σ_w^2, whereas the *actual* variance is $\tilde{\sigma}_w^2$.

To understand how such noise uncertainty leads to an SNR wall, consider the worst-case scenario. Specifically, the highest false alarm probability occurs when the actual noise variance is $\tilde{\sigma}_w^2 = \rho\sigma_w^2$ since in this case σ_w^2 becomes an underestimate of the true variance, forcing the CR receiver to more frequently decide that the channel is occupied. Similarly, the lowest probability of detection occurs when the actual noise variance is $\tilde{\sigma}_w^2 = (1/\rho)\sigma_w^2$. In this case, the CR receiver overestimates the true variance, leading to increasing the frequency of declaring a channel to be empty. Under such worst-case scenario, it can be shown that the ROC of the energy detector becomes [24]

$$P_d = Q\left(\frac{\rho Q^{-1}(P_f) - \sqrt{N}(\text{SNR} + 1/\rho - \rho)}{\text{SNR} + 1/\rho}\right). \tag{11}$$

Clearly, for $\rho = 1$, (11) simplifies to (3). From this expression, the sensing time can be derived to be

$$N = \frac{\left[\rho Q^{-1}(P_f) - Q^{-1}(P_d)(1/\rho + \text{SNR})\right]^2}{(\text{SNR} + 1/\rho - \rho)^2}. \tag{12}$$

It is evident that $N \to \infty$ when $\text{SNR} + 1/\rho - \rho = 0$, i.e., there exists an SNR wall where detection below that SNR value becomes impossible. More formally, for $\rho > 1$, the SNR wall occurs at

$$\text{SNR}_{\text{wall}} = \frac{\rho^2 - 1}{\rho}. \tag{13}$$

Figure 4 illustrates the theoretical sensing time in the presence and absence of noise uncertainty where $\rho_{dB} = 10\log_{10}(\rho)$. It is evident that even small uncertainty makes the energy detector poor in highly negative SNR regions. It is also observed that the modified sensing model captures the behavior observed in the experimental study illustrated in Fig. 2.

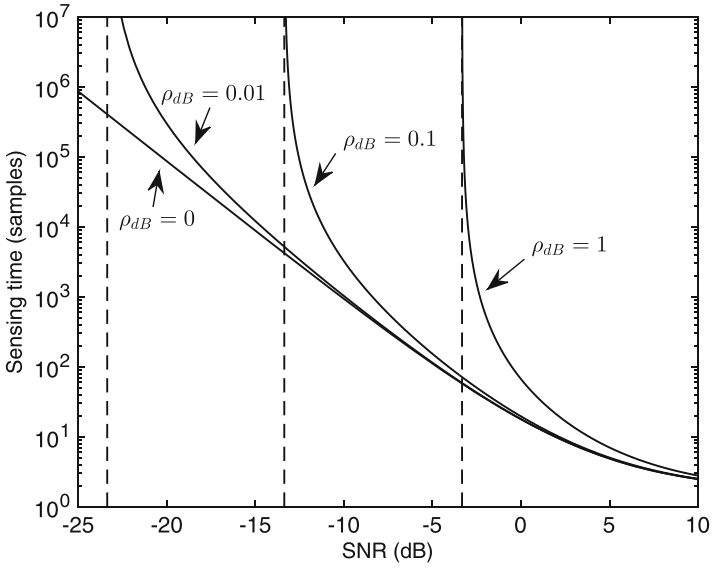

Fig. 4 Sensing time in the presence of noise uncertainty

Compensating Noise Uncertainty

Frequent noise power estimation becomes imperative, particularly in low SNR regimes. To this end, the CR receiver must collect noise-only samples. These samples, denoted as $w(n)$, can be used to estimate the noise variance using the following maximum likelihood (ML) estimator [13]

$$\hat{\sigma}_w^2 = \frac{1}{M} \sum_{m=0}^{M-1} |w(m)|^2. \tag{14}$$

The key issue here is the availability of such samples or inferring that the collected samples are actually noise-only samples instead of samples of a weak signal. One solution to this issue is to infrequently trigger a fine-sensing stage, where a feature detector is used [15]. Specifically, during the fine-sensing stage, if the decision is H_0, then the collected samples can, with high accuracy, be declared as noise-only samples, and hence they can be used to update $\hat{\sigma}_w^2$ for subsequent energy detection. Such approach can be implemented using the following detector:

$$\begin{aligned} \Lambda'_E &= \frac{\Lambda_E}{\hat{\sigma}_w^2} \\ &= \frac{M}{N} \frac{\sum_{n=0}^{N-1} |r(n)|^2}{\sum_{m=0}^{M-1} |w(m)|^2}. \end{aligned} \tag{15}$$

Figure 5 illustrates the enhanced energy detector. It consists of two stages: fine sensing of duration M, that is triggered infrequently, and energy sensing for duration N, which is triggered frequently. The former is motivated to reliably update the noise variance estimate, which will be used for subsequent fast energy detection.

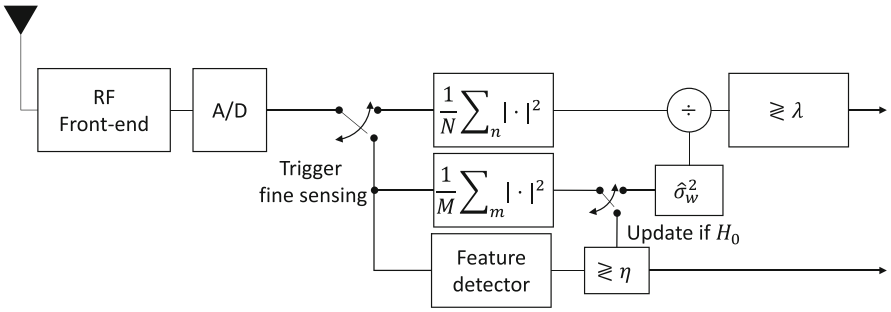

Fig. 5 The enhanced energy detector utilizes the noise variance estimate, which is periodically updated

The detection performance of this detector can be approximated as [15]

$$P_d = Q\left(\frac{1}{1+\text{SNR}}\left[Q^{-1}(P_f) - \sqrt{\frac{N \cdot M}{N+M}}\,\text{SNR}\right]\right). \tag{16}$$

From this expression, the sensing time of the energy detector is derived as follows:

$$\sqrt{\frac{N \cdot M}{N+M}} = \frac{Q^{-1}(P_f) - Q^{-1}(P_d)(1+\text{SNR})}{\text{SNR}}. \tag{17}$$

For instance, if $M = N$, the sensing time needed to achieve a specific (P_d, P_f) pair is

$$N = \frac{2\left[Q^{-1}(P_f) - Q^{-1}(P_d)(1+\text{SNR})\right]^2}{\text{SNR}^2}. \tag{18}$$

That is, there is an SNR penalty of $10\log_{10}(\sqrt{2}) \approx 1.5\,\text{dB}$ in comparison with the ideal energy detector. Note, however, that if $M = N^2$, then $\sqrt{\frac{N \cdot M}{N+M}} \approx \sqrt{N}$, i.e., the performance of Λ'_E reaches the ideal performance of Λ_E in the negative SNR regime.

Alternatively, the minimum SNR for which the detection is possible can be derived as [15]

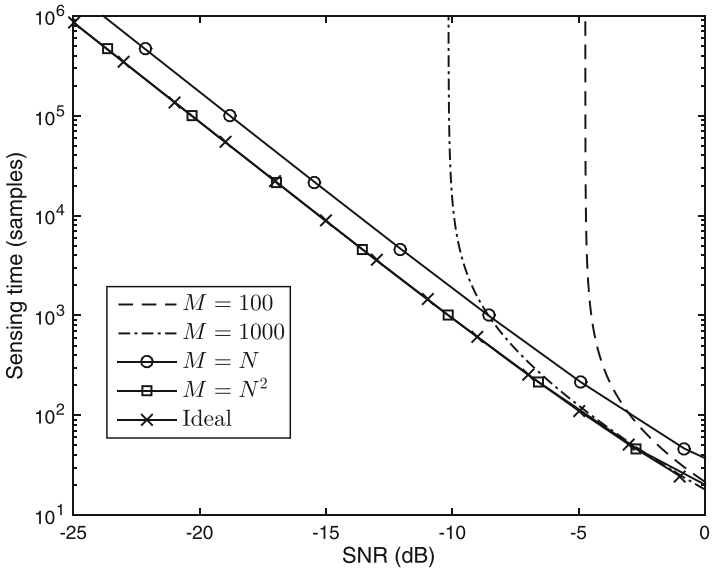

Fig. 6 Performance of the enhanced energy detector

$$\mathrm{SNR}_{\min} = \frac{1 + \sqrt{\frac{M+N}{N \cdot M}} Q^{-1}(P_f)}{1 + \sqrt{\frac{M+N}{N \cdot M}} Q^{-1}(P_d)} - 1. \tag{19}$$

It is clear that if $M = N$ or $M = N^2$, then $\mathrm{SNR}_{\min} \to 0$ as $N \to \infty$, i.e., there is no SNR wall. However, if M is a constant, e.g., $M = 100$, then $\mathrm{SNR}_{\min} > 0$ as $N \to \infty$.

Figure 6 illustrates the sensing time needed to achieve $P_f = 0.05$ and $P_d = 0.9$ when Λ'_E is used. As expected, having longer sensing periods to estimate the noise variance, i.e., larger M, improves the performance of the energy detector. However, to mitigate the SNR wall, the noise power estimation period should scale with the duration of the energy detector, e.g., $M = N$ and $M = N^2$.

Pilot Detection Under Frequency Offsets

The simplicity of the energy detector comes at the expense of a poor performance in negative SNR regimes. To circumvent this, pilot detection exploits certain signal features to robustify the detection performance, and particularly it relies on pilot tones that are sent alongside data-carrying signals. Indeed, the processing of the received samples via correlation provides *coherent* gains that make detection of very weak signals possible. However, this coherent processing requires the CR receiver to be in perfect synchronization with the pilot in the received signal.

Consider the ROC performance of the pilot detector in (6); then the sensing time needed to achieve any desired (P_d, P_f) pair can be shown to be

$$N = \frac{\left[Q^{-1}(P_f) - Q^{-1}(P_d)\right]^2}{\varepsilon\,\mathrm{SNR}}. \tag{20}$$

Thus, the theoretical scaling law of the sensing time is $N \sim 1/\mathrm{SNR}$. Comparing this scaling law with the one achieved using the energy detector, then it can be observed that the sensing time under pilot detection is a lower bound on that achieved using energy detection as long as $\varepsilon > \mathrm{SNR}$.

To verify the scaling law of the pilot detector, an experimental study is performed on a sinewave pilot, with signal levels varying from -110 to -136 dB. The measured sensing time is shown in Fig. 7 in the presence of different frequency offsets. It is observed that for strong pilot tones, the measured sensing time follows the theoretical scaling law. However, as the pilot power decreases, the sensing time deviates from the theoretical curve, leading to the SNR wall phenomenon.

The deviation of the experimental result from the theoretical curve is explained as follows. Practical receivers have imperfect thus inaccurate oscillators and circuitry, deeming perfect synchronization near impossible, particularly in negative SNR regimes. Typically, synchronization loops can estimate and reliably correct frequency offsets when the SNR at the receiver is positive. However, in negative

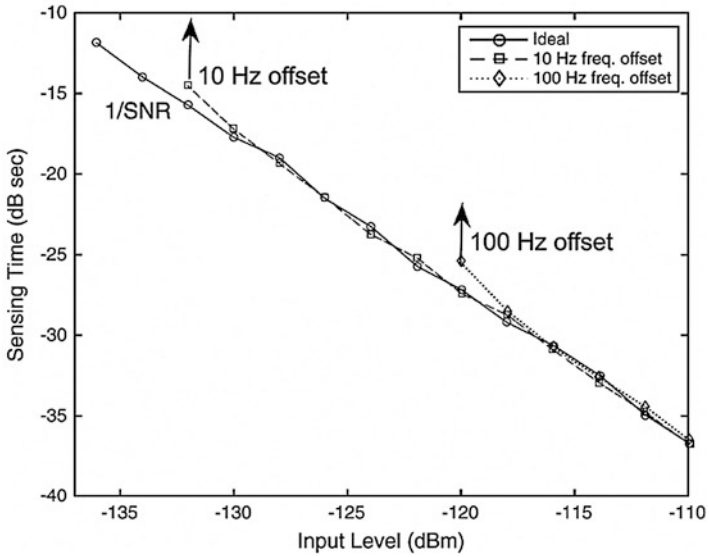

Fig. 7 Measured sensing time with variations of the sine wave signal power under different frequency offsets

SNRs these loops are driven by noise and cannot perform robust synchronization. The imperfect synchronization can severely affect the coherent processing gains achieved by correlating the received signal with the pilot tone.

Modeling Frequency Offsets

Consider the sinewave pilot tone $x_p(n) = \exp(j(\omega_o n + \theta))$, where ω_0 is the carrier frequency. Suppose there exists a frequency offset, ψ, between the primary transmitter and the CR receiver. This can be modeled by assuming that the pilot tone replica used at the receiver is equal to $\hat{x}_p(n) = x_p(n)\exp(j\psi n)$. Using the pilot detector, it can be shown that under H_1

$$\begin{aligned} \Lambda_P &= \frac{1}{N}\sum_{n=0}^{N-1} \hat{x}_p(n)^* r(n) \\ &\approx \frac{\sqrt{\varepsilon}}{N}\sum_{n=0}^{N-1} \exp(-j\psi n). \end{aligned} \tag{21}$$

If the sensing time N becomes comparable or larger than the period of the frequency offset, then the pilot detector loses its coherent processing gain. In other words, in

the presence of frequency offsets, the pilot detector can suffer from the SNR wall, explaining the measured curve in Fig. 7.

Compensating Frequency Offsets

As discussed in the previous section, the presence of frequency offsets can be detrimental if the sensing time is in the order of frequency offset time period. Thus, it is intuitive to break down the sensing time into shorter time periods to help achieve partial coherent processing gains. This motivates the following enhanced pilot detector [5]:

$$\Lambda'_P = \frac{1}{K}\sum_{k=0}^{K-1}\frac{1}{M}\left[\sum_{m=0}^{M-1}\hat{x}_p^*(kM+m)r(kM+m)\right]^2. \tag{22}$$

This detector can be interpreted as a two-stage pilot detector. Specifically, in the first stage, the CR receiver correlates the received signal with a replica of the pilot tone, but this time it is done over a short period, i.e., $M \ll N$. This process is repeated K times, and hence in the second stage, the CR receiver noncoherently averages over these collected K blocks, making the total sensing time $N = K \cdot M$. The receiver architecture of the two-stage pilot detector is shown in Fig. 8.

It can be shown that the performance of the enhanced pilot detector is

$$P_d = Q\left(\frac{1}{\sqrt{1+2M\varepsilon\,\mathrm{SNR}}}\left[Q^{-1}(P_f) - \sqrt{\frac{K}{2}}M\varepsilon\,\mathrm{SNR}\right]\right). \tag{23}$$

There are several key observations here. First, if $\varepsilon\,\mathrm{SNR} \ll 1$, then the performance can be approximated as

$$P_d \approx Q\left(Q^{-1}(P_f) - \sqrt{\frac{K}{2}}M\varepsilon\,\mathrm{SNR}\right). \tag{24}$$

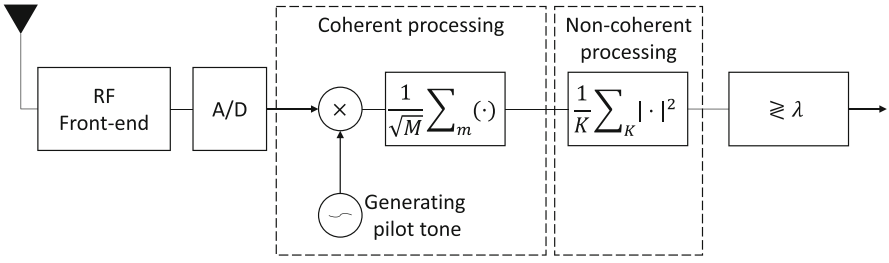

Fig. 8 The two-stage pilot detector complements coherent processing with noncoherent processing

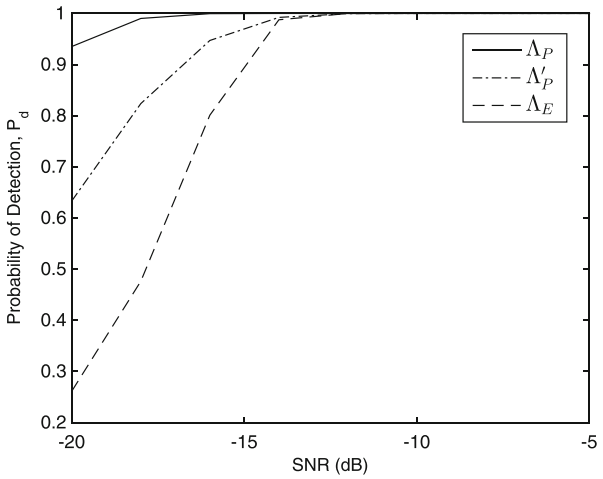

Fig. 9 The detection performance of the enhanced pilot detector

In this case, increasing K improves the performance with a similar scaling to the energy detector (cf. (3)). Yet, the coherent processing effectively improves the SNR by $10\log_{10}(M)$dB. In other words, comparing (24) with (3), it can be observed that under noise uncertainty, which affects nocoherent processing, the enhanced pilot detector moves the SNR wall by $10\log_{10}(M)$dB.

Second, if $\varepsilon\,\mathrm{SNR} \gg 1$, then the performance can be approximated as

$$P_d \approx Q\left(\frac{Q^{-1}(P_f)}{\sqrt{2M\varepsilon\,\mathrm{SNR}}} - \sqrt{\frac{KM\varepsilon\,\mathrm{SNR}}{4}}\right). \tag{25}$$

In this case, the performance of the enhanced pilot detector is similar to the performance of the ideal pilot detector (cf. (6)).

Figure 9 shows the detection performance of the enhanced pilot detector in negative SNR regimes. The enhanced detector is compared with the ideal energy and pilot detectors in (2) and (5), respectively. It is assumed that $P_f = 0.05$, $\varepsilon = 0.1$, and $N = 10{,}000$, where $K = 10$ and $M = 1000$. It is clear that the enhanced pilot detector benefits from the coherent processing gains in very negative SNRs, and since $M \ll N$, the robustness against frequency offsets improves.

Cyclostationarity Detection Under Imperfect Synchronization

Similar to pilot detection, where prior knowledge about pilot tones is needed, cyclostationarity detection requires knowledge about the cyclic frequency of the modulated signal. Such feature exploitation helps robustify detection in negative SNR regimes. However, it is critical to analyze the detection performance when such knowledge is not perfectly known.

Consider the zero-lag CAF, i.e., $\tau = 0$, which is expressed as

$$R_r^{\alpha}(0) = \frac{1}{N} \sum_{n=0}^{N-1} r(n) r^*(n) e^{-j2\pi\alpha n T_s}. \tag{26}$$

Clearly, for $\alpha = 0$, the cyclostationarity detector simplifies to the energy detector in (2). From this, one can interpret this detector for $\alpha \neq 0$ as computing the energy of the received signal at a cyclic frequency α. In the presence of noise-only samples, it can be shown that as $N \to \infty$ then $R_r^{\alpha}(0) \to 0$ for $\alpha \neq 0$ at all SNRs. That is, the detector can *theoretically* suppress noise at the negative SNR regime by increasing the sensing time N due to averaging a stationary noise process.

The robustness of the cyclostationarity detector in negative SNR regimes is attained when α is perfectly known, yet this is difficult to achieve in practice. Specifically, the presence of Doppler shifts, imperfect estimation of carrier frequencies, and the frequency mismatch due to local oscillators all introduce *cyclic frequency offsets* (CFOs) that can degrade the performance. Such performance degradation is verified experimentally [20]. In particular, a BPSK signal with a symbol period $T = 10\mu s$ is generated. At the receiver end, the detector in (26) is implemented at $\alpha = 1/T = 100\,\text{KHz}$ with a sampling frequency $1/T_s = 2\,\text{MHz}$. The cyclic feature of the BPSK signal is analyzed in the presence of different frequency offsets Δ_α given in units per million (ppm). Figure 10 shows the impact of increasing the sensing time N on the cyclic feature. Interestingly, as the sensing time increases, it

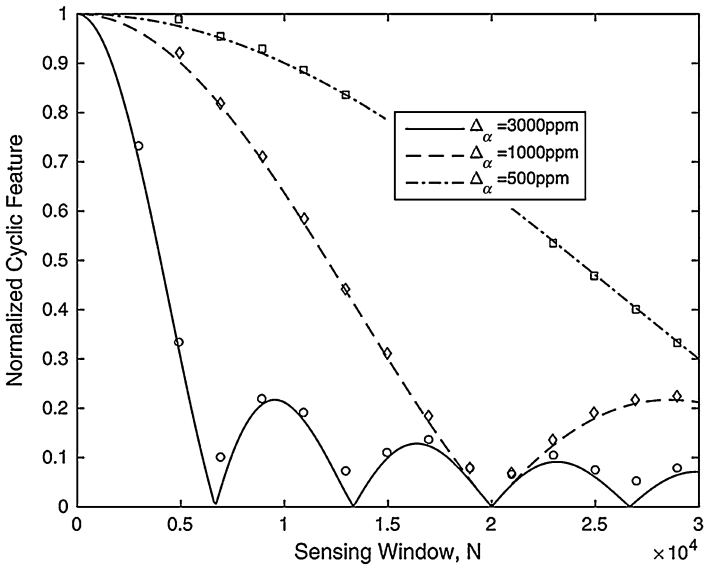

Fig. 10 Normalized cylic feature in the presence of CFOs. *Markers* denote the experimental results and *curves* denote the theoretical expression in (29)

becomes harder to detect the cyclic feature. Thus, although increasing N averages the noise process in negative SNR regimes, the cyclic feature becomes harder to detect, leading to an SNR wall phenomenon. The decay in the cyclic feature is theoretically investigated in the next section.

Modeling Cyclic Frequency Offsets

To model the CFO, it can be assumed that the test statistic is computed at a cyclic frequency that is deviated from the correct one by Δ_α, i.e., the cyclic frequency used is

$$\hat{\alpha} = \alpha(1 + \Delta_\alpha). \tag{27}$$

Note that the CFO will not affect the noise process since it is stationary. Hence, noiseless signals are considered in the subsequent analysis.

For illustration purposes, consider a single-carrier signal $r(n) = \sum_m a(mT_b)\, p(nT_s - mT) \exp(-2\pi f_0 nT_s)$, where $a(mT_b)$ are data symbols with period T_b, e.g., for BPSK $a(mT_b) \in \{+1, -1\}$, $p(\cdot)$ is a pulse shaping filter, and f_0 is the carrier frequency. Then,

$$\begin{aligned} R_r^{\hat{\alpha}}(0) &= \frac{1}{N}\sum_{n=0}^{N-1} r(n) r^*(n) e^{-j2\pi\hat{\alpha}nT_s} \\ &= \frac{1}{N}\sum_{n=0}^{N-1} \left|\sum_m a(mT_b)\, p(nT_s - mT)\right|^2 e^{-j2\pi\alpha nT_s} e^{-j2\pi\alpha\Delta_\alpha nT_s} \\ &\approx \frac{R_r^\alpha(0)}{N} \frac{e^{-j2\pi\alpha\Delta_\alpha NT_s} - 1}{e^{-j2\pi\alpha\Delta_\alpha T_s} - 1} \\ &= R_r^\alpha(0) e^{-j2\pi\alpha\Delta_\alpha(N-1)T_s} \frac{\sin(\pi\alpha\Delta_\alpha NT_s)}{N\sin(\pi\alpha\Delta_\alpha T_s)}. \end{aligned} \tag{28}$$

Note that $R_r^{\hat{\alpha}}(0) \to R_r^\alpha(0)$ as $\Delta_\alpha \to 0$. The test statistic to detect the cyclic feature is shown to be [20, 29]

$$|R_r^{\hat{\alpha}}(0)| = |R_r^\alpha(0)| \left|\frac{\sin(\pi\alpha\Delta_\alpha NT_s)}{N\sin(\pi\alpha\Delta_\alpha T_s)}\right|. \tag{29}$$

It can be observed that for $\Delta_\alpha \neq 0$, the cyclic feature decays as N increases. This makes $|R_r^{\hat{\alpha}}(0)|$ under H_1 to be similar to $|R_r^{\hat{\alpha}}(0)|$ under H_0, making detection very difficult. Figure 10 shows the theoretical curves of the normalized cyclic feature in the presence of CFOs, which match the results obtained via the experimental study.

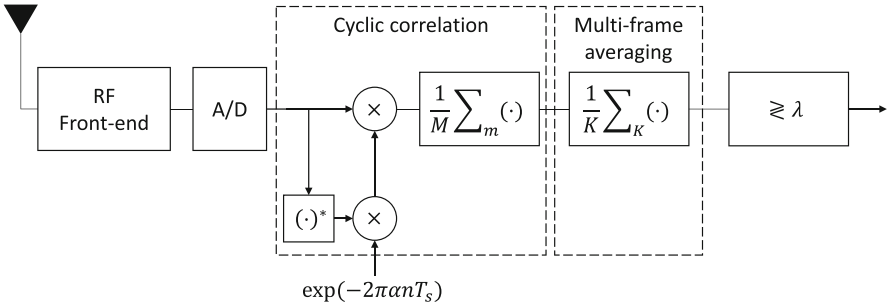

Fig. 11 The enhanced cyclostationarity detector

Compensating Frequency Offsets

It is shown that long sensing windows severely impact the cyclostationarity detector in the presence of CFOs. However, long sensing windows are necessary to average noise, particularly in negative SNR regimes. This suggests a two-stage sensing detector similar to the approach used in improving the pilot detector. Specifically, the N samples are broken into K blocks, where each one is of length M. In each block of samples, cyclostationarity detection is done, yet $M < N$, and hence the impact of the CFO is reduced. At the same time, $K > 1$ in order to average noise. Mathematically, the two-stage detector is given as [21]

$$R_r^{\alpha}(0)' = \frac{1}{K \cdot M} \sum_{k=0}^{K-1} \sum_{m=0}^{M-1} r(kM + m) r^*(kM + m) e^{-j2\pi\alpha m T_s}. \tag{30}$$

The enhanced cyclostationarity detector is shown in Fig. 11. Similar to the analysis given for $R_r^{\hat{\alpha}}(0)$, it can be shown that the impact of the CFO on $R_r^{\alpha}(0)'$ is given by

$$|R_r^{\hat{\alpha}}(0)'| = |R_r^{\alpha}(0)'| \left| \frac{\sin(\pi\alpha\Delta_{\alpha} M T_s)}{M \sin(\pi\alpha\Delta_{\alpha} T_s)} \cdot \frac{\sin(\pi\alpha K M T_s)}{K \sin(\pi\alpha M T_s)} \right|. \tag{31}$$

Figure 12a shows the normalized cyclic frequency under the enhanced detector for different number of frames. It is evident that breaking the N samples into several frames can significantly reduce the rate at which the cyclic feature decays, making it more reliable to detect in negative SNR regimes. Figure 12b illustrates the cyclic feature with variations of the CFO, where $N = 20{,}000$. It can be observed that increasing K does not always provide the highest gains. For instance, the cyclic feature is weak for $K = 5$ when the CFO is small. This emphasizes that the number of samples and how these samples are divided into blocks both affect the performance. This suggests an optimization framework that maximizes the cyclic feature by optimizing K and M [20].

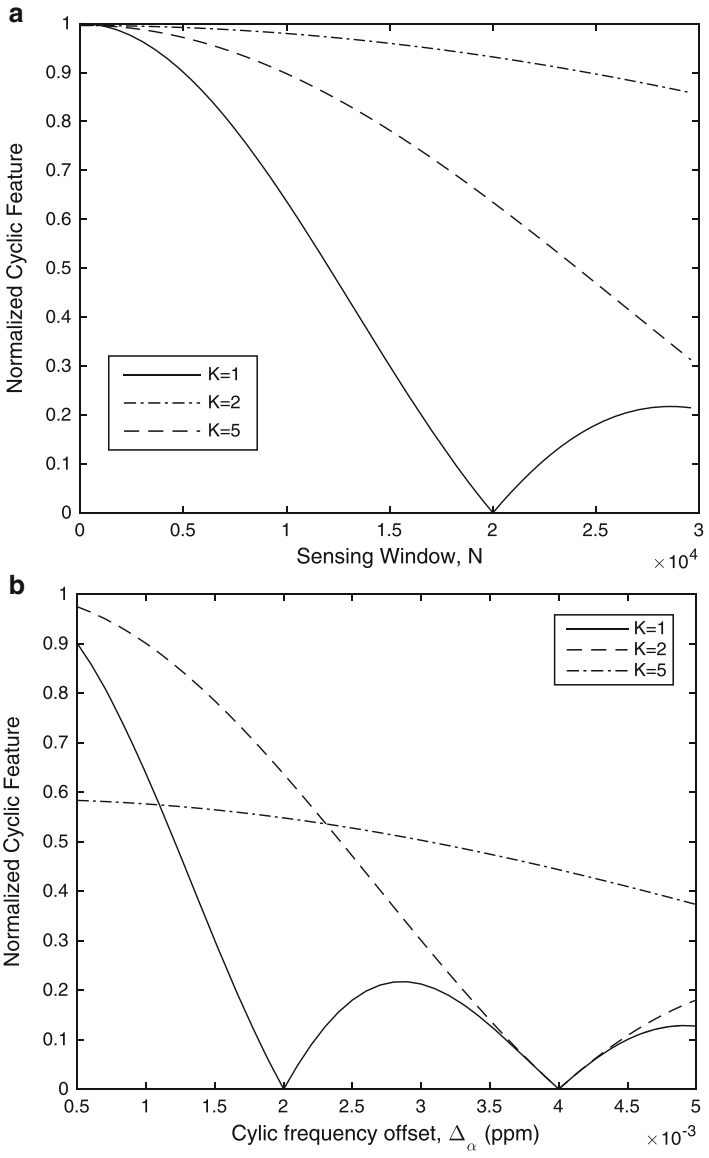

Fig. 12 Normalized cyclic frequency under the enhanced cyclostationarity detector

So far, it is assumed that there are no phase offsets between the different blocks, which occur when $M \alpha T_s$ is an integer, i.e., the estimation of the CAF is done over an integer number of periods of the cyclic frequency. However, *sampling clock offsets* (SCOs) resulted in the analog-to-digital conversion stage may prevent coherent integration of the different blocks.

One way to model the SCO is to rewrite the sampling period as

$$\hat{T}_s = T_s(1+\delta). \tag{32}$$

Here, it is assumed that $\Delta_\alpha = 0$ to explicitly understand how the SCO affects the performance of the enhanced cyclostationarity detector. Hence, and similar to the analysis done for the CFO, it can be shown that

$$|\hat{R}_r^\alpha(0)'| = |R_r^\alpha(0)'| \left| \frac{\sin(\pi\alpha K M T_s(1+\delta))}{K \sin(\pi\alpha M T_s(1+\delta))} \right|, \tag{33}$$

where $\hat{R}_r^\alpha(0)'$ denotes the enhanced detector in the presence of the SCO.

The impact of the SCO on the enhanced detector is studied for $K = 5$. Figure 13a shows the normalized cyclic frequency with variations of the number of samples, whereas Fig. 13b shows the impact of δ, where $N = 10{,}000$. It is assumed that $\alpha = 1/T = 100\,\text{KHz}$ and $1/T_s = 2\,\text{MHz}$. It is clear that sampling offsets have detrimental effects on the performance.

The enhanced detector, in general, requires optimizing K and M to limit the performance loss due to CFOs and SCOs [21]. An optimization framework can be formulated when these two impairments are modeled as random variables. Figure 14 illustrates the detection performance of the enhanced detector, where both impairments are modeled as zero-mean Gaussian random variables with variances $\sigma_{cfo}^2 = 2 \times 10^{-4}$ and $\sigma_{sco}^2 = 1 \times 10^{-5}$. The signal to be detected is assumed to be BPSK with $\alpha = 5\,\text{MHz}$, and $1/T_s = 10\,\text{MHz}$. Figure 14a shows the simulated ROC performance for different number of frames, where SNR $= -5\,\text{dB}$. The total sensing window is fixed at $N = K \cdot M = 5000$ samples. It can be observed that the way by which the samples are split is critical to the detector's performance. Figure 14b shows the detection performance for $K = 12$ under different SNR regimes. Overall, the detector provides robust performance in negative SNR regimes if K and M are optimized.

Wideband Sensing: Challenges and Solutions

To realize a full-scale uptake of cognitive radio systems, it is imperative to explore a wide swath of the spectrum in order to identify as many spectral opportunities as possible. Hence, it is critical to equip CR receivers with wideband sensing capabilities, i.e., scanners that can scan many channels in parallel. Not only this provides more bandwidth, and hence more throughput, but also enables the receiver to move from one channel to another when a primary system reappears.

Typically in wideband sensing, the received wideband signal is fed into a filter bank to channelize it into nonoverlapping subbands. In this case, the wideband sensing model becomes a collection of narrowband sensing models. Hence, the

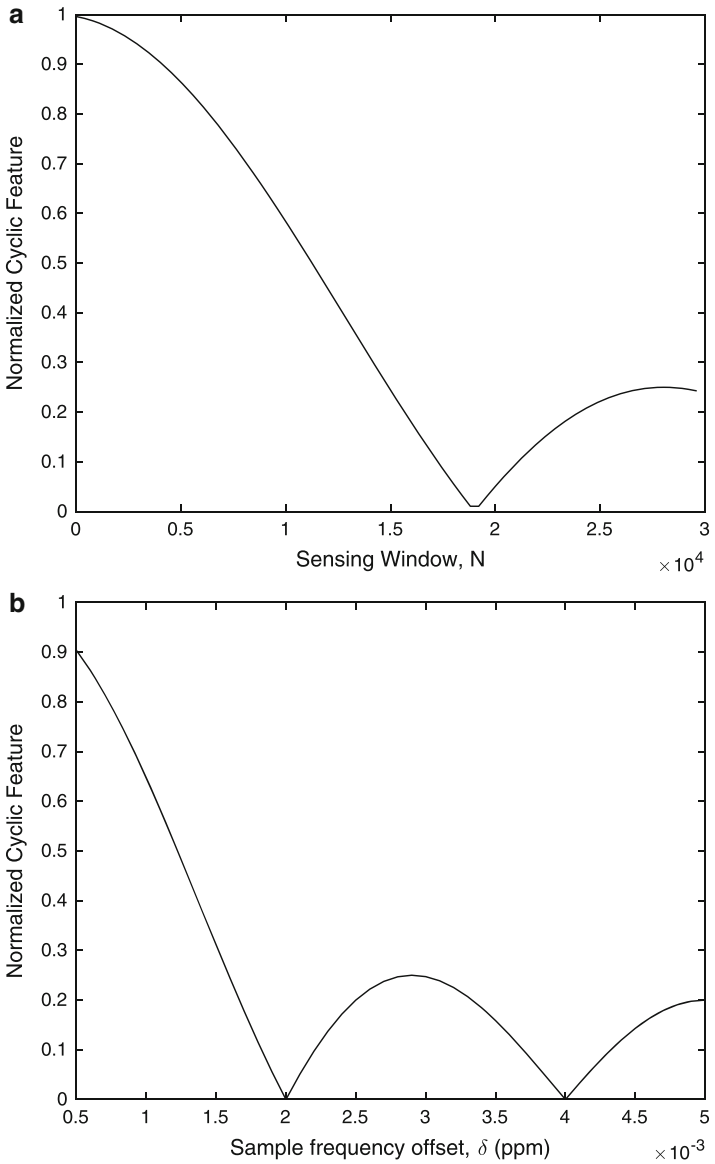

Fig. 13 Normalized cyclic frequency in the presence of SCOs

impairments discussed in the previous sections can still occur for each subband, e.g., noise uncertainty, imperfect synchronization, frequency offsets, etc.

Besides the aforementioned impairments, there are other impairments and design challenges inherited in wideband sensing. For instance, consider the general wideband sensing architecture shown in Fig. 15. Observe that the digital signal

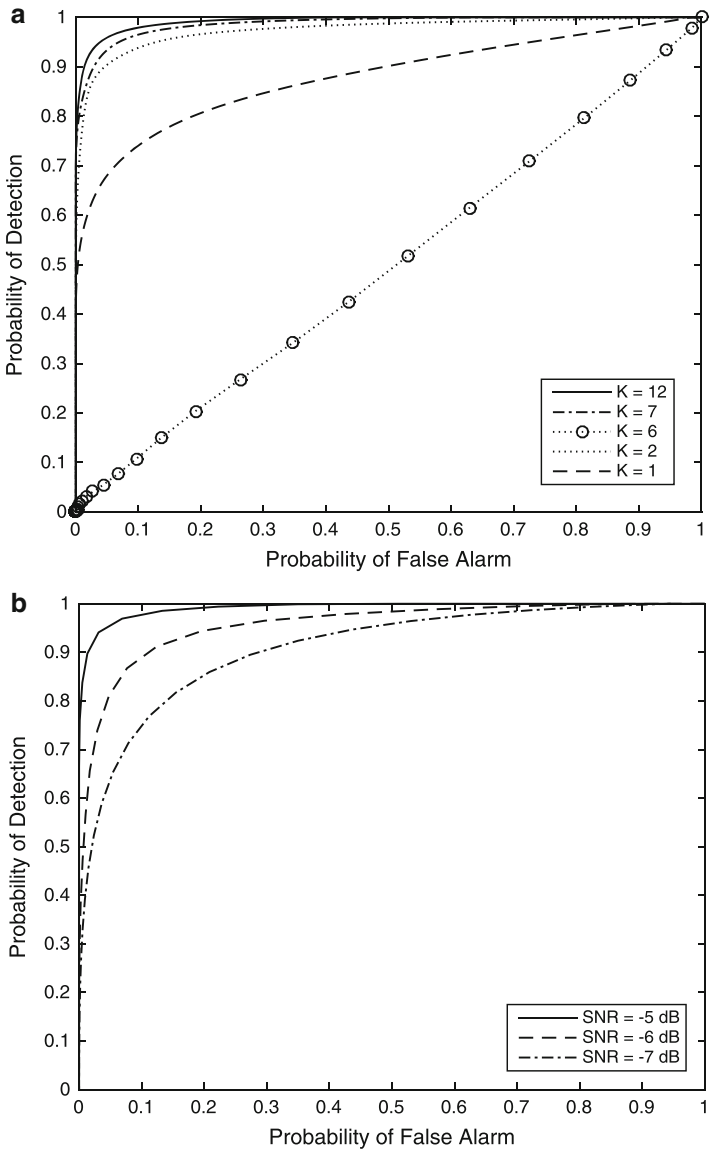

Fig. 14 Detection performance of the enhanced detector in the presence of CFOs and SCOs

processor (DSP) has the additional block *channelization* (or filtering) to convert the wideband signal into several narrowbands. Such filtering procedure is nonideal, causing leakage and interference in the channel of interest. In addition, due to the high bandwidth of the signal, the low-power amplifier (LNA) in the RF front-end may be pushed to operate in a nonlinear region, causing the wideband signal to be distorted. These two impairments will be the focus of this section.

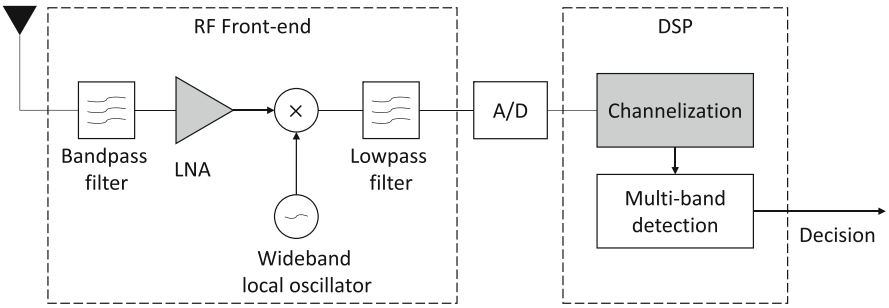

Fig. 15 A typical wideband sensing architecture

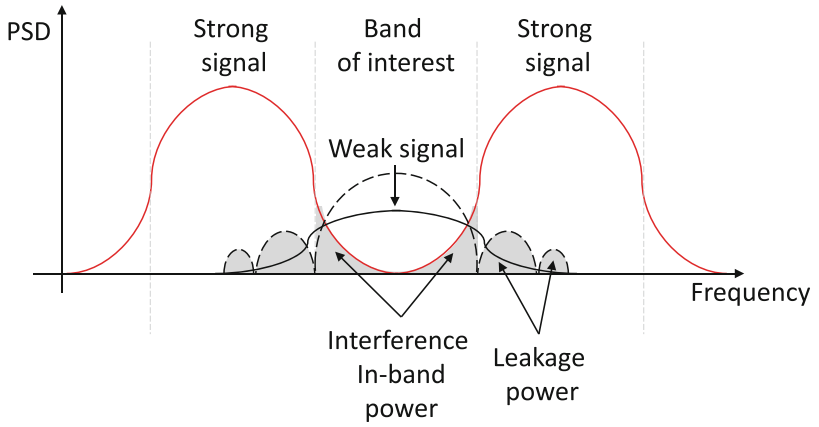

Fig. 16 Nonideal channelization and filtering result in adjacent interfering power

Adjacent Band Interfering Power

Consider a wideband signal that is composed of several nonoverlapping narrowband primary users, where for simplicity all bands are assumed to be of equal bandwidth and modulation scheme. Figure 16 illustrates an example of the power spectral density (PSD) of three nonoverlapping signals. Consider detecting the weak primary signal, which is adjacent to two strong primary signals. In an ideal architecture, each signal can be processed and detected independently of the other signals. However, in a practical receiver, there are two issues that arise. First, the filters in frequency domain are not perfectly rectangular, with sharp edges. Hence, the tail of a strong adjacent signal may introduce interference to the band of interest. In other words, even if the band of interest is unoccupied, the interference present in that channel may increase false alarms. Second, the channelization of the time-domain samples can introduce spectral leakage to other channels. These two issues will be collectively referred as *adjacent band interfering power* [26].

Modeling Adjacent Interference Power

The discrete-time domain received wideband signal $r(n)$ is a superposition of primary signals corrupted with noise. In other words, let $w(n) \sim \mathcal{N}(0, \sigma_w^2)$ be the noise samples; then $r(n) = \sum_{l=1}^{L} x_l(n) + w(n)$, where $x_l(n)$ is the transmitted primary signal over the l-th channel. The received signal can be decoupled into narrowband signals using the frequency domain representation of $r(n)$, which is computed by the normalized fast Fourier transform (FFT) as follows

$$R_k[m] = \frac{1}{N_F} \sum_{n=0}^{N_F-1} r(n + kN_F) e^{-2\pi nm/N_F}, \tag{34}$$

where k is the FFT block index, m is the frequency bin, and N_F is the FFT size. Each channel is represented by M bins. Using Parseval's theorem, the signal power in the l-th channel can be computed in frequency domain as

$$\Lambda_{E,l} = \frac{1}{KM} \sum_{k=0}^{K-1} \sum_{m} |R_k[m]|^2, \tag{35}$$

where the second sum term is over the l-th channel bins. The issue here is that $R_{k,l} = \sum_m |R_k[m]|^2$ is not the power of noise-only samples in case of H_0 (or noise-plus-signal samples in case of H_1) since now these samples are corrupted by the adjacent interference. In this case, the variance of the samples under H_0 is higher than σ_w^2, increasing false alarms if the threshold is not corrected. As a result, it is critical to not only reduce the interference but also to estimate it in order to correct the decision threshold.

Mitigating Adjacent Interference Power

The high-level overview of the procedure that mitigates the adjacent interference power is shown in Fig. 17. In the first step, the RF antennas are switched off to calibrate the noise power. In the second step, a coarse estimation of the PSD is performed, where each channel is sensed using an energy detector with the same number of samples. By measuring the power in each adjacent channel to the band of interest, the interfering power is estimated in the third step.

Once the interference power, $\sigma_{I,l}^2$, is estimated for each channel, the sensing time needed for each channel to perform a fine PSD estimation is optimized. The PSD estimation can be robustified against power leakages using a windowed FFT instead of using (34). In the windowed FFT, the received samples $r(n)$ are weighted first by a normalized window coefficient $\omega(n)$ before computing the FFT. This weighting, however, comes at the expense of reducing the spectral resolution. To maintain a high spectral resolution, a multitap-windowed FFT can be used instead. Mathematically, the multitap-windowed FFT is implemented as [26]

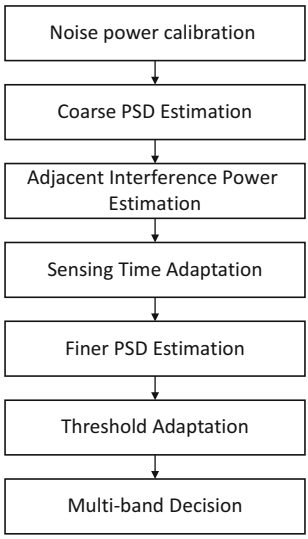

Fig. 17 A high-level procedure to mitigate adjacent interference power

$$\hat{R}_k[m] = \frac{1}{N_F} \sum_{n=0}^{N_F-1} \left(\sum_{p=0}^{P-1} \omega(n + pN_F) r(n + pN_F + kN_F) \right) e^{-2\pi nm/N_F}, \quad (36)$$

where p is the tap index and P is the total number of taps. In this case, the multitap-windowed energy detector is expressed as

$$\Lambda_{ME,l} = \frac{1}{N_l} \sum_{k=0}^{N_l-1} \sum_{m} |\hat{R}_k[m]|^2, \quad (37)$$

where N_l is the channel-specific sensing time. The sensing time differs across channels depending on the interfering powers in each channel. For a desired (P_f, P_d) pair and SNR sensitivity, N_l can be computed as follows:

$$N_l = \mu \left[\left(1 + \frac{\sigma_{I,l}^2}{\sigma_w^2} \right) \frac{Q^{-1}(P_f) - Q^{-1}(P_d)}{\text{SNR}} - Q^{-1}(P_d) \right]^2, \quad (38)$$

where μ is a fitting factor that can be calculated beforehand. This expression can be derived from the detection performance of the multitap-windowed energy detector, which is shown to be [25]

$$P_d = Q \left(\frac{1}{1 + \text{SNR} + \sigma_{I,l}^2/\sigma_w^2} \left[Q^{-1}(P_f)(1 + \sigma_{I,l}^2/\sigma_w^2) - \sqrt{\frac{N_l}{\mu}}\, \text{SNR} \right] \right). \quad (39)$$

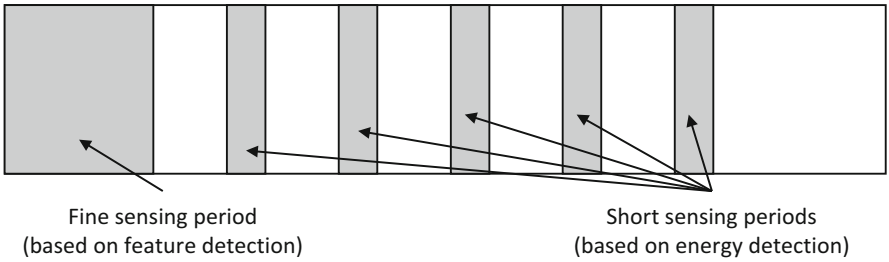

Fig. 18 The multitap-windowed energy detector

Once the PSD is finely estimated for each channel, the threshold is corrected before the multiband detection. Specifically, it is computed as

$$\lambda_l = \left(\sigma_w^2 + \sigma_{I,l}^2\right)\left(\sqrt{\mu/N_l}\,Q^{-1}(P_f) + 1\right). \tag{40}$$

Figure 18 illustrates the DSP used for the multitap-windowed energy detector.

Figure 19a shows the number of samples needed for $(P_f, P_d) = (0.1, 0.9)$ with variations on the interfere-to-noise-power ratio (INR), i.e., $\sigma_{I,l}^2/\sigma_w^2$. Three detectors are shown: the multitap-windowed detector; the windowed detector, i.e., $P = 1$; and the conventional one, i.e., no windowing is used. It is assumed that SNR $= -5$ dB, and the adjacent interferes are one bin away from the band of interest. It is evident that the multitap-windowed detector provides a significant reduction in the sensing time. Figure 19b shows the false alarm probability with variations of the INR. It is clear that adapting the threshold maintains the false alarm to 0.1 as desired.

RF Front-End Nonlinearity

In wideband sensing, the received signal may contain multiple primary user signals. Even if all primary signals are transmitted with the same power, at the CR receiver, these signals can have various power levels, depending on the distance of these users to the CR receiver and channel fading. In the presence of strong signals, the receiver's LNA may operate in a nonlinear region. Such nonlinearity introduces harmonics and intermodulation (IM) terms.

Figure 20 shows a receiver sensing a wideband spectrum that contains two strong signals, henceforth denoted as *blockers*, located at f_{b1} and f_{b2}. The signal of interest is located at $f_0 = 2f_{b2} - f_{b1}$. At the output of the LNA, the blockers introduce IM terms in the same band as the desired signal. These spurious terms remain after downconverting the wideband spectrum into baseband. Hence, the received samples, resulted from digitizing the baseband, are corrupted with the IM terms.

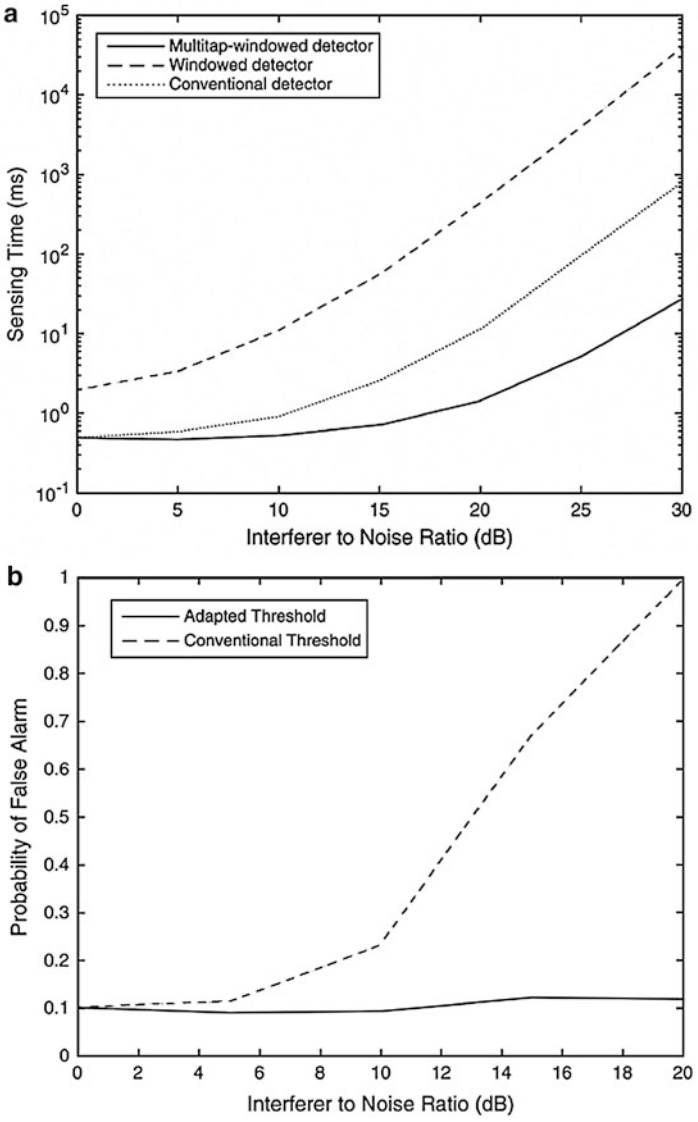

Fig. 19 Performance of different energy-based detectors in the presence of adjacent interference

Modeling LNA Nonlinearities

Different IM terms are generated due to the nonlinearity of the LNA. However, not all these terms affect the received samples. For instance, even-order IM terms lie outside the frequency support of the signal of interest, and hence they can be filtered efficiently. Similarly, odd-order nonlinearities are typically dominated by third-order nonlinearities, making the impact of high odd-order terms, e.g., 5th order

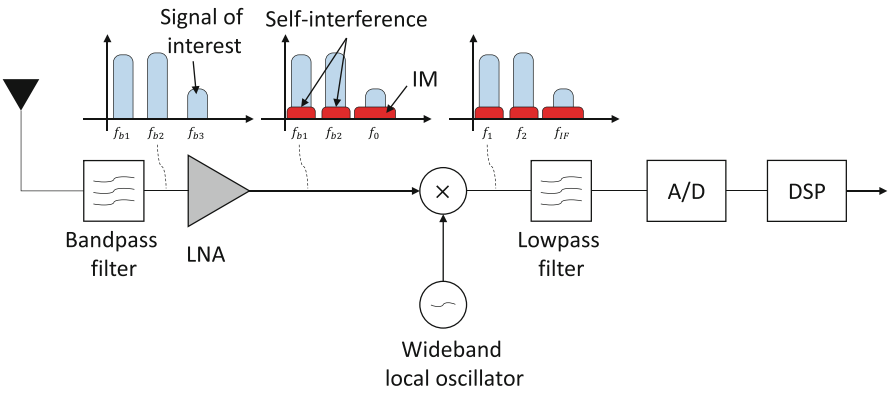

Fig. 20 LNA nonlinearity introduces IM terms

and higher, negligible. Hence, only third-order nonlinearities are considered in the subsequent analysis.

In the presence of nonlinearities, the received samples can be modeled as [19,30]

$$r(n) = \beta_1 x(n) + \beta_3 x(n)|x(n)|^2 + w(n), \tag{41}$$

where $x(n)$ is the wideband signal and $w(n)$ is an additive white Gaussian noise. Here, β_1 and β_3 are constants that are characteristics of the receiver front-end. Note that $\beta_1 x(n)$ is the linear term, whereas $\beta_3 x(n)|x(n)|^2$ is the third-order nonlinear term.

In the example of a single pair of blockers, it can be shown that the signal in the channel of interest is given by [30]

$$r_d(n) \approx \left(\beta_1 x_d(n) + \frac{3}{2}\beta_3 x_{b1}^*(n) x_{b2}^2(n)\right) e^{2\pi f_{if} n T_s} + w(n), \tag{42}$$

where $x_d(n)$ is the signal of interest, $x_{b1}(n)$ and $x_{b2}(n)$ are the two blockers, and $f_{if} = 2f_2 - f_1$ is the intermediate frequency, where the signal of interest resides. Note that $x_d(n)$ is present in H_1 and absent in H_0, and the CR receiver must determine which hypothesis is true. The challenge here is that in the presence of strong blockers, the IM terms can be stronger than the signal of interest, making the detection difficult.

Mitigating LNA Nonlinearities

By viewing the IM terms as interference, one may follow the same approach used in Fig. 17, where the sensing time and the decision threshold are adapted. This requires estimating the blocker power [19]. The challenge here is that estimating the blocker, say in f_{b1}, cannot be directly done by measuring the energy in that channel since it

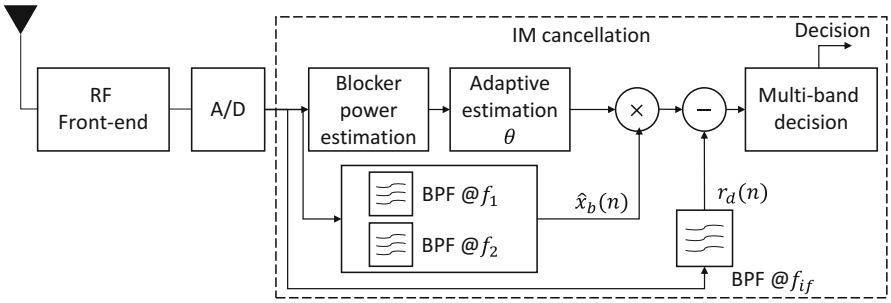

Fig. 21 An architecture that cancels the IM terms

does not only contain the blocker signal but also the self-interference as shown in Fig. 20. Indeed, recall the received signal:

$$r(n) = \underbrace{\left(\beta_1 x_d(n) + \frac{3}{2} x_{b1}^*(n) x_{b2}^2(n)\right) e^{2\pi f_{if} n T_s}}_{\text{signal at } f_{if}} + \underbrace{\bar{x}_{b1}(n) e^{2\pi f_1 n T_s}}_{\text{signal at } f_1} + \underbrace{\bar{x}_{b2}(n) e^{2\pi f_2 n T_s}}_{\text{signal at } f_2}$$

$$+ w(n), \tag{43}$$

where $\bar{x}_{bi}(n)$ is a function of the i-th blocker signal $x_{bi}(n)$, and it can be shown that [19]

$$\bar{x}_{b1}(n) = \beta_1 x_{b1}(n) + \frac{3}{2}\beta_3 x_{b1}(n)|x_{b1}(n)|^2 + 3\beta_3 x_{b1}(n)|x_{b2}(n)|^2. \tag{44}$$

The self-interference is hence defined as $\phi_i(n) = \bar{x}_{bi}(n) - \beta_1 x_{bi}(n)$. It is observed that estimating the blocker power cannot be implemented using a time average of $\bar{x}_{bi}(n)$ due to the presence of self-interference. Hence, a more advanced estimation is needed. Once estimated, the sensing time and the decision threshold can be adapted.

An alternative approach is to cancel the IM terms instead of estimating them since the latter approach typically requires increasing the sensing time to mitigate the presence of interference. Indeed, it is shown in (38) that $N_l \propto \sigma_{I,l}^2/\sigma_w^2$, which shows that higher interference power requires longer sensing duration in order to mitigate it.

The cancellation scheme is as follows. An additional band-pass filtering stage is applied to the received samples to estimate the IM terms that fall in the channel of interest, i.e.,

$$\hat{x}_b(n) = \frac{1}{\beta_1^3} \bar{x}_{b1}(n) \bar{x}_{b2}^2(n). \tag{45}$$

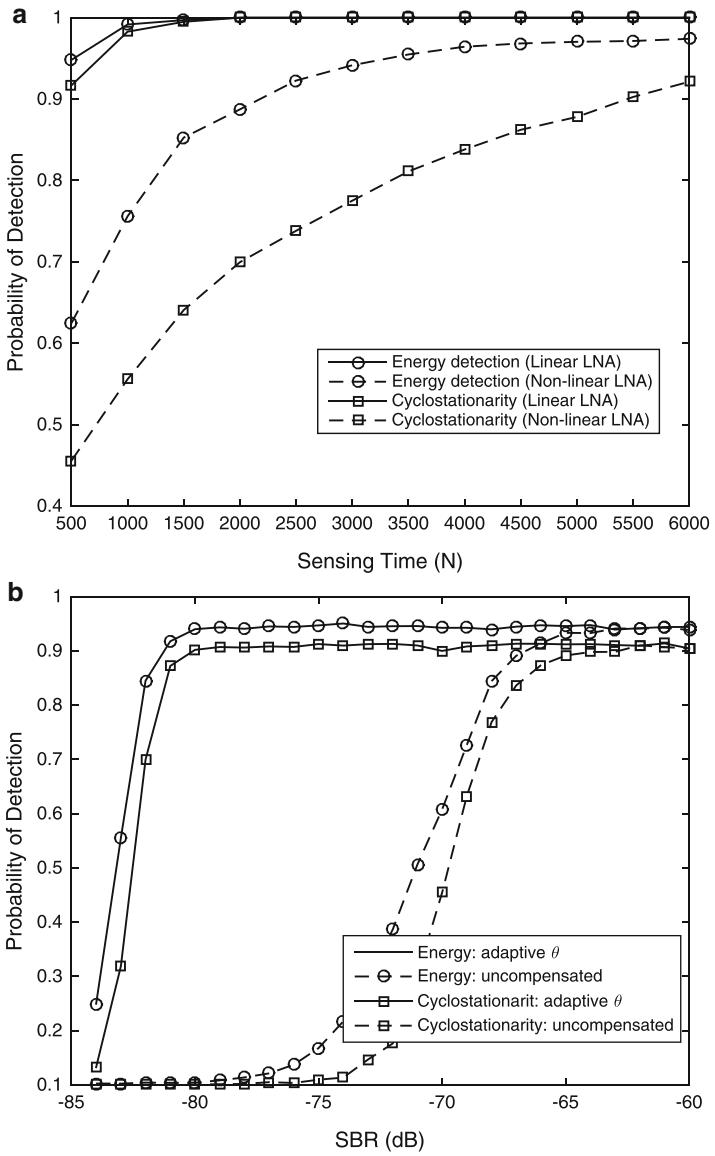

Fig. 22 Effect of nonlinearities on detection performance in the presence and absence of the compensation algorithm

Then, this estimate is subtracted from the received signal in the band of interest, i.e.,

$$\hat{r}_d(n) = r_d(n) - \frac{3}{2}\theta \hat{x}_b(n), \tag{46}$$

where θ is a parameter that can be optimized using an adaptive filter to minimize the IM term. The receiver architecture of this method is shown in Fig. 21.

Figure 22a shows the detection performance of the energy and cyclostationarity detectors in the presence and absence of LNA nonlinearities. It is assumed that the signal-to-blocker ratio (SBR) is set to -70 dB, SNR $= 3$ dB, and the thresholds are optimized to achieve $P_f = 0.1$. It is observed that the detection performance is degraded when the LNA operates in the nonlinear regime, making it critical to compensate for this impairment. Figure 22b shows the probability of detection with variations of the SBR, where the compensation algorithm presented in Fig. 21 is used with adaptive θ [19]. It is assumed that $N = 500$ and SNR $= 3$ dB. Using the cancellation algorithm, the performance significantly improves particularly when the blocker power is strong relative to the signal power.

Summary

Spectrum sensing is an integral component of the cognitive radio system. To this end, modeling the different sensing techniques is critical to ensure reliable detection. While spectrum sensing has been largely studied using the classical detection modeling tools, there are key differences that are inherited to cognitive radio. In particular, spectrum sensing should be robust in negative SNR regimes, where measurements have shown that the detection performance may deviate from that predicted by the theoretical expressions. Indeed, in negative SNRs, noise power estimation becomes difficult and synchronization leads to frequency offsets. In addition, it is shown that converting the wideband sensing problem into several narrowband sensing problems requires additional care due to the adjacent interfering power resulted from the presence of strong signals and the IM terms resulted from the RF front-end nonlinearities.

Abstract

Spectrum sensing is the process of determining if a spectrum slot is occupied or not by a primary signal. This tutorial emphasizes energy detection based spectrum sensing and provides a broad overview of the tools necessary for performance analysis of several spectrum sensing algorithms. A detailed description of the spectrum sensing problem is provided as a binary hypothesis test. The main parameters of interest – decision statistic, detection, and false-alarm probabilities and the decision threshold – are discussed. These parameters of the energy detector, which computes the energy of the received signal, are described. The use of the central limit theorem (CLT) to achieve energy detection with prescribed performance level is discussed. The receiver operating characteristic (ROC) curve and area under the curve (AUC) are described. Fading, a fundamental wireless channel impairment, can be mitigated with multiple antenna techniques, which provide spatial diversity gains. The performance of the energy detector with two low-complexity diversity techniques is described. The performance is analyzed for Rayleigh fading, for spatial correlation, and in the high signal-to-noise ratio (SNR) regime. General analytical techniques are highlighted. Double-threshold energy detector, P-norm detector, and energy detection for full-duplex nodes are described. Alternative to energy detection includes cyclostationary detection, matched filter-based detection, and waveform-based detection. These methods are briefly discussed. Spectrum sensing is an essential part of smart grid, Internet of things, and cognitive radio. An overview is provided.

Introduction

The growth of global mobile wireless networks is exponential and robust. It is driven by the use of smartphones, tablets, laptops, and other wireless devices that allow subscribers to browse the Web, use email, and download videos, multimedia, and applications. For example, by 2021, the monthly mobile data traffic will exceed 49 exabytes, mobile devices per capita will be 1.5, the wireless connection rate will increase to 20 Mbps, over 50% of mobile connections will be from smartphones, and mobile-to-mobile connections will be the majority [1].

Consequently, increasing demands for wireless mobile broadband are likely to outstrip the available radio spectrum. For example, while the 0.1–5 GHz band is perhaps the most advantageous for communications, much of it has already been allocated to about 40 different radio services such as fixed, mobile, satellite, amateur, radio navigation and radio astronomy. In fact, International Telecommunication Union (ITU) divides spectrum in to bands and assigns them to these services in order to avoid radio interference [30]. Moreover, although frequencies above 5 GHz offer the potential vast bandwidths, high attenuation, blockage, and other impairments pose significant difficulties. Therefore, spectrum congestion may hem the rapid growth of next-generation (e.g., 5G) wireless networks and users.

One potential solution is to note that much of the current licensed/assigned spectrum remains unused at different times and/or locations. Those temporary spectrum slots (aka spectrum holes or white spaces) [19, 39] can be as high as 15–85% of the licensed spectrum [29]. Radio nodes that can identify and utilize such spectrum holes while minimizing potential interference on licensed users (aka primary users) are called cognitive radios (aka secondary users). They clearly improve overall spectrum usage, alleviating the need for new spectrum. The process of identification of spectrum holes is called spectrum sensing.

Depending on when a secondary user accesses a primary spectrum slot regardless if it is occupied or not, there are three different cognitive radio paradigms [30]:

1. Interweave – secondary user transmits only in an unused spectrum hole currently unoccupied by a primary user. To do so, secondary user must know if primary signals are present or absent in the frequency band. Thus, this paradigm clearly needs spectrum sensing.
2. Underlay – secondary user is allowed to transmit in both unused and used spectrum slots. In the latter, secondary user must adjust its transmission power such that interference on primary network is below a certain threshold. Again, the secondary requires spectrum sensing, for instance, to determine its transmit power levels.
3. Overlay – the secondary access mechanism is similar to that of underlay mode. However, secondary user earns the right to spectrum access by helping to enhance primary communication capability and by taking suitable measures to limit interference on the primary network. To achieve these two goals, secondary user needs to know some characteristics of primary signals (e.g., modulation formats, frequency, and more) in advance. This information is then used to improve communication quality of both the primary and secondary users. For example, secondary user may take proactive signal coding solutions to cancel interference on primary network. To enhance primary rates, secondary user can relay primary data. Thus, in this paradigm, secondary user must acquire much more primary information than is the case with overlay and underlay modes. Nevertheless, a critical part of the overall acquisition process is spectrum sensing.

Overall, since spectrum is essential to all the three paradigms, solid understanding of the performance of sensing algorithms in different propagation environments and in network configurations is necessary. The reliability and performance can be quantified with rigorous analytical techniques. Before discussing the basics of the performance analysis, it should be mentioned that standards with spectrum sensing include IEEE 802.22 WRAN (wireless regional area network) and its amendments, IEEE 802.11af for wireless LANs, IEEE 1900.x series, and licensed shared access (LSA) for LTE mobile operators [17]. In particular, WRAN is cognitive radio designed to operate in empty TV bands, which provides additional spectrum for wireless mobile networks on a non-interfering basis.

This tutorial aims to provide a broad overview of the tools necessary for performance analysis of spectrum sensing algorithms, with particular emphasis on energy detection. The tutorial is organized as follows:

1. The spectrum sensing problem is formulated as a binary hypothesis test. The decision statistic, detection, false-alarm probabilities, and decision threshold are discussed. The energy detector, one of the most common sensing algorithms, is described in terms of its basic performance parameters. The use of CLT to estimate the number of samples needed for the energy detection with prescribed performance level is discussed. The ROC curve and AUC are described.
2. Fading is mitigated by the use of multiple antenna techniques, which provide spatial diversity gains. The performance of the energy detector with selection and combining diversity techniques is described. Moreover, the performance is analyzed for Rayleigh fading, for spatial correlation, and in the high-SNR regime. General analytical techniques based on probability density function (PDF) and moment generating function (MGF) are highlighted.
3. Double-threshold energy detector, P-norm detector, and energy detection for full-duplex nodes are described. Alternative to energy detection includes cyclostationary detection, matched filter-based detection, and waveform-based detection. These methods are briefly discussed.
4. An overview of spectrum sensing for smart grid, Internet of things, and cognitive radio is provided.

Spectrum Sensing Problem Formulation

Clearly, accurate, reliable, and low-complexity spectrum sensing is essential for opportunistic spectrum access. To this end, secondary nodes must detect the presence/absence of a primary signal in a given frequency band $[f_0, f_1]$ for a particular time slot. This process is commonly called spectrum sensing. It can be readily formulated as a binary hypothesis test. For example, the complex signal observed at time t by the secondary user in the desired band $[f_0, f_1]$ may be modeled as [47]

$$y(t) = \begin{cases} n(t) & : H_0 \\ h(t)s(t) + n(t) & : H_1 \end{cases} \tag{1}$$

where $n(t)$ is an additive complex white Gaussian noise process, $h(t)$ represents a fading process (e.g., nonfading means $h(t) = 1$), and $s(t)$ is a signal transmitted by the primary node [47]. The sensing decisions are made using $N \gg 1$ samples of $y(t)$. The choice of N will be discussed later. Starting with this observational model, it is possible to formulate a wide array of spectrum sensing techniques based on signal energy, matched filtering, cyclostationary features, covariances, and others. These will be discussed subsequently.

Let $y(k)$ be the k-th ($k = 1, 2, \ldots, N$) sample of $y(t)$. All the samples are placed in to the vector $\mathbf{y} = [y(1), \ldots, y(n)]'$. These samples are used to compute a decision statistic $T(\mathbf{y})$. The hypothesis test for spectrum sensing is then given by

$$\text{if} \begin{cases} T(\mathbf{y}) < \lambda & \text{accept} \ : H_0 \\ T(\mathbf{y}) > \lambda & \text{accept} \ : H_1 \end{cases} \tag{2}$$

where $0 < \lambda < \infty$ is called the decision threshold. The reliability associated with the decision the rule (2) can be characterized by probability of detection P_d and probability of false alarm P_f. The former is the probability of detecting the primary signal when it is actually present in the frequency band, $[f_0, f_1]$. Consequently, large detection probability is highly desirable. Mathematically, it is a conditional probability given by

$$P_d = \Pr(T(\mathbf{y}) > \lambda | H_1).$$

Equivalently, the complement of this probability $P_{md} = 1 - P_d$ is also widely used for illustration and design purposes.

On the other hand, the test might incorrectly decide that $s(t)$ is present in $[f_0, f_1]$ when it actually is not, and this false-alarm probability may be written as

$$P_f = \Pr\left(T(\mathbf{y}) > \lambda | H_0\right).$$

The exact values of P_d and P_f depend on how $T(\mathbf{y})$ is constructed using received samples, channel estimates, propagation characteristics, the choice of the threshold, and other information. The false alarms will clearly reduce spectrum access opportunities for secondary users, and hence the expected improvements in spectral efficiency are not materialized. This problem may be alleviated by choosing the decision threshold λ for an optimum balance between P_d and P_f. However, this requires knowledge of noise and detected signal powers. Estimation of both noise power and signal power can be challenging as they are depend on evolving transmission standards and the locations of primary and secondary nodes. In practice, with the knowledge of noise variance, the threshold is chosen to obtain a certain false-alarm rate (section "Threshold Optimization Techniques").

Notations

$\mathbb{P}(\cdot)$, $\mathbb{E}(\cdot)$, $\mathrm{Var}(\cdot)$ denote the probability measure, expectation, and variance. $\Gamma(z) = \int_0^\infty t^{z-1}e^{-t}dt$, $\Gamma(z, x) = \int_x^\infty t^{z-1}e^{-t}dt$, ${}_2F_1(a, b; c; z) = \sum_{k=0}^\infty \frac{(a)_k (b)_k (z)^k}{(c)_k k!}$ is the Gauss hypergeometric function, with $(x)_y$ denoting the Pochhammer symbol. If $X_1, \ldots, X_k$ are independent Gaussian $N(0, \mu_k)$ random variables, then $Y = \sum_{i=1}^k X_i^2$, is noncentral chi-square, $\chi_k^2(\delta)$, with k degrees of freedom and $\delta = \sum \mu_k^2$. If all $\mu_k = 0$, Y is central chi-square, χ_k^2. The generalized

Marcum-Q function is $Q_l(a,b) = \int_b^\infty \frac{x^l}{a^{l-1}} e^{-(x^2+a^2)/2} I_{l-1}(ax)dx$, where $I_l(x)$ is the l-th order modified Bessel function. The Gaussian-Q function is $Q(x) = \int_x^\infty \frac{e^{-t^2/2}}{\sqrt{2\pi}} dt$.

Classical Energy Detector

As mentioned before, although the exponential growth of mobile data traffic is likely to outstrip the available spectrum, licensed users may not be active at a given spectrum slot (e.g., 54–806 MHz TV band), a time, and a location. To access those spectral holes, secondary user may first sense them via the most popular spectrum sensing algorithm: energy detector, which has thus attracted massive wireless research interest due to its simple structure and low hardware complexity [7].

This detector computes a proxy for the energy of received signal over the spectrum slot that is being tested. The basic concept is that the computed energy must be sufficiently high if the slot contains primary signals; otherwise, the slot contains noise only. Thus, this detection problem can be formulated as a special case of the hypothesis test (2) with the decision statistic given by

$$T(\mathbf{y}) = \sum_{i=1}^{N} |y_i|^2 \tag{3}$$

where y_i is the i-th ($i = 1, 2, \ldots, N$) sample of $y(t)$ and N is the number of samples. It can be readily shown that $T(\mathbf{y})$ conditional on H_0 and H_1 are distributed as central chi-square χ^2_{2N} and noncentral chi-square $\chi^2_{2N}(2\gamma)$, respectively, both with $2N$ degrees of freedom. The noncentrality parameter is 2γ where γ is the SNR. For a static channel scenario, false-alarm and detection probabilities may be expressed as

$$P_f = \Gamma(N, \lambda/2)/\Gamma(N) \tag{4}$$

$$P_d = Q_N(\sqrt{2\gamma}, \sqrt{\lambda}), \tag{5}$$

where $\Gamma(a,b)$ and $Q_N(a,b)$ are incomplete Gamma function and the Marcum-Q function, respectively. The choice of a suitable value for N has critical ramifications on both performance and complexity. The method of choosing N will be discussed in Sect. "Use of the CLT." The SNR γ is a fixed quantity if the channel is static (e.g., $h(t) = 1$); otherwise, it will be modeled as a random variable (this case will be treated subsequently).

The Eqs. (4) and (5) connect false-alarm and missed-detection probabilities with the SNR, the decision threshold, and the number of samples. Thus, many design choices and requirements can be made depending on specific requirements. For example, very low SNR is -20 dB with a signal power of -116 dBm and a noise

floor of −96 dBm [7]. For this reason, IEEE 802.22 prescribes both P_d and P_f be less than 0.1. While energy detection performs well at moderate and high SNRs, low-SNR operation typically requires large N, which impacts the sensing and processing time. For example, IEEE 802.22 limits the maximal detection latency to 2 s which may include sensing time and subsequent processing time. This maximal time limit is critical at low-SNR spectrum sensing.

In the literature, the detection probability P_d has also been analyzed extensively, treating propagation characteristics, multiple antennas, cooperative diversity, and other factors [3, 5, 16, 20, 42]. However, exact analysis tends to be complicated (special functions, infinite series, and so on). Moreover, since closed-form P_d for more complicated versions of energy detection appears intractable, several computational methods have been developed [40]. To detect potential spectrum opportunities rapidly, sensing algorithms must operate with the fewest possible number of samples and offer high reliability. Therefore, selection of a suitable number of samples, N, is considered next.

Use of the CLT

When the number of samples N is sufficiently large, CLT can be used instead of the exact equations (4) and (5) [7]. Thus, false-alarm and detection probabilities may be approximated as

$$P_{f,CLT} \approx Q\left(\frac{\lambda - 2N}{2\sqrt{N}}\right) \tag{6}$$

$$P_{d,CLT} \approx Q\left(\frac{\lambda - 2N(1+\gamma)}{2(1+\gamma)\sqrt{N}}\right) \tag{7}$$

where primary signal $s(t)$ is assumed to be zero-mean, complex Gaussian and $Q(x)$ is the standard Gaussian upper tail probability function. Although it is possible to consider different models for $s(t)$, the details are omitted for brevity. This approximation has been utilized to investigate sensing-throughput tradeoff [28], multiple-band spectrum sensing [35], low-SNR spectrum sensing [6, 31], and numerous others. However, it may not be accurate enough for small sample sizes [37].

Next the above is used to determine the suitable sample size N. Suppose the prescribed performance point is (P_f, Pd). By using (6) and (7), and solving for N, it turns out that

$$N \approx \left[\gamma^{-1}Q^{-1}(P_f) - (1+\gamma^{-1})Q^{-1}(P_d)\right]^2.$$

Based on the CLT, this estimate may be accurate only when N is sufficiently high but not when P_f is low and P_d is high [37]. To get around these challenges, [37]

has developed an estimate of N using the cube-of-Gaussian approximation (CGA), and further results have been reported in [9, 38].

Threshold Optimization Techniques

In (2), the key parameter is the decision threshold, λ. This threshold must be optimized for each detection technique to improve its performance. The threshold may be chosen by considering P_f and P_d. A common practice is to set the threshold is based on a constant false-alarm probability, say, P_f. For example, then based on the normalized threshold is

$$\lambda^* = 2\sqrt{N}\left(Q^{-1}(P_f) + \sqrt{N}\right)$$

which must adjusted based on the variance of the additive noise. Note that P_d and P_f are functions of λ. In general, it is chosen to make P_d large and P_f small as possible (e.g., in IEEE 802.22 WRAN needs $P_f \leq 0.1$ and $P_d \geq 0.9$). More generally, the threshold may be optimized by considering noise level, total error rate, and other factors [7].

ROC Curves

Although detection (or missed detection) and false-alarm probabilities are key measures, detection capability is typically illustrated with a so-called ROC curve – a plot of the detection probability versus the false-alarm probability when the threshold varies from 0 to ∞. Thus, the ROC curve is defined parametrically as pair (x, y) with

$$x = P_f(\lambda) \quad y = P_d(\lambda), \quad 0 \leq \lambda < \infty. \tag{8}$$

A set of ROC curves for the basic energy detector ($N = 10$) in a static channel is depicted in Fig. 1. Each ROC curve corresponds to a particular SNR, γ. The upper left corner or coordinate (0,1) of the ROC space, representing 0% false alarms and 100% detection, depicts the best possible detector. The diagonal line ($P_d = P_f$) from the left bottom to the top right corners depicts a random detector such as detection by flipping coins (heads or tails). The further away is the ROC curve from the diagonal, the better is the detector performance. The ROC figures have been widely used to illustrate the energy detector performance for small-scale and large-scale fading, diversity reception techniques, and cooperative spectrum sensing [7].

However, a single summarizer of detection capability is also desirable. This is called area under the ROC curve (AUC) [2]. The AUC is a number between 0 and 1, and a perfect detector has an AUC of 1. Moreover, an AUC of 0.5 represents a random detector (e.g., coin flip). In fact, the more far AUC is from 0.5, the better

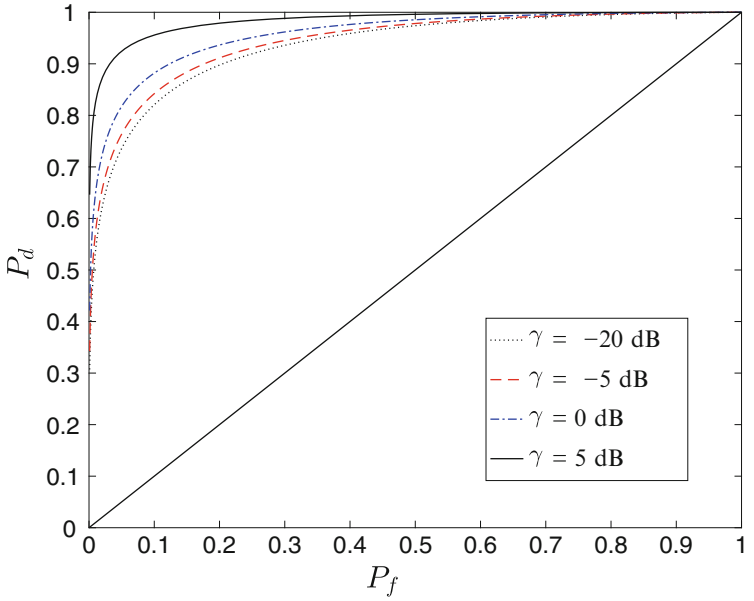

Fig. 1 ROC for energy detection

is performance. If AUC is below 0.5, the detector output must be inverted. For example, if AUC is zero, the inverted detector output yields a perfect decision. The AUC may be evaluated as

$$\mathscr{A} = \int_0^1 P_d \, dP_f. \tag{9}$$

By substituting the values of P_d and P_f from (5) and (4), the AUC of classical energy detector can be obtained as [2]

$$\mathscr{A}(\gamma) = 1 - \sum_{k=0}^{u-1} \frac{1}{2^k k!} \gamma^k e^{\frac{-\gamma}{2}} + \sum_{k=1-u}^{u-1} \frac{\Gamma(u+k)}{2^{u+k}\Gamma(u)} e^{-\gamma} \, {}_1F_1\left(u+k; 1+k; \frac{\gamma}{2}\right) \tag{10}$$

where ${}_1F_1(a, b, c)$ is the regularized confluent hypergeometric function. The expression (10) shows that as SNR tends to infinity, the AUC approaches one, which is desirable.

AUC and complementary AUC (CAUC) (e.g., $1 - \mathscr{A}$) have been derived for an energy detector with no diversity reception, with several popular diversity schemes, with channel estimation errors, with fading correlations, and with relay signaling [2] and [4]. However, the analysis of [2,4] may not work for cooperative spectrum sensing. Moreover, special functions (e.g., Marcum-Q and confluent and regularized confluent hypergeometric functions) in P_d make closed-form evaluation

of the AUC rather intractable. To circumvent these drawbacks, AUC can be related to the MGF of the received SNR. The resulting calculations are simple, avoid special functions, and are readily available in modern mathematical platforms (e.g., Mathematica and MAPLE). This approach will be developed in Sect. "MGF-Based Approach."

Performance in Fading Channels

Wireless channel impairments include small-scale fading, shadowing, and path loss [18,32]. Modeling these impairments is critical to characterize and analyze spectrum sensing algorithms. Small-scale fading is characterized by various models such as Rayleigh, Nakagami-m, and Rician [32]. A detailed sensing performance analysis for these channels is beyond the scope of this tutorial. Moreover, although fading does not impact P_f (4), P_d (5) must be averaged over the distribution. For instance, the performance under Rayleigh fading (i.e., $f_\gamma(x) = \frac{1}{\bar{\gamma}} e^{-x/\bar{\gamma}}, 0 \le x < \infty$) is given as [16,21]

$$\overline{P}_d = e^{-\frac{\lambda}{2}} \sum_{i=0}^{N-2} \frac{\left(\frac{\lambda}{2}\right)^i}{i!} + \left(\frac{1+\bar{\gamma}}{\bar{\gamma}}\right)^{N-1} \times \left[e^{-\frac{\lambda}{2(1+\bar{\gamma})}} - e^{-\frac{\lambda}{2}} \sum_{i=0}^{N-2} \frac{\left(\frac{\lambda\bar{\gamma}}{2(1+\bar{\gamma})}\right)^i}{i!} \right]. \quad (11)$$

A set of ROC curves for the basic energy detector ($N = 10$) in a Rayleigh fading channel is depicted in Fig. 2. Each ROC curve corresponds to a particular SNR, $\bar{\gamma}$. The diagonal line ($\bar{P}_d = P_f$) from the left bottom to the top right corners depicts a random detector such as detection by flipping coins (heads or tails). The further away is the ROC curve from the diagonal, the better is the detector performance. Thus, note that as $\bar{\gamma}$ increases, the ROC moves away from the diagonal and toward the (0,1) point, which is the ideal performance.

Spatial Diversity for Spectrum Sensing

Spatial diversity (e.g., multiple antennas) can be exploited to mitigate fading. In the literature, a large body of research has investigated the use of $L > 1$ antennas to enhance the performance of spectrum sensing (see [7] and references therein). With multiple antenna systems, channel states of individual antenna branches and spatial correlations must be considered. These factor will complicate the analysis and operation of common energy detector. Nevertheless, two diversity schemes are briefly described next. In square-law combiner (SLC), the individual energy measurements of different antennas are added together to form the total. The decision statistics is thus $T(\mathbf{y}) = \sum_{i=}^{L} Y_i$ where Y_i is the decision statistic for the i-th antenna branch ($i = 1, \ldots, L$). The equivalent SNR is thus given by $\gamma_{SLC} = \sum_{i=1}^{L} \gamma_i$ where γ_i is the SNR associated with the i-th antenna branch

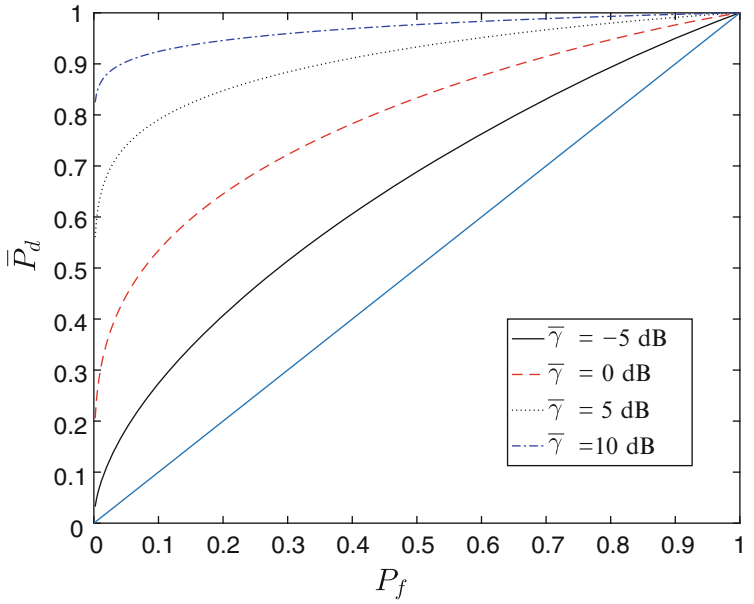

Fig. 2 ROC for energy detection in a Rayleigh channel

($i = 1, \ldots, L$). The final decision is made after comparing $T(\mathbf{y})$ against the threshold. The false-alarm and the detection probabilities are thus obtained as [16]

$$P_{f,SLC} = \frac{\Gamma(LN, \frac{\lambda}{2})}{\Gamma(LN)},$$

$$P_{d,SLC} = Q_{LN}\left(\sqrt{2\gamma_{SLC}}, \sqrt{\lambda}\right).$$

In square-law selection (SLS), only the branch with the largest energy is selected. The decision statistics is thus $T(\mathbf{y}) = \max(Y_1, \ldots, Y_L)$ where Y_i is the decision statistic for the i-th antenna branch ($i = 1, \ldots, L$). Thus, false-alarm and detection probabilities can be obtained as [16]

$$P_{f,SLS} = 1 - \left[1 - \frac{\Gamma\left(N, \frac{\lambda}{2}\right)}{\Gamma(N)}\right]^L$$

$$P_{d,SLS} = 1 - \prod_{i=1}^{L}\left[1 - Q_N\left(\sqrt{2\gamma_i}, \sqrt{\lambda}\right)\right].$$

A set of ROC curves for the basic energy detector ($N = 10$) with SLC in Rayleigh fading is depicted in Fig. 3. Each ROC curve corresponds to a particular

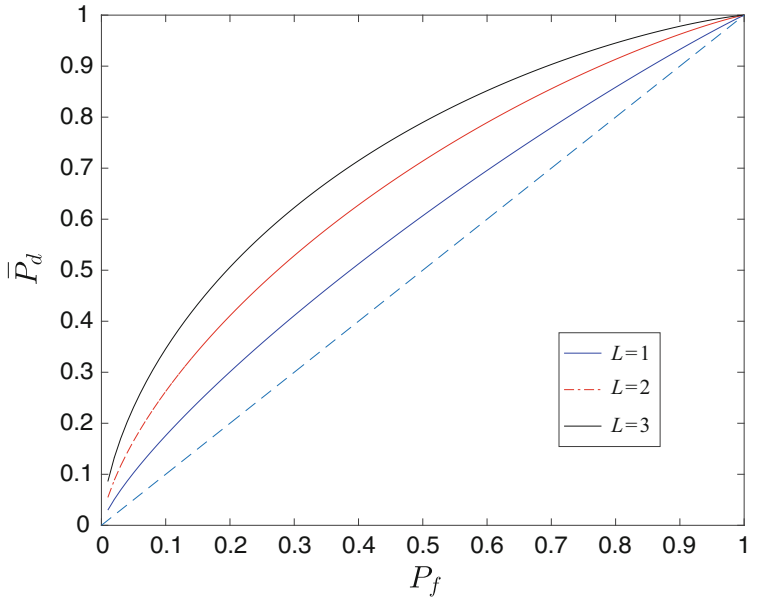

Fig. 3 ROC for energy detection and SLC for different numbers of antennas

number of antennas, L. The diagonal line ($\bar{P}_d = P_f$) from the left bottom to the top right corners depicts a random detector such as detection by flipping coins (heads or tails). The further away is the ROC curve from the diagonal, the better is the detector performance. Thus, note that as L increases, the ROC moves away from the diagonal and toward the (0,1) point, which is the ideal performance. This suggests that the spatial diversity of SLC improves the energy detector performance.

Thus far, it has been seen that the average of P_d in fading channels requires the PDF of γ. In many wireless problems, this PDF can be a highly complex expression or even intractable.

MGF-Based Approach

To avoid such difficulties, the MGF of γ can be utilized for analysis [43–45]. The reason of this wide applicability is that MGF of a sum of independent random variables is equal to the product of individual MGFs [25, 26].

Using the alternative representation of the Marcum-Q function [44], the average of P_d (5) in a multiple antenna system can be expressed as

$$\overline{P}_d = \frac{e^{-\frac{\lambda}{2}}}{2\pi j} \oint_{\Delta} M\left(1 - \frac{1}{z}\right) \frac{e^{\frac{\lambda}{2} z}}{z^q (1-z)} dz \tag{12}$$

where MGF $M(s) = \mathbb{E}(e^{-s\gamma})$, $j = \sqrt{-1}$, $\triangle$ is a circular contour of radius $0 < r < 1$ that encloses origin, and q is a positive integer which depends on N, the number of antennas and diversity combining method. For example, with SLC described earlier, $q = LN$. The integral expression (12) can thus be customized for many diversity systems where the MGF is readily available.

This equation (12) can also be used to derive average AUC under different fading channels. Since $\bar{\mathscr{A}} = \int_0^1 \bar{P}_d dP_f$, average AUC is obtained as

$$\bar{\mathscr{A}} = \frac{1}{j2\pi} \oint_{\triangle} M\left(1 - \frac{1}{z}\right) \frac{1}{z^q (1-z)(z-2)^N} dz. \tag{13}$$

Both (12) and (13) are versatile and provide a powerful basis for analysis of energy detector with various diversity schemes (see [7] for further examples).

Antenna Correlation

Standards like the Long-Term Evolution (LTE) Advanced, WiMax, and International Mobile Telecommunications (IMT) Advanced have promised high data rate services; they motivate the use of multiple antenna terminals. With such secondary nodes, the antenna correlation is an important factor that affects the overall performance of energy detection. To illustrate the impact of antenna correlation, energy detection with SLC can be analyzed. The branch SNR's γ_i $(i = 1, \ldots, L)$ are related by a correlation matrix. The PDF of SNR may be written as

$$f_{\gamma_{SLC}}(x) = \frac{1}{\bar{\gamma}} \sum_{k=1}^{L} \frac{\pi_k}{\mu_k} e^{-x/(\bar{\gamma}\mu_k)}, \quad 0 \le x < \infty \tag{14}$$

where μ_k is the k-th eigenvalue of the correlation matrix and $\pi_k = \prod_{i \neq k} \frac{\mu_k}{\mu_k - \mu_i}$. The correlation matrix is called exponential if the ij-th entry $\rho_{ij} = \rho^{|i-j|}$. However, this model is not universal. For example, the correlation depends the placement, spacing and height of antenna elements, signal incident angles, and so on. Another common model is the Toeplitz structure where $\rho_{ij} = [\rho_{|i-j|}]$ with $\rho_0 = 1$.

For illustration purposes, consider two correlated (ρ) antennas. The two eigenvalues can be shown to be

$$\mu_1, \mu_2 = (1 \pm \rho). \tag{15}$$

The ROC curves for this system are shown in Fig. 4. It is clear that the correlation penalizes the performance. That is, as ρ increases, the ROC curves move toward the diagonal line. The impact of correlation is not high because this is

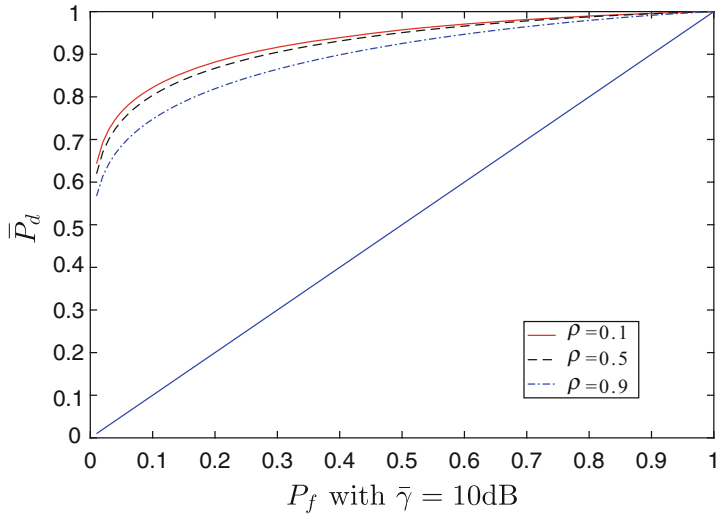

Fig. 4 ROC for SLC energy detection with antenna correlation

a system with two branches only. A higher impact can be expected for systems with more antennas.

Asymptotic Performance Measures

As mentioned before, the SNR γ in a fading environment is a random variable, and hence average of P_d over the distribution of γ, denoted by $\overline{P}_d$, is often computed. The details of the averaging process are as follows. First, $P_d(\gamma)$ for a fixed channel realization is given in (5). It is convenient to express SNR as the product $\gamma = \overline{\gamma}\beta$, where $\overline{\gamma}$ is the average SNR (in static channels $\beta = 1$ and $\gamma = \overline{\gamma}$), and β is a nonnegative random variable, which accounts for system conditions including channel propagation conditions, antenna diversity, interference, and others. Thus, β is characterized by PDF $f(\beta)$. In the second step, $P_d(\gamma)$ is integrated over $f(\beta)$.

The average probability detection can thus be expressed as

$$\overline{P}_d = \int_0^\infty Q_N(\sqrt{2\overline{\gamma}\beta}, \sqrt{\lambda}) f(\beta) d\beta. \tag{16}$$

Thus, the main challenge in (16) is the lack of closed-form solutions for integrals involving the Marcum-Q function or tedious analytical expressions involving complicated special functions and/or infinite series [33]. One solution is to use the MGF approach (12).

An alternative solution is to simplify $f(\beta)$ in order to facilitate the evaluation of (16) in simple yet accurate form. To this end, an idea of Wang and Giannakis [49] may be utilized. The basic concept is that in the high-SNR regime (e.g., $\bar{\gamma} \to \infty$),

the integral (16) can be tightly approximated by simply using just the first term of the Taylor series expansion of $f(\beta)$ at $\beta = 0$. Thus, let exact PDF $f(\beta)$ have the monomial expansion as $\beta \to 0^+$ [49]

$$f^{\text{wg}}(\beta) = a\beta^t + O(\beta^{t+1}), \tag{17}$$

where the parameters a and t define the first term of the PDF expansion, which in turn depend on the operating conditions. These two can be obtained by utilizing the exact PDF or MGF of the diversity structure. Moreover, (17) holds for many practical fading models like Rayleigh, Nakagami-q, Nakagami-n, and Nakagami-m [49]. Further developments on (17) can be found in [14, 15].

By utilizing $f^{\text{wg}}(\beta)$, [48] has derived the asymptotic

$$\overline{P}_{md} \approx \frac{A}{\bar{\gamma}^{t+1}}, \quad \bar{\gamma} \to \infty \tag{18}$$

where A is a constant independent of $\bar{\gamma}$. This shows that for large SNRs ($\overline{\gamma} \gg 1$), missed-detection probability decreases at rate of $t + 1$ on a log-log scale. This observation leads to the notion of sensing gain, which is equal to $t + 1$. However, this approximation is accurate only in the high-SNR regime (say, $\overline{\gamma} \geq 20\,\text{dB}$). This means something other than $f^{\text{wg}}(\beta)$ is needed to approximate $\overline{P}_{md}$ which is accurate over a wider range of SNRs (say, $0 \leq \overline{\gamma} < \infty$). New approximations with such properties can be developed [14, 15, 41].

P-Norm Detection

This idea generalizes classical energy detection (19). Instead of simply squaring, the magnitudes of the signal samples are raised to power $p > 0$ [12, 31, 40]. Thus, the decision variable becomes

$$T(\mathbf{y}) = \sum_{i=1}^{N} |y_i|^p \tag{19}$$

where y_i is the i-th sample and N is the number of samples. Note that $p = 2$ reverts to the classical energy detector (Sect. "Classical Energy Detector"). Several approximations for conditional decision variables $T|H_0, T|H_1$ and probabilities P_f and P_d are analyzed in [8]. One idea is to approximate $T(\mathbf{y})$ a three-parameter gamma distribution. The approximate detection probability is given as [8]

$$P_d^{tg} = \frac{1}{\Gamma(\alpha)} \Gamma\left(\alpha, \frac{\lambda - \delta}{\beta}\right). \tag{20}$$

where δ, α, and β are calculated by cumulant matching. Using this, AUC or area under the ROC curve can be derived. This single figure of merit for P-norm detection [7] has been elusive for arbitrary sample sizes. As well, exact computational methods for P_d and P_f exploiting Talbot's method of numerical integration and Laguerre-polynomials can be found in [40].

Double Threshold Energy Detection

Although the classical energy detector has the benefits of low complexity and blind operation (e.g., without needing primary signal information), the optimum threshold value to achieve target probabilities of false alarm and detection is prone to estimation errors, e.g., noise estimation error. Moreover, these two probabilities cannot be independently adjusted to desirable levels using a single decision threshold. These drawbacks can be alleviated with a double threshold energy detection [22], which allows independent setting of arbitrarily low P_f and P_{md} at the cost of an increased uncertainty region. For this detector, the hypothesis test is thus defined as

$$\text{if} \begin{cases} T(\mathbf{y}) < \lambda_0 & \text{accept} \ : H_0 \\ \lambda_0 \leq T(\mathbf{y}) < \lambda_1 & \text{No decision} \\ T(\mathbf{y}) \geq \lambda_1 & \text{accept} \ : H_1 \end{cases} \tag{21}$$

Thus, false-alarm and detection probabilities (4) and (5) depend on λ_0 and λ_1. However, for double threshold energy detection, a new parameter of probability of uncertainty is incorporated and expressed as a function of λ_0 and λ_1. Probability of uncertainty is given by [22]

$$P_c = \frac{\Gamma(N, \lambda_0/2) - \Gamma(N, \lambda_1/2)}{\Gamma(N)} + Q_N\left(\sqrt{2\gamma}, \sqrt{\lambda_0}\right) - Q_N\left(\sqrt{2\gamma}, \sqrt{\lambda_1}\right). \tag{22}$$

If $\lambda_0 = \lambda_1$, this rule reverts to the classical (2).

Energy Detection with Full Duplex Nodes

Radio nodes typically operate in half-duplex (HD) mode, e.g., transmission and reception functions require distinct, separate time or frequency slots. However, if both functions occur simultaneously on the same frequency band, spectral efficiency potentially doubles at the cost of self-interference. Since this self-interference poses a fundamental limit, cancellation methods have been developed with recent advances in antenna design and analog/digital signal processing techniques [10]. Nevertheless, residual self-interference will limit the system performance.

This residual interference will affect the ability of a radio node to sense spectrum holes. Thus, the complex signal observed at time t by the secondary full-duplex user in the desired band $[f_0, f_1]$ may be modeled as [36]

$$y(t) = \begin{cases} d(t) + n(t) & : H_0 \\ h(t)s(t) + d(t)n(t) & : H_1 \end{cases} \tag{23}$$

where $d(t)$ is the residual self-interference signal. According to this model, the effective SNR can be expressed as [36]

$$\gamma_{FD} = \frac{\gamma_t}{\gamma_i + 1}, \tag{24}$$

where γ_t and γ_i denote SNR at transmitter and the ratio between self-interference power and thermal noise, respectively. Assuming self-interference $d(t)$ to follow complex Gaussian with mean 0 and variance σ_i^2 [36], false-alarm and detection probabilities may be expressed as

$$P_f = \Gamma\left(N, \lambda/2\left(1+\sigma_i^2\right)\right)/\Gamma(N) \tag{25}$$

$$P_d = Q_N\left(\sqrt{2\gamma_{FD}}, \sqrt{\lambda}/\left(1+\sigma_i^2\right)\right). \tag{26}$$

The ROC curves can be plotted by using these equations. Thus, it is possible to evaluate the performance of full-duplex energy detection.

Alternatives

As mentioned before, energy detection offers not only a low-complexity and low-cost solution for spectrum sensing but also avoids a prior information about primary signals. However, it sometimes performs poorly. For example, when a primary signal and multiple interfering signals are present in a band, the energy detector may not readily differentiate among these, and hence spectrum access decisions can be overly conservative. In the following, three alternatives are briefly described.

Cyclostationary Based Detection

Cyclostationarity signals are signals that exhibit periodic probability structures (e.g., periodic mean and autocorrelation). These periodicities are in turn caused by special features such as modulation formats and cyclic components of primary signals or may even be introduced deliberately in order to assist spectrum sensing. Such detection algorithms can readily differentiate H_0 from H_1 because simply additive noise does not exhibit any correlation structures. Furthermore, they may

even distinguish among different types of transmissions and primary users. Their performance has been surveyed in [11, 50].

Matched Filter Based Detection

The received signal is correlated with a copy of the primary signal [7, 27]. If the primary signal and channel response are known, this detector is thus optimal (Neyman-Pearson sense) and maximizes the SNR. It can also take advantage of matched-filter implementations ion existing networks. For example, a matched filter is used by IEEE 802.11 (WiFi) nodes to detect incoming packets, and the same filter may also be leveraged to help with spectrum sensing. This detector also requires perfect timing and synchronization and thus incur computational complexity. Its performance decreases dramatically when channel response changes rapidly or when there are multiple primary user signals over the same band. However, a matched filter can be customized for each primary signal, but the overall complexity will be high. The performance of a matched filter (noise level of one) is given in [11].

Waveform-Based Detection

Current wireless networks periodically transmit special signal patterns for synchronization or for other purposes. They include prefixes for frame delineation, pilot patterns, spreading sequences, and others [50]. Thus, such a preamble can be correlated with the received signal. Such waveform-based (WF) sensing or coherent sensing can outperform energy detector in terms of reliability and convergence time. The performance advantage increases as the length of the known signal pattern increases. WF sensing performs well even with very low SNRs.

Applications

Smart Grids

A smart electrical grid includes a variety of operational and energy measures including smart meters, smart appliances, renewable energy resources, and energy-efficient resources. The communication goals of smart grid can be served by the use of spectrum sensing. For example, [13] studied the energy detector-based spectrum sensing in smart grids and its impact on the performance of demand response management. Matched filter-based spectrum sensing may also be used. A feature detection-based spectrum sensing for smart grid has been examined in [34]. However, sophisticated spectrum sensing algorithms may require significantly high power requirements. On the other hand, cooperative energy-efficient sensing schemes are suitable for dense smart grid environments [24]. Several practical spectral sensing approaches for CR in smart grids have been surveyed in [24].

Internet of Things (IoT)

Cognitive radio is expected to have a variety of IoT applications where very large numbers of sensors will coexist in a small physical space. Thus, spectrum sensing technologies are highly important for WSAN (wireless sensor and actuator networks) based IoT and the requirements and issues related to adaptive systems and architectures [23]. WSANs generally utilize the industrial, scientific, and medical (ISM) radio bands. However, overcrowded ISM bands negatively affect WSAN performance. Thus, improved spectrum sensing and spectrum data processing must be developed [46].

Spectrum Sensing in Standards

Spectrum sensing has been considered in IEEE 802.22 (for TV white spaces) and ECMA 392 [30]. However, specific techniques are not prescribed. Thus, anyone which satisfies the false-alarm and missed-detection requirements of the standard can be chosen. Coexistence among different standards is also important. For example, in heterogeneous network settings, coexistence between IEEE 802.22 WRAN and IEEE 802.11af Super Wi-Fi in the TV white spaces may be required. However, maximum transmit power of an 802.22 node is 1 W while that for an 802.11af is 100 mW. Thus, such power disparities will affect the ability of the spectrum sensing algorithm to differentiate between presence/absence of primary signals. Moreover, its performance may also be affected by interference from random numbers of nodes located randomly.

Summary

This tutorial provides a broad overview of the tools necessary for performance analysis of spectrum sensing algorithms, with particular emphasize on energy detection. The following contributions are made.

1. The spectrum sensing problem is provided as a binary hypothesis test. The decision statistic, detection, and false-alarm probabilities and the decision threshold are discussed. The basic parameters of the energy detector are described. The use of CLT to estimate the number of samples and prescribed performance levels is discussed. The ROC and AUC are described.
2. Fading is mitigated with multiple antenna techniques, which provide spatial diversity gains. The performance is analyzed for Rayleigh fading, diversity combining, and spatial correlation and in the high-SNR regime. General analytical techniques are highlighted.
3. Double-threshold energy detector, P-norm detector, and energy detection for full-duplex nodes are described. Alternative to energy detection includes cyclo-

stationary detection, matched filter-based detection, and waveform-based detection. These methods are briefly discussed. Spectrum sensing is an essential part of smart grid, Internet of things, and cognitive radio. An overview is provided.

Contents

Abstract

5G is the expected next step of the mobile cellular network evolution, and it is considered as the answer to the ongoing huge increase of cellular users and services. The architecture envisioned for 5G includes a large number of different network entities and systems that share a common spectrum resource via a dynamic spectrum access (DSA) approach. This solution is expected to significantly increase the overall spectrum efficiency but also introduces the challenge of optimizing the coexistence between the entities forming the overall

network, by limiting their mutual interference. Within this context, the cognitive radio (CR) paradigm, mainly focusing on its peculiar function, that is, spectrum sensing (SS), is being currently proposed as one of the main enablers for efficient DSA with limited interference. The goal of this chapter is to provide a comparative analysis on CR-inspired spectrum resource management (CR-SRM) mechanisms recently proposed for the 5G architecture, which mainly exploit SS, in order to characterize up-to-date research trends on the topic and highlight still-open challenges and possible future work directions.

Introduction

The rapid increase of cellular devices and services calls for the development of a new generation of the mobile cellular system, and considering the previous generations, the 5G acronym is currently widely adopted for indicating both envisioned requirements and possible solutions. On one hand, three main pillars synthesize the 5G requirements: (a) ubiquitous connectivity, (b) extreme low latency, and (c) very high data rate [1]; on the other hand, three categories identify the possible solutions: (a) massive and heterogeneous network densification, (b) increased bandwidth and spectrum efficiency, and (c) improved energy efficiency [2]. All together, the 5G architecture will include a huge number of different network entities mostly sharing a common spectrum resource, formed by licensed and unlicensed frequency bands, via a *dynamic spectrum access* (DSA) approach rather than traditional, and less efficient, static band assignment; while this solution is expected to significantly increase the overall spectrum efficiency, it also introduces the challenge of optimizing the coexistence between different devices, systems, and technologies.

Within this context, the *cognitive radio* (CR) paradigm and technology, as envisioned in [3], is being currently proposed as one of the main enablers for efficient and dynamic spectrum sharing between 5G network entities. For this reason, in recent years, several *CR*-inspired *spectrum resource management* (CR-SRM) mechanisms have been proposed, at different levels of the 5G architecture, for efficient DSA with limited interference. The key idea of these mechanisms is to exploit the CR capability of obtaining information on the occupation of a spectrum resource and subsequently apply an appropriate action strategy. The function of gathering information on the spectrum resource is usually referred to as *spectrum sensing* (SS); results of spectrum sensing are then used for optimizing the spectrum sharing among network entities.

The goal of this chapter is to provide a comparative analysis on CR-SRM mechanisms recently proposed for the 5G architecture, which mainly exploit SS, in order to characterize up-to-date research trends on the topic and also highlight still-open challenges and possible future work directions.

The rest of the work is organized as follows: section "Towards the 5G Era: Requirements, Enabling Technologies, and the Interference Challenge" introduces 5G basic concepts, first reporting a brief history of the mobile cellular system evolution and then highlighting requirements, most investigated solutions, and one of the

main challenges of the incoming generation, that is, the interference management. Section "The Cognitive Radio Paradigm for 5G" frames the topic of this work, providing a brief introduction to DSA and CR paradigms, while also considering the 5G scenarios in which they are envisioned to be applied. Section "CR-Inspired Spectrum Resource Management" is focused on the comparative analysis of recent CR-SRM mechanisms proposed for 5G. Finally, section "Conclusions and Future Work" concludes the chapter and describes open challenges and possible future work.

Towards the 5G Era: Requirements, Enabling Technologies, and the Interference Challenge

Evolution of the Mobile Cellular System

The 5G technology is the next step of the mobile cellular network evolution, and it is globally considered as the answer to the enormous increase of cellular users and cellular-based services. Research communities and industries hypothesize that 5G standards might be introduced in early 2020s. This prediction might confirm the chronological rule of thumb on the development of a new cellular system generation each ten years approximately: the introduction of 1G systems are in fact dated 1982, while the 2G ones were commercially distributed in 1992. 3G systems were then deployed in early 2000s, while 4G systems are being fully exploited since 2010s. Considering the huge amount of users, devices, and systems, the 5G network is expected to have capabilities that significantly overcome the previous system generations, particularly in terms of system capacity, data rate, latency, network reliability and availability, and energy costs and consumption. Many recent reports and projects summarize numerical requirements for the above categories [4–9], and the comparison with the previous generations, in particular with the 4G one, highlights the huge scale of the forecast (see section "5G Requirements" for details). Several proposals are being currently analyzed in terms of solutions and enabling technologies. On one hand, the improved use of existing 3G/4G architectures and systems is considered a good practice, in order to allow interoperability and compatibility; on the other hand, new technological solutions are needed in order to achieve the 5G requirements (see section "5G Enabling Technologies" for details).

5G Requirements

This section highlights the most important 5G requirements, which range from expected data rates to latency indicators, reporting either their absolute values or, when possible, comparative indicators with the 4G assessed performance. References for the reported data are in particular industry reports such as [4–9], among the others.

Massive capacity. In order to deal with the exponential growth of traffic volume, 5G technologies target to increase the overall network capacity, compared with the existing architectures. In particular, when compared to LTE-A, a 100-fold or higher increase of area capacity in Mbit/s per unit area is being targeted.

High connectivity. Compared to LTE-A, a $\geq$ tenfold increase in the number of connected users is expected.

High data rate everywhere. 5G data rate will also significantly increase. In particular, the target of network operators is a $\geq$ tenfold increase in user-experienced throughput (Mbits/s) compared to 4G, aiming at a maximum of 1 Gbps experienced user throughput everywhere, including sparsely populated rural areas. For indoor and dense outdoor environments, a peak data rate exceeding 10 Gbps is expected.

Ultralow latency. Real-time applications, such as tactile Internet, augmented reality, traffic safety, and control of critical infrastructures and industry processes, require much lower latency compared to the 4G performance. 5G is expected to provide an end-to-end latency of about 1 ms or less and almost "zero latency" in case of cloud-based applications.

Improved energy efficiency. This factor is considered extremely important in the 5G context, because it can help in reducing costs and allow energy harvesting, making the network more sustainable. A 100-fold increase of network energy efficiency in bits/Joule is being targeted, together with a ten times prolonged battery life of devices.

Ultrahigh reliability and availability. Besides the above requirements, 5G network should provide connectivity with ultrahigh reliability and availability. In particular, high availability has to be ensured in new mission-critical control services, such as control of critical infrastructures and traffic safety. An availability of 99.999% can be sought in many industrial applications, e.g., energy/smart grid or medical services, to guarantee successful packet delivery within 1 ms. For autonomous vehicles and industrial automation, ultrahigh reliability is expected to be provided with extremely low loss rate.

Table 1 reports a numerical comparison of the main performance indicators between 4G, in particular the LTE-A technology, and 5G, also highlighting the expected order of increase.

Table 1 Comparison of 4G performance and 5G requirements

Performance indicator	4G	5G	Order of increase
Area capacity [Mbits/s/m^2]	0.1	10–100	100–1000
Connection density [devices/km^2]	10^5	10^6–10^7	10–100
User data rate [Mbits/s]	10	100–1000	10–100
Latency [ms]	10	$\leq$1	$\geq$10
Energy efficiency (bits/Joule)	–	–	100

5G Enabling Technologies

This section highlights the most investigated enabling technologies for the 5G vision. References for the reported solutions are in particular survey papers on 5G such as [1, 2, 10] and [11], among the others.

Network heterogeneous densification. The 5G architecture will be an ultra-dense mixture of network tiers of different sizes and transmit powers, front/backhaul connections, device-to-device (D2D) links, and different radio access technologies (RATs) [12]. Focusing on the cellular network, the coexistence of several classes of base stations (BSs), including macrocells (MBSs) and femto-, pico-, and microcells, generically indicated as small cells (SBSs), will provide improved coverage and spectrum efficiency, if robust mechanisms for interference avoidance are provided. This aspect is analyzed in detail in the following chapter, together with a discussion on cognitive radio-based mechanisms for interference mitigation.

Massive multiple-input multiple-output technology. Massive MIMO, also referred to as large-scale antenna systems, very large MIMO, hyper-MIMO, and full-dimension MIMO and ARGOS, has been recently added to the 5G vision. A massive MIMO system is formed by a BS equipped with a very large number (hundreds to thousands) of colocated or distributed antennas that coherently serves many users within the same time-frequency resource. On one hand, the large number of simultaneously operating antennas can improve significantly the performance in terms of data rate, link reliability, and energy efficiency due to multiplexing and array gains [13, 14]; on the other hand, it increases the hardware complexity while stressing out the need of efficient cooperation between many low-cost low-precision components.

Millimeter-wave communications. The 5G system is expected to work at new, high-frequency bands that are nowadays unused. Among the others, the use of the millimeter-wave (mm-wave) frequency spectrum is of great interest, considering that it exists a vast amount of idle spectrum in the range from 30 to 300 GHz, and preliminary measurements showed that 28 and 38 GHz frequency bands can be used with steerable directional antennas [15]. Issues of using the mm-wave spectrum derive from strong pathloss and atmospheric absorption, low diffraction and penetration around/through obstacles, strong phase noise, and high equipment costs.

Full-duplex communications. Thanks to recent advances in interference cancelation techniques and digital baseband technologies, a full-duplex (FD) transceiver is nowadays capable of transmitting and receiving signals on the same frequency at the same time, thus solving the old days issue of simultaneous Tx/Rx due to high self-interference [16]. FD systems are envisioned to be applied to 5G, thus furtherly increasing the spectrum efficiency. However, several complex types of interference are also introduced, for example, in a multiuser channel sharing system, besides intra-cell interference (among the users in a

Table 2 5G requirements and enabling technologies

Requirement	Main enabling technologies
Massive capacity and connectivity	Network heterogeneous densification, massive MIMO, mm-wave, C-RAN
High data rate everywhere	Network heterogeneous densification, massive MIMO, mm-wave, full-duplex
Ultralow latency	Full-duplex, C-RAN, D2D
Improved energy efficiency	Energy harvesting, D2D
Ultrahigh reliability and availability	Network heterogeneous densification, C-RAN, WNV

cell), intercell downlink-to-uplink interference, and intercell inter-user uplink-to-downlink interference also appear.

Energy harvesting. Energy harvesting has been recently proposed as a potential enabler for solving the energy efficiency requirement. Among the others, several environmental energy sources (e.g., solar and wind energy) and ambient radio signals (e.g., RF energy harvesting) are being analyzed as possible harvesting solutions [17].

Cloud-based access and wireless network virtualization. Cooperation and network virtualization are promising methodologies to be applied in the 5G system; cloud-based radio access network (C-RAN) and wireless network virtualization (WNV), as examples, make possible (a) a distributed architecture for a single BS and (b) simplified resource sharing among many operators, respectively [11]. Several advantages and challenges are being investigated in C-RAN and WNV, as summarized in [18] and [19], respectively.

Table 2 summarizes the above technologies, matching them with the 5G requirements.

The 5G Interference Challenge

In order to highlight the challenge regarding the interference among the heterogeneous 5G network entities, this section introduces in detail the architecture envisioned for the 5G system, first focusing on the cellular network (section "The 5G Cellular Network") and then moving on the more general view of 5G as network of networks (section "5G as Network of Networks"). Definitions of interference at various levels of the 5G architecture are consequently provided and discussed.

The 5G Cellular Network

As briefly introduced in section "5G Enabling Technologies", the cellular part of the overall 5G network will continue the process of *heterogeneous densification* started with the 4G systems. The cellular heterogeneous networks, referred in the following to as *HetNets* or multitier networks, will be the core of the overall 5G architecture:

traditional outdoor MBSs will be massively overlaid with power-limited SBSs, e.g., femtocells, picocells, and microcells (in order to provide a general analysis, this work discusses the interference challenge with the wide concept of small cells. For this reason, the difference between femto-/pico-/microcells is not furtherly highlighted), in space and, possibly, spectrum domains, thus providing an improved network capacity, thanks to (a) a cost-efficient network expansion, in particular for indoor areas [2, 20], and (b) an intelligent traffic balance at each tier via offloading techniques and cell association schemes [21, 22]. Moreover, in a more general view of the network, entities such as relays, operating in a decode-and-forward (DF) mode, and repeaters, working in an amplify-and-forward (AF) mode, will be also developed to increase the coverage area and decrease the power consumption of the network entities [23,24]. It is being proposed that either SBSs or their corresponding users (SUEs) could act as relays for either MBSs or MUEs when needed, thus defining *cooperative* HetNets, in contrast with *noncooperative* ones [25]. While it is clear that MBSs and SBSs will spatially overlay, three main solutions are being proposed for the spectrum domain [26]:

1. **Dedicated-channel**, in which the overall HetNets bandwidth is statically divided in two portions, one dedicated to MBSs/MUEs and the other to SBSs/SUEs.
2. **Partial-channel-sharing**, in which the SBSs/SUEs bandwidth portion is shared with MBSs/MUEs.
3. **Co-channel**, in which the HetNets bandwidth is globally shared between macro- and small cell tiers.

Regarding the HetNets bandwidth, it is assumed that, due to limited availability of the licensed cellular spectrum, it will be formed by both licensed and unlicensed bands, with the latter being free to be used by different systems (e.g., the ISM band). Partial-channel-sharing and co-channel solutions are applicative scenarios of the DSA approach, as will be descripted in section "Dynamic Spectrum Access and Cognitive Radio": in both cases, macro- and small cell tier coexistence is challenging, and the interference arising among them is traditionally referred to as *cross-tier interference* (Cr-TI). Moreover, in all previous spectrum solutions, efficient coexistence between entities within small cell tiers is also a challenge, mainly due to the extremely dense deployment at random locations of SBSs; the interference in this case is referred to as *co-tier interference* (Co-TI). Cr/Co-TI can be seen as particular cases of *intra-network interference* (Intra-NI). In detail, this kind of interference can appear under different forms: the up-/downlink scheduling of macro- and small cell tiers will be in fact asynchronous, and for this reason, if difference between SBSs and SUEs is negligible due to similar locations and transmission powers, intra-NI appears a) from SBSs/SUEs to MBSs, b) from SBSs/SUEs to MUEs, c) from MBSs to SBSs/SUEs, d) from MUEs to SBSs/SUEs, and e) from SBSs/SUEs to SBSs/SUEs [23]. Figure 1 shows the intra-NI scenario in case of downlink transmissions (from MBSs/SBSs to corresponding MUEs/SUEs): intra-NI is indicated as generically affecting the Tx/Rx data link, thus causing interference to both involved transmitter and receiver.

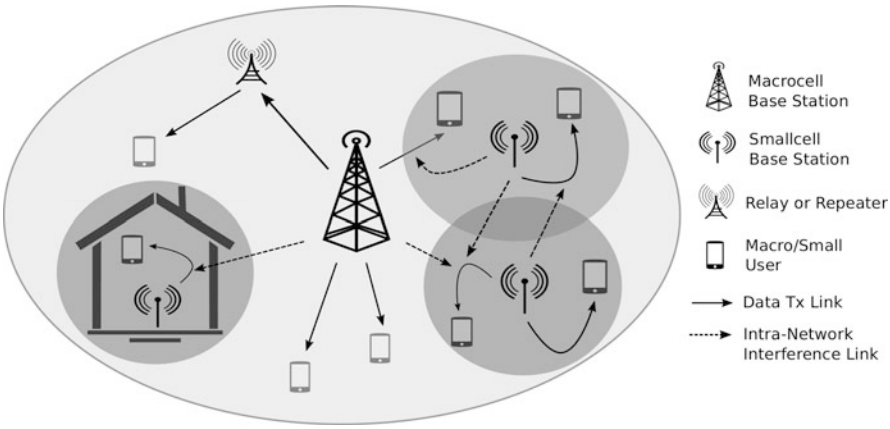

Fig. 1 Representation of HetNets intra-NI scenario in case of downlink transmissions (*straight lines* indicate data links; *dashed lines* indicate intra-NI links)

5G as Network of Networks

As mentioned in section "5G Enabling Technologies", besides the cellular network, the overall 5G architecture will be a mixture of several *radio access technologies* (RATs), allowing the generic 5G user to dynamically connect to different RATs, in order to preserve its required quality of service/experience and the overall network capacity. Among the others, 5G devices will support new 5G standards but also numerous releases of 3G/4G systems, several types of Wi-Fi, and device-to-device (D2D) direct links, all across many spectrum resources [2]. The 5G network will be thus a combination of *multi-RAT HetNets*, and the definition of optimized RAT selection and automatic offloading schemes will be of paramount importance [27].

Within this vision, the use of unlicensed bands opens new opportunities and challenges: some of the RATs will overlay in the spectrum domain (e.g., different releases of Wi-Fi and the small cell tiers, at ISM band and higher frequencies), and these scenarios will require efficient resource management in order to limit the arising *inter-network interference* (inter-NI) [28]. Figure 2 shows the inter-NI scenario in case of downlink transmissions for both cellular network and Wi-Fi and in the presence of D2D communication links: inter-NI is indicated as generically affecting the Tx/Rx data link, thus causing interference to both involved transmitter and receiver.

The Cognitive Radio Paradigm for 5G

In this section, a brief introduction to DSA and CR is provided, in order to highlight general definitions and contributions within this research area, and a focus on SS approaches and techniques is also reported; the application of DSA and CR to the 5G architecture is then discussed.

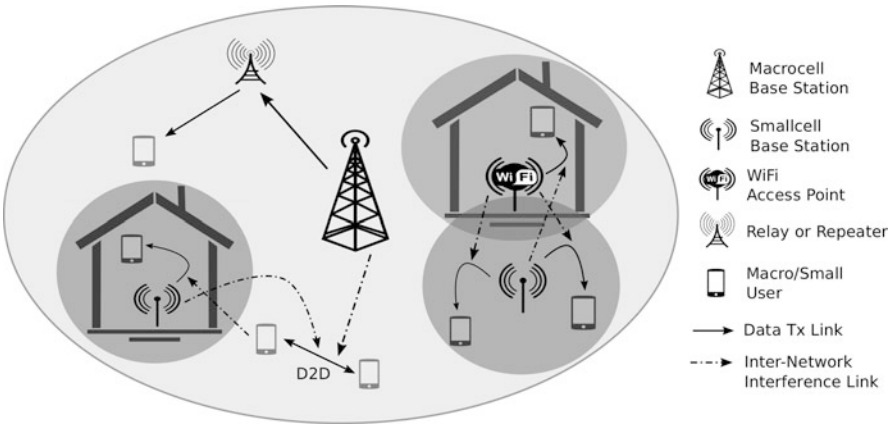

Fig. 2 Representation of multi-RAT HetNets inter-NI scenario in case of downlink transmissions and D2D direct links (*straight lines* indicate data links; *slash-dotted lines* indicate inter-NI links)

Dynamic Spectrum Access and Cognitive Radio

The optimal use of the spectrum resource is an important challenge given the ongoing increase of wireless technologies, systems, and applications. The inefficient spectrum used is largely due to the static assignment of frequency bands to different systems rather than physical shortage, given that, as suggested by several measurements campaigns, many portions of the licensed spectrum are not used either for significant periods of time or in specific geographical areas by the incumbent systems [29, 30]. The need of reforming the spectrum usage has stimulated several activities in the engineering, economics, and regulation communities, having the common goal of optimizing the use of spectrum resources, allowing their use to new services and systems, without damaging the existing ones.

The term dynamic spectrum access is generally used to encompass various approaches to the spectrum reform. According to taxonomy and definitions in [31], DSA approaches can be roughly divided in three main categories:

1. **Dynamic exclusive use model**, in which the static and licensed spectrum assignment is saved but flexibility is introduced in the form of different solutions such as spectrum trading, leasing, and short-time agreement between licensed and unlicensed systems [32].
2. **Hierarchical access model**, mostly applied in case of a licensed band to be shared between licensed primary users (PUs) and unlicensed secondary users (SUs), with the goal of letting the SUs access to the band by exploiting its possible underutilization, while limiting the interference to the PUs [33]. The modalities of the SU spectrum access furtherly identify three sharing scenarios within this model: (a) *underlay* spectrum access, in which the interference between PUs and SUs is controlled by limiting the SUs transmission power;

(b) *overlay* spectrum access, also known as *opportunistic* access, in which the SUs are allowed to transmit full power if they are able to discover, within the licensed band, portions temporarily PU-free; and (c) *hybrid* spectrum access, which combines overlay and underlay access in order to increase the sharing efficiency [34].

3. **Open sharing model**, in which, inspired by the huge success of wireless services operating at unlicensed bands (e.g., the ISM band), different systems openly share the spectrum resource by adopting efficient, either centralized or distributed spectrum sharing mechanisms, with the latter including solutions with roots in game, graphs, and optimization theories [35].

Software-defined radio (SDR) and CR paradigms find a basic application scenario within the DSA context, particularly for hierarchical access and open sharing models. While SDR has been defined as a software-reconfigurable, multi-band device supporting multiple interfaces and protocols, CR, built upon SDR, has been introduced as a context-aware intelligent radio, capable of autonomous reconfiguration by learning from and adapting to the communication environment [3]. The theoretical CR exploits the spectrum resource, by adapting its behavior to the environment, while also considering the requirements of the specific user. Moreover, it is able to learn from past situations in order to always provide the best possible configuration. CR actions are typically scheduled in the so-called cognitive cycle: (a) observe the surrounding environment, (b) plan possible action strategies, (c) decide the optimal operative strategy, (d) learn from experience and derive new action strategies, and (e) act by applying the selected strategy.

While theoretical CR could process an extremely wide range of contextual information, including audiovisual and spatial inputs, CR-related research has been traditionally focused on analyzing and deriving information on the spectrum resource, limiting the contextual information to the one obtained by observing the spectrum domain. In this case, as introduced above, the main function of CRs is spectrum sensing and the cognitive cycle can be simplified in four steps [34], reported in Table 3.

Table 3 The cognitive cycle

Phase	Description
Spectrum sensing	The CRs observe the targeted spectrum resource, thus detecting the traffic activities of noncognitive users and highlighting possible transmission opportunities
Spectrum decision	Depending on the SS results, the CRs plan and decide the action strategy in terms of several functions, e.g., the selection of the best spectrum opportunity, modulation type, and transmission power
Spectrum sharing	The strategy for accessing the spectrum opportunity is applied among all CRs requiring to transmit
Spectrum mobility	The CRs modify their action strategies if a noncognitive user changes its behavior within the spectrum opportunities

The design of a CR network results of paramount importance in all DSA scenarios where different entities and/or networks share the same spectrum resource and therefore could mutually interfere [36]. From the perspective of a hierarchical access model, for example, the SUs should undoubtedly synthesize a CR network while the PUs might be traditional devices: on one hand, in the underlay mode, the SUs can sense the PU activities, estimate the current interference from/to the PUs, and adapt, if necessary, their transmission features, in order to minimize the interference; on the other hand, in the overlay mode, the SUs try to discover via SS, on the overall band, spectrum opportunities free from PUs, and opportunistically use them, until one or more PUs reappear.

The Spectrum Sensing Function

Spectrum sensing plays a fundamental role toward the success of the CR paradigm in terms of spectrum efficiency and coexistence capability, and its definition closely follows the definition of spectrum opportunity. For example, by defining the spectrum opportunity as a band of frequencies that are not being used by the licensed PU at a particular time and/or in a particular geographical area, it immediately arises that SS at least involves frequency, time, and space domains. There are several other dimensions that are possible to explore in order to define and find a spectrum opportunity, e.g., the code and signal propagation direction. On one hand, it is important to define an SS acting across many domains; on the other hand, this requires increased computational complexity and costs for developing and managing the SS function [37].

When focusing on traditional frequency/time/space SS, several definitions can be provided, each one related to a particular highlighted feature [37, 38]. Considering the size of the spectrum resource of interest, SS can be classified into *wideband* and *narrowband* SS: in the first case, the goal is the detection of spectrum opportunities as portions of the overall resource, while, in the second case, the SS is focused on a single portion. Wideband and narrowband SS are usually operated jointly, assuming an intermediate phase in which the sensing device decides a single opportunity where narrowband SS should be applied, among several opportunities previously discovered with wideband SS. In terms of device architecture, SS can be performed in *single radio* and *dual radio*: in the single radio case, specific time allocation for SS is assumed, thus leading to performance of detection and spectrum efficiency depending on the sensing time duration; in the dual radio case, one Tx/Rx chain is dedicated to data transmission/reception, while another chain is dedicated to SS. In this case, SS is also referred to as spectrum monitoring, and performance is improved at the cost of increased hardware complexity and power consumption. The previous definitions assume that the sensing devices are also the ones asking for data transmission such as the SUs in a hierarchical access model. This approach is referred to as *internal* SS, in contrast with *external* SS, where the presence of external network agents, dedicated to SS and able to broadcast the results to the communication devices, is assumed. External SS can solve some problems related to internal SS, such as spectrum and power efficiency, but it introduces new challenges because of the need of exchanging the sensing results on a dedicated

control channel. This challenge arises in general when cooperation between sensing devices, in both internal and external SS configurations, is introduced. In fact, in contrast to *local* SS (LSS), in which each device takes independent decisions on the spectrum status, a *cooperative* SS (CSS) approach can be defined, in which the devices share their decisions in order to improve the overall accuracy of SS. Decisions can be shared either with a central unit, also named fusion center, thus defining *centralized* CSS, or among all neighboring devices, referred to as *distributed* CSS. Cooperation leads in general to SS performance improvement, but this depends on the control channel reliability, the type and the fusion rules of shared information, and the number of involved devices; the trade-off between SS accuracy improvement, on one hand, and architecture complexity and overhead due to control message exchange, on the other, have to be considered while designing CSS algorithms [39].

Besides the above definitions, a plethora of SS techniques, approaches, and methodologies, together with challenges and issues, can be highlighted. Providing a survey on SS is out of the scope of this chapter and the interested reader can refer to [37,38,40], among the others, for detailed and complete reviews. However, observing that CR devices do not in general interact with noncognitive users to verify their presence, indirect detection sensing techniques for (a) *transmitter*, (b) *receiver*, and (c) *interference temperature* detection have been introduced in recent years. The first case is the most investigated one, and the corresponding techniques, ranging from traditional energy and feature detectors to recent wavelet transform-based, statistical and sub-Nyquist approaches, differ each other depending on the a priori knowledge on the device to be detected and the accuracy/complexity trade-off. Complexity and adaptability of the SS technique to different environments play a fundamental role in the 5G context, considering the high number of possible scenarios of interference, and the level of heterogeneity expected for and required by the 5G architecture, as already reported in section "5G Enabling Technologies".

CR-Inspired Spectrum Resource Management

In this section, the state of the art of CR-SRM mechanisms proposed for the 5G architecture is reported and analyzed, first focusing on the HetNets case and then moving on the more general multi-RAT HetNets one.

Focus on HetNets

Focusing on the HetNets forming the cellular network, the application of CR capabilities depends on the possible HetNets usage scenarios. On one hand, with reference to noncooperative HetNets, the scenario in which cognitive small cell tiers provide support to the macrocell tiers while acting on the same spectrum resource is particularly analyzed in recent literature, and it is also actively pursued by the industry; on the other hand, in case of cooperative HetNets, the scenario suggesting

the presence of cognitive relays/repeaters, capable of autonomously selecting the optimal relying/amplifying strategy for further cellular coverage enhancement, is of particular interest. Since centralized control for both spectrum access and intra-NI mitigation is hard to implement, because of scalability of control message exchange among and within tiers [41], CR-SRM mechanisms in the form of cognitive DSA are highly desirable, also considering that the DSA hierarchical access model perfectly matches the HetNets scenarios of partial-channel sharing and co-channel deployment, with macrocells and small cell tiers having the role of PUs and cognitive SUs, respectively.

Solutions Based on Local Spectrum Sensing

Within this context, SS is mainly adopted for a direct analysis of the spectrum resource, in order to estimate and mitigate the intra-NI. Focusing on Cr-TI, several approaches might be used for making possible an efficient spectrum access to low-priority small cell tiers: on one hand, considering an overlay access scenario, interference from/to MBSs/MUEs might be avoided through direct SS by SBSs/SUEs [21]; on the other hand, considering an underlay access scenario, SS-based mechanisms might be used to estimate the interference from/to MBSs/MUEs within the targeted spectrum resource. More complex hybrid access might be also considered: in [23], for example, when considering SBSs/SUEs and MBSs/MUEs spatially overlapped, overlay access is proposed on the spectrum opportunities, while underlay access is carried out on spectrum portions being used by MBSs/MUEs covering different geographical areas, after estimating, through SS-based mechanisms, the possible interference caused to them.

Focusing on Co-TI, several different approaches can be highlighted. On one hand, SBSs/SUEs access might be regulated via SS-based access schemes, as proposed in [21], where Aloha-like access vs. SS-based CSMA have been comparatively evaluated; on the other hand, the recent trend seems to prefer solutions based on game theory [42] and optimization methods [43, 44], with a particular emphasis on maximizing the small cell throughput.

Cr-TI and Co-TI are mostly analyzed in conjunction and, also in this case, SS mechanisms are used in particular for Cr-TI mitigation, while game and optimization theories are preferred for Co-TI [26, 28]. Furthermore, it can be highlighted that the reuse of existing 4G functionalities is being widely analyzed for 5G SS mechanisms: in [26], each SBS mitigates Cr-TI by comparing the gathered information on macrocell scheduled transmission activities, broadcasted by the MBSs in a common dedicated signaling channel, with the SS measurements of the received interference power, which is an indicator already adopted as a sensing quantity in LTE-A tiers. Besides the received interference power, reference signal received quality and number of neighboring cells are the others 4G indicators to be possibly used in 5G interference scenarios, as analyzed in [28]; Cr-TI mitigation is here achieved by also introducing a first step of cooperation within the small cell tier: while the SBS measures the received interference power, thus obtaining a global tier interference indicator, the SUEs measure their own reference signal received quality, thus obtaining a local interference indicator. The SUE measurements are

then reported to the SBS, which decides on the spectrum resource occupancy, by applying a compressed sensing approach for overcoming the possible huge amount of received data.

Solutions Based on Cooperative Spectrum Sensing

While in [28] a centralized CSS scheme has been suggested for Cr-TI mitigation only, both centralized and distributed CSS approaches are being proposed for global intra-NI interference mitigation. Within this context, one of the main challenges is the energy efficiency, to be achieved by minimizing SS efforts and control message exchange. For this reason, when considering centralized CSS, a sequential SS algorithm with hibernation state for the sensing devices has been proposed in [45], while external CSS architecture with dedicated network entities referred to as spectrum agents (SAs) has been recently discussed in [46]. Even in this case, mechanisms for energy efficiency are highlighted: the SAs are in fact supposed to be activated through an explicit sensing request either by the SBS/SUE needed to transmit or by a central unit that is also in charge of the final decision on the resource occupancy. Figures 3 and 4 graphically clarify some of the concepts being discussed; on one hand, Fig. 3 reports a representation of three different internal SS mechanisms that are local SS, centralized CSS, and distributed CSS: considering the downlink scenario, it is assumed that, in all cases, the SBS activates the SS function in order to transmit data to the SUEs, and in case of centralized CSS, it also acts as central unit. On the other hand, Fig. 4 reports two simplified scenarios of external and centralized CSS: in this case, considering again the downlink scenario, it is assumed that, the SBS needed to transmit activates the SAs, they apply SS and report the results either to the SBS or to a dedicated central unit. It is worth noting that the cases reported in both Figs. 3 and 4 consider the execution of SS within an isolated small cell tier: approaches considering possible cooperation between near/overlapping small cell tiers can be also taken into account.

Considering that the reliability of the common control channel is another factor significantly affecting the CSS performance, an MAC protocol with dynamic common control channel selection has been recently proposed in [47], referred to as DCCC-MAC, and formed by four phases: (a) CSS by the SUEs on the channels forming the spectrum resource, (b) selection by the SBS of a common control channel among the channels sensed as free from macrocell activities, (c) contention-free allocation and data transmission of the cooperative SUEs on the other channels detected as free, and (d) beaconing for synchronization purposes within the cell.

In the context of distributed CSS, joint optimization of sensing parameters, transmission powers, and spectrum resource allocation has been discussed in [48], where an optimal trade-off between the power spent for transmission and the power spent for sensing is also derived. CSS has been also proposed in the hypothesis of mobile PUs, which mainly matches the HetNets uplink scenario (MUE/SUE transmitting to corresponding MBS/SBS), for joint estimation of spectrum occupancy and spatial localization of MUEs [49].

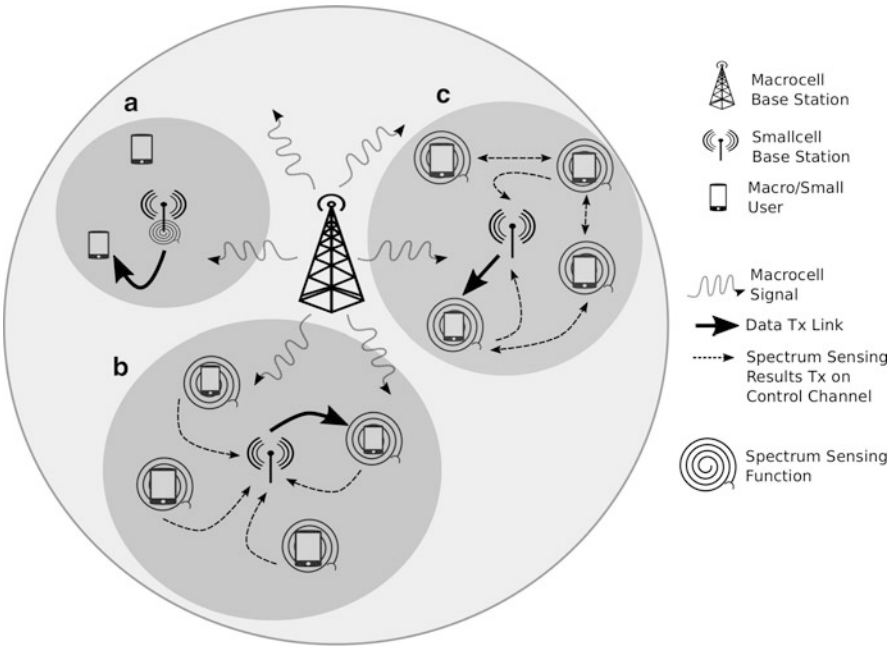

Fig. 3 Representation of three internal SS scenarios, in case of downlink transmissions: (**a**) local SS by the SBS; (**b**) centralized CSS, the SUEs, activated by the SBS, apply SS and report their results to the SBS that also acts as central unit; (**c**) distributed CSS, the SUEs, activated by the SBS, apply SS and forward their results to the nearest neighbors

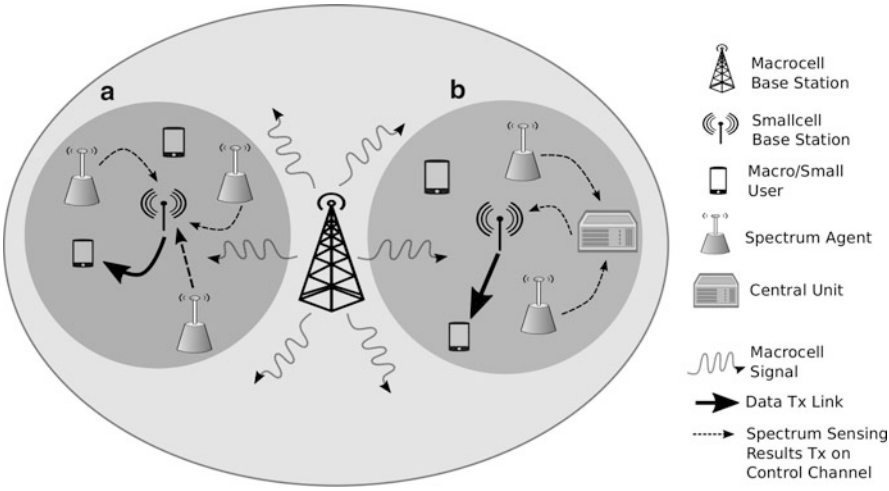

Fig. 4 Representation of two external SS scenarios, in case of downlink transmissions: (**a**) centralized SS mode 1, the SBS activates the SAs and acts as control unit; (**b**) centralized SS mode 2, the SBS activates the SAs and receives the final SS decision from a dedicated central unit

Imperfect Spectrum Sensing

The imperfection of SS due to possible miss-detections and false alarms is a nontrivial problem that significantly affects the expected network performance. It recently started to be explicitly considered in the HetNets design and spectrum allocation schemes: on one hand, the spectrum allocation framework proposed in [50, 51] for OFDMA small cells considers both constraints deriving from intra-NI and SS errors on the channels forming the spectrum resource; on the other hand, the problem deriving from possible SS low reliability can be mitigated by limiting its use within a more sophisticated sharing mechanism, as suggested in [52], where a centralized spectrum sharing has been proposed: distributed SS is executed by SUEs, and results are reported to the nearest SBS. However, the SS results are only used by MBSs/SBSs as side information, and the final spectrum sharing decisions are mainly based on the policies defined by a centralized controller.

Energy Efficiency

Spectrum efficiency and interference mitigation issues are mostly analyzed in conjunction with many other challenges deriving from 5G requirements. As already observed in section "Solutions Based on Cooperative Spectrum Sensing", one of the most investigated combinations is with energy efficiency and harvesting, considering their paramount importance for the creation of 5G devices and infrastructures [25]. When considering CR-SRM mechanisms, energy efficiency of spectrum sensing and sharing assumes primary importance: it has been demonstrated that the energy consumption of energy detector SS with off-the-shelf components is nearly twice the one of a normal transmission state, and for this reason, the constraint on the power consumption has to be considered in the SS time duration optimization [53]. Moreover, in the context of HetNets, energy-efficient SBS/SUE spectrum sharing is being investigated: once a spectrum opportunity has been discovered, the optimization of the SBS/SUE transmission power can be achieved by considering that the highest its value, the highest the possible intra-NI and power consumption [53].

Energy harvesting is also highlighted in the 5G HetNets scenarios: different network entities can be empowered by different energy harvesting solutions, and CSS mechanisms for discovering spectrum opportunities should take this aspect into account in order to adaptively selecting the optimal number of cooperative neighbors and the energy that can be consumed by each one in the SS phase. In [54] an MAC protocol synthesizing these aspects, divided into contention, sensing, and transmission phases, has been proposed and analyzed.

Focus on Multi-RAT HetNets

As discussed in section "The 5G Cellular Network", the HetNets architecture is interference-affected, given that macro- and small cell tiers share the licensed spectrum. Even if the CR-SRM mechanisms discussed in section "Focus on

HetNets" could mitigate this interference, the large-scale deployment of small cells is posing an increasing challenge. For this reason, research communities and industries are discussing on the utilization of other spectrum resources for small cells, including unlicensed spectrum bands, such as the 2.4 and 5 GHz bands that Wi-Fi systems operate in [55].

Within the 4G context, tentatives of exploring the unlicensed spectrum currently used by Wi-Fi systems for LTE/LTE-A systems are mainly known as LTE-unlicensed (LTE-U) or licensed-assisted access using LTE (LAA-LTE) and clearly pose an initial inter-NI issue to be managed between the cellular network and the Wi-Fi systems; when considering 5G networks, the coexistence of HetNets and Wi-Fi becomes even more challenging and requires in-depth research, considering the increasing number of overall network scenarios and entities. As an example, the same systems are also possibly interfering at the 60 GHz mm-wave bands, where the new IEEE 802.11ad standard, also known as WiGig, is about to work, and on parallel, 5G small cell SBSs/core network backhaul links are being envisioned, given that wired and in-band wireless links may not perform well because of the dense deployment of small cells [56].

Nowadays, considering their huge proliferation, Wi-Fi systems are mainly playing an important role in offloading traffic from the heavily loaded cellular network, especially in indoor traffic hotspots and in poor cellular coverage areas, and the huge amount of recent work on the topic proves that efficient offloading schemes and intelligent RAT selection are fundamental tools in achieving satisfactory network performance, if inter-NI mitigation is provided [57].

HetNets vs. Wi-Fi: Inter-NI Mitigation

HetNets and Wi-Fi coexistence can be envisioned to be cooperative or otherwise; considering that the first case implies modification of existing protocols due to the need of control message exchange, most of the work has been nowadays focused on noncooperative RATs, thus proposing CR-based solutions.

Resource partitioning between HetNets and Wi-Fi are being discussed: while unlicensed spectrum partitioning guarantees fairness between small cells and Wi-Fi but suboptimal spectrum efficiency [58], time-domain dynamic resource sharing, based on the almost blank subframe (ABSs) mechanism, is expected to be a more efficient solution. In the context of LTE/Wi-Fi coexistence, the ABSs, which are subframes with reduced power and data, are randomly transmitted by the LTE network, without coordination with the Wi-Fi system; the Wi-Fi access points can detect the ABSs (via CSMA/CA or SS) and use them for their own transmissions. It has been shown that this mechanism sets a reasonable trade-off between the Wi-Fi and the LTE throughput performance [59,60]. Moreover, interference avoidance can be obtained, as previously discussed in section "Solutions Based on Local Spectrum Sensing", by adopting 4G SS indicators [28] and estimating the density of nearby Wi-Fi transmissions [60]. Coexistence at the 60 GHz mm-wave has been recently investigated in [61], where wavelet transform-based SS and filter bank multicarrier modulation techniques have been proposed to increase the small cell tier throughput.

Conclusions and Future Work

This chapter has presented a comparative analysis of recent CR-SRM mechanisms proposed in literature for the incoming 5G network and exploiting, in particular, the SS function. After reporting a summary on 5G envisioned requirements and possible enabling technologies, the interference challenge at different levels of the 5G architecture has been discussed, and the application of the CR paradigm, with a particular focus on SS and CSS, has been descripted in light of recent literature. The analysis suggests that CR is being extensively analyzed in the context of 4G/5G multi-RAT HetNets: in particular, when considering the cellular part of the 5G network, SS-based approaches seem to be extremely suitable for Cr-TI mitigation scenarios, where a particular emphasis is being given to cooperative approaches, energy efficiency, and an overall optimal sensing/transmission network organization through specific MAC protocols; when considering the multi-RAT scenarios, SS-based approaches are being proposed for improving the coexistence of different RATs on a common unlicensed spectrum resource, with a particular focus on the optimization of HetNets and Wi-Fi coexistence, given the importance of Wi-Fi, as supporting technology for offloading, in the general 5G vision.

Nowadays, the presented topic is still extremely open and challenging and calls for further research in a broad range of scenarios. For example, most of the work either does not indicate the SS technique to be used or assumes simple energy detector SS schemes. However, the SS technique might be selected with reference to the applicative scenarios: for example, in case of Cr-TI mitigation within the cellular licensed spectrum, it can be assumed that small cell tiers are focused on discovering macrocell activities and thus, knowing their transmission features, more complex and performing SS techniques might be used. In general, specificity of SS should be considered for more detailed performance analysis. Another aspect that might be addressed more in detail is the possible users' mobility, considering that majority of 5G users is assumed to be mobile in the area of interest; this is extremely relevant also for D2D communications and cooperative architectures with relays and repeaters. Finally, full-duplex and massive MIMO might be taken into account in all the above scenarios, given that they are considered as fundamental technologies for a complete success of the 5G era.

Abstract

The rising popularity of wireless services resulting in spectrum shortage has motivated dynamic spectrum sharing to facilitate efficient usage of the under-utilized spectrum. Cognitive radio has emerged as one of the most promising candidate solutions to improve spectrum utilization, by allowing secondary users (SUs) to opportunistically access the temporarily unused spectrum, without introducing harmful interference to primary users (PUs). A crucial requirement in cognitive radio networks (CRNs) is wideband spectrum sensing, in which SUs

should detect spectral opportunities across a wide frequency range. However, wideband spectrum sensing could lead to unaffordable high sampling rates at energy-constrained SUs. Sub-Nyquist sampling was developed to overcome this issue by exploiting the sparse property of the wideband signals. Additionally, to relax the sensing requirements, hybrid framework that combines the advantages of both geo-location database and spectrum sensing is explored. The experimental results show that the hybrid schemes can achieve improved detection performance with reduced hardware and computation complexity in comparison with the sensing and database only approach.

Introduction

With the explosive proliferation of wireless devices and rapid growth of wireless services, spectrum scarcity has become a major bottleneck for wireless industry. The threat of spectrum shortage has encouraged the governments to take critical steps toward releasing multiple bands for dynamic spectrum sharing, motivated by the fact that the actual spectrum is underutilized in practice [13, 22]. In particular, TV white space (TVWS) is one of the most promising section for dynamic spectrum sharing, which is composed of the channels that are not used by digital terrestrial televisions (DTT) or program making and special events (PMSE) users, and those freed up by the switchover from analog to digital TV broadcasting [11,22]. The UK communications regulator, Office of Communications (Ofcom), has announced the license exempt regulations for TVWS in December 2015 [24]. Compact and low-power white space devices for rural broadband/WiFi-like accesses and machine-to-machine (M2M) communications could therefore operate on these vacant channels without causing interferences to the primary transmissions [9].

To make the SUs aware of the spectrum occupancy, one way is geo-location database, which is a centralized database to store the maximum allowed equivalent isotropic radiated power (EIRP) for each vacant TVWS channel at a specific location [13]. However, the real-time changes of the propagation environment pose significant challenges to the database approach [23]. Spectrum sensing over the wide bandwidth is thus desirable to detect spectral opportunities over a wide frequency range. However, for the wideband sensing at high frequency, it requires a high-rate analog-to-digital converter (ADC) for the signal sampling, which is quite expensive and high-power consuming. Sub-Nyquist sampling techniques were thus introduced to implement wideband sensing using sampling rate lower than the Nyquist rate to reduce the requirements of high-speed signal processing. In [39], Tian and Giannaki first applied compressed sensing to implement wideband sensing by exploiting the sparseness of the wideband signal in the frequency domain. In [30], each SU implements wideband channel division to sense K out of L channels, and then matrix completion is performed at a fusion center to reconstruct the original spectrum for decision making. To further relax the sensing requirements, an efficient blind sub-Nyquist cooperative wideband spectrum sensing scheme is proposed in [17] that reduce energy consumption in wideband signal acquisition, processing and transmission, with reliable performance guarantee.

Spectrum sensing provides instant channel occupancy information but may cause interference to some reserved channels as they would be determined as vacant by sensing and hence utilized by SUs for unlicensed transmission. To reduce the risk of interference caused by the unregistered PMSE and improve the spectrum efficiency, Wang et al. proposed a hybrid framework incorporating the advantages of both geo-location database and spectrum sensing, in which different spectrum sensing modules are performed after the spectrum occupancies were initially determined by geo-location database in [47]. Due to the energy constraint in compact SUs, efficient and reliable real-time wideband spectrum sensing emerges as a crucial challenge for dynamic spectrum sharing in CRNs. To further relax the sensing requirements, the data provided by the geo-location database calculation algorithm can be utilized to improve the detection performance.

Spectrum Sensing

Spectrum sensing is a critical functionality to enable the implementation of dynamic spectrum access in cognitive radio systems [20]. Its goal is to allow SUs to identify the spectrum occupancy states before opportunistically exploiting the temporarily vacant frequency channels while protecting PUs from harmful interferences caused by secondary transmissions.

Many narrowband spectrum sensing algorithms have been studied in the literature [35], including matched filtering [7], energy detection [15], and cyclostationary feature detection [37]. While present narrowband spectrum sensing algorithms focus on exploiting spectral opportunities over a narrow frequency range, cognitive radio networks will eventually be required to exploit spectral opportunities over a wide frequency range for achieving higher opportunistic throughput. If a PU reappears over a certain band, the availability of several other possible vacant channels facilitates the seamless handoff from one spectrum channel to another, which reduces secondary data transmission interruptions. However, for conventional wideband spectrum sensing, a stringent requirement arises from the Nyquist signal acquisition, which is quite expensive, power-consuming, and computation intensive. Efficient real-time wideband spectrum sensing emerges as a crucial challenge for dynamic spectrum sharing.

Narrowband Spectrum Sensing

As the core component of cognitive radio, spectrum sensing aims to obtain awareness about the spectrum usage and the existence of PU in a certain geographical area at a particular duration of time. The spectrum sensing problem can be formulated as follows.

Assume that the received signal is sampled at sampling frequency f_s. To detect the primary signal, SU poses a binary hypothesis testing problem as

$$\begin{aligned} H_0 &: r(t) = w(t), \\ H_1 &: r(t) = h(t) * s(t) + w(t), \end{aligned} \tag{1}$$

where $s(t) \in C^{N\times 1}$ is the transmitted signal, $h(t)$ is the channel gain between the transmitter and receiver, $w(t) \sim \mathscr{CN}(0, \sigma_\omega^2 \mathbf{I}_N)$ refers to additive white Gaussian noise (AWGN) distributed independently and identically with zero mean and variance σ_ω^2, $\mathbf{I}_N$ is the identity matrix, and N is the product of the sensing duration T_s and the sampling frequency f_s.

Traditional narrowband sensing can be mainly divided into three types, matched filtering [7], energy detection [15], and cyclostationary feature detection [37].

Among there three methods, energy detection is a non-coherent detection method that avoids the need for prior knowledge of the PUs. It is easy to implement and the computational complexity is relatively low but with a drawback of poor detection resolution under low SNR scenarios. Once the signal is received by SUs, the energy detector is used to calculate the energy of the received signal over the sensing interval and compare it with a predefined threshold to decide whether the frequency band is occupied or not.

Based on the central limit theorem, the test statistic T approximately follows the Gaussian Distribution [36]:

$$\begin{aligned} T &\sim \mathscr{N}(\sigma_\omega^2, 2\sigma_\omega^4/N), && H_0 \\ T &\sim \mathscr{N}((1+\gamma)\sigma_\omega^2, 2(1+\gamma)^2\sigma_\omega^4/N), && H_1, \end{aligned} \tag{2}$$

where N is the signal size and γ is the received SNR at the SU.

The performance of the detection scheme can be evaluated by two metrics: probability of detection P_d and probability of false-alarm P_f. P_d is the probability of correctly detecting the existence of PU on the sensing sub-channel when it is truly present and thus can be formulated as

$$P_d = P(T > \lambda | H_1) = Q\left(\frac{\lambda - \sigma_\omega^2(\gamma+1)}{\sigma_\omega^2(\gamma+1)\sqrt{\frac{2}{N}}}\right). \tag{3}$$

P_f is the probability of falsely testing that the considered channel is occupied by PU when it is actually not and can be computed as

$$P_f = P(T > \lambda | H_0) = Q\left(\frac{\lambda - \sigma_\omega^2}{\sigma_\omega^2\sqrt{\frac{2}{N}}}\right), \tag{4}$$

where $Q(x)$ is the standard Gaussian complementary distribution function (CDF).

To achieve the predefined false-alarm probability P_f, the threshold λ in each channel is set as

$$\lambda = \left[\sqrt{\frac{2}{N}}Q^{-1}(P_f) + 1\right] \cdot \sigma_\omega^2, \tag{5}$$

where $Q^{-1}(\cdot)$ denotes the inverse complementary distribution function of the standard normal distribution.

In order to maximize the benefit for both PUs and SUs, an adaptive threshold setting algorithm is developed in [48] to achieve the best trade-off between detection probability P_d and false alarm probability P_f, which can be formulated to an equivalent form of minimizing the error decision probability P_e as

$$\lambda^* = \arg\min_{\lambda} P_e(\lambda) = \arg\min_{\lambda}\{(1-\Omega)P_f + \Omega(1-P_d)\}, \tag{6}$$

where Ω ($0 \leq \Omega \leq 1$) is the PU's spectrum utilization ratio, $(1-\Omega)$ stands for the probability that the channel being vacant and full of noise, and $(1-P_d)$ represents the missed detection probability that indicates PUs are absent while actually present. After mathematical derivation, the adaptive threshold λ^* that can minimize the error decision probability is

$$\lambda^* = \sigma_n^2 \cdot \frac{1 + \sqrt{1 + \frac{4}{N} \cdot \left(1 + \frac{2}{SNR}\right) \cdot \ln\left(\frac{(1-\Omega)}{\Omega} \cdot (1+SNR)\right)}}{(2+SNR)/(1+SNR)}, \tag{7}$$

and it can be further simplified when the sample points N is approaching to positive infinite:

$$\lambda^* \approx \frac{2\sigma_n^2 \cdot (1+SNR)}{(2+SNR)} (N \to +\infty). \tag{8}$$

Wideband Spectrum Sensing

Against narrowband techniques aforementioned, wideband spectrum sensing techniques aim to sense a frequency bandwidth that exceeds the coherence bandwidth of the channel. For example, for exploiting spectral opportunities in the whole ultrahigh frequency (UHF) TV band (between 300 MHz and 3 GHz), wideband spectrum sensing techniques should be employed. Narrowband sensing techniques cannot be directly used for performing wideband spectrum sensing, because they make a single binary decision for the whole spectrum and thus cannot identify individual spectral opportunities that lie within the wideband spectrum [3].

Wideband spectrum sensing can be broadly divided into two types: Nyquist wideband sensing and sub-Nyquist wideband sensing. Nyquist wideband sensing processes the received signals at or above the Nyquist rate, which can lead to unaffordable high sampling rate or implementation complexity. Sub-Nyquist sampling technique therefore attracts more and more attention to achieve a more flexible and faster wideband spectrum sensing, such as compressive sensing (CS) [39, 52, 53], multicoset sampling [8, 46], etc.

Nyquist Wideband Sensing

A direct approach of wideband spectrum sensing is to directly acquire the wideband signal using a standard ADC and then use the digital signal processing techniques to detect spectral opportunities. In [31], a multiband joint detection algorithm is proposed. As shown in Fig. 1, the wideband signal is directly sensed by a wideband ADC, and then it is processed by a serial-to-parallel conversion circuit to divide the sampled data into parallel data streams. Fast Fourier transform (FFT) is implemented to covert the wideband signals into frequency domain. Then the wideband spectrum is divided into series of narrowband spectrum. Finally, spectrum occupancy of each narrow band is determined by using an optimized threshold. It achieved a better detection performance than the aforementioned narrowband spectrum sensing.

In addition, a wavelet-based spectrum sensing algorithm was proposed in [38]. In this algorithm, the power spectral density (PSD) of the wideband spectrum was modeled as a train of consecutive frequency subbands, where the PSD is smooth within each subband but exhibits discontinuities and irregularities on the border of two neighboring subbands. The wavelet transform was then used to locate the singularities of the wideband PSD, and the wideband spectrum sensing was formulated as a spectral edge detection problem.

However, in the wideband regime, a major challenge arises from the stringent requirements on the high sampling rate at the ADCs to transform the received signals into digital signals by sampling at the Nyquist rate, which presents significant challenges in the high-speed sampling hardware and signal processing algorithms.

A simple approach to relax the high sampling rate requirement for wideband spectrum sensing is to use a tunable narrowband bandpass filter (BPF) at the radio-frequency (RF) front-end to scan through all of the narrow channels one by one to detect the existence or nonexistence of licensed primary transmissions [26,50]. The tuning range of each BPF needs to be preselected. The occupancy of each channel can be determined by measuring the energy of the signal at the output of each filter. However, the sequential nature of such scheme could introduce a long sensing period. Such delay in the sensing process will also cause missed opportunities or interferences to PUs.

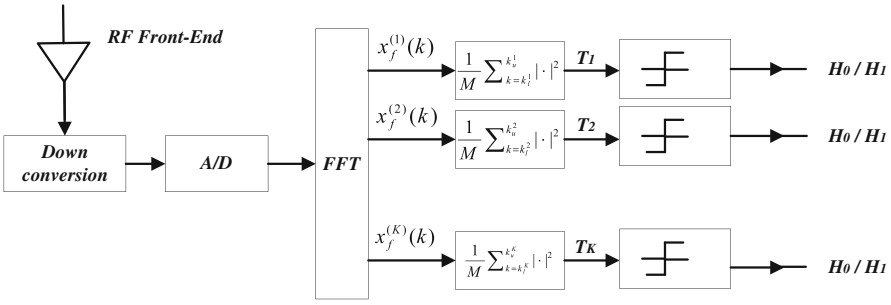

Fig. 1 Schematic illustration of multiband joint detection

Sub-Nyquist Wideband Sensing

Due to the drawbacks of high sampling rate or high implementation complexity in Nyquist systems, sub-Nyquist approaches are drawing more and more attention. Sub-Nyquist wideband spectrum sensing refers to the procedure of acquiring wideband signals using a sampling rate lower than the Nyquist rate and detecting spectral opportunities using these partial measurements. Two important types of sub-Nyquist wideband sensing are CS-based wideband sensing and multichannel sub-Nyquist wideband sensing. In the subsequent section, we give some discussions and comparisons regarding these sub-Nyquist algorithms and their applications to the wideband spectrum sensing.

Sub-Nyquist Wideband Spectrum Sensing

The well-known Nyquist sampling theory requires that sampling rate should be at least twice of the signal bandwidth. Therefore, the sampling rate is very challenging for wideband spectrum sensing. The high-speed ADC for wideband signals is difficult or expensive to implement at SUs, especially for power-limited devices. To guarantee the stable reconstruction of multiband signals, Landau [14] demonstrated that the sampling rate should be no less than the measure of the occupied part of the spectrum, which is below the corresponding Nyquist sampling rate. As the wideband spectrum of interest is normally underutilized in reality [22], the spectrum exhibits a sparse property in the frequency domain, which makes sub-Nyquist sampling possible for spectrum sensing.

Compressed Sensing

Compressed sensing (CS) is a technique that can efficiently acquire a signal using relatively few measurements, by which unique representation of the signal can be found based on the signal's sparseness in some domain. As the wideband spectrum is sparse due to its low spectrum utilization, CS becomes a promising candidate to realize wideband spectrum sensing by using sub-Nyquist sampling rates. The process of CS can be summarized as follows:

1. *Sparse representation of received signals.*
   It is assumed that bandwidth of the whole spectrum is B Hz. The received signal at an SU is given by:

$$r(t) = h(t) * s(t) + w(t), \tag{9}$$

   where $s(t) \in C^{N\times 1}$ is the transmitted signal, $h(t)$ is the channel gain between the transmitter and receiver, and $w(t) \sim \mathscr{CN}(0, \sigma_\omega^2 \mathbf{I}_N)$ refers to AWGN where σ_ω^2 refers to the noise variance and $\mathbf{I}_N$ is the identity matrix.

The received signals $r(t)$ is assumed to be sparse in the frequency domain. It can be expressed as $r_f = s_f + w_f$, where r_f, s_f, and w_f are the discrete Fourier transform (DFT) of $r(t)$, $s(t)$, and $w(t)$. As aforementioned, s_f is sparse since the spectrum is normally underutilized. This sparse property makes it possible to reduce sampling rates by implementing CS at the SU.

2. *Compressed measurement collection.*

The received compressed measurements at the SU can be expressed by:

$$x = \Phi \mathscr{F}^{-1} r_f = \Theta r_f = \Theta \left(s_f + w_f \right), \tag{10}$$

where $\Phi \in C^{P \times N}$ $(P \leq N)$ is a measurement matrix to collect the compressed measurements $x \in C^{P \times 1}$, where $P/N \leq 1$ refers to the compression ratio.

There are three conditions that should be fulfilled by the measurement matrix: (i) each column of it is normalized, (ii) each row of it has approximately equal norm, and (iii) the rows of it are orthogonal [42]. In practical settings, structured random matrices are often employed for improved implementation affordability, such as the analog-to-information converter (AIC sampler) [41]. The AIC sampler mainly contains three components: a high-rate pseudonoise sequence, a low-pass anti-aliasing filter, and a low-speed ADC. This structure alleviates the burden on the ADCs, at the expense of slightly degraded recovery performance compared with those fully random Gaussian samplers.

3. *Signal recovery.*

In order to make accurate decisions about spectrum occupancy, the signal recovery should be performed by solving the following l_1 norm minimization as:

$$\widehat{s}_f = \arg \ \min \ \left\| \widehat{s}_f \right\|_1, \ s.t. \ \left\| \theta \cdot \widehat{s}_f - x \right\|_2^2 \leq \varepsilon \tag{11}$$

where ε is an upper bound on the size of the noisy contribution.

4. *Decision making.* When the estimated signal $\hat{s}_f$ is obtained, energy detection is performed to determine the spectrum occupancy. Specifically, the energy density of each channel in the recovered signal is compared with a predefined threshold to make a decision. In practice, the noise power (σ_w^2) can be calibrated in a given channel which is known to be idle, such as channel 21 in TVWS that is supposed to be vacant currently in the UK.

If the energy of the reconstructed signal is higher than the threshold, the corresponding channel is determined as occupied, and SUs are forbidden to access it. Otherwise, the corresponding channel is determined as vacant, and SUs can access it for transmission.

In order to reduce the complexity in signal recovery and enhance the robustness to imperfect channel environments, a two-phase spectrum sensing algorithm is proposed in [30]. In the first phase, a channel division scheme is applied to reduce the computation complexity for signal recovery. In the second phase, a denoising algorithm is proposed to improve the sensing robustness against heavy channel noise.

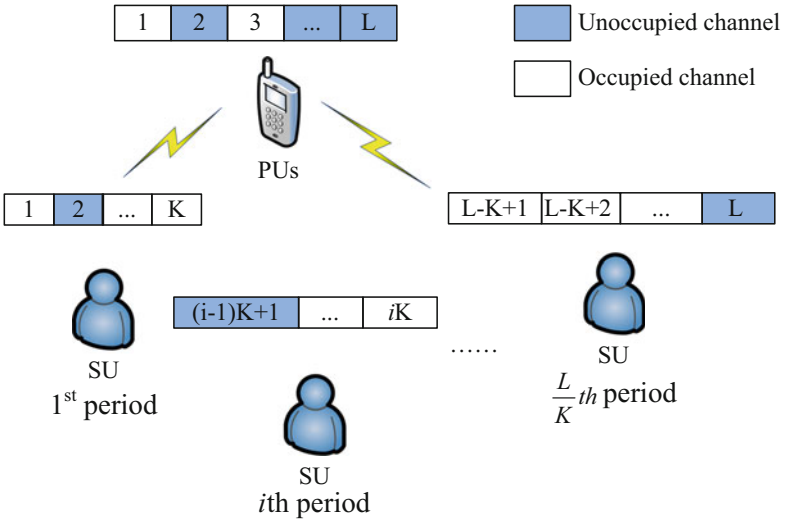

Fig. 2 Channel division scheme

1. *The efficient channel division scheme*

   In the l_1 minimization recovery process, the computational complexity is dependent on the number of samples to be recovered. Assuming that there are L channels in the spectrum of interest, a channel division scheme is proposed in which only K ($K < L$) channels are expected to be sensed in each sensing period to reduce the number of samples to be recovered. As shown in Fig. 2, each K-channel group is indexed by i $\left(i = 1, 2, \cdots, \frac{L}{K}\right)$. If any vacant channel is detected, the SU would stop sensing and start data transmission. Otherwise, it senses the next channel group in the following sensing period. As a result, the required sampling rates for exact recovery are reduced at the SU.

   Once signal for a K channel group $s_{fi} \in C^{n\times 1}$ ($n = \frac{KN}{L}$) arrives, compressed samples x_i are collected at the SU, and its original spectrum can be recovered by l_1 norm minimization as:

$$\hat{s}_{fi} = \arg \min \left\|\hat{s}_{fi}\right\|_1, \text{ s.t. } \left\|\Theta_i \cdot \hat{s}_{fi} - x_i\right\|_2^2 \leq \varepsilon_i, \tag{12}$$

   where $\Theta_i \in C^{p\times n}$, $p = \frac{KP}{L}$ and ε_i is the error tolerance in the reconstruction process.

2. *The denoised spectrum sensing algorithm*

   The recovery performance of the l_1 norm minimization is degraded by heavy channel noise and reduced number of compressed samples. Furthermore, it is noticed that the amplitudes of recovered signal $\hat{s}_{fi}$ may be negative with high absolute values. As the power spectrum s_{fi} is nonnegative, if those negative values are used to calculate the energy density, it would become higher than

its real energy value. Therefore, it will result in a higher P_f, so that the vacant channels might be determined as occupied. In order to improve the detection performance, a denoising algorithm is proposed to implement at each SU.

In the denoising algorithm, the amplitude of each frequency bin in the recovered signal $\hat{s}_{fi}$ is compared with the noise level. If the amplitude of is higher than the noise level, the compressed measurement collected $r_{fi}(b)$ is kept for the recovered signal. Otherwise, the corresponding value will be set to zero to reduce the recovery error. The denoised signal $\hat{s}_{fi\_d}$ can be expressed as:

$$\hat{s}_{fi\_d}(b) = \begin{cases} r_{fi}(b) & \text{if } \hat{s}_{fi}(b) \geq \sigma(b) \\ 0 & \text{otherwise,} \end{cases} \tag{13}$$

where b is the index of each frequency bin.

After the denoising algorithm, the energy density in the denoised signal is compared with the corresponding threshold to determine the spectrum occupancy of each considered K channel group. If any channel group is determined as vacant, it can be used by SUs to transmit the unlicensed signals. Otherwise, the SU should continue sensing the next channel group until any vacant channel is found out or the final $\frac{L}{K}$ sensing periods are run out. As there is a high probability that the spectrum vacant in last loop remains free in the current sensing loop, the SU should sense the channel group determined as free in the last sensing loop at the beginning of the new sensing loop. The whole process of the two-phase spectrum sensing algorithm based on CS is summarized as Algorithm 1.

Algorithm 1 Two-phase CS-based single node spectrum sensing scheme

Initialization:

Set threshold λ as (5);

$i = 1$.

1: **while** $i \leq \frac{L}{K}$ or $E\left(\hat{s}_{fi\_d}\right) < \lambda$ **do**

2: The SU takes measurements at sub-Nyquist rate for the i-th K-channel group to collect r_i in the i-th sensing period.

3: Perform signal recovery by l_1 algorithm as (12) to get the recovered signal $\hat{s}_{fi}$.

4: Perform denoising to $\hat{s}_{fi}$ to get $\hat{s}_{fi\_d}$.

5: Increase i by 1.

6: **end while**

Decision:

If $E\left(\hat{s}_{fi\_d}\right) < \lambda$, SU can access the i-th K-channel group. If $i = \frac{L}{K}$, a new sensing loop begins. The SU senses from the K-channel group which is vacant in last sensing loop or from the first K-channel group in the new sensing loop.

Figure 3 shows P_d for the traditional l_1 norm minimization based spectrum sensing (labeled as traditional CS-based SS) and the two-phase CS-based spectrum sensing (labeled as denoised CS-based SS) under a different number of collected measurements. The detection performance is also compared with that of spectrum

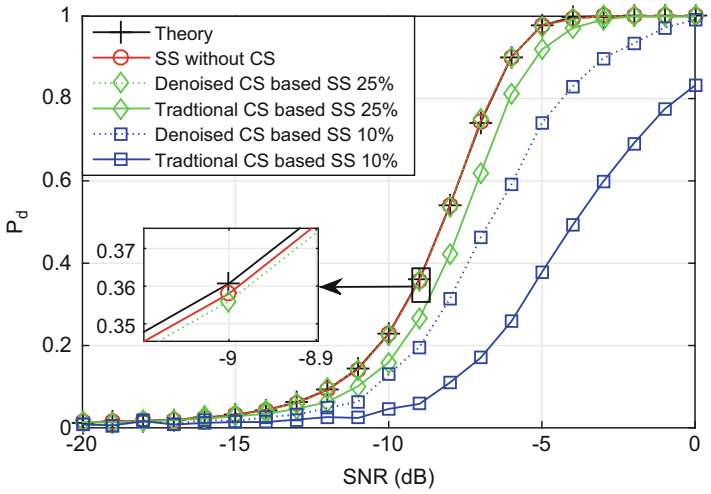

Fig. 3 Probability of detection P_d comparison with different compression ratios under different SNR values

sensing without CS implementation (labeled as SS without CS), as well as the theoretical values derived from (3). In the simulation, primary signals are orthogonal frequency-division multiplexing (OFDM) generated, which is used in Digital Video Broadcasting-Terrestrial (DVB-T) over the TVWS from 470 MHz to 790 MHz in the UK [22]. There are $L = 40$ channels in total with 8MHz for each channel. The number of channels sensed by the SU in each sensing period is set to be $K = 8$. Therefore, at most $\frac{L}{K} = 5$ sensing periods are needed for the whole spectrum of interest. The P_f is set to be 0.01. The SNR is defined as the ratio of signal power and noise power of the K channel group. The number of occupied channels is 1 among 8. Therefore, the sparsity level is set to be 12.5%.

As Fig. 3 shows, performance of the two-phase spectrum sensing based on CS is better than that of the CS-based spectrum sensing without denoising when the compression ratio is 25% and 10%. This gain benefits from the denoising algorithm to improve the signal recovery accuracy. As the recovery accuracy becomes higher with higher compression ratio, detection performance of the two-phase spectrum sensing algorithm gets closer to the theoretical curves. The simulation result shows that the two-phase spectrum sensing algorithm can reduce the sampling rates by 75% without degrading detection performance.

Multichannel Sub-Nyquist Sampling

Although the energy consumption at the CS-based wideband signal sampling part is reduced, compressive sensing requires random sub-Nyquist projections [3]. Therefore, custom ADCs with complex hardware that can perform analog mixing or

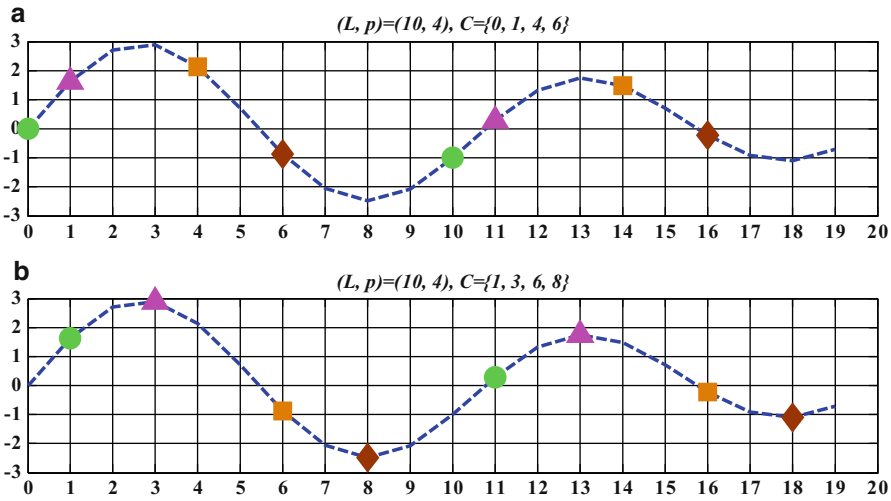

Fig. 4 Examples of two sampling patterns for $(L, p) = (10, 4)$. (**a**) $C = \{0, 1, 4, 6\}$; (**b**) $C = \{1, 3, 6, 8\}$

analog matrix multiplication at high frequency are needed in compressive wideband spectrum sensing schemes, which do not work well with low-power commodity hardware [10, 19, 41].

In [8], a wideband spectrum sensing scheme based on multicoset sampling was proposed, which is a nonuniform sub-Nyquist sampling technique and can be realized using an efficient multichannel architecture. Given the prior information on the number of channels L, multicoset sampling is first executed at each SU by taking nonuniform samples at the time instants $t = (mL + c_i)T$, where $i = 1, \ldots, p$, $p \leq L$, $m \in \mathbb{Z}$, and $1/T = f_s$ is the Nyquist sampling rate. The set $C = \{c_i\}_{i=1}^{p}$, which comprises of p distinct integers chosen from $\{0, 1, \ldots, L-1\}$, is referred as a (L, p) sampling pattern. Figure 4 presents two multicoset sampling patterns for $(L, p) = (10, 4)$.

To implement the periodic nonuniform sampling, a multicoset sampler can be realized by p parallel cosets, each of which takes uniform samples at time instants $\{mLT + c_i T\}$, $m \in \mathbb{Z}$, via a decimated sampling rate $\frac{1}{LT} = f_s/L$ with a sampling time offset of $\{c_i T\}$, $i = 1, \ldots, p$, as shown in Fig. 5.

From the practical standpoint, the nonuniform sub-Nyquist sampling can be realized by a time-interleaved ADC, in which only a subset of channels are used. In [16, 28], efficient fabrications of time-interleaved ADC implemented as a single integrated circuit are proposed. As multicoset sampler only needs fewer channels than the time-interleaved ADC ($p \leq L$), the hardware implementation would be simpler and less power-consuming. In addition, the time offsets can be realized by connecting the antenna to different ADCs using different delay lines.

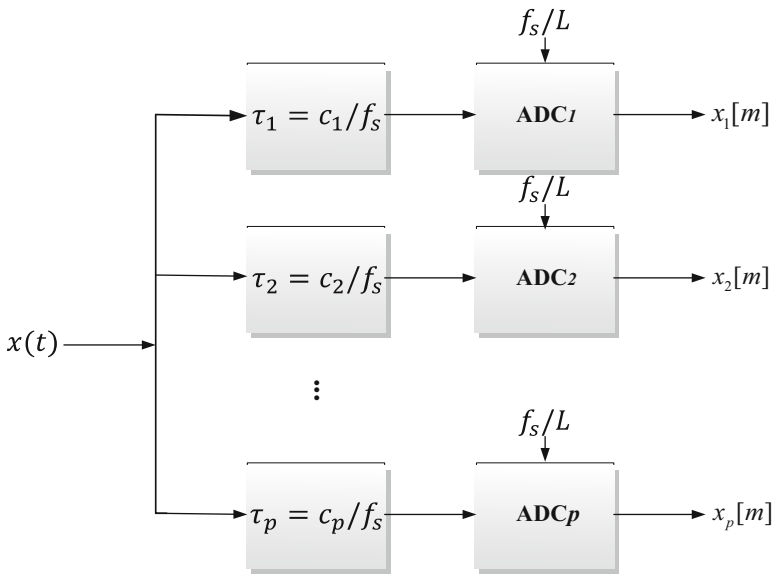

Fig. 5 The parallel implementation of the nonuniform sub-Nyquist sampling

The measurement sequence of the i-th coset is defined as

$$x_{c_i}[n] = \begin{cases} x(nT), & n = mL + c_i, m \in \mathbb{Z} \\ 0, & \text{otherwise} \end{cases} \tag{14}$$

In practice, the ADCs of the parallel cosets provide p sample sequences, given by

$$x_i[m] = x[(mL + c_i)T], \ m \in \mathbb{Z}, \ i = 1, 2, \ldots, p. \tag{15}$$

In (14), each sequence $x_{c_i}[n], \ i = 1, \ldots, p$, contains $L - 1$ zeros in between the downsampled signals. To get $x_{c_i}[n]$, each $x_i[m]$ is upsampled by a factor of L:

$$x_{u_i}[n] = \begin{cases} x_i\left[\frac{n}{L}\right], & n = mL, \ m \in \mathbb{Z} \\ 0, & \text{otherwise}, \end{cases} \tag{16}$$

and then filtered to get $x_{h_i}[n] = x_{u_i}[n] * h[n]$, where $h[n]$ is an interpolation filter with the frequency response:

$$H(f) = \begin{cases} 1, & f \in [0, B] \\ 0, & \text{otherwise}. \end{cases} \tag{17}$$

The filtered sequence is then delayed with c_i samples to obtain $x_{c_i}[n]$ as

$$x_{c_i}[n] = x_{h_i}[n - c_i]. \tag{18}$$

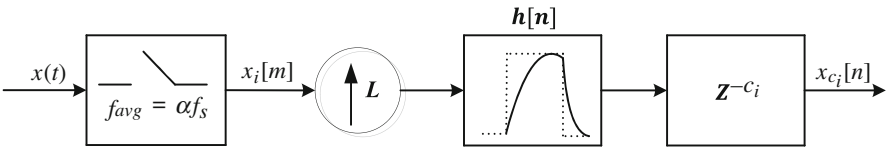

Fig. 6 Flow chart to get the multicoset sampling measurements

The whole process to obtain the compressed measurements in multicoset sampling can be implemented as shown in Fig. 6 [8].

The average sampling rate of each (L, p) multicoset sampling pattern is

$$\frac{1}{T_{\text{avg}}} = \frac{p}{LT}, \tag{19}$$

where $\alpha = p/L$ is termed as the sub-Nyquist sampling ratio. According to the Landau's theorem [14], α is lower-bounded by the maximum possible spectrum occupancy ratio. However, an average sampling rate above the Landau's rate, which equals the total bandwidth of the occupied spectrum, may not be sufficient for individual blind spectrum recovery, and the number of cosets $p \geq 2\kappa$ is needed when the band locations are unknown [18], where κ is the number of active channels occupied by PUs during the sensing period.

Applying Fourier transform to $x_{c_i}[n]$ gives the link between its spectrum $X_{c_i}(e^{j2\pi fT})$ and the unknown Fourier Transform of $x(t)$ [8]:

$$\begin{aligned} X_{c_i}(e^{j2\pi fT}) &= \textstyle\sum_{n=-\infty}^{+\infty} x_{c_i}[n] e^{-j2\pi fnT} \\ &= \tfrac{1}{LT} \textstyle\sum_{l=0}^{L-1} \underbrace{X\left(f + \dfrac{l}{LT}\right)}_{X_l(f)} e^{j\frac{2\pi}{L}c_i l} \\ &= \tfrac{1}{LT} \textstyle\sum_{l=0}^{L-1} X_l(f) e^{j\frac{2\pi}{L}c_i l} \quad \forall f \in [0, B], \end{aligned} \tag{20}$$

for every $1 \leq i \leq p$, where $X_l(f)$, $l = 0, \ldots, L-1$, corresponds to the pieces of the original spectrum $X(f)$ in the channel l, which is shifted to the left by $\frac{l}{LT}$ units such that all L channels are folded into the first narrowband $[0, B]$.

Assume that the observed signal is given by $x(t) = s(t) + n(t)$, where $s(t)$ is the primary signal and $n(t)$ is the additive white Gaussian noise with zero mean and variance σ_n^2. The corresponding Fourier transform is given by $X(f) = S(f) + N(f)$. Define $S_l(f) = S(f + \frac{l}{LT})$, $l = 0, \ldots, L-1$, and $\mathbf{S}(f) = [S_0(f), S_1(f), \ldots, S_{L-1}(f)]^T$. Similarly we define $N_l(f)$ and $\mathbf{N}(f)$. We can rewrite (20) into the matrix form as

$$\underbrace{\begin{bmatrix} X_{c_1}(e^{j2\pi fT}) \\ X_{c_2}(e^{j2\pi fT}) \\ \vdots \\ X_{c_p}(e^{j2\pi fT}) \end{bmatrix}}_{\mathbf{Y}(f)} = \underbrace{\frac{1}{LT}\begin{bmatrix} e^{\frac{j2\pi c_1 0}{L}} & e^{\frac{j2\pi c_1 1}{L}} & \cdots & e^{\frac{j2\pi c_1 (L-1)}{L}} \\ e^{\frac{j2\pi c_2 0}{L}} & e^{\frac{j2\pi c_2 1}{L}} & \cdots & e^{\frac{j2\pi c_2 (L-1)}{L}} \\ \vdots & \vdots & \vdots & \vdots \\ e^{\frac{j2\pi c_p 0}{L}} & e^{\frac{j2\pi c_2 1}{L}} & \cdots & e^{\frac{j2\pi c_p (L-1)}{L}} \end{bmatrix}}_{\mathbf{A}} \times \underbrace{\begin{bmatrix} X_0(f) \\ X_1(f) \\ \vdots \\ X_{L-1}(f) \end{bmatrix}}_{\mathbf{X}(f)} = \mathbf{A}[\mathbf{S}(f) + \mathbf{N}(f)], \quad \forall f \in [0, B], \tag{21}$$

where $\mathbf{Y}(f)$ is a matrix whose i-th row is $X_{c_i}(e^{j2\pi fT})$, $\mathbf{X}(f) = [X_0(f), X_1(f), \ldots, X_{L-1}(f)]^T$ is the unknown spectrum vectors of $x(t)$ in the L channels, and $\mathbf{A} \in \mathbb{C}^{p \times L}$ is a matrix with (i, j)-th element given by

$$\mathbf{A}_{i,j} = \frac{1}{LT} e^{j\frac{2\pi}{L}c_i(j-1)}. \tag{22}$$

As the parameter L in the adopted multicoset sampler is set according to the number of channels in the original spectrum, the support of the original spectrum $supp(\mathbf{S}(f))$ in (21) is equivalent to the active channel index set S. Thus, signal reconstruction is unnecessary and only the support of the spectrum is of interest in this wideband spectrum sensing scheme.

With multicoset samplers, each SU gets p sample sequences in a matrix from $\mathbf{Y}(f) \in \mathbb{C}^{p \times N}$, where N is the number of samples in each coset. The correlation matrix of the sampled sequence $\mathbf{Y}(f)$ is defined as

$$\mathbf{R} \triangleq \mathbb{E}[\mathbf{Y}(f)\mathbf{Y}^H(f)], \tag{23}$$

where the superscript $()^H$ denotes the Hermitian transpose. Since there is no correlation between the signal and the noise, it follows that

$$\mathbf{R} = \mathbf{A}[\mathbf{R}_s + \sigma_n^2 \mathbf{I}]\mathbf{A}^H, \tag{24}$$

where $\mathbf{R}_s \triangleq \mathbb{E}[\mathbf{S}(f)\mathbf{S}^H(f)]$ is the primary signal correlation matrix. Note that $\mathbf{A}$ is a sub-matrix of the complex conjugate of the $L \times L$ discrete Fourier transform

matrix (consisting of p rows indexed by the sampling pattern C) multiplied by a factor of $\frac{1}{LT}$. It is shown that for a larger L, the randomly selected sampling pattern C enables the matrix $\mathbf{A}$ to have almost orthogonal columns, i.e., $<a_i, a_j> = 0$ for $i \neq j$ and $<a_i, a_j> = \frac{1}{LT^2}$ for $i = j$ with a high probability [2,3]. Therefore, $\mathbf{R}$ can be derived as:

$$\mathbf{R} = \mathbf{A}\mathbf{R}_s\mathbf{A}^H + \frac{\sigma_n^2}{LT^2}\mathbf{I}. \tag{25}$$

From Parseval's identity [1, 51], the correlation matrix $\hat{\mathbf{R}}$ can be computed directly from the sampled sequence $x_{c_i}[n]$ in the time domain, where $\hat{\mathbf{R}}_{ij} = \frac{1}{N}\sum_{n=1}^{N} x_{c_i}[n]x_{c_j}^H[n]$. It is shown in [21,45] that when the number of measurement samples N is much larger than the observation dimension p, $\hat{\mathbf{R}}$ is an accurate estimator of the true correlation matrix.

As there are up to κ active channels occupied during the sensing period, i.e., $\mathbf{R}_s$ has a rank of κ and $\mathbf{A}$ is of full rank, it follows that the rank of $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$ equals κ. Denoting $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_p$ and $\mu_1, \mu_2, \ldots, \mu_p$ as the eigenvalues and corresponding eigenvectors of $\mathbf{R}$, respectively, i.e.,

$$\mathbf{R}\mu_i = \lambda_i\mu_i,\ i = 1, \ldots, p. \tag{26}$$

We then have

$$[\mathbf{A}\mathbf{R}_s\mathbf{A}^H + \frac{\sigma_n^2}{LT^2}\mathbf{I}][\mu_1, \ldots, \mu_p] = [\mu_1, \ldots, \mu_p]\begin{bmatrix}\lambda_1 & & & 0\\ & \lambda_2 & & \\ & & \ddots & \\ 0 & & & \lambda_p,\end{bmatrix}, \tag{27}$$

i.e.,

$$\begin{aligned}&[\mathbf{A}\mathbf{R}_s\mathbf{A}^H][\mu_1, \ldots, \mu_p]\\ &\quad = [\mu_1, \ldots, \mu_p]\begin{bmatrix}\lambda_1 - \frac{\sigma_n^2}{LT^2} & & & 0\\ & \lambda_2 - \frac{\sigma_n^2}{LT^2} & & \\ & & \ddots & \\ 0 & & & \lambda_p - \frac{\sigma_n^2}{LT^2},\end{bmatrix}.\end{aligned} \tag{28}$$

Since $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$ has a rank of κ, there must be $p - \kappa\lambda_i$'s equal to $\frac{\sigma_n^2}{LT^2}$. As $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$ is positive semidefinite, the λ_i's with values equal to $\frac{\sigma_n^2}{LT^2}$ must be the smallest ones of λ_i's. Therefore, we have

$$\lambda_{\kappa+1} = \lambda_{\kappa+2} = \ldots = \lambda_p = \frac{\sigma_n^2}{LT^2}. \tag{29}$$

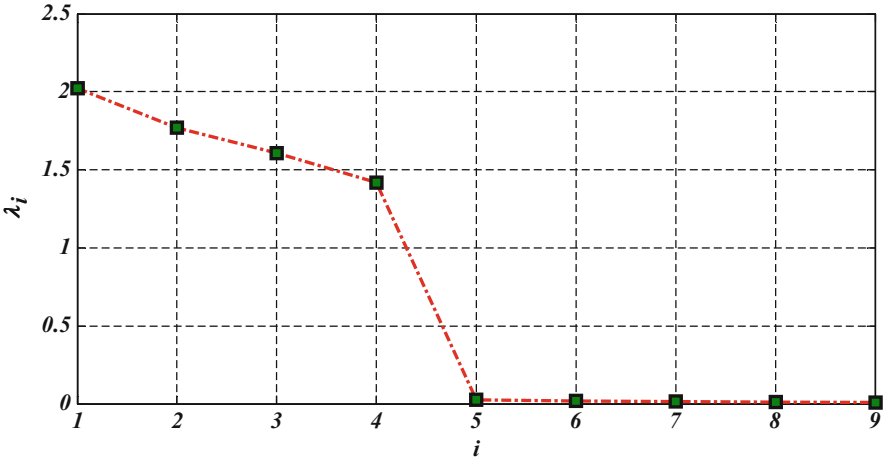

Fig. 7 Eigenvalues of the sample correlation matrix ordered in decreasing order with $p = 9$, $\kappa = 4$

As $N \to \infty$, it follows that except for the κ largest, the eigenvalues of $\mathbf{R}$ are related to the noise variance σ_n^2, as shown in Fig. 7.

Thus $\mathbf{R}$ can be decomposed via the rank-revealing eigenvalue decomposition (RREVD) as

$$\mathbf{R} = \mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^H = \mathbf{U}_s\boldsymbol{\Lambda}_s\mathbf{U}_s^H + \frac{\sigma_n^2}{LT^2}\mathbf{U}_n\mathbf{U}_n^H, \tag{30}$$

where $\mathbf{U} = [\mathbf{U}_s, \mathbf{U}_n]$, $\boldsymbol{\Lambda}_s = \text{diag}\{\lambda_1, \ldots, \lambda_\kappa\}$ contains the κ non-increasing principal eigenvalues and $\mathbf{U}_s$ contains the corresponding eigenvectors, while $\mathbf{U}_n$ contains the corresponding eigenvectors associated with the smallest $p - \kappa$ eigenvalues $\frac{\sigma_n^2}{LT^2}$. As the noise term only perturbs the eigenvalues, the range of $\mathbf{R}$, spanned by $\mathbf{U}_s$, coincides with the signal subspace spanned by $\mathbf{AS}(f)$, and its orthogonal complement spanned by $\mathbf{U}_n$ is the noise subspace. Therefore, we choose the κ largest eigenvalues $\boldsymbol{\Lambda}_s$ and the corresponding eigenvectors $\mathbf{U}_s$ to construct the measurement matrix as $\boldsymbol{\chi}_s = \mathbf{U}_s\sqrt{\boldsymbol{\Lambda}_s}$; so we can define the following linear system

$$\boldsymbol{\chi}_s = \mathbf{A}\boldsymbol{v}_s, \tag{31}$$

where the support of the sparest solution to (31) converges to the original primary signal, i.e., $supp(\boldsymbol{v}_s) = supp(\mathbf{S}(f))$. Moreover, using $\boldsymbol{\chi}_s \in \mathbb{C}^{p\times\kappa}$ for support recovery instead of $\mathbf{Y}(f) \in \mathbb{C}^{p\times N}$ reduces the transmission overhead and enhances the computational efficiency.

The separation between the signal and noise eigenvalues needs a threshold. Depending on the noise variance and the number of samples, the threshold could vary. To avoid the tricky threshold setting, some information theoretic criteria for

the model order selection, such as exponential fitting test (EFT), can be applied for the estimation of the signal support dimension $\hat{\kappa}$ [32].

As only κ active channels are assumed to be occupied by primary transmissions, $\boldsymbol{\nu}_s$ can be approximated to be jointly κ-sparse as it contains no more than κ significant rows. Reconstruction of the unknown matrix $\boldsymbol{\nu}_s$ with jointly sparse columns in (31) is referred to as the joint sparse problem, which aims to estimate the support of $\boldsymbol{\nu}_s$ from the measurement matrix $\boldsymbol{\chi}_s$. Some existing greedy algorithms for the sparse recovery problem could be extended to this joint sparse problem, such as SOMP [40]. To improve the detection robustness against noise interference and reduce the computation complexity, SOMP is applied to the constructed low-dimensional measurement matrix $\boldsymbol{\chi}_s$, denoted as subspace-augmented SOMP (SA-SOMP). The detailed procedure of the joint sparse recovery in the individual wideband spectrum sensing is summarized in Algorithm 2.

As sub-Nyquist measurements are quite vulnerable to channel degradations, cooperation among multiple SUs is necessary in sub-Nyquist wideband sensing. Assume that there are J coexisting SUs within the local region that cooperatively sense the wideband to locate the active channel set S. The received signals at the SUs are from the same primary transmissions but affected differently by fading and shadowing from the common PU transmitter to each SU. Thus all SUs share a common sparse support with different amplitudes.

The cooperative spectrum sensing based on the multicoset sampling scheme can be formulated into a three-step framework:

1. Each SU implements a multicoset sampler that independently samples the signal with a different sampling pattern $C^{(j)}$ from the others, e.g., randomly chosen to allow for more sampling diversity.
2. Measurement matrix $\boldsymbol{\chi}_s^{(j)}$ is constructed at each SU from its sub-Nyquist samples based on subspace decomposition. Then the local matrix $\boldsymbol{\chi}_s^{(j)}$ with the sampling pattern $C^{(j)}$ is transmitted to the fusion center.
3. The fusion center locates the active channels by jointly fusing measurements shared among the SUs to reach a global sensing decision with enhanced accuracy.

Based on the measurement matrix $\boldsymbol{\chi}_s^{(j)}$ and the sampling pattern $C^{(j)}$ sent from each SU, the fusion center computes the corresponding reconstruction matrix $\mathbf{A}^{(j)}$ and then locates the active channels by exploiting the common signal support shared by $\boldsymbol{v}_s^{(j)}$, $j = 1, \cdots, J$, across all SUs. At each SU, the following relationship holds:

$$\boldsymbol{\chi}_s^{(j)} = \mathbf{A}^{(j)} \boldsymbol{v}_s^{(j)}, \ 1 \leq j \leq J. \tag{32}$$

Exploiting the common sparse support shared by the J SUs, the fusion center fuses measurements sent from all SUs to locate the original active channels. Grouping the rows of $\boldsymbol{v}_s^{(j)}$, $j = 1, \ldots, J$, with the same indices, forms the matrix $\boldsymbol{\zeta}_s$ as

$$\boldsymbol{\zeta}_s = \left[\underbrace{\boldsymbol{v}_s^{(1)}[1]^T \cdots \boldsymbol{v}_s^{(J)}[1]^T}_{\boldsymbol{v}_s[1]^T} \cdots \underbrace{\boldsymbol{v}_s^{(1)}[L]^T \cdots \boldsymbol{v}_s^{(J)}[L]^T}_{\boldsymbol{v}_s[L]^T} \right]^T, \tag{33}$$

where $\boldsymbol{v}_s^{(j)}[i]$ denotes the i-th row of $\boldsymbol{v}_s^{(j)}$ at the j-th SU. Furthermore, $\boldsymbol{\zeta}_s$ can be partitioned as a concatenation of blocks $\boldsymbol{v}_s[l]^T$, $l = 1, \ldots, L$, and the block size is equal to the number of SUs J. As there are at most κ channels occupied, $\boldsymbol{\zeta}_s$ can be modeled as a block κ-sparse matrix. Thus, in each iteration, the block index that accounts for the largest residual norm among all SUs is selected, i.e.,

$$l_t = \arg\max_{l} \sum_{j=1}^{J} \parallel \mathbf{a}_l^{(j)\mathbf{H}} \mathbf{R}_{t-1}^{(j)} \parallel_2, \ l \in 1, \ldots, L, \tag{34}$$

where $\mathbf{R}_{t-1}^{(j)}$ is the residue at the $(t-1)$-th iteration at the j-th SU, $\mathbf{a}_l^{(j)}$ is the l-th column in $\mathbf{A}^{(j)}$, and l_t is the selected index. The detailed algorithm for the joint support recovery at the fusion center is described in Algorithm 3, where each SU implements EFT to estimate the signal sparsity $\hat{\kappa}^{(j)}$, and then the fusion center takes the average $\hat{\kappa}$, i.e.,

$$\hat{\kappa} = \frac{1}{J} \sum_{j=1}^{J} \hat{\kappa}^{(j)}, \tag{35}$$

for the number of iterations at the joint support recovery in Algorithm 3.

Based on the measurements shared among the SUs, the detection performance is improved in low SNR regimes. Moreover, thanks to the measurement diversity across multiple SUs given the different sampling patterns, the fusion center could obtain an accurate estimate of the occupied channel locations at the sampling rate approaching the Landau's rate as the number of SUs increases [17]. This is due to the fact that the sub-coherence within the block,

$$\mu = \max_{1 \leq l \leq L} \ (\max_{1 \leq i \neq j \leq J} ||a_l^{(i)H} a_l^{(j)}||), \tag{36}$$

Algorithm 3 Measurement fusion in the proposed centralized cooperative spectrum sensing scheme

Initialization: $\boldsymbol{\chi}_s^{(j)} \in \mathbb{C}^{p\times\hat{\kappa}^{(j)}}, \hat{\kappa}^{(j)}, \mathbf{A}^{(j)} = [\mathbf{a}_1^{(j)}, \ldots, \mathbf{a}_L^{(j)}] \in \mathbb{C}^{p\times L}$
Decision: S
1: $\hat{\kappa} = \frac{1}{J}\sum_{j=1}^{J}\hat{\kappa}^{(j)}$
2: $t = 0, \mathbf{R}_0^{(j)} = \boldsymbol{\chi}_s^{(j)}, \boldsymbol{\nu}_0^{(j)} = \varnothing, S = \varnothing$

is substantially smaller than the conventional coherence in the equivalent reconstruction matrix $\mathbf{A}$ [5]. Reconstruction of the block sparse signal in the cooperative sensing scheme therefore can be guaranteed with an eased requirement comparing to the reconstruction in the individual scheme. Therefore, a small number of cosets p proportional to the signal sparsity κ is sufficient for cooperative spectrum sensing. The computation complexity of support recovery at the fusion center could be expressed as $O(\kappa^3 LJ)$.

Geo-Location and Its Hybrid

As reported by the Federal Communications Commission (FCC) and the Ofcom in the UK, a large percentage of spectrum resources are underutilized [22]. It is noticed that spectrum used to be allocated to analog TV signals has been cleaned and opened to access due to the digital-switchover. To implement cognitive radio in TVWS successfully, there are mainly two goals to be achieved: (1) to protect incumbent licensed users from harmful interference and (2) to utilize the available spectrum efficiently [20].

In order to avoid any harmful interference to primary services, SUs, also named as white space devices (WSDs), should have the knowledge of spectrum occupancy. Two approaches have been proposed to make SUs aware of the spectrum occupancy. One is geo-location database which is a centralized database to store the maximum allowable EIRP for each vacant TVWS channel. So far, several geo-location database providers such as Google, Nominet, Spectrum Bridge, etc. have been approved by Ofcom in UK [24]. The geo-location database calculates the interference generated in wireless communication systems through theoretical propagation models rather than actual measurements, which may result in inaccurate results for spectrum occupancy [25]. Furthermore, the real-time events and dynamic changes of the propagation environment pose significant challenges to the database approach, as it can only protect the registered users. Some PMSE users, such as the

wireless microphone, operate mostly on an unlicensed basis, without any record in the database [23]. The other is spectrum sensing, which provides instant channel occupancy information but may cause interference to some reserved channels as they would be determined as vacant by sensing alone and hence utilized by SUs for unlicensed transmission. To relax the sensing requirements on the WSDs, hybrid framework that combines the advantages of both geo-location database and spectrum sensing is explored.

Geo-Location Database Model

For geo-location databases, a power control model is used to calculate the maximum permitted EIRP [49]. It makes use of a two-ray path loss model to measure the power attenuation. However, there are two main problems for this model. Firstly, the DTT receivers cannot be located precisely which leads that the path loss cannot be calculated by the exact distance between SUs and DTT receivers. All known information is the number of households located within a 100×100 m pixel [43]. Secondly, different environmental scenarios, which would lead to different tolerance levels for DTT receivers, are not considered in the power control model. For example, the power attenuation in urban areas is much higher than that of open areas. As a result, the maximum allowable EIRP of a specific SU in open areas is higher than that in urban areas.

To solve these problems, the concept of location uncertainty is introduced in the location probability model, which classifies the location relationship between SUs and DTT receivers into four different scenarios. In addition, transmission environment can be classified as open, suburban, and urban areas. Power attenuation is measured by coupling gain that depends both on location relationship and transmission environment. Figure 8 shows the location probability model for the geo-location database. It is assumed that a DTT reception is located on the edge

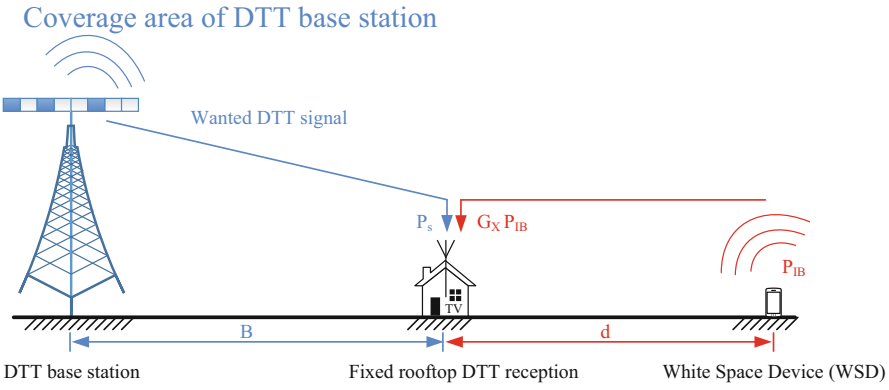

Fig. 8 DTT location probability model

area of a DTT base station, which receives the lowest wanted power from the DTT base station. The average received power of wanted DTT signal is labeled as P_s, and R is the coverage radius of the DTT base station and d is distance between the DTT receiver and the mobile WSD, which can be obtained from the DTT transmitter's database available at [44]. A mobile WSD radiates an inbound EIRP P_{IB} with a power attenuation factor coupling gain (G), which is dependent on the different areas.

DTT location probability is defined as the probability with which a DTT receiver could operate accurately at a specific location, i.e., the probability with which the average received wanted signal level is appropriately greater than a minimum required value. DTT location probability is used to limit the maximum allowable EIRP and it can be expressed in linear domain as follows [43]:

$$q_1 = \Pr\left\{ P_s \geq P_{s,\min} + \sum\nolimits_{k=1}^{K} r_{U,k} P_{U,k} \right\}, \tag{37}$$

$$q_2 = \Pr\left\{ P_s \geq P_{s,\min} + \sum\nolimits_{k=1}^{K} r_{U,k} P_{U,k} + r\left(\Delta f, m_s\right) G P_{IB} \right\}, \tag{38}$$

where $P_{s(dBm)}$ is modeled as a Gaussian random variable with median m_s and standard deviation σ_s, and $P_{s,\min}$ is DTT receiver's reference sensitivity level. The parameter $P_{U,k}$ refers to received power of the k-th unwanted DTT signals, and $r_{U,k}$ is the protection ratio of the received wanted DTT power and received k-th unwanted DTT power at the point where DTT receiver fails. $\Delta f = f_{\mathrm{WSD}} - f_{\mathrm{DTT}}$, where f_{WSD} is the frequency in which a WSD device operates and f_{DTT} is the DTT carrier frequency. The mean value of received power of wanted DTT signal P_s is labeled as m_s. The DTT receiver's location probability in the absence of interference from WSDs is labeled as q_1, and q_2 is the DTT receiver's location probability when considering the additional WSDs' interference. When the interference from WSDs is considered, it results in a reduction in location probability $\Delta q = q_1 - q_2$. To identify the maximum allowable EIRP P_{IB} in (38), Δq is maximized by assigning a maximal allowed value Δq_T to Δq.

We can express (37) in decibel domain as follows [34]:

$$\begin{aligned} q_1 &= \Pr\left\{ P_s \geq P_{s,\min} + \sum\nolimits_{k=1}^{K} r_{U,k} P_{U,k} \right\} \\ &= \Pr\left\{ P_s \geq P_{s,\min} + V \right\} \\ &= \Pr\left\{ 1 \geq \frac{P_{s,\min}}{P_s} + \frac{V}{P_s} \right\} \\ &= \Pr\left\{ 1 \geq A + B \right\} \\ &= \Pr\left\{ 1 \geq X \right\} \end{aligned}, \tag{39}$$

where $V_{(dBm)}$ is modeled as a Gaussian random variable with median m_V and standard deviation σ_V. Furthermore, $A_{(dB)}$ and $B_{(dB)}$ can be modeled as Gaussian random variables. In addition, $X_{(dB)}$ can be modeled as a Gaussian random

variable with median m_X and standard deviation σ_X. As a result, (39) can be given by:

$$q_1 = \Pr\left\{0 \geq X_{(dB)}\right\} = \frac{1}{2}\text{erfc}\left(\frac{m_X}{\sqrt{2}\sigma_X}\right). \tag{40}$$

Similarly, q_2 can be expressed in decibel domain as follows:

$$\begin{aligned} q_2 &= \Pr\left\{P_s \geq P_{s,\min} + \sum_{k=1}^{K} r_{U,k} P_{U,k} + r\left(\Delta f, m_s\right) G P_{IB}\right\} \\ &= \Pr\left\{P_s \geq P_{s,\min} + V + r\left(\Delta f, m_s\right) G P_{IB}\right\} \\ &= \Pr\left\{1 \geq \frac{P_{s,\min}}{P_s} + \frac{V + r(\Delta f, m_s) G P_{IB}}{P_s}\right\} \\ &= \Pr\left\{1 \geq A + \frac{V+C}{P_s}\right\} \\ &= \Pr\left\{1 \geq A + \frac{D}{P_s}\right\} \\ &= \Pr\{1 \geq A + E\} \\ &= \Pr\{1 \geq Y\} \end{aligned}, \tag{41}$$

where $C_{(dBm)}$ is a Gaussian random variable. V and C are two uncorrelated log-normal random variables, $D_{(dBm)}$ can be modeled as a Gaussian random variable with median m_D and standard deviation σ_D. Furthermore, as D and P_S are both log-normal random variables, $E_{(dB)}$ is also Gaussian variable with $m_E = m_D - m_S$ and $\sigma_E = \sqrt{\sigma_D^2 + \sigma_S^2}$. Eventually, as A and E are both log-normal random variables, $Y_{(dB)}$ can be modeled as a Gaussian random variable with mean m_Y and standard deviation σ_Y.Furthermore, (41) can be expressed as:

$$q_2 = \Pr\left\{0 \geq Y_{(dB)}\right\} = \frac{1}{2}\text{erfc}\left(\frac{m_Y}{\sqrt{2}\sigma_Y}\right). \tag{42}$$

Once q_2 is obtained, the corresponding P_{IB} can be calculated for each channel to indicate the maximum allowable EIRP as the output of the geo-location database.

Hybrid Framework with Spectrum Sensing and Geo-Location Database

Geo-location database can only protect registered channel users, while some of the PUs may not be registered, which may pose significant challenges to a geo-location database. For example, PMSE devices operate mostly on an unlicensed basis, without any record in TVWS [33]. Therefore, the approach to protect unregistered applications such as wireless microphone is through spectrum sensing. Spectrum sensing requires SUs to have the capability to detect spectrum holes that are not occupied by PUs. However, it may cause interference to some reserved channels as they would be determined as vacant by sensing alone.

As the geo-location database will not be updated instantly when the PUs temporally stop or begin the data transmission, conventional geo-location database cannot make a full utilization of vacant channels and prevent interference to the incumbent users concurrently. To reduce the risk of interference caused by the unregistered PMSE and improve the spectrum efficiency, Wang et al. proposed a hybrid framework incorporating the advantages of both geo-location database and spectrum sensing, where different spectrum sensing modules will be performed when the channel state is initially determined by the geo-location database [47], as illustrated in Fig. 9. WSDs classifies the vacant and occupied channels by referring to the geo-location database which contains the information of registered licensed users. If the channel is vacant on the geo-location database, PMSE sensing module will be applied such that if unregistered PMSE users appear on the vacant channel, instant sensing will provide a good protection to these users. While if geo-location database presents that the channel is occupied, the assistance of the DTT sensing module shown in the left dotted square circle of Fig. 9 helps the SUs to use the bands in which PUs temporally pause the data transmission.

Considering the appearance of unregistered PMSE users with probability 0.1, Fig. 10 shows the spectral efficiency of SUs against different SNRs for the geo-location database alone, hybrid database-augmented sensing with fixed (5) or adaptive threshold (7), and sensing only algorithm. Both fixed and adaptive database-augmented sensing algorithms' spectral efficiency outperform that of the

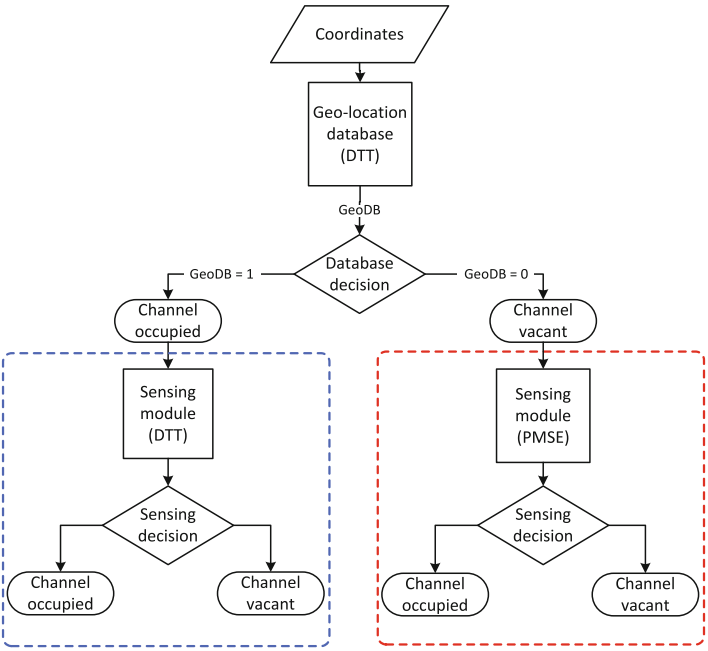

Fig. 9 The framework of the database-augmented spectrum sensing algorithm in [47]

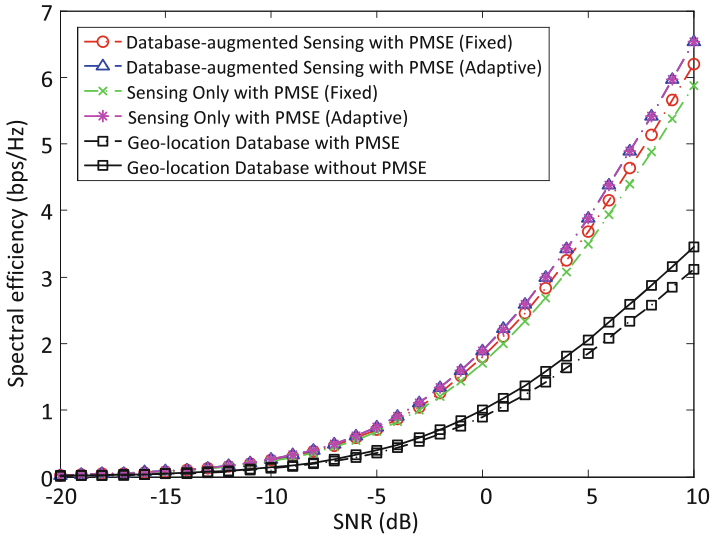

Fig. 10 Spectral efficiency for geo-location database, the database-augmented sensing with fixed and adaptive threshold

geo-location database alone approach about 1.83 bps/Hz at SNR $= 5$ dB. This is because of the increased number of paused transmission bands. The database-augmented sensing algorithm incorporated with the adaptive sensing algorithm has a better spectral efficiency than that of the fixed threshold, especially with the increasing SNRs. This is due to the lower P_f obtained by the adaptive sensing approach compared to that of the fixed one. Generally, it seems the sensing only algorithm could have almost the same spectral efficiency with that of the database-augmented sensing one. However, due to the reduced number of sensing bands, the database-augmented sensing algorithm relaxes the computation complexity required for the secondary device.

However, the hybrid framework requires the WSDs to set up a direct link to the remote geo-location database, which will require an initial wired or wireless link available at the WSD in order to report its location to the central database and retrieve the related channel state information from database. Moreover, the sensing module is based on the sequential manner to scan through the multiple channels one by one, which could introduce a long sensing period and thus cause missed opportunities or interferences to PUs.

In order to reduce the necessary sampling rate, the network load, and the inevitable transmission errors between geo-location database and SUs, a hybrid framework combining geo-location database and compressive spectrum sensing is proposed in [29], called as data-assisted non-iterative reweighted least square (DNRLS)-based compressive wideband sensing, where the maximum permitted EIRP P_{IB} of each channel obtained from geo-location database is utilized as the prior information for compressive spectrum sensing. In addition, in order to further

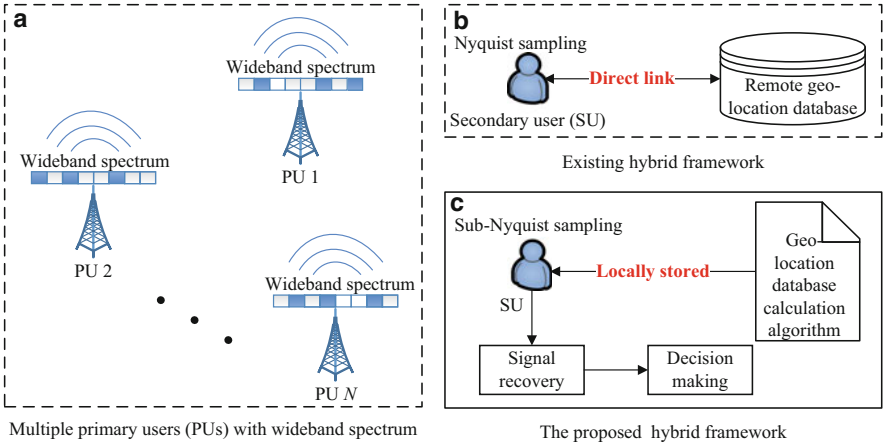

Fig. 11 (**a**) Scenario of wideband spectrum sensing with multiple primary users; (**b**) the existing hybrid framework with a direct link to remote database and conventional spectrum sensing at Nyquist rate; and (**c**) the hybrid framework with the locally stored geo-location database calculation algorithm and the data-assisted non-iterative reweighted least square (DNRLS)-based compressive spectrum sensing at sub-Nyquist rate [29]

relax the SU, a Wilkinson's method [6]-based DTT location probability is proposed to calculate the maximum permitted EIRP P_{IB} of each channel locally at the SU. The whole procedure of the proposed standalone hybrid framework is shown in Fig. 11c.

In order to rectify a key difference between l_0 and l_1 minimization and balance the penalty on large coefficients and smaller coefficients of the sparse signal, Candes et al. [19] proposed an iteratively reweighted l_1 minimization algorithm by introducing weight for each bin of the signal to be recovered. Another approach to recover a sparse signal with fewer measurements is to replace the l_1 norm with l_P norm. In order to solve the l_p norm problem, an iteratively reweighted least squares (IRLS) algorithm was proposed to perform sparse signal reconstruction [22–24,47–49]. The optimization problem can be formulated in Lagrangian form as follows:

$$\min \quad \left\| \Theta \cdot h_f \hat{s}_f - x \right\|_2^2 + \lambda W \cdot \hat{s}_f^2, \tag{43}$$

where W is a diagonal matrix $W = diag\{w_1, \ldots, w_n, \ldots, w_N\}$, which is updated in each iteration. In the l-th $(l = 0, 1, \ldots, L)$ iteration of IRLS algorithm, the weights are calculated with the recovered signal $\hat{s}_{f\_n}^{(l-1)}$ in the $(l-1)$-th iteration as:

$$w_n^{(l)} = \left(\left(\hat{s}_{f\_n}^{(l-1)} \right)^2 + \varepsilon^{(l)} \right)^{1-\frac{p}{2}}, \tag{44}$$

where $\varepsilon^{(l)}$ is updated in each iteration, and it is a positive value to make sure that a zero-valued component in $\bar{s}_f$ does not strictly prohibit a nonzero estimate in the next iteration of weights update. In addition, the solution of (43) at the l-th iteration can be expressed as:

$$\begin{aligned}\hat{s}_{f\_n}^{(l)} &= \arg\ \min\ \left\|\Theta \cdot h_f \hat{s}_f - x\right\|_2^2 + \lambda W^{(l)} \cdot \hat{s}_f^2 \\ &= W^{(l)}\Theta^{\mathrm{T}}\left(h_f \Theta W^{(l)}\Theta^{\mathrm{T}} + \lambda \mathbf{I}_P\right)^{-1} x,\end{aligned} \tag{45}$$

where the initial value for the weights w_n in W is 1, and then $W^{(0)} = \mathbf{I}_N$. As a result, $\hat{s}_{f\_n}^{(0)} = \Theta^{\mathrm{T}}\left(h_f + \lambda \mathbf{I}_P\right)^{-1} x$. It is noticed that (43) is a nonconvex optimization problem when $p < 1$. As a result, the solution to (43) is a local minima. It is proved in [4] that the computed local minimizers of (43) are actually global minimizer when solved by IRLS.

In the traditional IRLS-based compressive spectrum sensing, it is noticed that the key challenge is to find the optimal set of weights W in an iterative process for a better estimate of the original signal. The iteration process generates more computational complexities during signal recovery process. When part of the allowable maximum EIRPs is available in advance, the iterative process can be removed without degrading the recovery performance. The geo-location database calculation algorithm is implemented at SUs locally to provide data for weights calculation in a non-iterative method so that SUs would not need any additional link to a centralized geo-location database. The weights are calculated as:

$$w_n = \frac{1}{|\overline{\gamma_n}| + \varepsilon}, \tag{46}$$

where $\bar{\gamma}_n$ is constructed by the channel history information which would be introduced in details in the following part.

In the $(t+1)$-th sensing period, the geo-location database calculates the maximum allowable EIRP $P_{IB}(t+1)$ for current period before performing spectrum sensing by the Wilkinson's method-based DTT location probability model. It is mapped to $\gamma(t+1)$. Furthermore, the averaged $\bar{\gamma}(t+1)$ is calculated as:

$$\bar{\gamma}(t+1) = (\bar{\gamma}(t) + \gamma(t+1))/2, \tag{47}$$

where $\bar{\gamma}(t)$ is the average values to construct the weights at the t-th sensing period, $t = \{0, 1, \ldots, T\}$, and T is the window size for SUs to fuse the current allowable maximum P_{IB} with the history data. At an SU, only the $\bar{\gamma}(t)$ is stored locally after the t-th sensing period. If there is any new unregistered user showing up in the spectrum of interest in t-th period, the DTT transmitter database, which is used to calculate P_{IB}, is updated locally. This rule makes the weights calculation robust to the new unregistered users. Meanwhile, the DTT transmitter database at other SUs would not be influenced. In the $(t+1)$-th period, the $\gamma(t+1)$ provided

by the local geo-location database would be updated accordingly by considering the unregistered users. After $\bar{\gamma}(t+1)$ for the current sensing period obtained to calculate the weights, a better spectrum estimation can be obtained by solving the following non-iterative problem:

$$\begin{aligned}\hat{s}_f &= \arg \min \left\|\Theta \cdot h_f \hat{s}_f - x\right\|_2^2 + \lambda \tilde{W} \cdot \hat{s}_f^2 \\ &= \tilde{W}\Theta^{\mathrm{T}}\left(h_f \hat{s}_f \tilde{W}\Theta^{\mathrm{T}} + \lambda \mathrm{I}_P\right)^{-1} x,\end{aligned} \tag{48}$$

where $\tilde{W} = diag(w_1, \ldots, w_n, \ldots, w_N)$ is a diagonal matrix in which w_n is calculated by (46) to replace the iterative update of (44). In the DNRLS-based compressive spectrum sensing algorithm, the accuracy of $\bar{\gamma}$ would influence the recovery performance.

If there is no unregistered user in the spectrum of interest, which means the values of γ used to construct the weights are accurate, the recovery performance of DNRLS is very good. When unregistered users show up in the spectrum of interest at the first period, the $\bar{\gamma}(1)$ is not accurate on all the bins of the signal to be recovered as $\gamma(1)$ is not accurate. As a result, the detection performance would be degraded correspondingly. In the $(t+1)$-th period after the unregistered user shows up in the spectrum of interest, $\gamma(t+1)$ provided by the local geo-location database is updated corresponding to the decision in t-th period. The accuracy of weights would depend on the window size T for the weights fusion at SUs. The weights fusion process is shown as follows when unregistered users show up in the spectrum of interest:

$$\begin{aligned}\bar{\gamma}(1) &= \frac{\bar{\gamma}(0)+\gamma(1)}{2}, \text{(1st period)} \\ \bar{\gamma}(2) &= \frac{\bar{\gamma}(1)+\gamma(2)}{2}, \text{(2nd period)} \\ &\vdots \\ \bar{\gamma}(t) &= \frac{\bar{\gamma}(T-1)+\gamma(t)}{2}, \text{(Tth period)}\end{aligned} \tag{49}$$

where $\bar{\gamma}(0)$ is the history average value for weights construction before unregistered user showing up, and $\gamma(1)$ is the data obtained from the geo-location database in current period. As $\gamma(2) = \cdots = \gamma(t) = \gamma$, which is the data from local geo-location database after the unregistered users show up, $\bar{\gamma}(t)$ can be expressed as:

$$\begin{aligned}\bar{\gamma}(t) &= \frac{\bar{\gamma}(0)}{2^T} + \frac{\gamma(1)}{2^T} + \frac{\frac{1}{2} \times \left(1 - \left(\frac{1}{2}\right)^{T-1}\right) \times \gamma}{1 - \frac{1}{2}} \\ &= \frac{\bar{\gamma}(0)}{2^T} + \frac{\gamma(1)}{2^T} + \left(1 - \left(\frac{1}{2}\right)^{T-1}\right) \times \gamma.\end{aligned} \tag{50}$$

Algorithm 4 Data-assisted non-iterative reweighted least square-based compressive spectrum sensing

1: Input: $p, \lambda, \Theta, x, \varepsilon, \bar{\gamma}(t)$.
2: Calculate $P_{IB}(t+1)$ by the Wilkinson's method.
3: Map $P_{IB}(t+1)$ to $\gamma(t+1)$.
4: Calculate $\bar{\gamma}(t+1)$ by (47).
5: Perform signal recovery by (48) to get $\hat{s}_f$.
6: Make decision on spectrum occupancy by compare $\hat{s}_f$ with the threshold λ defined in (5).

It is noticed that $\bar{\gamma}(t)$ would converge fast to γ after unregistered users show up in the spectrum of interest. In addition, part of channels are fixed and utilized by DTV signals in TVWS and some channels are reserved for other purposes. Therefore, at least the weights for those fixed channels in $\bar{\gamma}(0)$ and $\gamma(1)$ are accurate. This would make sure the recovery performance would not be degraded heavily when unregistered users show up in the spectrum of interest. With increasing window size T, the influence of inaccurate parts in $\bar{\gamma}(0)$ and $\gamma(1)$ degrades.

The computational complexity reduction of the DNRLS-based compressive spectrum sensing comes from two parts. In the traditional IRLS algorithm, the inverse of $\left(h_f \Theta W^{(l)} \Theta^T + \lambda \mathrm{I}_P\right)$ takes $\mathrm{O}\left(P^3\right)$ and it is required in each iteration. In large-size compressive sensing problem, solving a problem with complexity $\mathrm{O}\left(P^3\right)$ L times is time consuming. By implementing the DNRLS-based compressive spectrum sensing to update the weights at SUs as summarized in Algorithm 4, the signal recovery step in the algorithm is performed in a non-iterative approach. Therefore, the computational complexity is $\frac{1}{L}$ of the traditional IRLS-based compressive spectrum sensing in which L iterations are required to get a good estimation of the spectrum. Another reason of complexity reduction is that the DNRLS algorithm can achieve exact recovery with fewer measurements. In the DNRLS algorithm, the minimal number of measurements P for exact recovery can be reduced to $\tilde{P}\left(\tilde{P} < P\right)$ which leads to a big complexity reduction as the complexity of solving the inverse of $\left(h_f \Theta W^{(l)} \Theta^T + \lambda \mathrm{I}_P\right)$ is $\mathrm{O}\left(\tilde{P}^3\right)$. The additional complexity of the DNRLS-based compressive spectrum sensing comes from the calculation of P_{IB} for each channel in TVWS. To minimize the necessary computational complexity at SU, the Wilkilson's method is proposed to calculate P_{IB} with lower complexity.

At an SU, the calculation of maximum permitted EIRP P_{IB} of each channel in TVWS should be efficient and accurate. Monte Carlo method and Schwartz-Yeh's method are the two algorithms approved by Ofcom to calculate the maximum allowable EIRP P_{IB}. Schwartz-Yeh's method is an approximate algorithm in which infinite loops are used to calculate the mean and standard deviation values of log-normal distribution variables like variables A, B, and E in (39) and (41) [27]. As a result, the large computational complexity and low efficiency are difficult to overcome at power-limited SUs. Therefore, Wilkinson's method is proposed to calculate the median and standard deviation values of log-normal distribution variables for the calculation of q_1, q_2 and P_{IB} in a more efficient way.

Assuming variable I_k $(k = 1, 2, \ldots, K)$ is a log-normal random variable, $M_k = 10\log_{10} I_k$ can be modeled as a Gaussian random variable and $M = 10\log_{10}\left(\sum_{k=1}^{K} 10^{\frac{M_k}{10}}\right)$. It is assumed that $e^{\Lambda_1} + e^{\Lambda_2} + \cdots + e^{\Lambda_K} = e^Z = 10^M$ and $Z = \rho M$, $\rho = \frac{1}{10}\ln 10 = 0.2302$, the mean and standard deviation of parameter M could be calculated by bringing in two parameters μ_1 and μ_2 as follows:

$$\mu_1 = \mathrm{E}\left(m_Z + \frac{1}{2}\sigma_Z^2\right) = \sum\nolimits_{i=1}^{K} \mathrm{E}\left(m_{\Lambda_i} + \frac{1}{2}\sigma_{\Lambda_i}^2\right), \tag{51}$$

$$\begin{aligned}\mu_2 = \mathrm{E}\left(2m_Z + 2\sigma_Z^2\right) &= \sum\nolimits_{i=1}^{K} \mathrm{E}\left(2m_{\Lambda_i} + 2\sigma_{\Lambda_i}^2\right) \\ &+ 2\sum\nolimits_{i=1}^{K-1}\sum\nolimits_{j=i+1}^{K} \mathrm{E}\left(m_{\Lambda_i} + m_{\Lambda_j}\right) \\ &\times \mathrm{E}\left[\frac{1}{2}\left(\sigma_{\Lambda_i}^2 + \sigma_{\Lambda_j}^2 + 2r_{ij}\sigma_{\Lambda_i}\sigma_{\Lambda_j}\right)\right],\end{aligned} \tag{52}$$

where m_{Λ_i} and σ_{Λ_i} are the median and standard deviation of Λ_i, and r_{ij} are the correlation coefficients of Λ_i and Λ_j. Consequently, the median and standard deviation of M can be calculated as:

$$\sigma_M = \frac{1}{\rho}(2\ln\mu_1 - \frac{1}{2}\ln\mu_2), \tag{53}$$

$$\sigma_M = \frac{1}{\rho}(\ln\mu_2 - 2\ln\mu_1)^{\frac{1}{2}}. \tag{54}$$

Based on the Wilkinson's method explained above, q_1 and q_2 can be calculated. Taking the calculation of q_1 as an example, as shown in (39), $\frac{P_{s,\min}}{P_s} + \frac{V}{P_s} = A + B \leq 1$. $10\log_{10}(A + B) \leq 0$, which is equivalent to $X_{(dB)} = 10\log_{10}\left(10^{\frac{A_{dB}}{10}} + 10^{\frac{B_{dB}}{10}}\right) \leq 0$. It can be fitted into the precondition of Wilkinson's method to get $10^{\frac{A_{dB}}{10}} + 10^{\frac{B_{dB}}{10}} = 10^{X_{dB}} = e^{\Lambda_1} + e^{\Lambda_2}$. Therefore, $\Lambda_1 = \rho \times A_{(dB)}$ and $\Lambda_2 = \rho \times B_{(dB)}$. The relevant correlation coefficient of A and B can be given as:

$$r_{A,B} = \frac{\mathrm{cov}\left(A_{(dB)},\ B_{(dB)}\right)}{\sqrt{\mathrm{var}\left(A_{(dB)}\right)\mathrm{var}\left(B_{(dB)}\right)}} = \frac{\sigma_S}{\sqrt{\sigma_S^2 + \sigma_V^2}}, \tag{55}$$

where σ_S and σ_V can be calculated based on the DTT transmitter database available at [44]. According to (51) and (52), μ_1 and μ_2 can be obtained. Consequently, m_X and σ_X can be calculated according to (53) and (54).

Similarly, q_2 can be calculated by Wilkinson's method by the following procedure:

1. Input m_S, σ_S, m_V, σ_V, m_C, and σ_C as shown in (41), which can be calculated based on the DTT transmitter database available at [44];
2. Calculate m_D and σ_D by Wilkinson's method based on m_V, σ_V, m_C, and σ_C;
3. Calculate m_A, σ_A, m_E, and σ_E by Wilkinson's method based on m_S, σ_S, m_D, and σ_D;
4. Calculate m_Y and σ_Y by Wilkinson's method based on m_A, σ_A, m_E, and σ_E;
5. Calculate q_2 by (42) based on m_A, σ_A, m_E, and σ_E.

In summary, the procedure of calculating P_{IB} with the Wilkinson's method is shown in Fig. 12. Firstly, input the median and standard derivation of the received power of wanted DTT signal, i.e., P_s and the minimum required power of wanted DTT signal, i.e., V which can be obtained from the DTT transmitter database from [44]. Secondly, the predefined maximum permitted value is assigned to P_{IB}. As defined in IEEE 802.22 standard, the maximum permitted EIRP that can be utilized in TV frequency band is 4 watts [12]. In addition, q_1 and q_2 are calculated by the Wilkinson's method as aforementioned. Consequently, the corresponding P_{IB} is updated until $q_2 \leq q_1 - \Delta q_T$.

By taking the values calculated by Monte Carlo simulation as a benchmark, the accuracy of the Schwartz-Yeh's method and Wilkinson's method can be measured by error rate $\Delta Q(\cdot)/Q_{(\text{Monte Carlo})}(\cdot)$, where $Q_{(\text{Monte Carlo})}(\cdot)$ refers to values calculated by Monte Carlo simulation and $\Delta Q(\cdot)$ refers to the absolute difference of parameters' values calculated by the Schwartz-Yeh's method and Wilkinson's method and that calculated by Monte Carlo simulation. More specifically, $\Delta Q(q_1) = \left|q_1^{S,W} - q_1^M\right|$, $\Delta Q(q_2) = \left|q_2^{S,W} - q_2^M\right|$, and $\Delta Q(P_{IB}) =$

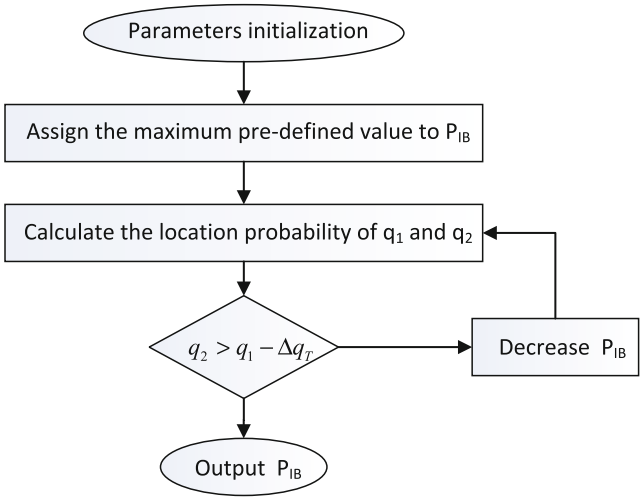

Fig. 12 The procedure of calculating maximum allowable P_{IB} by the Wilkinson's method

Table 1 Error rates comparison

	q_1	q_2	P_{IB}
Schwartz-Yeh's method	31.25%	4.76%	7.87%
Wilkinson's method	9.36%	1.31%	1.54%

Table 2 Running time comparison

	q_1	q_2	P_{IB}
Schwartz-Yeh's method	15966.04%	153278.65%	75462.57%
Wilkinson's method	99.06%	98.89%	99.47%

$\left|P_{IB}^{S,W} - P_{IB}^{M}\right|$, where $q_1^{S,W}$, $q_2^{S,W}$, and $P_{IB}^{S,W}$ refer to the corresponding values calculated by the Schwartz-Yeh's method and Wilkinson's method, respectively, and q_1^M, q_2^M, and P_{IB}^M refer to the corresponding values calculated by Monte Carlo simulation. The error rates of q_1, q_2, and P_{IB} calculated by the Schwartz-Yeh's method and Wilkinson's method are shown in Table 1. It shows that the Wilkinson's method-based DTT location probability calculation outperforms that of the Schwartz-Yeh's method.

Similarly as the error rate calculation, running time of Monte Carlo simulation with 10,000 points is chosen as a benchmark when measuring the running time for q_1, q_2, and q_{IB} calculation. Table 2 shows the running time comparison of the Schwartz-Yeh's and Wilkinson's methods for the calculation of q_1, q_2, and P_{IB}. We can see that the Wilkinson's method can reduce the running time significantly in comparison with the Schwartz-Yeh's method. Therefore, the Wilkinson's method is more suitable for SUs with limited power to obtain the q_1, q_2, and P_{IB} efficiently.

With the validation of the accuracy and efficiency of the Wilkinson's method, a national grid reference (NGR)-based geo-location database is built with the Wilkinson's method. By using the data from the DTT transmitter database available at [44], P_{IB} can be calculated by the Wilkinson's method-based DTT location probability model for a specific location. To show the performance, an NGR number of SP515065 in Oxford is chosen as a test location. The average allowed EIRP calculated by the power control and the proposed location probability model are shown in Table 3.

As shown in Table 3, there are 11 available channels at SP515065 in total. In the Wilkinson's location probability model, the transmission environment is classified into three situations: open, suburban, and urban. Coupling gain in different situations is treated differently, leading to different interference toleration levels of DTT receivers. It is obvious that the power attenuation in open areas is much lower than suburban and urban areas. As a result, the actual maximum allowable EIRP P_{IB} in open areas is lower than the other two situations at a certain NGR location. Taking channel 51 as an example, the P_{IB} is 0.0002 watts in power control model, while the power could be utilized more effectively if the environment is classified into

different scenarios in location probability model. It is 0.3981 watts in open areas, 1.2589 watts in suburban areas, and 4.0000 watts in urban areas.

Based on the maximum allowable EIRP P_{IB} from the local geo-location database, the weights for the DNRLS-based compressive spectrum sensing can be constructed by fusing with the historical data. Figure 13 shows detection performance of the sensing only approach with IRLS and the hybrid framework with DNRLS algorithms implemented at SUs, where p is set to be 0.1. It is observed

that the detection performance of spectrum sensing only approach without CS implemented at an SU is matched with the theoretical curve, which is presented as a benchmark.

Figure 13 shows that detection performance of the sensing only approach with IRLS used for signal recovery is lower than the theoretic curve due to the signal recovery errors caused by the sub-Nyquist sampling (20%). However, it is noticed that the sensing only approach with IRLS requires an iterative process to update the weights. When the hybrid framework with DNRLS is performed, detection probability increases greatly which can almost match with the theoretic curve. The reason for the large performance improvement is that the data used to constructed the weights is the exact representation of the spectrum of interest if there is no unregistered user. As a result, the DNRLS-based compressive spectrum sensing can achieve better detection performance with $\frac{L-1}{L}$ of computational complexity reduced in comparison with the sensing only approach with IRLS.

Conclusion

Cognitive radio has emerged as one of the most crucial candidate solutions to improve spectrum utilization in next-generation cellular networks. An important requirement for future cognitive radio networks is wideband spectrum sensing, where SUs can detect spectral opportunities across a wide frequency range. However, special attention should be paid to the high signal sampling rate. Therefore, sensing wideband spectrum presents a significant challenge in building sampling hardware that operates at a sufficiently high rate and designing high-speed signal processing algorithms. Sub-Nyquist approaches are drawing more and more attention in wideband spectrum sensing, which refers to the procedure of acquiring wideband signals using sampling rates lower than the Nyquist rate and detecting spectral opportunities using these partial measurements. To fully explore the advantages of both geo-location database and spectrum sensing, hybrid frameworks are explored to maximize the benefits for both PUs and SUs based on the initial information from geo-location database. The partially information from geo-location database can be utilized to further reduce the number of sampling measurements and computation complexity and improve the detection performance for dynamic spectrum sensing.

Introduction

Spectrum sensing is widely regarded as a key enabling technology to support dynamic spectrum access (DSA) for cognitive radio (CR) systems[1–20]. Though in principle spectrum sensing can be viewed as a traditional signal detection problem, the design of spectrum sensing algorithms needs to take into account certain stringent requirements due to the nature of CR systems. Firstly, it is important for spectrum sensing algorithms to be robust to signal models as it is often difficult in practice for secondary users (SUs) to acquire complete or even partial knowledge about primary signals. Secondly, a small detection delay is essential for the spectrum sensing even under a fairly low detection signal-to-noise ratio (SNR) level with low detection error probabilities. To this end, a number of spectrum sensing algorithms have been proposed and studied [21–26]. Roughly speaking, spectrum sensing can be classified into two categories: single-band sensing and multiband sensing. As far as spectrum sensing is concerned, the major difference between single-band sensing and multiband sensing is that in a multiband system, sensing needs to be performed over spectrum bands that support different primary user (PU) activities. In this chapter, we treat each single band as an entity in the sense that a single band no matter whether it is a single-carrier or multi-carrier single band only has two possible states: unoccupied or occupied.

This chapter focuses on a particular type of spectrum sensing algorithms, called *sequential* spectrum sensing algorithms for CR systems. Compared with block-based sensing algorithms, sequential sensing algorithms enable us to make important detection decision with minimum delay while still providing certain performance guarantee. The goal of this chapter is to introduce the sequential sensing method and the performance benefits it brings under various scenarios.

In particular, we will first illustrate the benefits of sequential sensing for single-band systems in section "Sequential Detection for Single Channel." We will then present sequential algorithms that enable us to quickly locate all available channels for multiband systems in section "Quickest Spectrum Scanning."

Single-Band Sensing

Typical examples of single-band spectrum sensing algorithms include energy detection [27], generalized likelihood ratio test [7], covariance sensing [21–23], and feature detection [24]. From a practical point of view, energy detection is very attractive, primarily because it has a low implementation complexity and requires no deterministic knowledge of PU signals. However, to achieve a high sensing accuracy, energy detection entails a large amount of sensing time especially when the detection SNR is low [28].

To reduce sensing time, several sequential probability ratio test (SPRT)-based sensing algorithms have been proposed under various CR settings [26, 29, 30]. The main motivation of using SPRT as a sensing algorithm is that SPRT requires the shortest average sensing time for any given false-alarm and misdetection probabilities in the simple hypothesis testing case [31, 32]. However, the detection delay of SPRT is highly variable. Although the average detection delay of SPRT is less than that of the fixed-sample-size detection algorithm under the same error probabilities requirements, the detection delay of SPRT in a particular realization might be significantly larger than the average value. In CR systems, on the other hand, the decision must be made within a short period of sensing time [37]. In other words, sequential sensing algorithms used in practice are essentially truncated algorithms. There are two major drawbacks in the existing (truncated) SPRT-based sensing algorithms [26, 29]. First, the complexity of SPRT under practical signal models is high. In particular, the test statistic of SPRT is updated and is compared to lower and upper thresholds after taking each sample. Thus, the computational complexity of the test statistic determines the feasibility of SPRT. While in the simple hypothesis testing case, evaluating the test statistic of SPRT is simple, but it requires the perfect knowledge of primary signals. However, acquiring such knowledge in practice is difficult in general. In the absence of such knowledge, the evaluation of the test statistics at each time slot involves significant computation. Second, the performance of SPRT is fairly sensitive to the choices of upper and lower thresholds. In [31], Wald proposed an elegant method for selecting upper and lower thresholds for the non-truncated SPRT. Existing SPRT-based algorithms simply apply Wald's method to select thresholds. Such selection does not work well for truncated sensing algorithms since it leads to an increase in detection error probabilities.

In this chapter, we introduce a low-complexity truncated sequential spectrum sensing algorithm, called the sequential shifted chi-square test (SSCT). SSCT possesses several attractive features: (1) similar to energy detection, SSCT requires only the knowledge on the noise power and does not require any deterministic knowledge

of primary signals; (2) compared to fixed-sample-size detection algorithms such as energy detection, SSCT is capable of achieving a comparable detection performance with much reduced average sensing time; (3) in comparison with existing SPRT-based sensing algorithms [29], SSCT has a much simpler test statistic and a lower implementation complexity; and (4) SSCT offers desirable flexibility to strike a trade-off between detection performance and sensing delay when the operating SNR is higher than the minimum detection SNR. Furthermore, to evaluate the detection performance of SSCT and hence guide the proper choice of parameters, which is typically a challenging task, we derive the exact false-alarm probability and provide numerical integration algorithms to compute the misdetection probability and the average sample number (ASN) in a recursive manner.

Multiband Sensing

Besides single-band sensing, multiband (multichannel) spectrum sensing has recently gained considerable research attention. More specifically, in [25] and [26], multiple narrow-band sensors (detectors), each for a spectrum band, are used to simultaneously observe multiple spectrum bands. Multiband joint energy detection [25] and sequential detection [26] were developed to maximize overall throughput performance. When the number of candidate bands is large, these spectrum sensing schemes require a large number of sensors and joint simultaneous operation of these sensors and thus are of prohibitively large implementation complexity. In [33] and [34], a detector based on a wide-band receiver is used to collect signal samples from all multiple candidate bands. SPRT and fixed-sample-size (FSS) sensing algorithms are developed to minimize multiband sensing delay. However, a wide-band detector typically requires a high-speed analog-to-digital converter (ADC) and extra signal processing elements, thus incurring additional cost/complexity.

This chapter considers the problem of how to determine the availability of each spectrum band in a multiband primary system with small delay and small error probabilities using a single or few sensors. With one or a small number of sensors, SUs are able to observe one band or a small subset of candidate bands at a time. Two scenarios of practical interests are investigated. In the first scenario, there is a strict delay constraint on the spectrum scanning. That is, the spectrum scanning needs to be complete within a certain time period. In the second scenario, there is no strict time constraint for the scanning. That is, the spectrum scanning continues until the completion of the entire detection process. In both scenarios, our goal is to design spectrum scanning schemes that minimize a cost function that strikes a balance between error probabilities and detection delay.

We first consider a single sensor case, in which only one spectrum band is observed at a time. To minimize the scanning cost, the detector needs to design (1) *selection rules* that decide which band to collect signal samples at each time; (2) *termination rules* that decide when to terminate the entire scanning process; and (3) *terminal decision rules* that decide the availability of each band after the scanning process is complete. We first show that the problem at hand can be converted

into a Markovian optimal stopping time problem [35]. Using mathematical tools from the optimal stopping theory, we derive the optimal algorithms for both scenarios with and without a delay constraint. We show that in the scenario without a delay constraint, the optimal scanning algorithm is a concatenated sequential probability ratio test (C-SPRT). More specifically, we perform a SPRT test for the first band. Once the SPRT test is complete for this band, we switch to another band and carry out another SPRT on the newly switched band. The scanning process completes once all the bands have been detected by using SPRT. Hence, the scanning algorithm can be efficiently implemented. On the other hand, the implementation of the optimal algorithm for the scenario with a strict delay constraint requires large lookup tables and frequent updating of posterior probabilities, thus incurring a prohibitively high computational complexity. To reduce the complexity for the delay-constrained scenario, we also propose several truncated C-SPRT algorithms that have very low implementation complexity yet are asymptotically optimal.

We next generalize the study to the multiple sensor case, in which multiple spectrum bands can be simultaneously observed. The detector again needs to design band selection rules (in this case, select a subset of bands), termination rules, and terminal decision rules to minimize the cost function. The problem can also be converted into a Markovian optimal stopping time problem, and optimal rules can be derived using the tools from the optimal stopping theory. To reduce the complexity, we also design several low-complexity algorithms. Extensive numerical results are presented to show the effectiveness of the proposed algorithms.

Notation: Boldface upper and lower case letters are used to denote matrices and vectors, respectively; $\boldsymbol{I}_k$ denotes a $k \times k$ identity matrix; $E[\cdot]$ denotes the expectation operator. $(\cdot)^T$ denotes the transpose operation; $\mathbf{1}_k$ denotes a $k \times 1$ vector whose entries are all ones; $\aleph_p^q$ denotes a set of consecutive integers from p to q, i.e., $\aleph_p^q := \{p, \ldots, q\}$, where p is a non-negative integer and q is a positive integer greater than p or $+\infty$; $(\cdot)^c$ denotes a complement of a set; $\mathbb{I}_{\{x \geq t\}}$ denotes an indicator function defined as $\mathbb{I}_{\{x \geq t\}} = 1$ if $x \geq t$ and $\mathbb{I}_{\{x \geq t\}} = 0$ if $x < t$, where x is a variable and t is a constant.

Sequential Detection for Single Channel

In this section, we start by presenting a statistical formulation of the spectrum sensing problem for a single SU CR system. We next give a brief overview on two sensing algorithms that are closely related to SSCT: energy detection and a SPRT-based sensing algorithm.

Problem Formulation

In this section, we assume that there is a single SU in the CR system, which is allowed to access the licensed spectrum of PU in an opportunistic manner. Upon receiving signal samples, denoted by r_i, SU is required to detect whether there are primary signals or not before using the licensed spectrum. We use s_i, $i = 1, 2, \ldots$ to

denote the primary signal samples. Such a signal detection problem can be written as the following classic binary hypothesis testing problem:

$$H_0: \ r_i = w_i, \ i = 1, 2, \ldots, \tag{1}$$

$$H_1: \ r_i = hs_i + w_i, \ i = 1, 2, \ldots, \tag{2}$$

where w_i denotes additive white Gaussian noise (AWGN) with zero mean and variance $\sigma_w^2/2$ per dimension, i.e., $w_i \sim \mathscr{CN}(0, \sigma_w^2)$, and h is the channel coefficient between PU and SU. We further assume that the channel coefficient h is a constant during the sensing process, and the primary signal samples s_i are independent and identically distributed (i.i.d.).

Preliminaries

Energy detection is a fixed-sample-size sensing algorithm in the sense that the decision is made after collecting a fixed number of samples, say, M. Let $\boldsymbol{r}$ be the $1 \times M$ received signal vector defined as $\boldsymbol{r} := [r_1, r_2, \ldots, r_M]$. In energy detection, we compute the energy of $\boldsymbol{r}$ and compare it with a predetermined value. Mathematically, the testing procedure is described as: accept H_1, if $T(\boldsymbol{r}) := \sum_{i=1}^{M} |r_i|^2 \geq \gamma_{\text{ed}}$; Accept H_0, if $T(\boldsymbol{r}) < \gamma_{\text{ed}}$, where γ_{ed} denotes a threshold for energy detection.

Since w_i is a zero mean complex Gaussian random variable (RV) with variance $\sigma_w^2/2$ per dimension, $2T(\boldsymbol{r})/\sigma_w^2$ is a central chi-square RV with $2M$ degrees of freedom under H_0 and is a noncentral chi-square RV with $2M$ degrees of freedom and noncentrality parameter $2|h|^2 \sum_{i=1}^{M} |s_i|^2/\sigma_w^2$ under H_1 conditioning on $|s_i|^2, i = 1, \ldots, M$. As M increases, $2|h|^2 \sum_{i=1}^{M} |s_i|^2/\sigma_w^2$ approaches $2M|h|^2\sigma_s^2/\sigma_w^2$, where σ_s^2 denotes the average symbol energy. Define $\texttt{SNR}_m$ as the minimum detection SNR, at which the requirements on the target false-alarm and misdetection probabilities are satisfied. The minimum detection SNR is a design parameter, which depends on implementation scenarios but is not directly related to a particular channel realization. In practice, it is highly likely that $\texttt{SNR}_m$ is different from the exact operating SNR, which is defined as $|h|^2\sigma_s^2/\sigma_w^2$. The exact operating SNR depends on the channel gain h between PU and SU, which is difficult to acquire in practice. To distinguish these two different SNRs, we denote by $\texttt{SNR}_o$ the exact operating SNR.

It follows directly from the central limit theorem (CLT) that as M approaches infinity, the distribution of $2T(\boldsymbol{r})/\sigma_w^2$ converges to a normal distribution as follows [36]: $2T(\boldsymbol{r})/\sigma_w^2 \sim \mathscr{N}(2M, 4M)$ under H_0 while $2T(\boldsymbol{r})/\sigma_w^2 \sim \mathscr{N}\big(2M(1 + \texttt{SNR}_m), 4M(1 + 2\texttt{SNR}_m)\big)$ under H_1. Let $\bar{\alpha}_{\text{ed}}$ and $\bar{\beta}_{\text{ed}}$ be the target false-alarm and misdetection probabilities, respectively. Generally speaking, the number of required signal samples M is determined by $\bar{\alpha}_{\text{ed}}$ and $\bar{\beta}_{\text{ed}}$. We use $M_{\text{ed}}^{\min}$ to denote the minimum number of sensing samples required to meet the target $\bar{\alpha}_{\text{ed}}$ and $\bar{\beta}_{\text{ed}}$ requirements when the detection SNR is $\texttt{SNR}_m$. As shown in [37], we have

$$M_{\text{ed}}^{\min} = \left\lceil \ \texttt{SNR}_m^{-2}\left[\mu - \nu \cdot \sqrt{2\texttt{SNR}_m + 1}\right]^2 \right\rceil \tag{3}$$

where $\mu := Q^{-1}(\bar{\alpha}_{\text{ed}})$, $\nu := Q^{-1}(1-\bar{\beta}_{\text{ed}})$, and $\lceil x \rceil$ denotes the smallest integer greater than or equal to x, $Q(\cdot)$ denotes the complementary cumulative distribution function of the standard normal RV, i.e., $Q(x) := (2\pi)^{-1/2}\int_x^\infty e^{-t^2/2}dt$, and $Q^{-1}(\cdot)$ denotes its inverse function. It is evident from (3) that for energy detection, the minimum number of samples is proportional to $\texttt{SNR}_m^{-2}$ for a sufficiently small $\texttt{SNR}_m$ [28].

It is clear from the description above that energy detection has a simple test statistic and a low implementation complexity [27]. In addition, known as a form of non-coherent detection, energy detection requires only the knowledge of noise power and does not rely on any deterministic knowledge about the primary signal s_i. However, one major drawback of the energy detection is that, at a low SNR, it requires a large amount of sensing time to achieve low detection error probabilities.

In comparison with a fixed-sample-size detection such as energy detection, SPRT is capable of achieving the same detection performance with a much reduced ASN [32]. We next investigate a SPRT-based sensing algorithm that relies on the amplitude squares of the received signal samples [26, 29].

To simplify the description, we review a case in which the amplitude squares of primary signals, $|s_i|^2$, $i = 1, 2, \ldots$, are perfectly known at SU. In this case, the spectrum sensing problem formulated in (1) becomes a simple hypothesis testing problem, which is the original setup considered by Wald [31]. Normalize $|r_i|^2$ as $v_i := 2|r_i|^2/\sigma_w^2$ for the convenience of derivation. Note that under H_0, v_i is an exponential RV with rate parameter $1/2$, and under H_1, v_i is a noncentral chi-square RV (conditional on $|s_i|^2$) with two degrees of freedom and noncentrality parameter λ_i that can be readily obtained as $\lambda_i = 2|h|^2|s_i|^2/\sigma_w^2$. Hence, the probability density function (PDF) of v_i under H_0 is

$$q_0(v_i) = \frac{1}{2}e^{-v_i/2} \tag{4}$$

whereas under H_1, the PDF of v_i (conditional on λ_i) is

$$q_1(v_i|\lambda_i) = \frac{1}{2}e^{-(v_i+\lambda_i)/2} I_0(\sqrt{\lambda_i v_i}) \tag{5}$$

where $I_0(\cdot)$ is the zeroth-order modified Bessel function of the first kind. After collecting N samples, we can express the accumulative log-likelihood ratio as

$$L_N(\boldsymbol{v}_N|\boldsymbol{\lambda}_N) = \log\frac{q_{\boldsymbol{v}|H_1}(\boldsymbol{v}_N|\boldsymbol{\lambda}_N)}{q_{\boldsymbol{v}|H_0}(\boldsymbol{v}_N)} = \sum_{i=1}^N z_i = -\sum_{i=1}^N \lambda_i/2 + \sum_{i=1}^N \log I_0(\sqrt{\lambda_i v_i}) \tag{6}$$

where $\boldsymbol{v}_N := (v_1, v_2, \ldots, v_N)$, $z_i = \log\big(q_1(v_i|\lambda_i)/q_0(v_i)\big)$, and $\boldsymbol{\lambda}_N := (\lambda_1, \lambda_2, \ldots, \lambda_N)$. The test procedure is given as follows: accept H_1, if $L_N(\boldsymbol{v}_N|\boldsymbol{\lambda}_N) \geq b_L$; accept H_0, if $L_N(\boldsymbol{v}_N|\boldsymbol{\lambda}_N) \leq a_L$; and continue sensing, if $a_L < L_N(\boldsymbol{v}_N|\boldsymbol{\lambda}_N) < b_L$. In [31], Wald specified a particular choice of

thresholds a_L and b_L for the *non-truncated* SPRT as follows: $a_L = \log \bar{\beta}_{\text{sprt}}/(1 - \bar{\alpha}_{\text{sprt}})$, and $b_L = \log(1 - \bar{\beta}_{\text{sprt}})/\bar{\alpha}_{\text{sprt}}$ where $\bar{\alpha}_{\text{sprt}}$ and $\bar{\beta}_{\text{sprt}}$ denote the target false-alarm and misdetection probabilities, respectively. For a non-truncated SPRT, the Wald's choice on a_L and b_L yields true false-alarm and misdetection probabilities that are fairly close to the target ones.

Let z be a RV having the same PDF as z_i. It has been pointed out in [39] that, in SPRT, if hypotheses H_0 and H_1 are distinct, then $E_{H_0}(z) < 0 < E_{H_1}(z)$, where $E_{H_i}(\cdot)$ denotes the expectation under H_i, $i = 1, 2$. As evident from (6), one shortcoming of this SPRT-based sensing algorithm is that the test statistic contains a modified Bessel function, which may result in a high implementation complexity. When the perfect knowledge of the instantaneous amplitude squares of the primary signals is not available, PDF under H_1 is not completely known, i.e., the alternative hypothesis is composite. Generally speaking, two approaches, the Bayesian approach and the generalized likelihood ratio test, can be used to deal with such a case. In the Bayesian approach, *a prior* PDF of the amplitude squares of the primary signals is required and multiple summations over all possible amplitudes of the primary signals need to be performed, whereas in the generalized likelihood ratio test, a maximum likelihood estimation (MLE) of the amplitude squares of the primary signals is needed [7]. Either of these two approaches, however, leads to a considerable increase in the implementation complexity.

A Low-Complexity Sequential Spectrum Sensing Algorithm

We now propose a low-complexity sequential spectrum sensing algorithm depicted as follows:

$$\Lambda_N = \sum_{i=1}^{N} \left(|r_i|^2 - \Delta \right), \tag{7}$$

in which Δ is a fixed and predetermined parameter. Suppose that the detector has a decision deadline M. That is, the detector needs to make a decision within M samples. We propose the following test procedure:

$$\texttt{Accept } H_1 :$$

$$\text{if } \Lambda_N \geq b \text{ for } 0 < N \leq M - 1, \text{ or if } \Lambda_M \geq \gamma; \tag{8}$$

$$\texttt{Accept } H_0 :$$

$$\text{if } \Lambda_N \leq a \text{ for } 0 < N \leq M - 1, \text{ or if } \Lambda_M < \gamma; \tag{9}$$

$$\texttt{Continue Sensing} :$$

$$\text{if } \Lambda_N \in (a, b) \text{ for } 0 < N \leq M - 1 \tag{10}$$

where a, b, and γ denote three predetermined and fixed constants satisfying the following conditions: $a < 0$, $b > 0$, and $\gamma \in (a, b)$. In statistical term, the test

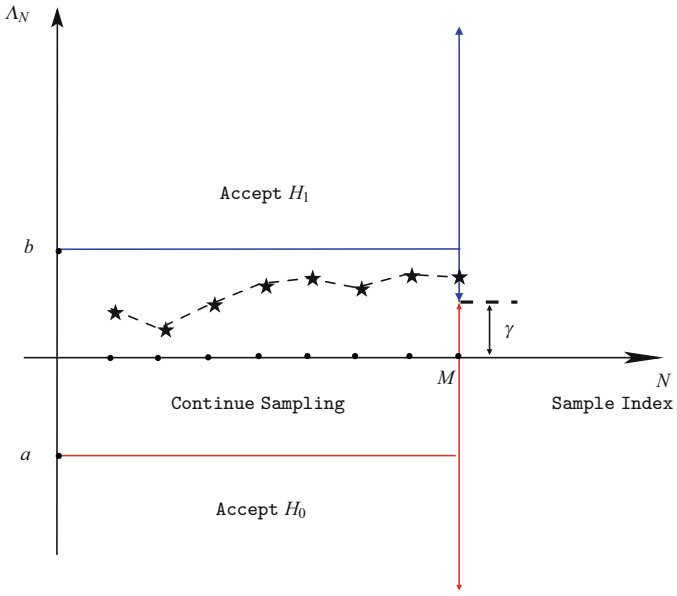

Fig. 1 The test region of SSCT

procedure given in (8), (9), and (10) is nothing but a *truncated* sequential test. As depicted in Fig. 1, the stopping boundaries of the test region consist of horizontal lines b and a, which we call the upper and lower boundary, respectively. Notice that each term $|r_i|^2 - \Delta$ in Λ_N is nothing but a shifted chi-square RV. Hence, we simply name this sensing algorithm described in (8), (9), and (10) *sequential shifted chi-square test* (SSCT). As can be seen from (7), SSCT has a simple test statistic that contains only the amplitude squares of the received signals and the parameter Δ.

Let r be a RV with the same PDF as $|r_i|^2 - \Delta$, which is the ith incremental term in the test statistic (7). Similar to the SPRT case, we choose $\sigma_w^2 < \Delta < \sigma_w^2(1 + \mathrm{SNR}_m)$ to ensure $E_{H_0}(r) < 0 < E_{H_1}(r)$. In SSCT, we have $E_{H_0}(r) = \sigma_w^2 - \Delta$ and $E_{H_1}(r) = \sigma_w^2(1 + \mathrm{SNR}_o) - \Delta$. Using $\mathrm{SNR}_m \le \mathrm{SNR}_o$ and $\sigma_w^2 < \Delta < \sigma_w^2(1 + \mathrm{SNR}_m)$, we always have $E_{H_0}(r) < 0 \le \mathrm{SNR}_o - \mathrm{SNR}_m < E_{H_1}(r)$. Note that with this choice, the constant Δ depends on the minimum detection SNR instead of the exact operating SNR. Normalize the test statistic Λ_N by $\sigma_w^2/2$ and define $\bar{\Lambda}_N := 2\Lambda_N/\sigma_w^2$. We rewrite (7) as

$$\bar{\Lambda}_N = \sum_{i=1}^{N} (v_i - 2\Delta/\sigma_w^2) \tag{11}$$

where $v_i := 2|r_i|^2/\sigma_w^2$. Let ξ_N denote the sum of v_i for $i = 1, \ldots, N$, i.e., $\xi_N = \sum_{i=1}^{N} v_i$ and let $\bar{\Delta}$ denote $2\Delta/\sigma_w^2$. Applying this notation, we rewrite $\bar{\Lambda}_N$ as $\bar{\Lambda}_N = \xi_N - N\bar{\Delta}$. We let $\bar{\Lambda}_0$ and ξ_0 be 0 for notational simplicity. We further define a_i and

b_i as: $a_i = 0$ for $\aleph_0^P$, $a_i = \bar{a} + i\bar{\Delta}$ for $i \in \aleph_{P+1}^{\infty}$, and $b_i = \bar{b} + i\bar{\Delta}$ for $b \in \aleph_0^{\infty}$, where $\bar{a} := 2a/\sigma_w^2$, $\bar{b} := 2b/\sigma_w^2$, and P denotes the largest integer not greater than $-a/\Delta$, i.e., $P := \texttt{floor}(-a/\Delta)$. Applying the notation $\xi_N = \sum_{i=1}^{N} v_i$, we express the test procedure (8), (9), and (10) as

$$\texttt{Accept } H_1 : \tag{12}$$
$$\texttt{if } \xi_N \geq b_N \text{ for } 0 < N \leq M-1, \texttt{ or if } \xi_M \geq \bar{\gamma}_M;$$
$$\texttt{Accept } H_0 : \tag{13}$$
$$\texttt{if } \xi_N \leq a_N \text{ for } 0 < N \leq M-1, \texttt{ or if } \xi_M < \bar{\gamma}_M;$$
$$\texttt{Continue Sensing} : \tag{14}$$
$$\texttt{if } \xi_N \in (a_N, b_N) \text{ for } 0 < N \leq M-1$$

where $\bar{\gamma}_M = \bar{\gamma} + M\bar{\Delta}$ with $\bar{\gamma} := 2\gamma/\sigma_w^2$. The corresponding test region is depicted in Fig. 2, where the stopping boundaries comprise two slant line segments.

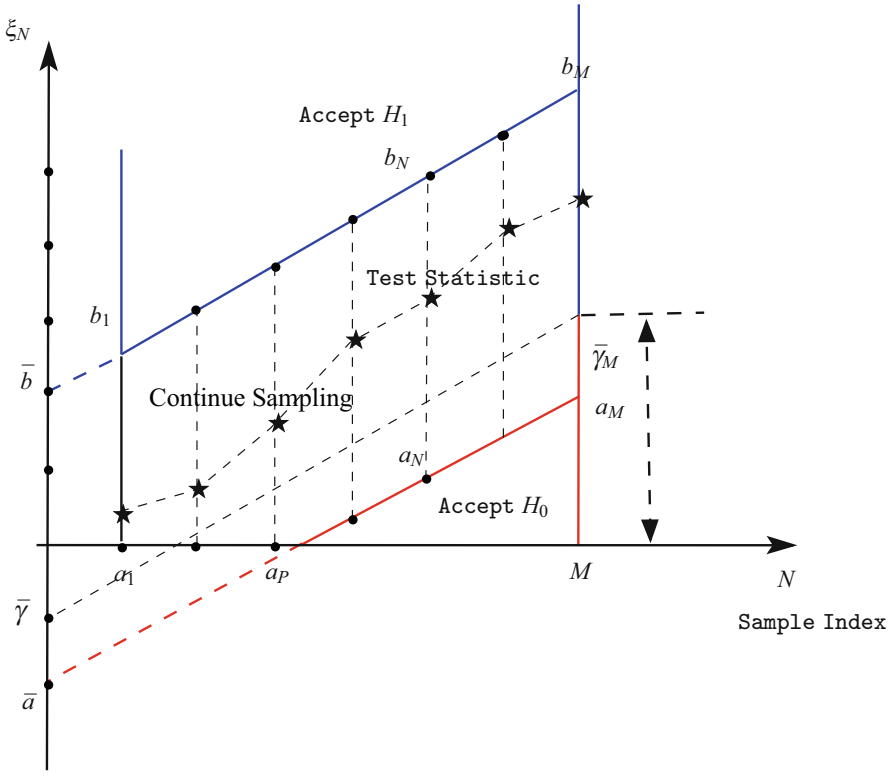

Fig. 2 The test region of the transformed test procedure

Define α_{ssct} and β_{ssct} as the false-alarm and misdetection probabilities of SSCT, respectively.

The issue of how to select thresholds a, b, and γ is critical to the performance of SSCT. In [31], Wald proposed a method to select appropriate thresholds for the non-truncated SPRT. Since the proposed test procedure in (8), (9), and (10) is a truncated sequential test and is not necessarily a SPRT, the thresholds selected by the Wald's method cannot meet target detection performance requirements in general.

As a result, an alternative approach to select thresholds is needed. Typically, the thresholds a, b, γ, the parameter Δ, and the truncated size M are selected *beforehand and off-line*, either purposefully or randomly, and the corresponding α_{ssct} and β_{ssct} are then computed. If the resulted α_{ssct} and β_{ssct} do not meet the requirement, the thresholds and truncated size are subsequently adjusted. This process continues until a desirable error probability performance is obtained. In the above process, the key and challenging step is to accurately and efficiently evaluate α_{ssct} and β_{ssct} as well as ASN for any prescribed thresholds a, b, γ, the parameter Δ, and the truncated size M. In the following section, we will show how to evaluate these quantities for SSCT.

Evaluations of False-Alarm and Misdetection Probabilities

In this section, we present the exact false-alarm probability result and a numerical integration algorithm that obtains the misdetection probability in a recursive manner [38] for any given thresholds.

Preparatory Tools

We introduce the first integral as follows:

$$f_{\boldsymbol{\chi}_k}^{(k)}(\xi) = \int_{\chi_k}^{\xi} d\xi_k \int_{\chi_{k-1}}^{\xi_k} d\xi_{k-1} \cdots \int_{\chi_1}^{\xi_2} d\xi_1, \ k \geq 1$$

and $f_{\boldsymbol{\chi}_k}^{(k)}(\xi) = 1$ for $k = 0$, where $\boldsymbol{\chi}_0 = \emptyset$ and $\boldsymbol{\chi}_k := [\chi_1, \ldots, \chi_{k-1}, \chi_k]$ with $0 \leq \chi_1 \leq \ldots \leq \chi_k$. The superscript k and the subscript $\boldsymbol{\chi}_k$ are used to indicate that $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ is a k-fold multiple integral with ordered lower limits specified by $\boldsymbol{\chi}_k$. Evidently, the integral $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ is a polynomial in ξ of degree k. Lemma 1 shows that the exact value of $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ can be computed recursively.

Lemma 1. *The integral $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ is given by*

$$f_{\boldsymbol{\chi}_k}^{(k)}(\xi) = \sum_{i=0}^{k-1} \frac{f_i^{(k)}(\xi - \chi_{i+1})^{k-i}}{(k-i)!} + f_k^{(k)} \tag{15}$$

where $f_i^{(k)}$, $i = 0, \ldots, k$, *for* $k \geq 1$ *can be obtained recursively as follows:* $f_i^{(k)} = f_i^{(k-1)}$, $i \in \aleph_0^{k-1}$ *and*

$$f_k^{(k)} = -\sum_{i=0}^{k-1} \frac{f_i^{(k-1)}}{(k-i)!}(\chi_k - \chi_{i+1})^{k-i}$$

with $f_0^{(0)} = 1$. *For the case where* $\chi_1 = \chi_2 = \ldots = \chi_k = \chi$, *the coefficients* $f_{\boldsymbol{\chi}_k}^{(k)}$ *is given by*

$$f_{\boldsymbol{\chi}_k}^{(k)} = \frac{1}{k!}(\xi - \chi)^k.$$

Additionally, the integral $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ *has the following useful properties: 1) Differential Property:* $df_{\boldsymbol{\chi}_k}^{(k)}(\xi)/d\xi = f_{\boldsymbol{\chi}_{k-1}}^{(k-1)}(\xi)$ *with* $\boldsymbol{\chi}_{k-1} = [\chi_1, \ldots, \chi_{k-1}]$ *and* $k \geq 2$*; 2) Scaling Property:* $f_{t\boldsymbol{\chi}_k}^{(k)}(t\xi) = t^k f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$ *for* $t > 0$*; 3) Shift Property:* $f_{\boldsymbol{\chi}_k - \delta \mathbf{1}_k}^{(k)}(\xi - \delta) = f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$.

It is noteworthy to mention that formula (15) together with scaling and shift properties are particularly useful in reducing round-off errors when evaluating $f_{\boldsymbol{\chi}_k}^{(k)}(\xi)$. These two properties will be used to ensure the numerical stability of the false-alarm probability computation method presented later in this section. The second integral that will be useful is

$$I^{(0)} := 1, \text{ and } I^{(n)} := \int_{\Omega^{(n)}} \cdots \int d\boldsymbol{\xi}_n, \; n \geq 1 \tag{16}$$

where $\boldsymbol{\xi}_n := [\xi_1, \xi_2, \ldots, \xi_n]$ with $0 \leq \xi_1 \leq \xi_2 \cdots \leq \xi_n$, and $\Omega^{(n)} = \{(\xi_1, \xi_2, \ldots, \xi_n) : 0 \leq \xi_1 \leq \cdots \leq \xi_n; a_i < \xi_i < b_i, i \in \aleph_1^n\}$. For $n = 1$, we have $I^{(1)} = \int_{a_1}^{b_1} d\xi_1 = b_1 - a_1$. We define c and d as two parameters satisfying $0 \leq c < d$, $a_{N-1} \leq c \leq b_N$ and $a_N \leq d$. For $N \geq 2$, we define the following vector

$$\boldsymbol{\psi}_{n,c}^N = \begin{cases} [\underbrace{b_{n+1}, \ldots, b_{n+1}}_{Q}, \underbrace{a_{Q+n+1}, \ldots, a_{N-1}, c}_{N-Q-n}], n \in \aleph_0^{N-Q-2} \\ [\underbrace{b_{n+1}, \ldots, b_{n+1}, c}_{N-n}], n \in \aleph_{N-Q-1}^{s-1} \\ b_{n+1}\mathbf{1}_{N-n}, n \in \aleph_s^{N-2} \end{cases}$$

where s and Q denote the integers satisfying $b_s < c \leq b_{s+1}$ and $a_Q \leq b_1 < a_{Q+1}$ respectively. Let us define $\boldsymbol{A}_i$ as an $(N-n) \times (N-n-i)$ matrix $\boldsymbol{A}_i = [\boldsymbol{I}_{N-i-n} | \mathbf{0}_{(N-i-n)\times i}]^T$ with $i \in \aleph_1^{N-n}$. In addition, we define the following vectors $\boldsymbol{\psi}_{n,c}^{N-i} = \boldsymbol{\psi}_{n,c}^N \cdot \boldsymbol{A}_i$, $i \in \aleph_1^{N-n} \boldsymbol{a}_{n_1}^{n_2} = [a_{n_1+1}, \ldots, a_{n_2}]$, $n_2 \geq n_1 \geq 0$, where $\boldsymbol{\psi}_{n,c}^{N-i}$

is an $(N-i-n)\times 1$ vector and $\boldsymbol{a}_{n_1}^{n_2}$ is an $(n_1-n_2)\times 1$ vector. If $n_1=n_2$, we define $a_{n_1}^{n_2}$ as $\emptyset$. In what follows, we show that we can compute the exact value of $I^{(N)}$ in (16) recursively.

Lemma 2. *The exact value of the integral $I^{(N)}$ is given by*

$$I^{(N)}=f_{\boldsymbol{a}_0^N}^{(N)}(b_N)-\begin{cases}\mathbb{I}_{\{N\geq 2\}}\sum_{n=0}^{N-2}\dfrac{(b_N-b_{n+1})^{N-n}I^{(n)}}{(N-n)!}, & N\in\aleph_1^Q\\ \sum_{n=0}^{N-2}f_{\boldsymbol{\psi}_{n,a_N}^N}^{(N-n)}(b_N)I^{(n)}, & N\in\aleph_{Q+1}^{\infty}\end{cases}$$

with $I^{(0)}=1$.

The third integral is given by

$$J_{c,d}^{(N)}(\theta):=\underset{\Upsilon_{c,d}^{(N)}}{\int\cdots\int}e^{-\theta\xi_N}d\boldsymbol{\xi}_N$$

where $\theta>0$, $N\geq 1$, and $\Upsilon_{c,d}^{(N)}:=\{(\xi_1,\ldots,\xi_N):0\leq\xi_1\leq\ldots\leq\xi_N;a_i<\xi_i<b_i,i\in\aleph_1^{N-1};c<\xi_N<d\}$. Recall that c and d are two non-negative numbers satisfying $a_{N-1}\leq c\leq b_N$ and $0\leq c<d$ and $d\geq a_N$. We define the following function

$$g_{c,d}^{(n)}(\theta)=\begin{cases}I^{(n)}\Big[\theta^{n-N}e^{-\theta b_{n+1}}-\sum_{i=1}^{N-n}\theta^{-i}\times f_{b_{n+1}\mathbf{1}_{N-n-i}}^{(N-n-i)}(d)e^{-\theta d}\Big], & c\leq b_1,n\in\aleph_0^{N-2}\\ I^{(n)}\sum_{i=1}^{N-n}\theta^{-i}\Big[f_{\boldsymbol{\psi}_{n,c}^{N-i}}^{(N-n-i)}(c)e^{-\theta c}-f_{\boldsymbol{\psi}_{n,c}^{N-i}}^{(N-n-i)}(d)e^{-\theta d}\Big], & c>b_1,n\in\aleph_0^{s-1}\\ I^{(n)}\Big[\theta^{n-N}e^{-\theta b_{n+1}}-\sum_{i=1}^{N-n}\theta^{-i}\times f_{b_{n+1}\mathbf{1}_{N-n-i}}^{(N-n-i)}(d)e^{-\theta d}\Big], & c>b_1,n\in\aleph_s^{N-2}.\end{cases}$$

In the cases of $(c,d)=(\bar{\gamma}_N,\infty)$ and $(c,d)=(a_N,b_N)$, the exact values of the integral $J_{c,d}^{(N)}(\theta)$ in (17) can be obtained from the following lemma.

Lemma 3. *For any $\bar{\gamma}_N$ satisfying $a_N\leq\bar{\gamma}_N<b_N$, the exact values of the integrals $J_{\bar{\gamma}_N,\infty}^{(N)}(\theta)$ and $J_{a_N,b_N}^{(N)}(\theta)$ are given by*

$$J_{\bar{\gamma}_N,\infty}^{(N)}(\theta)=\sum_{i=1}^{N}\theta^{-i}f_{\boldsymbol{a}_0^{N-i}}^{(N-i)}(\bar{\gamma}_N)e^{-\theta\bar{\gamma}_N}-\mathbb{I}_{\{N\geq 2\}}\sum_{n=0}^{N-2}g_{\bar{\gamma}_N,\infty}^{(n)}(\theta)$$

$$J_{a_N,b_N}^{(N)}(\theta)=\sum_{i=1}^{N}\theta^{-i}\Big[f_{\boldsymbol{a}_0^{N-i}}^{(N-i)}(a_N)e^{-\theta a_N}-f_{\boldsymbol{a}_0^{N-i}}^{(N-i)}(b_N)e^{-\theta b_N}\Big]-\mathbb{I}_{\{N\geq 2\}}\sum_{n=0}^{N-2}g_{a_N,b_N}^{(n)}(\theta).$$

We next show how to apply these preparatory results to evaluate the exact false-alarm probability.

False-Alarm Probability

Define $E_N := \{\Lambda_N \geq b \text{ and } a < \Lambda_n < b \text{ for } n \in \aleph_1^{N-1} \text{ with } N \in \aleph_1^{M-1}\}$ and $E_M := \{\Lambda_M \geq \gamma \text{ and } a < \Lambda_n < b \text{ for } n \in \aleph_1^{M-1}\}$ and let $P_{H_0}(E_N)$ be the probability of event E_N occurring under H_0. Since the test procedure described in (8), (9), and (10) is the same as that described in (12) (13), and (14), we have

$$P_{H_0}(E_N) = \begin{cases} P_{H_0}(a_i < \xi_i < b_i, i \in \aleph_1^{N-1}; \xi_N \geq b_N), \text{for } N \in \aleph_1^{M-1}; \\ P_{H_0}(a_i < \xi_i < b_i, i \in \aleph_1^{M-1}; \xi_M \geq \bar{\gamma}_M), \text{for } N = M. \end{cases} \tag{17}$$

Clearly, the false-alarm probability α_{ssct} can be written $\alpha_{\text{ssct}} = \sum_{N=1}^{M} P_{H_0}(E_N)$. The following proposition gives the exact false-alarm probability α_{ssct}.

Proposition 1. *The false-alarm probability, α_{ssct}, is given by $\alpha_{ssct} = \sum_{N=1}^{M} P_{H_0}(E_N)$, where $P_{H_0}(E_N)$ is given by*

$$P_{H_0}(E_N) = \begin{cases} A_N \dfrac{b_1 b_N^{N-2}}{(N-1)!}, \ N \in \aleph_1^{P+1}; \\ A_N \Big[f_{\boldsymbol{a}_0^{N-1}}^{(N-1)}(b_{N-1}) - \mathbb{I}_{\{N \geq 3\}} \displaystyle\sum_{n=0}^{N-3} e^{\frac{b_{n+1}}{2}} \frac{P_{H_0}(E_{n+1})(b_{N-1} - b_{n+1})^{N-n-1} 2^n}{(N-n-1)!} \Big], \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad N \in \aleph_{P+2}^{Q+1}; \\ A_N \Big[f_{\boldsymbol{a}_0^{N-1}}^{(N-1)}(b_{N-1}) - \displaystyle\sum_{n=0}^{N-3} f_{\boldsymbol{\psi}_{n,a_{N-1}}^{N-1}}^{(N-1-n)}(b_{N-1}) 2^n e^{\frac{b_{n+1}}{2}} P_{H_0}(E_{n+1}) \Big], \ N \in \aleph_{Q+2}^{M-1}; \\ 2^{-M} J_{\bar{\gamma}_M, \infty}^{(M)}(1/2), \ N = M, \end{cases} \tag{18}$$

where $A_N := 2^{-(N-1)} e^{-b_N/2}$.

Misdetection Probability

We now show how to evaluate the misdetection probability β_{ssct} for SSCT. Evaluating β_{ssct} is more difficult than evaluating α_{ssct}. The main reason is that to compute β_{ssct}, one needs to know $q_1(v_i)$. However, computing $q_1(v_i)$ is intractable except when primary signal samples have the constant-modulus property, i.e., $|s_i|^2 = \sigma_s^2$. We next show that at a relatively low detection SNR level, the misdetection probability obtained by using constant-modulus primary signals can be used to well approximate the actual β_{ssct}. Our arguments are primarily based on the following two properties of SSCT.

The first property shows that as N approaches infinity, the distribution of the test statistic ξ_N in SSCT converges to a normal distribution that is independent of a specific choice of $\lambda_1, \lambda_2, \ldots, \lambda_N$.

Property 1. *The statistical distribution of ξ_N converges to a normal distribution given by*

$$\xi_N \sim \begin{cases} \mathcal{N}(2N, 4N), & \text{under } H_0, \\ \mathcal{N}\big(2N(1+\mathtt{SNR}_m), 4N(1+2\mathtt{SNR}_m)\big), & \text{under } H_1, \end{cases}$$

as N approaches infinity.

The property can be readily proved by using CLT [39]. However, unlike energy detection, this property alone is not sufficient to explain that the constant-modulus assumption is valid in approximating β_{ssct}. This is because each ξ_N for $N = 1, \ldots, M$, including small values of N, may potentially affect the value of β_{ssct}. To complete our argument, we first present the following definitions. Let $\tilde{\xi}_i$ denote the test statistic using the constant-modulus assumption, i.e., $|s_i|^2 = \sigma_s^2$. Define $\rho_N := b_N$ for $N \in \aleph_1^{M-1}$ and $\rho_M := \bar{\gamma}_M$ for $N = M$. Let F_N and $\tilde{F}_N$ denote the events that $\xi_N \geq \rho_N$, and $a_i < \xi_i < b_i$ for $i \in \aleph_1^M$, and $\tilde{\xi}_N \geq \rho_N$ and $a_i < \tilde{\xi}_i < b_i$ for $i \in \aleph_1^M$, respectively. Let $P_{H_1}(F_N)$ and $P_{H_1}(\tilde{F}_N)$ denote the probabilities of the events F_N and $\tilde{F}_N$ under H_1. Let $\tilde{\beta}_{\text{ssct}}$ denote the misdetection probability obtained by assuming constant-modulus signals with average symbol energy σ_s^2, i.e., $|s_i|^2 = \sigma_s^2$. As clear from their definitions, we have $\beta_{\text{ssct}} = \sum_{N=1}^{M} P_{H_1}(F_N)$ and $\tilde{\beta}_{\text{ssct}} = \sum_{N=1}^{M} P_{H_1}(\tilde{F}_N)$.

Let $\mathscr{A}_N^{l_N}$ denote the event that $a_i < \xi_i < b_i$, $i \in \aleph_1^{l_N}$ for some integer $l_N \in \aleph_1^N$, and let $\tilde{\mathscr{A}}_N^{l_N}$ denote its counterpart for the constant-modulus case. Let $\mathscr{B}_N^{l_N}$ denote the event that $\xi_N \geq \rho_N$ and $a_i < \xi_i < b_i$, $i \in \aleph_{l_N+1}^N$ and let $\tilde{\mathscr{B}}_N^{l_N}$ denote its counterpart in the constant-modulus case. We now present the second property.

Property 2. *For any $\varepsilon > 0$, if for each N, there exists a positive integer $l_N \in \aleph_1^N$ such that $P_{H_1}(\mathscr{A}_N^{l_N}) \geq 1 - \varepsilon/(3M)$, $P_{H_1}(\tilde{\mathscr{A}}_N^{l_N}) \geq 1 - \varepsilon/(3M)$, and $|P_{H_1}(\mathscr{B}_N^{l_N}) - P_{H_1}(\tilde{\mathscr{B}}_N^{l_N})| < \varepsilon/(3M)$, then $|\beta_{ssct} - \tilde{\beta}_{ssct}| \leq \varepsilon$.*

Relying on these two properties, we provide an outline of our arguments. To achieve a high detection accuracy at a low SNR level, ASN and M are typically quite large. When the sample index N is relatively small, it is highly unlikely that the test statistics ξ_N and $\tilde{\xi}_N$ cross either of the two boundaries. In such a situation, there exists some integer l_N such that $P_{H_1}(\mathscr{A}_N^{l_N})$ and $P_{H_1}(\tilde{\mathscr{A}}_N^{l_N})$ are fairly close to 1, whereas $P_{H_1}(\mathscr{B}_N^{l_N})$ and $P_{H_1}(\tilde{\mathscr{B}}_N^{l_N})$ are fairly close to 0. Hence, the conditions in Property 2 can be easily satisfied. On the other hand, when N is relatively large, one can find a sufficiently large l_N such that $P_{H_1}(\mathscr{A}_N^{l_N})$ and $P_{H_1}(\tilde{\mathscr{A}}_N^{l_N})$ are fairly close to one, while $|P_{H_1}(\mathscr{B}_N^{l_N}) - P_{H_1}(\tilde{\mathscr{B}}_N^{l_N})|$ is sufficiently small due to Property 1 guaranteed by the CLT. Collectively, at a low detection SNR level, $\tilde{\beta}_{\text{ssct}}$ evaluated under the constant-modulus assumption is a close approximation of

β_{ssct}. Therefore, we will focus on the case in which all λ_i's are equal to a constant $\lambda := 2|h|^2\sigma_s^2/\sigma_w^2 = 2\text{SNR}_m$.

Recall that under H_1, v_i is a noncentral chi-square random variable, whose PDF involves the zeroth-order modified Bessel function of the first kind as given in (5). Hence, it is mathematically intractable to evaluate $\tilde{\beta}_{\text{ssct}}$ by applying the computational approach used in section "False-Alarm Probability." To obtain $\tilde{\beta}_{\text{ssct}}$, we apply a numerical integration algorithm proposed in [38].

Defining $u_i = v_i - \bar{\Delta}$, we express $\bar{\Lambda}_N$ in (11) as $\bar{\Lambda}_N = \sum_{i=1}^{N} u_i$. Clearly, the PDF of u_i under hypothesis H_1 can be rewritten as

$$q_1(u_i) = \frac{1}{2} e^{-(u_i+\bar{\Delta}+\lambda)} I_0\Big(\sqrt{\lambda(u_i+\bar{\Delta})}\Big), u_i > -\bar{\Delta}.$$

Note that SSCT observes at most M samples before making a decision. Let t_k denote $\bar{\Lambda}_{M-k}$. We also use $G_k(t_k)$ to denote the conditional misdetection probability conditioning on the follow event: the first $(M-k)$ samples have been collected, the present observation value is $t_k = \bar{\Lambda}_{M-k}$, and the test statistic of the previous $(M-k-1)$ samples has not crossed either the upper or lower boundary. When $\bar{a} < t_k < \bar{b}$ for $k = 1, \ldots, M$, SSCT needs to collect an additional sample (the $(M-k+1)$th sample). For notation simplicity, we use u to denote the next observed value of u_i. We can write the conditional probability $G_k(t_k|u)$ as

$$G_k(t_k|u) = \begin{cases} 0 & \text{if } u > \bar{b} - t_k \\ 1 & \text{if } u < \bar{a} - t_k \\ G_{k-1}(t_k + u) & \text{if } \bar{a} - t_k \le u \le \bar{b} - t_k. \end{cases} \tag{19}$$

Using (19), we can compute $G_k(t_k)$ as

$$G_k(t_k) = \int_{-\infty}^{\bar{a}-t_k} q_1(u)du + \int_{\bar{a}-t_k}^{\bar{b}-t_k} G_{k-1}(t_k+u)q_1(u)du \tag{20}$$

for $k = 1, \cdots, M$ with the following initial condition: $G_0(t_0) = 0$ if $t_0 \ge \bar{\gamma}$ and $G_0(t_0) = 1$, otherwise. Note that $G_M(0)$ is indeed the misdetection probability $\tilde{\beta}_{\text{ssct}}$. By applying the backward recursion algorithm described above, the value of $G_M(0)$ is obtained.

Evaluation of the Average Sample Number

In this section, we discuss how to evaluate ASN of the proposed algorithm. Let N_s denote the number of samples required to yield a decision. Clearly, N_s is a RV in SSCT, and its mean value is ASN, which can be written as

$$E(N_s) = E_{H_0}(N_s)\pi_0 + E_{H_1}(N_s)\pi_1 \tag{21}$$

where $E_{H_i}(N_s)$ denotes ASN under H_i, and π_i denotes the priori probability of hypothesis H_i, for $i = 0, 1$.

According to (8), (9), and (10), we have $1 \leq N_s \leq M$. Hence, we can express $E_{H_i}(N_s)$ as

$$E_{H_i}(N_s) = \sum_{N=1}^{M} N P_{H_i}(N_s = N),\ i = 0, 1 \tag{22}$$

where $P_{H_i}(N_s = N)$ is the probability that the detector makes a decision at the Nth sample under H_i. We now need to determine $P_{H_i}(N_s = N)$. Let $\mathscr{C}_N$ denote the event that the test statistics $(\xi_1, \xi_2, \ldots, \xi_N)$ do not cross either the upper or lower boundary before or at the Nth sample, i.e., $\mathscr{C}_N = \{(\xi_1, \xi_2, \ldots, \xi_N) \in \Upsilon^{(N)}_{a_N, b_N}\}$ for $N \in \aleph_1^M$. For notional convenience, let us define $\mathscr{C}_0$ as a universe set. Hence, we have $P(\mathscr{C}_0) = 1$. The test procedure described in (12) (13), and (14) implies that $P_{H_i}(N_s = N),\ i = 0, 1$ can be obtained as

$$P_{H_i}(N_s = N) \overset{(a)}{=} P_{H_i}\left(\mathscr{C}_{N-1}\right) - P_{H_i}\left(\mathscr{C}_N\right),\ N \in \aleph_1^{M-1} \tag{23}$$

$$P_{H_i}(N_s = M) \overset{(b)}{=} P_{H_i}\left(\mathscr{C}_{M-1}\right), \qquad N = M \tag{24}$$

where $P_{H_i}(\mathscr{C}_{N-1})$ and $P_{H_i}(\mathscr{C}_N)$ in (a) denote the respective probabilities of the following events: under H_i, the test statistic does not cross either the upper or lower boundary before or at the $(N-1)$th sample and the Nth sample for $N \in \aleph_1^{M-1}$; and $P_{H_i}(\mathscr{C}_{M-1})$ in (b) denotes the probability of the following event: under H_i, the test statistic does not cross either upper or lower boundary before or at the $(M-1)$th sample. Clearly, using (23) and (24), we can express (22) as

$$E_{H_i}(N_s) = \sum_{N=1}^{M-1} N\left(P_{H_i}(\mathscr{C}_{N-1}) - P_{H_i}(\mathscr{C}_N)\right) + M P_{H_i}(\mathscr{C}_{M-1}) = 1 + \sum_{N=1}^{M-1} P_{H_i}(\mathscr{C}_N). \tag{25}$$

Applying (23), and (24), we obtain $P_{H_0}\left(\mathscr{C}_N\right) = 2^{-N} J^{(N)}_{a_N, b_N}(1/2),\ N \in \aleph_1^{M-1}$. Hence, according to (25), we have

$$E_{H_0}(N_s) = 1 + \sum_{N=1}^{M-1} 2^{-N} J^{(N)}_{a_N, b_N}(1/2). \tag{26}$$

We next show how to obtain $P_{H_1}(\mathscr{C}_N)$ or equivalently how to obtain $P_{H_1}(\mathscr{C}_N^c)$. To compute $P_{H_1}(\mathscr{C}_N^c)$, we apply a similar computation method to the one used in computing the misdetection probability. It should be noted that $\mathscr{C}_N^c$ indicates the following event: under H_1, the test procedure given in (12) (13), and (14) stops before or at the Nth sample, i.e., the test statistic crosses either the upper or lower

boundary before or at the Nth sample. With a slight abuse of notation, we rewrite $G_k(t_k)$ as $G_k(t_k, \bar{\gamma})$. We use V_N to denote the following event: the test statistic crosses the lower boundary before or at the Nth sample under H_1, and we use U_N to denote the following event: the test statistic *does not* cross the upper boundary before or at the Nth sample under H_1. By the definitions of V_N, U_N, and G_N, we have $P_{H_1}(V_N) = G_N(0, \bar{a})$ and $P_{H_1}(U_N) = G_N(0, \bar{b})$. Clearly, we can write $P_{H_1}(\mathscr{C}_N^c)$ as

$$P_{H_1}\left(\mathscr{C}_N^c\right) = G_N(0, \bar{a}) + 1 - G_N(0, \bar{b}) \tag{27}$$

where $G_N(t, \bar{a})$ and $G_N(t, \bar{b})$ can be obtained by applying (20) recursively. From (27), we have $P_{H_1}(\mathscr{C}_N) = G_N(0, \bar{b}) - G_N(0, \bar{a})$. According to (25), we have

$$E_{H_1}(N_s) = 1 + \sum_{N=1}^{M-1} (G_N(0, \bar{b}) - G_N(0, \bar{a})). \tag{28}$$

In the following proposition, we present the ASN of SSCT.

Proposition 2. *The ASN of SSCT can be obtained as*

$$E(N_s) = \pi_0 \left(1 + \sum_{N=1}^{M-1} 2^{-N} J_{a_N, b_N}^{(N)}(1/2)\right) + \pi_1 \left(1 + \sum_{N=1}^{M-1} (G_N(0, \bar{b}) - G_N(0, \bar{a}))\right).$$

Numerical Examples

In this section, we present several numerical examples to test the SSCT algorithm and validate the results obtained in sections "Evaluations of False-Alarm and Misdetection Probabilities" and "Evaluation of the Average Sample Number." In these examples, the parameter $\bar{\Delta}$ is selected to be $2 + \mathtt{SNR}_m$. With this choice of $\bar{\Delta}$, we have $E_{H_0}(|r_i|^2 - \Delta) = E_{H_1}(|r_i|^2 - \Delta) = -\sigma_s^2/2$ and thus $E_{H_0}(\Lambda_N) = -E_{H_1}(\Lambda_N)$ for every $N \geq 0$. It implies that statically, the test statistic Λ_N moves the same distance on average upward or downward at each step. Roughly speaking, such choice of the parameter Δ will lead to an approximately same average sample number under H_0 or H_1. In the first three test examples, we select the parameter M to be the minimum required sample number $M_{\text{ed}}^{\min}$ for energy detection to achieve the target false-alarm and misdetection probabilities, and we choose $\bar{a}$ to be $-\bar{b}$. In all test examples, the channel gains $|h|$ are equal to one, and primary signals are constant-modulus quadrature phase shift-keying (QPSK) signals except for Test Example 2, in which the modulation formats of the primary signals are explicitly stated. Following conventional terminology in the sequential detection, we define the efficiency of SSCT as $\mathscr{E}_{\text{SSCT}} = 1 - \text{ASN}_{\text{SSCT}}/M_{\min}^{ed}$.

Table 1 SCCT versus energy detection

$\mathtt{SNR}_m$ (dB)	0	−5	−10	−15
$\bar{\gamma}$	−8.5	−5.69	−4	−1.897
$\bar{b}$	27	35.32	69.30	158.47

β_{ssct} (Monte Carlo)	0.008	0.046	0.099	0.154
β_{ssct} (Numerical)	0.008	0.047	0.100	0.156
β_{ed} (Energy detect.)	0.008	0.046	0.096	0.149
ASN (Monte Carlo)	26	95	509	3154
ASN (Numerical)	26	96	515	3185
M (Energy detect.)	40	140	730	4450
Efficiency η	35%	32%	30%	29%

Test Example 1: Table 1 lists false-alarm and misdetection probabilities and ASN for different $\mathtt{SNR}_m$ for both SSCT and energy detection. For $\mathtt{SNR}_m = 0, -5, -10$, and -15 dB, we select the corresponding truncation sizes to be the minimum sample sizes required by energy detection to achieve $(\bar{\alpha}_{\text{ed}}, \bar{\beta}_{\text{ed}}) = (0.01, 0.01), (0.05, 0.05)$, $(0.1, 0.1)$, and $(0.15, 0.15)$, respectively. The parameters $\bar{b}$, $\bar{\Delta}$, and $\bar{\gamma}$ are given in the table. Table 1 shows that while maintaining a comparable detection performance, SSCT is capable of achieving about $29\% \sim 35\%$ savings in terms of the average sensing time as compared with energy detection. We use an abbreviation, numerical, in the parenthesis, to indicate the results obtained by either the exact formula (18) for false-alarm probabilities or by the numerical integration algorithm for misdetection probabilities. As can be seen from the table, the results obtained by the numerical approach and those obtained by the Monte Carlo simulation are fairly close.

Test Example 2: In this example, we assume that primary signals are square 64-quadrature amplitude modulation (QAM) signals with $\sigma_s^2 = 10^{\mathtt{SNR}_m/10}\sigma_w^2$. Table 2 lists misdetection probabilities and ASN for SSCT and energy detection when $\mathtt{SNR}_m = 0, -5, -10$, and -15 dB. To demonstrate the fact that SSCT does not rely on the knowledge of the modulation format of primary signals, we determine the parameters $\bar{a}$, $\bar{b}$, $\bar{\gamma}$, $\bar{\Delta}$, and M in SSCT, by applying QPSK signals with average symbol energy $\sigma_s^2 = 10^{\mathtt{SNR}_m/10}\sigma_w^2$ while we apply these design parameters determined by QPSK primary signals to detect the i.i.d. 64-QAM signal samples, which are drawn from 64-QAM constellation points with equal probability. It is evident from the table that the misdetection probabilities obtained in the 64-QAM case and the QPSK case match well except for the case of $\mathtt{SNR}_m = 0$ dB (correspondingly, $M = 40$). This is because M is not large enough to neglect errors caused by using the CLT approximation. However, the energy detection and SSCT sensing algorithms have a similar amount of approximation error in terms of the misdetection probability.

Table 2 Detection performance without knowing modulation types of the primary signals

$\mathtt{SNR}_m$ (dB)	0	−5	−10	−15

M (Energy detect.)	4450	4450	4450	4450
$\mathscr{E}_{ssct}$	46%	40%	34%	29%

Test Example 3: In this example, we study the detection performance of SSCT and the energy detection when there is a mismatch between $\mathtt{SNR}_o$ and $\mathtt{SNR}_m$. For $\mathtt{SNR}_o = -12, -13, -14$ dB, and $\mathtt{SNR}_m = -15$ dB, the false-alarm and misdetection probabilities and ASN are listed in Table 3. We choose the parameters for SSCT and energy detection such that target false-alarm and misdetection probabilities are around $(0.15, 0.15)$ at $\mathtt{SNR}_m = -15$ dB. As can be seen from the table, for both SSCT and energy detection, the misdetection probabilities decrease as $\mathtt{SNR}_o$ increases, while the false-alarm probabilities keep the same. It is clear from the table that the false-alarm and misdetection $(\alpha_{\text{ssct}}, \beta_{\text{ssct}})$ satisfy the target detection error probability requirements. As the mismatch between $\mathtt{SNR}_o$ and $\mathtt{SNR}_m$ increases, the efficiency of SSCT increases from 29% to 46%. This implies that compared with the energy detection, SSCT offers an additional flexibility in striking a desirable sensing time and detection performance trade-off in the SNR mismatch case.

Quickest Spectrum Scanning

In this section, we consider the problem of how to determine the availability of each spectrum band in a multiband primary system with small delay and small error probabilities using a single or few sensors. With one or a small number of

sensors, secondary users (SUs) are able to observe one band or a small subset of candidate bands at a time. Two scenarios of practical interests are investigated. In the first scenario, there is a strict delay constraint on the spectrum scanning. That is, the spectrum scanning needs to be complete within a certain time period. In the second scenario, there is no strict time constraint for the scanning. That is, the spectrum scanning continues until the completion of the entire detection process. In both scenarios, our goal is to design spectrum scanning schemes that minimize a cost function that strikes a balance between error probabilities and detection delay.

System Model and Problem Formulation

In the system considered, the SU can make simultaneous observations on a subset of M spectrum bands from the set $\mathscr{K}$, which consists of all K candidate spectrum bands. Let $r_i^{(k)}$ denote the signal sample received by the SU, at time i from band k. Compared with section "Sequential Detection for Single Channel," we have multiple channels in this section, and hence we additionally use (k) to denote the channel index. If there is no primary transmission over band k at time i, then the received signal sample $r_i^{(k)}$ can be written as $r_i^{(k)} = w_i^{(k)}$, in which $w_i^{(k)}$ is the background noise, whereas, if there is a primary transmission over band k at time i, then $r_i^{(k)}$ can be written as $r_i^{(k)} = h^{(k)} s_i^{(k)} + w_i^{(k)}$, in which $h^{(k)} s_i^{(k)}$ is the primary signal sample. Mathematically, the detection of the primary signals at the kth band can be formulated as a binary hypothesis testing problem as follows:

$$\begin{aligned} H_0^{(k)} &: r_i^{(k)} = w_i^{(k)}, \quad i = 1, 2, \cdots, \\ H_1^{(k)} &: r_i^{(k)} = h^{(k)} s_i^{(k)} + w_i^{(k)}, \quad i = 1, 2, \cdots \end{aligned} \tag{29}$$

where $H_0^{(k)}$ refers to the hypothesis that channel k is free and $H_1^{(k)}$ refers to the hypothesis that channel k is occupied. We use $q_0^{(k)}(\cdot)$ to denote the density function of the signal received at the k^{th} band when there is only noise and use $q_1^{(k)}(\cdot)$ to denote the density function of the signal received at the k^{th} band when there is primary signal. The algorithms developed in this chapter work for any form of density functions $q_0^{(k)}(\cdot)$ and $q_1^{(k)}(\cdot)$. Furthermore, for generality, we allow the density functions to be different for different k.

Let $\pi_0^{(k)}$ denote the a priori probability that band k is occupied by the primary user (PU). Generally speaking, the values of $\pi_0^{(k)}$ can be different for different bands. We further assume that the status (occupied/unoccupied) of each band is independent of the status of other bands and the channel status remains unchanged during the scanning process. Our goal is to design an algorithm to decide the presence/absence of the PU on each band in a way that minimizes an appropriate measure, which takes into account detection error probabilities and the sampling

cost. We consider a sequential testing setup in which the SU needs to detect the status of all K candidate spectrum bands. At each time i, the SU tunes to a subset of bands $\mathscr{M}$ from the set $\mathscr{K}$ to make an observation, the set $\mathscr{M}$ has a size of M that represents the number of simultaneous observations. After taking one observation each from these M bands, the detector needs to decide whether to terminate the scanning or to continue. Let τ denote the *termination rule* that SU uses to decide whether or not to terminate the scanning. If SU terminates the scanning at time i, then it determines the occupancy of all bands using a *terminal decision rule* $\boldsymbol{\delta}_i = (\delta_i^{(1)}, \cdots, \delta_i^{(K)})$, in which $\delta_i^{(k)}$ takes values in $\{0, 1\}$ with 0 indicating that band k is free and 1 indicating that band k is occupied. Let $\boldsymbol{\delta} = \{\boldsymbol{\delta}_i,\ i = 1, 2, \cdots\}$ denote the sequence of decision rules used at the SU. If SU chooses to continue scanning, then it uses the *band selection function* ϕ_i to select M bands from the set $\mathscr{K}$ and makes another observation from the selected band. We use $\boldsymbol{\phi} = \{\phi_i,\ i = 1, 2, \ldots, \}$ to denote the sequence of band selection functions. At the end of the scanning process, there are two types of error probabilities for band k. The first one is the false-alarm probability $P_{FA}^{(k)}$ that is the probability of declaring hypothesis $H_1^{(k)}$ is true, while hypothesis $H_0^{(k)}$ is true, and the second one is the misdetection probability $P_{MD}^{(k)}$ that is the probability of declaring hypothesis $H_0^{(k)}$ to be true while hypothesis $H_1^{(k)}$ is true.

Intuitively speaking, the lower $P_{FA}^{(k)}$ is, the higher number of spectrum bands are successfully identified as free and hence more secondary transmission opportunities can be exploited. Whereas the lower $P_{MD}^{(k)}$ is, the lower the probability that the SU interferes with primary transmissions. Both types of error probabilities can be made arbitrarily small by letting the number of samples go to infinity. However, this will incur significant delay to reach a decision. Therefore, an appropriate cost function needs to strike a desirable trade-off between the decision delay and the detection error probabilities. In this chapter, we aim to determine the *termination rule* τ, the *terminal decision rules* $\boldsymbol{\delta}$ and the *band selection rules* $\boldsymbol{\phi}$ that minimize the cost

$$\inf_{\tau, \boldsymbol{\delta}, \boldsymbol{\phi}} \left[c\mathbb{E}\{\tau\} + \sum_{k=1}^{K} \left(c_0^{(k)} (1 - \pi_0^{(k)}) P_{FA}^{(k)} + c_1^{(k)} \pi_0^{(k)} P_{MD}^{(k)} \right) \right], \tag{30}$$

where $\mathbb{E}$ is expectation under the probability measure $\boldsymbol{q}_\pi = [q^{(1)}, q^{(2)}, \ldots, q^{(K)}]$ with $q^{(k)} := (1 - \pi_0^{(k)}) q_0^{(k)} + \pi_0^{(k)} q_1^{(k)}$. The parameter c denotes the cost of unit delay, and hence the term $c\mathbb{E}\{\tau\}$ in the cost function represents the average cost of scanning delay. Similarly, $c_0^{(k)}$ denotes the cost of a false-alarm event happening over band k, and $c_1^{(k)}$ denotes the cost of a misdetection event happening over band k. For generality, we allow $c_0^{(k)}$ and $c_1^{(k)}$ to be different for different bands. Clearly, the term $(1 - \pi_0^{(k)}) c_0^{(k)} P_{FA}^{(k)} + \pi_0^{(k)} c_1^{(k)} P_{MD}^{(k)}$ is the average cost of detection errors over band k. Hence, the cost function specified in (30) takes into consideration detection error probabilities and sampling cost, which are two key parameters closely related to the throughput of the SU systems.

Two different scenarios will be considered. In the first scenario, the SU needs to stop the scanning by time T. That is, the stopping time τ is restricted to a finite interval $[0, T]$, called the delay-constrained scenario. This models the situation in which there is a strict delay constraint. In the second scenario, there is no delay constraint on the scanning time, called the non-delay-constrained scenario. Relying on results from optimal stopping theory, we obtain optimal solutions for both scenarios.

The Single Observation Case

In this section, we develop scanning algorithms that solve (30) for both delay-constrained and non-delay-constrained scenarios when $M = 1$, i.e., the single observation case. Hence, at time i, the detector will use the band selection rule ϕ_i to select which band to perform sensing. The results for this special case provide insights for the solution of the general case.

Let $\pi_i^{(k)}$ denote the posterior probability that band k is occupied after collecting observations up to time i. We define $\boldsymbol{\pi}_i := (\pi_i^{(1)}, \cdots, \pi_i^{(K)})$. If $\phi_i = k$, then the SU selects band k to sense at time i. Via Bayesian rule, we can update the posterior probability of band k being occupied after collecting an observation $r_i^{(k)}$ using the following equation

$$\pi_i^{(k)} = \frac{\pi_{i-1}^{(k)} q_1^{(k)}(r_i^{(k)})}{\pi_{i-1}^{(k)} q_1^{(k)}(r_i^{(k)}) + (1 - \pi_{i-1}^{(k)}) q_0^{(k)}(r_i^{(k)})}, \tag{31}$$

where the sequence $\pi_i^{(k)}$ is evaluated recursively as in [35]. For band k that is not selected at time i, the posterior probability $\pi_i^{(k)}$ is not updated, i.e., $\pi_i^{(k)} = \pi_{i-1}^{(k)}$.

At this point, it is not clear whether or not $\boldsymbol{\pi}_i$ is a sufficient statistic for the optimization problem (30). If $\boldsymbol{\pi}_i$ is a sufficient statistic, then at time i, we can make our termination rule τ, terminal decision rule $\boldsymbol{\delta}$ and band selection rule $\boldsymbol{\phi}$ solely based on $\boldsymbol{\pi}_i$. This will greatly simplify our problem. We will show below that $\boldsymbol{\pi}_i$ is indeed a sufficient statistic for the problem under study.

We first study the optimal terminal decision rule $\boldsymbol{\delta}$. For any given termination rule τ and band selection rules $\boldsymbol{\phi}$, following a standard argument in [40], it is easy to show that the following simple terminal decision rule is optimal:

$$\delta_\tau^{(k)} = \begin{cases} 1, & \text{if } \ c_1^{(k)} \pi_\tau^{(k)} \geq c_0^{(k)} (1 - \pi_\tau^{(k)}), \\ 0, & \text{if } \ c_1^{(k)} \pi_\tau^{(k)} < c_0^{(k)} (1 - \pi_\tau^{(k)}), \end{cases} \tag{32}$$

for any $k \in \{1, \ldots, K\}$. The interpretation of this decision rule is clear. More specifically, $c_1^{(k)} \pi_\tau^{(k)}$ is the average cost of making a misdetection error. That is, we declare band k to be free while band k is busy. Similarly $c_0^{(k)}(1 - \pi_\tau^{(k)})$ is the average cost of making a false-alarm error, that is we declare band k to be busy while

band k is free. Thus, we declare that band k is occupied if the cost of a misdetection event is larger than that of a false-alarm event and vice visa. This result suggests that the terminal decisions can be made only based on $\boldsymbol{\pi}_i$. With these terminal decision rules, the objective function in (30) is then converted into

$$\inf_{\tau,\boldsymbol{\phi}} \mathbb{E}\left[c\tau + \sum_{k=1}^{K} \min\left\{ c_0^{(k)}(1-\pi_\tau^{(k)}), c_1^{(k)}\pi_\tau^{(k)} \right\} \right]. \tag{33}$$

We will use results from optimal stopping theory [35] to solve this problem.

The Delay-Constrained Scenario

We first consider the scenario in which we have strict delay constraint T, i.e., we need to finish the scanning by time T. At each time instant i, the SU needs to decide whether or not to terminate the scanning based on the observations that have been collected so far. Let $\mathscr{F}_i$ denote the set of observations till time i, and let $\tilde{J}_{i,T}(\mathscr{F}_i)$ denote the minimal expected cost-to-go function at time i. This is the minimal value of the expected additional cost that will incur by any strategy between time i and T. Note that $\tilde{J}_{i,T}(\mathscr{F}_i)$ is a function of $\mathscr{F}_i$, i and T. At this stage, it is not clear what the optimal strategy between time i and T is, and it is also not clear what the form of the function $\tilde{J}_{i,T}(\mathscr{F}_i)$ is. In the following, we will obtain the form of this function recursively using dynamic programming and then obtain the optimal solution based on this function.

At first, it is clear that $\tilde{J}_{T,T} = \sum_{k=1}^{K} \min\left\{ c_0^{(k)}(1-\pi_T^{(k)}), c_1^{(k)}\pi_T^{(k)} \right\}$, since we have to stop at time T. Given $\tilde{J}_{i+1,T}(\mathscr{F}_{i+1})$, we have the following equation:

$$\tilde{J}_{i,T}(\mathscr{F}_i) = \min\left\{ \sum_{k=1}^{K} \min\left\{ c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)} \right\}, c + \inf_{\phi_i} \mathbb{E}\left\{ \tilde{J}_{i+1,T}(\mathscr{F}_{i+1}) | \mathscr{F}_i, \phi_i \right\} \right\}.$$

In this equation, the term $\sum_{k=1}^{K} \min\left\{ c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)} \right\}$ is the additional cost that will incur if the SU decides to stop scanning at time i. The term

$$c + \inf_{\phi_i} \mathbb{E}\left\{ \tilde{J}_{i+1,T}(\mathscr{F}_{i+1}) | \mathscr{F}_i, \phi_i \right\}$$

is the minimal expected additional cost that will incur if the SU does not stop at time i. Note that the term $\mathbb{E}\left\{ \tilde{J}_{i+1,T}(\mathscr{F}_{i+1}) | \mathscr{F}_i, \phi_i \right\}$ depends on $\mathscr{F}_i$, the observation up to time i and ϕ_i, the band selection rule. Hence, $\tilde{J}_{i,T}(\mathscr{F}_i)$ also depends on the entire observation up to time i, namely, $\mathscr{F}_i$. The following lemma shows that one can greatly simplify the form of these functions.

Lemma 4. *For each i, the minimal expected cost-to-go function $\tilde{J}_{i,T}(\mathscr{F}_i)$ can be written as a function of $\boldsymbol{\pi}_i$, say, $J_{i,T}(\boldsymbol{\pi}_i)$ and the optimal band selection function ϕ_i depends only on $\boldsymbol{\pi}_i$.*

Proof. We will prove the lemma by induction. Clearly,

$$\tilde{J}_{T,T}(\mathscr{F}_T) = \sum_{k=1}^{K} \min\left\{c_0^{(k)}(1-\pi_T^{(k)}), c_1^{(k)}\pi_T^{(k)}\right\} \tag{34}$$

is a function of $\boldsymbol{\pi}_T$ only. Let $J_{T,T}(\boldsymbol{\pi}_T)$ denote this function.

Suppose that $\tilde{J}_{i+1,T}(\mathscr{F}_{i+1})$ depends on $\boldsymbol{\pi}_{i+1}$ only. Let us use $J_{i+1,T}(\boldsymbol{\pi}_{i+1})$ to denote it. We now show that $\tilde{J}_{i,T}(\mathscr{F}_i)$ depends on $\boldsymbol{\pi}_i$ only. First, we have

$$\begin{aligned}\tilde{J}_{i,T}(\mathscr{F}_i) &= \min\left\{\sum_{k=1}^{K} \min\left\{c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)}\right\}, c + \inf_{\phi_i} \mathbb{E}\left\{\tilde{J}_{i+1,T}(\mathscr{F}_{i+1})|\mathscr{F}_i, \phi_i\right\}\right\} \\ &= \min\left\{\sum_{k=1}^{K} \min\left\{c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)}\right\}, c + \inf_{\phi_i} \mathbb{E}\left\{J_{i+1,T}(\boldsymbol{\pi}_{i+1})|\mathscr{F}_i, \phi_i\right\}\right\}.\end{aligned}$$

Since ϕ_i admits only K possible values, the term $c + \inf_{\phi_i} \mathbb{E}\left\{J_{i+1,T}(\boldsymbol{\pi}_{i+1})|\mathscr{F}_i, \phi_i\right\}$ can be written as $c + \min_{\phi_i} \mathbb{E}\left\{J_{i+1,T}(\boldsymbol{\pi}_{i+1})|\mathscr{F}_i, \phi_i\right\}$. If $\phi_i = k$, then

$$\begin{aligned}&\mathbb{E}\left\{J_{i+1,T}(\boldsymbol{\pi}_{i+1})|\mathscr{F}_i, \phi_i = k\right\} \\ &\quad= \int J_{i+1,T}\left(\pi_i^{(1)}, \cdots, \frac{\pi_i^{(k)} q_1^{(k)}(y_{i+1}^{(k)})}{\pi_i^{(k)} q_1^{(k)}(y_{i+1}^{(k)}) + (1-\pi_i^{(k)}) q_0^{(k)}(y_{i+1}^{(k)})}, \cdots, \pi_i^{(k)}\right) \\ &\qquad\left[\pi_i^{(k)} q_1^{(k)}(y_{i+1}^{(k)}) + (1-\pi_i^{(k)}) q_0^{(k)}(y_{i+1}^{(k)})\right] dy_{i+1}^{(k)} := A_{i,T}^{(k)}(\boldsymbol{\pi}_i),\end{aligned} \tag{35}$$

since if we select band k, only the posterior probability of band k will be updated. Clearly, this is a function of $\boldsymbol{\pi}_i$, and we will use $A_{i,T}^{(k)}(\boldsymbol{\pi}_i)$ to denote this function.

As a result, we have

$$\begin{aligned}\tilde{J}_{i,T}(\mathscr{F}_i) &= \min\left\{\sum_{k=1}^{K} \min\left\{c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)}\right\}, c + \inf_{\phi_i} \mathbb{E}\left\{\tilde{J}_{i+1}^{T}(\mathscr{F}_{i+1})|\mathscr{F}_i, \phi_i\right\}\right\} \\ &= \min\left\{\sum_{k=1}^{K} \min\left\{c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)}\right\}, c + \min_{k}\left\{A_{i,T}^{(k)}(\boldsymbol{\pi}_i)\right\}\right\},\end{aligned} \tag{36}$$

is a function of $\boldsymbol{\pi}_i$ only, and we will use $J_{i,T}(\boldsymbol{\pi}_i)$ to denote this function.

Now, the optimal band selection function is given by

$$\phi_i = \arg\left\{A_{i,T}^{(k)}(\boldsymbol{\pi}_i)\right\}, \tag{37}$$

which depends on $\boldsymbol{\pi}_i$.

From this result, we know that $\boldsymbol{\pi}_i$ is a sufficient statistic for this problem. Without loss of optimality, we can make our decisions solely based on $\boldsymbol{\pi}_i$. Furthermore, since ϕ_i depends on $\boldsymbol{\pi}_i$ only, we have that $\{\boldsymbol{\pi}_i : i = 0, 1, \cdots\}$ forms a Markov process.

Regarding the functions $J_{i,T}(\boldsymbol{\pi}_i)$ and $A_{i,T}^{(k)}(\boldsymbol{\pi}_i)$, we have the following result. Let $\mathbf{0}$ denote a vector whose entries are all zeros and $\mathbf{1}$ denote a vector whose entries are all ones.

Lemma 5. *The functions $J_{i,T}(\boldsymbol{\pi}_i)$ and $A_{i,T}^{(k)}(\boldsymbol{\pi}_i)$ are non-negative concave functions of $\boldsymbol{\pi}_i$. And $J_{i,T}(\mathbf{0}) = J_{i,T}(\mathbf{1}) = A_{i,T}^{(k)}(\mathbf{0}) = A_{i,T}^{(k)}(\mathbf{1}) = 0$.*

These supporting lemmas show that the finite-horizon version of the optimization problem (33) can be converted to a Markov optimal stopping time problem [35]. Using the results from optimal stopping theory, we know that the optimal termination rule τ has the following form

$$\tau_{\text{opt}} = \inf\left\{ i : \sum_{k=1}^{K} \min\left\{ c_0^{(k)}(1-\pi_i^{(k)}), c_1^{(k)}\pi_i^{(k)} \right\} = c + \min_k \left\{ A_{i,T}^{(k)}(\boldsymbol{\pi}_i) \right\} \right\}. \quad (38)$$

That is, the optimal time to terminate the scanning is the time when the cost that will incur if SU decides to stop scanning is equal to the minimal expected cost that will incur if SU does not stop.

In summary, the optimal scanning algorithm with a deadline T is described as follows:

1. Initialization: Given the maximum sensing time T, density functions $q_0^{(k)}$ and $q_1^{(k)}$, the cost of errors $c_0^{(k)}$ and $c_1^{(k)}$, we use (34), (35), and (36) to recursively compute the functions $J_{i,T}(\boldsymbol{\pi})$ and $A_{i,T}^{(k)}(\boldsymbol{\pi})$.
2. After collecting a sample, we use (31) to update the posterior probability that a selected band is being occupied.
3. Use (37) to select which band to sense if we decide to continuing sensing.
4. Use (38) to decide whether we should terminate scanning or not. If we decide to continue scanning, go back to (2). If we decide to terminate scanning, then we use decision rule (32) to decide the availability of each band.

Remark 1. In the delay-constrained scenario, the optimal algorithm involves recursive computation of $J_{i,T}(\boldsymbol{\pi})$ and $A_{i,T}^{(k)}(\boldsymbol{\pi})$ and frequent updating of the posterior probability $\pi_j^{(k)}$. These steps incur high computational complexity and thus are the major hurdles in the implementation. We will develop several low-complexity algorithms in section "Truncated C-SPRT Schemes" based on insights gained from the non-delay-constrained scenario discussed in section "The Non-delay-Constrained Scenario."

The Non-delay-Constrained Scenario

In this section, we consider the non-delay-constrained scenario. We can obtain the optimal solution for this problem via two approaches. The first one is to let the delay constraint T defined in section "The Delay-Constrained Scenario" go to ∞. For each T, we obtain the optimal solution as outlined in section "The Delay-Constrained Scenario." As T increases, the solution will converge to the optimal solution for the case with no deadline constraint. The convergence is guaranteed by Theorem 3.7 of [35].

Another approach is to exploit the **decoupled** structure of the optimization problem (33). In the following, we will adopt this approach. For any stopping time τ, let $\tau^{(k)}$ be the amount of time we spend on detecting band k. We can express (33) as

$$c\mathbb{E}\left\{\sum_{k=1}^{K}\tau^{(k)}\right\}+\sum_{k=1}^{K}\min\left\{c_0^{(k)}(1-\pi_\tau^{(k)}),c_1^{(k)}\pi_\tau^{(k)}\right\}$$

$$=\sum_{k=1}^{K}\left\{c\mathbb{E}\{\tau^{(k)}\}+\min\left\{c_0^{(k)}(1-\pi_\tau^{(k)}),c_1^{(k)}\pi_\tau^{(k)}\right\}\right\}. \quad (39)$$

As a result, the quantity to be minimized is related to only the total amount of detection time. Particularly, the quantity is irrespective of sensing ordering $\boldsymbol{\phi}$ (band selection rules). Once $\mathbb{E}\{\tau^{(k)}\}+\min\left\{c_0^{(k)}(1-\pi_\tau^{(k)}),c_1^{(k)}\pi_\tau^{(k)}\right\}$ is minimized for each band, the summation is also minimized. One key observation is that these K optimization problems are **independent** of each other. We can minimize each term independently. Note that this is not the case for the scenario considered in section "The Delay-Constrained Scenario." In section "The Delay-Constrained Scenario", we need to stop before time T, and hence we have an additional constraint $\sum_{k=1}^{K}\tau^{(k)}\le T$, which couples these K optimization problems.

For each k, the solution that minimizes $\mathbb{E}\{\tau^{(k)}\}+\min\left\{c_0^{(k)}(1-\pi_\tau^{(k)}),c_1^{(k)}\pi_\tau^{(k)}\right\}$ is the well-known SPRT algorithm [35]. More specifically, for any c, $c_0^{(k)}$, $c_1^{(k)}$, $q_0^{(k)}$ and $q_1^{(k)}$, the solution is parameterized by two parameters $U^{(k)}$ and $L^{(k)}$. The stopping rule of the sequential test at the kth band is

$$\psi_\tau^{(k)}=\begin{cases}0, & \text{if } L^{(k)}<\pi_i^{(k)}<U^{(k)},\\ 1, & \text{otherwise,}\end{cases} \quad (40)$$

and the terminal decision rule in (32) becomes

$$\delta_\tau^{(k)}=\begin{cases}1, & \text{if } \pi_i^{(k)}\ge U^{(k)},\\ 0, & \text{if } \pi_i^{(k)}\le L^{(k)}.\end{cases} \quad (41)$$

The stopping rule in (40) requires the sequential test to continue if the posterior probability lies within the boundaries $U^{(k)}$ and $L^{(k)}$ and to stop sensing otherwise. Once the sequential test is stopped, a decision should be made based on the terminal

decision rule of (41). That is, claiming hypothesis $H_0^{(k)}$ if $\pi_i^{(k)} \leq L^{(k)}$ or claiming hypothesis $H_1^{(k)}$ if $\pi_i^{(k)} \geq U^{(k)}$. In the original Wald's SPRT [41], there is no upper limit on the number of observations required to reach a decision. This may lead to an increase in number of samples in case of ambiguous observations. However, this problem will be treated in section "Truncated C-SPRT Schemes" by truncation as we propose different truncation schemes as an alternative to the optimal multiband delay-constrained scenario.

The optimization problem does not depend on $\boldsymbol{\phi}$, and no delay constraint is imposed on the scanning process. Hence, with no loss of optimality, we can start scanning from band 1; once we finish scanning band 1, we switch to band 2. The entire scanning process is terminated, once we finish scanning band K. In summary, we have the following solution:

1. Initialization: Given density functions $q_0^{(k)}$ and $q_1^{(k)}$, the costs of errors $c_0^{(k)}$ and $c_1^{(k)}$, compute parameters $L^{(k)}$ and $U^{(k)}$.
2. Starting from band 1, after taking each sample from band k, use (31) to update the posterior probability. If $\pi^{(k)} \in (L^{(k)}, U^{(k)})$, stay on band k to collect more samples. If $\pi_k \geq U^{(k)}$, claim that band k is busy, and switch to band $k+1$ to sense. If $\pi^{(k)} \leq L^{(k)}$, claim that band k is free, and switch to band $k+1$ to sense.
3. The scanning is finished, once we finish scanning band K.

Remark 2. It is clear that the optimal algorithm is a concatenation of SPRTs (C-SPRT), which is much simpler as compared with the solution for the delay-constrained scenario.

This algorithm can be further simplified for specific density functions. Here, we give an example for Gaussian random variables. In this example, we assume

$$q_0(r_i^{(k)}) = \frac{1}{\pi[\sigma^{(k)}]^2} \exp\Big(-\frac{|r_i^{(k)}|^2}{[\sigma^{(k)}]^2}\Big), \tag{42}$$

$$\text{and} \quad q_1(r_i^{(k)}) = \frac{1}{\pi(P^{(k)} + [\sigma^{(k)}]^2)} \exp\Big(-\frac{|r_i^{(k)}|^2}{P^{(k)} + [\sigma^{(k)}]^2}\Big). \tag{43}$$

Here, $[\sigma^{(k)}]^2$ is the variance of the Gaussian noise over band k and $P^{(k)}$ is the power of the signal over band k. Let $\mathscr{S}^{(k)}$ denote the set of time slot in which we select band k to sense up to time j. Using Bayes' rule and the fact that the observations are assumed to be independent and identically distributed (i.i.d.) [40], the posterior probability can be written as

$$\pi_i^{(k)} = \frac{\pi_0^{(k)} \prod\limits_{i \in \mathscr{S}^{(k)}} q_1^{(k)}(Y_i^{(k)})}{\pi_0^{(k)} \prod\limits_{i \in \mathscr{S}^{(k)}} q_1^{(k)}(Y_i^{(k)}) + (1-\pi_0^{(k)}) \prod\limits_{i \in \mathscr{S}^{(k)}} q_0^{(k)}(Y_i^{(k)})},$$

hence $\pi_i^{(k)} > U^{(k)}$ and $\pi_i^{(k)} < L^{(k)}$ imply that

$$\frac{\prod_{l\in\mathscr{S}^{(k)}} q_1^{(k)}(Y_l^{(k)})}{\prod_{l\in\mathscr{S}^{(k)}} q_0^{(k)}(Y_l^{(k)})} > \frac{U^{(k)}(1-\pi_0^{(k)})}{\pi_0^{(k)}(1-U^{(k)})} := B_U^{(k)}, \tag{44}$$

$$\text{and} \quad \frac{\prod_{l\in\mathscr{S}^{(k)}} q_1^{(k)}(Y_l^{(k)})}{\prod_{l\in\mathscr{S}^{(k)}} q_0^{(k)}(Y_l^{(k)})} < \frac{L^{(k)}(1-\pi_0^{(k)})}{\pi_0^{(k)}(1-L^{(k)})} := B_L^{(k)},$$

respectively. Let $SNR^{(k)} = P^{(k)}/[\sigma^{(k)}]^2$ denote the signal-to-noise ratio (SNR) at band k. Since $Q_0 \sim \mathscr{CN}(0, [\sigma^{(k)}]^2)$ and $Q_1 \sim \mathscr{CN}(0, P^{(k)} + [\sigma^{(k)}]^2)$, these two equations can be further simplified as

$$\sum_{l\in\mathscr{S}^{(k)}} [Y_l^{(k)}]^2 > d^{(k)} \left(|\mathscr{S}^{(k)}| \log\left(1 + SNR^{(k)}\right) + \log B_U^{(k)} \right), \tag{45}$$

$$\sum_{l\in\mathscr{S}^{(k)}} [Y_l^{(k)}]^2 < d^{(k)} \left(|\mathscr{S}^{(k)}| \log\left(1 + SNR^{(k)}\right) + \log B_L^{(k)} \right), \tag{46}$$

in which $d^{(k)} = [\sigma^{(k)}]^2(SNR^{(k)}+1)/SNR^{(k)}$ and $|\mathscr{S}^{(k)}|$ is the size of the set $\mathscr{S}^{(k)}$.

In general, it is difficult to obtain a closed form expressions for the boundary values $B_U^{(k)}$ and $B_L^{(k)}$ [41]. Since the optimal solution is the concatenated SPRT, we can use the approximation techniques for the SPRT to simplify the computation of $B_L^{(k)}$ and $B_U^{(k)}$. In practice, we will first specify the target error probabilities. That is, $\bar{P}_{FA}^{(k)}$ and $\bar{P}_{MD}^{(k)}$ are given. Then, using Wald's approximation [35,41], we have

$$B_U^{(k)} = (1 - \bar{P}_{MD}^{(k)})/\bar{P}_{FA}^{(k)}, \quad B_L^{(k)} = \bar{P}_{MD}^{(k)}/(1 - \bar{P}_{FA}^{(k)}). \tag{47}$$

The actual false-alarm and misdetection probabilities of SPRT using upper- and lower bounds in (47) are upper bounded by the target $\bar{P}_{FA}^{(k)}$ and $\bar{P}_{MD}^{(k)}$, respectively, and more importantly the actual error probabilities become quite close to the target counterparts when $\bar{P}_{FA}^{(k)}$ and $\bar{P}_{MD}^{(k)}$ are small. In SPRT, the number of observations required to reach a decision is a random number. The average (expected) sample number (ASN) is thus considered as a useful benchmark for SPRT.

We next evaluate ASN of C-SPRT. Let us first consider the kth band. Let $\tau_l^{(k)}$ be the sample number required to reach a decision for the kth band under H_l for $l = 0, 1$. Let us define $Z_i^{(k)} := \log\left[q_1^{(k)}(Y_i^{(k)})/q_0^{(k)}(Y_i^{(k)})\right]$ and $r^{(k)} = 1/(SNR^{(k)}+1)$. We can readily compute $Z_i^{(k)}$ as

$$Z_i^{(k)} = \log r^{(k)} + |Y_i^{(k)}|^2/d^{(k)},$$

By some straightforward computation, we have

$$\mu_0^{(k)} := E[Z_i^{(k)}|H_0] = \log r^{(k)} + 1 - r^{(k)}, \text{ and } \mu_1^{(k)} := E[Z_i^{(k)}|H_1] = \log r^{(k)} + [r^{(k)}]^{-1} - 1.$$

Following from [35], we have

$$E\left[\tau_l^{(k)}|H_l\right] \approx \frac{1}{\mu_l^{(k)}} \frac{B_L^{(k)}[\exp(t_l B_U^{(k)}) - 1] + B_U^{(k)}[1 - \exp(t_l B_L^{(k)})]}{\exp(t_l B_U^{(k)}) - \exp(t_l B_L^{(k)})}, \ l = 0, 1$$

where t_l is a nonzero constant satisfying $E[\exp(t_l Z_i^{(k)})|H_l] = 1$. It can be readily determined that t_0 is equal to 1 while t_1 is equal to -1. Clearly, the overall ASN can be expressed as

$$E(\tau) = \sum_{k=1}^{K} E\left[\tau_l^{(k)}|H_0\right](1 - \pi_0^{(k)}) + E\left[\tau_l^{(k)}|H_1\right]\pi_0^{(k)}. \tag{48}$$

To compare the ASN of C-SPRT with the fixed sample size (FSS) of the energy detector, we compute the minimum FSS required to achieve target $\bar{P}_{FA}^{(k)}$ and $\bar{P}_{MD}^{(k)}$ in the multiband setup for the same density functions above. The test statistic in this case is the energy of the received signal compared to a threshold [42]. By simple manipulations, the FSS can be expressed as

$$FSS = \sum_{k=1}^{K} \left(\frac{1}{SNR^{(k)}} \left[Q^{-1}(\bar{P}_{FA}^{(k)}) - (SNR^{(k)} + 1) Q^{-1}(1 - \bar{P}_{MD}^{(k)}) \right] \right)^2. \tag{49}$$

In summary, we have the following simplified scanning scheme:

1. Given target error probabilities $\bar{P}_{MD}^{(k)}$ and $\bar{P}_{FA}^{(k)}$, we use (47) to compute $B_L^{(k)}$ and $B_U^{(k)}$.
2. After taking a sample $Y_i^{(k)}$ from band k, we use (45) and (46) to decide whether we should skip to the next band or not. If (45) is satisfied, claim that band k is busy and skip to the next band. If (46) is satisfied, then we declare that band k is free and skip to the next band. If neither of these two is satisfied, stay on band k to observe more samples.

Truncated C-SPRT Schemes

As mentioned above, the complexity of the optimal solution for the delay-constrained scenario is very high. Inspired by the solution for the scenario with no delay constraint, we propose several truncated C-SPRT that can be used for the delay-constrained scenario. In the truncated C-SPRT, SPRT will be run on

each band. However, a deadline will be imposed on each band. If SPRT does not finish before the deadline is reached, then it will be forced to finish, and a decision will be made using the information gathered at that time. In the following, we consider several truncation methods, namely, uniform truncation, tail truncation, uniformly added truncation, and sequentially added truncation. All these truncated algorithms are asymptotically optimal as the delay constraint is relaxed. In these truncation schemes, we adopt a simple scanning order (from channel 1 to channel K), which is not necessarily optimal. One can find the optimal scanning order following the steps in [43]. However, the complexity of the algorithm for finding the optimal scanning order is very high. Since our goal is to find a low complexity but asymptotically optimal schemes, we opt to use this simple scanning order.

Uniform Truncation

In the uniform truncation, we need to finish detecting each band within a period of time T/K as illustrated in Fig. 3. That is, the maximal detection time is equal for all bands. In particular, the saved time for detecting a band will not be reallocated for detecting other bands. As it can be seen from the above description, the advantage of uniform truncation is that it can always guarantee no random decision will take place in the detection process, but the disadvantage of the method is that it does not utilize the saved time from the bands that can be quickly detected.

Tail Truncation

In the tail truncation, we need to finish the detection process within a period of time T. It implies that detection time is distributed unevenly among K bands. To be specific, the maximum detection time for the kth band is $T - \sum_{l=1}^{k-1} \tau^{(l)}$ as shown in Fig. 4. Intuitively, if T is sufficiently large, then C-SPRT with tail truncation will be able to scan all the bands, thus being able to achieve a probability similar to one achieved by the non-truncated C-SPRT. If T is quite small, then it is highly likely that C-SPRT with tail truncation will not have time to finish detecting

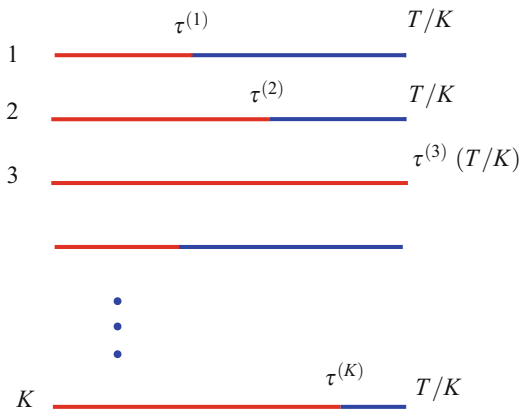

Fig. 3 An illustration of C-SPRT with the uniform truncation

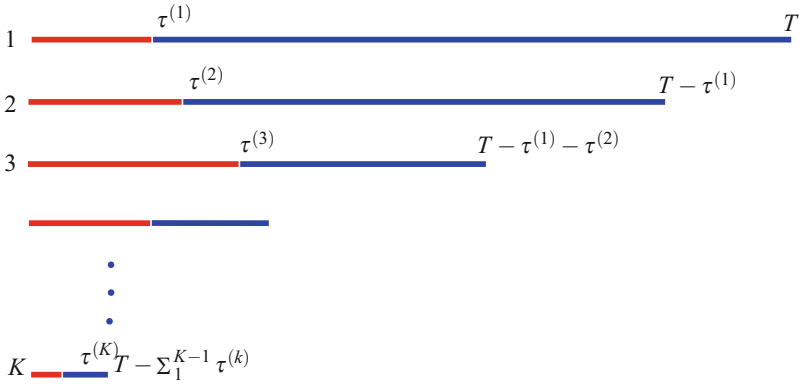

Fig. 4 An illustration of C-SPRT with the tail truncation

all K bands. In such a case, we assume that a random decision (like tossing a coin) will be made for undetected bands, thus incurring high detection errors. This is the major disadvantage of C-SPRT with tail truncation.

Uniformly Added Truncation

To overcome potential drawbacks of the uniform truncation and the tail truncation, we next present the uniformly added truncation. As shown in Fig. 5, we initially set the maximal detection time to be T. During the detection process, we will use the detection time saved in any detection stage to extend the maximal detection time for a later detection stage in a uniform manner. That is, the saved detection time will be added to the maximum detection time of the undetected bands equally. The maximum detection time for the kth band is $T/K + \Delta^{(k-1)}$, where $\Delta^{(k)}$ can be recursively computed as

$$\Delta^{(0)} = 0, \text{ and } \Delta^{(k)} = \Delta^{(k-1)} + \left\lceil \frac{T/K + \Delta^{(k-1)} - \tau^{(k)}}{K-k} \right\rceil^{+}, \ k = 1, \ldots, K-1,$$

where $\lceil x \rceil^{+}$ denotes $\max\{0, x\}$. As an example, if $K = 16$, $T = 1600$ and $\tau^{(1)} = 10$, then after detecting the first band, we save 90 sample periods and will use it to equally extend the maximum detection time for the rest 15 bands. Thus, the maximum detection time for the rest bands now is 106 sample periods. By doing so, uniformly added truncation can guarantee that no random detection will take place and the detector can fully utilize available detection time.

Sequentially Added Truncation

In the uniformly added truncation, the saved detection time will be added to the maximum detection time of the undetected bands in a uniform manner. Apparently,

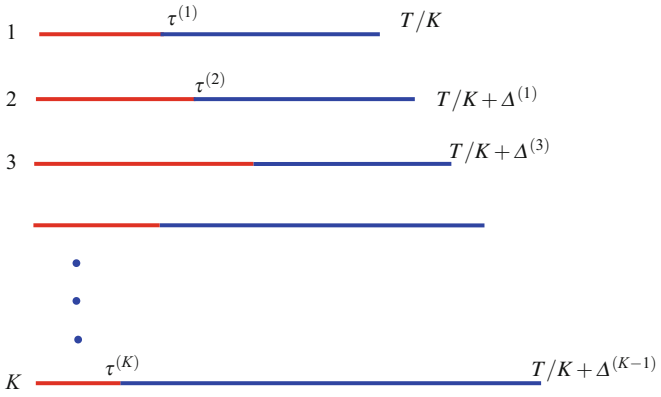

Fig. 5 An illustration of C-SPRT with the uniformly added truncation

when T is small, it may lead to too much truncation in an early detection stage. To amend this deficiency, we next propose an alternative truncation method, called the sequential added truncation. The method is the same as the uniformly add truncation except that the saved time on detecting the current band will be used to extend only the maximum detection time of the next band. The maximum detection time of the kth band can be written as $T/K + \delta^{(k-1)}$, where $\delta^{(0)} = 0$ and $\delta^{(k)} = \delta^{(k-1)} + \lceil T/K - \tau^{(k)} \rceil^+$.

Numerical Examples

In this section, we provide several numerical examples to illustrate the effectiveness of the algorithms developed in this chapter. In all the examples, we assume that $\pi_0^{(k)}$ for $k = 1, \ldots, K$ is equal to $1/2$ unless indicated otherwise, and the results are obtained by using Monte Carlo simulations. Furthermore, we assume that both noise and signal are complex Gaussian.

Table 4 compares C-SPRT in terms of false-alarm and misdetection probabilities and ASN for different SNR for $K = 4, 16, 64$ for the single observation case. In this table, we use P_{FA} and P_{MD} to denote average false-alarm and misdetection probabilities. That is, $P_{FA} = \sum_{k=1}^{K} P_{FA}^{(k)}/K$ and $P_{MD} = \sum_{k=1}^{K} P_{MD}^{(k)}/K$. As can be observed from the table, ASN increases linearly as K increases. ASN obtained by Monte Carlo simulation is quite close to one obtained by using an approximation in (48). Table 4 also compares C-SPRT and energy detection in terms of the number of samples required to achieve the same false-alarm and misdetection probabilities. As can be seen from the table, C-SPRT requires much less ASN than energy detection in the cases of $(P_{FA}, P_{MD}) = (0.1, 0.1)$ and $(P_{FA}, P_{MD}) = (0.01, 0.01)$. Furthermore, it can be observed from the table that as compared to energy detection, the lower the target error probabilities are, the higher the ASN savings can be achieved for C-SPRT.

Table 4 Detection performance of C-SPRT for $K = 4, 16, 64$

SNR (dB)	0	−5	−10
P_{FA} ($K = 4$, Monte Carlo)	0.005	0.04	0.09
P_{FA} ($K = 16$, Monte Carlo)	0.005	0.04	0.09
P_{FA} ($K = 64$, Monte Carlo)	0.005	0.04	0.09
P_{MD} ($K = 4$, Monte Carlo)	0.008	0.05	0.1
P_{MD} ($K = 16$, Monte Carlo)	0.008	0.05	0.1
P_{MD} ($K = 64$, Monte Carlo)	0.008	0.05	0.1
ASN ($K = 4$, Monte Carlo)	85	305	1615
ASN ($K = 16$, Monte Carlo)	342	1222	6468
ASN ($K = 64$, Monte Carlo)	1368	4888	25,875
ASN ($K = 4$, Numerical)	76	281	1548
ASN ($K = 16$, Numerical)	304	1126	6194
ASN ($K = 64$, Numerical)	1216	4502	24,775
ASN ($K = 16$, $P_{FA} = P_{MD} = 0.1$)	161	844	6468
FSS ($K = 16$, $P_{FA} = P_{MD} = 0.1$)	240	1424	11,600
ASN ($K = 16$, $P_{FA} = P_{MD} = 0.01$)	342	1990	16,138
FSS ($K = 16$, $P_{FA} = P_{MD} = 0.01$)	784	4656	38,192

In this example, we compare four truncation methods in terms of the false-alarm probability, the misdetection probability for different cases of SNR, the number of bands, and truncation time for the single observation case. The results of the error probabilities for three different parameter configuration cases are shown in Table 5.

Figure 6 shows ASN versus SNR for the first case. Comparing the results of P_{FA} and P_{MD} in this case (i.e., $K = 16$, $T = 3560$) and ASN in Fig. 6 yields to a conclusion that when the delay constraint is strict, all truncations suffers from large error when SNR is small while the non-truncated C-SPRT suffers from large ASN to scan all the available bands when SNR is small. The tail truncation approach suffers a large number of random decision errors and requires the largest ASN among these truncation methods to achieve similar detection performance. The overall performance shows that among the four truncation methods, the sequentially added truncation method yields the most desirable trade-off between the detection performance and the detection delay. This is because the sequentially added truncation method avoids random detection and fully utilizes available detection time. In the second case, both the number of bands K and the allowed time T are increased by a factor of 4. From Table 5, it is clear that the performance is very similar to the first case. The results in the third case shows that the average number of errors decreases considerably when the allowable delay T is increased while K is fixed. The truncated schemes perform similarly to non-truncated C-SPRT when SNR increases.

Table 5 Detection performance of C-SPRT for different values of SNR

		SNR = −15 dB		SNR = −10 dB		SNR = −5 dB	
Case 1: $K = 16, T = 3560$	Methods	P_{FA}	P_{MD}	P_{FA}	P_{MD}	P_{FA}	P_{MD}
	No truncation	0.1014	0.1051	0.0917	0.0933	0.0773	0.0875

Conclusion

In this chapter, we have reviewed sequential spectrum sensing algorithms for CR systems. Compared with block-based sensing algorithms, sequential sensing algorithms enable us to make detection decision with minimum delay while still providing certain performance guarantee. We have illustrated the benefits of sequential detection for a single-band system. We have also discussed how to design quickest sequential scanning algoithms for multiband systems to quickly identify free channels. These algorithms enable us to deal with scenarios where SUs do not have complete or even partial knowledge about primary signals. They also enable us to achieve a small detection delay even under a fairly low detection SNR level with low detection error probabilities.

Abstract

The first and foremost function in cognitive radio is spectrum sensing. To overcome the performance bottleneck created by fading and shadowing effects of the wireless channel, cooperation among sensing users is proposed as a promising solution. However, most designs of cooperative sensing strategies are developed in a rather ad hoc manner due to the lack of the fundamental knowledge on the cooperation gain. Hence, in this chapter, the cooperation gain in the context of cooperative spectrum sensing is rigorously quantified via diversity and error exponent analyses. The fundamental limits of the diversity and error exponent are derived as functions of key system parameters. After that, a couple of case studies are presented to illustrate how the concepts of diversity and error exponent can guide practical designs of cooperative spectrum sensing.

Introduction

In cognitive radio systems, the unlicensed wireless users (a.k.a. secondary users) take chances to access the spectrum (temporarily or spatially) released by the licensed users (a.k.a. primary users) so that the spectrum access is dynamic and somewhat opportunistic [27]. To realize this, the first step is to find such opportunities in the primary users' spectrum usage; this is spectrum sensing.

Among existing work on spectrum sensing, some focus on algorithms to improve a single-user's sensing performance by utilizing some side information (see, e.g., [2, 13]). Nonetheless, single-user spectrum sensing is still the system performance bottleneck due to fading and shadowing effects of the wireless channel, as well as the noise uncertainty of the device [22]. To this end, cooperative spectrum sensing by multiple secondary users can significantly improve the sensing performance. Hence, this has become the focus of most ongoing research (see, e.g., [10, 12, 13, 20, 26]).

At the center of all these research reside the rules by which the cooperating sensing users and the fusion center act and interact. These rules determine how each sensing user processes the local sensing data, what information the sensing users will forward to the fusion center, and how the fusion center makes a decision on the spectrum sensing. However, most existing designs of such rules are developed in a rather ad hoc manner due to the lack of the fundamental knowledge on the cooperation gain. In fact, though the benefit of cooperative sensing as

opposed to an individual user sensing has been recognized in various scenarios, the fundamental cooperation gain has never been rigorously defined, proved, or quantified.

Hence, the rigorous quantification of the cooperation gain in the context of cooperative spectrum sensing has both scientific and practical promises: in addition to furthering the fundamental understanding of this very problem, it can also provide the necessary knowledge to guide systematic design of the rules governing the sensing user interactions. In this chapter, we discuss the fundamental limits and practical designs of cooperative spectrum sensing in the following two aspects: (i) cooperative spectrum sensing performance scaling with signal parameters: we will quantify the cooperation gain using the notion of "diversity," which characterizes how the cooperative spectrum sensing performance scales with the signal parameter when the number of cooperative sensing users is fixed (section "Performance Scaling with SNR: Cooperative Diversity"); (ii) cooperative spectrum sensing performance scaling with the number of cooperative sensing users: we will extract this scaling factor in the form of the error exponent based on large deviation analysis. We will first determine the exact scaling factor. Due to the interweaved nature of this scaling factor and the optimum local and fusion rules, we show that the local rules that are globally optimum can be obtained (section "Performance Scaling with the Number of Sensing Users: Error Exponent"). Based on the discussions on the fundamental limits in these two aspects, a couple of practical design issues will be investigated in section "Practical Designs: Case Studies". Specifically, in section "Sensing with Ternary Local Decisions: A Design from the Diversity Perspective", diversity is used as a guideline to design a simple but effective fusion rule for sensing fusion with local ternary decisions, and in section "Sensing with Joint Diversity and Error Exponent Considerations", a joint analysis of diversity and error exponent is used to derive a closed-form local threshold for cooperative spectrum sensing to achieve both the maximum diversity and error exponent.

Notation: Subscripts "f," "md," "d," and 'e' refer to false alarm, missed detection, detection, and average error, respectively. $x \sim \mathcal{CN}(\mu, \sigma^2)$ denotes a proper complex Gaussian random variable x with mean μ and variance σ^2; $b \sim \text{Ber}(p_0)$ denotes a Bernoulli random variable b with $p_0 = Pr[b = 0]$; $X \sim \text{Bin}(N, p)$ denotes a binomial random variable; $u \sim \mathcal{U}(a, b)$ denotes a real random variable u uniformly distributed over interval $[a, b]$. $f(\gamma) \sim g(\gamma)$ denotes two functions of γ with $\lim_{\gamma\to+\infty} \frac{f(\gamma)}{g(\gamma)} = k$, where k is a nonzero constant; $g(\gamma) \approx f(\gamma)$ means $\lim_{\gamma\to+\infty} \frac{g(\gamma)}{f(\gamma)} = 1$. Throughout this chapter, $D_{\text{KL}}(p||q)$ denotes the Kullback-Leibler distance between Bernouilli distributions, $\text{Ber}(p)$ and $\text{Ber}(q)$. That is,

$$D_{\text{KL}}(p||q) = E_p \log\left(\frac{\text{Ber}(p)}{\text{Ber}(q)}\right) = p \log\left(\frac{p}{q}\right) + (1-p)\log\left(\frac{1-p}{1-q}\right).$$

Performance Scaling with SNR: Cooperative Diversity

While *diversity* has been well acknowledged as the intuitive benefit of cooperative sensing, its rigorous meaning in this setup has remained largely unexplored. In this section, we will determine quantitatively the diversity order in various cooperative spectrum sensing schemes.

Diversity has been widely adopted as a fundamental performance indicator in communication systems, where it is defined and quantified in terms of the signal-to-noise ratio (SNR)-dependent behavior of the bit error rate (BER) for symbol detection [23, Chapter 3] or the probability distribution of the mutual information [23, Chapter 5]. This concept was also extended to the context of cooperative estimation in wireless sensor networks [5]. Therein, diversity refers to the SNR-dependent behavior of the outage probability that the estimation variance exceeds a predefined value. In [18], the missed detection probability is adopted for the determination of diversity in a cooperative detection scenario while keeping the false alarm probability fixed (SNR independent). In [26], the opposite is considered by emphasizing the false alarm probability while fixing the missed detection probability. However, in the spectrum sensing problem, none of these measures can sufficiently and appropriately quantify diversity.

Unlike traditional detection problems where focusing on either the false alarm or missed detection probabilities while fixing the other is a rather common exercise, doing so in a spectrum sensing problem will risk unbalanced treatment between the system *efficiency* and *reliability*. On the one hand, false alarm probability is of critical importance because the whole purpose of cognitive radio is to maximally utilize the spectrum vacancies, while false alarms lead to undetected spectrum holes and can significantly reduce the efficiency of such usage. On the other hand, missed detections lead to deteriorated "cognition" level and give rise to unexpected interference from the secondary users to the primary ones. In short, false alarm and missed detection probabilities, respectively, capture the *efficiency* and *reliability* of the overall cognitive system. Hence, a diversity measure of cooperative sensing performance should fairly account for both probabilities. In this work, we consider the false alarm and missed detection probabilities both individually and jointly in terms of the average error probability, which balances system efficiency and reliability.

The technical contributions of this section are summarized as follows: (i) We derive the optimum detection thresholds by minimizing the average error probability in both noncooperative single-user and cooperative multiuser sensing scenarios. The diversity orders of all three probabilities are then quantified under the optimum thresholds. We also prove that such thresholds lead to the maximum diversity order in both sensing scenarios. (ii) We consider two cooperative strategies, namely, multiuser sensing with soft information fusion and hard/binary information fusion. The former provides a theoretical bound on the diversity orders and error probability performance in an ideal cooperative sensing setup, whereas the latter leads to practical fusion and decision rules together with their respective quantified diversity orders. (iii) We investigate the trade-off between the system efficiency (via false

alarm probability) and reliability (via missed detection probability) and present analytical results to guide practical system designs with differing preferences. (iv) Depending on whether the secondary users have knowledge of the number of cooperative users, we find that the optimal hard fusion rules are, respectively, the majority-fusion rule and the OR-fusion rule. (v) We verify the benefit of cooperative sensing and compare the performances of majority-fusion and OR-fusion rules at low SNR.

Sensing Strategies and Performance Metrics

In the spectrum sensing process, the sensing users observe signals under the following two hypotheses:

H_0 : absence of primary user in the spectrum band of interest,

H_1 : presence of primary user in the spectrum band of interest.

We adopt the signal model in [13], where the channels between the primary and the sensing users are Rayleigh fading with additive white Gaussian noise (AWGN). Then the received signal at the sensing user is given by [13]:

$$\begin{aligned} r|H_0 &= n \sim \mathscr{CN}(0, \sigma_n^2), \\ r|H_1 &= hx + n \sim \mathscr{CN}(0, E_x\sigma_h^2 + \sigma_n^2), \end{aligned}$$

where n is AWGN with variance σ_n^2, h is the channel coefficient with variance σ_h^2, and x is the signal from the primary user with energy E_x. Suppose that the sensing users know the noise variance, hence, without loss of generality, we normalize the noise variance to 1. Accordingly, the signal at the sensing users becomes:

$$\begin{aligned} r|H_0 &= n \sim \mathscr{CN}(0, 1), \\ r|H_1 &= hx + n \sim \mathscr{CN}(0, \gamma + 1), \end{aligned} \tag{1}$$

where $\gamma \triangleq E_x\sigma_h^2/\sigma_n^2$ is the average signal-to-noise ratio (SNR) at the sensing users.

With geographically distributed sensing users, it is reasonable to assume that they experience independent fading channels. Thus, the received signals for different sensing users r_is are conditionally identically independently distributed (i.i.d.) under each hypothesis.

Cooperative spectrum sensing requires cooperation among multiple sensing users. In our analysis, a fusion center collects information from all secondary users and facilitates their cooperation. Ideally, the cooperation benefit is maximized if all sensing information from all secondary users reaches the fusion center without any loss. This condition, however, cannot always be satisfied due to the limited spectrum resource available to the secondary user system. Hence, we will next

consider two types of sensing strategies, namely, cooperative multiuser sensing with soft information fusion and cooperative multiuser sensing with hard/binary information fusion.

Cooperative Sensing with Soft Information Fusion

In this case, the fusion center can obtain information from the distributed secondary users perfectly. This provides a best case scenario for cooperative sensing among multiple secondary users. Although this may not be practically achievable, it does provide a useful bound on the multiuser sensing performance. Moreover, this is also a good model for the case where multiple independent faded copies of the primary user's signal are collected at a single secondary user. For example, multiple receive antennas with appropriate antenna spacing can provide independent faded copies of the signal, or in the case of a fast fading scenario, the signals from different time slots are independently distributed. In these cases, the single secondary user can be regarded as the fusion center and the different sources of independent faded signals can be regarded as the multiple spectrum sensing nodes with lossless transmission to the fusion center, leading to soft information fusion.

Cooperative Sensing with Hard/Binary Information Fusion

In a more practical multiuser setup, each distributed secondary user senses the spectrum usage and then only transmits the one-bit sensing decision, "0" for absence of primary users or "1" for presence of primary users, to the fusion center.

Performance Metric and Diversity Order

In traditional signal detection problems, the receiver operating characteristic (ROC) curves (false alarm probability P_f vs. missed detection probability P_{md}) are generally used to graphically illustrate the detection performance [19]. Every ROC curve is plotted for a certain combination of the system parameters such as SNR, number of cooperative users, and so on. As a result, they do not provide an explicit quantitative relationship between the system parameters and the system metrics (false alarm, missed detection, and average detection error probabilities) [10]. Hence, to better illustrate the effects of the system parameters on the performance, in this chapter, we analyze each single system metric as a function of the system parameter variables.

As aforementioned, the performance of spectrum sensing is indicated by the false alarm probability P_f, the missed detection probability P_{md}, and the average error probability P_e. P_f is the probability of deciding on H_1 when H_0 is true (type I error); P_{md} is the probability of deciding on H_0 when H_1 is true (type II error); P_e is the average probability of making a wrong decision. Physically, P_f determines the capability of detecting the available spectrum resource, and thus the *efficiency* of the system; and P_{md} indicates the level of interference that the secondary user system introduces to the primary user system and thus the *reliability* of the system. As a result, P_e combines the efficiency and reliability considerations. We denote the probability of the absence of the primary user (H_0) as π_0 and thus that of the

presence of the primary user (H_1) as $(1-\pi_0)$, and then the average error probability is $P_e = \pi_0 P_f + (1-\pi_0) P_{md}$.

The concept of diversity was introduced in wireless communications to quantify the effects of independent fading in space, time, frequency, or code space on the improvement of the system performance [23]. Quantitatively, the diversity order is defined as:

$$d = -\lim_{\text{SNR}\to+\infty} \frac{\log P}{\log \text{SNR}}$$

where P can be the bit error rate or the outage probability of the communication system and SNR is the average signal-to-noise ratio. In cooperative sensing, the fusion center also receives multiple copies of the original signal under independent fading. Hence, the sensing performance is expected to exhibit a similar behavior. Here we define the diversity order in sensing scenarios as:

$$d_* = -\lim_{\gamma\to+\infty} \frac{\log P_*}{\log \gamma}$$

where $*$ can be f (false alarm), md (missed detection), or e (average error). Accordingly, there will be false alarm diversity d_f, missed detection diversity d_{md} and average error diversity d_e. Obviously, $d_e = \min\{d_f, d_{md}\}$ when $d_f \neq d_{md}$. In the following, we will quantify the diversity order of spectrum sensing according to the definitions above for three cases: single-user sensing, multiuser cooperative sensing with soft information fusion, and multiuser cooperative sensing with hard/binary information fusion. In addition, we will show that, though the diversity order is defined in the limit when $\gamma \to +\infty$, it actually shows up quite early at low SNR.

Diversity Analysis for Single-User Sensing

To achieve uniformly most powerful detection performance, we use the Neyman-Pearson (NP) detector [19]. With our signal model, the NP test is the likelihood ratio test:

$$\lambda = |r|^2 \underset{H_0}{\overset{H_1}{\gtrless}} \theta \tag{2}$$

where θ is the threshold of the test. According to (1), the distribution of the decision statistic is:

$$\begin{aligned} f(\lambda|H_0) &= e^{-\lambda} \quad (\lambda > 0) \\ f(\lambda|H_1) &= \frac{1}{\gamma+1} e^{-\frac{\lambda}{\gamma+1}} \quad (\lambda > 0). \end{aligned} \tag{3}$$

Hence, the probabilities of false alarm and missed detection are, respectively:

$$P_f = \int_{\theta}^{+\infty} f(\lambda|H_0)d\lambda = \int_{\theta}^{+\infty} e^{-\lambda}d\lambda = e^{-\theta} \tag{4}$$

and

$$P_{md} = \int_{0}^{\theta} f(\lambda|H_1)d\lambda = \int_{0}^{\theta} \frac{1}{\gamma+1} e^{-\frac{\lambda}{\gamma+1}} d\lambda = 1 - e^{-\frac{\theta}{\gamma+1}}. \tag{5}$$

Diversity Order When Minimizing P_e

As shown in (4) and (5), the performance metrics P_f, P_{md}, and P_e all rely on the choice of the decision threshold θ. Clearly, one may choose different thresholds when optimizing different performance metrics. Recall that P_f captures the cognitive system's *efficiency* while P_{md} captures its *reliability*. To balance the system efficiency and reliability, we will optimize the threshold θ by minimizing the average error probability $P_e = \pi_0 P_f + (1-\pi_0)P_{md}$. Setting $dP_e/d\theta = 0$ and solving for θ, we obtain the optimum threshold as:

$$\theta^o = \left(1 + \frac{1}{\gamma}\right) \log\left[\frac{\pi_0}{1-\pi_0}(\gamma+1)\right], \tag{6}$$

where log is base-e throughout this chapter unless otherwise specified. Using this threshold, as $\gamma \to +\infty$, we have:

$$\begin{aligned} P_f = e^{-\theta} &= e^{-(1+\frac{1}{\gamma})\log\left[\frac{\pi_0}{1-\pi_0}(\gamma+1)\right]} \\ &= (\gamma+1)^{-(1+\frac{1}{\gamma})} \left(\frac{\pi_0}{1-\pi_0}\right)^{-\left(1+\frac{1}{\gamma}\right)} \sim (1+\gamma)^{-1} \end{aligned} \tag{7}$$

and

$$\begin{aligned} P_{md} = 1 - e^{-\frac{\theta}{\gamma+1}} &= 1 - e^{-\frac{1}{\gamma}\log\left[\frac{\pi_0}{1-\pi_0}(\gamma+1)\right]} \\ &\sim \gamma^{-1} \log\left[\frac{\pi_0}{1-\pi_0}(\gamma+1)\right]. \end{aligned} \tag{8}$$

Thus, their respective diversity orders can be obtained as:

$$\begin{aligned} d_f &= -\lim_{\gamma\to+\infty} \frac{\log P_f}{\log \gamma} = 1 \\ d_{md} &= -\lim_{\gamma\to+\infty} \frac{\log P_{md}}{\log \gamma} = 1 \\ d_e &= \min(d_f, d_{md}) = 1. \end{aligned} \tag{9}$$

Accordingly, we establish the following result:

Theorem 1. *For single-user spectrum sensing, when the threshold θ is chosen to minimize the average error probability P_e as in (6), the diversity order of the NP detector is $d_e = d_f = d_{md} = 1$.*

This theorem is quite intuitive since any single sensing user only has one copy of the original signal going through the fading channel, and it is well known that the probability of deep fading in this case is proportional to γ^{-1} (see, e.g., [23]).

From the analysis above, we see that the prior probabilities of the hypotheses π_0 and $(1-\pi_0)$ do not affect the diversity orders of the performance. Without loss of generality, to simplify the following analyses on the diversity orders, we choose $\pi_0 = \frac{1}{2}$ for the rest of this chapter.

False Alarm Diversity Versus Missed Detection SNR Gain

In Theorem 1, we choose θ^o to minimize the average detection error probability P_e, which is the average of efficiency and reliability. However, in some systems, the two features may have different levels of importance. Thus, we will next analyze P_f and P_{md} separately. Our analysis will reveal an interesting trade-off between the system efficiency and reliability. This trade-off can be exploited to achieve the desirable P_f and P_{md} performance and accordingly the preferable spectrum usage efficiency and interference level.

From (4) and (6), we notice that, if one changes the threshold to $\theta' = d_0\theta^o$, then the false alarm diversity order changes from 1 in (9) to:

$$d'_f = -\lim_{\gamma\to+\infty}\frac{\log P'_f}{\log\gamma} = -\lim_{\gamma\to+\infty}\frac{-d_0(1+\frac{1}{\gamma})\log(\gamma+1)}{\log\gamma} = d_0. \tag{10}$$

On the other hand, with this new threshold θ', as $\gamma\to+\infty$, we have:

$$P'_{md} = 1 - e^{-\frac{\theta'}{\gamma+1}} = 1 - e^{-\frac{d_0}{\gamma}\log(\gamma+1)} \sim d_0\gamma^{-1}\log(\gamma+1). \tag{11}$$

This implies that $d'_{md} = 1$, which is identical to d_{md} in (9) with threshold θ^o. In other words, the missed detection diversity order remains unaltered. However, the scalar difference between (8) and (11) suggests that, to ensure $P'_{md} \approx P_{md}$ as $\gamma\to+\infty$, ones needs $\gamma' = d_0\gamma$. This implies that the missed detection probability P_{md} exhibits a $-10\log_{10}d_0$ dB SNR gain (or equivalently $10\log_{10}d_0$ dB SNR loss) when the threshold is chosen as $\theta = d_0\theta^o$. This interesting phenomenon may result from the fact that the false alarm probability is the right tail of the Rayleigh distribution which decays very rapidly, whereas the missed detection is the left tail of the Rayleigh distribution which decays quite slowly.

We summarize the trade-off between the false alarm diversity and the missed detection SNR gain in the following corollary:

Corollary 1. *For single-user spectrum sensing, when the threshold is set to* $d_0\theta^o$ *with* θ^o *given in* (6)*, the false alarm diversity order becomes* $d_f = d_0$*, while the missed detection diversity order remains* $d_{md} = 1$ *but the* P_{md} *curve exhibits* $a - \log_{10} d_0$ *dB SNR gain.*

The trade-off between the false alarm diversity and the missed detection SNR gain presented above provides system designers with a flexible tool to achieve the desirable trade-off between the spectrum usage efficiency of the secondary users and the reliability of the primary users. For example, if the primary users in the cognitive system are capable of interference suppression and the spectrum usage efficiency is of major concern for the system designer, then, by the properties above, the secondary users can set the threshold as $d_0\theta^o$ with $d_0 > 1$. This means, the false alarm diversity is increased to $d_0(> 1)$ by sacrificing a $10\log_{10} d_0$ dB SNR loss for the missed detection probability. On the other hand, if the primary users are vulnerable to interference and the performance of primary users in the cognitive system is of the major concern, then the secondary users can set the threshold at $d_0\theta^o$ with $0 < d_0 < 1$. As a result, there will be a $-10\log_{10} d_0$ dB SNR gain for the missed detection probability by reducing the false alarm diversity to $d_0(< 1)$.

As shown later in section "Hard/Binary Information Fusion", this flexibility of the false alarm diversity can also be utilized to maximize the diversity order of the multiuser sensing with hard/binary information fusion.

Diversity Analysis for Multiuser Sensing

Soft Information Fusion

With a soft information fusion strategy, the fusion center receives $r_1, r_2, \ldots, r_N$ from the distributed sensing users, where N is the total number of cooperative sensing users and r_is are conditionally independent identically distributed (i.i.d.) under both H_0 and H_1. Similar to section "Diversity Analysis for Single-User Sensing", the NP test is

$$\lambda_s = \sum_{i=1}^{N} |r_i|^2 \underset{H_0}{\overset{H_1}{\gtrless}} \theta_s, \tag{12}$$

where the subscript "s" refers to soft information fusion.

Since r_is are conditionally independent, and according to (1), we have:

$$\begin{aligned} f(\lambda_s|H_0) &= \lambda_s^{N-1} \frac{e^{-\lambda_s}}{(N-1)!} \quad (\lambda_s > 0) \\ f(\lambda_s|H_1) &= \lambda_s^{N-1} \frac{e^{-\frac{\lambda_s}{\gamma+1}}}{(N-1)!(\gamma+1)^N} \quad (\lambda_s > 0). \end{aligned} \tag{13}$$

Hence, the probabilities of false alarm and missed detection are, respectively:

$$P_{f,s} = \int_{\theta_s}^{+\infty} f(\lambda_s|H_0)d\lambda_s = \left(\sum_{i=0}^{N-1} \frac{\theta_s^i}{i!}\right) e^{-\theta_s} \tag{14}$$

and

$$P_{md,s} = \int_{0}^{\theta_s} f(\lambda_s|H_1)d\lambda_s = \left(\sum_{i=N}^{+\infty} \frac{\theta_s^i}{i!(\gamma+1)^i}\right) e^{-\frac{\theta_s}{\gamma+1}}. \tag{15}$$

Accordingly, the average error probability is $P_{e,s} = \frac{1}{2}P_{f,s} + \frac{1}{2}P_{md,s}$. Similar to section "Diversity Analysis for Single-User Sensing", minimizing $P_{e,s}$ by taking $dP_{e,s}/d\theta_s = 0$, we obtain the optimum threshold as:

$$\theta_s^o = N\left(1 + \frac{1}{\gamma}\right)\log(\gamma+1). \tag{16}$$

Using this threshold, we establish the following theorem:

Theorem 2. *For multiuser sensing with soft information fusion, when the threshold θ_s is chosen as in (16) to minimize the average error probability $P_{e,s}$, the diversity order of the NP detector is $d_{e,s} = d_{f,s} = d_{md,s} = N$, where N is the number of cooperative users.*

Proof. See section "Appendix 1: Proof of Theorem 2".

This theorem is also intuitive in that the fusion center has copies of the original received signals from N independently fading channels. Similar to section "False Alarm Diversity Versus Missed Detection SNR Gain", we can also choose the threshold as $\theta_s' = d_0\theta_s^o$, where d_0 can be any positive number and is not necessarily an integer, to increase the false alarm diversity to d_0N while keeping the missed detection diversity unaltered at N. In this case, there is also a trade-off between the missed detection SNR gain and the false alarm diversity. For the false alarm diversity to be d_0N, the missed detection probability will exhibit a $-10\log_{10} d_0$ dB SNR gain (or equivalently $10\log_{10} d_0$ dB SNR loss).

Hard/Binary Information Fusion

With the hard/binary information fusion strategy, each sensing user makes its own local hard decision and then sends the binary decision b_i to the fusion center. For simplicity, we assume that all distributed sensing users employ the same threshold θ_l for their local decisions where subscript "l" stands for local. The corresponding local false alarm and missed detection probabilities are denoted as $P_{f,l}$ and $P_{md,l}$, respectively. Clearly, b_i follows conditionally i.i.d. Bernoulli distribution with $(1 - P_{f,l})$ and $P_{md,l}$ as the probabilities of value 0 under H_0 and H_1, respectively; that is:

$$\begin{aligned} b_i|H_0 &\sim \text{Ber}(1-P_{f,l}) \\ b_i|H_1 &\sim \text{Ber}(P_{md,l}). \end{aligned} \tag{17}$$

In this case, the NP test becomes:

$$\lambda_h = \sum_{i=1}^{N} b_i \underset{H_0}{\overset{H_1}{\gtrless}} \theta_h, \quad \theta_h = 1, 2, \ldots, N, \tag{18}$$

where subscript "h" refers to hard information fusion. Accordingly, the distribution of λ_h is:

$$\begin{aligned} f(\lambda_h|H_0) &= \binom{N}{\lambda_h} P_{f,l}^{\lambda_h}(1-P_{f,l})^{N-\lambda_h}, \ \lambda_h = 0, 1, \ldots, N; \\ f(\lambda_h|H_1) &= \binom{N}{\lambda_h}(1-P_{md,l})^{\lambda_h} P_{md,l}^{N-\lambda_h}, \ \lambda_h = 0, 1, \ldots, N. \end{aligned} \tag{19}$$

In hard information fusion, there are two levels of decision making, each level having its own decision performance. For the local decision, there are diversity orders for the local false alarm probabilities ($d_{f,l}$) and local missed detection probabilities ($d_{md,l}$). At the fusion center, there are also corresponding diversity orders for the overall hard decision false alarm probability ($d_{f,h}$), missed detection probability ($d_{md,h}$), and average error probability ($d_{e,h}$). Here we establish the relationship between the local decision diversity orders with the overall diversity orders at the fusion center in the following theorem:

Theorem 3. *For multiuser sensing with* 1*-bit hard information fusion, and with the fusion center threshold* θ_h *(*$\theta_h = 1, 2, \ldots, N$*), the diversity orders of the NP detector are* $d_{f,h} = \theta_h d_{f,l}$, $d_{md,h} = (N-\theta_h+1)d_{md,l}$, *and* $d_{e,h} = \min\{\theta_h d_{f,l}, (N-\theta_h+1)d_{md,l}\}$, *where* N *is the number of cooperative users.*

Proof. See section "Appendix 2: Proof of Theorem 3".

Similar to the single-user sensing and cooperative sensing with soft information fusion, cooperative sensing with hard information fusion also provides the system designer with the flexibility of balancing between the spectrum efficiency of the secondary users (via $d_{f,h}$) and the reliability of the primary users (via $d_{md,h}$) by the choice of the threshold θ_h. A larger θ_h will improve the false alarm performance, leading to higher spectrum usage efficiency of the secondary users, while a smaller θ_h will improve the missed detection performance, leading to enhanced reliability of the primary users. However, it is worth noting that the trade-off and flexibility here are very different from what we have discussed in Corollary 1 for the single-user sensing and the multiuser soft-fusion cases. In previous cases, the trade-off was between the false alarm *diversity* and the missed detection *SNR gain*, while here in

the case of multiuser hard fusion, the trade-off is between the false alarm *diversity* and the missed detection *diversity*.

Note that, though the local threshold θ_l does not appear explicitly in Theorem 3, it affects the overall system implicitly via $d_{f,l}$ and $d_{md,l}$. Hence, if one opts to minimize $P_{e,h} = \frac{1}{2}P_{f,h} + \frac{1}{2}P_{md,h}$, one needs to jointly choose both the optimum local threshold θ_l at the individual sensing users and the optimum hard decision threshold θ_h at the fusion center. However, under this fusion rule, θ_l has a very complicated form in $P_{e,h}$ through parameters $P_{f,l}$ and $P_{md,l}$, rendering optimization intractable. Even with numerical techniques, the optimization over θ_l still requires knowledge of the total number of distributed sensors in the network N, which is not always available to the secondary users in real applications. However, with Theorem 3, one can optimize the overall hard decision fusion performance from the diversity perspective with different strategies as detailed in the following two scenarios.

(B.1) Number of Cooperative Users *N* Unknown

In this case, the sensing users can only perform their optimum detection locally. From Theorem 1, the local threshold is $\theta_l = \theta^o$ and the local diversities are $d_{f,l} = d_{md,l} = 1$. According to Theorem 3, the diversity orders at the fusion center are $d_{f,h} = \theta_h$, $d_{md,h} = N-\theta_h+1$ and $d_{e,h} = \min\{\theta_h, N-\theta_h+1\}$. With equal emphasis on false alarm and missed detection performance, by maximizing $\min\{\theta_h, N - \theta_h + 1\}$, we obtain the optimum threshold θ_h^o at the fusion center that maximizes the detection error diversity:

Corollary 2. *For multiuser sensing with* 1*-bit hard information fusion, and with each sensing user using the locally optimum threshold* $\theta_l = \theta^o$*, the optimum threshold at the fusion center in the sense of maximizing the detection error diversity is* $\theta_h^o = \lfloor \frac{N+1}{2} \rfloor$ *or* $\theta_h^o = \lceil \frac{N+1}{2} \rceil$ *with* $d_{e,h} = \lfloor \frac{N+1}{2} \rfloor$*, where* N *is the number of cooperative users.*

In this case, the strategy is the so-termed majority-fusion rule. Notice that under this rule, about half of the diversity is lost compared with the soft information fusion. This indicates that a hard decision at each local sensing user leads to considerable information loss of the received signal.

(B.2) Number of Cooperative Users *N* Known

From Corollary 1, we have seen that the false alarm diversity at each local sensing user is flexible. It is shown in the following corollary that this property can be utilized to maximize the average error diversity.

Corollary 3. *For multiuser sensing with* 1*-bit hard information fusion, if each distributed sensing user knows the number of cooperative users* N*, the average error diversity order at the fusion center can be maximized by choosing local decision threshold* $\theta_l = N\theta^o$ *with* θ^o *given in* (6) *and the fusion decision threshold* $\theta_h = 1$.

Proof. See section "Appendix 3: Proof of Corollary 3".
Notice that the decision strategy turns out to be the so-termed OR-fusion rule. From this corollary, we see that with the number of sensors known at each local sensor, the diversity of the average detection error probability of hard information fusion equals that of soft information fusion ($d_{e,h} = d_{e,s} = N$). In other words, knowledge of N completely compensates for the loss of information by local hard decisions, in terms of the detection error diversity. However, we should also notice that though the diversity performance of the two cases are identical, their average error probability performances are still different. As detailed in section "False Alarm Diversity Versus Missed Detection SNR Gain", there is a $10 \log N$ SNR loss for the missed detection probability $P_{md,l}$ by setting $\theta_l = N\theta^o$ (such that $d_{f,l} = N$).

Remark 1. As stated in section "Sensing Strategies and Performance Metrics", our results on multiuser sensing with soft information fusion can be readily applied to the case of combining signals from different multiple time slots at a single user, as long as the combined received signals experience independent fading. In this case, if the system also uses cooperative multiuser sensing with hard/binary information fusion among these multiple time slot sensors, our analysis in this section can be readily extended by combining the results in Theorems 2 and 3. In addition, for the correlated fading case, intuitively, we expect that the diversity orders equal the rank of the correlation matrix of the received signals, which will be justified in the following section.

Simulations

Single-User Sensing

For single-user sensing, we use the test given by (2) and the threshold of (6) to obtain the average error probability, false alarm probability, and the missed detection probability. These probabilities are shown as the solid curves in Fig. 1. All three curves exhibit the same slope, indicating diversity orders $d_f = d_{md} = d_e = 1$.

To illustrate the trade-off between the false alarm diversity and missed detection SNR gain (loss) discussed in section "False Alarm Diversity Versus Missed Detection SNR Gain", we change the threshold to $\theta' = 2\theta^o$ and obtain the dashed curves in Fig. 1. From the figure, we see that $d'_f = 2$ and $d'_{md} = d_{md} = 1$, as predicted by Corollary 1. In addition, by comparing the solid curve with the dashed one for P_{md}, one can easily verify that at high SNR, there is an approximately $10 \log_{10} d_0 = 3$ dB SNR loss. This is the price paid for the increase of the diversity for the false alarm probability.

Multiuser Sensing with Soft Information Fusion

Here, we simulate the multiuser sensing with soft information fusion strategy. The total number of cooperative users is $N = 5$. From the analysis in section "Soft Information Fusion", we expect the relative performance of $P_{e,s}$, $P_{f,s}$ and $P_{md,s}$ to

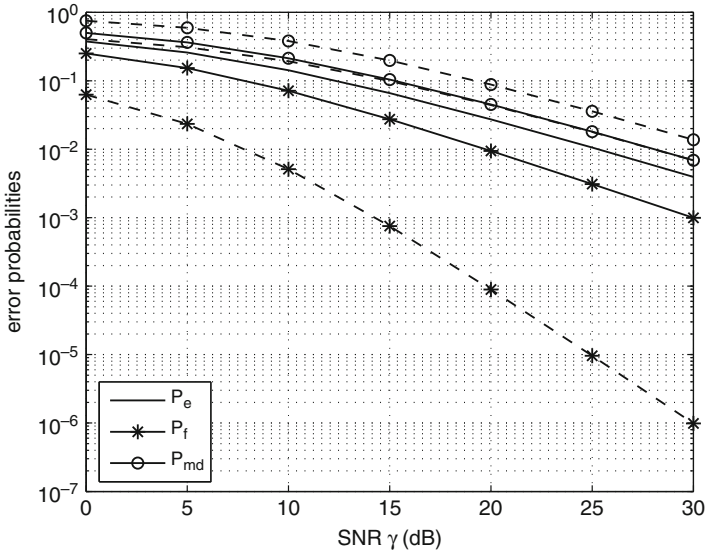

Fig. 1 Single-user sensing. *Solid curves*: threshold $\theta = \theta^o$; *dashed curves*: threshold $\theta = 2\theta^o$

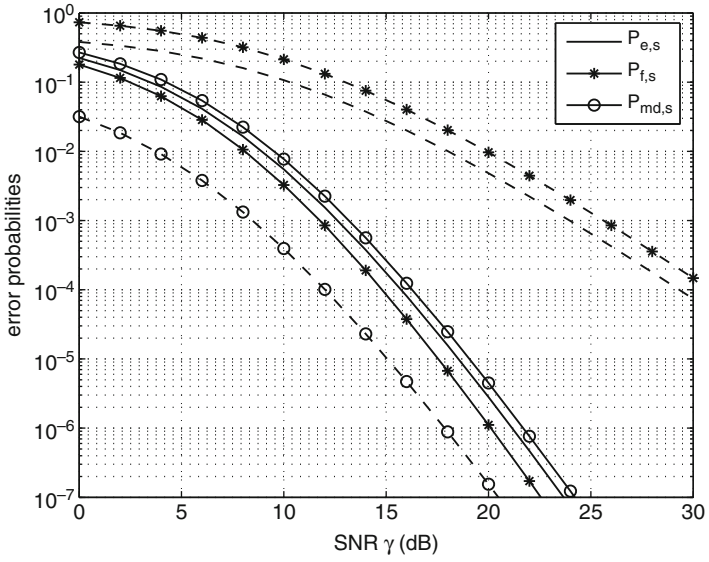

Fig. 2 $N = 5$ multiuser sensing with soft decision fusion *Solid curves*: threshold $\theta = \theta_s^o$; *dashed curves*: threshold $\theta = 0.5\theta_s^o$

be similar to the single-user sensing case, except for the diversity order of 5. This is verified in Fig. 2. The solid curves show that with the threshold minimizing the average error probability, the diversity orders are $d_{e,s} = d_{f,s} = d_{md,s} = N = 5$. In multiuser sensing with soft information fusion, we can also set the threshold

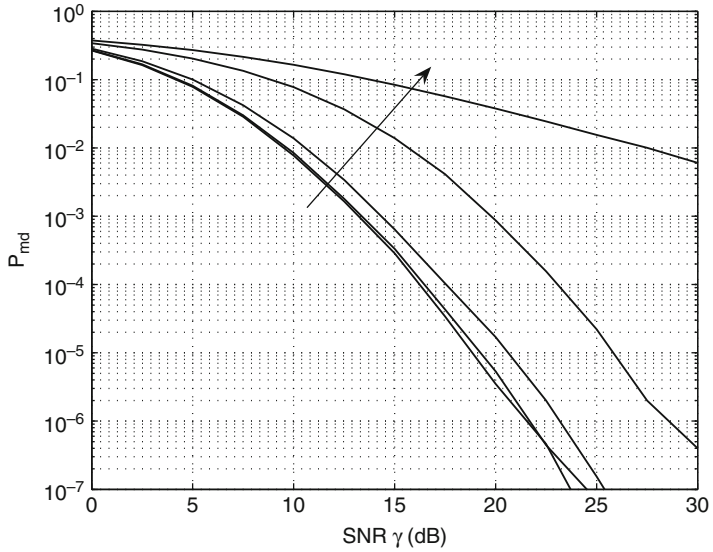

Fig. 3 $N = 5$ multiuser sensing with soft decision fusion on correlated signals with correlation $\mathbb{E}[h_i^* h_j] = r^{|i-j|}$. In the direction of *arrow*: $r = 0, r = 0.2, r = 0.5, r = 0.9, r = 1$, respectively

to $\theta_s' = d_0\theta_s^o$ to make $d_{f,s} = d_0 N$. The dashed curves in Fig. 2 show $P_{f,s}$ and $P_{md,s}$ with $d_0 = 0.5$. Similar to the single-user sensing case, comparing the solid curve with the dashed one for $P_{md,s}$, we verify that at high SNR, there is approximately $-10\log_{10} d_0 = 3$ dB SNR gain for the decrease of the false alarm diversity (from 5 to 2.5).

In the simulations above, the fading coefficients at each user are assumed to be independent. However, for multi-time-slot sensing which can be modeled as multiuser sensing with soft information fusion, the fading coefficients can be correlated. To investigate the diversities in this case, we plot the simulation results of the detector under the threshold η_s^o in Fig. 3. Notice that in this case, the signals under hypothesis H_0 remains unaltered; thus, it suffices to give the missed detection performances only. In this simulation, the number of time slots $N = 5$ and the correlations of the fading coefficients are assumed to be $\mathbb{E}[h_i^* h_j] = r^{|i-j|}$ where i and j are indices for the time slot. Under this assumption, the correlation matrix is

$$\Lambda_{\mathbf{h}} = \mathbb{E}[\mathbf{h}^H \mathbf{h}] = \begin{bmatrix} 1 & r & r^2 & r^3 & r^4 \\ r & 1 & r & r^2 & r^3 \\ r^2 & r & 1 & r & r^2 \\ r^3 & r^2 & r & 1 & r \\ r^4 & r^3 & r^2 & r & 1 \end{bmatrix}$$

In Fig. 3, we see that when the correlation (r) among the fading coefficients increases, the performance degrades. However, as long as the correlation matrix $\Lambda_{\mathbf{h}}$ is full rank, the diversity results obtained under the independent fading scenario still hold. When the matrix loses rank to rank 1 at $r = 1$, the diversity order reduces to 1.

Multiuser Sensing with Hard/Binary Information Fusion

For the multiuser sensing with hard/binary information fusion in section "Hard/Binary Information Fusion", we first consider the case where the number of cooperative users N is not available to the individual sensing users. Then, each distributed sensing user makes the locally optimum hard decision, i.e., $\theta_l = \theta^o$ as defined in (6). In this case, as Theorem 3 dictates, the false alarm diversity, the missed detection diversity, and the average error diversity are all heavily dependent on the threshold θ_h at the fusion center. Figure 4 shows the behavior of $P_{f,h}$, $P_{md,h}$, and $P_{e,h}$ of the hard information fusion strategy with $\theta_h = 1$ (solid curves) and $\theta_h = 2$ (dashed curves) when the number of cooperative users is $N = 5$. When $\theta_h = 1$, the solid curves show that $d_{f,h} = 1$, $d_{md,h} = 5$, and $d_{e,h} = 1$; when $\theta_h = 2$, the dashed curves show that $d_{f,h} = 2$, $d_{md,h} = 4$, and $d_{e,h} = 2$. These results are consistent with Theorem 3 and illustrate the trade-off between the false alarm diversity and the missed detection diversity.

With locally optimum hard decision ($\theta_l = \theta^o$) at distributed sensing users, the threshold maximizing the average error diversity should be chosen as $\lfloor \frac{N+1}{2} \rfloor$ or $\lceil \frac{N+1}{2} \rceil$ according to Corollary 2. This result is shown in Fig. 5 when $N = 5$.

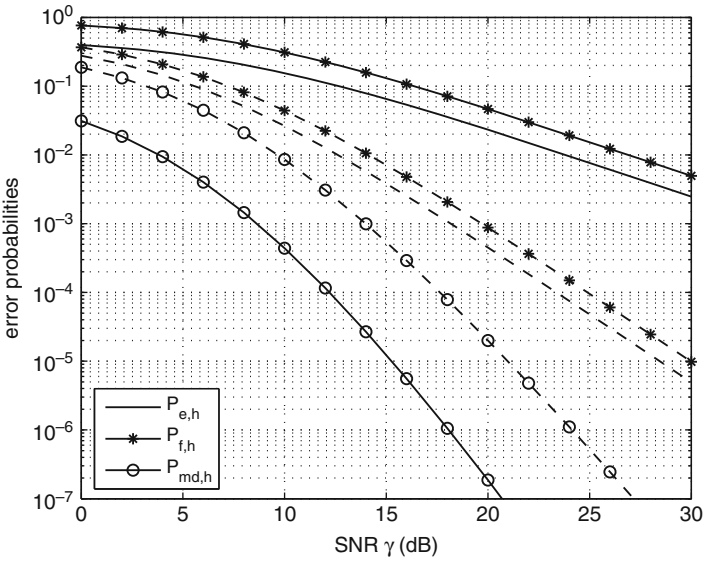

Fig. 4 $N = 5$ multiuser sensing with hard decision fusion. *Solid curves*: threshold $\theta_l = \theta^o$, $\theta_h = 1$; *dashed curves*: threshold $\theta_l = \theta^o$, $\theta_h = 2$

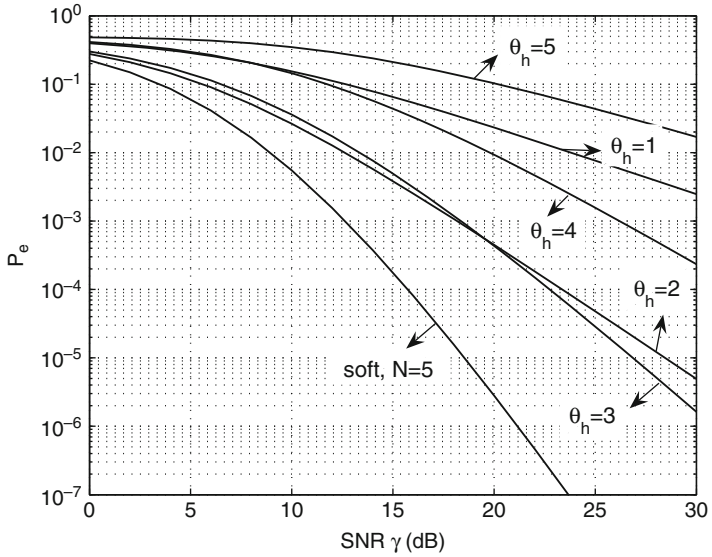

Fig. 5 $N = 5$ multiuser sensing with soft information fusion and hard information fusion with $\theta_l = \theta^o$ and various θ_hs

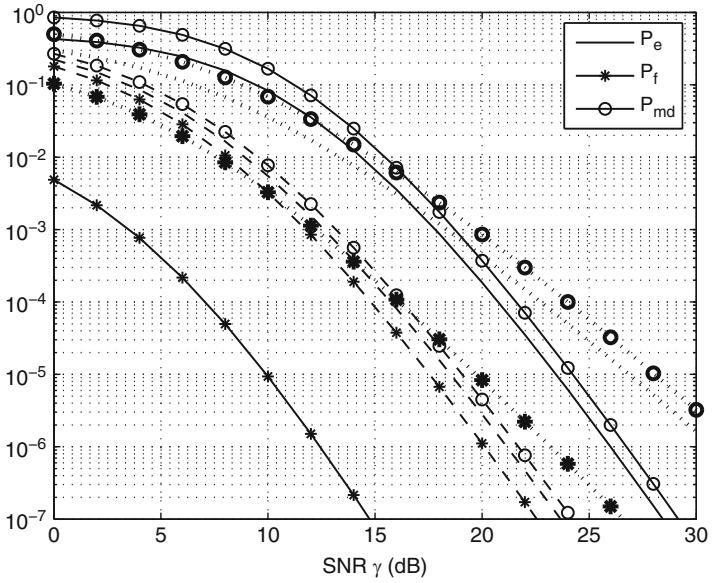

Fig. 6 $N = 5$ multiuser sensing with OR-fusion rule with $\theta_l = N\theta^o$ (*solid curves*), majority-fusion rule with $\theta_l = \theta^o$ (*dotted curves*), and soft information fusion (*dashed curves*)

From this figure, we see that $\theta_h = 3$ gives the maximum average error diversity. Compared with the error performance under soft information fusion, we see here that this locally optimum hard decision strategy suffers from a large loss of diversity.

When the distributed sensing users know the number of cooperative users in the network, then the flexibility of the false alarm diversity in Corollary 1 can be utilized to maximize the diversities of the hard information fusion. In this case, the local decision threshold is $\theta_l = N\theta^o$ where θ^o is defined in (6). Figure 6 shows the performance with this strategy and compares this with that of the soft information fusion strategy. From this figure, we see that in terms of diversity order d_e, the hard information fusion with adjusted local threshold equals the soft information fusion. However, the soft information fusion has a huge SNR advantage over the hard information fusion on the missed detection and average error probabilities. This is due to the fact that in the local decisions, a $10\log_{10} 5 = 7$ dB SNR loss of missed detection probability is introduced to increase the false alarm diversity from $d_{f,l} = 1$ to $d_{f,l} = 5$ by setting $\theta_l = 5\theta^o$. This also explains why the false alarm performance in this hard information fusion strategy with knowledge of the number of cooperative users is better than that in the soft information fusion strategy. In addition, compared with the dotted curves, we see that this strategy recovers the diversity loss introduced by the locally optimum hard decision.

Discussions

In this section, we analyzed various cooperative spectrum sensing strategies under different scenarios. By considering both false alarm and missed detection probabilities individually and jointly via the average error probability, we found several trade-offs between the system efficiency and reliability under three different spectrum sensing strategies. For single-user sensing and multiuser sensing with soft information fusion, the trade-off is between the false alarm diversity gain and the missed detection SNR loss by altering the detection threshold. For multiuser sensing with hard/binary information fusion without information of cooperative user number, there is a trade-off between the diversities of false alarm and missed detection. In addition, under hard information fusion, with the knowledge of cooperative user number, the soft decision diversity can be achieved at a given missed detection SNR loss. With these diversity and trade-off results, we derived the optimum threshold in each cooperative strategy to guide practical system design. Simulations have also been presented to further illustrate the analytical results and compare the various cooperative strategies.

Performance Scaling with the Number of Sensing Users: Error Exponent

In our previous discussions, we have characterized the cooperative sensing performance scaling with the signal parameter (i.e., SNR) for *fixed number of cooperative users* by diversity. In this section, we will see how the cooperative sensing

performance scales with the number of cooperative users for *fixed signal model*. Since now we are not aiming at writing the sensing performance as a function of any signal parameter, we start with a general sensing problem without any particular signal model and then apply the results to our spectrum sensing problem with the signal model given in section "Performance Scaling with SNR: Cooperative Diversity".

For a general detection fusion problem, we begin by assuming the prior probability of an event is known, and the number of functioning sensors is known. Each of these assumptions may be called into question. When they are, then various strategies may be considered, which we review and analyze in this section. Interestingly enough, when the asymptotically optimum detector is derived, it is found to be an equalizer rule that is invariant to the prior probability of an event, and therefore it is a minimax rule. Moreover the threshold setting at the fusion center scales with the number of reported sensor decisions, so that the number of cooperative sensors is not required to be known a priori.

The crux of the problem is this. At the global fusion center, the decision rule to minimize the global error probability is known. It depends on the number of sensors in the network, the prior probabilities of the underlying state, and the operating point on the ROC curve of each individual sensor. So the only problem is to determine the operating point on the local ROC curve for each individual sensor that minimizes the global error probability. This problem is intractable [24], so approximations are sought. Some designs for the operating point simply ignore the global error probability and use an operating point at the local sensors that achieves an objective like maximum entropy (ME), minimum error probability (MEP), or maximum mutual information (MMI). None of these designs has any claim to optimality. Other designs use an asymptotic theory to exponentially bound global error probability and seek an operating point that maximizes the error exponent. The result of this section uses the method of large deviations (LD) to do it.

Joint Optimization of Local and Fusion Decisions

In our analysis of the error exponent, we assume that the system is applying the cooperative sensing scheme with hard/binary information fusion. As discussed at the beginning of this section, we start with the sensing with any general signal models. That is, with probability π_0, each sensor (sensing user) measures a random variable distributed as F_0, and with probability π_1 each sensor measures a random variable distributed as F_1. Each local detector will make its own local decision $D_i \in \{0, 1\}$ based on its observed signal (i.e., information fusion with hard/binary information fusion). Then, a fusion center will collect all D_i's and make a fused binary decision $\phi(D_1, D_2, \ldots, D_N) = 0$ or $\phi(D_1, D_2, \ldots, D_N) = 1$.

Tsitsiklis [24] has shown that in the case of dependent signals at the local detectors, the solution for optimal detection fusion is non-deterministic polynomial-time hard [25]. Therefore, in our analysis, we assume that the signals at different detectors are independent, which is the case in many applications, including our

cooperative spectrum sensing problem discussed so far. Under this assumption, Tsitsiklis [24] proved that, asymptotically in the number of sensors, all local detectors use the same decision rule. For a finite number of local detectors, it is suboptimal. Under this setup, the D_is are conditionally i.i.d. binary random variables.

To describe the distribution of the local decision D_i, we denote $P_{f,l} = P(D_i = 1|H_0)$ as the local false alarm probability and $P_{d,l} = P(D_i = 1|H_1)$ as the local detection probability. Then, the local decisions $\{D_i\}$ are conditionally i.i.d. Bernoulli distributed with probabilities $P_{f,l}$ and $P_{d,l}$ under H_0 and H_1, respectively. Note that $(P_{f,l}, P_{d,l}) \in [0, 1] \times [0, 1]$ is constrained to lie on ROC curve for the local sensors, governed by the measurement model. At the fusion center that collects all N detectors' local decisions, $D_i \in \{0, 1\}$, the joint distribution of $(D_1, D_2, \ldots, D_N)$ is

$$P(D_1, D_2, \ldots, D_N|H_0) = P_{f,l}^{\sum_{i=1}^N D_i} \left(1 - P_{f,l}\right)^{N-\sum_{i=1}^N D_i},$$
$$P(D_1, D_2, \ldots, D_N|H_1) = P_{d,l}^{\sum_{i=1}^N D_i} \left(1 - P_{d,l}\right)^{N-\sum_{i=1}^N D_i}.$$

Accordingly, $V = \sum_{i=1}^{N} D_i$ is the sufficient statistic and it follows a binomial distribution under each hypothesis; that is,

$$\begin{aligned} V|H_0 &\sim \text{Bin}(N, P_{f,l}), \\ V|H_1 &\sim \text{Bin}(N, P_{d,l}). \end{aligned} \tag{20}$$

A global binary decision strategy will involve both a detection rule for mapping measurements into decision D_i at local detectors and a detection rule ϕ at the fusion center. We adopt the global average error probability $P_{e,h} = \pi_0 P(\phi(V) = 1|H_0) + \pi_1 P(\phi(V) = 0|H_1)$ as the performance metric. To obtain the optimum performance, one needs to find a local threshold and a corresponding fusion rule that jointly minimize $P_{e,h}$.

At the fusion center, if the local detector performance $(P_{f,l}, P_{d,l})$ is known, then the maximum *a posteriori* (MAP) detector will minimize the global error probability, $P_{e,h}$, via the likelihood ratio test:

$$\frac{\pi_1 P_{d,l}^v (1 - P_{d,l})^{N-v}}{\pi_0 P_{f,l}^v (1 - P_{f,l})^{N-v}} \underset{H_0}{\overset{H_1}{\gtrless}} 1. \tag{21}$$

The result is a threshold test,

$$v \underset{H_0}{\overset{H_1}{\gtrless}} v^{\text{MAP}} \tag{22}$$

where

$$v^{\mathrm{MAP}} = \frac{\left(\log \frac{1-P_{f,l}}{1-P_{d,l}}\right) N + \log\left(\frac{\pi_0}{\pi_1}\right)}{\log \frac{P_{d,l}}{P_{f,l}} + \log \frac{1-P_{f,l}}{1-P_{d,l}}}. \tag{23}$$

Importantly, this threshold may be written, asymptotically in N, as

$$v^{\mathrm{MAP}} = N\theta^{\mathrm{LD}};\ \theta^{\mathrm{LD}} = \frac{\left(\log \frac{1-P_{f,l}}{1-P_{d,l}}\right)}{\log \frac{P_{d,l}}{P_{f,l}} + \log \frac{1-P_{f,l}}{1-P_{d,l}}}. \tag{24}$$

The θ^{LD} is the LD solution to be found in section "A Large Deviation (LD) Solution of the Local Threshold". It is also the finite-N solution when $\pi_0 = \pi_1$.

This solution scales with N, the number of decisions reported to the global fusion center, and it is independent of the prior probabilities, π_0 and π_1. It will be shown that the threshold $N\theta^{\mathrm{LD}}$ is in fact the asymptotically optimum solution returned from a large deviations error bound. So already the asymptotic solution for the fusion threshold is known. The problem is to determine the asymptotic expression for the global error probability,

$$P_{e,h} = \pi_0 \sum_{v \geq v^{\mathrm{MAP}}} \binom{N}{v} P_{f,l}^{v} (1 - P_{f,l})^{N-v} + \pi_1 \sum_{v < v^{\mathrm{MAP}}} \binom{N}{v} P_{d,l}^{V} (1 - P_{d,l})^{N-v}. \tag{25}$$

The theory of LD will allow us to tightly bound this error probability for large N and solve for the operating point that minimizes it.

From (23) and (25), it can be readily verified that for any given local false alarm probability $P_{f,l}$, the larger the local detection probability $P_{d,l}$ is, the smaller the global average error probability $P_{e,h}$ will be. Therefore, at the local detectors, the NP detection rule maximizes the detection probability $P_{d,l}$ for any given false alarm probability P_f. However, the NP detector only determines an ROC curve $(P_{f,l}, P_{d,l})$ for the individual detectors. What remains to be determined is how to select the operating point $(P_{f,l}, P_{d,l})$ on the ROC curve for the local NP detector that minimizes the global error probability, $P_{e,h}$. From (23) and (25), we see that the minimization of $P_{e,h}$ depends on the prior probabilities, the number of sensors reporting, and the local error probabilities. This optimization problem is non-convex. However, asymptotically, the operating point $(P_{f,l}, P_{d,l})$ may be determined independently of these parameters.

In summary,

- It is asymptotically optimal to select the same decision strategy for all local sensors [24];
- The minimization of the average global error probability forces the local sensors to use an NP detector;

- Given the local operating point on a local ROC curve, the optimum fusion rule is the threshold test of (21),
- The fundamental design problem is to determine the operating point $(P_{f,l}, P_{d,l})$ on the ROC curve for the local NP detector.

Detectors Based Only on a Local Optimality Criterion

None of the local detectors described in this section has any claim to global optimality. But each has been proposed as a candidate for sensor fusion when the prior probability of an event, π_0, is known, but the number of functioning sensors in the network is unknown.

Maximum Entropy (ME)

The local maximum entropy detector maximizes the entropy of the local decision by equalizing $P(D_i = 0)$ and $P(D_i = 1)$ (see, e.g., [3]). Under this condition, the local operating point $(P_{f,l}, P_{d,l}) \in$ local ROC is determined as

$$\text{choose}_{(P_{f,l},P_{d,l})\in \text{ local ROC}} \text{ such that } .\pi_1 P_{d,l} - \pi_0 P_{f,l} = 0 \tag{26}$$

This operating point treats each sensor as a source encoder, which "encodes" the sensor measurement into the reported decision. However, this decision rule has nothing to do with how the binary decision variable D carries the information about the binary state variable H, so it is expected to perform poorly.

Local MEP

The local MEP detector selects the operating point on the local ROC that minimizes the local average error probability:

$$\min_{(P_{f,l},P_{d,l})\in \text{ local ROC}} \left(\pi_0 P_{f,l} + \pi_1(1 - P_{d,l})\right). \tag{27}$$

This detection rule minimizes local error probability, but it does not minimize global error probability.

Maximum Mutual Information (MMI)

Maximizing the mutual information between the local decision D and the hypothesis H maximizes the rate at which D carries information about the hypothesis H, and it minimizes equivocation. Similar performance metrics were introduced in [11] where the aim was to optimize over dependent operating points rather than common points.

The mutual information $I(H, D)$ between the binary decision variable $D \in \{0, 1\}$ and the binary hypothesized state $H \in \{H_0, H_1\}$ is defined to be $E_{H,D}\left[\log\left(\frac{P(H,D)}{P(H)P(D)}\right)\right]$. Then, with prior probabilities $P(H_0) = \pi_0$, $P(H_1) = \pi_1$;

and conditional probabilities $P(D = 1|H_0) = P_{f,l}$, $P(D = 1|H_1) = P_{d,l}$, a few lines of algebra shows mutual information to be

$$I(D, H) = \pi_0 D_{\mathrm{KL}}\left(P_{f,l}||\left(\pi_0 P_{f,l} + \pi_1 P_{d,l}\right)\right) + \pi_1 D_{\mathrm{KL}}\left(P_{d,l}||\left(\pi_0 P_{f,l} + \pi_1 P_{d,l}\right)\right). \tag{28}$$

So the local operating point that maximizes mutual information is determined as,

$$\max_{(P_{f,l}, P_{d,l}) \in \text{ local ROC}} I(D, H) \tag{29}$$

It will be shown in due course that the local MMI operating point is superior to the MEP operating point, which is superior to the ME operating point.

A Large Deviation (LD) Solution of the Local Threshold

In this section the operating point on the local ROC that minimizes global error probability, asymptotically when the number of sensors approaches infinity, is designed using LD.

Asymptotically Optimum Local Decision Rule

The sufficient statistics at the fusion center $V = \sum_{i=1}^{N} D_i$ is binomial distributed as in (20). With $\theta \in (0, 1)$ such that $P_{f,l} < \theta < P_{d,l}$, and by large deviation analysis, the global error probabilities are asymptotically exponential decaying functions of N [1]:

$$\begin{aligned} P_{f,h} &= P(V \geq \theta N|H_0) \quad \sim e^{-N D_{\mathrm{KL}}(\theta||P_{f,l})}, \\ P_{md,h} &= P(V < \theta N|H_1) \quad \sim e^{-N D_{\mathrm{KL}}(\theta||P_{d,l})}. \end{aligned} \tag{30}$$

Accordingly, the global average error probability is asymptotically

$$\begin{aligned} P_{e,h} &= \pi_0 P_{f,h} + \pi_1 P_{md,h} \\ &\sim \pi_0 e^{-N D_{\mathrm{KL}}(\theta||P_{f,l})} + \pi_1 e^{-N D_{\mathrm{KL}}(\theta||P_{d,l})} \sim e^{-N \min\left(D_{\mathrm{KL}}(\theta||P_{f,l}), D_{\mathrm{KL}}(\theta||P_{d,l})\right)}. \end{aligned} \tag{31}$$

This error probability is maximized, globally, by maximizing the error exponent, $\min(D_{\mathrm{KL}}(\theta||P_{f,l}),\ D_{\mathrm{KL}}(\theta||P_{d,l}))$. Hence, the operating point $(P_{f,l},\ P_{d,l})$ is determined as

$$\max_{(P_{f,l}, P_{d,l}) \in \text{ local ROC}} \min_{\theta} \left(D_{\mathrm{KL}}(\theta||P_{f,l}), D_{\mathrm{KL}}(\theta||P_{d,l})\right). \tag{32}$$

For $P_{f,l} < \theta < P_{d,l}$, $D_{\mathrm{KL}}(\theta||P_{f,l})$ is an increasing function of θ and $D_{\mathrm{KL}}(\theta||P_{d,l})$ is a decreasing function of θ. As a result, the maximum is achieved when $D_{\mathrm{KL}}(\theta||P_{f,l}) = D_{\mathrm{KL}}(\theta||P_{d,l})$. Accordingly, the equalizing value of θ is

$$\theta^{\mathrm{LD}} = \frac{\log \frac{1-P_{d,l}}{1-P_{f,l}}}{\log \frac{P_{f,l}}{P_{d,l}} + \log \frac{1-P_{d,l}}{1-P_{f,l}}}, \tag{33}$$

and the corresponding value of the error exponent is

$$D_{\mathrm{KL}}(\theta^{\mathrm{LD}}||P_{f,l}) = D_{\mathrm{KL}}\left(\frac{\log \frac{1-P_{d,l}}{1-P_{f,l}}}{\log \frac{P_{f,l}}{P_{d,l}} + \log \frac{1-P_{d,l}}{1-P_{f,l}}}||P_{f,l}\right). \tag{34}$$

Notice that the operating point $(P_{f,l}, P_{d,l})$ and resulting error exponent are independent of the prior probabilities π_0 and π_1. Thus the LD solution is asymptotically an equalizer rule and therefore minimax.

In summary, the asymptotically optimum local decision rule is determined as

$$\max_{(P_{f,l},P_{d,l})\in \text{ local ROC}} D_{\mathrm{KL}}(\theta^{\mathrm{LD}}||P_{f,l}). \tag{35}$$

This large deviation (LD) solution for the local threshold has a number of important properties:

- *Semi-parametric*. The asymptotically optimal local decision strategy is *independent* of the total number of sensors N and the prior probabilities π_0 and π_1 but only dependent on the measurement model at the local sensors.
- *Asymptotically Minimax*. As shown in (32), the LD solution maximizes the minimum of the false alarm and missed detection error exponents. Therefore, asymptotically, the LD solution is an equalizer rule and consequently minimax [21, Chapter 5.3]. In other words, the LD solution has constant error exponents under any prior probabilities of the local hypotheses.
- *One-Dimensional Search*. In (35), we see that though $(P_{f,l}, P_{d,l})$ is two-dimensional, it actually only has one degree of freedom, as $(P_{f,l}, P_{d,l})$ is constrained by the ROC of the local detectors. This renders the optimization a one-dimensional search. In fact, under many signal models, the NP local detectors are in the form of a scalar compared against a single threshold, and in this case $P_{f,l}$ and $P_{d,l}$ can be computed as a function of this threshold, analytically in closed form. The objective function $D_{\mathrm{KL}}(\theta^{\mathrm{LD}}||P_{f,l})$ is convex and hence can be easily optimized by line search techniques such as those in [4, Chapter 7].
- *Universality*. The $(P_{f,l}, P_{d,l})$ pair in (35) has to reside within the $[0, 1] \times [0, 1]$ region of the local ROC curve. In Fig. 7, we plot the contours of the error exponent $D_{\mathrm{KL}}(\theta^{\mathrm{LD}}||P_{f,l})$ vs. the pair $(P_{f,l}, P_{d,l})$. This function is symmetrical

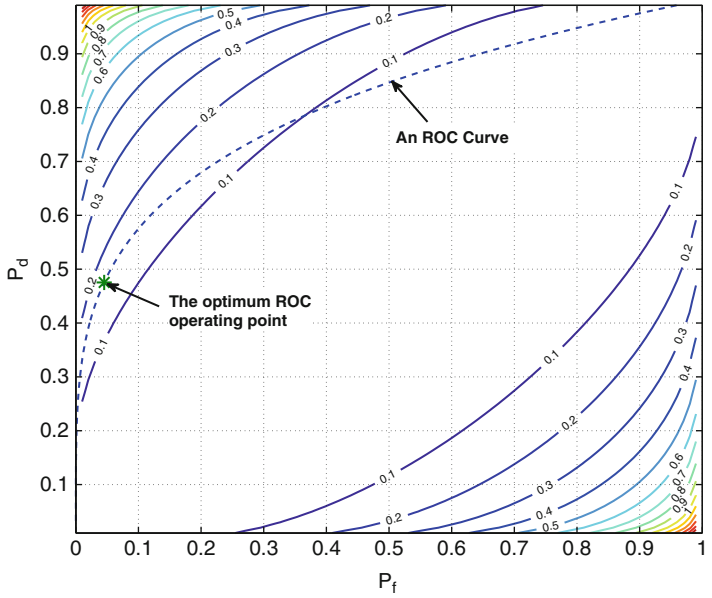

Fig. 7 Contours of error exponent in ROC region

about the line $P_{f,l} = P_{d,l}$ which agrees with the fact that the fusion center can always treat the hypotheses H_0 and H_1 symmetrically. These contours are convex and universal, in the sense that they depend only on the binomial distribution at the fusion center and are independent of the local measurement model. The local measurement model determines where the local ROC intersects the universal set of error exponents.

Simulations

The LD result obtained is applicable to general detection fusion problems with any signal models. Here, we apply the result to our cooperative spectrum sensing problems with the signal model given in section "Sensing Strategies and Performance Metrics".

Performance Surface and Local Threshold Convergence

In Fig. 8 the global error probability ($P_{e,h}$) for the energy sensing problem is plotted versus the local and fusion thresholds according to (25). In this figure, the number of local detectors is $N = 20$. Evidently, there are four local minima. This verifies our discussion of non-convexity in section "Joint Optimization of Local and Fusion Decisions".

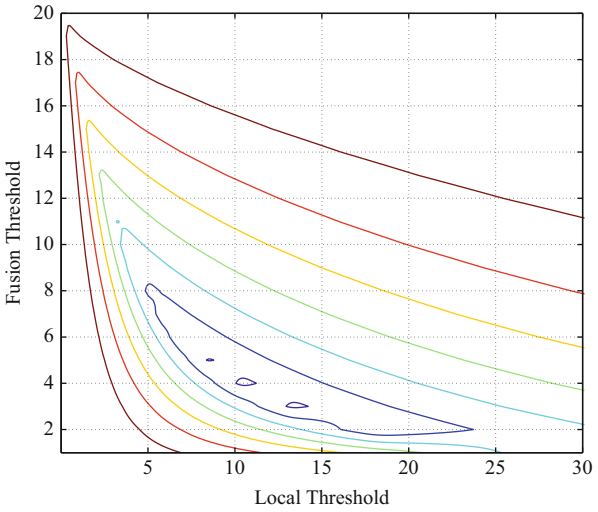

Fig. 8 The performance surface under local and fusion thresholds with $N = 20$

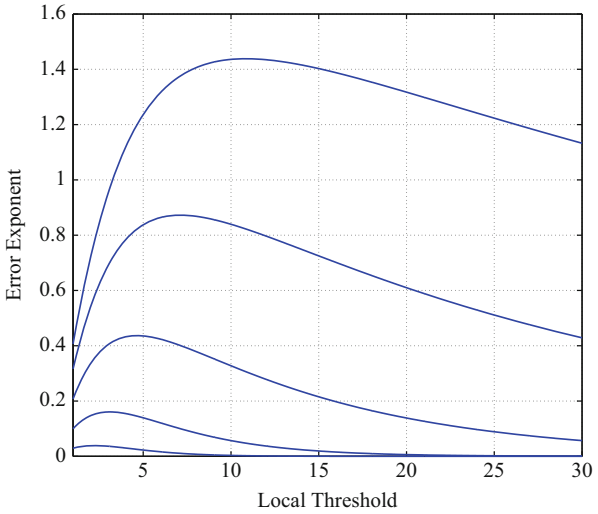

Fig. 9 Error exponent under different local thresholds. From bottom to top, the SNR is $\gamma = 0, 5, 10, 15, 20$ dB

The LD error exponent is plotted versus the local decision threshold in Fig. 9. In this figure, it can be observed that the error exponent is a unimodal function of the local threshold. Therefore, the optimal local threshold can be found using a one-dimensional line search algorithm.

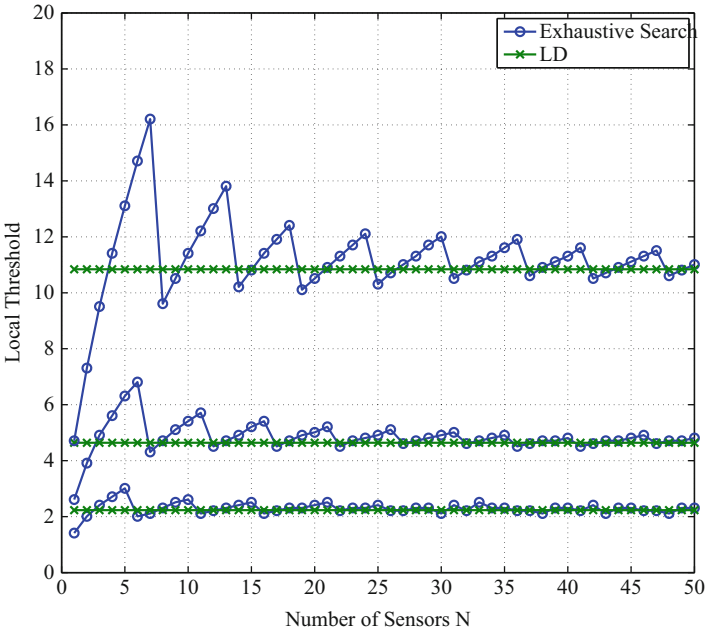

Fig. 10 Local decision thresholds under joint optimization by exhaustive search and large deviation analysis. From bottom to top, the per sensor SNR is $\gamma = 0, 10, 20$ dB

In Fig. 10, the optimum local thresholds, obtained by exhaustive search, are plotted versus N and compared with the thresholds determined by LD. There are three curves, for three values of SNR γ. These curves illustrate the approximation of the optimum thresholds, which depend on N, by the LD thresholds.

The behavior of the corresponding global fusion threshold is also interesting. In Fig. 11, we see that, instead of converging to the LD solution from one side of the ROC curve, the trace of the optimum operating points starts from the right side (larger P_f and P_d) of the LD solution, and then as the number of sensors increases, it passes through the LD solution and then reaches the leftmost point (smaller P_d and P_f). Then, the optimum operating point will return to the other side of, but at a closer distance to, the LD. This pattern repeats. This phenomenon comes from the fact that the value of the global fusion statistics can only take integer values. Within a certain range of N, the number of terms in the first summation in (25) will remain at a constant, so the increase of N within this range is accounted for by an increasing local threshold moving from right to left on the ROC curve in Fig. 11. As N increases beyond this range, the number of terms in the first summation in (25) will be increased by 1, bringing the local threshold down to the right side again.

To see this more clearly, consider a given number of sensors N, and the corresponding optimal local ROC operating point $(P_{f,l}(N), P_{d,l}(N))$ and fusion threshold $v^{\mathrm{MAP}}(N)$. It then follows that

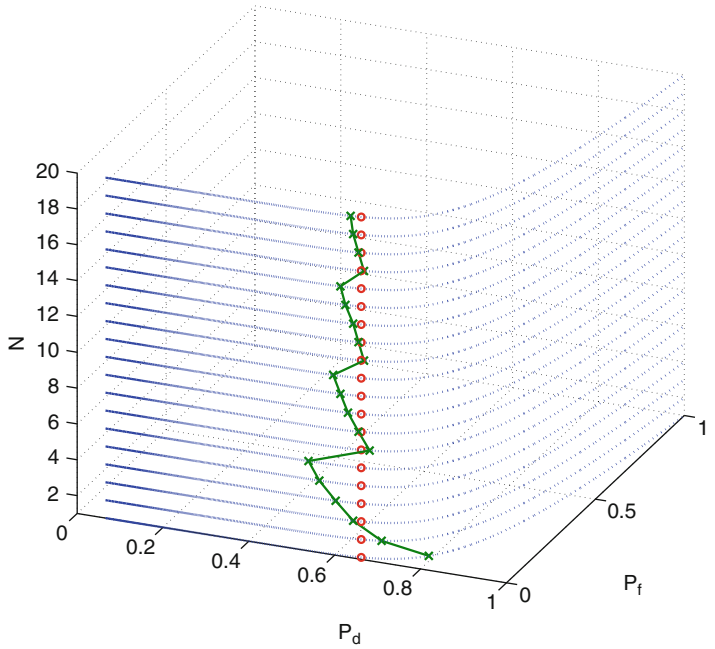

Fig. 11 The convergence of the optimal ROC operating points. SNR = 0 dB

$$
\begin{aligned}
P_{f,h}(N) &= \pi_0 \sum_{v=\lceil v^{\mathrm{MAP}}(N)\rceil}^{N} \binom{N}{v} \left(P_{f,l}(N)\right)^{v} \left(1-P_{f,l}(N)\right)^{N-v}, \\
P_{md,h}(N) &= \pi_1 \sum_{v=0}^{\lceil v^{\mathrm{MAP}}(N)\rceil-1} \binom{N}{v} \left(P_{d,l}(N)\right)^{v} \left(1-P_{d,l}(N)\right)^{N-v}.
\end{aligned}
\tag{36}
$$

When the number of sensors increases to $(N+1)$, we have

$$
\begin{aligned}
P_{f,h}(N+1) &= \pi_0 \sum_{v=\lceil v^{\mathrm{MAP}}(N+1)\rceil}^{N+1} \binom{N+1}{v} \left(P_{f,l}(N+1)\right)^{v} \left(1-P_{f,l}(N+1)\right)^{N+1-v}, \\
P_{md,h}(N+1) &= \pi_1 \sum_{v=0}^{\lceil v^{\mathrm{MAP}}(N+1)\rceil-1} \binom{N+1}{v} \left(P_{d,l}(N)\right)^{v} \left(1-P_{d,l}(N)\right)^{N+1-v}.
\end{aligned}
\tag{37}
$$

If $\lceil v^{\mathrm{MAP}}(N+1)\rceil = \lceil v^{\mathrm{MAP}}(N)\rceil$, $P_{f,h}(N+1)$ has one additional term compared with $P_{f,h}(N)$, whereas $P_{md,h}(N+1)$ has the same number of terms as $P_{md,h}(N)$. To minimize $(\pi_0 P_{f,h}(N+1) + \pi_1 P_{md,h}(N+1))$, one has to reduce $P_{f,l}(N)$ to

compensate for the extra term in $P_{f,h}(N+1)$. This leads to a higher local threshold and results in the leftward movement of the optimal ROC point in Fig. 11. On the other hand, if $\lceil v^{\text{MAP}}(N+1)\rceil = \lceil v^{\text{MAP}}(N)\rceil + 1$, there will be one additional term in $P_{md,h}(N+1)$, which by a similar argument will require a larger $P_{d,l}(N)$ and hence a lower local threshold. As a result, we have the abrupt changes of the ROC operating point when N increases from 6 to 7, from 11 to 12 and from 16 to 17 in Fig. 11.

Performance Comparisons

In this section, we compare the performance of the LD solution with previously proposed local detectors. In Fig. 12, we show the traces of their respective local detectors on the ROC curve as the SNR varies. Three of the ROC curves are illustrated, but operating points are computed for 20 different SNRs. We see that the LD solution has a lower operating point than other alternatives, and it remains very close to the exhaustive search solution for any SNR value. Among local detectors, the MMI detector is far superior to the others and nearly globally optimum for this example.

In Fig. 13, we plot the global average error probability at SNR $\gamma = 15$ dB as a function of the number of local sensors N, using various local decision rules. It can be observed that the average error probability decays exponentially with N as the large deviation analysis indicates. In addition, LD closely approximates the performance optimized by exhaustive search and actually does not require N to be very large to approach the optimal performance. Interestingly, from Figs. 10 and 13,

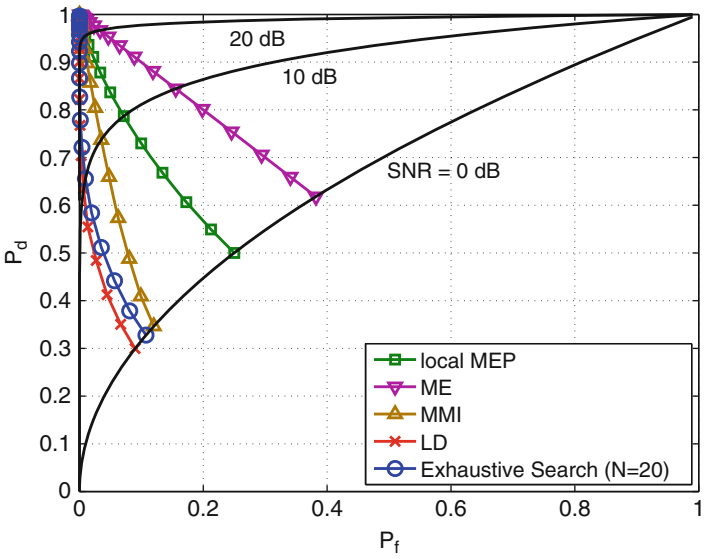

Fig. 12 The operating ROC trace under different local thresholds

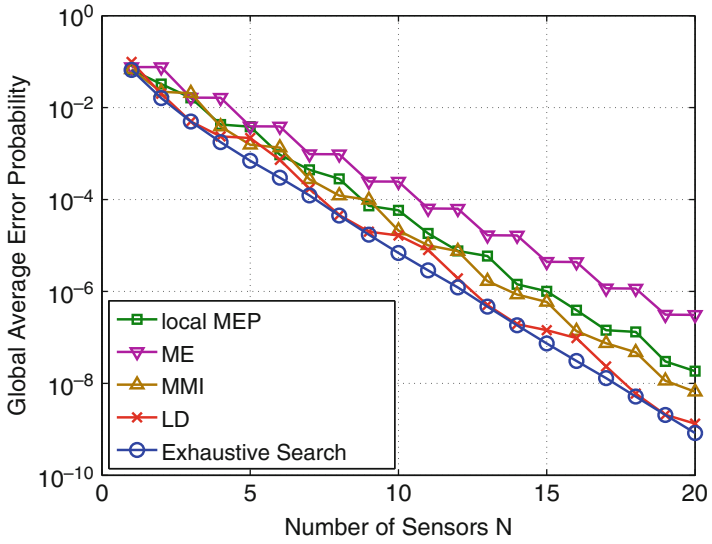

Fig. 13 Global average error probability under different local decision criteria at SNR $\gamma = 15$ dB as a function of the number of local sensing users N

we see that the exhaustive search solution with a fluctuating threshold results in a smooth performance curve, while LD with a constant threshold leads to a fluctuating performance curve, as our analysis in the preceding subsection implies.

Discussions

In this section, the method of LD is used to derive the operating point on local ROCs that minimizes the global error probability in cooperative sensing, asymptotically as the number of sensors grows large. The LD solution also establishes an important connection with Kullback-Leibler divergence and with a solution that maximizes mutual information at the local sensors. The LD solution is independent of the prior probabilities of the hypotheses and the total number of sensors, can be found by a simple line search, and is asymptotically minimax. It is also worth noting that the LD solution is applicable so long as a local (theoretical or empirical) ROC curve is known, regardless of whether or not it is the ROC curve for an NP detector.

Practical Designs: Case Studies

In this section, we will use two case studies to show how the fundamental limits in terms of diversity and error exponent we derived can guide practical designs in various system setups.

Sensing with Ternary Local Decisions: A Design from the Diversity Perspective

In section "Performance Scaling with SNR: Cooperative Diversity", the gain of cooperation is quantified in terms of the *cooperative diversities* for missed detection, false alarm, and average error probabilities. Using diversity as the performance metric, we optimally designed the sensing threshold strategies for cooperative sensing with both soft information fusion (SCoS) and hard information fusion or equivalently binary information fusion (BCoS). We found that while SCoS can achieve the maximum diversity, BCoS either loses half of the diversity or achieves the full diversity at the price of some signal-to-noise ratio (SNR) loss.

While the performance of SCoS is desirable, it is impractical since it requires infinite bandwidth for the communications between the sensing users and the fusion center. Intuitively, the performance gap between SCoS and BCoS results from the loss of information with the single-bit local decisions in BCoS. It should be possible to improve the performance by allowing the sensing users to provide more information. In this section, we investigate a cooperative sensing scheme with local ternary decisions. While developing the optimum strategies is complicated and mathematically intractable, our focus is to show that with local ternary decisions, it is possible to gain in terms of both diversity and SNR. This is in sharp contrary with the inevitable diversity-SNR trade-off when binary local decisions are used.

Compared with existing work on cooperative spectrum sensing with multi-threshold local decisions such as [3, 14–16] and [17], our design provides simple and closed-form expressions for both the local thresholds and fusion rule based on the metric of cooperative diversity. Moreover, we also obtain an explicit analytical expression for the performance gain, which has only been illustrated by simulations in the literature.

Binary Local Decision vs. Ternary Local Decision

Binary Local Decision (BD) and BCoS-k_0

For BCoS introduced in section "Performance Scaling with SNR: Cooperative Diversity", the secondary users make local binary decisions $D_i \in \{0, 1\}$ and a fusion center will collect all decisions and make a global decision. The local decisions are:

$$D_i = \begin{cases} 0 & \text{if } 0 \le \|r_i\|^2 < \theta_{l,B} \\ 1 & \text{if } \|r_i\|^2 > \theta_{l,B}. \end{cases} \tag{38}$$

If the local decision threshold is $\theta_{l,B} = k_0\theta^o$, where $\theta^o = (1 + \frac{1}{\gamma})\log(1 + \gamma)$ is the local optimum threshold. Then, as $\gamma \to +\infty$, $P_{f,l} = e^{-\theta_{l,B}} \approx \gamma^{-k_0}$, and $P_{md,l} = e^{\frac{\theta_{l,B}}{\gamma+1}} \approx k_0\gamma^{-1}$. With the NP detector $\sum_{i=1}^{N} D_i \underset{<H_0}{\overset{\ge H_1}{}} \theta_{f,B}$, the diversities are $d_{f,B} = k_0\theta_{f,B}$ and $d_{md,B} = N - \theta_{f,B} - 1$, where N is the total number of secondary users. To jointly optimize both diversities, the fusion threshold can

be selected as (It should be noticed that at the fusion center, $\sum D_i$'s can only take integer values. However, to simplify the notation, the integer restrictions are neglected without affecting the analysis.): $\arg\max_{\theta_{f,B}}(\min(k_0\theta_{f,B}, N-\theta_{f,B}-1)) = \frac{N+1}{k_0+1}$. The optimized diversities can be determined accordingly as $d_e = d_f = d_{md} = \frac{k_0}{k_0+1}(N+1)$.

This indicates that with larger k_0, BCoS-k_0 can achieve higher diversities by setting larger local threshold. However, in this case, the local decisions have missed detection probabilities $P_{md,B} \approx k_0\gamma^{-1}$ with $-10\log_{10}k_0$ SNR loss and smaller false alarm probabilities $P_{f,B} \approx \gamma^{-k_0}$. The larger missed detection probability P_{md} will dominate the overall average error probabilities performance P_e. Furthermore, instead of the diversity gain, the SNR losses for the missed detection probabilities will dominate the overall average error probability P_e at low-to-medium SNR.

Ternary Local Decision (TD)

The local decisions for TD are:

$$D_i = \begin{cases} 0 & \text{if } 0 \le \|r_i\|^2 < \theta_{l,1} \\ \spadesuit & \text{if } \theta_{l,1} \le \|r_i\|^2 \le \theta_{l,2} \\ 1 & \text{if } \|r_i\|^2 > \theta_{l,2}, \end{cases} \tag{39}$$

where $\theta_{l,2} > \theta_{l,1}$ are two local decision thresholds and $\spadesuit$ means "not sure." Then, the "0" or "1" decisions (Note that the sensor will remain silent when the local decision is $\spadesuit$.) are sent to the fusion center for the global decision $D \in \{0, 1\}$.

Under this local decisions, the conditional probabilities under each hypothesis are:

$$\begin{aligned} P(D_i = 0|H_0) &= \alpha_1 = 1 - e^{-\theta_{l,1}}, \\ P(D_i = \spadesuit|H_0) &= \alpha_2 = e^{-\theta_{l,1}} - e^{-\theta_{l,2}}, \\ P(D_i = 1|H_0) &= \alpha_3 = e^{-\theta_{l,2}}, \\ P(D_i = 0|H_1) &= \beta_1 = 1 - e^{-\frac{\theta_{l,1}}{\gamma+1}}, \\ P(D_i = \spadesuit|H_1) &= \beta_2 = e^{-\frac{\theta_{l,1}}{\gamma+1}} - e^{-\frac{\theta_{l,2}}{\gamma+1}}, \\ P(D_i = 1|H_1) &= \beta_3 = e^{-\frac{\theta_{l,2}}{\gamma+1}}. \end{aligned} \tag{40}$$

At the fusion center, D_is follow the trinomial distribution as:

$$\begin{aligned} P(D_1, D_2, \ldots, D_N|H_0) &= \alpha_1^{n_0}\alpha_2^{N-n_0-n_1}\alpha_3^{n_1}, \\ P(D_1, D_2, \ldots, D_N|H_1) &= \beta_1^{n_0}\beta_2^{N-n_0-n_1}\beta_3^{n_1}, \end{aligned} \tag{41}$$

where $n_0 = \{\text{the number of } D_i = 0\}$, $n_1 = \{\text{the number of } D_i = 1\}$, and N is the total number of cooperating local detectors. Accordingly, the sufficient statistics is (n_0, n_1). Denoting $\mathscr{R}_1$ as the set of (n_0, n_1) to make global decision $D = 1$ and $\mathscr{R}_0$ vice versa, we have:

$$\begin{aligned} P_f &= \sum_{(n_0,n_1)\in\mathscr{R}_1} P(n_0, n_1|H_0), \\ P_{md} &= \sum_{(n_0,n_1)\in\mathscr{R}_0} P(n_0, n_1|H_1). \end{aligned} \tag{42}$$

Based on Eqs. (40), (41), and (42), the optimum fusion rule can be obtained by jointly optimizing $P_e = \frac{1}{2}(P_f + P_{md})$ over $\theta_{l,1}$, $\theta_{l,2}$, and $\mathscr{R}_1$. However, not only that this is mathematically intractable, the solution also does not provide any clear insights on the diversity-SNR trade-off. As an alternative, we will first find the relationship between fusions with TD and BD and then develop the fusion rule for cooperative sensing with ternary local decisions (TCoS).

TCoS Fusion Rule

It is worth noting that at the fusion center, BD has a one-dimensional sufficient statistics set with $n_0 + n_1 = N$, while TD has a two-dimensional set with $n_0 + n_1 \leq N$. We find that when the fusion center with TD makes a global decision based on only one of n_0 and n_1, it is equivalent to the fusion with BD as the following:

Theorem 4. *For cooperative sensing based on local ternary decisions with thresholds $\theta_{l,1}$ and $\theta_{l,2}$:*

1. *If $\mathscr{R}_1 = \{(n_0, n_1) : n_1 \geq \theta_t\}$, this TD fusion is equivalent to BD fusion with local threshold $\theta_{l,B} = \theta_{l,2}$ and fusion threshold $\theta_{f,B} = \theta_t$;*
2. *If $\mathscr{R}_0 = \{(n_0, n_1) : n_0 \geq N - \theta_t + 1\}$, this TD fusion is equivalent to BD fusion with local threshold $\theta_{l,B} = \theta_{l,1}$ and fusion threshold $\theta_{f,B} = \theta_t$;*

Proof. See section "Appendix 4: Proof of Theorem 4".

With the relationship between BD and TD established in Theorem 4, we will next develop the fusion rule for TCoS. In particular, with local sensing thresholds $\theta_{l,1} = k_1\theta^o$ and $\theta_{l,2} = k_2\theta^o$ and $k_1 < k_2$, the corresponding sensing strategy is termed as TCoS-k_1-k_2.

Recall that from section "Binary Local Decision vs. Ternary Local Decision", BCoS-k_1 has a smaller diversity order. On the other hand, BCoS-k_2 achieves larger diversity but suffers from the SNR loss with the missed detection probability. Therefore, here we try to improve BCoS-k_2 missed detection performance by moving part of the decision region $\mathscr{R}_0$ to $\mathscr{R}_1$ while maintaining its larger false alarm and hence the overall diversity.

With TCoS-k_1-k_2, the probabilities for local decisions are $\alpha_1 \approx 1 - \gamma^{-k_1}, \alpha_2 \approx \gamma^{-k_1}, \alpha_3 \approx \gamma^{-k_2}$ and $\beta_1 \approx k_1\gamma^{-1}, \beta_2 \approx (k_2 - k_1)\gamma^{-1}, \beta_3 \approx 1 - k_2\gamma^{-1}$. Accordingly,

$$P(n_0, n_1|H_0) \approx \alpha_2^{N-n_0-n_1}\alpha_3^{n_1} \sim \gamma^{-(k_1N-k_1n_0+(k_2-k_1)n_1)}, \tag{43}$$

$$P(n_0, n_1|H_1) \approx \beta_1^{n_0}\beta_2^{N-n_0-n_1} \sim \gamma^{-(N-k_1)}. \tag{44}$$

The false alarm probability can be then calculated as:

$$\begin{aligned} P_f &= \sum_{(n_0,n_1)\in\mathscr{R}_1} P(n_0, n_1|H_0) \\ &\sim \sum_{(n_0,n_1)\in\mathscr{R}_1} \gamma^{-(k_1N-k_1n_0+(k_2-k_1)n_1)}. \end{aligned} \tag{45}$$

By Theorem 4, the decision region corresponding to BCoS-k_2 is $\mathscr{R}_1 = \{(n_0, n_1) : n_1 \geq \frac{N+1}{k_2+1}\}$, $\mathscr{R}_0 = \{(n_0, n_1) : n_1 < \frac{N+1}{k_2+1}\}$, and $d_{f,\text{BCoS}-k_2} = \frac{k_2}{k_2+1}(N+1)$. In order to reduce the missed detection probability which dominates the average error performance, we want to increase the decision region of $\mathscr{R}_1$ or equivalently decrease $\mathscr{R}_0$. At the same time, however, the false alarm diversity should be preserved. From Eq. (43), if $k_1N - k_1n_0 + (k_2 - k_1)n_1 \geq \frac{k_2}{k_2+1}(N+1)$, or equivalently $n_0 \leq (k_2 - k_1)n_1 + \frac{k_1(k_2+1)N-k_2(N+1)}{k_2+1}$, $P(n_0, n_1|H_0)$ will have a larger exponent of γ^{-1} than $d_{f,\text{BCoS}-k_2}$. Therefore, all points in $\mathscr{R}_0$ satisfying $n_0 \leq (k_2 - k_1)n_1 + \frac{k_1(k_2+1)N-k_2(N+1)}{k_2+1}$ can be moved into $\mathscr{R}_1$ without affecting the false alarm diversity according to (45). As a result, the boundary between $\mathscr{R}_1$ and $\mathscr{R}_0$ of the resultant fusion rule is the line $n_0 = (\frac{k_2}{k_1} - 1)n_1 + \frac{k_1(k_2+1)N-k_2(N+1)}{k_1(k_2+1)}$, which starts from $(n_0, n_1) = \left(\frac{k_1(k_2+1)N-k_2(N+1)}{k_1(k_2+1)}, 0\right)$ and ends at $(n_0, n_1) = \left(\frac{k_2N-1}{k_2+1}, \frac{N+1}{k_2+1}\right)$ where $\frac{k_2N-1}{k_2+1} + \frac{N+1}{k_2+1} = N$.

The decision region for TCoS-k_1-k_2 is illustrated in Fig. 14. The bold line is the boundary between $\mathscr{R}_0$ and $\mathscr{R}_1$ for TCoS-k_1-k_2, while the dashed line is the boundary corresponding to BCoS-k_2.

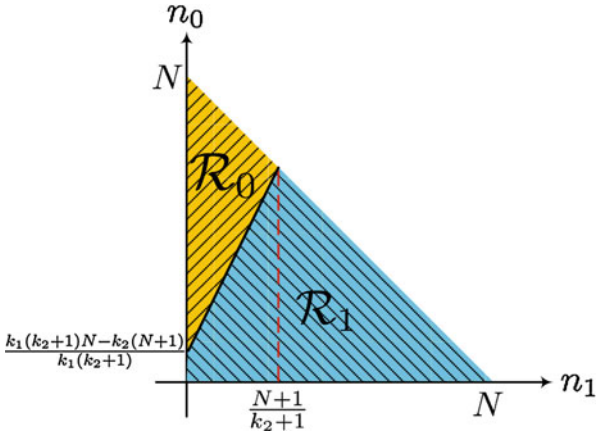

Fig. 14 The decision region for TCoS-k_1-k_2 with the points at the boundary belonging to $\mathscr{R}_1$

Compared with BCoS-k_2, TCoS-k_1-k_2 will provide the same overall diversities with $d_e = d_{md} = d_f = \frac{N+1}{k_2+1}$. Denoting

$$\Delta\mathscr{R} = \left\{(n_0, n_1) : 0 \le n_1 < \frac{N+1}{k_2+1}, 0 \le n_0 \le (k_2 - k_1)n_1 + \frac{k_1(k_2+1)N - k_2(N+1)}{k_2+1}\right\},$$

the difference between the missed detection probabilities of TCoS-k_1-k_2 and BCoS-k_2 is

$$\Delta P_{md} = P_{md,\text{TCoS}-k_1-k_2} - P_{md,\text{BCoS}-k_2} = -\sum_{\Delta\mathscr{R}} \beta_1^{n_0} \beta_2^{N-n_0-n_1} \beta_3^{n_1}, \tag{46}$$

and the difference between the false alarm probabilities of TCoS-k_1-k_2 and BCoS-k_2 is

$$\Delta P_f = P_{f,\text{TCoS}-k_1-k_2} - P_{f,\text{BCoS}-k_2} = \sum_{\Delta\mathscr{R}} \alpha_1^{n_0} \alpha_2^{N-n_0-n_1} \alpha_3^{n_1}. \tag{47}$$

It should be noticed that $\Delta P_e = P_{e,\text{TCoS}-k_1-k_2} - P_{e,\text{BCoS}-k_2} = \frac{1}{2}(\Delta P_{md} + \Delta P_f) < 0$. Therefore, we obtain overall performance gain over BCoS-k_2. This once again confirms that TCoS not only keeps the diversity gain that captures high SNR performance but also improves the SNR gain that characterizes the low to medium.

Simulations

Although it is possible to optimize k_1 for any given k_2 to obtain the maximum performance gain of TCoS by the analytical expressions given in section "TCoS Fusion Rule", the complexity is high. Therefore, we opt to verify and demonstrate the performance gain of TCoS over BCoS using some simple k_1 and k_2 values.

To illustrate the performance gain of TCoS-k_1-k_2 over both BCoS-k_1 and BCoS-k_2, we simulate TCoS-1-2 with 5 cooperating users and compare its performance with BCoS-1 and BCoS-2 in Fig. 15. We see that BCoS-2 exhibit a higher diversity than BCoS-1, but a worse performance at low SNR. Our proposed TCoS-1-2 not only retains the higher diversity of BCoS-2 but also has better performance at low SNR.

In Fig. 16, the performance of our proposed TCoS-1-2 is compared with the optimal TCoS with exhaustive search. It can be seen that our TCoS-1-2 only sacrifices a little performance ($\approx$1.5 dB) in exchange for the low-complexity closed-form local and global decision rules.

In addition, we know that BCoS-N achieves the maximum diversity but suffers from considerable SNR loss. Here, we compare the performance of TCoS-2.5-5

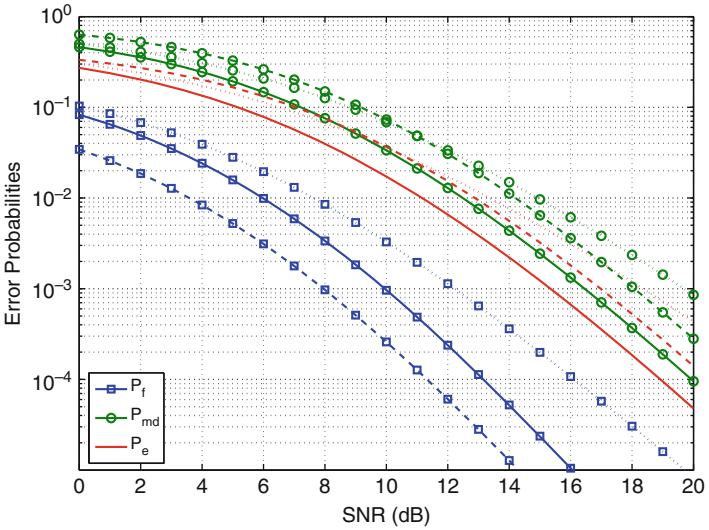

Fig. 15 TCoS-1-2 (*solid*) vs. BCoS-1 (*dotted*) and BCoS-2 (*dashed*) with $N = 5$

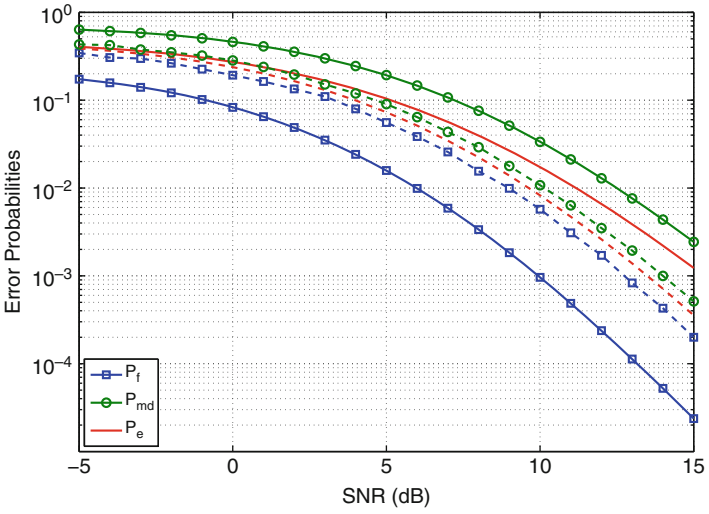

Fig. 16 TCoS-1-2 (*solid*) vs. optimal TCoS by exhaustive search (*dashed*) with $N = 5$

and BCoS-5 in Fig. 17. It can be observed that TCoS-2.5-5 also achieves the same full diversity ($d_e = 5$), but has about 2dB SNR gain. Together with Fig. 15, it is confirmed that the overall SNR gain is obtained without losing any false alarm diversity.

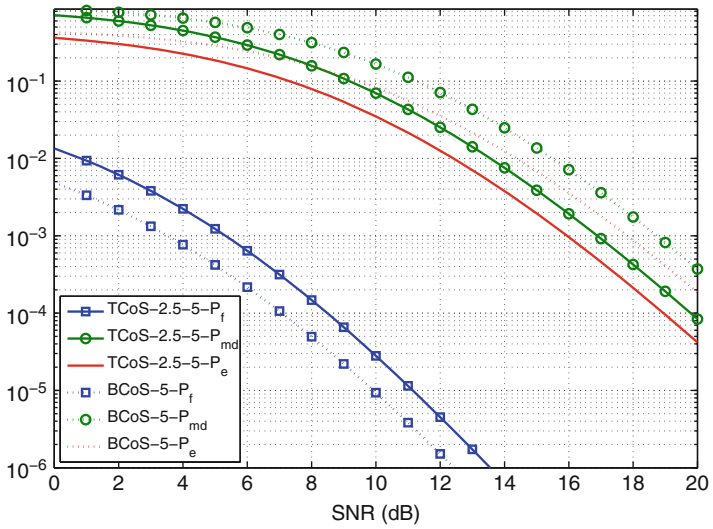

Fig. 17 TCoS-2.5-5 vs. BCoS-5 with $N = 5$

Discussions

In this case study, we introduced cooperative sensing with ternary local decisions (TCoS) to improve upon binary hard decisions (BCoS) by gaining SNR while maintaining the same diversity. The link between the fusion with BD and TD has been established and further used to determine the fusion rule for TCoS. The algorithm developed in this section provides simple and closed-form expressions for both the local decision thresholds and the fusion rule. The performance gain was also derived analytically. Furthermore, simulations confirmed that, as the middle ground between BCoS and SCoS, TCoS provides a practical yet effective solution for the inevitable diversity-SNR trade-off encountered by BCoS.

Sensing with Joint Diversity and Error Exponent Considerations

As discussed in section "Performance Scaling with SNR: Cooperative Diversity", for cooperative spectrum sensing, when the number of cooperative sensing users N is fixed, the error probability decreases with SNR γ at a certain rate. Generally speaking, when the number of cooperating sensing users N increases, the decreasing rate of error probabilities in λ will increase, thanks to more extensive sensing cooperation. To quantify the gain of multiple sensors, the diversity order is defined as

$$d(N) = -\lim_{\gamma \to +\infty} \frac{\log P_{e,h}(N, \gamma)}{\log \gamma}, \tag{48}$$

where $P_{e,h}$ is the global average error probability for the hard/binary information fusion. By definition, the diversity notion comes from the asymptotic performance in terms of the signal model parameter γ. It is shown in section "Performance Scaling with SNR: Cooperative Diversity" that the maximum diversity order for fusion with N sensors is N. It is interesting to see whether the large deviation solution proposed in section "Performance Scaling with the Number of Sensing Users: Error Exponent" also achieves the maximum diversity.

Diversity Analysis of the LD Solution for Spectrum Sensing

To evaluate the diversity of the LD solution which is the asymptotic performance in terms of the average SNR γ, we take $\gamma \to +\infty$. In this case, the local probabilities will have $P_{f,l} \to 0$ and $P_{d,l} \to 1$. Then, the first term within the KL divergence in (34) is

$$\frac{\log \frac{1-P_{d,l}}{1-P_{f,l}}}{\log \frac{P_{f,l}}{P_{d,l}} + \log \frac{1-P_{d,l}}{1-P_{f,l}}} \approx \frac{\log(1-P_{d,l})}{\log P_{f,l} + \log(1-P_{d,l})} \triangleq \theta^{\mathrm{LD}}. \tag{49}$$

As such, the objective function in (35) can be expanded as

$$\begin{aligned} D_{\mathrm{KL}}(\theta^{\mathrm{LD}} || P_{f,l}) &= \theta^{\mathrm{LD}} \log \frac{\theta^{\mathrm{LD}}}{P_{f,l}} + (1-\theta^{\mathrm{LD}}) \log \frac{1-\theta^{\mathrm{LD}}}{1-P_{f,l}} \\ &= \theta^{\mathrm{LD}} \log \theta^{\mathrm{LD}} + (1-\theta^{\mathrm{LD}}) \log(1-\theta^{\mathrm{LD}}) \theta^{\mathrm{LD}} \log P_{f,l} - (1-\theta^{\mathrm{LD}}) \log(1-P_{f,l}). \end{aligned}$$

In the four terms of the resulting expansion, when $P_{f,l} \to 0$, we have

$$\begin{aligned} &0 \le \theta^{\mathrm{LD}} \log \theta^{\mathrm{LD}} + (1-\theta^{\mathrm{LD}}) \log(1-\theta^{\mathrm{LD}}) \le 1 \ll E(\gamma), \\ &(1-\theta^{\mathrm{LD}}) \log(1-P_{f,l}) \approx 0. \end{aligned} \tag{50}$$

As a result, the error exponent

$$E(P_{f,l}, P_{d,l}) \approx \max_{(P_{f,l}, P_{d,l})} (-\theta^{\mathrm{LD}} \log P_{f,l}) = \max_{(P_{f,l}, P_{d,l})} \frac{-\log P_{f,l} \log(1-P_{d,l})}{\log P_{f,l} + \log(1-P_{d,l})}, \tag{51}$$

where $P_{f,l}$ and $P_{d,l}$ are

$$\begin{aligned} P_{f,l} &= e^{-\theta_l}, \\ P_{d,l} &= e^{-\frac{\theta_l}{\gamma+1}}, \end{aligned} \tag{52}$$

according to the signal model given in (1) and θ_l is the local decision threshold in (2).

When $\gamma \to +\infty$, $P_{d,l} = e^{-\frac{\theta_l}{\gamma+1}} \approx 1 - \frac{\theta_l}{\gamma+1}$, then

$$E(P_{f,l}, P_{d,l}) \approx \frac{-\log P_{f,l} \log(1 - P_{d,l})}{\log P_{f,l} + \log(1 - P_{d,l})} = \frac{-(-\theta_l) \log \frac{\theta_l}{\gamma+1}}{(-\theta_l) + \log \frac{\theta_l}{\gamma+1}}. \tag{53}$$

Setting $\frac{dE(P_{f,l}, P_{d,l})}{d\theta_l} = 0$, we can see that the large deviation local threshold satisfies

$$\log \theta_l + \theta_l^{\frac{1}{2}} = \log(\gamma + 1). \tag{54}$$

When $\gamma \to +\infty$, we have $\theta_l \to +\infty$, and therefore $\log \theta_l \ll \theta_l^{\frac{1}{2}}$. Ignoring the term $\log \theta_l$ in (54), we have an approximated optimal threshold in closed form:

$$\tilde{\theta}_l^{\mathrm{LD}} \approx (\log(\gamma + 1))^2 . \tag{55}$$

With this large deviation solution $\tilde{\theta}_l^{\mathrm{LD}}$ and by (53), the error exponent becomes

$$\tilde{E}^{\mathrm{LD}}(\gamma) \approx \log(\gamma + 1). \tag{56}$$

An illustration of the resultant error exponents under the threshold achieved by (35), (54) and (55) is given in Fig. 18. It could be observed that the closed-form expression

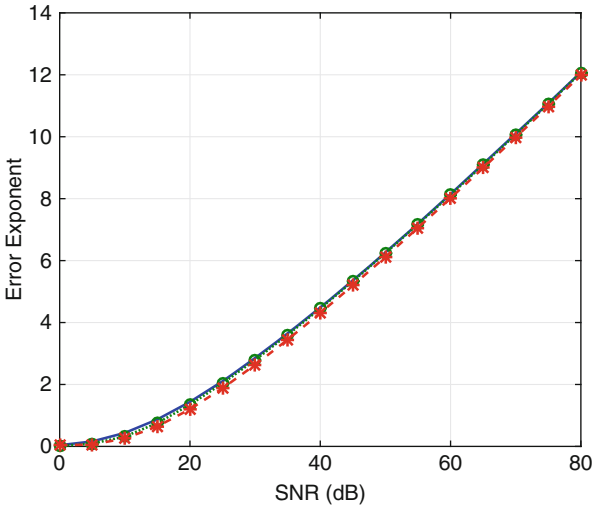

Fig. 18 The error exponent $E(\gamma)$ for cooperative spectrum sensing using different thresholds: (1) *solid curve*, by solving (35); (2) *dotted curve* with *circles*, by solving (54); and (3) *dashed curve* with *stars*: by using the closed-form expression (55)

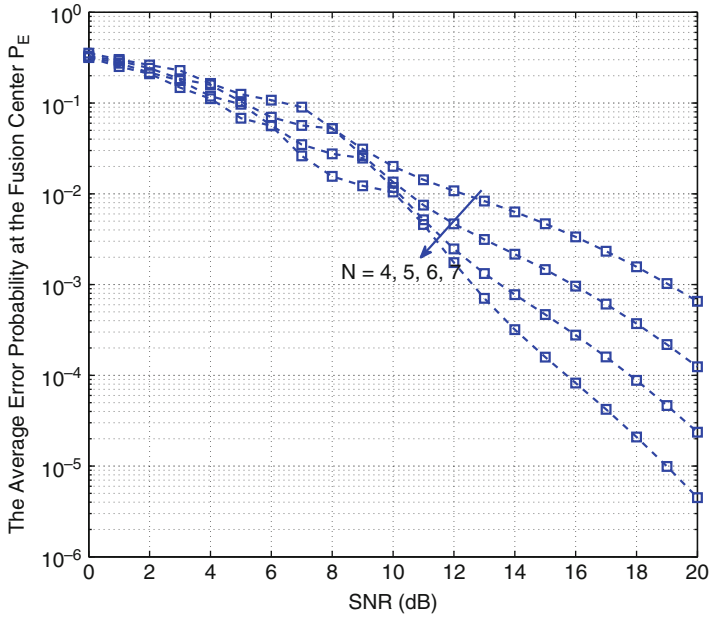

Fig. 19 The LD solution achieves full diversity

can achieve the error exponent of the optimum large deviation solution given in (35) very well.

To obtain the diversity of the resultant cooperative sensing strategy, by the definition of the error exponent, as $N \to +\infty$,

$$\begin{aligned} d(N) &= -\lim_{\lambda \to +\infty} \frac{\log P_{e,h}(N,\gamma)}{\log \gamma} = -\lim_{\gamma \to +\infty} \frac{\log(e^{-NE(\gamma)})}{\log \gamma} \\ &= -\lim_{\gamma \to +\infty} \frac{-N \log(\gamma+1)}{\log \gamma} = N. \end{aligned} \tag{57}$$

That is, the proposed large deviation solution can achieve the maximum diversity gain. An illustration of the average error probability vs. N is shown in Fig. 19.

Discussions

From our analysis, we see that although in general the LD solution requires a one-dimensional search, at high SNR we find a closed-form analytical solution for large N, for the cooperative spectrum sensing problem. It should be noticed that this closed-form solution will only be expected to achieve the optimal performance when both the SNR γ and the number of cooperative users N approaches infinity. For cooperative spectrum sensing with fixed finite number of users, the strategies provides in section "Performance Scaling with SNR: Cooperative Diversity" might

still be better alternatives. However, another unique advantage of the closed-form strategy given by joint considerations of diversity and error exponent is that the resultant solution is entirely local and independent of the total number of sensing users in cooperations. Therefore, it can be readily applied in the cases where the number of sensing users is unknown and/or changing over time.

Summary

In this chapter, we have quantified the fundamental limits of cooperative spectrum sensing performance (i) by diversity when the signal parameter SNR approaches infinity and (ii) by error exponent when the number of cooperative users approaches infinity. These fundamental limits can effectively guide practical designs under different system setups. In particular, with the notion of diversity, we have seen how cooperative spectrum sensing with ternary local decisions can be designed to approach the performance with soft information fusion. On the other hand, combining the LD solution with the notion of diversity in our spectrum sensing problem, we have obtained a closed-form expression for the optimal local threshold when both the SNR and the number of cooperative users approaches infinity.

Appendices

Appendix 1: Proof of Theorem 2

With $\theta_s = N(1+\frac{1}{\gamma})\log(\gamma+1)$, as $\gamma \to +\infty$, $e^{-\theta_s} = (1+\gamma)^{-N(1+\frac{1}{\gamma})} \sim (\gamma+1)^{-N}$ and $\sum_{i=0}^{N-1} \theta_s^i/i! = \sum_{i=0}^{N-1} N^i(1+\frac{1}{\gamma})^i(\log(\gamma+1))^i/i! \sim N^{N-1}(\log(\gamma+1))^{N-1}/(N-1)!$. Thus, according to (14), $P_{f,s} \sim \frac{N^{N-1}}{(N-1)!}(\log(\gamma+1))^{N-1}(\gamma+1)^{-N}$ and

$$d_{f,s} = -\lim_{\gamma\to+\infty} \frac{\log P_{f,s}}{\log \gamma} = N.$$

Also, with θ_s defined above, as $\gamma \to +\infty$, $e^{-\theta_s/(\gamma+1)} = e^{-\frac{N}{\gamma}\log(\gamma+1)} \to 1$ and $\sum_{i=N}^{+\infty} \theta_s^i/(i!(\gamma+1)^i) = \sum_{i=N}^{+\infty} N^i(1+\frac{1}{\gamma})^i(\log(\gamma+1))^i/(i!(\gamma+1)^i) \sim N^N(\log(\gamma+1))^N(\gamma+1)^{-N}/N!$. Thus, according to (15), $P_{md,s} \sim \frac{N^N}{N!}(\log(\gamma+1))^N(\gamma+1)^{-N}$ and

$$d_{md,s} = -\lim_{\gamma\to+\infty} \frac{\log P_{md,s}}{\log \gamma} = N.$$

Accordingly, $d_{e,s} = \min(d_{f,s}, d_{md,s}) = N$.

Appendix 2: Proof of Theorem 3

From (18) and (19),

$$P_{f,h} = P(\lambda_h \geq \theta_h | H_0) = \sum_{i=\theta_h}^{N} \binom{N}{i} P_{f,l}^{i} (1 - P_{f,l})^{N-i}.$$

The false alarm diversity at the local sensing decision is $d_{f,l}$, so as $\gamma \to +\infty$, $P_{f,l} \sim (\gamma+1)^{-d_{f,l}}$, $1 - P_{f,l} \to 1$; thus $P_{f,l}^{i}(1 - P_{f,l})^{N-i} \sim (\gamma+1)^{-i d_{f,l}}$. In the summation of $P_{f,h}$, as $\gamma \to +\infty$, the term with lowest power order of $(\gamma+1)^{-1}$ will dominate; thus $P_{f,h} \sim \binom{N}{\theta_h}(\gamma+1)^{-\theta_h d_{f,l}}$, and the false alarm diversity order is

$$d_{f,h} = -\lim_{\gamma \to +\infty} \frac{\log P_{f,h}}{\log \gamma} = \theta_h d_{f,l}, \quad \theta_h = 1, 2, \ldots, N.$$

From (18) and (19),

$$P_{md,h} = P(\lambda_h < \theta_h | H_1) = \sum_{i=0}^{\theta_h - 1} \binom{N}{i} (1 - P_{md,l})^{i} P_{md,l}^{N-i}.$$

From the same argument, the missed detection diversity order is

$$d_{md,h} = -\lim_{\gamma \to +\infty} \frac{\log P_{md,h}}{\log \gamma} = (N - \theta_h + 1) d_{md,l}, \ \theta_h = 1, 2, \ldots, N.$$

Appendix 3: Proof of Corollary 3

From Corollary 1, we know that the local threshold can be chosen as $\theta_l = d_0 \theta^o$ ($d_0 > 0$). In this case, $d_{f,l} = d_0$ and $d_{md,l} = 1$. By Theorem 3, if the hard decision threshold is θ_h ($\theta_h \in \{1, 2, \ldots, N\}$), the average error diversity is $d_{e,h} = \min(\theta_h d_0, N - \theta_h + 1)$. To maximize $d_{e,h}$, we need to maximize both $\theta_h d_0$ and $(N - \theta_h + 1)$ simultaneously. By maximizing the latter, we obtain $\theta_h = 1$. Then $d_{e,h} = \min(d_0, N)$. Thus, as long as $d_0 \geq N$, we obtain the maximum diversity $d_{e,h} = N$. However, as stated in Corollary 1, higher d_0 will cause higher SNR loss for the missed detection performance. Thus, we choose $d_0 = N$ to minimize the SNR loss for the missed detection performance while achieving the maximum average error diversity.

Appendix 4: Proof of Theorem 4

If $\mathscr{R}_1 = \{(n_0, n_1) : n_1 \geq \theta_t\}$, then:

$$P_{f,t} = \sum_{n_1=\theta_t}^{N} \sum_{n_0=0}^{N-n_1} \frac{N!}{n_0!(N-n_0-n_1)!n_1!} \alpha_1^{n_0} \alpha_2^{N-n_0-n_1} \alpha_3^{n_1}$$
$$= \sum_{n_1=\theta_t}^{N} \frac{N}{n_1!(N-n_1)!} (1-\alpha_3)^{N-n_1} \alpha_3^{n_1},$$

and

$$P_{md,t} = \sum_{n_1=0}^{\theta_t-1} \sum_{n_0=0}^{N-n_1} \frac{N!}{n_0!(N-n_0-n_1)!n_1!} \beta_1^{n_0} \beta_2^{N-n_0-n_1} \beta_3^{n_1}$$
$$= \sum_{n_1=0}^{\theta_t-1} \frac{N}{n_1!(N-n_1)!} (1-\beta_3)^{N-n_1} \beta_3^{n_1}.$$

This is equivalent to BT with $\theta_{l,B} = \theta_{l,2}$ and $\theta_{f,B} = \theta_t$.

If $\mathscr{R}_0 = \{(n_0, n_1) : n_0 \geq N + 1 - \theta_t\}$, then:

$$P_{f,t} = \sum_{n_0=0}^{N-\theta_t+1} \sum_{n_1=0}^{N-n_0} \frac{N!}{n_0!(N-n_0-n_1)!n_1!} \alpha_1^{n_0} \alpha_2^{N-n_0-n_1} \alpha_3^{n_1}$$
$$= \sum_{n_0=0}^{N-\theta_t+1} \frac{N}{n_0!(N-n_0)!} \alpha_1^{n_0} (1-\alpha_1)^{N-n_0},$$

and

$$P_{md,t} = \sum_{n_0=N-\theta_t+1}^{N} \sum_{n_1=0}^{N-n_1} \frac{N!}{n_0!(N-n_0-n_1)!n_1!} \beta_1^{n_0} \beta_2^{N-n_0-n_1} \beta_3^{n_1}$$
$$= \sum_{n_0=N-\theta_t+1}^{N} \frac{N}{n_0!(N-n_0)!} \beta_1^{n_0} (1-\beta_1)^{N-n_0}.$$

This is equivalent to BT with $\theta_{l,B} = \theta_{l,1}$ and $\theta_{f,B} = \theta_t$.

Abstract

Enabling cognitive radio (CR) requires revisiting the traditional task of spectrum sensing with specific and demanding requirements in terms of detection performance, real-time processing, and robustness to noise. Unfortunately, conventional spectrum sensing methods do not satisfy these demands. In particular, the Nyquist rate of signals typically sensed by a CR is prohibitively high so that sampling at this rate necessitates sophisticated and expensive analog to digital converters, which lead to a torrent of samples. Over the past few years, several sampling methods have been proposed that exploit signals' a priori known structure to sample them below Nyquist. In this chapter, we review some of these techniques and tie them to the task of spectrum sensing for CRs. We then show how other spectrum sensing challenges can be tackled in the sub-Nyquist regime. First, to cope with low signal-to-noise ratios, spectrum sensing may be based on second-order statistics recovered from the low rate samples. In particular, cyclostationary detection allows to differentiate between communication signals and stationary noise. Next, CR networks, that perform collaborative low rate spectrum sensing, have been proposed to overcome fading and shadowing channel effects. Last, to enhance CR efficiency, we present joint spectrum sensing and direction of arrival estimation methods from sub-Nyquist samples. These allow to map the temporarily vacant bands both in terms of frequency and space. Throughout this chapter, we highlight the relation between theoretical algorithms and results and their practical implementation. We show hardware simulations performed on a prototype built with off-the-shelf devices, demonstrating the feasibility of sub-Nyquist spectrum sensing in the context of CR.

Introduction

In order to increase the chance of finding an unoccupied spectral band, cognitive radios (CRs) have to sense a wide band of spectrum. Nyquist rates of wideband signals are high and can even exceed today's best analog to digital converters (ADCs) front-end bandwidths. In addition, such high sampling rates generate a large number of samples to process, affecting speed and power consumption. To overcome the rate bottleneck, several sampling methods have been proposed that leverage the a priori known received signal's structure, enabling sampling rate reduction [1,2]. These include the random demodulator [3], multi-rate sampling [4], multicoset sampling, and the modulated wideband converter (MWC) [5–8].

The CR then performs spectrum sensing on the acquired samples to detect the presence of primary users' (PUs) transmissions. The simplest and most common spectrum sensing approach is energy detection [9], which does not require any a priori knowledge on the input signal. Unfortunately, energy detection is very sensitive to noise and performs poorly in low signal-to-noise ratio (SNR) regimes. This becomes even more critical in sub-Nyquist regimes since the sensitivity of energy detection is amplified due to aliasing of the noise [10]. Therefore, this

scheme fails to meet CR performance requirements in low SNRs. In contrast, matched filter (MF) detection [11, 12], which correlates a known waveform with the input signal to detect the presence of a transmission, is the optimal linear filter for maximizing SNR in the presence of additive stochastic noise. However, this technique requires perfect knowledge of the potential received transmission. When no a priori knowledge is assumed on the received signals' waveform, MF is difficult to implement. A compromise between both methods is cyclostationary detection [13, 14]. This strategy is more robust to noise than energy detection but at the same time only assumes that the signal of interest exhibits cyclostationarity, which is a typical characteristic of communication signals. Consequently, cyclostationary detection is a natural candidate for spectrum sensing from sub-Nyquist samples in low SNRs.

Besides noise, the task of spectrum sensing for CRs is further complicated due to path loss, fading, and shadowing [15]. These phenomena are due to the signal's propagation that can be affected by obstacles and multipath and result in the attenuation of the signal's power. To overcome these practical issues, collaborative CR networks have been considered, where different users share their sensing results and cooperatively decide on the licensed spectrum occupancy [15–17]. Cooperative spectrum sensing can be classified into three categories based on the way the data is shared by the CRs in the network: centralized, distributed, and relay-assisted. In each of these settings, two options of data fusion arise: decision fusion, or hard decision, where the CRs only report their binary local decisions, and measurement fusion, or soft decision, where they share their samples [15]. Cooperation has been shown to improve detection performance and relax sensitivity requirements by exploiting spatial diversity.

Finally, CRs may require, or at least benefit from, joint spectrum sensing and direction of arrival (DOA) estimation. DOA recovery can enhance CR performance by allowing exploitation of vacant bands in space in addition to the frequency domain. For example, a spectral band occupied by a PU situated in a certain direction with respect to the CR may be used by the latter for transmission to the opposite direction, where receivers do not sense the PU's signal. In order to estimate jointly the carrier frequencies and DOAs of the received transmissions, arrays of sensors have been considered. DOA recovery techniques, such as MUSIC [18, 19], ESPRIT [20], or compressed sensing (CS) [21] techniques, may then be adapted to the joint carrier and DOA estimation problem both in Nyquist and sub-Nyquist regimes.

This chapter focuses on the spectrum sensing challenges for CR outlined above. We first review sub-Nyquist sampling methods for multiband signals and then consider different aspects of spectrum sensing performed on low rate samples, including cyclostationary detection, collaborative spectrum sensing, and joint carrier frequency and DOA estimation. Our emphasis is on practical low rate acquisition schemes and tailored recovery that can be implemented in real CR settings. The approach adopted here focuses on the analog to digital interface of CRs. In particular, we are concerned with compressive spectrum sensing, including the application of CS to analog signals. Modeling the analog to digital conversion

allows demonstrating the realization of the theoretical concepts on hardware prototypes. We focus on the implementation of one sampling scheme reviewed here, the MWC, and show how the same low rate samples can be used in the different extensions of spectrum sensing described above.

Sub-Nyquist Sampling for CR

CR receivers sense signals composed of several transmissions with unknown support, spread over a wide spectrum. Such sparse wideband signals belong to the so-called multiband model [6, 7]. An example of a multiband signal $x(t)$ with K bands is illustrated in Fig. 1. The bandwidth of each band is no greater than B and is centered around unknown carrier frequencies $|f_i| \leq f_{\text{Nyq}}/2$, where f_{Nyq} denotes the signals' Nyquist rate and i indexes the transmissions. Note that, for real-valued signals, K is an even integer due to spectral conjugate symmetry and the number of transmissions is $N_{\text{sig}} = K/2$.

When the frequency support of $x(t)$ is known, classic sampling methods such as demodulation, undersampling ADCs, and interleaved ADCs (see [1, 2] and references therein) may be used to reduce the sampling rate below Nyquist. Here, since the frequency location of the transmissions are unknown, classic processing first samples $x(t)$ at its Nyquist rate f_{Nyq}, which may be prohibitively high. To overcome the sampling rate bottleneck, several blind sub-Nyquist sampling and recovery schemes have been proposed that exploit the signal's structure and in particular its sparsity in the frequency domain, but do not require knowledge of the carrier frequencies. It has been shown in [6] that the minimal sampling rate for perfect blind recovery in multiband settings is twice the Landau rate [22], that is twice the occupied bandwidth. This rate can be orders of magnitude lower than Nyquist. In the remainder of this section, we survey several sub-Nyquist methods that theoretically achieve this minimal sampling rate.

Multitone Model and the Random Demodulator

Tropp et al. [3] consider a discrete multitone model for multiband signals and suggest sampling using the random demodulator, depicted in Fig. 2. Multitone functions are composed of K active tones spread over a bandwidth W, such that

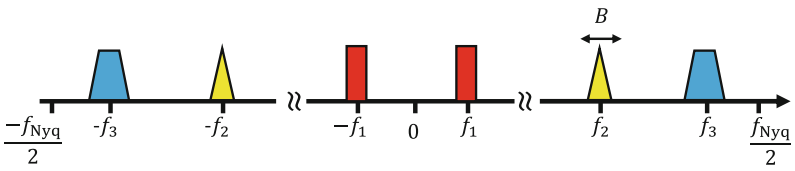

Fig. 1 Multiband model with $K = 6$ bands. Each band does not exceed the bandwidth B and is modulated by an unknown carrier frequency $|f_i| \leq f_{\text{Nyq}}/2$, for $i = 1, 2, 3$

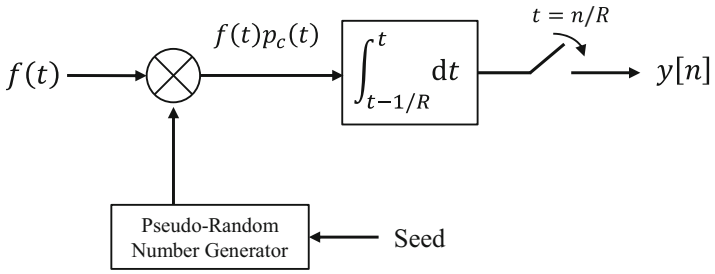

Fig. 2 Block diagram for the random demodulator, including a random number generator, a mixer, an accumulator, and a sampler [3]

$$f(t) = \sum_{\omega \in \Omega} b_\omega \mathrm{e}^{-2\pi i \omega t}, \quad t \in [0, 1). \tag{1}$$

Here, Ω is a set of K normalized frequencies, or tones, that satisfies

$$\Omega \subset \{0, \pm 1, \pm 2, \ldots, \pm(W/2 - 1), \pm W/2\}, \tag{2}$$

and b_ω, for $\omega \in \Omega$, are a set of complex-valued amplitudes. The number of active tones K is assumed to be much smaller than the bandwidth W. The goal is to recover both the tones ω and the corresponding amplitudes b_ω.

To sample the signal $f(t)$, it is first modulated by a high rate sequence $p_c(t)$ created by a pseudorandom number generator. It is then integrated and sampled at a low rate, as shown in Fig. 2. The random sequence used for modulation is a square wave, which alternates between the levels ± 1 with equal probability. The K tones present in $f(t)$ are thus aliased by the pseudorandom sequence. The resulting modulated signal $y(t) = f(t)p_c(t)$ is integrated over a period $1/R$ and sampled at the low rate R. This integrate-and-dump approach results in the following samples

$$y_m = R \int_{m/R}^{(m+1)/R} y(t)\mathrm{d}t, \quad m = 0, 1, \ldots, R - 1. \tag{3}$$

The samples y_m acquired by the random demodulator can be written as a linear combination of the $W \times 1$ sparse amplitude vector $\mathbf{b}$ that contains the coefficients b_ω at the corresponding locations ω [3]. In matrix form, we write

$$\mathbf{y} = \mathbf{A}\mathbf{b}, \tag{4}$$

where $\mathbf{y}$ is the vector of size R that contains the samples y_m and $\mathbf{A}$ is the known sampling matrix that describes the overall action of the system on the vector of amplitudes $\mathbf{b}$, namely, modulation and filtering (see [3] for more details). Capitalizing on the sparsity of the vector $\mathbf{b}$, the amplitudes b_ω and their respective locations ω can be recovered from the low rate samples $\mathbf{y}$ using CS [21] techniques,

in turn allowing for the recovery of $f(t)$. CS provides a framework for simultaneous sensing and compression of finite-dimensional vectors, which relies on linear dimensionality reduction. It provides both recovery conditions and algorithms to reconstruct sparse vectors from low-dimensional measurement vectors, represented as linear combinations of the former. Here, the minimal required number of samples R for perfect recovery of $f(t)$ in noiseless settings is $2K$ [21].

The random demodulator is one of the pioneer attempts to extend the inherently discrete and finite CS theory to analog signals. However, truly analog signals, as those we consider here, require a prohibitively large number of harmonics to approximate them well within the discrete model. When attempting to approximate signals such as those from the multiband model, the number of tones W is on the order of the Nyquist rate, and the number of samples R is a multiple of KB. This in turn renders the reconstruction computationally prohibitive and very sensitive to the grid choice (see [1] for a detailed analysis). Furthermore, the time domain approach precludes processing at a low rate, even for multitone inputs since interpolation to the Nyquist rate is an essential ingredient of signal reconstruction. In terms of hardware and practical implementation, the random demodulator requires accurate modulation by a periodic square mixing sequence and accurate integration, which may be challenging when using analog signal generators, mixers, and filters.

In contrast to the random demodulator, which adopts a discrete multitone model, the rest of the approaches we focus on treat the analog multiband model, illustrated in Fig. 1, which is of interest to us in the context of CR.

Multi-rate Sampling

An alternative sampling approach is based on the synchronous multi-rate sampling (SMRS) [4] scheme, which has been proposed in the context of electro-optical systems to undersample multiband signals. The SMRS samples the input signal at P different sampling rates F_i, each of which is an integer multiple of a basic sampling rate Δf. This procedure aliases the signal with different aliasing intervals, as illustrated in Fig. 3. The Fourier transform of the undersampled signals is then related to the original signal through an underdetermined system of linear equations,

$$\mathbf{z}(f) = \mathbf{Q}\mathbf{x}(f). \tag{5}$$

Here, $\mathbf{x}(f)$ contains frequency slices of size Δf of the original signal $x(t)$ and $\mathbf{z}(f)$ is composed of the Fourier transform of the sampled signal. Each channel contributes $M_i = F_i/\Delta f$ equations to the system (5), which concatenates the observation vector of all the channels. The measurement matrix $\mathbf{Q}$ has exactly P nonzero elements in every column that correspond to the locations of the spectral replica in each channel baseband $[0, F_i]$.

This approach assumes that either the signal or the sampling time window is finite. The continuous variable f is then discretized to a frequency resolution of Δf. Since $x(t)$ is sparse in the frequency domain, the vector $\mathbf{x}(f)$ is sparse and

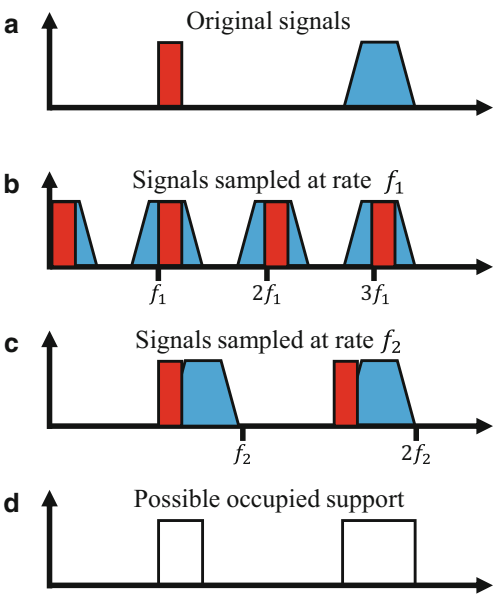

Fig. 3 Action of the SMRS on a multiband signal: (**a**) the input signal with $K = 2$ bands, (**b**) signals sampled at rate F_1 in channel 1, (**c**) signals sampled at rate F_2 in channel 2, and (**d**) possible support which is the intersection of the supports in channel 1 and 2 [4]

can be recovered from (5) using CS techniques, for each discrete frequency f. An alternative recovery method, referred to as the reduction procedure, consists of detecting baseband frequencies in which there is no signal, by observing the samples. These frequencies are assumed to account for the absence of signals of interest in all the frequencies that are down-converted to that baseband frequency. This allows to reduce the number of sampling channels. This assumption does not hold in the case where two or more frequency components cancel each other due to aliasing, which happens with probability zero. The procedure is illustrated in Fig. 3. Once the corresponding components are eliminated from (5), the reduced system can be inverted using the Moore-Penrose pseudo-inverse to recover $\mathbf{x}(f)$.

There are several drawbacks to the SMRS that limit its performance and potential implementation. First, the discretization process affects the SNR since some of the samples are thrown out. Furthermore, spectral components down-converted to off the grid frequencies are missed. In addition, the first recovery approach requires a large number of sampling channels, proportional to the number of active bands K, whereas the reduction procedure does not ensure a unique solution and the inversion problem is ill-posed in many cases. Finally, in practice, synchronization between channels sampling at different rates is challenging. Moreover, this scheme samples wideband signals using low rate samplers. Practical ADCs introduce an inherent bandwidth limitation, modeled by an anti-aliasing low-pass filter (LPF) with cutoff frequency determined by the sampling rate, which distorts the samples. To avoid this issue, the multi-rate strategy would require low rate samplers with large analog bandwidth.

Multicoset Sampling

A popular sampling scheme for sampling wideband signals at the Nyquist rate is multicoset or interleaved ADCs [1, 6, 23] in which several channels are used, each operating at a lower rate. We now discuss how such systems can be used in the sub-Nyquist regime.

Multicoset sampling may be described as the selection of certain samples from the uniform Nyquist grid, as shown in Fig. 4, where $T_{\text{Nyq}} = 1/f_{\text{Nyq}}$ denotes the Nyquist period. More precisely, the uniform grid is divided into blocks of N consecutive samples, from which only $M < N$ are kept. Mathematically, the ith sampling sequence is defined as

$$x_{c_i}[n] = \begin{cases} x(nT_{\text{Nyq}}), & n = mN + c_i, m \in \mathbb{Z} \\ 0, & \text{otherwise}, \end{cases} \tag{6}$$

where the cosets c_i are ordered integers so that $0 \le c_1 < c_2 < \cdots < c_M < N$. A possible implementation of the sampling sequences (6) is depicted in Fig. 5. The building blocks are M uniform samplers at rate $1/NT_{\text{Nyq}}$, where the ith sampler is shifted by $c_i T_{\text{Nyq}}$ from the origin. When sampling at the Nyquist rate, $M = N$ and $c_i = (i-1)$.

The samples in the Fourier domain can be written as linear combinations of spectrum slices of $x(t)$, such that [6]

$$\mathbf{z}(f) = \mathbf{A}\mathbf{x}(f), \qquad f \in \mathscr{F}_s. \tag{7}$$

Here, $\mathscr{F}_s = [-f_s/2, f_s/2]$ with $f_s = \frac{1}{NT_{\text{Nyq}}} \ge B$ the sampling rate of each channel. The mth row of $\mathbf{z}(f)$ contains the discrete time Fourier transform of the samples $z_m[n]$. The $N \times 1$ vector $\mathbf{x}(f)$ denotes the spectrum slices of $x(t)$, where the ith row of $\mathbf{x}(f)$ is $\mathbf{x}_i(f) = X(f + (i - \lfloor (N+2)/2 \rfloor) f_p)$, and $X(f)$ is the Fourier transform of $x(t)$. Since $x(t)$ is assumed to be sparse, $\mathbf{x}(f)$ is sparse as well, and its support, that is the set that contains the indices corresponding to its nonzero rows, is determined by the frequency locations of the transmissions of $x(t)$. The $M \times N$

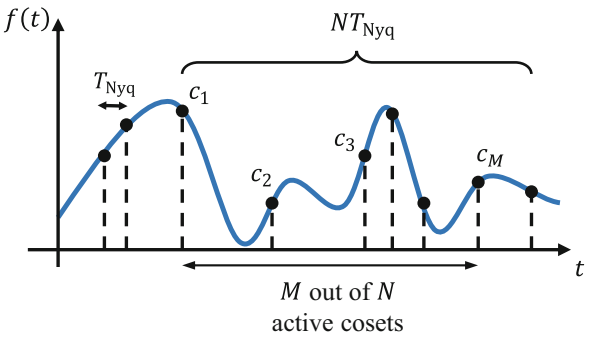

Fig. 4 Illustration of multicoset sampling

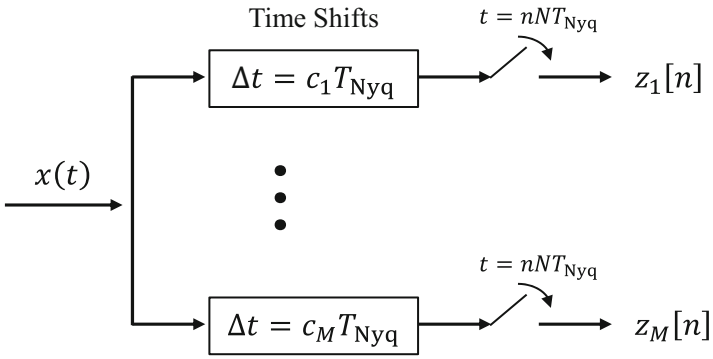

Fig. 5 Schematic implementation of multicoset sampling. The input signal $x(t)$ is inserted into the multicoset sampler that splits the signal into M branches and delays each one by a fixed coefficient $c_i T_{\text{Nyq}}$. Every branch is sampled at the low rate $1/(NT_{\text{Nyq}})$ and then digitally processed to perform spectrum sensing and signal reconstruction

sampling matrix $\mathbf{A}$ is a Vandermonde matrix with factors determined by the selected delays or cosets c_i. This relation is illustrated in Fig. 6. In the Nyquist regime, when $M = N$, $\mathbf{A}$ is the Fourier matrix. The recovery processing described below is performed in the time domain, where we have

$$\mathbf{z}[n] = \mathbf{A}\mathbf{x}[n], \qquad n \in \mathbb{Z}. \tag{8}$$

The vector $\mathbf{z}[n]$ collects the measurements at $t = n/f_s$ and $\mathbf{x}[n]$ contains the sample sequences corresponding to the spectrum slices of $x(t)$. Obviously, the sparsity pattern of $\mathbf{x}[n]$ is identical to that of $\mathbf{x}(f)$, and it follows that $\mathbf{x}[n]$ are jointly sparse over time.

Our goal is to recover $\mathbf{x}[n]$ from the samples $\mathbf{z}[n]$. The system (8) is underdetermined due to the sub-Nyquist setup and known as infinite measurement vector (IMV) in the CS literature [2, 21]. The digital reconstruction algorithm consists of the following three stages [6] that we explain in more detail below:

1. The continuous-to-finite (CTF) block constructs a finite frame (or basis) from the samples.
2. The support recovery formulates an optimization problem whose solution's support is identical to the support S of $\mathbf{x}[n]$, that is the active slices.
3. The signal is then digitally recovered by reducing (8) to the support of $\mathbf{x}[n]$.

The recovery of $\mathbf{x}[n]$ for every n independently is inefficient and not robust to noise. Instead, the CTF method, developed in [6], exploits the fact that the bands occupy continuous spectral intervals so that $\mathbf{x}[n]$ are jointly sparse, that is they have the same spectral support S over time. The CTF then produces a finite system of equations, called multiple measurement vectors (MMV) [2, 21] from the infinite number of linear systems described by (8). The samples are first summed as

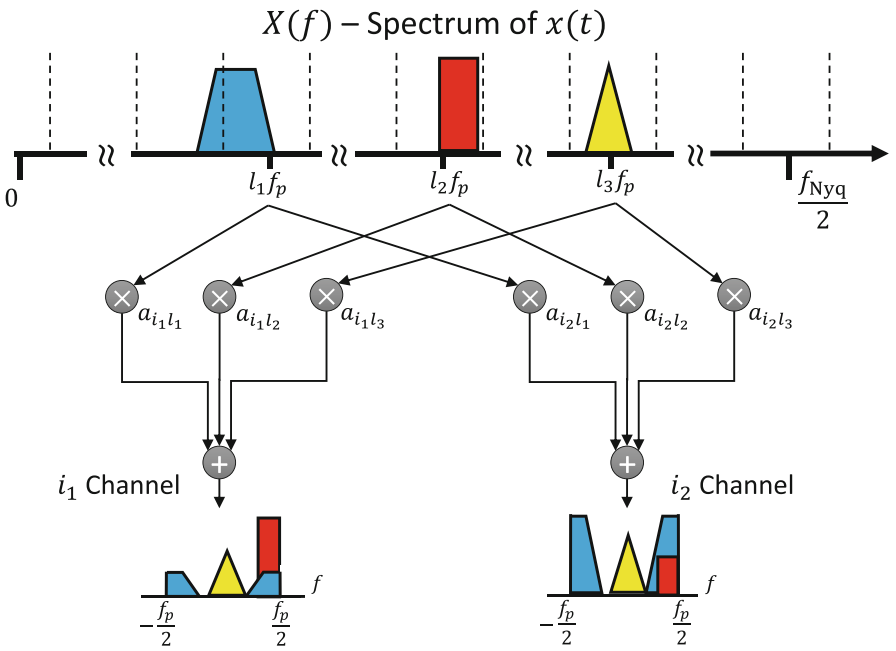

Fig. 6 The spectrum slices of the input signal $\mathbf{x}(f)$ are shown here to be multiplied by the coefficients a_{il} of the sensing matrix $\mathbf{A}$, resulting in the measurements z_i for the ith channel. Note that in multicoset sampling, only the slices' complex phase is modified by the coefficients a_{il}. In the MWC sampling described below, both the phases and amplitudes are affected

$$\mathbf{Q} = \sum_n \mathbf{z}[n]\mathbf{z}^H[n], \tag{9}$$

and then decomposed to a frame $\mathbf{V}$ such that $\mathbf{Q} = \mathbf{V}\mathbf{V}^H$. Clearly, there are many possible ways to select $\mathbf{V}$. One option is to construct it by performing an eigendecomposition of $\mathbf{Q}$ and choosing $\mathbf{V}$ as the matrix of eigenvectors corresponding to the nonzero (or large enough) eigenvalues. The finite-dimensional MMV system

$$\mathbf{V} = \mathbf{A}\mathbf{U} \tag{10}$$

is then solved for the sparsest matrix $\mathbf{U}$ with minimal number of nonidentically zero rows using CS techniques [2, 21]. The key observation of this recovery strategy is that the indices of the nonzero rows of $\mathbf{U}$ coincide with the active spectrum slices of $\mathbf{z}[n]$ [6]. These indices are referred to as the support of $\mathbf{z}[n]$ and are denoted by S.

Once the support S is known, $\mathbf{x}[n]$ is recovered by reducing the system of equations (8) to S. The resulting matrix $\mathbf{A}_S$, that contains the columns of $\mathbf{A}$ corresponding to S, is then inverted

$$\mathbf{x}_S[n] = \mathbf{A}_S^{\dagger}\mathbf{z}[n]. \tag{11}$$

Here, $\mathbf{x}_S[n]$ denotes the vector $\mathbf{x}[n]$ reduced to its support. The remaining entries of $\mathbf{x}[n]$ are equal to zero.

The overall sampling rate of the multicoset system is

$$f_{\text{Total}} = Mf_s = \frac{M}{N} f_{\text{Nyq}}. \tag{12}$$

The minimal number of channels is dictated by CS results [21] which imply that $M \geq 2K$ with $f_s \geq B$ per channel. The sampling rate can thus be as low as $2KB$, which is twice the Landau rate [22].

Although this sampling scheme seems relatively simple and straightforward, it suffers from several practical drawbacks [1]. First, as in the multi-rate approach, multicoset sampling requires low rate ADCs with large analog bandwidth. Another issue arises from the time shift elements, since maintaining accurate time delays between the ADCs on the order of the Nyquist interval T_{Nyq} is difficult. Last, the number of channels M required for recovery of the active bands can be prohibitively high. The MWC, presented in the next section, uses similar recovery techniques while overcoming these practical sampling issues.

MWC Sampling

The MWC [7] exploits the blind recovery ideas developed in [6] and combines them with the advantages of analog RF demodulation. To circumvent the analog bandwidth issue in the ADCs, an RF front-end mixes the input signal $x(t)$ with periodic waveforms. This operation imitates the effect of delayed undersampling used in the multicoset scheme and results in folding the spectrum to baseband with different weights for each frequency interval. The MWC achieves aliasing by mixing the signal, which is filtered prior to sampling. The ADC's input is thus a narrowband signal in contrast with multicoset which samples a wideband signal at a low rate to create aliasing. This characteristic of the MWC enables practical hardware implementation, which will be described in section "MWC Hardware".

More specifically, the MWC is composed of M parallel channels. In each channel, $x(t)$ is multiplied by a periodic mixing function $p_i(t)$ with period $T_p = 1/f_p$ and Fourier expansion

$$p_i(t) = \sum_{l=-\infty}^{\infty} a_{il} \mathrm{e}^{j\frac{2\pi}{T_p}lt}. \tag{13}$$

The mixing process aliases the spectrum, such that each band appears in baseband. The signal then goes through a LPF with cutoff frequency $f_s/2$ and is sampled at rate $f_s \geq f_p$. The analog mixture boils down to the same mathematical relation between the samples and the $N = f_{\text{Nyq}}/f_s$ frequency slices of $x(t)$ as in multicoset sampling, namely, (7) in frequency and (8) in time, as shown in Fig. 6. Here, the

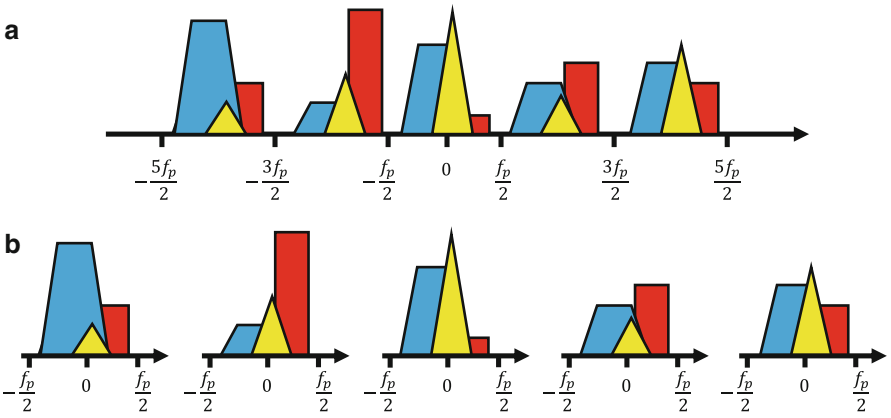

Fig. 7 Illustration of the expander configuration for $q = 5$. (**a**) Spectrum of the output $\tilde{z}_i[n]$ of the physical ith channel, (**b**) spectrum of the samples $z_{i,j}[n]$ of the $q = 5$ equivalent virtual channels, for $j = 1, \ldots, 5$, after digital expansion

$M \times N$ sampling matrix $\mathbf{A}$ contains the Fourier coefficients a_{il} of the periodic mixing functions. The recovery conditions and algorithm are identical to those described for multicoset sampling.

Choosing the channels' sampling rate f_s to be equal to the mixing rate f_p results in a similar configuration as the multicoset scheme in terms of the number of channels. In this case, the minimal number of channels required for the recovery of K bands is $2K$. The number of branches dictates the total number of hardware devices and thus governs the level of complexity of the practical implementation. Reducing the number of channels is a crucial challenge for practical implementation of a CR receiver. The MWC architecture presents an interesting flexibility property that permits trading channels for sampling rate, allowing to drastically reduce the number of channels, even down to a single channel.

Consider a configuration where $f_s = qf_p$, with odd q. In this case, the ith physical channel provides q equations over $\mathscr{F}_p = [-f_p/2, f_p/2]$, as illustrated in Fig. 7. Conceptually, M physical channels sampled at rate $f_s = qf_p$ are equivalent to Mq channels sampled at $f_s = f_p$. The number of channels is thus reduced at the expense of higher sampling rate f_s in each channel and additional digital processing. The output of each of the M physical channels is digitally demodulated and filtered to produce samples that would result from Mq equivalent virtual branches. This happens in the so-called expander module, directly after the sampling stage and before the digital processing described above, in the context of multicoset sampling. At its brink, this strategy allows to collapse a system with M channels to a single branch with sampling rate $f_s = Mf_p$ (further details can be found in [7, 24, 25]).

The MWC sampling and recovery processes are illustrated in Fig. 8. This approach results in a hardware-efficient sub-Nyquist sampling method that does not suffer from the practical limitations described in previous sections, in particular,

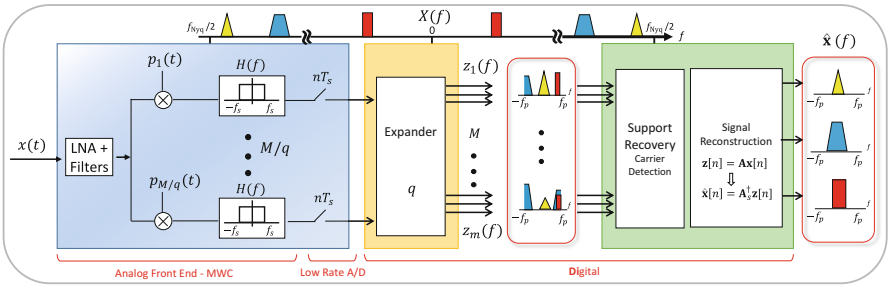

Fig. 8 Schematic implementation of the MWC analog sampling front-end and digital signal recovery from low rate samples

the analog bandwidth limitation of low rate ADCs. In addition, the number of MWC channels can be drastically reduced below $2K$ to as few as one, using a higher sampling rate f_s in each channel and additional digital processing. This tremendously reduces the burden on hardware implementation. However, the choice of appropriate periodic functions $p_i(t)$ to ensure correct recovery is challenging. Some guidelines are provided in [2, 26, 27].

Uniform Linear Array-Based MWC

An alternative sensing configuration, composed of a uniform linear array (ULA) and relying on the sampling paradigm of the MWC, is presented in [28]. The sensing system consists of a ULA composed of M sensors, with two adjacent sensors separated by a distance d, such that $d < c/(|\cos(\theta)| f_{\text{Nyq}})$, where c is the speed of light and θ is the angle representing the DOA of the signal $x(t)$. This system, illustrated in Fig. 9, capitalizes on the different accumulated phases of the input signal between sensors, given by $e^{j2\pi f_i \tau_m}$, where

$$\tau_m = \frac{d\,m}{c}\cos(\theta) \tag{14}$$

is the delay at the mth sensor with respect to the first one. Each sensor implements one channel of the MWC, that is the input signal is mixed with a periodic function, low-pass filtered and then sampled at a low rate.

This configuration has three main advantages over the standard MWC. First, it allows for a simpler design of the mixing functions which can be identical in all sensors. The only requirement on $p(t)$, besides being periodic with period $T_p \leq 1/B$, is that none of its Fourier series coefficients within the signal's Nyquist bandwidth is zero. Second, the ULA-based system outperforms the MWC in terms of recovery performance in low SNR regimes. Since all the MWC channels belong to the same sensor, they are all affected by the same additive sensor noise. In the ULA architecture, each channel belongs to a different sensor with uncorrelated

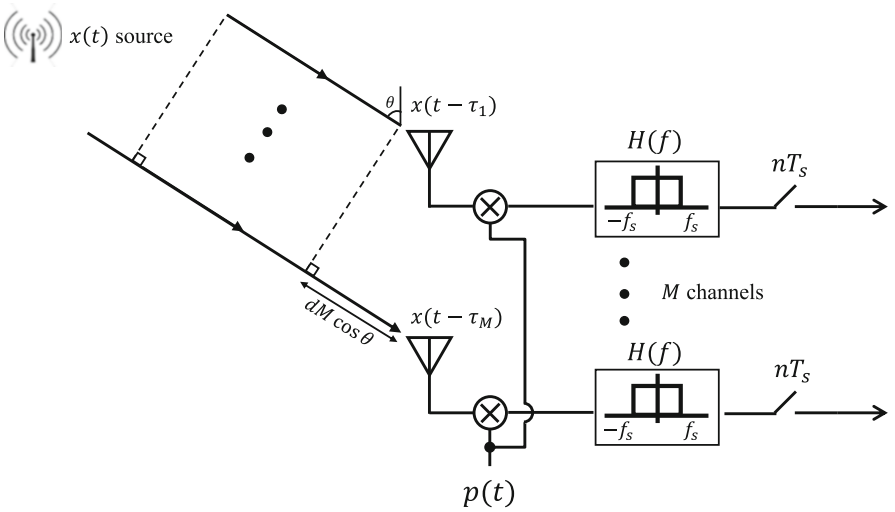

Fig. 9 ULA configuration with M sensors, with distance d between two adjacent sensors. Each sensor includes an analog front-end composed of a mixer with the same periodic function $p(t)$, a LPF and a sampler, at rate f_s

sensor noise between channels. The alternative approach benefits from the same flexibility as the standard MWC in terms of collapsing the channels, which translates into reducing the antennas in the alternative configuration. This lead to a trade-off exists between hardware complexity, governed by the number of antennas, and SNR. Finally, as will be shown in section "The CaSCADE System", the modified system can be easily extended to enable joint spectrum sensing and DOA estimation.

Similarly to the previous sampling schemes, the samples $\mathbf{z}(f)$ can be expressed as a linear transformation of the unknown vector of slices $\mathbf{x}(f)$, such that

$$\mathbf{z}(f) = \mathbf{A}\mathbf{x}(f), \qquad f \in \mathscr{F}_s. \tag{15}$$

Here, $\mathbf{x}(f)$ is a non-sparse vector that contains cyclic shifted, scaled, and sampled versions of the active bands, as shown in Fig. 10. In contrast to the previous methods, in this configuration, the matrix $\mathbf{A}$, defined by

$$\mathbf{A} = \begin{pmatrix} \mathrm{e}^{j2\pi f_1 \tau_1} & \cdots & \mathrm{e}^{j2\pi f_N \tau_1} \\ \vdots & & \vdots \\ \mathrm{e}^{j2\pi f_1 \tau_M} & \cdots & \mathrm{e}^{j2\pi f_N \tau_M} \end{pmatrix}, \tag{16}$$

depends on the unknown carrier frequencies. As before, in the time domain

$$\mathbf{z}[n] = \mathbf{A}\mathbf{x}[n], \quad n \in \mathbb{Z}. \tag{17}$$

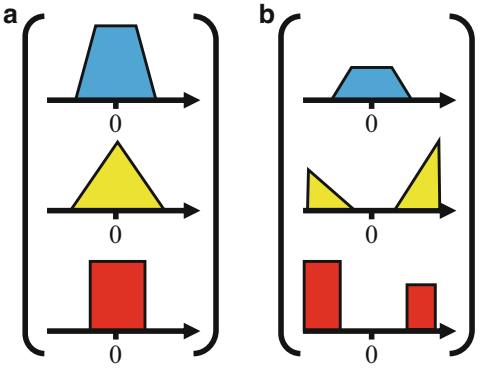

Fig. 10 (**a**) Original source signals at baseband (before modulation), (**b**) output signals at baseband $\mathbf{x}(f)$ after modulation, mixing, filtering, and sampling

Two approaches are presented in [28] to recover the carrier frequencies of the transmissions composing the input signal. The first is based on CS algorithms and assumes that the carriers lie on a predefined grid. In this case, the resulting sensing matrix, which extends $\mathbf{A}$ with respect to the grid, is known and the expanded vector $\mathbf{x}(f)$ is sparse. This leads to a similar system as (7) or (8) which can be solved using the recovery paradigm from [6], described in the context of multicoset sampling.

In the second technique, the grid assumption is dropped, and ESPRIT [20] is used to estimate the carrier frequencies. This approach first computes the sample covariance of the measurements

$$\mathbf{R} = \sum_n \mathbf{z}[n]\mathbf{z}^H[n] \tag{18}$$

and performs a singular value decomposition (SVD). The nonzero singular values correspond to the signal's subspace, and the carrier frequencies are then estimated from these. Once the carriers are recovered, the signal itself is reconstructed by inverting the sampling matrix $\mathbf{A}$ in (17).

The minimal number of sensors required by both reconstruction methods in noiseless settings is $M = 2K$, with each sensor sampling at the minimal rate of $f_s = B$ to allow for perfect signal recovery [28]. The proposed system thus achieves the minimal sampling rate $2KB$ derived in [6]. We note that the expander strategy proposed in the context of the MWC can be applied in this configuration as well.

MWC Hardware

MWC Prototype

One of the main aspects that distinguish the sub-Nyquist MWC from other sampling schemes is its practical implementation [24], proving the feasibility of sub-Nyquist sampling even under distorting effects of analog components and

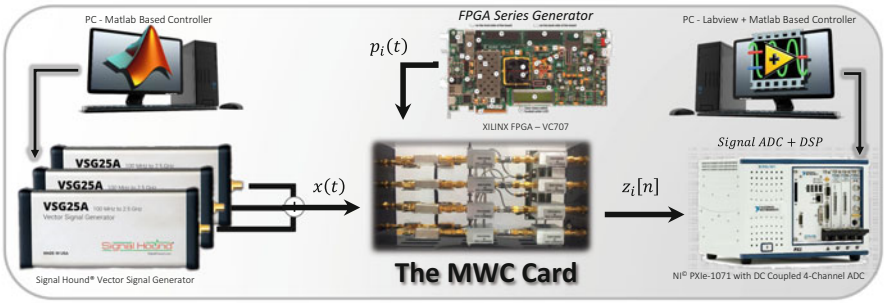

Fig. 11 Hardware implementation of the MWC prototype, including the RF signal generators, analog front-end board, FPGA series generator, ADC, and DSP

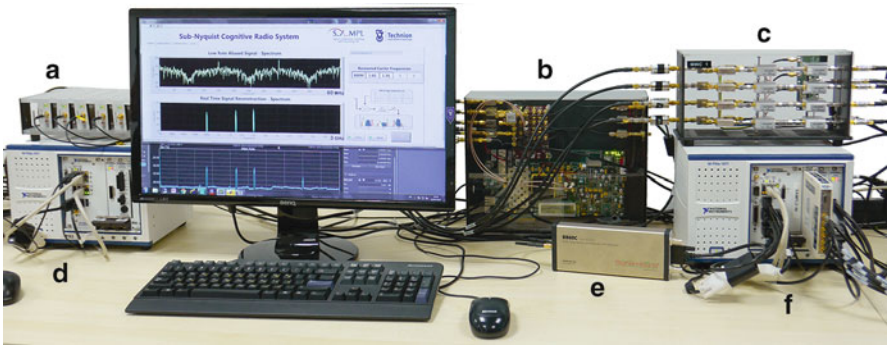

Fig. 12 MWC CR system prototype: (**a**) vector signal generator (VSG), (**b**) FPGA mixing sequences generator, (**c**) MWC analog front-end board, (**d**) RF combiner, (**e**) spectrum analyzer, (**f**) ADC, and DSP

physical phenomena. A hardware prototype, shown in Fig. 11, was developed and built according to the block diagram in Fig. 8. The main hardware components that were used in the prototype can be seen in Fig. 11. In particular, the system receives an input signal with Nyquist rate of 6 GHz and spectral occupancy of up to 200 MHz and samples at an effective rate of 480 MHz, that is only 8% of the Nyquist rate and 2.4 times the Landau rate. This rate constitutes a relatively small oversampling factor of 20% with respect to the theoretical lower sampling bound. This section describes the different components of the hardware prototype, shown in Fig. 12, explaining the various considerations that were taken into account when implementing the theoretical concepts on actual analog components.

At the heart of the system lies the proprietary MWC board [24] that implements the sub-Nyquist analog front-end. The card uses a high-speed 1-to-4 analog splitter that duplicates the wideband signal to $M = 4$ channels, with an expansion factor of $q = 5$, yielding $Mq = 20$ virtual channels after digital expansion. Then, an analog preprocessing step, composed of preliminary equalization, impedance

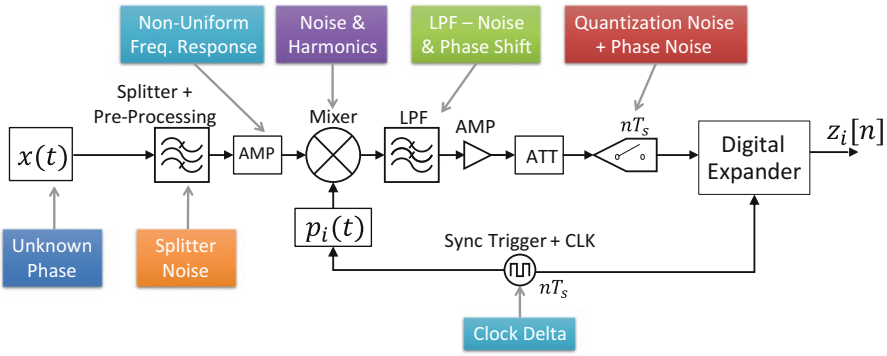

Fig. 13 Hardware RF chain detailed schematics, including amplifiers, attenuators, filters, mixers, samplers, and synchronization signals required for precise and accurate operation. The distortions induced by each component are indicated as well

corrections, and gain adjustments, aims at maintaining the dynamic range and fidelity of the input in each channel. Indeed, the signal and mixing sequences must be amplified to specific levels before entering the analog mixers to ensure proper behavior emulating mathematical multiplication with the mixing sequences. The entire analog path of the multiband input signal is described in Fig. 13.

The modulated signal next passes through an analog anti-aliasing LPF. The anti-aliasing filter must be characterized by both an almost linear phase response in the pass band, between 0 to 50 MHz, and an attenuation of more than 20 dB at $f_s/2 = 60$ MHz. A Chebyshev LPF of 7th order with cutoff frequency (-3 dB) of 50 MHz was chosen for the implementation. After impedance and gain corrections, the signal now has a spectral content limited to 50 MHz that contains a linear combination of the occupied bands with different amplitudes and phases, as seen in Fig. 6. Finally the low rate analog signal is sampled by a National Instruments© ADC operating at 120 MHz, leading to a total sampling rate of 480 MHz.

The mixing sequences that modulate the signal play an essential part in signal recovery. They must have low cross-correlations with each other, while spanning a large bandwidth determined by the Nyquist rate of the input signal, and yet be easy enough to generate with relatively cheap, off-the-shelf hardware. The sequences $p_i(t)$, for $i = 1, \ldots, 4$, are chosen as truncated versions of Gold Codes [29], which are commonly used in telecommunication (CDMA) and satellite navigation (GPS). Mixing sequences based on Gold codes were found to give good results in the MWC system [26], primarily due to small bounded cross-correlations within a set.

Since Gold codes are binary, the mixing sequences are restricted to alternating ± 1 values. This fact allows to digitally generate the sequences on a dedicated FPGA. Alternatively, they can be implemented on a small chip with very low power and complexity. The added benefit of producing the mixing sequences on such a platform is that the entire sampling scheme can be synchronized and triggered using the same FPGA with minimally added phase noise and jitter, keeping a closed

synchronization loop with the samplers and mixers. A XiLinX VC707 FPGA acts as the central timing unit of the entire sub-Nyquist CR setup by generating the mixing sequences and the synchronization signals required for successful operation. It is crucial that both the mixing period $T_p = 1/f_p$ and the low rate samplers operating at $(q+1)f_p$ (due to intended oversampling) are fully synchronized, in order to ensure correct modeling of the entire system and consequently guarantee accurate support detection and signal reconstruction.

The digital back-end is implemented using a National Instruments© PXIe-1065 computer with DC-coupled ADC. Since the digital processing is performed at the low rate f_s, very low computational load is required in order to achieve real-time recovery. MATLAB®and LabVIEW® environments are used for implementing the various digital operations and provide an easy and flexible research platform for further experimentations, as discussed in the next sections. The sampling matrix $\mathbf{A}$ is computed once off-line, using the calibration process outlined in [25].

Support Recovery

The prototype is fed with RF signals composed of up to 5 carrier transmissions with an unknown total bandwidth occupancy of up to 200 MHz and Nyquist rate of 6 GHz. An RF input $x(t)$ is generated using vector signal generators (VSG), each producing one modulated data channel with individual bandwidth of up to 20 MHz. The input transmissions then go through an RF combiner, resulting in a dynamic multiband input signal. This allows to test the system's ability to rapidly sense the input spectrum and adapt to changes, as required by modern CR standards (e.g., IEEE 802.22). In addition, the described setup is able to simulate more complex scenarios, including collaborative spectrum sensing [30,31], joint DOA estimation [28], cyclostationary-based detection [32], and various modulation schemes such as PSK, OFDM, and more, for verifying sub-Nyquist data reconstruction capabilities.

Support recovery is digitally performed on the low rate samples, as presented above in the context of multicoset sampling. The prototype successfully recovers the support of the transmitted bands transmitted, when SNR levels are above 15 dB, as demonstrated in Fig. 14. Additional simulations presenting different input scenarios can be found in [2]. More sophisticated detection schemes, such as cyclostationary detection, allow to achieve perfect support recovery from the same sub-Nyquist samples in lower SNR regimes of $0-10$ dB, as seen in Figs. 23 and 24, and will be further discussed in section "Cyclostationary Detection".

The main advantage of the MWC is that sensing is performed in real time for the entire spectral range, even though the operation is performed solely on sub-Nyquist samples, which results in substantial savings in both computational and memory complexity. In additional tests, it is shown that the bandwidth occupied in each band can also be very low without impeding the performance, as seen in Fig. 15, where the support of signals with very low bandwidth (just 10% occupancy within the 20 MHz band) is correctly detected.

Fig. 14 Screenshot from the MWC recovery software: low rate samples acquired from one MWC channel at rate 120 MHz (*top*), digital reconstruction of the entire spectrum, performed from sub-Nyquist samples (*middle*), true input signal $x(t)$ showed using a fast spectrum analyzer (*bottom*)

Signal Reconstruction

Once the support is recovered, the data is reconstructed from the sub-Nyquist samples. Reconstruction is performed by inverting the reduced sampling matrix $\mathbf{A}_S$ in the recovered support, applying (11). This step is performed in real time, reconstructing the signal bands $\mathbf{z}[n]$ one sample at a time, with low complexity due to the small dimensions of the matrix-vector multiplication. We note that reconstruction does not require interpolation to the Nyquist grid. The active transmissions are recovered at the low rate of 20 MHz, corresponding to the bandwidth of the slices $\mathbf{z}(f)$.

The prototype's digital recovery stage is further expanded to support decoding of common communication modulations, including BPSK, QPSK, QAM, and OFDM. An example for the decoding of three QPSK modulated bands is given in Fig. 16, where the I/Q constellations are shown after reconstructing the original transmitted signals $\mathbf{x}_S$ (11), from their low rate and aliased sampled signals $\mathbf{z}_n$ (8). The I/Q constellations of the baseband signals is displayed, each individually decoded using a general QPSK decoder. In this example, the user broadcasts text strings that are then deciphered and displayed on screen.

Fig. 15 The setup is identical to Fig. 14. In this case, the individual transmissions have low bandwidth, highlighting the structure of the signal when folding to baseband

There are no restrictions regarding the modulation type, bandwidth, or other parameters, since the baseband information is exactly reconstructed regardless of its respective content. Therefore, any digital modulation method, as well as analog broadcasts, can be transmitted and deciphered without loss of information, by applying any desirable decoding scheme directly on the sub-Nyquist samples.

By combining both spectrum sensing and signal reconstruction, the MWC prototype serves as two separate communication devices. The first is a state-of-the-art CR that can perform real-time spectrum sensing at sub-Nyquist rates, and the second is a unique receiver able to decode multiple data transmissions simultaneously, regardless of their carrier frequencies while adapting to temporal spectral changes in real time. In cases where the support of the potential active transmissions is a priori known (e.g., potential cellular carriers), the MWC may be used as an RF demodulator that efficiently acquires several frequency bands simultaneously. Other schemes would require a dedicated demodulation channel for each potentially active band. In this case, the mixing sequences should be designed so that their Fourier coefficients are nonzero only in the bands of interest, increasing SNR, and the support recovery stage is not needed [33].

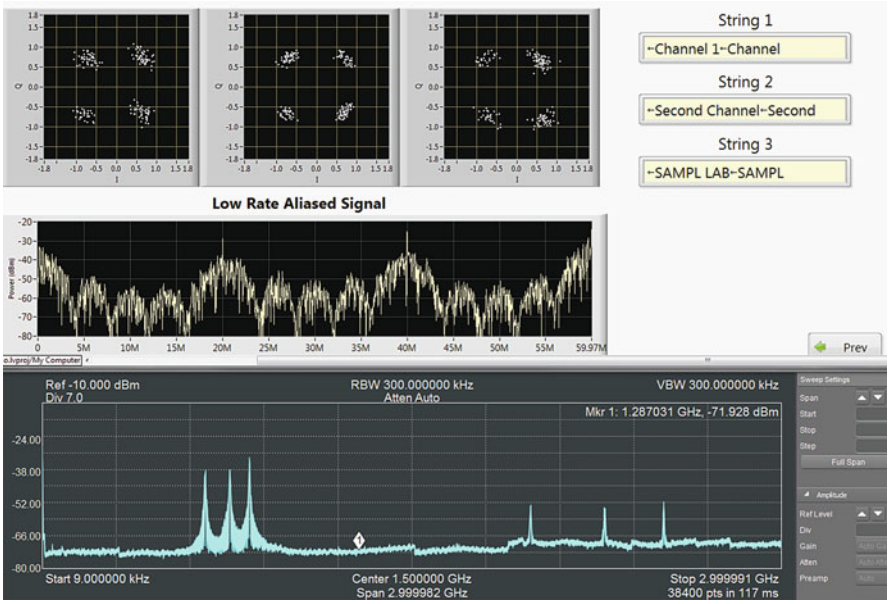

Fig. 16 Demodulation, reconstruction, and detection of $N_{\text{sig}} = 3$ inputs from sub-Nyquist samples using the MWC CR prototype. At the *bottom*, the signal is sampled by an external spectrum analyzer showing the entire bandwidth of 3 GHz. Sub-Nyquist samples from an MWC channel $z_i[n]$ in the Fourier domain are displayed in the *middle*. The I/Q phase diagrams, showing the modulation pattern of the transmitted bands after reconstruction from the low rate samples, are presented at the *top left*. In the *upper right corner*, we see the information that was sent on each carrier, proving successful reconstruction

Statistics Detection

In the previous sections, we reviewed recent sub-Nyquist sampling methods that reconstruct a multiband signal, such as a CR signal, from low rate samples. However, the final goal of CRs often only requires detection of the presence or absence of the PUs' transmissions and not necessarily their perfect reconstruction. In this case, several works have proposed performing detection on second-order signal statistics, which share the same frequency support as the original signal. In particular, power and cyclic spectra have been considered for stationary and cyclostationary [13] signals, respectively. Instead of recovering the signal from the low rate samples, its statistics are reconstructed and the support is estimated [32, 34–40].

Recovering second-order statistics rather than the signal itself benefits from two main advantages. First, it allows to further reduce the sampling rate, as we will discuss in the remainder of this section. Intuitively, statistics have fewer degrees of freedom than the signal itself, requiring less samples for their reconstruction. This follows from the assumption that the signal of interest is either stationary or

cyclostationary. Going one step further, the sparsity constraint can even be removed in this case, and the power/cyclic spectrum of non-sparse signals is recoverable from samples obtained below the Nyquist rate [32, 34, 37, 38, 40]. This is useful for CRs operating in less sparse environments, in which the lower bound of twice the Landau rate may exceed the Nyquist rate. Second, the robustness to noise is increased due to the averaging performed to estimate statistics. This is drastically improved in the case of cyclostationary signals in the presence of stationary noise. Indeed, exploiting cyclostationarity properties exhibited by communication signals allows to separate them from stationary noise, leading to better detection in low SNR regimes [41]. In this section, we first review power spectrum detection techniques in stationary settings and then extend these to cyclic spectrum detection of cyclostationary signals.

Power Spectrum-Based Detection

In the statistical setting, the signal $x(t)$ is modeled as the sum of uncorrelated wide-sense stationary transmissions. The stationarity assumption is key to further reducing the sampling rate. In frequency, stationarity is expressed by the absence of correlation between distinct frequency components. Specifically, as shown in [42], the Fourier transform of a wide-sense stationary signal is a nonstationary white process, such that

$$\mathbb{E}[X(f_1)X^*(f_2)] = S_x(f_1)\delta(f_1 - f_2). \tag{19}$$

Here, the power spectrum $S_x(f)$ of $x(t)$ is the Fourier transform of its autocorrelation $r_x(\tau)$. Thus, obviously, the support of $S_x(f)$ is identical to that of $X(f)$. In addition, due to (19), the autocorrelation matrix of the N spectrum frequency slices of $x(t)$ comprising $\mathbf{x}(f)$ is diagonal, containing only N degrees of freedom, which allows sampling rate reduction.

Another intuitive interpretation to the reduced number of degrees of freedom in statistics recovery is given in the time domain. There, the autocorrelation of stationary signals $r_x(\tau) = \mathbb{E}[x(t)x(t-\tau)]$ is only a function of the time lags τ. The cardinality of the difference set, namely, the set that contains the time lags, may be greater than that of its associated original set, up to the order of its square, for an appropriate choice of sampling times [35, 43]. When the sampling scheme is not tailored to power spectrum recovery, the sampling rate can be as low as the Landau rate [38], which constitutes a worst-case scenario in terms of sampling rate. With appropriate design, the autocorrelation or power spectrum may be estimated from samples with arbitrarily low average sampling rate [34, 35, 43–45] at the expense of increased latency.

We first review power spectrum recovery techniques that do not exploit any specific design. We then present methods that further reduce the sampling rate by adapting the sampling scheme to the purpose of autocorrelation or power spectrum estimation. Finally, we extend these results to the cyclostationary model.

Power Spectrum Recovery

In this section, we first focus on sampling with generic MWC or multicoset schemes without specific design of the mixing sequences or cosets, respectively.

To recover $S_x(f)$ from the low rates samples $\mathbf{z}(f)$, consider the correlation matrix of the latter $\mathbf{R_z}(f) = \mathbb{E}[\mathbf{z}(f)\mathbf{z}^H(f)]$ [38]. Using (7), $\mathbf{R_z}(f)$ can be related to correlations between the slices $\mathbf{x}(f)$, that is $\mathbf{R_x}(f) = \mathbb{E}[\mathbf{x}(f)\mathbf{x}^H(f)]$ as follows

$$\mathbf{R_z}(f) = \mathbf{A}\mathbf{R_x}(f)\mathbf{A}^H, \qquad f \in \mathscr{F}_s. \tag{20}$$

From (19), the correlation matrix $\mathbf{R_x}(f)$ is diagonal and contains the power spectrum $S_x(f)$ at the corresponding frequencies, as

$$\mathbf{R}_{\mathbf{x}_{(i,i)}}(f) = S_x(f + if_s - \frac{f_{\text{Nyq}}}{2}), \qquad f \in \mathscr{F}_s. \tag{21}$$

Recovering the power spectrum $S_x(f)$ is thus equivalent to recovering the matrix $\mathbf{R_x}(f)$. Exploiting the fact that $\mathbf{R_x}(f)$ is diagonal and denoting by $\mathbf{r_x}(f)$ its diagonal, (20) can be reduced to

$$\mathbf{r_z}(f) = (\bar{\mathbf{A}} \odot \mathbf{A})\mathbf{r_x}(f), \tag{22}$$

where $\mathbf{r_z}(f) = \text{vec}(\mathbf{R_z}(f))$ concatenates the columns of $\mathbf{R_z}(f)$. The matrix $\bar{\mathbf{A}}$ is the conjugate of $\mathbf{A}$ and $\odot$ denotes the Khatri-Rao product [46].

Generic choices of the sampling parameters, either mixing sequences or cosets, which are only required to ensure that $\mathbf{A}$ is full spark, are investigated in [38]. Then, the Khatri-Rao product $(\bar{\mathbf{A}} \odot \mathbf{A})$ is full spark as well if $M > N/2$, that is the number of rows of $\mathbf{A}$ is at least half the number of slices N. The minimal sampling rate to recover $\mathbf{r_x}(f)$, and consequently $S_x(f)$, from $\mathbf{r_z}(f)$ in (22) is thus equal to the Landau rate KB, namely, half the rate required for signal recovery [38]. The recovery of $\mathbf{r_x}(f)$ is performed using the procedure presented in the context of signal recovery on (22), that is CTF, support recovery, and power spectrum reconstruction (rather than signal reconstruction).

The same result for the minimal sampling rate is valid for non-sparse signals, for which KB is in the order of f_{Nyq} [38]. The power spectrum of such signals may be recovered at half their Nyquist rate. This means that even without any sparsity constraints on the signal in crowded environments, a CR can retrieve the power spectrum of the received signal by exploiting the stationarity property of the latter. In this case, the system (22) is overdetermined, and $\mathbf{r_x}(f)$ is obtained by a simple pseudo-inverse operation.

Obviously, in practice, we do not have access to $\mathbf{R_z}(f)$, which thus needs to be estimated. The overall sensing time is divided into N_f frames of length N_s samples. In [38], different choices of N_f and N_s are examined for a fixed sensing time. In order to estimate the autocorrelation matrix $\mathbf{R_z}(f)$ in the frequency domain, we first compute the estimates of $\mathbf{z}_i(f), 1 \leq i \leq M$, denoted by $\hat{\mathbf{z}}_i(f)$, using the fast

Fourier transform (FFT) on the samples $z_i[n]$ over a finite time window. We then estimate the elements of $\mathbf{R}_\mathbf{z}(f)$ as

$$\hat{\mathbf{R}}_\mathbf{z}(i,j,f) = \frac{1}{N_f}\sum_{\ell=1}^{N_f} \hat{\mathbf{z}}^\ell(i,f)\hat{\mathbf{z}}^\ell(j,f), \quad f \in \mathscr{F}_s, \tag{23}$$

where $\hat{\mathbf{z}}^\ell(i,f)$ is the value of the FFT of the samples $\mathbf{z}_i[n]$ from the ℓth frame, at frequency f. In practice, the number of samples dictates the number of FFT coefficients in the frequency domain and therefore the resolution of the reconstructed power spectrum.

Once $\hat{\mathbf{r}}_\mathbf{x}(f)$ is reconstructed, the following test statistic,

$$\Gamma_i = \sum_{f\in\mathscr{F}_s} |\hat{\mathbf{r}}_{\mathbf{x}_i}(f)|^2, \qquad 1 \le i \le N, \tag{24}$$

may be adopted in order to detect the occupied support. Here, $\hat{\mathbf{r}}_{\mathbf{x}_i}(f)$ is the ith entry of $\hat{\mathbf{r}}_\mathbf{x}(f)$, and the sum is performed over the frequency band of interest to detect the presence of a PU. Alternatively, other detection statistics can be used on the reconstructed power spectrum, such as eigenvalue-based test statistics [47].

Power Spectrum Sensing: Tailored Design

Sampling approaches specifically designed for estimating the autocorrelation of stationary signals at much finer lags than the sample spacings have been studied recently in detail [35,43,44,48]. The key observation here is that the autocorrelation is a function of the lags only, namely, the differences between pairs of sample times. Thus, it is estimated at all-time lags contained in the difference co-array, composed of all the differences between pairs of elements from the original sampling array. Since the size of the difference co-array may be greater than that of the sampling set, it is possible to sample below the Nyquist rate and estimate the correlation at all lags on the Nyquist grid, from the low rate samples. Therefore, the sampling times should be carefully chosen so as to maximize the cardinality of the difference co-array.

The first approach we present adopts multicoset sampling previously reviewed while specifically designing the cosets to obtain a maximal number of differences. In the previous section, the results were derived for any coset selection. Here, we show that the sampling rate may be lower if the cosets are carefully chosen. When using multicoset sampling, the sampling matrix $\mathbf{A}$ in (20) or (22) is a partial Fourier matrix with (i,k)th element $e^{j\frac{2\pi}{N}c_i k}$. A typical element of $(\bar{\mathbf{A}} \odot \mathbf{A})$ is then $e^{j\frac{2\pi}{N}(c_i - c_j)k}$. If all cosets are distinct, then the size of the difference set over one period is greater than or equal to $2M-1$. This bound corresponds to a worst-case scenario, as discussed in the previous section, and leads to a sampling rate of at least half Nyquist in the non-sparse setting and at least Landau for a sparse signal with unknown support. This happens, for example, if we select the first or last M cosets or if we keep only the even or odd cosets.

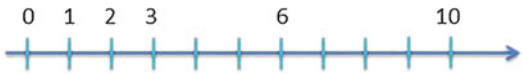

Fig. 17 Minimal sparse ruler of order $M = 6$ and length $N = 10$

To maximize the size of the difference set and increase the rank of $(\bar{\mathbf{A}} \odot \mathbf{A})$, the cosets can be chosen [35,48] using minimal linear and circular sparse rulers [49]. A linear sparse ruler is a set of integers from the interval $[0, N]$, such that the associated difference sets contain all integers in $[0, N]$. Intuitively, it can be seen as a ruler with some marks erased but still able to measure all integer distances between 0 and its length. For example, consider the minimal sparse ruler of length $N = 10$. This ruler requires $M = 6$ marks, as shown in Fig. 17. Obviously, all the lags $0 \leq \tau \leq 10$ on the integer grid are identifiable. There is no closed form expression for the maximum compression ratio M/N that is achievable using a sparse ruler; however, the following bounds hold

$$\frac{\sqrt{\tau(N-1)}}{N} \leq \frac{M}{N} \leq \frac{\sqrt{3(N-1)}}{N}, \tag{25}$$

where $\tau \approx 2.4345$ [48]. A circular or modular sparse ruler extends this idea to include periodicity. Such designs that seek minimal sparse rulers, that is rulers with minimal number of marks M, allow to achieve compression ratios M/N on the order of $\sqrt{N}$. As N increases, the compression ratio may be arbitrarily low.

Two additional sampling techniques specifically designed for autocorrelation recovery are nested arrays [43] and co-prime sampling [44], presented in the context of autocorrelation estimation as well as beamforming and DOA estimation applications. In nested and co-prime structures, similarly to multicoset, the corresponding co-arrays have more degrees of freedom than those of the original arrays, leading to a finer grid for the time lags with respect to the sampling times. We now briefly review both sampling structures and their corresponding difference co-arrays and show how the autocorrelation of an arbitrary stationary signal can be recovered on the Nyquist grid from these low rate samples.

In its simplest form, the nested array [43] structure has two levels of sampling density. The first-level samples are at the N_1 locations $\{\ell T_{\text{Nyq}}\}_{1 \leq \ell \leq N_1}$, and the second-level samples are at the N_2 locations $\{(N_1+1)kT_{\text{Nyq}}\}_{1 \leq k \leq N_2}$. This nonuniform sampling is then repeated with period $(N_1+1)N_2T_{\text{Nyq}}$. Since there are N_1+N_2 samples in intervals of length $(N_1+1)N_2T_{\text{Nyq}}$, the average sampling rate of a nested array sampling set is given by

$$f_s = \frac{N_1+N_2}{(N_1+1)N_2T_{\text{Nyq}}} \equiv \frac{1}{N_1T_{\text{Nyq}}} + \frac{1}{N_2T_{\text{Nyq}}}, \tag{26}$$

which can be arbitrarily low since N_1 and N_2 may be as large as we choose, at the expense of latency.

Now, consider the difference co-array which has contribution from the cross-differences and the self-differences. The non-negative cross-differences, normalized by T_{Nyq} for clarity, are given by

$$n = (N_1 + 1)k - \ell, \quad 1 \le k \le N_2, 1 \le \ell \le N_1. \tag{27}$$

All differences in the range $1 \le n \le (N_1 + 1)N_2 - 1$ are covered, except for the multiples of $N_1 + 1$. These are precisely the self-differences among the second array. As a result, the difference co-array is a filled array represented by the set of all integers $-[(N_1 + 1)N_2 - 1] \le n \le [(N_1 + 1)N_2 - 1]$. Going back to our autocorrelation or power spectrum estimation problem, this result shows that by proper averaging, we can estimate $R(\tau)$ at any lag τ on the Nyquist grid for any stationary signal from the nested array samples, with arbitrarily low sampling rate.

Co-prime sampling involves two uniform sampling sets with spacing $N_1 T_{\text{Nyq}}$ and $N_2 T_{\text{Nyq}}$, respectively, where N_1 and N_2 are co-prime integers. Therefore, the average sampling rate of such a sampling set, given by

$$f_s = \frac{1}{N_1 T_{\text{Nyq}}} + \frac{1}{N_2 T_{\text{Nyq}}}, \tag{28}$$

can be made arbitrarily small compared to the Nyquist rate $1/T_{\text{Nyq}}$.

The associated difference set normalized by T_{Nyq} is composed of elements of the form $n = N_1 k - N_2 \ell$. Since N_1 and N_2 are co-prime, there exist integers k and ℓ such that the above difference achieves any integer value n. Therefore, the autocorrelation can be estimated by proper averaging, as

$$\hat{R}[n] = \frac{1}{Q} \sum_{q=0}^{Q-1} x(N_1(k + N_2 q)) x^*(N_2(\ell + N_1 q)), \tag{29}$$

where Q is the number of snapshots used for averaging. Again, the autocorrelation of any stationary signal may be estimated over the Nyquist grid from samples with arbitrarily low rate, and without any sparsity constraint.

The main drawback of both techniques, besides the practical issue of analog bandwidth and channel synchronization similarly to multicoset sampling, is the added latency required for sufficient averaging. In addition, nested array sampling still requires one sampler operating at the Nyquist rate. Thus, there is no saving in terms of hardware but only in memory and computation.

Cyclostationary Detection

Communication signals typically exhibit statistical periodicity, due to modulation schemes such as carrier modulation or periodic keying [50]. Therefore, such signals are better modeled as cyclostationary rather than stationary processes. A characteristic function of such processes, the cyclic spectrum $S_x^{\alpha}(f)$, extends the traditional power spectrum to a two dimensional map, with respect to two frequency variables, angular and cyclic. The cyclic spectrum exhibits spectral peaks at certain frequency

locations, the cyclic frequencies, which are determined by the signal's parameters, particularly the carrier frequency and symbol rate [41]. This constitutes the main advantage of cyclostationary detection. Stationary noise and interference exhibit no spectral correlation [41], as shown in (19), rendering such detectors highly robust to noise. Compressive power spectrum recovery techniques have been extended to reconstruction of the cyclic spectrum from the same compressive measurements. In this section, we first provide some general background on cyclostationarity and then review sub-Nyquist cyclostationary detection approaches.

Cyclostationarity

A process $x(t)$ is said to be wide-sense cyclostationary with period T_0 if its mean $\mu_x(t) = \mathbb{E}[x(t)]$ and autocorrelation $R_s(t,\tau) = \mathbb{E}[x(t)x(t+\tau)]$ are both periodic with period T_0 [13], that is

$$\mu_x(t+T_0) = \mu_x(t), \qquad R_x(t+T_0,\tau) = R_x(t,\tau), \tag{30}$$

for all $t \in \mathbb{R}$. Given a wide-sense cyclostationary random process, its autocorrelation $R_x(t,\tau)$ can be expanded in a Fourier series

$$R_x(t,\tau) = \sum_{\alpha} R_x^{\alpha}(\tau) \mathrm{e}^{j2\pi\alpha t}, \tag{31}$$

where the sum is over integer multiples of the fundamental frequency $1/T_0$ and the Fourier coefficients, referred to as cyclic autocorrelation functions, are given by

$$R_x^{\alpha}(\tau) = \frac{1}{T_0} \int_{-T_0/2}^{T_0/2} R_x(t,\tau) \mathrm{e}^{-j2\pi\alpha t} \mathrm{d}t. \tag{32}$$

The cyclic spectrum is the Fourier transform of (32) with respect to τ, namely,

$$S_x^{\alpha}(f) = \int_{-\infty}^{\infty} R_x^{\alpha}(\tau) \mathrm{e}^{-j2\pi f\tau} \mathrm{d}\tau, \tag{33}$$

where α is referred to as the cyclic frequency and f is the angular frequency [13]. If there is more than one fundamental frequency $1/T_0$, then the process $x(t)$ is said to be poly-cyclostationary in the wide sense. In this case, the cyclic spectrum contains harmonics (integer multiples) of each of the fundamental cyclic frequencies [41]. These cyclic frequencies are governed by the transmissions' carrier frequencies and symbol rates as well as modulation types.

An alternative and more intuitive interpretation of the cyclic spectrum expresses it as the cross-spectral density $S_x^{\alpha}(f) = S_{uv}(f)$ of two frequency-shifted versions of $x(t)$, $u(t)$ and $v(t)$, such that

$$u(t) \triangleq x(t)\mathrm{e}^{-j\pi\alpha t}, \quad v(t) \triangleq x(t)\mathrm{e}^{+j\pi\alpha t}. \tag{34}$$

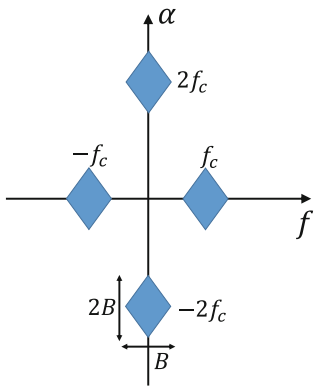

Fig. 18 Support region of the cyclic spectrum of a bandpass cyclostationary signal with carrier frequency f_c and bandwidth B

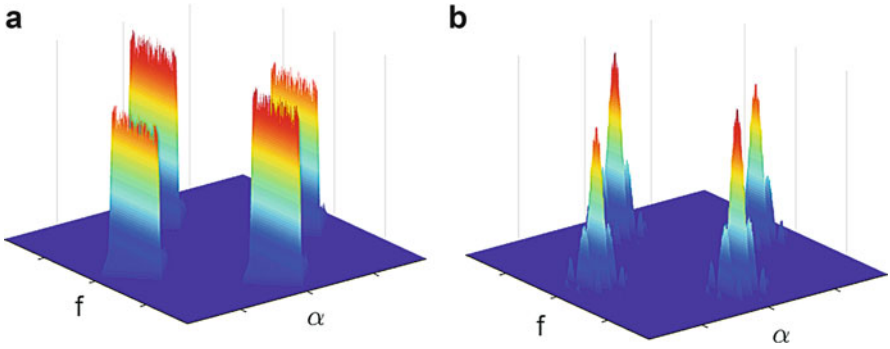

Fig. 19 Cyclic spectrum magnitude of signals with (**a**) AM and (**b**) BPSK modulations

Then, from [42], it holds that

$$S_x^{\alpha}(f) = S_{uv}(f) = \mathbb{E}\left[X\left(f + \frac{\alpha}{2}\right)X^*\left(f - \frac{\alpha}{2}\right)\right]. \tag{35}$$

Thus, the cyclic spectrum $S_x^{\alpha}(f)$ measures correlations between different spectral components of $x(t)$. Stationary signals, which do not exhibit spectral correlation between distinct frequency components, appear only at $\alpha = 0$. This property is the key to robust detection of cyclostationary signals in the presence of stationary noise, in low SNR regimes.

The support region in the (f, α) plane of the cyclic spectrum of a bandpass cyclostationary signal is composed of four diamonds, as shown in Fig. 18. Therefore, the cyclic spectrum $S_x^{\alpha}(f)$ of a multiband signal with K uncorrelated transmissions is supported over $4K$ diamond-shaped areas. Figure 19 illustrates the cyclic spectrum of two modulation types, AM and BPSK.

Cyclic Spectrum Recovery

In the previous section, we showed how the power spectrum $S_x(f)$ can be reconstructed from correlations $\mathbf{R_z}(f)$ between the samples obtained using the

MWC or multicoset sampling. To that end, we first related $S_x(f)$ to the slices' correlation matrix $\mathbf{R}_\mathbf{x}(f)$ and then recovered the latter from $\mathbf{R}_\mathbf{z}(f)$. Here, this approach is extended to the cyclic spectrum $S_x^\alpha(f)$. We first show how it is related to shifted correlations between the slices, namely, $\mathbf{R}_\mathbf{x}^a(\tilde{f}) = \mathbb{E}\left[\mathbf{x}(\tilde{f})\mathbf{x}^H(\tilde{f}+a)\right]$, for $a \in [0, f_s]$ and $\tilde{f} \in [0, f_s - a]$. Next, similarly to power spectrum recovery, $\mathbf{R}_\mathbf{x}^a(\tilde{f})$ is reconstructed from shifted correlations of the samples $\mathbf{R}_\mathbf{z}^a(\tilde{f}) = \mathbb{E}\left[\mathbf{z}(\tilde{f})\mathbf{z}^H(\tilde{f}+a)\right]$. Once the cyclic spectrum $S_x^\alpha(f)$ is recovered, we estimate the transmissions' carriers and bandwidth by locating its peaks. Since the cyclic spectrum of stationary noise $n(t)$ is zero for $\alpha \neq 0$, cyclostationary detection is more robust to noise than stationary detection.

The alternative definition of the cyclic spectrum (35) implies that the elements in the matrix $\mathbf{R}_\mathbf{x}^a(\tilde{f})$ are equal to $S_x^\alpha(f)$ at the corresponding α and f. Indeed, it is easily shown [32] that

$$\mathbf{R}_\mathbf{x}^a(\tilde{f})_{(i,j)} = S_x^\alpha(f), \tag{36}$$

for

$$\begin{aligned} \alpha &= (j-i)f_s + a \\ f &= -\frac{f_{\text{Nyq}}}{2} + \tilde{f} - \frac{f_s}{2} + \frac{(j+i)f_s}{2} + \frac{a}{2}. \end{aligned} \tag{37}$$

Here $\mathbf{R}_\mathbf{x}^a(\tilde{f})_{(i,j)}$ denotes the (i,j)th element of $\mathbf{R}_\mathbf{x}^a(\tilde{f})$. This means that each entry of the cyclic spectrum $S_x^\alpha(f)$ can be mapped to an element from one of the correlation matrices $\mathbf{R}_\mathbf{x}^a(\tilde{f})$ and vice versa. Using (7) and similarly to (20) in the context of power spectrum recovery, we relate the shifted correlations matrices of $\mathbf{x}(f)$ and $\mathbf{z}(f)$ as

$$\mathbf{R}_\mathbf{z}^a(\tilde{f}) = \mathbf{A}\mathbf{R}_\mathbf{x}^a(\tilde{f})\mathbf{A}^H, \quad \tilde{f} \in [0, f_s - a], \tag{38}$$

for all $a \in [0, f_s]$.

Recall that, in the context of stationary signals, $\mathbf{R}_\mathbf{x}(f)$ is diagonal. Here, understanding the structure of $\mathbf{R}_\mathbf{x}^a(\tilde{f})$ is more involved. It was shown [32] that $\mathbf{R}_\mathbf{x}^a(\tilde{f})$ contains nonzero elements on its 0, 1, and -1 diagonals and anti-diagonals. Besides the nonzero entries being contained only in the three main and anti-diagonals, additional structure is exhibited, limiting to two the number of nonzero elements per row and column of the matrix $\mathbf{R}_\mathbf{x}^a(\tilde{f})$. The above pattern follows from two main considerations. First, each frequency component, namely, each entry of $\mathbf{x}(f)$, is correlated to at most two frequencies from the shifted vector of slices $\mathbf{x}(\tilde{f}+a)$, one from the same frequency band and one from the symmetric band. Second, the correlated component can be either in the same/symmetric slice or in one of the adjacent slices.

Figures 21 and 22 illustrate these correlations for $a = 0$ and $a = f_s/2$, respectively. First, in Fig. 20, an illustration of the spectrum of $x(t)$, namely, $X(f)$,

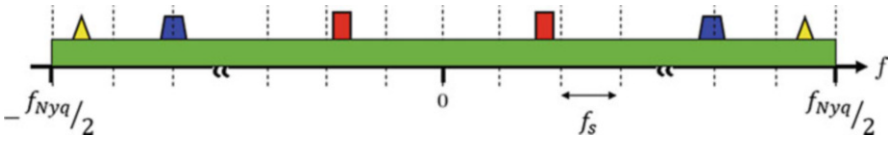

Fig. 20 Original spectrum $X(f)$. The cyclostationary transmissions are shown as a *triangle-*, *trapezoid-*, and *rectangle-shaped* spectral components, buried in a flat stationary noise

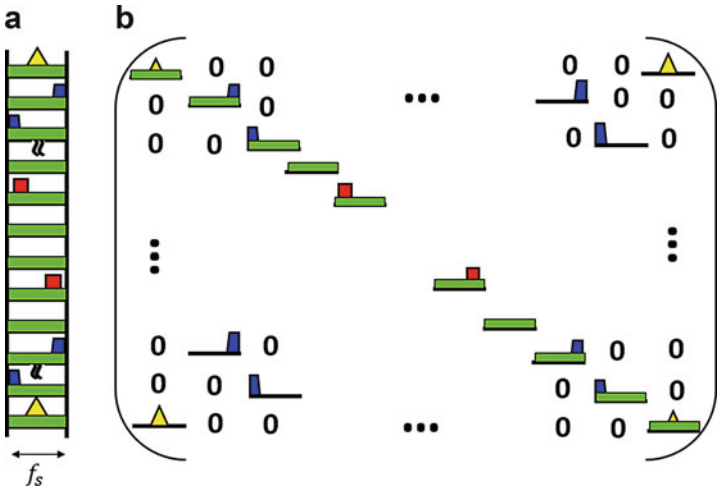

Fig. 21 (**a**) Spectrum slices vector $\mathbf{x}(\tilde{f})$, (**b**) correlated slices of $\mathbf{x}(\tilde{f})$ in the matrix $\mathbf{R}_{\mathbf{x}}^{0}(\tilde{f})$

is presented for the case of a sparse signal buried in stationary noise. It can be seen that frequency bands of $X(f)$ either appear in one f_p-slice or are split between two slices at most since $f_p \geq B$. The resulting vector of spectrum slices $\mathbf{x}(f)$ and the correlations between these slices without any shift, namely, $\mathbf{R}_{\mathbf{x}}^{0}(\tilde{f})$, are shown in Fig. 21a, b, respectively. In Fig. 21b, we observe that self-correlations appear only on the main diagonal since every frequency component is correlated with itself. In particular, the main diagonal contains the noise's power spectrum (in green). Cross-correlations between the yellow symmetric triangles appear in the 0-anti-diagonal, whereas those of the blue trapezes are contained in the -1 and $+1$ anti-diagonals. The red rectangles do not contribute any cross-correlations for $a = 0$.

Figure 22a, b show the vector $x(\tilde{f})$ and its shifted version $x(\tilde{f}+a)$ for $a = f_s/2$, respectively. The resulting correlation matrix $\mathbf{R}_{\mathbf{x}}^{a}(\tilde{f})$ appears in Fig. 22c. Here, the self-correlations of the triangle-shaped frequency component appear in the main diagonal and that of the trapezoid-shaped component in the -1 diagonal. The cross-correlations all appear in the anti-diagonal for the shift $a = f_s/2$. Note that since the noise is assumed to be wide-sense stationary, from (19), a noise frequency component is correlated only with itself. Thus, $n(t)$ contributes nonzero elements only on the diagonal of $\mathbf{R}_{\mathbf{x}}^{0}(\tilde{f})$.

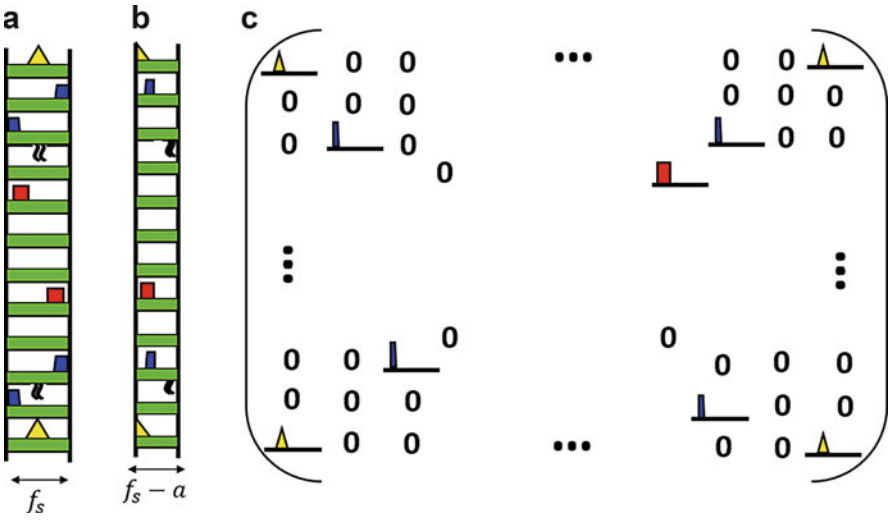

Fig. 22 (**a**) Spectrum slices vector $\mathbf{x}(\tilde{f})$, (**b**) spectrum slices shifted vector $\mathbf{x}(\tilde{f}+a)$, for $a = f_s/2$, (**c**) correlated slices of $\mathbf{x}(\tilde{f})$ and $\mathbf{x}(\tilde{f}+a)$ in the matrix $\mathbf{R}^a_{\mathbf{x}}(\tilde{f})$, with $a = f_s/2$

To recover $\mathbf{R}^a_{\mathbf{x}}(\tilde{f})$ from $\mathbf{R}^a_{\mathbf{z}}(\tilde{f})$, structured CS techniques are used in [32] that aim at reconstructing a sparse matrix while taking into account its specific structure, as described above. Once the cyclic spectrum is reconstructed, the number of transmissions and their respective carrier frequencies and bandwidths are estimated, as discussed in the next section. The detection performed on the cyclic spectrum is more robust to stationary noise than power spectrum-based detection, at the expense of a slightly higher sampling rate, as shown in [32]. More precisely, in the presence of stationary noise, the cyclic spectrum may be reconstructed from samples obtained at $4/5$ of the Nyquist rate, without any sparsity assumption on the signal. If the signal of interest is sparse, then the minimal sampling rate is further reduced to $8/5$ of the Landau rate [32].

Carrier Frequency and Bandwidth Estimation

Many detection and classification algorithms based on cyclostationarity have been proposed (see reviews [13, 14]). To assess the presence or absence of a signal, a first group of techniques requires a priori knowledge of its parameters and particularly of the carrier frequency, which is the information that CRs should uncover in the first place. A second strategy focuses on a single transmission, which does not fit the multiband model. Alternative approaches apply machine learning tools to the modulation classification of a single signal with unknown carrier frequency and symbol rate. Besides being only suitable for a single transmission, these methods require a training phase, which would be a main drawback for CR purposes. In particular, these techniques can only cope with PUs whose modulation type and parameters were part of the training set.

For CR purposes, we need a detector designed to comply with certain requirements: (1) carrier frequency and bandwidth estimation rather than simple detection of the presence or absence of a signal; (2) blind detection, namely, without knowledge of the carrier frequencies, bandwidths, and symbol rates of the transmissions; (3) simultaneous detection of several transmissions; (4) non-learning approach, i.e., with no training phase. The parameter estimation algorithm, presented in [51], is a simple parameter extraction method from the cyclic spectrum of multiband signals that answers these requirements. It allows the estimation of several carriers and several bandwidths simultaneously, as well as the number of transmissions, namely, half the number of occupied bands $K/2$ for real-valued signals. The proposed parameter estimation algorithm can be decomposed into the following four main steps: preprocessing, thresholding, clustering, and parameter estimation.

The preprocessing simply aims at compensating for the presence of stationary noise in the cyclic spectrum at the cyclic frequency $\alpha = 0$, by attenuating the energy of the cyclic spectrum at this frequency. Thresholding is then applied to the resulting cyclic spectrum in order to find its peaks. The locations and values of the selected peaks are then clustered using k-means to find the corresponding cyclic feature, after estimating the number of clusters by applying the elbow method [52]. It follows that, apart from the cluster present in DC, the number of real signals, namely, $N_{\text{sig}} = K/2$, is equal to half the number of clusters. Next, the carrier frequency f_i, which corresponds to the highest peak [41], is estimated for each transmission. The bandwidth B_i is found by locating the edge of the support of the angular frequencies at the corresponding cyclic frequency $\alpha_i = 2f_i$.

Results presented in [32] demonstrate that cyclostationary-based detection, as described in this section, outperforms energy detection carried on the signal's spectrum or power spectrum, at the expense of increased complexity. We now show similar results obtained from hardware simulations, performed using the prototype from Fig. 12.

Hardware Simulations: Robustness to Noise

Cyclostationary detection has been implemented in the MWC CR prototype. The analog front-end is identical to that of the original prototype, and only the digital recovery part is modified since the cyclic spectrum is recovered directly from the MWC low rate samples. Preliminary testing suggests that sensing success is achievable at SNRs lower by 10 dB than those allowed by energy detection performed on the recovered spectrum or power spectrum. Representative results shown in Figs. 23 and 24 demonstrate the advantage of cyclostationary detection over energy detection in the presence of noise. The figures show the reconstructed cyclic spectrum from samples of the MWC prototype as well as cross-sections at $f = 0$ and $\alpha = 0$, which corresponds to the power spectrum. This increased robustness to noise comes at the expense of more complex digital processing on the low rate samples, stemming from the higher dimensionality involved, since we reconstruct the 2-dimensional cyclic spectrum rather than the 1-dimensional (power) spectrum.

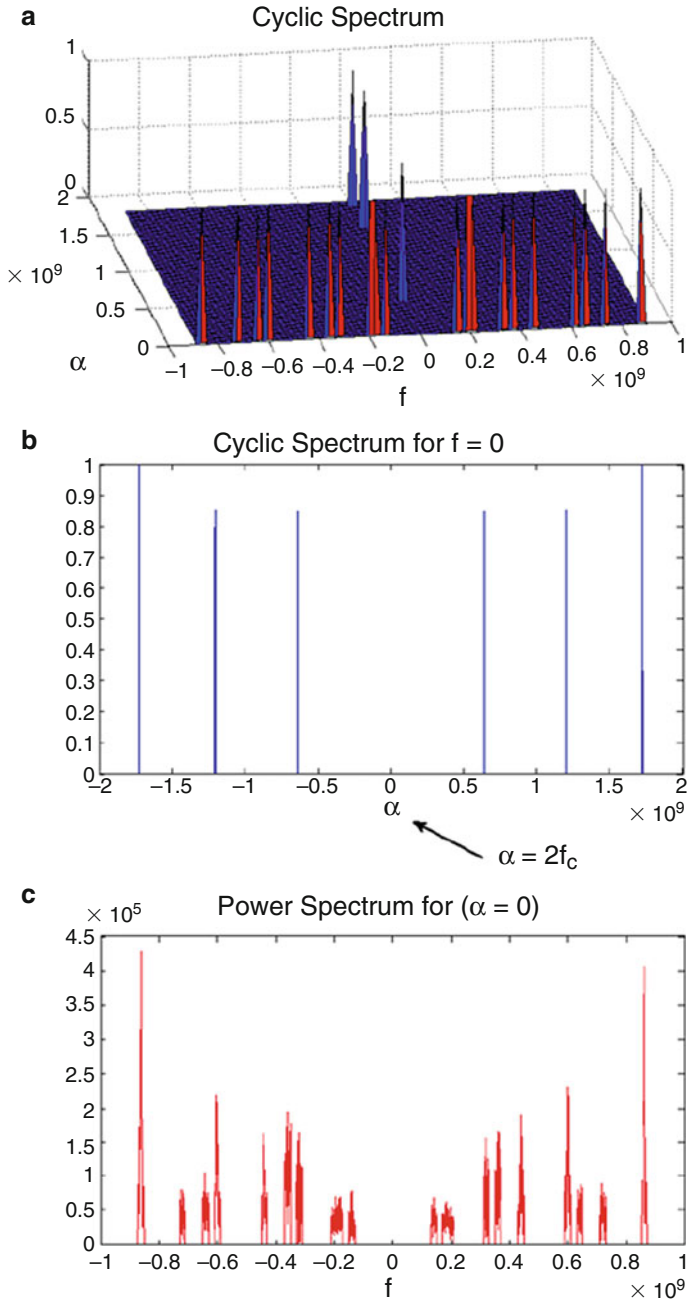

Fig. 23 Screenshot from the MWC with cyclostationary detection. The input signal is composed of $N_{\text{sig}} = 3$ transmissions (or $K = 6$ bands) with carriers $f_1 = 320\,\text{MHz}$, $f_2 = 600\,\text{MHz}$ and $f_3 = 860\,\text{MHz}$. (**a**) The recovered cyclic spectrum from low rate samples. (**b**) The cyclic spectrum profile at the angular frequency $f = 0$; the cyclic peaks are clearly visible at twice the carrier frequencies. (**c**) The power spectrum recovery is displayed and shown to fail in the presence of noise

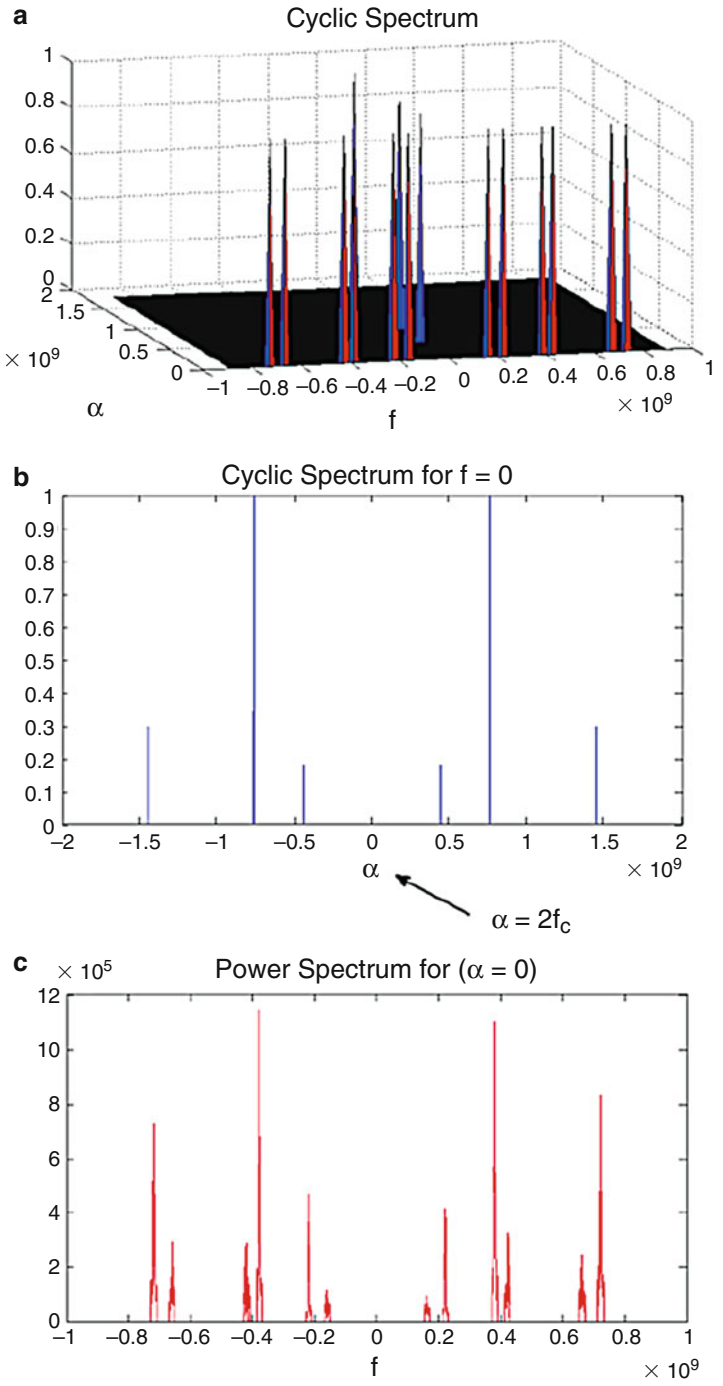

Fig. 24 The setup is identical to Fig. 23, with carrier frequencies $f_1 = 220\,\text{MHz}$, $f_2 = 380\,\text{MHz}$ and $f_3 = 720\,\text{MHz}$

Collaborative Spectrum Sensing

Collaborative Model

Until now, we assumed direct observation of the spectrum. In practice, the task of spectrum sensing for CR is further complicated due to physical channel effects such as path loss, fading, and shadowing [15]. To overcome these practical issues, collaborative CR networks have been considered, where different users share their sensing results and cooperatively decide on the licensed spectrum occupancy.

The different collaborative approaches can be distinguished according to several criteria [15]. First, cooperation can be either centralized or distributed. In centralized settings, the data is sent to a fusion center which combines the shared data to jointly estimate the spectrum or determine its occupancy. In the distributed approach, the CRs communicate among themselves and iteratively converge to a common estimate or decision. While centralized cooperation does not require iterations and can reach the optimal estimate based on the shared data, convergence to this estimate is not always guaranteed in its distributed counterpart. On the other hand, the latter is less power hungry and more robust to node and link failure, increasing the network survivability. An additional criterion concerns the shared data type; the CRs may share local binary decisions on the spectrum occupation (hard decision) or a portion of their samples (soft decision).

We consider the following collaborative model. A network of N_{rec} CRs receives the N_{sig} transmissions, such that the received signal at the jth CR is given by

$$x^{(j)}(t) = \sum_{i=1}^{N_{\text{sig}}} r_{ij}(t) = \sum_{i=1}^{N_{\text{sig}}} s_i(t) * h_{ij}(t). \tag{39}$$

The channel response $h_{ij}(t)$ is determined by fading and shadowing effects. Typical models are Rayleigh fading, or small-scale fading, and log-normal shadowing, or large-scale fading [16, 53, 54]. In the frequency domain, the Fourier transform of the jth received signal is given by

$$X^{(j)}(f) = \sum_{i=1}^{N_{\text{sig}}} S_i(f) H_{ij}(f). \tag{40}$$

Therefore, the support of $x^{(j)}(t)$ is included in the support of the original signal $x(t)$. Since the transmissions are affected differently by fading and shadowing from each transmitter to each CR, we can assume that the union of their respective supports is equivalent to the frequency support of $x(t)$. The goal here is therefore to assess the support of the transmitted signal $x(t)$ from sub-Nyquist samples of the received $x^{(j)}(t), 1 \leq j \leq N_{\text{rec}}$, by exploiting their joint frequency sparsity.

A simple and naive approach is to perform support recovery at each CR from its low rate samples and combine the local binary decisions, either in a fusion center for centralized collaboration or in a distributed manner. In this hard decision

strategy, the combination can be performed using several fusion rules such as AND, OR, or majority rule. Although this method is attractive due to its simplicity and low communication overhead, it typically achieves lower performance than its soft decision counterpart. To mitigate the communication overhead, soft decision-based methods can rely on sharing observations based on the low rate samples with smaller dimensions, rather than the samples themselves. In the next section, we review such techniques both in centralized and distributed contexts.

Centralized Collaborative Support Recovery

One approach [55, 56] to centralized spectrum sensing considers a digital model based upon a linear relation between the M sub-Nyquist samples $\mathbf{z}^{(j)}$ at CR j and N Nyquist samples $\mathbf{x}^{(j)}$ obtained for a given sensing time frame, namely,

$$\mathbf{z}^{(j)} = \mathbf{A}\mathbf{x}^{(j)}, \tag{41}$$

where $\mathbf{A}$ is the sampling matrix. In particular, the authors consider multicoset sampling where $\mathbf{z}$ selects certain samples from the Nyquist grid $\mathbf{x}$ and $\mathbf{A}$ is the corresponding selection matrix. The goal is to recover the power spectrum of the true signal $\mathbf{x}$, assumed to be stationary. To that end, the covariance matrices of sub-Nyquist and Nyquist samples are related by the following quadratic equation

$$\mathbf{R_z}^{(j)} = \mathbf{A}\mathbf{R_x}^{(j)}\mathbf{A}^H, \tag{42}$$

where $\mathbf{R_x}^{(j)}$ is diagonal. Each CR sends its autocorrelation matrix $\mathbf{R_z}^{(j)}$ to the fusion center. The common sparsity of the diagonal of $\mathbf{R_x}^{(j)}$ is then exploited in the frequency domain across all CRs to jointly reconstruct them at the fusion center, using a modified simultaneous orthogonal matching pursuit (SOMP) [21] algorithm.

In [55] only the autocorrelation $\mathbf{R_z}^{(j)}$ between the samples of each CR j is considered. This approach is extended in [56] to include cross-correlations between measurements from different CRs,

$$\mathbf{R}_{\mathbf{z}^{(j)}\mathbf{z}^{(k)}} = \mathbb{E}[\mathbf{z}^{(j)}(\mathbf{z}^{(k)})^H], \tag{43}$$

where j and k are the indices of two CRs. Here, each CR sends its measurement vector $\mathbf{z}^{(j)}$ to the fusion center and the cross-correlations are then computed. The cross-correlations are related to the common power spectrum $\mathbf{s_x} = \mathbf{F}\mathbf{r_x}$ by

$$\mathbf{R}_{\mathbf{z}^{(j)}\mathbf{z}^{(j)}} = \mathbf{C}^{(j)}\mathbf{S_x}(\mathbf{C}^{(j)})^H, \tag{44}$$

where $\mathbf{S_x}$ is the diagonal matrix that contains the power spectrum vector $\mathbf{s_x}$ and $\mathbf{C}^{(j)} = \mathbf{A}^{(j)}\mathbf{F}^H\mathbf{H}^{(j)}$. The sampling matrix $\mathbf{A}^{(j)}$ can be different for each CR j, $\mathbf{F}$ is the $N \times N$ Fourier matrix, and $\mathbf{H}^{(j)}$ is a diagonal matrix that contains the frequency channel state information (CSI). After vectorization, similarly to (42), the N^2 auto- and cross-correlation measurements are concatenated and the goal is to

recover $\mathbf{s_x}$, that is the diagonal of $\mathbf{S_x}$ from these. It is shown that if the total number of samples $N_{\text{rec}}M$ is greater than N and these are suitably chosen to account for enough measurement diversity, then the power spectrum $\mathbf{s_x}$ of a non-sparse signal can be recovered from compressed samples from a sufficient number of CRs. This shows that the minimal rate per CR is lower by a factor of N_{rec} with respect to that required for an individual CR and the number of receivers may be traded for the number of samples per CR. However, increasing the number of samples per CR does not increase spatial diversity, as does increasing the number of receivers. A drawback of this technique is that CSI is traditionally unknown by the CRs and should be estimated prior to detection.

An alternative approach [31] relies on the analog model from (7) and does not assume any a priori knowledge on the CSI. This method considers collaborative spectrum sensing from samples acquired via multicoset sampling or the MWC at each CR. In this approach, the j th CR shares its observation matrix $\mathbf{V}^{(j)}$, as defined in (10), rather than the sub-Nyquist samples themselves, and its measurement matrix $\mathbf{A}^{(j)}$, with a fusion center. The sampling matrices are considered to be different from one another in order to allow for more measurement diversity. However, the same known matrix may be used to reduce the communication overhead. The underlying matrices $\mathbf{U}^{(j)}$ are jointly sparse since fading and shadowing do not affect the original signal's support. Capitalizing on the joint support of $\mathbf{U}^{(j)}$, the support of the transmitted signal $x(t)$ can be recovered at the fusion center by solving

$$\begin{aligned} \arg\min_{\mathbf{U}^{(j)}} \quad & \bigcup_{i=1}^{N_{\text{rec}}} ||\mathbf{U}^{(j)}||_0 \\ \text{s.t.} \quad & \mathbf{V}^{(j)} = \mathbf{A}^{(j)}\mathbf{U}^{(j)}, \text{ for all } 1 \leq j \leq N_{\text{rec}}. \end{aligned} \tag{45}$$

To recover the joint support of $\mathbf{U}^{(j)}$ from the observation matrices $\mathbf{V}^{(j)}$, both the orthogonal matching pursuit (OMP) and iterative hard thresholding (IHT) algorithms, two popular CS techniques, are extended to the collaborative setting [31]. Previously we considered support recovery from an individual CR, which boils down to an MMV system of equations (10). CS algorithms have been extended to this case, such as SOMP from [57] and simultaneous IHT (SIHT) presented in [58]. These now need to account for the joint sparsity across the CRs.

The distributed CS-SOMP (DCS-SOMP) algorithm [59], which extends the original SOMP to allow for different sampling matrices $\mathbf{A}^{(j)}$ for each receiver, is adapted to the CR collaborative setting [31]. The main modification appears in the computation of the index that accounts for the greatest amount of residual energy. Here, the selected index is the one that maximizes the sum of residual projections over all the receivers. Once the shared support is updated, the residual matrices can be computed for each CR separately. The resulting modified algorithm is referred to as block sparse OMP (BSOMP) [31]. The sparse IHT algorithm can also be extended to this setting by selecting the indices of the common support though averaging over all the estimated $\mathbf{U}^{(j)}$ in each iteration. Once the support is selected, the update calculations are performed separately for each receiver [31]. Both methods are suitable for centralized cooperation, in the presence of a fusion

center. As in the previous approach, if the CSI is known, then the sampling rate per CR can be reduced by a factor of N_{rec} with respect to the rate required from an individual CR.

Distributed Collaborative Support Recovery

In the distributed approach, there is no fusion center, and the CRs are restricted to communicate only with their neighbors. Both the digital and analog centralized approaches have been extended to the distributed settings. First, in [60, 61], the digital model (41) is used, and the low rate samples $\mathbf{z}^{(j)}$ of the jth CR are expressed with respect to the spectrum $\mathbf{w}^{(j)} = \mathbf{F}\mathbf{x}^{(j)}$, such that

$$\mathbf{z}^{(j)} = \mathbf{A}^{(j)}\mathbf{F}^H\mathbf{H}^{(j)}\mathbf{w}^{(j)}. \tag{46}$$

Both unknown and known CSI cases are considered. In the first case, each CR computes its local binary decision $\mathbf{c}^{(j)}$ for each spectral band by recovering the sparse spectrum using CS techniques and comparing the local spectrum estimate $\mathbf{w}^{(j)}$ to a chosen threshold. Then, an average consensus approach is adopted, with respect to the shared hard decision. Specifically, each node j broadcasts its current decision $\mathbf{c}^{(j)}(t)$ to its neighbors $\mathcal{N}^{(j)}$ and updates itself by adding a weighted sum of the local discrepancies, that is

$$\mathbf{c}^{(j)}(t+1) = \mathbf{c}^{(j)}(t) + \sum_{k\in\mathcal{N}^{(j)}} \alpha_{jk}(\mathbf{c}^{(k)}(t) - \mathbf{c}^{(j)}(t)), \tag{47}$$

where α_{jk} is a weight associated with the edge (j,k). If the CSI is known, then the joint spectrum itself and not only its support can be collaboratively recovered. Each CR iteratively solves an ℓ_1 optimization problem for the sparse spectrum $\mathbf{w}^{(j)}$ constrained to consent with one-hop neighbors. In [60], the proposed algorithm iterates through the following steps: local spectrum reconstruction given the support and consensus averaging on the spectrum estimate. In [61], a distributed augmented Lagrangian algorithm is adopted.

Another approach extends the method presented in [31], based on the analog model (7), to comply with distributed settings [30]. The ith CR contacts a random neighbor j, chosen with some probability P_{ij}, according to the Metropolis-Hastings scheme for random transition probabilities,

$$P_{ij} = \begin{cases} \min\{\frac{1}{d_i}, \frac{1}{d_j}\} & (i,j) \in E, \\ \sum_{(i,k)\in E} \max\{0, \frac{1}{d_i} - \frac{1}{d_k}\} & i = j, \\ 0 & \text{otherwise.} \end{cases} \tag{48}$$

Here d_i denotes the cardinality of the neighbor set of the ith CR, and E is the set of communication links between CRs in the network.

A single vector, computed from the low rate samples (and that will be defined below for each recovery algorithm), is passed between the CR nodes in the network, rather than the samples themselves, effectively reducing communication overhead. When a CR receives this vector, it performs local computation to update both the shared vector and its own estimate of the signal support accordingly. Finally, the vector is sent to a neighbor CR, chosen according to the random walk with probability (48). Two distributed algorithms are presented in [30]. The first, distributed one-step greedy algorithm (DOSGA), extends the OSGA from [59] to distributed settings. The second method, referred to as randomized distributed IHT (RDSIHT), adapts the centralized BSIHT [31] to the distributed case.

To describe the DOSGA algorithm, we first present its centralized counterpart OSGA. Each CR computes the ℓ_2-norm of the projections of the observation matrix $\mathbf{V}^{(j)}$ onto the columns of the measurement matrix $\mathbf{A}^{(j)}$, stored in the vector $\mathbf{w}^{(j)}$ of size N. The fusion center then averages over all receivers' vectors, such that

$$\hat{\mathbf{w}} = \frac{1}{N_{\text{rec}}} \sum_{j=1}^{N_{\text{rec}}} \mathbf{w}^{(j)}, \tag{49}$$

and retains the highest values of $\hat{\mathbf{w}}$ whose indices constitute the support of interest. In the absence of a fusion center, finding this average is a standard distributed average consensus problem, also referred to as distributed averaging or distributed consensus. DOSGA [30] then uses a randomized gossip algorithm [62] for this purpose, where the vectors $\mathbf{w}^{(j)}$ are exchanged, with the Metropolis-Hastings transition probabilities.

Next, we turn to the RDSIHT algorithm, which adapts the centralized BSIHT [31] to the distributed scenario. The distributed approach from [30] was inspired by the randomized incremental subgradient method proposed in [63] and recent work on a stochastic version of IHT [64]. A vector $\mathbf{w}$ of size N, that sums the ℓ_2-norms of the rows of the estimates of $\mathbf{U}^{(j)}$ before thresholding, is shared in the network through a random walk. The indices of its k largest values correspond to the current estimated support. When the ith CR receives $\mathbf{w}$, it locally updates it by performing a gradient step using its own objective function that is then added to $\mathbf{w}$. Next, it selects a neighbor j to send the vector to with probability P_{ij} (48). The joint sparsity across the CRs is exploited by sharing one common vector $\mathbf{w}$ by the network. It is shown numerically in [30] that both DOSGA and RDSIHT converge to their centralized counterparts.

Hardware Simulations: Collaborative vs. Individual Spectrum Sensing

Here, we would like to confirm that the collaborative algorithms for spectrum sensing perform better than their individual counterparts. We demonstrate a collaborative setting simulated on the MWC CR prototype, as can be seen in Fig. 25.

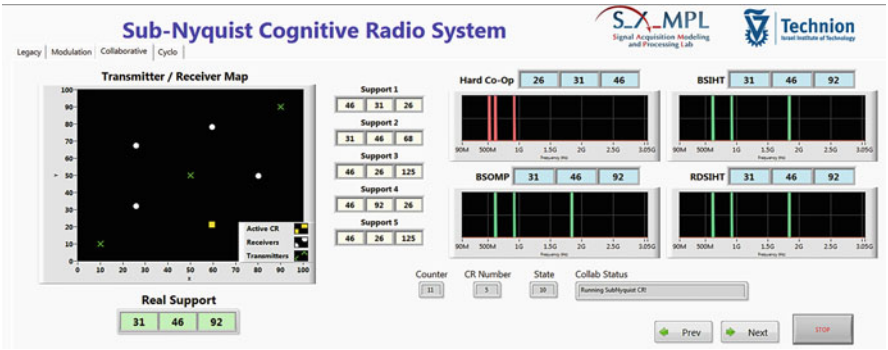

Fig. 25 Screenshot from the MWC CR collaborative hardware prototype. On the upper left side, we see the spatial map of the receivers in *white* and transmitters in *green*. On the bottom left, the occupied band indices of the real spectral support are shown, while to the right of the transmitter/receiver map, the estimated indices by each CR individually are presented. On the right, we see the spectrum sensing results of 4 different algorithms: Hard Co-Op (hard decision collaboration that selects the most popular frequency band indices), BSIHT, BSOMP, and RDSIHT. These results show both the superiority of collaborative spectrum sensing methods over individual detection and that of soft decision methods compared to the plain union of all the CR results

During the simulations conducted, $N_{\text{rec}} = 5$ CR receivers, spread across different locations, are emulated, denoted by white circles on the transmitter/receiver map. The transmitters are also positioned in various locations depicted by green x-marks. The transmitter positions and broadcasts are mimicking the effects of physical channel phenomena, i.e., fading and shadowing. The frequency support recovered by each of the CRs is false, since they individually receive only a partial spectral image of their surroundings, as expected in a real-world scenario.

In all simulated scenarios, collaborative spectrum sensing outperforms detection realized by individual CRs. This result is expected, since the soft collaborative methods take advantage of the spatial deployment of the receivers to reproduce the exact spectral map of the environment. Moreover, the centralized and distributed algorithms BSOMP, BSIHT and RDSIHT, based on soft decisions, showed superior results in comparison with a hard decision method. The same result can be seen in Fig. 25, where the hard decision support algorithm (Hard Co-Op) fails to recover the entire active frequency support (depicted by red bins).

Joint Carrier Frequency and Direction Estimation

The final extension we consider is joint spectrum sensing and DOA estimation. In order for CRs to map vacant bands more efficiently, spatial information about the PUs' locations can be of great interest. Consider the network of CRs presented in Fig. 26 and focus on CR1. Now, picture a scenario where PU2, with DOA θ_2 with respect to CR1, is transmitting in a certain frequency band with carrier f_2.

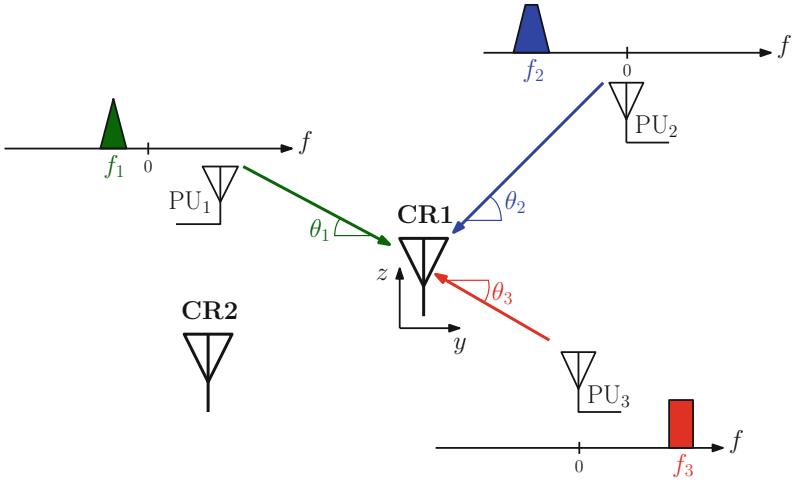

Fig. 26 Illustration of $N_{\text{sig}} = 3$ source signals in the yz plane. Each transmission is associated with a carrier frequency f_i and DOA θ_i

Assuming that CR2 does not receive PU2's transmission, CR1 may transmit in the same frequency band in the opposite direction of PU2 toward CR2. DOA estimation can thus enhance CR performance by allowing exploitation of vacant bands in space in addition to the frequency domain.

Model and System Description

To formulate the joint spectrum sensing and DOA estimation problem mathematically, assume that the input signal $x(t)$ is composed of N_{sig} source signals $s_i(t)$ with both unknown and different carrier frequencies f_i and DOAs θ_i. The main difference between this scenario and the one that has been discussed in the previous sections is the additional unknown DOAs θ_i. Figure 26 illustrates this signal model. To recover the unknown DOAs, an array of sensors is required. A similar problem thoroughly treated in the literature is the 2D-DOA recovery problem, where two angles are traditionally recovered and paired. In our case, the second variable is the signal's carrier frequency instead of an additional angle.

Multicoset Approach

A few works have recently considered joint DOA and spectrum sensing of multiband signals from sub-Nyquist samples. In [65] and [66], the low rate samples are obtained using multicoset sampling. In [65], which considers the digital model (41), both time and spatial compression are applied by selecting samples from the Nyquist grid and receivers from a uniform linear array (ULA), such that

$$\mathbf{Z}[n] = \mathbf{C}_s \mathbf{X}[n] \mathbf{C}_t. \tag{50}$$

Here, $\mathbf{X}[n]$ is the matrix of Nyquist samples from all receivers in the ULA, the selection matrices $\mathbf{C}_s$ and $\mathbf{C}_t$ operate on the spatial and time domain, respectively, to form the matrix of compressed samples $\mathbf{Z}[n]$. The 2D power spectrum matrix of the underlying signal is then reconstructed from the samples, where every row gives the power spectrum in the frequency domain for a given DOA and every column provides the power spectrum information in the angular domain for a given frequency.

In [66], an L-shaped array with two interleaved, or multicoset, channels, with a fixed delay between the two, τT_{Nyq} with $\tau \in [0, 1]$, samples the signal below the Nyquist rate. The delayed path signal received at the mth sensor is approximated by

$$x_m^d(t) = \sum_{i=1}^{K} s_i(t) \mathrm{e}^{j 2\pi f_i \left(t - \tau T_{\text{Nyq}} + \tau_m(\theta_i)\right)}, \tag{51}$$

using the narrowband assumption on the envelope $s_i(t)$. Here, K denotes the number of transmissions, f_i and θ_i are the carrier and DOAs of transmission i and $\tau_m(\theta_i)$ is the time difference between the mth element to the reference point for a plane wave arriving from the source i in direction θ_i. The samples of both paths is then written in frequency as

$$\mathbf{Z} = \mathbf{A}\mathbf{X}, \quad \mathbf{Z}^d = \mathbf{A}\mathbf{D}\mathbf{X}, \tag{52}$$

where $\mathbf{Z}$ and $\mathbf{Z}^d$ concatenate all samples for each sensor of the direct and delayed path, respectively. Here, $\mathbf{A}$ is the unknown steering matrix that depends on f_i and θ_i, $\mathbf{X}$ is the unknown matrix that contains frequency slices of the signal, and

$$\mathbf{D} \triangleq \operatorname{diag}\left[\mathrm{e}^{j 2\pi f_1 \tau T_{\text{Nyq}}} \cdots \mathrm{e}^{j 2\pi f_K \tau T_{\text{Nyq}}}\right]. \tag{53}$$

Exploiting correlations between samples from the direct path and its delayed version, the frequencies and their corresponding DOAs are estimated using MUSIC [18, 19]. However, the pairing issue between the two, that is matching each frequency with its corresponding angle, is not discussed.

In the next section, we describe the compressed carrier and DOA estimation (CaSCADE) system, presented in [28], that utilizes the sampling principles of the MWC. This technique addresses the pairing problem and avoids the hardware issues involved in multicoset sampling.

The CaSCADE System

The CaSCADE system implements the modified, or ULA based, MWC over an L-shaped array with $2M - 1$ sensors (M sensors along the y axis and M sensors

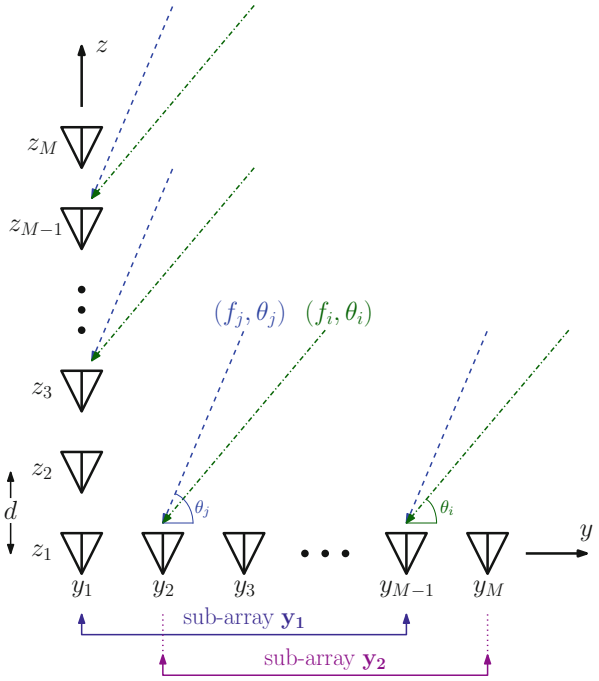

Fig. 27 CaSCADE system: L-shaped array with M sensors along the y axis and M sensors along the z axis including a common sensor at the origin. The sub-arrays $\mathbf{y}_1$ and $\mathbf{y}_2$ (and similarly $\mathbf{z}_1$ and $\mathbf{z}_2$) are defined in the derivation of the 2D-ESPRIT algorithm

along the z axis including a common sensor at the origin) in the yz plane. Each transmission $s_i(t)$ impinges on the array with its corresponding DOA θ_i, as shown in Fig. 27. The array sensors have the same sampling pattern as the alternative MWC. Each sensor is composed of an analog mixing front-end, implementing one physical branch of the MWC, that includes a mixer, a LPF, and a sampler.

By treating the L-shaped array as two orthogonal ULAs, one along the y axis and the other along the z axis, two systems of equations similar to (15) can be derived. For the ULA along the y axis, we obtain

$$\mathbf{y}(f) = \mathbf{A}_y \mathbf{x}(f), \quad f \in \mathscr{F}_s, \tag{54}$$

where

$$\mathbf{A}_y = \begin{bmatrix} e^{j2\pi f_1 \tau_1^y(\theta_1)} & \cdots & e^{j2\pi f_K \tau_1^y(\theta_K)} \\ \vdots & & \vdots \\ e^{j2\pi f_1 \tau_M^y(\theta_1)} & \cdots & e^{j2\pi f_K \tau_M^y(\theta_K)} \end{bmatrix}. \tag{55}$$

Similarly, along the z axis, we get

$$\mathbf{z}(f) = \mathbf{A}_z \mathbf{x}(f), \quad f \in \mathscr{F}_s, \tag{56}$$

where $\mathbf{A}_z$ is defined accordingly. Here,

$$\tau_m^y(\theta) = \frac{d\,m}{c}\cos(\theta), \quad \tau_m^z(\theta) = \frac{d\,m}{c}\sin(\theta) \tag{57}$$

denote the delays at the mth sensors in the y and z axis, respectively, with respect to the first sensor. The matrices $\mathbf{A}_y$ and $\mathbf{A}_z$ thus depend on both the unknown carrier frequencies and DOAs. In the time domain,

$$\mathbf{y}[n] = \mathbf{A}_y\mathbf{x}[n], \quad n \in \mathbb{Z} \tag{58}$$

$$\mathbf{z}[n] = \mathbf{A}_z\mathbf{x}[n], \quad n \in \mathbb{Z}. \tag{59}$$

Two joint recovery approaches for the carrier frequencies and DOAs of the transmissions are proposed in [28]. Note that once the carriers and DOAs are estimated, the signals can be reconstructed, as shown for the alternative MWC. For the sake of simplicity, a statistical model where $x(t)$ is wide-sense stationary is considered. The first recovery approach is based on CS techniques and allows recovery of both parameters assuming the electronic angles $f_i\cos\theta_i$ and $f_i\sin\theta_i$ lie on a predefined grid. The CS problem is formulated in such a way that no pairing issue arises between the carrier frequencies and their corresponding DOAs. To that end, the samples from both ULAs are concatenated into one vector $\mathbf{v}[n] = \left[\mathbf{y}^T[n]\,\mathbf{z}^T[n]\right]^T$, whose correlation matrix,

$$\mathbf{R} = \mathbb{E}\left[\mathbf{v}[n]\mathbf{v}^H[n]\right] = \mathbf{A}\mathbf{R}_x\mathbf{A}^H, \tag{60}$$

is computed. Here, $\mathbf{A} = [\mathbf{A}_y^T\,\mathbf{A}_z^T]^T$ and the autocorrelation matrix $\mathbf{R}_x = \mathbb{E}\left[\mathbf{x}[k]\mathbf{x}^H[k]\right]$ is sparse and diagonal, from the stationarity of $x(t)$. From the grid assumption, (60) may be discretized with respect to the possible values taken by the electronic angles. The resulting sparse matrix derived from $\mathbf{R}_x$ is diagonal as well, and its sparse diagonal is recovered using traditional CS techniques, similarly to (22).

The second recovery approach, inspired by [67], extends the ESPRIT algorithm to the joint estimation of carriers and DOAs while overcoming the pairing issue. The 2D-ESPRIT algorithm presented in [28] is directly applied to the sub-Nyquist samples, by considering cross-correlation matrices between the sub-arrays of both axis. Dropping the time variable n for clarity, the samples from the sub-arrays can be written as

$$\begin{aligned} \mathbf{y}_1 &= \mathbf{A}_{y_1}\mathbf{x}, \quad & \mathbf{y}_2 &= \mathbf{A}_{y_2}\mathbf{x} \\ \mathbf{z}_1 &= \mathbf{A}_{z_1}\mathbf{x}, \quad & \mathbf{z}_2 &= \mathbf{A}_{z_2}\mathbf{x}, \end{aligned} \tag{61}$$

where $\mathbf{y}_1, \mathbf{y}_2, \mathbf{z}_1, \mathbf{z}_2$ are samples from the sub-arrays shown in Fig. 27. The matrices $\mathbf{A}_{y_1}$ and $\mathbf{A}_{y_2}$ are the first and last $M-1$ rows of $\mathbf{A}_y$, respectively, and $\mathbf{A}_{z_1}$ and $\mathbf{A}_{z_2}$

are similarly defined. Each couple of sub-array matrices along the same axis are related by

$$\begin{aligned} \mathbf{A}_{y_2} &= \mathbf{A}_{y_1}\mathbf{D}_{\phi} \\ \mathbf{A}_{z_2} &= \mathbf{A}_{z_1}\mathbf{D}_{\psi}, \end{aligned} \tag{62}$$

where

$$\begin{aligned} \mathbf{D}_{\phi} &\triangleq \text{diag}\left[\mathrm{e}^{j2\pi f_1 \tau_1^y(\theta_1)} \cdots \mathrm{e}^{j2\pi f_K \tau_1^y(\theta_K)}\right] \\ \mathbf{D}_{\psi} &\triangleq \text{diag}\left[\mathrm{e}^{j2\pi f_1 \tau_1^z(\theta_1)} \cdots \mathrm{e}^{j2\pi f_K \tau_1^z(\theta_K)}\right]. \end{aligned} \tag{63}$$

We can see from (63) that the carrier frequencies f_i and DOAs θ_i are embedded in the diagonal matrices $\mathbf{D}_{\phi}$ and $\mathbf{D}_{\psi}$. Applying the ESPRIT framework on cross-correlations matrices between the subarrays of both axis allows to jointly recover $\mathbf{D}_{\phi}$ and $\mathbf{D}_{\psi}$ [28]. This leads to proper pairing of the corresponding elements $f_i\tau_1^y(\theta_i)$ and $f_i\tau_1^z(\theta_i)$. The DOAs θ_i and carrier frequencies f_i are then given by

$$\theta_i = \tan^{-1}\left(\frac{\angle(D_{\psi})_{ii}}{\angle(D_{\phi})_{ii}}\right) \quad f_i = \frac{\angle(D_{\phi})_{ii}}{2\pi\frac{d}{c}\cos(\theta_i)}. \tag{64}$$

It is proven in [28] that the minimal number of sensors required for perfect recovery is $2K+1$. This leads to a minimal sampling rate of $(2K+1)B$, which is slightly higher than the minimal rate $2KB$ required for spectrum sensing in the absence of DOA recovery. These ideas can also be extended to jointly recover the transmissions' carrier frequencies, azimuth, and elevation angles in a 3D framework.

Summary

In this chapter, we reviewed several challenges imposed on the traditional task of spectrum sensing by the new application of CR. We first investigated sub-Nyquist sampling schemes, enabling sampling, and processing of wideband signals at low rate, by exploiting their a priori known structure. A possible extension of these works is to include adaptive updating of the detected support, triggered by a change in a PU's activity, either starting a transmission in a previously vacant band or withdrawing from an active band. To increase efficiency, this should be performed by taking the current detected support as a prior and updating it with respect to the newly acquired samples, without going through the entire support recovery process from scratch. Additional preliminary assumptions on the structure or statistical behavior of the potentially active signals, such as statistics on channel occupancy, can be exploited as well.

We then considered detection challenges in the presence of noise, where second-order statistics recovery, and in particular cyclostationary detection, is shown to

perform better than simple energy detection. Next, fading and shadowing channel effects were overcome by collaborative CR networks. We then addressed the joint spectrum sensing and DOA estimation problem, allowing for better exploitation of frequency vacant bands by exploiting spatial sparsity as well. All these methods should next be combined in order to map the occupied spectrum, in frequency, time, and space, thus maximizing the CR network's throughput. This would require an adequate spectrum access protocol as well that translates the data acquired by spectrum sensing into transmission opportunities for the CRs.

An essential part of the approach adopted in this survey is the relation between the theoretical algorithms and practical implementation, demonstrating real-time spectrum sensing from low rate samples using off-the-shelf hardware components. Indeed, we believe that prototype development is an important component to enabling sub-Nyquist sampling as a solution to the task of spectrum sensing in CR platforms.

Abstract

Cognitive radio (CR) technology is a promising solution to the inevitable problem of spectrum scarcity and underutilization. Cognitive radios can perform spectrum sensing, dynamically identify unused spectrum, and opportunistically utilize those spectrum holes for their own transmission. Cognitive radio

technology is also a key concept suggested to be part of the fifth generation of cellular wireless standards (5G). Efficient spectrum sensing is crucial to the effective deployment of CR networks. Cooperative spectrum sensing (CSS) schemes can significantly improve the sensing accuracy of CR networks by exploiting multiuser spatial diversity. However, the cooperative gain can be impacted by factors such as the detection performance of each secondary user (SU) and the fusion techniques used to combine the secondary users' decisions. Moreover, CSS incurs cooperation overhead that may deteriorate its overall performance. In this chapter, we provide a comprehensive survey on the different factors that contribute to the efficient design of CSS schemes for cognitive radio networks. We specifically focus on the elements of cooperative sensing that can leverage the achievable cooperative gain, limit the cooperation overhead, or provide trade-off between the gain and overhead such as the number of channels sensed in each sensing period, the selection of secondary users, the selection of the fusion scheme, and the correlation between the cooperating secondary users. We also highlight key open research challenges in cooperative spectrum sensing.

Introduction

Driven by the proliferation of new wireless services and applications, as well as the steadily increasing number of wireless users, the demand for radio spectrum has increased dramatically. The government regulatory agencies employ inflexible spectrum management approaches by granting each operator an exclusive license to operate in a certain frequency band. With most of the prime radio frequency spectrum already exclusively assigned, it is becoming exceedingly hard to find vacant bands to either deploy new services or enhance existing ones. However, this spectrum scarcity is mainly due to inefficient fixed frequency allocations rather than a physical shortage in the spectrum. This inefficiency in the spectrum usage necessitates a new communication paradigm to exploit the existing wireless spectrum opportunistically. Dynamic spectrum access (DSA) has been proposed as an alternative policy to allow the radio spectrum to be more efficiently utilized [1]. Using DSA, a portion of the spectrum can be licensed to one or more users, which are called primary users (PUs); however, the use of that spectrum is not exclusively granted to these licensed users, although they have higher priority in using it. The unlicensed users, which are referred to as secondary users, are allowed to opportunistically utilize the unused licensed bands, commonly referred to as "white spaces" or "spectrum holes," as long as the primary users' transmissions can be adequately protected. By doing so, the radio spectrum can be reused in an opportunistic manner or shared all the time which can significantly improve the spectrum utilization efficiency [2]. The key enabling technology of DSA is the cognitive radio (CR) technology.

A cognitive radio system is a radio system which is aware of its operational and geographical environment, established policies, and its internal state. Moreover, it is able to dynamically and autonomously adapt its operational parameters and

protocols and to learn from its previous experience [3]. Cognitive radios are enabled by the rapid and significant advancements in radio technologies (e.g., software-defined radios, frequency agility, power control, etc.) and can be characterized by the utilization of disruptive techniques such as wideband spectrum sensing, real-time spectrum allocation and acquisition, and real-time measurement dissemination [4]. To reliably identify the vacant licensed bands, some methods that the secondary users can employ are geolocation combined with access to database, beacons, spectrum sensing, or a combination of any of those methods [5,6]. In the geolocation method, primary users register the relevant data such as their location and transmit power as well as expected duration of usage at a centralized database. Secondary users then have to access this database to determine the availability of vacant licensed bands at their location. Geolocation database is based on field strength estimates for the primary users obtained using terrain-based radio propagation models. However, the limited geographical information restricts the achievable accuracy of the field strength estimates. Therefore, radio environment mapping (REM) has been introduced as an alternative or complementary procedure to radio propagation models [7–9].

In the beacon method, secondary users only transmit if they receive a control signal (beacon) identifying vacant channels within their service areas. Without reception of this control signal, no transmissions are permitted by the secondary users. In [10], beacon-assisted channel access was assumed in which a codeword from the codebook of the primary users is reserved as a beacon, and each time a primary user releases a channel, it broadcasts this beacon message. The authors assumed that the codebook of the primary users as well as the beacon codeword was a priori known to the secondary users. The proposed protocol showed performance gain in terms of more reliable detection of spectrum holes as well as achieving higher secondary channel capacity. In [11], novel detection schemes employed at the fusion center, namely, the robust estimator-correlator detector and the robust generalized likelihood detector, were proposed for multiple beacon signaling-based cooperative spectrum sensing in multiple-input multiple-output wireless cognitive radio networks with channel state information (CSI) uncertainty. Simulation results demonstrated that the proposed detection techniques yield a significant improvement in the detection performance compared to the conventional CSI uncertainty matched filter detector.

With the aforementioned methods, secondary devices will need additional connectivity in a different band in order to be able to access the database [5] or a dedicated standardized channel will be needed to broadcast the beacons [6]. In the spectrum sensing method, secondary users autonomously detect the presence of the primary signals and only use the channels that are not used by the primary users. All the abovementioned methods have their advantages and disadvantages. It is up to the regulator to decide on the best approach with the considerations from all the stakeholders. However, it is expected that in the future, both database and spectrum sensing techniques will be used together in order to have flexibility and achieve maximum efficiency for secondary users [12]. In this chapter, we focus on spectrum sensing performed by cognitive radios because of its relatively lower

infrastructure cost and its compatibility with licensed primary systems which allows for broader application areas.

Spectrum sensing enables the capability of a cognitive radio to measure, learn, and be aware of the radio's operating environment, such as the spectrum availability and interference status. Availability of radio spectrum varies depending on time, frequency, and location resulting in spectrum access opportunities. Secondary users can use the available idle spectrum in an opportunistic manner by identifying the available spectrum reliably and rapidly. It also helps in quickly determining if the primary users have become active in the bands used by secondary users so that those bands can be vacated immediately. This is important for ensuring that the interference caused to the primary users' transmissions remains below a permitted level. Moreover, detection of other secondary users may be necessary as well for coexistence with other secondary networks. However, due to the effects of multipath fading and shadowing, the signal-to-noise ratio (SNR) of the received primary signal can be extremely low, and a secondary user may not be able to distinguish between a deeply faded band and an idle one. Since receiver sensitivity indicates the capability of detecting weak signals, the sensitivity requirement of the secondary user's receiver may end up being too stringent. In order to mitigate these effects, secondary users often cooperate for spectrum sensing.

The main idea of cooperative spectrum sensing (CSS) is to enhance the sensing performance by exploiting the spatial diversity in the observations of spatially located secondary users [13–17]. Having multiple cooperating secondary users increases diversity by providing multiple measurements of the signal and, therefore, guarantees a better detection performance. Consequently, the diversity gain achieved through cooperative spectrum sensing improves the overall detection sensitivity without imposing higher sensitivity requirements on individual secondary users [18]. A less stringent sensitivity requirement is particularly appealing from the implementation point of view due to the reduced hardware cost and complexity. The performance improvement due to spatial diversity is called cooperative gain. However, cooperative gain is not limited to the improved detection performance and relaxed sensitivity requirement. For instance, since it is difficult, using a single radio, to transmit on a licensed band and sense it simultaneously, sensing has to be interleaved with data transmission [13, 19]. Therefore, if the sensing time can be reduced due to cooperation, secondary users will have more time for data transmission so as to improve their opportunistic throughput which is also considered a part of the cooperative gain. From the above discussion, it is apparent that well-designed techniques for cooperative spectrum sensing can significantly contribute to improving the achievable cooperative gain. However, CSS can incur cooperation overhead and the achievable cooperative gain can be impacted by many factors. The goal of this chapter is to point out several aspects of cooperative spectrum sensing. These aspects are discussed in the rest of this chapter.

In section "Fundamental Concepts of Spectrum Sensing," we present the fundamental concepts of spectrum sensing. In section "Sensing Techniques," we review the most common spectrum sensing techniques for cognitive radio networks and detail their advantages and disadvantages. In section "Cooperative Spectrum

Sensing (CSS)," we present the different elements of cooperative spectrum sensing. In section "Performance of Cooperative Spectrum Sensing," we discuss the different factors impacting the performance of cooperative spectrum sensing. We present some research challenges which offer directions for future work in section "Research Challenges." Section "Conclusions" concludes this chapter.

Fundamental Concepts of Spectrum Sensing

The spectrum sensing problem is traditionally formulated as a binary hypothesis testing problem as described below. To identify the idle spectrum and protect the primary users' transmissions, different local spectrum sensing techniques have been proposed for individual secondary users based on hypothesis testing. Some of the most common spectrum sensing techniques for the detection of primary users' transmissions for cognitive radio networks are discussed in section Sensing Techniques.

Hypothesis Testing

A key task in spectrum sensing is to decide whether the spectrum is idle or busy. The spectrum sensing problem is traditionally formulated as a binary hypothesis test [20]. The null hypothesis denoted by H_0 corresponds to the absence of the primary user's transmission, i.e., the received signal being only noise. On the other hand, the alternative hypothesis denoted by H_1 indicates that the primary user's transmission is present, i.e., the received signal contains the primary signal along with noise. In case the hypotheses have no unknown parameters, the hypotheses are called simple. If there are unknown or unspecified parameters, then the hypotheses are called composite. As an example, a binary hypothesis test for detecting the primary user's transmission in an additive white Gaussian noise (AWGN) channel is given by

$$x(n) = \begin{cases} v(n), & H_0 \\ h(n)s(n) + v(n), & H_1 \end{cases} \tag{1}$$

where $x(n)$ denotes the sampled received signal with sampling rate f_s (Hz) and an observation time T. The channel gain and primary user's transmitted signal are denoted by $h(n)$ and $s(n)$, respectively, and $v(n)$ is the AWGN noise.

In most practical cases, a test statistic Y is computed from the observation vector $\mathbf{x} = [x(1), x(2), .., x(N)]$ containing N observation samples, where $N \triangleq f_s T$ is assumed to be an integer. The detection is based on comparing the test statistic Y to the threshold γ. If the test statistic is greater than the threshold, i.e., $Y > \gamma$, then H_1 is declared true. Otherwise, H_0 is declared true. Two main performance metrics that are crucial in the design of spectrum sensing techniques are the probability

of miss-detection, P_m, and the probability of false alarm, P_f. The probability of miss-detection is defined as the probability that the detector declares the absence of a primary user (PU) transmission (decide H_0), when PU transmission is actually present (H_1 is true). The probability of false alarm is defined as the probability that the detector declares the presence of PU transmission (decide H_1), when PU transmission is actually absent (H_0 is true). Therefore, we represent the probabilities of miss-detection and false alarm, respectively, as [21]

$$P_m = P(H_0|H_1) = P(Y \leq \gamma|H_1), \tag{2}$$

and

$$P_f = P(H_1|H_0) = P(Y > \gamma|H_0). \tag{3}$$

It is clear that we need the probability of detection to be high as it indicates the level of protection of the primary users' transmissions from the interfering secondary users' transmissions. On the other hand, low probabilities of false alarm are necessary in order to maintain high opportunistic secondary throughput, since a false alarm would prevent the unused bands from being accessed by secondary users leading to inefficient spectrum usage.

Primary Transmitter Detection

The transmitter detection model is based on the detection of weak signals from a primary transmitter through the local observations of secondary users. This model has a wider applicability due to its compatibility with the licensed systems. The main drawback of the primary transmitter sensing model is its reliance on the detection of primary transmitters to infer the availability of white spaces while the interference happens at the primary receivers. As such, a detection margin has to be included in order to protect primary receivers [6].

When the primary system employs bursty transmission, the secondary user can detect the empty time slots and multiplex its signal over them without causing any performance degradation at the primary receivers. On the other hand, when the primary system employs continuous transmission, the secondary user has to estimate the interference it generates at the primary receivers by using signal level measurements. If the transmitter of the secondary user is far from the primary receiver, depending on the signal-to-interference ratio (SIR) limit at the receiver of the primary user supplied by the regulatory bodies, both the primary user and the secondary user could transmit data simultaneously [6, 22]. In this case, the interference range is defined as the minimum distance that a secondary transmitter should be away from the primary receiver such that it does not cause harmful interference at this receiver. Figure 1 shows the primary receiver located at a

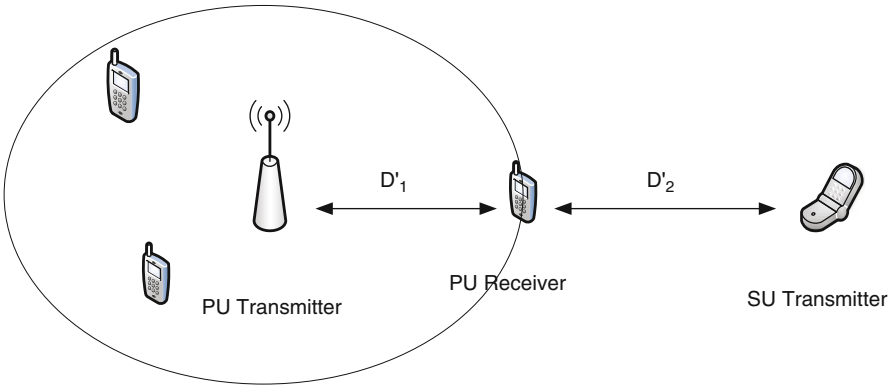

Fig. 1 Interference range of a cognitive radio

distance D_1' from the primary transmitter and D_2' is the interference range. The interference range will depend on the SU-transmitted power and the primary receiver's interference tolerance and can be obtained from [23]

$$\text{SIR} = \frac{P_u' h(D_1')}{P_s' h(D_2') + P_b'}, \tag{4}$$

where P_u' and P_s' are the transmit power of the primary and secondary users, respectively, $h(D')$ is the channel gain at distance D' from the transmitter, and P_b' is the background interference power at the primary receiver.

To avoid causing harmful interference to the primary receiver, the secondary user must be able to detect a signal from the primary transmitter within the range of $D_1' + D_2'$ which can translate to a certain sensitivity requirement for the secondary detector. Although the cases where an active primary transmitter is present but it is far away from the secondary user fall under hypothesis H_1, the interference to the primary receiver would not be harmful, and as such these cases should be treated as white space by definition. In particular, since the detection of the primary transmitter is dependent on the SNR at the secondary user as seen in (1), it would be unlikely for low-SNR primary signals to trigger the secondary user's detector resulting in unusable white spaces [24].

Sensing Techniques

In this section, we will discuss some of the most common spectrum sensing techniques for the detection of the primary transmitter in the cognitive radio literature. From the perspective of signal detection, sensing techniques can be classified into two broad categories: coherent and noncoherent detection. In coherent detection,

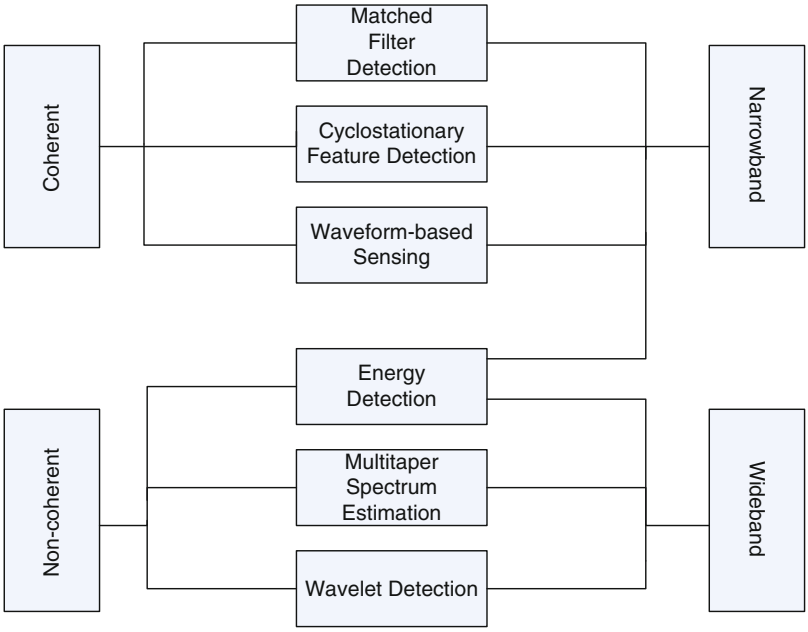

Fig. 2 Classification of spectrum sensing techniques

the primary signal can be coherently detected by comparing the received signal or the extracted signal characteristics with prior knowledge of primary signals. In noncoherent detection, no prior knowledge of the primary signal is required for detection. Another way to classify sensing techniques is based on the bandwidth of the spectrum of interest, that is, narrowband and wideband. The classification of sensing techniques is shown in Fig. 2. Next, we introduce matched filter detection, energy detection, and cyclostationary detection and briefly discuss some other spectrum sensing techniques. A more complete review on various spectrum sensing techniques and design challenges can be found in [25, 26].

Matched Filter Detection

Matched filtering is known as the optimum method for the detection of the primary signal when the transmitted signal is known, since it maximizes the received signal-to-noise ratio (SNR). The main advantage of matched filtering is the short time it requires to achieve a certain detection performance, such as low probabilities of miss-detection and false alarm [27], since a matched filter needs less received signal samples. However, matched filtering requires the secondary users to demodulate the received signals. Therefore, it requires perfect knowledge of the primary users' signaling features such as bandwidth, operating frequency, modulation type and

order, and pulse shaping as well as accurate synchronization at the secondary user [25, 28, 29]. However, in cognitive radio networks, such knowledge is not readily available to secondary users, and the implementation cost and complexity of this detector are high. Another significant drawback of matched filter detection is that a secondary user would need a dedicated receiver for every primary user class [30].

Energy Detection

Energy detection [21, 31] is a noncoherent detection method that is most commonly used if the receiver cannot gather sufficient information about the primary user's signal. This simple scheme accumulates the energy of the received signal during the sensing interval and declares the primary band to be occupied if the energy surpasses a certain threshold which depends on the noise floor [21]. Due to its simplicity and the fact that it does not require prior knowledge of the primary users' signals, energy detection is the most popular sensing technique among others for spectrum sensing [6, 15, 32–34]. However, some of the challenges with energy detection include selection of the threshold for detecting primary users, inability to differentiate interference from primary users' transmission and noise, and poor performance under low signal-to-noise ratio [29]. Moreover, energy detection does not work efficiently for detecting spread spectrum signals for which more sophisticated signal processing algorithms need to be devised [35].

In addition to narrowband sensing, energy detection has been used for multiband joint detection in wideband sensing by employing an array of energy detectors, each of which detects one frequency band [36]. The multiband joint detection framework enables secondary users to simultaneously detect primary users' signals across multiple frequency bands for efficient management of the wideband spectrum resource at the cost of detection hardware.

Cyclostationary Feature Detection

Another detection method that can be applied for spectrum sensing is the cyclostationary feature detection. Modulated signals are in general coupled with sinusoidal wave carriers, pulse trains, repeated spreading or hopping sequences, or cyclic prefixes, which result in built-in periodicity. Cyclostationary features are caused by the periodicity in the signal or in its statistics such as mean and autocorrelation [29]. Cyclostationary feature detection is a method for detecting primary user transmissions by exploiting the cyclostationary features of the received signals. Instead of power spectral density (PSD), cyclic correlation function is used for detecting signals present in a given spectrum. The cyclostationary-based detection algorithms can differentiate noise from primary users' signals. This is a result of the fact that noise is wide-sense stationary with no correlation, while modulated signals are cyclostationary with spectral correlation due to the redundancy of signal periodicity. Therefore, a cyclostationary feature detector can perform better than

the energy detector in discriminating against noise due to its robustness to the uncertainty in noise power [28, 37]. However, it is computationally complex and requires significantly long observation time. Moreover, it requires the knowledge of the cyclic frequencies of the primary users, which may not be available to the secondary users.

Other Sensing Techniques

Alternative spectrum sensing methods include waveform-based sensing, multitaper spectral estimation, and wavelet detection. Waveform-based sensing is usually based on correlation with known signal patterns. Known patterns are usually utilized in wireless systems to assist synchronization or for other purposes. Such patterns include preambles, regularly transmitted pilot patterns, and spreading sequences. In [35], it was shown that waveform-based sensing outperforms energy detector-based sensing in reliability and convergence time. Furthermore, it was shown that the performance of the sensing algorithm increases as the length of the known signal pattern increases. Waveform-based sensing, however, is only possible when the target primary user's signal contains known signal patterns.

In [38], the authors proposed a spectrum sensing method based on the auto-correlation of the received samples. The proposed method was evaluated by means of experiments wherein the probabilities of detection and false alarm at different signal-to-noise ratios (SNRs) were observed. A metric called the Euclidean distance was derived to analyze the autocorrelation of the received samples in order to decide whether only noise was present or signal plus noise. Simulation results showed that the proposed method is more efficient than using autocorrelation function at first lag method in terms of probability of detection and false alarm and more efficient than the energy detection method in terms of probability of false alarm.

Multitaper spectrum estimation was proposed in [39]. The proposed algorithm was shown to be an approximation to the maximum likelihood power spectral density estimator, and for wideband signals, it is nearly optimal. Most importantly, unlike the maximum likelihood spectral estimator, the multitaper spectral estimator is computationally feasible. In [40], wavelets are used for detecting edges in the power spectral density of a wideband channel. Once the edges, which correspond to transitions from an occupied band to an empty band or vice versa, are detected, the power within the bands between two edges is estimated. Using this information and the edges' positions, the power spectral density can be characterized as occupied or empty in a binary fashion. The assumptions made in [40], however, need to be relaxed for building a practical sensing algorithm. The method proposed in [40] was extended in [41] by using sub-Nyquist sampling (compressed sensing). Assuming that the signal spectrum is sparse, sub-Nyquist sampling is used to obtain a coarse spectrum knowledge in an efficient way. Table 1 presents a brief comparison of the above spectrum sensing techniques.

Table 1 Comparison of spectrum sensing techniques

Spectrum sensing technique	Advantages	Disadvantages
Matched filter detection	- Optimal performance - Low computational cost	Requires prior knowledge of the primary user's signal
Energy detection	- Low complexity - No primary knowledge required	- Poor performance for low SNR - Cannot differentiate signal and noise
Cyclostationary detection	- Robust in low SNR region - Robust against interference	- Requires partial prior information - High computational cost
Waveform-based detection	- Robust in low SNR region - Short measuring time	- Requires prior knowledge of the primary user's signal - Susceptible to synchronization errors
Multitaper spectrum estimation	- Near-optimal performance for wideband signals - No primary knowledge required	High implementation complexity
Wavelet detection	Effective for wideband signal detection	- Requires high sampling rate analog-to-digital converter - High computational cost

Cooperative Spectrum Sensing (CSS)

In cooperative spectrum sensing, information from multiple secondary users are incorporated for the detection of the primary signal. In the literature, cooperative sensing is discussed as a solution to problems that arise in spectrum sensing due to noise uncertainty, fading, and shadowing since the uncertainty in a single user's detection can be minimized [32]. The main idea of cooperative sensing is to enhance the sensing performance by exploiting the spatial diversity in the observations of spatially located secondary users. By cooperation, secondary users can share their sensing information for making a combined decision more accurate than the individual decisions [17]. The performance improvement due to spatial diversity is called cooperative gain. While cooperative gain such as improved detection performance and relaxed sensitivity requirement can be obtained, cooperative sensing can incur cooperation overhead. Cooperation overhead refers to any extra sensing time, delay, energy, and operations devoted to cooperative sensing and any performance degradation caused by cooperative sensing.

Cooperation Architecture

Depending on how the secondary users share their sensing data, several cooperative spectrum sensing architectures for CR networks have been proposed in the literature [15, 42–44]. The most commonly proposed architecture is the parallel fusion

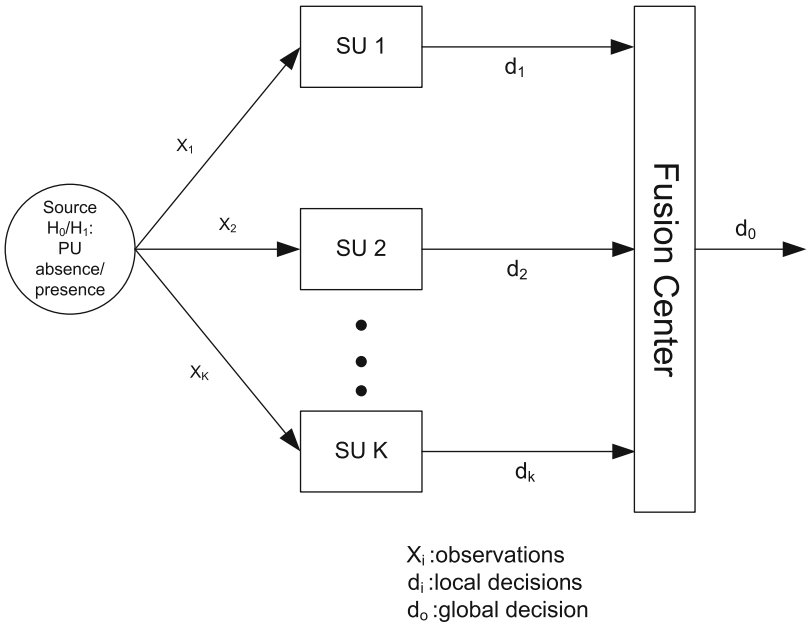

Fig. 3 Parallel fusion architecture

architecture, in which all the sensing secondary users send their sensing information directly to a centralized controller called a fusion center. This fusion center then makes a final decision regarding the presence or absence of the primary signal and broadcasts this information to other secondary users or directly controls the cognitive radio network traffic [15, 32, 42]. The parallel fusion architecture is illustrated in Fig. 3.

Another possible sensing architecture is the decentralized sensing architecture which does not rely on a fusion center for making the cooperative decision [16, 35, 44]. In this case, secondary users exchange the sensing observations and converge to a unified decision on the presence or absence of primary user's transmissions by iterations. Based on a distributed algorithm, each secondary user sends its own sensing data to other users, combines its data with the received sensing data, and decides whether or not the primary user's transmission is present by using a local criterion. If the criterion is not satisfied, secondary users send their combined results to other users again and repeat this process until the algorithm is converged and a decision is reached. The decentralized sensing architecture is illustrated in Fig. 4.

Fusion Schemes

In cooperative sensing, a fusion scheme refers to the process of combining locally sensed data of individual secondary users. Depending on which type of sensing data

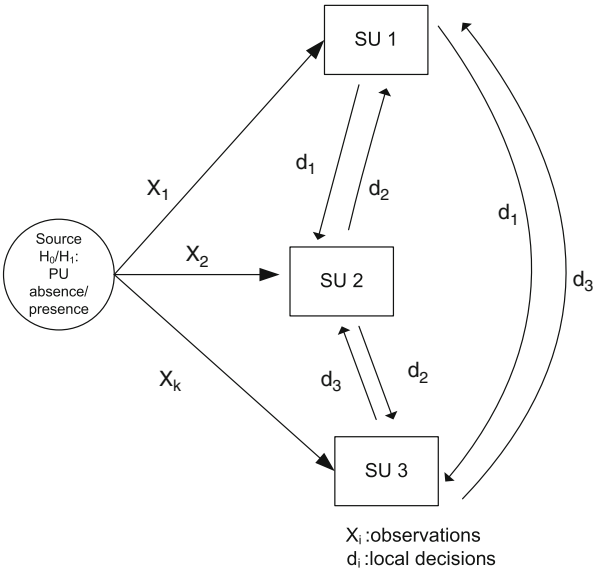

Fig. 4 Decentralized fusion architecture

is transmitted to the fusion center or shared with neighboring users, CSS can employ data or decision fusion schemes. In soft-decision schemes (data fusion), secondary users exchange their test statistics calculated from their local observations. On the other hand, in the hard decision schemes (decision fusion), secondary users only exchange their individual binary decisions.

Soft Combining and Data Fusion

Existing receiver diversity techniques such as equal gain combining (EGC) and maximal ratio combining (MRC) can be utilized for soft combining of local observations or test statistics. If the channel state information (CSI) between the primary users and the secondary users are perfectly known, the optimal combining strategy, which is MRC, can be used for achieving the highest output SNR. In MRC, the local observations of secondary users are weighted proportionately to their channel gain and then summed up [45]. In EGC, the local observations of secondary users are weighted equally [46]. The EGC scheme has a performance close to that of MRC but with simpler implementation.

It was shown in [47] that the soft combining scheme yields better gain than the hard combining scheme. However, there is a significant difference in the cooperation overhead between the hard- and soft-decision-based detectors, which requires a wideband control channel for the soft-decision cooperative approach. The soft information-based signal detection method for the single-carrier case and multi-carrier case was investigated in [48]. In [33], a linear cooperation strategy was developed which is based on the optimal combination of the local statistics from

spatially distributed secondary users. In [49], an optimal soft combination scheme based on Neyman-Pearson criterion was proposed to combine the weighted local observations. The proposed scheme reduces to EGC at high SNR and reduces to MRC at low SNR. Since such a soft combining scheme results in large overhead, a softened two-bit combining scheme was also proposed for energy detection. In this method, there are three decision thresholds dividing the whole range of test statistics into four regions. Each secondary user reports the quantized two-bit information of its local test statistics. The performance of this method is comparable to the performance of the EGC scheme with less complexity and overhead.

In [50], the authors proposed a cooperation strategy in which the local decisions are combined with weighting factors that reflect the local sensing reliability of each secondary user based on partial channel side information to make a final decision with the correspondingly optimized threshold level. In [51], the authors proposed a weighted cooperative spectrum sensing scheme for which the optimal weights are derived under the constraint of equal probabilities of false alarm and miss-detection. They also incorporated reference matrix into the weight setting procedure to store the most recent sensing data in either noise matrix or signal energy matrix according to their corresponding sensing decisions in order to acquire the primary user signal energies from the sensing data of the cooperating sensing nodes. In [52], the authors proposed a cooperative spectrum sensing technique which considers the spatial variation of secondary users, and each user's contribution is weighted by a factor that depends on the received power and path loss. The proposed scheme provides better probability of detection and spectrum utilization when compared to EGC scheme.

In [53], the authors proposed a weighted cooperative sensing scheme that assigns weights to secondary users based on the local detection accuracy of each SU, instead of SNR. In this scheme, the authors used the total error probability, which combines the false-alarm probability and miss-detection probability, to measure the detection accuracy. At the fusion center, each cooperating user is assigned a weight corresponding to its probability of error, i.e., an SU with higher probability of error is assigned lower weight. The optimal detection threshold, as well as the number of SUs required to participate in cooperative sensing, was derived, subject to a given total error probability. Simulation results showed that the proposed scheme provides performance improvement, in terms of the probability of error, when compared to the equal weighted and SNR-based weighted schemes. The authors in [54] proposed a penalty-based weight adjustment mechanism for cooperative spectrum sensing (CSS) to enhance the adaptability of secondary users in time-varying environments. Similar to [53], each secondary user is characterized by its probability of error but the weight factor is adjusted using a penalty mechanism based on the current local decision made by the secondary user. The final result is then computed by fusion of weighted soft decisions made by each cooperating secondary user.

In [55], an adaptive weighting scheme with double threshold energy detection based on the water-filling principle was proposed for cooperative spectrum sensing. For this scheme, each secondary user was allocated a weighting factor based on the relation between the instantaneous SNR of the sensing channel and the water

level. The authors showed that the proposed weighting scheme can achieve better detection performance and lower average number of sensing bits when compared to the equal weighted and SNR weighted schemes. A cooperative spectrum sensing scheme based on ROCQ reputation management model for cognitive radio networks was proposed in [56]. The ROCQ scheme is a reputation-based trust management system that computes the trustworthiness of peers on the basis of transaction-based feedback. The ROCQ model combines four parameters: (i) reputation, (ii) a peer's global trust rating or opinion formed by a peer's firsthand interactions, (iii) credibility of a reporting peer, and (iv) the quality or the confidence a reporting peer puts on the feedback it provides. In this scheme, each secondary user has a reputation degree used to calculate its coefficient in the linear fusion process, and the reputation degree is initialized and adjusted by the fusion center according to each secondary user's sensing result, sensing correctness, and report consistency. Simulation results showed that the detection performance of the proposed scheme in [56] is approximately the same as that of the optimal linear fusion scheme while it requires no instantaneous SNR.

Hard Combining and Decision Fusion

In the hard combining scheme, the final decision is reached by taking into consideration the individual local decisions reported by each secondary user. When binary local decisions are reported to the fusion center, it is convenient to apply linear fusion rules to obtain the cooperative decision. The main advantage of the hard combining scheme is the reduction of communication overhead. Hard decision combining for CSS has been considered in several works [47,49,57]. The commonly used fusion rules are AND, OR, and majority voting rules which are special cases of the general K-out-of-M rule. Those decision fusion rules can be summarized as below [58]:

- **K-out-of-M rule**: In this fusion rule, the fusion center decides on the presence of the primary user's transmission if, and only if, K or more than K secondary users out of the total M cooperating secondary users report the detection of the primary user's signal, where $K \in [1, M]$. Therefore, in the K-out-of-M rule, if K users or more decide in favor of H_1, then the cooperative decision declares that H_1 is true. If the decisions from all the secondary users are independent, the network probabilities of detection and false alarm are, respectively, given by [59]

$$P_D = \sum_{k=0}^{M-K} \binom{M}{K+k} (1 - P_{d,k})^{M-K-k} (P_{d,k})^{K+k}, \tag{5}$$

and

$$P_F = \sum_{k=0}^{M-K} \binom{M}{K+k} (1 - P_{f,k})^{M-K-k} (P_{f,k})^{K+k}, \tag{6}$$

where $P_{d,k}$ and $P_{f,k}$ are, respectively, the probabilities of detection and false alarm of the kth secondary user and $\binom{M}{K+k} = \frac{M!}{(K+k)!(M-K-k)!}$.

- **Majority voting (MV) rule**: In the MV fusion rule, also known as half-voting rule, if half, or more than half, of the local detectors decide that there is a primary user's transmission, then the final decision at the fusion center declares that there is a primary user's transmission [58]. Therefore, for the MV rule, the cooperative decision declares H_1 only if half or more than half of the secondary users decide on H_1, i.e., $K = \lceil \frac{M}{2} \rceil$ in (5) and (6), where $\lceil \frac{M}{2} \rceil$ denotes the smallest integer not less than $\frac{M}{2}$. If the decisions from all the secondary users are independent, the network probabilities of detection and false alarm are, respectively, given by

$$P_D = \sum_{k=0}^{M-\lceil \frac{M}{2} \rceil} \binom{M}{\lceil \frac{M}{2} \rceil + k} (1 - P_{d,k})^{M-\lceil \frac{M}{2} \rceil - k} (P_{d,k})^{\lceil \frac{M}{2} \rceil + k}, \tag{7}$$

and

$$P_F = \sum_{k=0}^{M-\lceil \frac{M}{2} \rceil} \binom{M}{\lceil \frac{M}{2} \rceil + k} (1 - P_{f,k})^{M-\lceil \frac{M}{2} \rceil - k} (P_{f,k})^{\lceil \frac{M}{2} \rceil + k}. \tag{8}$$

- **Logical OR rule**: In this fusion rule, the fusion decides on the presence of primary user's transmission if any of the secondary users reports the detection of the primary user's transmission. Therefore, for the OR rule, the cooperative decision declares H_1 if any of the secondary users decides on H_1, i.e., setting $K = 1$ in (5) and (6). Since an SU occupying a licensed frequency band may cause interference to the primary users, the risk of SUs causing interference to the primary users is minimized using the logical OR rule. If the decisions from all the secondary users are independent, the network probabilities of detection and false alarm are, respectively, given by

$$P_D = 1 - \prod_{k=1}^{M} (1 - P_{d,k}), \tag{9}$$

and

$$P_F = 1 - \prod_{k=1}^{M} (1 - P_{f,k}). \tag{10}$$

- **Logical AND rule**: In the AND fusion rule, if all local detectors decide that there is a primary user's transmission, then the final decision at the fusion center declares that there is a primary user's transmission [58]. Therefore, for the AND rule, the cooperative decision declares H_1 only if all of the secondary users decide on H_1, i.e., setting $K = M$ in (5) and (6). Using this fusion rule, the

probability of false alarm is minimized, but the risk of causing interference to primary users will increase. If the decisions from all the secondary users are independent, the network probabilities of detection and false alarm are, respectively, given by

$$P_D = \prod_{k=1}^{M} P_{d,k}, \tag{11}$$

and

$$P_F = \prod_{k=1}^{M} P_{f,k}. \tag{12}$$

In [60], the authors proposed a decision fusion rule for the sensing-throughput trade-off design that considers the differences in the signal-to-noise ratios of the secondary users. These differences were reflected in the weighing of the decisions based on the likelihood ratio test at the fusion center. A decision fusion scheme was proposed in [61] that combines all secondary users decisions, taking into account the credibility of each decision via Dempster-Shafer (D-S) theory of evidence. This scheme can give a significant improvement in detection probability as well as reduction in false-alarm rate and is best suited for a fast-changing radio frequency environment. In [62], an enhanced scheme was proposed that assigns a reliability value to each detector based on its SNR. This value reflects the relative relationship between detectors and is used to adjust the credibility of each decision to a more accurate value before combining the decisions via D-S theory. In [63], the authors proposed a trust weighted cooperative spectrum sensing scheme to identify malicious secondary users and mitigate their harmful effect on sensing performance. To make an accurate final decision, the trust weight factor of each SU is calculated by their trust values. The fusion center initializes the trust values of SUs by the number of true sensing that agrees with the primary user's actual behavior and the number of total sensing. The trust value for each secondary user is then increased or decreased according to whether it provides true or false sensing information. Simulation results showed a performance improvement in the probability of detection as compared to the conventional cooperative spectrum sensing scheme without trust weighted factors for OR, AND, and majority fusion rules. In [64], a centralized trust management scheme for secondary user base station was proposed. The authors introduced the notion of self-confidence and trust. Self-confidence is a rate supplied by a sensing secondary user of its own confidence on the accuracy of its sensing results. Trust is a measure of reputation and represents the historical accuracy of secondary user's sensing reports. The authors incorporated the trustworthiness evaluation from a modified beta reputation model into the K-out-of-M decision fusion rule to give greater weight to the opinions of more trustworthy secondary users.

Performance of Cooperative Spectrum Sensing

In this section, we discuss some of the factors affecting the performance of CSS, in terms of cooperation gain or incurred overhead, such as the number of channels sensed in each sensing period, the selection of secondary users, the selection of the fusion scheme, and the correlation between the cooperating secondary users. We also discuss the performance of cooperative wideband spectrum sensing.

Cooperative User Selection

The selection of secondary users for cooperative sensing plays a key role in determining the performance of CSS because it can be utilized to improve the trade-off between cooperative gain and cooperation overhead. In [57], for the case of independent secondary users' observations with energy detection-based cooperation, it was shown that cooperating with all users in the network does not necessarily achieve the optimum performance. It was observed that including secondary users experiencing bad channels, in terms of the SNR received at a secondary user, for cooperation may degrade the performance. In order to relax the requirement on prior knowledge of the received SNR at each secondary user, the authors in [65] proposed to select the sensing secondary users that have the best detection probabilities with respect to a given false-alarm probability. Specifically, the false-alarm probability is set to be identical at each secondary user. Therefore, the SU that reports the largest number of 1's is first chosen to participate in cooperative sensing. In [66], the optimal number of secondary users, K, that minimizes the total error probability for secondary users with independent local decisions for the general K-out-of-M fusion rule was found to be approximately half of the total number of secondary users M. A user selection strategy based on a modified deflection coefficient with low complexity was proposed in [67]. The optimal number of secondary users and the user set were obtained in order to provide sufficient protection to the primary users and improve the total throughput of the cognitive radio network. CSS using counting rule was studied in [68], and the sensing errors were minimized by choosing the optimal probability of false alarm to satisfy a given constraint and the optimal number of cooperating secondary users for both matched filtering and energy detection.

When the cooperating secondary users experience correlated shadowing, it was shown in [18] that selecting independent secondary users for cooperation can improve the robustness of sensing results. In [69], a correlation-aware user selection algorithm was developed to address the dynamic changes in the spatial correlation experienced by mobile secondary users. To accurately derive the spatial correlation coefficient, a correlation model between mobile secondary users was first developed. Based on this correlation model, a distributed user selection algorithm that adaptively selects uncorrelated secondary users through the spatial correlation coefficient was designed. In [70], a joint spatial-temporal sensing scheme for CR

networks was proposed, where secondary users collaboratively estimate the location and transmit power of the primary transmitter. Based on those estimates, secondary users determine their maximum allowable transmission power and use the location information to decide which users should participate in cooperative sensing in order to minimize the correlation among the secondary users' observations. CSS with correlated secondary users' local decisions was studied in [71]. The probability of sensing error was minimized by choosing the optimal assignments for the number of cooperating secondary users, K, in the K-out-of-M fusion rule and the local threshold for a certain correlation index.

Moreover, removing malicious users from cooperation ensures the security and the reliability of the network. A robust secondary user selection algorithm for CSS considering the presence of malicious users was proposed in [72]. The users were selected based on the consistency check with known trusted users, and simulation results showed that the proposed algorithm is effective in identifying and excluding malicious secondary users. The authors in [73] presented a soft-decision reporting scheme that is robust against malicious users. They proposed a heuristic approach to iteratively identify malicious users, where the fusion center computes the secondary user's suspicious level, i.e., the posterior probability that this SU is an attacker, based on the honest SU and malicious SU report probabilities. These probabilities are estimated assuming that the fusion center knows the position of the users' and the attackers' policy. When the suspicious level of the secondary user goes beyond a threshold, it is discarded from the final decision process and moved into a malicious user set. This process is repeated until no more malicious users can be found, and only the reports from honest users are fused to make the final decision.

Most of the existing cooperative sensing schemes assume all the secondary users are willing to cooperate. In reality, some selfish secondary users may refuse to provide the sensing results to save energy or transmission time, while benefiting from sensing results of other users which may disrupt CSS. To enhance the cooperation, several researchers investigate this incentive problem from the perspective of game theory.

In [74], the authors modeled the cooperative spectrum sensing as an N-player horizontal infinite game and then studied various strategies with it. They examined the classical grim trigger strategy and proved it can sustain cooperation easily but will result in poor performance under uncertainty of wireless channel. They then proposed a strategy based on the carrot-and- stick strategy which can recover cooperation from deviation. The authors proved that the proposed strategy can achieve mutual cooperation as well as recover from failures. Performance evaluation showed that the proposed strategy can achieve good network performance and reduce interference to primary users.

In [75], the author proposed an evolutionary game-theoretic framework to develop the best cooperation strategy for cooperative sensing with selfish users. Using replicator dynamics, users can try different strategies (behavior dynamics) and learn a better strategy through strategic interactions (evolutionarily stable strategy). The authors also proposed a distributed learning algorithm that aids the secondary users approach the evolutionarily stable strategy only with their own

payoff history. Simulation results showed that the proposed game has a better performance, in terms of total throughput, than having all secondary users sense at every time slot.

In [76], the authors proposed a game in which every user can choose to collaborate or not in each time slot depending on whether the benefit of the cooperation is worth the cost. From this perspective, the cooperative spectrum sensing game was modeled as the stag hunt game. The authors then proposed cooperative communication incentive scheme (CCIS) to enhance the cooperative sensing. The basic idea is to introduce a periodically available trusted authority to compensate the secondary users (e.g., using the relay to help transmit their data during transmission time) who suffer losses in the cooperative sensing.

Cooperation Overhead

The exploitation of spatial diversity in cooperative sensing results in a significant improvement in detection performance. However, cooperation among secondary users may also introduce a variety of overheads that limit or even compromise this improved detection performance. The overhead associated with all elements of cooperative sensing is called cooperation overhead. Cooperation overhead can refer to any transmission cost, extra sensing time, delay, energy, and operations devoted to cooperative sensing and any performance degradation caused by cooperative sensing.

Since the sensing time is proportional to the number of samples taken by each individual secondary user, the longer the sensing time is, the better the detection performance will be. However, when each secondary user is equipped with a single radio transceiver, it will be difficult for the secondary users to simultaneously perform sensing and transmission. Therefore, the more time is devoted to sensing, the less time is available for transmissions which reduces the secondary users' throughput, also known as opportunistic throughput. In addition, the cooperation overhead due to the extra sensing time will generally increase with the number of cooperating users due to the increased volume of data that needs to be reported to and be processed by the fusion center. This is known as the sensing efficiency problem [77] or the sensing-throughput trade-off [59] in spectrum sensing.

The cooperation overhead, in terms of the extra sensing time or reduced opportunistic throughput, will also increase as the delay in finding an available channel increases [78]. In [79], a sensing-period optimization mechanism and an optimal channel-sequencing algorithm were developed to maximize the discovery of spectrum access opportunities and minimize the delay in discovering an available channel when all secondary users participate in sensing an identical channel in each sensing period. In [80], two different channel sensing policies, the random sensing policy and the negotiation-based sensing policy, were proposed to discover the available channels. In both policies, different users are allowed to sense different channels that are selected either randomly or through negotiation, which enables SUs to identify and utilize the maximum number of vacant channels. The authors

assumed that each secondary user is equipped with two transceivers. One transceiver is tuned to the dedicated control channel, and another transceiver is used to periodically sense and dynamically use the identified unused channels. Parallel cooperative sensing was proposed in [81,82] where the cooperative secondary users are divided into multiple groups, and each group senses one channel such that more than one channel are sensed in each sensing period. Since multiple channels are detected in one sensing period, the cooperation overhead associated with the delay in finding an available channel is significantly reduced.

Since each sensing phase is usually separated into several subslots used for signal detection and decision reporting, reporting delay will also affect the performance of cooperative spectrum sensing. In [83], the authors proposed cooperative spectrum sensing where the secondary network optimizes the decision thresholds at the sensors and the division between time samples used for sensing the primary users and time slots used for reporting the sensing results. Simulation results showed that joint optimization of thresholds and sensing/reporting time slots achieve good sensing performance in terms of the network probabilities of false alarm and miss-detection.

In [84], the authors proposed two distributed reporting SU selection methods to reduce the overall sensing overhead and to mitigate the interference to PUs in CR networks. The authors also considered the reporting channel errors and the interference impact on PUs induced by decision reporting. Simulation results showed that the proposed strategies achieve better detection performance and lower sensing overhead than the traditional case.

In cooperative sensing, secondary users involve in activities such as local sensing and data reporting that consume additional energy. The energy consumption overhead can be significant if the number of cooperating secondary users or the amount of sensing results to be reported is large. One approach to address this issue is to use censoring to limit the amount of reported sensing data according to certain criteria or constraints. Since the censoring criteria are chosen to refrain cooperating secondary users from transmitting unnecessary or uninformative data, the energy efficiency can be improved in cooperative sensing. In [85], a simple censoring method was proposed to decrease the average number of sensing bits reported to the fusion center. In this method, the energy detector output of each secondary user is compared to two thresholds, and the decision is sent to the fusion center if the energy detector output is between those two thresholds. Otherwise, no decision is made and this sensing output is censored from reporting. The simulation results showed that even though the network probability of false alarm may degrade due to the possibility that the sensing outputs of all secondary users are censored, the amount of reported local decisions can be dramatically reduced. Therefore, the energy efficiency can be traded off with the network probability of false alarm.

Another approach to reduce the cooperation overhead in terms of energy consumption is to minimize the energy consumption with detection performance constraints. In [86], the energy efficiency problem was addressed by energy minimization under detection performance constraints. This method investigates the trade-off between the two aspects of sensing time. On one hand, longer sensing

time consumes more energy at each secondary user. On the other hand, longer sensing time can improve detection performance at each secondary user and reduce the number of cooperating users and the associated energy consumption overhead. Therefore, this method finds the optimal sensing time and the optimal number of cooperating users to balance the energy consumption in local sensing and the energy overhead due to cooperation for a required detection performance.

An energy-efficient CSS scheme was proposed in [87] to maximize the energy efficiency. The authors proposed a method in which sensing time, sensing threshold, and the number of cooperating SUs are jointly optimized. In [88], the authors proposed an efficient algorithm to solve the general problem of spectrum efficiency and energy efficiency trade-off in cognitive radio with cooperative sensing. The authors then considered the trade-off between spectrum efficiency and energy efficiency such that the energy efficiency (spectrum efficiency) is maximized via joint optimization of sensing duration and final decision threshold under the constraint that the spectrum efficiency (energy efficiency) requirement is satisfied. Simulation results showed that different spectrum efficiency (energy efficiency) requirements need different optimal values of sensing duration and final decision threshold, and there exists a trade-off between the spectrum efficiency and energy efficiency.

To alleviate the energy deficiency, radio frequency (RF) harvesting techniques have become alternative methods through which green energy can be used to power the next generation wireless networks [89]. Recently, energy harvesting communication has been considered for cognitive radio networks in order to improve both energy and spectral efficiency in wireless and mobile networks. In [90], the transmitters in a CR network either opportunistically harvest RF energy from transmissions by nearby devices in a primary network or transmit data if the devices are not in the interference range of any other primary network. The optimal transmit power and density of the secondary transmitters that maximize the throughput of the CR network were derived under an outage probability constraint. The authors in [91] investigated the optimal detection threshold for opportunistic spectrum access in an energy harvesting CR network to maximize the expected total throughput under both the energy causality constraint and the collision constraint. In [92], the authors extended the work in [91] to investigate the optimal sensing duration and sensing threshold that jointly maximize the average throughput for a given amount of harvested energy.

Multiband Spectrum Sensing

Wideband spectrum sensing, which we also refer to in this chapter as multiband sensing, faces technical challenges, and there is limited work on it in the literature. To sense multiple frequency bands simultaneously, secondary users may need to scan the spectrum or use multiple radio frequency (RF) front ends for sensing multiple bands. However, using these approaches for wideband sensing either causes long sensing delay or incurs high computational complexity and hardware

cost. Recent advances in compressed sensing [41, 93] enable the sampling of the wideband signals at sub-Nyquist rate to relax the analog-to-digital converter (ADC) requirements. The techniques of compressed sensing provide promising solutions to promptly recover wideband signals and facilitate wideband sensing at a reasonable computational complexity. Compressed sensing can be achieved by various sensing matrix techniques such as random matrices. However, due to the sub-Nyquist rate sampling and insufficient number of samples, a weak primary user's signal with a nearby strong signal may not be properly reconstructed for detection in a wideband spectrum [17]. In addition, a new ADC architecture with nonuniform timing and a pseudorandom clock generator is needed [94]. In [95], the authors proposed two algorithms for wideband spectrum sensing at sub-Nyquist sampling rates for the single node and cooperative multiple nodes, respectively. In single node spectrum sensing, a two-phase spectrum sensing algorithm based on compressive sensing is proposed to reduce the computational complexity and improve the robustness at secondary users. In the cooperative multiple node case, the signals received at SUs exhibit a sparsity property that yields a low-rank matrix of compressed measurements at the fusion center. This leads to a two-phase cooperative spectrum sensing algorithm for cooperative multiple SUs based on low-rank matrix completion. The numerical results showed that the proposed algorithms are robust to channel noise with low computational complexity.

In multiband cooperative sensing, secondary users cooperate to sense multiple narrowbands instead of focusing on one band at a time. In [36], a multiband joint detection scheme was proposed for combining the statistics of sensing multiple bands from spatially distributed secondary users. The fusion center calculates the test statistic and makes a cooperative decision in each band. The weight coefficients and detection thresholds of all bands were obtained by jointly maximizing the aggregate opportunistic throughput in each band subject to constraints on the miss-detection and false-alarm probabilities. To enable the multiband sensing at each secondary user, an energy detector is required for each band of interest. As a result, the method may incur high hardware cost when the number of bands for cooperative sensing is large. In [96], the authors proposed a multiband adaptive joint detection framework for wideband spectrum sensing that collectively searches the secondary transmission opportunities over multiple frequency bands. In this framework, both the sensing slot duration and detection thresholds for each narrowband detector were jointly optimized to maximize the achievable opportunistic throughput of the secondary network subject to a limit on the interference introduced to primary users.

In [81], a parallel cooperative sensing scheme was proposed to enable the multichannel sensing by optimally selected cooperating secondary users. Different from the multiband sensing scheme in [36, 96], each cooperating secondary user senses a different channel. In [82], the authors proposed a group-based CSS scheme in which the cooperative secondary users are divided into several groups, and each group senses a different channel during a sensing period, while the secondary users in the same group perform joint detection on the targeted channel. In [97], the authors proposed an adaptive user-group assignment algorithm for group-based CSS that considers cooperating secondary users with heterogeneous sensing ability in

terms of the sensing accuracy. By the methods in [81,82,97], multiple channels can be cooperatively sensed in each sensing period. The objective is to maximize the secondary opportunistic throughput while minimizing the sensing overhead such as the sensing time and the number of secondary users required for cooperation.

Implementation of Sensing Techniques on Testbeds

Testbeds are essential to advance the development of cognitive radio networks by verification of proposed sensing techniques in a practical system and evaluation of key performance metrics. Some of the existing CR testbed researches are focusing on the algorithms of spectrum sensing and signal processing. In [98], the authors proposed an experimental setup based on the Berkeley Emulation Engine 2 (BEE2) platform, which is a multi-FPGA emulation platform, to experiment with various sensing techniques and develop a set of metrics and test cases to allow them to measure the sensing performance of these techniques. The authors in [99] proposed KNOWS, which has a reconfigurable transceiver based on a modified Wi-Fi hardware. The hardware consists of a development board with a scanner/receiver radio and a reconfigurable transceiver. KNOWS spectrum allocation engine maintains up-to-date information about the spectrum usage by all its neighbors and stores it in a resource allocation matrix (RAM). The authors studied the bandwidth allocation problem and designed a spectrum-aware medium access control (MAC) protocol. The MAC protocol uses the RAM to dynamically decide on the portion of the spectrum to use for a given communication. Simulations results showed that KNOWS significantly increases the capacity when compared to IEEE 802.11-based systems.

In [100], the authors presented a real-time testbed, based on programmable system-on-chip processors, for the evaluation of cognitive radio MAC algorithms. The proposed testbed is much easier to configure and control than the traditional FPGA-based testbed. The authors introduced the testbed implementation details of the spectrum sensing of PHY layer, the channel selection strategy, and the access control strategy of MAC layer.

In [101], the author studied the performance of normal collaborative spectrum sensing (NCSS) based on coalitional games and implemented NCSS in wireless open-access research platform. Wireless open-access research platform is a scalable and extensible programmable wireless platform, developed by Rice University [102], to prototype advanced wireless networks. Based on testbed implementation, the authors showed that under poor reporting channel conditions, the coalition splits and the weaker SUs exhibit inefficient sensing performance. The authors then proposed relay-based collaborative spectrum sensing that uses neighboring SU with low error-prone relay path to share sensing results between affected SUs and channel. Testbed results revealed that relay-based collaborative spectrum sensing performs better than all other collections of coalitions, and it improves sum-utility by 20%, as compared to NCSS at the cost of minimal 2.3% loss in energy efficiency.

Research Challenges

Many operations in cooperative spectrum sensing, such as sharing data, broadcasting spectrum-aware routing information, and coordinating spectrum access, rely on control message exchange on a common control channel. The implementation of a common control channel is one of the most challenging issues in cognitive radio networks, since a fully reliable control channel cannot be created without reserving bandwidth specifically for this purpose. However, if a dedicated channel is used, the bandwidth available for traffic communications reduces. In addition, since the common control channel may be subject to primary user's activity, secondary users have to negotiate a new control channel when the original one is occupied by primary users. In [103], the authors investigate a promising solution that exploits the ultrawideband (UWB) technology to allow the secondary users to discover each other and exchange control information for establishing a communication link. Other works assume that secondary users use an out-of-band common control channel to report the local sensing results to the fusion center to avoid interfering with the primary user [104, 105]. Setting up and maintaining common control channel is still an open issue for CR networks.

In cooperative spectrum sensing, it is usually assumed that all cooperating CR users are perfectly synchronized, and their sensing results are also assumed to be available instantly at the fusion center. In reality, this is not always valid, and therefore, the CSS scheme should consider the case of asynchronous observations and reporting delay which result in time offsets between local sensing observations and the final decision at the fusion center. In [106], a probability-based combination scheme was proposed to combine asynchronous reports at the fusion center. The proposed combining scheme considers both detection errors and time offsets between local sensing observations and the final decision. Based on the knowledge of the primary user channel usage model and the Bayesian decision rule, the conditional probabilities of the local sensing decisions received at different times, conditioned on each hypothesis, and their combined likelihood ratio were calculated to make the final decision at the fusion center.

Most of the studies on CSS analyze its performance based on the assumption of perfect knowledge of the average received SNR at the secondary user. However, in practice, this is not always the case. The effect of average SNR estimation errors on the performance of CSS was examined in [107]. In the noiseless sample-based case, it was found that the probability of false alarm decreases as the average SNR estimation error decreases for both independent and correlated shadowing. In the noise sample-based case, it was found that there exists a threshold for the noise level. Below this threshold, the probability of false alarm increases as the noise level increases, while above the threshold, the probability of false alarm decreases as the noise level increases.

Spectrum mobility, in which SU has to move from one spectrum hole to another to avoid interference in case of the reappearance of PU, is another challenging problem in CR networks. CR networks need to perform mobility management

adaptively depending on the heterogeneous spectrum availability that is dependent on the primary traffic.

Some new research directions focus on the design of architectures for the integration of cognition network and cooperative communications in wireless heterogeneous networks (HetNet) for better utilization of radio resources and guaranteeing quality of service. The authors in [108] have focused their research on the coexistence of wireless fidelity (Wi-Fi)and 4G cellular networks sharing the unlicensed spectrum. They have introduced the network architecture for long-term evolution (LTE)/LTE-advanced small cells to exploit unlicensed spectrum used by Wi-Fi systems. They showed that the proposed architecture along with interference avoidance schemes increases the capacity of 4G cellular networks by maintaining the quality of service (QoS)of Wi-Fi systems. Cognitive radio networks are also highly promising for providing timely smart grid wireless communications by utilizing all available spectrum resources [109].

Conclusions

Cognitive radio technology allows a wireless network to expand its spectrum on demand at a relatively low cost, thereby offering a natural solution to cope with random and diverse mobile data traffic which makes it a promising candidate for 5G communication networks. In this chapter, the most common spectrum sensing techniques for cognitive radio networks were surveyed and classified to provide an overview of the research direction in the area of cognitive radio networks. To address the limitations of the spectrum sensing techniques by a single secondary user, cooperative spectrum sensing and its main elements have been discussed. Different cooperation architectures and fusion schemes for fusion the decisions of cooperating secondary users were presented, and their advantages and disadvantages were highlighted.

We further identified some of the main factors that contribute to the efficient design of cooperative spectrum sensing schemes for cognitive radio networks. Different criteria for selecting the cooperating secondary users were discussed, and the performance improvement achieved by the different selection criteria was highlighted. The performance degradation due to cooperation overhead in terms of transmission cost, extra sensing time, delay, energy, and operations devoted to cooperative sensing was investigated which provided an insight on some of the key challenges facing cooperative spectrum sensing in cognitive radio networks.

Abstract

In this chapter, an application-aware spectrum sharing and allocation problem for cellular systems with multiple frequency bands is presented. Mobile users are categorized based on applications running on their devices. They could be either delay-tolerant or real-time applications which are approximated by logarithmic utility functions and sigmoidal-like utility functions, respectively. The objective is to share spectrum resources from multiple base stations with different frequency bands according to a utility proportional fairness policy. This policy guarantees no user is dropped, i.e., allocated zero resource. Additionally, it ensures that mobile users with real-time applications are given priority in resource allocation to achieve higher overall user satisfaction with the available shared resources. Hence, this problem is casted as a convex optimization problem to ensure optimality and the existence of a tractable global optimal solution. Using optimization techniques, e.g., duality and Lagrange multipliers, a distributed spectrum sharing and allocation algorithm is constructed. This algorithm is tested for convergence in different traffic conditions. Based on the convergence analysis, a robust resource allocation and sharing algorithm is developed to allocate the optimal resources for high-traffic situations where conventional resource allocation algorithms fail to converge. Additionally, this algorithm provides the option of traffic-dependent pricing for network providers. This pricing approach can be used to flatten the network traffic and decrease cost per bandwidth for mobile users. The simulation results of the performance of this robust optimal algorithm are explored for a single-carrier and two-carrier scenarios.

Keywords

Inelastic traffic · Convex optimization · Robust algorithm · Traffic-dependent pricing · Optimal resource allocation · Joint carrier aggregation · Application-aware · Sigmoidal-like utility

Introduction

Nowadays, mobile phones are becoming smarter with a wide variety of advanced applications that are hungry for bandwidth resources. Mobile phone industry is witnessing a rapid growth in both number of subscribers and traffic consumption per subscriber. Mobile subscribers are currently running multiple applications, simultaneously, on their smart phones. Network providers are moving from single service (e.g., Internet access) to multiple service offering (e.g., multimedia telephony, mobile-TV, etc.) [16]. In order to meet this strong demand for wireless resources by mobile users, more spectrum resources are needed [40]. However, due to the scarcity of the dedicated cellular spectrum, it is difficult to have a single frequency band fulfilling this demand. Therefore, the dedicated cellular frequency bands are not sufficient to satisfy demands of this industry, and sharing other frequency bands is necessary for pushing further advances in the mobile phone industry.

The National Broadband Plan (NBP) and the findings of the President's Council of Advisors on Science and Technology (PCAST) spectrum study have recommended that underutilized federal spectrum be made available for secondary use [19,36]. Furthermore, National Telecommunications and Information Administration (NTIA) findings revealed that not efficiently sharing radar band can result in large exclusion zones that reach up to tens of kilometers from the west and east coasts [34]. Hence, this excludes millions of mobile users living within tens of kilometers from the west and east coasts from aggregating additional secondary band to their existing primary spectrum. Additionally, the Federal Communications Commission (FCC) recommended the use of small cells, i.e., low-power wireless base stations, to operate in the 3.5 GHz radar band efficiently [21]. Hence, radar band can be shared by cellular networks similar to previous sharing examples, e.g., Wi-Fi, Bluetooth, wireless local area network (WLAN), etc. [20].

Making more spectrum available will certainly provide opportunities for mobile broadband capacity gains, but only if those resources can be aggregated efficiently with the existing commercial mobile system [35,49,50]. The efficient sharing and aggregation of federal spectrum with the existing cellular network is a challenging task. The challenges are both in hardware implementation and sharing and allocation of spectrum resource from multiple carriers with different bands. Hardware implementation challenges are in the need for multiple oscillators, multiple RF chains, more powerful signal processing, and longer battery life [5]. For sharing of spectrum resources from multiple base stations, e.g., macro cells and small cells, with multiple bands, e.g., dedicated cellular bands and secondary radar bands, a distributed resource allocation and aggregation algorithm is needed to optimally allocate these spectrum resources from different carriers operating using different frequency bands. Hence, the problem boils down to optimally allocating resources from different carriers with different frequency bands. In other words, it is a resource allocation optimization problem with carrier aggregation. This problem holds for sharing federal or commercial spectrum from various network providers as well [39].

The area of resource allocation optimization has received significant interest since the seminal network utility maximization problem presented in [28]. The network utility maximization problem allocates the resources among users based on bandwidth proportional fairness and using Lagrange multiplier methods of optimization theory. An iterative algorithm based on the dual problem has been proposed to solve the resource allocation optimization problem in [32]. The utility functions used in early research work, as in [28] and [32], are logarithmic utility functions that are good approximations of elastic Internet traffic for wired communication networks. Therefore, all utility functions are strictly concave functions, and hence the optimization problem is convex and converges to the global optimal solution.

Nowadays, there has been an increasing demand for wireless adaptive real-time applications. The utility functions that approximate real-time applications are non-concave functions. Applications with utility functions that are not strictly concave are presented in [41]. For example, voice-over-IP (VoIP) can be approximated as a step function where the utility percentage is zero below a certain rate threshold

and is 100% above that threshold, while rate-adaptive applications, e.g., video streaming, have utility functions that can be approximated as a sigmoidal-like function according to [41]. The sigmoidal-like function is a convex function for rates below the curve inflection point and is a concave function for rates above that inflection point. Hence, there is an urgent need to provide an optimal sharing and allocation algorithm that is aware of different applications running on mobile devices. The developed algorithm has to allocate shared spectrum resources based on the characteristics of the applications running on users' devices and the impact of that on users' experience. In other words, an application-aware spectrum sharing solution is needed.

In this chapter, a single carrier resource allocation optimization problem that includes users with non-concave utility functions (i.e., sigmoidal-like functions) and users with strictly concave utility functions (i.e., logarithmic utility functions) is discussed first. The optimization problem is formulated to ensure application awareness and fairness when allocating available evolved Node B (eNodeB) resources to all users. A resource allocation algorithm is developed to give priority to real-time application users who have non-concave utility functions approximated by sigmoidal-like functions with different parameters for different real-time applications. The algorithm and corresponding optimization problem inherently guarantee by construction that all users are assigned a fraction of the resources. This satisfies the objective of cellular system to provide a minimum quality of service (QoS) for all the users subscribing for the mobile service.

This developed rate allocation algorithm converges to the optimal rate only when the maximum available rate by the eNodeB exceeds the mid-utilization point for all the real-time application users as shown in section "Convergence Analysis". So, this algorithm does not converge for eNodeB with scarce bandwidth resources with respect to the number of users. This situation is a realistic situation during peak network traffic hours. Therefore, a modified algorithm to solve this problem is presented in section "A More Robust Algorithm". The modified algorithm provides a more robust algorithm that converges for both scarce and abundant bandwidth resources. Additionally, this robust algorithm provides traffic-dependent pricing. This pricing approach can be utilized by network providers to incentivize users to use the mobile service during less congested times [25].

By extending the single carrier optimization problem, an application-aware spectrum sharing optimization problem is formulated. In this problem multiple spectrum bands are shared by solving for resource allocation of multiple carriers. This resource allocation optimization problem with joint carrier aggregation is casted into a convex optimization framework. Application awareness is augmented by usage of logarithmic and sigmoidal-like utility functions to represent delay-tolerant and real-time applications, respectively. This model supports both contiguous and noncontiguous carrier aggregation from one or more frequency bands. The corresponding distributed algorithm allocates resources from one or more carriers to provide the lowest resource prices for mobile users. In addition, this algorithm uses utility proportional fairness policy to be aware of the priority of real-time applications over delay-tolerant applications when allocating resources.

Related Work

A distributed power allocation algorithm for mobile cellular system is presented in [30]. The authors used non-concave sigmoidal-like utility functions. The proposed algorithm approximates the global optimal solution but could drop users to maximize the overall system utilities; therefore, it does not guarantee minimum QoS for all users. In [7,46,47], the authors presented novel algorithms for different scenarios of power allocation in cellular systems that are optimal based on the optimality proof in [24].

A weighted aggregation of elastic and inelastic utility functions in each user equipment (UE) is presented in [29]. These aggregated utility functions are then approximated to the nearest concave utility function from a set of functions using minimum mean-square error. That approximate utility function is used to solve the rate allocation problem using a modified version of distributed rate allocation algorithm presented in [28]. In [24], the authors showed that sigmoidal-like and logarithmic utility functions are suitable for representing real-time and delay-tolerant applications, respectively.

In [43] and [44], the authors presented a non-convex optimization formulation for the maximization of utility functions in wireless networks. They used both elastic and sigmoidal-like utility functions and proposed a distributed algorithm to solve it when the duality gap is zero. But the algorithm does not converge to the optimal solution for a positive duality gap. A fair allocation heuristic is included to ensure network stability which resulted in a high aggregated utility.

In [26], the authors proposed a utility max-min fairness resource allocation for users with elastic and real-time traffic sharing a single path in the network. In [45], the authors proposed a utility proportional fair optimization formulation for high-SINR wireless networks using a utility max-min architecture. They compared their algorithm to the traditional bandwidth proportional fair algorithms [33] and presented a closed form solution that prevents oscillations in the network.

In [25], the authors conducted a pilot trial with 50 iPhone or iPad 3G data users, who were charged according to time-dependent pricing algorithms. Their results show that time-dependent pricing benefits both operators and customers. The algorithms flatten demand fluctuations over time. It also allows users to choose the time and volume of their usage and hence save money. However, this method lacks application awareness which is essential in advancing mobile service industry.

A Round Robin packet scheduling method which distributes the load among multiple component carriers across the network is proposed in [48]. A collaborative scheme, where users covered by multiple base stations are allocated resources from the base station with the best channel, is presented in [15]. The problem of spectrum sharing of resources using carrier aggregation for LTE Advanced is addressed in [42]. The authors consider modulation and coding scheme (MCS) selection and mobile users' MIMO capabilities. These proposed methods in [15, 42, 48] are not application-aware and hence are less efficient in maximizing user's satisfaction and quality of experience. In this chapter, we address quality of experience by including application-awareness into spectrum sharing problem.

Our Contributions

Our contributions in this chapter are summarized as:

- An application-aware utility proportional fairness optimization problem that solves for utility functions that are both strictly concave and non-concave (i.e., sigmoidal-like [24]) is formulated. In addition, the optimization problem inherently gives priority to real-time application users (i.e., with sigmoidal-like utility functions) while allocating resources.
- The proposed application-aware optimization problem is convex, and therefore the global optimal solution is tractable. A distributed rate allocation algorithm is presented.
- The convergence of the distributed rate allocation algorithm is analyzed. A modified distributed rate allocation algorithm that converges to the optimal rates for high-traffic and low-traffic periods is identified.
- A pricing policy is proposed for service providers to charge to service subscribers that can flatten traffic load on the network.
- Extension of the application-aware optimization problem to include spectrum sharing with carrier aggregation between multiple different frequency bands is formulated.
- Simulation results for one- and two-carrier scenarios are explored.

The chapter is organized as follows. Section "Single-Carrier Scenario" presents the single-carrier problem formulation. Section "Optimality" shows that the single-carrier optimization problem is convex, and section "UE and eNodeB Subproblems" provides the corresponding distributed subproblems. Section "Distributed Algorithm for Single-Carrier Scenario" presents a single-carrier algorithm. Section "Simulation Example: One Carrier" explores the simulation results for a single-carrier scenario setup. Section "Convergence Analysis" analyzes the algorithm convergence. Section "A More Robust Algorithm" constructs a more robust single-carrier algorithm, and the corresponding simulation results are shown in section "Simulation Example: One Carrier (Cont.)". The multiple-carrier optimization problem is formulated in section "Multiple-Carrier Scenario", its optimality shown in section "Optimality and Subproblems", corresponding algorithm developed in section "Distributed Algorithm for Multiple-Carrier Scenario", and its simulation results provided in section "Simulation Example: Two Carriers". Section "Conclusion and Future Direction" concludes the chapter with future direction.

Single-Carrier Scenario

A single-cell system consisting of a single eNodeB and M UEs is considered as our system model. The bandwidth allocated by the eNodeB to ith UE is given by r_i. Each UE has its own utility function $U_i(r_i)$ that corresponds to the type of traffic

being handled by it. Our objective is to determine the bandwidth the eNodeB should allocate to the UEs. We assume the utility functions $U_i(r_i)$ to be strictly concave or a sigmoidal-like functions. The utility functions have the following properties:

- $U_i(0) = 0$, and $U_i(r_i)$ is an increasing function of r_i.
- $U_i(r_i)$ is twice continuously differentiable in r_i.

In our model, we use the normalized sigmoidal-like utility function, as in [24, 30], that can be expressed as

$$U_i(r_i) = c_i\left(\frac{1}{1+e^{-a_i(r_i-b_i)}} - d_i\right) \tag{1}$$

where $c_i = \frac{1+e^{a_i b_i}}{e^{a_i b_i}}$ and $d_i = \frac{1}{1+e^{a_i b_i}}$. So, it satisfies $U(0) = 0$ and $U(\infty) = 1$. In Fig. 1, the normalized sigmoidal-like utility function with $a = 5$ and $b = 10$ is a good approximation for a step function (e.g., VoIP), and $a = 0.5$ and $b = 20$ is a good approximation to an adaptive real-time application (e.g., video streaming). In addition, we use the normalized logarithmic utility function, as in [18, 45], that can be expressed as

$$U_i(r_i) = \frac{\log(1+k_i r_i)}{\log(1+k_i r_{\max})} \tag{2}$$

where $r_{\max}$ is the required rate for the user to achieve 100% utility percentage and k_i is the rate of increase of utility percentage with the allocated rate r_i. So, it satisfies $U(0) = 0$ and $U(r_{\max}) = 1$. The logarithmic utility functions with $k = 15$ and

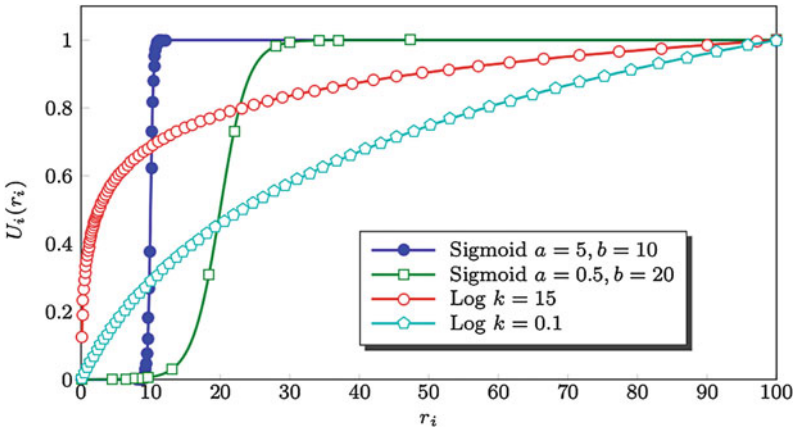

Fig. 1 The sigmoidal-like utility functions (representing real-time traffic) and logarithmic utility functions (representing delay-tolerant traffic) $U_i(r_i)$

$k = 0.1$ are shown in Fig. 1. We consider the utility proportional fairness objective function given by

$$\max_{\mathbf{r}} \prod_{i=1}^{M} U_i(r_i) \tag{3}$$

where $\mathbf{r} = \{r_1, r_2, \ldots, r_M\}$ and M is the number of UEs in the coverage area of the eNodeB. The goal of this resource allocation objective function is to allocate the resources for each UE that maximize the total mobile system objective (i.e., the product of the utilities of all the UEs) while ensuring proportional fairness between individual utilities. This resource allocation objective function ensures nonzero resource allocation for all users. Therefore, the corresponding resource allocation optimization problem guarantees minimum QoS for all users. In addition, this approach allocates more resources to users with real-time applications providing improvement to the QoS of cellular system.

The basic formulation of the utility proportional fairness resource allocation problem is given by the following optimization problem:

$$\begin{aligned} \max_{\mathbf{r}} \quad & \prod_{i=1}^{M} U_i(r_i) \\ \text{subject to} \quad & \sum_{i=1}^{M} r_i \leq R \\ & r_i \geq 0, \quad i = 1, 2, \ldots, M. \end{aligned} \tag{4}$$

where R is the total rate of the eNodeB covering the M UEs, and $\mathbf{r} = \{r_1, r_2, \ldots, r_M\}$.

We prove in section "Optimality" that there exists a tractable global optimal solution to the optimization problem (4).

Optimality

In the optimization problem (4), since the objective function $\arg\max_{\mathbf{r}} \prod_{i=1}^{M} U_i(r_i)$ is equivalent to $\arg\max_{\mathbf{r}} \sum_{i=1}^{M} \log(U_i(r_i))$, then optimization problem (4) can be written as:

$$\begin{aligned} \max_{\mathbf{r}} \quad & \sum_{i=1}^{M} \log(U_i(r_i)) \\ \text{subject to} \quad & \sum_{i=1}^{M} r_i \leq R \\ & r_i \geq 0, \quad i = 1, 2, \ldots, M. \end{aligned} \tag{5}$$

In section "Single-Carrier Scenario", we assume that all the utility functions of the UEs are strictly concave or sigmoidal-like functions. In the strictly concave utility function case, recall the utility function properties in section "Single-Carrier Scenario"; the utility function is positive $U_i(r_i) > 0$, increasing, and twice differentiable with respect to r_i. Then, it follows that $U_i'(r_i) = \frac{dU_i(r_i)}{dr_i} > 0$ and $U_i''(r_i) = \frac{d^2U_i(r_i)}{dr_i^2} < 0$. It follows that, the utility function $\log(U_i(r_i))$ in the optimization problem (5) has $\frac{d\log(U_i(r_i))}{dr_i} = \frac{U_i'(r_i)}{U_i(r_i)} > 0$ and $\frac{d^2\log(U_i(r_i))}{dr_i^2} = \frac{U_i''(r_i)U_i(r_i) - U_i'^2(r_i)}{U_i^2(r_i)} < 0$. Therefore, the strictly concave utility function $U_i(r_i)$ natural logarithm $\log(U_i(r_i))$ is also strictly concave. It follows that the natural logarithm of the logarithmic utility function in equation (2) is strictly concave.

In the sigmoidal-like utility function case, the utility function of the normalized sigmoidal-like function is given by equation (1) as $U_i(r_i) = c\left(\frac{1}{1+e^{-a_i(r_i-b_i)}} - d\right)$. For $0 < r_i < R$, we have $0 < 1 - d_i(1 + e^{-a_i(r_i-b_i)}) < \frac{1}{1+c_i d_i}$. It follows that for $0 < r_i < R$, we have the first and second derivative as

$$\frac{d}{dr_i}\log U_i(r_i) > 0 \text{ and } \frac{d^2}{dr_i^2}\log U_i(r_i) < 0.$$

Therefore, the sigmoidal-like utility function $U_i(r_i)$ natural logarithm $\log(U_i(r_i))$ is strictly a concave function.

All the utility functions in the optimization problem presented in equation (5) have strictly concave natural logarithms. For visualization, an example of four users is shown in Fig. 1 where two users run applications with sigmoidal-like utility functions and the other two users run application with logarithmic utility functions. The sigmoidal-like utility functions parameters are $a = \{5, 0.5\}$ and $b = \{10, 20\}$, respectively. The logarithmic utility functions parameters are $k = \{15, 0.1\}$ and $r_{\max} = 100$. The natural logarithms of the utility functions of Fig. 1 are shown in Fig. 2, and the derivatives of natural logarithms of the utility functions are shown in Fig. 3. It follows that for all UEs, utility functions are strictly concave. Therefore, the

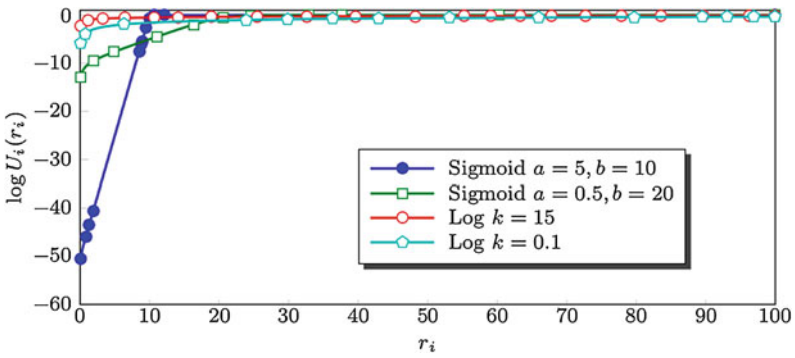

Fig. 2 The natural logarithm of sigmoidal-like and logarithmic utility functions $\log U_i(r_i)$

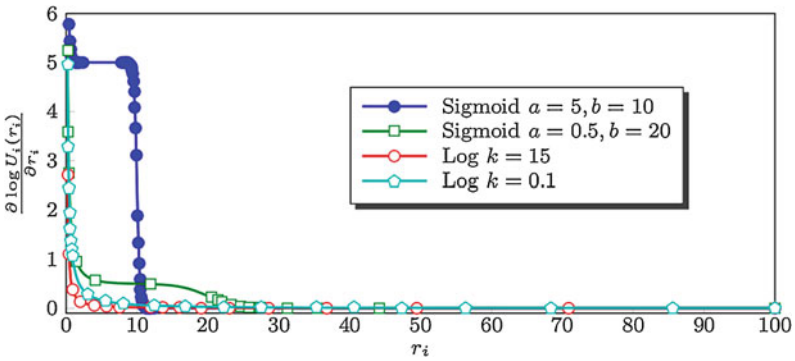

Fig. 3 The first derivative of the natural logarithm of sigmoidal-like and logarithmic utility functions $\frac{\partial \log U_i(r_i)}{\partial r_i}$

optimization problem (5) is a convex optimization problem [10]. The optimization problem (5) is equivalent to optimization problem (4); therefore it is also a convex optimization problem. For a convex optimization problem, there exists a unique tractable global optimal solution [8].

UE and eNodeB Subproblems

The key to UE and eNodeB subproblems from the primal problem in (5) is to convert to the dual problem, similar to [28] and [32]. The optimization problem (5) can be divided into two simpler problems by using the dual problem. We define the Lagrangian

$$L(\mathbf{r}, p) = \sum_{i=1}^{M} \log(U_i(r_i)) - p\left(\sum_{i=1}^{M} r_i + z - R\right) \tag{6}$$

where $z \geq 0$ is the slack variable and p is Lagrange multiplier or the shadow price (i.e., the total price per unit bandwidth for all the M channels). Therefore, the ith UE bid for bandwidth can be given by $w_i = pr_i$, and we have $\sum_{i=1}^{M} w_i = p\sum_{i=1}^{M} r_i$. The first term in equation (6) is separable in r_i. Hence, the dual problem objective function can be written as

$$D(p) = \sum_{i=1}^{M} \max_{r_i}\Big(\log(U_i(r_i)) - pr_i\Big) + p(R - z) \tag{7}$$

The dual problem is given by

$$\begin{aligned} \min_{p} \quad & D(p) \\ \text{subject to} \quad & p \geq 0. \end{aligned} \tag{8}$$

Hence,

$$\frac{\partial D(p)}{\partial p} = R - \sum_{i=1}^{M} r_i - z = 0 \tag{9}$$

substituting by $\sum_{i=1}^{M} w_i = p \sum_{i=1}^{M} r_i$ we have

$$p = \frac{\sum_{i=1}^{M} w_i}{R - z} \tag{10}$$

Now, divide the primal problem (5) into two simpler optimization problems in the UEs and the eNodeB. The ith UE optimization problem is given by:

$$\begin{aligned} \max_{r_i} \quad & \log U_i(r_i) - p r_i \\ \text{subject to} \quad & p \geq 0 \\ & r_i \geq 0, \quad i = 1, 2, \ldots, M. \end{aligned} \tag{11}$$

The eNodeB optimization problem is given by:

$$\begin{aligned} \min_{p} \quad & D(p) \\ \text{subject to} \quad & p \geq 0. \end{aligned} \tag{12}$$

The minimization of shadow price p is achieved by the minimization of the slack variable $z \geq 0$ from equation (10). Therefore, the maximum utility percentage for the available eNodeB bandwidth is achieved by setting the slack variable $z = 0$. In this case, we replace the inequality in primal problem (5) constraint by equality constraint, and so we have $\sum_{i=1}^{M} w_i = pR$. Therefore, we have $p = \frac{\sum_{i=1}^{M} w_i}{R}$ where $w_i = p r_i$ is transmitted by the ith UE to the eNodeB. The utility proportional fairness in the objective function of the optimization problem (4) is guaranteed in the solution of the optimization problems (11) and (12).

Distributed Algorithm for Single-Carrier Scenario

The distributed application-aware resource allocation algorithm for optimization problems (11) and (12) is an iterative algorithm for allocating the network resources with awareness of applications running on UEs. For the Algorithm in (1) and (2), each UE starts with an initial bid $w_i(1)$ which is transmitted to the eNodeB. The eNodeB calculates the difference between the received bid $w_i(n)$ and the previously received bid $w_i(n-1)$ and exits if it is less than a prespecified threshold δ. Note that $w_i(0) = 0$. If the value is greater than the threshold δ, eNodeB calculates the shadow price $p(n) = \frac{\sum_{i=1}^{M} w_i(n)}{R}$ and sends that value to all the UEs. Each UE receives the

Algorithm 1 UE algorithm for a single-carrier scenario

Send initial bid $w_i(1)$ to eNodeB
loop
  Receive shadow price $p(n)$ from eNodeB
  if STOP from eNodeB **then**
    Calculate allocated rate $r_i^{\text{opt}} = \frac{w_i(n)}{p(n)}$
    STOP
  else
    Solve $r_i(n) = \arg\max_{r_i} \left(\log U_i(r_i) - p(n) r_i \right)$
    Send new bid $w_i(n) = p(n) r_i(n)$ to eNodeB
  end if
end loop

Algorithm 2 eNodeB algorithm for a single-carrier scenario

loop
  Receive bids $w_i(n)$ from UEs {Let $w_i(0) = 0 \ \forall i$}
  if $|w_i(n) - w_i(n-1)| < \delta \ \forall i$ **then**
    Allocate rates, $r_i^{\text{opt}} = \frac{w_i(n)}{p(n)}$ to user i
    STOP
  else
    Calculate $p(n) = \frac{\sum_{i=1}^{M} w_i(n)}{R}$
    Send new shadow price $p(n)$ to all UEs
  end if
end loop

shadow price to solve for the rate r_i that maximizes $\log U_i(r_i) - p(n) r_i$. That rate is used to calculate the new bid $w_i(n) = p(n) r_i(n)$. Each UE sends the value of its new bid $w_i(n)$ to the eNodeB. This process is repeated until $|w_i(n) - w_i(n-1)|$ is less than the prespecified threshold δ.

Simulation Example: One Carrier

In this section, the Algorithm in (1) and (2) is applied to the cell in Fig. 4 with six utility functions corresponding to six UEs shown in Fig. 5. We use real-time applications represented by equation (1) with different parameters, $a = 5, b = 10$, which is an approximation to VoIP application at rate $r = 10$, $a = 3, b = 20$ which is an approximation of a standard definition video streaming application with inflection point at rate $r = 20$, and $a = 1, b = 30$ which is also an approximation of a high definition video streaming application with inflection point at rate $r = 30$. We use three logarithmic functions that are expressed by equation (2) with $r_{\max}$ =100 and different k_i parameters which are approximations for delay-tolerant applications (e.g., browsing, FTP, emails). We use $k = \{15, 3, 0.5\}$, and eNodeB has $R = 100$ [23].

In Fig. 6, the allocated rates for each users per iteration are shown. The real-time applications have priority over delay-tolerant applications. In Fig. 7, the

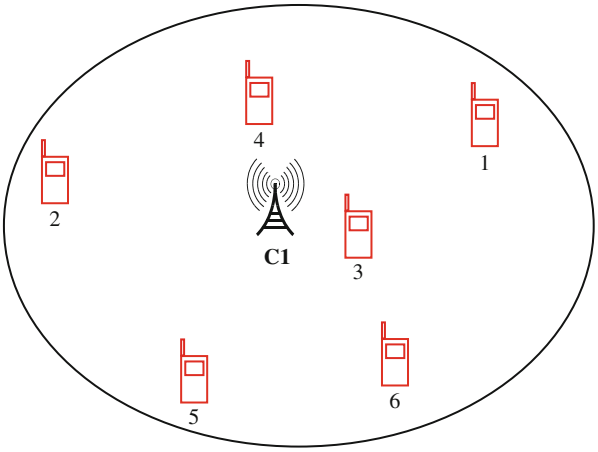

Fig. 4 System model with one carrier and six users

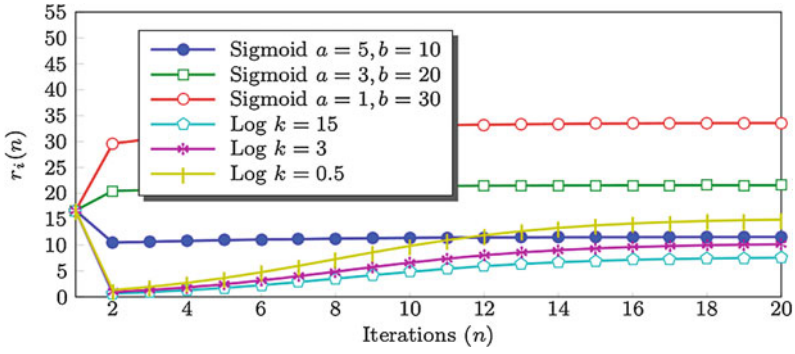

Fig. 6 The users allocated rate convergence $r_i(n)$ with number of iterations n for eNodeB rate $R = 100$

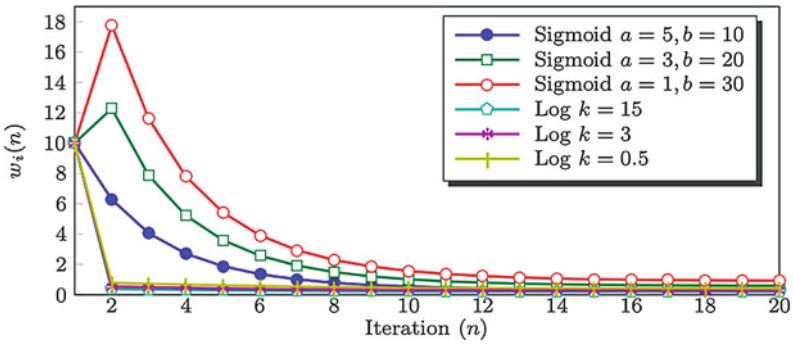

Fig. 7 The users bid convergence $w_i(n)$ with number of iterations n for eNodeB rate $R = 100$

corresponding bids per iteration are shown. Note that the distributed algorithm avoids the situation of allocating zero rate to any user (i.e., no user is dropped).

Convergence Analysis

In this section, the convergence analysis of Algorithms (1) and (2) for different values of R is explored.

For the sigmoidal-like function $U_i(r_i) = c_i(\frac{1}{1+e^{-a_i(r_i-b_i)}} - d_i)$, let $S_i(r_i) = \frac{\partial \log U_i(r_i)}{\partial r_i}$ be the slope curvature function. Then,

$$\frac{\partial S_i}{\partial r_i} = \frac{-a_i^2 d_i e^{-a_i(r_i-b_i)}}{c_i\left(1 - d_i(1+e^{-a_i(r_i-b_i)})\right)^2} - \frac{a_i^2 e^{-a_i(r_i-b_i)}}{\left(1+e^{-a_i(r_i-b_i)}\right)^2}$$

and

$$\frac{\partial^2 S_i}{\partial r_i^2} = \frac{a_i^3 d_i e^{-a_i(r_i-b_i)}\left(1 - d_i(1-e^{-a_i(r_i-b_i)})\right)}{c_i\left(1 - d_i\left(1+e^{-a_i(r_i-b_i)}\right)\right)^3} + \frac{a_i^3 e^{-a_i(r_i-b_i)}(1-e^{-a_i(r_i-b_i)})}{\left(1+e^{-a_i(r_i-b_i)}\right)^3}. \tag{13}$$

By inspection, $\frac{\partial S_i}{\partial r_i} < 0 \quad \forall\, r_i$. The first term S_i^1 of $\frac{\partial^2 S_i}{\partial r_i^2}$ in equation (13) can be written as

$$S_i^1 = \frac{a_i^3 e^{a_i b_i}(e^{a_i b_i} + e^{-a_i(r_i-b_i)})}{(e^{a_i b_i} - e^{-a_i(r_i-b_i)})^3} \tag{14}$$

and hence

$$\lim_{r_i \to 0} S_i^1 = \infty, \text{ and } \lim_{r_i \to b_i} S_i^1 = 0 \text{ for } b_i \gg \frac{1}{a_i}. \tag{15}$$

For second term S_i^2 of $\frac{\partial^2 S_i}{\partial r_i^2}$ in equation (13), the following properties are satisfied

$$S_i^2(b_i) = 0, \ S_i^2(r_i > b_i) > 0, \text{ and } S_i^2(r_i < b_i) < 0. \tag{16}$$

From equations (15) and (16), S_i has an inflection point at $r_i = r_i^s \approx b_i$. In addition, the curvature of S_i changes from a convex function close to origin to a concave function before the inflection point $r_i = r_i^s$ then to a convex function after the inflection point. **Therefore, the first remark is that for sigmoidal-like utility functions $U_i(r_i)$, the slope curvature function $\frac{\partial \log U_i(r_i)}{\partial r_i}$ has an inflection point at $r_i = r_i^s \approx b_i$ and is convex for $r_i > r_i^s$.**

For the sigmoidal-like function $U_i(r_i) = c_i(\frac{1}{1+e^{-a_i(r_i - b_i)}} - d_i)$, the optimal solution is achieved by solving the optimization problem (5). In Algorithms (1), an important step to reach to the optimal solution is to solve the optimization problem $r_i(n) = \arg\max_{r_i}(\log U_i(r_i) - p(n) r_i)$ for every UE. The solution of this problem can be written using Lagrange multipliers method in the form

$$\frac{\partial \log U_i(r_i)}{\partial r_i} - p = S_i(r_i) - p = 0. \tag{17}$$

From equation (15) and (16), the curvature of $S_i(r_i)$ is convex for $r_i > r_i^s \approx b_i$. The Algorithm in (1) and (2) is guaranteed to converge to the global optimal solution when the slope $S_i(r_i)$ of all the utility functions natural logarithm $\log U_i(r_i)$ is in a convex domain, similar to the analysis of logarithmic functions in [27] and [12]. Therefore, the natural logarithm of sigmoidal-like functions $\log U_i(r_i)$ converges to the global optimal solution for $r_i > r_i^{\approx} b_i$. The inflection point of sigmoidal-like function $U_i(r_i)$ is at $r_i^{\inf} = b_i$. For $\sum_{i=1}^{M} r_i^{\inf} \ll R$, Algorithms (1) and (2) allocate rates $r_i > b_i$ for all users. Since $S_i(r_i)$ is convex for $r_i > r_i^s \approx b_i$, then the optimal solution can be achieved by Algorithm (1) and (2). We have from equation (17), and $S_i(r_i)$ is convex for $r_i > r_i^s \approx b_i$, that $p_{ss} < S_i(r_i = \max b_i)$ where $S_i(r_i = \max b_i) = \frac{a_{i_{\max}} d_{i_{\max}}}{1 - d_{i_{\max}}} + \frac{a_{i_{\max}}}{2}$ and $i_{\max} = \arg\max_i b_i$. **Therefore, the second remark is that if $\sum_{i=1}^{M} r_i^{\inf} \ll R$ then Algorithms (1) and (2) converge to the global optimal rates which corresponds to the steady state shadow price $p_{ss} < \frac{a_{i_{\max}} d_{i_{\max}}}{1 - d_{i_{\max}}} + \frac{a_{i_{\max}}}{2}$ where $i_{\max} = \arg\max_i b_i$.**

For $\sum_{i=1}^{M} r_i^{\inf} > R$ there exists i such that the allocated rates $r_i^{\text{opt}} < b_i$. Therefore, if $p_{ss} \approx \frac{a_i d_i e^{\frac{a_i b_i}{2}}}{1 - d_i(1 + e^{\frac{a_i b_i}{2}})} + \frac{a_i e^{\frac{a_i b_i}{2}}}{(1 + e^{\frac{a_i b_i}{2}})}$ is the optimal shadow price for optimization problem (5), then a small change in the shadow price $p(n)$ in the nth iteration can lead to rate $r_i(n)$ (root of $S_i(r_i) - p(n) = 0$) to fluctuate

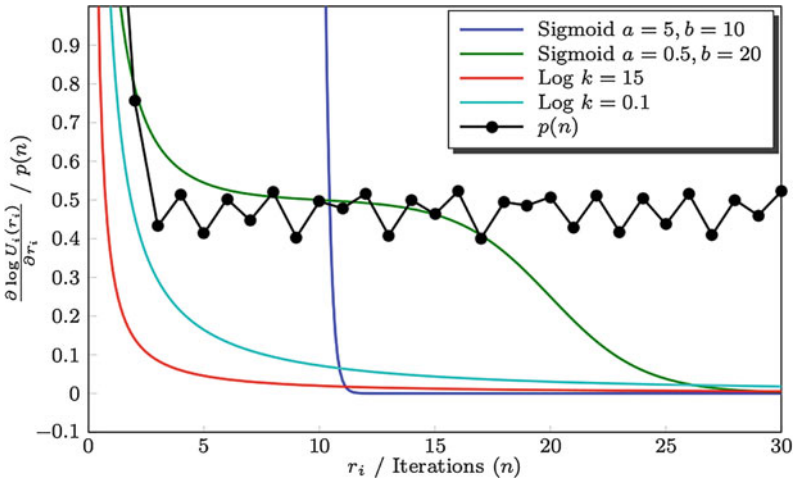

Fig. 8 The $\frac{\partial \log U_i(r_i)}{\partial r_i}$ diff log of sigmoidal-like utility function and shadow price $p(n)$ in algorithm (1) and (2) for $R = 25$

between the concave and convex curvature of slope curvature $S_i(r_i)$ for the ith user. Hence, this causes fluctuation in the bid $w_i(n)$ sent to eNodeB and fluctuation in the shadow price $p(n)$ set by eNodeB. Then, the iterative solution of Algorithms (1) and (2) fluctuates about the global optimal rates r_i^{opt}. **Therefore, the third remark is that for $\sum_{i=1}^{M} r_i^{\text{inf}} > R$ and the global optimal shadow price $p_{ss} \approx \frac{a_i d_i e^{\frac{a_i b_i}{2}}}{1-d_i(1+e^{\frac{a_i b_i}{2}})} + \frac{a_i e^{\frac{a_i b_i}{2}}}{(1+e^{\frac{a_i b_i}{2}})}$, then Algorithms (1) and (2) fluctuate about the global optimal solution.**

From the first, second, and third remarks, the Algorithm in (1) and (2) does not converge to the global optimal solution for all values of R.

Oscillation example: An example of four users with the utilities shown in Fig. 1 and the assumption that eNodeB maximum rate is $R = 25$, i.e., $\sum_{i=1}^{4} r_i^{\text{inf}} = 30 > R = 25$. Therefore, we cannot guarantee convergence with Algorithms (1) and (2), as stated in section "Convergence Analysis". In Fig. 8, the shadow price $p(n)$ oscillates between a concave and convex curvature of the $\frac{\partial \log U_i(r_i)}{\partial r_i}$ curve. The oscillation in the shadow price $p(n)$ causes an oscillation in the allocated rates and hinders the convergence to the optimal rates, and therefore the optimal rate allocation is not achievable by Algorithm in (1) and (2).

A More Robust Algorithm

In this section, a robust algorithm is developed to ensure the proposed rate allocation algorithm converges for all values of the eNodeB rate R. For $\sum r_i^{\text{inf}} > R$, the

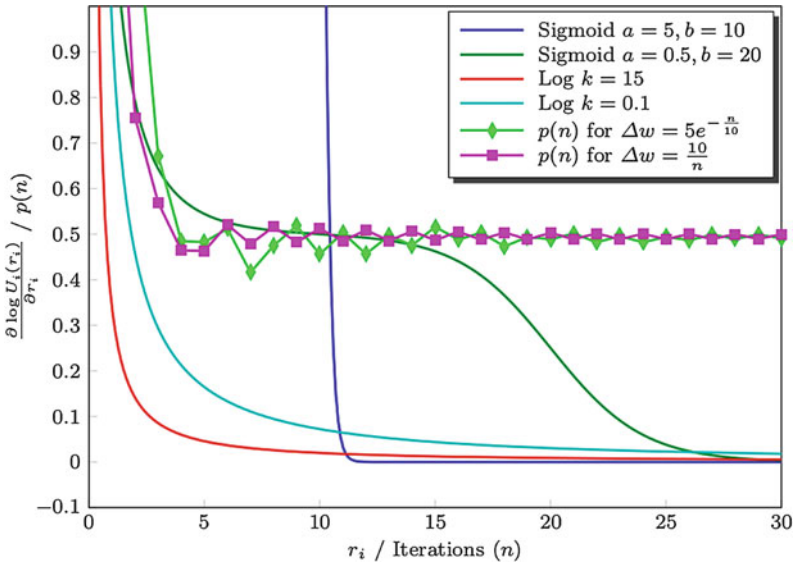

Fig. 9 The $\frac{\partial \log U_i(r_i)}{\partial r_i}$ diff log of sigmoidal-like utility function and $p(n)$ for Algorithm in (3) and (4) with $\Delta w = 5e^{-\frac{n}{10}}$ and $\Delta w = \frac{10}{n}$ and $R = 25$

algorithm must avoid fluctuations in the non-convergent region discussed in section "Convergence Analysis". This is achievable by adding a convergence measure $\Delta w(n)$ that senses the fluctuations in the bids w_is. In case of fluctuations, this robust algorithm decreases the step size between current and previous bid $w_i(n) - w_i(n-1)$ for each user i using fluctuations decay function. The fluctuations decay function could be in the following forms:

- *Exponential function*: It takes the form $\Delta w(n) = l_1 e^{-\frac{n}{l_2}}$.
- *Rational function*: It takes the form $\Delta w(n) = \frac{l_3}{n}$.

where l_1, l_2, l_3 can be adjusted to change the rate of decay of the bids w_is. The fluctuations decay function can be included in Algorithm (3) of the UE or Algorithm (4) of the eNodeB. In this model, the decay part is added to Algorithm (3) of the UE. The example of four users with the utilities shown in Fig. 1 and $R = 25$ is executed with fluctuation decay functions as shown in Fig. 9.

Simulation Example: One Carrier (Cont.)

In this section, simulation setup and parameters are similar to section "Simulation Example: One Carrier" with the exception of $R = 45$ for a comparison between Algorithm in (1) and (2) and Algorithm in (3) and (4). Here, we choose the

Algorithm 3 Modified UE algorithm for a single-carrier scenario

Send initial bid $w_i(1)$ to eNodeB
Set $r_i^{\min} = 0$
loop
  Receive shadow price $p(n)$ from eNodeB
  if STOP from eNodeB **then**
    Calculate allocated rate $r_i^{\text{opt}} = \frac{w_i(n)}{p(n)}$
  else
    Calculate new bid $w_i(n) = p(n) r_i(n)$
    if $|w_i(n) - w_i(n-1)| > \Delta w(n)$ **then**
      $w_i(n) = w_i(n-1) + \text{sign}(w_i(n) - w_i(n-1))\Delta w(n)$ $\{\Delta w = l_1 e^{-\frac{n}{l_2}}$ or $\Delta w = \frac{l_3}{n}\}$
    end if
    Send new bid $w_i(n)$ to eNodeB
  end if
end loop

Algorithm 4 Modified eNodeB algorithm for a single-carrier scenario

Receive r_i^{inf} from UEs
loop
  Receive bids $w_i(n)$ from UEs {Let $w_i(0) = 0 \ \forall i$}
  if $|w_i(n) - w_i(n-1)| < \delta \ \forall i$ **then**
    STOP and calculate rates $r_i^{\text{opt}} = \frac{w_i(n)}{p(n)}$
  else
    Calculate $p(n) = \frac{\sum_{i=1}^{M} w_i(n)}{R}$
    Send new shadow price $p(n)$ to all UEs
  end if
end loop

eNodeB rate R to be less than the sum of real-time application user inflection points $\sum b_i$. As expected Algorithm in (1) and (2) does not converge in this region as shown in Fig. 10 for rates and in Fig. 11 for bids. On the other hand, Algorithm in (3) and (4) behavior is more robust due to the fluctuation decay function. It damps the fluctuations with every iteration for rates as shown in Fig. 12 and for bids as shown in Fig. 13. Figure 14 shows the oscillatory shadow price $p(n)$ of Algorithm in (1) and (2) and the damping shadow price $p(n)$ of Algorithm in (3) and (4).

For $\delta = 10^{-3}$ and R changing between 5 and 100 with step of 5, the final rates and the corresponding final bids of different users with different eNodeB rate R are shown in Figs. 15 and 16, respectively. Note that the eNodeB allocates the majority of its resources to the UEs running adaptive real-time application until they reach their inflection rates $r_i = b_i$. When the total rate R exceeds the sum of the inflection rates $\sum b_i$ of all the adaptive real-time applications, eNodeB allocates more resources to the UEs with delay-tolerant application. Additionally, real-time application users bid higher when the resources are scare, and their bids decrease as R increases. Therefore, the pricing which is proportional to the bids is traffic-dependent. This gives the service providers the option to increase the service price

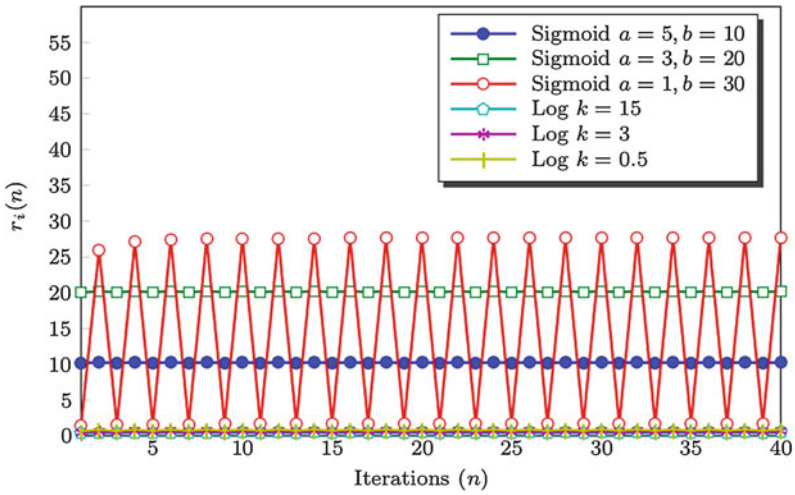

Fig. 10 The rate convergence $r_i(n)$ of Algorithm in (1) and (2) with number of iterations n for different users and $R = 45$

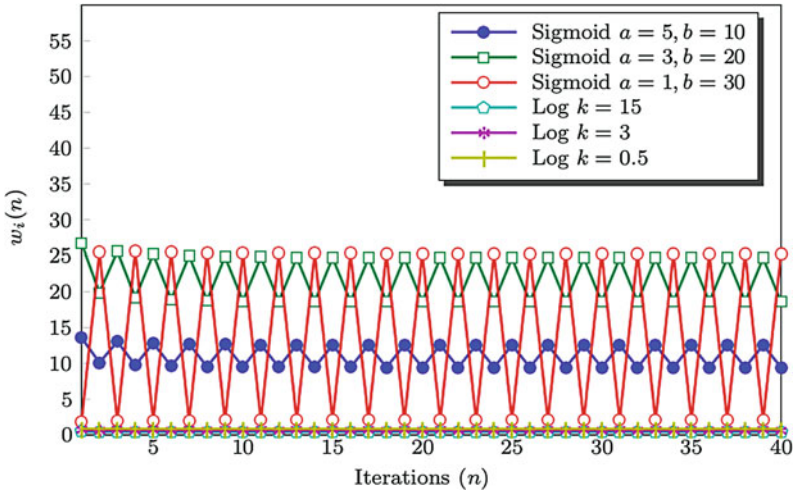

Fig. 11 The bid convergence $w_i(n)$ of Algorithm in (1) and (2) with number of iterations n for different users and $R = 45$

for subscribers when the traffic load on the cellular system is high. In other words, service providers can motivate subscribers to use the network when the traffic is lower as they pay less for the same QoS. Figure 17 shows the shadow price $p(n)$ with eNodeB rate R. The price is high for high-traffic case (i.e., fixed number of users but less resources, R is small) which decreases for low traffic (i.e., same number of users but more resources, R is large).

Multiple-Carrier Scenario

In this scenario, UEs share the spectrum of K carriers eNodeBs. These carriers could be forming macro or small cells, i.e., K cells, with M UEs distributed in these cells. The rate allocated by the lth carrier eNodeB to ith UE is given by r_{li} where $l = \{1, 2, \ldots, K\}$ and $i = \{1, 2, \ldots, M\}$. Each UE has its own utility function $U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})$ that corresponds to the type of traffic being handled by the ith UE. The objective is similar to section "Single-Carrier Scenario" which is to determine the optimal rates that the lth carrier eNodeB should allocate to UEs under its coverage. The utility functions $U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})$ are assumed to be a strictly concave or a sigmoidal-like functions. Hence, the utility functions satisfy the following properties:

- $U_i(0) = 0$ and $U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})$ is an increasing function of r_{li} for all l.
- $U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})$ is twice continuously differentiable in r_{li} for all l.

In our model, we use the normalized sigmoidal-like utility function, as in [37], that can be expressed as

$$U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}) = c_i\left(\frac{1}{1 + e^{-a_i(\sum_{l=1}^{K} r_{li} - b_i)}} - d_i\right) \tag{18}$$

where $c_i = \frac{1+e^{a_i b_i}}{e^{a_i b_i}}$ and $d_i = \frac{1}{1+e^{a_i b_i}}$. So, it satisfies $U_i(0) = 0$ and $U_i(\infty) = 1$. We use the normalized logarithmic utility function, as in [38], that can be expressed as

$$U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}) = \frac{\log(1 + k_i \sum_{l=1}^{K} r_{li})}{\log(1 + k_i r_{\max})} \tag{19}$$

where $r_{\max}$ is the required rate for the user to achieve 100% utilization and k_i is the rate of increase of utilization with allocated rates. So, it satisfies $U_i(0) = 0$ and $U_i(r_{\max}) = 1$. We consider the utility proportional fairness objective function given by

$$\max_{\mathbf{r}} \prod_{i=1}^{M} U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}) \tag{20}$$

where $\mathbf{r} = \{\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_M\}$ and $\mathbf{r}_i = \{r_{1i}, r_{2i}, \ldots, r_{Ki}\}$. This resource allocation objective function has a similar goal which is to allocate the resources that maximizes the total system utility while ensuring proportional fairness between utilities (i.e., the product of the utilities of all UEs). This construction of resource allocation objective function ensures nonzero resource allocation for all users. Therefore, the corresponding resource allocation optimization problem provides minimum QoS for all users. In addition, this approach allocates more resources to users with real-time applications which improves QoS for cellular system.

Hence, the formulation of application-aware resource allocation with spectrum sharing is given by the following optimization problem:

$$\begin{aligned} \max_{\mathbf{r}} \quad & \prod_{i=1}^{M} U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}) \\ \text{subject to} \quad & \sum_{i=1}^{M} r_{1i} \le R_1, \sum_{i=1}^{M} r_{2i} \le R_2, \ldots \\ & \ldots \ , \ \sum_{i=1}^{M} r_{Ki} \le R_K, \\ & r_{li} \ge 0, \quad l = 1, 2, \ldots, K, i = 1, 2, \ldots, M. \end{aligned} \tag{21}$$

where R_l is the total available rate at the lth carrier eNodeB.

Optimality and Subproblems

Similar to the analysis in section "Optimality", the optimization problem (21) can be written as:

$$\begin{aligned} \max_{\mathbf{r}} \quad & \sum_{i=1}^{M} \log\left(U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})\right) \\ \text{subject to} \quad & \sum_{i=1}^{M} r_{1i} \le R_1, \sum_{i=1}^{M} r_{2i} \le R_2, \ldots \\ & \ldots \ , \ \sum_{i=1}^{M} r_{Ki} \le R_K, \\ & r_{li} \ge 0, \quad l = 1, 2, \ldots, K, i = 1, 2, \ldots, M. \end{aligned} \tag{22}$$

For strictly concave utility function in section "Multiple-Carrier Scenario", the utility function is positive $U_i(r_{1i} + \ldots + r_{Ki}) > 0$, increasing, and twice differentiable with respect to r_{li}. Then, it follows that $\frac{\partial U_i(r_{1i}+\ldots+r_{Ki})}{\partial r_{li}} > 0$ and $\frac{\partial^2 U_i(r_{1i}+\ldots+r_{Ki})}{\partial r_{li}^2} < 0$. It follows that the utility function $\log(U_i(r_{1i}+r_{2i}+\ldots+r_{Ki}))$ in the optimization problem (22) has $\frac{\partial \log(U_i(r_{1i}+\ldots+r_{Ki}))}{\partial r_{li}} > 0$ and $\frac{\partial^2 \log(U_i(r_{1i}+\ldots+r_{Ki}))}{\partial r_{li}^2} < 0$. Hence, the strictly concave utility function $U_i(r_{1i}+r_{2i}+\ldots+r_{Ki})$ natural logarithm $\log(U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}))$ is also strictly concave. It follows that the natural logarithm of the logarithmic utility function in equation (19) is strictly concave.

In the sigmoidal-like utility function case, the utility function of the normalized sigmoidal-like function is given by equation (18) as $U_i(r_{1i} + r_{2i} + \ldots + r_{Ki}) = c_i\left(\frac{1}{1+e^{-a_i(\sum_{l=1}^{K} r_{li} - b_i)}} - d_i\right)$. For $0 < \sum_{l=1}^{K} r_{li} < \sum_{l=1}^{K} R_l$, we have

$$0 < 1 - d_i\left(1 + e^{-a_i(\sum_{l=1}^{K} r_{li} - b_i)}\right) < \frac{1}{1 + c_i d_i}.$$

It follows that for $0 < \sum_{l=1}^{K} r_{li} < \sum_{l=1}^{K} R_l$, we have the first and second derivative as $\frac{\partial}{\partial r_{li}} \log U_i(r_{1i} + \ldots + r_{Ki}) > 0$ and $\frac{\partial^2}{\partial r_{li}^2} \log U_i(r_{1i} + \ldots + r_{Ki}) < 0$. Hence, the sigmoidal-like utility function $U_i(r_{1i} + \ldots + r_{Ki})$ natural logarithm $\log(U_i(r_{1i} + \ldots + r_{Ki}))$ is strictly concave function. Then, all the utility functions in our model have strictly concave natural logarithm. Therefore, the optimization problem (22) is a convex optimization problem [10]. The optimization problem (22) is equivalent to optimization problem (21); therefore it is a convex optimization problem. For a convex optimization problem, there exists a unique tractable global optimal solution [9].

Similar to section "UE and eNodeB Subproblems", the optimization problem (22) can be divided into simpler subproblems by using the dual problem. We define the Lagrangian

$$\begin{aligned} L(\mathbf{r}, \mathbf{p}) = &\sum_{i=1}^{M} \log\left(U_i\left(r_{1i} + r_{2i} + \ldots + r_{Ki}\right)\right) \\ &- p_1\left(\sum_{i=1}^{M} r_{1i} + z_1 - R_1\right) - \ldots \\ &- p_K\left(\sum_{i=1}^{M} r_{Ki} + z_K - R_K\right) \end{aligned} \tag{23}$$

where $z_l \geq 0$ is the lth slack variable and p_l is Lagrange multiplier or the shadow price of the lth carrier eNodeB and $\mathbf{p} = \{p_1, p_2, \ldots, p_K\}$. Therefore, the ith UE bid for rate from the lth carrier eNodeB can be written as $w_{li} = p_l r_{li}$, and we have $\sum_{i=1}^{M} w_{li} = p_l \sum_{i=1}^{M} r_{li}$. The first term in equation (23) is separable in $\mathbf{r}_i$. Hence, the dual problem objective function can be written as

$$D(\mathbf{p}) = \sum_{i=1}^{M} \max_{\mathbf{r}_i}\left(L_i\left(\mathbf{r}_i, \mathbf{p}\right)\right) + \sum_{l=1}^{K} p_l(R_l - z_l) \tag{24}$$

and the corresponding dual problem is given by

$$\begin{aligned} \min_{\mathbf{p}} \quad & D(\mathbf{p}) \\ \text{subject to} \quad & p_l \geq 0, \quad l = 1, 2, \ldots, K. \end{aligned} \tag{25}$$

By differentiating $\frac{\partial D(\mathbf{p})}{\partial p_l}$ and substituting by $\sum_{i=1}^{M} w_{li} = p_l \sum_{i=1}^{M} r_{li}$, we have

$$p_l = \frac{\sum_{i=1}^{M} w_{li}}{R_l - z_l}. \tag{26}$$

Now, divide the primal problem (22) into simpler optimization problems in the UEs and the eNodeBs. The ith UE optimization problem is given by:

$$\begin{aligned} \max_{r_i} \quad & \log(U_i(r_{1i} + r_{2i} + \ldots + r_{Ki})) - \sum_{l=1}^{K} p_l r_{li} \\ \text{subject to} \quad & p_l \geq 0 \\ & r_{li} \geq 0, \quad i = 1, 2, \ldots, M, l = 1, 2, \ldots, K. \end{aligned} \tag{27}$$

The second problem is the lth eNodeB optimization problem for rate proportional fairness that is given by:

$$\begin{aligned} \min_{p_l} \quad & D(\mathbf{p}) \\ \text{subject to} \quad & p_l \geq 0. \end{aligned} \tag{28}$$

The minimization of shadow price p_l is achieved by the minimization of the slack variable $z_l \geq 0$ from equation (26). Therefore, the maximum utilization of the lth eNodeB rate R_l is achieved by setting the slack variable $z_l = 0$. In this case, replace the inequality in primal problem (22) constraints by equality constraints and so $\sum_{i=1}^{M} w_{li} = p_l R_l$. Accordingly, $p_l = \frac{\sum_{i=1}^{M} w_{li}}{R_l}$ where $w_{li} = p_l r_{li}$ is transmitted by the ith UE to lth eNodeB. The utility proportional fairness in the objective function of the optimization problem (21) is guaranteed in the solution of the optimization problems (27) and (28).

Distributed Algorithm for Multiple-Carrier Scenario

In this section, a distributed algorithm for multiple-carrier scenario using optimization problems (27) and (28) is presented. The algorithm provides a share spectrum mechanism from multiple carriers simultaneously with an application awareness policy. The algorithm is divided into the ith UE algorithm shown in Algorithm (5) and the lth eNodeB carrier algorithm shown in Algorithm (6). In Algorithms

(5) and (6), the ith UE starts with an initial bid $w_{li}(1)$ which is transmitted to the lth carrier eNodeB. The lth eNodeB calculates the difference between the received bid $w_{li}(n)$ and the previously received bid $w_{li}(n-1)$ and exits if it is less than a prespecified threshold δ. We set $w_{li}(0) = 0$. If the value is greater than the threshold, the lth eNodeB calculates the shadow price $p_l(n) = \frac{\sum_{i=1}^{M} w_{li}(n)}{R_l}$ and sends that value to all the UEs in its coverage area. The ith UE receives the shadow prices p_l from the in-range carrier eNodeBs and compares them to find the first minimum shadow price $p^1_{\min}(n)$ and the corresponding carrier index $l_1 \in L$ where $L \in \{1, 2, \ldots, K\}$. The ith UE solves for the l_1 carrier rate $r_{l_1 i}(n)$ that maximizes $\log U_i(r_{1i} + \ldots + r_{Ki}) - \sum_{l=1}^{K} p_l(n) r_{li}$ with respect to $r_{l_1 i}$. The rate $r^1_i(n) = r_{l_1 i}(n)$ is used to calculate the new bid $w_{l_1 i}(n) = p^1_{\min}(n) r^1_i(n)$. The ith UE sends the value of its new bid $w_{l_1 i}(n)$ to the l_1 carrier eNodeB. Then, the ith selects the second minimum shadow price $p^2_{\min}(n)$ and the corresponding carrier index $l_2 \in L$. The ith UE solves for the l_2 carrier rate $r_{l_2 i}(n)$ that maximizes $\log U_i(r_{1i} + \ldots + r_{Ki}) - \sum_{l=1}^{K} p_l(n) r_{li}$ with respect to $r_{l_2 i}$. The rate $r_{l_2 i}(n)$ subtracted by the rate from l_1 carrier $r^2_i(n) = r_{l_2 i}(n) - r^1_i(n)$ is used to calculate the new bid $w_{l_2 i}(n) = p^2_{\min}(n) r^2_i(n)$ which is sent to l_2 carrier eNodeB. In general, the ith UE selects the mth minimum shadow price $p^m_{\min}(n)$ with carrier index $l_m \in L$ and solves for the l_m carrier rate $r_{l_m i}(n)$ that maximizes $\log U_i(r_{1i} + \ldots + r_{Ki}) - \sum_{l=1}^{K} p_l(n) r_{li}$ with respect to $r_{l_m i}$. The rate $r_{l_m i}(n)$ subtracted by $l_1, l_2, \ldots, l_{m-1}$ carrier rates $r^m_i(n) = r_{l_m i}(n) - (r^1_i(n) + r^2_i(n) + \ldots + r^{m-1}_i(n))$ is used to calculate the new bid $w_{l_m i}(n) = p^m_{\min}(n) r^m_i(n)$ which is sent to l_m carrier eNodeB. This process is repeated until $|w_{li}(n) - w_{li}(n-1)|$ is less than the threshold δ.

This application-aware spectrum sharing algorithm ensures no user is dropped. Additionally, the UE chooses from the nearby carrier eNodeBs the one with the lowest shadow price and request spectrum resources from that carrier eNodeB. If the allocated rate is not enough or the price of the resources increases due to high demand on that carrier eNodeB resources from other UEs, the UE switches to allocate the rest of the required resources from another nearby eNodeB carrier with a lower resource price. This is done iteratively until an equilibrium between demand and supply of resources is achieved and the optimal rates are allocated in the mobile network.

Simulation Example: Two Carriers

In this section, Algorithm in (5) and (6) is used to simulate spectrum sharing of frequency bands of two carriers and 18 UEs shown in Fig. 18. The UEs are divided into three groups. The 1st group is connected to 1st carrier eNodeB only (index $i = 1, 2, 3, 4, 5, 6$), the 2nd group is connected to 2nd carrier eNodeB only (index $i = 7, 8, 9, 10, 11, 12$), and the 3rd group is connected to both 1st and 2nd carrier eNodeBs (index $i = 13, 14, 15, 16, 17, 18$). Hence, the 3rd group of users experiences spectrum sharing from 1st and 2nd carrier eNodeBs. Similar utility functions as in section "Simulation Example: One Carrier", shown in Fig. 5,

  end if
end loop

are used. UEs with indexes $i = \{1, 7, 13\}$ have utility parameters $a = 5$ and $b = 10$, indexes $i = \{2, 8, 14\}$ have utility parameters $a = 3$ and $b = 20$, and indexes $i = \{3, 9, 15\}$ have utility parameters $a = 1$ and $b = 30$, while UEs with indexes $i = \{4, 10, 16\}$ have utility parameters $k = 15$ and $r_{\max} = 100$, indexes $i = \{5, 11, 17\}$ have utility parameters $k = 3$ and $r_{\max} = 100$, and indexes $i = \{6, 12, 18\}$ have utility parameters $k = 0.5$ and $r_{\max} = 100$.

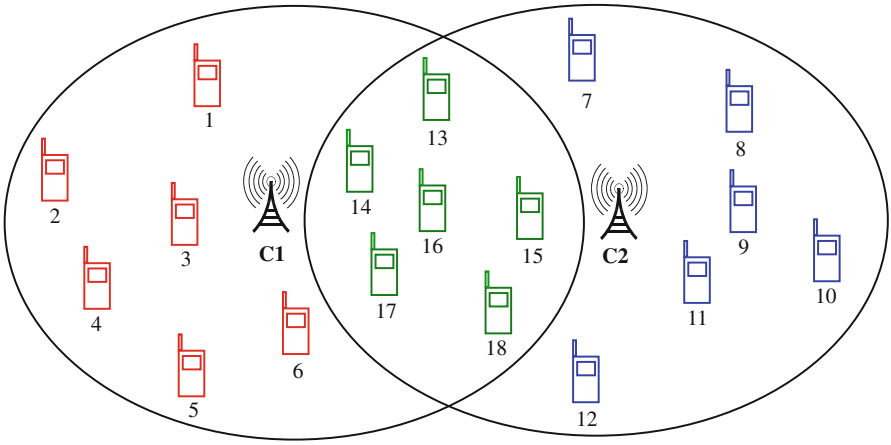

Fig. 18 System model with three groups of users and two carriers. The 1st group with UE indexes $i = \{1, 2, 3, 4, 5, 6\}$ (*red*), 2nd group with UE indexes $i = \{7, 8, 9, 10, 11, 12\}$ (*blue*), and 3rd group with UE indexes $i = \{13, 14, 15, 16, 17, 18\}$ (*green*)

The simulation setup is $\delta = 10^{-3}$, the 1st carrier eNodeB rate R_1 takes values between 20 and 300 with step of 10, and the 2nd carrier eNodeB rate is fixed at $R_2 = 100$. In Fig. 19, the final rates of different users with different 1st carrier eNodeB total rates R_1 are shown. In Fig. 19a, c, the increase in the rate allocated to the users of 1st and 3rd groups is due to the increase in R_1 (i.e., in range carrier). In Fig. 19b, the increase in the rate allocated to the users of 2nd groups is associated with the increase in R_1 (i.e., out of range carrier). This is due to the decrease in the number of users requesting resources from the 2nd carrier eNodeB (the users of the 3rd group allocate most of their rates from the resources of 1st carrier eNodeB and so decrease the load/demand on the 2nd carrier eNodeB). In spite of fixed 2nd carrier eNodeB rate at $R_2 = 100$, an increase in the allocated rates in the 2nd group is observed with the increase in R_1. This is more clear when monitoring the change in the rates allocated to the 3rd group of users from the 1st carrier eNodeB in Fig. 20a and from the 2nd carrier eNodeB in Fig. 20b. In Fig. 20a, b, when the resources available at the 2nd carrier is more than that at 1st carrier, most of the 3rd group rates are allocated by the 2nd carrier. With the increase in R_1, a gradual increase in the 3rd group rates allocated from the 1st carrier is observed as well as a gradual decrease from the 2nd carrier eNodeB resources. This shift in the resource allocation increases the available resources to be allocated to 2nd group of users by 2nd carrier eNodeB.

The final bids of different users with different values of R_1 are shown in Fig. 21. It is observed that the users bid high when the resources are scarce and their bids decrease as R_1 increases. Hence, pricing in this model is traffic-dependent

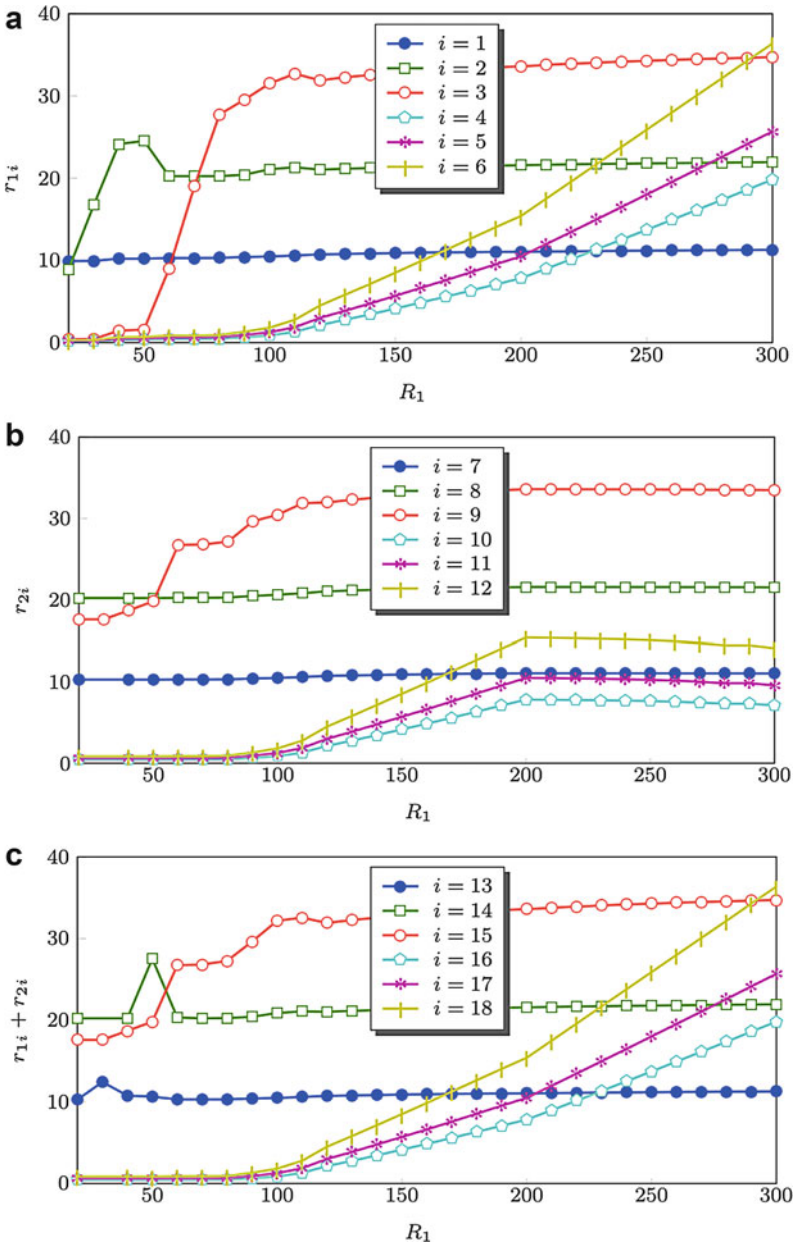

Fig. 19 The rates r_{li} of the 3rd group of users verses 1st carrier rate $20 < R_1 < 300$ with 2nd carrier rate fixed at $R_2 = 100$. (**a**) The rates allocated r_{1i} from the 1st carrier eNodeB to users of the 1st group (i.e., $i = 1, 2, 3, 4, 5, 6$). (**b**) The rates allocated r_{2i} from 2nd carrier eNodeB to users of the 2nd group (i.e., $i = 7, 8, 9, 10, 11, 12$). (**c**) The rates allocated $r_{1i} + r_{2i}$ from 1st and 2nd carriers eNodeBs to users of the 3rd group (i.e., $i = 13, 14, 15, 16, 17, 18$)

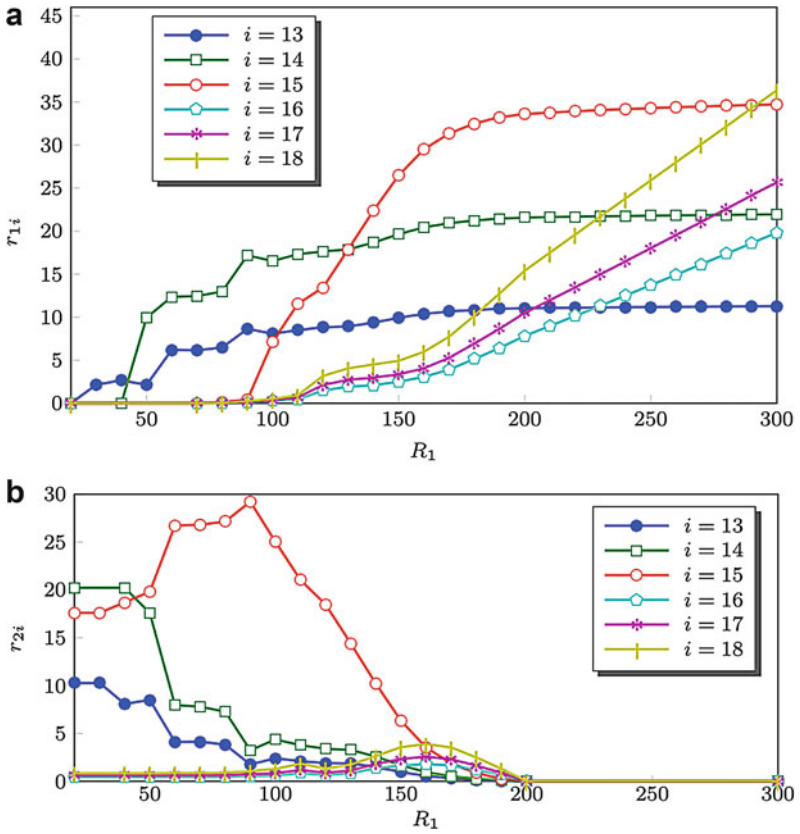

Fig. 20 The allocated rates r_{li} from the lth carrier eNodeB to the 3rd group of users with 1st carrier eNodeB rate $20 < R_1 < 300$ and 2nd carrier eNodeB rate fixed at $R_2 = 100$. (**a**) The allocated rates r_{1i} from the 1st carrier eNodeB to the 3rd group of users. (**b**) The allocated rates r_{2i} from the 2nd carrier eNodeB to the 3rd group of users

(i.e., demand by users increase the price increase and vice versa). In Fig. 21a, c, the decrease in the 1st and 3rd group users' bids with the increase in R_1 is noticeable. The supply increases, and the demand is still the same. In Fig. 21b, the decrease in the 2nd group users' bids with the increase in R_1 (which is an out-of-range carrier) is observable. This is due to the decrease in the demand on 2nd carrier eNodeB resources with fixed supply from 2nd carrier. In Fig. 22, the shadow price of the 1st carrier eNodeB is higher than that of 2nd carrier eNodeB for $R_1 \leq 50$, approximately equal for $60 < R_1 \leq 200$, and lower for $R_1 > 200$. This shows how it is very efficient to have joint carrier aggregation on the pricing of the user. In addition, provided this traffic-dependent pricing, the network providers can flatten the traffic specially during peak hours by setting traffic-dependent bandwidth resource price, which gives an incentive for users to use the network during less-congested hours.

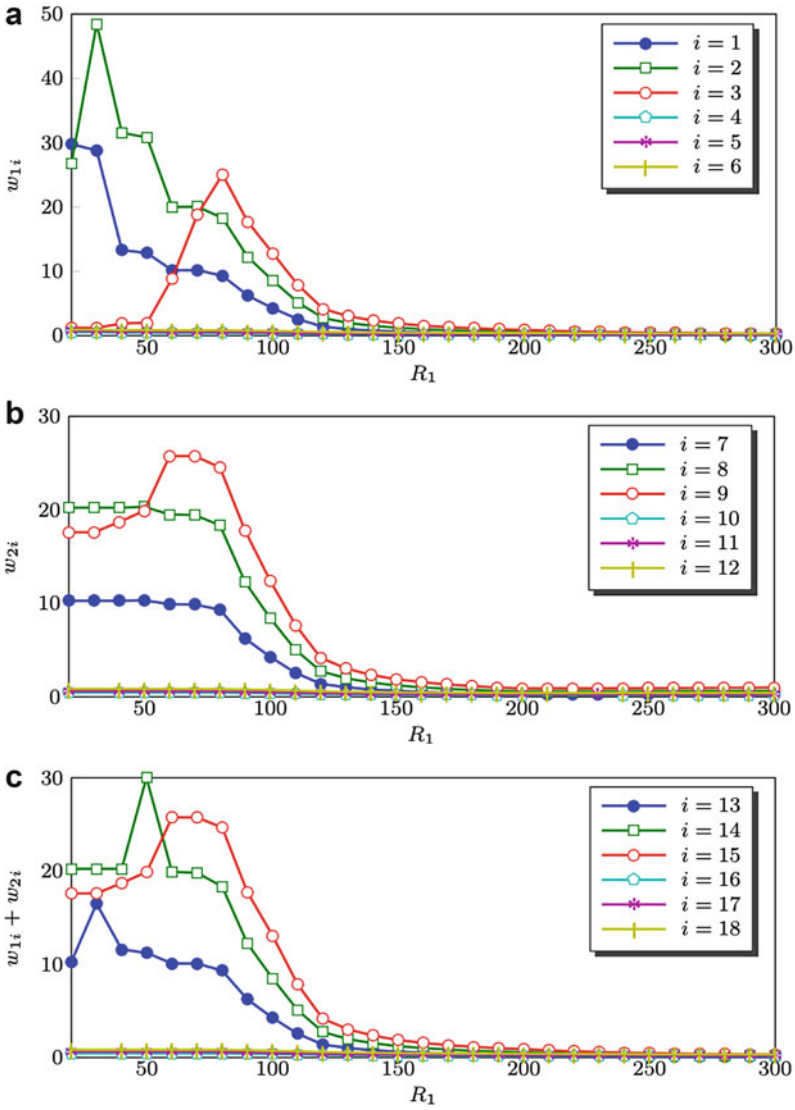

Fig. 21 The users final bids w_{1i} (i.e., network provider pricing) for the three group of users vs 1st carrier eNodeB available rate $20 < R_1 < 300$ with 2nd carrier rate fixed at $R_2 = 100$. (**a**) The bids w_{1i} of users of the 1st group (i.e., $i = 1, 2, 3, 4, 5, 6$). (**b**) The bids w_{2i} of users of the 2nd group (i.e., $i = 7, 8, 9, 10, 11, 12$). (**c**) The bids $w_{1i} + w_{2i}$ of users of the 3rd group (i.e., $i = 13, 14, 15, 16, 17, 18$)

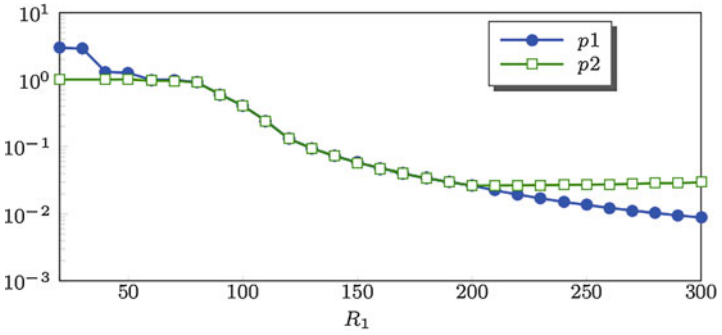

Fig. 22 The 1st carrier shadow price p_1 and 2nd carrier shadow price p_2 with the 1st carrier eNodeB rate $20 < R_1 < 300$ and the 2nd carrier eNodeB rate $R_2 = 100$

Conclusion and Future Direction

In this chapter, an application-aware optimization problem for UEs with delay-tolerant and real-time applications in cellular networks is presented. Two scenarios are discussed, i.e., one-carrier scenario and multiple-carrier scenario. Starting with one-carrier scenario, the global optimal solution exists and is tractable for the resource allocation optimization problem for UEs with logarithmic (delay-tolerant applications) and sigmoidal-like (real-time application) utility functions. A distributed algorithm for allocating the eNodeB resources optimally to the UEs is presented. Additionally, convergence analysis is discussed. A solution for ensuring convergence for different network traffic conditions is discussed. Hence, this modified robust algorithm converges for high and low traffic loads. The algorithm is aware of different applications and ensures fairness in the utility percentage achieved by the allocated resources for all the users. Therefore, the algorithm gives priority to the users with real-time applications over delay-tolerant applications. In addition, a minimum resource allocation for users with elastic or inelastic traffic is guaranteed to satisfy a minimum QoS for all service subscribers. Simulations provide that the robust algorithm converges to the optimal rates and allocates the eNodeB resources with priority to users running real-time applications. For multiple-carrier scenario, spectrum sharing through carrier aggregation is presented. The assumptions of applications running on smart phones are similar to one-carrier scenario. But in this case, users share multiple bands in an application-aware scheme. Optimality is shown for this scenario as well, and robustness of convergence is considered in the resource allocation algorithm design. Simulations provided for the two-carrier scenario for a proof of concept. The algorithm guarantees allocating resources from the carrier with the lowest resource price for the user. Hence, the algorithm converges to the optimal rate allocation with the lowest possible resource price.

The algorithms discussed in this chapter can be extended to include cellular system features such as frequency reuse [6]. Additionally, resource block allocation

problems for an application-aware spectrum sharing can be included in the mathematical model presented in this chapter. Some preliminary examples are shown in [17, 23]. The algorithm, presented in this chapter, provides a pricing approach for network providers to flatten network traffic over time. Hence, it provides a traffic-dependent pricing approach. This could be utilized to give the subscribers the incentive to decrease the cost of using the network by choosing to access the network at low-cost low-traffic load time. Additionally, the provided algorithm in this chapter can be extended to a centralized method rather than distributed to minimize overheads; more details are in [24].

The presented techniques could be used for allocating resources for smart grids and power system as well, for example, the extension of the research work in [31] to include sigmoidal-like utilities. Additionally, the pricing incentive used in the presented model could be extended to improve smart grid current models, e.g., [11]. Finally, this work can provide a platform for sharing radar spectrum with communication systems. For instance, carrier aggregation between radar and communication bands can improve the overall user QoS as shown in [22], radar transmitters can be utilized as auxiliary network base stations as shown in [4], and cooperative radar and communications signaling schemes can be considered as shown in [13, 14].

Abstract

From static spectrum allocation to nowadays more liberated policies such as spectrum refarming or even opportunistically exploiting the so-called spectrum holes or "white spaces," we have witnessed many changes all over the world regarding how spectrum is being allocated. The message is clear, and that spectrum allocation needs to be more dynamic and adaptive to the environment and applications. However, dynamic spectrum sharing and access is complicated in many ways. Firstly, it requires global knowledge of channel states for all communication links in the entire network and, secondly, the required large-scale optimization would be computationally prohibitive to achieve, not to mention that channel states vary over time as well. Importantly, there is a strong desire that such dynamic spectrum sharing be realized by a large number of uncoordinated mobile radios in a distributed and autonomous fashion. This is the focus of this chapter which discusses game-theoretic methods for self-optimization of cognitive mobile radios in spectrum sharing. The chapter will begin by reviewing the not-so-flexible spectrum management in cellular networks and then covering the topics of using forward-looking games in spectrum allocation. A major result is that autonomous spectrum sharing leading to spectral-efficient solutions is shown possible by well-designed games requiring only local channel knowledge at individual mobile radios and such interactive self-optimization can also be employed under the hierarchical spectrum sharing model in which primary spectrum owners are present and need to be protected.

Introduction

Wireless is an open medium that has not only given us the convenience for boundaryless communications, but its openness is unfortunately exposed to unwanted interference. For wireless communications to be useful, simultaneous communications have to be managed in a way that mutual interference is either eliminated or controlled to an acceptable level. In the past, this was usually achieved by separating coexisting communication links onto disjoint radio resource units (e.g., time, frequency, code, etc.), and occupying the same radio channel was deemed destructive and therefore prohibitive. On the policy level, this approach implies an exclusive use spectrum allocation model which grants exclusive use to licensees who pay multibillion dollars for several MHz of spectrum. This static spectrum management policy has, nevertheless, fueled the misbelief that the spectrum was precious.

The fundamental problem of today's wireless communications provision is spectrum scarcity because the usable spectrum is inevitably limited, while the demand is kept on increasing at an alarming rate. The wasteful static allocations

from tight regulations on the spectrum use and lack of network coordination have made the problem even worse [1]. Historically, spectrum regulation is more about "command and control" with primary considerations on economics and politics. Since mid-1980s, a market-based approach by various forms of auction has been adopted to assign new spectrum. A well-known example was the multibillion dollars price for a 20 MHz frequency band at the European 3G spectrum auction [2].

In the command-and-control management approach, the allocation decisions are often static in both temporal and spatial dimensions, which are valid for extended periods of time (usually 10s of years) and for large geographical regions (countrywide). The usage for each spectrum band is often set to be exclusive to a single provider (licensee), hence maintaining interference-free communication. However, this approach is unable to encourage the development and use of some spectrum-efficient technologies because it may not provide the freedom needed for these technologies to operate across existing spectrum designations.

The issue is further clarified by the regulatory bodies such as FCC in the USA and Ofcom in the UK, reporting that most of the radio spectrum was inefficiently utilized and that spectrum usage depends strongly on both time and place. For example, amateur radio and paging frequencies are very lightly loaded most of the time. Spectrum will become abundant if these spectrum holes, a.k.a. "white spaces," can be released for use by other users in need. In an attempt to unlock those available spectrum spaces, we have witnessed some radical changes on spectrum allocation in recent years worldwide. For instance, FCC has reclaimed approximately 85 MHz of UHF broadcast spectrum and authorized the reuse of 500 MHz of spectrum for a novel tower-based video and data service that shares spectrum with existing satellite television. Germany also switched off analogue broadcasting in Berlin and reclaimed the spectrum for other uses. In the UK, Ofcom also granted permission to the UK's mobile operators to redeploy their existing 2G and 3G radio spectrum for 4G services in 2013. The decision was Ofcom's one of many attempts to liberalize mobile spectrum for use with all currently available technologies for improved spectrum utilization. It is also anticipated that there will be relaxation of the commercial limitations on existing spectrum licenses by, for example, granting existing mobile radio licensees the right to lease or resell their spectrum to third parties that value it most. An example of this was the May 2003 order by FCC in the USA, permitting cellular licensees to lease some or their entire spectrum, reshaping the market, and leading to a new business model for service providers.

Recognizing the fact that the low spectral efficiency is all down to the rigid and inflexible use of spectrum, there have been restless efforts attempting to make spectrum utilization more intelligent, from reusing the frequency bands of the macrocells for small cells in a heterogeneous network (HetNet) to a conventional cellular network permitting the use of frequency channels in adjacent cells and to the dynamic frequency allocation autonomously achieved by a self-organizing group of cognitive radios in an open spectrum access environment, just to name a few.

The focus of this chapter is on *autonomous dynamic spectrum access technologies* that allow mobile radios to compete and share the same spectrum in a healthy and self-organizing fashion without coordination. This setup is motivated by the new

understanding of spectrum scarcity together with the increasing capability of mobile handsets, leading to reconfigurable software-defined radios, a.k.a. *cognitive radios*, which are expected to possess the ability to sense, observe the radio environment, and adapt their operating parameters for optimized performance on the fly.

Before we describe autonomous technologies for dynamic spectrum access, this chapter will first review the spectrum management in cellular networks in section "Spectrum Management in Cellular Networks" and the well-known models for dynamic spectrum access in section "Models for Dynamic Spectrum Access Strategies." In section "Dynamic Spectrum Access as a Global Resource Allocation Optimization Problem," we describe the orthogonal frequency-division multiple-access (OFDMA) interference channel model and use it as the model to discuss how to achieve the optimal frequency allocation to users, if a centralized spectrum manager exists. Section "The OFDMA Forward-Looking Game" then views the OFDMA interference channel as a resource competition game with radio users modeled as players so that self-optimization of the radio users can be investigated and analyzed. In particular, section "The OFDMA Forward-Looking Game" will introduce the forward-looking game, a specific type of games that is especially useful for designing efficient games. This chapter will be concluded by considering the cognitive radio scenarios where the frequency allocation of the secondary users (SUs) is optimized autonomously and at the same time avoiding the channels occupied by the primary users (PUs) by using well-designed games. Concluding remarks will be provided in section "Conclusions."

Spectrum Management in Cellular Networks

Radio spectrum is a precious natural resource, and mobile service providers need to pay billions and billions of dollars to operate on those designated frequency bands. Notwithstanding this, providing radio coverage is far more challenging than simply assigning a band to a service user. First, in order to generate revenues, there is a strong desire to cope with as many users as possible for the given bandwidth, with the aim to maximizing the spectral efficiency (sometimes measured in bps/Hz/km^2). In addition, coverage is an important criterion for reflecting the quality of service (QoS) of a mobile service operator. Nevertheless, a radio base station can provide radio coverage over only a limited area because the power of a radio wave attenuates as it propagates, regardless of whether it is in indoor or outdoor. It is thus important not to drain the power of the base station while not compromising the coverage. Meeting these mutually conflicting objectives requires the cellular radio approach.

In a cellular radio system, a large area is divided into many small areas (usually called *cells*), each of which is served by a base station located at the center of the cell. When joined together, these cells provide radio coverage over a wide geographic area. This enables a large number of portable transceivers (e.g., mobile phones, etc.) to communicate with each other anywhere in the network, via base stations.

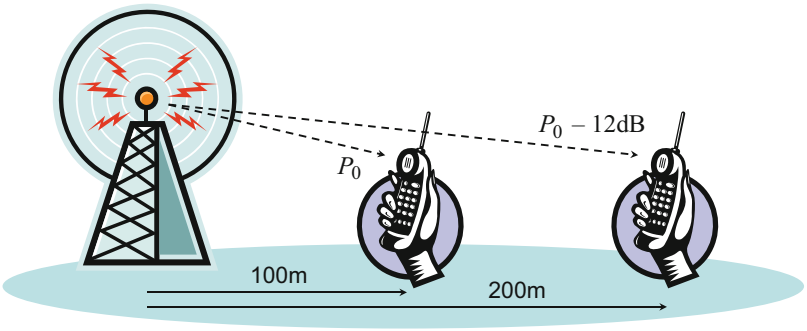

Fig. 1 The range-and-power relationship if $\alpha = 4$

Moving from a single large cell to many small cells has many advantages. First of all, radiation power attenuates severely as it propagates (i.e., $\propto d^{-\alpha}$ with distance d and the pathloss exponent α typically ranging from 3 to 6). Thus, just to extend the range only slightly would require a substantial effort in raising the transmit power of the base station in the downlink (or mobile terminal in the uplink). For instance, as shown in Fig. 1, if we like to extend the range from 100 to 200 m, then one will need to increase its transmit power by 16 times or 12 dB for the same quality to be achieved if $\alpha = 4$. Secondly, in general, the actual coverage of a cell can be very irregular due to different propagation environments in different directions. This will either cause coverage holes (or dead spots) in certain directions or excessive transmit power will have to be used in some directions leading to excessive interference in these directions. This problem will be greatly alleviated if the cell is smaller, hence motivating the small cell architecture in recent years. These properties can be easily converted to increased capacity, larger coverage area, and reduced interference.

The requirement of a cellular radio system is that more base stations need to be placed to provide coverage and they are required to be connected to the mobile switching centers (MSCs) to handle mobility managements and handover from one cell to another. The MSCs are also connected to the wider public switched telephone network (PSTN), a worldwide net of telephone lines, fiber-optic and undersea telephone cables, microwave transmission links, cellular networks, and satellites.

Frequency Reuse

To design a cellular radio system and characterize its network performance, it is required to consider the geometrical tessellation of the overall coverage region. With idealized propagation (i.e., same pathloss properties in all directions, no shadowing and fading), the most natural choice is to fill the region by circular coverage areas; see Fig. 2b. However, circles overlap (or leave gaps) which confuses the responsibility of the base stations. Hexagonal cells are therefore a much better

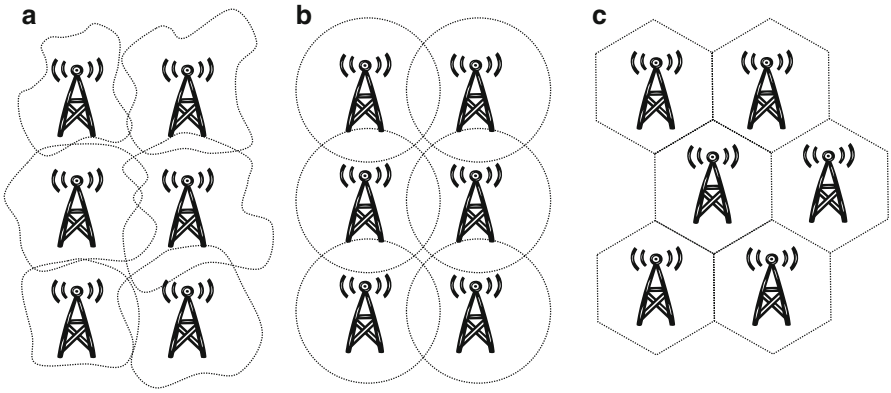

Fig. 2 Illustration of cell tessellation. (**a**) Actual coverage areas. (**b**) Circular coverage areas. (**c**) Hexagonal coverage areas

choice which can partly reflect the circular propagation pattern and fill the area without gaps or overlapping areas, as shown in Fig. 2c.

In conventional designs, the base station of each cell is only responsible for providing coverage of its own cell, and its transmit power should be assigned to just do that. As such, it is possible to reuse the same set of frequency channels at a different cell (referred to as a co-channel cell) or location if it is sufficiently far away so that the interference has traveled long enough to die down to an acceptable level. Frequency reuse is an important concept for cellular networks which allows us to increase the network capacity per unit area. Much of the work for cellular radio system planning is to do with choosing an appropriate *frequency reuse factor* to yield a desirable system performance. Before we discuss this, let us introduce the mathematical tools to describe the frequency reuse system and define the parameters.

For two-dimensional systems, only certain channel reuse patterns are allowable, with a few examples given in Fig. 3. To see this, we define shift parameters, k and l, that range over the positive integers. For hexagonal cells, the procedure for determining co-channel cells is as follows (see Fig. 4a):

- Pick a starting cell with the frequency channel set, say A.
- Move k cells along any one of the six directions perpendicular to the sides of the hexagons.
- Then, turn clockwise 120° and move l cells. The resulting cell is a cell that reuses the same channel set A as the starting cell and is by definition a co-channel cell.
- Repeat the same procedure for each of the other 5 sides of the starting hexagonal cell identifies all the 6 closest co-channel cells. Repeat for each of the co-channel cells will identify all co-channel cells on the entire coverage region.

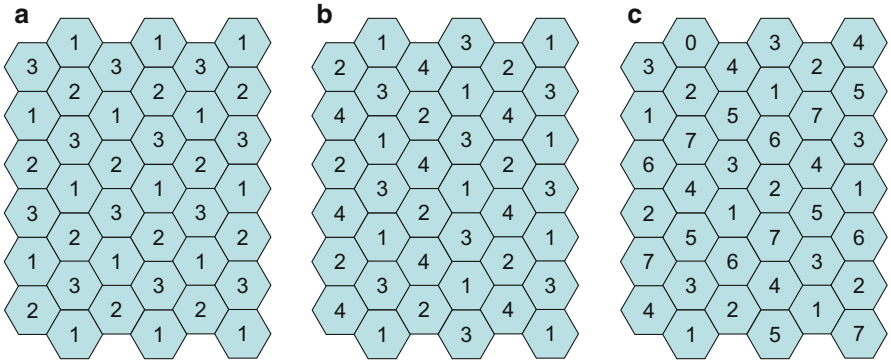

Fig. 3 Examples of cellular systems with different reuse patterns. (**a**) Reuse factor = 3. (**b**) Reuse factor = 4. (**c**) Reuse factor = 7

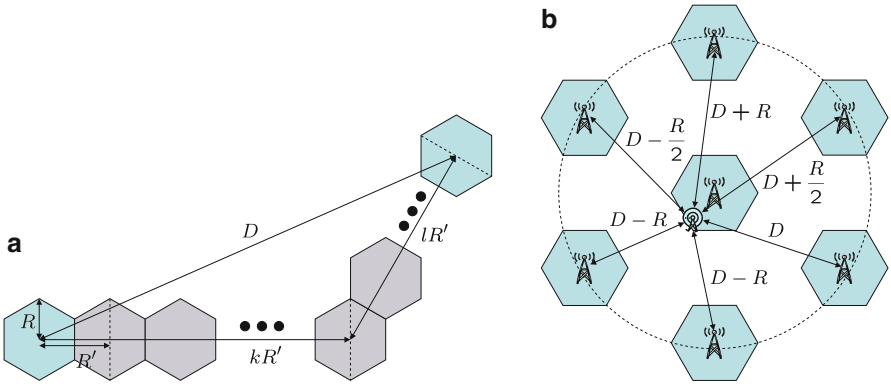

Fig. 4 Identifying the co-channel cell through the shift parameters, k and l. (**a**) Geometry of locating a co-channel cell. (**b**) Worst-case first-tier co-channel interference (CCI) in the downlink

The number of channel sets in the reuse pattern, defined as the *frequency reuse factor*, N, depends on k and l. To obtain N, let R be the radius of each cell, R' be the center-to-cell distance of two neighboring cells, and D be the center-to-center distance of two co-channel cells, as shown in Fig. 4a. As such,

$$N = \frac{\text{Area of the group}}{\text{Area of the cell}} \equiv \frac{A}{a}. \tag{1}$$

The area of the cell, a, can be easily found as

$$a = 6\left(\frac{1}{2}R^2 \sin 60^\circ\right) = \frac{3\sqrt{3}R^2}{2}, \tag{2}$$

while the area of the group, A, can be evaluated similarly by imagining a group radius $\frac{\left(\frac{D}{2}\right)}{\cos 30^\circ} = \frac{D}{\sqrt{3}}$ so that

$$A = 6\left(\frac{1}{2}\left(\frac{D}{\sqrt{3}}\right)^2 \sin 60^\circ\right) = \frac{\sqrt{3}D^2}{2}. \tag{3}$$

As a consequence, we have

$$N = \frac{D^2}{3R^2} \text{ or } Q \triangleq \frac{D}{R} = \sqrt{3N}, \tag{4}$$

where Q is regarded as the co-channel reuse ratio. On the other hand, from the basic geometry, we can express D in terms of R' (or $R' = \sqrt{3}R$) by

$$D^2 = \left(kR' + \frac{lR'}{2}\right)^2 + \left(\frac{lR'\sqrt{3}}{2}\right)^2 = \left(k^2 + kl + l^2\right) R'^2 = 3\left(k^2 + kl + l^2\right) R^2. \tag{5}$$

As a result, it can be derived by substituting (5) into (4) that

$$N = k^2 + kl + l^2. \tag{6}$$

The allowable reuse pattern therefore ranges over $1, 3, 4, 7, 9, 12, 13, \ldots$.

SIR Versus Cell Capacity

Frequency reuse greatly enhances the network capacity. This can be exemplified by considering a 50 MHz band, half of which is dedicated for the forward link or downlink (the communication path from a base station transmitter to its mobile user receivers) and another half for the reverse link or uplink (the communication path from the mobile user transmitters to a base station receiver). Assume that the band is divided into 200-kHz-wide frequency channels, each of which can support 8 users by, say, time-division multiple-access (TDMA) technologies. Then without cellular structure and frequency reuse, at any given time, at most $\frac{25\text{M}}{200\text{k}} \times 8 = 1000$ full-duplex users can be accommodated. In contrast, if each frequency channel is reused M times, then $1000M$ full-duplex users will be supported.

Network or cell capacity is increased with M. Increasing M implies a smaller co-channel reuse ratio Q and a smaller reuse factor N. For instance, when $N = 1$, the same channel set will be reused at every cell. However, the capacity performance for each cell will be limited by the interference or CCI, as users in co-channel cells interfere with each other. Signal-to-interference ratio (SIR) is therefore an important performance measure to the optimization of N for acceptable cell performance. In particular, the worst-case SIR in the downlink can be directly expressed as

$$\text{SIR} = \frac{S}{\sum_\ell I_\ell} = \frac{P_0 R^{-\alpha}}{\sum_\ell P_0 D_\ell^{-\alpha}}, \tag{7}$$

where P_0 is the transmit power of the base station. Taking into account only the first-tier CCI, i.e., the nearest adjacent co-channel cells, and assuming equal distance D from the 6 interfering cells, then we have

$$\text{SIR} = \frac{\left(\sqrt{3N}\right)^\alpha}{6}. \tag{8}$$

As such, N cannot be too small; otherwise, the SIR may be too low to have any acceptable performance. There is hence a trade-off between SIR and cell capacity. Advanced coding and decoding methods will be able to help the terminals to operate at low SIRs for decent performance. Other alternative approaches may avoid as much as possible the co-channel cells to operate at the same time by scheduling.

An accurate estimate of the SIR can be obtained by an observation in Fig. 4b so that

$$\begin{aligned}
\text{SIR} &= \frac{R^{-\alpha}}{\sum_\ell D_\ell^{-\alpha}} \\
&= \frac{R^{-\alpha}}{(D+R)^{-\alpha} + \left(D+\frac{R}{2}\right)^{-\alpha} + D^{-\alpha} + 2(D-R)^{-\alpha} + \left(D-\frac{R}{2}\right)^{-\alpha}} \qquad (9) \\
&= \frac{1}{\frac{2(Q+1)^\alpha + (Q-1)^\alpha}{(Q^2-1)^\alpha} + \frac{(Q+0.5)^\alpha + (Q-0.5)^\alpha}{(Q^2-0.25)^\alpha} + \frac{1}{Q^\alpha}}. \qquad (10)
\end{aligned}$$

For $\alpha = 4$, to achieve SIR ≥ 10 dB, we need to have $Q \geq 3.325$ and $N \geq 3.7$. Thus, the minimum reuse factor is $N = 4$. Similarly, if SIR ≥ 20 dB is required, $N \geq 9.58$, and the reuse factor will be 12. Note that the contributions from higher-tier co-channel base stations are much weaker (especially when $\alpha > 3$ as is typical in real environments) than those from the first tier and hence neglected in the evaluation.

Evaluation of SIR in the case of downlink above is relatively straightforward. In the uplink, however, the interference situation is highly variable depending upon the locations of co-channel mobile users at other base stations. For this reason, even if the uplink and downlink propagation is reciprocal, the uplink and downlink CCI will not be reciprocal. Uplink CCI is a more complex function of mobile user positions, and in real systems the mobile user positions tend to be random. Though it may still be possible to estimate the worst case, such result may be overly conservative.

Fixed and Dynamic Frequency Assignment

Following the above, in a cellular radio system, the same set of frequency channels is assigned to co-channel cells, with properly chosen N to control the CCI. Different

channels are assigned such that channels adjacent in the frequency domain are not in the same cells as well as neighboring cells so that adjacent channel interference is minimized. Because of that, each cell has only a fraction of the total channels and call may be blocked if all the channels assigned to a cell are all occupied, even though channels in other cells are unused. To improve trunking efficiency, possible solutions include channel borrowing (see section "Channel Borrowing in Cellular Networks") and more generally dynamic frequency assignment (DFA) (see section "Dynamic Spectrum Access as a Global Resource Allocation Optimization Problem"). In DFA, MSC holds all the frequency channels and allocates a channel to a user based on demand and performance considerations in order that some or more of the followings are achieved:

- Interference (CCI, adjacent channel) is managed in meeting the minimum SIR;
- The likelihood of future blocking using current traffic information is minimized or controlled to an acceptable level with the aid of queueing analysis;
- The likelihood of future drop call during unsuccessful handoff from one cell to another is minimized or controlled to an acceptable level.

The network-centric approach by DFA has the ability to design for actual interference, as opposed to the worst case in the fixed frequency assignment and can therefore reduce the probability of blocking and drop call considerably as well as increase the network capacity. More discussion and practical algorithms on DFA in the context of dynamic spectrum access will be presented in sections "Dynamic Spectrum Access as a Global Resource Allocation Optimization Problem," "The OFDMA Forward-Looking Game," and "Cognitive OFDMA."

The disadvantages of DFA are mainly the increased processing complexities and loading on MSC which are required to keep track of channel allocation, received signal strength indicator (RSSI) measurement for all the links, the user traffic and usage, etc. Estimating the SIR accurately for all the communication links at all available channels itself is challenging, and even with today's technologies, it is not feasible. In addition, the global optimization of the entire network is utterly complex and to achieve this in real-time where users are mobile, some at high speeds, is inconceivable, if not impossible. In section "The OFDMA Forward-Looking Game," we will discuss autonomous schemes that could achieve DFA in a self-optimizing manner while possessing only local channel information. This will make DFA much more attractive and practical.

Channel Borrowing in Cellular Networks

In this section, we will consider the basic cellular network where frequency channels are assigned to individual cells but can be borrowed from one to another, in order to enhance the spectral efficiency of the network. This method relaxes the rigidity of the original static frequency allocation among the cells. Adding flexibility to the static fixed frequency allocation can be very simple, and the simplest scheme is the

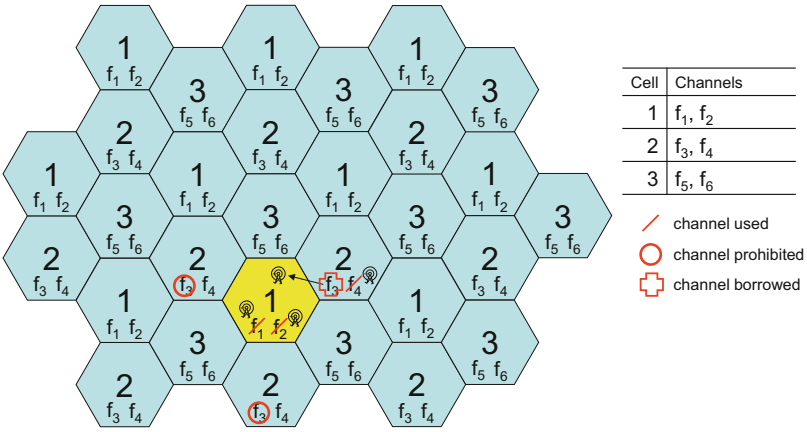

Fig. 5 Channel borrowing in a cellular radio system with frequency reuse factor of 3

channel borrowing scheme in [3, 4], where a channel in a cell (the donor cells) can be borrowed by another cell (the acceptor cell) if needed and if the borrowed channel does not interfere with existing calls. When a channel is borrowed, several other cells are prohibited from using it, due to CCI. Hence, the reduction in call blocking probability of the acceptor cell is achieved at the expense of the increase in call blocking probability of not only the donor cell but also many other cells.

The idea can be clearly explained by the diagram in Fig. 5 in which it can be seen that in the light-colored cell 1, all channels have been used and it needs an extra channel to serve the new arrival user. Therefore, channel f_3 from the donor cell 2 is borrowed and used to serve this new user by the acceptor cell 1. In this case, f_3 will be locked in the other two neighboring cells to avoid CCI.

Once the call dealt with by the borrowed channel is completed, the borrowed channel is returned to the original donor cell. It has been illustrated that channel borrowing can greatly decrease the call blocking probability under light and moderate traffic. Nonetheless, in heavy traffic conditions, such *channel locking* will worsen the overall blocking probability. On the other hand, it is quite possible that when channel borrowing is needed, there may be more than one candidate channels for borrowing. In this case, channel selection can be done with an aim to minimize the future call blocking probability in the cell that is most affected by the channel borrowing. A variety of ad hoc channel borrowing schemes with various objectives have been developed, some with sectoring, to achieve different trade-offs.

Models for Dynamic Spectrum Access Strategies

At present, spectrum is exclusively used by the licensee, and due to the problem of interference, for cellular radio systems, as discussed in the previous section, frequency allocation is carefully, but rigidly, planned for the worst-case scenarios in

terms of the SIR for every cell. One can choose an appropriate frequency reuse factor to yield an acceptable SIR performance. In practice, an SIR guard margin will be added as a precaution to deal with the possible channel fading effects. Overall, this static approach will be overly conservative, sacrificing the trunking efficiency for each cell, and has been the culprit for the poor spectrum utilization. There is clearly a need for spectrum reform so that more flexible use of spectrum will be permitted. Depending on the approaches to spectrum reform, such *dynamic spectrum access* will appear in different forms. Here, we review three main models [2].

Dynamic Exclusive Use Model

The first model is the dynamic exclusive use model which is by and large the traditional exclusive use model, with the major difference that the licensees are now allowed to sell and trade spectrum and to freely choose technology. This approach is also widely referred to as the spectrum property rights model [5] in which the licensees will be incentivized to achieve the most profitable use of spectrum which in return should lead to an increase in the spectrum utilization. However, in this approach, economy and market will play a more important role than any physical performance metrics, which may not necessarily improve spectrum utilization.

In the exclusive use model, dynamic spectrum access will still be possible if all channels are placed in a pool and there exists a *centralized and global* spectrum manager who assigns channels from the pool to new calls as needed, while monitoring to make sure that every user's SIR performance is acceptable. To optimize the performance of dynamic channel allocation, adaptive power control is usually employed to have better control on the CCI. The joint optimization of power control and dynamic channel allocation will be discussed in section "Dynamic Spectrum Access as a Global Resource Allocation Optimization Problem." It should be noted however that even a fully dynamic approach will not eliminate spectrum holes because nonsubscribers of the spectrum licensees will not be allowed to access the spectrum even if it is idle. This motivates the next two models.

Open Sharing Model

In open sharing model, the spectrum is open to everyone who wants to access it. The most well-known successful example of such is the unlicensed industrial, scientific, and medical (ISM) band. In this case, the spectrum usage will be maximized; however, it does not always translate to high spectrum utilization in terms of bits per second per Hz because users are inherently selfish, and if they do not control their signals properly, every user will suffer excessive CCI and the entire network may collapse. A great deal of researches have made progress toward dynamic spectrum access in this highly competitive wireless environment by a centralized spectrum server or manager [6] or distributed schemes, e.g., [7–9]. When a centralized spectrum server exists, the dynamic spectrum access technique will operate in the

same way as those for the exclusive use model. By contrast, if dynamic spectrum access were to achieve in a distributed and self-organized fashion, a whole new approach such as game-theoretic techniques, which allow users to negotiate the spectrum among themselves, will be required. This will be discussed in section "The OFDMA Forward-Looking Game."

Hierarchical Access Model

It is possible to have a hierarchical access model in which users are classified into primary and secondary, with the PUs (primary users) being the licensees who have the primary right to use the spectrum and SUs (secondary users) being the cognitive users who may share the spectrum with the PUs if their signals are properly controlled so that the interference perceived by the PUs is tolerable.

Under this hierarchical access model, coexistence of PUs and SUs may be achieved by one of the following three approaches:

- Underlay – If the SUs can control their signal power to be below the noise floor of the PU receivers, then the SU's communications in the same channel will not harm or affect the PU's communications, allowing them to coexist to increase the spectrum efficiency. This approach is the most natural and nonintrusive way to boost the spectrum utilization. However, the main drawback is that it might not always be possible to obtain useful rates for the SUs if their power is too low.
- Overlay – Advanced signal processing techniques such as dirty-paper coding [10] permit simultaneous transmission of PU and SU signals with zero interference at the PU receivers. In addition, the SUs can also act as relays to enhance the achievable rates of the PU links. The challenge of realizing this, however, is that the SUs need to have knowledge of the PUs' messages, which may not always be realistic. Also, the tremendous increase in processing complexity at the SUs may be an issue, as SUs are sometimes expected to be simple devices.
- Interweave – The interweave paradigm adopts the *opportunistic spectrum access* approach in which spectrum holes will be filled by SUs if they are identified [11, 12]. If those filled spectrum holes are reclaimed by any of the PUs, then the SUs will cease their transmissions immediately and return the spectrum back to the PUs who have the access priority over SUs. The main issue for the interweave approach is erroneous detection of spectrum holes caused by the hidden-terminal problem. The problem of automatically identifying and filling spectrum holes left out from the PUs by the SUs will be discussed in section "Cognitive OFDMA."

Self-Optimizing Cognitive Mobile Radios

There is a huge scope for dynamic spectrum access or DFA as discussed in the previous sections. The more challenging scenario is, though, when those DFA algorithms need to be achieved in a distributed fashion without any centralized

spectrum manager. This is greatly motivated by recent advances in digital signal processing (DSP), and general-purpose microprocessing technologies have brought *software-defined radio* to become reality. In particular, the term "software-defined radio" is often used to refer to the new digital radio technology which operates by software modules running on field programmable gate arrays (FPGAs), DSPs, and general-purpose processors (GPPs) and can change its operation characteristics by simply loading a new software. A software-defined radio can be reconfigured to switch functions and operations, but it generally does not imply capability of reconfiguring itself into the most effective form. The self-reconfigurable radio, now widely known as *cognitive radio*, was first envisioned by Mitola and Maguire in 1999 [13].

In addition to being programmable, a cognitive mobile radio is trainable, capable of being aware of its radio environments, and has the ability to learn and adaptively change its operating parameters in real time with the objective of providing reliable and spectral-efficient communications anywhere anytime [14]. An important application for cognitive radio is therefore dynamic spectrum access, due to its environmental awareness and the intelligence of rapidly reconfiguring itself for interference avoidance to other users sharing the same spectrum.

A cognitive radio network finds applications in the open sharing model in section "Open Sharing Model" and the hierarchical sharing model in section "Hierarchical Access Model," in the latter of which it operates in a spectrum originally allocated to a primary network consisting of one or more PUs. The fundamental principle of cognitive radio is to identify PUs that use the spectral resource and then design a transmission strategy that minimizes interference to and from those PUs in a nonintrusive manner [14–16]. When the PUs are idle and not occupying the spectrum, which is referred to as spectrum holes or white spaces, spectrum certainly can be reused by SUs. A great deal of efforts to achieve such opportunistic spectrum access are to sense and predict the PUs' activities and then take advantages of any vacant channels accurately.

Next, we will briefly review some basics of cognitive radios before providing a mathematical treatment in the dynamic spectrum access of cognitive radio using a game-theoretic framework later in sections "The OFDMA Forward-Looking Game" and "Cognitive OFDMA."

Spectrum Sensing

A cognitive radio needs to understand the status of the spectrum to take judicious decisions, and a continuous monitoring of the spectrum of interest is usually needed to preserve and maximize its adaptive capability. For instance, in the hierarchical model, a white space (i.e., an empty spectrum space) which is taken by a cognitive SU may be reclaimed by the PU at a later time. The detection of PU activities which relies on accurate spectrum sensing will be crucial. Sensing process could be performed in a centralized or distributed fashion and should be as accurate as possible because the QoS requirements for the PUs are rigorous.

Spectrum Analysis and Decision

Based on the spectrum availability and possibly the internal and external policies, a cognitive SU has to decide which channels it will occupy. Making a spectrum decision is complex, and it has to minimize the impact on the PUs while providing sufficient spectrum resources for this SU to achieve its QoS. For instance, the decision may be obtained by solving some resource allocation problems, through a centralized manager. Once spectrum decision is made, the cognitive SU will select and adjust its operating parameters to adapt to the decision for transmission.

Spectrum Sharing

Since there may be many SUs trying to access the same spectrum, cognitive spectrum access should be coordinated, and there should be a negotiation process for the SUs to come to a desirable operating point. This operation is required to ensure compliance of the secondary system with license issues and also take care of issues regarding collision, transmission, synchronization, and other relevant parameters.

Spectrum Mobility

SUs are regarded as visitors to the spectrum where the PUs are the owners. Therefore, if a PU reclaims certain part of the spectrum, where an SU is active, then the latter will have to cease its transmission or continue operating in another band, to avoid disturbance of the licensed system under certain QoS requirements.

Dynamic Spectrum Access as a Global Resource Allocation Optimization Problem

Section "Channel Borrowing in Cellular Networks" has given a taste of what is possible for more flexible frequency allocation as an attempt to unlock the spectrum in cellular networks. In the extreme case, however, one would anticipate that if all the frequency channels are available for all cells, the spectral efficiency will then be fully maximized, realizing the true dynamic spectrum access [2, 17]. In this section, we will characterize the mobile communications network as an OFDMA interference channel where multiple users share the same number of narrow frequency bands, but interfere with each other when more than one users occupy the same bands. We will first review some simple strategies to dynamically allocate channels to users. Then a global perspective which looks at dynamic channel allocation as a global optimization problem is studied.

Dynamic spectrum access is all about to assign the best channel to each user so that the interference to other co-channel users is properly controlled to an acceptable level, while maintaining the flexibility of using any channel in the central pool to take new calls (i.e., no more channel locking) (see section "Channel Borrowing in Cellular Networks"). Since the amount of CCI received by a user depends on the transmit power of the users causing the CCI, the performance of dynamic channel allocation is closely related to how well the users' transmit power is controlled. In fact, the overall dynamic spectrum access problem can be viewed as

a resource allocation optimization problem that deals with jointly the power control and channel allocation. It is fair to say that Wong et al. [18] were arguably the first work that illustrated the importance of multiuser diversity in the DFA problem for OFDM communications. In [18], the transmit power minimization problem in the downlink was addressed, with joint subcarrier and bit allocation to all users. This is regarded as a margin adaptive optimization.

The OFDMA Interference Channel

The dynamic power and channel allocation problem can be viewed as finding the optimal strategy for an OFDMA interference channel. Consider a K-user OFDMA system, as shown in Fig. 6, in which each user is free to occupy any of the N orthogonal frequency channels (or subcarriers) for communications to its designated destination receiver. The users operate in a noncooperative manner (i.e., no signal and information exchange between the base stations and between the mobile users is permitted), forming a multi-carrier interference channel where they inherently compete with and cause interference to each other, if they communicate on the same subcarriers. For user k, typically, the total transmitted power is constrained by

$$\sum_{n=1}^{N} p_k[n] \leq P_k, \ \forall k \in \{1, 2, \ldots, K\}, \tag{11}$$

where $p_k[n] \geq 0$ denotes the power allocated for the nth subcarrier (or subchannel) by user k and P_k represents the total power budget for user k. We also define the power allocation vector

$$\mathsf{p}_k \triangleq \{p_k[1], p_k[2], \ldots, p_k[N]\} \tag{12}$$

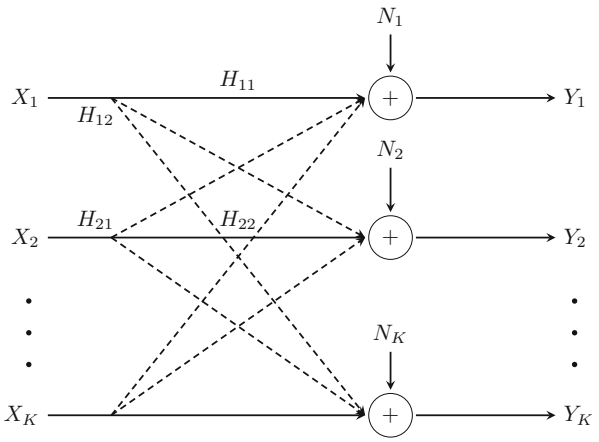

Fig. 6 A multiuser interference channel model

as the power allocation pattern of user k, which is drawn from some power allocation strategy $\mathscr{P}_k$, or it can be written as $\mathsf{p}_k \in \mathscr{P}_k$.

Let $H_{ij}[n]$ be the channel coefficient from transmitter i to receiver j (which is subject to channel flat fading and regarded as static under which the rate is evaluated) and $N_k[n]$ be the noise power density for the complex additive white Gaussian noise (AWGN) at receiver k on the nth subchannel. The flat fading assumption would be valid as long as the each subcarrier is sufficiently narrow compared to the coherence bandwidth of the channel. The achievable rate for user k can be written as

$$R_k = \sum_{n=1}^{N} R_k[n] = \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]\,|H_{kk}[n]|^2}{N_k[n] + \sum_{\substack{i=1 \\ i \neq k}}^{K} p_i[n]\,|H_{ik}[n]|^2} \right), \tag{13}$$

which can be further reexpressed as

$$\begin{aligned} R_k &= \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{\frac{N_k[n]}{|H_{kk}[n]|^2} + \sum_{\substack{i=1 \\ i \neq k}}^{K} p_i[n] \frac{|H_{ik}[n]|^2}{|H_{kk}[n]|^2}} \right) \\ &= \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{\sigma_k[n] + \sum_{\substack{i=1 \\ i \neq k}}^{K} p_i[n]\theta_{ik}[n]} \right) \qquad (14) \\ &= \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{\sigma_k[n] + I_k[n]} \right) \equiv \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{c_k[n]} \right), \qquad (15) \end{aligned}$$

where in (14), $\sigma_k[n] \triangleq \frac{N_k[n]}{|H_{kk}[n]|^2}$ is the normalized noise power on subchannel n, $\theta_{ik}[n] \triangleq \frac{|H_{ik}[n]|^2}{|H_{kk}[n]|^2}$ denotes the normalized (by user k) channel power gain from transmitter (or interference) i to receiver k, and $I_k[n] = \sum_{\substack{i=1 \\ i \neq k}}^{K} p_i[n] \frac{|H_{ik}[n]|^2}{|H_{kk}[n]|^2}$ is the total interference power on subchannel n for user k and, in (15), $c_k[n] \triangleq \sigma_k[n] + I_k[n]$ corresponds to the overall "noise" on subchannel n for user k.

Under this interference model, users compete on their individual achievable rates. In particular, a user may choose to allocate more power on its own good subchannels to boost its rate but will interfere other users more on these subchannels. Channel allocation will be automatically done through the power allocation. If $p_k[n] = 0$ for some n, then it means that the nth subchannel is not assigned to user k.

Optimal Spectrum Balancing

Typically, the problem of interest is to maximize the network capacity under the power constraints of the transmitters (base stations in the downlink and

mobile users in the uplink). This is called a rate-adaptive optimization problem. That is,

$$\max_{\{p_k[n]\geq 0,\forall k,n\}} \sum_{k=1}^{K} R_k \quad \text{s.t.} \quad \sum_{n=1}^{N} p_k[n] \leq P_k \ \forall k. \tag{16}$$

When a global optimizer or centralized spectrum manager who knows the channel state information (CSI) of all the user links exists, it is possible to find the optimal solution of (16). The problem (16), however, is not convex and a multidimensional global optimization problem involving a large number of variables (KN unknowns).

In [19], (16) is optimally solved by considering the dual domain and forming the Lagrangian dual

$$\mathscr{L}(\{p_k[n]\},\{\lambda_k\}) = \sum_{k=1}^{K} R_k + \sum_{k=1}^{K} \lambda_k \left(P_k - \sum_{n=1}^{N} p_k[n] \right), \tag{17}$$

where $\{\lambda_k\}$ are the Lagrange multipliers. The dual objective function $g(\{\lambda\})$ can be defined as the maximization of an unconstrained maximization of the Lagrangian

$$g(\{\lambda_k\}) = \max_{\{p_k[n]\geq 0,\forall k,n\}} \mathscr{L}(\{p_k[n]\},\{\lambda_k\}). \tag{18}$$

The dual optimization problem is $\min_{\{\lambda_k\geq 0,\forall k\}} g(\{\lambda_k\})$.

The optimal solution may be found by a nested bisection search in the λ-space. It can be shown that the optimal spectrum balancing (OSB) algorithm has a computational complexity that is linear in the number of frequency carriers N.

However, the computational complexity of the OSB algorithm, although linear in N, is exponential in the number of users K. For a cellular radio system where the number of users, K, is in the order of thousands or more and it has hundreds of channels, it would be too demanding to solve hundreds of thousands unknowns in real-time resource allocation. The required complexity is prohibitive.

Iterative Spectrum Balancing

To solve (16) at much lower complexity, [20] established a general theory of dual optimization for OFDMA systems and showed that the duality gap for multiuser spectrum optimization always tends to zero as the number of frequency subcarriers goes to infinity, regardless of whether the optimization problem is convex. This observation has led to efficient search methods that optimize the dual objective function (17) directly. In particular, evaluating (17) can be realized by decoupling into N independent problems as

$$g(\{\lambda_k\}) = \sum_{n=1}^{N} \left\{ \max_{\{p_k[n] \geq 0, \forall k\}} \left[\sum_{k=1}^{K} \log_2 \left(1 + \frac{p_k[n]}{c_k[n]} \right) - \sum_{k=1}^{K} \lambda_k \, p_k[n] \right] \right\} + \sum_{k=1}^{K} \lambda_k \, P_k, \tag{19}$$

which, even though may still involve an exhaustive search, is unconstrained and much more manageable. Sub-gradient and ellipsoidal searches were also possible to improve the efficiency of the search over the λ-space.

The OFDMA Forward-Looking Game

In section "A Belief-Directed Game of Forward-Looking Players," we have revealed that the dynamic power and channel allocation can be obtained by solving the problem (16) which can be solved optimally by the OSB algorithm in [19] and near optimally by the ISB algorithm in [20]. Such optimization is able to reconcile the users' interest to maximize the achievable network sum-rate by a central spectrum manager. The major drawback of this approach is unfortunately that in a cellular radio network where there are a large number of users, such centralized optimization would be too complex to perform. For open spectrum access such as the white space, such centralized manager is also unlikely to exist. An alternative approach is to view the competition between users as a game, and negotiation on the resource allocation between users may be achieved by *playing* in which mobile users (considered as players) negotiate with each other by varying their actions intelligently and interactively according to the network response.

Consider the OFDMA interference channel described in section "A Subsystem Model for the OFDMA Game" (see also Fig. 6). Let $\mathscr{P} = \{\mathscr{P}_1, \mathscr{P}_2, \ldots, \mathscr{P}_K\}$ denote the set of collection for all users' power allocation strategies, with $\mathsf{p}_k \in \mathscr{P}_k \ \forall k$, and define $\mathsf{p}_{-k} \triangleq \{\mathsf{p}_1, \ldots, \mathsf{p}_{k-1}, \mathsf{p}_{k+1}, \ldots, \mathsf{p}_K\}$. We also let $\mathsf{BP}_k \in \mathscr{P}_k$ be user k's best power allocation strategy in response to the interference pattern seen by that user $\mathsf{I}_k \triangleq \{I_k[1], I_k[2], \ldots, I_k[N]\}$. Then, mathematically, BP_k is given by

$$\mathsf{BP}_k = \arg \max_{\mathsf{p}_k \in \mathscr{P}_k} \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{\sigma_k[n] + I_k[n]} \right) \ \text{s.t.} \ \sum_{n=1}^{N} p_k[n] \leq P_k. \tag{20}$$

Figure 7 shows a power game subsystem which illustrates how users interact with each other in a competitive way. Given the interference pattern seen by user k, it optimizes its power allocation to give $\mathsf{p}_k = \mathsf{BP}(\mathsf{I}_k)$ which in return changes the interference patterns of other users $\{\mathsf{I}_l\}_{l \neq k}$ giving rise to their new power allocation strategies $\{\mathsf{BP}(\mathsf{I}_l)\}_{l \neq k}$. The power $\{\mathsf{BP}(\mathsf{I}_l)\}_{l \neq k}$ will become the cause of the changes in the interference pattern for user k, I_k. That is,

$$\mathsf{I}_k = \mathsf{I}_k \left(\{\mathsf{BP}(\mathsf{I}_l(\mathsf{p}_k))\}_{l \neq k} \right). \tag{21}$$

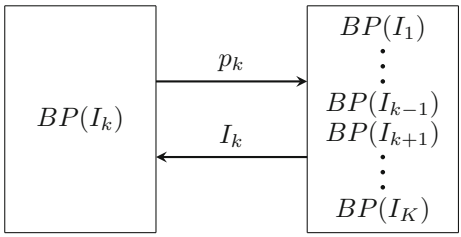

Fig. 7 The power game subsystem

For convenience, we abuse our notation slightly and define

$$\mathsf{BP}_{-k}(\mathsf{p}_k) \triangleq \{\mathsf{BP}(\mathsf{I}_1), \ldots, \mathsf{BP}(\mathsf{I}_{k-1}), \mathsf{BP}(\mathsf{I}_{k+1}), \ldots, \mathsf{BP}(\mathsf{I}_K)\}. \tag{22}$$

Clearly, the interference pattern for user k, $\mathsf{I}_k(\mathsf{BP}_{-k}(\mathsf{p}_k))$, is recognized to be a function of its own power allocation strategy p_k. Depending on how users react to the change of the environments and how the power game runs, if the system converges, then it will converge to some equilibrium.

Throughout, we shall use the superscript $*$ to denote the parameters at the equilibrium so that at the equilibrium, the power allocation strategy is $\mathbf{P}^* = \{\mathsf{p}_k^*, \mathsf{p}_{-k}^*\}$.

A Subsystem Model for the OFDMA Game

In this setup, users are all uncoordinated individuals, and each allocates its power over the subcarriers to maximize its own rate based on its observation of the environment, $\{c_k[n]\}$ for all n (which is referred to as the local CSI possessed by user k), and its belief on how the environment would react to its action. The environment user k observations can change because other users may alter their strategies to respond to user k's action. It is a dynamic process where users all interact and may compromise to an equilibrium, if their interactions converge over time.

To model this interaction, from user k's viewpoint, we can regard other users as a subsystem (or the environment seen by user k), as shown in Fig. 7, which takes its action at time t as inputs (i.e., $\mathsf{p}_k^t = \{p_k^t[n]\}$) and produces a new interference pattern at time $t+1$ as outputs (i.e., $\mathsf{c}_k^{t+1} = \{c_k^{t+1}[n]\}$). The subsystem reacts by an overall response from the actions of all other users, $\mathsf{p}_{-k}^t \triangleq \{\mathsf{p}_1^t, \ldots, \mathsf{p}_{k-1}^t, \mathsf{p}_{k+1}^t, \ldots, \mathsf{p}_K^t\}$.

Based on the rate (15), the distributed optimization problem for the OFDMA channel can be written as

$$\max_{\mathsf{p}_k \in \mathscr{S}_k} R_k, \ \forall k, \tag{23}$$

where $\mathscr{S}_k \triangleq \{\mathsf{p}_k : \sum_{n=1}^{N} p_k[n] \leq P_k\}$. The challenge to the above optimization is that R_k is a time-varying function (via c_k) which changes, according to the action or reaction of the remaining users. One way of characterizing the interactive process is to use the framework of the Nash game with forward-looking players in [21].

A Belief-Directed Game of Forward-Looking Players

Definitions

A player is said to be forward-looking if it uses some belief function to quantify the future reaction of the environment according to its action at present. Before presenting the definition of a Nash game with forward-looking players, the following functions are introduced:

- *Environmental function* – In a competition process, the reward for player k depends not only on its own strategy x_k but also others' strategies $\boldsymbol{x}_{-k}$ at any given time instant t. We use the environmental function $r_k(\boldsymbol{x}^t_{-k})$ to quantify the influence of other players' strategies onto player k's reward.
- *Belief function* – A player's understanding on its environmental function reflects its cognition about the competition in the game. In a belief-directed game, it is considered that player k possesses the knowledge of a belief function, which is denoted as $r^{\mathsf{B}}_k(x_k, \boldsymbol{x}^t_{-k})$, where $\boldsymbol{x}^t_{-k}$ denotes the strategies from all the players at time instant t except player k, and, clearly, $r^{\mathsf{B}}_k(x^t_k, \boldsymbol{x}^t_{-k}) = r_k(\boldsymbol{x}^t_{-k})$. The belief function may be constructed using some form of Taylor series expansion, e.g.,

$$r^{\mathsf{B}}_k(x_k, \boldsymbol{x}^t_{-k}) = r_k(\boldsymbol{x}^t_{-k}) + \varphi^t_k(x_k - x^t_k), \tag{24}$$

  where $\varphi^t_k \triangleq \frac{\partial r^{\mathsf{B}}_k(x_k, \boldsymbol{x}^t_{-k})}{\partial x_k}$ is regarded as the *interference derivative* that predicts the amount of future reaction from the environment due to present change in strategy. The selection of the interference derivative φ^t_k by the player permits engineering of the equilibrium of the game. Moreover, the belief function $r^{\mathsf{B}}_k(\cdots)$ can be understood as player k's cognition on what the environment function $r_k(\cdots)$ would be, given a strategy x_k and the present state $\boldsymbol{x}^t_{-k}$. Note that φ^t_k is only a belief for player k and whether the derivative $\frac{\partial r_k}{\partial x_k}$ actually exists or not is irrelevant.
- *Predicted reward* – The predicted reward function, $f_k(x_k, r^{\mathsf{B}}_k(x_k, \boldsymbol{x}^t_{-k}))$, gives the amount of reward player k believes to achieve by the strategy, x_k, given other players' strategies at time t, $\boldsymbol{x}^t_{-k}$, and the belief function $r^{\mathsf{B}}_k(\cdots)$ that player k uses to predict the future impact in the environment.

Based on the above definitions, we now can present the Nash equilibrium with forward-looking players (i.e., with some cognition in the form of belief functions). Mathematically, it is written as

$$f_k(x_k^*, r_k^{\mathsf{B}}(x_k^*, \boldsymbol{x}_{-k}^*) \geq f_k(x_k, r_k^{\mathsf{B}}(x_k, \boldsymbol{x}_{-k}^*)), \ \forall k, \tag{25}$$

where $r_k^{\mathsf{B}}(\cdot)$ is the belief function reflecting player k's cognition ability and $f_k(\cdot)$ is the predicted reward function for player k. Note that (25) can be rewritten as

$$f_k(x_k^*, \boldsymbol{x}_{-k}^*) \geq f_k(x_k, r_k^{\mathsf{B}}(x_k, \boldsymbol{x}_{-k}^*)), \ \forall k. \tag{26}$$

This can be explained by recognizing the fact that according to (24), $r_k^{\mathsf{B}}(x_k^*, \boldsymbol{x}_{-k}^*) = r_k(\boldsymbol{x}_{-k}^*)$ and as such at the equilibrium, we have

$$f_k(x_k^*, r_k^{\mathsf{B}}(x_k^*, \boldsymbol{x}_{-k}^*) = f_k(x_k^*, r_k(\boldsymbol{x}_{-k}^*)) = f_k(x_k^*, \boldsymbol{x}_{-k}^*). \tag{27}$$

In this model, the belief function $r_k^{\mathsf{B}}(\cdot)$ can be chosen arbitrarily, and it only serves to indicate player k's understanding about the competition environment. In fact, (26) embraces the conventional Nash equilibrium in which players have the belief function $r_k^{\mathsf{B}}(x_k, \boldsymbol{x}_{-k}^t) = r_k(\boldsymbol{x}_{-k}^t)$ which effectively treats the environment player k observations at any present time instant t as fixed and constant and ignores the subsequent changes in other players' strategies provoked by player k's new strategy.

The equilibrium of a Nash game with belief functions is referred to as a belief-directed Nash equilibrium (BNE).

The OFDMA BNE

For the OFDMA system, the reward function is the achievable rate R_k in (15), and the strategy for player k (or user k) is the power allocation strategy p_k. Also, the environmental function is the overall interference resulting from other users' strategies $\mathsf{c}_k(\mathsf{p}_{-k}^t)$. As a result, under BNE, we can form the belief function to enable player k's cognition using a general form inspired by the Taylor series

$$c_k^{\mathsf{B}}[n] \triangleq c_k^t[n] + \sum_{\ell=1}^{\infty} \varphi_k^{t\,(\ell)}[n](p_k[n] - p_k^t[n])^{\ell}, \tag{28}$$

where $\varphi_k^{t\,(\ell)}[n]$ denotes the ℓth order derivative of the belief function with respect to (w.r.t.) the strategy $p_k[n]$ at time t. The derivatives $\{\varphi_k^{t\,(\ell)}[n]\}$ can be chosen freely to give a different belief function for the player (which will result in a different BNE) and hence play the role of the engineering parameters for the BNE. Also, we write $\mathsf{c}_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t) = \{c_k^{\mathsf{B}}[1], c_k^{\mathsf{B}}[2], \ldots, c_k^{\mathsf{B}}[N]\}$, which may be viewed as a prediction to $\mathsf{c}_k(\mathsf{p}_{-k})$. Based on the belief function $\mathsf{c}_k^{\mathsf{B}}$, user k has the predicted reward function (or predicted rate) given by

$$f_k(\mathsf{p}_k, \mathsf{c}_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)) \triangleq \sum_{n=1}^{N} \log_2\left(1 + \frac{p_k[n]}{c_k^{\mathsf{B}}[n]}\right), \tag{29}$$

which is the achievable rate in (15) after replacing $c_k[n]$ by $c_k^{\mathsf{B}}[n]$. Note that $f_k(\cdots)$ provides a predictive rate given the strategy p_k and the present state p_{-k}^t at time instant t. Mathematically, at the BNE, we have

$$f_k(\mathsf{p}_k^*, \mathsf{c}_k^{\mathsf{B}}(\mathsf{p}_k^*, \mathsf{p}_{-k}^*)) \geq f_k(\mathsf{p}_k, \mathsf{c}_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^*)), \ \forall \mathsf{p}_k \in \mathscr{S}_k \text{ and } \forall k. \tag{30}$$

Nash equilibrium is a special case of BNE, and this can be seen when $\varphi_k^{(\ell)*}[n] = 0 \ \forall \ell \geq 1$ and $\forall n, k$. In this case, $\mathsf{c}_k^{\mathsf{B}} = \mathsf{c}_k^t$ and the BNE is therefore degenerated to

$$f_k(\mathsf{p}_k^*, \mathsf{c}_k(\mathsf{p}_{-k}^*)) \geq f_k(\mathsf{p}_k, \mathsf{c}_k(\mathsf{p}_{-k}^*)), \ \forall \mathsf{p}_k \in \mathscr{S}_k \text{ and } \forall k. \tag{31}$$

The above basically states that at the equilibrium, the rewards for all the players are maximized, giving no incentive for players to deviate from it. In other words, the mobile users all settle on their power allocation strategies $\{\mathsf{p}_k^*\}$.

It is worth emphasizing that the predicted rate does not need to be accurate for the game to work, though the general sense is that an accurate prediction should help the users find better strategies. Note that Nash equilibrium is a result from an unrealistic prediction (based on the assumption of a static environment).

Forward-Looking Water-Filling Optimization

It is well known that for the power allocation of the OFDM type problem, the solution usually has an interpretation of water filling over the subchannels. It is no different in the OFDMA scenario even if the mobile users are forward-looking.

In the OFDMA BNE game, at time t, user k aims to find the strategy for time $t+1$ by solving

$$\mathsf{p}_k^{t+1} = \arg \max_{\mathsf{p}_k \in \mathscr{S}_k} f_k(\mathsf{p}_k, \mathsf{c}_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)). \tag{32}$$

In order to make (32) solvable, it is advisable to choose $\{\varphi_k^{t\,(\ell)}[n]\}$ such that

$$c_k^{\mathsf{B}}[n] > 0, \tag{33a}$$

$$\frac{\partial f_k(\mathsf{p}_k, \mathsf{c}_k^{\mathsf{B}})}{\partial p_k[n]} > 0, \tag{33b}$$

$$\frac{\partial^2 f_k(\mathsf{p}_k, \mathsf{c}_k^{\mathsf{B}})}{\partial (p_k[n])^2} < 0, \tag{33c}$$

so that (32) is a convex optimization problem. Note that (28) is a very general form to define the belief function, and how to best utilize it to design the most spectral efficient OFDMA BNE game is unknown. In this chapter, for mathematical tractability, we propose to choose $\{\varphi_k^{t\,(1)}[n]\}$ appropriately to optimize the BNE while setting $\varphi_k^{t\,(\ell)}[n] = 0$ for $\ell \geq 3$ and $\forall t, n$. Also, we can set

$$\varphi_k^{t\,(2)}[n] > -\frac{c_k^t[n] + \varphi_k^t[n](p_k[n] - p_k^t[n])}{(p_k[n] - p_k^t[n])^2} \tag{34}$$

to ensure that $c_k^{\mathsf{B}}[n] > 0$ is satisfied, where $\varphi_k^t[n] = \varphi_k^{t\,(1)}[n]$ for notational brevity.

Based on the definition of BNE (30), at time instant t, forward-looking user k aims to solve

$$\mathsf{p}_k^{t+1} = \arg\max_{\mathsf{p}_k \in \mathscr{S}_k} \sum_{n=1}^{N} \log_2\left(1 + \frac{p_k[n]}{c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n]}\right). \tag{35}$$

The following theorem gives the optimal strategy update for p_k^{t+1}.

Theorem 1. *Assuming that any (infinitesimal) change in user k's strategy on subcarrier n only affects the interference on subcarrier n but not others $m \neq n$, the optimal strategy update for user k is given by*

$$p_k^{t+1}[n] = \left(\frac{w_k^t x_k^t[n] - (x_k^t[n])^2}{w_k^t y_k^t[n] + x_k^t[n]}\right)^+, \tag{36}$$

where $(a)^+ = \max\{0, a\}$, $x_k^t[n] \triangleq c_k^{\mathsf{B}}(\mathsf{p}_k^{t+1}, \mathsf{p}_{-k}^t)[n]$, $y_k^t[n] \triangleq \left.\frac{\partial c_k^{\mathsf{B}}[n]}{\partial p_k[n]}\right|_{p_k[n]=p_k^{t+1}[n]}$ *and* $w_k^t (> 0)$ *is regarded as the water level that ensures the equality of the power constraint (11) for the maximization.*

Proof. The problem (35) can be solved by introducing the Lagrange multiplier λ, using a Lagrangian multiplier formulation

$$\mathscr{L} = \sum_{n=1}^{N} \ln\left(1 + \frac{p_k[n]}{c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n]}\right) - \lambda\left(\sum_{n=1}^{N} p_k[n] - P_k\right). \tag{37}$$

To proceed, we first obtain

$$\frac{\partial \mathscr{L}}{\partial p_k[n]} = \frac{1}{1 + \frac{p_k[n]}{c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n]}}\left(\frac{c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n] - p_k[n]\frac{\partial c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n]}{\partial p_k[n]}}{(c_k^{\mathsf{B}}(\mathsf{p}_k, \mathsf{p}_{-k}^t)[n])^2}\right) - \lambda. \tag{38}$$

Then by setting $\left.\frac{\partial \mathscr{L}}{\partial p_k[n]}\right|_{p_k[n]=p_k^{t+1}[n]} = 0$ (which is the necessary condition for the maximization), and using the definitions

$$\begin{cases} x_k^t[n] \triangleq c_k^{\mathsf{B}}(\mathsf{p}_k^{t+1}, \mathsf{p}_{-k}^t)[n], \\ y_k^t[n] \triangleq \left.\dfrac{\partial c_k^{\mathsf{B}}[n]}{\partial p_k[n]}\right|_{p_k[n]=p_k^{t+1}[n]}, \end{cases} \tag{39}$$

we get

$$p_k^{t+1}[n] = \left(\frac{\frac{1}{\lambda}x_k^t[n] - (x_k^t[n])^2}{\frac{1}{\lambda}y_k^t[n] + x_k^t[n]}\right)^+, \tag{40}$$

where $(\cdot)^+$ ensures the positiveness of the power. Finally, renaming $\frac{1}{\lambda}$ as w_k^t yields the desired result, which completes the proof. □

The power allocation solution (36) is based on the maximization of a forward-looking achievable rate (via the belief function $\mathsf{c}_k^{\mathsf{B}}$). Note that its water-filling interpretation follows exactly the same way as the conventional water-filling power allocation for a single-user OFDM system with water-level w_k^t. As $t \to \infty$, if all users' strategies converge to a stable state, then from (28), we have

$$\begin{cases} x_k^*[n] = \left. c_k^{\mathsf{B}*}[n]\right|_{p_k[n]=p_k^*[n]} = c_k^*[n], \\ y_k^*[n] = \left.\dfrac{\partial c_k^{\mathsf{B}*}[n]}{\partial p_k[n]}\right|_{p_k[n]=p_k^*[n]} = \varphi_k^*[n], \end{cases} \tag{41}$$

and as a consequence, at the equilibrium, we obtain the users' strategies

$$p_k^*[n] = \left(\frac{w_k^* c_k^*[n] - (c_k^*[n])^2}{w_k^* \varphi_k^*[n] + c_k^*[n]}\right)^+, \quad \forall k, n. \tag{42}$$

The intuition is that although there can be many parameters $\{\varphi_k^{t\,(m)}[n]\}_{\forall m,n}$ that can be adjusted in a player's belief, the power allocation strategy at the equilibrium depends only on $\varphi_k^*[n]$ (i.e., the first derivative but not the higher-order ones), or the choice of $\{\varphi_k^{t\,(m)}[n]\}_{\forall m \geq 2}$ plays no role in defining the BNE. This justifies the earlier assumption of setting the higher-order derivatives in the belief function to zeros.

A common structure in the OFDMA power allocation game, regardless of the equilibrium, is to solve (20), which can be tackled by the Lagrangian multiplier method. In particular, this is done by defining

$$\mathscr{L} = \sum_{n=1}^{N} \log_2\left(1 + \frac{p_k[n]}{\sigma_k[n] + I_k[n]}\right) - \lambda \sum_{n=1}^{N} p_k[n], \tag{43}$$

where λ denotes the Lagrange multiplier, and finding p_k that maximizes $\mathscr{L}$. The Karush-Kuhn-Tucker (KKT) conditions for optimality can be derived as

$$\frac{\partial \mathscr{L}}{\partial p_k[n]} \begin{cases} = 0 \text{ for } p_k[n] > 0, \\ \leq 0 \text{ for } p_k[n] = 0. \end{cases} \tag{44}$$

Moreover, with

$$\frac{\partial \mathscr{L}}{\partial p_k[n]} = \frac{1}{\sigma_k[n] + I_k[n] + p_k[n]} \left(\frac{\sigma_k[n] + I_k[n] - p_k[n] \frac{\partial I_k[n]}{\partial p_k[n]}}{\sigma_k[n] + I_k[n]} \right) - \lambda \tag{45}$$

and defining $\varphi_k[n] \triangleq \frac{\partial I_k[n]}{\partial p_k[n]}$, it can be simplified as

$$\frac{\partial \mathscr{L}}{\partial p_k[n]} = \frac{1}{\frac{c_k^2[n] + \varphi_k[n] p_k^2[n]}{c_k[n] - \varphi_k[n] p_k[n]} + p_k[n]} - \lambda \equiv \frac{1}{\eta_k[n] + p_k[n]} - \lambda. \tag{46}$$

As a consequence, the optimal power allocation (or best power) for user k has the well-known water-filling interpretation and is given by

$$p_k[n] = (w_k - \eta_k[n])^+, \tag{47}$$

where $(a)^+ = \max(0, a)$ and

$$w_k = \frac{(\sigma_k[n] + I_k[n])^2 + \varphi_k[n] p_k^2[n]}{\sigma_k[n] + I_k[n] - \varphi_k[n] p_k[n]} + p_k[n], \tag{48}$$

which is chosen to satisfy the user's power constraint $\sum_n p_k[n] \leq P_k$ and is interpreted as the "water level" of the solution. Though this version of water-filling solution may appear complicated (as both w_k and $\eta_k[n]$ are functions of $\{p_k[n]\}$), this is much more general and facilitates the design of algorithms converging to different equilibria by obtaining an appropriate (belief) function $\varphi_k[n]$ to model various level of cognition ability of the user. The introduction of the interference derivative $\varphi_k[n]$ is significant because this provides the parameter that, if properly chosen, can guide the negotiation process between the users to reach a desired equilibrium.

For Nash equilibrium as an example, $\varphi_k[n] = 0$ is applied (because the user believes that $c_k^{\mathsf{B}}[n]$ is fixed and does not depend on the strategy $p_k[n]$ or $\varphi_k[n] = \frac{\partial c_k^{\mathsf{B}}[n]}{p_k[n]} = 0$) and (47) can therefore be greatly simplified as

$$p_k[n] = (w_k - \sigma_k[n] - I_k[n])^+. \tag{49}$$

Various Equilibria

Nash Equilibrium

At Nash equilibrium, $\mathsf{p}_k^* = \mathsf{BP}(\mathsf{I}_k^*)$ and $\mathsf{p}_{-k}^* = \mathsf{BP}_{-k}(\mathsf{p}_k^*)$, so the strategy profile can be written as

$$\mathbf{P}^* = \{\mathsf{BP}(\mathsf{I}_k^*), \mathsf{BP}_{-k}(\mathsf{p}_k^*)\}. \tag{50}$$

Additionally, Nash equilibrium can be formulated formally as

$$R_k(\mathsf{p}_k^*, \mathsf{BP}_{-k}(\mathsf{p}_k^*)) \geq R_k(\mathsf{p}_k, \mathsf{BP}_{-k}(\mathsf{p}_k^*)),\ \forall \mathsf{p}_k \in \mathscr{P}_k \text{ and } \forall k \in \{1, 2, \ldots, K\}. \tag{51}$$

User k's data rate, R_k^*, is therefore given by

$$\begin{aligned} R_k^* &= \max_{\mathsf{p}_k \in \mathscr{P}_k} \sum_n \log_2\left(1 + \frac{p_k[n]}{\sigma_k[n] + I_k^*[n]}\right) \\ &= \max_{\mathsf{p}_k \in \mathscr{P}_k} \sum_n \log_2\left(1 + \frac{p_k[n]}{\sigma_k[n] + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^*))[n]}\right). \end{aligned} \tag{52}$$

Note that the above maximization is done under a fixed interference pattern I_k^*. As mentioned before, achieving Nash equilibrium will have $\varphi_k[n] = \frac{\partial I_k^*[n]}{\partial p_k[n]} = 0$ and

$$\mathsf{p}_k^* = \mathsf{BP}(\mathsf{I}_k(\mathsf{BP}_{-k}(\mathsf{p}_k^*)))\ \forall k. \tag{53}$$

This can be achieved by the iterative (multiuser) water-filling algorithm as follows:

$$p_k^t + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^{t-1})) = w_k^t \tag{54a}$$

$$p_k^{t+1} + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^t)) = w_k^{t+1} \tag{54b}$$

$$\vdots$$

$$p_k^* + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^*)) = w_k^* \tag{54c}$$

where the superscript t denotes the iteration time index and becomes $*$ at the equilibrium, and in the above the subchannel index $[n]$ has been omitted for convenience. The iterations (54) follow largely from the single-user water-filling solution in (49), but the only difference is that the interference pattern seen by user k changes due to a new response from other users before reaching to the steady state.

Every user in the equilibrium is deemed self-optimal giving the highest possible rate, with respect to other users' steady-state power allocation. Thus, a user does not gain by not agreeing to the equilibrium. However, the Nash system can be overly competitive leading to a very suboptimal power game equilibrium.

Stackelberg Equilibrium

It is possible to reach a different equilibrium that to some user allows better reconciliation between users to outperform Nash equilibrium. One such equilibrium is the Stackelberg equilibrium where one user is regarded as the Stackelberg leader, say user κ, who can maximize its own rate, R_κ, by finding its optimal strategy knowing that other users (regarded as followers) will know its action and respond by their (Nash-like) best power allocation. Mathematically, we have, for user κ,

$$R_\kappa(\mathsf{p}_\kappa^*, \mathsf{BP}_{-\kappa}(\mathsf{p}_\kappa^*)) \geq R_\kappa(\mathsf{p}_\kappa, \mathsf{BP}_{-\kappa}(\mathsf{p}_\kappa)),\ \forall \mathsf{p}_\kappa \in \mathscr{P}_\kappa. \tag{55}$$

As a result, user κ's data rate, R_κ^*, can be formulated as

$$\begin{aligned} R_\kappa^* &= \sum_n \log_2\left(1 + \frac{p_\kappa^*[n]}{\sigma_\kappa[n] + I_\kappa^*[n]}\right) \\ &= \max_{\mathsf{p}_\kappa \in \mathscr{P}_\kappa} \sum_n \log_2\left(1 + \frac{BP(\mathsf{I}_\kappa(\mathsf{BP}_{-\kappa}(\mathsf{p}_\kappa)))[n]}{\sigma_\kappa[n] + I_\kappa(\mathsf{BP}_{-\kappa}(\mathsf{p}_\kappa))[n]}\right). \end{aligned} \tag{56}$$

To reach the leader-followers Stackelberg equilibrium, the leader (i.e., user κ) can play the generalized water-filling power allocation (47) with appropriately chosen $\{\varphi_\kappa[n]\}$ while the followers (i.e., the remaining users) respond by the traditional water-filling power allocation (49) with $\varphi_k[n] = 0$. As such, the following iterative water-filling algorithm can take the users to the Stackelberg equilibrium:

$$\text{Leader } \kappa \begin{cases} p_\kappa^t + \eta_\kappa^t(\mathsf{p}_\kappa^{t-1}) = w_\kappa^t \\ p_\kappa^{t+1} + \eta_\kappa^t(\mathsf{p}_\kappa^t) = w_\kappa^{t+1} \\ \qquad\qquad \vdots \\ p_\kappa^* + \eta_\kappa^* = w_\kappa^* \end{cases} \tag{57}$$

and

$$\text{for all Followers } k \neq \kappa \begin{cases} p_k^t + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^{t-1})) = w_k^t, \\ p_k^{t+1} + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^t)) = w_k^{t+1}, \\ \qquad\qquad\qquad\qquad \vdots \\ p_k^* + \sigma_k + I_k(\mathsf{BP}_{-k}(\mathsf{p}_k^*)) = w_k^*. \end{cases} \tag{58}$$

Note that $\eta_\kappa^t[n] \triangleq \frac{(c_\kappa^t[n])^2 + \varphi_\kappa^t[n](p_\kappa^t[n])^2}{c_\kappa^t[n] - \varphi_\kappa^t[n]p_\kappa^t[n]}$ (which was defined in (46) earlier).

In the literature, when solving (56), a brute-force optimization is usually needed, which is not only prohibitively complex but also that no known method exists to play the leader to reach the Stackelberg equilibrium. However, using the BNE game as

a tool, one could choose $\varphi_\kappa[n]$ appropriately to reach the Stackelberg equilibrium. Note that there are likely many choices of $\varphi_\kappa[n]$ that can all permit the users to converge to the Stackelberg equilibrium. Here, nevertheless, we provide a choice without proof by setting

$$\varphi_\kappa[n] = -\frac{c_\kappa[n]}{2c_\kappa[n] + p_\kappa[n]} \ \forall n. \tag{59}$$

There are a few observations we can make to understand why this choice is good. First, to derive a judicious belief on $\varphi_\kappa^*[n]$, the interference derivative should be negative, or $\varphi_\kappa^*[n] \leq 0$ because it then has a strong tendency to invest power on a good subcarrier. In contrast, if $\varphi_\kappa^*[n] > 0$, this will imply that the more the power it allocates for a subcarrier, the more the interference it gets, thus ending up occupying a poor subcarrier at the equilibrium. On the other hand, it can be shown that as long as $-\frac{c_\kappa^*[n]}{2c_\kappa^*[n]+p_\kappa^*[n]} \leq \varphi_\kappa^*[n] \leq 0$ is true, the equilibrium is unique, and therefore, any value in this interval could be a sensible choice for the interference derivative $\varphi_\kappa^t[n]$. However, it should also be noted that the magnitude of $\varphi_\kappa^*[n]$ reflects the forward-looking capability, or if $\varphi_\kappa^*[n] = 0$, the user is myopic and not forward-looking. As a result, (59) is a proper choice that is anticipated to optimize user κ's rate.

In Fig. 8, we provide a simulation example for the power allocation of a 3-user 9-subcarrier interference channel (e.g., cellular system with game-theoretic dynamic spectrum access) under different game-theoretic equilibria. In the simulations, every subcarrier channel is modeled by an equal-power four-independent-ray Rayleigh fading channel (see Fig. 9) [22], i.e., $|H_{ij}[n]|^2 = |h_{ij}^{(1)}[n]|^2 + |h_{ij}^{(2)}[n]|^2 + |h_{ij}^{(3)}[n]|^2 + |h_{ij}^{(4)}[n]|^2, \ \forall i, j$, with $\mathrm{E}[|H_{ij}[n]|^2] = x$ and $\mathrm{E}[|h_{ij}^{(\ell)}[n]|^2] = 0.25x \ \forall \ell$, for $i \neq j$, where x measures the relative severeness of the interference channel. For $i = j$, it is set that $\mathrm{E}[|H_{kk}[n]|^2] = 1$ and $\mathrm{E}[|h_{kk}^{(\ell)}[n]|^2] = 0.25 \ \forall \ell$. We also assumed that $P_k = 100 \ \forall k$, $N_k[n] = 0.01 \ \forall k, n$ and $x = 0.4$ (a typical interference channel).

Several observations can be made from the results in Fig. 8. First of all, for Nash equilibrium, all three users are Nash users, and they operate using the conventional water-filling power allocation. Therefore, we can see that the water level for each user, which is shown in this example, is very close to each other because their power constraints as well as the channel statistics are set to be the same. Also, users 2 and 3 in one-leader Stackelberg equilibrium are Nash users, and the same is observed in their power allocation strategies. By contrast, user 1 in OSE is the Stackelberg leader, and its water level depends upon η_k (not c_k) and cannot be directly visualized. In addition, the results illustrate that the power allocation strategies for users 2 and 3 in both equilibria are very similar, while the Stackelberg leader, user 1 in OSE, and the Nash user 1 in NE have profoundly different strategies. Specifically, the Stackelberg leader recognizes the fact that subcarriers 2, 5, and 6 are weak and very noisy, so decides not to occupy these subcarriers and concentrates on the good subcarriers 3, 4, and 8 leading to a substantial increase in its sum-rate from 14.8 to 19.3 (bps/Hz), whereas the sum-rates for users 2 and 3 in both equilibria are very similar and they are not compromised.

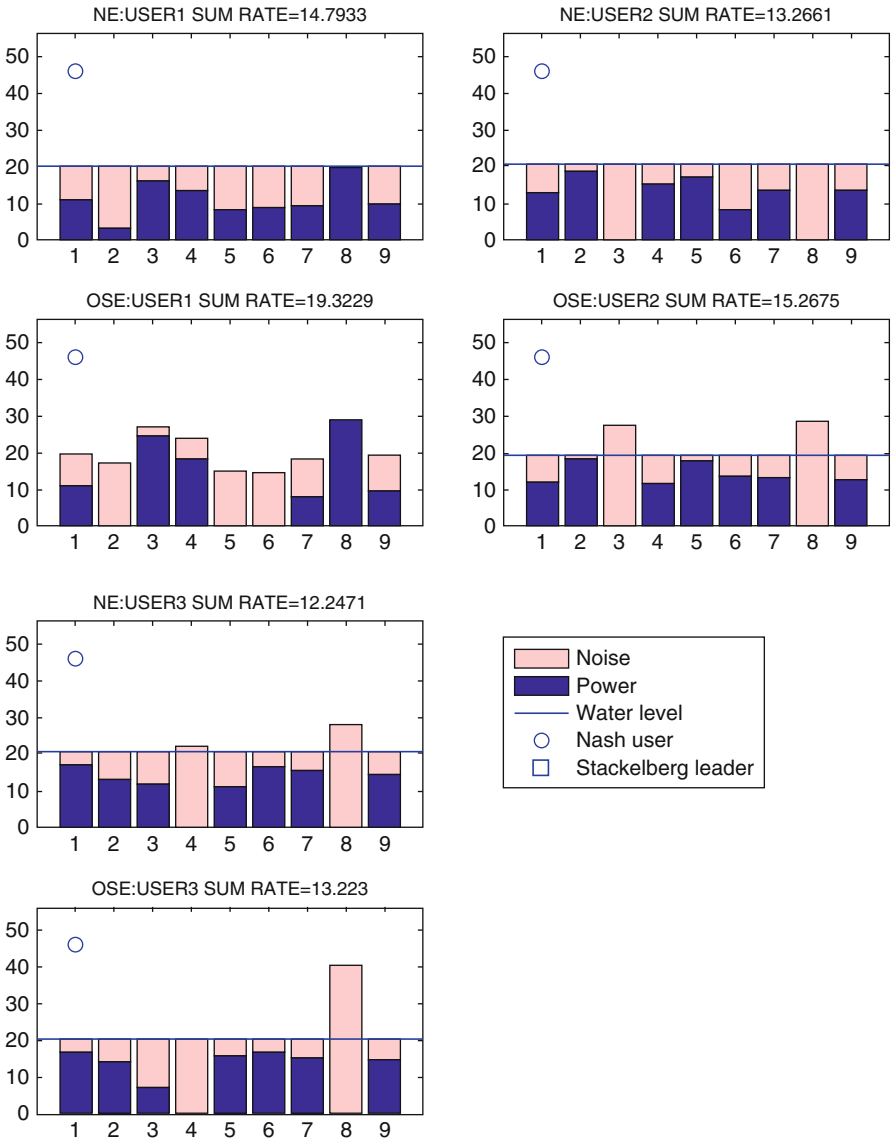

Fig. 8 An example showing the power allocation for each user over a 3-user 9-subcarrier interference channel under Nash and one-leader Stackelberg equilibria (NE and OSE)

Equilibrium Resulting from All Forward-Looking Players

Both Nash and Stackelberg equilibria can be achieved autonomously as each individual user simply needs to perform its water-filling power allocation, and their simultaneous interactions, once converged, will lead to the results. Therefore, spectrum sharing is done in a self-organizing and autonomous way. However, so

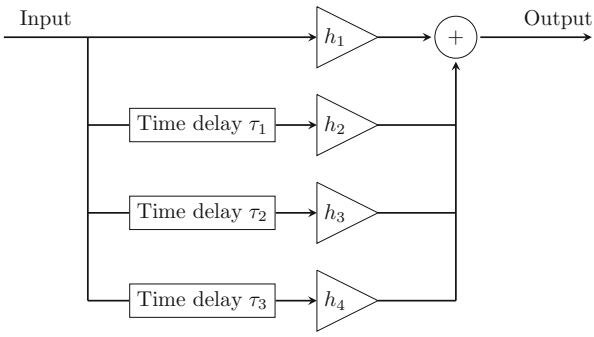

Fig. 9 A four-ray Rayleigh fading channel model

Table 1 Average users' sum-rates for the 3-user 9-subcarrier interference channel

Sum-rate	User 1	User 2	User 3
NE	13.9944	13.8966	13.8021
OSE	16.5275	15.5493	15.4743
AFE	32.6641	32.8518	33.0399

far, only the Stackelberg leader is forward-looking, while the Nash users are all myopic. In order to let all users become forward-looking, all $\{\varphi_k[n]\}$ need to be set to nonzero. It is in fact possible to use (59) for all the users, but further analysis, which is omitted here, can show that by setting

$$\varphi_k[n] = -\sqrt{\frac{c_k[n]}{2c_k[n] + p_k[n]}} \ \forall k, n, \tag{60}$$

the results are even better. The idea is to harmonize their competition, avoid destructive competition, and facilitate autonomous negotiation.

In Table 1, results are provided for the average users' sum-rates for a 3-user 9-subcarrier interference channel, with $P_k = 100 \ \forall k$, $N_k[n] = 0.01 \ \forall k, n$, and $x = 0.4$. Results show that there is a considerable gain in the sum-rates using AFE (the equilibrium achieved by having all forward-looking users using (60)) over NE and OSE. Furthermore, we compare the rate performance between AFE and ISB [20] in Fig. 10 for $x = 0.5$ and various signal-to-noise ratio (SNR) which is defined as $\frac{P_0}{NN_0}$ where $P_k = P_0 \ \forall k$, $N_k[n] = N_0 \ \forall k, n$. Results show that AFE achieves nearly the same average sum-rate as ISB and significantly outperforms OSE and NE in terms of rates for the entire range of SNR. Note that ISB is the centralized approach that has been known to achieve nearly the optimal performance.

OFDMA with MIMO Antennas

Multiple-input multiple-output (MIMO) antennas promise to deliver extraordinary gains in energy and spectral efficiencies and have been adopted in the current-

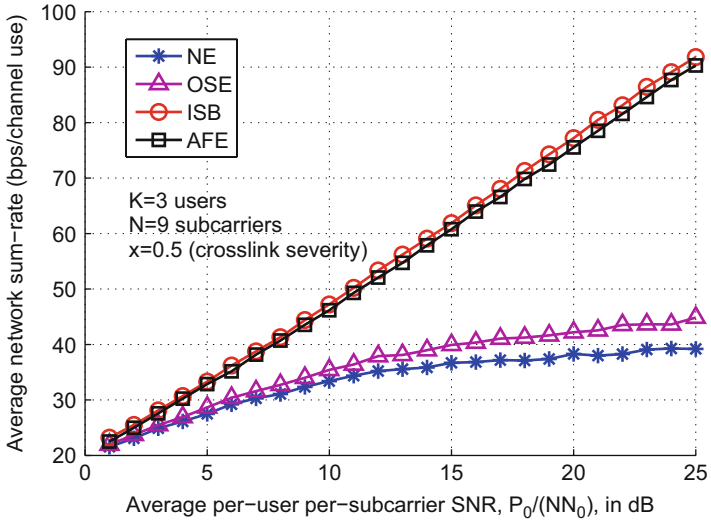

Fig. 10 The average sum-rate comparison against the SNR

as well as future-generation mobile communications networks. The autonomous spectrum sharing approaches discussed earlier, if adopted, will need to be integrated with MIMO antenna technologies. The extension is nevertheless not trivial as the spatial subchannels brought by MIMO compete within and among users.

Consider the OFDMA system with MIMO user terminals. We assume that every transmitter has N_t antennas and every receiver has N_r antennas. (Different numbers of antennas at the terminals can be easily incorporated.) In this case, assuming full-rank MIMO channels, a user, say k, has $N_t \times N$ subchannels (N_t spatial subchannels on each subcarrier) to transmit with power $p_k[\ell, n]$, on spatial subchannel ℓ and subcarrier n. For user k, the total transmit power is constrained by

$$\sum_{n=1}^{N} \sum_{\ell=1}^{N_t} p_k[\ell, n] \leq P_k, \ \forall k \in \{1, 2, \ldots, K\}. \tag{61}$$

With MIMO links, we denote the channel matrix between transmitter i and receiver j on subcarrier n by $\mathbf{H}_{ij}[n]$, and $N_k[n]$ is still the noise power spectral density at receiver k, but at every receive antenna. Assuming that user k has perfect CSI knowledge of $\{\mathbf{H}_{kk}[n]\}_{\forall n}$, the capacity-achieving scheme (from user k's viewpoint and ignoring the interference) is to use singular-value decomposition to diagonalize the channel using the right singular matrix $\mathbf{V}_k[n]$ as the precoding matrix and the left singular matrix $\mathbf{U}_k^{\dagger}[n]$ as the decoding matrix (where $\dagger$ denotes the hermitian operation) so that the received spatial subchannel signals at receiver k is

$$\mathbf{y}_k[n] = \Lambda_k[n]\mathbf{x}_k[n] + \mathbf{U}_k^{\dagger}[n]\left(\sum_{\substack{j=1\\ j\neq k}}^{K}\mathbf{H}_{jk}[n]\mathbf{V}_j[n]\mathbf{x}_j[n] + \boldsymbol{\mu}_k[n]\right), \tag{62}$$

in which $\Lambda_k[n]$ is the diagonal matrix containing the singular values of $\mathbf{H}_{kk}[n]$, $\mathbf{x}_j[n]$ denotes the information vector transmitted from user j on subcarrier n, and $\boldsymbol{\mu}_k[n]$ is the complex AWGN vector at user k. Now, define $\tilde{\boldsymbol{\mu}}_k[n] \triangleq \mathbf{U}_k^{\dagger}[n]\boldsymbol{\mu}_k[n]$ and $\tilde{\mathbf{H}}_{jk}[n] \triangleq \mathbf{U}_k^{\dagger}[n]\mathbf{H}_{jk}[n]\mathbf{V}_j[n]$. Then we have

$$\mathbf{y}_k[n] = \Lambda_k[n]\mathbf{x}_k[n] + \sum_{\substack{j=1\\ j\neq k}}^{K}\tilde{\mathbf{H}}_{jk}[n]\mathbf{x}_j[n] + \tilde{\boldsymbol{\mu}}_k[n]. \tag{63}$$

As a result, the achievable rate for user k is given by

$$\begin{aligned} R_k &\equiv \sum_{n=1}^{N}\sum_{\ell=1}^{M} R_k[\ell,n] \\ &= \sum_{n=1}^{N}\sum_{\ell=1}^{M}\log_2\left(1 + \frac{|(\Lambda_k[n])_{\ell,\ell}|^2 p_k[\ell,n]}{\sum_{\substack{j=1\\ j\neq k}}^{K}\sum_{\ell=1}^{M}|(\tilde{\mathbf{H}}_{jk}[n])_{\ell,j}|^2 p_j[\ell,n] + N_k[n]}\right), \end{aligned} \tag{64}$$

where $M = \min(N_t, N_r)$ and $(\cdot)_{\ell,j}$ returns the (ℓ, j)th entry of the input matrix. Now, introducing

$$c_k[\ell,n] \triangleq \sum_{\substack{j=1\\ j\neq k}}^{K}\sum_{\ell=1}^{M}\frac{|(\tilde{\mathbf{H}}_{jk}[n])_{\ell,j}|^2 p_j[\ell,n]}{|(\Lambda_k[n])_{\ell,\ell}|^2} + \frac{N_k[n]}{|(\Lambda_k[n])_{\ell,\ell}|^2}, \tag{65}$$

which is the overall noise (interference plus noise) on spatial subchannel ℓ and subcarrier n for user k, (64) is then written as

$$R_k = \sum_{n=1}^{N}\sum_{\ell=1}^{M}\log_2\left(1 + \frac{p_k[\ell,n]}{c_k[\ell,n]}\right), \tag{66}$$

which has a similar form as (15) in the single-antenna case.

The Nash-Stackelberg Game

For OFDMA without MIMO antennas, it is possible to use the BNE analysis or the belief function to regulate user competition. However, the MIMO channels make it difficult to extend the analysis, and how users can be regulated to approach a desirable equilibrium is unknown. To get round this, we regard the resource

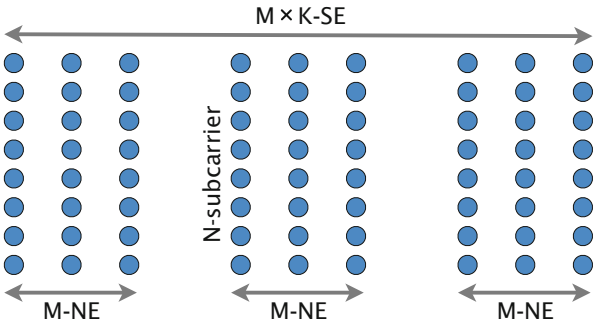

Fig. 11 The Nash-Stackelberg game: M OFDMA AFE games competing in a Nash manner

negotiation game as M mutually interfering single-antenna OFDMA AFE games; see Fig. 11.

To proceed, we let

$$r_k[\ell] = \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[\ell, n]}{c_k[\ell, n]}\right), \tag{67}$$

which corresponds to the sum-rate of all the subcarriers over spatial subchannel ℓ achieved by user k. Hence,

$$R_k = \sum_{\ell=1}^{M} r_k[\ell]. \tag{68}$$

For each spatial OFDMA game, say spatial subchannel ℓ, we have the constraints

$$\sum_{n=1}^{N} p_k[\ell, n] \leq P_k[\ell], \text{ for some } P_k[\ell], \tag{69a}$$

$$\sum_{\ell=1}^{M} P_k[\ell] \leq P_k. \tag{69b}$$

For a given spatial subchannel ℓ and if $P_k[\ell]$ is known, (67) can be maximized to approach the AFE of the single-antenna OFDMA network by the generalized water-filling method (47). Thus, the power allocation on subcarrier n by user k is

$$p_k[\ell, n] = (w_k[\ell] - \eta_k[\ell, n])^+, \ \forall n, \tag{70}$$

where the water level, $w_k[\ell]$, is chosen to satisfy (69a) and

$$\begin{cases} \eta_k[\ell,n] = \dfrac{c_k^2[\ell,n] + \varphi_k[\ell,n]p_k^2[\ell,n]}{c_k[\ell,n] - \varphi_k[\ell,n]p_k[\ell,n]}, \\ \varphi_k[\ell,n] = -\sqrt{\dfrac{c_k[\ell,n]}{2c_k[\ell,n] + p_k[\ell,n]}}. \end{cases} \tag{71}$$

For user k, the M chunks of OFDMA subcarriers compete with each other as well in terms of the power resources. With the simplified view that at a good steady state, the M-chunk AFE games should have the same achievable sum-rate, i.e., $r_k[\ell]$ is the same for all ℓ, the total sum-rate for user k (68) can be maximized by reinforcing a Nash equilibrium. To do so, we set

$$w_k[\ell] = \frac{1}{M}\sum_{l=1}^{M} w_k[\ell] \equiv w_k^{\mathsf{NE}} \text{ for } \ell = 1, 2, \ldots, M. \tag{72}$$

This results in changes of the power constraints in the spatial domain $\{P_k[\ell]\}_{\forall \ell}$.

Figure 11 shows a Nash-Stackelberg game which can be formulated as

$$R_k(\tilde{\mathsf{p}}_k^{NE}, \boldsymbol{\eta}_k^{AFE}(\tilde{\mathsf{p}}_k^{NE})) \geq R_k(\tilde{\mathsf{p}}_k, \boldsymbol{\eta}_k^{AFE}(\tilde{\mathsf{p}}_k^{NE})),\ \forall \tilde{\mathsf{p}}_k \in \tilde{\mathscr{P}}_k \text{ and } \forall k, \tag{73}$$

and all users' rates can be enhanced and formulated as

$$R_k^{N-S} = \max_{\tilde{\mathsf{p}}_k \in \tilde{\mathscr{P}}_k} \sum_{\ell} R_{k(\ell)}^{AFE}\ \forall k. \tag{74}$$

For approaching the Nash-Stackelberg equilibrium (N-SE), (70) and (71) are used, and the iterative water-filling algorithm runs for all users as follows:

$$p_k^t + \eta_k^t(\mathsf{p}_k^{t-1}) \xrightarrow{t \text{ increasing}} \cdots\cdots \rightarrow p_k^* + \eta_k^* = w_k^*. \tag{75}$$

In the simulations, we model each subcarrier by a Rayleigh fading channel with $\mathrm{E}[|\mathbf{H}_{jk}[n]|^2] = 0.4$, which is the severeness indicator for the interference channel. There are $K = 3$ users and $N = 14$ subcarriers with $N_k[n] = N_0$, $P_k = P_0$, and $\mathrm{E}[|\mathbf{H}_{kk}[n]|^2] = 1$ for those subcarriers. The SNR for all users is defined as $\frac{P_0}{NN_0}$.

Figure 12 compares the N-SE and Nash equilibrium (NE in the figure) for various SNR assuming $N_0 = 0.01$. Results illustrate that NE game fails to reconcile users' competition and has pretty *flat* user rates as a function of SNR but the N-SE game can achieve an order of magnitude gain in user rates which also grow with the SNR.

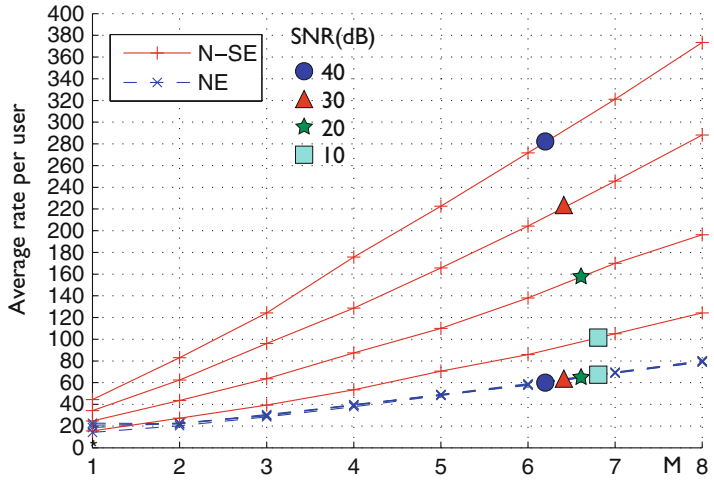

Fig. 12 The sum-rate results against M

Self-Optimization by Virtual Channel Construction

The Nash competition among the AFE games appears to degrade the performance of the resulting equilibrium. This can be improved using the virtual channel construction approach, which is discussed in this section.

Before we present this, let us extend the system model by writing

$$\mathsf{P}_k \triangleq \{p_k[1,1], p_k[2,1], \ldots, p_k[M,1], p_k[1,2], p_k[2,2], \ldots, p_k[M,2], \cdots, p_k[1,N], p_k[2,N] \ldots, p_k[M,N]\} \tag{76}$$

as the spatial-frequency power allocation profile for the kth user, which is drawn from some strategy $\mathscr{P}_k$, or $\mathsf{P}_k \in \mathscr{P}_k$. For convenience, we also define the non-k user's power profile:

$$\mathsf{P}_{-k} \triangleq \{\mathsf{P}_1, \ldots, \mathsf{P}_{k-1}, \mathsf{P}_{k+1}, \ldots, \mathsf{P}_K\}. \tag{77}$$

We let $\mathsf{BP}_k \in \mathscr{P}_k$ be user k's best power allocation strategy in response to the overall noise pattern experienced by that user $\mathsf{C}_k \triangleq \{c_k[\ell,n]\}_{\forall \ell,n}$. Then BP_k is given by

$$\mathsf{BP}_k = \arg \max_{\mathsf{P}_k \in \mathscr{P}_k} \sum_{n=1}^{N} \sum_{\ell=1}^{M} \log_2 \left(1 + \frac{p_k[\ell,n]}{c_k[\ell,n]}\right) \text{ s.t. (61).} \tag{78}$$

Given the overall noise pattern seen by user k, i.e., local CSI C_k, it optimizes its power allocation by $\mathsf{P}_k = \mathsf{BP}_k(\mathsf{C}_k)$ which changes the noise patterns of other users

$\{\mathsf{C}_l\}_{l\neq k}$ resulting in their new power allocation profiles $\{\mathsf{BP}_l(\mathsf{C}_l)\}_{l\neq k}$ which will become the cause of the changes in C_k. That is,

$$\mathsf{C}_k = \mathsf{C}_k\left(\{\mathsf{BP}_l(\mathsf{C}_l(\mathsf{P}_k))\}_{l\neq k}\right). \tag{79}$$

For convenience, we abuse our notation slightly and define

$$\mathsf{BP}_{-k}(\mathsf{P}_k) \triangleq \{\mathsf{BP}_1(\mathsf{C}_1),\ldots,\mathsf{BP}_{k-1}(\mathsf{C}_{k-1}),\mathsf{BP}_{k+1}(\mathsf{C}_{k+1}),\ldots,\mathsf{BP}_K(\mathsf{C}_K)\}. \tag{80}$$

Clearly, the noise pattern observed by user k, $\mathsf{C}_k(\mathsf{BP}_{-k}(\mathsf{P}_k))$, is a function of its own strategy P_k. At the equilibrium, the strategy is denoted by $\mathsf{P}^* = \{\mathsf{P}_k^*, \mathsf{P}_{-k}^*\}$.

Depending on how users react to the environmental changes, the system may converge to an equilibrium. For autonomous sharing in OFDMA, we need algorithms that can take users to equilibriums that benefit all by exploiting users' local CSI. Without MIMO antennas, this was shown possible using AFE (based on BNE).

Formally, under the MIMO-OFDMA model, we have, for all k,

$$R_k(\mathsf{P}_k^*, \mathsf{BP}_{-k}(\mathsf{P}_k^*)) \geq R_k(\mathsf{P}_k, \mathsf{BP}_{-k}(\mathsf{P}_k)),\ \forall \mathsf{P}_k \in \mathscr{P}_k. \tag{81}$$

Hence, all users' rates can be enhanced and formulated as

$$R_k^* = \max_{\mathsf{P}_k\in\mathscr{P}_k} \sum_{n,\ell} \log_2\left(1+\frac{p_k[\ell,n]}{c_k(\mathsf{BP}_{-k}(\mathsf{P}_k))[\ell,n]}\right)\ \forall k. \tag{82}$$

The challenge of a MIMO-OFDMA power allocation game is the competition in both spatial and frequency domains and that the interference derivative analysis for the single-antenna OFDMA in section "The OFDMA BNE" does not seem to be generalizable. To get round this, section "The Nash-Stackelberg Game" uses an N-SE game, but the Nash subgame unnecessarily restricts the optimization and competes harmfully in the spatial domain.

Here, based on the MIMO-OFDMA system, we provide an alternative approach by constructing a virtual *single-antenna* OFDMA game in which we have

$$\check{R}_k \equiv \sum_{n=1}^{N} \check{R}_k[n] = \sum_{n=1}^{N} \log_2\left(1+\frac{\check{p}_k[n]}{\check{c}_k[n]}\right), \tag{83}$$

where $\check{c}_k[n] \triangleq \sum_{\ell=1}^{M} c_k[\ell,n]$ denotes the overall noise power over the virtual subcarrier n seen by user k and $\check{p}_k[n]$ is the power allocated for the nth virtual subcarrier.

To achieve AFE of the virtual OFDMA network in (81), it has been shown that the optimal power allocation for user k is given by

$$\check{p}_k[n] = (\check{w}_k - \eta_k[n])^+, \tag{84}$$

where for those n such that $\check{p}_k[n] \geq 0$, we have

$$\check{w}_k = \underbrace{\frac{(\check{c}_k[n])^2 + \varphi_k[n]\check{p}_k^2[n]}{\check{c}_k[n] - \varphi_k[n]\check{p}_k[n]}}_{\eta_k[n]} + \check{p}_k[n], \tag{85}$$

which is the "water level" satisfying the total power constraint P_k, and as discussed before, $\varphi_k[n]$ is the *interference derivative* that helps regulate user competition to converge to a desired equilibrium, chosen as

$$\varphi_k[n] = -\sqrt{\frac{\check{c}_k[n]}{2\check{c}_k[n] + \check{p}_k[n]}}, \ \forall k, n. \tag{86}$$

The power allocation on the nth virtual subcarrier, $\check{p}_k[n]$, provides a useful estimate on the overall power budget for the spatial subchannels of subcarrier n, i.e., $\sum_{\ell=1}^{M} p_k[\ell, n] = \check{p}_k[n]$. Thus, to obtain the actual power allocation, user k can suballocate $\check{p}_k[n]$ into the spatial subchannels by a water-filling procedure according to the noise pattern $\{c_k[\ell, n]\}_{\forall \ell}$. As such, we get

$$p_k[\ell, n] = (w_k[n] - c_k[\ell, n])^+, \ \forall \ell, \tag{87}$$

where $w_k[n]$ is the water level on subcarrier n for user k and chosen to satisfy the power constraint $\check{p}_k[n]$.

The proposed interactive game, which does the autonomous spectrum sharing in MIMO-OFDMA systems, therefore runs for all users from the tth iteration until convergence, i.e.,

$$\begin{cases} \check{p}_k^t[n] + \eta_k^t(\check{\mathbf{p}}_k^{t-1}, \check{\mathbf{c}}_k^t)[n] = \check{w}_k^t \ \forall n \text{ (virtual)} \\ \quad p_k^t[\ell, n] + c_k^t[\ell, n] = w_k^t[n] \ \forall n, \ell \text{ (actual)} \\ \quad \xrightarrow{t \text{ increasing}} \cdots\cdots \rightarrow \begin{cases} \check{p}_k^*[n] + \eta_k^*[n] = \check{w}_k^* \ \forall n \text{ (virtual)} \\ p_k^*[\ell, n] + c_k^*[\ell, n] = w_k^*[n] \ \forall n, \ell \text{ (actual).} \end{cases} \end{cases} \tag{88}$$

In the simulations, we assume $\mathrm{E}[|\mathbf{H}_{jk}[n]|^2] = 1$, $N_k[n] = N_0 \ \forall k, n$, and $P_k = P_0 \ \forall k$ and define the system SNR as $\frac{P_0}{N_0}$ (slightly different from before). Results for the proposed virtual AFE (labeled "VAFE" in the figure), the N-S game ("N-SE") in the previous section, NE, and a single-user MIMO-OFDMA ("Single") performance bound are provided and compared. For "single," the optimal sum-rate per subcarrier with the same total network sum-power KP_0, which is the one with zero interference by default, is provided for comparison and also an important benchmark.

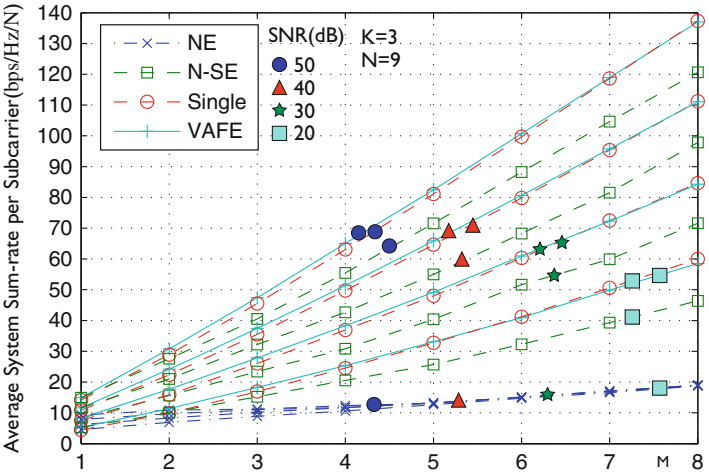

Fig. 13 The network sum-rate per subcarrier against M

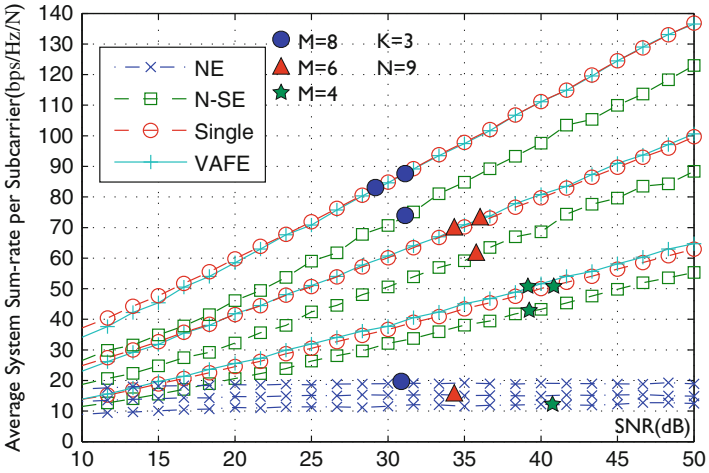

Fig. 14 The network sum-rate per subcarrier against the SNR

Figures 13 and 14 show the average sum-rate results for various SNR and sizes of MIMO when there are 9 subcarriers and 3 users. As can be seen, the sum-rates of NE increase only very slowly with M and are even flat with the SNR indicating that inter-user interference is not managed. In contrast, this is not true for VAFE, N-SE, and the single-user case. Results also illustrate that VAFE outperforms significantly N-SE and achieves the sum-rates very close to the single-user case.

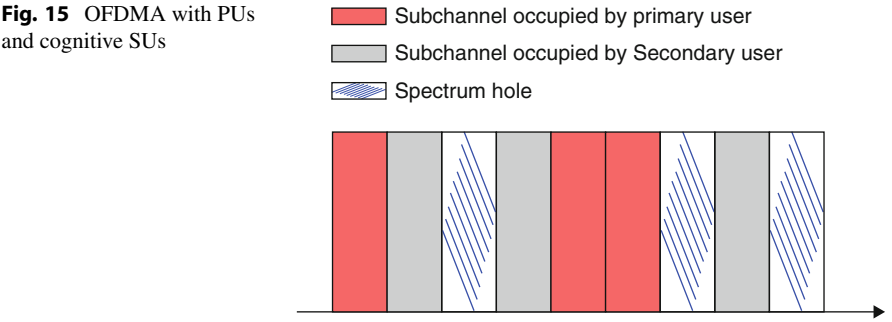

Fig. 15 OFDMA with PUs and cognitive SUs

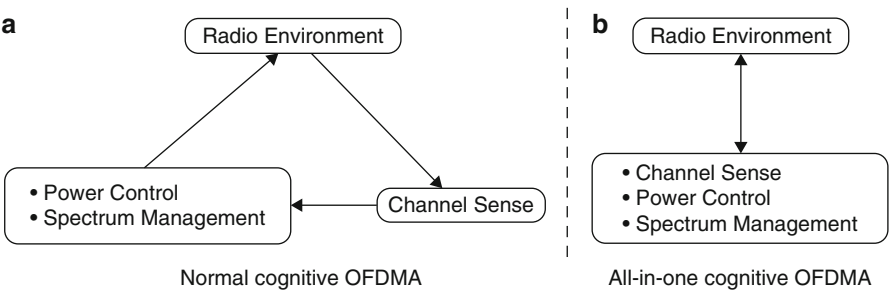

Fig. 16 The cognition cycle

Cognitive OFDMA

Game-theoretic approaches such as described above provide a promising method for uncoordinated users to negotiate and share spectrum resources among themselves in a distributed and autonomous manner. Remarkably, it has been demonstrated that playing strategies can be devised to take users to a desired equilibrium yielding the network sum-rate close to what previously only achievable by a centralized ISB optimization approach in [20]. This makes it a perfect solution for cognitive SUs to maximize their achievable rates among themselves *by playing* when they see white space opportunities, where the PUs are idle in the hierarchical model.

A typical scenario in cognitive radio networks is that there will be a number of PU transmitter-and-receiver pairs with ongoing communications and a number of SUs are observing the radio environment to identify any white spaces for their disposal. For instance, if the PUs have occupied the first, fifth, and sixth channels, as shown in Fig. 15, then ideally, the SUs should optimize their channel allocation and power control over the remaining channels (i.e., white spaces) by either a centralized spectrum manager or the game-theoretic techniques. If a centralized manager is present, then the channels used by the PUs will be obviously quarantined for the OSB (or ISB) optimization for the SUs. However, in playing the game without a centralized manager, how do the SUs know about the quarantined channels?

This is a very challenging problem because a seemingly occupied channel does not necessarily mean that it is being used by a PU and quarantined, as it might be occupied by another SU who is yet to negotiate with any other SU for the channel use. Cognitive transmission is normally done in the following way. First, the SUs will sense the channels and then gather the information about the channel occupancy for spectrum management and power control through a centralized spectrum manager or by some exchange of information. As a final step, the centralized optimal (or suboptimal) solution will be performed that affects the radio environment. By contrast, the cognition cycle in game-theoretic approaches is lumped into a single iteration process of playing the game, which may be designed to arrive at a desired equilibrium, as discussed previously. Figure 16 compares the cognition cycles between standard approaches and the game-theoretic approaches. Nevertheless, it is not at all clear how game-theoretic techniques can coexist with the PUs while being operated for optimizing the access capacity of the SUs. Clearly, the SUs are required to have the *cognition* capability to avoid those channels used by PUs and also compete among themselves for rate maximization. We will defer such discussion by first introducing the use of the transmit interference temperature limit (ITL).

In fact, regulators are skeptical about the effectiveness of ITL model in cognitive radio. FCC defined the model in 2003 intending to control cognitive SUs' interference to the spectrum PUs but abandoned it in 2007 [23] because having an ITL to constrain the transmit power of SUs not only fails to guarantee the PUs' performance but greatly compromises the SUs' achievable performance [24].

Limiting interference to the PUs is the primary concern for cognitive radios [25, 26]. Yet, using an ITL as a precautionary measure has been ineffective as the actual interference experienced by the PUs depends not only upon the transmit power of SUs but the channels between the SUs and the PUs. A too low ITL would provide no protection to the PUs, but if the ITL is set too high, meaningful communications of SUs would be impossible. This is an unresolved challenge of the model, and there has not been a solution to make it sustainable. Another weakness of the model is that even if the channel is genuinely idle, the SUs can never be certain and will not operate at full power to avoid any potential harmful interference to PUs.

Despite the problems it faces, the ITL model's beauty is its simplicity. In this section, we will show that there are ways to make this model useful. In particular, an ITL can work if used as a threshold for the SUs to decide whether or not to transmit rather than to impose a limit on the transmit power. The ITL can also be set very low for extra protection to the PUs and other coexisting users.

Transmit ITL

Consider the OFDMA model without MIMO antennas in section "A Subsystem Model for the OFDMA Game." Now, we introduce an ITL, S_k, for user k, serving

as a threshold for the channel activity to decide whether user k should transmit on a subcarrier. In particular, user k should only occupy subcarrier n if $I_k[n] < S_k$, or it satisfies

$$p_k[n](S_k - I_k[n]) \geq 0. \tag{89}$$

The value of S_k reflects the level of protection to the PUs. In the extreme cases, if $S_k = 0$, the SUs will never be admitted, while if $S_k = \infty$, there will be no protection to the PUs. There is clearly a trade-off between SUs' capacity and protection for PUs. Later, we will propose to use a *transient* ITL, $\tilde{S}_k$, for SU power allocation so that the SUs could violate S_k to gain useful spectrum information for optimizing their strategies but should satisfy the ITL S_k after the adaptation process. Such violation in S_k is undesirable but necessary for distributed learning and self-optimization.

LCP Formulation with ITL

This section presents a linear complementarity problem (LCP) formulation for the OFDMA model given a fixed interference pattern $\{I_k[n]\}$ and a fixed ITL $\tilde{S}_k$. The LCP permits the optimal power allocation strategy $\mathsf{p}_k \triangleq (p_k[1], p_k[2], \ldots, p_k[N])$ to be solved by the well-known Lemke's method [27] and can be viewed as an extension of [28] to cope with the transmit ITL for PU protection.

From user k's point of view, the optimal power allocation strategy in response to the interference pattern experienced by that user can be found by solving the following problem:

$$\max_{\mathsf{p}_k} \sum_{n=1}^{N} \log_2 \left(1 + \frac{p_k[n]}{c_k[n]}\right) \quad \text{s.t. (11) \& } \tilde{S}_k \text{ in (89).} \tag{90}$$

The solution to this is the water-filling power allocation:

$$\begin{cases} p_k[n] = (w_k - c_k[n])^+, & \text{if } I_k[n] < \tilde{S}_k, \\ p_k[n] = 0, & \text{if } I_k[n] \geq \tilde{S}_k, \end{cases} \tag{91}$$

in which w_k is the water level satisfying the power constraint (11). (Note that (91) is of the form of the well-known water-filling solution, which can be optimally realized by a one-dimensional search of w_k satisfying the power constraint. However, motivated by the increased analytical capability, an LCP formulation is preferred here [28].)

The problem (91) can be converted into an LCP of the form:

$$\begin{cases} \mathbf{z}_k \geq \mathbf{0}, \\ \mathbf{M_k z}_k + \mathbf{q}_k \geq \mathbf{0}, \\ \mathbf{z}_k^T (\mathbf{M}_k \mathbf{z}_k + \mathbf{q}_k) = 0, \end{cases} \tag{92}$$

which aims to find a vector $\mathbf{z}_k$ for some vector $\mathbf{q}_k$ and matrix $\mathbf{M}_k$. In (92), the superscript T denotes the transposition and $\mathbf{0}$ is an all-zero column vector. The LCP in (92) can be efficiently and optimally solved by the Lemke's method [27].

To convert (90) into an LCP, we see that when $I_k[n] < \tilde{S}_k$, we have

$$\begin{cases} p_k[n] \geq 0, \\ p_k[n] + c_k[n] - w_k \geq 0, \\ p_k[n](p_k[n] + c_k[n] - w_k) = 0. \end{cases} \tag{93}$$

On the other hand, when $I_k[n] \geq \tilde{S}_k$, we only need to replace $c_k[n] - w_k$ in (93) by 0. For $\sum_{n=1}^{N} p_k[n] = P_k$, we have

$$\begin{cases} \sum_{n=1}^{N} p_k[n] \geq 0, \\ P_k - \sum_{n=1}^{N} p_k[n] \geq 0, \\ \sum_{n=1}^{N} p_k[n] \left(P_k - \sum_{n=1}^{N} p_k[n] \right) = 0. \end{cases} \tag{94}$$

The unknowns are the power allocation p_k and its water-level w_k. From (93) and (94), we can form an LCP by setting

$$\mathbf{z}_k = (p_k[1], p_k[2], \ldots, p_k[N], w_k)^T, \tag{95}$$

$\mathbf{q}_k = (q_k[1], q_k[2], \ldots, q_k[N])^T$ where

$$q_k[n] = \begin{cases} c_k[n] & \text{if } I_k[n] < \tilde{S}_k, \\ 0 & \text{if } I_k[n] \geq \tilde{S}_k, \\ P_k & \text{if } n = N + 1, \end{cases} \tag{96}$$

and

$$\mathbf{M}_k = \begin{pmatrix} 1 & 0 & \cdots & 0 & m_k[1] \\ 0 & 1 & \ddots & \vdots & m_k[2] \\ \vdots & \ddots & \ddots & 0 & \vdots \\ 0 & \cdots & 0 & 1 & m_k[N] \\ -1 & -1 & \cdots & -1 & 0 \end{pmatrix}, \tag{97}$$

where $m_k[n] = -\mathsf{sgn}(\tilde{S}_k - I_k[n])$, in which $\mathsf{sgn}(x)$ returns one if $x > 0$ and zero otherwise. With the above formulation, (92) and (95), (96), and (97), the optimal power allocation strategy for a user for a given interference pattern can be obtained.

The next section will address the interaction between users (both PUs and SUs) using game theory and a proper adaptation in $\tilde{S}_k$ for trading off between SU admission and interference avoidance (i.e., the more we allow users to coexist, the more likely an SU is admitted but a higher level of interference).

A Cognitive Nash Game with Transmit ITL

NE for Rate Competition

From the SUs' perspective and viewing the PU signals as *fixed* background noise, (We assume that the PUs do not change their strategies during which the SUs adapt their strategies, since the PUs are the primary owner and should not be altered regardless of what the SUs do.) we here focus on how the SUs self-optimize their strategies through interaction under the game-theoretic framework. In particular, in the ITL-aided OFDMA model, one can use simultaneous water-filling procedures (similar to the one in [29]) for the SUs to learn each other's action and compromise to an agreed operating point, also known as the NE (or BNE if users are considered forward-looking based on some belief functions). Here, we consider NE as an example. Mathematically, the steady-state solution at the NE, denoted by $(\cdot)^*$, is defined as the strategy which satisfies

$$R_k(\mathsf{p}_k^*, \mathsf{p}_{-k}^*) \geq R_k(\mathsf{p}_k, \mathsf{p}_{-k}^*), \ \forall \mathsf{p}_k \text{ s.t. (11) and } \forall k. \tag{98}$$

Note that while (98) appears to be identical to the simultaneous water-filling process in [29], the key difference is the introduction of $\tilde{S}_k$ into the solution for each SU; see (91). It is however true that without properly designing $\tilde{S}_k$, such NE rate competition could give rise to a highly inefficient operating point causing severe interference to both the SUs and the PUs. It is worth pointing out that in the ITL approach, $\tilde{S}_k$ plays the key role to harmonize the competition among users, analogous to the roles of the belief functions in BNE. Thus, with the transmit ITL integrated with the water-filling competition, a pure NE is sufficient to deliver good results.

The Algorithm, ITL Violation, and Settlement

The main idea of the game-theoretic water-filling interaction is to give opportunity to the SUs to learn the spectrum environment and decide on their resource allocation strategies. Nevertheless, the drawback is that during this interaction and before the SUs identify the subcarriers occupied by the PUs, there will be interference spikes to the PUs. As a result, it is necessary that the water-filling iteration converges rapidly to minimize the impact to the PUs and that at the equilibrium, for all the subcarriers chosen by the SUs, they should satisfy $I_k^*[n] < S_k$.

In particular, a good transient ITL can be chosen as

$$\tilde{S}_k = \max\left(S_k, \frac{\sum_{n=1}^{N} I_k[n]\mathsf{sgn}(p_k[n])}{\sum_{n=1}^{N} \mathsf{sgn}(p_k[n])}\right). \tag{99}$$

For each iteration, SU k uses $\tilde{S}_k$ as a criterion to eliminate the subcarriers and performs the water-filling power allocation based on the LCP described in section "LCP Formulation with ITL." The iterative water-filling procedure can be viewed as a process of sequentially eliminating highly probable "poor" subcarriers and is described as follows:

Step (1) For any SU k, it evaluates $\tilde{S}_k$ by (99);
Step (2) Obtain $\{p_k[n]\}$ by solving the LCP in (92);
Step (3) Repeat Steps 1 and 2 until convergence.

Assuming convergence, the following two propositions analyze the properties of the algorithm at the equilibrium (i.e., NE) and give justification of $\tilde{S}_k$ in (99).

Proposition 1. *At the NE, the transient ITL is given by*

$$\tilde{S}_k^* = \max\left(S_k, \min_n I_k^*[n]\right). \tag{100}$$

Proof. From (99), it is seen that the iterative water-filling process subsequently eliminates weaker subcarriers, and less subcarriers will be remained toward convergence. If

$$\min_n I_k^*[n] > S_k, \tag{101}$$

then only one subcarrier will be hired by SU k and

$$\tilde{S}_k^* = \min_n I_k^*[n]. \tag{102}$$

In this case, however, the converged $\tilde{S}_k^*$ will exceed the preset ITL S_k, which is undesirable and should be avoided. On the other hand, $\tilde{S}_k^* = S_k$, which means that the transient ITL will converge to the preset ITL. As a result, (100) is obtained. □

Note that if $\min_n I_k^*[n] > S_k$, this means that there should not be any subcarrier available for use by SU k. This algorithm manages to learn this by water-filling interaction at the cost of interference spikes during the interaction. The proposition below presents a property of the algorithm if $\tilde{S}_k^* = S_k$.

Proposition 2. *At the NE, if* $\sum_{n=1}^{N} \mathsf{sgn}\left(p_k^*[n]\right) \geq 2$, *then*

$$\tilde{S}_k^* = S_k, \tag{103}$$

or if there are more than one subcarriers selected by SU k after convergence, then they will all satisfy the ITL S_k.

Proof. Obtained immediately by definition. □

Propositions 1 and 2 together assert that using this algorithm the possible outcome for each SU is either that the SU cannot be admitted if the ITL condition $I_k^*[n] < S_k$ cannot be satisfied or the SU has (self-)optimized its power allocation to maximize its rate after negotiation with other SUs while satisfying the ITL $I_k^*[n] < S_k$ (i.e., meeting the requirement for avoiding the PUs).

Analysis

The ITL-regulated Nash game has always at least one NE. The proof follows immediately from [30, Theorem 1]. However, whether the NE is unique is not understood. For large S_k, the algorithm is reduced to the traditional iterative water-filling algorithm, and the convergence condition has been studied in [29,31]. For small S_k, users will have strong tendency to avoid each other and should converge.

The choice of S_k governs the admission of SUs based on an artificial projection of interference to the PUs, with the thought that a small S_k would provide strong protection to the PUs. It is therefore important to see if it is possible to have a small S_k for the game to be carried out effectively for self-optimization of the SUs. This will be answered by the numerical results in the next section.

Results

In this section, simulation results are provided to evaluate the performance of the proposed ITL-aided simultaneous water-filling solution, which is referred to as a cognitive NE ("CNE" in the figures). The benchmark to be compared to is the traditional simultaneous water-filling solution, or simply "NE," where no control is imposed onto the SUs and the SUs can freely compete with the PUs for transmission. In the simulations, it is assumed that there are totally 20 subcarriers or $N = 20$, randomly selected four of which are occupied by the PUs. For SU k, we have

$$I_k[n] = \sum_{\substack{j=1 \\ j \neq k}} p_j[n] \frac{|H_{jk}[n]|^2}{|H_{kk}[n]|^2} + \tilde{p}[n] \frac{|\tilde{h}_k[n]|^2}{|H_{kk}[n]|^2} + \frac{N_k[n]}{|H_{kk}[n]|^2}, \tag{104}$$

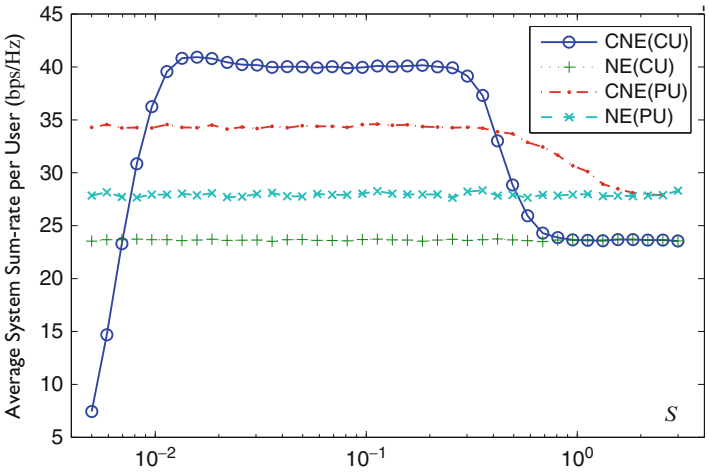

Fig. 17 Sum-rate against the ITL S with $H_0 = 0.4$ and SNR $= 16.5$ dB

where $\tilde{p}[n]$ denotes the transmit power of the PU on subcarrier n, $\tilde{h}_k[n]$ is the channel between the PU and SU k on the nth subcarrier, and $N_k[n]$ is the noise power at user k on the nth subcarrier. It is also assumed that $N_k[n] = N_0 \ \forall k, n$ and $\frac{\tilde{p}[n]}{N_0} = 27$ dB for all those subcarriers used by the PU. We model each cross talk link for every subcarrier by an equal-power four-ray Rayleigh fading channel with $\mathrm{E}[|H_{jk}[n]|^2] = \mathrm{E}[|\tilde{h}_k[n]|^2] = H_0$, and H_0 indicates the severeness for the interference. For the desired link, $\mathrm{E}[|H_{kk}[n]|^2] = 1 \ \forall k, n$. Three SUs are assumed, i.e., $K = 3$ and $S_k = S \ \forall k$. Also, $P_k = P_0 \ \forall k$ and the SNR for an SU is defined as $\frac{P_0}{NN_0}$. In the figures, the sum-rate per PU or SU averaged over independent channel realizations is provided.

First, we investigate how the sum-rate performance of the ITL-aided Nash game varies with the choice of the transmit ITL S. In Fig. 17, it is observed that CNE (i.e., the ITL-based scheme) significantly outperforms the conventional NE in that the SUs can achieve a much higher rate and at the same time the PUs suffer the least, if the ITL is chosen to be $0.01 \leq S \leq 0.3$. For NE, they are independent of S.

Setting the ITL $S = 0.1$ (a good choice as suggested by the results in Fig. 17), Fig. 18 shows the sum-rate results against the SNR of the SU. Results illustrate that as expected the sum-rates of the SUs increase with the SNR for both the ITL-based CNE and NE. However, for NE, the PUs suffer a huge rate loss due to interference from the SUs. In contrast, in the ITL-based CNE, the PU sum-rate is unaffected meaning that the SUs can avoid the subcarriers used by the PUs.

Figure 19 shows the rate performance against the number of interactions between the users. In the simulations, we assume that the SUs interact in a sequential order. Results reveal that both CNE and NE converge very quickly in a few interactions. Also, we see that there is only a slight dip in the PU rate for CNE during which the

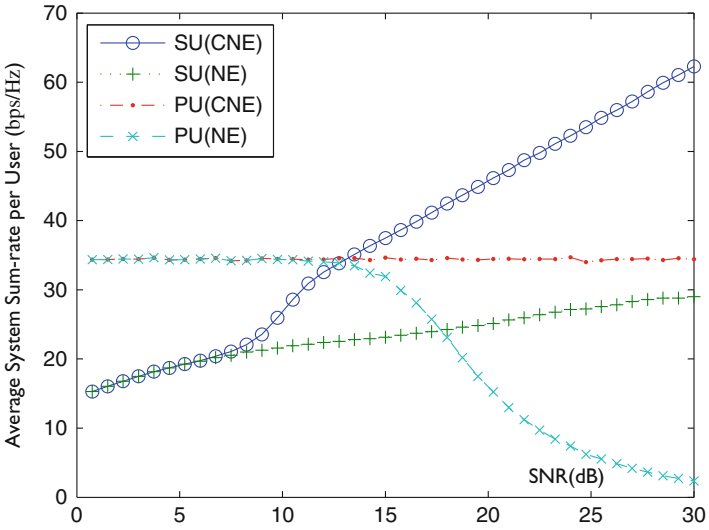

Fig. 18 Sum-rate against the SNR with $H_0 = 0.4$ and $S = 0.1$

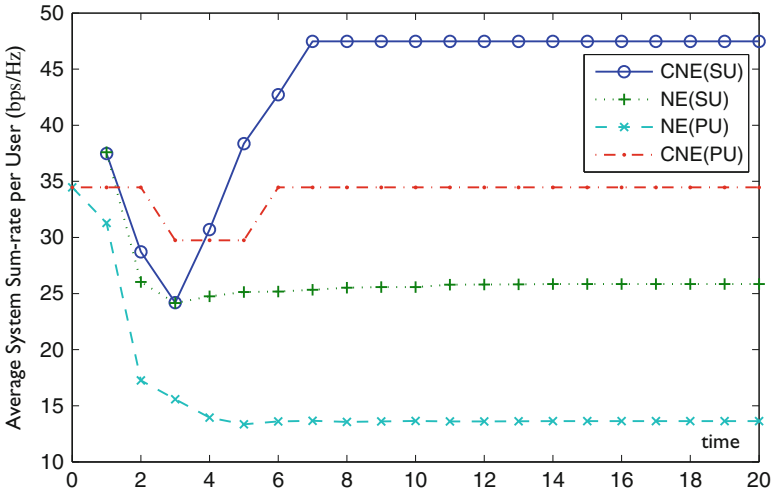

Fig. 19 Sum-rate against the number of interactions for the cognitive Nash game between users with $H_0 = 0.4$, $S = 0.1$, and SNR= 20 dB

SUs learn the spectrum environment to maximize their rates. At convergence, the PUs can regain their rate since the SUs then avoid their subcarriers completely.

As a major result, it has been shown possible to design a game-theoretic strategy for cognitive SUs to optimize their access to the shared spectrum, while completely avoiding the PUs without prior knowledge of the channels occupied by the PUs.

Conclusions

In this chapter, well-designed games utilizing the concepts of forward-looking players and the transmit ITL have been investigated to achieve spectrally efficient autonomous spectrum sharing. The mathematical framework of a belief-directed game has been shown suitable to characterize the cognition ability of mobile radios via a belief function, which can then be designed to facilitate negotiation among competing radios to reach a rate-maximization equilibrium. The use of a transmit ITL on the other hand has been demonstrated as a simple way to effectively protect the PUs while the SUs negotiate among themselves to optimize their access. The extraordinary network performance of these approaches appears to come from the users' forward-lookingness empowering their acceptance and willingness to trade strategies for negotiating toward a desirable equilibrium. This chapter, however, has only touched upon a tip of an iceberg and more have to be done. For example:

- How chaotic a wireless environment would be and any harmful impact, if such game-theoretic methods are adopted? Note that there could be new joining users every now and then inviting negotiation. Do these methods really work?
- An assumption that is implicit in the game-theoretic approaches is that every user has instant knowledge of its own predicted reward function. In the OFDMA rate-maximization problem, it means that each user knows its instantaneous achievable rate. Although it can be easily measured and fed back to its transmitter, the feedback could be too much, if the game takes many cycles to converge.
- Would it be possible for adversarial users to manipulate the game for better self-returns? In the ITL-aided method, for example, the reason why the PUs can be avoided even if the SUs do not know a priori which channels they are using is that the PUs are not responding to the SUs' actions and thus the SUs end up trading among themselves leaving the PUs' channels unaffected. If an adversary plays stubbornness to own certain channels, it will win. How to avoid that?

Obviously, many directions still need to be conquered in the future, but it is hoped that this chapter has shed sufficient light on the possible performance that could be resulted from well-designed games, and more researches will follow suit.

Abstract

Among the many different techniques that have been suggested for spectrum sensing, the eigenvalue-based spectrum sensing (EBSS) techniques exhibit some important advantages. Specifically, they can operate in a totally blind manner while they offer remarkably improved performance for specific types of signals, especially when compared to energy-based methods. Until recently, most of the cooperative EBSS techniques that could be found in the literature were batch and centralized ones, thus suffering from limitations that render them impractical in several cases. Practical cooperative adaptive versions of typical EBSS techniques, which could be applied in a completely distributed manner, have been proposed very recently. The aim of this chapter is (a) to briefly review existing cooperative EBSS techniques of the batch and centralized type and (b) to present in more detail adaptive and distributed versions of typical EBSS techniques. Focusing on the latter case, at first, we present adaptive EBSS techniques for the maximum eigenvalue detector (MED), the maximum-minimum eigenvalue detector (MMED), and the generalized likelihood ratio test (GLRT) scheme, respectively, for a single-user (noncooperative) case. Then, a distributed subspace tracking method is presented which enables the cooperating nodes to track the joint subspace of their received signals. Based on this method, cooperative distributed versions of the adaptive EBSS techniques have been developed that overcome the limitations of the previous batch centralized approaches. Numerical results show that the distributed techniques exhibit good performance, even though they require reduced computational complexity compared to their batch and centralized counterparts.

Introduction

The exponentially increasing demands for higher data rate mobile communication services [6] require new methods for efficient managing the available spectrum resources. Current wireless services are "squeezed" in a spectrum area of a few GHz, and several studies conducted worldwide [4,5,7,41,48] have shown that many of the frequency bands licensed to wireless systems are significantly underutilized. This motivated the development of techniques within the context of cognitive radio (CR) [17]. The concept of CR was introduced via the seminal works [32–34], and its core idea is to allow non-licensed users (Secondary Users – SUs) to transmit their data in a spectrum area that is licensed to the so-called primary users (PUs) of the system.

A large part of the related literature is mainly addressing the co-existence problem between the PUs-SUs by proposing efficient techniques for different examined system models. According to the spectrum access policy, the CR techniques can be categorized into three different categories [13]. In the underlay techniques, the SUs are allowed to transmit simultaneously with the PUs as long as the generated interference is below a predefined threshold. In the overlay CR techniques, cooperation is allowed between the SUs and PUs nodes so as to jointly

optimize their transmissions. Finally, the interweave, techniques which are based on the so-called opportunistic communications concept, rely on the idea that the SUs can operate via spectrum areas that are not used temporally by the PUs. The latter unused spectrum areas are commonly referred to as "spectral holes," and they provide transmission opportunities to the SU without degrading the performance of the PU. A desired characteristic of the interweave approach is that the SUs can employ transmission techniques that require very little or no interaction with the corresponding PUs.

Key role in the interweave/opportunistic approaches play the spectrum sensing techniques which are employed by the SUs in order to detect the spectrum holes. Due to the fact that the performance of both the PUs and SUs depends highly on the successful detection of the corresponding spectrum holes, a major part of the recent CR literature has focused on the design of efficient spectrum sensing techniques.

Spectrum sensing may be implemented either by a single-radio architecture or by a dual-radio one [40,61,69]. In the single-radio case, which is the most common one, a fixed portion of each time slot is dedicated to spectrum sensing, and the remaining part is employed for data transmission. As a consequence, the accuracy of the spectrum sensing results is limited. Furthermore, single-radio architectures are less spectrally efficient, since a portion of the available time slot is allocated to spectrum sensing, instead of data transmission [40, 62]. On the contrary, it is obvious that a single-radio architecture is simple to implement and of low cost. In the dual-radio architecture, one radio-frequency (RF) chain is dedicated to data transmission and reception, while a second RF chain is dedicated to continuous spectrum monitoring [19, 73]. In general, the dual-radio approach provides higher spectrum efficiency and better sensing accuracy; however it should employ very low-complexity spectrum sensing techniques due to its "continuous" nature.

Several spectrum sensing schemes have been proposed over the last few years. The most common approach is via energy-based detectors (EBD) [8, 11, 24] which are usually simple to implement; however, they require knowledge of the involved noise variance. The test statistic of the energy detector is the average energy of the observed samples. The decision is taken by comparing that test statistic with a threshold, usually related to the underlying statistics of the noise that corrupts the received samples. In case, the noise variance is not known, it is estimated via standard methods, though this results in significant performance degradation of the EBD techniques [21, 46, 50]. If information related to the PU signal is available at the SU, the optimal detection method is the matched filter approach [18, 30]. In these techniques, the known primary signal is correlated with the received secondary signal to detect the PU existence in the latter and thus maximize the signal-to-noise ratio. The matched filter detection achieves satisfactory performance, even for very small number of samples, though as already mentioned, it requires the strong assumption that the PU signal is known at the SU. The estimation of the required information at the SU side may be very difficult or even impossible, and thus the matched filter approach, in many cases, cannot be applied. The cyclostationary-based spectrum sensing techniques [12, 47] belong to the feature detector's category and exploit the cyclostationary feature of the

signals in order to detect the PU's presence. It is based on the analysis of the cyclic autocorrelation function of the received signal or its Fourier series expansion. The Fourier series expansion exhibits peaks when cyclostationary signals are present on the received one. Thus, if the PU is not present, no peaks are observed, since the noise is considered as a non-cyclostationary signal, in general. A cyclostationary-based detector achieves satisfactory performance on detecting weak signals even for low SNR values. A category that has gained significant interest over the past years is that of the eigenvalue-based spectrum sensing techniques (EBSS) [23, 35, 36, 49, 63, 71, 72]. The EBSS methods (particularly, the MMED and GLRT) may operate without the knowledge of the noise variance, and, moreover, they may offer remarkably improved performance for specific signal categories. However, this is done at the expense of high complexity since they require the EigenValue Decomposition (EVD) of the received signal's sample covariance matrix. Moreover, the computation of the involved decision thresholds is generally based on the asymptotic (limiting) distributions of the corresponding test statistics and requires a large number of samples in order to attain a satisfactory performance. Recently, close approximations for the distribution functions of the test statistics have been proposed in the literature [23, 36] though they have quite a complex form. Thus, the computation of the decision thresholds is actually performed by numerical methods which increase even further the computational complexity.

The high complexity required for implementing the batch EBSS techniques makes them impractical for cases where continuous monitoring of a specific spectrum band is required (dual-radio approach). In such cases, the aim is to detect as soon as possible an abrupt change (i.e., the PU starts or stops its transmission at a random time). To this end, a number of different solutions have been proposed in literature so far based on the quickest detection of change as well as sequential detection approaches [3, 15, 22, 65, 68, 70, 74]. According to the aforementioned approaches, the SU updates sequentially its corresponding tests statistics upon the reception of a new data sample and decides if a change has occurred in the spectrum area of interest. The decision is based on thresholds which are computed in order to optimize a metric, i.e., a mean detection delay which is usually defined as the mean time required by the SU to detect a change subject to the targeted probability of false alarms.

There are two standard formulations in the area of change detection: Bayesian and min-max. The Bayesian formulation was developed by Shiryaev [43–45]. In this approach the change point is assumed to be a random variable with a certain (known) prior distribution, and the objective is to minimize the mean detection delay subject to an upper bound on the false alarm probability. In the min-max approach, introduced by Lorden [28], the change point is assumed to be an unknown deterministic parameter, and the objective is to minimize the worst-case conditional detection delay subject to an inequality constraint on the average run false alarm length. Each one of the approaches is suited for different regimes, and both of them have been applied in the cognitive radio literature during the past years [3, 15, 22, 65, 68, 70, 74]. Note that these approaches are mainly based on the energy detector whereas, to the best of our knowledge, none of them was of the EBSS type.

An approach based on the batch EBSS techniques would require high computational complexity if small mean detection delay was sought since periodic computation of the EVD of the SU's sample covariance matrix would be required for updating the corresponding test statistics so as to detect as quickly as possible an abrupt change in the PU's behavior.

Thus, in this chapter which is an updated and extended version of [56,58], at first, online implementations of the EBSS techniques based on low-complexity subspace tracking (ST) techniques [9–67] (and references therein) are presented. The aim of a ST technique is to update in an adaptive manner the estimation of the subspace of an input signal provided that a new data sample of the signal is available at each time index. In other words the EVD of the sample covariance matrix is updated each time a new data sample is received. The main advantage of a ST technique is that the EVD update can be done with complexity of $O(R_x L)$ operations, where L is the rank of the desired subspace. Contrariwise, recall that in the batch approach, the subspace of the signal is updated by computing the EVD of the sample covariance matrix at each time index which exhibits a prohibited computational complexity of $O(R_x^3)$ operations.

The previously mentioned spectrum sensing techniques are suitable for single-user systems. The performance of a single-user spectrum sensing technique deteriorates significantly in environments where the fading and shadowing effects of the wireless channels degrade the quality of the received signals. Cooperation among multiple secondary users has been proposed in literature in order to improve the sensing performance. It is noteworthy, however, that the existing approaches (see [1, 2, 10, 25, 27, 31, 37, 60, 75] and references therein) are cooperative variations of the generic energy detector. To the best of our knowledge, cooperative techniques of the EBSS type have not been considered in literature so far, apart from the case where a fusion center collects the sensed data and applies the EBSS in a centralized batch manner [23]. A centralized approach comes with a number of limitations concerning the high-power costs in transmitting local information to the fusion center and conveying global decisions back to the SUs. Furthermore, a centralized SU network is quite sensitive to node and link failures. On the contrary, a decentralized approach exhibits low communication overhead, and it is robust to node and link failures. Each SU node communicates only with its adjacent SU nodes via one-hop transmissions resulting in transmissions with reduced power consumption during the sensing period. The SU nodes exchange information for several rounds so as to reach global convergence. Upon convergence, each node can reach the same decision concerning the PU existence without the need of a fusion center node.

Thus, in the second part of this chapter, cooperative adaptive EBSS techniques [58] are presented that function in a completely decentralized manner so as to overcome the limitations of the centralized batch approaches. It is noteworthy to mention that a constituent part of the these cooperative EBSS techniques is a distributed ST algorithm which is also presented here. In literature so far, little work concerning the problem of distributed ST has been published. The authors in [26] develop a consensus-based technique of the so-called OJA rule in which

several ST methods are based. In [39] a distributed version of the well-known PAST technique is presented. The previous methods are more suitable for ad hoc wireless sensor networks with a large number of nodes since they are based on consensus strategies. In the scenario studied in this chapter, the number of nodes that are involved in the network topology is relatively small, and thus, distributed strategies that minimize the required communication overhead are more suitable. Moreover, the approaches of [26] and [39] provide estimations for the eigenvectors only and not for the corresponding eigenvalues. Furthermore, they converge rather slowly since they are gradient flow-based approaches [9], and finally they do not guarantee the orthogonality of the estimated eigenvectors resulting in severe performance degradation.

More specifically, the techniques that are presented in this chapter are the following ones. At first, single SU (noncooperative) adaptive EBSS techniques are discussed based on well-known ST methods. Then, the distributions of the adaptive test statistics are derived in order to compute the required decisions thresholds. It turns out that accurate approximations of the test statistics correspond to well-known tabulated functions improving further the practicality of the presented adaptive schemes over the batch ones. Next, a cooperative adaptive EBSS method is proposed by first developing a distributed adaptive ST algorithm. The adaptive EBSS and cooperative adaptive EBSS methods that are presented in this chapter are compared to the corresponding batch EBSS approaches, in terms of performance for single (fixed spectrum sensing time)- and dual (continuous spectrum monitoring)-radio architectures.

The rest of this chapter is organized as follows. In section "System Description," the system description is provided. In section "Centralized Batch Cooperative Eigenvalue-Based Spectrum Sensing," a brief description is given for the EBSS techniques considered here. In section "Adaptive Eigenvalue-Based Spectrum Sensing for the Single SU Case," adaptive versions of the EBSS (AD-EBSS) techniques are derived. In section "Test Statistics Distributions and Decision Thresholds," the test statistics' distribution functions of the proposed AD-EBSS techniques, and the corresponding decision thresholds are derived. In section "Cooperative Decentralized Adaptive Eigenvalue-Based Spectrum Sensing," the cooperative EBSS schemes are presented. Section "Numerical Results" presents the numerical results, and section "Conclusion" concludes the chapter.

System Description

Let us assume that a single-antenna PU node and K SU nodes of R_x antennas each one are operating in the same frequency band in a typical interweave CR scheme (Fig. 1) [13]. The system description is given for the single-radio approach, though it can be easily modified for the dual-radio one. Thus, the time axis is assumed to be divided into transmit time intervals (time slots). The time slot is considered as the basic unit of time scheduling. At the beginning of each SU time slot, the SUs sense the frequency band so as to determine if it is occupied by a PU transmission.

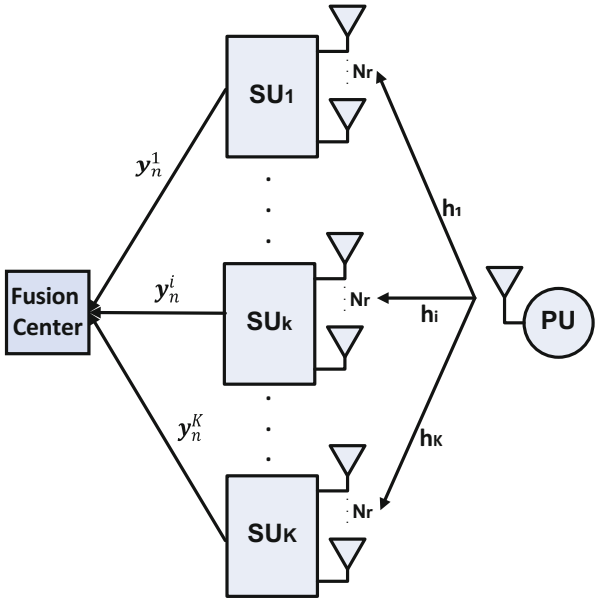

Fig. 1 Fusion based centralized EBSS technique

Let us also assume that during each sensing period, each one of the K SUs collects N sample vectors $\mathbf{y}_n^i$, $1 \leq n \leq N$ and $1 \leq i \leq K$, of dimensions $1 \times R_x$. In a centralized approach, a node that plays the role of the fusion center (Fig. 1) receives from the SUs the collected vector samples. Then, the fusion center node processes the samples jointly, decides if active PU transmissions exist in the environment, and notifies accordingly the SUs. More specifically, in the related cooperative spectrum sensing problem, the following hypothesis test is considered at the fusion center,

$$\mathscr{H}_0 : \mathbf{y}_n = \mathbf{z}_n \tag{1}$$

$$\mathscr{H}_1 : \mathbf{y}_n = \mathbf{h}x_n + \mathbf{z}_n, \tag{2}$$

where $\mathbf{y}_n = \left[\mathbf{y}_n^1, \ldots, \mathbf{y}_n^K\right]^T$, $\mathbf{z}_n$ is an $KR_x \times 1$ additive noise random variable modeled as $\mathscr{CN}\left(0, \sigma_z^2\right)$, $\mathbf{h} = [\mathbf{h}_1, \ldots, \mathbf{h}_K]^T$ is a $KR_x \times 1$ vector that contains all complex flat channel gains that correspond to the links between the PU and the antennas of all SUs, and x_n is the transmitted PU symbol. That is, under the hypothesis $\mathscr{H}_0$, the PU is idle and the received signals $\mathbf{y}_n^i$ at the SUs contain only noise. On the other hand, under the hypothesis $\mathscr{H}_1$, the PU transmits data, and the received SUs' signals are a superposition of these data (scaled by the channel gains) and noise. An EBSS technique decides between the two hypotheses by employing test statistics that are functions of the eigenvalues of the received signals' sample covariance matrix. In the following section, a brief description of the existing EBSS techniques is given.

Centralized Batch Cooperative Eigenvalue-Based Spectrum Sensing

In literature so far, only batch EBSS techniques have been considered, in the sense that the derivation of the test statistics is based on the EVD of the sample covariance matrix formed by a number of N collected vectors. Moreover, only centralized cooperative extensions of the EBSS techniques have been proposed so far. As long as a fusion center exists to collect the SU vector samples $\mathbf{y}_n^i$ in the cooperative case, the application of a batch EBSS technique is almost identical for both the noncooperative (single) SU and the cooperative cases.

In the rest of this section, we provide a brief description of the existing approaches for the cooperative case, though they are directly applicable to the noncooperative case by setting the number of SU nodes equal to $K = 1$. We consider that the fusion center receives the SUs' sample vectors $\mathbf{y}_n^i$ through noise-free communication links and forms the aggregate vector $\mathbf{y}_n = \left[\mathbf{y}_n^1, \ldots, \mathbf{y}_n^K\right]^T$ as discussed in the previous section. The covariance matrix $\mathbf{R}$ of the received signal $\mathbf{y}_n$, under the two hypotheses, is given by

$$\mathbf{R} = \mathbb{E}\{\mathbf{y}_n \mathbf{y}_n^H\} = \begin{cases} \sigma_z^2 \mathbf{I}_{KR_x} & \mathscr{H}_0 \\ \sigma_x^2 \mathbf{h}\mathbf{h}^H + \sigma_z^2 \mathbf{I}_{KR_x} & \mathscr{H}_1 \end{cases}, \tag{3}$$

where $\mathbb{E}\{\cdot\}$ denotes the expectation operator, σ_x^2 is the PU's transmitted signal's variance, and $(\cdot)^H$ denotes the Hermitian of a matrix. In practice, the fusion center (or a single SU) computes the sample covariance matrix of the received signals, which is given by

$$\hat{\mathbf{R}} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{y}_n \mathbf{y}_n^H. \tag{4}$$

Let us denote with $\lambda_1 \geq \cdots \geq \lambda_{R_x}$ the ordered eigenvalues of matrix $\hat{\mathbf{R}}$. As it is known from the relevant literature, the eigenvalues of the sample covariance matrix can be used to form a sufficient test statistics for the spectrum sensing problem. In the following equations, three different test statistics are defined:

$$T^{MED}(\lambda_1) = \frac{\lambda_1}{\sigma_z^2}, \tag{5}$$

$$T^{GLRT}(\lambda_1, \ldots, \lambda_{R_x}) = \frac{\lambda_1}{\frac{1}{N-1} \sum_{m=2}^{R_x} \lambda_m}, \tag{6}$$

$$T^{MMED}(\lambda_1, \lambda_{R_x}) = \frac{\lambda_1}{\lambda_{R_x}}. \tag{7}$$

The noise eigenvalues of the sample covariance matrix are random variables due to the finite number of samples that are used for its computation. The distribution of these noise eigenvalues is used to compute the decision threshold

in a Neyman-Pearson sense for a predefined probability of false alarm. Detailed information on how to compute the decision thresholds is given in [49, 71, 72].

We may now proceed with the development of the cooperative adaptive EBSS methods. For clarity purposes, we first deal with the noncooperative case in which only a single SU is involved. Then, the extension of the proposed adaptive approaches to the cooperative case is derived.

Adaptive Eigenvalue-Based Spectrum Sensing for the Single SU Case

In this section the adaptive eigenvalue-based spectrum sensing techniques are presented for the single-user (noncooperative) case. First, the single-radio-fixed spectrum sensing time case will be considered. Then, the double-radio-continuous spectrum monitoring scenario will be developed. The complexity analysis for both the adaptive approaches is also analyzed and compared to the one of the corresponding batch counterparts.

Single-Radio Approach

Let us now proceed to the description of the adaptive EBSS technique for the single-radio approach. In this paper the complex version of the Fast Data Projection Method (FDPM) is employed [9]. The FDPM steps are summarized in the following equations:

$$\mathbf{r}_n = \mathbf{U}_{n-1}^H \mathbf{y}_n \tag{8}$$

$$\mathbf{U}_n = \mathbf{U}_{n-1} \pm \mu \mathbf{y}_n \mathbf{r}_n^H \tag{9}$$

$$\mathbf{U}_n = orth\{\mathbf{U}_n\} \tag{10}$$

$$\boldsymbol{\lambda}_n = \alpha \boldsymbol{\lambda}_{n-1} + (1-\alpha)|\mathbf{r}_n|^2, \tag{11}$$

where $\mathbf{U}_n$ and $\boldsymbol{\lambda}_n$ are the $R_x \times L$ matrix and $L \times 1$ vector that contain the L principal (minor) eigenvectors and eigenvalues, respectively; $|\mathbf{r}_n|^2$ is the vector of the squared absolute values of the elements of vector $\mathbf{r}_n$; and α, μ are step-size parameters. Note that in (9) the sign is a $(+)$ or $(-)$ depending on whether the signal or the noise subspace, respectively, is updated. Equation (11) tracks the corresponding eigenvalues. An orthonormalization procedure is applied in (10) based on a low-complexity Householder transformation [9] given by the following equations:

$$\mathbf{a}_n = \mathbf{r}_n - \|\mathbf{r}_n\| e^{j(angle(\mathbf{e}_1^H \mathbf{y}_n))} \mathbf{e}_1 \tag{12}$$

$$\mathbf{U}_n = \mathbf{U}_n - \frac{2}{\|\mathbf{a}_n\|^2} (\mathbf{U}_n \mathbf{a}_n) \mathbf{a}_n^H \tag{13}$$

$$\mathbf{U}_n = norm\{\mathbf{U}_n\} \tag{14}$$

In (12) $\mathbf{e}_1 = [1, 0 \dots 0, 0]$ and in (13), $norm\{\cdot\}$ denotes the operator that normalizes the columns of a matrix. For the MED test statistic, only the first (maximum) eigenvalue is required, so $\mathbf{U}_n$ is a $R_x \times 1$ matrix and $\boldsymbol{\lambda}_n$ is a scalar that contains the current estimate of the maximum eigenvalue. The orthonormalization step is also reduced to a simple normalization one, i.e., $\mathbf{U}_n = \mathbf{U}_n / \|\mathbf{U}_n\|$. In a similar way, the MMED test statistic is estimated. At first, the signal subspace version of the FDPM is employed (with $(+)$ in (9)) to track the maximum eigenvalue, and then the noise subspace version follows (with $(-)$ in (9)) to track the minimum one. For the GLRT test statistic, the complete FDPM (8), (9), (10), and (11) is used since all the R_x eigenvalues of $\hat{\mathbf{R}}_n$ are required in (6).

It is evident that, by employing the FDPM method, the SU is capable of tracking, with low complexity, the value of any of the test statistics under consideration at every time index within the sensing period. Therefore, once a new signal vector is received, the SU updates the employed test statistic and decides if a change in the state has been occurred (from $\mathscr{H}_0$ to $\mathscr{H}_1$ and vice versa). Thus, the adaptive EBSS techniques can be applied in both the single- and in the dual-radio approach. In the single-radio approach, the adaptive techniques can be applied in fixed sensing periods in a similar way to the batch ones. That is for each time slot within the sensing period, the corresponding test statistics are updated and at the end of the sensing period a decision is taken according to a threshold whose computation is given in section "Test Statistics Distributions and Decision Thresholds".

Complexity Analysis for the Single-Radio Approach

Let us now derive the complexity of the adaptive and the batch EBSS techniques for the single-radio case. The complexity is given in terms of the total required complex mathematical operations (additions/subtractions, multiplications/divisions, and square roots) at a sensing period of N timeslots. According to [9], the FDPM algorithm requires at each timeslot $12R_xL+5L+2$ operations, to update L principal components of the covariance matrix $\mathbf{R}$ at the SU receiver, provided that a new $R_x \times 1$ sample $\mathbf{y}_n$ is available (see [9] for a detailed analysis). In the aforementioned complexity, we must add $3L$ operations since (11) is not included in the original version of the FDPM presented in [9]. Note that (11) requires only $3L$ operations since the entries of the vector $|\mathbf{r}_n|$ are already computed in (8) and in (12). Thus, the overall complexity is $12R_xL + 8L + 2$ per update/timeslot. Since the sensing period is associated with N signals, a total of $N(12R_xL + 8L + 2)$ operations are required. Now the complexity of each one of the adaptive EBSS techniques can be derived by properly setting the value of the parameter L and then adding the number of operations that are required for the computation of the specific test statistic according to (5), (6), an(7). That is, for the MED test statistic $L = 1$ and the complexity is $N(12R_x + 10) + 1$ operations. In a similar way, the MMED test statistic requires two applications of the FDPM with $L = 1$ (section "Single-Radio Approach") resulting in complexity of $2N(12R_x + 10) + 1$ operations. Finally,

$L = R_x$ for the GLRT test statistic and the complexity is $N(12R_x^2 + 8R_x + 2) + R_x$ operations.

Let us now derive the complexity of the batch approaches. In this case matrix $\hat{\mathbf{R}}$ is updated at each timeslot. The latter requires $2NR_x^2$ complex operations. Then, the SVD of the $\mathbf{R}$ is computed requiring approximately $13R_x^3$ operations according to [51]. Thus, the overall computational cost of each one of the batch EBSS techniques is equal to $13R_x^3 + 2NR_x^2$. Now, in order to derive the explicit complexity of each one of the test statistics, we should count for the operations of (5), (6), and (7), similarly to the adaptive case. Therefore, the MED and MMED test statistics require $13R_x^3 + 2NR_x^2 + 1$ operations, and the GLRT one requires $13R_x^3 + 2NR_x^2 + R_x$ operations. It is evident that the adaptive methods exhibit significantly reduced complexity compared to the batch ones. As it is shown in the following section, the complexity savings can be more significant for the case of the dual-radio approach.

Dual-Radio Approach

We now present the adaptive EBSS techniques for the dual-radio architecture. Let us assume that the SU employs the FDPM method so as to track continuously the test statistics during consecutive periods of N samples. We follow the approach of [74] where it is assumed that the PU changes its behavior at a random sample number within the sensing period. The change point T_0 is assumed to follow a known geometric distribution parametrized by p, that is,

$$P\{T_0 = n\} = p(1-p)^{n-1}(1-\lambda_0),\ 0 < n \leq N, \tag{15}$$

where $\lambda_0 = P\{T_0 = 0\}$ denotes the probability that a change occurs before the sensing period. According to the Bayesian formulation, the problem of quickest detection of change is to design a detection rule that gives the stopping time T_d so that the mean detection delay $E\{(T_d - T_0)^+\}$ is minimized subject to a constraint on the probability of false alarm, that is $P\{T_d < T_0\} \leq \zeta$. Note that the definition of the probability of false alarm here differs from the single-radio approach, since now is denoted as the probability that a change is detected prior the actual time of change ($T_d < T_0$). The solution to that problem requires the knowledge of the exact distribution of the samples under both hypotheses which is not possible to be derived for the case of the EBSS techniques. Moreover a closed form is in general intractable even in case of the simple energy detector. Thus, in order to develop an efficient and simple technique, the following approach is adopted which is summed up in Algorithm 1. The SU for each block of N samples updates sequentially the EBSS test statistics under consideration. At each time index n of the sensing block, the updated test statistic is compared to a global threshold. The global threshold is computed so as the probability of false alarm is set to a specific value

Algorithm 1 : Adaptive EBSS for the single SU case

Initialization:
The SU detects the present state ($\mathscr{H}_0$ or $\mathscr{H}_1$) by applying the adaptive EBSS technique for a sufficient number of received signals, until an initial decision is taken. For each block of N symbols
for $n = 1 \rightarrow N$ **do**
  Update the employed Test-Statistic T via the FDPM (8), (9), (10), and (11)
  if $T \geq \eta_d$ under $\mathscr{H}_0$ || $T < \eta_d$ under $\mathscr{H}_1$ **then**
    Raise an alarm, change in the state has been detected;
  end if
end for

$P\{T_d < T_0\} = \zeta$. The threshold computation in this approach is more complex than the simple radio one, and it is described in section "Test Statistics Distributions and Decision Thresholds".

Remark 1. One may argue that the batch EBSS approaches can be extended easily to the dual-radio case. Indeed, let us assume that within the sensing period of N symbols, the EVD of the sample covariance matrix is periodically computed every $N_s < N$ samples so as to update the values of the test statistics. This could increase significantly the complexity due to a number of $\lfloor \frac{N}{Ns} \rfloor$ SVD that are required. Clearly a small number of N_s reduces the detection delay though it results in high complexity and vice versa. A detailed analysis of the complexity is given in the following subsection.

Complexity Analysis for the Dual-Radio Approach

Let us assume that a dual-radio sensing approach is applied for a period of N symbols. For the subspace update given in section "Single-Radio Approach", the adaptive techniques require the same complexity with the single-radio case. The difference in the dual-radio case is that the computation of the test statistics is done at every timeslot $n \in [1, N]$, and thus, the operations of (5), (6), and (7) must be added N times to the overall complexity. Thus, it is easy to see that in the dual-radio approach, the complexity for the MED technique is $N(12R_x + 10) + N$; for the MMED one, it is $2N(12R_x + 10) + N$; and for the GLRT one, it is $N(12R_x^2 + 8R_x + 2) + NR_x$ operations, respectively.

According to Remark 1, the dual-radio version of the batch approaches requires the computation of $\lfloor \frac{N}{Ns} \rfloor$ SVDs for a sensing period of N symbols. According to section "Complexity Analysis for the Single-Radio Approach," the latter costs $13\lfloor \frac{N}{Ns} \rfloor R_x^3$ operations. In order to derive the overall complexity, one should also add $\lfloor \frac{N}{Ns} \rfloor$ times the operations of (5), (6), and (7) similarly to the adaptive case. Therefore, the MED and MMED test techniques require $13\lfloor \frac{N}{Ns} \rfloor R_x^3 + \left(2N + \lfloor \frac{N}{Ns} \rfloor - 1\right) R_x^2 + \lfloor \frac{N}{Ns} \rfloor$ operations, and the GLRT one requires

$13\lfloor\frac{N}{Ns}\rfloor R_x^3 + \left(2N + \lfloor\frac{N}{Ns}\rfloor - 1\right) R_x^2 + \lfloor\frac{N}{Ns}\rfloor R_x$ operations. Clearly, the complexity gains for employing the adaptive EBSS techniques are even greater in the dual-radio sensing approach especially for small values of the parameter N_s. In Fig. 10 of section "Numerical Results," the complexity of the adaptive EBSS techniques is compared to the one of the batch techniques for different values of the involved parameters.

Test Statistics Distributions and Decision Thresholds

In this section, the cumulative distribution functions (CDF) of the three test statistics of (5), (6), and (7) are derived for the adaptive case, under the hypothesis $\mathscr{H}_0$, i.e., when no information signal is present in the signal received by the SU. Based on (11) of the FDPM, the distribution functions of the involved test statistics can be tracked at every time index n. The following lemma provides expressions for the distribution functions of the corresponding test statistics.

Lemma 1. *The distribution functions of the adaptive test statistics updated by (11) for a SU of R_x antennas under the hypothesis $\mathscr{H}_0$ can be approximated by the functions*

$$F_{T^{MED}}(x;\xi,\rho) \approx \frac{\gamma(\xi x,\rho)}{\Gamma(\rho)}, \tag{16}$$

$$F_{T^{GLRT}}(x;\rho,R_x) \approx \mathscr{I}_{\frac{(R_x-1)x}{x+1}}(\rho,(R_x-1)\rho), \tag{17}$$

$$F_{T^{MMED}}(x;\rho) \approx \mathscr{I}_{\frac{x}{x+1}}(\rho,\rho), \tag{18}$$

respectively, where $\xi = \frac{(1-\alpha^n)(1+\alpha)}{((1-\alpha)(1-\alpha^{2n}))}$, $\rho = \frac{(1-\alpha^n)^2(1+\alpha)}{((1-\alpha)(1-\alpha^{2n}))}$, $\gamma(x,\rho) = \int_0^x t^{\rho-1}e^{-t}dt$ is the lower incomplete gamma function, $\Gamma(\rho) = \int_0^\infty t^{\rho-1}e^{-t}dt$ denotes the ordinary gamma function, and $\mathscr{I}_x(\rho_1,\rho_2) = \int_0^x t^{\rho_1-1}(1-t)^{\rho_2-1}dt$ is the incomplete beta function.

Proof. Observe that, under hypothesis $\mathscr{H}_0$, the signal vector $\mathbf{y}_n$ received by the SU consists of i.i.d. complex Gaussian noise samples $\mathscr{CN}(0,\sigma_z^2)$. Since matrix $\mathbf{U}_{n-1}$ is orthonormal, the entries $\mathbf{r}_n^{(i)}$ of vector $\mathbf{r}_n = \mathbf{U}_{n-1}^H\mathbf{y}_n$ are also i.i.d. $\mathscr{CN}(0,\sigma_z^2)$. From (11), the l-th eigenvalue of the covariance matrix is estimated as

$$\lambda_l(n) = \sum_{i=0}^{n} \alpha^i(1-\alpha)|\mathbf{r}_n^{(i)}|^2. \tag{19}$$

According to the previous equation, the MED test statistic can be expressed as a weighted sum of chi-squared variables with each one derived by squaring the absolute value of a random variable $\phi_i \sim \mathscr{CN}(0,1)$. A close approximation to the

previous distribution can be derived by properly applying the results of [64] to our case. Let us consider the following RV:

$$T \triangleq \sum_{i=1}^{m} w_i \zeta_i^2, \tag{20}$$

where $\zeta_i \sim \mathcal{N}(0,1)$ and $w_i \in \mathbb{R}$. Welch, in a 1938 paper [64], proposed an approximation of the distribution of variable T by a scaled chi-squared distribution of ρ degrees of freedom. That is, $T \sim \frac{1}{\xi}\chi^2_\rho$, where $\xi = \frac{\sum_{i=1}^m w_i}{\sum_{i=1}^m w_i^2}$, $\rho = \frac{(\sum_{i=1}^m w_i)^2}{\sum_{i=1}^m w_i^2}$, and the corresponding CDF is given by

$$F_T(x;\xi,\rho) = \frac{\gamma(\xi/2x, \rho/2)}{\Gamma(\rho/2)}. \tag{21}$$

Now, by defining $w_i = \alpha^i(1-\alpha)/2$ and using (21) in the case of complex normal variables ϕ_i, we can apply the previous results to the MED test statistic (5). Moreover, observe that the weights w_i are actually terms of a geometric sequence enabling as to compute closed forms for the parameters ρ and ξ. Thus, it can be verified that $\xi = \frac{2(1-\alpha^n)(1+\alpha)}{((1-\alpha)(1-\alpha^{2n}))}$ and $\rho = \frac{2(1-\alpha^n)^2(1+\alpha)}{((1-\alpha)(1-\alpha^{2n}))}$. Finally, by combining these expressions with (21), the proof for MED is completed.

In the case of the MMED test statistic, we seek for the distribution of the ratio of two eigenvalues of matrix $\hat{\mathbf{R}}_n$ that are estimated via (11). The required distribution is equivalent to the distribution of the ratio $\frac{T^{MED}(\lambda_1)}{T^{MED}(\lambda_{R_x})}$. Therefore, the corresponding CDF is equal to the one of the ratio of two independent T^{MED} random variables. It turns out that the distribution of the MMED statistic can be approximated by the beta prime distribution with the corresponding CDF given by (18). The detailed proof is given at Appendix.

Finally, the CDF of the GLRT test statistic can be computed by firstly observing that the random variable $\sum_{m=2}^{R_x}\lambda_m \sim \frac{1}{\xi}\chi^2_{(R_x-1)\rho}$, where the parameters ξ and ρ are defined similar to the case of the MED distribution. Then, the CDF of the ratio of the two independent random variables $\frac{\lambda_1}{\sum_{m=2}^{R_x}\lambda_m}$ is computed in a similar way to the MMED case. As long as the CDF of the ratio under consideration is computed, it is easy then to compute the CDF of the scaled random variable $T^{GLRT} = \frac{\lambda_1}{\frac{1}{R_x-1}\sum_{m=2}^{R_x}\lambda_m}$, given by (17). □

Threshold Computation for the Single-Radio Approach

From Lemma 1, the CDFs of the adaptive test statistics involve the computation of well-known tabulated functions, and the same comment is true for their corresponding inverse functions. The latter observation enables the SU to easily compute the

decision thresholds in a Neyman-Pearson sense, for a predefined probability of false alarm $\mathscr{P}_f$, as opposed to the case of the batch test statistics where usually numerical methods are required. To proceed further, first, the decision threshold η^{MED} for the MED test statistic is computed. We equivalently have

$$P_f = P\left\{T^{MED} > \eta^{MED} | \mathscr{H}_0\right\} = 1 - F_{T^{MED}}(x; \xi, \rho) \Rightarrow$$

$$\eta^{MED} = F^{-1}_{T^{MED}}\left(1 - P_f; \xi, \rho\right). \tag{22}$$

The decision thresholds for the adaptive MMED and GLRT test statistics can be computed in a similar way, and they are given by the following equations:

$$\eta^{MMED} = \frac{\mathscr{I}^{-1}\left(1 - P_f; \rho, \rho\right)}{1 - \mathscr{I}^{-1}\left(1 - P_f; \rho, \rho\right)}, \tag{23}$$

$$\eta^{GLRT} = \frac{\mathscr{I}^{-1}\left(1 - P_f; \rho, (R_x - 1)\rho\right)}{(R_x - 1) - \mathscr{I}^{-1}\left(1 - P_f; \rho, (R_x - 1)\rho\right)}. \tag{24}$$

Threshold Computation for the Dual-Radio Approach

According to section "Complexity Analysis for the Single-Radio Approach" in the dual-radio approach, the threshold is computed so as to set the probability of false alarm $P\{T_d < T_0\}$ to a specific value ζ. In order to compute the previous probability, we require the probability that a PU is detected at least one time before the time index of change T_0 under $\mathscr{H}_0$. Given the fact that the test statistics are updated by adding each time index a new positive random variable and that the parameter α is set to values close to 1, the latter probability can be approximated by the probability the test statistic is greater than the threshold at time index $T_0 - 1$, that is $P\{T_{T_0-1} > \eta_d | \mathscr{H}_0\} = 1 - F_{T_{T_0-1}}(\eta_d)$, where $F_{T_{T_0-1}}(\eta_d)$ denotes the CDF of the corresponding test statistic given by (16), (17), and (18) for each one of the cases considered here. Now, by assuming that the time of change is independent to the values of the test statistics and taking the summation over all the $0 < n \leq N$, it can be seen that the required false alarm probability can be approximated by the following equation:

$$P\{T_d < T_0\} \approx \sum_{n=0}^{N} (1 - F_{T_{n-1}}(\eta_d)) p (1-p)^{n-1} (1 - \lambda_0). \tag{25}$$

Finally, by setting $P\{T_d < T_0\} = \zeta$ and solving numerically (25), the desired threshold is computed.

Cooperative Decentralized Adaptive Eigenvalue-Based Spectrum Sensing

In this section, the previously derived adaptive EBSS techniques are extended to the cooperative case, in which multiple SUs sense the spectrum in a collaborative manner. The distributed technique is designed so as (a) to improve the sensing performance by forming a virtual multiple antenna system that performs a joint EBSS technique, (b) to distribute the computation overhead among the SU nodes, and (c) to enable each user to track the joint test statistics at each time index within the sensing period so as to reach a common decision in a decentralized manner. Apart from the benefits of a decentralized approach discussed in the Introduction, the latter feature is crucial in scenarios where the multiple nodes employ a cooperative transmission scheme [16,52–55,57,59], and thus all the involved nodes should reach a common decision concerning the PU existence. Clearly, the proposed decentralized adaptive EBSS methods require the development of a distributed adaptive subspace tracking method in order to track the corresponding test statistics of (5), (6), and (7). Therefore, a novel distributed subspace tracking scheme is first developed by extending the FDPM of [9]. The present section is divided into two subsections. In section "Distributed Data Projection Method (DDPM)," the proposed distributed subspace tracking method is described. Then, in section "Cooperative EBSS Techniques," the cooperative EBSS methods are described.

Distributed Data Projection Method (DDPM)

Let us assume that K SU nodes form a network where the i-th node is connected via direct links only to the $(i-1)$-th and the $(i+1)$-th nodes. The communication links are assumed to be established via ideal (noise-free) channels. Note that the latter assumption is typical in both the distributed adaptive signal processing [42] and cooperative spectrum sensing literature [10, 31, 37, 60, 75]. For simplicity, we assume that each SU node has the same number of R_x antennas, though the results are directly applicable in cases where the nodes may have different numbers of antennas. At each time index of the sensing period, the i-th SU obtains a $R_x \times 1$ vector of samples $\mathbf{y}_n^i$. Let us now assume that we are interested in tracking the L first principal (or minor) components of the correlation matrix $\mathbf{R}$ of the aggregate vector $\left[\mathbf{y}_n^1, \ldots, \mathbf{y}_n^K\right]^T$. The task of tracking each one of the L eigenvectors is properly distributed to the SU nodes in a way that the i-th node tracks the elements of the sub-matrix $\mathbf{U}_n\left((i-1)R_x+1 : iR_x, 1 : L\right)$ of the aggregate eigenvectors matrix $\mathbf{U}_n$. For simplicity, the later sub-matrix will be denoted by $\mathbf{U}_n^i$. Thus, each node needs to update only a specific part of the subspace. Moreover, each node is capable of tracking the corresponding L principal (minor) eigenvalues of the aggregate system, denoted by $\boldsymbol{\lambda}_n^i$. As explained below, at each time index n, the DDPM requires three spatial iterations in order to update the eigenvectors and eigenvalues matrices. By observing (9), the subspace update can be done in a local computation step at node i given by

$$\mathbf{U}_n^i = \mathbf{U}_{n-1}^i \pm \mu \mathbf{y}_n^i \mathbf{r}_n^H \tag{26}$$

Now, in order to execute the local update step of (26), each node must know the value of $\mathbf{r}_n$. Observe that the computation of $\mathbf{r}_n$ requires a spatial iteration in which the i-th node performs the local computation of (27) and sends the quantity $\mathbf{r}_{loc}^i$ to the $(i+1)$-th node. That is,

$$\mathbf{r}_{\text{loc}}^i = \mathbf{r}_{\text{loc}}^{i-1} + \mathbf{U}_{n-1}^{*^i} \mathbf{y}_n^i \tag{27}$$

Thus, starting from the first node, the variable $\mathbf{r}_{\text{loc}}^i$ is updated in an incremental manner, and at the end of this first spatial iteration, the K-th node has the exact value of $\mathbf{r}_n$ given by

$$\mathbf{r}_n = \sum_{i=1}^{K} \mathbf{r}_{\text{loc}}^i \tag{28}$$

The second spatial iteration starts from the last node K of the network. As it was mentioned, the K-th node has already the exact value of $\mathbf{r}_n$ in (28), and therefore it is able to update the corresponding sub-matrix of eigenvectors as determined by (26), then update the eigenvalues by using (11) locally, and apply the orthogonalization transformation to the updated eigenvectors sub-matrix, that is

$$\mathbf{U}_n^i = \mathbf{U}_n^i - \frac{2}{\|\mathbf{a}_n\|^2} \left(\mathbf{U}_n^i \mathbf{a}_n\right) \mathbf{a}_n^H, \tag{29}$$

where the quantity $\mathbf{a}_n$ is computed by applying (12) locally. Clearly, in order to complete the eigenvectors update, the normalization step of (13) is required. Therefore, the last local computation of the $i-th$ node at the second spatial iteration is given by

$$\mathbf{T}_{\text{loc}}^i = \mathbf{T}_{\text{loc}}^{i-1} + \sum_{l=1}^{L} |\mathbf{U}_n^j(:, l)|^2 \tag{30}$$

Now observe that by incrementally applying (30) at the end of the second spatial iteration, the first node has the vector $\mathbf{T}_n = \left[\|\mathbf{U}_n(:, l)\|^2, \ldots, \|\mathbf{U}_n(:, L)\|^2\right]$ whose i-th element is the squared normed of the i-th eigenvector. Note that as already mentioned, the incremental strategy requires the transmission of the quantities $\mathbf{r}_n$ and $\mathbf{T}_{\text{loc}}^i$ from the i-th node to the $(i+1)$-th one.

The aim of the third iteration is to normalize the updated eigenvalues matrix $\mathbf{U}_n$. It is easy to see that the latter can be done by performing sequentially the following steps at the i-th node

$$\mathbf{U}_n^i = diag\left(\mathbf{T}_n\right)^{1/2} \mathbf{U}_n^i \tag{31}$$

Algorithm 2 : The DDPM algorithm

1: **Initialization:** $\mathbf{U}_0 \leftarrow \mathbf{I}_{R_x \times L}$ & $\boldsymbol{\lambda}_0 \leftarrow \mathbf{0}_{L\times 1}$
2: **Previous Instant Data:** Node i has $\mathbf{U}^i_{n-1}$ and $\boldsymbol{\lambda}^i_{n-1}$
3: **New Data:** Node i has a new vector sample $\mathbf{y}^i_n$
4: **Apply:**
5: **1st Spatial Iteration:**
6: $\mathbf{r}^0_{\text{loc}} \leftarrow \mathbf{0}_{L\times 1}$ $\mathbf{T}^{K+1}_{\text{loc}} \leftarrow \mathbf{0}_{L\times 1}$

21: **end for**

where $diag\,(\cdot)$ denotes the operator that transforms the vector operand to a diagonal matrix. The complete DDPM is summarized in Algorithm 2.

Cooperative EBSS Techniques

In this subsection the extension of the adaptive EBSS technique to the case of multiple SUs is described. Let us consider that the nodes of SUs network apply the DDPM of Algorithm 2 so as to jointly track the subspace of the received data covariance matrix of the aggregate virtual multi-antenna SU system (Fig. 2). As it is evident from line 13 of Algorithm 2, each node, at each time index, updates the local estimates of the eigenvalues of the sample covariance matrix. Therefore, each node is also able to compute the test statistics of (5), (6), and (7) of the aggregate system and can perform the detection tests independently. Moreover, the test statistics distributions, under the hypothesis $\mathscr{H}_0$, are again given by Lemma 1, by replacing R_x with KR_x. Observe also that in a dual-radio approach, each SU node can employ independently Algorithm 1 so as to reach a common decision concerning a detection of a change in the PU activity.

Let us now comment on the specificities of each one of the cooperative EBSS techniques. If the MED method is employed, then it suffices to track only the maximum eigenvalue, and thus, in the DDPM algorithm the cooperating SUs may set $L = 1$. Moreover, the distributed orthogonalization steps (lines 15–16 on

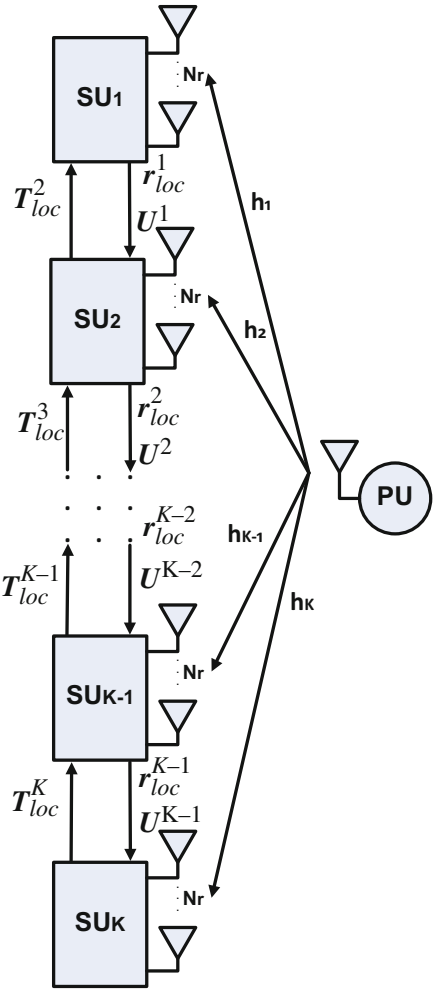

Fig. 2 Distributed EBSS technique

Algorithm 2) are not performed at all, in a way similar to the single SU case. In the case of the MMED method, again in a similar way to the single SU one, each of the SUs tracks the maximum and the minimum eigenvalues of the covariance matrix by employing twice the DDPM for $L = 1$. Specifically, first the signal subspace version (with $(+)$ in (9)) is employed so as to track the maximum eigenvalue, and then the noise subspace version follows (with $(-)$ in (9)) in order to track the minimum one. Recall that this approach has been adopted in order to avoid the complexity of tracking the complete subspace of the covariance matrix. Of course the steps of each one of the two versions of the DDPM can be applied simultaneously at each time index. Finally, for the adaptive GLRT EBSS method, the SU nodes should apply the complete DDPM algorithm with $L = KR_x$.

Computational and Network Complexity of the Decentralized Adaptive EBSS Techniques

Let us first examine the computational complexity. From the description of the DDPM technique, it is evident that its computational complexity equals to the one of a centralized FDPM for a system of $K \times R_x$ receiver antennas, though (11) is executed K times, that is one time for each one of the participating SUs. Therefore according to [9] and the discussion of section "Complexity Analysis for the Single-Radio Approach," the complexity for subspace estimation for a sensing period of N timeslots is $N(12KR_xL + 5L + 3KL + 2)$ operations. Now, by noting that each one of the SUs employs (22) and (23), and following the same procedure with the single SU case, the complexity at both the single- and the dual-radio case can be derived easily. Thus, we have for the single-radio case $N(12KR_x+3K+7)+K$ operations for the MED test statistic, $2N(12KR_x+3K+7)+K$ operations for the MMED, one and $N(12K^2R_x^2+11KR_x+2)+KR_x$ for the GLRT one, respectively. Accordingly we have for the dual-radio case $N(12KR_x+3K+7)+NK$ operations for the MED test statistic, $2N(12KR_x + 3K + 7) + KN$ operations for the MMED one and $N(12K^2R_x^2 + 11KR_x + 2) + NKR_x$ operations for the GLRT one, respectively.

Note that in a similar way, one may also derive the complexity of the batch EBSS techniques by simply replacing R_x with KR_x in the expressions derived in sections "Complexity Analysis for the Single-Radio Approach" and "Complexity Analysis for the Dual-Radio Approach" (omitted here to avoid repetition).

The network complexity is derived in terms of the complex scalar quantities that must be transmitted during a sensing period of N data samples. From the description of the DDPM technique (Algorithm 2), the MED test statistic requires $3NK$ scalar quantities to be transmitted, and the MMED and the GLRT require $6NK$ and $3NKR_x$, respectively. A centralized approach requires NKR_x scalar transmissions in order for the SUs to transmit the data samples to the fusion center and K transmissions to notify the users for its decision. Clearly, for SUs with number of antennas greater than 3, the decentralized MED test statistic exhibits lower complexity than the corresponding centralized approach. In a similar way, the MMED test statistic exhibits less communication burden when the number of antennas of each node is greater than 6. Finally, the GLRT exhibit always greater communication complexity than the centralized. The network complexity is depicted also in Fig. 11 in the simulations section.

Numerical Results

In this section, numerical results are presented in order to evaluate the performance of the adaptive EBSS methods. We assume that the PU transmits a binary phase-shift keying (BPSK) modulated signal. The step of the FDPM algorithm is set to $\mu = 0.8/\|\mathbf{y}_n\|^2$. First, the methods for the single SU case are tested.

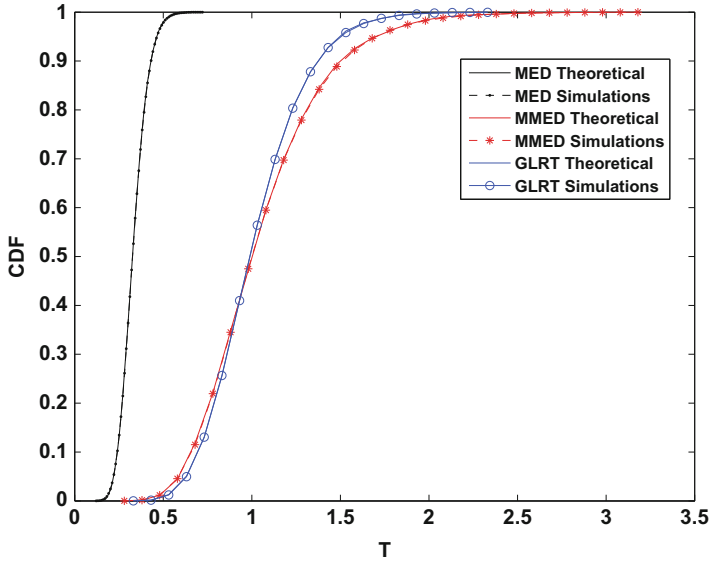

Fig. 3 CDFs of the test statistics under $\mathscr{H}_0$ (16), (17), and (18)

In Fig. 3, the theoretical CDFs of the MED, MMED, and GLRT adaptive test statistics under the $\mathscr{H}_0$ (Lemma 1) are compared to the empirical ones when a block of $N = 20$ received signal vectors at the SU is used to estimate them. The results of 10000 simulations are averaged so as to compute the empirical CDFs for a SU receiver with $R_x = 4$. As it is shown, the derived theoretical CDFs are very close to the empirical ones even for this small number of received signals.

In Fig. 4, the performance of the AD-EBSS techniques is compared to the one of the batch techniques in terms of the achieved probability of detection $\mathscr{P}_d$ under different SNR values for probability of false alarm $\mathscr{P}_f = 0.1$ for the single-radio case.

The parameter a of the FDPM algorithm in (11) is set to $a = 0.98$. The performance is examined considering constant channels within each timeslot of duration $N = 100$ symbols. The taps of all the involved channels are derived as $\mathscr{CN}(0, 1)$, and the results of 10000 realizations are averaged. Note that, even in single-radio approach, the AD-EBSS techniques exhibit reduced complexity compared to the batch ones, as they do not require the computation of the sample covariance matrix given by (4).

As it is shown, the adaptive versions of the test statistics achieve, in general, performance close to the batch ones (or even better, in some cases). This is due to the fact that the CDFs of the adaptive test statistics (16) (17), and (18) are close approximations to the exact ones, whereas for the batch case asymptotic expressions are used. This can be also verified by the results depicted in Fig. 5 where the simulations of Fig. 4 were repeated, but now the decision thresholds

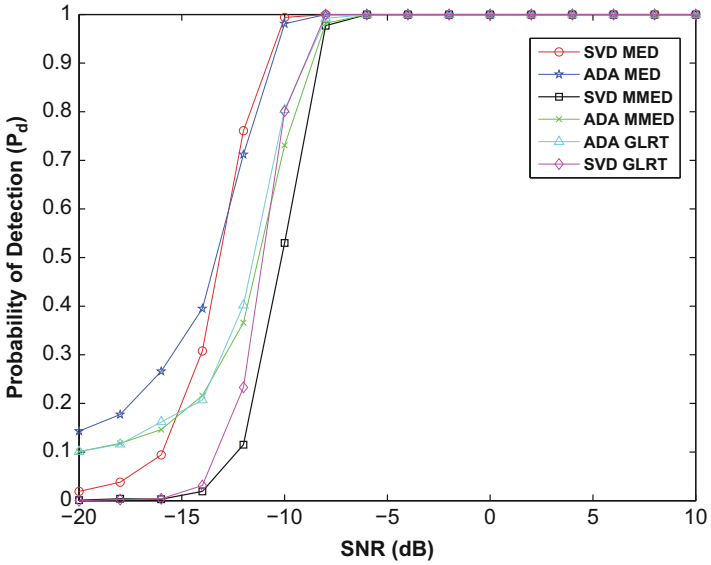

Fig. 4 $\mathscr{P}_d$ for i.i.d. noise samples and uncorrelated fading

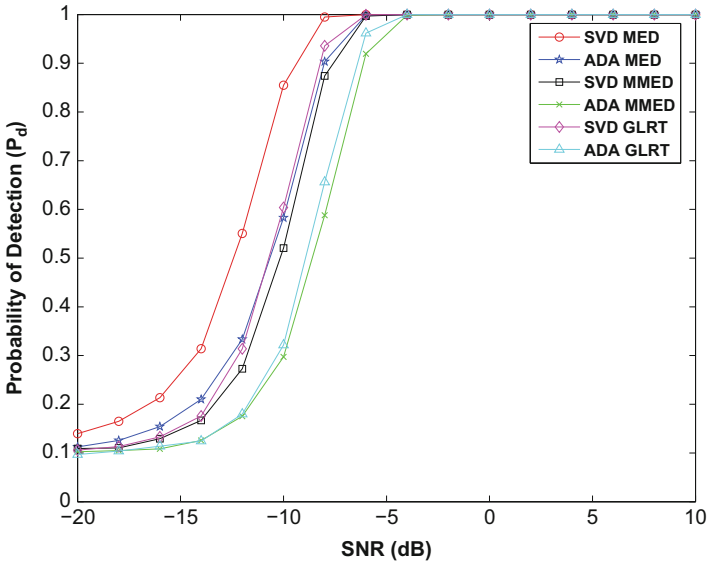

Fig. 5 Experimental setup of Fig. 4 for numerical thresholds

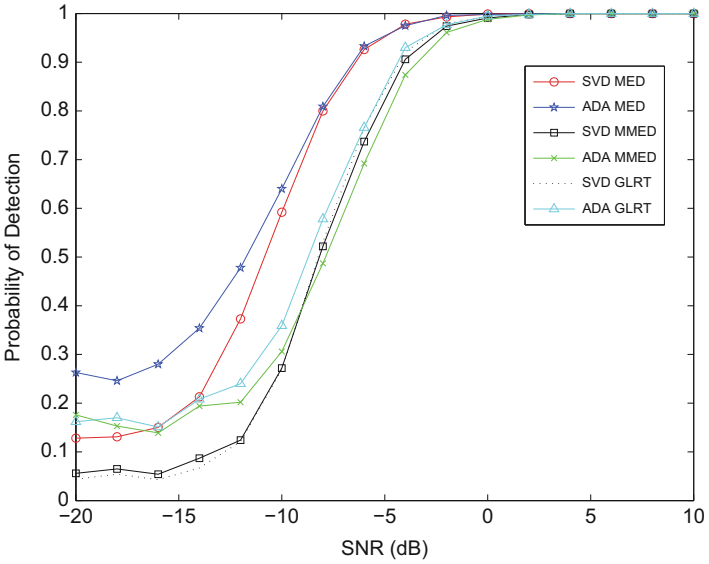

Fig. 6 $\mathscr{P}_d$ for non i.i.d. noise samples and uncorrelated fading

were computed numerically. The batch techniques exhibit improved performance due to accurate values of the employed thresholds. In Fig. 6, the same experiment of Fig. 4 is repeated, though now, we consider that the noise samples are no longer i.i.d. due to calibration errors at the SU. According to the relevant literature [14, 38], the correlation matrix of the noise samples can be considered diagonal. In the simulations of the present figure, the noise covariance matrix is given by $\mathbf{R}_z = diag\{1.1, 0.9, 0.8, 1.2\}$. As it was expected, both the adaptive and the batch techniques exhibit worse performance compared to the i.i.d. case. Nevertheless, for high SNR regimes, the EBSS techniques achieve high detection rates. Similar conclusions can be derived in the case of correlated fading coefficients at the SU antennas. The results are depicted in Fig. 7, where the fading coefficients are correlated such that each entry of their covariance matrix is given by $c_{m,n} = \rho_c^{|m-n|}$ [29], where $\rho_c \in \mathbb{R}$ is the correlation coefficient that satisfies $|\rho_c| \leq 1$.

Note that the noise samples are assumed to be i.i.d. in order to evaluate the effect of correlated fading to the EBSS techniques' performance. Again, for low SNR regimes, performance degradation is observed for both the adaptive and the batch EBSS methods.

In Fig. 8, the mean detection delay of an abrupt change is compared for each one of the batch and the adaptive EBSS techniques for different SNR values in order to evaluate the performance of the method in the dual-radio case. We consider timeslots of N = 1000 symbols in which an abrupt change in the channel state occurred at a random symbol time. The time at which a change occurs is assumed to follow the geometric distribution of (15) with parameters $p = 0.1$, $\lambda_0 = 0.01$ and a targeted

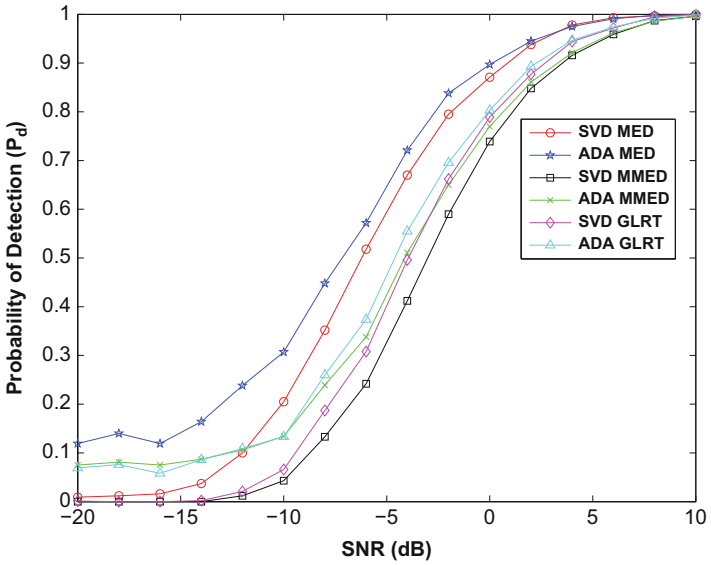

Fig. 7 $\mathscr{P}_d$ for i.i.d. noise samples and correlated fading

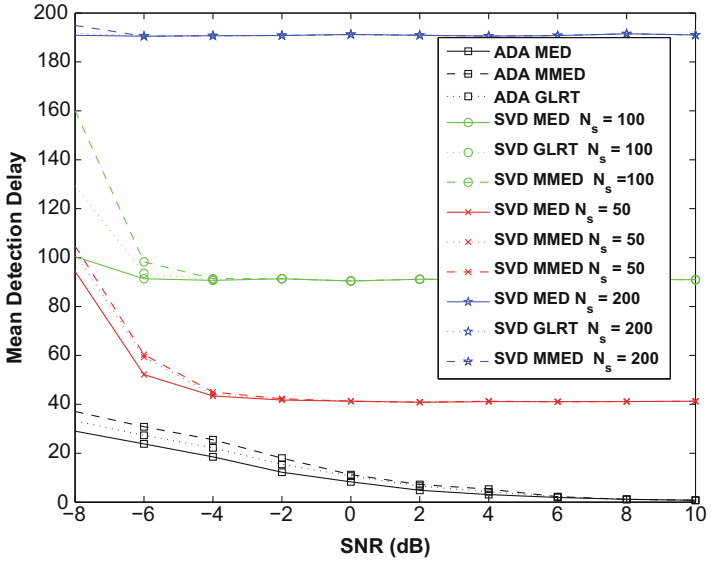

Fig. 8 Mean detection delay of an abrupt change

probability of false alarm $P_f = 0.01$. The decision threshold of the adaptive methods is computed by (25), as it is described in section "Threshold Computation for the Dual-Radio Approach." The threshold of the batch EBSS techniques is computed by simulations since a similar expression of the probability of false alarm was not possible to be found for this case. The adaptive EBSS techniques employ Algorithm 1. The batch EBSS techniques are employed periodically at every block of $N_s = \{50, 100, 200\}$ symbols, as it is described in Remark 1. It is evident that the adaptive EBSS techniques detect very fast the change even for low SNR regimes, since the detection test is applied at every sample time. The batch techniques' detection delay is related to the number N_s that dictates the frequency of their application.

Let us now study the multiple SUs case. In Fig. 9, the experiments of Fig. 4 are repeated, though now 7 SUs of 4 antennas each one are cooperating. The performance of the cooperative adaptive EBSS methods that employ the DDPM of Algorithm 2 is compared to the one of the single-user adaptive EBSS methods. The performance improvement offered by the cooperative methods is evident, and it is due to the fact that they process jointly the samples of the aggregate system of the KR_x receive antennas. In the same figure, the performance of a fusion-based method, that collects the samples for all the users and performs the batch EBSS techniques, is shown for comparison purposes. As it is shown, the cooperative adaptive EBSS schemes, apart from their benefits due to their completely decentralized nature and their low complexity, exhibit also satisfactory performance compared to the centralized batch ones, as it was also shown in the single SU case. Finally in Figs. 10 and 11, the computational and network

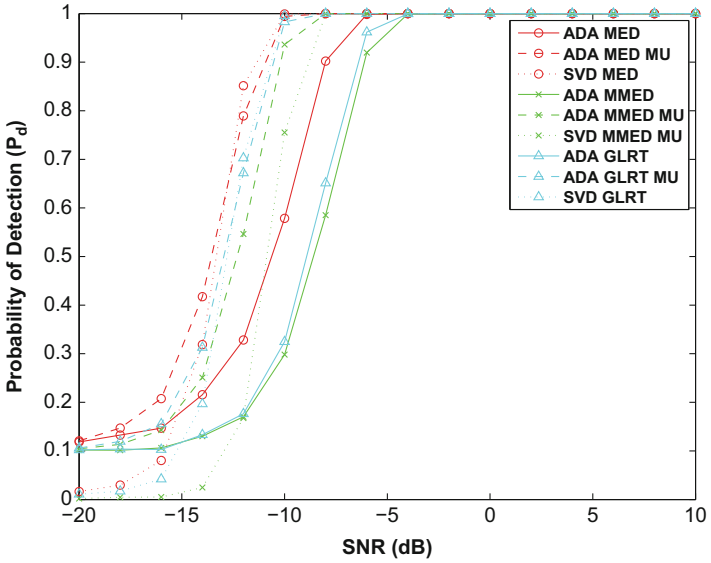

Fig. 9 Probability of detection ($\mathscr{P}_d$) for $K = 7$ SUs

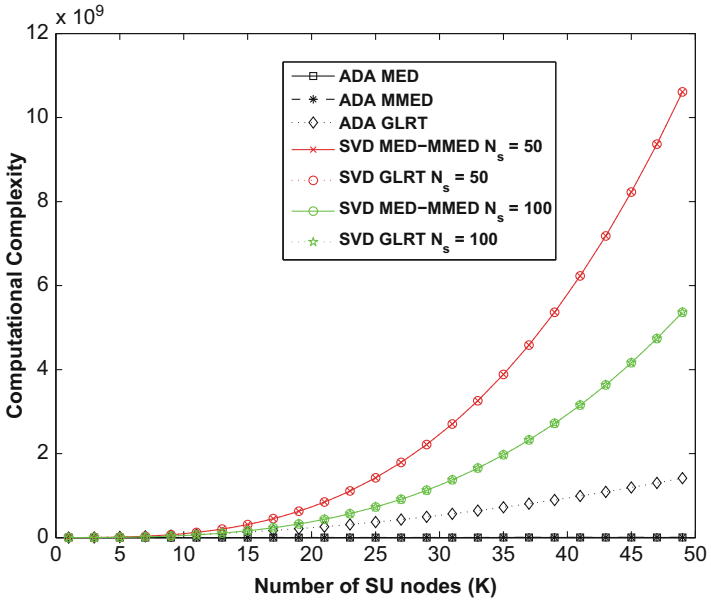

Fig. 10 Computational complexity vs. number of SUs

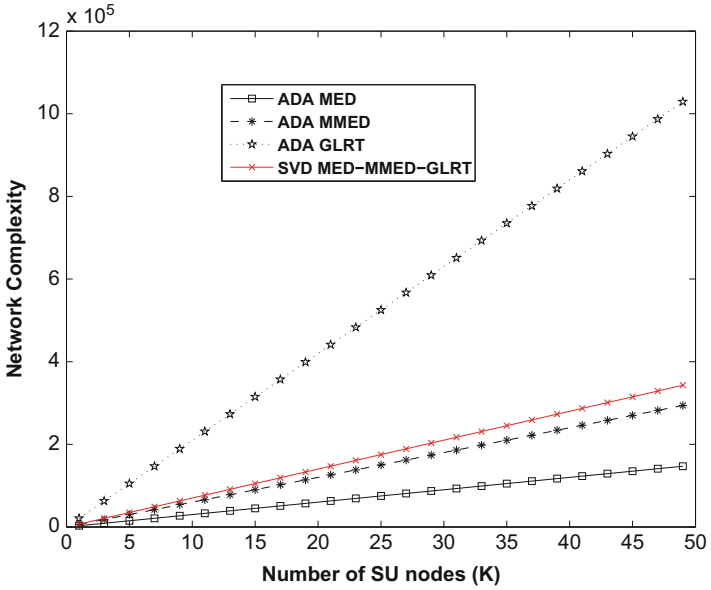

Fig. 11 Network complexity vs. number of SUs

complexity of the decentralized dual-radio approach is examined for a different number K of SUs. Each one of the SUs is considered to have $R_x = 7$ antennas. In the same figures, we present also the corresponding complexities for the batch centralized EBSS techniques. As it is evident, the adaptive EBSS techniques can provide significant reduction in the required complexities, especially for large network sizes.

Conclusion

In this chapter, cooperative decentralized adaptive versions of the well-known EBSS techniques were presented for multi-antenna cognitive receivers. The proposed techniques offer low complexity and improved performance especially in cases when continuous spectrum monitoring is applied. Moreover due to their decentralized nature, they exhibit reduced power consumption at the transmissions during the sensing period and provide robustness against node and link failures. In order to compute the decision thresholds for each one of the adaptive test statistics, the derivation of close approximations for the associated distribution functions was shown. A novel distributed subspace tracking method was also presented as a constituent part of the proposed decentralized EBSS techniques. The distributed ST method enables the SUs to track jointly the subspace of their received signals in a completely decentralized manner. The performance of the presented EBSS techniques was verified via indicative simulations and compared to those of the corresponding batch centralized approaches.

Appendix: Derivation of the Distribution of the MMED Test Statistic Under the $\mathscr{H}_0$ Hypothesis

Let us assume that two RVs T_1 and T_2 follow the same distribution with that of the MED test statistic. The CDF of the later distribution is given by (16). The corresponding probability density function (PDF) is computed by taking the derivative of (16). That is,

$$f_{T_i}(\tau_i) = \frac{\xi^\rho}{\Gamma(\rho)} \tau_i^{\rho-1} e^{-\rho\tau_i}. \tag{32}$$

We are interested in the distribution of the random variable $Y_1 = T_1/T_2$. Let us also define the auxiliary random variable $Y_2 = T_2$. Thus we have,

$$\begin{aligned} f_1(t_1, t_2) &= \frac{t_1}{t_2} \\ f_2(t_1, t_2) &= t_2, \end{aligned} \tag{33}$$

where $t_i \in \mathbb{R}^+$. The inverse functions of the ones of (33) are given by

$$f_1^{-1}(t_1, t_2) = t_1 t_2$$
$$f_2^{-1}(t_1, t_2) = t_2, \tag{34}$$

The joint PDF of variables Y_1 and Y_2 is given by

$$f_{Y_1,Y_2}(y_1, y_2) = f_{T_1,T_2}\big(f_1^{-1}(y_1, y_2), f_2^{-1}(y_1, y_2)\big)|J(y_1, y_2)|, \tag{35}$$

where $J(y_1, y_2) = \frac{\partial(t_1,t_2)}{\partial(y_1,y_2)}$ is the Jacobian matrix of the transformation and $|J(y_1, y_2)| = y_2$ is its determinant.

Observe now that, since the eigenvalues are estimated via (11), there are statistically independent. That is, the joint PDF of the variables under consideration T_1 and T_2 can be computed as the product of the corresponding marginal ones (16). Therefore, from (35) the joint PDF of Y_1 and Y_2 is given by

$$\begin{aligned} f_{Y_1,Y_2}(y_1, y_2) &= f_{T_1}(y_1 y_2) f_{T_2}(y_2) y_2 \\ &= \frac{\xi^{2\rho}}{\Gamma^2(\rho)} y_1^{\rho-1} y_2^{2\rho-1} e^{-\xi y_2(y_1+1)} \end{aligned} \tag{36}$$

In order to compute the marginal PDF of RV Y_1, we integrate the joint one of (36) with respect to y_2. That is

$$\begin{aligned} f_{Y_1}(y_1) &= \frac{y_1^{\rho-1}}{\xi^{2\rho}\Gamma^2(\rho)} \int_0^{+\infty} y_2^{2\rho-1} e^{-\xi y_2(y_1+1)} dy_2 \\ &= \frac{y_1^{\rho-1}\xi^{2\rho}\Gamma(2\rho)}{(1+y_1)^{2\rho}\xi^{2\rho}\Gamma^2(\rho)} = \frac{y_1^{\rho-1}}{B(\rho,\rho)(1+y_1)^{2\rho}}, \end{aligned} \tag{37}$$

where the following property of the beta function [20] was used

$$B(\rho_1, \rho_2) = \int_0^1 x^{\rho_1}(1-x)^{\rho_2-1} dx = \frac{\Gamma(\rho_1+\rho_2)}{\Gamma(\rho_1)\Gamma(\rho_2)}. \tag{38}$$

By integrating (37) we derive the corresponding CDF of the beta prime distribution given by (18) of Lemma 1, and the proof is completed. □

Abstract

The Cognitive Radio (CR) paradigm represents an innovative solution to mitigate the spectrum scarcity problem. Enabling a Dynamic Spectrum Access (DSA), it conciliates the existing conflict between the ever-increasing spectrum demand and the currently inefficient spectrum utilization. The basic idea of DSA is to provide proper solutions that allow sharing radio spectrum among several radio communication systems and optimize the overall spectrum utilization. The first part of this chapter gives a general overview of the CR concept to enable DSA, whereas the second part of the chapter addresses the problem of modeling a cognitive management framework with innovative strategies for spectrum management in different scenarios. The presented framework is able to characterize the environment dynamicity through long-term predictions based on the so-called belief vector. This demonstrates that a reliable characterization of the radio environment that combines awareness of its surrounding with a statistical evaluation of the system dynamics in terms of traffic generation patterns is able to guarantee an efficient utilization of the available spectrum resources. From a methodological point of view, the development and assessment of the proposed cognitive management framework involves an analytical study and a real-time platform implementation.

Introduction

The licensed static spectrum allocation policy, in use since the early days of radio communications, was proved to effectively control interference among the radio communication systems. However, the overwhelming proliferation of new operators, innovative services, and wireless technologies during the last years resulted, under the static regulatory regime, in the exhaustion of spectrum bands with commercially attractive radio propagation characteristics. The vast majority of spectrum considered as usable has already been assigned hindering commercial rollout of new emerging services. This situation produced a common belief of a depletion the usable radio frequencies. This was certainly strengthened by the overly crowded frequency allocation charts of many countries worldwide. Notwithstanding, some preliminary field measurements of spectrum usage revealed that most of the allocated spectrum was vastly underutilized [1], with temporal and geographical variations in the use of the assigned spectrum ranging from 15 to 85% [2].

More recent spectrum measurement campaigns carried out all over the world have confirmed the underutilization of the spectrum. This indicated also that the spectrum scarcity problem actually results from the static and inflexible spectrum management policies rather than the physical depletion of usable radio frequencies. For instance, in [3], the authors illustrate a spectral occupancy measurement campaign conducted in the frequency range between 806 and 2750 MHz in Auckland, New Zealand. In [4], a detailed analysis from 20 MHz to 3 GHz spectrum band in

different locations in Guangdong (province of China) is presented. Several spectrum measurement campaigns covering wide frequency ranges have been carried out in different locations and scenarios also in the USA [5–9] to determine the usage degree of allocated spectrum bands in real wireless communication systems. In [10], the authors provide an extensive measurement campaign conducted in Germany, comparing indoor and outdoor measurement results in the band from 20 MHz to 3 GHz. All these studies have confirmed that the static spectrum allocation policy which was appropriate in the recent past is becoming an outdated scheme that has become obsolete. Therefore, new spectrum management paradigms are required for a more efficient exploitation of the scarce radio resources. This has motivated the emergence of flexible spectrum access policies to overcome the shortcomings of the inefficient static allocation policies.

In this context, the so-called Cognitive Radio (CR) represents an innovative way to detect and use the wireless spectrum resources. CR was originally defined as a context-aware intelligent radio, capable of autonomous reconfiguration by learning from and adapting to the surrounding. In particular, it interacts with the environment following the cognition cycle as defined in [11], which allows CRs to continually observe their Radio Frequency (RF) environment, orienting themselves, creating a plan, deciding, and then acting. In addition, learning may be pursued in the background. Enabling Dynamic Spectrum Access (DSA), the CR paradigm is considered as a key solution to mitigate the spectrum scarcity problem [12].

DSA is the opposite of the static spectrum management policy and covers any innovative solution to share spectrum among several radio systems and increase the overall spectrum utilization. The basic idea of the DSA is to allow the so-called secondary users to access in an opportunistic and noninterfering way some licensed bands temporarily unoccupied by the licensed (or primary) users. Secondary terminals monitor the spectrum in order to identify time and unused frequency gaps, perform transmissions, and vacate the channel as soon as primary users return active. Secondary transmissions are allowed as long as they do not result in harmful interference to primary users. The temporarily unused portions of spectrum in time, frequency, and space domains are called spectrum White Spaces (WSs).

The basic concept of the CR paradigm introduced in [11] has been reconsidered in the literature in several papers which aimed at redefining it for specific scenarios. In the DSA context, the tasks of the CR cycle (see section "Cognitive Radio Paradigm" for more details) should be characterized to enable the following capabilities [12]:

- *Radio-scene analysis*: which consists in estimating interference conditions of the radio environment and identifying the set of available spectrum holes or WSs.
- *Channel identification*: which consists in estimating the Channel State Information (CSI) and predicting the channel capacity.
- *Transmit-power control and spectrum management*: which adjusts transmission parameters based on a received feedback.

With the advent of the CR, high interest has been devoted to Cognitive Radio Networks (CRNs) which allow a wireless communication system based on the cognitive cycle to observe the environment, act, and learn in order to optimize its performance. For instance, in [13], a CRN is defined as a wireless network with the capabilities of radio environment awareness, autonomous decision-making, adaptive reconfiguration of its infrastructure, and intelligent learning from experience of a continuously changing environment to solve the challenges of efficient spectrum management and high-quality end-to-end performance. Hence, a CRN foresees the ability to be aware of certain information, such as the available spectrum, the operation mode of the wireless network, the transmitted waveform, the network protocol, the geographical information, the type of services, the user needs, and the security policy. Furthermore, a CRN must analyze the achieved information and make the decision to optimize the end-to-end performance of the wireless network. Based on the optimized decision, a CRN must finally reconfigure its network parameters when necessary. Moreover, CRNs deal with challenges in terms of coexistence with primary users and different Quality of Service (QoS) requirements associated with the various cognitive communications. According to [14], in a network that guarantees the cognitive capabilities, the following issues have to be considered:

- *Interference avoidance*: to operate while controlling the amount of interference perceived by primary networks.
- *QoS awareness*: to enable QoS-aware communications in dynamic and heterogeneous spectrum environments.
- *Seamless communication*: to provide seamless communications regardless of the activity of primary users.

Several contributions in the literature have illustrated the expected benefits of developing cognitive management functional architectures, which support CRNs to exploit the mentioned cognitive radio capabilities for efficient spectrum management and high-quality end-to-end performance [13, 15, 16]. These studies have motivated the development of advanced cognitive management tools in many specific scenarios. For instance, in [16], a cognitive management framework is illustrated to carry out an autonomous optimization of resource usage in next-generation home networks. The proposed framework is able to autonomously improve the performance of network nodes in a dynamic environment according to the objectives, the restrictions, and the policy regulations formulated by network stakeholders. Although the benefits of CR and DSA supported by cognitive management architectures have been discussed in several studies (e.g., [17–20]), many aspects are still under investigation. Spectrum sensing strategies to identify spectrum opportunities, coordination of opportunistic spectrum access among different users, or spectrum selection are some examples for this.

The main objective of this chapter is to propose a cognitive management framework that provides innovative strategies for spectrum management exploiting the CR capabilities. The proposed framework is developed in order to combine the

observations carried out during the CR cycle with a statistical characterization of the system dynamic. The spectrum management strategies illustrated in this chapter rely on the so-called belief vector concept as a means to characterize and predict the environmental dynamics. The belief vector assesses the probability that the radio environment is under specific conditions (e.g., interference levels) at a certain instant of time based on past measurements. As long as the belief vector predicts the existing conditions with sufficient accuracy when the decision is made, proper decisions can be made with minimum requirements in terms of observations. The proposed framework aims at demonstrating that a reliable characterization of the radio environment in terms of traffic generation pattern that combines awareness of its surrounding with a statistical evaluation of the system dynamics can guarantee an efficient utilization of the available spectrum resources in CRNs. The proposed framework is experimentally evaluated making use of a real-time platform.

The rest of this chapter is organized as follows. The introduction of CR and a detailed description of the CR cycle are provided in section "Cognitive Radio Paradigm". Section "Dynamic Spectrum Access to Exploit Cognitive Radio Paradigm" presents the basic concepts of the DSA and how it is enabled by the CR. A typical example of CRNs with the corresponding functionalities, which enables DSA, is also provided. Section "Proposed Framework for Spectrum Management" presents the proposed framework, which implements the spectrum management strategies. Section "Real-Time Testbed Design and Implementation" illustrates the implementation of the real-time testbed used to assess the performance of the proposed framework, while a detailed analysis in different scenarios is presented in section "Performance Evaluation". Concluding remarks are given in section "Conclusions and Future Directions".

Cognitive Radio Paradigm

The CR concept was introduced by J. Mitola III as a smart, context-sensitive radio that can be programmed and configured dynamically under varying environmental conditions [11]. The operations of the CR systems are typically assumed to follow the cognitive cycle illustrated in Fig. 1 in order to interact with the environment. Any CR system following this cycle gathers observations from the outside world through different types of sensors, orients itself, creates a plan of possible courses of actions, decides, and then acts. During this cycle, the CR system also learns from the outcomes of its decisions and sensory inputs from the outside world. Clearly this original definition of CR is very general, applicable to a vast number of scenarios; in details, in the original study of J. Mitola III, the observations were focused on the following inputs: (i) radio spectrum, (ii) images from cameras, (iii) speech recognition, and (iv) geo-location. Hence, a general CR paradigm is an adaptive, self-organizing architecture for holistic resource management in wireless networks, capable of adjusting its own behavior through learning.

A CR system can observe a number of different aspects of its environment. The most commonly mentioned example is the radio environmental information

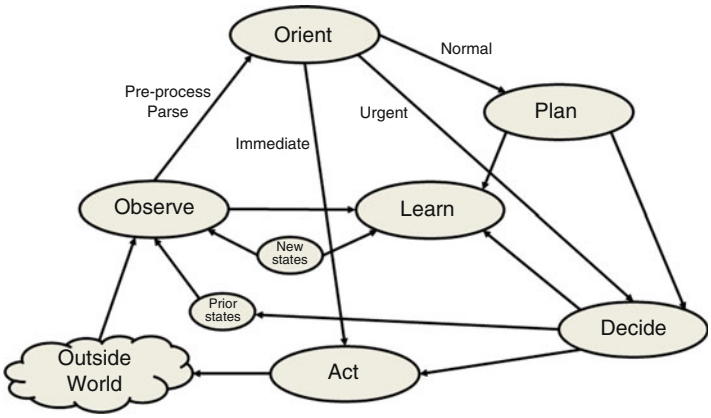

Fig. 1 Cognitive cycle

achieved by a spectrum sensor. Usually, a spectrum sensor would measure features such as either the sensed power in a range of frequencies or the presence of signals transmitted through particular technologies or digital modulation schemes. This spectrum sensor could also be implemented either on an individual CR system by a hardware component, or it could be based on cooperation between several CR systems in the neighborhood. The observations could also be done through explicit communication among different radios such as transmitters that send control information on the used frequencies.

The orientation stage involves the processing of the information achieved from the different sensors and the integration with any prior knowledge for updating the estimated state of the system and its environment. Depending on the diversity of the sensing information and available prior knowledge, numerous different state estimation and learning mechanisms can be used in the orientation state. For instance, further processing of information achieved by spectrum sensors can be gathered with location information to make logical conclusions whether certain transmitters are active or not. Depending on the change in state, the CR shifts either to the planning state or, in case urgent reaction is needed, to the decision state. After reaching the decision-making state, the CR should potentially act according to the decisions made. Actions here would usually relate to change in any of the tuneable parameters across the entire protocol stack, including selection of protocols to be used, and actual links or end-to-end connections established to other nodes. During the learning state, the CR updates the different models that have been constructed on the environment, on the properties of other radios, and on the dynamics of its own state.

The CR paradigm relies often, but not necessarily, on the use of the Software-Defined Radio (SDR) technology, which is a multiband radio supporting multiple air interfaces and protocols. It is reconfigurable through software running on a Digital Signal Processor (DSP), Field-Programmable Gate Array (FPGA), or general purpose microprocessor [21]. Hence, CR systems, usually built upon a SDR

platform, are context-aware intelligent radio capable of autonomous reconfiguration by learning from and adapting to the surrounding communication environment [22]. They are capable of sensing their Radio Frequency (RF) environment, learning about their radio resources and user and application requirements, and adapting their behavior accordingly. The idea behind SDR is to define all radio functionalities in software rather than in dedicated hardware, in order to reuse a single platform for many different radio standards.

Through SDR the following main characteristics of the CR defined in [12, 15] can be exploited: cognitive capability, i.e., the ability to capture information from the radio environment, and reconfigurability, which enables the transmitter parameters to be dynamically programmed and modified according to the radio environment. In fact, SDR is capable of sensing spectrum occupancy and opportunistically adapting transmission parameters to utilize empty frequency bands without causing harmful interference to primary networks. Moreover, through SDR, a CR system is able to reconfigure several parameters such as the operating frequency (to take profit of spectrum holes detected on different frequency bands), modulation and/or channel coding (to adapt to the application requirements and the instantaneous channel quality conditions), transmission power (to control interference), and communication technology (to adapt to specific communication needs). Based on the characteristics of the detected spectrum holes, these parameters can be reconfigured so that the CR is switched to a different spectrum band, transmitter and receiver parameters are reconfigured, and the appropriate communication protocols and modulation schemes are used.

Dynamic Spectrum Access to Exploit Cognitive Radio Paradigm

Spectrum underutilization has motivated different activities and initiatives in the regulatory, economic, and research communities, to look for better spectrum management policies [23]. DSA solutions have been proposed to provide procedures or schemes to achieve flexible spectrum access approaches aimed at overcoming the disadvantages and shortcoming of the currently inefficient static allocation policies. The key enabler of the DSA concept is the CR that provides functionalities such as the possibility to use the spectrum in an opportunistic way observing the outside world.

Dynamic Spectrum Access Models

Several DSA models have been defined to optimize the spectrum usage depending on the particular radio environment as shown in Fig. 2. The following classification can be defined:

- **Dynamic exclusive use model.** It basically keeps the structure of the static spectrum allocation policy. Spectrum bands are licensed to operators, technologies,

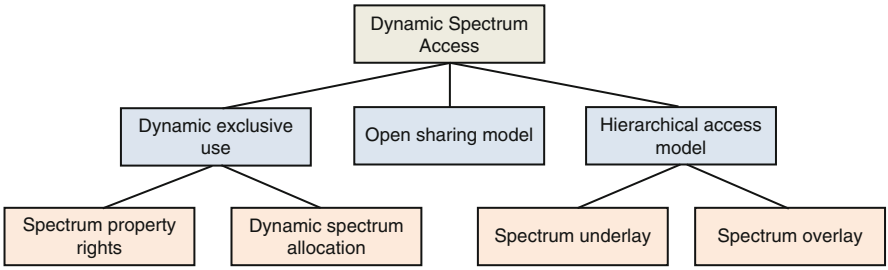

Fig. 2 Classification of the dynamic spectrum access models

and/or services for exclusive use, but some flexibility is introduced to optimize the spectrum efficiency. Two different approaches can be distinguished in this model:

- *Spectrum property rights* [24]. It enables licensed users to sell and lease some portions of its licensed spectrum and to select the technology to be employed as well as the service to be given in that band. Hence, in this context, economy and market would play a more important role in driving the most profitable use of spectrum under this scheme. It is worth highlighting that even though licensed users can sell or lease the spectrum for economic profit, this spectrum sharing is not mandated by the regulatory organism.
- *Dynamic spectrum allocation* [25]. It aims at managing the spectrum used by a converged radio system and sharing it between participating Radio Access Networks (RANs) over space and time to optimize overall spectrum efficiency. A bandwidth reservation will result in unused spectrum for long periods of time and along large geographical areas. Hence, spectrum efficiency can be improved by exploiting the spatial and temporal traffic variations of different services. The underlying idea of DSA methods is to enable two or more networks of a converged radio system to share an overall block of spectrum such that spectrum allocations can adapt to either temporal or spatial variations. However, these strategies allocate, at a given time and region, a portion of the spectrum to a RAN for its exclusive use. Furthermore, the allocation varies at a much faster scale than the current policy (e.g., traffic demands usually exhibit a periodic daily pattern).

- **Open sharing model** [26]. Also defined as spectrum commons, it considers open sharing among peer users as the basis for managing a spectral region in a similar way as wireless services operating in the unlicensed Industrial, Scientific, and Medical (ISM) band. Spectrum commons proponents declare that wireless transmissions can be regulated by baseline rules enabling users to coordinate their utilization, avoiding interference-producing collisions, and preventing congestion.
- **Hierarchical access model.** This is a hybrid model of the dynamic exclusive use model and the open sharing model. It is built upon a hierarchical access structure that distinguishes between primary or licensed users and secondary or

license-exempt users. The basic idea is to open licensed spectrum to secondary users limiting the interference perceived by primary ones. Two approaches to spectrum sharing between primary and secondary users have been considered:

- *Spectrum underlay*. It enables to overlap transmissions from secondary users but imposes severe constraints on their transmission power so that they operate below the noise floor of primary users. Therefore, secondary transmissions have to spread over a wide frequency band, which can be achieved by means of technologies such as Code Division Multiple Access (CDMA) or Ultra Wide Band (UWB). This approach enables secondary users to potentially obtain short-range high data rates with extremely low transmission power. Another advantage is that the activity of primary users does not need to be tracked by secondary ones. The most important problem in this approach is that the low transmission power still limits the applicability of spectrum underlay to short-range applications [27].
- *Spectrum overlay.* It is not necessarily characterized by severe restrictions on the transmission power of secondary users but rather on when and where they may transmit. The basic idea of this approach is to define spatial and temporal spectrum gaps not occupied by primary users, referred to as spectrum holes or white spaces, and place secondary transmissions within these spaces. Hence, the purpose of this scheme is to define and exploit local and instantaneous spectrum availability in a nonintrusive and opportunistic way. This approach is also defined as Opportunistic Spectrum Access (OSA) [28].

Cognitive Radio as an Enabler of Dynamic Spectrum Access

The CR technology in the context of DSA enables the users to (1) determine which portion of the spectrum is available and detect the presence of licensed users when a user operates in a licensed band (spectrum sensing), (2) select the best available channel (spectrum decision), (3) coordinate access to this channel with other users (spectrum sharing), and (4) free the channel when a licensed user is detected (spectrum mobility). Focusing on these functions, the result is the simplified version of the full cognitive cycle and is shown in Fig. 3 [29]. The states defined in the cycle can be characterized as:

1. *Spectrum sensing*. A CR user can only allocate an unused portion of the spectrum. Therefore, the CR user should monitor the available spectrum bands, capture their information, and then detect the spectrum holes.
2. *Spectrum decision.* Based on the spectrum availability, CR users can allocate a channel. This allocation not only depends on spectrum availability, but it is also determined based on internal (and possibly external) policies.
3. *Spectrum sharing.* Since there may be multiple CR users trying to access the spectrum, CR network access should be coordinated in order to prevent multiple users colliding in overlapping portions of the spectrum.

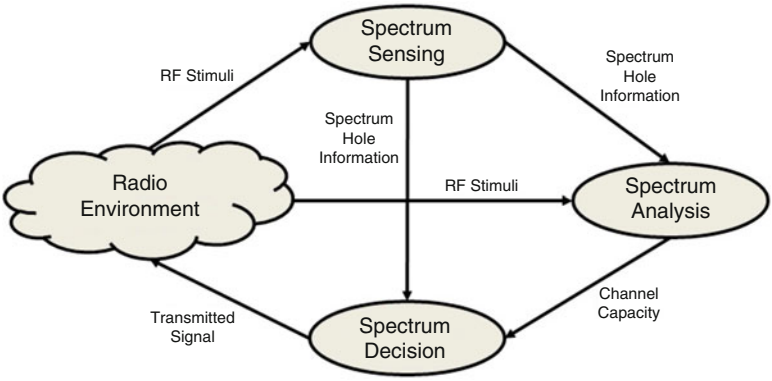

Fig. 3 Specialization of the cognitive cycle to the DSA case

4. *Spectrum mobility.* If the specific portion of the spectrum in use is required by a primary user, or if the Quality of Service (QoS) of the spectrum worsens, the communication needs to be continued in another vacant portion of the spectrum.

However, compared to the full cognitive cycle, the loop missed a few important components. For instance, one is the learning module, which prevents mistakes from previous iterations from being made on future ones. Several schemes have been proposed to classify the functions required in the context of the described CR and the DSA cycle. For instance, according to [1], the main functions are categorized into:

1. *Spectrum opportunity identification.* It is responsible for accurately identifying and intelligently tracking idle frequency bands that are dynamic in both time and space. Hence, this function is equivalent to the spectrum sensing function previously described.
2. *Spectrum opportunity exploitation.* It takes input from the spectrum opportunity identification function, and it decides whether and how a transmission should be carried out. This function comprises the aforementioned spectrum decision and spectrum sharing ones.
3. *Regulatory policy.* It defines the basic etiquette for secondary users, dictated by a regulatory body, to guarantee compatibility with legacy systems. An example of this DSA policy is Dynamic Frequency Selection (DFS) [2]. DFS allows unlicensed 802.11 communications devices in the 5 GHz band to coexist with legacy radar systems. The policy specifies the sensor detection threshold as well as the timeline for radar sensing, usage, abandoning the channel, and a non-occupancy time after detection. This policy allows limited but minimal harm to legacy radar systems by accounting for the specific form of sensor for detection and prescribing the timeline for channel use and release.

The spectrum mobility function is not explicitly considered in the classification criterion proposed in [1], but it could be included within the spectrum opportunity exploitation function.

DSA/CR Networks Architecture

Once a radio supports the capability to select the best available channel, the next challenge is to make the network protocols adaptive to the available spectrum. Therefore, new functionalities are required in a DSA/CRN (CRN for simplicity from here on) to support this adaptively and to achieve spectrum-aware communication protocols. A typical CRN architecture is illustrated in Fig. 4 according to the open sharing and hierarchical DSA models described in section "Dynamic Spectrum Access Models" [29]. For each of these models, the interconnection architecture may be built without a central network entity, such as a Base Station (BS) or an access point (CR ad hoc Access), or rely on some additional network nodes (CR Network Access). Moreover, the figure illustrates how the network allows the access to both unlicensed band and licensed bands according to the open sharing and hierarchical access models, respectively. In case of hierarchical access model, when licensed bands are considered, the components of the network can be classified in two groups: the primary network and the CR network or secondary network. The primary network is the legacy network having an exclusive right to a certain spectrum band such as the common cellular and TV broadcast networks, while the CR network does not have a license to operate in the desired band.

The spectrum access is allowed only in an opportunistic manner. The basic components of primary networks are:

- *Primary user.* It is authorized to use always a particular spectrum band. This use is controlled only by the primary BS, and it should not be affected by the operations of other unlicensed users. Primary users do not need any modification or additional functions for coexistence with BSs and CR users.
- *Primary BS.* It is a fixed infrastructure network component which has a spectrum license such as BS Transceiver system (BST) in a cellular system. In principle, the primary BS does not have any CR capability for sharing spectrum with CR users. However, the primary BS may be requested to have both legacy and CR protocols for the primary network access of CR users.

The basic elements of the CR network are defined as follows:

- *CR user.* It does not hold a spectrum license, and it uses detected spectrum holes in an opportunistic way which requires additional functionalities to share the licensed spectrum band.
- *CR BS.* It is a fixed infrastructure component with CR capabilities. The CR BS provides single hop connection to CR users without spectrum access license. Through this connection, a CR user can access other networks.

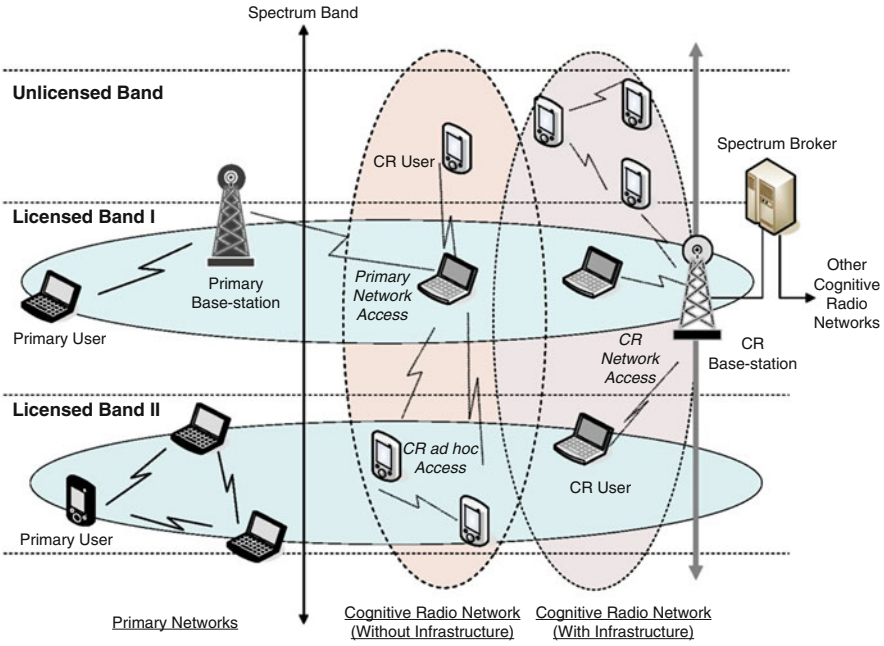

Fig. 4 CRN architecture for DSA applications [29]

- *CR spectrum broker.* It is a central network entity that controls the spectrum sharing among different CRNs. The spectrum broker can be connected to each network and can serve as a spectrum information manager to enable coexistence of multiple CRNs.

Since CRNs can operate in both licensed and unlicensed bands, the required functionalities that the cognitive management tools should provide vary according to the characteristic of the spectrum. The following CRNs operations can be distinguished [29]:

- **CRN on licensed band.** In this case, there are temporarily unused spectrum holes. Therefore, CRNs can be deployed to use these spectrum holes through cognitive communication techniques. This architecture is illustrated in Fig. 5. It can be observed that the CRN coexists with the primary network at the same location and on the same spectrum band. There exist various challenges for CRNs on licensed band due to the existence of the primary users. Although the main objective of the CRN is to find the best available spectrum, the interference avoidance with primary users is the most important issue in this architecture. In fact, when primary users appear in the spectrum band occupied by CR users, this must release the current spectrum band and select a new available spectrum.

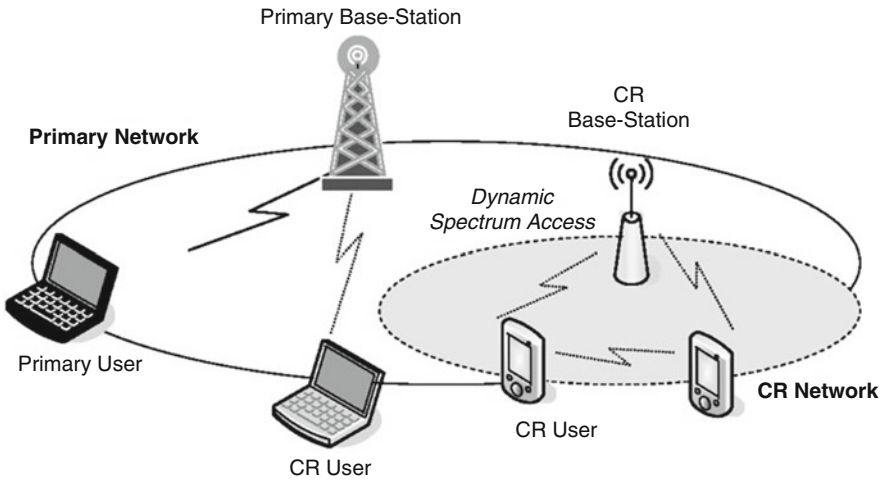

Fig. 5 CRN on licensed band [29]

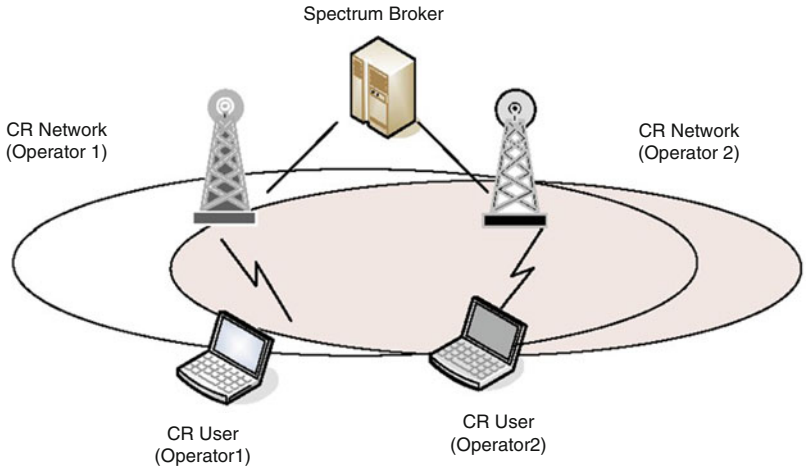

Fig. 6 CRN on unlicensed band [29]

- **CRN on unlicensed band.** The open spectrum policy that began in the ISM band has provoked a wide variety of innovative technologies. Notwithstanding, due to the interference among multiple heterogeneous networks, the spectrum efficiency of the ISM band is worsening. CRNs can be designed for operation on unlicensed bands such that the efficiency is improved in this portion of the spectrum. The CRN on unlicensed band architecture is shown in Fig. 6. As there are no license holders, all the entities of the network have the same right to access the spectrum bands. Multiple CRNs can coexist in the same area and share the same portion of the spectrum. Therefore, intelligent spectrum sharing algorithms are needed

to improve the efficiency of spectrum usage. In this architecture, CR users focus on detecting the transmissions of other CR users; hence, sophisticated spectrum sharing methods among CR users are required. If multiple CRN operators reside in the same unlicensed band, a fair spectrum sharing among these networks is also required.

Proposed Framework for Spectrum Management

Motivations

The cognitive management framework proposed in this chapter is designed to provide a powerful tool to assess efficient spectrum management solutions in different scenarios and use cases. Specifically, the framework is based on the DSA/CR cycle paradigm presented in section "Cognitive Radio as an Enabler of Dynamic Spectrum Access". This includes observation, analysis, decision, and action in order to perform efficient decision-making strategies for spectrum selection in CRNs. Moreover, it is implemented for the open sharing model and spectrum overlay hierarchical DSA model introduced in section "Dynamic Spectrum Access Models".

The observation of the radio environment and the analysis of such observations will allow to acquire knowledge about the state of the potential spectrum blocks that can be selected (e.g., the amount of measured interference, their occupation, etc.) as well as their dynamic behavior (e.g., how the interference changes with time). Observations of the radio environment involve making measurements at several nodes of a CRN. Then, these measurements need to be reported to the node in charge of the decision-making. This is usually done through signaling procedures supported by cognitive control channels [30]. As a result, the observation stage can be very costly in terms of practical requirements such as signaling overhead, battery consumption, etc. Consequently, decision-making strategies able to efficiently operate with the minimum amount of measurements would be of high interest. The proposed spectrum management framework is based on the so-called belief vector to predict the environment dynamics, which allows avoiding measurements when possible.

In detail, the belief vector assesses the probability that the radio environment is under specific conditions at a certain time, based on past measurements (observations). Moreover, the proposed framework can be particularized to different observation strategies to determine the instants when measurements of the radio environment need to be performed, assessing the trade-off existing between performance and observation requirements of the cognitive cycle. Some illustrative use cases representing DSA-based scenarios where this framework can be applicable are (1) a Digital Home (DH) environment in which different devices need to communicate, (2) a set of cognitive small cells deployed in a cellular network that make use of an additional spectrum to increase the network capacity, and (3) an opportunistic Device-to-Device (D2D) radio link created to extend the coverage

of certain cellular terminals that are outside the coverage area of the cellular infrastructure.

The authors in [31] have introduced the spectrum management approach based on the belief vector concept, which can be particularized for different observation strategies relying only on simulation analysis. In particular, the achieved results have assessed the impact of the environment dynamics in terms of the traffic generation patterns in the observation strategies supporting the decision-making solution in Matlab-based simulated scenarios. The spectrum management framework has also been assessed experimentally in [32] through a real-time testbed, evaluating an actual scenario where the best trade-off between performance and measurements requirements has been achieved through an appropriate combination between periodical measurements of the radio environment and statistical characterization of the interference variations. Finally, in [33], the authors have compared the belief-based spectrum management approach against other state-of-the-art solutions to demonstrate the effectiveness of this spectrum selection strategy through Matlab-based simulations. Hence, the functionalities of this framework have already achieved satisfactory results [31–33]. Notwithstanding, these publications either provide only simulation analysis [31] and [33] or address a particular use case in a real-time scenario [32]. The use of simulations is typical within the research and industrial communities and can be convenient for achieving preliminary performance results. However, to carry out appropriate and relevant studies and to properly evaluate the performance of innovative solutions before progressing to a prototype or full-scale deployment, assessment on realistic platforms is a crucial step. In this context, real-time platforms enable the emulation of realistic scenarios to test algorithms, applications, protocols, and policies under realistic conditions and represent a powerful tool for assessing the Quality of Experience (QoE) of end-users that could not be obtained through off-line simulations, as well as the QoS. Guided by these motivations, this chapter extends (i) the results achieved in [31] and [33] in a realistic environment provided by a real-time platform and (ii) the preliminary experimental results obtained in [32] providing new functionalities that enhance the proposed framework.

System Model and Problem Formulation

The considered system model assumes a set of $j = 1, \cdots, L$ radio links, each intended to support data transmission between either a pair of terminals or between a terminal and an infrastructure node. The j-th radio link will support a certain data service characterized by a required bit rate $R_{\text{req},j}$ and will generate data transmission sessions of a certain duration D_j. The focus will be to take the *decision* based on observations, which determines the spectrum to be assigned to each radio link. For this purpose, it is assumed that the L radio links are controlled by a centralized cognitive management entity in charge of spectrum selection decisions.

The spectrum is organized in a set of $i = 1, \cdots, M$ spectrum blocks, each characterized by a central frequency and bandwidth. The considered candidate

spectrum blocks can belong to different bands allowing different degrees of spectrum sharing with other systems in accordance with the DSA models considered in our implementation (e.g., non-licensed ISM bands, licensed bands allowing primary/secondary spectrum sharing such as TV White Spaces bands, licensed bands with exclusive use such as those belonging to the mobile network operator in charge of the CRN, etc.).

The considered strategies consist in performing an efficient allocation of the j-th spectrum block to the j-th radio link by properly matching the bit rate requirements with the achievable bit rate in each spectrum block. This will be conducted by the execution of the spectrum selection decision-making, which will take a so-called *action*, corresponding to the allocation of a spectrum block to a radio link, anytime that a data transmission session is initiated on this radio link. The action made for the j-th link at time t is denoted as $a_i(t) \in \{1, \cdots, M\}$ and corresponds to the selected spectrum block among those currently available.

For the interference model, we denote as $I_{i,j} = I_{\max,j,i} \cdot \sigma_i(t)$ the interference spectral density measured by the receiver of the j-th in the i-th spectrum block at a given time due to other external transmitters (i.e., outside the control of the decision-making entity). In order to capture that interfering sources may exhibit time-varying characteristics, we consider the term $\sigma_i(t)$ which is a spectrum block-specific term between 0 and 1 (i.e., $\sigma_i(t) = 0$ when no interference exists and $\sigma_i(t) = 1$ when interference reaches its maximum value $I_{\max,j,i}$). For modeling purposes, the set of possible values of $\sigma_i(t)$ is translated into a discrete set of interference states $S^{(i)}(t) \in \{0, 1, \cdots, K\}$ where state $S^{(i)}(t) = k$ corresponds to $\sigma_{k-1} < \sigma_i(t) < \sigma_k$ for $k > 0$ and to $\sigma_i(t) = \sigma_0 = 0$ for $K = 0$; note also that $\sigma_K = 1$. The system state at time t is given by the M-column vector $S(t) = [S^{(i)}(t)]$. Moreover, assuming that the state of each spectrum block remains the same for a time step of duration Δt, the interference evolution for the i-th block is modeled as a discrete-time Markov process with the state transition probability from state k to k' given by:

$$P^{(i)_{k,k'}} = P_r[S^{(i)}(t + \Delta t) = k' | S^{(i)}(t) = k] \tag{1}$$

Then, the state transition probability matrix for the i-th spectrum block is defined as:

$$\mathbf{P^{(i)}} = \begin{Bmatrix} p^{(i)}_{0,0} & \cdots & p^{(i)}_{0,K} \\ \vdots & \ddots & \vdots \\ p^{(i)}_{K,0} & \cdots & p^{(i)}_{K,K} \end{Bmatrix} \tag{2}$$

It is assumed that the state of the i-th spectrum block $S^{(i)}(t)$ evolves independently from the other blocks and that the state evolution is independent from the assignments made by the spectrum selection strategy. Moreover, let us define $\phi^{(i)} = [\phi^{(i)}_0 \phi^{(i)}_1 \cdots \phi^{(i)}_k]^T$, where superscript T denotes the transpose operation, as

the steady-state probability vector. $\phi_k^{(i)}$ is the probability that the i-th spectrum block is in the k-th interference state. Each radio link with a data session in progress (referred to as an active link) will obtain a reward that measures the obtained performance depending on the interference state of the allocated spectrum block at each time. The reward vector of the j-th link in the different interference states of the i-th SB is $r^{(i)} = [r_0^{(i)} r_1^{(i)} \cdots r_k^{(i)}]^T$. Supposing the use of the j-th link, the element $r_{j,k}^{(i)}$ denotes the reward that this link receives when using its allocated spectrum block i and the interference state is $S^{(i)}(t)$. The reward is a metric between 0 and 1 capturing how suitable the i-th spectrum block is for the j-th radio link, depending on the bit rate that can be achieved in this spectrum block with respect to the bit rate required by the application. Several possible definitions of the reward metric as a function of the bit rate may exist such as sigmoid functions, linear functions, or fittingness factor [34, 35]. The average reward experienced by the j-th link in the i-th spectrum block along a session starting to transmit data at time $t+1$ and ending after a certain duration of D_j time steps is given by:

$$r_{\text{Session},j}^{(i)} = \frac{1}{D_j} \sum_{n=1}^{D_j} r_{j,S^{(i)}(t+n)}^{(i)} \tag{3}$$

The spectrum selection policy illustrated in this chapter is executed at time t for the j-th radio link and targets the maximization of the expected reward that the session will experience along its duration:

$$a_i(t) = \arg\max_i \frac{1}{\overline{D_j}} \sum_{n=1}^{\overline{D_j}} r_{j,S^{(i)}(t+n)}^{(i)} \tag{4}$$

The selection is made among the available spectrum blocks, i.e., those that are not allocated to any other radio link at the decision-making time t. The analysis of the future evolution of the reward in each of the spectrum blocks until the session ends exploits the measurements of the interference state of the different spectrum blocks carried out at specific time instants in the past, together with the statistical characterization of the interference dynamics in each spectrum block. In details, the statistical characterization of the interference dynamics in the i-th spectrum block is given by the belief vector $\mathbf{b^{(i)}}(t)$. The computation of the belief vector of the i-th spectrum block at a certain time instant t is performed recursively, starting from the last observation of the actual interference state that was taken in the i-th spectrum block at time step $t - m^{(i)}$. In particular, the belief vector at a time instant $t > t - m^{(i)}$ can be obtained from the belief vector at the previous $m^{(i)}$ time steps using the state transition probabilities of the interference states recursively.

The envisaged framework to implement the spectrum selection strategies consists of the main entities illustrated in Fig. 7 and is described in the following.

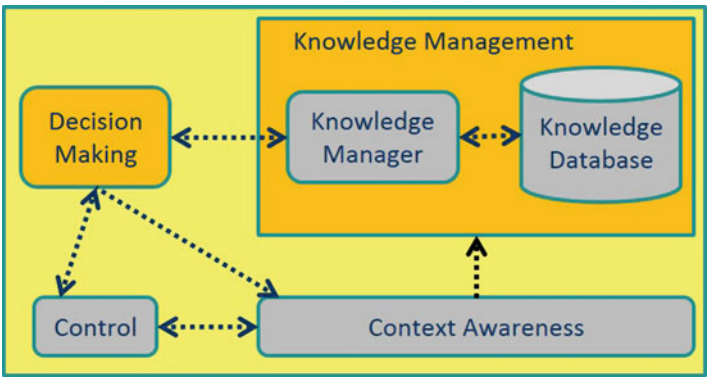

Fig. 7 Proposed framework for spectrum management

The Knowledge Management block is in charge of storing and managing the relevant knowledge obtained from the radio environment that will be used by the decision-making entity. In details, it includes the Knowledge Database (KD) that stores different statistic information about the radio environment and the Knowledge Manager (KM), which is in charge of computing and updating this information. The Knowledge Management relies on an *initial acquisition functionality* implemented in the KM to perform an estimation of the parameters stored in the KD based on real-time observations of the interference states in the different spectrum blocks. The estimation is done by averaging a sufficient number of samples for each parameter. To ensure that the estimated value has properly converged to the real value, the γ confidence interval is used. More specifically, let us consider the estimation of a transition probability of link i from state k to state k' as $P_{k,k'}^{(i)}$, called P from now on for simplicity reasons. Let us define $\overline{P}$ as the mean of this parameter after averaging a total of N samples. The Υ confidence interval can be defined as the interval $[\overline{P_{\min}(N)}, \overline{P_{\max}(N)}]$ such that the real value of P falls within this interval with probability Υ:

$$P_r\left[P \in [\overline{P_{\min}(N)}, \overline{P_{\max}(N)}]\right] = \Upsilon \tag{5}$$

Assuming large-sample conditions, the values of the Υ confidence interval after averaging N samples are given by:

$$\overline{P_{\min}(N)} = \overline{P(N)} - z_{(1-\Upsilon)/2}\frac{\overline{\sigma_P(N)}}{\sqrt{N}}\Upsilon \tag{6}$$

$$\overline{P_{\max}(N)} = \overline{P(N)} + z_{(1-\Upsilon)/2}\frac{\overline{\sigma_P(N)}}{\sqrt{N}}\Upsilon \tag{7}$$

where $z_{(1-\Upsilon)/2}$ is defined as follows:

$$z_{(1-\Upsilon)/2} = \Phi^{-1}(1 - \frac{1-\Upsilon}{2}) \tag{8}$$

Function $\Phi(\cdot)$ denotes the inverse of the normal cumulative distribution function, and $\overline{\sigma_P(N)}$ in (6) and (7) is the standard deviation with N samples. Note that as the number of samples N increases, the Υ confidence interval gets narrower, meaning that the estimation given by the sample mean $P_{\min}(N)$ tends to converge to the real value. Then, the required number of samples N that provides a sufficiently accurate estimate of parameter P by its sample mean $\overline{P(N)}$ is the first value of N that fulfills the following convergence condition:

$$\overline{P_{\max}(N)} - \overline{P_{\min}(N)} < \eta \overline{P(N)} \tag{9}$$

where $0 < \eta < 1$ is a parameter to be set; here it is assumed to have $\Upsilon = 95\%$, so that the term $z_{(1-\Upsilon)/2}$ in (6) and (7) equals 1.96.

The KM is also in charge of computing the analysis of the belief vector based on the information stored in the KD. In detail, the belief vector $\mathrm{b}^{(\mathrm{i})}$ at time $t - m^{(i)}$ (i.e., when the last observation of the actual interference state was taken in the i-th spectrum block) is given by:

$$\mathbf{b^{(i)}}(t - m^{(i)}) = \mathbf{x}(S^{(i)}(t - m^{(i)})) \tag{10}$$

where $\mathbf{x}(k)$ is defined as a column vector of $K + 1$ components numbered from 0 to K that has all of them equal to 0 except the k-th component, which is equal to 1. Then, the belief vector at a time instant $t - m^{(i)}$ can be obtained at the previous time step $t - 1$ using the state transition probability matrix $\mathbf{P^{(i)}}$ stored in the KD as follows:

$$\mathbf{b^{(i)}}(t) = \mathbf{b^{(i)}}(t-1)[\mathbf{P^{(i)}}] \tag{11}$$

By recursively applying (11) for the last $m^{(i)}$ time steps and making use of (10), the belief vector at time t as a function of the last observation is given by:

$$\mathbf{b^{(i)}}(t) = \mathbf{b^{(i)}}(t - m^{(i)})[\mathbf{P^{(i)}}]^{m^{(i)}} \tag{12}$$

This functionality executes the selection of the most appropriate radio spectrum block whenever requested by a radio link in accordance with the statistic information stored in the knowledge management. It also triggers the execution of the measurements of the radio environment made by the Context Awareness (CA). In particular, the proposed spectrum selection strategy based on the belief vector implements the decision provided by the decision-making functionality, which maximizes the expected reward and that can be particularized for the following observation strategies:

- *Instantaneous Measurements (IM) strategy*: It consists of performing instantaneous measurements of the interference states in all the spectrum blocks at the time t when a new session has to be established, i.e., at the time when the spectrum selection decision-making is executed. In this case, the belief vector always is computed with $m^{(i)} = 0$ to capture the exact interference state at time t.
- *Periodic Measurements (PM) strategy*: It consists of performing periodic measurements of the i-th spectrum block with observation period $T_{\text{obs}}^{((i))}$. In this manner, the elapsed time $m^{(i)}$ between the last observation of the i-th spectrum block and the decision-making time t will always be upper-bounded by $m^{(i)} < T_{\text{obs}}^{((i))}$.
- *Steady-state (StS) strategy:* It is the case when no actual observations are performed. In this case, it can be easily proved making use of the properties of the ergodic discrete-time Markov processes that the values of the belief vector will be equal to the steady-state probabilities [36].

In the decision-making entity, the following functionalities are implemented: (i) the *observation strategy decision-making* in charge of selecting one of the observation strategies among the IM, the PM, and the StS to be applied in the i-th spectrum block depending on the traffic generation patterns and the interference behavior and (ii) the *spectrum selection decision-making* in charge of selecting a spectrum block each time that a new session is established in the j-th radio link particularized for one of selected observation strategies. Moreover, it targets the maximization of the expected reward that the session will experience along its duration D_j at future time instants $t + n$ relying on the belief vector, which can be achieved recursively through (11), leading to:

$$\mathbf{b^{(i)}}(t+n) = \mathbf{b^{(i)}}(t)[\mathbf{P^{(i)}}]^n \tag{13}$$

Then, the *action* implemented in the spectrum selection decision-making policy introduced by (4) is reformulated as:

$$a_i(t) = \arg\max_i \frac{1}{\overline{D_j}} \sum_{n=1}^{\overline{D_j}} \mathbf{b^{(i)}}(t+n)\mathbf{r_j^{(i)}} \tag{14}$$

where $\mathbf{r_j^{(i)}}$ represents the reward vector of the j-th link in the different interference states of the i-th spectrum block and $\mathbf{b^{(i)}}(t+n)$ is achieved by (13). Notice that $\mathrm{b^{(i)}}(t)$ in (13), which is computed through (12) by the KM, provides at the decision-making time t the future evolution of the reward in each of the spectrum blocks until the session end, exploiting past measurements of the interference state together with the statistical characterization of the interference dynamics. Finally, given that the session duration D_j is typically unknown at the decision-making time t, it is assumed to be characterized statistically in terms of its average value.

The CA entity is responsible for acquiring the required measurements to support the operation of the Knowledge Management entity. Specifically, it will provide the different observations that will be used by the KM and stored in the KD. Measurements will be triggered either by the decision-making functionality in accordance with the observation strategy or by the *initial acquisition functionality* implemented in the KM.

The control entity will provide the signaling means to support the communication between the cognitive management entity and the different nodes of the network. In the context of the spectrum selection processes considered in this chapter, two main functions are envisaged for this control entity:

- Whenever a new session has to be established in a given radio link, the control entity will trigger the decision-making requesting the allocation of a spectrum block and will inform the involved nodes about the result of this allocation.
- Whenever the CA needs to collect a measurement at a certain node of the network, the control entity will exchange the necessary signaling messages with this node to request and retrieve the measurement.

The signaling exchange relies on a cognitive control channel that allows for the transmission of different information elements and the realization of diverse operations within a cognitive radio system. Details on the specific implementation and signaling exchange are outside the scope of this chapter.

Real-Time Testbed Design and Implementation

This section presents the real-time testbed developed to implement and evaluate the spectrum management solutions illustrated in section "Proposed Framework for Spectrum Management". In detail, section "Individual Node" presents the implementation of the individual node with details about hardware and software components, while section "Testbed Architecture" illustrates the architecture of the platform for the implementation of the framework for spectrum management based on the belief vector, in which an individual node can implement both the centralized framework and a user node.

Individual Node

Each individual node is implemented through Universal Software Radio Peripheral (USRP) version 1 integrated boards [37] controlled by a Personal Computer (PC) running Linux Operating System (OS) where GNU radio [38], a software for properly configuring the transmission and reception parameters of the USRP modules, is implemented. The Linux OS was selected for the implementation of the testbed for its capability to guarantee appropriate levels of real-time management while guaranteeing a high degree of flexibility and for its interprocess communication

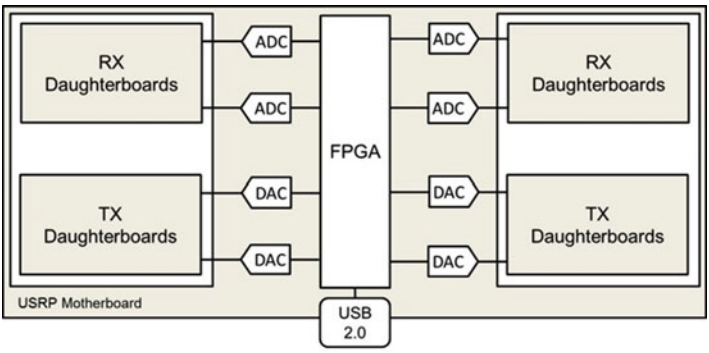

Fig. 8 USRP motherboard

methods considered in order to exploit the auto reconfigurability functionality of the hardware.

USRP incorporates Analog to Digital and Digital to Analog Converters (ADC/DAC), a Radio Frequency (RF) front end, a Field-Programmable Gate Array (FPGA), and a USB 2.0 interface to connect to the PC. A typical setup of the USRP board is illustrated in Fig. 8, and it consists of one motherboard that supports up to four daughterboards, where up to two receivers and up to two transmitters can be plugged in. The RF front ends are implemented on the daughterboards.

In details, the motherboard contains 4 high-speed 12-bit ADCs and 4 high-speed 14-bit DACs. All the ADCs and DACs are connected to the FPGA that performs high bandwidth math procedures such as filtering, interpolation, and decimation. The DACs clock frequency is 128 Msample/s, while ADCs work at 64 Msample/s to digitize the received signal. The USB 2.0 controller sends the digital signal samples to the PC in 16-bit I and 16-bit Q complex data format (4 bytes per complex sample); since the maximum USB data rate is 32 MB/s, 8 Msample/s is the maximum sample rate manageable by the USB controller. Consequently, the FPGA has to perform filtering and digital down-conversion (decimation) to adapt the incoming data rate to the USB 2.0 and PC computing capabilities. The maximum RF bandwidth that can be handled is thus 8 MHz. There exist different kinds of daughterboards that allow a very high USRP reconfigurability. A complete list of daughterboards that can be used with the USRP motherboard can be found in [37], while, in the testbed proposed in this chapter, Transceivers *XCVR2450* working in the frequency ranges 2.4–2.5 GHz and 4.9–5.9 GHz have been used.

Notice that the first range includes specifically the 13 sub-bands around the 2.4 ISM band (2.412–2.472 GHz in 5 MHz steps), used by Wi-Fi applications (i.e., IEEE 802.11b, 802.11g, and 802.11n standards). The bands from 5.170 to 5.320 GHz and from 5.500 to 5.825 GHz are also used by Wi-Fi applications (i.e., IEEE 802.11a standard). The bandwidth of each Wi-Fi channel is 20 MHz, and the mentioned ranges are illustrated in Fig. 9.

GNU radio software is a free and open-source toolkit that provides a library of signal processing blocks like modulators, demodulators, lters, etc., for building

SDRs. It is an empowering tool that enables to explore new ways of using the electromagnetic spectrum growing into a widely used cross-platform package that supports SDRs. In GNU radio, the programmer builds a SDR by creating a graph where the vertices are signal processing blocks and the edges represent the data flow between them. All the signal processing blocks are written in C++; these blocks process streams of data from their input port to their output one. The input and output ports of a signal process block are variable; hence, a block can have multiple outputs and multiple inputs. Python programming language is used to create a network or graphs and glue the signal processing blocks together.

The Simplified Wrapper and Interface Generator (SWIG) is an open-source package used by GNU radio as a glue such that the C++ classes can be used from Python. SWIG has the ability to convert the C++ classes into Python-compatible ones. As a result, the whole GNU radio framework is capable of putting together and exploiting the benefits of both C++ and Python. The input and output ports of a signal process block are variable; hence, a block can have multiple outputs and multiple inputs. GNU radio has been used to implement all the processes carried out at the different entities of the proposed cognitive management framework described section "Proposed Framework for Spectrum Management". Moreover, GNU radio has been considered to enable the data and control communication between USRP transceivers. There is also a graphical environment available to create a custom radio called GNU Radio Companion (GRC) [38], which allows connecting graphically the signal processing blocks. Figure 10 illustrates an example of screenshot of the GRC.

Figure 11 illustrates a general scheme of two USRP nodes acting as transmitter and receiver, respectively, reflecting the transmission and reception processes and

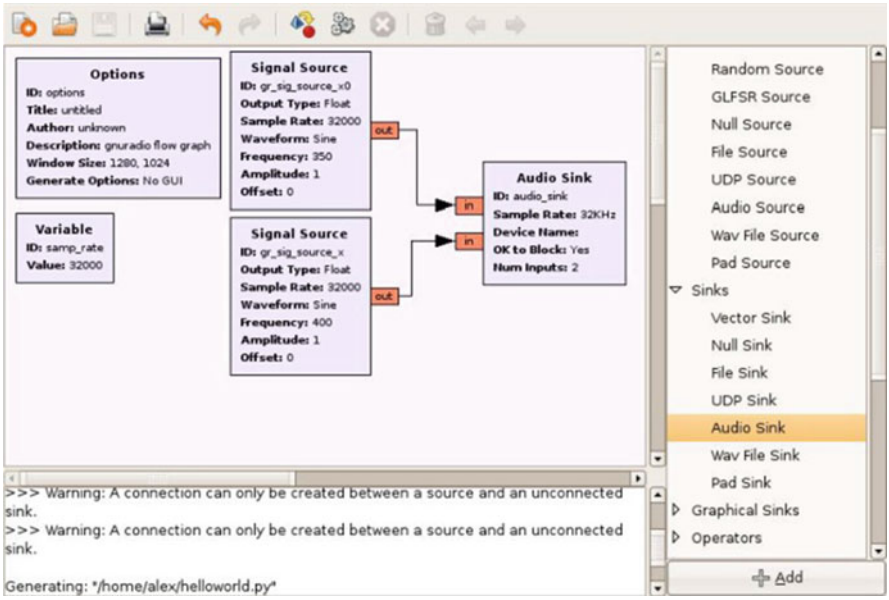

Fig. 10 GNU Radio Companion screenshot

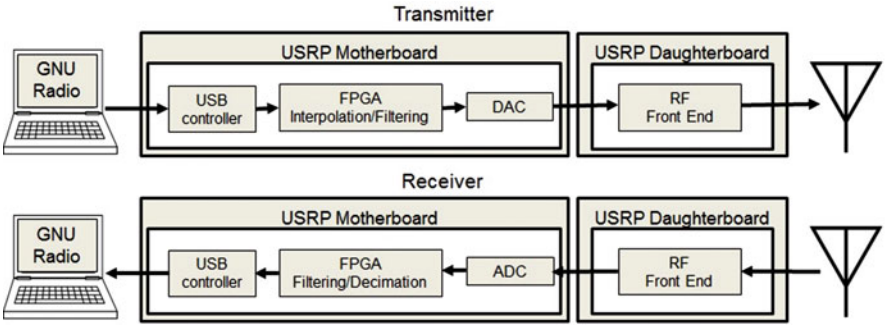

Fig. 11 Transmitter/receiver nodes implemented through USRP and GNU radio

the connection of the PCs running GNU radio software to the hardware platforms. Each individual node can act as either transmitter or receiver in the testbed, and it provides spectrum sensing and data transmission functionalities. Regarding the spectrum sensing functionality, it is exploited by the CA implemented in the node that represents the cognitive management entity in order to provide the observations in the belief-based spectrum selection solution proposed in section "Proposed Framework for Spectrum Management". Moreover, this functionality is exploited by the KM during the *initial acquisition functionality* implemented to estimate the transition probabilities stored in the KD. The spectrum sensing implemented in the nodes is based on measurements performed by means of the energy detection

functionality implemented in the USRPs. Energy detection for each spectrum block is performed during a sensing time Δt_m. Then, based on the detected energy, the CA identifies the interference states of each spectrum block. The energy threshold to decide if a spectrum block is free of interference is set based on [39].

The script "*usrp_spectrum_sense.py*" has been considered for the design of the spectrum sensing functionality implemented in the individual node of the testbed; it can be found in the toolkit provided by GNU radio software. This script has been used as a basic code for implementing a wideband spectrum analyzer. In details, the script has been extended in order to properly sense the spectrum bands considered in the strategies explained in the next sections. The USRP cannot examine more than 8 MHz of RF spectrum due to the USB 2.0 limitations. Notwithstanding, USRP RF front end can be tuned in suitable steps in order to scan across a RF spectrum wider than 8 MHz.

The script receives several input parameters from the user such as the lowest frequency of the band to be sensed $f_{\min}$, the highest frequency of the band to be sensed $f_{\max}$, how long the spectrum sensing functionality is executed in the entire frequency range whose bandwidth is $f_{\max} - f_{\min}$, the decimation factor that adapts the incoming data rate to the USB 2.0 and PC computing capabilities, and the Fast Fourier Transform (FFT) size parameter that is the number of samples considered to perform the magnitude analysis of the sensed signal. In particular, the selection of this parameter allows dividing the entire frequency range to be sensed into smaller spectrum blocks. The output of this script provides the signal energy detected in each sample during the execution of the spectrum sensing functionality.

Regarding the data transmission functionality, it allows sending either signaling messages among nodes or user data between a pair of terminals. The data transmission functionality has been implemented through the GNU radio "*benchmark_tx.py*" and "*benchmark_rx.py*" scripts. In details, the file "*benchmark_tx.py*" is the transmitter code that generates packets whose size is specified by the user, while the file "*benchmark_rx.py*" is the receiver code, which listens for incoming packets and checks for errors in each received one through the Cyclic Redundancy Check (CRC) error-detecting code. These scripts take the following input parameters from the users: a modulation scheme between the Gaussian Minimum Shift Keying (GMSK) and the Differential Binary Phase Shift Keying (DBPSK), the data transmission bit rate, the packet size, and the central frequency of the spectrum block for the data transmission.

The main problem found in these scripts is that the implementation uses only one way data flow; therefore, the transmitter cannot receive ACK (positive acknowledge) or NACK (negative acknowledge) messages useful to allow retransmissions of either lost or erroneous packets. Hence, these scripts have been modified by adding a stop and wait error-control method that uses acknowledgement messages in order to monitor the performance of the data transmission. Stop and wait is the simplest kind of Automatic Repeat reQuest (ARQ) method.

In an ARQ scheme, a number of parity-check bits are generated for each block of information and then transmitted together with the information. At the receiver side, the parity checking is performed on the received data. If the parity checking

is successful, the received block is assumed to be error-free, delivered to higher layers, and the receiver notifies that the block has been successfully received sending an ACK. If there is a parity failure, errors are detected in the received data, and the transmitter is requested sending a NACK in order to retransmit the same block of information. The stop and wait scheme implemented in the testbed enables the following procedures illustrated in time line order:

- "*benchmark_rx.py*" takes the input parameter and then it listens to the selected spectrum block waiting for data reception;
- "*benchmark_tx.py*" takes the input parameter and then it sends the i-th packet to "*benchmark_rx.py*";
- "*benchmark_rx.py*" checks for a possible error in the received packet through the CRC, and it sends the corresponding acknowledgement message to "*benchmark_tx.py*";
- "*benchmark_tx.py*" waits for the i-th ACK or NACK message from "*benchmark_rx.py*" during a certain time (defined as timeout);
- if the i-th ACK is received before the timeout is expired, then "*benchmark_tx.py*" sends the next packet to "*benchmark_rx.py*";
- if the i-th NACK is received or the i-th ACK is not received before the timeout is expired, "*benchmark_tx.py*" retransmits the i-th packet to "*benchmark_rx.py*".

Testbed Architecture

The testbed consists of six reconfigurable individual nodes to implement two terminals communicating through the radio link, the central node where the cognitive management processes are executed, and three nodes representing interference sources; see Fig. 12. Node#1 in the figure is the centralized entity where the framework of Fig. 7 has been implemented. Node#2 and Node#3 are the terminals that need to establish a radio link for supporting a data communication under the control of Node#1 that will decide the spectrum block to be used by this radio link. The control messages are sent among the nodes through Ethernet cables. Nodes#4, #5, and #6 are external interference sources transmitting in certain spectrum blocks.

Node#1 includes the decision-making, the knowledge management, and the CA functionalities. Specifically, the CA entity performs measurements by means of the spectrum sensing functionality implemented in the USRPs for each spectrum block during a sensing time Δt_m. Then, based on the detected energy, the CA identifies the interference states of each spectrum block. These measurements are triggered either by the KM during the *initial acquisition functionality* in order to fill the KD with transition probabilities of the spectrum blocks or by the decision-making in accordance to an observation strategy selected among the IM, PM, and StS by the *observation strategy decision-making*.

By properly processing the measurements of the interference states, the KM derives samples of the durations of each state. From these durations, the KM estimates the values of state transition probabilities and steady-state probabilities

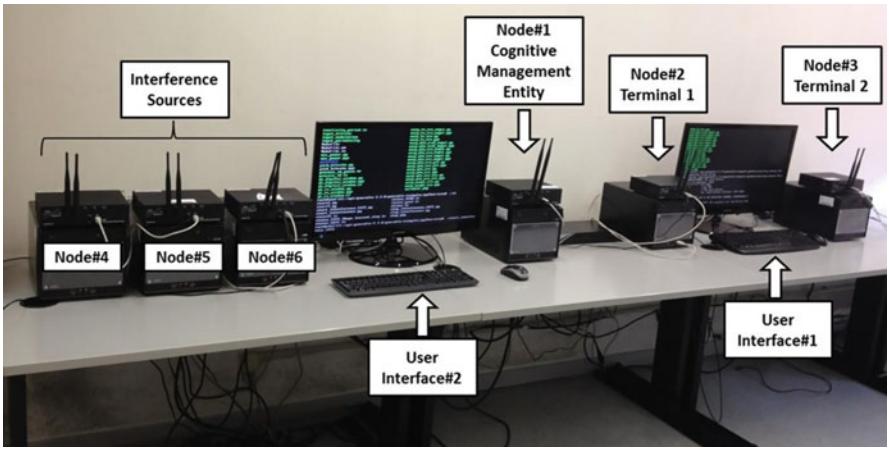

Fig. 12 Testbed architecture for the belief-based spectrum selection

to be stored in the KD through the *initial acquisition functionality*. The estimation of each parameter will be done as the average of a sufficient number of sample that ensures convergence under some reasonable limits, as explained in section "Proposed Framework for Spectrum Management". In particular, the considered convergence condition in this chapter is that the size of the 95% confidence interval of every measured parameter is below a fraction of the measured average value. The convergence criterion defined in section "Proposed Framework for Spectrum Management" is used with $\eta = 0.2\%$.

The KM is in charge of providing the *observation strategy decision-making* implemented in the decision-making with the dynamism information of the radio environment in terms of traffic generation patterns. Moreover, each time that a new session is established in a radio link, the KM provides the data function parameters to the *spectrum selection decision-making* that selects the most appropriate spectrum block following (12) particularized for the observation strategy decided in the *observation strategy decision-making* entity.

Node#2 is programmed to compute periodically the system session reward in order to measure the achieved performance depending on the experienced bit rate in the allocated spectrum block. Moreover, the USRP-based interference sources implemented in Nodes #4, #5, and #6 are transmitting in specific spectrum blocks following random patterns whose statistics can be controlled at the testbed configuration. As seen in Fig. 12, two screens connected to two switches are the user interfaces that allow running and controlling the testbed operation. Specifically, the User Interface#1 allows configuring the parameters of the cognitive management entity and the communicating terminals, while the User Interface#2 allows the configuration of the interference sources. In each emulation run, the testbed produces a number of performance statistics that are stored in files so that they can be post-processed later on. In particular, statistics related to the performance obtained in the

communication through the radio link between Terminal 1 and Terminal 2 are stored in Node#2, while the statistics related to the cognitive management entity are stored in Node#1.

Performance Evaluation

Configuration

The emulation assumptions and scenario parameters that have been considered are described in the following. A set of $M = 3$ spectrum blocks are taken into account. The bandwidth is 200 kHz for all the spectrum blocks, and the central frequencies are 5472, 5490, and 5508 MHz. Two different interference states are considered for the spectrum blocks: $S^{(i)} = 0$ when no interference exists and $S^{(i)} = 1$ when the interference corresponds to its maximum value. The average durations of the interferences states for each spectrum block are presented in Table 1, considering that the testbed operates in time steps of 10 s.

$L = 1$ radio link is considered to transfer the data flow between Node#2 and Node#3 of the testbed (see Fig. 12) with bit rate requirement $R_{\text{req}} = 512$ kbps. During the data transmission sessions, Node#2 computes the system session reward value in the selected i-th spectrum block. Different values of the average link session duration $\overline{D_j} = \overline{D}$ and average session rate ρ are considered as indicated in Table 2. Specifically, three different scenarios are considered with different values of session duration and session generation rate. This allows demonstrating the effect of the observation and decision-making strategies under different situations in terms of traffic patterns. For the PM strategy, the observation period $T_{\text{obs}}^{(i)}$ is set to 2 time steps.

In order to assess the performance of the proposed observation strategies, appropriate KPIs are also defined for the belief-based policy for the performance study in the real-time environment provided by the testbed. In particular:

Table 1 Characterization of the interference states

Spectrum block	State $S^{(i)} = 0$ (time steps)	State $S^{(i)} = 1$ (time steps)
#1	480	120
#2	60	480
#3	480	160

Table 2 Characterization of the scenarios

Scenario	$\overline{D_j} = \overline{D}$ (time steps)	ρ (sessions/time step)
1	15	0.013
2	15	0.063
3	500	1.810-3

- *Average system session reward:* it is the reward experienced by each data transmission session depending on the interference state of the allocated spectrum block averaged along the total emulation time.
- *Average throughput:* it is the bit rate in kb/s achieved in the radio link averaged along the total emulation time.
- *Observation rate:* it is the average number of observations per time step that are performed to determine the interference state of the different spectrum blocks during the system operation. This KPI is only applicable to IM and PM policies, while StS strategy does not require observations.

Performance Results

This section compares the performance obtained in a real-time environment by each of the observation strategies and associated spectrum selection decision-making criteria considered in section "Proposed Framework for Spectrum Management", namely, IM, PM, and StS, respectively. For this purpose, the different scenarios considered in Table 2 are evaluated during a total emulation time $T_{em} = 3600$ steps (i.e., 10 h) starting from the time when the KD statistics have been acquired under the considered convergence criterion enabled through the *initial acquisition functionality* and implemented in the KD.

Figures 13, 14, and 15 present the time evolution of the average system reward for the different strategies in all the scenarios. As a baseline reference, the random strategy in which the spectrum block is randomly selected among the available ones at the time that each session is established is also included in the comparison. Table 3 summarizes the average reward, throughput, and observation rate for the different strategies along the whole emulation time. Moreover, the last column of Table 3 indicates the strategy that will be selected by the proposed *observation strategy decision-making* entity in each of the considered scenarios.

It can be observed from the figures and Table 3 that the proposed strategies in all the scenarios allow achieving a clear improvement in terms of both reward and throughput with respect to the random selection of the spectrum block. Focusing on scenario 1, the session duration is much shorter than the interference dynamics, and the session generation rate is low. Results in Fig. 13 and Table 3 show that IM outperforms PM and StS in terms of reward and throughput. Moreover, it allows achieving the highest reward and throughput with reduced requirements in terms of observation rate. On the contrary, scenario 2 is characterized by a higher session generation rate. In this case, it can be noticed that IM suffers an increase in the observation rate that is almost five times higher than with scenario 1. PM strategy becomes a better option since it allows achieving a similar reward and throughput as IM but with much less observation requirements, as seen in Table 3 and Fig. 14. Moreover, it achieves an important improvement in terms of reward and throughput in around 15% with respect to StS.

Scenario 3 is characterized by a session duration that is much longer compared to the session generation rate. In this case, results in Table 3 and Fig. 15 reveal

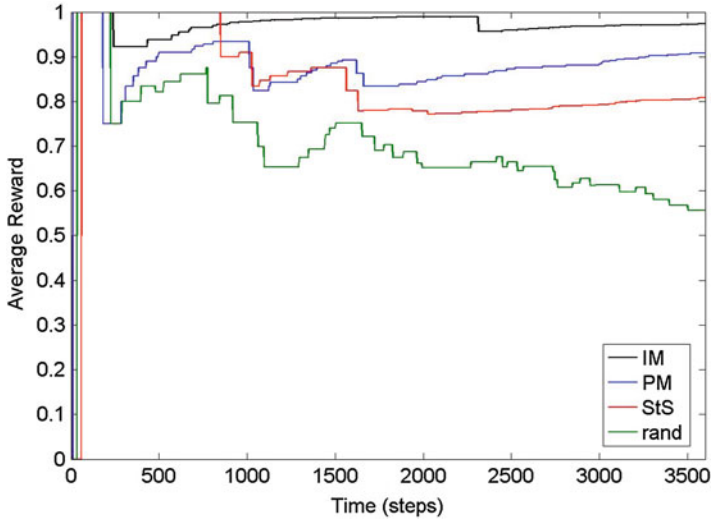

Fig. 13 Avg. system reward scenario 1 emulated by the testbed

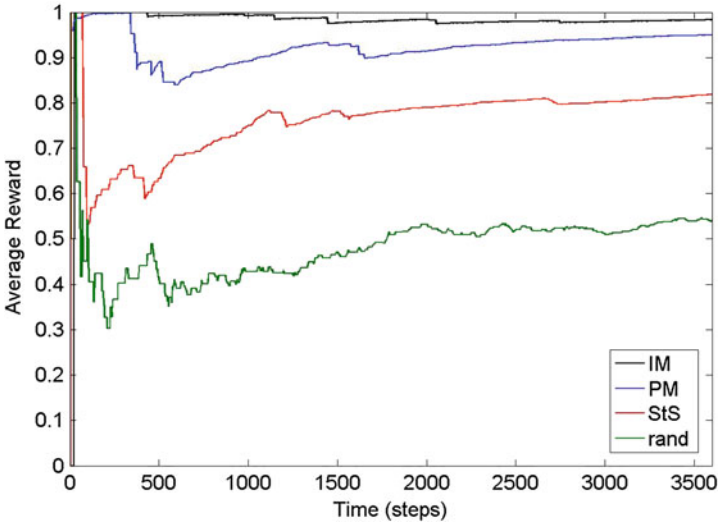

Fig. 14 Avg. system reward scenario 2 emulated by the testbed

that IM, PM, and StS techniques tend to converge to similar values of the reward and the throughput. The reason is that, when a spectrum block is allocated to a link for a long time, the link will tend to experience the steady-state conditions in this spectrum block. Therefore, the reward estimation based on the steady-state probabilities made by the StS at the decision-making time becomes a good estimate

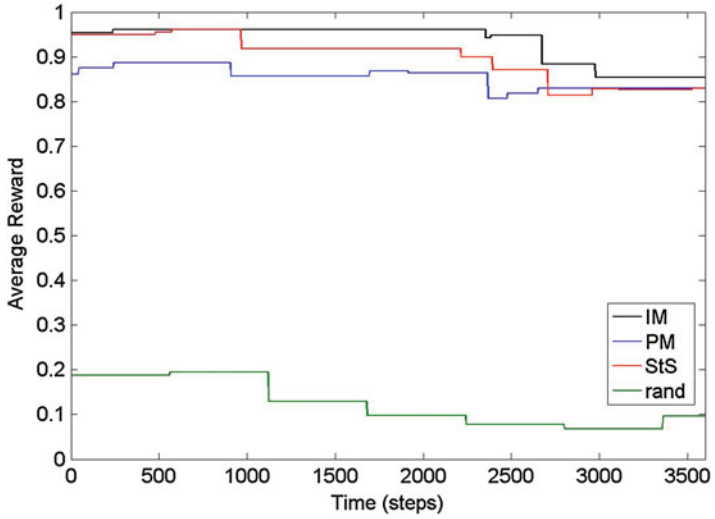

Fig. 15 Avg. system reward scenario 3 emulated by the testbed

of the actual performance that will be achieved. Correspondingly, for long session durations, StS becomes the most adequate strategy because it is capable of properly estimating the performance without requiring any observations.

Based on the obtained results, it can be concluded that the traffic generation pattern plays a key role when deciding the most adequate observation strategy in a belief-based decision-making approach. For long session durations (see scenario 3 with D_j equal to 500 time steps), the best approach is the decision-making based on steady-state conditions because it allows properly estimating the performance without requiring dynamic observations of the environment. On the contrary, for shorter session durations, the choice between IM and PM is related to the session arrival rate ρ that reflects the rate at which the spectrum selection functionality is triggered. In particular, a belief-based decision-making with periodic observations becomes a good approach for large session generation rates ρ, because it allows achieving good performance in terms of reward while significantly reducing the observation rate requirements, while for lower session generation rates, it is more convenient the IM approach.

The presented results focused on the performance achieved after the proper convergence of the KD statistics in the *initial acquisition functionality*. In order to complement the analysis, the operation of this functionality is studied next. Specifically, Fig. 16 depicts the initial acquisition process for one of the parameters stored in the KD, namely, the state transition probability $p^{(1)}_{(0,0)}$ for spectrum block #1. To compute it, the CA entity performs on spectrum block #1 a measurement once per time step during a sensing time $\Delta t_m = 2$s. Then, based on the detected energy, it sends the interference state to the KD acquisition entity where the different samples

Table 3 Average performance in terms of reward, throughput (kb/s), and observation rate (observations/time step)

Scenario	KPI	IM	PM	StS	Random	Best observation strategy
1	Reward	0.97	0.91	0.79	0.55	IM
	Throughput	491	465	406	274	
	Observation rate	0.04	0.06	0.0	0.0	
2	Reward	0.98	0.95	0.82	0.54	PM
	Throughput	502	486	413	305	
	Observation rate	0.19	0.06	0.0	0.0	
3	Reward	0.85	0.83	0.83	0.09	StS
	Throughput	441	388	409	47	
	Observation rate	0.01	0.07	0.0	0.0	

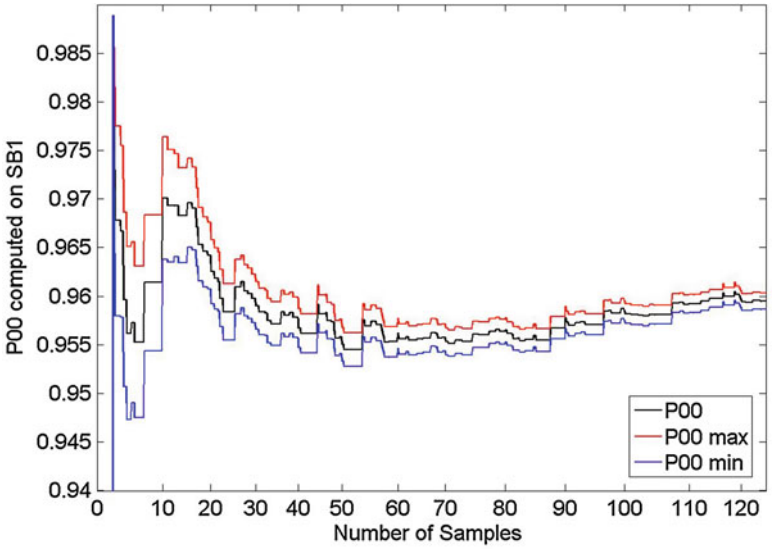

Fig. 16 Evolution of the initial acquisition process for parameter $p^{(1)}_{(0,0)}$

of $p^{(1)}_{(0,0)}$ are computed. Figure 16 presents the evolution of the sample average $\overline{p^{(1)}_{(0,0)}}$ and the 95% confidence interval bounds $p^{(1)}_{(0,0,\text{min})}$ and $p^{(1)}_{(0,0,\text{max})}$ as a function of the number of samples N. It can be observed in the figure how the confidence interval gets narrower when increasing the number of samples. Then, considering the convergence condition with parameter $\eta = 0.2\%$, it is shown in the figure that the convergence is achieved after $N = 100$ samples. The sample average $\overline{p^{(1)}_{(0,0)}}$ existing at this point of time is the one stored in the KD.

Conclusions and Future Directions

In this chapter, an overview of the Cognitive Radio paradigm has been presented as an innovative solution to mitigate the spectrum scarcity problem by enabling Dynamic Spectrum Access. It provided a general description of the CR paradigm including the so-called cognitive cycle and then the basic DSA concepts with particular emphasis on the different existing models and the exploitation of the CR cycle. The modeling of cognitive strategies for spectrum management suitable for different scenarios and use cases in the context of DSA/CR networks is also presented. A belief-based framework for decision-making in CR networks has been introduced, focusing on the spectrum selection problem where a number of radio links with different requirements have to be established. This exploits the belief vector concept to predict the environment dynamics at the decision-making time and in later instants based on past measurements. In this context, the chapter has analyzed the trade-off existing between performance and observation requirements of the cognitive cycle. For that purpose, a general formulation of the belief-based decision-making has been presented and has been particularized for different observation strategies. These have been evaluated to assess the impact of the environment dynamics in terms of the traffic generation patterns.

Results have demonstrated that for long session durations, a steady-state-based strategy that does not require dynamic observations becomes the best approach. Instead, for short session durations, the use of periodic measurements achieves a good trade-off between reward and observation rate for large session generation rates, while for low session generation rates, the use of instantaneous measurements made at the decision-making time becomes adequate.

The cognitive management frameworks presented in this chapter provide new research possibilities in the practical development of other aspects in the context of LTE that currently is the most advanced International Mobile Telecommunications (IMT) technology. Although LTE operating in licensed spectrum is characterized by a prominent deployment across the world, the integration of unlicensed carrier has been proposed as an innovative and promising way to further expand its capacity and to meet the growing traffic demands. This integration, which is carried out by adapting LTE air interface to operate in the unlicensed spectrum, leads to the so-called Unlicensed LTE (U-LTE) technology. Regarding the spectrum regulation in the context of U-LTE, the 5 GHz band is considered as the main candidate in terms of large amounts of unlicensed available spectrum, as well as relatively good channel propagation performance. One of the challenging topics in the context of U-LTE is the definition of spectrum management policies [40, 41] such as mechanisms of Dynamic Frequency Selection (DFS) based on spectrum sensing strategies, which allow avoiding interference among IMT devices and to non-IMT systems working at the same band (e.g., radar systems). For instance, Listen-Before-Talk (LBT) techniques are designed and enforced by EU regulations, in order to impose a flexible and fair coexistence among IMT systems by enabling channel sensing before the use of the spectrum resource and dynamic channel occupancy.

Abstract

The device in conventional half-duplex WiFi networks cannot perform carrier sensing while in data transmission; thus it suffers from long collision duration. To mitigate this problem, this chapter introduces full-duplex (FD) technology into WiFi networks. A novel CSMA/CD protocol design is first presented for single-channel FD-WiFi, which facilitates continuous carrier sensing and transmission suspension. The network throughput performance is comprehensively analyzed by considering possible sensing errors (i.e., false alarm and miss detection) due to self-interference, and simulation results verify the performance analysis and the effectiveness of CSMA/CD protocol. Then the protocol for multi-channel FD-

WiFi is provided, where the CSMA/CD protocol for accessing a certain channel is modified by adopting a contention window adjustment rule, and a distributed channel selection strategy is proposed based on the best-response algorithm. Simulation results indicate the performance improvement of multi-channel FD-WiFi protocol design.

WiFi Network Basics

WiFi technologies have received a rapid proliferation over the past few decades [1]. As a part of the 802 standard family, IEEE 802.11 provides an international standard for the conventional WiFi networks. Detailed medium access control (MAC) and physical layer (PHY) specifications for the 802.11 protocol are summarized in [2].

The fundamental access mechanism for 802.11 protocol is the distributed coordination function (DCF), which is a random access scheme and based on carrier sense multiple access with collision avoidance (CSMA/CA) [3, 4]. In DCF, users are required to listen to the channel before access. If the channel is sensed busy, users need to wait until channel becomes idle; then they enter into a random backoff procedure. This prevents multiple users from accessing the medium immediately after completion of the preceding transmission and leading to collisions.

Specifically, in the CSMA/CA protocol, every active node which has a new packet for transmission monitors the channel activity first. The node persists to carrier sense until the channel is measured idle for a period of time equal to a distributed interframe space (DIFS). At this point, the node generates a random backoff time by setting an internal timer to an integer number of slot times, which can be expressed as the following:

$$\text{Backoff Time} = \text{Rand(CW)} \times \text{Slot Time}, \tag{1}$$

where CW is called the contention window. The backoff time decreases in any slot as long as the channel is sensed to be idle, "freezes" when the channel is judged busy, and "reactivates" decrement when the channel is sensed idle again for a DIFS. The active node transmits the data packet when its backoff timer counts down to zero.

However, the collision is still possible due to concurrent transmission between different users. The exponential backoff scheme is thus adopted in the CSMA/CA protocol to further reduce collision. At the first transmission attempt, the user's backoff stage is zero and CW is set equal to $\text{CW}_{\min}$, called the minimum contention window. After each successful transmission, the backoff stage increases and CW is doubled, up to the maximum contention window $\text{CW}_{\max} = 2^{W_{\max}}\text{CW}_{\min}$, in which $W_{\max}$ is called the maximum backoff stage.

Upon packet reception, the acknowledgment (ACK) is required, i.e., the receiver transmits an ACK signal back after the interval of one short interframe space (SIFS)

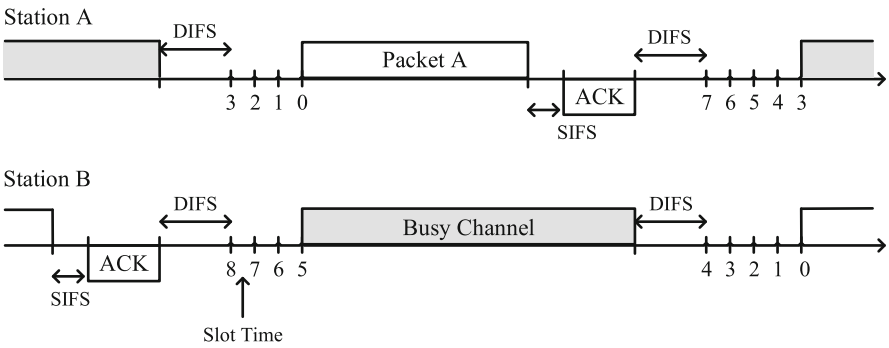

Fig. 1 Example of CSMA/CA protocol in conventional WiFi networks

when transmission is finished. The SIFS is shorter than the DIFS so that the other contending users cannot start to decrease their backoff time, which means that the ACK has higher priority than other regular transmissions. The transmission is unsuccessful if the transmitter fails to receive the ACK signal.

Figure 1 illustrates an example of the CSMA/CA protocol. Two stations A and B share the same wireless channel for data transmission. At the end of previous data transmission, they wait for a DIFS and randomly choose backoff time. Station A chooses 3 while station B chooses 8. Thus, after three slots, the backoff time of station A counts down to zero, and station A starts to transmit its data packet, during which station B has its backoff time frozen. After station A finishes transmission and the channel is sensed idle again for a DIFS, station B decrements its backoff time, and station A again chooses backoff time and contends the channel.

Although carrier sense is performed in the CSMA/CA protocol, the transmitter's sensing result may wrongly indicate the channel condition at the receiver due to different network topology, which leads to two problems called hidden terminal and exposed terminal [5]. A hidden terminal lies in the transmission range of a receiving station, but it is out of the range of the transmitting station. Therefore, the hidden terminal is oblivious of the ongoing transmission and can initiate a new transmission that will cause a collision at the receiver. The occurrence of these collisions reduces the overall performance of the network. On the other hand, an exposed terminal lies in the transmission range of the transmitter but out of the transmission range of the receiver. Therefore, a transmission initiated by this terminal would not cause a collision at the receiver. However, it remains silent due to the busy channel detection. This effect reduces the overall throughput by stopping some stations from transmitting despite the fact that they would not cause a collision.

To resolve the two problems, the RTS/CTS (request to send/clear to send) scheme is adopted by IEEE 802.11 as an optional mechanism [6]. In this scheme, an active node which wants to transmit a packet, waits until the channel is sensed idle for a DIFS, follows the backoff procedure explained above, and then, instead of the packet, preliminarily transmits a special RTS frame. When the receiving node

detects an RTS frame, it responds, after a SIFS, with a CTS frame. The transmitting node is allowed to transmit data packet only if the CTS frame is correctly received. By listening to RTS/CTS frame, the neighboring nodes of transmitter and receiver can get the transmission range information; thus hidden terminal and exposed terminal problems can be resolved. The main drawback of RTS/CTS scheme is long overhead caused by two frames.

Although the CSMA/CA protocol has been shown effective in the WiFi networks, it suffers from the problem of long collision duration. The main reason is that conventional WiFi networks are based on the half-duplex (HD) technology, due to the limitation of which, unlike the CSMA/CD (collision detection) protocol in Ethernet, the WiFi users cannot perform carrier sense and collision detection once transmitting. Thus if collision happens between some transmitting users, they cannot detect it and still transmit left collided data packets.

The full-duplex (FD) communication technology [7], by which the users can simultaneously transmit and receive data on the same band, has the potential to resolve the problem in conventional HD-WiFi networks. Recent years witness the revival of FD research due to the development of self-interference suppression (SIS) techniques in propagation, analog circuit, and digital domains, which significantly reduce the self-interference to a limited level [8, 9]. Apart from the development of the SIS techniques in PHY layer, some FD-MAC protocols have also been proposed recently [10–13]. In [10], a centralized FD-MAC protocol is proposed with shared random backoff, header snooping, and virtual backoffs. In [11], the authors design a decentralized FD-MAC protocol by adding FD acknowledgment bits. Both protocols in [10] and [11] discuss dual-link transmissions between two and three nodes. While [12] and [13] enable simultaneous spectrum sensing and data transmission for wireless users, the former is for cognitive radio networks and the latter is for ad hoc networks.

To mitigate the long collision duration problem in conventional HD-WiFi networks, similar to [12] and [13], this chapter introduces the FD technology into WiFi networks to realize simultaneous carrier sensing and data transmission. In the rest of this chapter, we first present the proposed CSMA/CD protocol for single-channel FD-WiFi networks [14]; then we extend this FD protocol to the multi-channel WiFi scenario [15].

Full-Duplex CSMA/CD Protocol

In this section, we elaborate the CSMA/CD protocol for single-channel FD-WiFi networks to resolve the long collision duration problem in conventional HD-WiFi networks. By taking advantage of FD techniques, each user can sense the spectrum and determine whether other users are occupying it while transmitting its own data simultaneously. We start with the system model, followed by the FD-WiFi protocol description. Performance analysis and simulation results are provided to show the protocol's effectiveness.

System Model

As shown in Fig. 2, we consider a FD-WiFi network consisting of one access point (AP) and N users $(U_1, \ldots, U_N)$, where the users are independently and randomly distributed in the coverage area of the AP. Each user is equipped with two antennas to realize FD communications. We focus on the uplink traffic, in which data packets are transmitted from the users to the AP, and each user is assumed to always have a packet to transmit with the same transmission power.

The channel can serve at most one user at a time; otherwise the collision happens. Therefore, as shown in the upper part of Fig. 2, each user performs carrier sensing to detect the channel state and contends for the idle channel against each other by the proposed protocol. When a certain user, say U_n $(n \in \{1, 2, \ldots, N\})$, accesses the channel, it uses one antenna for carrier sensing and the other antenna for data transmission simultaneously. However, the residual self-interference (RSI) between those two antennas leads to imperfect sensing, as shown in the lower part of Fig. 2. False alarm happens when the user mistakenly judges the channel to be occupied by other users when it is not, while miss detection means that the user fails to detect the channel occupation of other transmitting users. Both of the sensing errors degrade the network performance and, thus, should be taken into consideration for performance analysis. We now further discuss the carrier sensing in FD-WiFi networks as follows.

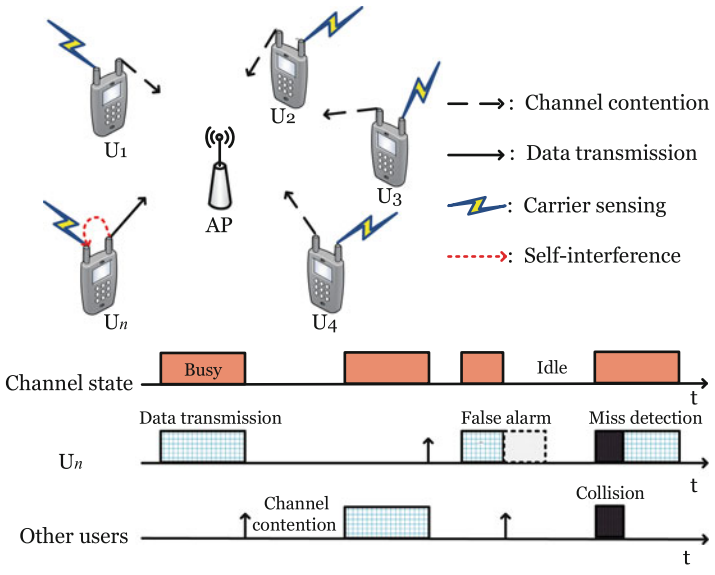

Fig. 2 The CSMA/CD protocol for the uplink traffic of FD-WiFi and two types of sensing errors (false alarm and miss detection) due to self-interference

Full-Duplex Carrier Sensing

Since noise is negligible compared to collision signal and self-interference, it is omitted in this chapter. Thus, a silent user has a perfect sensing, and we only need to analyze the sensing errors for transmitting users. Furthermore, the probability for the case with more than two collided users is negligible compared to the probability that only two users collide, and even when the case happens, the sensing performance is also better due to the accumulated collision signal. Thus perfect sensing is also assumed for the case that three or more users collide, and the sensing errors only exist in the following two cases: (1) $\mathscr{H}_0$, the transmitting user singly occupies the channel and (2) $\mathscr{H}_1$, the transmitting user has a collision with another user.

The received signal for sensing at the transmitting user can be given by

$$y = \begin{cases} h_r s_t, & \mathscr{H}_0, \\ h_r s_t + h_c s_c, & \mathscr{H}_1, \end{cases} \tag{2}$$

where s_t denotes the transmitting user's signal and s_c is the collided user's signal, h_c represents the collision channel, and h_r denotes the equivalent RSI channel indicating the SIS degree, which depends on the adopted SIS techniques and network environment. We adopt a typical path loss Rayleigh fading channel; thus, $h_c s_c$ is zero-mean complex Gaussian distributed with average power $\overline{P}_r(\frac{\overline{d}}{d})^{\alpha}$, where α is the path loss exponent, $\overline{P}_r$ is the reference received signal power at the reference distance $\overline{d}$, and d is the distance between two users. Moreover, according to [16], $h_r s_t$ is also a complex Gaussian variable with zero mean and average power $\beta^2 \overline{P}_r$, where β^2 denotes the SIS factor.

As for the sensing strategy, energy detection is adopted, and we assume the process is time slotted. Thus the sensing test statistics can be given by

$$M = \sum_{m=1}^{N_s} |y(m)|^2, \tag{3}$$

where $y(m)$ denotes the mth sample of received sensing signal and N_s is the sampling number in one slot.

The transmitting user compares M with the sensing threshold to decide whether a collision happens or not. Two types of sensing errors exist, i.e., false alarm and miss detection. As shown in the lower part of Fig. 2, false alarm wastes available channel slots, while miss detection causes collisions. We need to balance the two types of sensing errors to ensure network performance.

CSMA/CD Protocol Design

Based on the FD technology and conventional CSMA/CA concepts, we now propose the CSMA/CD protocol for FD-WiFi networks. Figure 3 shows the proposed protocol, which consists of the following several parts.

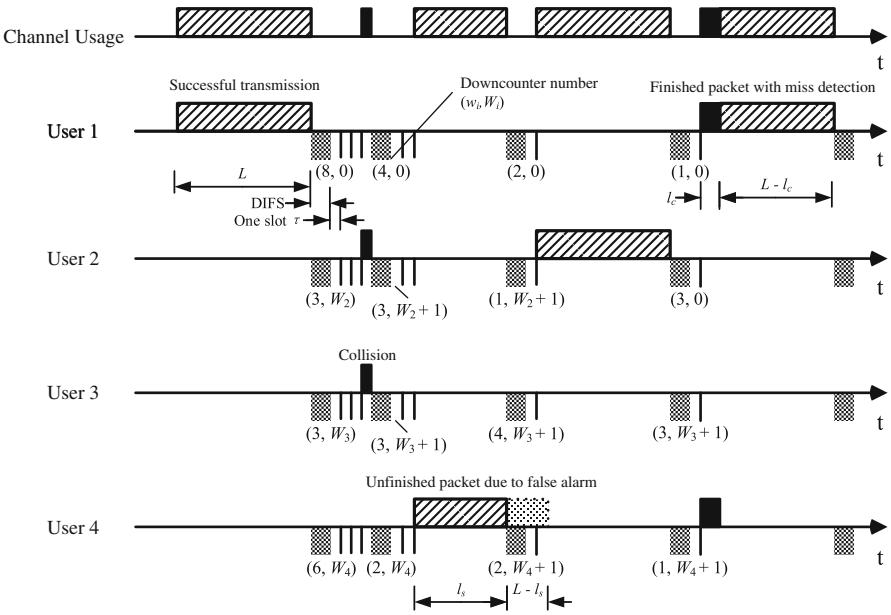

Fig. 3 The proposed CSMA/CD protocol for FD-WiFi networks, in which (w_i, W_i) denotes the residual backoff time and the backoff stage of U_i

Sensing: All users keep sensing the channel continuously regardless of its own activity and make decisions of the channel usage at the end of each slot with duration τ, which is the required time to reliably detect the transmission of any other user.

Backoff mechanism: Once the channel is judged idle without interruption for a certain period of time as long as a distributed interframe space (DIFS) (shown as the dotted area below each line), users check their own backoff timers and generate a random backoff time for additional deferral if their timers have counted down to zero. The additional backoff time after a DIFS is also slotted by τ, i.e., the backoff time is expressed as

$$\text{Backoff Time} = w \times \tau = \text{Random}\,(\text{CW}) \times \tau, \tag{4}$$

where $\text{CW} = 2^W \cdot \text{CW}_{\min}$ is the contention window length and $w = \text{Random}\,(\text{CW})$ is a random integer drawn from the uniform distribution over the interval $[0, \text{CW})$, where $W \in [0, W_{\max}]$ is the backoff stage depending on the number of unsuccessful transmissions for a packet. The countdown starts right after the DIFS and suspends when the channel is detected occupied by others.

Channel access and transmission suspension: A user accesses the channel and begins transmission when its timer reaches zero. During the transmission, if it

detects the signal from other users, it stops its transmission and switches to the backoff procedure immediately. If the packet is finished, the user resets the backoff stage $W = 0$. Otherwise, it sets $W = \min\{W + 1, W_{\max}\}$.

Performance Analysis

In this part, we study the analytical performance of the proposed FD-WiFi CSMA/CD protocol and derive its saturation throughput. We first analyze the carrier sensing performance and derive expressions for sensing error probabilities; then we derive the throughput performance of the CSMA/CD protocol by taking the sensing errors into consideration. Note that when only one user is transmitting, all other users can detect its transmission perfectly, which means that once a collision-free transmission begins, it either completes the packet or suspends it because of false alarm. This process is independent with other users' sensing and contending, and thus, contention and transmission can be considered separately.

Carrier Sensing Performance

We mainly derive the expressions of false alarm probability (p_f) and miss detection probability (p_m). With Rayleigh fading channels, the sampling signal power ($|y(m)|^2$) is Chi-square distributed. Furthermore, M is the sum of sampling signal power in one slot; thus according to [17], M is gamma distributed, the probability density function of which can be expressed as

$$f_M(x) = \frac{x^{N_s-1}e^{-\frac{x}{\phi}}}{\phi^{N_s}\Gamma(N_s)}, \tag{5}$$

where $\phi = \beta^2\overline{P}_r$ and $\phi = \left(\beta^2 + \left(\frac{\overline{d}}{d}\right)^{\alpha}\right)\overline{P}_r$ for $\mathscr{H}_0$ and $\mathscr{H}_1$, respectively.

With a certain sensing threshold ϵ, we can obtain the expressions of p_f and p_m

$$p_f = \mathrm{P_r}(M > \epsilon \mid \mathscr{H}_0) = 1 - \Gamma\left(N_s, \frac{\epsilon}{\beta^2\overline{P}_r}\right), \tag{6}$$

$$p_m(d) = \mathrm{P_r}(M < \epsilon \mid \mathscr{H}_1) = \Gamma\left(N_s, \frac{\epsilon}{\left(\beta^2 + \left(\frac{\overline{d}}{d}\right)^{\alpha}\right)\overline{P}_r}\right), \tag{7}$$

where $\Gamma(m, x) = \frac{1}{\Gamma(m)}\int_0^x t^{m-1}e^{-t}dt$ is the incomplete gamma function. By deriving the expression of ϵ in terms of p_f from (6) and substituting that into (7), the following equations are presented:

$$\epsilon(p_f) = a\beta^2\overline{P}_r, \tag{8}$$

$$p_m(d) = \Gamma\left(N_s, a - \frac{b}{d^\alpha + c}\right), \tag{9}$$

where $a = \Gamma^{-1}\left(N_s, 1 - p_f\right)$, $b = a\frac{\overline{d}^\alpha}{\beta^2}$, and $c = \frac{\overline{d}^\alpha}{\beta^2}$, in which $\Gamma^{-1}(m, x)$ is the inverse incomplete gamma function.

Furthermore, users are independently and randomly distributed in AP's coverage area, the radius of which is denoted by R. Then we can derive the average miss detection probability:

$$p_m = \frac{2}{\pi R^4}\int_0^R \int_0^R \int_0^{2\pi} \Gamma\left(N_s, a - \frac{b}{d^\alpha + c}\right) r_0 r_1 d\theta dr_0 dr_1, \tag{10}$$

where r_0, r_1 are the distances of transmitting user and collided user away from the AP, θ is their included angle, and $d = \sqrt{r_0^2 + r_1^2 - 2r_0 r_1 \cos\theta}$ is the distance between them. We can find that the expression of p_m is related to the path loss exponent. Particularly, when free-space channel is considered, i.e., $\alpha = 2$, we can derive an approximation of p_m:

$$\begin{aligned} p_m &= \frac{2}{\pi R^4}\int_0^R \int_0^R \int_0^{2\pi} \Gamma\left(N_s, a - \frac{b}{d^2 + c}\right) r_0 r_1 d\theta dr_0 dr_1 \\ &\approx \frac{1}{R^4}\left(\int_0^{R^2} x\Gamma\left(N_s, a - \frac{b}{x + c}\right) dx + \int_{R^2}^{2R^2} \left(2R^2 - x\right)\Gamma\left(N_s, a - \frac{b}{x + c}\right) dx\right) \\ &\approx \frac{2}{3}\Gamma\left(N_s, a - \frac{b}{R^2 + c}\right) + \frac{1}{6}\Gamma\left(N_s, a - \frac{b}{2R^2 + c}\right). \end{aligned} \tag{11}$$

According to (6), (7), (8), (9), (10), and (11), p_f is negatively related to ϵ, while p_m is positively related. Therefore, the sensing threshold should be well designed to balance false alarm probability and miss detection probability.

Transmission Probability

To obtain the network throughput, we need to calculate users' transmission probability first. We follow the assumption in [4] that each packet gets collided with the same probability independent of the value of CW_i. Let $\{w_n, W_n\}$ denote the state of the nth contending user. For each user, the state change can be modeled as a discrete-time Markov chain illustrated in Fig. 4. The nonzero transition probabilities are given as

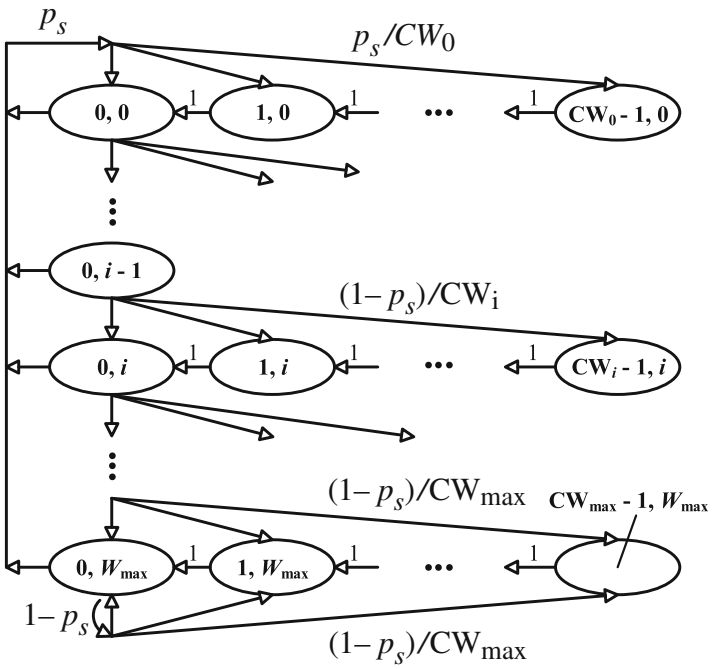

Fig. 4 Discrete-time Markov chain of the backoff window size

$$\begin{cases} P\left(w_n - 1, W_n | w_n, W_n\right) = 1, & w_n \in (0, \mathrm{CW}_i), W_n \in [0, W_{\max}], \\ P\left(w_n, 0 | 0, W_n\right) = \dfrac{p_s}{\mathrm{CW}_{\min}}, & w_n \in [0, \mathrm{CW}_{\min}), W_n \in [0, W_{\max}], \\ P\left(w_n, W_n + 1 | 0, W_n\right) = \dfrac{1 - p_s}{\mathrm{CW}_{i+1}}, & w_n \in [0, \mathrm{CW}_{i+1}), W_n \in [0, W_{\max}), \\ P\left(w_n, W_{\max} | 0, W_{\max}\right) = \dfrac{1 - p_s}{\mathrm{CW}_{\max}}, & w_n \in [0, \mathrm{CW}_{\max}), \end{cases} \tag{12}$$

where p_s denotes the probability that the considered user successfully finishes its transmission without awareness of collision. Note that p_s does not equal to the non-collision probability due to imperfect sensing. Specifically, if two users collide, it is possible that only one user stops and the other user still transmits due to miss detection, and even when one single user is transmitting without collision, it may cease the transmission due to false alarm.

Considering the steady-state distribution of the discrete-time Markov chain, the probability that one user stays in each state can be calculated. Let $p_{w,W}$ denote the probability that one user is in the state of $\{w, \mathrm{W}\}$, and the probability that a certain user begins transmission in the next slot is

$$p = \sum_{W=0}^{W_{\max}} p_{0,W} = \frac{2\left(2p_s - 1\right)}{\left(2p_s - 1\right)\left(\mathrm{CW}_{\min} + 1\right) + \left(1 - p_s\right)\mathrm{CW}_{\min}\left(1 - \left(2 - 2p_s\right)^{W_{\max}}\right)}. \tag{13}$$

Then, we consider the relation between p_s and p. For simplicity, we assume the packet length L is fixed. The calculation of p_s has two prerequisites:

1. The probability that the transmitting user begins collision-free transmission after colliding for l slots, which can be expressed as

$$p_a\left(l\right) = \begin{cases} \left(1-p\right)^{N-1}, & l = 0, \\ \left(N-1\right)p\left(1-p\right)^{N-2} p_m^{2l-1}\left(1-p_m\right), & 1 \le l \le L-1, \\ \left(N-1\right)p\left(1-p\right)^{N-2} p_m^{2L-1}, & l = L. \end{cases} \tag{14}$$

2. The probability that the transmitting user successfully transmits l collision-free slots, which can be denoted as

$$p_b\left(l\right) = \left(1-p_f\right)^l, 0 \le l \le L. \tag{15}$$

Successful transmission requires at least one user transmits the entire packet without the awareness of collision. Thus, p_s can be calculated as

$$\begin{aligned} p_s =& \sum_{l=0}^{L} p_a(l) p_b(L-l), \\ =& (1-p)^{N-1}(1-p_f)^L + (N-1)p(1-p)^{N-2} p_m \frac{(1-p_f)^L - p_m^{2L}}{1-p_f-p_m^2}. \end{aligned} \tag{16}$$

Combining (13) and (16), the values of p and p_s can be solved numerically.

Throughput Performance

We use the time fraction that the channel is occupied for successful transmission as the normalized throughput, i.e., the throughput is defined as

$$\begin{aligned} C =& \frac{\mathbb{E}\left[\text{Successful transmission length}\right]}{\mathbb{E}\left[\text{Consumed time for a successful transmission}\right]} \\ =& \frac{P_s L_s}{P_e + P_s\left(L_s + \mathrm{DIFS}\right) + P_c\left(L_c + \mathrm{DIFS}\right)}, \end{aligned} \tag{17}$$

where $P_s = Np\left(1-p\right)^{N-1}$ denotes the probability that a successful transmission occurs, $P_e = \left(1-p\right)^N$ is the probability that the channel is empty, $P_c = 1 - P_e - P_s$ represents the collision probability, and L_s, L_e, and L_c denote the average length of

successful transmission, empty state, and collision, respectively. The average length of successful transmission and collision can be calculated as, respectively,

$$\begin{aligned} L_s &= \sum_{l=1}^{L-1} l\left(1-p_f\right)^{l-1} p_f + L\left(1-p_f\right)^{L-1} \\ &= \frac{1-(1-p_f)^{L-1}}{p_f} + (1-p_f)^{L-1}, \end{aligned} \tag{18}$$

$$\begin{aligned} L_c &= \frac{P_c + \binom{N}{2} p^2 (1-p)^{N-2} \sum_{l=1}^{L-1} p_m^{2l}\left(1-p_m^2\right) l}{P_c} \\ &= 1 + \binom{N}{2} p^2 (1-p)^{N-2} \frac{p_m^2\left(1-p_m^{2L-2}\right)}{P_c\left(1-p_m^2\right)}. \end{aligned} \tag{19}$$

The throughput is readily obtained by substituting (18) and (19) into (17). We can find that L_s is negatively related to p_f, while L_c is positively proportional to p_m. Thus, the network with a larger sensing threshold can obtain a longer average successful transmission length; however, it also suffers from a longer average collision length. Therefore, the sensing threshold should be properly designed to achieve the maximum throughput, which can be obtained through numerical.

Comparison with the Basic CSMA/CA Mechanism

We make a comparison between the proposed protocol for FD-WiFi with the conventional CSMA/CA for HD-WiFi in this part. For fairness, we consider the same system with N users and omit the noise term. The analytical performance of the CSMA/CA protocol is elaborated in [4], which are omitted here due to the space limitation. Some main differences between the two protocols are listed as follows.

- **Collision length.** In conventional CSMA/CA, the "blindness" in transmission results in long collision, which is typically a packet length. FD allows users to detect collision while transmitting. Thus, the average collision length L_c, as is derived in (19), is slightly more than one slot, which is sharply reduced compared with CSMA/CA.
- **Successful transmission length.** In CSMA/CA, once a collision-free transmission begins, it can always be finished successfully without interruption. However, in the FD-WiFi network, the transmission may get ceased due to false alarm, especially for long packets. According to (18), if L is sufficiently large, L_s goes to $\frac{1}{p_f}$. Also, false alarm leads to unnecessary backoff and increase of contention window, which may further degrade the performance of FD-WiFi. Thus, in FD-WiFi networks, the sensing threshold should be well designed to balance the probabilities of two sensing errors.

Simulation Results

In this subsection, simulation results are presented to show the performance of the proposed FD-WiFi CSMA/CD protocol. We consider 20 users and AP's radius R is set as 10 m. We set $\alpha = 2$ and $\overline{P}_r = 10\,\text{mW}$ with $\overline{d} = 1$ unit. The slot sampling number N_s is set as 100. Furthermore, the packet length is fixed to be 100 slots and DIFS is 2 slots. We run for 10^3 transmission attempts to fully develop the WiFi network and proceed with another 10^6 packet transmissions to obtain the simulated results by MATLAB. For comparison, we provide the throughput performance of conventional HD-WiFi and bidirectional FD transmission, which is similar to [10] and [11] and named by "dual-link FD-WiFi." Specifically, for the dual-link simulation, once a certain user transmits data to the AP, AP also transmits data packets back to this user. Moreover, due to RSI, the rate of dual link at one end is less than that of single link. For simplicity, the single-link sum rate is normalized as 1, and the dual-link sum rate is denoted as the relevant ratio.

In Fig. 5, we show the throughput of the proposed FD-WiFi protocol versus false alarm probability, which consists of two cases with the SIS factor $\beta^2 = 0.15$ and $\beta^2 = 0.3$, respectively. Note that the normalized throughput is denoted as the time ratio that the channel is occupied for successful transmissions, as shown in (17); thus it has no dimension. Figure 5 shows that there exists an optimal value of p_f

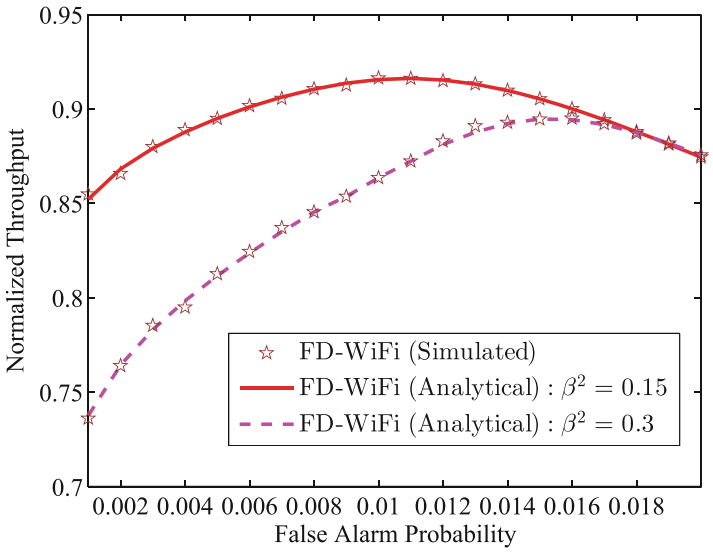

Fig. 5 Normalized throughput C versus false alarm probability p_f, where the number of users $N = 20$, the minimum contention window size $\text{CW}_{\text{min}} = 2^3$, and the maximum contention window size $\text{CW}_{\text{max}} = 2^8$

for FD-WiFi to achieve the maximum throughput. Since p_f is determined by ϵ, as shown in (6), the sensing threshold should be well designed to achieve the maximum throughput. We can also find that the optimal value of p_f for the case with $\beta^2 = 0.3$ is higher than that with $\beta^2 = 0.15$, which can be explained as follows. Higher SIS factor leads to worse sensing performance. Setting p_f the optimal value for the case with $\beta^2 = 0.15$, the collision is more frequent due to higher p_m when β^2 increases to 0.3. Thus, to obtain the maximum throughput, p_m should be decreased by increasing p_f.

In Fig. 6, by considering two cases with the packet length $L = 50$ and $L = 200$, we present the relationship between network throughput and the maximum backoff stage, with the throughput of convention HD-WiFi and dual-link FD-WiFi for comparison. According to Fig. 6, we can find that with proper parameters, the proposed FD-WiFi protocol has a better throughput performance than HD-WiFi and dual-link FD-WiFi. For the HD-WiFi and dual-link FD-WiFi, with higher $W_{\max}$, collision is less likely to happen, so the throughput increases monotonously. However, the throughput of proposed FD-WiFi protocol may drop with large $W_{\max}$, which can be found in the dashed line. The reason is that the asymptotic value of L_s is 100 with $p_f = 0.01$, and for $L > 100$ slots, false alarm is quite likely to happen during transmission, and the users are likely to enlarge their contention windows up to $\mathrm{CW}_{\max}$ due to the unsuccessful transmissions. Thus, more time is spent in the backoff procedure and the throughput gets smaller.

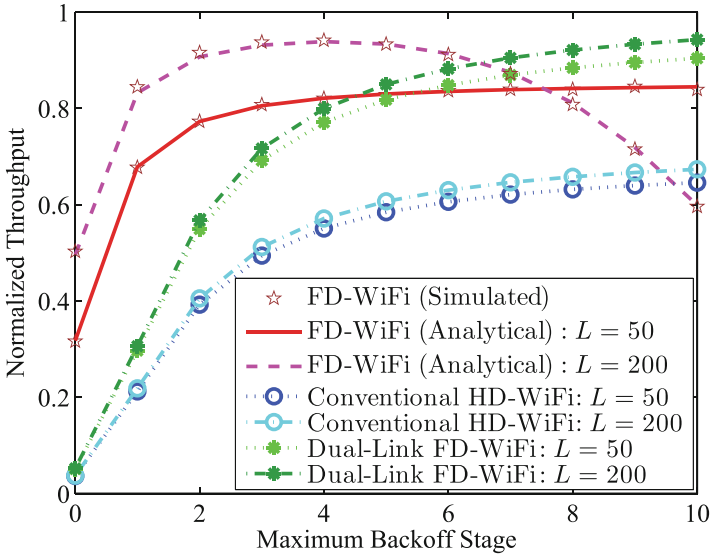

Fig. 6 Normalized throughput C of different protocols versus the maximum backoff stage $W_{\max}$, where $\mathrm{CW}_{\min} = 2^3$, SIS factor $\beta^2 = 0.15$, and the false alarm probability in FD-WiFi CSMA/CD protocol $p_f = 0.01$

Multi-channel Full-Duplex WiFi

In this section, we extend the proposed single-channel CSMA/CD protocol to the scenario with multiple available wireless channels in the FD-WiFi networks. For the multi-channel scenario, the WiFi users need to resolve the following two problems: (1) channel selection, users choose certain channels for access according to their channel state information (CSI), and (2) channel access, the contending users, which select the same channel, need to perform a contention-based access mechanism to alleviate collisions (Fig. 7).

For the channel access problem, we propose a random access strategy based on the CSMA/CD protocol described in section "Full-Duplex CSMA/CD Protocol." With the existence of multiple channels, the number of contending users on a certain channel change with time, and a fixed setting of contention parameters may lead to severe collision or over much waiting time in some cases. Therefore, different from the single-channel scenario, an adjustment of contention window is added in the channel access strategy.

As for the channel selection problem, some previous papers present their protocol designs for HD multi-channel systems. In [18], the authors propose a multiple spanning tree-based load-balancing routing algorithm for wireless mesh network. In [19], the authors design a multi-channel MAC protocol for ad hoc networks by channel preference negotiation between the transmitter and the receiver. In [20], the authors derive game theoretic results for multi-channel cognitive radio networks. In this section, we take advantage of game theory to propose a distributed channel selection scheme for multi-channel FD-WiFi networks. Our goal is to improve network performance, so user's channel selection strategy is based on comparison of

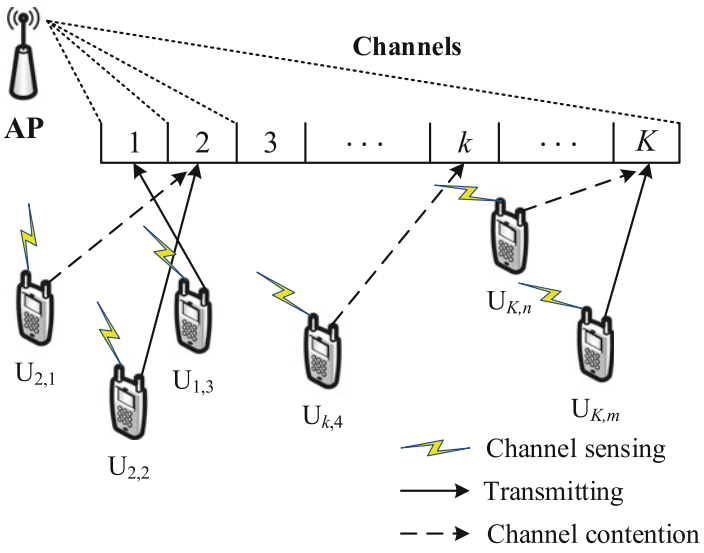

Fig. 7 Multi-channel full-duplex WiFi networks with one AP, N users and K orthogonal channels

expected throughput on different channels, which can be evaluated from the channel access strategy.

The rest of this section is organized as follows. We first discuss the system model for multi-channel FD-WiFi networks; then the channel access strategy and channel selection strategy are presented, respectively. Comparison with CSMA/CA and HD protocols and simulation results are provided finally.

System Model

We consider a network consisting of one AP and N FD users. There are K orthogonal channels, denoted by $\mathcal{K} = \{1, 2, \ldots, K\}$, each of which can serve at most one user at a time; otherwise the collision happens. The FD users, whose set is denoted by $\mathcal{N} = \{1, 2, \ldots, N\}$, have the same self-interference cancelation capability and the same transmission power P. Each user $n \in \mathcal{N}$ is assumed to have the knowledge of perfect CSI of any channel $k \in \mathcal{K}$ between the AP and itself, denoted by $\{h_{nk}\}_{k=1}^{K}$.

Similar to section "Full-Duplex CSMA/CD Protocol," we mainly focus on the uplink transmissions, where data are sent by users to the AP. Moreover, the WiFi network is considered to be distributed, which means that the AP has no way to allocate the users or schedule their traffic. We also assume that each user is capable of detecting the occupancy of all channels and transmitting on at most one channel at a time. Let τ be the minimum required time for each user to make a reliable channel sensing decision. We assume a time-slotted system in which users can transmit the data during each slot. The users can change their channels and activity only at the beginning of a slot.

By taking advantage of FD techniques, simultaneous carrier sensing and data transmission become possible [21,22]. In particular, one antenna is for transmission, while the other can be used as a receiver to sense the channel information. However, when a user is transmitting, the RSI due to the imperfect self-interference cancelation degrades the reliability of sensing on its own current operating channel [23]. Let P_f be the false alarm probability that one user falsely detects others' presence on the channel, and P_m denote the miss detection probability that one user fails to detect the collision while it is transmitting on the channel. Since the RSI exists only when a user is transmitting, we can simply assume perfect sensing for silent users.

The transmission procedure contains the following two steps:

1. According to the expected utilities of different channels, each user n selects a certain channel c_n to contend.
2. User n preforms a CSMA-/CD-based channel access strategy to avoid collision. After each successful or suspended transmission attempt, user n adjusts the contention window and the expected utility of channel c_n.

Since the expected channel utility is derived according to the specific channel access strategy, in the remaining section, we first present the CSMA-/CD-based

channel access mechanism and then propose the channel selection algorithm by taking advantage of game theory.

Channel Access Strategy

In this part, based on the CSMA/CD protocol in section "Full-Duplex CSMA/CD Protocol," we present a random access strategy adopted by the FD users when they are contending for the same channel. Here, the number of contending users is unknown to users, and it may change with time. By using FD technology, users can sense the channel while transmitting and stop transmission immediately when a collision is detected. Thus, collided transmissions can be significantly shorter than successful transmissions, which can be observed by all contending users, who can adjust the contention window size accordingly.

Protocol Description

As shown in Fig. 8, the proposed random access protocol for FD users on a single channel includes the following four phases:

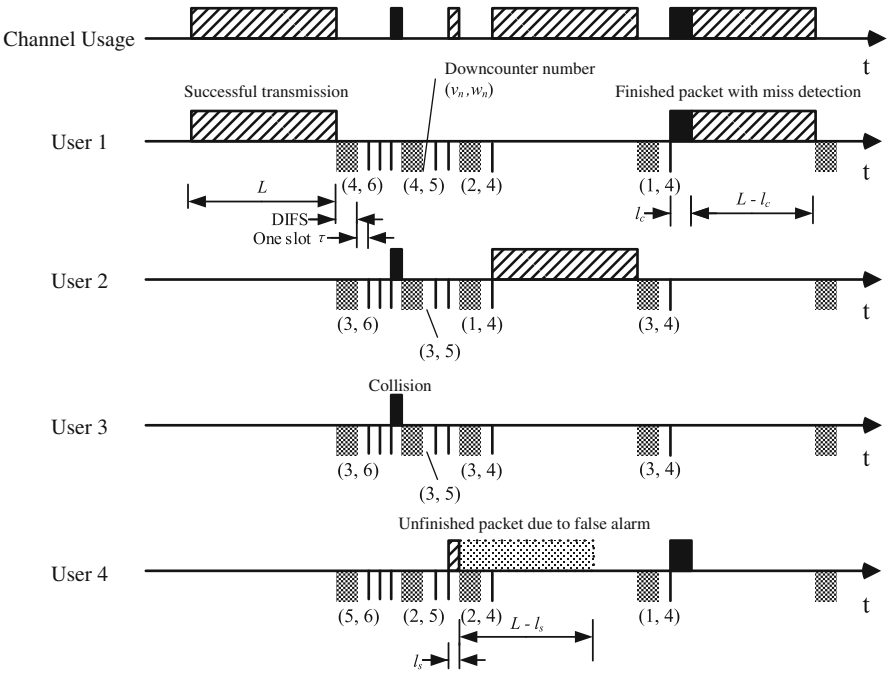

Fig. 8 Channel access protocol in decentralized FD networks, in which (v_n, w_n) denotes the residual backoff time and the contention window of user n

Sensing: All users keep sensing the channel continuously regardless of its own activity and make decisions of the channel usage at the end of each slot.

Backoff mechanism: Once the channel is sensed idle without interruption for a certain period of time equal to DIFS, users generate a random backoff time for an additional deferral, which can be expressed as follows:

$$\text{Backoff Time} = v \times \tau = \text{Random}\,(w) \times \tau, \tag{20}$$

where w is the length of contention window and $v = \text{Random}\,(w)$ is a random integer drawn from the uniform distribution over the interval $[0, w)$. The backoff timer starts countdown immediately after the DIFS and suspends when the channel is detected occupied by others.

Channel access and transmission suspension: A user accesses the channel and begins transmission when its backoff timer reaches zero before other transmissions are detected. During the first slot of the transmission, if it detects the signal from other users, a user stops its transmission and switches to the backoff procedure immediately. Otherwise, it keeps transmitting the packet until finished.

Adjustment of the contention window: When a transmission on the channel is detected finished, all users adjust the contention window size by the following contention window adjustment rule and begin the contention procedure for the next round.

Adjustment Rule of the Contention Window Size

When there are m users contending for a single channel, the optimum contention window size can be proved to be m. However, in a fully distributed system, the number of users, m, is unknown, and it may change dynamically. Thus, users cannot directly use m as the contention window. In this scenario, the conventional CSMA/CA mechanism cannot perform well, when m is smaller than the minimum contention window size or larger than the maximum size. Note that the lengths of collisions and successful transmissions can be different. All users are aware of whether the previous transmission is successful or not, as well as the average interval between two transmission attempts, based on which they can estimate the number of contending users and adjust the contention window accordingly.

When there are m users contending for a single channel with the contention window size w, the access probability for a certain user can be calculated as $p_{a,w} = \frac{2}{w+1}$ [4], and the probability that none of these users accesses the channel in the next coming slot can be expressed as the following:

$$p_i = (1 - p_{a,w})^m . \tag{21}$$

Moreover, the waiting time between two transmission attempts has the geometric distribution with parameter p_i and mean $L_w = \frac{p_i}{1-p_i}$. Thus, with the observed average waiting time, the number of contending users can be estimated as follows:

$$\hat{m} = \frac{\ln\left(\frac{L_w}{L_w+1}\right)}{\ln\left(1-p_{a,w}\right)} = \frac{\ln\left(\frac{L_w}{L_w+1}\right)}{\ln\left(\frac{w-1}{w+1}\right)}. \tag{22}$$

Remark 1. Notice that there exists a special case in (22) when the contention window $w = 0$. In this case, users access the channel with probability one, and average waiting time is 0. Collisions occur once there are more than one user on the channel. Thus, it is only possible to tell whether there are multiple users on the channel by observing the length of transmissions.

Remark 2. If users can sense the channel for a long time without changing the contention window, $\hat{m}$ can be a precise estimation of m, and the users can change their contention window to m to achieve the optimal throughput. However, it is inefficient and may be ineffective if the value of m varies during the longtime estimation. Thus, we propose the adjustment rule in a dynamic learning way as shown in Algorithm 1.

In Algorithm 1, T is the number of transmissions for calculating the average waiting time, and β is the step length in the adjustment rule. These two parameters directly influence the convergence time and stability of the algorithm. Generally, when β is large, the contention window size approaches the number of contending users more quickly, but meanwhile, the contention window size is more vulnerable to the fluctuation of the estimation of L_w, which may lead to the instability of the network. On the other hand, small β guarantees the stability, but the contention

else
  Estimate number of users $\hat{m}$ according to (22);
  $w' \leftarrow \lceil w + \beta(\hat{m} - w) \rceil$, where $\beta \in (0, 1)$;
end if

window size may be unable to keep pace with the change of the number of contention users. Thus, a mediate value of β requires careful design. Similar analysis can be applied for T: shorter T introduces instability to the network, while longer T leads to low sensitivity to the change of number of users.

Expected Throughput

Since our goal is to improve the network throughput performance, the expected throughput on certain channel is considerably important for the channel selection strategy, which is derived as follows. For any user n attempting to transmit on the channel, the expected throughput can be written as follows:

$$u_n = \frac{p_s L_s \cdot r_n}{p_s L_s + p_c L_c + L_w + \text{DIFS}}, \tag{23}$$

where p_s is the probability that the user successfully accesses the channel without collision, $p_c = 1 - p_s$ is the collision probability, L_s is the average successful transmission length, L_c is the average collision length, L_w is the average waiting time for channel contention, and $r_n = \log_2(1 + \lambda |h_n|^2)$ is the achievable rate of user n, in which λ is proportional to each user's transmit power.

The probability that the user n successfully accesses the channel k without collision can be estimated as follows:

$$p_s = \begin{cases} \left(\frac{w-1}{w+1}\right)^{\hat{m}-1} & n \text{ is on the channel,} \\ \left(\frac{w-1}{w+1}\right)^{\hat{m}} & n \text{ is not on the channel,} \end{cases} \tag{24}$$

and the collision probability is $p_c = 1 - p_s$.

Then, we consider the average successful transmission and the collision length. We assume a fixed packet length L for all users. Taking the false alarm probability into account, the average successful transmission length can be written as follows:

$$L_s = \left(1 - P_f\right) L + P_f. \tag{25}$$

Similarly, the average collision length is given by considering the miss detection probability:

$$L_c = (1 - P_m) + P_m L. \tag{26}$$

It can be seen from Algorithm 1 and (24) that all users can adjust the contention window size to the same value and estimate the expected throughput on the channel in a fully distributed manner.

Channel Selection Strategy

In this part, we tackle with the channel selection problem and formulate it as a distributed multi-channel random access game, in which each user uses the local information and observation of all channels to determine its channel selection strategy. Since our goal is to improve the network throughput, the expected throughput on each channel is adopted as the utility.

More specifically, in the multi-channel FD-WiFi network, each user needs to choose one channel to contend. After selecting the channel, the user performs access or backoff using the strategy described in section "Channel Access Strategy." According to our assumption, all users can monitor the occupancy of all channels. Thus, a user can estimate its expected throughput on each channel by using the method in section"Expected Throughput," and we can assume that when a user switches to a new channel, it can automatically adopt the same contention window size as the ongoing users on the same channel.

By extending (24) to multi-channel scenario, we can derive the utility for any user n attempting to transmit on channel k_n as the following:

$$u_n\left(k_n, \boldsymbol{k}_{-n}\right) = \frac{p_{s,k_n} L_s \cdot r_{nk_n}}{p_{s,k_n} L_s + p_{c,k_n} L_c + L_{w,k_n} + \mathrm{DIFS}}, \tag{27}$$

where $k_n \in \mathscr{S}_n$ is the strategy of user n, $\boldsymbol{k}_{-n} = (k_1, k_2, \ldots, k_{n-1}, k_{n+1}, \ldots, k_N)$ is the strategy vector of all users except user n, p_{s,k_n} is the probability that user n successfully accesses channel k_n, p_{c,k_n} is the collision probability, L_{w,k_n} is the average waiting time for channel contention on channel k, and $r_{nk} = \log_2(1 + \lambda|h_{nk}|^2)$ is the achievable rate of user n on channel k.

In this distributed network, each user tries to maximize its own expected throughput by adjusting its channel selection strategy, which can be formally written as follows:

$$k_n^* = \arg \max_{k_n \in \mathscr{S}_n} u_n\left(k_n, \boldsymbol{k}_{-n}\right), \ \forall n \in \mathscr{N}. \tag{28}$$

Note that the expected throughput of any user n on any channel k is largely dependent on the choices of other users. Thus, we formulate the channel selection process as a game defined as follows.

Definition 1. A channel selection game $\mathscr{G}$ is defined as $\mathscr{G} := < \mathscr{N}, (\mathscr{S}_n)_{n\in\mathscr{N}}, (u_n)_{n\in\mathscr{N}} >$, where $\mathscr{N} = \{1, 2, \ldots, N\}$ is the set of users, $\mathscr{S}_n := \{k_n = 1, 2, \ldots, K\}$ is the set of all possible choices of user n, and $u_n\left(k_n, \boldsymbol{k}_{-n}\right)$ is the utility function of user n when all users choose $\boldsymbol{k}_{-n}$.

We are interested in the Nash equilibrium of the channel selection game, which provides the strategy stability of each user's selection strategy.

Definition 2 (Nash Equilibrium). A strategy profile $\boldsymbol{k}^*$ is a pure strategy Nash equilibrium if and only if no user can improve its utility by deviating unilaterally, i.e.,

$$u_n\left(k_n^*, \boldsymbol{k}_{-n}^*\right) \geq u_n\left(k_n, \boldsymbol{k}_{-n}^*\right), \ \forall n \in \mathcal{N}, \ k_n \in \mathcal{S}_n. \tag{29}$$

Theorem 1. *The channel selection game $\mathcal{G}$ has at least one pure strategy Nash equilibrium.*

Proof. The utility function $u_n\left(k_n, \boldsymbol{k}_{-n}\right)$ defined in (27) is quasiconcave continuous in k. The feasible set is also compact and convex. Consequently, according to [24], there exists at least a pure Nash equilibrium. Similar proof for Aloha game can be also found in [25].

To achieve the Nash equilibrium, we present a best-response-based channel selection mechanism. In this algorithm, each user chooses the channel with the largest expected throughput to contend on and then performs random channel access strategy in section "Channel Access Strategy." Meanwhile, each user monitors the states of all channels continuously and adjusts the contention window size according to the channels' occupancy. Once the user fails to contend for a channel or finishes a transmission, it estimates the expected throughput of all channels and chooses the channel with the largest expected throughput to update its selection strategy. This channel selection mechanism is formally described in Algorithm 2.

Performance Analysis and Comparison

In this subsection, we provide theoretical comparison of the proposed FD protocol with CSMA/CA and HD protocols.

Comparison with CSMA/CA Protocols

We make a comparison between the proposed FD-WiFi channel access protocol on a single channel with the conventional CSMA/CA mechanism in this part. For fairness, we consider the single-channel network with m users and omit the noise term.

In CSMA/CA, there exists the minimum contention window length $\mathrm{CW}_{\min}$ and the maximum backoff stage $w_{\max}$. After each failed transmission attempt, the transmitted user doubles its contention window until to the maximum contention window length $\mathrm{CW}_{\max} = 2^{w_{\max}}\mathrm{CW}_{\min}$. After each successful transmission, the user resets the contention window as $\mathrm{CW}_{\min}$. According to the analysis in [4], the average access probability can be written as follows:

$$p = \frac{2\left(2p_s - 1\right)}{\left(2p_s - 1\right)\left(\mathrm{CW}_{\min} + 1\right) + \left(1 - p_s\right)\mathrm{CW}_{\min}\left(1 - \left(2 - 2p_s\right)^{w_{\max}}\right)}, \tag{30}$$

where p_s is the successful transmission probability, given by

Algorithm 2 Channel selection mechanism

Step 1: Initialization

1: $\forall n \in \mathcal{N}$, estimate the value of h_{nk}, for all $k = 1, 2, \ldots, K$;
2: Initialize contention window $w_k = 1, \forall k \in \mathcal{K}$;
3: Initialize backoff time $v_{nk} = 0, \forall n \in \mathcal{N},\ k \in \mathcal{K}$;
4: Set $c_n = \arg \max_k \{|h_{nk}|^2\}$;

Step 2: Channel selection and random access

1: **while** in each time slot **do**
2: **for** $k = 1 : K$ **do**
3: **if** Channel is currently occupied **then**
4: Transmitting users keep transmitting and detecting whether their current transmissions collide with other transmissions. If collision is detected, stop transmission;
5: **else**
6: All users on channel k keep downcounting v_{nk}, a user n accesses channel k when v_{nk} reaches 0;
7: **end if**
8: **end for**
9: All users sense and judge the occupancy of all channels during the whole slot;
10: **for** all channel k whose occupancy has just changed **do**
11: All users that fail to contend for channel k or users that just finish a transmission collect $L_{w,k'}$ ($k' = 1, 2, \ldots, K$), and update the utilities $u_{nk'}$ of all channels according to (27). We denote the set of these users as $\mathcal{N}_{\text{tochange}}$;
12: $\forall n \in \mathcal{N}_{\text{tochange}}$, update channel selection strategy as $c_n = \arg \max_k \{u_{nk}\}$;
13: Update contention window w_k according to Algorithm 1;
14: **end for**
15: **if** there exists a set of channels $\mathcal{K}_i$ whose waiting time exceeds the contention window **then**
16: Judge all the channels $k \in \mathcal{K}_i$ as unoccupied by any users, and set contention windows $w_k = 1$;
17: **end if**
18: **end while**

$$p_s = 1 - (1 - p)^{m-1}. \tag{31}$$

It can be verified that the access probability is less than $\frac{2}{m+1}$, which is the asymptotic value of access probability under the proposed contention adjustment rule.

Comparison with Half-Duplex Protocols

Compared with the HD protocols, the most significant difference is that users can sense the channels while transmitting, i.e., users are no longer "blind" in transmission. Once a collision is detected, users can stop transmission immediately. This feature can significantly reduce the average length of collision. Additionally, contending users can obtain additional information of whether the previous transmission is successful by simply detecting the length of the transmission.

- **Collision length.** In HD protocols, the "blindness" in transmission results in long collision, which is typically a packet length. FD allows users to detect

collision while transmitting. As derived in (26), the average collision length $L_c = 1 + P_m (L - 1)$, as is derived in (26), is slightly more than one slot, which is substantially reduced from a packet length L.

- **Successful transmission length.** In HD protocols, once a collision-free transmission begins, it can always be finished successfully without interruption. However, in the proposed FD protocol, the transmission may be ceased due to false alarm. According to (25), it can be seen that $L_s = L - (L - 1) P_f$ is reduced because of false alarm. Furthermore, false alarm may lead to unnecessary increase of contention window and decrease of expected throughput of the channel, which may further degrade the performance of the proposed protocol.

Simulation Results

In this part, simulation results are presented to evaluate the performance of the proposed protocol for multi-channel FD-WiFi network. We consider $K = 4$ channels with up to $N = 15$ users. The packet length L is fixed on 50 slots, and DIFS time is 2 slots. The number of transmissions taken into account for contention window adjustment is $T = 10$. The channel sensing error probabilities, i.e., P_m and P_f, are set as 0.01.

In Fig. 9, we first verify the effectiveness of the proposed FD protocol. We consider the channel selection process of ten users. It can be seen from Fig. 9 that the channel selection mechanism converges to the Nash equilibrium quickly, and all users do not change their strategies afterward.

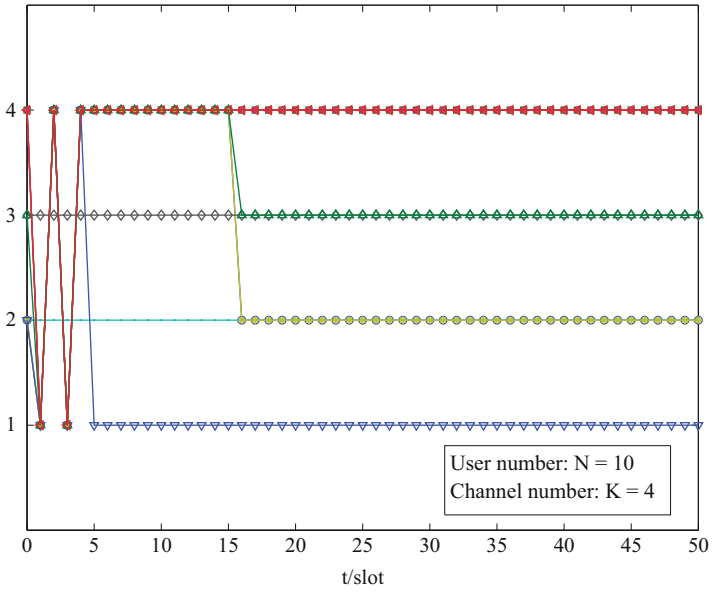

Fig. 9 Channel selection process under the proposed mechanism

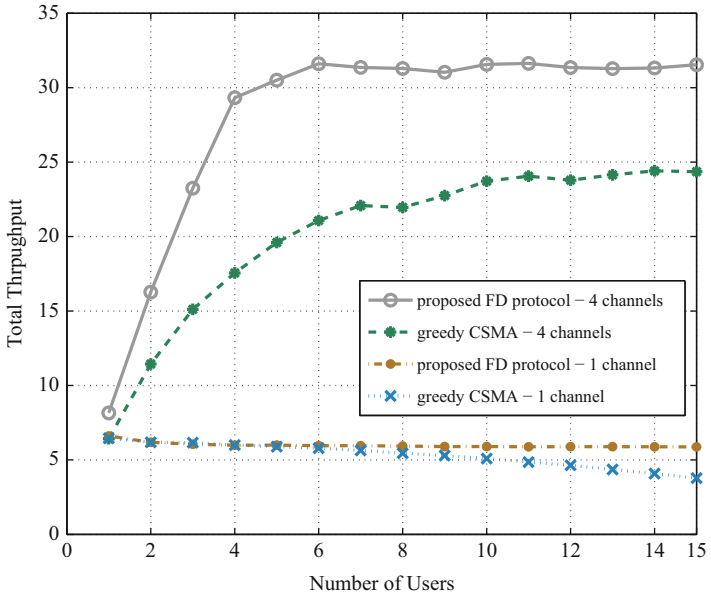

Fig. 10 Channel selection process under the proposed mechanism

In Fig. 10, we consider the total throughput of the multichannel network, which is the throughput of all the N users on all K channels. We present comparison between the proposed FD protocol and a greedy CSMA-based FD protocol in which each user accesses the channel with maximum achievable rate and performs contention based on CSMA mechanism with minimum contention window $\mathrm{CW}_{\min} = 1$ and maximum backoff stage $w_{\max} = 4$. Note that we do not adopt the original window size $\mathrm{CW}_{\min} = 8$ and $w_{\max} = 5$ in CSMA in the simulation since the number of users is small, and the adoption of large contention window size leads to worse performance. Firstly, it is shown in the dash-dotted and dotted lines in Fig. 10 that the proposed protocol can achieve higher throughput in single-channel case, especially when the number of users is large. This is because the contention window adjustment rule guarantees a more proper window size for all users to maximize their access and successful transmission probability. Also, Fig. 10 shows in the solid and dashed lines that the proposed protocol can achieve higher total throughput than that of the greedy CSMA, especially when the number of users is close to the number of channels. This is because in the proposed protocol, users can automatically avoid to choose crowded channels to increase their access and successful transmission probability. Additionally, it can be seen that when $N \leq K$ ($N \leq 4$ in Fig. 10), the throughput increases almost proportionally with the number of users, and the slope is close to $\mathbb{E}[\log_2(1 + \lambda|h|^2)]$. This indicates that all users intend to occupy a channel exclusively without sharing with other users. However, when the number of users increases, the greedy mechanism may gradually approach the proposed protocol. This is because when many users contending for

limited channels, it is likely that all channels are crowded at a similar level, and the users do not have the much motivation to deviate from the channel with the largest rate. This makes the channel selection profile almost the same as the greedy mechanism.

Summary

This chapter has first discussed the CSMA/CA protocol in conventional HD-WiFi networks and pointed out its long collision duration problem due to the failure of carrier sensing during transmission. To mitigate this problem, the CSMA/CD protocol has been proposed for single-channel WiFi networks by taking advantage of the FD technology. Compared with CSMA/CA protocol, the new CSMA/CD protocol has two adaptations: (1) continuous carrier sensing by enabling simultaneous sensing and transmission and (2) transmission suspension procedure, by which users stop transmitting immediately once detecting a collision. To obtain a comprehensive network performance analysis, this chapter has calculated two types of sensing error probabilities due to residual self-interference, namely, false alarm and miss detection. The normalized throughput has also been derived as the average channel utilization for successful data transmission. Both performance analysis and simulation results have shown that the full-duplex CSMA/CD protocol improves WiFi throughput performance.

Then this chapter has extended the CSMA/CD protocol to the multi-channel FD-WiFi network and divided this scenario into two parts: (1) channel selection, each user selects which channel for access, and (2) channel access, all contending users, which select same channel, perform a contention-based channel access scheme. For the channel access problem, a random access strategy has been proposed based on the described CSMA/CD protocol for single-channel scenario, except not adopting the exponential backoff scheme. Instead, by learning from historical waiting time, the proposed channel access strategy provides an adjustment rule of contention window size to accommodate the number change of contending users. For the channel selection problem, a distributed selection protocol has also been provided based on the best-response algorithm, by which the WiFi user always selects the channel with the highest expected throughput. Simulation results have also been provided to verify the effectiveness of multi-channel FD-WiFi protocol.

Abstract

WiFi offloading is regarded as one of the most promising techniques to deal with the explosive increasing data usage over the existing 4G cellular network due to its high quality of service, high data transmission rate, and low requirement on devices. In this chapter, we investigate two key issues, i.e., association rules and incentive mechanisms, for data offloading through third-party WiFi access points (APs) in a cellular mobile system. Firstly, by assuming the data offloaded through the third-party WiFi AP is charged based on usage, we formulate the user association problem as an utility maximization problem from the cellular operator's perspective. By considering whether the successive interference cancelation (SIC) decoders are available at the BS and/or the WiFi AP, different utility functions are considered. Then, the optimal user association rules are derived for each case when the number of users is large. Secondly, incentive mechanisms to motivate WiFi APs to provide data offloading services are studied. In particular, a salary plus bonus-based incentive mechanism is proposed. Under the proposed incentive scheme, WiFi APs are rewarded not only based on the amount of offloaded data but also based on the quality of the offloading service. The interactions between the WiFi APs and the mobile network operator are investigated using Stackelberg game.

Introduction

Background and Motivation

Due to the rapid development in mobile phones and wireless communications in the recent years, the popularity of using smartphones to access the Internet and the social networking services, which generates a lot of data usage over the cellular network, is increasing [1]. Due to the unprecedented explosion of mobile data traffic, the cellular operators around the world are facing the glut of mobile data on their networks because of the capacity constraints of these networks. Most cellular networks are of high probability to be overloaded in the near future. In fact, most 4G networks are already overloaded, especially in crowded areas and during peak hours. Mobile users in overloaded areas are forced to use the degraded cellular services, such as low transmission rate, missed calls, and unreliable coverage.

To tackle with these problems and enhance users' network experience, cellular operators are forced to increase their network capacity. A straightforward way to is to add more base stations with smaller cell size such as femtocells [2, 3]. However, these options require large investment in the network equipment and are not cost-effective. A more promising approach is to offload portion of the mobile data usage through the existing WiFi networks. WiFi offloading is a strong candidate for mobile data offloading due to the following reasons: (1) No equipment upgrading is required at the user side. This is due to the fact that the bulk of the demand for high-speed data services is created by smartphones, which have already integrated WiFi modules.

(2) No licensed spectrum band is required. WiFi devices operate in unlicensed ISM 2.4 and 5 GHz bands. (3) High quality of service and high data rates. WiFi is the only wireless technology that can deliver data rates as high as 600 Mbps, which is much faster than the current 4G technology.

Though WiFi offloading is a promising technology and has many advantages, without economic incentives, WiFi APs may be reluctant to provide data offloading service for the mobile network operator (MNO). This is because providing offloading service for the MNO will inevitably incur additional operation cost, such as energy cost and data-usage cost. Besides, when providing data service for guest users from the cellular network, WiFi APs may have to sacrifice its own users' benefit, such as bandwidth, transmission rate, and quality of service. Thus, a WiFi AP has no reason to providing offloading service for the MNO unless it is purely altruistic. Therefore, there is a compelling need to design effective incentive mechanisms to motivate WiFi APs to participate in WiFi offloading. Using monetary reward as an incentive to motivate the WiFi APs will inevitably decrease the profit of the MNO. Thus, when and how the users should be offloaded to the WiFi APs is another important issue for data offloading. Therefore, we also investigate the user association problem in this chapter.

Related Work

Due to various advantages and its promising future, WiFi offloading becomes a hot research topic and has attracted the attention of many researchers all over the world. In [4], the authors investigated the feasibility of augmenting 3G using WiFi. The key ideas is to leverage WiFi's delay tolerance property and its fast switching mechanism. They have shown that WiFi can greatly reduce the burden on the cellular network. In [5], the authors conducted a quantitative study on the performance of 3G mobile data offloading through WiFi networks. Their trace-driven simulation showed that WiFi can offload about 65% of the total mobile data traffic and saves 55% of battery power without using any delayed transmission for 97 iPhone users from metropolitan areas. In [6], the authors quantitatively evaluated the gains of citywide WiFi offloading using real traces and gave out the numbers of APs needed for different requirements of quality of service for data delivery in large metropolitan area. In [7], the authors proposed to opportunistically offload traffic from the cellular network to WiFi with the aid of social participation. The authors showed that through identifying the social groups of the users and delivering specific contents to a particular social group, a large fraction of data can be offloaded from the cellular network. In [8], the author gives a tutorial on the basics and key concepts of data offloading techniques from the network layer perspective. In [9], based on Lyapunov optimization, a dynamic offloading algorithm is proposed to save energy for mobile computing. In [10], the authors investigate the outage probability and ergodic rate for a heterogeneous network when flexible cell association scheme is adopted. In [11], the authors investigate the downlink user association problem for

loading balancing in a heterogeneous cellular networks. In [12], the authors develop a general and tractable model for data offloading in heterogeneous networks with different tiers of APs.

Some recent works, such as [13–15], investigate the network economics of the mobile data offloading through WiFi APs using the game theory [16]. In [13], the authors proposed the so-called market-based data offloading where the MNO pays WiFi APs for offloading traffic. An offloading game between the MNO and WiFi APs was formulated to study the pricing strategy of the MNO and the offloading strategies of WiFi APs. However, in [13], the MNO pays WiFi APs only based on the amount of data offloaded, while the quality of the data offloading service was not taken into consideration in designing the incentive mechanism. In [14], the authors focused on the interactions between the MNO and the mobile users. The MNO pays the mobile users if they direct their delay-tolerant data service to WiFi APs. The economic benefits brought to the MNO and the users due to the delayed WiFi offloading were then studied. In [15], the authors investigated the tradeoff between the amount of traffic being offloaded and the users' satisfaction. An incentive framework to motivate users to leverage their delay tolerance for cellular traffic offloading was proposed. However, the proposed incentive mechanisms in [14, 15] are aimed at providing incentives for mobile users rather than WiFi APs.

Main Contribution

Different from the aforementioned research works, in this chapter, we investigate the user association rules and incentive mechanisms for data offloading through a third-party WiFi AP in a cellular mobile system. The main contribution and results of this chapter can be summarized as follow.

Association rules: In this chapter, by assuming the data offloaded through the third-party WiFi AP is charged based on usage, we formulate mobile data offloading problem as an utility maximization problem from the cellular operators perspective. By considering whether the successive interference cancelation (SIC) decoders are available at the BS and/or the WiFi AP, three different cases are considered. Then, the optimal data offloading scheme is derived for each case when the number of users is large. It is shown that the optimal data offloading schemes for different cases are not alike and have their own characteristics. When *SIC decoders are not available at both the BS and the WiFi AP*, it is shown that one-one association is optimal, i.e., one user with the best channel connects to the BS and the other user with the best channel to the AP connects to the WiFi AP. When *the SIC decoder is available only at the BS*, the optimal solution is at most one user connecting to the WiFi AP, and all the other users connect to the BS. When *SIC decoders are available at both the BS and the WiFi AP*, a centralized association algorithm is obtained by solving the relaxation problem. We have rigorously proved that SIC decoders are beneficial for the cellular operator in terms of maximizing its utility.

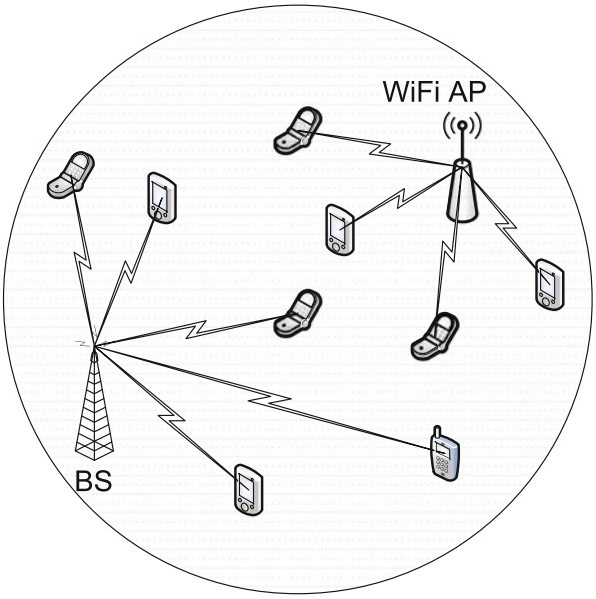

Fig. 1 System model

Incentive mechanisms: For providing strong incentives for WiFi APs to participate in data offloading, we further investigate the incentive mechanisms and propose a *salary plus bonus* reward scheme. Particularly, the proposed incentive mechanism rewards WiFi APs not only based on the amount of data offloaded but also based on the quality of the offloading service. Under the proposed incentive mechanism, we investigate the interactions between the MNO and WiFi APs using Stackelberg game. We derive the best response functions for WiFi APs which lead to the Nash equilibrium (NE). From the economic point of view, we investigate the optimal bonus and salary rate that the MNO should set in order to maximize its utility. Closed-form solutions are obtained when all WiFi AP cases are of the same type. For the heterogeneous WiFi AP case, we start with the two-AP case and then extend the results to the multi-AP case. It is shown that the MNO should adopt a low-salary high-bonus strategy or a high-salary low-bonus strategy to achieve a higher utility (Fig. 1).

System Model

In this chapter, to study the association rule, we first consider a cellular network with N users served by a base station (BS). We assume that there is a third-party WiFi access point (AP) within the coverage area of the BS. We assume that the WiFi AP and the BS use orthogonal frequencies. Thus, there is no inter-network interference between WiFi and cellular network. To maximize its network

throughput and improve the overall network performance, the cellular operator is able to direct its users to transmit through the WiFi AP rather than its BS. Since the WiFi AP is operating by a third-party operator, the cellular operator has to pay the third-party AP operator for the data usage. This monetary reward serves as an incentive for the third-party operator to operate its WiFi AP in an open access model for the users served by the cellular operator.

We assume that all the users adopt fixed power transmission, i.e., P_i for user i. For the convenience of analysis, we assume that $P_i = P, \forall i$. We assume the users are uniformly distributed in the coverage area. The channel power gain between user i and the BS is denoted by $g_{i,B}$, and the channel power gain between user i and the WiFi AP is denoted by $g_{i,A}$. We assume that $g_{i,B}$s and $g_{i,A}$s are mutually independent and have continuous probability distribution function (pdf). Besides, we assume that the power of the additive Gaussian noises at the BS and the AP is σ_B^2 and σ_A^2, respectively. Without specific declaration, we assume that all the channel state information and users' transmit power are known at the BS. We only consider the uplink scenario. Now, we define $x_i \in \{0, 1\}$ and $y_i \in \{0, 1\}$ as two indicator functions to indicate user i's connection to BS or AP, respectively. If user i connects to BS, $x_i = 1$; otherwise, $x_i = 0$. Similarly, if user i connects to AP, $y_i = 1$; otherwise, $y_i = 0$. Besides, at any time, user i is only allowed to connect to either BS or AP, but not allowed to connect to both of them simultaneously, i.e., $x_i + y_i \leq 1, \forall i$.

We assume that the cellular operator charges its users at λ per nat of data sent for data usage, and it pays the third-party operator at μ per nat of data sent through its WiFi AP. Thus, its utility can be defined as

$$U(\boldsymbol{x}, \boldsymbol{y}) = \lambda R_B(\boldsymbol{x}) + (\lambda - \mu) R_A(\boldsymbol{y}), \tag{1}$$

where $R_B(\boldsymbol{x})$ is the sum rate at the BS and $R_A(\boldsymbol{y})$ is the sum rate at the WiFi AP. Then, according to [17], if the successive interference cancelation (SIC) decoder is available at the BS, the sum-rate at the BS can be written as $R_B^w(\boldsymbol{x}) = \ln(1 + \sum_{i=1}^N \frac{g_{i,B} P_i}{\sigma_B^2} x_i)$; on the other hand, if the SIC decoder is not available at the BS, $R_B^o(\boldsymbol{x}) = \sum_{i=1}^N \ln\big(1 + \frac{x_i g_{i,B} P}{\sum_{j=1, j\neq i}^N x_j g_{j,B} P + \sigma_B^2}\big)$. Similarly, at the WiFi AP side, with SIC decoder, we have $R_A^w(\boldsymbol{x}) = \ln\big(1 + \sum_{i=1}^N \frac{g_{i,A} P_i}{\sigma_A^2} y_i\big)$; without SIC decoder, we have $R_A^o(\boldsymbol{x}) = \sum_{i=1}^N \ln\big(1 + \frac{y_i g_{i,A} P}{\sum_{j=1, j\neq i}^N y_j g_{j,A} P + \sigma_A^2}\big)$.

Then, based on the fact that whether SIC decoder is available at BS/AP, we have the following four possible utility functions:

$$U^{ww}(\boldsymbol{x}, \boldsymbol{y}) = \lambda R_B^w(\boldsymbol{x}) + (\lambda - \mu) R_A^w(\boldsymbol{y}), \tag{2}$$

$$U^{oo}(\boldsymbol{x}, \boldsymbol{y}) = \lambda R_B^o(\boldsymbol{x}) + (\lambda - \mu) R_A^o(\boldsymbol{y}), \tag{3}$$

$$U^{wo}(\boldsymbol{x}, \boldsymbol{y}) = \lambda R_B^w(\boldsymbol{x}) + (\lambda - \mu) R_A^o(\boldsymbol{y}), \tag{4}$$

$$U^{ow}(\boldsymbol{x}, \boldsymbol{y}) = \lambda R_B^o(\boldsymbol{x}) + (\lambda - \mu) R_A^w(\boldsymbol{y}). \tag{5}$$

Association Rules

With SIC Decoder at Both Sides

In this subsection, we investigate the case that both the BS and the WiFi AP are equipped with a SIC decoder. Thus, the utility maximization problem of the cellular operator can be formulated as

Problem 1.

$$\max_{\{x_i,y_i,\forall i\}} \ \lambda \ln\left(1+\sum_{i=1}^{N} S_{i,B}x_i\right)+(\lambda-\mu)\ln\left(1+\sum_{i=1}^{N} S_{i,A}y_i\right), \tag{6}$$

$$\text{s.t. } x_i \in \{0,1\}, \ \forall i, \tag{7}$$

$$y_i \in \{0,1\}, \ \forall i, \tag{8}$$

$$x_i + y_i \leq 1, \ \forall i, \tag{9}$$

where $S_{i,B} \triangleq \frac{g_{i,B}P_i}{\sigma_B^2}$ and $S_{i,A} \triangleq \frac{g_{i,A}P_i}{\sigma_A^2}$.

It is observed from this problem formulation that the third-party operator's pricing strategy μ has a great influence on the optimal solution of the above problem. When μ is larger than λ, the cellular operator will not assign any user to the AP, which is rigorously proved by the following proposition.

Proposition 1. *When $\lambda \leq \mu$, the optimal solution of Problem 1 is $\boldsymbol{x}^* = \mathbf{1}_N, \boldsymbol{y}^* = \mathbf{0}_N$, where $\mathbf{1}_N$ and $\mathbf{0}_N$ denote the N-dimension all-one vector and all-zero vector, respectively.*

Proof. To prove $\boldsymbol{x}^* = \mathbf{1}_N$ and $\boldsymbol{y}^* = \mathbf{0}_N$ is the optimal solution of Problem 3.1, we have to show that $f(\boldsymbol{x}^*, \boldsymbol{y}^*)$ is larger than $f(\boldsymbol{x}, \boldsymbol{y})$, where $f(\boldsymbol{x}, \boldsymbol{y})$ denotes the objective function of Problem 1 and $(\boldsymbol{x}, \boldsymbol{y})$ is any feasible solution of Problem 1. Suppose $(\tilde{\boldsymbol{x}}, \tilde{\boldsymbol{y}})$ is a feasible solution of Problem 1, then it follows that

$$\begin{aligned} f(\tilde{\boldsymbol{x}}, \tilde{\boldsymbol{y}}) &= \lambda f_B(\tilde{\boldsymbol{x}}) + (\lambda-\mu) f_A(\tilde{\boldsymbol{y}}) \\ &\overset{a}{\leq} \lambda f_B(\tilde{\boldsymbol{x}}) + (\lambda-\mu) f_A(\mathbf{0}_N) \\ &\overset{b}{\leq} \lambda f_B(\mathbf{1}_N) + (\lambda-\mu) f_A(\mathbf{0}_N), \end{aligned} \tag{10}$$

where the inequality "a" results from the fact that $\lambda - \mu \leq 0$ and $f_A(\boldsymbol{y})$ is always nonnegative. The inequality "b" results from the fact that $f_B(\boldsymbol{x})$ is an increasing function with respect to $\boldsymbol{x}$, and thus the equality holds only when $\boldsymbol{x}^* = \mathbf{1}_N$.

The above proposition indicates that the cellular operator will not offload any mobile data through the WiFi AP if the third-party operator charges at a price higher than its revenue, i.e., $\mu \geq \lambda$. On the other hand, from the third-party operator's

perspective, if the cellular operator does not offload mobile data through its WiFi AP, it will earn nothing, which is a lose-lose situation. Thus, a reasonable third-party operator will charge a price lower than λ, which is the scenario we consider in the following studies, i.e., $\mu < \lambda$.

Proposition 2. *The optimal solution of Problem 1 is obtained when (9) holds with equality for arbitrary i.*

Proof. This can be proved by contradiction. Suppose $(\boldsymbol{x}^*, \boldsymbol{y}^*)$ is the optimal solution of Problem 1, and it has an element (x_k^*, y_k^*) satisfying $x_k^* + y_k^* < 1$. Then, from (7) and (8), it follows that $x_k^* = 0, y_k^* = 0$. Now, we show that we can always find a feasible solution $(\tilde{\boldsymbol{x}}, \tilde{\boldsymbol{y}})$ with its elements satisfying $x_i^* + y_i^* = 1, \forall i$, which will result in a higher value of (6). We let $\tilde{\boldsymbol{x}}_{-k} = \boldsymbol{x}_{-k}^*, \tilde{\boldsymbol{y}}_{-k} = \boldsymbol{y}_{-k}^*$. Then, since the logarithm function is an increasing function, it is clear that if we set $\tilde{x}_k^* = 1, \tilde{y}_k^* = 0$ or $\tilde{x}_k^* = 0, \tilde{y}_k^* = 1$ will result in a higher value of (6) than that resulted by $x_k^* = 0, y_k^* = 0$. This contradicts with our presumption. Proposition 2 is thus proved.

With the results given in Proposition 2, we can reduce the complexity of Problem 1 by setting $y_i = 1 - x_i$. Problem 1 can be converted to the following problem.

Problem 2.

$$\max_{x_i, \forall i} \ \lambda \ln\left(1+\sum_{i=1}^{N} S_{i,B} x_i\right) + (\lambda-\mu) \ln\left(1+\sum_{i=1}^{N} S_{i,A}(1-x_i)\right), \tag{11}$$

$$\text{s.t. } x_i \in \{0, 1\}, \ \forall i. \tag{12}$$

This problem is a nonlinear integer programming problem. When the number of users is small, it can be solved by exhaustive search. However, when the number of users is large, exhaustive search is not applicable due to the high complexity. Thus, we solve Problem 2 by solving its relaxation problem and rigorously prove that the gap between the relaxation problem and Problem 2 is negligible when the number of the users is large.

The **relaxation problem** of Problem 2 is given as follows:

Problem 3.

$$\max_{x_i, \forall i} \ \lambda \ln\left(1+\sum_{i=1}^{N} S_{i,B} x_i\right) + (\lambda-\mu) \ln\left(1+\sum_{i=1}^{N} S_{i,A}(1-x_i)\right), \tag{13}$$

$$\text{s.t. } 0 \le x_i \le 1, \ \forall i. \tag{14}$$

This problem is easy to solve as it is a convex optimization problem. To show its convexity, we only need to show that the objective function is convex or concave

since all the constraints are linear. Denote the objective function of the relaxation problem as f_r, then f_r is convex/concave if its Hessian is positive/negative semidefinite. Denote the Hessian of f_r as $\boldsymbol{H}$, we show that $\boldsymbol{H}$ is negative semidefinite by the following proposition.

Proposition 3. *The Hessian $\boldsymbol{H}$ is negative semidefinite.*

Proof. The Hessian of f can be written as

$$\boldsymbol{H} = \begin{pmatrix} \frac{\partial^2 f}{\partial x_1^2} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_N} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial x_N \partial x_1} & \cdots & \frac{\partial^2 f}{\partial x_N^2} \end{pmatrix}, \tag{15}$$

where the diagonal elements and off-diagonal elements can be obtained as $\frac{\partial^2 f}{\partial x_k^2} = -\frac{\lambda S_{k,B}^2}{\left(1+\sum_{i=1}^N S_{i,B} x_i\right)^2} - \frac{(\lambda-\mu) S_{k,A}^2}{\left(1+\sum_{i=1}^N S_{i,A}(1-x_i)\right)^2}$, and $\frac{\partial^2 f}{\partial x_k \partial x_j} = -\frac{\lambda S_{k,B} S_{j,B}}{\left(1+\sum_{i=1}^N S_{i,B} x_i\right)^2} - \frac{(\lambda-\mu) S_{k,A} S_{j,A}}{\left(1+\sum_{i=1}^N S_{i,A}(1-x_i)\right)^2}$.

It is observed that $\boldsymbol{H}$ can be rewritten as

$$\boldsymbol{H} = -\frac{\lambda}{\left(1+\sum_{i=1}^N S_{i,B} x_i\right)^2} \boldsymbol{B} - \frac{(\lambda-\mu)}{\left(1+\sum_{i=1}^N S_{i,A}(1-x_i)\right)^2} \boldsymbol{A}, \tag{16}$$

where the matrices $\boldsymbol{B}$ and $\boldsymbol{A}$ have the same structure as the following matrix $\boldsymbol{X}$

$$\boldsymbol{X} = \begin{pmatrix} S_{1,X}^2 & \cdots & S_{1,X} S_{N,X} \\ \vdots & \ddots & \vdots \\ S_{N,X} S_{1,X} & \cdots & S_{N,X}^2 \end{pmatrix}, \tag{17}$$

where $X = B$ for matrix $\boldsymbol{B}$ and $X = A$ for matrix $\boldsymbol{A}$.

It can be shown that for any vector $\boldsymbol{c} = [c_1 \ \cdots \ c_N]^T$, $\boldsymbol{c}^T \boldsymbol{X} \boldsymbol{c}$ can be obtained as

$$\boldsymbol{c}^T \boldsymbol{X} \boldsymbol{c} = (c_1 S_{1,X} + \cdots + c_N S_{N,X})^2 \geq 0. \tag{18}$$

Thus, it is clear that both $\boldsymbol{B}$ and $\boldsymbol{A}$ are positive semidefinite. Then, since both λ and $\lambda - \mu$ are nonnegative, it is easy to see that $\boldsymbol{H}$ is negative semidefinite. Therefore, the objective function is strictly concave.

Since Problem 3 is a convex optimization problem, the duality gap between it and its dual problem is zero. Thus, solving its dual problem is equivalent to solving the original problem. Now, we consider its dual problem.

The Lagrangian of the relaxation problem can be written as

$$L(\boldsymbol{x},\boldsymbol{\alpha},\boldsymbol{\beta}) = (\lambda-\mu)\ln\left(1+\sum_{i=1}^{N} S_{i,A}(1-x_i)\right)$$
$$+\lambda\ln\left(1+\sum_{i=1}^{N} S_{i,B}x_i\right) - \sum_{i=1}^{N}\alpha_i(x_i-1) + \sum_{i=1}^{N}\beta_i x_i, \tag{19}$$

where $\boldsymbol{\alpha} = [\alpha_1 \ \cdots \ \alpha_N]^T$ and $\boldsymbol{\beta} = [\beta_1 \ \cdots \ \beta_N]^T$ are the nonnegative dual variables associated with the constraints.

The dual function is $q(\boldsymbol{\alpha},\boldsymbol{\beta}) = \max_{\boldsymbol{x}} L(\boldsymbol{x},\boldsymbol{\alpha},\boldsymbol{\beta})$. The Lagrange dual problem is then given by $\min_{\boldsymbol{\alpha}\succcurlyeq 0,\boldsymbol{\beta}\succcurlyeq 0} q(\boldsymbol{\alpha},\boldsymbol{\beta})$. Therefore, the optimal solutions need to satisfy the following Karush-Kuhn-Tucker (KKT) conditions [18]:

$$\alpha_k(x_k^*-1) = 0, \tag{20}$$
$$\beta_k x_k^* = 0, \tag{21}$$
$$0 \le x_k^* \le 1, \tag{22}$$
$$\alpha_k^* \ge 0, \ \beta_k^* \ge 0, \tag{23}$$
$$\frac{\partial L(\boldsymbol{x},\boldsymbol{\alpha},\boldsymbol{\beta})}{\partial x_k^*} = -\frac{(\lambda-\mu)S_{k,A}}{1+\sum_{i=1}^{N} S_{i,A}(1-x_i^*)} + \frac{\lambda S_{k,B}}{1+\sum_{i=1}^{N} S_{i,B}x_i^*} - \alpha_k + \beta_k = 0, \tag{24}$$

Due to the complexity of the problem, solving the above KKT conditions will not render us a closed-form solution. However, from these KKT conditions, we are able to gain some significant features of the optimal solution.

Theorem 1. *The optimal solution of the relaxation problem has at most one user indexed by k ($k \in \{1,2,\cdots,N\}$), with a fractional x_k satisfying $0 < x_k < 1$.*

Proof. This theorem can be proved by contradiction. Suppose that there are two arbitrary users denoted by m and n having fractional x_m and x_n, respectively, i.e., $0 < x_m < 1$ and $0 < x_n < 1$. From (20) and (21), it follows that $\alpha_m = 0$, $\alpha_n = 0$, $\beta_m = 0$, and $\beta_n = 0$. Then, applying these facts to (24), it follows that

$$\frac{\lambda S_{m,B}}{1+\sum_{i=1}^{N} S_{i,B}x_i^*} - \frac{(\lambda-\mu)S_{m,A}}{1+\sum_{i=1}^{N} S_{i,A}(1-x_i^*)} = 0, \tag{25}$$
$$\frac{\lambda S_{n,B}}{1+\sum_{i=1}^{N} S_{i,B}x_i^*} - \frac{(\lambda-\mu)S_{n,A}}{1+\sum_{i=1}^{N} S_{i,A}(1-x_i^*)} = 0. \tag{26}$$

Then, for these two users, the following equality must hold

$$\frac{S_{m,B}}{S_{m,A}} = \frac{S_{n,B}}{S_{n,A}} = \frac{(\lambda-\mu)}{\lambda}\frac{1+\sum_{i=1}^{N} S_{i,B}x_i^*}{1+\sum_{i=1}^{N} S_{i,A}(1-x_i^*)}. \tag{27}$$

Table 1 Proposed centralized data offloading scheme

Proposed centralized data offloading scheme
(1) Solve Problem 3 by standard convex optimization algorithms, such as interior-point method [19], or existing solvers such as CVX [20]
(2) Convert the obtained solution into a feasible solution of Problem 2 by rounding the fractional indicator function to its nearest integer (0 or 1)

It is easy to observe that $\frac{S_{m,B}}{S_{m,A}} = \frac{S_{n,B}}{S_{n,A}}$ is equivalent to $\frac{g_{m,B}}{g_{m,A}} = \frac{g_{n,B}}{g_{n,A}}$, However, it can be verified that the equality $\frac{g_{m,B}}{g_{m,A}} = \frac{g_{n,B}}{g_{n,A}}$ is satisfied with a zero probability since the channel power gains are mutually independent and have continuous pdf. This result contradicts with our presumption. Thus, it is concluded that there is at most one user with a fractional x_k, i.e., $0 < x_k < 1$. Theorem 1 is thus proved.

From Theorem 1, it is observed that there is at most one user with a fractional indicator for the optimal solution of the relaxation problem. This indicates that the optimal solution of Problem 3 is either equal to or just one-user away from that of Problem 2. Thus, the following scheme is proposed to find the optimal solution of Problem 2.

In general, the above algorithm provides a suboptimal solution to Problem 2. However, due to the special feature presented in Theorem 1, we are able to prove that the proposed solution given in the Table 1 is near optimal when the number of users is large, which is given below.

Theorem 2. *The gap between the optimal solution of the Problem 2 and the proposed solution given in Table 1 is negligible when the number of users is large.*

Proof. For the convenience of exposition, we denote the maximum values of Problem 2 attained at the optimal solution and at the proposed solution given in Table 1 as f_o^* and f_s^*, respectively. Since the solution given in Table 1 is also a feasible solution of Problem 2. Thus, it follows that

$$f_s^* \leq f_o^*. \tag{28}$$

On the other hand, it is clear that the maximum value of Problem 2 is upper bounded by its relaxation problem. Thus, if we denote the maximum values of the relaxation problem attained at the optimal solution as f_r^*, it follows that

$$f_o^* \leq f_r^*. \tag{29}$$

Combining the above facts together, we have

$$f_s^* \leq f_o^* \leq f_r^*. \tag{30}$$

Thus, if we are able to show that the gap between f_s^* and f_r^* is negligible when the number of users is large, it is clear that the gap between f_s^* and f_o^* will also be negligible when the number of users is large.

Now, we show that the gap between f_s^* and f_r^* is negligible when the number of users is large. Suppose $\boldsymbol{x}^*$ is the optimal solution of the relaxation problem and user k is the user who has a fractional indicator function x_k^*. Then, the value of f_r^* is $\lambda \ln\left(1+\sum_{i=1}^{N} S_{i,B} x_i^*\right)+ (\lambda - \mu) \ln\left(1+\sum_{i=1}^{N} S_{i,A}(1 - x_i^*)\right)$. While the value of f_s^* is obtained by either setting $x_k = 0$ when $x_k < 0.5$ or setting $x_k = 1$ when $x_k \geq 0.5$. Obviously, it follows that $f_s^* > \tilde{f}_s{}^*$, where $\tilde{f}_s{}^* \triangleq \lambda \ln\left(1 + \sum_{i=1,i\neq k}^{N} S_{i,B} x_i^*\right) + (\lambda - \mu) \ln\left(1 + \sum_{i=1,i\neq k}^{N} S_{i,A}(1 - x_i^*)\right)$, which corresponds to the scenario where user k connects to neither the BS nor the AP.

Then, the gap Δ between f_s^* and f_r^* satisfies

$$\begin{aligned}\Delta < f_r^* - \tilde{f}_s{}^* &= \lambda \ln\left(1 + \frac{S_{k,B} x_k^*}{1+\sum_{i=1,i\neq k}^{N} S_{i,B} x_i^*}\right) \\ &+ (\lambda - \mu) \ln\left(1 + \frac{S_{k,A}(1-x_k^*)}{1+\sum_{i=1,i\neq k}^{N} S_{i,A}(1 - x_i^*)}\right). \end{aligned} \tag{31}$$

Since the users are uniformly distributed in the area, thus when the number of users is large, it is inferred that the denominators of the above equation will be very large. Consequently, the value of Δ is close to zero. Theorem 2 is thus proved.

Without SIC Decoder at Both Sides

In this subsection, we consider the scenario that both the BS and the WiFi AP are not equipped with SIC decoder. Then, the utility maximization problem of the cellular operator for this case can be formulated as

Problem 4.

$$\begin{aligned}\max_{\{x_i, y_i\}} \ & \lambda \sum_{i=1}^{N} \ln\left(1 + \frac{x_i g_{i,B} P}{\sum_{j=1,j\neq i}^{N} x_j g_{j,B} P + \sigma_B^2}\right) \\ & + (\lambda - \mu) \sum_{i=1}^{N} \ln\left(1 + \frac{y_i g_{i,A} P}{\sum_{j=1,j\neq i}^{N} y_j g_{j,A} P + \sigma_A^2}\right), \end{aligned} \tag{32}$$

$$\text{s.t.} \quad x_i \in \{0, 1\}, \ \forall i, \tag{33}$$

$$y_i \in \{0, 1\}, \ \forall i, \tag{34}$$

$$x_i + y_i \leq 1, \ \forall i. \tag{35}$$

Problem 4 is a nonlinear integer programming problem which is difficult to solve directly due to its high complexity. Besides, it is not difficult to verify that the relaxation problem of Problem 4 is non-convex. Thus, we are able not to solve this problem in the same way as Problem 1. Therefore, to solve Problem 4, we first consider the following two subproblems.

Subproblem 4a.

$$\max_{\{x_i,\forall i\}} \quad \lambda \sum_{i=1}^{N} \ln\left(1+\frac{x_i g_{i,B} P}{\sum_{j=1,j\neq i}^{N} x_j g_{j,B} P + \sigma_B^2}\right), \tag{36}$$

$$\text{s.t.} \quad x_i \in \{0,1\},\ \forall i. \tag{37}$$

Subproblem 4b.

$$\max_{\{y_i,\forall i\}} \quad (\lambda-\mu) \sum_{i=1}^{N} \ln\left(1+\frac{y_i g_{i,A} P}{\sum_{j=1,j\neq i}^{N} y_j g_{j,A} P + \sigma_A^2}\right), \tag{38}$$

$$\text{s.t.} \quad y_i \in \{0,1\},\ \forall i. \tag{39}$$

Denote the optimal solution of Subproblem 4a as $x_i^*,\ \forall i \in \{1,2,\cdots,N\}$ and that of Subproblem 4b as $y_i^*,\ \forall i \in \{1,2,\cdots,N\}$. Then, it is clear that if x_i^* and y_i^* satisfy the constraints (35) for all $i \in \{1,2,\cdots,N\}$, x_i^* and y_i^* will be the optimal solution for Problem 4. In the following, we will show that when the number of users is large, Problem 4 can be solved by individually solving Subproblems 4a and 4b. It is seen that Subproblems 4a and 4b have the same structure. As a result, the optimal solutions of these two subproblems should also have the same structure. Thus, we only need to solve one of them. In the following, using Subproblem 4b as an example, we present the optimal solution of subproblems.

Lemma 1. *If we sort the users according to their channel power gains in the following order:* $g_{1,A} \geq g_{2,A} \geq \cdots \geq g_{N,A}$, *then only the first* k^* *users are allowed to transmit at the optimal solution, where* k^* *is given by* $k^* = argmax_k \sum_{i=1}^{k} \ln\left(1+\frac{h_i P}{\sum_{j=1,j\neq i}^{k} h_j P+\sigma_A^2}\right)$ *and* $k \in \{1,2,\cdots,N\}$. *Especially, if* $g_{1,A} \geq \frac{(e-1)\sigma_A^2}{P}$ *is satisfied,* $k^* = 1$, *i.e., only the user with the largest channel power gain is allowed to transmit at the optimal solution.*

Proof. To solve Subproblem 4b, we first consider its relaxation problem, which is given as below.

Problem 5.

$$\max_{\{y_i,\forall i\}} \quad \sum_{i=1}^{N} \ln\left(1+\frac{y_i g_{i,A} P}{\sum_{j=1,j\neq i}^{N} y_j g_{j,A} P + \sigma_A^2}\right), \tag{40}$$

$$\text{s.t.} \quad 0 \leq y_i \leq 1,\ \forall i. \tag{41}$$

Let $P_i \triangleq y_i P, \forall i$; it is not difficult to observe that Problem 5 can be converted to the following problem,

Problem 6.

$$\max_{\{P_i, \forall i\}} \sum_{i=1}^{N} \ln\left(1 + \frac{g_{i,A} P_i}{\sum_{j=1, j\neq i}^{N} g_{j,A} P_j + \sigma_A^2}\right), \tag{42}$$

$$\text{s.t.} \quad 0 \leq P_i \leq P, \ \forall i. \tag{43}$$

This problem is shown to be Schur convex in [21]. By using the Schur convex properties, they showed that the optimal power allocation is binary power allocation, i.e., either 0 or P for all i. This indicates that the optimal solution for Problem 5 is either 0 or 1 for all i. Thus, it can be observed that Problem 5 is actually equivalent to Subproblem 4b. Then, the results obtained for Problem 6 can be directly applied to Subproblem 4b. Based on the results obtained in [21] (Theorems 1 and 4), it is not difficult to obtain the results presented in this lemma. Details are omitted here for brevity.

With the results given in Lemma 1, we are now ready for the following theorem.

Theorem 3. *When the number of users N is sufficiently large, the optimal solution for Problem 4 is as below.*

- *Only two users are left in the network: one connects to the BS, and the other one connects to the WiFi AP.*
- *Denote the index of the users connecting to the BS and the WiFi AP as m and n, respectively. Then, user m has the best channel between it and the BS, i.e., $m = argmax_i \ g_{i,B}$, and user n has the best channel between it and the WiFi AP, i.e., $n = argmax_i \ g_{i,A}$.*

Proof. This proof consists of two steps.

Step 1. Denote the probability that there exists at least one user satisfying $g_{i,A} \geq \frac{(e-1)\sigma_A^2}{P}$ as $\mathscr{P}_A$, and denote the probability that there exists at least one user satisfying $g_{i,B} \geq \frac{(e-1)\sigma_B^2}{P}$ as $\mathscr{P}_B$. Now, we show that when the number of users is large, both $\mathscr{P}_A$ and $\mathscr{P}_B$ are large.

$$\mathscr{P}_A = 1 - \text{Prob}\left\{g_{i,A} < \frac{(e-1)\sigma_A^2}{P}, \forall i\right\} \tag{44}$$

$$\stackrel{a}{=} 1 - \left(\text{Prob}\left\{g_A < \frac{(e-1)\sigma_A^2}{P}\right\}\right)^N \tag{45}$$

$$= 1 - \left(\int_0^{(e-1)\sigma_A^2/P} dF(g_A) \right)^N, \tag{46}$$

where the equality "a" results from the fact that the channel power gains are i.i.d. and $F(g_A)$ denotes the CDF of the channel power gain. Since $\int_0^{(e-1)\sigma_A^2/P} dF(g_A)$ is less than 1, it is clear that $\mathscr{P}_A$ goes to 1 as N goes to $+\infty$. Then, based on Lemma 4.1, as long as there exists a user satisfying $g_{i,A} \geq \frac{(e-1)\sigma_A^2}{P}$, the optimal solution for the Subproblem 4.1b should be $k^* = 1$, and the user should have the largest channel power gain among all the users, i.e., $n = \text{argmax}_i \; g_{i,A}$.

Using the same approach, we can show that when N is large, the optimal solution for the Subproblem 4a is that only the user with the largest channel power gain of the channel between it and the BS is allowed to transmit, i.e., $m = \text{argmax}_i \; g_{i,m}$. Details are omitted here for brevity.

Step 2. Denote the probability that there exists one user having the best channel between it and the BS and simultaneously having the best channel between it and the WiFi AP as $\mathscr{P}_C$. Now, we show that $\mathscr{P}_C$ is zero when the number of users is large.

$$\mathscr{P}_C = \binom{1}{N} \text{Prob}\{j = \text{argmax}_i \; g_{i,A} \text{ and } j = \text{argmax}_i \; g_{i,B}\} \tag{47}$$

$$\overset{a}{=} N \text{Prob}\{j = \text{argmax}_i \; g_{i,A}\} \text{Prob}\{j = \text{argmax}_i \; g_{i,B}\} \tag{48}$$

$$= \frac{1}{N} \tag{49}$$

where the equality "a" results from the fact that the channel power gains are i.i.d. Then, it is observed that $\mathscr{P}_C$ is a decreasing function with respect to N. Thus, it is clear that $\mathscr{P}_C$ goes to 0 as N goes to $+\infty$.

Theorem 3 is thus proved.

With SIC Decoder at One Side

In this subsection, we consider the scenario that the SIC decoder is only available at one side. Particularly, we only study the case that the SIC decoder is only available at the BS. This is due to the fact that the case that the SIC decoder is only available at the WiFi AP is a symmetric case of the case studied here and thus can be solved in the same way.

Problem 7.

$$\max_{\{x_i, y_i, \forall i\}} \; \lambda \ln\left(1 + \sum_{i=1}^N \frac{x_i g_{i,B} P}{\sigma_B^2}\right) + (\lambda - \mu) \sum_{i=1}^N \ln\left(1 + \frac{y_i g_{i,A} P}{\sum_{j=1, j\neq i}^N y_j g_{j,A} P + \sigma_A^2}\right), \tag{50}$$

$$\text{s.t.} \quad x_i \in \{0,1\},\ \forall i, \tag{51}$$

$$y_i \in \{0,1\},\ \forall i, \tag{52}$$

$$x_i + y_i \leq 1,\ \forall i. \tag{53}$$

Similar as Problem 4, we are not able to solve this problem directly or by solving its relaxation problem. Thus, to solve Problem 7, we first consider the following two subproblems.

Subproblem 7a.

$$\max_{\{x_i,\forall i\}} \ \lambda \ln\left(1+\sum_{i=1}^{N} \frac{x_i g_{i,B} P}{\sigma_B^2}\right), \tag{54}$$

$$\text{s.t.} \quad x_i \in \{0,1\},\ \forall i. \tag{55}$$

Subproblem 7b.

$$\max_{\{y_i,\forall i\}} \ (\lambda-\mu)\sum_{i=1}^{N} \ln\left(1+\frac{y_i g_{i,A} P}{\sum_{j=1,j\neq i}^{N} y_j g_{j,A} P + \sigma_A^2}\right), \tag{56}$$

$$\text{s.t.} \quad y_i \in \{0,1\},\ \forall i. \tag{57}$$

Denote the optimal solution of Subproblem 7a as $x_i^*,\ \forall i \in \{1,2,\cdots,N\}$ and that of Subproblem 7b as $y_i^*,\ \forall i \in \{1,2,\cdots,N\}$. Subproblem 7a is easy to solve, and the optimal solution is $x_i^* = 1, \forall i$. Subproblem 7b is exactly the same as Subproblem 4b, and thus the optimal solution of Subproblem 7b can be obtained from Lemma 1. It is obvious that x_i^* and y_i^* cannot satisfy the constraints (53) for all $i \in \{1,2,\cdots,N\}$. Thus, Problem 7 cannot be solved by directly solving Subproblems 7a and 7b. This makes Problem 7 more challenging than Problem 4.

To solve Problem 7, we need the following lemma.

Lemma 2. *The optimal solution of Problem 7 is obtained when* (53) *holds with equality for all* i.

Proof. This can be proved by contradiction. Suppose $(\boldsymbol{x}^*, \boldsymbol{y}^*)$ is the optimal solution of Problem 7 and it has an element (x_k^*, y_k^*) satisfying $x_k^* + y_k^* < 1$. Then, from (51) and (52), it follows that $x_k^* = 0, y_k^* = 0$. Now, we show that we can always find a feasible solution $(\tilde{\boldsymbol{x}}, \tilde{\boldsymbol{y}})$ with its elements satisfying $x_i^* + y_i^* = 1, \forall i$, which will result in a higher value of (50). We let $\tilde{\boldsymbol{x}}_{-k} = \boldsymbol{x}_{-k}^*, \tilde{\boldsymbol{y}}_{-k} = \boldsymbol{y}_{-k}^*$. Clearly, if we set $\tilde{x}_k^* = 1, \tilde{y}_k^* = 0$ will result in a higher value of (50) than that resulted by $x_k^* = 0, y_k^* = 0$ since the logarithm function is an increasing function. This contradicts with our presumption. Lemma 2 is thus proved.

Based on Lemma 2 and the optimal solutions of Subproblems 7a and 7b, we are able to obtain the following theorem.

Theorem 4. *When the number of users N is sufficiently large, the optimal solution for Problem 7 is: At most one user connects to the AP, and all the other users connect to the BS.*

Proof. Using the same approach as the proof of Theorem 3, we can easily show that the optimal solution of subproblems 7b is one-user dominant transmission (i.e. $k^* = 1$, only the user with the best channel is allowed to transmit.) when the number of users N is large. Based on this result, we prove Theorem 4 by contradictory as follows.

Let $\mathscr{S}^*$ be the optimal set of users connecting to the WiFi AP. Suppose $|\mathscr{S}^*| = 2$, where $|\cdot|$ denotes the cardinality of a set. Given this assumption, we have two possible cases: (1) There is a dominant user is in the set $\mathscr{S}^*$. (2) There is no dominant user in the set $\mathscr{S}^*$. In the following, we investigate these two cases, respectively.

- Case 1: *With a dominant user in* $\mathscr{S}^*$. In this case, if we assign the nondominant user to the BS, the utility at the BS side $\lambda R_B^w(\boldsymbol{x})$ will increase. On the other hand, based on Lemma 1, we know that the utility at the AP side is maximized if only the dominant user connects to the AP. Thus, by assigning the nondominant user to the BS, we can also increase the utility at the AP side $(\lambda - \mu) R_B^o(\boldsymbol{y})$. Then, it is clear that the total utility of the operator increases if we assign the nondominant user to the BS. This contradicts with our presumption.
- Case 2: *Without a dominant user in* $\mathscr{S}^*$. In this case, we assume that the dominant user is not in $\mathscr{S}^*$. We denote the channel power gain of the channel between the dominant user and the BS as $h_{1,B}$. Besides, we denote the channel power gains of the channels between the two nondominant users and the BS as $h_{m,B}$ and $h_{n,B}$, respectively. Based on the relationship between $h_{1,B}$ and $h_{m,B}$, $h_{n,B}$. It can be observed that if we switch the two nondominant users to the BS side and switch the dominant user to the WiFi AP side, we have four possible scenarios, which are listed in the following Table 2.

  It is observed that for the first three cases, the total utility of the cellular operator increases if we switch the connections of the nondominant users with that of the dominant user. However, for the last case, though the utility at the AP side increases, whether the utility at the BS side increase or not is uncertain. It is not difficult to observe that the utility at the BS side will increase if the following condition is satisfied.

Table 2 Four possible scenarios

	Conditions	Utility at BS	Utility at AP	Total utility
1	$h_{1,B} < h_{m,B},\ h_{1,B} < h_{n,B}$	Increase	Increase	Increase
2	$h_{1,B} < h_{m,B},\ h_{1,B} > h_{n,B}$	Increase	Increase	Increase
3	$h_{1,B} > h_{m,B},\ h_{1,B} < h_{n,B}$	Increase	Increase	Increase
4	$h_{1,B} > h_{m,B},\ h_{1,B} > h_{n,B}$	Uncertain	Increase	Uncertain

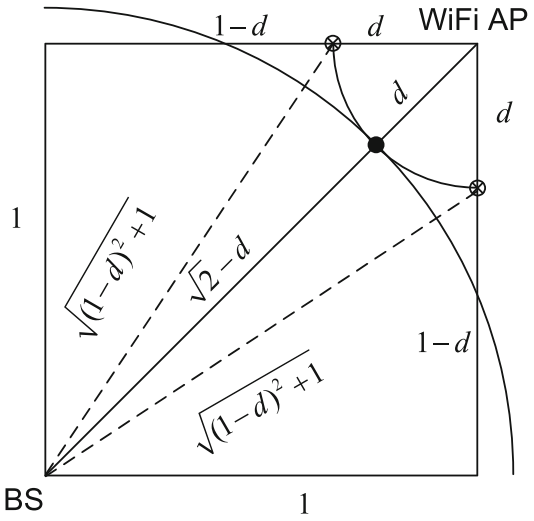

Fig. 2 Path loss model. ⊗ denotes the nondominant user, and • denotes the dominant user

$$h_{m,B}P + h_{n,B}P \geq h_{1,B}P. \tag{58}$$

In the following, we show that (58) always holds when the number of users is large. For the convenience of illustration, the proof given out here is based on the geometry of the network given in Fig. 2. However, it is worthy pointing out that the same result obtained here can be extended to any other geometries with minor revisions. In Fig. 2, we consider a 1 by 1 square area with the BS at coordinate $(0, 0)$ and the WiFi AP at $(1, 1)$. The number of users is denoted by N, and we assume these N users are uniformly scattered in the square area. The channel power gains are modeled by path loss model, i.e., $g = d^{-\gamma}$, where γ is the path loss exponent. For the convenience of analysis, we assume that $\gamma = 2$.

Based on the geometry given in Fig. 2, we consider the worst-case scenario. Thus, the utility of the BS will increase if $\frac{2P}{(1-d)^2+1} \geq \frac{P}{(\sqrt{2}-d)^2}$ holds, which is equivalent to $d < 0.67$. When there are N users in the network, the probability that this condition holds is given by $\mathscr{P}_{\text{in}} = 1 - (\text{Prob}\{d > C\})^N$. It can be observed that $\mathscr{P}_{\text{in}}$ goes to 1 when N goes to $+\infty$. This indicates that when the number of users is very large, the utility at the BS side will increase with almost probability one. Based on the results given above, it is concluded that when the number of users is large, switching the two nondominant users with the dominant user will always result in the increase of the total utility. This contradicts with our presumption.

Combining the results obtained in Cases 1 and 2, it is observed that $|\mathscr{S}^*|$ should not be equal to 2. Using the same approach, we can show that $|\mathscr{S}^*|$ cannot be equal to any number in the set $\{3, 4, \cdots, N\}$. Therefore, it is concluded that there is at most one user connecting to the WiFi AP at the optimal solution of Problem 7.

Table 3 Proposed data offloading scheme for Problem 7

Proposed data offloading scheme for Problem 7
1. **For** $k = 1 : N$;
initialize $\boldsymbol{x} = [1, 1, \cdots, 1]^T$; $\boldsymbol{y} = [0, 0, \cdots, 0]^T$;
set $\boldsymbol{x}(k) = 0$; $\boldsymbol{y}(k) = 1$;
compute $\boldsymbol{F}(k) = U(\boldsymbol{x}, \boldsymbol{y})$;
end
2. Find the optimal allocation and the maximum value of $\boldsymbol{F}$, $[F_{\max}, \text{index}] = \max \boldsymbol{F}$;
3. Compare $F_{\max}$ with the utility without offloading $U(\mathbf{1}_N, \mathbf{0}_N)$

Theorem 4 is thus proved.

Based on the result given in Theorem 4, the optimal solution of Problem 7 can be easily found by the following algorithm (Table 3).

Benefit of SIC Decoder

In this subsection, we investigate the role of the SIC decoder plays in the utility maximization of the cellular operator. We rigorously prove that the SIC decoder is beneficial for the cellular operator in terms of maximizing its utility.

Theorem 5. *Let* $(\boldsymbol{x}^*, \boldsymbol{y}^*)$, $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*)$, *and* $(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ *be the optimal solutions of Problems 1, 4, and 7, respectively. In general, the following inequality always holds*

$$U^{ww}(\boldsymbol{x}^*, \boldsymbol{y}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) \geq U^{oo}(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*). \tag{59}$$

Proof. To prove Theorem 5, we first show that $U^{ww}(\boldsymbol{x}^*, \boldsymbol{y}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$. It can be observed that $U^{ww}(\boldsymbol{x}^*, \boldsymbol{y}^*) \geq U^{ww}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$. This is due to the fact that $(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ is a feasible solution of Problem 1, while $(\boldsymbol{x}^*, \boldsymbol{y}^*)$ is the optimal solution of Problem 1. Thus, if we can show that $U^{ww}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ holds, $U^{ww}(\boldsymbol{x}^*, \boldsymbol{y}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ will hold. In the following, we show that $U^{ww}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ always holds. Since $U^{ww}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) = \lambda R_B^w(\tilde{\boldsymbol{x}}^*) + (\lambda - \mu) R_A^w(\tilde{\boldsymbol{y}}^*)$ and $U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) = \lambda R_B^w(\tilde{\boldsymbol{x}}^*) + (\lambda - \mu) R_A^o(\tilde{\boldsymbol{y}}^*)$, we only need to show that $R_A^w(\tilde{\boldsymbol{y}}^*) \geq R_A^o(\tilde{\boldsymbol{y}}^*)$ always holds, which is presented as below.

Assume that K elements of $\tilde{\boldsymbol{y}}^*$ are equal to 1, where $K \in \{1, 2, \cdots, N\}$. Then, it follows that

$$\begin{aligned} R_A^w(\tilde{\boldsymbol{y}}^*) &= \ln\left(1 + \sum_{i=1}^{K} \frac{g_{i,A} P}{\sigma_A^2}\right) \\ &= \ln\left(\frac{\sigma_A^2 + \sum_{i=1}^{K} g_{i,A} P}{\sigma_A^2}\right) \end{aligned}$$

$$
\begin{aligned}
&= \ln\left[\left(\frac{\sigma_A^2+\sum_{i=1}^{K} g_{i,A}P}{\sigma_A^2+\sum_{i=2}^{K} g_{i,A}P}\right)\left(\frac{\sigma_A^2+\sum_{i=2}^{K} g_{i,A}P}{\sigma_A^2+\sum_{i=3}^{K} g_{i,A}P}\right)\cdots\left(\frac{\sigma_A^2+\sum_{i=K}^{K} g_{i,A}P}{\sigma_A^2}\right)\right] \\
&\overset{a}{=} \sum_{j=1}^{K} \ln\left(\frac{\sigma_A^2+\sum_{i=j}^{K} g_{i,A}P}{\sigma_A^2+\sum_{i=j+1}^{K} g_{i,A}P}\right) \\
&= \sum_{j=1}^{K} \ln\left(1+\frac{g_{j,A}P}{\sigma_A^2+\sum_{i=j+1}^{K} g_{i,A}P}\right) \\
&\overset{b}{\geq} \sum_{j=1}^{K} \ln\left(1+\frac{g_{j,A}P}{\sigma_A^2+\sum_{i=1,i\neq j}^{K} g_{i,A}P}\right) = R_A^o(\tilde{\boldsymbol{y}}^*),
\end{aligned} \tag{60}
$$

where we introduce a dumb item $\sum_{i=K+1}^{K} g_{i,A}P = 0$ in the equality "a" for notation convenience. The inequality "b" follows from the fact that $\sum_{i=1,i\neq j}^{K} g_{i,A}P \geq \sum_{i=j+1}^{K} g_{i,A}P$ for each j.

Then, it is clear that $U^{ww}(\boldsymbol{x}^*, \boldsymbol{y}^*) \geq U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*)$ always holds. Using the same approach, we can easily show that $U^{wo}(\tilde{\boldsymbol{x}}^*, \tilde{\boldsymbol{y}}^*) \geq U^{oo}(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*)$ always holds. Theorem 5 is thus proved.

From Theorem 5, it is observed that SIC decoder plays an important role in the utility maximization of the cellular operator. In the long run, it is always beneficial for the operator to equip the BS and/or AP with SIC decoders in terms of maximizing its utility.

Incentive Mechanisms

In the previous section, we use a very simple incentive mechanism when studying the association rules. In this section, we investigate the incentive mechanisms and show its impact on the system performance. Stackelberg game is adopted to design and analyze the proposed incentive mechanism.

Game Formulation

A Stackelberg game [3] is a strategic game that consists of a leader and several followers competing with each other on certain resources. The leader moves first and the followers move subsequently. We consider a heterogeneous network with a MNO and multiple WiFi APs. The set of WiFi APs is denoted by $\mathcal{N}$. All the WiFi APs can provide data offloading service for the MNO. In particular, we consider the case that each WiFi AP may have its home users (HUs), and thus it should reserve certain bandwidth for its HUs. Like the existing work [13–15], we design incentive mechanism purely from the data level. Thus, the related physical layer and MAC layer issues to implement the data offloading schemes are out of concern.

We formulate the MNO as the leader and the WiFi APs as the followers. The MNO (leader) announces a salary and a bonus to the WiFi APs. Then, each WiFi AP (follower) determines its optimal amount of data (that it intends to offload) to maximize its utility based on the salary and the bonus. Thus, the Stackelberg game consists of two parts, the game at the WiFi APs and the game at the MNO, which are introduced as follows.

Game at the WiFi APs

Let p denote the pay rate, i.e., cash paid to a WiFi AP on per unit of data offloaded. Let B denote the total amount of bonus paid to all WiFi APs for data offloading. Then, the utility function of an arbitrary WiFi AP can be modeled as

$$\mathscr{U}_i^F(\boldsymbol{d}, p, B) = \mathscr{S}_i(p, d_i) + \mathscr{B}_i(B, \boldsymbol{w}, \boldsymbol{d}) - \mathscr{C}_i(d_i), \tag{61}$$

where $\boldsymbol{d} \triangleq [d_1, \cdots, d_N]^T$ with entry d_i denoting the amount of data that AP_i offloads for the MNO and $\boldsymbol{w} \triangleq [w_1, \cdots, w_N]^T$ with entry w_i denoting the quality of offloading service provided by AP_i.

It is observed from (61) that each AP's utility function consists of three parts: $\mathscr{S}_i(p, d_i)$, $\mathscr{B}_i(B, \boldsymbol{w}, \boldsymbol{d})$, and $\mathscr{C}_i(d_i)$. In the following, we present how to model them under the proposed incentive mechanism.

Salary: $\mathscr{S}_i(p, d_i)$ denotes the salary of AP_i, i.e., the payment received for providing data offloading service for the MNO. $\mathscr{S}_i(p, d_i)$ is a function of d_i and p. Intuitively, the more work you have done, the more payment you should receive. Thus, $\mathscr{S}_i(p, d_i)$ should be an increasing function of d_i. Besides, $\mathscr{S}_i(p, d_i)$ also should be an increasing function of p, since the higher the pay rate is, the more payment you will receive. In this paper, for simplicity, we use a linear function to model the salary, which is given as

$$\mathscr{S}_i(p, d_i) = p d_i. \tag{62}$$

Bonus: $\mathscr{B}_i(B, \boldsymbol{w}, \boldsymbol{d})$ denotes the bonus paid to AP_i by the MNO. In game theory literature, there are many bonus distribution models, such as equal share, Shapley value [16], and marginal contribution. In this work, to better stimulate WiFi APs to participate in data offloading, we use the weighted proportional share model, which is

$$\mathscr{B}_i(B, \boldsymbol{w}, \boldsymbol{d}) = \frac{w_i d_i}{\sum_{j \in \mathscr{N}} w_j d_j} B. \tag{63}$$

It is observed from (61) that AP_i's bonus $\mathscr{B}_i$ not only depends on its own performance (quality of offloading service w_i and amount of data offloaded d_i) but also depends on other APs' performance ($\boldsymbol{w}_{-i}$ and $\boldsymbol{d}_{-i}$). This is analogous to the bonus system in human's society, where a staff's bonus not only depends on his/her own performance but also depends on other staffs' performance.

Cost: $\mathscr{C}_i(d_i)$ denotes the cost incurred when AP_i provides data offloading service for the MNO. Usually, when a WiFi AP provides data service for more users, it will incur more cost, such as electricity cost, data usage cost, etc. In general, the cost increases with the increasing of the amount of data offloaded. Thus, in this work, we model the cost as

$$\mathscr{C}_i(d_i) = c_i d_i, \tag{64}$$

where c_i is a positive constant that relates the amount of data offloaded to the cost of AP_i.

Under the Stackelberg game formulation, the amount of data that AP_i intends to offload depends on the pay rate p and the bonus B. In general, if the MNO sets a high p and a high B, AP_i is willing to offload more data and vice versa. Thus, each WiFi AP has to determine its optimal d_i^* given p, B and other APs' offloading amount. Mathematically, the problem can be written as

Problem 8.

$$\max_{d_i \geq 0} \quad p d_i + \frac{w_i d_i}{\sum_{j \in \mathscr{N}} w_j d_j} B - c_i d_i, \tag{65}$$

$$\text{s.t.} \quad d_i \leq T_i, \tag{66}$$

where $T_i \triangleq T_i^C - T_i^H$. T_i^C is the maximum amount of data that can be admitted within the AP_i's capacity and T_i^H is the data quota reserved for its HUs. Thus, the constraint (66) represents the maximum amount of data that a WiFi AP can offload.

Game at the MNO

We define the MNO's utility and present the game at the MNO. Without loss of generality, in this paper, we define the MNO's utility function as

$$\mathscr{U}^L(p, B, \boldsymbol{d}) \triangleq \mathscr{R}^L(p, B, \boldsymbol{d}) - \mathscr{C}^L(p, B, \boldsymbol{d}), \tag{67}$$

where $\mathscr{R}^L(p, B, \boldsymbol{d})$ is the payoff/benefit gained from offloading data and $\mathscr{C}^L(p, B, \boldsymbol{d})$ is the cost incurred due to data offloading.

Note that the MNO's utility function consists of two parts: payoff and cost. Both of them are functions of p, B, and $\boldsymbol{d}$. In the following, we present how to model them under the proposed incentive mechanism.

Payoff: The MNO's payoff is the benefit or reward gained from offloading data. In this paper, we model the MNO's payoff as

$$\mathscr{R}^L(p, B, \boldsymbol{d}) = \lambda f(\boldsymbol{d}), \tag{68}$$

where $f(\boldsymbol{d})$ is the *offloading beneficial factor* (OBF) for the MNO and λ is a positive constant converting the offloading benefit into monetary reward. In this paper, we use a log function to model the OBF, i.e.,

$$f(\boldsymbol{d}) \triangleq \log_2\left(1+\sum_{i\in\mathcal{N}} d_i\right). \tag{69}$$

Though other functions (such as linear functions or exponential functions) can also be used to model OBE, log functions are shown in literatures to be more suitable to representing the relationship between the network performance and a large class of elastic data traffics [22]. It is observed from (69) that when the amount of data offloaded is zero ($\sum_{i\in\mathcal{N}} d_i = 0$), the OBE f is zero. Besides, the OBE increases with the increasing of the amount of data offloaded. These indicate that (69) is able to capture the relationship between the MNO's benefit and the data offloaded.

Cost: The MNO's cost includes two parts: the salary and the bonus. With a unified pay rate p, the total salary paid to WiFi APs is $p\sum_{i\in\mathcal{N}} d_i$. We assume that the bonus that the MNO intends to hand out is B. Thus, the cost function of the MNO can be modelled as

$$\mathscr{C}^L(p, B, \boldsymbol{d}) = p\sum_{i\in\mathcal{N}} d_i + B. \tag{70}$$

As pointed out in the previous subsection, the amount of data that each AP intends to offload depends on the pay rate p and the bonus B. Thus, the MNO can easily control the total amount of data offloaded to WiFi APs by controlling p and B. However, the benefit of the MNO received from data offloading also depends on p and B. Setting high pay rate and high bonus can help the MNO offload more data; however, this also increases the operating cost of the MNO. Therefore, the MNO needs to find the optimal p^* and B^* in order to maximize its utility. Mathematically, the problem can be written as

Problem 9.

$$\max_{p,\ B}\ \lambda \ln\left(1+\sum_{i\in\mathcal{N}} d_i(p,B)\right) - p\sum_{i\in\mathcal{N}} d_i(p,B) - B, \tag{71}$$

$$\text{s.t.}\quad p \geq 0,\ B \geq 0. \tag{72}$$

Optimal Solutions and Equilibrium Analysis

Problems 8 and 9 together form a Stackelberg game. The objective of this game is to find the Stackelberg equilibrium (SE) point(s) from which neither the MNO (leader) nor the WiFi APs (followers) have incentives to deviate. For the proposed Stackelberg game, the SE is defined as follows.

Definition 1. Let d_i^* be the solution for Problem 8 and (p^*, B^*) be the solution for Problem 9. Then, the point $(\boldsymbol{d}^*, p^*, B^*)$ is a SE for the proposed Stackelberg game if, for any $(\boldsymbol{d}, p, B)$, the following conditions are satisfied:

$$\mathscr{U}^L(p^*, B^*, \boldsymbol{d}^*) \geq \mathscr{U}^L(p, B, \boldsymbol{d}^*), \tag{73}$$

$$\mathscr{U}_i^F(d_i^*, p^*, B^*) \geq \mathscr{U}_i^F(d_i, p^*, B^*), \forall i. \tag{74}$$

where $\mathscr{U}^L$ and $\mathscr{U}_i^F$ are the utilities of the MNO and the WiFi AP$_i$, respectively.

To find the SE, the optimal strategies for the followers (WiFi APs) must be obtained first, and then the leader (MNO) derives its optimal strategy on those of the followers. This is also known as *backward induction* in game-theoretic studies. For the proposed game, the optimal strategies are derived in the following two subsections, respectively.

Optimal Strategies of WiFi APs

To find the optimal strategies of WiFi APs, we first look at the best response of each WiFi AP given p, B, and other APs' strategies, which is given in the following theorem.

Theorem 6. *The best response function of AP$_i$ is*

$$d_i^* = \begin{cases} 0, & \text{if } a_i > 0 \text{ and } B \leq a_i \frac{z_i}{w_i}, \\ T_i, & \text{if } a_i \leq 0 \text{ or } B \geq a_i \frac{z_i}{w_i}(1 + \frac{w_i T_i}{z_i})^2, \\ \sqrt{\frac{B z_i}{a_i w_i}} - \frac{z_i}{w_i}, & \text{otherwise.} \end{cases} \tag{75}$$

where

$$z_i \triangleq \sum_{j \in \mathscr{N}/\{i\}} w_j d_j \text{ and } a_i \triangleq c_i - p. \tag{76}$$

Proof. Take the derivative of $\mathscr{U}_i^F$ with respect to d_i, we have

$$\frac{\partial \mathscr{U}_i^F}{\partial d_i} = p + \frac{B w_i \sum_{j \in \mathscr{N}/\{i\}} w_j d_j}{\left(\sum_{j \in \mathscr{N}} w_j d_j\right)^2} - c_i, \tag{77}$$

- Case 1: $p - c_i \geq 0$. When $p - c_i \geq 0$, $\frac{\partial \mathscr{U}_i^F}{\partial d_i}$ is always positive, which indicates $\mathscr{U}_i^F$ is monotonically increasing with d_i. Thus, $\mathscr{U}_i^F$ attains its maximum when $d_i^* = T_i$.
- Case 2: $p - c_i < 0$. When $p - c_i < 0$, let $\frac{\partial \mathscr{U}_i^F}{\partial d_i}\big|_{d_i = d_i^\circ} = 0$, we have

$$d_i^\circ = \sqrt{\frac{B \sum_{j \in \mathscr{N}/\{i\}} w_j d_j}{w_i (c_i - p)}} - \frac{\sum_{j \in \mathscr{N}/\{i\}} w_j d_j}{w_i}. \tag{78}$$

Since $\frac{\partial^2 \mathscr{U}_i^F}{\partial d_i^2} = -\frac{2Bw_i^2 \sum_{j\in\mathscr{N}/\{i\}} w_j d_j}{\left(\sum_{j\in\mathscr{N}} w_j d_j\right)^3} < 0$, $\mathscr{U}_i^F$ is concave in d_i, and it follows that

$$d_i^* = \begin{cases} 0, & \text{if } d_i^\circ \le 0, \\ d_i^\circ, & \text{if } 0 < d_i^\circ < T_i, \\ T_i, & \text{if } d_i^\circ \ge T_i. \end{cases} \tag{79}$$

Then, let $z_i \triangleq \sum_{j\in\mathscr{N}/\{i\}} w_j d_j$ and $a_i \triangleq c_i - p$. Theorem 6 follows by combining the results obtained in Cases 1 and 2.

Now, we investigate the Nash equilibrium (NE) of this subgame. First, we show the existence of NE.

Existence of NE: It is observed from Problem 8 that APs' strategy set is compact and convex. The utility of AP_i is continuous and concave in d_i and continuous in $\boldsymbol{d}_{-i}$. Thus, according to the **Debreu-Glicksberg-Fan** theorem [16], a pure strategy NE exists.

Next, we show how to find the NE. To find the multiuser NE is very difficult and may be mathematically intractable. Thus, to get close-form solutions and obtain useful insights, we assume all the WiFi APs are of the same type, i.e., $w_i = w$, $c_i = c$, $T_i = T$, $\forall i$. For this case, the NE is computed as follows.

- When $a \le 0$, the NE is

$$d_i^{ne} = T, \ \forall i. \tag{80}$$

- When $a > 0$, the NE is

$$d_i^{ne} = \begin{cases} \frac{B(|\mathscr{N}|-1)}{a|\mathscr{N}|^2}, & \text{if } \frac{B}{a} < \frac{|\mathscr{N}|^2 T}{|\mathscr{N}|-1}, \\ T, & \text{if } \frac{B}{a} \ge \frac{|\mathscr{N}|^2 T}{|\mathscr{N}|-1}, \end{cases} \tag{81}$$

where $|\cdot|$ denotes the cardinality of a set.

It is observed that (i) different values of p and B will result in different NE; (ii) for given p and B, the NE is unique; and (iii) all the WiFi APs have the same strategy at the NE.

Optimal Strategy of the MNO

Given the AP's strategy, we now study the best strategy of the MNO. To find the optimal strategy of the MNO, we need to substitute the subgame NE given in (81) into Problem 9.

First, we look at the case that $a \le 0$, i.e., $p \ge c$. For this case, the subgame NE is given by (80). Substitute (80) into Problem 9, the MNO's utility maximization problem becomes

$$\max_{p,B} \ \lambda \ln(1+|\mathcal{N}|T) - p|\mathcal{N}|T - B, \tag{82}$$

$$\text{s.t.} \quad p \geq 0, \ B \geq 0. \tag{83}$$

The optimal solution of this problem is

$$p^* = c, \ B^* = 0. \tag{84}$$

This result indicates that p is bounded by c and the MNO will never set a p^* larger than c.

Now, we look at the case that $a > 0$, i.e., $p < c$. For this case, we first present the following theorem.

Theorem 7. *For any given p with $0 \leq p < c$, the best strategy of the MNO is*

$$B^* = \begin{cases} \frac{\lambda}{1+p\frac{|\mathcal{N}|-1}{a|\mathcal{N}|}} - \frac{1}{\frac{|\mathcal{N}|-1}{a|\mathcal{N}|}}, & \text{if } \tilde{\mathscr{U}}^{\mathrm{L}} < \hat{\mathscr{U}}^{\mathrm{L}}, \\ \frac{a|\mathcal{N}|^2 T}{|\mathcal{N}|-1}, & \text{if } \tilde{\mathscr{U}}^{\mathrm{L}} \geq \hat{\mathscr{U}}^{\mathrm{L}}. \end{cases} \tag{85}$$

where $\tilde{\mathscr{U}}^{L} \triangleq \lambda \ln(1+|\mathcal{N}|T) - p|\mathcal{N}|T - \frac{a|\mathcal{N}|^2 T}{|\mathcal{N}|-1}$ *and* $\hat{\mathscr{U}}^{L} \triangleq \ln\left(\frac{\lambda}{p+\frac{a|\mathcal{N}|}{|\mathcal{N}|-1}}\right) + \frac{a|\mathcal{N}|}{|\mathcal{N}|-1} + p - \lambda$.

Proof. (i) When $B < \frac{a|\mathcal{N}|^2 T}{|\mathcal{N}|-1}$, the MNO's utility can be written as

$$\max_{B \geq 0} \ \lambda \ln\left(1 + \frac{B(|\mathcal{N}|-1)}{a|\mathcal{N}|}\right) - p\frac{B(|\mathcal{N}|-1)}{a|\mathcal{N}|} - B, \tag{86}$$

It is easy to verify (86) is concave in B by looking at its second-order derivative. Then, the optimal $\hat{B}^*$ can be obtained by setting the first-order derivative of (86) to zero, which is

$$\lambda \frac{\frac{(|\mathcal{N}|-1)}{a|\mathcal{N}|}}{\frac{(|\mathcal{N}|-1)}{a|\mathcal{N}|}\hat{B}^* + 1} - p\frac{(|\mathcal{N}|-1)}{a|\mathcal{N}|} - 1 = 0, \tag{87}$$

Then, it follows that

$$\hat{B}^* = \frac{\lambda}{1+p\frac{|\mathcal{N}|-1}{a|\mathcal{N}|}} - \frac{1}{\frac{|\mathcal{N}|-1}{a|\mathcal{N}|}}. \tag{88}$$

and the resultant utility is

$$\hat{\mathscr{U}}^L = \ln\left(\frac{\lambda}{p + \frac{a|\mathscr{N}|}{|\mathscr{N}|-1}}\right) + \frac{a|\mathscr{N}|}{|\mathscr{N}|-1} + p - \lambda. \tag{89}$$

(ii) When $B \geq \frac{a|\mathscr{N}|^2 T}{|\mathscr{N}|-1}$, it is easy to observe that

$$\tilde{B}^* = \frac{a|\mathscr{N}|^2 T}{|\mathscr{N}|-1}, \tag{90}$$

and the resultant utility is

$$\tilde{\mathscr{U}}^L = \lambda \ln(1 + |\mathscr{N}|T) - p|\mathscr{N}|T - \frac{a|\mathscr{N}|^2 T}{|\mathscr{N}|-1}. \tag{91}$$

Combining (i) and (ii), (85) follows.
It is observed from Theorem 7 that for any given p satisfying $0 \leq p < c$, the optimal B^* is unique. Besides, as pointed out in (84), p^* is bounded by c. Thus, the optimal p^* can be obtained by searching over the region $[0, c]$. Therefore, the Stackelberg game is solved, and the SE always exists since there exists a unique subgame NE for any given p and B.

Heterogeneous WiFi APs

In the previous subsection, to obtain closed-form solutions and get useful insights, we assume all the WiFi APs are homogeneous, i.e., having the same type. In this subsection, we consider the case that different WiFi APs have different parameters. To facilitate the analysis, we start with the two-AP case and then extend the results to multi-AP case.

Optimal Strategies of WiFi APs

We first derive the optimal strategies of WiFi APs. For given p and B, the best response functions of WiFi APs are given by (75). Based on (75), the subgame NE is obtained in the following theorem.

Theorem 8. *Assume $c_2 > c_1$, the subgame NE denoted by (d_1^{ne}, d_2^{ne}) is given as*

(i) When $p \geq c_2 > c_1$, the NE is

$$(d_1^{ne}, d_2^{ne}) = (T_1, T_2). \tag{92}$$

(ii) When $c_2 > p \geq c_1$, the NE is

$$(d_1^{ne}, d_2^{ne}) = \begin{cases} (T_1, 0), & \text{if } 0 \leq B < \frac{a_2}{w_2} w_1 T_1, \\ \left(T_1, \sqrt{\frac{B w_1 T_1}{w_2 a_2}} - \frac{w_1 T_1}{w_2}\right), & \text{if } \frac{a_2 w_1 T_1}{w_2} \leq B < \frac{a_2}{T_1} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2}, \\ (T_1, T_2), & \text{if } \frac{a_2}{T_1} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2} \leq B. \end{cases} \tag{93}$$

(iii) When $c_2 > c_1 > p \geq 0$ and $a_1 T_1 < a_2 T_2$, the NE is

$$(d_1^{ne}, d_2^{ne}) = \begin{cases} \left(\frac{B w_1 w_2 a_2}{(w_1 a_2 + w_2 a_1)^2}, \frac{B w_1 w_2 a_1}{(w_1 a_2 + w_2 a_1)^2}\right) & \text{if } B \in \mathscr{A}_1, \\ \left(T_1, \sqrt{\frac{B w_1 T_1}{w_2 a_2}} - \frac{w_1 T_1}{w_2}\right), & \text{if } B \in \mathscr{A}_2, \\ (T_1, T_2), & \text{if } B \in \mathscr{A}_3. \end{cases} \tag{94}$$

where the regions are defined as: $\mathscr{A}_1 \triangleq \left(0, \frac{(w_1 a_2 + w_2 a_1)^2}{w_1 w_2} \frac{T_1}{a_2}\right)$, $\mathscr{A}_2 \triangleq \left[\frac{(w_1 a_2 + w_2 a_1)^2}{w_1 w_2} \frac{T_1}{a_2}, \frac{a_2}{T_1} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2}\right)$, *and* $\mathscr{A}_3 \triangleq \left[\frac{a_2}{T_1} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2}, \infty\right)$.

(iv) When $c_2 > c_1 > p \geq 0$ and $a_1 T_1 > a_2 T_2$, the NE is

$$(d_1^{ne}, d_2^{ne}) = \begin{cases} \left(\frac{B w_1 w_2 a_2}{(w_1 a_2 + w_2 a_1)^2}, \frac{B w_1 w_2 a_1}{(w_1 a_2 + w_2 a_1)^2}\right) & \text{if } B \in \tilde{\mathscr{A}_1}, \\ \left(\sqrt{\frac{B w_2 T_2}{w_1 a_1}} - \frac{w_2 T_2}{w_1}, T_2\right), & \text{if } B \in \tilde{\mathscr{A}_2}, \\ (T_1, T_2), & \text{if } B \in \tilde{\mathscr{A}_3}. \end{cases} \tag{95}$$

where the regions are defined as: $\tilde{\mathscr{A}_1} \triangleq \left(0, \frac{(w_1 a_2 + w_2 a_1)^2}{w_1 w_2} \frac{T_2}{a_1}\right)$, $\tilde{\mathscr{A}_2} \triangleq \left[\frac{(w_1 a_2 + w_2 a_1)^2}{w_1 w_2} \frac{T_2}{a_1}, \frac{a_1}{T_2} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2}\right)$, *and* $\tilde{\mathscr{A}_3} \triangleq \left[\frac{a_1}{T_2} \frac{(w_1 T_1 + w_2 T_2)^2}{w_1 w_2}, \infty\right)$.

From Theorem 8, we can observe that:

- For any given p and B, the NE is unique.
- The order of $a_i T_i$s has an impact on the NE. The WiFi AP with lower $a_i T_i$ is more likely to reach its capacity limit T_i first.

Optimal Strategy of the MNO

Now, given WiFi AP's strategy, we derive the optimal strategies of the MNO. Problem 9 becomes a non-convex optimization problem given WiFi AP's strategy. Thus, convex optimization techniques or existing convex optimizers cannot be applied here. However, we can show that (i) the optimal p^* is bounded by c_2 and

(ii) for a given p, Problem 9 is concave in B for each separate region of B (such as $\mathscr{A}_1$, $\mathscr{A}_2$, and $\mathscr{A}_3$). Thus, the optimal B for each separate region can be easily obtained using the convex optimization techniques. Then, the optimal B^* can be obtained by comparing the maximum utility function of each separate region. Based on these facts, the optimal strategy of the MNO can be obtained in the following two steps: (i) For a given p, compute the optimal B^*. (ii) Search for the optimal p^* over the region $[0, c_2]$.

Multi-AP Case

For given p and B, the best response for each AP is given by (75). However, the subgame NE cannot be obtained in closed-form due to the high complexity. Numerically, the subgame NE can be computed by the simplicial method [23]. The basic idea is to solve the nonlinear equilibrium problem by solving a piecewise linear approximation of the problem. Details are omitted here for brevity. Interested readers can refer to [23] for details. For the MNO's side, the optimal strategy cannot be obtained in closed form since there is no explicit expression of the WiFi AP's strategy. Numerically, we can solve the MNO's optimal strategy in the following way. Similar as the two-AP case, we can show that p^* is bounded by $\text{argmax}_i c_i$. We can further show that B^* is bounded by $\text{argmax}_i \frac{a_i}{w_i z_i} \left(\sum_{i \in \mathscr{N}} w_i T_i\right)^2$. Since both p^* and B^* are bounded, the MNO's optimal strategy can be obtained by performing a two-dimensional grid search over p and B.

Numerical Results

In this section, numerical results are provided to evaluate the performance of the proposed studies.

Simulation Parameters

The simulation setup is as follows. We consider a 1 by 1 square area with the base station at coordinate $(0, 0)$ and the WiFi AP at $(1, 1)$. The number of users is denoted by N, and we assume these N users are uniformly scattered in the square area. For simplicity, without specific declaration, we assume that the transmit power of each user is the same and given by 1. For the convenience of exposition, the path loss model is adopted to model the channel power gain. Let $(\text{posx}_i, \text{posy}_i)$ denotes the position of user i; then the channel power gain between it and the BS can be modeled as $g_{i,B} = \left(\sqrt{\text{posx}_i^2 + \text{posy}_i^2}\right)^{-\gamma}$, where γ is the path loss coefficient. Similarly, the channel power gain between the user i and the AP can be modeled as $g_{i,A} = \left(\sqrt{(1 - \text{posx}_i)^2 + (1 - \text{posy}_i)^2}\right)^{-\gamma}$. In this paper, we adopt the free space path loss model where $\gamma = 2$. The power of the additive Gaussian noises at the BS

and the AP is set to 1, i.e., $\sigma_B^2 = 1$ and $\sigma_A^2 = 1$. The revenue coefficient λ of the BS is set to 1, and the cost coefficient μ is set to 0.5.

Association Rules

With SIC Decoder at Both Sides

In Fig. 3, we investigate the gap between the proposed centralized data offloading scheme given in Table 1 and the optimal solution. For the purpose of illustration, the gap is normalized by the value of the utility attained at the optimal solution. The result presented in Fig. 3 is averaged over 100 channel realizations for each N. It is observed from Fig. 3 that the normalized utility gap decreases with the increase of the number of users. When there are only two users in the network, the normalized utility gap is as large as 0.85%. When the number of users goes up to 16, the normalized utility gap is almost zero.

In Fig. 4, we study the performance of the proposed centralized data offloading scheme. In this case, we also generate 1000 channel realizations for each N. We count the number of realizations, in which the normalized utility gap exceeds the given values. The given values actually indicate the accuracy of the proposed data offloading scheme. It is observed from Fig. 4 that the number of realizations decreases with the increasing number of users for all the four given values as expected. It is also observed from Fig. 4 that, when there are only two users in the

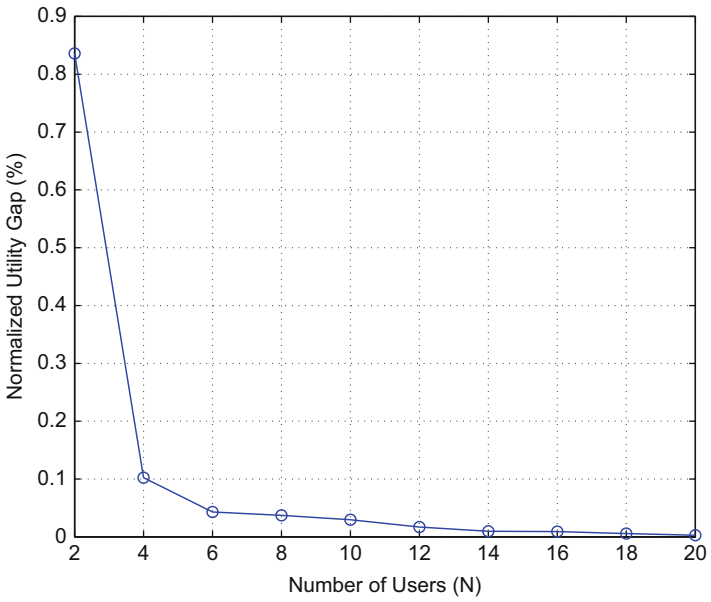

Fig. 3 Normalized utility gap vs. the number of users

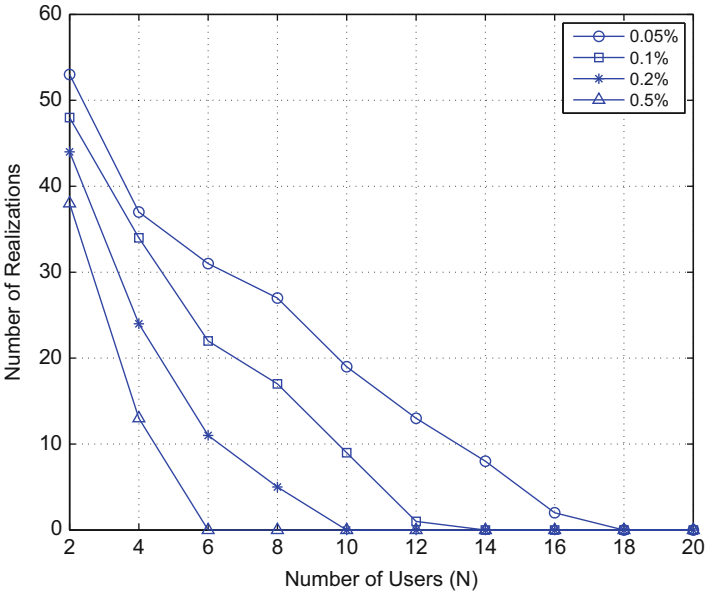

Fig. 4 Performance of the centralized data offloading scheme

network, almost 40 realizations will result in the utility gap that is larger than 0.5%. However, when the number of users increases to 6, the number of realizations that results in a utility gap larger than 0.5% is zero. This indicates that when the system requirement is not too high, the proposed data offloading scheme will perform well even when the number of users is not large. It is also observed from Fig. 4 that, even when the system requirement is very high, such as 0.05%, the proposed data offloading scheme can produce a satisfactory performance when there are more than 16 users in the network.

Without SIC Decoder at Both Sides

In Figs. 5 and 6, we investigate the performance of the proposed data offloading scheme for the case that SIC decoders are not available at both BS and the AP side. In Fig. 5, we generate 1000 channel realizations for each N. We count the number of realizations, in which the proposed data offloading scheme is optimal. First, it is observed that for all the curves, the number of realizations that the proposed data offloading scheme is optimal increases with the increasing of the number of users. This is in accordance with our theoretic analysis. Secondly, it is observed that the transmit power of the users also plays an important role in the performance of the proposed data offloading scheme. For the same number of users, when the transmit power of the users is large, the number of realizations that the proposed data offloading scheme is optimal is large. This is due to the fact that when P is large, the value of $\frac{(e-1)\sigma_A^2}{P}$ is small, and thus the probability that $g_{1,A} \geq \frac{(e-1)\sigma_A^2}{P}$ is

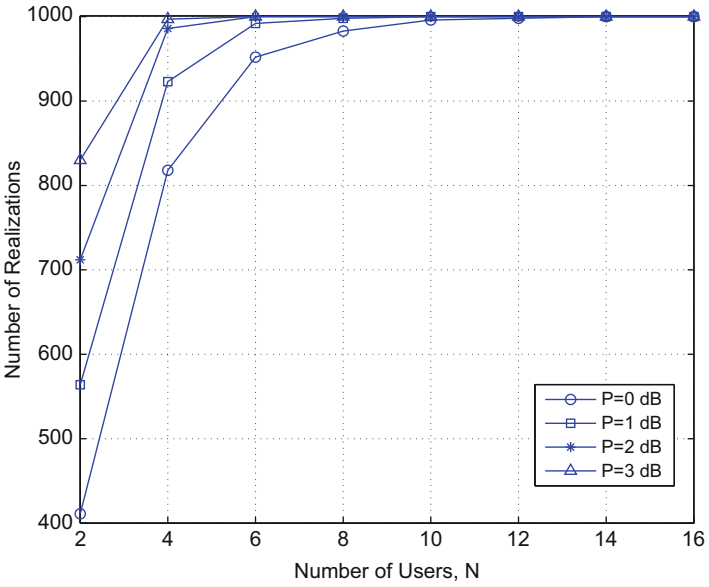

Fig. 5 Performance of the data offloading scheme: without SIC decoder at both sides

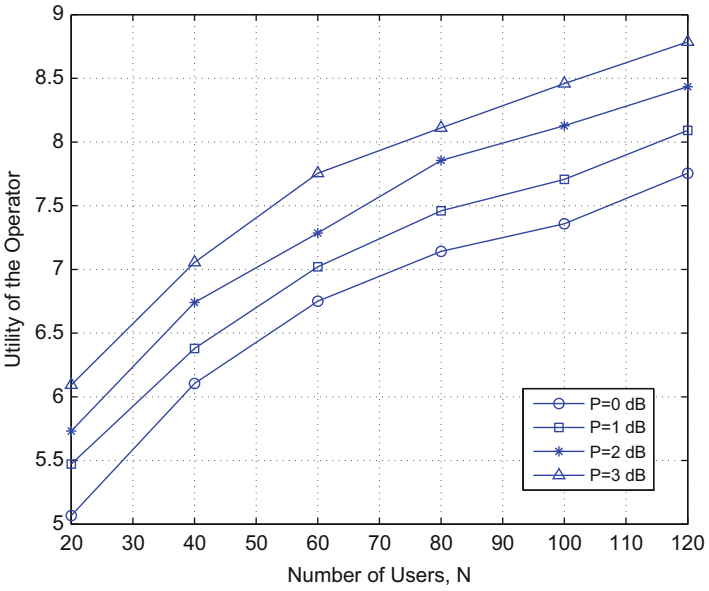

Fig. 6 Performance of the data offloading scheme: without SIC decoder at both sides

large for the same number of users. Thirdly, it is observed that when the number of users is larger than 10, the proposed data offloading scheme is always optimal for all the cases. This indicates that the proposed data offloading scheme can achieve a satisfactory performance even when the number of users is not very large.

With SIC Decoder at One Side

In Figs. 7 and 8, we investigate the performance of the proposed data offloading scheme for the case that SIC decoders are only available at the BS side. In Fig. 7, we generate 1000 channel realizations for each N. We count the number of realizations, in which the proposed data offloading scheme is optimal. It is observed that for all the curves, the number of realizations that the proposed data offloading scheme is optimal increases with the increasing of the number of users. This is in accordance with our theoretic analysis. Secondly, it is observed that the transmit power of the users almost does not affect the performance of the proposed data offloading scheme. This is quite different from the results obtained in Fig. 5. This is due to the fact that for this case, the proposed data offloading scheme is optimal only when both $g_{1,A} \geq \frac{(e-1)\sigma_A^2}{P}$ and $d < 0.67$ are satisfied simultaneously. For the case considered here, the condition that $d < 0.67$ always dominates. Since this condition is irrelevant with the transmit power, the performance of the proposed date offloading scheme is not affected by the transmit power of the users. Finally, it is observed that when the number of users is larger than 12, the proposed data offloading scheme is always optimal. This indicates that the proposed data

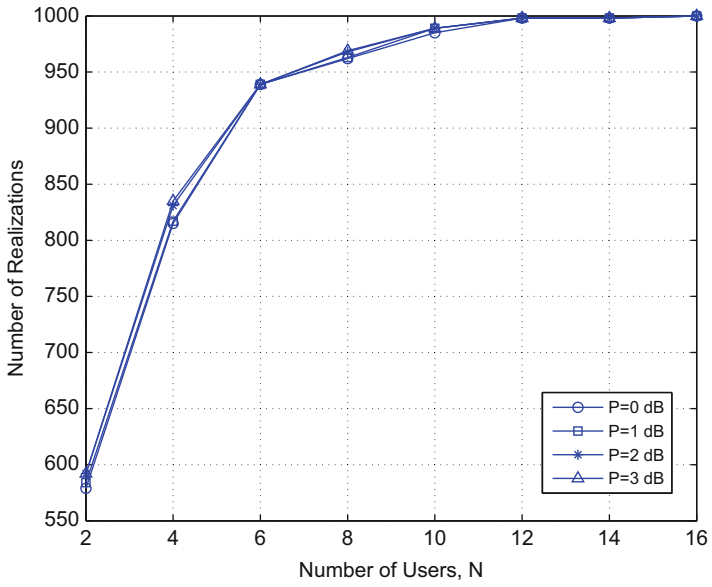

Fig. 7 Performance of the data offloading scheme: with SIC decoder at one side

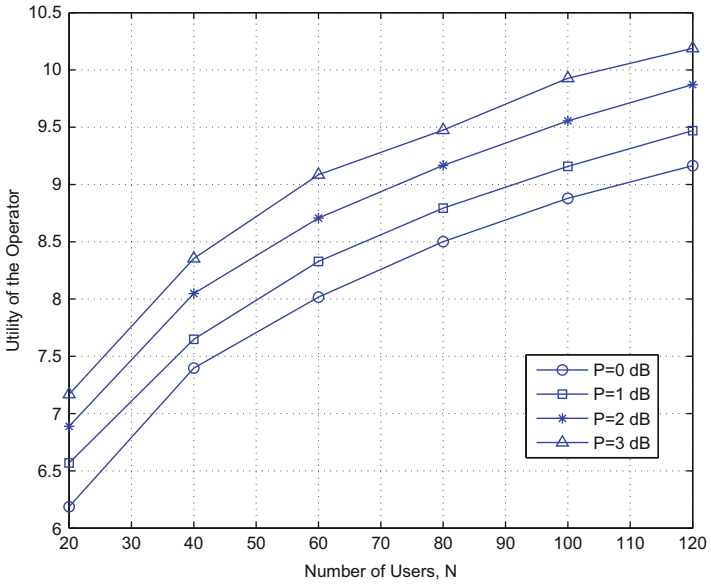

Fig. 8 Performance of the data offloading scheme: with SIC decoder at one side

offloading scheme can achieve a good performance even when the number of users is not large.

Incentive Mechanisms

In this subsection, two numerical examples are given to investigate the proposed incentive mechanisms.

Example 1: The Utility of the MNO

In this example, we assume that there are two heterogeneous APs existing in the HetNet. The simulation parameters are given as $c_1 = 2$, $c_2 = 3$, $T_1 = T_2 = 5$, $w_1 = 0.2$, $w_2 = 0.3$, and $\lambda = 50$. It is observed from Fig. 9 that the utility function of the MNO is neither convex nor concave in p and B. It is also observed that when both p and B are large or small, the utility of the MNO is low, while the MNO's utility is high when one of them (either p or B) is large and the other one of them is small. This indicates that the MNO should in general adopt either the low-salary high-bonus strategy or the high-salary low-bonus strategy to achieve high utilities.

Example 2: Subgame NE Analysis

In this example, we assume that there are three heterogeneous APs existing in the HetNet. The simulation parameters are chosen as follows: $c_1 = 2$, $c_2 = 3$, $c_3 = 4$, $T_1 = T_2 = T_3 = 5$, $w_1 = 0.2$, $w_2 = 0.3$, and $w_3 = 0.5$. In this example, we

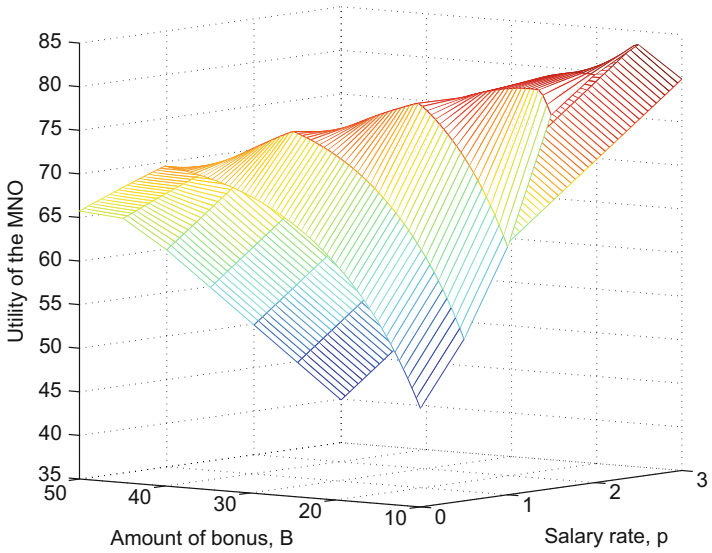

Fig. 9 Utility of the MNO under the Stackelberg game formulation

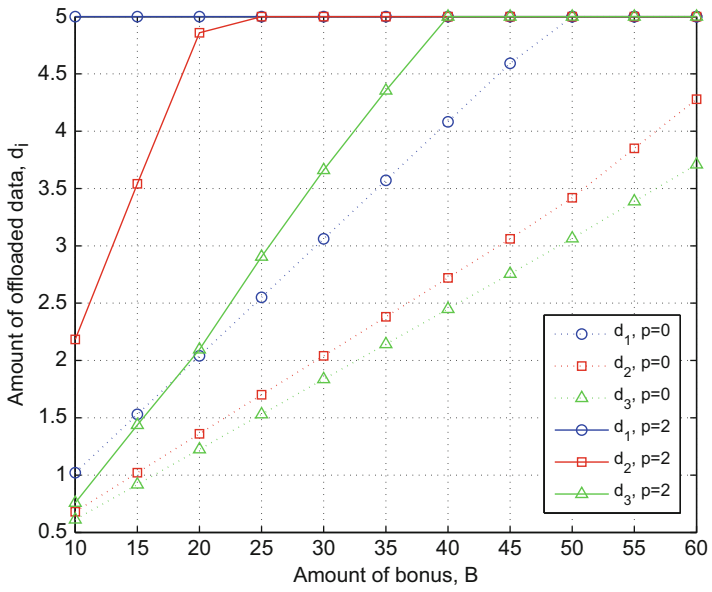

Fig. 10 Subgame nash equilibrium of three heterogeneous WiFi APs under different bonus B and different salary rate p

investigate the subgame equilibrium behavior of WiFi APs for given p and B. It is observed that for the same p and B, the AP with lower cost is willing to offload more data. Increasing the salary rate p is more effective in boosting up the amount of data offloaded. The AP with lower w_i is more sensitive to the bonus changes. When the bonus increases, the amount of offloaded data increases faster for the AP with lower w_i. This is because that the bonus distribution not only depends on d_i but also depends on w_i in the proposed incentive mechanism. Thus, in order to get the same partition of the bonus, the AP with lower w_i must offload more data than the AP with higher w_i. This also indicates that the proposed bonus scheme is bias toward to the AP with good quality of service w_i and thus provides an incentive for APs to improve their service quality (Fig. 10).

Conclusions

In this chapter, we have investigated the association rules and incentive mechanisms for mobile data offloading problem through a third-party WiFi AP in a cellular mobile system. Firstly, using a simple incentive mechanism, we have formulated the user association problem as an utility maximization problem. By considering whether the successive interference cancelation (SIC) decoders are available at the BS and/or the WiFi AP, different utility functions are considered. When the SIC decoders are available at both the BS and the WiFi AP, the utility maximization problem can be solved by considering its relaxation problem. It is strictly proved that the proposed user association scheme is near optimal when the number of users is large. When the SIC decoders are not available at both the BS and the WiFi AP, we have rigorously proved that the optimal solution is one-one association, i.e., one user connects to the BS, and the other user connects to the WiFi AP. When the SIC decoder is only available at the BS, we have shown that there is at most one user connecting to the WiFi AP and all the other users connect to the BS. We have rigorously proved that SIC decoders are beneficial for the cellular operator in terms of maximizing its utility. Secondly, to provide strong incentives for WiFi APs to provide data offloading service, we proposed an incentive mechanism using both salary and bonus. We investigated the interactions between the MNO and the WiFi APs using the Stackelberg game model. Under the Stackelberg game formulation, we derived the optimal amount of data that each WiFi AP was willing to offload and investigated the optimal bonus and salary rate that the MNO should set in order to maximize its utility. It has been shown that the MNO should adopt a low-salary high-bonus strategy or a high-salary low-bonus strategy to achieve a higher utility.

Abstract

Cognitive radio-enabled heterogeneous networks are an emerging technology to address the exponential increase of mobile traffic demand in the next-generation mobile communications. Recently, many technological issues such as resource allocation and interference mitigation pertaining to cognitive heterogeneous networks have been studied, but most studies focus on maximizing spectral efficiency. This chapter introduces the resource allocation problem in cognitive heterogeneous networks, where the cross-tier interference mitigation, imperfect spectrum sensing, and energy efficiency are considered. The optimization of power allocation is formulated as a non-convex optimization problem, which is then transformed to a convex optimization problem. An iterative power control algorithm is developed by considering imperfect spectrum sensing, cross-tier interference mitigation, and energy efficiency.

Keywords

Cognitive heterogeneous networks · Fairness · Imperfect spectrum sensing · Orthogonal frequency division multiple access (OFDMA) · Power control · Resource allocation Sensing time optimization

Introduction

Demand for mobile data traffic is increasing exponentially due to the wide usage of smart mobile devices and data-centric applications in mobile Internet. As a promising technology in the fifth-generation (5G) mobile communications, small cell can offload heavy traffics from primary macrocells by shortening the distance between basestation and users. Since small cell can effectively improve the coverage and spatial reuse of spectrum by deploying low-power access points, it is not surprising that small cell has attracted much research interests in both industry and academia. However, the benefits of small cell deployments come with a number of fundamental challenges, which include spectrum access, resource allocation, and interference mitigation [1–7].

Cognitive radio is also an emerging technology to improve the efficiency of spectrum access in the 5G networks [8]. The cognitive capabilities can improve the spectrum efficiency, radio resource utilization, and interference mitigation by efficient spectrum sensing, interference sensing, and adaptive transmission. Therefore, a cognitive radio-enabled small cell network can further improve the system performance by coexisting with a macrocell network [9]. There are three ways for a cognitive small cell to access the spectrum potentially used by a primary macrocell: (1) spectrum sharing, where the cognitive small cell can share the

spectrum with the primary macrocell; (2) opportunistic spectrum access, where the cognitive small cell can opportunistically access the spectrum that is detected to be idle; and (3) hybrid spectrum sensing, where the cognitive small cell senses the channel status and optimizes the power allocation based on the spectrum sensing result.

Orthogonal frequency division multiple access (OFDMA) working jointly with cognitive small cell can improve spectrum efficiency and energy efficiency via resource allocation and interference mitigation [10]. In [11], the authors investigated the resource allocation problems based on multistage stochastic programming for stringent quality of service (QoS) requirements of real-time streaming scalable videos in cognitive small cell networks. The issues on spectrum sensing and interference mitigation were studied in [12], where an interference coordination approach was adopted. Opportunistic cooperation between cognitive small cell users and primary macrocell users was provided for cognitive small cell networks based on a generalized Lyapunov optimization technique [13]. In [14], a spectrum-sharing scheme between primary macrocell and secondary small cell was investigated, and bounds on maximum intensity of simultaneously transmitting cognitive small cell that satisfies a given per-tier outage constraint in these schemes were theoretically derived using a stochastic geometry model. In [15], interferences due to different interfering sources were analyzed within cognitive-empowered small cell networks, and a stochastic dual control approach was introduced for dynamic sensing coordination and interference mitigation without involving global and centralized control efforts. Moreover, energy-efficient resource allocation has also been investigated for cognitive radio and small cell. In [16], the energy efficiency aspect of spectrum sharing and power allocation was studied using a Stackelberg game in heterogeneous cognitive radio networks with femtocells. While in [17], Nash equilibrium of a power adaptation game was derived to reduce energy consumption. Moreover, interference temperature limits, originated from the cognitive radio, were used in [18] to mitigate cross-tier interferences between macrocell and small cell.

This chapter includes two parts. In the first part, the power control and sensing time optimization problem in a cognitive small cell network are discussed. The resource allocation problem is solved by two new algorithms. In the second part, an iterative subchannel and power allocation algorithm is applied to the cognitive femtocells. The effectiveness of the provided algorithm in terms of capacity and fairness when compared to the other existing algorithms is verified by simulation.

Sensing Time Optimization and Power Control for Energy-Efficient Cognitive Small Cell with Imperfect Hybrid Spectrum Sensing

In this part, we study the optimization of sensing time and power control in an OFDMA-based cognitive small cell by considering energy efficiency, QoS requirement, cross-tier interference limitation, and imperfect hybrid spectrum sensing.

System Model and Problem Formulation

System Model

We consider an OFDMA cognitive small cell network where a co-channel cognitive small cell is overlaid on a primary macrocell and focus on resource allocation in the downlink of the cognitive small cell. The OFDMA system has a bandwidth of B, which is divided into N subchannels. The channel fading of each subcarrier is assumed to be the same within a subchannel, but may vary across different subchannels. The channel model for each subchannel includes path loss and frequency-nonselective Rayleigh fading. Before the small cell accesses the spectrum licensed to the primary macrocell, cognitive small basestation (CSBS) performs spectrum sensing to determine the occupation status of the subchannels. In each time frame, the cognitive small cell can sense N subchannels by energy detection-based spectrum sensing. The CSBS adapts the transmit power based on the spectrum sensing result [19]. The H_n^o is the hypothesis that the nth subchannel is occupied by the primary macrocell. The $\tilde{\mathscr{H}}_n^o$ represents the spectrum sensing result that the nth subchannel is occupied by the primary macrocell. The H_n^v is the hypothesis that the nth subchannel is not occupied by the primary macrocell. The $\tilde{\mathscr{H}}_n^v$ represents the spectrum sensing result that the nth subchannel is not occupied by the primary macrocell. The probabilities of false alarm and mis-detection on subchannel n are q_n^f and q_n^m, respectively. The user signal of the primary macrocell is a complex-valued phase shift keying (PSK) signal, and the noise at CSBS is circularly symmetric complex Gaussian (CSCG) with mean zero and variance σ^2 [19]. According to [20], the probability of mis-detection q_n^m can be approximated by

$$q_n^m(\varepsilon_n, \tau) = 1 - Q\left(\left(\frac{\varepsilon_n}{\sigma^2} - \gamma_n - 1\right)\sqrt{\frac{\tau f}{2\gamma_n + 1}}\right) \tag{1}$$

where ε_n is a chosen threshold of energy detector on subchannel n, τ is the spectrum sensing time, γ_n is the received signal-to-noise ratio (SNR) of the primary macrocell user measured at the CSBS on subchannel n, f is the sampling frequency, and the standard Gaussian Q-function is defined as

$$Q(x) = \frac{1}{\sqrt{2\pi}}\int_x^\infty \exp(-t^2/2)dt. \tag{2}$$

The probability of false alarm q_n^f can be approximated by [20]

$$\begin{aligned} q_n^f(\varepsilon_n, \tau) &= Q\left(\left(\tfrac{\varepsilon_n}{\sigma^2} - 1\right)\sqrt{\tau f}\right) \\ &= Q\left(\sqrt{2\gamma_n + 1}\left(Q^{-1}\left(\hat{q}_n^d\right)\right) + \sqrt{\tau f}\gamma_n\right) \end{aligned} \tag{3}$$

where $\hat{q}_n^d$ is the target probability of detection.

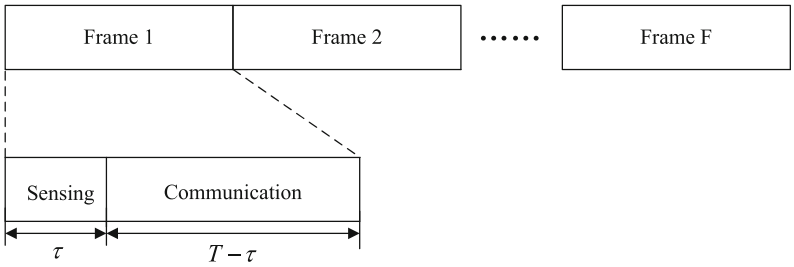

Fig. 1 The frame structure of cognitive small cell networks

The frame structure of the considered cognitive small cell network is shown in Fig. 1 [20]. As can be seen from Fig. 1, a spectrum sensing duration/time τ is inserted in the beginning of each frame. The CSBS adapts its transmit power based on the spectrum sensing decision made in the beginning of each frame. If the subchannel n is detected to be idle ($\tilde{\mathscr{H}}_n^v$), the cognitive small cell can transmit high-power $P_{s,n}^v$; if the subchannel n is detected to be occupied ($\tilde{\mathscr{H}}_n^o$), the cognitive small cell can transmit low-power $P_{s,n}^o$ in order to mitigate the interference caused to the primary macrocell. This approach is called hybrid spectrum sensing, and it is different from the opportunistic spectrum access and the spectrum-sharing approach. Based on the Shannon's capacity formula, when the spectrum sensing result is idle, the achievable capacity on subchannel n in the small cell is given by [19]

$$R_{v,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^v}{\sigma^2}\right) \tag{4}$$

where $g_{ss,n}$ is the channel gain of subchannel n between the small cell user and CSBS. If the spectrum sensing result is active/occupied, the achievable capacity on subchannel n in the small cell is given by [19]

$$R_{o,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^o}{g_{ms,n} \cdot P_{m,n}^o + \sigma^2}\right) \tag{5}$$

where $g_{ms,n}$ is the channel gain of subchannel n between the macrocell basestation (MBS) and CSBS and $P_{m,n}^o$ is the transmit power of MBS on subchannel n.

In a cognitive heterogeneous network, which typically consists of a cognitive small cell and a primary macrocell, imperfect spectrum sensing of CSBS can cause severe co-channel interference to the primary macrocell and thus degrade the performance of the heterogeneous cognitive small cell networks [19]. Since it is the CSBS that determines whether a subchannel is occupied by the primary

macrocell or not, according to [19], four different cases are to be considered as follows.

- Case 1: subchannel n is vacant in primary macrocell, and the spectrum sensing decision made by CSBS is vacant;
- Case 2: subchannel n is vacant in primary macrocell, but the spectrum sensing decision made by CSBS is occupied;
- Case 3: subchannel n is occupied in primary macrocell, but the spectrum sensing decision made by CSBS is vacant;
- Case 4: subchannel n is occupied in primary macrocell, and the spectrum sensing decision made by CSBS is occupied.

For the first and fourth cases, the CSBS makes the correct decisions. On the other hand, the second case is false alarm, and the third case is mis-detection. Therefore, the achievable capacities on subchannel n in small cell can be calculated for the four different cases as [19]

$$R_{1,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^{v}}{\sigma^2}\right), \tag{6}$$

$$R_{2,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^{o}}{\sigma^2}\right), \tag{7}$$

$$R_{3,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^{v}}{g_{ms,n} \cdot P_{m,n} + \sigma^2}\right), \tag{8}$$

$$R_{4,n} = \log_2\left(1 + \frac{g_{ss,n} \cdot P_{s,n}^{o}}{g_{ms,n} \cdot P_{m,n} + \sigma^2}\right). \tag{9}$$

Our objective is to maximize energy efficiency of cognitive small cell networks by optimizing sensing time and power allocation. The energy efficiencies of those four cases [19] are defined as follows:

$$\eta_{1,n} = \frac{R_{1,n}}{P_{s,n}^{v} + P_c}, \tag{10}$$

$$\eta_{2,n} = \frac{R_{2,n}}{P_{s,n}^{o} + P_c}, \tag{11}$$

$$\eta_{3,n} = \frac{R_{3,n}}{P_{s,n}^{v} + P_c}, \tag{12}$$

$$\eta_{4,n} = \frac{R_{4,n}}{P_{s,n}^{o} + P_c} \tag{13}$$

where P_c is the constant circuit power consumption which includes lowpass filter, mixer for modulation, frequency synthesizer, and digital-to-analog converter [21] and P_c is assumed to be independent of the transmitted power [22].

The average energy efficiency of subchannel n in the hybrid spectrum sensing scheme is [19]

$$\begin{aligned}\eta_n = & P\left(\mathscr{H}_n^v\right)\left(1-q_n^f\left(\varepsilon_n,\tau\right)\right)\eta_{1,n} \\ & +P\left(\mathscr{H}_n^v\right)q_n^f\left(\varepsilon_n,\tau\right)\eta_{2,n} \\ & +P\left(\mathscr{H}_n^o\right)q_n^m\left(\varepsilon_n,\tau\right)\eta_{3,n} \\ & +P\left(\mathscr{H}_n^o\right)\left(1-q_n^m\left(\varepsilon_n,\tau\right)\right)\eta_{4,n}\end{aligned} \tag{14}$$

where $P\left(\mathscr{H}_n^v\right)$ and $P\left(\mathscr{H}_n^o\right)$ are the probabilities of vacant status and occupied status of subchannel n, respectively.

Since the resource allocation is performed in CSBS, the transmit power of CSBS on subchannel n is constrained by [19]

$$\sum_{n=1}^{N}\left[\begin{array}{l}P\left(\mathscr{H}_n^v\right)\left(1-q_n^f\left(\varepsilon_n,\tau\right)\right)P_{s,n}^v \\ +P\left(\mathscr{H}_n^v\right)q_n^f\left(\varepsilon_n,\tau\right)P_{s,n}^o \\ +P\left(\mathscr{H}_n^o\right)q_n^m\left(\varepsilon_n,\tau\right)P_{s,n}^v \\ +P\left(\mathscr{H}_n^o\right)\left(1-q_n^m\left(\varepsilon_n,\tau\right)\right)P_{s,n}^o\end{array}\right]\frac{T-\tau}{T}\le P_{\max} \tag{15}$$

where $P_{\max}$ is the maximum average transmit power of CSBS.

Since primary macrocells play a fundamental role in providing cellular coverage, macrocell users' QoS should not be affected by cognitive small cell's deployment. Therefore, to implement cross-tier interference protection, an average interference power limit is imposed to constrain the cross-tier interference suffered by macrocell [19]. Let I_n^{th} denote the maximum tolerable interference level on subchannel n for the macrocell user. We have

$$P\left(\mathscr{H}_n^o\right)\cdot g_{sm,n}\left[\begin{array}{l}q_n^m\left(\varepsilon_n,\tau\right)P_{s,n}^v+ \\ \left(1-q_n^m\left(\varepsilon_n,\tau\right)\right)P_{s,n}^o\end{array}\right]\frac{T-\tau}{T}\le I_n^{th},\forall n \tag{16}$$

where $g_{sm,n}$ is the channel power gain from the small cell to the macrocell user on subchannel n.

In order to guarantee the QoS for the small cell, a minimum transmit data rate constraint is introduced as [19]

$$\begin{aligned}& P\left(\mathscr{H}_n^v\right)\left(1-q_n^f\left(\varepsilon_n,\tau\right)\right)R_{1,n}+P\left(\mathscr{H}_n^v\right)q_n^f\left(\varepsilon_n,\tau\right)R_{2,n} \\ & +P\left(\mathscr{H}_n^o\right)q_n^m\left(\varepsilon_n,\tau\right)R_{3,n}+P\left(\mathscr{H}_n^o\right)\left(1-q_n^m\left(\varepsilon_n,\tau\right)\right)R_{4,n}\ge R_{\min}\end{aligned} \tag{17}$$

where $R_{\min}$ is the minimum transmit data rate requirement of each subchannel.

For a target detection probability of $\widehat{q}_n^d$ on subchannel n, substituting $\widehat{q}_n^d$ into (1), we obtain

$$\left(\frac{\varepsilon_n}{\sigma^2} - \gamma_n - 1\right)\sqrt{\frac{\tau f}{2\gamma_n + 1}} = Q^{-1}\left(\widehat{q}_n^d\right). \tag{18}$$

Therefore, for a given sensing time $\widehat{\tau}$, the detection threshold ε_n can be determined as

$$\varepsilon_n = \left(\sqrt{\frac{2\gamma_n + 1}{\widehat{\tau} f}} Q^{-1}\left(\widehat{q}_n^d\right) + \gamma_n + 1\right)\sigma^2, \forall n. \tag{19}$$

Problem Formulation

In this part, the aim is to maximize the cognitive small cell's energy efficiency while protecting QoS of the primary macrocell users. The cross-tier interference power limit is sent by a primary MBS periodically. This process requires little overhead in the primary macrocell. In this case, the sensing time optimization and power control in primary macrocell are not part of optimization [19]. Thus, the corresponding sensing time optimization and power allocation problem for the downlink CSBS can be mathematically formulated as [19]

$$\max_{\{\tau, \mathbf{P}_s^v, \mathbf{P}_s^o\}} \sum_{n=1}^{N} \frac{T-\tau}{T} \eta_n\left(\tau, P_{s,n}^v, P_{s,n}^o\right) \tag{20}$$

s.t.

$$\begin{aligned}
&C1: \sum_{n=1}^{N} \left[\begin{array}{l} P(\mathscr{H}_n^v)(1 - q_n^f(\varepsilon_n, \tau))P_{s,n}^v + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n, \tau)P_{s,n}^o \\ + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n, \tau)P_{s,n}^v + P(\mathscr{H}_n^o)(1 - q_n^m(\varepsilon_n, \tau))P_{s,n}^o \end{array}\right]\frac{T-\tau}{T} \le P_{\max} \\
&C2: P(\mathscr{H}_n^o) \cdot g_{sm,n}\left[q_n^m(\varepsilon_n, \tau)P_{s,n}^v + (1 - q_n^m(\varepsilon_n, \tau))P_{s,n}^o\right]\frac{T-\tau}{T} \le I_n^{th}, \forall n \\
&C3: \begin{array}{l} P(\mathscr{H}_n^v)(1 - q_n^f(\varepsilon_n, \tau))R_{1,n} + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n, \tau)R_{2,n} \\ + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n, \tau)R_{3,n} + P(\mathscr{H}_n^o)(1 - q_n^m(\varepsilon_n, \tau))R_{4,n} \ge R_{\min}, \forall n \end{array} \\
&C4: P_{s,n}^v \ge 0, P_{s,n}^o \ge 0, \forall n \\
&C5: 0 \le \tau \le T
\end{aligned} \tag{21}$$

where $\mathbf{P}_s^v = [p_{s,n}^v]_{1\times N}$ and $\mathbf{P}_s^o = [p_{s,n}^o]_{1\times N}$ are the power allocation vectors of the N subchannels in the cognitive small cell. In (21), $C1$ limits the maximum transmit power of each CSBS to $P_{\max}$; $C2$ sets the tolerable interference power level on each subchannel of the macrocell user on subchannel n; $C3$ represents minimum QoS requirement of each subchannel; $C4$ represents the nonnegative power constraint of the transmit power on each subchannel; $C5$ expresses the constraint of sensing time in each frame.

Note that the optimization problem in (20) under the constraints of (21) is nonconvex with respect to $\{\tau, \mathbf{P}_s^v, \mathbf{P}_s^o\}$ [19]. Therefore, the problem of energy-efficient power control is investigated given the sensing time $\widehat{\tau}$.

Energy-Efficient Resource Optimization in One Cognitive Small Cell

Transformation of the Optimization Problem

Given the sensing time $\widehat{\tau}$, the power control problem in (20) under the constraints of (21) can be classified as a nonlinear fractional programming problem. Since the joint optimization problem of $\mathbf{P}_s^v$ and $\mathbf{P}_s^o$ in (20) can be decoupled into two separate subproblems, namely, one for $\mathbf{P}_s^v$ and the other for $\mathbf{P}_s^o$ [19]. The subproblem related to $\mathbf{P}_s^v$ is first solved. Since subchannels in (20) are independent, a nonnegative variable $\eta_{13,n}^*$ is defined for the sum of average energy efficiencies on subchannel n in Case 1 and Case 3 as [19]

$$\eta_{13,n}^* = \frac{\left\{\begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}_{s,n}^v) \\ +P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}_{s,n}^v) \end{array}\right\}}{\tilde{P}_{s,n}^v + P_c} \tag{22}$$

where $\widetilde{P}_{s,n}^v$ is the optimal solution to the problem of (20) under the constraints of (21).

Theorem 1. *$\eta_{13,n}^*$ is achieved if and only if (80) where the $P_{s,n}^v$ in (80) is one of the feasible solutions to (20) under the constraints of (21).*

The proof is provided in Appendix.

According to the Theorem 1, the objective function with respect to $\mathbf{P}_s^o$ in fractional form can also be transformed to a subtractive form by introducing a nonnegative variable $\eta_{24,n}^*$.

Iterative Energy Efficiency Maximization Algorithm

To solve the transformed optimization problem in the subtractive form under the constraints of (20), Algorithm 1 [19] is provided.

Algorithm 1 Energy-efficient power control algorithm

Initialize the maximum number of iterations $L_{\max}$ and convergence tolerance ε_η;
Set $\eta_{13,n}(1)=0$, $\eta_{24,n}(1)=0$, $l=0$;
Initialize power allocation with an equal power distribution and begin the outer loop;
for $n=1$ to N **do**
  repeat
    a) The inner loop power control problem is solved with outer loop results $\eta^*_{13,n}(l)$, $\eta^*_{24,n}(l)$, the Lagrangian method and (28), (31);
    b) Then, the power control solution $\underline{P}^v_{s,n}(l)$ and $\underline{P}^o_{s,n}(l)$ can be obtained;
    if $(P(\mathscr{H}^v_n)(1-q^f_n(\varepsilon_n,\widehat{\tau}))R_{1,n}(\widehat{\tau},\underline{P}^v_{s,n}(l)) + P(\mathscr{H}^o_n)q^m_n(\varepsilon_n,\widehat{\tau})R_{3,n}(\widehat{\tau},\underline{P}^v_{s,n}(l)) - \eta_{13,n}(l)(\underline{P}^v_{s,n}(l)+P_c)) < \varepsilon_\eta$ **then**
      Convergence= **true**; $\widetilde{P}^v_{s,n}=\underline{P}^v_{s,n}(l)$
      $\eta^*_{13,n}=\dfrac{P(H^v_n)(1-q^f_n(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}^v_{s,n})+P(H^o_n)q^m_n(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}^v_{s,n})}{\tilde{P}^v_{s,n}+P_c}$
    else
      $\eta_{13,n}(l+1)=\dfrac{P(H^v_n)(1-q^f_n(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\underline{P}^v_{s,n}(l))+P(H^o_n)q^m_n(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\underline{P}^v_{s,n}(l))}{\underline{P}^v_{s,n}(l)+P_c}$
      Convergence= **false**, $l=l+1$;
    end if
    if $(P(\mathscr{H}^v_n)q^f_n(\varepsilon_n,\widehat{\tau})R_{2,n}(\widehat{\tau},\underline{P}^o_{s,n}(l)) + P(\mathscr{H}^o_n)(1-q^m_n(\varepsilon_n,\widehat{\tau}))R_{4,n}(\widehat{\tau},\underline{P}^o_{s,n}(l)) - \eta_{24,n}(l)(\underline{P}^o_{s,n}(l)+P_c)) < \varepsilon_\eta$ **then**
      Convergence= **true**; $\widetilde{P}^o_{s,n}=\underline{P}^o_{s,n}(l)$
      $\eta^*_{24,n}=\dfrac{P(H^v_n)q^f_n(\varepsilon_n,\hat{\tau})R_{2,n}(\hat{\tau},\tilde{P}^o_{s,n})+P(H^o_n)(1-q^m_n(\varepsilon_n,\hat{\tau}))R_{4,n}(\hat{\tau},\tilde{P}^o_{s,n})}{\tilde{P}^o_{s,n}+P_c}$
    else
      $\eta_{24,n}(l+1)=\dfrac{P(H^v_n)q^f_n(\varepsilon_n,\hat{\tau})R_{2,n}(\hat{\tau},\underline{P}^o_{s,n}(l))+P(H^o_n)(1-q^m_n(\varepsilon_n,\hat{\tau}))R_{4,n}(\hat{\tau},\underline{P}^o_{s,n}(l))}{\underline{P}^o_{s,n}(l)+P_c}$
      Convergence= **false**, $l=l+1$;
    end if
  until Convergence= **true** or $l=L_{\max}$
end for

As shown in Algorithm 1, in each iteration of the outer loop, the lth inner loop power control problem is given as

$$\max_{\{\mathbf{P}^v_s,\mathbf{P}^o_s\}}\sum_{n=1}^{N}\frac{T-\hat{\tau}}{T}\left\{\begin{array}{l}P(\mathscr{H}^v_n)(1-q^f_n(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n})\\+P(\mathscr{H}^o_n)q^m_n(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n})\\+P(\mathscr{H}^v_n)q^f_n(\varepsilon_n,\hat{\tau})R_{2,n}(\hat{\tau},P^o_{s,n})\\+P(\mathscr{H}^o_n)(1-q^m_n(\varepsilon_n,\hat{\tau}))R_{4,n}(\hat{\tau},P^o_{s,n})\\-\eta_{13,n}(l)(P^v_{s,n}+P_c)\\-\eta_{24,n}(l)(P^o_{s,n}+P_c)\end{array}\right\} \tag{23}$$

$$\text{s.t. } C1-C4. \tag{24}$$

Since the optimization problem of (23) under the constraints of (24) is convex with respect to $\mathbf{P}_s^v$ and $\mathbf{P}_s^o$. The Lagrangian function is given by (25)

$$
\begin{aligned}
&L(\mathbf{P}_s^v, \mathbf{P}_s^o, \lambda, \boldsymbol{\mu}, \boldsymbol{\nu}) = \\
&\left\{ \sum_{n=1}^{N} \frac{T-\hat{\tau}}{T} \left[\begin{array}{l} (P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau}, P_{s,n}^v) \\ \quad + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau}, P_{s,n}^v) - \eta_{13,n}(l)P_{s,n}^v \\ \quad + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\hat{\tau})R_{2,n}(\hat{\tau}, P_{s,n}^o) \\ \quad + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\hat{\tau}))R_{4,n}(\hat{\tau}, P_{s,n}^o) - \eta_{24,n}(l)P_{s,n}^o \end{array} \right] \right\} \\
&-\lambda \left\{ \sum_{n=1}^{N} \left[\begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))P_{s,n}^v + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\hat{\tau})P_{s,n}^o + \\ P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})P_{s,n}^v + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\hat{\tau}))P_{s,n}^o \end{array} \right] \frac{T-\hat{\tau}}{T} - P_{\max} \right\} \\
&- \sum_{n=1}^{N} \mu_n \left\{ \left[\sum_{n=1}^{N} P(\mathscr{H}_n^o) g_{sm,n} (q_n^m(\varepsilon_n,\hat{\tau})P_{s,n}^v + (1-q_n^m(\varepsilon_n,\hat{\tau}))P_{s,n}^o) \right] \frac{T-\hat{\tau}}{T} - I_n^{th} \right\} \\
&+ \sum_{n=1}^{N} \nu_n \left\{ \left[\begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\tau))R_{1,n} + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\tau)R_{2,n} \\ + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\tau)R_{3,n} + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\tau))R_{4,n} \end{array} \right] - R_{\min} \right\}
\end{aligned}
\tag{25}
$$

where λ, $\boldsymbol{\mu_n}$, and $\boldsymbol{\nu_n}$ are the Lagrangian multipliers (also called dual variables) vectors for the constraints C1, C2, and C3 in (21), respectively. Thus, the Lagrangian dual function is [19] defined as

$$
g(\lambda, \boldsymbol{\mu}, \boldsymbol{\nu}) = \max_{\mathbf{P}_s^v, \mathbf{P}_s^o} \; L(\mathbf{P}_s^v, \mathbf{P}_s^o, \lambda, \boldsymbol{\mu}, \boldsymbol{\nu}). \tag{26}
$$

The dual problem can be expressed as [19]

$$
\min_{\lambda, \boldsymbol{\mu}, \boldsymbol{\nu} \geq 0} \; g(\lambda, \boldsymbol{\mu}, \boldsymbol{\nu}). \tag{27}
$$

Using Lagrangian function and the Karush-Kuhn-Tucker (KKT) conditions, the near optimal solution of $\widetilde{P}_{s,n}^v$ on subchannel n can be obtained as

$$
\tilde{P}_{s,n}^v = \left[\frac{A_{v,n} + \sqrt{B_{v,n}}}{2} \right]^+ \tag{28}
$$

where $[x]^+ = \max\{x, 0\}$, and $A_{v,n}$ and $B_{v,n}$ are given by (29) and (30), respectively.

$$
\begin{aligned}
A_{v,n} = &\frac{(1+\nu_n)(P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\widehat{\tau})) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\widehat{\tau}))}{\ln 2(\eta_{13,n}(l) + \lambda(P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau})) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\widehat{\tau})) \\
&\qquad + \mu_n g_{sm,n} P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\widehat{\tau}))} \\
&- \frac{2\sigma^2 + g_{ms,n} P_{m,n}^o}{g_{ss,n}}
\end{aligned}
\tag{29}
$$

$$B_{v,n} = A_{v,n}^2 - \frac{4}{g_{ss,n}} \cdot \left\{ \frac{\sigma^4 + \sigma^2 g_{ms,n} P_{m,n}^o}{g_{ss,n}} - \frac{\begin{array}{c}(1+\nu_n)[P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\widehat{\tau})(\sigma^2+g_{ms,n}P_{m,n}^o)) \\ +P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\widehat{\tau})\sigma^2]\end{array}}{\begin{array}{c}\ln 2(\eta_{13,n}(l)+\lambda(P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\widehat{\tau})+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\widehat{\tau})) \\ +\mu_n g_{sm,n} P(\mathscr{H}_n^o) q_n^m(\varepsilon_n,\widehat{\tau})))\end{array}} \right\}. \tag{30}$$

Similar to $\widetilde{P}_{s,n}^v$, the near optimal solution of $\widetilde{P}_{s,n}^o$ on subchannel n can be obtained as

$$\tilde{P}_{s,n}^o = \left[\frac{A_{o,n} + \sqrt{B_{o,n}}}{2} \right]^+ \tag{31}$$

$$A_{o,n} = \frac{(1+\nu_n)(P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\widehat{\tau}) + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\widehat{\tau})))}{\begin{array}{c}\ln 2(\eta_{24,n}(l)+\lambda(P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\widehat{\tau})+P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\widehat{\tau}))) \\ +\mu_n g_{sm,n} P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\widehat{\tau})))\end{array}} - \frac{2\sigma^2 + g_{ms,n}P_{m,n}^o}{g_{ss,n}} \tag{32}$$

$$B_{o,n} = A_{o,n}^2 - \frac{4}{g_{ss,n}} \cdot \left\{ \frac{\sigma^4 + \sigma^2 g_{ms,n} P_{m,n}^o}{g_{ss,n}} - \frac{\begin{array}{c}(1+\nu_n)[P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\hat{\tau})(\sigma^2+g_{ms,n}P_{m,n}^o) \\ +P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\hat{\tau}))\sigma^2]\end{array}}{\begin{array}{c}\ln 2(\eta_{13,n}(l)+\lambda(P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\hat{\tau})+P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\hat{\tau})) \\ +\mu_n g_{sm,n} P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\hat{\tau})))\end{array}} \right\}. \tag{33}$$

where $A_{o,n}$ and $B_{o,n}$ are given by (32) and (33), respectively.

Either the ellipsoid or the subgradient method can be adopted in updating the dual variables [23]. Here, the subgradient method is chosen to update the dual variables, and the update formulas are (34), (35), and (36)

$$\lambda^{l+1} = \lambda^l - \vartheta_1^l \left(P_{\max} - \sum_{n=1}^{N} \left[\begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\tau))P_{s,n}^v + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\tau)P_{s,n}^o + \\ P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\tau)P_{s,n}^v + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\tau))P_{s,n}^o \end{array} \right] \frac{T-\tau}{T} \right) \tag{34}$$

$$\mu_n^{l+1} = \mu_n^l - \vartheta_2^l \left(I_n^{th} - P(\mathscr{H}_n^o) \cdot g_{sm,n} \left[q_n^m(\varepsilon_n,\tau)P_{s,n}^v + (1-q_n^m(\varepsilon_n,\tau))P_{s,n}^o \right] \frac{T-\tau}{T} \right), \forall n \tag{35}$$

$$\nu_n^{l+1} = \nu_n^l - \vartheta_3^l \left(\left\{ \begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\tau))R_{1,n} + P(\mathscr{H}_n^v)q_n^f(\varepsilon_n,\tau)R_{2,n} + \\ P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\tau)R_{3,n} + P(\mathscr{H}_n^o)(1-q_n^m(\varepsilon_n,\tau)R_{4,n} \end{array} \right\} \frac{T-\tau}{T} - R_{\min} \right), \forall n \tag{36}$$

where ϑ_1^l, ϑ_2^l, and ϑ_3^l denote the step size of iteration l ($l \in \{1, 2, \ldots, L_{\max}\}$)for λ, $\boldsymbol{\mu}$, and $\boldsymbol{\nu}$, respectively, and $L_{\max}$ is the maximum number of iterations. Meanwhile, the step size must meet the following conditions

$$\sum_{l=1}^{\infty} \vartheta_i^l = \infty, \lim_{l \to \infty} \vartheta_i^l = 0, \ \forall i \in \{1, 2, 3\}. \tag{37}$$

Algorithm 1 is provided to optimize the power $P_{s,n}^v$ and $P_{s,n}^o$ of (20) given the sensing time $\hat{\tau}$ [19]. In Algorithm 1, the process of power control is decomposed to inner loop problem and outer loop problem. In each iteration, both $\eta_{13,n}^*(l)$ and $\eta_{24,n}^*(l)$ can be found through outer loop, the inner loop control problem is solved by the outer loop results $\eta_{13,n}^*(l)$ and $\eta_{24,n}^*(l)$, the Lagrangian method and (28), (31).

The near optimal sensing time scheme can be found in Algorithm 2 [19] based on a one-dimensional exhaustive search.

Algorithm 2 is provided to optimize the sensing time in (20) when the optimal power through Algorithm 1 has been obtained. Therefore, running Algorithm 1 with $\widehat{\tau}(l)$ to obtain the optimal power $\widetilde{P}_{s,n}^v$ and $\widetilde{P}_{s,n}^o$ has to be firstly done in Algorithm 2. Then the optimal sensing time is found based on a one-dimensional exhaustive search.

Complexity Analysis

The computational complexity of the provided algorithms is analyzed in this subsection. Suppose the subgradient method used in Algorithm 1 reguires Δ_1 iterations to converge; the updates of λ need $O(1)$ operations; $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ need $O(N)$ operations each. The method used in Algorithm 1 to calculate $\eta_{13,n}^*$ and $\eta_{24,n}^*$ on each subchannel in a small cell needs Δ_2 iterations to converge. The total complexity of Algorithm 1 is thus $O(N^2 \Delta_1 \Delta_2)$. The parameters Δ_1 and Δ_2 can be small enough if the initial values of λ, $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ are well chosen, together with suitable

Algorithm 2 Near optimal energy-efficient sensing time scheme

1: Initialize the maximum number of iterations $L_{\max}$ and convergence tolerance ε_τ
2: Set $l = 0$; Initialize $\widehat{\tau}(l)$;
3: **repeat**
4: Run Algorithm 1 with $\widehat{\tau}(l)$ to obtain the optimal power $\widetilde{P}_{s,n}^v$ and $\widetilde{P}_{s,n}^o$;
5: $P_{s,n}^v(l) = \widetilde{P}_{s,n}^v$, $P_{s,n}^o(l) = \widetilde{P}_{s,n}^o$;
6: $\widehat{\tau}(l) = \max_{\tau} \sum_{n=1}^{N} \frac{T-\tau}{T} \eta_n \left(\tau, P_{s,n}^v(l), P_{s,n}^o(l)\right)$;
7: **if** $\left|\widehat{\tau}(l) - \widehat{\tau}(l-1)\right| \le \varepsilon_\tau$ **then**
8: Convergence= **true**, $\widetilde{\tau} = \widehat{\tau}(l)$;
9: **else**
10: Convergence= **false**, $l = l + 1$;
11: **end if**
12: **until** Convergence= **true** or $l = L_{\max}$

values of iteration step sizes. In Algorithm 2, finding the optimal sensing time for each subchannel requires $O(L)$ operations. Therefore, the total computational complexity of Algorithm 2 is $O(NL)$ for the network with N subchannels [19].

Energy-Efficient Resource Optimization in Multiple Cognitive Small Cells

Multiple Cognitive Small Cells Scenario

In this subsection, the energy-efficient resource optimization is investigated in multiple cognitive small cells. The aforementioned method is applied to optimize the energy efficiency in multiple cognitive small cells network, where the interference between small cells will be considered. In multiple cognitive small cells, to maximize the total energy efficiency with the consideration of co-tier interference mitigation, the problem in (20) under the constraints of (21) can be formulated as [19]

$$\max_{\{\boldsymbol{\tau},\mathbf{P}^{\mathbf{v}}_{\mathbf{ms}},\mathbf{P}^{\mathbf{o}}_{\mathbf{ms}}\}} \sum_{k=1}^{K}\sum_{n=1}^{N} \frac{T-\tau_k}{T}\eta_{k,n}\left(\tau_k, P^v_{s,k,n}, P^o_{s,k,n}\right) \tag{38}$$

$$\begin{aligned}
\text{s.t.}\quad & C1: \sum_{n=1}^{N}\left[\begin{array}{l} P(\mathscr{H}^v_{k,n})(1-q^f_{k,n}(\varepsilon_{k,n},\tau_k))P^v_{s,k,n} + P(\mathscr{H}^v_{k,n})q^f_{k,n}(\varepsilon_{k,n},\tau_k)P^o_{s,k,n} \\ +P(\mathscr{H}^o_{k,n})q^m_{k,n}(\varepsilon_{k,n},\tau_k)P^v_{s,k,n} + P(\mathscr{H}^o_{k,n})(1-q^m_{k,n}(\varepsilon_{k,n},\tau_k))P^o_{s,k,n}\end{array}\right] \\
& \times \frac{T-\tau_k}{T} \le P_{\max} \\
& C2: P(H^o_{k,n})\cdot g^{sm}_{k,n}\left[q^m_{k,n}(\varepsilon_{k,n},\tau_k)P^v_{s,k,n} + (1-q^m_{k,n}(\varepsilon_{k,n},\tau_k))P^o_{s,k,n}\right]\frac{T-\tau_k}{T} \\
& \le I^{th}_{k,n}, \forall k,n \\
& C3: \begin{array}{l} P(\mathscr{H}^v_{k,n})(1-q^f_{k,n}(\varepsilon_{k,n},\tau_k))R^1_{k,n} + P(\mathscr{H}^v_{k,n})q^f_{k,n}(\varepsilon_{k,n},\tau_k)R^2_{k,n} \\ +P(\mathscr{H}^o_{k,n})q^m_{k,n}(\varepsilon_{k,n},\tau_k)R^3_{k,n} + P(\mathscr{H}^o_{k,n})(1-q^m_{k,n}(\varepsilon_{k,n},\tau_k))R^4_{k,n} \ge R_{\min}\end{array} \\

\end{aligned} \tag{39}$$

where $\boldsymbol{\tau} = [\tau]_{1\times K}$ is the sensing time vector of K cognitive small cells, N is the number of subchannels in each small cell, and $\mathbf{P^v_{ms}} = \left[P^v_{s,k,n}\right]_{K\times N}$ and $\mathbf{P^o_{ms}} = \left[P^o_{s,k,n}\right]_{K\times N}$ are the power allocation vectors of the N subchannels in K cognitive small cells. Constraint $C1$ limits the maximum transmit power of each CSBS to $P_{\max}$; $C2$ sets the tolerable interference power level for each small cell on each subchannel of the macrocell user on subchannel n; $C3$ represents minimum QoS requirement of each subchannel; $C4$ represents the tolerable interference power level from other small cells, where $\gamma^{th}_{k,n}$ denotes the co-tier interference limits on the nth subchannel in the kth small cell; $C5$ represents the nonnegative power constraint of the transmit power on each subchannel; $C6$ expresses the constraint of sensing time in each frame.

First of all, similar to the problem in (20), the problem of power control in (38) under the constraints of (39) can be decoupled into two separate subproblems respect to $\mathbf{P^v_{ms}}$ and $\mathbf{P^o_{ms}}$, respectively, when the sensing time $\hat{\tau}_k$ is given. The subproblem respect to $\mathbf{P^v_{ms}}$ is dealt with [19]. The variable $\eta^{13^*}_{k,n}$ is defined as

$$\eta^{13^*}_{k,n} = \frac{P(\mathscr{H}^v_{k,n})(1-q^f_{k,n}(\varepsilon_{k,n},\hat{\tau}_k))R^1_{k,n}(\hat{\tau}_k,\tilde{P}^v_{s,k,n}) + P(\mathscr{H}^o_{k,n})q^m_{k,n}(\varepsilon_{k,n},\hat{\tau}_k)R^3_{k,n}(\hat{\tau}_k,\tilde{P}^v_{s,k,n})}{\tilde{P}^v_{s,k,n}+P_c} \tag{40}$$

where $\eta^{13^*}_{k,n}$ represents the sum of average energy efficiencies on the nth subchannel of the kth small cell in Case 1 and Case 3. $\tilde{P}^v_{s,k,n}$ is the optimal solution to the problem of (38) under the constraints of (39).

Therefore, the optimization problem of (38) is transformed as optimization problem of (40) under the constraints of (39) [19]. Subsequently, Algorithm 1 is used to solve the transformed problem [19], and the near optimal solution can be obtained [19]

$$\tilde{P}^v_{s,k,n} = \left[\frac{A_{v,k,n}+\sqrt{B_{v,k,n}}}{2}\right]^+ \tag{41}$$

where $A_{v,k,n}$ and $B_{v,k,n}$ are given by

$$A_{v,k,n} = \frac{(1+\nu_{k,n})(P(\mathscr{H}^v_{k,n})(1-q^f_{k,n}(\varepsilon_{k,n},\hat{\tau}_k)) + P(\mathscr{H}^o_{k,n})q^m_{k,n}(\varepsilon_{k,n},\hat{\tau}_k))}{\left\{\begin{array}{l}\ln 2\left(\eta^{13}_{k,n}(l)+\lambda_{k,n}\left(P(\mathscr{H}^v_{k,n})\left(1-q^f_{k,n}(\varepsilon_{k,n},\hat{\tau}_k)\right)\right.\right.\\ \left.+P\left(\mathscr{H}^o_{k,n}\right)q^m_{k,n}(\varepsilon_{k,n},\hat{\tau}_k)\right)+\mu_{k,n}g^{sm}_{k,n}P(\mathscr{H}^o_{k,n})q^m_{k,n}(\varepsilon_{k,n},\hat{\tau}_k)\\ -\xi_{k,n}\sum\limits_{j=1,j\neq k}^{K}g_{j,k,n}\left[\begin{array}{l}P\left(\mathscr{H}^v_{j,n}\right)\left(1-q^f_{j,n}\left(\varepsilon_{j,n},\hat{\tau}_j\right)\right)\\ +P(\mathscr{H}^o_{j,n})q^m_{j,n}\left(\varepsilon_{j,n},\hat{\tau}_j\right)\end{array}\right]\end{array}\right\}}\\ -\frac{2\sigma^2+g^{ms}_{k,n}P^o_{m,n}}{g^{ss}_{k,n}} \tag{42}$$

$$B_{v,k,n} = A_{v,k,n}^2 \left\{ -\frac{4}{g_{k,n}^{ss}} \cdot \left\{ \frac{\sigma^4 + \sigma^2 g_{k,n}^{ms} P_{m,k,n}^o}{g_{k,n}^{ss}} - \frac{(1+\nu_{k,n})[P(\mathscr{H}_{k,n}^v)(1-q_{k,n}^f(\varepsilon_{k,n},\hat{\tau}_k))(\sigma^2 + g_{k,n}^{ms} P_{m,k,n}^o) + P(\mathscr{H}_{k,n}^o) q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k)\sigma^2]}{\left\{ \begin{array}{l} \ln 2(\eta_{k,n}^{13}(l) + \lambda_k(P(\mathscr{H}_{k,n}^v)(1-q_{k,n}^f(\varepsilon_{k,n},\hat{\tau}_k)) + P(\mathscr{H}_{k,n}^o) q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k) \\ +\mu_{k,n} g_{k,n}^{ms} P(\mathscr{H}_{k,n}^o) q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k) \\ -\xi_{k,n} \sum\limits_{j=1,j\neq k}^{K} g_{j,k,n} \left[P(\mathscr{H}_{j,n}^v)(1-q_{j,n}^f(\varepsilon_{j,n},\hat{\tau}_j)) + P(\mathscr{H}_{j,n}^o) q_{j,n}^m(\varepsilon_{j,n},\hat{\tau}_j) \right] \end{array} \right\} \right\} \tag{43}$$

Similar to $\tilde{P}_{s,k,n}^v$, the near optimal solution can be obtained

$$\tilde{P}_{s,k,n}^o = \left[\frac{A_{o,k,n} + \sqrt{B_{o,k,n}}}{2} \right]^+ \tag{44}$$

where $A_{o,k,n}$ and $B_{o,k,n}$ are given by (45) and (46), respectively.

$$A_{o,k,n} = \frac{(1+\nu_{k,n}) P(\mathscr{H}_{k,n}^v) q_{k,n}^f(\varepsilon_{k,n},\hat{\tau}_k) + P(\mathscr{H}_{k,n}^o)(1-q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k))}{\left\{ \begin{array}{l} \ln 2(\eta_{k,n}^{24}(l) + \lambda_{k,n} P(\mathscr{H}_{k,n}^v) q_{k,n}^f(\varepsilon_{k,n},\hat{\tau}_k) \\ +P(\mathscr{H}_{k,n}^o)(1-q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k)) + \mu_{k,n} g_{k,n}^{sm} P(\mathscr{H}_{k,n}^o)(1-q_{k,n}^m(\varepsilon_{k,n},\hat{\tau}_k)) \\ -\xi_{k,n} \sum\limits_{j=1,j\neq k}^{K} g_{j,k,n} \left[\begin{array}{l} P(\mathscr{H}_{j,n}^v) q_{j,n}^f(\varepsilon_{j,n},\hat{\tau}_j) \\ +P(\mathscr{H}_{j,n}^o)(1-q_{j,n}^m(\varepsilon_{j,n},\hat{\tau}_j)) \end{array} \right] \end{array} \right\}} - \frac{2\sigma^2 + g_{k,n}^{ms} P_{m,n}^o}{g_{k,n}^{ss}} \tag{45}$$

$$B_{o,k,n} = A_{o,k,n}^2 \left\{ -\frac{4}{g_{k,n}^{ss}} \cdot \left\{ \frac{\sigma^4 + \sigma^2 g_{k,n}^{ms} P_{m,k,n}^o}{g_{k,n}^{ss}} \right. \right. \left. \left. - \frac{(1+\nu_{k,n})[P(\mathscr{H}_{k,n}^v) q_{k,n}^f(\varepsilon_{k,n}, \hat{\tau}_k)(\sigma^2 + g_{k,n}^{ms} P_{m,k,n}^o) + P(\mathscr{H}_{k,n}^o)(1 - q_{k,n}^m(\varepsilon_{k,n}, \hat{\tau}_k))\sigma^2]}{\left\{ \begin{array}{l} \ln 2(\eta_{k,n}^{13}(l) + \lambda_k(P(\mathscr{H}_{k,n}^v) q_{k,n}^f(\varepsilon_{k,n}, \hat{\tau}_k) + P(\mathscr{H}_{k,n}^o)(1 - q_{k,n}^m(\varepsilon_{k,n}, \hat{\tau}_k)) \\ +\mu_{k,n} g_{k,n}^{ms} P(\mathscr{H}_{k,n}^o)(1 - q_{k,n}^m(\varepsilon_{k,n}, \hat{\tau}_k)) \\ -\xi_{k,n} \sum\limits_{j=1, j\neq k}^{K} g_{j,k,n} \left[P(\mathscr{H}_{j,n}^v) q_{j,n}^f(\varepsilon_{j,n}, \hat{\tau}_j) + P(\mathscr{H}_{j,n}^o)(1 - q_{j,n}^m(\varepsilon_{j,n}, \hat{\tau}_j)) \right] \end{array} \right\} } \right\} \tag{46}$$

Finally, the near optimal sensing time for each small cell can be found in Algorithm 2 based on a one-dimensional exhaustive search [19].

Complexity Analysis

In this part, the computational complexity of the provided algorithms in multiple small cells network is analyzed. Similar to the single small cell case, suppose the subgradient method used in Algorithm 1 needs Δ_1 iterations to converge; the updates of $\boldsymbol{\lambda}$ need $O(N)$ operations; $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ need $O(KN)$ operations each. The method used in Algorithm 1 to calculate $\eta_{13,n}^*$ and $\eta_{24,n}^*$ on each subchannel in a small cell needs Δ_2 iterations to converge. The total complexity of Algorithm 1 is thus $O(N^2K^2\Delta_1\Delta_2)$. The parameters Δ_1 and Δ_2 can be small enough if the values of iteration step sizes and initial values of $\boldsymbol{\lambda}$, $\boldsymbol{\mu}$, and $\boldsymbol{\nu}$ are well chosen. In Algorithm 2, finding the optimal sensing time for each subchannel requires $O(L)$ operations. Therefore, the total computational complexity of Algorithm 2 is $O(KNL)$.

Simulation Results and Discussion

In this part, simulation results are presented to evaluate the performance of the provided algorithms. The sampling frequency f is 6 MHz, $T = 0.1$ s, $N = 50$, and $\sigma^2 = 1 \times 10^{-4}$. The channel gains are modeled as block faded and exponentially

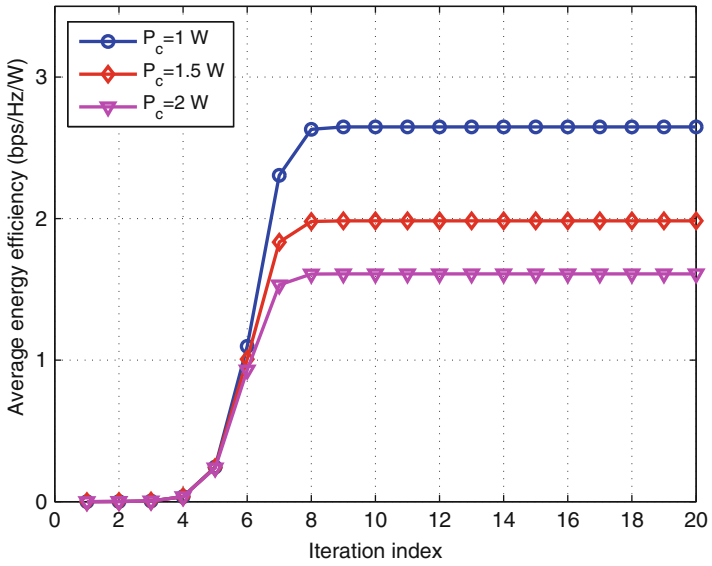

Fig. 2 Convergence in terms of average energy efficiency of small cell on each subchannel versus the number of iterations

distributed with mean of 0.1. The transmit power on each subchannel of primary macrocell is set at 25 mW. The QoS requirement of minimum data rate requirement is set as 0.3 bps/Hz. The target detection probability $\widehat{q}_n^d$ is set as 90% unless otherwise specified [19].

In Fig. 2, the convergence of Algorithm 1 is evaluated with the $P_{\max} = 15\,\text{dBm}$, the cross-tier interference limit $I_n^{th} = -10\,\text{dBm}$. As can be seen from Fig. 2, the average energy efficiency of small cell on each subchannel converges after nine iterations. This result, together with the previous analysis, indicates that the provided Algorithm 1 is practical in cognitive small cell [19].

Figure 3 displays the average energy efficiency of each subchannel in cognitive small cell network when the sensing time increases from 0.0005 to 0.015 s with $P_{\max} = 5, 10, 13, 15\,\text{dBm}$, the cross-tier interference limit $I_n^{th} = -10\,\text{dBm}$. The relation between sensing time and the average energy efficiency of each subchannel is exhibited [19]. As shown in Fig. 3, the average energy efficiency of each subchannel in cognitive small cell first increases and then drops when the sensing time is increased from 0.0005 to 0.015 s. It is estimated that the near optimal sensing time is between 0.002 and 0.004 s. Larger value of $P_{\max}$ results in higher average energy efficiency because a larger value of $P_{\max}$ enlarges the feasible region of the variables in the original optimization problem in (20)–(21).

Figure 4 shows the trend of average energy efficiency of each subchannel in cognitive small cell when $P_{\max}$ increases from 5 to 25 dBm [19]. The target detection probabilities $\widehat{q}_n^d = 0.8, 0.9$ and cross-tier interference limit $I_n^{th} = -10\,\text{dBm}$ in Fig. 4. As shown in Fig. 4, the average energy efficiency of each subchannel of

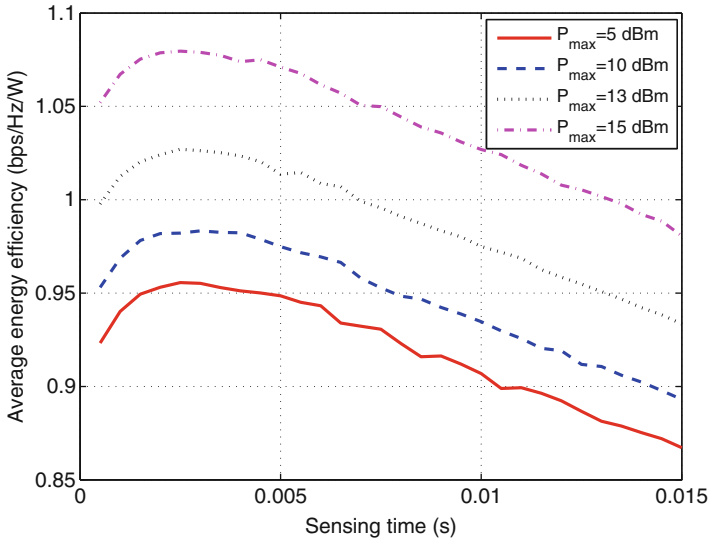

Fig. 3 Average energy efficiency versus sensing time with different $P_{\max}$ values

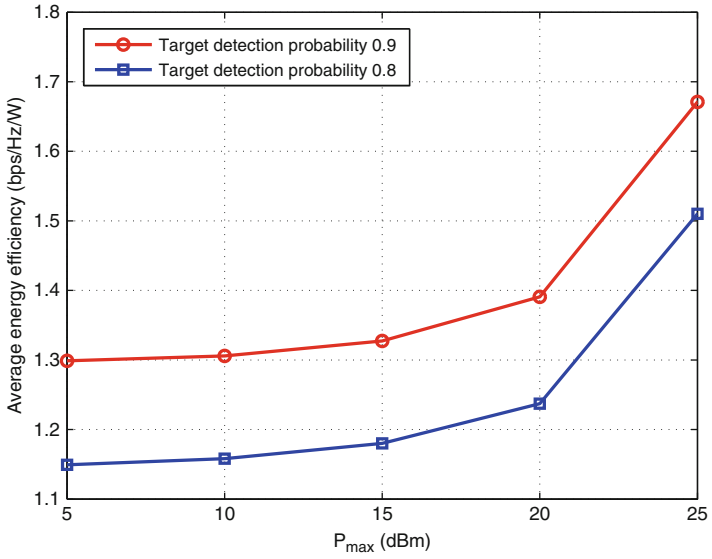

Fig. 4 Average energy efficiency versus $P_{\max}$ with different target detection probabilities

cognitive small cell increases when $P_{\max}$ is increased from 5 to 25 dBm, because a larger value of $P_{\max}$ results in a larger optimal power in (20)–(21). A larger target detection probability which results in better performance of the optimal average energy efficiency from Fig. 4 can be seen. The reason is that a larger target detection probability makes it more accurate in detection of spectrum sensing [19].

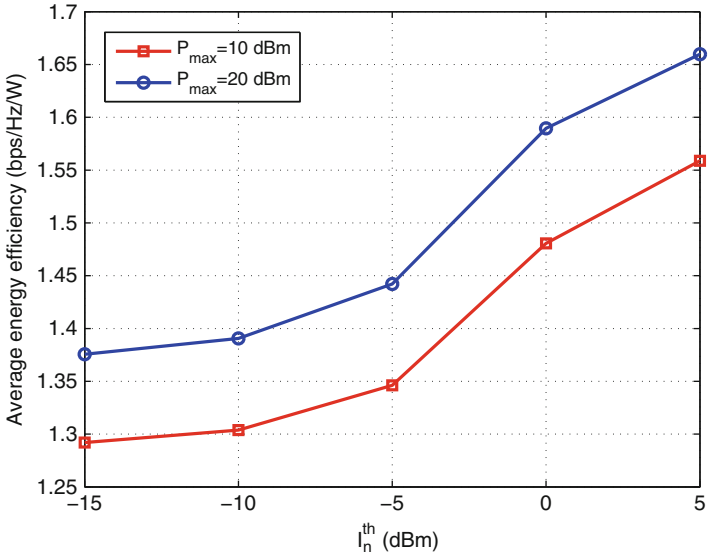

Fig. 5 Average energy efficiency versus the cross-tier interference limit with different $P_{\max}$ values

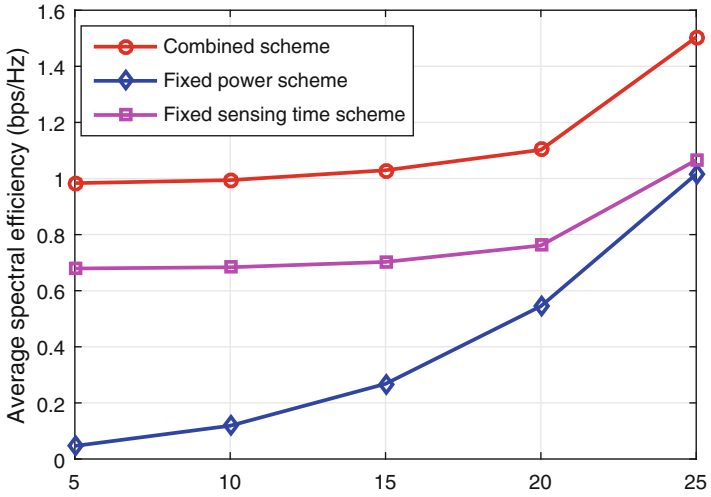

Fig. 6 Performance comparison of different schemes in terms of average spectral efficiency of small cell on each subchannel

Figure 5 shows the relation between cross-tier interference limit and the average energy efficiency of each subchannel with a different target detection probability. As shown in Fig. 5, the average energy efficiency of each subchannel in cognitive small cell increases when I_n^{th} is changed from −15 to 5 dBm. Similar to Fig. 3, this is because that a larger value of I_n^{th} can enlarge the feasible region of the optimizing variable of power in (20)–(21).

Figure 6 shows the performance comparison of average spectral efficiency with different schemes. The combined scheme is the combination of the provided Algorithm 1 and the provided near optimal sensing time scheme. Fixed sensing time scheme is the combination of the provided Algorithm 1 and a random selected sensing time scheme. Fixed power scheme is the combination of equal power allocation and the provided optimal sensing time scheme [19]. As shown in Fig. 6, the average spectral efficiency of each subchannel in the cognitive small cell with $P_{\max}$ increases from 5 to 25 mW. However, the combined scheme outperforms the fixed sensing time scheme and the fixed power scheme obviously.

Figure 7 provides the energy efficiency performance comparison between combined scheme and the other methods. In Fig. 7, the average energy efficiency of each subchannel in the cognitive small cell is shown when $P_{\max}$ increases from 8 to 18 mW, where the target detection probability $\widehat{q}_n^d = 0.9$ and cross-tier interference limit $I_n^{th} = -10$ dBm. As shown in Fig. 7, the combined scheme can achieve 15% higher energy efficiency than the fixed sensing time scheme. Fixed power scheme has the lowest curve, because of equal power allocation [19].

Figure 8 shows the relation between cross-tier interference limit and the optimal sensing time. As shown in Fig. 8, the near optimal sensing time decreases with an increase of I_n^{th}. Because when using KKT conditions related to $C2$, larger I_n^{th} results in larger optimized sensing time. Moreover, a larger value of $P_{\max}$ results in smaller optimized sensing time.

Figure 9 shows the relation between the sensing time and average energy efficiency of each subchannel in cognitive small cell network with a different cross-tier interference limit. As shown in Fig. 9, similar to Fig. 3, the average energy efficiency of each subchannel in cognitive small cell first increases and then drops as the sensing time is increased from 0.0005 to 0.015 s. It is because that the near

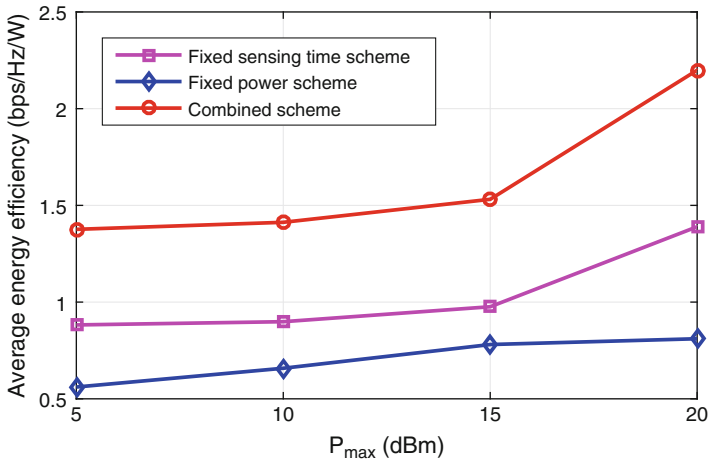

Fig. 7 Performance comparison of different schemes in terms of average energy efficiency of small cell on each subchannel

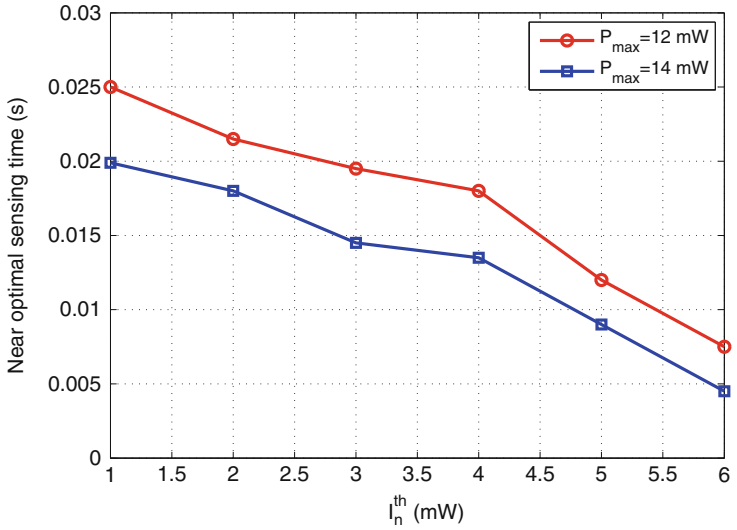

Fig. 8 Near optimal sensing time versus the cross-tier interference limit with different $P_{\max}$ values

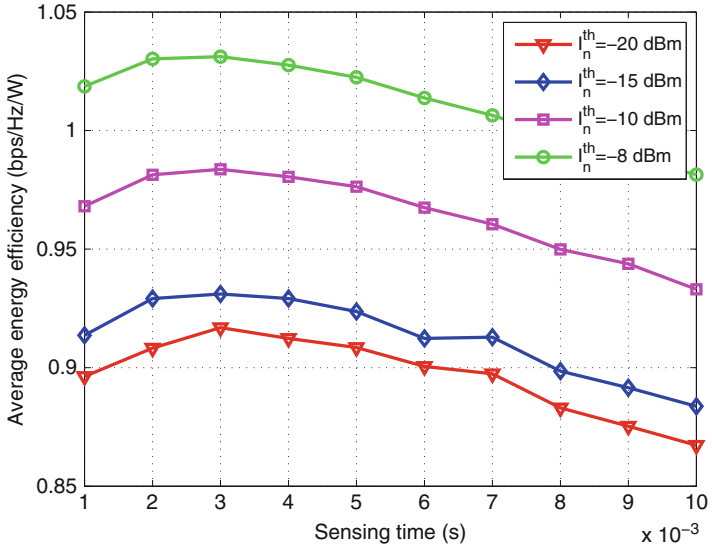

Fig. 9 Average energy efficiency versus sensing time with different cross-tier interference limits

optimal sensing time is between 0.002 and 0.004 s. Larger I_n^{th} value results in higher average energy efficiency since a larger of value of I_n^{th} leads to a larger optimization variable region in (20)–(21) [19].

Figure 10 displays the trend of average energy efficiency of each subchannel in cognitive small cell when $P_{\max}$ increases from 5 to 25 dBm with cross-tier

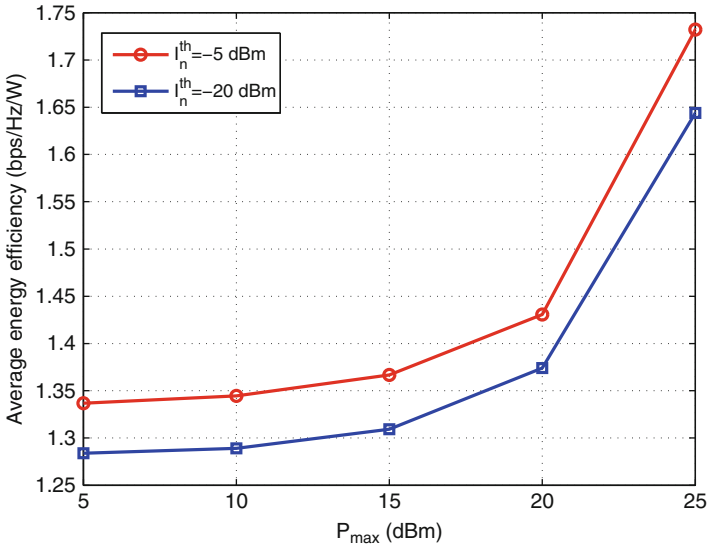

Fig. 10 Average energy efficiency versus $P_{\max}$ with different cross-tier interference limits

interference limit $I_n^{th} = -20, -5\,\text{dBm}$ and target detection probability $\widehat{q}_n^d = 0.9$ [19]. Similar to Fig. 4, Fig. 10 shows that the average energy efficiency of each subchannel in cognitive small cell increases when $P_{\max}$ is increased from 5 to 25 dBm. Besides, the larger cross-tier interference limit can result in improved performance in average energy efficiency.

Figure 11 shows the convergence performance of Algorithm 1 in the network consists of multiple cognitive small cells under the different circuit power P_c. As shown in Fig. 11, the total average energy efficiency on each subchannel of all small cells converges after 12 iterations. The practical applicability of Algorithm 1 in the multiple cognitive small cells is demonstrated through this figure.

Figure 12 shows that the total average energy efficiency on each subchannel of all small cells versus the number of small cells in network with the co-tier interference limits $\gamma^{th} = -10, -20\,\text{dBm}$, and $P_{\max} = 15\,\text{dBm}$. As shown in Fig. 12, the total average energy efficiency on each subchannel of all small cells increase gradually with the number of small cells. However, the rate of increase is diminishing, and it is caused by the co-tier interference among small cells [19]. A larger co-tier interference limit which results in better performance of the optimal total average energy efficiency can be seen. It implies that the provided method not only can optimize the energy efficiency but also can mitigate the co-tier interference in multiple cognitive small cells.

Figure 13 shows the total average energy efficiency on each subchannel of all the small cells versus the number of small cells in network with the cross-tier interference limits $I_n^{th} = -10, -13\,\text{dBm}$, and $P_{\max} = 15\,\text{dBm}$. The total average energy efficiency on each subchannel increases and then drops when the number of

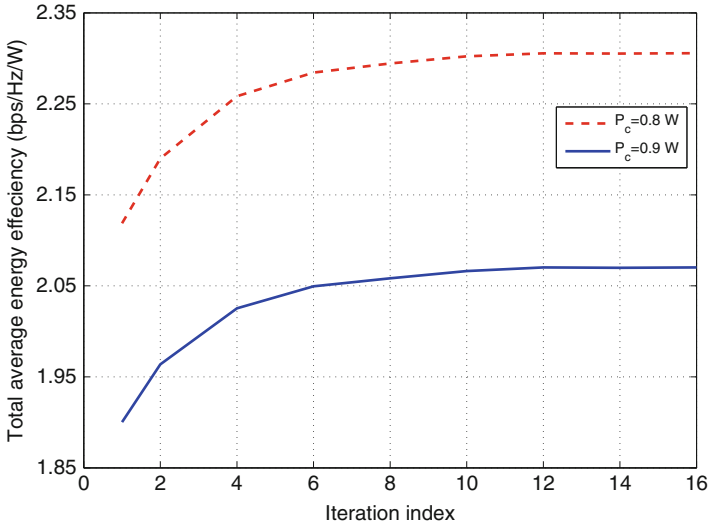

Fig. 11 Convergence in terms of sum of the average energy efficiency of small cells versus the number of iterations

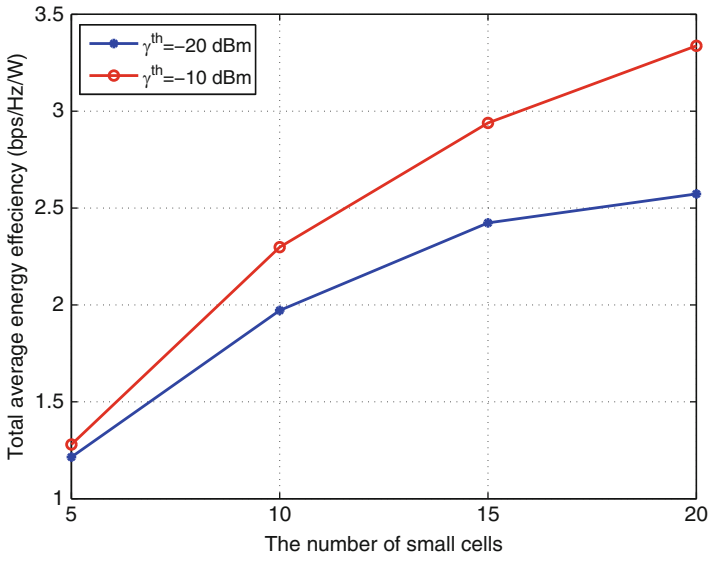

Fig. 12 Sum of the average energy efficiency versus the number of small cells with different co-tier interference limits

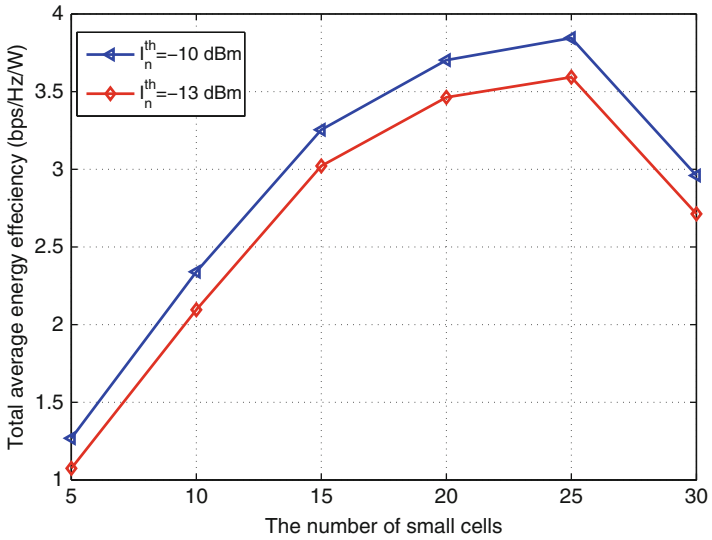

Fig. 13 Sum of the average energy efficiency versus the number of small cells with different cross-tier interference limits

small cells is increased from 5 to 30. The slope of lines is diminishing. Therefore, the provided scheme can mitigate the cross-tier interference when optimizing the energy efficiency.

Interference-Limited Resource Optimization in Cognitive Femtocells with Fairness and Imperfect Spectrum Sensing

This part studies joint subchannel and power allocation in OFDMA-based cognitive femtocells under femtocell user (FU) fairness constraints, QoS requirement, and co-/cross-tier interference temperature limits with imperfect spectrum sensing.

System Model

In the system model [18], we consider an OFDMA uplink of a network with one primary macrocell and K co-channel cognitive femtocells which are deployed randomly in the coverage area of a macrocell. Let M and F denote the numbers of active macro users (MUs) inside the primary macrocell and FUs in each cognitive femtocell, respectively. The OFDMA system has a bandwidth of B_w, which is divided into N_{total} subchannels. The channel model for each subchannel includes path loss and frequency-nonselective Rayleigh fading [18]. We focus on a resource allocation problem in the uplink of cognitive femtocells. The FUs opportunistically access the spectrum licensed to the primary macrocells via cognitive FBS, as illustrated in Fig. 14 [18]. In each time slot, the secondary network can sense N_{total}

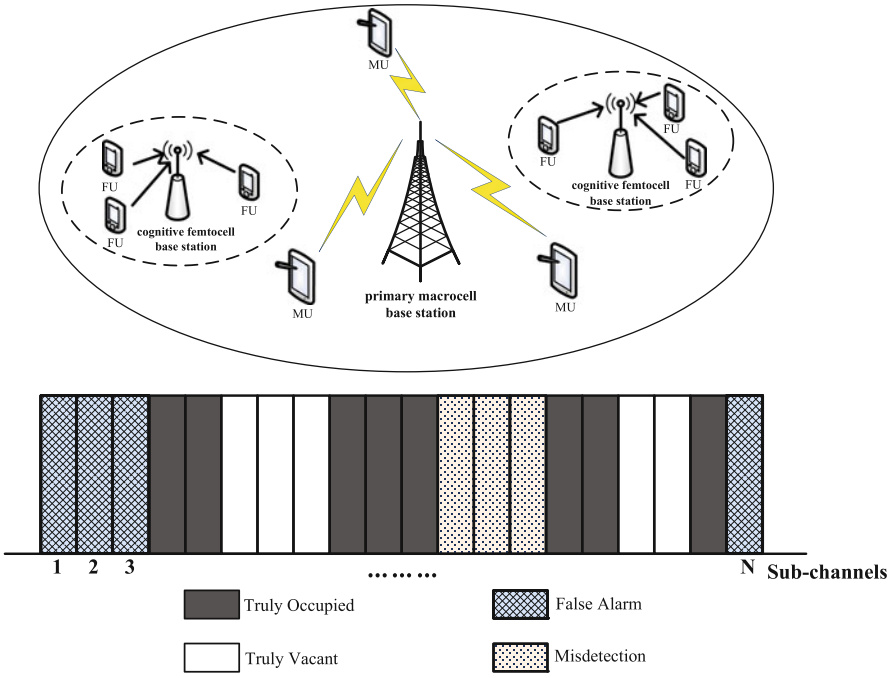

Fig. 14 A cognitive heterogeneous macro/femto network model

subchannels and opportunistically access idle channels by energy detection-based spectrum sensing. In a spectrum sensing period, the cognitive femtocell network senses N_{total} subchannels licensed to the primary macrocell network and determines available vacant/idle subchannels, which are denoted as $\mathcal{N} = 1, 2, \ldots, N$. Throughout this part, a cognitive femto base station is assumed to have perfect channel state information (CSI) between FBS and cognitive FUs/primary MUs. Therefore, the total capacity of the cognitive femtocell networks using resource scheduling schemes [18] will serve as an upper bound of the achievable capacity with channel estimation errors in practical scenarios.

The received signal-to-interference-plus-noise ratio (SINR) $\ell^{\text{F}}_{k,i,n}$ at the kth ($k \in \{1, \ldots, K\}$) cognitive FBS from its FU i ($i \in \{1, \ldots, F\}$) in the nth ($n \in \{1, \ldots, N\}$) subchannel is given as [18]

$$\ell^{\text{F}}_{k,i,n} = \frac{p^{\text{F}}_{k,i,n} \hbar^{\text{FF}}_{k,k,i,n}}{\sum\limits_{j=1, j\neq k}^{K} \sum\limits_{v=1}^{F} p^{\text{F}}_{j,v,n} \hbar^{\text{FF}}_{k,j,v,n} + p^{\text{M}}_{w,n} \hbar^{\text{FM}}_{k,w,n} + \sigma^2} \tag{47}$$

where $p^{\text{F}}_{k,i,n}$ is FU i's transmit power on subchannel n in cognitive femtocell k; $\hbar^{\text{FF}}_{k,j,v,n}$ and $\hbar^{\text{FM}}_{k,w,n}$ are the channel gains on subchannel n from FU v in cognitive femtocell j and from MU w to FBS k, respectively; w is a specific MU using

subchannel n; $p^{\mathrm{M}}_{w,n}$ is MU w's transmit power in subchannel n; and σ^2 is the additive white Gaussian noise (AWGN) power [18]. In such a case, based on the Shannon's capacity formula, the uplink capacity on subchannel n of FU i in cognitive femtocell k can be calculated by [18]

$$R^{\mathrm{F}}_{k,i,n} = \log_2\left(1 + \ell^{\mathrm{F}}_{k,i,n}\right). \tag{48}$$

Optimization Framework with Imperfect Spectrum Sensing

Imperfect Spectrum Sensing

Spectrum sensing has been extensively investigated in the previous works [24, 25]. Here, a cooperative spectrum sensing scheme [26] is presented, in which each cognitive FU senses subchannels and sends the sensing results to a cognitive FBS. Then, the cognitive FBS makes decision to determine whether or not the subchannels are vacant.

The interference from cognitive femtocell networks to primary macrocell networks occurs due to the following two reasons. One is the out-of-band emissions and the other is the spectrum sensing errors. The out-of-band emissions are due to power leakage in the sidelobes of OFDM signals [27]. The amount of out-of-band interference power of subchannel n introduced to subchannel j occupied by a primary macrocell (with unit transmit power) can be expressed as [18]

$$I^{s}_{k,i,n} = \int_{f^c_s - \frac{B_w}{2N_{\mathrm{total}}} + f^c_n}^{f^c_s + \frac{B_w}{2N_{\mathrm{total}}} + f^c_n} \varphi(f)\hbar^{FM}_{k,i,n,s}\,df \tag{49}$$

where f^c_n and f^c_s are the center frequencies of subchannel n and s, respectively, and $\hbar^{FM}_{k,i,n,s}$ is the channel gain from cognitive FU to primary MBS in subchannel s. In (47), power spectrum density (PSD) of OFDM signal $\varphi(f)$ is given as [18]

$$\varphi(f) = \frac{1}{T}\left(\frac{\sin(\pi(f - f^c_n)T)}{\pi(f - f^c_n)}\right)^2 \tag{50}$$

where T is the duration of an OFDM symbol.

Based on the analysis of the last part, there are four different cases in the cognitive femtocells network. Similarly, the probabilities for Cases 1, 2, 3, and 4 [18] for subchannel s are defined $\rho_{1,s}$, $\rho_{2,s}$, $\rho_{3,s}$, and $\rho_{1,s}$, respectively.

Based on the above analysis, the uplink cross-tier interference from cognitive femtocell to primary MBS, caused by out-of-band emission and co-channel interference, can be formulated as [18]

$$I^{MF}_{k,i,n} = p^{F}_{k,i,n} \underbrace{\left(\sum_{s\in\mathcal{N}_0} \rho_{3,s} I^{s}_{k,i,n} + \sum_{s\in\mathcal{N}_0} \rho_{4,s} I^{s}_{k,i,n}\right)}_{\tilde{G}^{MF}_{k,i,n}} \tag{51}$$

where $\mathcal{N}_v$ and $\mathcal{N}_o$ are the sets of vacant and occupied subchannels, respectively, and they are determined by the cognitive FBS. The amount of out-of-band interference power of subchannel n introduced to a primary macrocell-occupied subchannel j, with unit transmit power, can be expressed as $I^s_{k,i,n}$. In other words, since $I^s_{k,i,n}$ is calculated by unit transmit power, $I^s_{k,i,n}$ is the unit interference power here, which can be seen as channel gain. Moreover, both $\rho_{3,s}$ and $\rho_{4,s}$ are the probabilities, and therefore $\tilde{G}^{MF}_{k,i,n}$ can be interpreted as the channel gain on subchannel n from user i in cognitive femtocell k to the primary MBS [18].

General Optimization Framework

First, for resource allocation in cognitive femtocell networks, the total transmit power of cognitive FU is constrained by

$$\sum_{n=1}^{N} \tau_{k,i,n} p^{\mathrm{F}}_{k,i,n} \leq P_{\max}, \quad \forall k,\ i \tag{52}$$

where $\tau_{k,i,n} \in \{0, 1\}$ is the subchannel allocation indicator, and $\tau_{k,i,n} = 1$ indicates that subchannel n is occupied by user i in cognitive femtocell k; otherwise $\tau_{k,i,n} = 0$. $P_{\max}$ is the maximum transmit power of each cognitive FU [18].

Second, to maintain communication quality of cognitive FUs, a QoS requirement in terms of SINR is introduced for each FU. Thus, the QoS requirement can be written as [18]

$$\sum_{n=1}^{N} \tau_{k,i,n} R^{\mathrm{F}}_{k,i,n} \geq R^0_{k,i}, \quad \forall k, i \tag{53}$$

where $R^0_{k,i}$ is the QoS requirement for user i in cognitive femtocell k.

Third, a subchannel should be assigned to no more than one user at a time in a cognitive femtocell. Therefore, the subchannel assignment can be performed based on [18]

$$\sum_{i=1}^{F} \tau_{k,i,n} \leq 1, \quad \forall k, n. \tag{54}$$

Fourth, to obtain the fairness on FUs' level, the upper and lower bounds of the number of subchannels assigned to user i in cognitive femtocell k are set as [18]

$$\Gamma_{L,k,i} \leq \sum_{n=1}^{N} \tau_{k,i,n} \leq \Gamma_{U,k,i}, \quad \forall k, i \tag{55}$$

where $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$ are the upper and lower bounds of the number of subchannels assigned to user i in cognitive femtocell k, respectively. Finally, to protect the primary macrocell's transmission, an interference temperature limit is introduced to constrain cross-tier interference from cognitive femtocell to primary macrocell [18], i.e.,

$$\sum_{k=1}^{K}\sum_{i=1}^{F}\tau_{k,i,n}p_{k,i,n}^{F}\tilde{G}_{k,i,n}^{MF} \le I_{th,n}^{\mathrm{MF}}, \quad \forall n \tag{56}$$

where $I_{th,n}^{\mathrm{MF}}$ is the maximum tolerable cross-tier interference temperature in subchannel n in the primary macrocell.

Our resource allocation problem aims to maximize the total uplink capacity of K cognitive femtocells under a cross-tier interference constraint and FUs' QoS constraints, i.e. [18],

$$\max_{\{\tau_{k,i,n}\},\{p_{k,i,n}^{\mathrm{F}}\}} \sum_{k=1}^{K}\sum_{1=1}^{F}\sum_{n=1}^{N}\tau_{k,i,n}R_{k,i,n}^{\mathrm{F}} \tag{57}$$

$$\begin{aligned}
\text{s.t.} \quad & C_1 : \sum_{n=1}^{N}\tau_{k,i,n}p_{k,i,n}^{\mathrm{F}} \le P_{\max}, \quad \forall k,i, \\
& C_2 : p_{k,i,n}^{\mathrm{F}} \ge 0, \quad \forall k,i,n, \\
& C_3 : \sum_{n=1}^{N}\tau_{k,i,n}R_{k,i,n}^{\mathrm{F}} \ge R_{k,i}^{0}, \quad \forall k,i, \\
& C_4 : \tau_{k,i,n} \in \{0,1\}, \quad \forall k,i,n, \\
& C_5 : \sum_{i=1}^{F}\tau_{k,i,n} \le 1, \quad \forall k,n, \\
& C_6 : \Gamma_{L,k,i} \le \sum_{n=1}^{N}\tau_{k,i,n} \le \Gamma_{U,k,i}, \quad \forall k,i, \\
& C_7 : \sum_{k=1}^{K}\sum_{i=1}^{F}\tau_{k,i,n}p_{k,i,n}^{F}\tilde{G}_{k,i,n}^{MF} \le I_{th,n}^{\mathrm{MF}}, \quad \forall n
\end{aligned}$$

where C_1 limits the transmit power of each FU below the maximum power $P_{\max}$; C_2 indicates that the transmit power is nonnegative; C_3 sets the QoS requirement $R_{k,i}^{0}$ for user i in cognitive femtocell k; C_4 and C_5 guarantee that each subchannel can be assigned to no more than one user in each femtocell; C_6 ensures a fairness among users by setting $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$ as the upper and lower bounds of the number of subchannels assigned to user i in cognitive femtocell k, respectively. The priority of the user can be adjusted by setting appropriate values of $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$. The constraint C_7 imposes the maximum tolerable cross-tier interference temperature $I_{th,n}^{\mathrm{MF}}$ in subchannel n for the primary macrocell [18].

Joint Resource Optimization with Fairness and Imperfect Sensing

Transformation of the Optimization Problem

The problem in (57) is a non-convex mixed integer programming problem. It can be solved using a brute-force method, which however incurs a high computational complexity. To make the problem tractable, an additional co-tier interference temperature constraint C_8 is introduced as [18]

$$C_8: \sum_{j=1, j\neq k}^{K} \sum_{v=1}^{F} \tau_{j,v,n} p^{\mathrm{F}}_{j,v,n} \hbar^{\mathrm{FF}}_{k,j,v,n} \leq I^{\mathrm{FF}}_{th,n}, \quad \forall k, n \tag{58}$$

where $I^{\mathrm{FF}}_{th,n}$ is the co-tier interference limit in subchannel n for a cognitive femtocell. Each femtocell will potentially interfere each other when two neighbor femtocells use the same subchannel. Therefore, from physical/engineering point view in the real-world applications, $I^{\mathrm{FF}}_{th,n}$ is a co-tier interference limit for neighbor femtocell to mitigate co-tier interference. The value of $I^{\mathrm{FF}}_{th,n}$ can be broadcasted by each femtocell or set by each femtocell.

Moreover, inspired by [28], the $\tau_{k,i,n}$ in C_4 is relaxed to be a real variable in the range of [0,1], in which case $\tau_{k,i,n}$ can be interpreted as the fraction of time that subchannel n is assigned to user i in cognitive femtocell k during one transmission frame. Denote $\widehat{p}_{k,i,n} = \tau_{k,i,n} p^{\mathrm{F}}_{k,i,n}$ as the actual power allocated to user i in cognitive femtocell k on subchannel n. Denote $I_{k,i,n} = p^{\mathrm{M}}_{w,n} \hbar^{\mathrm{FM}}_{k,w,n} + I^{\mathrm{FF}}_{th,n} + \sigma^2$ and $\hat{R}^{\mathrm{F}}_{k,i,n} = \log_2\left(1 + \frac{\hat{p}_{k,i,n} \hbar^{\mathrm{FF}}_{k,k,i,n}}{\tau_{k,i,n} I_{k,i,n}}\right)$ as the upper bound of the total received interference power and lower bound of the capacity of user i on subchannel n in cognitive femtocell k, respectively. In such a case, the optimization problem in (57) can be rewritten as [18]

$$\max_{\{\tau_{k,i,n}\}, \{\widehat{p}_{k,i,n}\}} \sum_{k=1}^{K} \sum_{i=1}^{F} \sum_{n=1}^{N} \tau_{k,i,n} \widehat{R}^{\mathrm{F}}_{k,i,n} \tag{59}$$

$$\text{s.t. } C_1: \sum_{n=1}^{N} \widehat{p}_{k,i,n} \leq P_{\max}, \quad \forall k, i,$$

$$C_2: \widehat{p}_{k,i,n} \geq 0, \quad \forall k, i, n,$$

$$C_3: \sum_{n=1}^{N} \tau_{k,i,n} \widehat{R}^{\mathrm{F}}_{k,i,n} \geq R^0_{k,i}, \quad \forall k, i,$$

$$C_4: 0 \leq \tau_{k,i,n} \leq 1, \quad \forall k, i, n,$$

$$C_5: \sum_{i=1}^{F} \tau_{k,i,n} \leq 1, \quad \forall k, n,$$

$$C_6 : \Gamma_{L,k,i} \leq \sum_{n=1}^{N} \tau_{k,i,n} \leq \Gamma_{U,k,i}, \quad \forall k, i,$$

$$C_7 : \sum_{k=1}^{K} \sum_{i=1}^{F} \widehat{p}_{k,i,n} \tilde{G}^{\mathrm{MF}}_{k,i,n} \leq I^{\mathrm{MF}}_{th,n}, \quad \forall n,$$

$$C_8 : \sum_{j=1, j\neq k}^{K} \sum_{v=1}^{F} \tau_{j,v,n} \hbar^{\mathrm{FF}}_{k,j,v,n} \leq I^{\mathrm{FF}}_{th,n}, \quad \forall k, n.$$

Theorem 2. *The objective function in (59) is concave, and the corresponding optimization problem under the constraints C_1 to C_8 is a convex problem.*

The proof is provided in Appendix.

According to Theorem 2, the objective function in (59) is concave, and the corresponding optimization problem under the constraints C_1 to C_8 is a convex problem.

Joint Subchannel and Power Allocation with Imperfect Spectrum Sensing

The joint subchannel and power allocation problem in (59) can be solved using the Lagrangian dual decomposition method, which has been widely used in solving resource allocation problems. The Lagrangian function is given by [18]

$$\begin{aligned}
\mathscr{L}(\{\tau_{k,i,n}\}, \{\widehat{p}_{k,i,n}\}, \boldsymbol{\lambda}, \boldsymbol{\nu}, \boldsymbol{\delta}, \boldsymbol{\mu}, \boldsymbol{\eta}) = & \sum_{k=1}^{K} \sum_{u=1}^{F} \sum_{n=1}^{N} \tau_{k,i,n} \widehat{R}^{\mathrm{F}}_{k,i,n} \\
& + \sum_{k=1}^{K} \sum_{i=1}^{F} \lambda_{k,i} \left(P_{\max} - \sum_{n=1}^{N} \widehat{p}_{k,i,n} \right) + \sum_{n=1}^{N} \delta_n \left(I^{\mathrm{MF}}_{th,n} - \sum_{k=1}^{K} \sum_{i=1}^{F} \widehat{p}_{k,i,n} \tilde{G}^{\mathrm{MF}}_{k,i,n} \right) \\
& + \sum_{k=1}^{K} \sum_{n=1}^{N} \mu_{k,n} \left(I^{\mathrm{FF}}_{th,n} - \sum_{j=1, j\neq k}^{K} \sum_{v=1}^{F} \widehat{p}_{j,v,n} \hbar^{\mathrm{FF}}_{k,j,v,n} \right) + \sum_{k=1}^{K} \sum_{n=1}^{N} \eta_{k,n} \left(1 - \sum_{i=1}^{F} \tau_{k,i,n} \right) \\
& + \sum_{k=1}^{K} \sum_{i=1}^{F} \nu_{k,i} \left(\sum_{n=1}^{N} \tau_{k,i,n} \widehat{R}^{\mathrm{F}}_{k,i,n} - R^{0}_{k,i} \right)
\end{aligned} \tag{60}$$

where $\boldsymbol{\lambda}$, $\boldsymbol{\nu}$, $\boldsymbol{\delta}$, $\boldsymbol{\mu}$, and $\boldsymbol{\eta}$ are the Lagrange multiplier vectors for C_1, C_3, C_7, C_8, and C_5 in (59), respectively. The boundary constraints C_2, C_4, and C_6 in (59) are absorbed in the KKT conditions [23], which will be shown later. The dual function is defined as

$$g(\boldsymbol{\lambda}, \boldsymbol{\nu}, \boldsymbol{\delta}, \boldsymbol{\mu}, \boldsymbol{\eta}) = \max_{\{\tau_{k,i,n}\}, \{\widehat{p}_{k,i,n}\}} \mathscr{L}\Big(\{\tau_{k,i,n}\}, \{\widehat{p}_{k,i,n}\}, \boldsymbol{\lambda}, \boldsymbol{\nu}, \boldsymbol{\delta}, \boldsymbol{\mu}, \boldsymbol{\eta} \Big) \tag{61}$$

and the dual problem can be expressed by

$$\min_{\boldsymbol{\lambda},\boldsymbol{\nu},\boldsymbol{\delta},\boldsymbol{\mu},\boldsymbol{\eta}\geq 0} g\Big(\boldsymbol{\lambda},\boldsymbol{\nu},\boldsymbol{\delta},\boldsymbol{\mu},\boldsymbol{\eta}\Big). \tag{62}$$

Decomposing the Lagrangian dual problem into a master problem and $K \times N$ subproblems that can be solved iteratively [18]. Here the MBS solves the master problem, and each FBS solves N subproblems based on local information in each iteration. Accordingly, Eq. (60) is rewritten as [18]

$$\mathscr{L}(\{\tau_{k,i,n}\},\{\widehat{p}_{k,i,n}\},\boldsymbol{\lambda},\boldsymbol{\nu},\boldsymbol{\delta},\boldsymbol{\mu},\boldsymbol{\eta}) = \sum_{k=1}^{K}\sum_{n=1}^{N} L_{k,n}(\{\tau_{k,i,n}\},\{\widehat{p}_{k,i,n}\},\boldsymbol{\lambda},\boldsymbol{\nu},\boldsymbol{\delta},\boldsymbol{\mu},\boldsymbol{\eta})$$
$$+\sum_{k=1}^{K}\sum_{i=1}^{F}\lambda_{k,i}P_{\max}-\sum_{k=1}^{K}\sum_{i=1}^{F}\nu_{k,i}R_{k,i}^{0}+\sum_{n=1}^{N}\delta_n I_{th,n}^{\mathrm{MF}}+\sum_{k=1}^{K}\sum_{n=1}^{N}\mu_{k,n}I_{th,n}^{\mathrm{FF}}+\sum_{k=1}^{K}\sum_{n=1}^{N}\eta_{k,n} \tag{63}$$

where

$$\mathscr{L}_{k,n}(\{\tau_{k,i,n}\},\{\widehat{p}_{k,i,n}\},\boldsymbol{\lambda},\boldsymbol{\nu},\boldsymbol{\delta},\boldsymbol{\mu},\boldsymbol{\eta}) = \sum_{i=1}^{F}\tau_{k,i,n}\widehat{R}_{k,i,n}^{\mathrm{F}}-\sum_{i=1}^{F}\lambda_{k,i}\widehat{p}_{k,i,n}-\sum_{i=1}^{F}\eta_{k,n}\tau_{k,i,n}$$
$$+\sum_{i=1}^{F}\nu_{k,i}\tau_{k,i,n}\widehat{R}_{k,i,n}^{\mathrm{F}}-\mu_{k,n}\sum_{j=1,j\neq k}^{K}\sum_{l\in U_j}\widehat{p}_{j,l,n}\hbar_{k,j,l,n}^{\mathrm{FF}}-\sum_{g\neq k}^{K}\sum_{u\in U_k}\mu_{g,n}\widehat{p}_{k,i,n}\hbar_{g,k,i,n}^{\mathrm{FF}}$$
$$-\sum_{i=1}^{F}\delta_n\widehat{p}_{k,i,n}\tilde{G}_{k,i,n}^{\mathrm{MF}}. \tag{64}$$

The calculation of the derivatives with respect to $\hat{p}_{k,i,n}$ and $\tau_{k,i,n}$, respectively, gives the KKT condition as

$$\frac{\partial L_{k,n}(\ldots)}{\partial \hat{p}_{k,i,n}} = \Lambda_{k,i,n}-\lambda_{k,i}\leq 0 \tag{65}$$

where

$$\Lambda_{k,i,n} = \frac{(1+\nu_{k,i})\tau_{k,i,n}\hbar_{k,k,i,n}^{FF}}{\ln 2(\tau_{k,i,n}I_{k,i,n}+\hat{p}_{k,i,n}\hbar_{k,k,i,n}^{FF})}-\sum_{g=1,g\neq k}^{K}\mu_{g,n}\hbar_{g,k,i,n}^{\mathrm{FF}}-\delta_n\tilde{G}_{k,i,n}^{\mathrm{MF}}, \tag{66}$$

$$\hat{p}_{k,i,n}\left(\Lambda_{k,i,n}-\lambda_{k,i}\right)=0, \tag{67}$$

$$\lambda_{k,i}\left(P_{\max}-\sum_{n=1}^{N}\hat{p}_{k,i,n}\right)=0. \tag{68}$$

According to (65), (66), (67), and (68), the optimal power allocated to user i in cognitive femtocell k in subchannel n for (59) is [18]

$$p_{k,i,n}^{*\mathrm{F}} = \frac{\hat{p}_{k,i,n}}{\tau_{k,i,n}} = \left[\frac{(1+\nu_{k,i})}{\ln 2 \left(\lambda_{k,i} + \sum\limits_{g=1,g\neq k}^{K} \mu_{g,n} \hbar_{g,k,i,n}^{\mathrm{FF}} + \delta_n \tilde{G}_{k,i,n}^{\mathrm{MF}} \right)} - \frac{I_{k,i,n}}{\hbar_{k,k,i,n}^{\mathrm{FF}}} \right]^+, \forall k,i \tag{69}$$

where $[x]^+ = \max\{0, x\}$. Moreover, there is

$$\frac{\partial L_{k,n}(\ldots)}{\partial \tau_{k,i,n}} = \Xi_{k,i,n} - \eta_{k,n} \leq 0 \tag{70}$$

where

$$\Xi_{k,i,n} = (1+\nu_{k,i}) \left[\log_2 \left(1 + \frac{p_{k,i,n}^{*\mathrm{F}} \hbar_{k,k,i,n}^{\mathrm{FF}}}{I_{k,i,n}} \right) - \frac{1}{\ln 2} \left(\frac{p_{k,i,n}^{*\mathrm{F}} \hbar_{k,k,i,n}^{\mathrm{FF}}}{p_{k,i,n}^{*\mathrm{F}} \hbar_{k,k,i,n}^{\mathrm{FF}} + I_{k,i,n}} \right) \right], \tag{71}$$

$$\tau_{k,i,n} \left(\Xi_{k,i,n} - \eta_{k,n} \right) = 0, \tag{72}$$

$$\eta_{k,n} \left(1 - \sum_{i=1}^{F} \tau_{k,i,n} \right) = 0. \tag{73}$$

Based on (70), (71), (72), and (73), subchannel n is assigned to the user with the largest $\Xi_{k,i,n}$ in femtocell k, i.e.,

$$\widehat{\tau}_{k,i^*,n} = 1 \Big|_{i^* = \max\limits_{i} \Xi_{k,i,n}}, \quad \forall k,n. \tag{74}$$

Since the dual function is differentiable, the subgradient method can be used to solve the master dual minimization problem in (62). Based on the subgradient method, the master dual problem in (62) can be solved as [18]

$$\lambda_{k,i}^{(l+1)} = \left[\lambda_{k,i}^{(l)} - \varepsilon_1^{(l)} \left(P_{\max} - \sum_{n=1}^{N} \widehat{p}_{k,i,n} \right) \right]^+, \quad \forall k,i, \tag{75}$$

$$\nu_{k,i}^{(l+1)} = \left[\nu_{k,i}^{(l)} - \varepsilon_2^{(l)} \left(\sum_{n=1}^{N} \widehat{R}_{k,i,n}^{\mathrm{F}} - R_{k,i}^{0} \right) \right]^+, \quad \forall k,i, \tag{76}$$

$$\mu_{k,n}^{(l+1)} = \left[\mu_{k,n}^{(l)} - \varepsilon_3^{(l)} \left(I_{th,n}^{\mathrm{FF}} - \sum_{j \neq k}^{K} \sum_{l \in U_j} s_{j,l,n} \hbar_{k,j,l,n}^{\mathrm{FF}} \right) \right]^+, \quad \forall k, n, \tag{77}$$

$$\delta_n^{(l+1)} = \left[\delta_n^{(l)} - \varepsilon_4^{(l)} \left(I_{th,n}^{\mathrm{MF}} - \sum_{k=1}^{K} \sum_{i=1}^{F} \widehat{p}_{k,i,n} \tilde{G}_{k,i,n}^{\mathrm{MF}} \right) \right]^+, \quad \forall n \tag{78}$$

where $\varepsilon_1^{(l)}$, $\varepsilon_2^{(l)}$, $\varepsilon_3^{(l)}$, and $\varepsilon_4^{(l)}$ are step sizes of iteration i, $l \in \{1, 2, \ldots, L_{\max}\}$, $L_{\max}$ is the maximal number of iterations. The step sizes should satisfy $\sum_{l=1}^{\infty} \varepsilon_t^{(l)} = \infty$, $\lim_{l \to \infty} \varepsilon_t^{(l)} = 0$, $\forall t \in 1, \ldots, 4$. λ, ν, and μ are updated by the cognitive femtocells in a distributed manner, and $\delta_n^{(l+1)}$ is updated by the primary MBS. Figure 15 shows the three-layer architecture of the decomposed dual problem.

Iterative Resource Optimization Algorithm with Fairness

Although in the solution in (69), (74), (75), (76), (77), and (78) give a complete algorithm for the original problem, the fairness in subchannel occupation was not considered. Therefore, Algorithm 3 is provided as an implementation of the joint subchannel and power allocation scheme, as shown in the pseudo codes below.

In this part, the fairness is taken into consideration in terms of subchannel allocation. Specifically, to ensure the fairness on FUs' level, the upper and lower bounds of the number of subchannels are assigned to the users in a cognitive femtocell as shown in (55). In the problem formulation, C_6 ensures fairness among users by setting $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$ as the upper and lower bounds of the number of

subchannels assigned to user i in cognitive femtocell k, respectively, and the priority of the user can be adjusted by setting values of $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$ appropriately. After the transformation, the optimization problem is solved by Algorithm 3 [18].

In Algorithm 3, there are two procedures to ensure users' fairness in subchannel allocation. First, subchannels are allocated for the users whose subchannel occupation is below $\Gamma_{L,k,i}$, and this procedure is named as "subchannel allocation for user fairness" in Algorithm 3, to guarantee user's lowest requirement. In the second procedure, which is called "subchannel allocation for capacity enhancement," the algorithm tries to enhance the user's capacity while keeping users' subchannel occupation below the upper bound of $\Gamma_{U,k,i}$. With the help of the two procedures, Algorithm 3 can ensure that the subchannels assigned to user i in femtocell k is

between $\Gamma_{U,k,i}$ and $\Gamma_{L,k,i}$. Moreover, from lines 9–16 of Algorithm 3, subchannels will be assigned to cognitive femto users, and the used subchannels will be removed from subchannel set $\mathcal{N}$ based on line 12 of Algorithm 3. Algorithm 3 will check that whether any unused subchannels are left in line 18; if true, lines 19–20 will be executed until the subchannel set is empty. Therefore, lines 9–24 can ensure a full utilization of all vacant subchannels [18].

In practical scenarios, users' subchannel requirements are different, and traditional capacity-maximum subchannel algorithms tend to allocate the subchannels to the users with better channel conditions according to users' subchannel requirements. Therefore, the subchannel requirements of the other users with relatively poor channel conditions may not be satisfied. This is unfair for the users with poor subchannel conditions. In Algorithm 3, Procedure 1 can guarantee the lowest requirements of subchannels for users with poor channel conditions, and Procedure 2 can maximize the users' capacity while keeping the number of user's subchannel occupation below the upper bound.

Note that $\hbar^{\mathrm{FF}}_{g,k,i,n}$ required in (69), (71), and (77) can be known by a cognitive FBS from a FBS gateway or through available interfaces between FBSs, and $\tilde{G}^{\mathrm{MF}}_{k,i,n}$ required in (69) and (78) can be estimated by user i in femtocell k by measuring downlink channel gain of subchannel n from the MBS, assuming a symmetry between uplink and downlink channels. Furthermore, it is assumed that there are wired connections between FBSs and MBS [29,30], so that $\tilde{G}^{\mathrm{MF}}_{k,i,n}$ can be exchanged between the MBS and FBS's.

The following is the complexity analysis of the provided algorithm. Suppose that the subgradient method used in Algorithm 3 needs Δ iterations to converge. Since the updates of each $\boldsymbol{\lambda}$ and $\boldsymbol{\nu}$ need $O(F)$ operations [23], the computation of $\boldsymbol{\mu}$ and $\boldsymbol{\delta}$ requires $O(N)$ operations each, and Δ is a polynomial function of FN. Therefore, the asymptotic complexity of Algorithm 3 is $O(KFN(\log_2 N + \log_2 F)\Delta)$. Compared to the brute-force method, which has a complexity of $O(KF^N)$, the provided Algorithm 3 has a lower complexity, especially for a large N.

Simulation Results and Discussions

In the simulations, the primary macrocell's radius is set to 500 m, and the radius of each cognitive femtocell is set to 10 m. Cognitive femtocells and MUs are distributed randomly in the macrocell coverage area. The carrier frequency is 2 GHz. $B_w = 10\,\mathrm{MHz}$, $N_0 = -174\,\mathrm{dBm/Hz}$, $N = 50$, and $M = 20$ were used in the simulations, respectively [18]. The block-fading channel gains are modeled as independent identically distributed exponential random variables with unit mean. MUs' maximum transmit power is 23 dBm. The standard deviation of lognormal shadowing between MBS and users is 8 dB, while between an FBS and users is 10 dB. The probability of false alarm q_s^f, mis-detection q_s^m, and primary MU's occupation q_s^p are uniformly distributed over [0.05,0.1], [0.01,0.05], and [0,1], respectively. Assuming that $\mathcal{N}_o = \{1, 3, 5, \ldots, 49\}$ and $\mathcal{N}_v = \{2, 4, 6, \ldots, 50\}$,

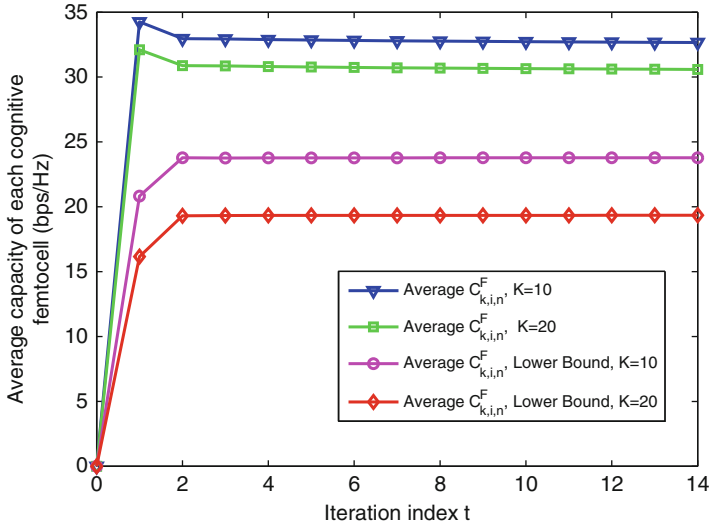

Fig. 16 Convergence in terms of average capacity of each femtocell versus the number of iterations

while the upper bounds [7, 7, 14, 14] and the lower bounds [3, 3, 7, 7] of subchannel assignment for FUs $i = \{1, 2, 3, 4\}$ per femtocell are assumed. For comparison purpose, the simulation included the scheduling scheme in [31] in conjunction with the power allocation scheme in Algorithm 3 and refered to it as the "existing scheme" hereafter. The indoor and outdoor pathloss models are based on [32].

Figure 16 shows the convergence of the Algorithm 3 in terms of the average capacity per femtocell versus the number of iterations i, where $K = 10, 20$, $R_{k,i}^0 = 9$ bps/Hz for all FUs, $P_{\max} = 23$ dBm, and $I_{th,n}^{\mathrm{FF}} = I_{th,n}^{\mathrm{MF}} = -100$ dBm. The provided algorithm in [18] takes only four iterations to converge, indicating that it is suitable for real-time implementation. The average capacity per femtocell for $K = 10$ is higher than that for $K = 20$, because co-tier interference increases with K. The lower bound of cognitive femtocell capacity used in (59) is also plotted and is shown to be in reasonably close agreement with the simulation results.

Figure 17 shows the total capacity of K cognitive femtocells versus the number of femtocells in term of different co-/cross-tier interference limits. The Algorithm 3 [18] with higher co-/cross-tier interference limits, $I_{th,n}^{\mathrm{FF}}$ and $I_{th,n}^{\mathrm{MF}}$, provides a higher total capacity of K cognitive femtocells, because of the higher transmit power used by users under the slacker constraint of co-/cross-tier interference. The effect on how additional constraint of C_8 affects the overall performance of the Algorithm 3 is investigated in the simulations, as showed in Fig. 17. The brute-force method without constraint of co-tier interference limit C_8 has a better performance in terms of total capacity of K cognitive femtocells than the provided algorithm with C_8, because of the slacker constraint of co-/cross-tier interference in the optimization problem [18].

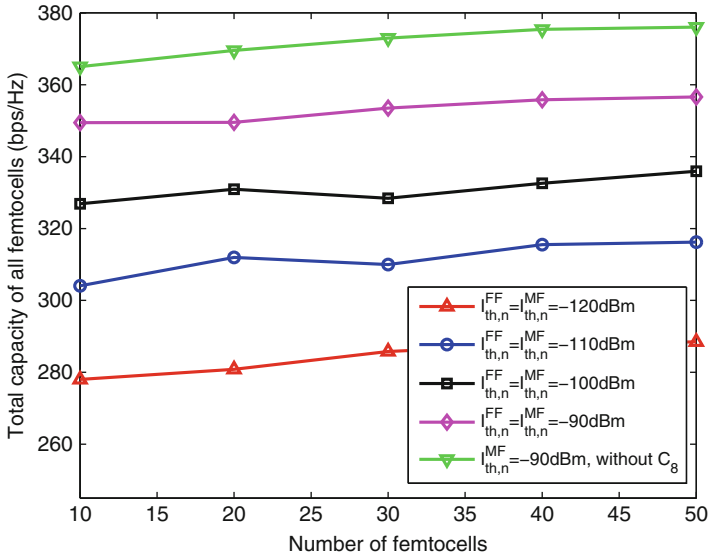

Fig. 17 Total capacity of femtocells versus number of femtocells

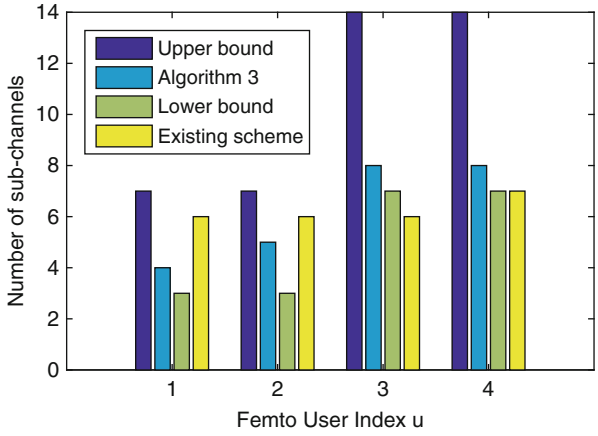

Fig. 18 Number of subchannels occupied by each FU

Figure 18 shows the average number of subchannels allocated by the provided Algorithm 3 [18] to each FU as compared with the "existing algorithm." It can be seen that subchannel assignments of the provided algorithm meet the requirements of different users given in C_6, while the "existing algorithm" does not always satisfy C_6, e.g., the number of assigned subchannels may fall below the lower bound. The provided algorithm tends to allocate a number of subchannels, which

is only slightly larger than the lower bound to each FU, leading to an efficient reuse of subchannels. The procedure of "subchannel allocation for user fairness" guarantees the lower bound for users' subchannel requirement, while the procedure of "subchannel allocation for capacity enhancement" guarantees that it does not exceed the upper bound.

Figure 19a shows the average cross-tier interference suffered in each subchannel of primary macrocell when the maximum transmit power $P_{\max}$ increases from 20 to 30 dBm, for the number of users per femtocell $F = 4$ and the number of femtocells $K = 10$. The other simulation parameters are set as $R_{k,i}^0 = 9$ bps/Hz for all k, and $I_{th,n}^{MF} = I_{th,n}^{FF} = -100$ dBm for all n. The total cross-tier interference increases as the increase of $P_{\max}$. This is because that the cross-tier interference is caused by transmit power per subchannel and the cross-tier channel gain, and a large value of $P_{\max}$ enlarges the feasible domain of the optimizing variable [18]. It also can be seen from the figure that the perfect spectrum sensing scheme has a higher cross-tier interference than the imperfect spectrum sensing scheme. The reason of this phenomenon is that mis-detection and false alarm in imperfect spectrum sensing overestimate the cross-tier interference. Moreover, the average interference from cognitive femtocell to primary macrocell in each su-channel in imperfect spectrum sensing is below the cross-tier interference threshold. Figure 19b shows the average co-tier interference suffered in each subchannel of neighboring femtocells when maximum transmit power $P_{\max}$ increases from 20 to 30 dBm. Note that perfect spectrum sensing of cross-tier channel gain at cognitive FBS side results in a higher co-tier interference than the imperfect spectrum sensing scheme [18], because mis-detection and false alarm in imperfect spectrum sensing overestimate the cross-tier interference.

Figure 20 shows the total capacity of all cognitive femtocells when maximum transmit power $P_{\max}$ increases from 20 to 30 dBm, for the number of users per femtocell $F = 4$ and the number of femtocells $K = 10$. The other simulation parameters are set as $R_{k,i}^0 = 9$ bps/Hz for all k, and $I_{th,n}^{MF} = I_{th,n}^{FF} = -100$ dBm for all n. The total capacity of all femtocells increases with $P_{\max}$. This is because a large value of $P_{\max}$ enlarges the feasible domain of the optimizing variable [18]. It also can be seen from the figure that perfect spectrum sensing scheme has a higher capacity of all cognitive femtocells than the imperfect spectrum sensing scheme, because mis-detection and false alarm in imperfect spectrum sensing overestimate the cross-tier interference, which shrinks the feasible domain of the optimizing variable.

Figure 21 shows the total capacity of all cognitive femtocells when minimum transmit rate requirement $R_{k,i}$ increases from 2 to 10 bps/Hz for the number of users per femtocell $F = 2, 3, 4$ and the number of femtocells $K = 10$. The other simulation parameters are set as $I_{th,n}^{MF} = I_{th,n}^{FF} = -100$ dBm for all n. The total capacity of all femtocells decreases as the decrease of $R_{k,i}^0$. This is because a large value of $R_{k,i}^0$ narrows the feasible domain of the optimizing variable. It can also be seen from the figure that a larger number of FUs per femtocell results in a higher capacity, because of the multiuser diversity in the resource allocation [18].

Conclusion

This chapter introduced the resource allocation problem in cognitive heterogeneous networks, where the cross-tier interference mitigation, imperfect spectrum sensing, and energy efficiency are considered. Through provided three algorithms for cognitive heterogeneous networks, the resource allocation problems were solved. Furthermore, the simulation results showed that the provided algorithms achieve improved performance.

Appendix

The proof of Theorem 1.

Proof. (1) Suppose that $\eta^*_{13,n}$ is the optimal solution of (22), the inequality can be obtained

$$\begin{aligned}\eta^*_{13,n} &= \frac{P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}^v_{s,n})}{\tilde{P}^v_{s,n}+P_c} \\ &\geq \frac{P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n})}{P^v_{s,n}+P_c}\end{aligned} \tag{79}$$

$$\begin{aligned}&\max_{P^v_{s,n}}\left\{P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n}) - \eta^*_{13,n}(P^v_{s,n}+P_c)\right\} \\ &= P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n}) - \eta^*_{13,n}(P^v_{s,n}+P_c) = 0.\end{aligned} \tag{80}$$

Hence, we have (81)

$$\begin{cases} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}^v_{s,n}) - \eta^*_{13,n}\left(\tilde{P}^v_{s,n}+P_c\right) = 0 \\ P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n}) + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n}) - \eta^*_{13,n}\left(P^v_{s,n}+P_c\right) \leq 0. \end{cases} \tag{81}$$

Therefore, $\max\limits_{P^v_{s,n}} \left\{ \begin{array}{l} P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P^v_{s,n}) \\ + P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P^v_{s,n}) \\ - \eta^*_{13,n}(P^v_{s,n}+P_c) \end{array} \right\} = 0$ can be concluded.
That is, eq. (80) is achieved.

(2) Suppose that $\widetilde{P}^v_{s,n}$ is a solution to the problem of (80). The definition of (80) implies that (82)

$$
\begin{aligned}
&P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P_{s,n}^v)+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P_{s,n}^v)\\
&-\eta_{13,n}^*\left(P_{s,n}^v+P_c\right)\le P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}_{s,n}^v)\\
&+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}_{s,n}^v)-\eta_{13,n}^*\left(\tilde{P}_{s,n}^v+P_c\right)=0\\
&or\\
&\begin{cases}
P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P_{s,n}^v)+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P_{s,n}^v)\\
-\eta_{13,n}^*\left(P_{s,n}^v+P_c\right)\le 0\\
P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}_{s,n}^v)+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}_{s,n}^v)\\
-\eta_{13,n}^*\left(\tilde{P}_{s,n}^v+P_c\right)=0.
\end{cases}
\end{aligned}
\tag{82}
$$

Therefore, we obtain

$$
\frac{\left\{\begin{array}{l}P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},\tilde{P}_{s,n}^v)\\+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},\tilde{P}_{s,n}^v)\end{array}\right\}}{\tilde{P}_{s,n}^v+P_c}=\eta_{13,n}^* \tag{83}
$$

and

$$
\frac{\left\{\begin{array}{l}P(\mathscr{H}_n^v)(1-q_n^f(\varepsilon_n,\hat{\tau}))R_{1,n}(\hat{\tau},P_{s,n}^v)\\+P(\mathscr{H}_n^o)q_n^m(\varepsilon_n,\hat{\tau})R_{3,n}(\hat{\tau},P_{s,n}^v)\end{array}\right\}}{P_{s,n}^v+P_c}\le\eta_{13,n}^*. \tag{84}
$$

□

Lemma 1. *Let $\boldsymbol{A}$ be an $N\times N$ symmetric matrix, $\boldsymbol{A}$ is negative semidefinite if and only if all the kth order principal minors of $\boldsymbol{A}$ are no larger than zero if k is odd, and not less than zero if k is even, where $1\le k\le N$.*

The proof of Theorem 2.

Proof. First, define the element $\tau_{k,i,n}\widehat{R}_{k,i,n}^{\mathrm{F}}$ in (59) as $f(\tau_{k,i,n},\widehat{p}_{k,i,n})=\tau_{k,i,n}\widehat{R}_{k,i,n}^{\mathrm{F}}$. The objective function in (59) is the sum of $f(\tau_{k,i,n},\widehat{p}_{k,i,n})$ over all possible values of k, i, and n. Substituting $\widehat{R}_{k,i,n}^{\mathrm{F}}=\log_2\left(1+\frac{\widehat{p}_{k,i,n}\hbar_{k,k,i,n}^{\mathrm{FF}}}{\tau_{k,i,n}I_{k,i,n}}\right)$ into $f(\tau_{k,i,n},\widehat{p}_{k,i,n})$, so we have

$$
f(\tau_{k,i,n},\widehat{p}_{k,i,n})=\tau_{k,i,n}\log_2\left(1+\frac{\widehat{p}_{k,i,n}\hbar_{k,k,i,n}^{\mathrm{FF}}}{\tau_{k,i,n}I_{k,i,n}}\right). \tag{85}
$$

Based on (85), one obtains

$$
\frac{\partial^2 f}{\partial{\tau_{k,i,n}}^2}=-\frac{1}{\ln 2}\frac{\left(\widehat{p}_{k,i,n}\hbar_{k,k,i,n}^{\mathrm{FF}}\right)^2}{\tau_{k,i,n}\left(\tau_{k,i,n}I_{k,i,n}+\widehat{p}_{k,i,n}\hbar_{k,k,i,n}^{\mathrm{FF}}\right)^2}, \tag{86}
$$

$$\frac{\partial^2 f}{\partial \tau_{k,i,n} \partial \widehat{p}_{k,i,n}} = \frac{\partial^2 f}{\partial \widehat{p}_{k,i,n} \partial \tau_{k,i,n}} = \frac{1}{\ln 2} \frac{\widehat{p}_{k,i,n} \left(\hbar^{\mathrm{FF}}_{k,k,i,n}\right)^2}{\left(\tau_{k,i,n} I_{k,i,n} + \widehat{p}_{k,i,n} \hbar^{\mathrm{FF}}_{k,k,i,n}\right)^2}, \tag{87}$$

$$\frac{\partial^2 f}{\partial \widehat{p}_{k,i,n}{}^2} = -\frac{1}{\ln 2} \frac{\tau_{k,i,n} \left(\hbar^{\mathrm{FF}}_{k,k,i,n}\right)^2}{\left(\tau_{k,i,n} I_{k,i,n} + \widehat{p}_{k,i,n} \hbar^{\mathrm{FF}}_{k,k,i,n}\right)^2}. \tag{88}$$

Consequently, the Hessian matrix of $f(\tau_{k,i,n}, \widehat{p}_{k,i,n})$ can be written as

$$\boldsymbol{H} = \begin{bmatrix} \frac{\partial^2 f}{\partial \tau_{k,i,n}{}^2} & \frac{\partial^2 f}{\partial \tau_{k,i,n} \partial \widehat{p}_{k,i,n}} \\ \frac{\partial^2 f}{\partial \widehat{p}_{k,i,n} \partial \tau_{k,i,n}} & \frac{\partial^2 f}{\partial \widehat{p}_{k,i,n}{}^2} \end{bmatrix}. \tag{89}$$

Substituting (86), (87), (88) to (89), we can show that the first-order principal minors of $\boldsymbol{H}$ are negative, and the second-order principal minor of $\boldsymbol{H}$ is zero. Therefore, $\boldsymbol{H}$ is negative semidefinite according to Lemma 1, and $f(\tau_{k,i,n}, \widehat{p}_{k,i,n})$ is concave. The objective function of (59) is concave because any positive linear combination of concave functions is concave [23,33]. As the inequality constraints in (59) are convex, the feasible set of the objective function in (59) is convex, and the corresponding optimization problem is a convex problem. This completes the proof. □

in cognitive ratio networks is given. Focusing on the eavesdropping attack, a secrecy problem of the communication between a secondary transmitter-receiver pair in the presence of randomly distributed eavesdroppers is specifically investigated. The dynamic transmit power control is adopted at the secondary-user transmitter to ensure that the spectrum sharing does not harm the primary network. Depending on the knowledge of the channel and the eavesdropper locations, four secure transmission schemes with dynamic spectrum sharing are introduced. A comprehensive performance analysis of each scheme is given. Moreover, the optimal design of the transmission scheme that maximizes the secrecy throughput subject to the secrecy constraint and the reliability constraint is derived. Numerical illustrations on the performance comparison between different schemes are also presented.

Security Issues in Cognitive Radio Networks

With the rapid adoption of wireless devices, there is an unprecedented growth in the demand for radio spectrum. To address the conflict between spectrum scarcity and spectrum underutilization, dynamic spectrum sharing has been regarded as a promising technology to solve the problem of inefficient spectrum usage. Spectrum sharing allows the primary and secondary users transmit concurrently while ensuring that the secondary network do not harm the primary network.

The adoption of spectrum sharing is not without drawbacks. The coexistence of licensed and unlicensed users in the same network makes the data transmissions vulnerable to security attacks [23]. The key security threats in cognitive radio networks include but not limited to the primary user emulation, the spectrum sensing data falsification, the jamming attack, and the eavesdropping.

When launching a primary user emulation attack, the attacker pretends to be a primary user and sends signals in the licensed band. As a result, second users may regard the attacker as a primary user, and the precious unused spectrum would be wasted. For the spectrum sensing data falsification, attackers intentionally send incorrect spectrum sensing signals to fusion centers or secondary users, which may lead to legitimate users' wrong decisions on the spectrum access and sharing. In a jamming attack, the attacker continuously or randomly broadcast interference signals to jam legitimate channels, so that the legitimate users may not be able to send or receive messages reliably. By eavesdropping attacks, malicious users attempt to listen to the transmission between legitimate users, which can result in the leakage of sensitive and confidential information of legitimated users. The detailed introduction on the security threats in cognitive radio networks and the conventional countermeasures can be found in [21] and [23].

Eavesdropping Threat

In the following, the eavesdropping threat in the cognitive network and the related studies are specifically discussed. Secure communication against eavesdropping attacks has drawn considerable attention from wireless researchers and engineers in recent years [2, 29], due to the unprecedented amount of private and sensitive data transmitted over wireless channels as a result of the ubiquitous adoption of wireless technology.

In cognitive radio networks, both primary and secondary networks are subject to the threat of eavesdropping, and protecting the transmission is not easy. For example, a transmitter in the secondary network wishes to send confidential information to a receiver the secondary network by dynamically sharing the spectrum with preliminary users. They have to make sure that the transmission is reliable to the receiver, unharmful to primary users, and not interceptable by eavesdroppers.

From an information-theoretic perspective, the performance of PLS in cognitive radio networks was studied in, e.g., [1, 16, 17, 26, 31]. The ergodic secrecy capacity for the cognitive radio network was evaluated in [16, 17] with the consideration of fast fading channels where the encoded messages are assumed to span sufficient channel realizations to capture the ergodic features of the fading channel. Considering the slow fading channels, the secrecy performance of the cognitive radio network was evaluated in [31] by the outage-based formulation. The secrecy throughput scaling laws were investigated in [1, 26]. More recently, various signal processing techniques and system design protocols were proposed to improve the secrecy performance of cognitive radio networks. For the multi-antenna cognitive radio network, beamforming designs and cooperative jamming techniques were studied in [5, 8, 22]. For the cognitive radio network with multiple SUs, the user scheduling scheme for improving the security level of cognitive transmissions was proposed in [30]. Furthermore, the cognitive radio network with decode and forward relays was studied in [19] where the optimal relay selection scheme to minimize the secrecy outage probability was proposed.

Randomly Distributed Eavesdroppers

Although considerable efforts have been paid to the PLS in cognitive radio networks, the practical situation where a large number of malicious users inside the cognitive radio network at random and possibly changing locations has been rarely studied. In practice, the number of malicious users in the network can be large, and the passive eavesdroppers would not reveal their location information to legitimate users. In addition, the eavesdroppers may frequently change their location to avoid being detected. Since the PLS relies on the characteristics of wireless channels, the lack of information on eavesdroppers' channels and locations makes it challenging to protect cognitive radio networks in such a situation.

Without the consideration of fading effects, the secrecy issue of cognitive radio networks with distributed eavesdroppers has been studied in [20, 21], in which a simplified channel model consisting of the pass loss effect only is assumed. It is worth mentioning that the performance of secure communication is very different between a fading and a non-fading scenario, and the presence of fading can be smartly utilized to achieve a better secrecy performance. Thus, it is important to take the fading effects into account when analyzing the physical layer security of cognitive radio networks with randomly distributed eavesdroppers [25].

Dynamic Spectrum Sharing in the Presence of Poisson Distributed Eavesdroppers

Consider a situation where a secondary transmitter (SU-Tx) wants to sends confidential messages to a secondary receiver (SU-Rx) in the presence of randomly distributed eavesdroppers. The secondary users dynamically share the spectrum with the primary users and guarantee that the transmission does not affect primary users. The eavesdroppers are assume to movable, and their locations change at each snapshot of time.

Problem Formulation

An illustration of the network model is shown in Fig. 1. The SU-Tx sends confidential messages to the SU-Rx in the presence of multiple movable eavesdroppers. The secondary network dynamically shares the spectrum of the primary network by an underlay method. That is, secondary users are allowed to utilize the licensed

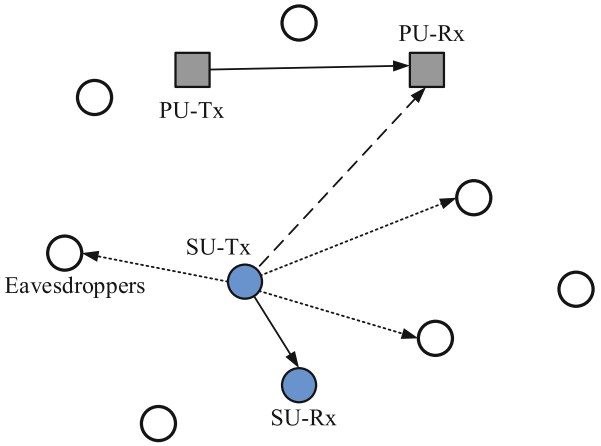

Fig. 1 Illustration of a cognitive radio network with randomly distributed eavesdroppers

spectrum while guaranteeing the interference at primary users not beyond an acceptable threshold.

The path-loss plus quasi-static Rayleigh fading channel model is considered and each communication node is assumed to have a single antenna. The received signal-to-noise ratios (SNRs) at the SU-Rx or the j-th eavesdropper is given by

$$\gamma_i = \frac{P}{\sigma_i^2} |h_i|^2 d_i^{-\alpha}, \quad i = s \text{ or } j \tag{1}$$

respectively, where the subscripts s and j denote the SU-Rx and the j-th eavesdropper, respectively, P denotes the transmitter power at SU-Tx, $\alpha \geq 2$ denotes the path-loss exponent, d_i denotes the distance from SU-Tx to the receiver, σ_i^2 denotes the variance of additive white Gaussian noise (AWGN) at the receiver, and $h_i \sim \mathcal{CN}(0, 1)$ denotes the normalized fading channel coefficient. It is assumed that $\sigma_s^2 = \sigma_j^2 = \sigma^2$ and the interferences from PU-Tx to the SU-Rx and the eavesdroppers are neglectable. It is assume that the receivers have the perfect estimation of their own channel, i.e., h_i. A low-complexity feedback scheme is possibly available from the SU-Rx to the SU-Tx, in which one-bit information about the instantaneous channel condition can be fed back to the SU-Tx. The eavesdroppers are totally passive and do not real their channel state information (CSI) to legitimate users.

Dynamic Transmit Power Control

The PU-Rx informs the SU-Tx of the instantaneous channel gain between them to enable the SU-Tx to dynamically control the transmit power so that its transmission does not harm the primary network. A spectrum-band manager may be required to mediate between the licensed and unlicensed users [15]. The instantaneous interference power at the PU-Rx from the SU-Tx is required to be lower than a threshold, denoted by I_0. Then, the SU-Tx adjusts its transmit power as

$$P = \frac{I_0}{\left|h_p\right|^2 d_p^{-\alpha}} \mathbf{1}_{(\text{condition})}, \tag{2}$$

where $h_p \sim \mathcal{CN}(0, 1)$ and d_p denote the fading channel coefficient and the distance between the SU-Tx and the PU-Rx, respectively. The $\mathbf{1}_{(\text{condition})}$ in (2) denotes an indicator function for whether the transmission is "on" or "off," which is given by

$$\mathbf{1}_{(\text{condition})} = \begin{cases} 1, & \text{if the condition holds} \\ 0, & \text{otherwise,} \end{cases} \tag{3}$$

where the condition depends on the specifical transmission scheme and will be detailed later.

Poisson Model of Eavesdropper Locations

The scenario where a large number of eavesdroppers are randomly distributed in the network is consider. The network with a large number of randomly distributed eavesdroppers is often investigated by adopting the tool from stochastic geometry [10]. Stochastic geometry is proved to be a good mathematic tool in analyzing wireless networks with a larger number of nodes [10]. The location set of the eavesdroppers, denoted by Φ_e, is modeled by a homogeneous Poisson point process (PPP) with density λ_e. The homogeneous PPP well models the set of communication nodes contained in large-scale wireless networks [9], which not only provides tractable closed-form results but also describes the randomness of eavesdropper locations in practical scenarios [4]. Thus, the homogeneous PPP model of eavesdropper locations has been widely adopted in the literature, e.g., [4,6,13,14,18,27].

The worst-case scenario is considered for a robust approach to analyzing the system. Specifically, all eavesdroppers are assumed to be able to collude and exchange the received information. The multiple eavesdroppers is then regarded as a single eavesdropper with multiple distributed antennas, and the equivalent received SNR at the colluding eavesdroppers is given by

$$\gamma_e = \frac{P}{\sigma^2} \sum\nolimits_{j \in \Phi_e} \left| h_j \right|^2 d_j^{-\alpha} = \frac{P}{\sigma^2} Z_{\Phi_e} \tag{4}$$

where $Z_{\Phi_e} = \sum_{j \in \Phi_e} |h_j|^2 d_j^{-\alpha}$.

Secure Encoding

The wiretap code [24] is adopted at the SU-Tx to encode the confidential messages. Denote the set of all possible Wyner codes as $\mathbb{C}(R_t, R_s)$, where R_t is the rate of transmitted codewords and R_s is the rate of confidential messages with $R_t > R_s$. The rate difference $R_t - R_s$ reflects the rate cost to secure the message against eavesdropping. The encoding rates are assumed to have been already designed, so that R_t and R_s are fixed during the transmission. In practice, applications like video streaming in multimedia applications often require fixed-rate transmission.

Performance Metrics

The metrics to comprehensively evaluate the performance are introduced as follows.

Transmission Probability

Depending on the transmission scheme, SU-Tx may not always transmit to avoid eavesdropping. Then, there exists a probability of transmission. A small probability of transmission will cause the delay of the information delivery. Thus, the

transmission probability is adopted to measure the performance of transmission delay given by

$$p_{\text{tx}} = \mathbb{P}\left(\mathbf{1}_{(\text{condition})} = 1\right), \tag{5}$$

where $\mathbb{P}(\cdot)$ denotes the probability measure.

Connection Outage Probability

A connection outage event happens when the message cannot be decoded at the intended receiver without error. The reliability performance is then measured by the connection outage probability given by

$$p_{\text{co}} = \mathbb{P}\left(C_s < R_t \,|\, \mathbf{1}_{(\text{condition})} = 1\right), \tag{6}$$

where $C_s = \log\left(1 + \gamma_s\right)$ denotes the channel capacity of the SU-Rx.

Secrecy Outage Probability

A secrecy outage event happens when the perfect secrecy of the message cannot be guaranteed. The secrecy performance is then measure by the secrecy outage probability, which is given by [28]

$$p_{\text{so}} = \mathbb{P}\left(C_e > R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right), \tag{7}$$

where $C_e = \log\left(1 + \gamma_e\right)$ denotes the channel capacity of the colluding eavesdroppers.

Secrecy Throughput

The overall performance of the system is measured by the secrecy throughput taking into account the transmission delay, the security performance and the reliability performance together. The secrecy throughput quantizes the average rate at which the messages are securely and reliably transmitted to the SU-Rx, which is given by

$$\eta = p_{\text{tx}} p_{\text{no}} R_s, \tag{8}$$

where p_{no} denotes the non-outage probability. The non-outage probability in (8) characterizes the probability that neither the secrecy outage event nor the connection outage event happens, which is given by

$$p_{\text{no}} = \mathbb{P}\left(C_s \geq R_t \;\&\; C_e \leq R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right). \tag{9}$$

Note that p_{no} cannot be simply given as a function of p_{co} and p_{so}, since p_{co} in (6) and p_{so} in (7) are correlated due to the correlation between γ_s and γ_e.

Secure Transmission Schemes with Dynamic Spectrum Sharing

There are mainly four secure transmission schemes with the dynamic spectrum sharing as introduced in [25]. These four schemes are suitable in different situations depending on the SU-Tx's knowledge about the channel and the eavesdropper locations. Specifically, the situations of interest are given as follows:

1. SU-Tx does not know any information about the channel condition to the SU-Rx and the eavesdropper locations;
2. SU-Tx does not know any information about the channel condition to the SU-Rx but can detect the existence of eavesdroppers in its vicinity;
3. SU-Rx has the one-bit feedback about the channel condition to the SU-Rx but does not know any information about the eavesdropper locations;
4. SU-Rx has the one-bit feedback about the channel condition to the SU-Rx and can detect the existence of eavesdroppers in its vicinity.

Full-Active Scheme

The full activity scheme is adopted in the situation where the SU-Tx can neither obtain the one-bit feedback from the SU-Rx nor detect the existence of eavesdroppers in its vicinity. In such a situation, the SU-Tx transmits all the time with the dynamic power control, and the indicator function in (3) is always equal to one.

The SNRs at the SU-Rx and the colluding eavesdroppers are given by

$$\gamma_s = \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 |h_p|^2 d_p^{-\alpha}} \tag{10}$$

and

$$\gamma_e = \frac{I_0}{\sigma^2 |h_p|^2 d_p^{-\alpha}} Z_{\Phi_e}, \tag{11}$$

respectively. The transmission probability is given by

$$p_{\text{tx}} = \mathbb{P}\left(\mathbf{1}_{(\text{condition})} = 1\right) = 1, \tag{12}$$

which indicates that there is no transmission delay. The connection outage probability can be obtained by substituting (10) into (6), which is given by

$$
\begin{aligned}
p_{\text{co}} &= \mathbb{P}\left(C_s < R_t \,|\, \mathbf{1}_{(\text{condition})} = 1\right) \\
&= \mathbb{P}\left(|h_s|^2 < \frac{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha}}{I_0 d_p^{\alpha}} \left|h_p\right|^2\right) \\
&= \frac{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha}}{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}.
\end{aligned} \tag{13}
$$

The secrecy outage probability can be obtained by substituting (11) into (7), which is given by

$$
\begin{aligned}
p_{\text{so}} &= \mathbb{P}\left(C_e > R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\
&= \mathbb{P}\left(\log_2\left(1 + \frac{I_0}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} Z_{\Phi_e}\right) > R_t - R_s\right) \\
&= \mathbb{E}_{\Phi_e}\left\{1 - \exp\left(-\frac{I_0 Z_{\Phi_e} d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right)\right\} \\
&= 1 - L_{Z_{\Phi_e}}\left(\frac{I_0 d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right),
\end{aligned} \tag{14}
$$

where $\mathbb{E}_{\Phi_E}\{\cdot\}$ denotes the expectation operator over Φ_e and $L_{Z_{\Phi_e}}(\cdot)$ denotes the Laplace transform of Z_{Φ_e}. From [3], $L_{Z_{\Phi_e}}(\cdot)$ is given by

$$
L_{Z_{\Phi_e}}(x) = \exp\left(-\frac{2\pi}{\alpha}\Gamma\left(\frac{2}{\alpha}\right)\Gamma\left(1-\frac{2}{\alpha}\right)\lambda_e x^{\frac{2}{\alpha}}\right) \tag{15}
$$

where $\Gamma(\cdot)$ denotes the gamma function. The non-outage probability can be obtained by substituting (10) and (11) into (9), which is given by

$$
\begin{aligned}
p_{\text{no}} &= \mathbb{P}\left(C_s \geq R_t \;\&\; C_e \leq R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\
&= \mathbb{E}_{\Phi_e}\left\{\int_{\frac{I_0 d_p^{\alpha} Z_{\Phi_e}}{\left(2^{R_t-R_s}-1\right)\sigma^2}}^{\infty} \exp\left(-\left(\frac{\left(2^{R_B}-1\right)\sigma^2 d_s^{\alpha}}{I_0 d_p^{\alpha}} + 1\right)x\right)\mathrm{d}x\right\} \\
&= \frac{I_0 d_p^{\alpha}}{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}} L_{Z_{\Phi_e}}\left(\frac{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right).
\end{aligned} \tag{16}
$$

Based on (8), (12), and (16), the secrecy throughput is given by

$$\begin{aligned}\eta &= p_{\text{tx}} p_{\text{no}} R_s \\ &= \frac{I_0 d_p^{\alpha} R_s}{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}} L_{Z_{\Phi_e}}\left(\frac{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right).\end{aligned} \tag{17}$$

Secrecy Guard Zone Scheme

The secrecy guard scheme is adopted in the situation where the SU-Tx is able to detect the existence of eavesdroppers within a finite range. As per the mechanism of secrecy guard zone [11,27], the finite range near the SU-Tx is modeled as a secrecy guard circle. Denote the location of the SU-Tx as the origin o. The secrecy guard circle around the SU-Tx with radius r is then denoted by $\mathcal{B}(o,r)$. With the secrecy guard zone scheme, the SU-Tx transmits only when no eavesdropper is detected inside $\mathcal{B}(o,r)$.

The SNRs at the SU-Rx and the colluding eavesdroppers are given by

$$\gamma_s = \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} \mathbf{1}_{(C_1)} \tag{18}$$

and

$$\gamma_e = \frac{I_0}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} Z_{\Phi_e} \mathbf{1}_{(C_1)}, \tag{19}$$

respectively, where C_1 denotes the event that all eavesdroppers are outside of the secrecy guard zone, i.e., $\left\{C_1 : \forall j \in \Phi_e, d_j > r\right\}$. Denote the number of eavesdroppers inside $\mathcal{B}(o,r)$ as $\pi r^2 \lambda_e$. Note that N is a Poisson random variable with mean $\pi r^2 \lambda_e$, and its probability mass function (PMF) is given by

$$\mathbb{P}(N=n) = \exp\left(-\pi r^2 \lambda_e\right) \frac{\left(\pi r^2 \lambda_e\right)^n}{n!}. \tag{20}$$

The transmission probability is then derived as

$$\begin{aligned} p_{\text{tx}} &= \mathbb{P}\left(\mathbf{1}_{(\text{condition})} = 1\right) \\ &= \mathbb{P}\left(C_1 : \forall j \in \Phi_e, d_j > r\right) \\ &= \mathbb{P}(N=0) \\ &= \exp\left(-\pi \lambda_e r^2\right). \end{aligned} \tag{21}$$

The connection outage probability can be obtained by substituting (18) into (6), which is identical to (13) and omitted here.

Denote $\widetilde{\Phi}_e$ as the new location set of the colluding eavesdroppers for the scenario where no eavesdropper is inside the secrecy guard zone. Following the steps of obtaining (14), the secrecy outage probability is given by

$$\begin{aligned} p_{\text{so}} &= \mathbb{P}\left(C_e > R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\ &= 1 - L_{Z_{\widetilde{\Phi}_E}}\left(\frac{I_0 d_{SP}^{\alpha}}{\left(2^{R_B - R_S} - 1\right)\sigma^2}\right). \end{aligned} \tag{22}$$

where $Z_{\widetilde{\Phi}_E} = \sum_{E_j \in \widetilde{\Phi}_E} \left|h_{SE_j}\right|^2 d_{SE_j}^{-\alpha}$. The Laplace transform of $Z_{\widetilde{\Phi}_E}$, i.e., $L_{Z_{\widetilde{\Phi}_E}}$, is given by

$$\begin{aligned} L_{Z_{\widetilde{\Phi}_e}}(x) &= \mathbb{E}_{\widetilde{\Phi}_e, \left|h_{SE_j}\right|^2}\left\{\exp\left(-x \sum_{j \in \widetilde{\Phi}_e} \left|h_j\right|^2 d_j^{-\alpha}\right)\right\} \\ &\overset{(a)}{=} \mathbb{E}_{\widetilde{\Phi}_e}\left\{\prod_{j \in \widetilde{\Phi}_e} \mathbb{E}_{\left|h_j\right|^2}\left\{\exp\left(-x\left|h_j\right|^2 d_j^{-\alpha}\right)\right\}\right\} \\ &\overset{(b)}{=} \mathbb{E}_{\widetilde{\Phi}_e}\left\{\prod_{j \in \widetilde{\Phi}_e} \frac{1}{1 + x d_j^{-\alpha}}\right\} \\ &\overset{(c)}{=} \exp\left(-\lambda_e \int_{\mathbb{R}^2 \setminus \mathcal{B}(o,r)} \left(1 - \frac{1}{1 + x s^{-\alpha}}\right) ds\right) \\ &= \exp\left(-\frac{2\pi}{\alpha} \lambda_e x^{\frac{2}{\alpha}} \mathrm{B}_{\left(r^{\alpha} x^{-1} + 1\right)^{-1}}\left(1 - \frac{2}{\alpha}, \frac{2}{\alpha}\right)\right), \end{aligned} \tag{23}$$

where $\mathrm{B}_a(p, q) = \int_0^a t^{p-1}(1-t)^{q-1}\,\mathrm{d}t$ is the incomplete Beta function [7], (a) follows from the independence between the channel gain $\left|h_j\right|^2$ and the location of eavesdroppers, (b) follows from the exponential distribution of $\left|h_j\right|^2$, and (c) follows from the generating function of the homogeneous PPP $\widetilde{\Phi}_E$.

Based on (18), (19), and (9), the non-outage probability is given by

$$\begin{aligned} p_{\text{no}} &= \mathbb{P}\left(C_s \geq R_t \;\&\; C_e \leq R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\ &= \frac{I_0 d_p^{\alpha}}{\left(2^{R_t} - 1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}} L_{Z_{\widetilde{\Phi}_e}}\left(\frac{\left(2^{R_t} - 1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t - R_s} - 1\right)\sigma^2}\right). \end{aligned} \tag{24}$$

With (8), (21), and (24), the secrecy throughput is derived as

$$\begin{aligned}\eta &= p_{\text{tx}} p_{\text{no}} R_s \\ &= \frac{I_0 d_p^{\alpha} R_s \exp\left(-\pi \lambda_e r^2\right)}{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}} L_{\widetilde{Z}_{\Phi_e}}\left(\frac{\left(2^{R_t}-1\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right).\end{aligned} \tag{25}$$

From (21), one can find that p_{tx} decreases as r increases, which implies that a large secrecy guard zone worsens the delay performance of the system. From (22), one can also find that p_{so} decreases as r increases, which implies that a large secrecy guard zone improves the secrecy performance of the network. Hence, the size of secrecy guard zone incurs a trade-off between the delay performance and the secrecy performance of the system.

Threshold-Based Scheme

The threshold-based scheme is adopted in the situation where the SU-Tx can obtain a one-bit feedback from the SU-Rx to enable a threshold-based on-off transmission. With the secrecy guard zone scheme, the SU-Tx transmits only when the received SNR at SU-Rx is larger than a predetermined threshold μ. To this end, the SU-Rx sends an instantaneous one-bit feedback to the SU-Tx for indicating whether its received SNR is larger the threshold μ.

The SNRs at the SU-Rx and the colluding eavesdroppers are given by

$$\gamma_s = \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 |h_p|^2 d_p^{-\alpha}} \mathbf{1}_{(C_2)} \tag{26}$$

and

$$\gamma_e = \frac{I_0}{\sigma^2 |h_p|^2 d_p^{-\alpha}} Z_{\Phi_e} \mathbf{1}_{(C_2)} \tag{27}$$

respectively, where C_2 denotes the event that the received SNR at the SU-Rx is larger than μ, i.e., $\left\{C_2 : \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 |h_p|^2 d_p^{-\alpha}} > \mu\right\}$. The transmission probability is given by

$$\begin{aligned} p_{\text{tx}} &= \mathbb{P}\left(\mathbf{1}_{(\text{condition})} = 1\right) \\ &= \mathbb{P}\left(C_2 : \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 |h_p|^2 d_p^{-\alpha}} > \mu\right) \\ &= \frac{I_0 d_p^{\alpha}}{\mu \sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}. \end{aligned} \tag{28}$$

The connection outage probability can be obtained by substituting (26) into (6), which is given by

$$\begin{aligned} p_{\text{co}} &= \mathbb{P}\left(C_s < R_t \,|\, \mathbf{1}_{(\text{condition})} = 1\right) \\ &= \begin{cases} 1 - \frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t}-1\right)\sigma^2 d_s^\alpha + I_0 d_p^\alpha}, & 0 \le \mu < 2^{R_t} - 1, \\ 0, & 2^{R_t} - 1 \le \mu. \end{cases} \end{aligned} \tag{29}$$

The secrecy outage probability can be obtained by substituting (27) into (7), which is given by

$$\begin{aligned} p_{\text{so}} &= \mathbb{P}\left(C_e > R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\ &= \frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{I_0 d_p^\alpha} \mathbb{E}_{\Phi_e} \left\{ \int_0^{\frac{I_0 d_p^\alpha Z_{\Phi_e}}{\left(2^{R_t - R_s}-1\right)N_0}} \exp\left(-\left(\frac{\mu\sigma^2 d_s^\alpha}{I_0 d_p^\alpha} + 1 \right) x \right) \mathrm{d}x \right\} \\ &= 1 - L_{Z_{\Phi_e}} \left(\frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t - R_s} - 1\right)\sigma^2} \right). \end{aligned} \tag{30}$$

The non-outage probability can be obtained by substituting (26) and (27) into (9), which is given by

$$\begin{aligned} p_{\text{no}} &= \mathbb{P}\left(C_s \ge R_t \;\&\; C_e \le R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\ &= \frac{1}{p_{\text{tx}}} \mathbb{E}_{\Phi_e} \left\{ \int_{\frac{I_0 d_p^\alpha}{\left(2^{R_t - R_s}-1\right)\sigma^2} Z_{\Phi_e}}^{\infty} \exp\left(-\left(\frac{\max\left\{\mu, 2^{R_t} - 1\right\}\sigma^2 d_s^\alpha}{I_0 d_p^\alpha} + 1 \right) x \right) \mathrm{d}x \right\} \\ &= \begin{cases} \frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t}-1\right)\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{Z_{\Phi_e}} \left(\frac{\left(2^{R_t}-1\right)\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t - R_s}-1\right)\sigma^2} \right), & 0 \le \mu < 2^{R_t} - 1, \\ L_{Z_{\Phi_e}} \left(\frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t - R_s}-1\right)\sigma^2} \right), & 2^{R_t} - 1 \le \mu. \end{cases} \end{aligned} \tag{31}$$

Based on (8), (28), and (31), the secrecy throughput is given by

$$\begin{aligned} \eta &= p_{\text{tx}} p_{\text{no}} R_s \\ &= \begin{cases} \frac{I_0 d_p^\alpha R_s}{\left(2^{R_t}-1\right)\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{Z_{\Phi_e}} \left(\frac{\left(2^{R_t}-1\right)\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t - R_s}-1\right)\sigma^2} \right), & 0 \le \mu < 2^{R_t} - 1, \\ \frac{I_0 d_p^\alpha R_s}{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{Z_{\Phi_e}} \left(\frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{\left(2^{R_t - R_s}-1\right)\sigma^2} \right), & 2^{R_t} - 1 \le \mu. \end{cases} \end{aligned} \tag{32}$$

From (29) and (30), one can note that p_{co} decreases as μ increases, while p_{so} increases as μ increases. This is due to the dynamic transmit power control at the SU-Tx to satisfy the requirement of spectrum sharing with the primary network.

Under the dynamic transmit power control, the received SNR at the eavesdropper is probably large when the received SNR at the SU-Rx is large. Thus, the value of SNR threshold arises a trade-off between the reliability performance and the secrecy performance of the system. In addition, one can find from (28) that p_{tx} decreases as μ increases, which implies that there is also a trade-off between the delay performance and the reliability performance incurred by the value of SNR threshold.

Hybrid Scheme

The hybrid scheme is adopted in the situation where the SU-Tx can obtain the one-bit feedback from the SU-Rx and detect the existence of eavesdroppers in its vicinity. In such a situation, the SU-Tx adopts a joint secrecy guard zone and SNR threshold-based transmission strategy. The SU-Tx transmits only when no eavesdropper is detected in the secrecy guard zone and the received SNR at SU-Rx is larger than the SNR threshold.

The SNRs at the SU-Rx and the colluding eavesdroppers are given by

$$\gamma_s = \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} \mathbf{1}_{(C_1 \& C_2)} \tag{33}$$

and

$$\gamma_e = \frac{I_0}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} Z_{\Phi_e} \mathbf{1}_{(C_1 \& C_2)}, \tag{34}$$

respectively, where $\{C_1 \& C_2 : \forall j \in \Phi_e, d_j > r \text{ and } \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} > \mu\}$. The transmission probability is given by

$$\begin{aligned} p_{\text{tx}} &= \mathbb{P}\left(\mathbf{1}_{(\text{condition})} = 1\right) \\ &= \mathbb{P}\left(C_1 \& C_2 : \forall j \in \Phi_e, d_j > r \text{ and } \frac{I_0 |h_s|^2 d_s^{-\alpha}}{\sigma^2 \left|h_p\right|^2 d_p^{-\alpha}} > \mu\right) \\ &= \frac{I_0 d_p^{\alpha} \exp\left(-\pi \lambda_e r^2\right)}{\mu \sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}. \end{aligned} \tag{35}$$

The expression for the connection outage probability is identical to (29) in the threshold-based scheme. The secrecy outage probability is derived as

$$\begin{aligned} p_{\text{so}} &= \mathbb{P}\left(C_e > R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) \\ &= 1 - L_{Z_{\Phi_e}}\left(\frac{\mu \sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t - R_s} - 1\right) \sigma^2}\right). \end{aligned} \tag{36}$$

The non-outage probability can be obtained by substituting (33) and (34) into (9), which is given by

$$p_{\text{no}} = \mathbb{P}\left(C_s \geq R_t \;\&\; C_e \leq R_t - R_s \mid \mathbf{1}_{(\text{condition})} = 1\right) = \begin{cases} \frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{(2^{R_t}-1)\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{\widetilde{Z}_{\Phi_e}}\left(\frac{(2^{R_t}-1)\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{(2^{R_t-R_s}-1)\sigma^2}\right), & 0 < \mu < 2^{R_t} - 1, \\ L_{\widetilde{Z}_{\Phi_e}}\left(\frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{(2^{R_t-R_s}-1)\sigma^2}\right), & 2^{R_t} - 1 \leq \mu. \end{cases} \tag{37}$$

Based on (8), (35), and (37), the secrecy throughput is derived as

$$\eta = p_{\text{tx}} p_{\text{no}} R_s = \begin{cases} \frac{I_0 d_p^\alpha \exp(-\pi\lambda_e r^2) R_s}{(2^{R_t}-1)\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{\widetilde{Z}_{\Phi_e}}\left(\frac{(2^{R_t}-1)\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{(2^{R_t-R_s}-1)\sigma^2}\right), & 0 < \mu < 2^{R_t} - 1, \\ \frac{I_0 d_p^\alpha \exp(-\pi\lambda_e r^2) R_s}{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha} L_{\widetilde{Z}_{\Phi_e}}\left(\frac{\mu\sigma^2 d_s^\alpha + I_0 d_p^\alpha}{(2^{R_t-R_s}-1)\sigma^2}\right), & 2^{R_t} - 1 \leq \mu. \end{cases} \tag{38}$$

Illustration of Performance of Transmission Schemes

In the following, we present and discuss the figure results that illustrate the performance of different transmission schemes.

Figure 2 shows the secrecy outage probability, p_{so}, and the connection outage probability, p_{co}, of different transmission schemes versus the density of eavesdroppers, λ_e. As depicted in the figure, p_{so} increases as λ_e increases, while p_{co} remains constant as λ_e increases. This is because the increase of eavesdropper density worsens the secrecy performance of the network but does not affect the reliability performance. Consider the full-active scheme as a baseline scheme for comparison. One can find that the secrecy guard zone scheme improves the secrecy performance without affecting the reliability performance. In contrast, the threshold-based scheme improves the reliability performance but at a cost of worsening the secrecy performance. Note that the finding of the impact of the threshold-based scheme is different from the results for the networks without dynamic spectrum sharing; see, e.g., [12, 28], in which the threshold-based scheme does not worsen the secrecy performance. As previously explained in section "Threshold-Based Scheme", the increase of p_{so} in the threshold-based scheme is because of the dynamic transmit power control at the SU-Tx for the spectrum sharing requirement. Moreover, taking the advantages of both the secrecy guard zone scheme and the threshold-based scheme, the hybrid scheme improves both the secrecy and reliability performance.

Figure 3 presents the impact of the radius of the secrecy guard zone, r; on the transmission probability, p_{tx}; the connection outage probability, p_{co}; and the secrecy outage probability, p_{so}. As shown in the figure, both p_{so} and p_{tx} decrease as r

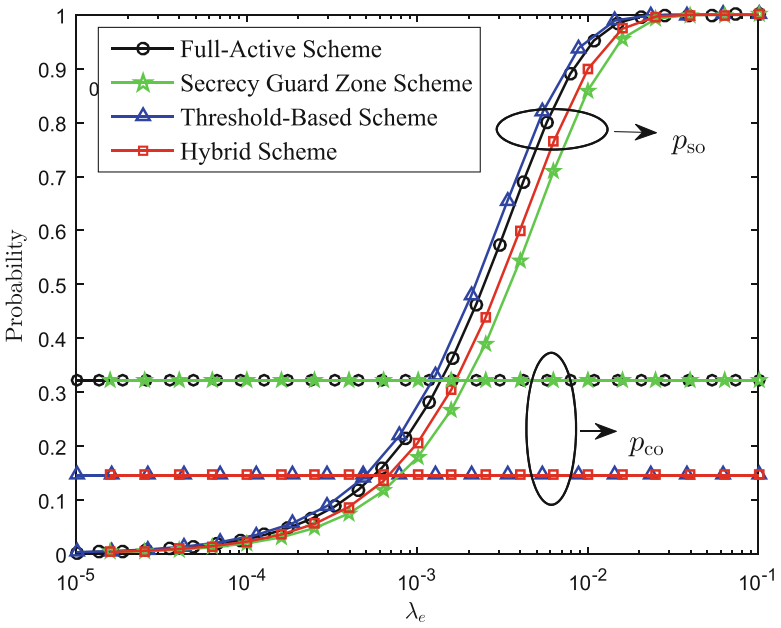

Fig. 2 The connection outage probability and the secrecy outage probability versus the eavesdropper density. The system parameters are $\alpha = 4$, $I_0/\sigma^2 = 10\,\mathrm{dB}$, $R_t = 1.5$, $R_s = 0.5$, $d_s = 5.4$, $d_p = 4.2$, $\mu = 1$, and $r = 5.4$

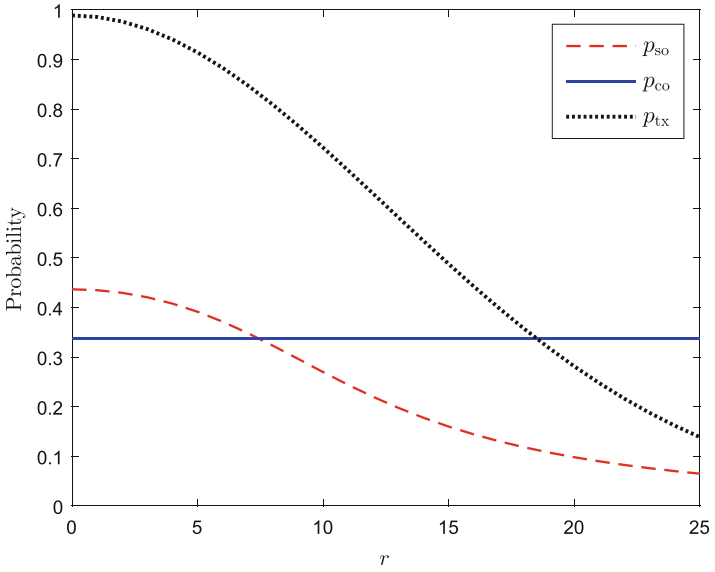

Fig. 3 The transmission probability, the connection outage probability, and the secrecy outage probability versus the radius of the secrecy guard zone. The system parameters are $\alpha = 4$, $I_0/\sigma^2 = 10\,\mathrm{dB}$, $R_t = 3$, $R_s = 1$, $d_s = 8.5$, $d_p = 7$, $\lambda_e = 10^{-3}$, and $\mu = 3$

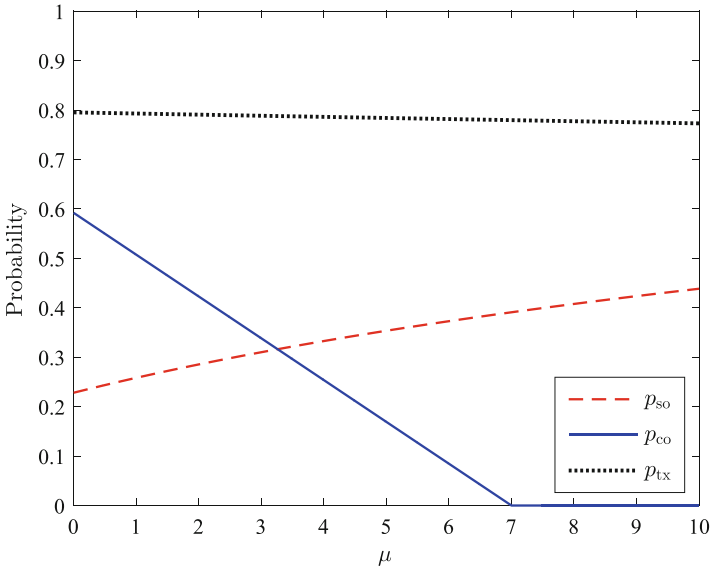

Fig. 4 The transmission probability, the connection outage probability, and the secrecy outage probability versus the SNR threshold. The system parameters are $\alpha = 4$, $I_0/\sigma^2 = 10$ dB, $R_t = 3$, $R_s = 1$, $d_s = 8.5$, $d_p = 7$, $\lambda_e = 10^{-3}$, and $r = 8.5$

increases, which implies that the radius of the secrecy guard zone incurs a trade-off between the secrecy performance and the performance of transmission delay. In addition, one can note that p_{co} does not change as r increases, which confirms that the reliability performance is not related to design of secrecy guard zone. Figure 4 demonstrates the impact of the SNR threshold, μ; on the transmission probability, p_{tx}; the connection outage probability, p_{co}; and the secrecy outage probability, p_{so}. As the figure shows, p_{co} decreases as μ increases, and it reaches zero when $\mu \geq 2^{R_t} - 1$, which indicates that the system can be perfectly reliable by having a sufficiently large SNR threshold. Besides, p_{so} increases as μ increases and p_{tx} decreases as μ increases. These observations confirms that a larger SNR threshold benefits the reliability performance but harms the secrecy performance and the performance of transmission delay.

Transmission Scheme Design

As previously discussed, the radius of the secrecy guard zone r and the SNR threshold μ play important roles in the performance of the system. Specifically, r incurs a trade-off between the delay performance and the secrecy performance. μ incurs trade-offs not only between the reliability performance and the secrecy performance, but also between the reliability performance and the delay performance.

In this section, the optimal design of r and/or μ that maximizes the secrecy throughput subject to secrecy outage and connection outage constraints is studied. The optimization problem is formulated as

$$\max_{r \text{ and/or } \mu} \quad \eta = p_{\text{tx}} p_{\text{no}} R_s \tag{39a}$$

$$\text{s.t.} \quad p_{\text{co}} \leq \delta, p_{\text{so}} \leq \varepsilon, r \geq 0, \mu \geq 0, \tag{39b}$$

where δ and ε denote the maximum acceptable connection outage probability and the maximum acceptable secrecy outage probability, respectively. For the secrecy guard zone scheme, the parameter to optimize is r. For the threshold-based scheme, the parameter to optimize is μ. For the hybrid scheme, the parameters to optimize are μ and r.

Feasibility of Constraints

Not all constraints on the connection outage probability and the connection outage probability, i.e., δ and ε, are feasible. Under infeasible constraints, the positive secrecy throughput is not achievable. The feasible constraint regions for the full-active scheme, the secrecy guard zone scheme, the threshold-based scheme, and the hybrid scheme, denoted by $F(1)$, $F(2)$, $F(3)$ and $F(4)$, respectively, are detailed as follows.

For the full-active scheme, the connection outage probability and the secrecy outage probability are uncontrollable, and hence the reliability and secrecy constraints are either always achievable or always not achievable. The feasible constraint region for the full-active scheme is given by

$$F(1) = \{(\delta, \varepsilon) : \delta_1 \leq \delta \leq 1, \varepsilon_1 \leq \varepsilon \leq 1\}, \tag{40}$$

where δ_1 and ε_1 denote the COP in (13) and the SOP in (14), respectively.

For the secrecy guard zone scheme, the secrecy outage probability is a decreasing function of r and $\lim_{r\to\infty} p_{\text{so}} = 0$, while the connection outage probability is still uncontrollable. The feasible constraint region for the secrecy guard zone scheme is given by

$$F(2) = \{(\delta, \varepsilon) : 0 < \varepsilon \leq 1, \delta_1 \leq \delta \leq 1\}. \tag{41}$$

For the threshold-based scheme, the connection outage probability is a decreasing function of μ, while the secrecy outage probability is an increasing function of μ. When $\delta \geq \delta_1$, the minimum achievable p_{so} is ε_1 by setting $\mu = 0$; when $\delta < \delta_1$, the minimum achievable p_{so} is given by

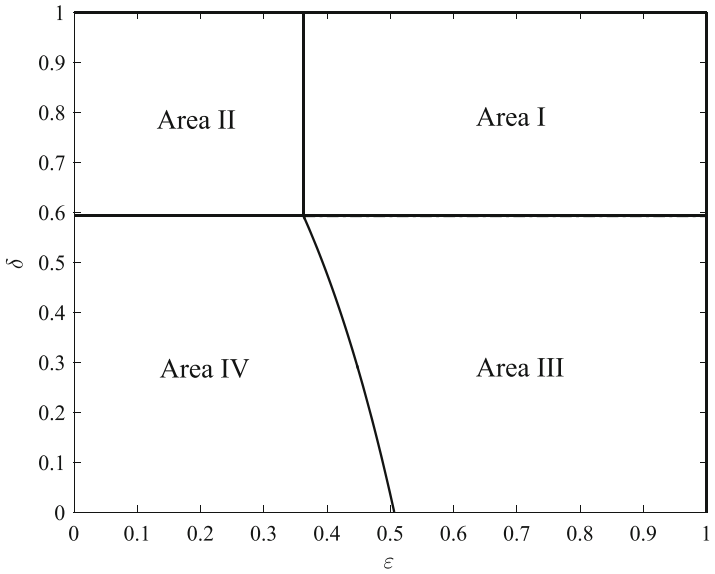

Fig. 5 An illustration of the feasible constraint region for the network with $\alpha = 4$, $I_0/\sigma^2 = 10\,\text{dB}$, $R_t = 3$, $R_s = 1$, $d_s = 8.5$, $d_p = 7$, and $\lambda_e = 10^{-3}$. $F(1)$ = Area I, $F(2)$ = Area I ∪ Area II, $F(3)$ = Area I ∪ Area III, and $F(4)$ = Area I ∪ Area II ∪ Area III ∪ Area IV

$$\varepsilon_2 = 1 - L_{Z_{\Phi_e}}\left(\frac{(1-\delta)\left(2^{R_t-1}\right)\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t-R_s}-1\right)\sigma^2}\right). \tag{42}$$

Thus, the constraint region for the threshold-based scheme is given by

$$F\,(3) = \{(\delta,\varepsilon) : 0 \le \delta \le 1, \max(\varepsilon_1,\varepsilon_2) \le \varepsilon \le 1\}. \tag{43}$$

$F\,(4)$: For the hybrid scheme, any required connection outage probability and secrecy outage probability are achievable by adjusting r and μ. Thus, the feasible constraint region for the hybrid scheme is given by

$$F\,(4) = \{(\delta,\varepsilon) : 0 \le \delta \le 1, 0 < \varepsilon \le 1\}. \tag{44}$$

An illustration of the feasible reliability and secrecy constraints for a different scheme is given in Fig. 5. As shown in the figure, the feasible constraint region for the full-active scheme is represented by Area I. The feasible constraint region for the secrecy guard zone scheme is depicted by Area I and Area II. The feasible constraint region of the threshold-based scheme is given by Area I and Area III. The feasible constraint region of the hybrid scheme is demonstrated by Area I, Area II, Area III, and Area IV. Compared with the full-active scheme, the secrecy guard zone scheme extends the feasible range of the secrecy constraint, and the threshold-based scheme

extends the feasible range of the reliability constraint. The feasible constraint region of the hybrid scheme becomes the whole $\varepsilon - \delta$ plane field.

Optimal Design

Note that the design of the hybrid scheme mathematically includes all of the other three transmission schemes as special cases. The hybrid protocol reduces to the full activity protocol when $r = 0$ and $\mu = 0$. The hybrid scheme reduces to the secrecy guard zone zone when $\mu = 0$. The hybrid scheme reduces to the threshold-based protocol when $r = 0$. Therefore, the optimal design of the hybrid protocol is presented only, and the designs of other schemes can be easily obtained accordingly.

Proposition 1. *The optimal design parameters* (r^*, μ^*) *of the hybrid scheme are given by*

$$\left(r^*, \mu^*\right) = \begin{cases} \left(0, [0, \mu_u]\right), & \text{if } \varepsilon \geq \varepsilon_1 \text{ and } \delta \geq \delta_1, \\ \left(g\left(0\right), 0\right), & \text{if } 0 < \varepsilon < \varepsilon_1 \text{ and } \delta \geq \delta_1, \\ \left(0, [\mu_l, \mu_u]\right), & \text{if } \varepsilon \geq \varepsilon_2 \text{ and } 0 \leq \delta < \delta_1, \\ \left(g\left(\mu_l\right), \mu_l\right), & \text{if } 0 < \varepsilon < \varepsilon_2 \text{ and } 0 \leq \delta < \delta_1, \end{cases} \tag{45}$$

where

$$g\left(x\right) = \left(\frac{x\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t} - R_s - 1\right)\sigma^2} \left(\left(B^{-1}_{\frac{-\alpha \ln(1-\varepsilon)}{2\pi\lambda_e \left(\phi(x)\right)^{1/\alpha}}} \left(1 - \frac{2}{\alpha}, \frac{2}{\alpha}\right) \right)^{-1} - 1 \right) \right)^{\frac{1}{\alpha}}, \tag{46}$$

$$\mu_l = \left(1 - \delta\right)\left(2^{R_t} - 1\right) - \frac{I_0 d_p^{\alpha}}{\sigma^2 d_s^{\alpha}}\delta, \tag{47}$$

$$\mu_u = \min\left\{ 2^{R_t} - 1, \left(\frac{-\alpha \ln\left(1 - \varepsilon\right)}{2\pi\lambda_e \Gamma\left(1 - \frac{2}{\alpha}\right)\Gamma\left(\frac{2}{\alpha}\right)} \right)^{\frac{\alpha}{2}} \frac{2^{R_t - R_s} - 1}{d_s^{\alpha}} - \frac{I_0 d_p^{\alpha}}{\sigma^2 d_s^{\alpha}} \right\} \tag{48}$$

Proof. Substituting (35) and (37) into (8), the secrecy throughput η is given by

$$\eta = \frac{I_0 d_p^{\alpha} \exp\left(-\pi\lambda_e r^2\right) R_s}{\max\left\{2^{R_t} - 1, \mu\right\}\sigma^2 d_s^{\alpha} + I_0 d_s^{\alpha}} L_{\widetilde{Z}_{\Phi_e}}\left(\frac{\max\left\{2^{R_t} - 1, \mu\right\}\sigma^2 d_s^{\alpha} + I_0 d_p^{\alpha}}{\left(2^{R_t - R_s} - 1\right)\sigma^2} \right). \tag{49}$$

Taking first-order derivative of η with respect to r yields

$$\frac{\partial \eta\left(r, \mu\right)}{\partial r} = -2\pi\lambda_e r \left(1 - \left(r^{\alpha}\omega^{-1} + 1\right)^{-1}\right)\eta < 0, \tag{50}$$

where $\omega = \left(\max\left\{\mu, 2^{R_B}-1\right\}\sigma^2 d_{SD}^{\alpha} + I_0 d_{SP}^{\alpha}\right) / \left(\sigma^2\left(2^{R_B-R_S}-1\right)\right)$. This implies that the secrecy throughput decreases as r increases. From (49), one can also find that η decreases as μ increases when $\mu > 2^{R_t}-1$, while η remains constant when $\mu \leq 2^{R_t}-1$. Thus, it is wise to have $\mu \leq 2^{R_t}-1$. The optimal r and μ subject to different reliability and secrecy constraints are discussed as follows:

Case 1: $\delta \geq \delta_1$ and $\varepsilon \geq \varepsilon_1$. Since the secrecy constraint is very loose and η decreases as r increases, it is optimal to set $r = 0$. The lower bound of μ is equal to zero due to the loose reliability constraint. While to satisfy the secrecy constraint, there is an upper bound of μ. By solving $p_{\text{so}} = \varepsilon$ for μ with the consideration of $\mu \leq 2^{R_B}-1$, the upper bound of μ is given as (48). Thus, the optimal r and μ for this case are given by $(r^*, \mu^*) = (0, [0, \mu_u])$.

Case 2: $\delta \geq \delta_1$ and $0 < \varepsilon < \varepsilon_1$. To satisfy the secrecy constraint, there is a lower bound of r. By solving $p_{\text{so}} = \varepsilon$ for r, the lower bound of r is given as (46). From (46), one can find that $g(\mu)$ increases as μ increases. Since $\delta \geq \delta_1$, it is optimal have $\mu = 0$. Hence, the optimal r and μ for this case are given by $(r^*, \mu^*) = (g(0), 0)$.

Case 3: $0 \leq \delta < \delta_1$ and $\varepsilon \geq \varepsilon_2$. To satisfy the reliability constraint, there is a lower bound of μ. By solving $p_{\text{co}} = \delta$ for μ, we derive the lower bound of μ as (47). Also, there is also an upper bound of μ given by (48) to satisfy the secrecy constraint. Thus, the optimal r and μ for this case are given by $(r^*, \mu^*) = (0, [\mu_l, \mu_u])$.

Case 4: $0 < \varepsilon < \varepsilon_2$ and $0 \leq \delta < \delta_1$. To satisfy the reliability constraint, there is a lower bound of μ given by (47). There is also a lower bound of r given by (46). Since $g(\mu)$ increases as μ increases, it is optimal to set $\mu = \mu_{\text{LB}}$. Hence, the optimal r and μ are given by $(r^*, \mu^*) = (g(\mu_l), \mu_l)$.

Summarizing the optimal r and μ for the four cases completes the proof. ■

From Proposition 1, one can note that the optimal r and μ are influenced by the reliability and secrecy constraints. In general, a stringent reliability constraint leads to a large μ^*, and a stringent secrecy constraint leads to a large r^*. One can also note that as the eavesdropper density increases, r^* increases and μ_u decreases, which will result in a decrease of the achievable secrecy throughput.

Figure 6 plots the secrecy throughput, η, against the SNR threshold, μ, and the radius of the secrecy guard zone, r. The reliability constraint and the secrecy constraint are set as $\delta = 0.4 < \delta_1$ and and $\varepsilon = 0.4 < \max(\varepsilon_1, \varepsilon_2)$, respectively. As shown in the figure, the positive secrecy throughput is achievable in the network with the appropriate design of μ and r. However, the unwise design of μ and r may result in the zero secrecy throughput. These observations emphasize the importance of the design of the SNR threshold and the radius of secrecy guard zone on overall performance of the network, i.e., the secrecy throughput. In addition, there is an optimal pair of (r, μ) which maximizes the secrecy throughput. From Proposition 1, one can obtain that the optimal pair of (r, μ) for the given network is $(r^*, \mu^*) = (2.7, 5.0)$, which is consistent with the results shown in the figure.

Figure 7 compares the achievable secrecy throughput for different transmission schemes versus the reliability constraint, δ, and the secrecy constraint, ε. Still con-

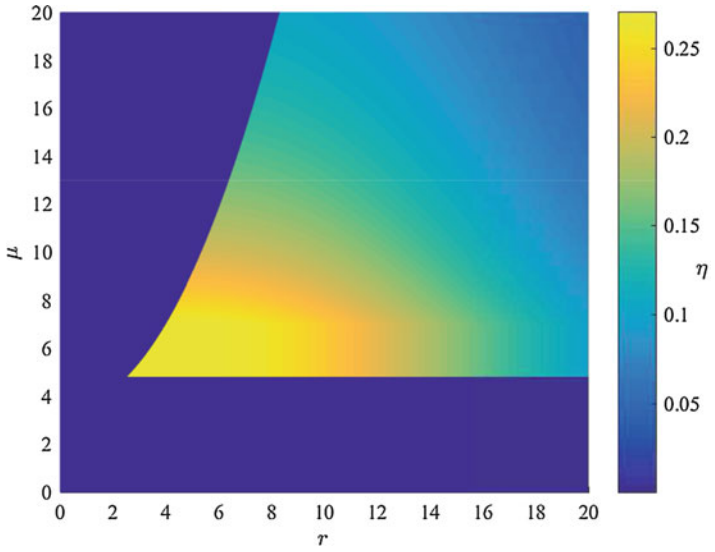

Fig. 6 The secrecy throughput versus the secrecy guard radius and the SNR threshold. The system parameters are $\alpha = 4$, $I_0/\sigma^2 = 10\,\text{dB}$, $R_t = 3$, $R_s = 1$, $d_s = 5.4$, $d_p = 4.2$, $\varepsilon = 0.2$, $\delta = 0.2$, and $\lambda_e = 10^{-3}$

sider the full-active scheme as the baseline scheme for comparison. As presented in the figure, the secrecy guard zone scheme enhances the achievability of the positive secrecy throughput subject to the stringent security constraint. The threshold-based scheme enhances the achievability of the positive secrecy throughput subject to the stringent reliability constraint. It is worth noting from the threshold-based scheme that the secrecy performance has to be compromised to obtain the positive secrecy throughput as the reliability constraint becomes stringent. Besides, the hybrid scheme can achieve the positive secrecy throughput under the most stringent secrecy and reliability constraints, compared with all three other three schemes. Based on these findings, one can summarize how to wisely choose the transmission scheme according to the condition/requirement of the system. When the secrecy constraint and the reliability constraint are loose, one can adopt the full-active scheme with its simple mechanism. When the secrecy constraint is stringent while the reliability constraint is loose, it is wise to use the secrecy guard zone scheme. When the reliability constraint is stringent while the security constraint is loose, it is preferable to adopt the threshold-based protocol. When both the secrecy constraint and the reliability constraint are stringent, one has to adopt the hybrid protocol. Of course, the adoption of different transmission schemes with the dynamic spectrum sharing is still mainly determined by the practical situations, i.e., the SU-Tx's knowledge about the channel and the eavesdropper locations.

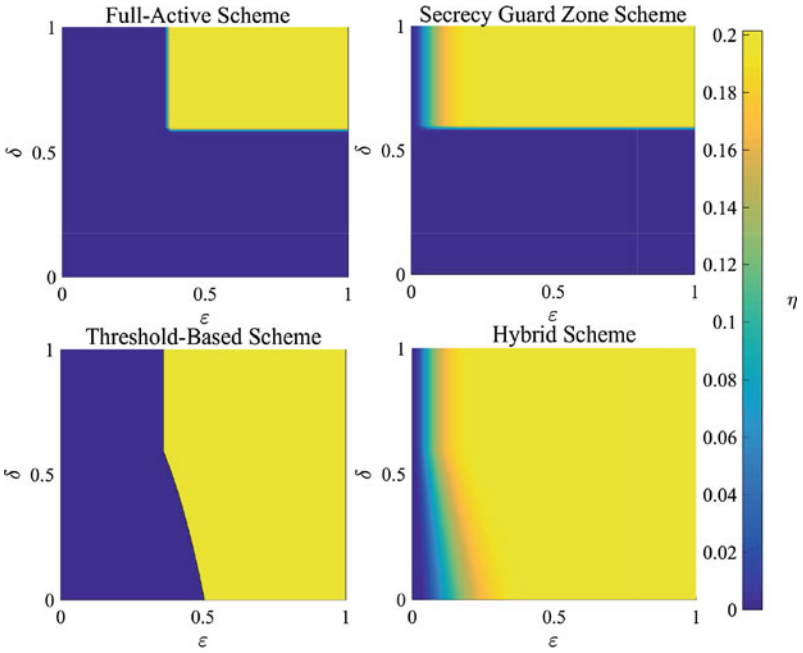

Fig. 7 The maximum achievable secrecy throughput versus the reliability constraint and the secrecy constraint. The system parameters are $\alpha = 4$, $I_0/\sigma^2 = 10\,\text{dB}$, $R_t = 3$, $R_s = 1$, $d_s = 8.5$, $d_p = 7$, $\lambda_e = 10^{-3}$

Conclusion and Future Directions

In this chapter, the security threats in cognitive radio networks have been briefly discussed. The secure transmission schemes with dynamic spectrum sharing in the presence of randomly distributed eavesdroppers have been introduced. Specifically, the secure communication in an underlay cognitive radio networks in the presence of multiple movable eavesdroppers has been studied. The location set of the eavesdroppers is modeled by a homogeneous PPP. The SU-Tx sends confidential messages to the SU-Rx with a dynamic transmit power in order not to interfere with the primary user. To combat eavesdropping in such a cognitive radio network, four transmission schemes have been introduced and investigated. The transmission delay performance, the secrecy performance, the reliability performance, and the overall secrecy throughout performance of different schemes have been comprehensively analyzed and compared. The optimal design parameters that maximize the secrecy throughput subject to the secrecy and reliability constraints have been further derived. It is shown that the secrecy guard zone

scheme improves the secrecy performance, the threshold-based scheme improves the reliability performance, and the hybrid protocol achieves the best overall performance.

In the considered transmission schemes, the encoding rates are assumed to be fixed and predesigned. An interesting future direction is to give more degrees of freedom for the transmission design by considering the encoding rates as designable parameters as well. Another interesting future direction is to investigate the physical layer security techniques to solve other security threats, while most existing studies on the physical layer security have focused on the eavesdropping threat only. As mentioned in section "Security Issues in Cognitive Radio Networks", there are many other security threats in cognitive radio network including but not limited to the primary user emulation, the spectrum sensing data falsification, and the jamming attack. Therefore, how to solve different security threats by physical layer security techniques is an important future direction.

Abstract

As one of the critical techniques to support the multimedia services over mobile wireless networks, the statistical quality of service (QoS) technique has been proved to be effective in statistically guaranteeing delay-bounded video transmissions over the time-varying wireless channels. In the meantime,

the full-duplex spectrum sensing (FD-SS) has been widely recognized as the promising candidate technique for maximizing the spectrum efficiency while provisioning the heterogeneous statistical QoS guarantees over cognitive radio-based 5G mobile wireless networks. However, due to the heterogeneity caused by different scenarios and applications of the multimedia traffics over CRNs, supporting diverse delay-bounded QoS guarantees for cognitive radio networks imposes many new challenges not encountered before. To effectively overcome the aforementioned problems, in this book chapter, we propose the heterogeneous statistical QoS provisioning schemes by applying the multiple-input-multiple-output generalized frequency division multiplexing (MIMO-GFDM) techniques to implement the FD-SS-based multimedia services in CRNs. In particular, under the Nakagami-*m* wireless channels, we derive the MIMO-GFDM-based physical (PHY)-layer model and the self-interference cancelation model. We develop the MIMO-GFDM-based FD-SS schemes and derive the miss-detection and false-alarm probabilities. Under the heterogeneous statistical QoS constraints, we develop the Markov chain model to characterize the aggregate effective capacity under the optimal power allocation policies using our proposed MIMO-GFDM architecture over FD-SS CRNs. Also conducted is a set of simulations which validate our proposed schemes, evaluate their performances, and show that our proposed schemes can outperform the other existing solutions under the heterogeneous statistical delay-bounded QoS constraints over cognitive radio-based 5G mobile wireless networks.

Keywords

Heterogeneous statistical quality of service (QoS) · Cognitive radio networks (CRNs) · Full-duplex spectrum sensing (FD-SS) · Self-interference cancelation · Multiple-input-multiple-output generalized frequency division multiplexing (MIMO-GFDM)

Introduction

With the explosive advances and emerging applications of wireless communications and networks, most available spectrum has already been allocated. However, there exists a large amount of white space in time and frequency. Most traditional fixed frequency allocation policies experience low spectrum utilization. As a result, researchers have made a great deal of efforts in investigating promising techniques to support the increasing demand of high-speed data rate and bandwidth for multimedia services over 5G mobile wireless networks [1, 2]. One of the most effective ways to solve the low spectrum utilization problem is the cognitive radio scheme, which is proposed to alleviate the severe scarcity of the spectrum with spectrum sensing technique.

In order to support the demands of multimedia applications, delay-bounded quality of service (QoS) [3, 4] guarantees are critically important for time-sensitive traffics over CRNs. One of the key design issues for multimedia wireless services –

the major traffic in 5G mobile wireless networks is how to efficiently guarantee the timely multimedia data transmissions within specified delay bounds. Due to the highly varying wireless channels, the deterministic delay-bounded QoS requirements are usually hard to guarantee. As a result, the statistical delay-bounded QoS guarantees [5–7], in terms of effective capacity and queue-length-bound/delay-bound violation probabilities, have been proposed and demonstrated as the powerful technique to characterize delay-bounded QoS requirements for wireless traffics.

However, the existing homogeneous statistical QoS guarantee techniques typically assume that the QoS provisioning for each link can be individually processed. Since all different links in wireless transmissions have joint power constraints, the statistical delay-bound QoS provisioning needs to be jointly considered for all links simultaneously. Under this circumstance, the users in the wireless mobile networks need to satisfy different delay-bound QoS requirements under the joint power constraint, simultaneously. The time sensitivities of different sets of services vary from 1 ms to a few seconds across different wireless links for different mobile users. As a result, the delay-bounded QoS guarantees for the different types of services in 5G mobile wireless networks demand the new heterogeneous statistical delay-bounded QoS provisioning architectures [8], schemes, algorithms, and 5G candidate framework, which can be implemented by integrating several 5G candidates, including massive MIMO and relay-based 5G promising techniques. Until now, how to guarantee heterogeneous statistical delay-bounded QoS requirements over relay-based cognitive radio networks (CRNs) is one of the main challenges for next generation wireless network services.

On the other hand, in traditional CRNs, secondary users (SUs) typically access the spectrum of primary users (SUs) by a two-stage listen-before-talk (LBT) protocol with the help of the wireless half-duplex (HD) energy detection spectrum sensing (HDSS) scheme, in which SUs sense the target channel before transmission. While the LBT protocol requires little infrastructure support, it suffers from sacrifice of transmitting time and discontinuity of transmission even if the white space of the spectrum is continuous. In order to fully utilize the channel spectrum, researchers have proposed an efficient listen-and-talk (LAT) protocol [8, 9] with the help of the wireless full-duplex (FD) spectrum sensing (FD-SS) technique [10, 11] that enables SUs to sense and access the vacant spectrum simultaneously. However, the self-interference introduced by the FD-SS transmission mode imposes many new challenges in decoding process.

In addition, to support the next-generation wideband wireless networks, various advanced wireless techniques, such as multiple-input multiple-output (MIMO) and orthogonal frequency division multiple (OFDM) [12, 13] techniques, have received widely attention in the past few years. MIMO technology utilizes the spatial multiplexing gain to achieve the higher spectral efficiency. Compared with the MIMO technology, OFDM scheme has been identified as a promising interface solution for wideband wireless networks for its excellence performance over frequency-selective channels. As multiple transmit antennas can be applied to OFDM-based cognitive radio systems, researchers have designed and proposed the very promising

candidate, called MIMO-OFDM [14, 15], which can compensate for shortage of capacity while increasing the spectral efficiency.

However, the complicated application scenarios associated with CRNs present new challenges making the OFDM technique less efficient in various advanced wireless networks. Therefore, the novel generalized frequency division multiplexing (GFDM) [16, 17] technique has been designed and implemented in order to overcome the aforementioned challenges. GFDM is well suitable for cognitive radio as the choice of pulse shaping filters makes the out-of-band leakage extremely small. Compared to OFDM, which has rectangular pulse shaping, GFDM with a choice of transmit pulse shaping causes less interference to the adjacent incumbent frequency bands, which leads to better peak-to-average ratio. However, how to efficiently integrate the wireless FD-SS-based system with the underlying MIMO-GFDM framework on supporting statistical QoS constraints over CRNs still remains as an open and challenging problem.

To effectively overcome the abovementioned challenges, in this chapter, we propose the heterogeneous statistical QoS provisioning schemes by extending MIMO-GFDM system to implement the FD-SS-based multimedia services in cognitive radio networks. In particular, under the Nakagami-*m* wireless channels, we establish MIMO-GFDM-based PHY-layer model, the non-time-slotted CRN model, and the self-interference cancelation model. We develop the FD-SS-based MIMO scheme to fully utilize the channel spectrum and derive the probabilities of miss-detection and false alarm for the proposed FD-SS-based MIMO model over CRNs. Under the heterogeneous statistical QoS constraints, we develop the Markov chain model to characterize the correctness of detections in channel sensing and then derive and analyze the aggregate effective capacity under our proposed optimal power allocation policies using the proposed GFDM architecture over FD CRNs. Also conducted is a set of simulations which evaluate the system performances and show that our proposed power allocation policies can outperform the other existing schemes under the heterogeneous statistical delay-bounded QoS constraints over cognitive radio-based 5G mobile wireless networks.

The rest of this chapter is organized as follows: section "Cognitive Radio-Based 5G Wireless Networks" establishes the spectrum sensing model under Nakagami-*m* wireless channels and also develops the MIMO-GFDM-based PHY-layer model, the non-time-slotted CRN model, and the self-interference cancelation model. Section "MIMO-GFDM-Based FD-SS Relaying Scheme" develops and analyzes the FD-SS-based MIMO-GFDM scheme to fully utilize the channel spectrum and derive the probabilities of miss-detection and false alarm for the proposed FD-SS-based MIMO-GFDM model over cognitive radio networks. Under the heterogeneous statistical QoS constraints, section "Heterogeneous Statistical Delay-Bounded QoS Guarantees Through Effective Capacity Over CRNs" develops the Markov chain model to characterize the correctness of detections in channel sensing and then derives and analyzes the aggregate effective capacity under our proposed optimal power allocation policies using the proposed MIMO-GFDM architecture over FD cognitive radio networks. Section "Simulation Evaluations" evaluates the system performances and shows

that our proposed scheme outperforms the other existing schemes in terms of aggregate effective capacity to efficiently implement the heterogeneous statistical QoS over MIMO-GFDM-based full-duplex CRNs. The chapter concludes with section "Conclusions".

Cognitive Radio-Based 5G Wireless Networks

Cognitive radio networks, where the secondary users (SUs) dynamically utilize the idle licensed channels of primary users (PUs), have been designed to effectively achieve high spectrum utilization and improve the quality of wireless applications. In CRNs, the SUs can sense the occupancy of the licensed channels and use the licensed channels when they are not occupied by the PUs based on the sensing results. The PUs and the SUs form the primary wireless network and the secondary wireless network, respectively. Although the basic idea of cognitive radio networks is simple, the efficient design imposes many new challenges that are not presented in the conventional wireless networks.

Spectrum Sensing Model Over CRNs

For the spectrum sensing model over CRNs, the MIMO-GFDM technique [15] is applied on the relay station. Consider K secondary source nodes ($S_1, S_2, \ldots, S_K$), K secondary destination nodes ($D_1, D_2, \ldots, D_K$), and one MIMO-GFDM-based full-duplex relay station in coexistence with primary users (PUs) for the CRNs, as illustrated in Fig. 1. Assume each source node and destination node is equipped with one transmit antenna and one receive antenna, while the relay station consists of M_t transmit antennas and M_r receive antennas. In order to achieve the wideband spectrum sensing, the entire system band is partitioned into several subbands with relatively small bandwidth. Suppose a licensed wideband spectrum having bandwidth B with Q nonoverlapping narrowband subchannels are licensed to a primary wireless network, where the channels are implemented by the same frequency spectra and time slots. PUs have the high priority to access the licensed channels over secondary users (SUs), which have low priority in using the licensed spectrum band. SUs with the low-priority queue seek idle spectrum opportunities in the licensed spectrum band. Using LAT protocol [9, 11], the secondary relay station needs to employ the wireless FD mode for transmitting data and sensing licensed spectrum simultaneously.

Assume that the cognitive relay station is within the transmission range of one PU node. Suppose that when one PU is in operation, it may occupy the whole or part of the wideband, and more than one relay node can share the radio spectrum within one PU operating range when the PU is inactive. This is the case for the current GFDM-based communication infrastructure where some of the GFDM subchannels are allocated to different users.

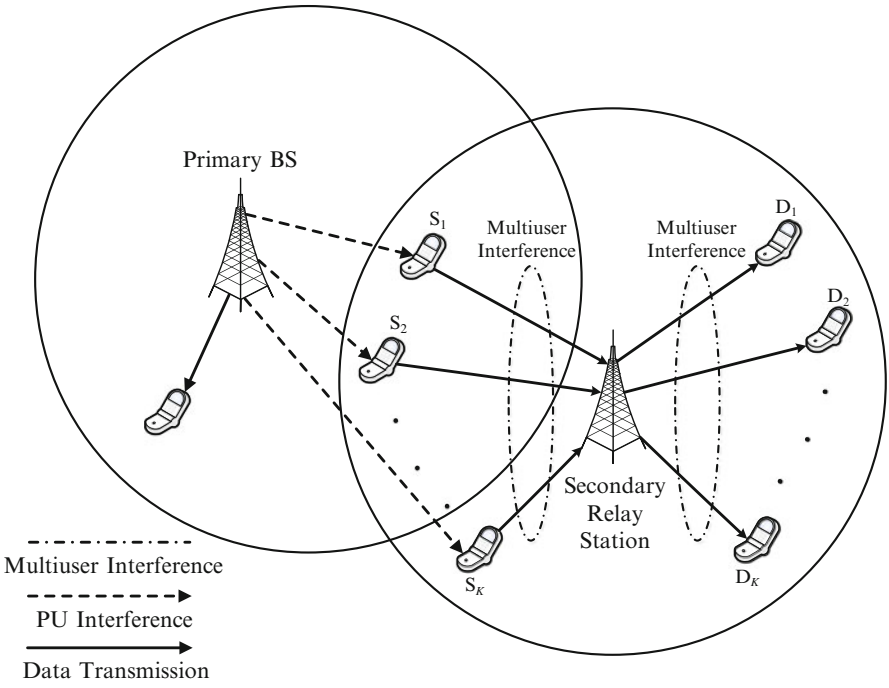

Fig. 1 MIMO-GFDM-based full-duplex cognitive radio network architecture with K secondary-user source-destination pairs

Assume that the PUs operate independently over a wideband spectrum; it is most likely that some portions of the spectrum may not be utilized by the primary systems over some time. In order to realize this seamless transmission within the cognitive relay network and share the radio spectrum when PU is inactive, cognitive relays first get the spectrum map of their local channel environment by spectrum sensing. Define the *spectrum indicator*, denoted by $\boldsymbol{b}_k$, of the kth user, where the entries of $\boldsymbol{b}_k \in \{\mathscr{H}_0, \mathscr{H}_1\}$ $(k = 1, 2, \ldots, K)$ denote the availability for the subchannel, where $\mathscr{H}_1$ implies that PU is active and $\mathscr{H}_0$ implies that PU is inactive while the kth secondary source node S_k is transmitting signals to the destination node, and $\mathscr{H}_0, \mathscr{H}_1 \in \{0, 1\}$. Clearly, the spectrum environment of the whole cognitive relay network can be characterized as follows:

$$\boldsymbol{B} = [\boldsymbol{b}_1, \boldsymbol{b}_2, \ldots, \boldsymbol{b}_K]^T, \tag{1}$$

where the matrix $\boldsymbol{B}$ is a binary matrix in which each entry is either zero or one. The total number of ones in $\boldsymbol{B}$ indicates the amount of spectrum opportunities and represents a degree of freedom in the cognitive relay network. When $\boldsymbol{B}$ is an all-one matrix, it is a special case for the conventional relay network, such as the

GFDM-based relay network where every relay has the same number of available subchannels.

MIMO-GFDM-Based PHY-Layer Model

The MIMO-GFDM-based system applies and analyzes for energy-efficient and low-complex communications over Nakagami-m wireless channels. The block diagram of MIMO-based GFDM system between the transmitter and the receiver under statistical QoS guarantees over MIMO wireless networks is shown in Fig. 2. The channel state information (CSI) is estimated at the receiver and fed back to the transmitter for advanced modulation techniques and MIMO diversity deployments. Based on the statistical QoS constraint θ (to be detailed soon in section "Heterogeneous Statistical Delay-Bounded QoS Guarantees Through Effective Capacity Over CRNs") required by the service, the transmitter needs to determine the optimal transmit power to jointly optimize the effective spectrum and power efficiencies. We concentrate on discrete time channel, indexed by $l = 1, 2, \ldots$.

In order to achieve the novel GFDM scheme [16], the initial binary data is modulated and divided into sequences of $Q \times P$ complex-valued data symbols, where each such sequence is spread across Q subcarriers and P time slots for transmission. The data sequence is denoted by means of block structure as follows:

$$\boldsymbol{D} = \begin{bmatrix} \boldsymbol{d}_0 \\ \boldsymbol{d}_1 \\ \vdots \\ \boldsymbol{d}_{(Q-1)} \end{bmatrix} = \begin{bmatrix} d_{0,0} & \cdots & d_{0,(P-1)} \\ \vdots & \ddots & \vdots \\ d_{(Q-1),0} & \cdots & d_{(Q-1),(P-1)} \end{bmatrix} \tag{2}$$

where $d_{q,p}$, with $p \in \{0, 1, \ldots, (P-1)\}$ and $q \in \{0, 1, \ldots, (Q-1)\}$, is the data sequence on the qth subchannel and in the pth time slot. Clearly, OFDM is a special case of GFDM, where $P = 1$, i.e., the data is spread only across frequencies and not in time.

After pulse shaping filter and carrier up-conversion, the resulting subchannel transmit signal, denoted by $x(n)$, can be derived as follows:

$$x(n) = \sum_{q=0}^{Q-1} \sum_{p=0}^{P-1} g_{q,p}(n) d_{q,p} \tag{3}$$

where $d_{q,p}$ is the data sequence specified by Eq. (2), and $g_{q,p}$(n) is the circular pulse shaping filter defined as follows:

$$q_{q,p}(n) = g[(n - pQ) \bmod N] e^{-\widetilde{j}\pi qn/N} \tag{4}$$

where $N \geq Q$ is the number of samples per time slot and $\widetilde{j} = \sqrt{-1}$.

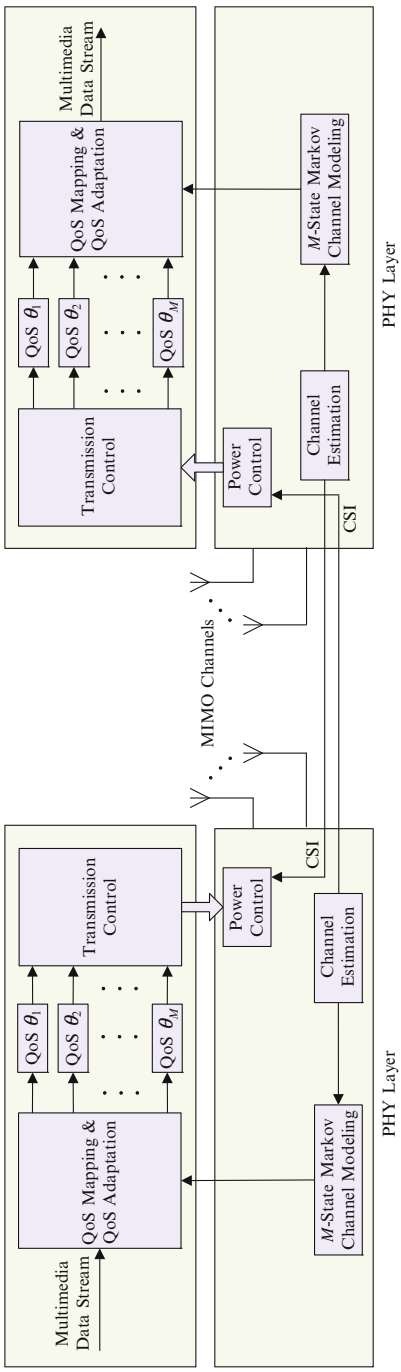

Fig. 2 The block diagram of MIMO-GFDM transceiver system model under cross-layer QoS mapping architecture with M_t transmit antennas and M_r receive antennas over CRNs, where the wireless channels experiencing the Nakagami-m fading

According to Eq. (3), a linear mapping from data symbols to transmit signal is applied as follows [16]:

$$\boldsymbol{x} = \boldsymbol{A}\boldsymbol{d} \tag{5}$$

where $\boldsymbol{d}$ represents the data symbols given by

$$\boldsymbol{d} = [d_{0,0}, d_{1,0}, \ldots, d_{(Q-1),0}, d_{0,1}, \ldots, d_{(Q-1),(P-1)}]^T \tag{6}$$

and $\boldsymbol{A}$ is a $(Q \times P) \times (Q \times P)$ modulation matrix given by

$$\boldsymbol{A} = [g_{0,0}(n), \ldots, g_{(Q-1),0}(n), g_{0,1}(n), \ldots, g_{(Q-1),(P-1)}(n)] \tag{7}$$

with all possible pulse shaping filter functions $g_{q,p}(n)$, where $p \in \{0, 1, \ldots, (P-1)\}$ and $q \in \{0, 1, \ldots, (Q-1)\}$.

In order to compare and analyze the performance of GFDM and OFDM systems, the peak-to-average ratio (PAPR), denoted by $f_r(\boldsymbol{x})$, can be expressed as follows:

$$f_r(\boldsymbol{x}) = 10 \log_{10} \frac{\max\limits_{0 \le n < N} |x(n)|^2}{\mathbb{E}_x[|x(n)|^2]} \tag{8}$$

Then, the complementary cumulative distribution function (CCDF), denoted by $F_c(\boldsymbol{x})$, which is one of the key performance measures for PAPR representing the probability that the PAPR of an GFDM symbol exceeds the given threshold, denoted by $f_{r_0}(\boldsymbol{x})$, can be determined as follows:

$$F_c(\boldsymbol{x}) = \Pr\{f_r(\boldsymbol{x}) > f_{r_0}(\boldsymbol{x})\} \tag{9}$$

Assume that the discrete-time channel is block fading. And the path gains are assumed to be invariant within a frame duration T_f, but vary independently from one frame to another. In the following discussions, the discrete-time index l when representing the channel's impulse response can be omitted. The multiple parallel spatial channel's impulse response, denoted by $\boldsymbol{H}$, can be derived as follows:

$$\boldsymbol{H} = \begin{bmatrix} H^{(0,0)} & \cdots & H^{(0,(M_t-1))} \\ \vdots & \ddots & \vdots \\ H^{((M_r-1),0)} & \cdots & H^{((M_r-1),(M_t-1))} \end{bmatrix} \tag{10}$$

where $H^{(i,j)}$ with $i \in \{0, 1, \ldots, (M_r - 1)\}$ and $j \in \{0, 1, \ldots, (M_t - 1)\}$ is a $(Q \times P) \times (Q \times P)$ matrix given by

$$H^{(i,j)} = \begin{bmatrix} \begin{matrix} h_{0,0}^{(i,j)} & h_{1,0}^{(i,j)} & \cdots & h_{0,(P-1)}^{(i,j)} \\ h_{0,1}^{(i,j)} & h_{1,1}^{(i,j)} & \cdots & h_{1,(P-1)}^{(i,j)} \\ \vdots & \vdots & \ddots & \vdots \\ h_{(Q-1),0}^{(i,j)} & h_{(Q-1),1}^{(i,j)} & \cdots & h_{(Q-1),(P-1)}^{(i,j)} \end{matrix} & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \begin{matrix} h_{0,0}^{(i,j)} & h_{1,0}^{(i,j)} & \cdots & h_{0,(P-1)}^{(i,j)} \\ h_{0,1}^{(i,j)} & h_{1,1}^{(i,j)} & \cdots & h_{1,(P-1)}^{(i,j)} \\ \vdots & \vdots & \ddots & \vdots \\ h_{(Q-1),0}^{(i,j)} & h_{(Q-1),1,}^{(i,j)} & \cdots & h_{(Q-1),(P-1)}^{(i,j)} \end{matrix} \end{bmatrix} \tag{11}$$

where $h_{q,p}^{(i,j)}$ with $p \in \{0, 1, \ldots, (P-1)\}$ and $q \in \{0, 1, \ldots, (Q-1)\}$ is the channel's impulse response over the Nakagami-m fading channels, where m is the shape factor of the Nakagami-m model, in our proposed system. In the special case, $m = 1$ represents Rayleigh fading, and $m = \infty$ corresponds to the Gaussian channel. The Nakagami-m channel impulse response function, denoted by $h_{q,p}^{(i,j)}(l)$, over qth subchannel between ith transmit antenna and jth receive antenna at time l over qth subchannel can be expressed as

$$h_{q,p}^{(i,j)}(l) = \alpha_{q,p}^{(i,j)} \delta\left(l - \tau_{q,p}^{(i,j)}\right) \exp\left(-\widetilde{j}\phi_{q,p}^{(i,j)}\right) \tag{12}$$

where $\widetilde{j} = \sqrt{-1}$; $q \in \{0, 1, \ldots, (Q-1)\}$; $\left\{\tau_{q,p}^{(i,j)}\right\}$ is the path delay; $\left\{\alpha_{q,p}^{(i,j)}\right\}$ is the path envelope; and $\left\{\phi_{q,p}^{(i,j)}\right\}$ is the phase shift. Assume that $\left\{\phi_{q,p}^{(i,j)}\right\}$ is independent and identically distributed (i.i.d) random variable uniformly distributed between $[0, 2\pi)$, and $\left\{\alpha_{q,p}^{(i,j)}\right\}$ is i.i.d. random variable following Nakagami-m distribution, which is specified by

$$f_\alpha(\alpha) = 2\left(\frac{m}{\Omega}\right)^m \frac{\alpha^{2m-1}}{\Gamma(m)} \exp\left(-m\frac{\alpha^2}{\Omega}\right) \tag{13}$$

where $\Omega = \mathbb{E}_\alpha\{[\alpha]^2\}$ is the average path gain and $\Gamma(\cdot)$ denotes the Gamma function.

The Non-time-Slotted Cognitive Radio Network Protocol

In this chapter, we focus on the non-time-slotted cognitive radio networks, which impose more challenges as compared with the time-slotted cognitive radio networks. The non-time-slotted cognitive radio network is defined as the wireless cognitive radio network where the PUs and the SUs are asynchronous. In particular, consider a scenario where a spectrum licensed to the PUs consists of Q subchannels,

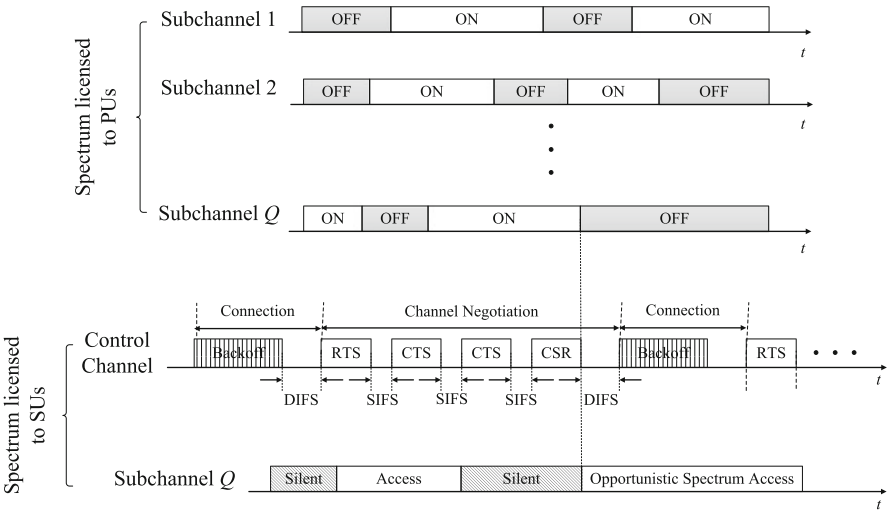

Fig. 3 The non-time-slotted cognitive radio network model, where SIFS is the duration of the short inter-frame space, and DIFS is the duration of DCF inter-frame space

as illustrated in Fig. 3, in which the PUs operating at different subchannels are unsynchronized. Figure 3 shows the timing control sequences of PUs and SUs in non-time-slotted CRNs, where the PUs randomly access and leave the licensed channels. Assume that for each subchannel, the subchannel usage pattern of the PUs follows independent and identically distributed (i.i.d.) ON/OFF renewal process. An ON state represents that the channel is occupied by the PUs. An OFF state represents that the PU is idle and thus the channel can be opportunistically used by the SUs. Note that the average ON and OFF periods depend on the channel usage pattern of the PUs.

On the other hand, as for SUs, the channel is alternating between ON (busy) and OFF (idle) states. Let random variables $T_{q,1}$ and $T_{q,0}$ represent the idle and busy duration, respectively, for the qth licensed subchannel. Without loss of generality, assume that $T_{q,1}$ is independent of $T_{q,0}$. Denote $f_{q,1}(n)$ and $f_{q,0}(n)$ as the probability density functions (pdf) for the durations of the ON state and OFF state for the qth licensed subchannel, respectively. Then, the probability, denoted by $p_{q,0}$, that the channel is in its ON state at an arbitrary time instance can be derived as follows:

$$p_{q,0} = \frac{\int_0^\infty n f_{q,1}(n) dn}{\int_0^\infty n f_{q,1}(n) dn + \int_0^\infty n f_{q,0}(n) dn} = \frac{\overline{T}_{q,1}}{\overline{T}_{q,1} + \overline{T}_{q,0}} \tag{14}$$

where $\overline{T}_{q,1}$ and $\overline{T}_{q,0}$ denote the mean duration of ON and OFF states, respectively, for qth subchannel. Assume that the PUs' subchannel utilization pattern is homogeneous.

The non-time-slotted cognitive radio protocol employs a common control channel as the rendezvous where SUs exchange control packets for multichannel resource reservation [18]. Under the non-time-slotted cognitive radio protocol, the interference from SU's transmission must be constrained in a modest level which the PUs can tolerate; we limit each channel access time of SUs to be not more than the maximum tolerable interference period. The key of the non-time-slotted cognitive radio protocol is to employ four types (two pairs) of control packets, namely, ready-to-send/clear-to-send (RTS/CTS) packets and channel-state-transmitter/channel-state-receiver (CST/CSR) packets, to implement the channel negotiation. All of the above four types of control packets are exchanged over the control channel. The goal of the RTS/CTS control packets is to prevent the collisions among the SUs, while the object of the CST/CSR control packets is to avoid the collisions between the SUs and the PUs. In particular, when a SU sender wants to communicate with a SU receiver over the cognitive radio networks, the SU sender contends for the data channels via the control channel, as shown in Fig. 3. After successful backoff stage, the SU sender conducts the channel negotiation with the SU receiver by exchanging RTS/CTS/CST/CSR control packets over the control channel. As shown in Fig. 3, the common idle licensed channels for the SU sender and SU receiver are subchannel Q; after the successful channel negotiation, the SU sender utilizes subchannel Q to send the data to the SU receiver.

Self-Interference Cancelation-Based Full-Duplex System Model

In this section, consider the full-duplex MIMO-GFDM-based wireless communication at the relay station, as illustrated in Fig. 4. To suppress the self-interference caused by FD communication, the combined analog-domain and digital-domain interference cancelation (ADIC) [19, 20] technique is employed at the receiver of the relay node to cancel the residual self-interference after the propagation-domain interference suppression (PDIS) schemes.

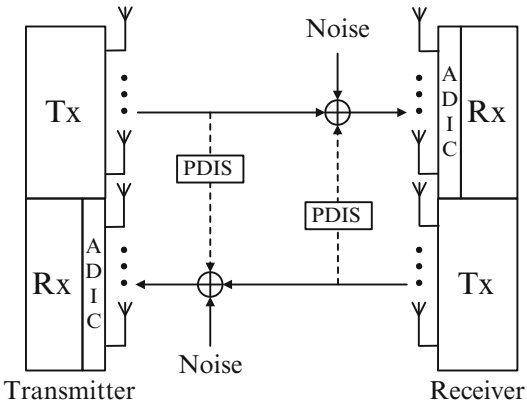

Fig. 4 Full-duplex communications across the secondary source users and the relay station

Let $M = M_r = M_t$. The full-duplex transceiver receives not only the signal of interest $\widehat{\boldsymbol{y}}_a^{(k)}(l) \in \mathbb{C}^{M\times 1}$ but also a self-interference signal $\widetilde{\boldsymbol{y}}_a^{(k)}(l) \in \mathbb{C}^{M\times 1}$ due to bidirectional transmissions. As illustrated in Fig. 4, we can denote the MIMO channel's impulse response for wireless channels from the source node S_k to the relay station in a considered kth source-destination pair as $\boldsymbol{H}_S^{(k)}(l) \in \mathbb{C}^{M\times M}$, which is specified in Eq. (10). Denote the channel's impulse response for wireless channels from the relay station to the destination node D_k as $\boldsymbol{H}_R^{(k)}(l) \in \mathbb{C}^{M\times M}$. The self-interference experiences the channel's impulse responses, denoted by $\boldsymbol{\Phi}^{(k)}(n) \in \mathbb{C}^{M\times M}$, with $n = 1, 2, \ldots$ being the delay index from local transmitter to local receiver at the relay station. Consequently, the received analog composite signal can be determined as follows:

$$\overline{\boldsymbol{y}}_a^{(k)}(l) = \widehat{\boldsymbol{y}}_a^{(k)}(l) + \widetilde{\boldsymbol{y}}_a^{(k)}(l) \tag{15}$$

for which the self-interference signal at the relay node yields

$$\widetilde{\boldsymbol{y}}_a^{(k)}(l) = \sum_{n=0}^{\infty} \boldsymbol{\Phi}^{(k)}(n)\boldsymbol{x}^{(k)}(l-n) \tag{16}$$

The principle of ADIC scheme can be briefly described in the following two aspects:

1. **Analog Cancelation**: Analog cancelation technique uses knowledge of the transmission to cancel self-interference in the RF signal, before it is digitized. The principle of analog self-interference cancelation is to process the known transmitted signal with a frequency-selective filter to generate a negative signal that, when added to the composite signal, reverts the effect of the self-interference propagating through $\boldsymbol{\Phi}^{(k)}(n)$. Denoting the channel's impulse response of the cancelation filter by $\boldsymbol{C}_a^{(k)}(n) \in \mathbb{C}^{M\times M}$, then, the signal, denoted by $\boldsymbol{y}_a^{(k)}(l)$, after analog cancelation can be determined as follows:

$$\boldsymbol{y}_a^{(k)}(l) = \overline{\boldsymbol{y}}_a^{(k)}(l) \sum_{n=0}^{\infty} \boldsymbol{C}_a^{(k)}(n)\boldsymbol{x}^{(k)}(l-n) \tag{17}$$

The self-interference could be ideally removed already in analog domain by choosing $\boldsymbol{C}_a^{(k)}(n) = -\boldsymbol{\Phi}^{(k)}(n)$ for all n. However, in reality, $\boldsymbol{C}_a^{(k)}(n)$ is an analog filter which is difficult and expensive to implement. For example, a practical implementation may include only an $M \times M$ matrix of amplification and phase shift operations which can cancel at its best the strongest multipath component of each MIMO branch as follows [21]:

$$\left\{\boldsymbol{C}_a^{(k)}(n)\right\}_{i,j} = \begin{cases} \left\{\boldsymbol{\Phi}^{(k)}(n)\right\}_{i,j}, & \text{if } n = n_{i,j}^* \\ 0, & \text{otherwise} \end{cases} \tag{18}$$

where $n_{i,j}^* = \arg\max_n \left|\left\{\boldsymbol{\Phi}^{(k)}(n)\right\}_{i,j}\right|^2$.

2. **Digital Cancelation**: Denoting the impulse response of the cancelation filter by $\boldsymbol{C}_d^{(k)}(n) \in \boldsymbol{C}^{M\times M}$, then, we can derive the signal, denoted by $\boldsymbol{y}_d^{(k)}(l)$, after digital cancelation as follows:

$$\boldsymbol{y}_d^{(k)}(l) = \overline{\boldsymbol{y}}_d^{(k)}(l) \sum_{n=0}^{\infty} \boldsymbol{C}_d^{(k)}(n)\boldsymbol{x}^{(k)}(l-n) \tag{19}$$

where $\overline{\boldsymbol{y}}_d^{(k)}(l)$ represents the received digital composite signal. The self-interference could be removed now by choosing

$$\boldsymbol{C}_d^{(k)}(n) = -\boldsymbol{A}\left(\boldsymbol{\Phi}^{(k)}(n) + \boldsymbol{C}_a^{(k)}(n)\right) \tag{20}$$

where $\boldsymbol{A}$ is a real diagonal matrix, and we can obtain that $\widehat{\boldsymbol{y}}_d^{(k)}(l) = \boldsymbol{A}\widehat{\boldsymbol{y}}_a^{(k)}(l)$ and $\widetilde{\boldsymbol{y}}_d^{(k)}(l) = \boldsymbol{A}\widetilde{\boldsymbol{y}}_a^{(k)}(l)$.

MIMO-GFDM-Based FD-SS Relaying Scheme

FD-SS Scheme with Imperfect CSI

To detect the random access and departure of the PUs, the SUs need to sense the licensed channel not only in the sensing period but also in the transmission period. To enable the SU sensing during the transmission period, the SUs need to use the wireless FD mode with transmitting and sensing simultaneously. Consequently, we apply the wireless FD-SS scheme [9] over CRNs.

Since we assume that the source node and the destination node are far enough from each other, there is no direct channel link between them due to shadowing conditions and the transmit power limitation, thus the information needs to be forwarded through the MIMO-based relay node in the networks. The relaying process consists of two phases. In the first phase, the source nodes transmit signals to the relay station after detecting the spectral white space.

Under the wireless FD-SS-based MIMO-GFDM model, the kth secondary source node S_k detects the PU's presence while it is transmitting signals to the relay station. Consequently, the self-interference is introduced to S_k because of S_k's FD transmission with PU. When S_k is transmitting signals to the destination node, the spectrum detection problem as a hypothesis testing problem presents with the

following two hypotheses:

$$\boldsymbol{y}_S^{(k)} = \begin{cases} \sqrt{P_P}\boldsymbol{H}_P^{(k)}\boldsymbol{x}^{(p)} + \sum\limits_{n\neq k}^{K}\sqrt{P_S^{(n)}}\boldsymbol{H}_S^{(n)}\boldsymbol{x}_S^{(n)} + \boldsymbol{n}_S^{(k)}, & \text{if } \mathscr{H}_1; \\ \sqrt{\kappa P_S^{(k)}}\boldsymbol{H}_S^{(k)}\boldsymbol{x}_S^{(k)} + \sum\limits_{n\neq k}^{K}\sqrt{P_S^{(n)}}\boldsymbol{H}_S^{(n)}\boldsymbol{x}_S^{(n)} + \boldsymbol{n}_S^{(k)}, & \text{if } \mathscr{H}_0; \end{cases} \tag{21}$$

where $\mathscr{H}_1$ implies that PU is active and $\mathscr{H}_0$ implies that PU is inactive while the secondary source node S_k is transmitting signals to the destination node; κ with $0 \leq \kappa \leq 1$ is the self-interference suppression coefficient defined as the impact of self-interference mitigation on the wireless FD communication [22]; $P_S^{(k)}$ and $P_S^{(n)}$ are the transmit power of the kth source node and nth source node, respectively; P_P represents the transmit power of the PU base station (BS). $\boldsymbol{x}_S^{(k)}$ and $\boldsymbol{x}_S^{(n)}$ denote the signals sent from the kth secondary-user source node and nth secondary-user source node, respectively; $\boldsymbol{x}^{(p)}$ denotes the signals sent from the PU BS. $\boldsymbol{H}_S^{(k)}$ and $\boldsymbol{H}_S^{(n)}$ denote the channel's impulse response from the transmitter of kth source node and nth source node to the receiver of the relay node, specified by Eq. (10), respectively; $\boldsymbol{H}_P^{(k)}$ denotes the channel's impulse response from the PU base station to the receiver of the relay node; and $\boldsymbol{n}_S^{(k)}$ represents the additive white Gaussian noise (AWGN) with zero mean and unit variance matrix.

In practice, the relay station usually does not have perfect knowledge of CSI. With imperfect CSI, the minimum mean-square error (MMSE) channel estimation for $\boldsymbol{H}_S^{(k)}$ and $\boldsymbol{H}_R^{(k)}$ can be derived as follows:

$$\begin{cases} \widehat{\boldsymbol{H}}_S^{(k)} = \boldsymbol{H}_S^{(k)} - \boldsymbol{\varepsilon}_S^{(k)}; \\ \widehat{\boldsymbol{H}}_R^{(k)} = \boldsymbol{H}_R^{(k)} - \boldsymbol{\varepsilon}_R^{(k)}, \end{cases} \tag{22}$$

where $\boldsymbol{\varepsilon}_S^{(k)}$ and $\boldsymbol{\varepsilon}_R^{(k)}$ represent the estimation error matrices for $\boldsymbol{H}_S^{(k)}$ and $\boldsymbol{H}_R^{(k)}$, respectively. According to [23], rows of $\widehat{\boldsymbol{H}}_S^{(k)}$, $\boldsymbol{\varepsilon}_S^{(k)}$, $\widehat{\boldsymbol{H}}_R^{(k)}$, and $\boldsymbol{\varepsilon}_R^{(k)}$ are mutually independent and distributed as $\mathscr{CN}\left(\boldsymbol{0}, \widehat{\boldsymbol{D}}_S^{(k)}\right)$, $\mathscr{CN}\left(\boldsymbol{0}, \boldsymbol{D}_S^{(k)} - \widehat{\boldsymbol{D}}_S^{(k)}\right)$, $\mathscr{CN}\left(\boldsymbol{0}, \widehat{\boldsymbol{D}}_R^{(k)}\right)$, and $\mathscr{CN}\left(\boldsymbol{0}, \boldsymbol{D}_R^{(k)} - \widehat{\boldsymbol{D}}_R^{(k)}\right)$, respectively, where $\widehat{\boldsymbol{D}}_S^{(k)}$ and $\widehat{\boldsymbol{D}}_R^{(k)}$ are the diagonal matrices and $\boldsymbol{x} \sim \mathscr{CN}(\boldsymbol{0}, \boldsymbol{\Sigma})$ denotes a complex Gaussian vector $\boldsymbol{x}$ with zero mean and covariance matrix $\boldsymbol{\Sigma}$. Define $\mathbf{W}_S^{(k)} \triangleq \widehat{\boldsymbol{H}}_S^{(k)}\left(\widehat{\boldsymbol{H}}_S^{(k)}\right)^H$, as a random nonnegative definite matrix, which has real, nonnegative eigenvalues, denoted by $\lambda_S^{(k)}$. Also, define $\mathbf{W}_R^{(k)} \triangleq \widehat{\boldsymbol{H}}_R^{(k)}\left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H$, as a random nonnegative definite matrix with eigenvalues, denoted by $\lambda_R^{(k)}$. Assuming that each eigenvalues is i.i.d..

By applying the MMSE channel estimation technique, the channel's impulse response is estimated at the receiver of the relay station as $\widehat{\boldsymbol{H}}_P^{(k)}$ and $\widehat{\boldsymbol{H}}_S^{(k)}$. Because

$\boldsymbol{x}_S^{(k)}$ is known to the receiver of the relay station, in conjunction with the channel estimation results specified by Eq. (21), the received signal after combined ADIC at the relay station, denoted by $\boldsymbol{z}_S^{(k)}$, takes the following form:

$$\boldsymbol{z}_S^{(k)} = \begin{cases} \sqrt{P_P}\widehat{\boldsymbol{H}}_P^{(k)}\boldsymbol{x}^{(p)} + \boldsymbol{I}_{S,1}^{(k)}, & \text{if } \mathscr{H}_1; \\ \sqrt{\kappa P_S^{(k)}}\widehat{\boldsymbol{H}}_S^{(k)}\boldsymbol{x}_S^{(k)} + \boldsymbol{I}_{S,0}^{(k)}, & \text{if } \mathscr{H}_0, \end{cases} \tag{23}$$

where $\boldsymbol{I}_{S,1}^{(k)}$ and $\boldsymbol{I}_{S,0}^{(k)}$ are the residual self-interference-plus-noise items after combined ADIC at the relay station given by

$$\begin{cases} \boldsymbol{I}_{S,1}^{(k)} = \sqrt{P_P}\boldsymbol{\varepsilon}_P^{(k)}\boldsymbol{x}^{(p)} + \sum\limits_{n\neq k}^{K}\sqrt{P_S^{(n)}}\left(\widehat{\boldsymbol{H}}_S^{(n)} + \boldsymbol{\varepsilon}_S^{(n)}\right)\boldsymbol{x}_S^{(n)} + \boldsymbol{n}_S^{(k)}, & \text{if } \mathscr{H}_1; \\ \boldsymbol{I}_{S,0}^{(k)} = \sqrt{\kappa P_S^{(k)}}\boldsymbol{\varepsilon}_S^{(k)}\boldsymbol{x}_S^{(k)} + \sum\limits_{n\neq k}^{K}\sqrt{P_S^{(n)}}\left(\widehat{\boldsymbol{H}}_S^{(n)} + \boldsymbol{\varepsilon}_S^{(n)}\right)\boldsymbol{x}_S^{(n)} + \boldsymbol{n}_S^{(k)}, & \text{if } \mathscr{H}_0, \end{cases} \tag{24}$$

where $\boldsymbol{\varepsilon}_P^{(k)}$ represents the channel estimation error coefficients for the PU communication link. Then, the power of $\boldsymbol{I}_{S,1}^{(k)}$ and $\boldsymbol{I}_{S,0}^{(k)}$, denoted by $\Theta_{S,1}^{(k)}$ and $\Theta_{S,0}^{(k)}$, respectively, can be derived as follows:

$$\begin{cases} \Theta_{S,1}^{(k)} = \boldsymbol{I} + P_p\left\|\boldsymbol{\varepsilon}_P^{(k)}\right\|^2 + \sum\limits_{n\neq k}^{K}P_S^{(n)}\left\|\widehat{\boldsymbol{H}}_S^{(n)}\right\|^2 + \sum\limits_{n\neq k}^{K}P_S^{(n)}\left\|\boldsymbol{\varepsilon}_S^{(n)}\right\|^2, & \text{if } \mathscr{H}_1; \\ \Theta_{S,0}^{(k)} = \boldsymbol{I} + \kappa P_S^{(k)}\left\|\boldsymbol{\varepsilon}_S^{(k)}\right\|^2 + \sum\limits_{n\neq k}^{K}P_S^{(n)}\left\|\widehat{\boldsymbol{H}}_S^{(n)}\right\|^2 + \sum\limits_{n\neq k}^{K}P_S^{(n)}\left\|\boldsymbol{\varepsilon}_S^{(n)}\right\|^2, & \text{if } \mathscr{H}_0; \end{cases} \tag{25}$$

where $\boldsymbol{I}$ is the identity matrix. According to Eqs. (23) and (25), the received signal-to-noise-plus interference ratio (SINR), denoted by $\gamma_{S,1}^{(k)}$ and $\gamma_{S,0}^{(k)}$, at the relay station when the channels are idle or not can be expressed as follows:

$$\begin{cases} \gamma_{S,1}^{(k)} = \dfrac{P_p\left\|\boldsymbol{H}^{(p)}\right\|^2}{\Theta_{S,1}^{(k)}}, & \text{if } \mathscr{H}_1; \\ \gamma_{S,0}^{(k)} = \dfrac{\kappa P_S^{(k)}\left\|\boldsymbol{H}_S^{(k)}\right\|^2}{\Theta_{S,0}^{(k)}}, & \text{if } \mathscr{H}_0. \end{cases} \tag{26}$$

In the second phase, considering the MIMO-based FD relay networks, to keep the system complexity low, linear processing schemes are proven to be close to optimal [23]. Among all the linear processing techniques, we adopt the zero-forcing (ZF) processing technique. Define the vector for the received signal at the relay station as $\boldsymbol{Z}_S \triangleq \left[\boldsymbol{z}_S^{(1)}, \boldsymbol{z}_S^{(2)}, \ldots, \boldsymbol{z}_S^{(K)}\right]$, where $\boldsymbol{z}_S^{(k)}$ $(k = 1, 2, \ldots, K)$ is specified by Eq. (23). Then, after receiving the signal from the source node, the relay station applies the ZF receiver to detect the received signal. Thus, we have

$$\boldsymbol{s}_R^{(k)} = \left(\boldsymbol{W}^{(k)}\right)^H \boldsymbol{z}_S^{(k)}, \tag{27}$$

where $(\cdot)^H$ denotes the Hermitian transpose and $\boldsymbol{W} = \left[\boldsymbol{w}^{(1)}, \boldsymbol{w}^{(2)}, \ldots, \boldsymbol{w}^{(K)}\right]$ is the $M \times M$ beamforming matrix given by [24, 25]

$$\boldsymbol{W}^H \triangleq \left(\widehat{\boldsymbol{H}}_R^H \widehat{\boldsymbol{H}}_R\right)^{-1} \widehat{\boldsymbol{H}}_R^H. \tag{28}$$

The estimated received signal is then amplified and forwarded to the destination node using the beamforming matrix $\boldsymbol{A} = \left[\boldsymbol{A}^{(1)}, \boldsymbol{A}^{(2)}, \ldots, \boldsymbol{A}^{(K)}\right]$. Consequently, after linear processing, the transmit signal at the relay station can be expressed as $\boldsymbol{x}_R^{(k)} = \left(\boldsymbol{A}^{(k)}\right)^H \boldsymbol{s}_R^{(k)}$ where

$$\boldsymbol{A}^{(k)} = a_{ZF} \widehat{\boldsymbol{H}}_R^{(k)} \left(\left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \widehat{\boldsymbol{H}}_R^{(k)}\right)^{-1}, \tag{29}$$

where a_{ZF} denotes the normalization constant, chosen to satisfy a long-term total meet the power constraint at the relay node, we have [25]

$$a_{ZF} = \sqrt{\frac{M-K}{\sum_{k=1}^{K} \left(\lambda_R^{(k)}\right)^{-2}}}. \tag{30}$$

Consequently, with imperfect knowledge of desired channels, the received signal, denoted by $\boldsymbol{y}_R^{(k)}$, at the kth destination node can be derived as follows:

$$\begin{cases} \boldsymbol{y}_R^{(k)} = \sqrt{P_P} \left(\widehat{\boldsymbol{H}}_P^{(k)}\right)^H \boldsymbol{A}^{(k)} \boldsymbol{x}_P^{(k)} + \sum_{n \neq k}^{K} \sqrt{P_R^{(n)}} \left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \boldsymbol{A}^{(n)} \boldsymbol{x}_R^{(n)} \\ \qquad + \sum_{n=1}^{K} \sqrt{P_R^{(n)}} \left(\boldsymbol{\varepsilon}_R^{(k)}\right)^H \boldsymbol{A}^{(n)} \boldsymbol{x}_R^{(n)} + \boldsymbol{n}_D^{(k)}, & \text{if } \mathscr{H}_1; \\ \boldsymbol{y}_R^{(k)} = \sqrt{\kappa P_R^{(k)}} \left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \boldsymbol{A}^{(k)} \boldsymbol{x}_R^{(k)} + \sum_{n \neq k}^{K} \sqrt{P_R^{(n)}} \left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \boldsymbol{A}^{(n)} \boldsymbol{x}_R^{(n)} \\ \qquad + \sum_{n=1}^{K} \sqrt{P_R^{(n)}} \left(\boldsymbol{\varepsilon}_R^{(k)}\right)^H \boldsymbol{A}^{(n)} \boldsymbol{x}_R^{(n)} + \boldsymbol{n}_D^{(k)}, & \text{if } \mathscr{H}_0, \end{cases} \tag{31}$$

where $\widehat{\boldsymbol{H}}_R^{(k)}$ denotes the estimated channel's impulse response from the relay node to kth secondary destination node; $\boldsymbol{\varepsilon}_R^{(k)}$ represents the estimation error for $\boldsymbol{H}_R^{(k)}$; $P_R^{(k)}$ is the transmit power at the relay node; and $\boldsymbol{n}_R^{(k)}$ represents the additive white Gaussian noise (AWGN) with zero mean and unit variance matrix.

Define the power of the interference-plus-noise item for the received signal at the kth secondary destination node when PU is active or not as follows:

$$\boldsymbol{\Theta}_{R,1}^{(k)} = \boldsymbol{\Theta}_{R,0}^{(k)} = \sum_{n\neq k}^{K} P_R^{(n)} \left\| \left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \boldsymbol{A}^{(n)} \right\|^2 + \sum_{n=1}^{K} P_R^{(n)} \left\| \left(\boldsymbol{\varepsilon}_R^{(n)}\right)^H \boldsymbol{A}^{(n)} \right\|^2. \tag{32}$$

Consequently, the SNR, denoted by $\gamma_{R,1}^{(k)}$ and $\gamma_{R,0}^{(k)}$, from the relay station to the kth secondary destination node can be derived as follows:

$$\begin{cases} \gamma_{R,1}^{(k)} = \dfrac{P_P \left| \left(\widehat{\boldsymbol{H}}_P^{(k)}\right)^H \boldsymbol{A}^{(k)} \right|^2}{\boldsymbol{\Theta}_{R,1}^{(k)}}, & \text{if } \mathscr{H}_1; \\ \gamma_{R,0}^{(k)} = \dfrac{\kappa P_R^{(k)} \left| \left(\widehat{\boldsymbol{H}}_R^{(k)}\right)^H \boldsymbol{A}^{(k)} \right|^2}{\boldsymbol{\Theta}_{R,1}^{(k)}}, & \text{if } \mathscr{H}_0. \end{cases} \tag{33}$$

Probability of Miss-Detection and False Alarm

We assume the detection threshold is ε. We can rewrite the test statistics of wireless FD energy detection for the channel from the secondary source node to the secondary destination node, denoted by $Y_k(n)$, as follows:

$$Y_k(n) = \frac{1}{N_s} \left(\sum_{n=0}^{N_s} \left| y_R^{(k)}(n) \right|^2 \right) \tag{34}$$

where N_s is the number of samples for the entire sensing period. Note that $y_R^{(k)}(n)$ in each sample is i.i.d. and we assume N_s is large enough. According to the central limit theorem (CLT), the probability density function (pdf) of $Y_k(n)$ can be approximated by a Gaussian distribution.

Lemma 1. *The false-alarm probability, denoted by p_f, and the miss-detection probability, denoted by p_m, for our proposed MIMO-GFDM-based full-duplex cognitive radio networks are determined, respectively, as follows:*

$$\begin{cases} p_f = \Pr\{Y_k(n) > \varepsilon | \mathscr{H}_0\} = Q\left(\left(\frac{\varepsilon}{(1+\gamma_0)} - 1 \right) \sqrt{N_s} \right); \\ p_m = \Pr\{Y_k(n) < \varepsilon | \mathscr{H}_1\} = 1 - Q\left(\left(\frac{\varepsilon}{(1+\gamma_1+\gamma_0)} - 1 \right) \sqrt{N_s} \right), \end{cases} \tag{35}$$

where $Q(\cdot)$ represents the Q function, ε is the detection threshold and N_s denotes the number of samples for the entire sensing period; the end-to-end SINR, denoted by γ_1 and γ_0 when PU is present or not, is given as follows:

$$\begin{cases} \gamma_1 = \sum_{k=1}^{K} \frac{\gamma_{S,1}^{(k)} \gamma_{R,1}^{(k)}}{1+\gamma_{S,1}^{(k)}+\gamma_{R,1}^{(k)}}; \\ \gamma_0 = \sum_{k=1}^{K} \frac{\gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1+\gamma_{S,0}^{(k)}+\gamma_{R,0}^{(k)}}. \end{cases} \tag{36}$$

Proof. The expression for SINR received at the destination node due to the kth secondary-user source-destination link is given by [26]

$$\gamma_0^{(k)} = \frac{\gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + \gamma_{S,0}^{(k)} + \gamma_{R,0}^{(k)}}. \tag{37}$$

Consequently, using the maximum ratio combining (MRC) at the secondary destination node, the total end-to-end SINR due to the full-duplex-based relay network is given as

$$\gamma_0 = \sum_{k=1}^{K} \gamma_0^{(k)}. \tag{38}$$

Because the pdf of $Y_k(n)$ under hypothesis $\mathscr{H}_0$ can be approximated by a Gaussian distribution with mean, denoted by μ_0, as follows:

$$\mu_0^{(k)} = 1 + \gamma_0, \tag{39}$$

where γ_0 is the end-to-end SINR at the secondary destination node when the channels are idle. Then, we can derive the variance, denoted by σ_0 as follows:

$$\sigma_0^2 = \frac{(1 + \gamma_0)^2}{N_s} \tag{40}$$

Thus, we can derive the probability of false alarm as follows:

$$\begin{aligned} p_f &= \Pr\{Y_k(n) > \varepsilon | \mathscr{H}_0\} = \int_{\varepsilon}^{\infty} \frac{1}{\sqrt{2\pi}\sigma_0} \exp\left(-\frac{(x-\mu_0)^2}{2\sigma_0^2}\right) dx \\ &= \frac{1}{\sqrt{2\pi}} \int_{\varepsilon}^{\infty} \frac{\sqrt{N_s}}{(1+\gamma_0)} \exp\left(-\frac{(x-(1+\gamma_0))^2}{2\frac{(1+\gamma_0)^2}{N_s}}\right) dx \end{aligned} \tag{41}$$

Defining new function $z_0(x)$ as follows:

$$z_0(x) \triangleq \frac{x - (1 + \gamma_0)}{1 + \gamma_0} \sqrt{N_s} \tag{42}$$

and plugging Eq. (42) into Eq. (41), we can obtain

$$p_f = Q\left(\left(\frac{\varepsilon}{(1+\gamma_0)} - 1\right)\sqrt{N_s}\right) \tag{43}$$

which is Eq. (35). In the similar way, we can derive the miss-detection probability p_m specified in Eq. (35). Thus, Lemma 1 follows. □

Heterogeneous Statistical Delay-Bounded QoS Guarantees Through Effective Capacity Over CRNs

In this section, we apply the heterogeneous statistical QoS-driven power allocation scheme to maximize the aggregate effective capacity of the FD-based MIMO-GFDM system with heterogeneous statistical delay-bound QoS requirements.

Preliminary for Effective Capacity for Homogeneous Statistical QoS

The statistical QoS guarantees [27, 28] have been extensively studied for analyzing the queueing behavior for time-varying arrival and service processes. Based on large deviation principle (LDP), under sufficient conditions, the queue length process $Q(l)$ converges in distribution to a random variable $Q(\infty)$ such that

$$-\lim_{Q_{th}\to\infty} \frac{\log\left(\Pr\{Q(\infty) > Q_{th}\}\right)}{Q_{th}} = \theta \tag{44}$$

To be more specific, Eq. (44) states that the probability of the queue length exceeding a certain threshold Q_{th} decays exponentially fast as the threshold Q_{th} increases. The parameter θ is called QoS exponent and plays a critically important role for statistical QoS guarantees. The larger θ corresponds to the more stringent QoS requirement, while the smaller θ leads to the looser delay constraint, which implies the system can only provide a looser QoS guarantee. For a certain $\theta > 0$, Q_{th} denotes the queue length bound.

Definition 1. The *effective capacity* [29] is defined as the maximum constant arrival rate that a given service process can support in order to guarantee a QoS requirement specified by θ. Given a service process $R(l)$, the effective capacity of the service process, denoted by $E_c(\theta)$, where $\theta > 0$, is defined as follows [29]:

$$E_c(\theta) = -\frac{1}{\theta}\log\left(\mathbb{E}\left[e^{-\theta R(l)}\right]\right) = -\frac{1}{\theta}\log\left(\mathbb{E}\left[e^{-\theta R(1)}\right]\right) \tag{45}$$

where $\mathbb{E}(\cdot)$ is the expectation operation.

Furthermore, define the resource allocation policy, denoted by $\boldsymbol{\mu} \triangleq \boldsymbol{\mu}(\theta, \gamma)$, as a function of not only the SNR γ but also of the QoS exponent θ [4]. Applying the resource allocation policy, the instantaneous transmit power becomes $P(\boldsymbol{\mu}) = \boldsymbol{\mu}\overline{P}$. Assume that the channel is block fading. In addition, assume that all secondary users are heterogeneous, that is, they have different power allocation schemes but they all subject to the same unit mean power constraint. Let the mean transmit power be upper-bounded by $\overline{P}$. Therefore, the power control law needs to satisfy the mean power constraint:

$$\int_0^\infty P(\boldsymbol{\mu}) p_\gamma(\gamma) d\gamma \leq 1, \qquad \text{for all } \theta > 0 \tag{46}$$

where $p_\gamma(\gamma)$ denotes the pdf of the SINR over Nakagami-m fading channel given by

$$p_\gamma(\gamma) = \frac{\gamma^{m-1}}{\Gamma(m)} \left(\frac{m}{\overline{\gamma}}\right)^m \exp\left(-\frac{m\gamma}{\overline{\gamma}}\right) \tag{47}$$

where $\overline{\gamma}$ denotes the average SINR.

Markov Chain Model for QoS-Driven CRN

Each channel is modeled as an ON/OFF source alternating between state ON (busy) and state OFF (idle) [30]. Suppose that each channel changes its state independently, and the state transition probabilities do not depend on the original state. To characterize the correctness of detections in channel sensing, there are three possible scenarios, as illustrated in Fig. 5, as shown in the following:

Scenario 1: When channel is busy and detected as busy, or when channel is idle but detected as busy, implying that channel is in ON state. As a result, the probability of staying in ON state can be derived as follows [31]:

$$p_{11} = p_{21} = p_{31} = \left[p_0(1 - p_m) + (1 - p_0)p_f\right]^M \tag{48}$$

where p_0 denotes the prior probability of channel being busy; p_f is the false-alarm probability, specified by Eq. (13);

Scenario 2: When channel is idle and detected as idle, implying that channel is in OFF state, that is, the probability of staying in OFF state is determined as follows:

$$p_{12} = p_{22} = p_{32} = \widetilde{c}(1 - p_0)(1 - p_f) \tag{49}$$

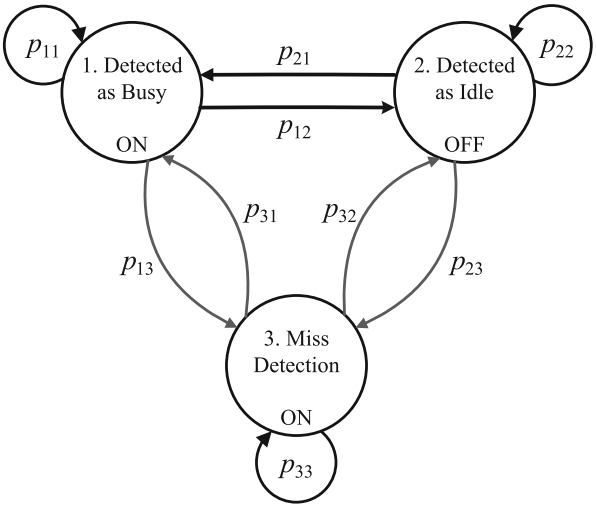

Fig. 5 Markov chain modeling for cognitive radio channel state transitions

where

$$\widetilde{c} = \sum_{i=0}^{M-1} (1 - p_{11})^{M-1-i} (p_{11})^{i} \frac{M!}{(M-i)!i!} = \frac{1 - (p_{11})^{M}}{p_{11}} \tag{50}$$

where let $M = M_t = M_r$.

Scenario 3: When channel is busy but detected as idle, implying that there is no reliable transmitted data. The probability of staying in this scenario is denoted as follows:

$$p_{13} = p_{23} = p_{33} = \widetilde{c} p_0 p_m \tag{51}$$

where p_m denotes the miss-detection probability, specified by Eq. (13).

Then, the 3×3 state transition probability matrix can be derived as follows:

$$\mathbf{S} = \begin{bmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{bmatrix} = \begin{bmatrix} p_1 & p_2 & p_3 \\ p_1 & p_2 & p_3 \\ p_1 & p_2 & p_3 \end{bmatrix} \tag{52}$$

Note that in each frame duration, data is transmitted and received at rate R_1 and R_2 bits in the **Scenario 1** and **Scenario 2**, respectively, while the transmitted number of bits is assumed to be zero in **Scenario 3**.

Assume that if the channel is detected as busy, SUs are considered in the listen-and-talk mode, that is, SUs simultaneously transmit data and sense the target spectrum band with transmitting power $P_S^{(k)}$ and $P_R^{(k)}$. Otherwise, SUs are considered in the half-duplex (HD) sensing mode, that is, SUs just sense the target spectrum band.

Optimizing Effective Capacity with Heterogeneous Statistical QoS Requirements Over CRNs

Considering the Markov-based relaying model, for the different K-link transmissions at the relay station, it is unrealistic to still assume that all the links have the homogeneous statistical QoS requirements. Thus, the diverse delay-bound QoS provisionings for different links at the same time, which represents the new heterogeneous statistical QoS provisioning framework and imposes many new challenges, need to be considered. Let θ_k ($k \in [1, K]$) denote the QoS exponents for different link transmissions at the relay station. Define the power allocation vector $\mathbf{P}_S(\boldsymbol{\mu}) = [P_S^{(1)}(\boldsymbol{\mu}), P_S^{(2)}(\boldsymbol{\mu}), \cdots, P_S^{(K)}(\boldsymbol{\mu})]$ and $\mathbf{P}_R(\boldsymbol{\mu}) = [P_R^{(1)}(\boldsymbol{\mu}), P_R^{(2)}(\boldsymbol{\mu}), \cdots, P_R^{(K)}(\boldsymbol{\mu})]$.

Different relay protocols have been investigated in the last decades [4, 8]. In this section, we mainly focus on the simple relay protocols proposed, that is, amplify-and-forward (AF) and decode-and-forward (DF) protocols as follows:

1. AF Protocol: In AF mode, the relay station simply amplifies and then forwards what it receives to the destination node. This strategy is also called non-regenerative relay or analog relay protocol. Then, with the assumption that there is no direct channel link between the source node and the destination node, the achievable rate of AF protocol, denoted by R_{AF}, can be derived as follows [32]:

$$R_{AF} = T_f B \log_2 \left(1 + \frac{4P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_S^{(k)}\gamma_R^{(k)}}{1 + 2P_S^{(k)}(\boldsymbol{\mu})\gamma_S^{(k)} + 2P_R^{(k)}(\boldsymbol{\mu})\gamma_R^{(k)}}\right), \tag{53}$$

   where $\gamma_S^{(k)}$ and $\gamma_R^{(k)}$ denote the SINR from the secondary source node k to the relay station and from the relay station to the secondary destination node k, respectively.
2. DF Protocol: With DF protocol, the relay station can decode its received message and forward it to the destination node. The achievable rate of DF protocol, denoted by R_{DF}, can be expressed as follows:

$$R_{DF} = T_f B \log_2 \min\left\{\left(1 + \kappa\gamma_S^{(k)}P_S^{(k)}\right), \left(1 + \gamma_R^{(k)}P_R^{(k)}\right)\right\}. \tag{54}$$

Scenario 1: According to the Markov state transition model, for the first scenario (channel is in ON state, $\mathscr{H}_0$), the transmission rate as a function of $\boldsymbol{\mu}$ is derived as follows:

$$\begin{cases} R_{S,0}^{(k)}(\boldsymbol{\mu}) = T_f B \left\{ \log_2 \left(1 + \gamma_{S,0}^{(k)} \right) \right\}; \\ R_{R,0}^{(k)}(\boldsymbol{\mu}) = T_f B \left\{ \log_2 \left(1 + \gamma_{R,0}^{(k)} \right) \right\}. \end{cases} \tag{55}$$

Based on AF protocol in Eq. (53), the achievable rate, denoted by $R_{AF,0}^{(k)}(\boldsymbol{\mu})$, of the MIMO-GFDM-based relaying scheme can be expressed as follows:

$$R_{AF,0}^{(k)}(\boldsymbol{\mu}) = T_f B \left\{ \log_2 \left(1 + \frac{4 P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2 P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2 P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \tag{56}$$

Suppose a set $\mathscr{S}_k$ of subchannels allocated to the kth secondary source-destination pair. Since in the MIMO-GFDM structure each subchannel is only allocated to one secondary pair, $\mathscr{S}_k \bigcap \mathscr{S}_n = \emptyset$ where $k \neq n$ and $\bigcup_{k=1}^{K} \mathscr{S}_k = \{1, 2, \ldots, K\}$. With regard to the abovementioned assumptions and long-term power constraint, our maximization problem $\mathbf{P_1}$ with heterogeneous statistical delay-bound QoS requirements under $\mathscr{H}_0$ hypnosis can be formulated as follows:

$$\mathbf{P_1} : = \arg \max_{P_S^{(k)}(\boldsymbol{\mu}), P_R^{(k)}(\boldsymbol{\mu})} C_{AF,0}^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K) \tag{57}$$

$$\begin{aligned} \text{s.t.}: \quad & (1)\ \mathscr{S}_k \bigcap \mathscr{S}_n = \emptyset \quad \text{if } k \neq n; \\ & (2)\ P_S^{(k)}(\boldsymbol{\mu}) > 0 \quad \text{and} \quad P_R^{(k)}(\boldsymbol{\mu}) > 0; \\ & (3)\ \mathbb{E}\left[\sum_{k=1}^{K} P_S^{(k)}(\boldsymbol{\mu}) \right] \leq \overline{P}_S, \quad \mathbb{E}\left[\sum_{k=1}^{K} P_R^{(k)}(\boldsymbol{\mu}) \right] \leq \overline{P}_R. \end{aligned} \tag{58}$$

Theorem 1. *For optimizing the aggregate effective capacity for problem* $\mathbf{P_1}$*, there exists the unique optimal QoS exponent* θ_o ($\theta_{\min} \leq \theta_o \leq \theta_{\max}$ *where* $\theta_{\min} = \min\{\theta_1, \theta_2, \ldots, \theta_K\}, \theta_{\max} = \max\{\theta_1, \theta_2, \ldots, \theta_K\}$) *such that the equivalent aggregate effective capacity, denoted by* $\widetilde{C}_{AF,0}(\theta_1, \theta_2, \ldots, \theta_K)$*, for different links in the relay-based cognitive radio networks is given as follows [8]:*

$$\widetilde{C}_{AF,0}(\theta_1,\theta_2,\ldots,\theta_K) \triangleq -\frac{1}{\theta_o}\log\left\{\mathbb{E}_\gamma\left[\exp\left\{-\sum_{k=1}^{K}\theta_k T_f B \cdot \left\{\log_2\left(1+\frac{4P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{1+2P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+2P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)\right\}\right\}\right]\right\} \tag{59}$$

and the approximation for the optimal value of θ_o in the high-end SINR region is determined as follows:

$$\theta_o \approx \begin{cases} \dfrac{\prod_{k=1}^{K}\theta_k \sum_{n=1}^{K}\log\left\{\mathbb{E}_\gamma\left[\exp\left[-\theta_k T_f B\log_2\left(1+\frac{2\overline{P}_S^{(n)}(\boldsymbol{\mu})\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)}\gamma_{R,0}^{(n)}}{\overline{P}_S^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)}+\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{R,0}^{(n)}}\right)\right]\right]\right\}}{\sum_{k=1}^{K}\left(\prod_{n\neq k}^{K}\theta_n\right)\log\left\{\mathbb{E}_\gamma\left[\exp\left[-\theta_k T_f B\log_2\left(1+\frac{2\overline{P}_S^{(k)}(\boldsymbol{\mu})\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{\overline{P}_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)\right]\right]\right\}}, \\ \qquad\qquad \text{if } m\le 1 \text{ or } m>1 \text{ and } \theta_{\max}\le 10^{-2}; \\ \frac{1}{K}\sum_{k=1}^{K}\theta_k, \qquad\qquad \text{if } m>1 \text{ and } \theta_{\min}>10^{-2}; \\ \dfrac{\prod_{k=1}^{N}\theta_k \sum_{n=1}^{N}\log\left\{\mathbb{E}_\gamma\left[\exp\left[-\theta_k T_f B\log_2\left(1+\frac{2\overline{P}_S^{(n)}(\boldsymbol{\mu})\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)}\gamma_{R,0}^{(n)}}{\overline{P}_S^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)}+\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{R,0}^{(n)}}\right)\right]\right]\right\}}{\sum_{k=1}^{N}\left(\prod_{n\neq k}^{N}\theta_n\right)\log\left\{\mathbb{E}_\gamma\left[\exp\left[-\theta_k T_f B\log_2\left(1+\frac{2\overline{P}_S^{(k)}(\boldsymbol{\mu})\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{\overline{P}_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)\right]\right]\right\}}, \\ \qquad\qquad \text{if } m>1, \theta_{\min}\le 10^{-2}, \text{ and } \theta_{\max}>10^{-2}, \end{cases} \tag{60}$$

where N $(1 \le N \le K)$ is the number of QoS exponents which are less than or equal to 10^{-2} and $\overline{P}_S^{(k)}(\boldsymbol{\mu})$ and $\overline{P}_R^{(k)}(\boldsymbol{\mu})$ are the average transmit power.

Proof. The proof is provided in section "Appendix A: Proof of Theorem 1". □

According to Theorem 1, in the high-end SINR region, the above non-convex optimization problem $\mathbf{P_1}$ can be converted into a convex problem $\mathbf{P_2}$ as follows:

$$\begin{aligned}\mathbf{P_2}: &\arg\min_{P_S^{(k)}(\boldsymbol{\mu}),P_R^{(k)}(\boldsymbol{\mu})} \mathbb{E}_\gamma\left[\exp\left\{-\sum_{k=1}^{K}\theta_k T_f B\left\{\log_2\left(1+\frac{2P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)\right\}\right\}\right] \\ &= \arg\min_{P_S^{(k)}(\boldsymbol{\mu}),P_R^{(k)}(\boldsymbol{\mu})} \mathbb{E}_\gamma\left[\prod_{k=1}^{K}\left(1+\frac{2P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)^{-\beta_k}\right]\end{aligned} \tag{61}$$

subject to the same constraints given in Eq. (58). Define $\beta_k \triangleq \theta_k T_f B/(2\log 2)$ as the normalized QoS exponent corresponding to θ_k.

To obtain the global optimal solution for $\mathbf{P_2}$, first the Lagrangian function is applied for problem $\mathbf{P_2}$ as follows:

$$J = \mathbb{E}_{\gamma}\left[\prod_{k=1}^{K}\left(1+\frac{2P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)^{-\beta_k}\right]+\widetilde{\lambda}_S\mathbb{E}\left[P_S^{(k)}(\boldsymbol{\mu})-\overline{P}_S\right] + \widetilde{\lambda}_R\mathbb{E}\left[P_R^{(k)}(\boldsymbol{\mu})-\overline{P}_R\right], \tag{62}$$

where $\widetilde{\lambda}_S$ and $\widetilde{\lambda}_R$ are the Lagrange multipliers. Then, applying the Karush-Kuhn-Tucker (KKT) condition, we can take the derivative of J with respect to $P_S^{(k)}(\boldsymbol{\mu})$ and $P_R^{(k)}(\boldsymbol{\mu})$ and set the results to zero as follows:

$$\begin{cases} \frac{\partial J}{\partial P_S^{(k)}(\boldsymbol{\mu})} = -\beta_k\frac{2\gamma_{S,0}^{(k)}\left(\gamma_{R,0}^{(k)}\right)^2\left(P_R^{(k)}(\boldsymbol{\mu})\right)^2}{\left(P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}\right)^2}\prod_{k=1}^{K}\left(1+\frac{2P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)^{-\beta_k-1} \\ \qquad \cdot p_\gamma(\gamma)+\widetilde{\lambda}_S p_\gamma(\gamma)=0; \\ \frac{\partial J}{\partial P_S^{(k)}(\boldsymbol{\mu})} = -\beta_k\frac{2\left(\gamma_{S,0}^{(k)}\right)^2\gamma_{R,0}^{(k)}\left(P_S^{(k)}(\boldsymbol{\mu})\right)^2}{\left(P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}\right)^2}\prod_{k=1}^{K}\left(1+\frac{2P_S^{(k)}(\boldsymbol{\mu})P_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{P_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}+P_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}}\right)^{-\beta_k-1} \\ \qquad \cdot p_\gamma(\gamma)+\widetilde{\lambda}_R p_\gamma(\gamma)=0. \end{cases} \tag{63}$$

Thus,

$$\widetilde{\lambda}_S\gamma_{S,0}^{(k)}\left(\gamma_{R,0}^{(k)}\right)^2\left(P_R^{(k)}(\boldsymbol{\mu})\right)^2=\widetilde{\lambda}_R\left(\gamma_{S,0}^{(k)}\right)^2\gamma_{R,0}^{(k)}\left(P_S^{(k)}(\boldsymbol{\mu})\right)^2 \tag{64}$$

Plugging Eq. (64) back into Eq. (63), we can observe that although the generic optimal heterogeneous statistical QoS-driven recourse allocation for the MIMO-GFDM-based cognitive radio networks can only be obtained through numerical methods, the closed-form for the special case with $K=1$ which can maximize the effective capacity given in Eq. (57) under **Scenario 1** can be derived as follows:

$$\begin{cases} P_S^{(k)}(\boldsymbol{\mu})=\frac{\gamma_{S,0}^{(k)}+\nu^{(k)}\gamma_{R,0}^{(k)}}{2\nu^{(k)}\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}\left[\left(\frac{\widetilde{\lambda}_S^{\text{opt}}\left(\gamma_{S,0}^{(k)}+\nu^{(k)}\gamma_{R,0}^{(k)}\right)^2}{2\beta_k\gamma_{S,0}^{(k)}\left(\nu^{(k)}\gamma_{R,0}^{(k)}\right)^2}\right)^{-\frac{1}{\beta_k+1}}-1\right]; \\ P_R^{(k)}(\boldsymbol{\mu})=\nu^{(k)}P_S^{(k)}(\boldsymbol{\mu}), \end{cases} \tag{65}$$

where $\nu^{(k)}\triangleq\sqrt{\widetilde{\lambda}_S^{\text{opt}}\gamma_{S,0}^{(k)}/\left(\widetilde{\lambda}_R^{\text{opt}}\gamma_{R,0}^{(k)}\right)}$ and $\widetilde{\lambda}_S^{\text{opt}}$ and $\widetilde{\lambda}_R^{\text{opt}}$ are the optimal Lagrangian multipliers and can be numerically obtained by substituting Eq. (65) into Eq. (58). Then, the rest of the cases where $K=2,3,\ldots$ can be determined. Consequently, the maximum aggregate effective capacity using the optimal resource allocation policy is obtained.

Scenario 2: Similar with **Scenario 1**, using $\gamma_{S,1}^{(k)}$ and $\gamma_{R,1}^{(k)}$, we can obtain the optimal power allocation policy for our proposed MIMO-GFDM-based full-duplex cognitive radio networks when channel is in OFF state ($\mathscr{H}_1$). Therefore, the maximum effective capacity, denoted by $C_{AF,1}^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K)$, can be derived.

Scenario 3: In this scenario, since the transmitted number of bits is assumed to be zero, the value of the QoS exponent θ does not affect the value of effective capacity. Consequently, the effective capacity in **Scenario 3** can be omitted.

Based on the abovementioned three scenarios, the maximum aggregate effective capacity, denoted by $E_c^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K)$, can be derived as follows:

$$C_{AF,0}^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K) = p_1 C_{AF,0}^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K) + p_2 C_{AF,1}^{\text{opt}}(\theta_1, \theta_2, \ldots, \theta_K). \tag{66}$$

Dynamic Power Allocations for DF Relay-Based Massive MIMO Cognitive Radio Networks

In the FD relaying network, interference may degrade system performance severely, and MIMO is proposed for interference suppression with the help of its extra spatial dimensions. In order to mitigate the self-interference introduced by FD scheme, during the last decades, massive MIMO systems [33, 34] that use large antenna arrays with a few hundred antennas for multiuser operation have been an emerging technology that delivers all the attractive benefits compared with the traditional MIMO system, but at a much larger scale. Such massive MIMO system substantially reduces the effects of noise, fast fading, and interference and provide increased capacity. Researchers have been studying the massive MIMO system and identify the key result is that, with very large antenna arrays at each base station, both the intracell and intercell interferences can be substantially reduced with simple linear beamforming (BF) processing techniques.

Scenario 1: For the massive MIMO system, according to DF protocol in Eq. (54), the achievable rate, denoted by $R_{DF,0}^{(k)}(\boldsymbol{\mu})$, of the MIMO-GFDM-based relaying scheme can be expressed as follows:

$$R_{DF,0}^{(k)}(\boldsymbol{\mu}) = T_f B \log_2 \min\left\{\left(1 + \kappa \gamma_{S,0}^{(k)} P_S^{(k)}\right), \left(1 + \gamma_{R,0}^{(k)} P_R^{(k)}\right)\right\}. \tag{67}$$

Similar with the AF protocol, we can derive a function for the maximization problem under DF protocol as follows:

$$\widetilde{C}_{DF,0}^{(k)}(\theta_1, \theta_2) = -\frac{1}{\theta_i} \log\left\{\mathbb{E}\left[\exp\left\{-\theta_i T_f B \min\left\{\left(1 + \kappa \gamma_{S,0}^{(k)} P_S^{(k)}\right), \left(1 + \gamma_{R,0}^{(k)} P_R^{(k)}\right)\right\}\right\}\right]\right\}, \tag{68}$$

the QoS exponent θ_i $(i = \{1, 2\})$ with $i = 1$ if $R_{S,0}^{(k)} < R_{R,0}^{(k)}$ and $i = 2$ if $R_{S,0}^{(k)} > R_{S,0}^{(k)}$. Then, the maximization problem $\mathbf{P_3}$ with heterogeneous statistical delay-bound QoS requirements under $\mathscr{H}_0$ hypnosis can be formulated as follows:

$$\mathbf{P_3}: \arg \min_{P_S, P_R} \{\mathbb{E}[\max\{\mathscr{F}_1(\boldsymbol{\nu}), \mathscr{F}_2(\boldsymbol{\nu})\}]\} \geq \arg \min_{P_S, P_R} \{\max\{\mathbb{E}[\mathscr{F}_1(\boldsymbol{\nu})], \mathbb{E}[\mathscr{F}_2(\boldsymbol{\nu})]\}\} \tag{69}$$

subject to the same constraints given in Eq. (58) where

$$\begin{cases} \mathscr{F}_1(\boldsymbol{\nu}) = \left(1 + \kappa \gamma_{S,0}^{(k)} P_S^{(k)}\right)^{-\beta_1}; \\ \mathscr{F}_2(\boldsymbol{\nu}) = \left(1 + \gamma_{R,0}^{(k)} P_R^{(k)}\right)^{-\beta_2}, \end{cases} \tag{70}$$

where $\beta_1 \triangleq \theta_1 T_f B / \log 2$ and $\beta_2 \triangleq \theta_2 T_f B / \log 2$ are defined as the normalized QoS exponents.

With ZF linear processing techniques at the relay station, the closed-form expression for $\mathbb{E}[\{\mathscr{F}_1(\boldsymbol{\nu})\}]$ and $\mathbb{E}[\{\mathscr{F}_2(\boldsymbol{\nu})\}]$ of the FD relaying system in the high-end SNR region with a finite number of transmit and receive antennas can be, respectively, approximated as follows [35]:

$$\begin{cases} \mathbb{E}[\{\mathscr{F}_1(\boldsymbol{\nu})\}] \approx \left(\dfrac{P_S(M-K)\left(\lambda_S^{(k)}\right)^2}{\sum\limits_{n=1}^{K} P_S\left(\alpha_S^{(k)} - \left(\lambda_S^{(n)}\right)^2\right) + \frac{K(M-K)}{M}\kappa^2 P_R + 1} \right)^{-\beta_1}; \\ \mathbb{E}[\{\mathscr{F}_2(\boldsymbol{\nu})\}] \approx \left(\dfrac{P_R(M-K)\left(\lambda_R^{(k)}\right)^2}{KP_R\left(1 - \frac{K}{M}\alpha_R^{(k)} - \left(\lambda_R^{(k)}\right)^2\right) + 1} \right)^{-\beta_2}. \end{cases} \tag{71}$$

where $\alpha_R^{(k)}$ is the path envelop of the Nakagami-m fading channels.

To obtain the global optimal solution for $\mathbf{P_3}$, we need to convert the non-convex optimization problem $\mathbf{P_3}$ to an equivalent convex optimization problem. Because $\mathbb{E}[\mathscr{F}_1(\boldsymbol{\nu})]$ and $\mathbb{E}[\mathscr{F}_2(\boldsymbol{\nu})]$ are both convex functions, their point-wise maximum function $\max\{\mathbb{E}[\mathscr{F}_1(\boldsymbol{\nu})], \mathbb{E}[\mathscr{F}_2(\boldsymbol{\nu})]\}$ is also a convex function [28]. Therefore, problem $\mathbf{P_3}$ is a strictly convex problem. To fine the optimal power adaptation, we have

$$\mathbb{E}[\mathscr{F}_1(\boldsymbol{\nu})] = \mathbb{E}[\mathscr{F}_2(\boldsymbol{\nu})] \tag{72}$$

Thus, we can derive an equivalent problem $\mathbf{P_4}$ as follows:

$$\mathbf{P_4}: \arg \min_{P_R} \{\mathbb{E}[\mathscr{F}_2(\boldsymbol{\nu})]\} \tag{73}$$

subject to the same constraints given in Eq. (58). For the FD-based massive MIMO system, as $M \gg K$, we can rewrite the approximate expression for $\mathbb{E}\left[\{\mathscr{F}_1(\boldsymbol{\nu})\}\right]$ and $\mathbb{E}\left[\{\mathscr{F}_2(\boldsymbol{\nu})\}\right]$ as follows:

$$\begin{cases} \mathbb{E}\left[\{\mathscr{F}_1(\boldsymbol{\nu})\}\right] \approx \left(\dfrac{MP_S\left(\lambda_S^{(k)}\right)^2}{\sum\limits_{n=1}^{K} P_S\left(\alpha_S^{(n)} - \left(\lambda_S^{(n)}\right)^2\right) + K\kappa^2 P_R + 1} \right)^{-\beta_1}; \\ \mathbb{E}\left[\{\mathscr{F}_2(\boldsymbol{\nu})\}\right] \approx \left(\dfrac{MP_R\left(\lambda_R^{(k)}\right)^2}{KP_R\left(1 - \left(\lambda_R^{(k)}\right)^2\right) + 1} \right)^{-\beta_2}. \end{cases} \tag{74}$$

Consequently, for massive MIMO system, we can formulate an equivalent problem $\mathbf{P_4}$ as follows:

$$\mathbf{P_4} : \arg\min_{P_R} \left\{ \left(\frac{MP_R\left(\lambda_R^{(k)}\right)^2}{KP_R\left(1 - \lambda_{R,k}^2\right) + 1} \right)^{-\beta_2} \right\} \tag{75}$$

subject to the same constraints given in Eq. (58).

Theorem 2. *For our proposed massive MIMO system, the optimal resource adaptation policy which maximizes the effective capacity at the relay station given in Eq. (26) is derived as follows:*

$$P_R^{\text{opt}} = \left(\frac{\mu^{\text{opt}}\left(M\left(\lambda_R^{(k)}\right)^2\right)^{\beta_2}}{\beta_2\left(K\left(1 - \left(\lambda_R^{(k)}\right)^2\right)\right)^{\beta_2 - 1}} \right)^{\frac{1-\beta_2}{1+\beta_2}}, \tag{76}$$

where μ^{opt} can be obtained by substituting Eq. (76) into Eq. (58).

Proof. The proof is provided in section "Appendix B: Proof of Theorem 2". □

Substituting Eq. (76) into Eqs. (72) and (74), the optimal power adaptation policy, denoted by P_S^{opt}, for the source node can be determined as follows:

$$P_S^{\text{opt}} = \frac{\left(\dfrac{M\left(\lambda_R^{(k)}\right)^2 P_R^{\text{opt}}}{K\left(1 - \left(\lambda_R^{(k)}\right)^2\right) P_R^{\text{opt}} + 1} \right)^{\frac{\beta_2}{\beta_1}} \left(K\kappa^2 P_R^{\text{opt}} + 1\right)}{M\left(\lambda_S^{(k)}\right)^2 - \sum\limits_{n=1}^{K} \left(\alpha_S^{(n)}\left(\lambda_S^{(n)}\right)^2\right) \left(\dfrac{M\left(\lambda_R^{(k)}\right)^2 P_R^{\text{opt}}}{K\left(1 - \left(\lambda_R^{(k)}\right)^2\right) P_R^{\text{opt}} + 1} \right)^{\frac{\beta_2}{\beta_1}}}. \tag{77}$$

Scenario 2: Similar with **Scenario 1**, using $\gamma_{S,1}^{(k)}$ and $\gamma_{R,1}^{(k)}$, we can obtain the optimal power allocation policy for our proposed MIMO-GFDM-based full-duplex cognitive radio networks when channel is in OFF state ($\mathscr{H}_1$).

Scenario 3: In this scenario, the effective capacity in **Scenario 3** can be omitted.

Simulation Evaluations

MATLAB simulation is used to validate and evaluate the QoS-aware MIMO-GFDM-based CRNs. Throughout our simulations, set the bandwidth $B = 100$ KHz, the time frame length $T_f = 2$ ms, the average transmit power for the source nodes and the relay station $\overline{P}_S = 0.5$ W, and $\overline{P}_R = 1$ W. Without loss of generality, we set the self-interference mitigation factors for secondary users as $\kappa = 0.95$.

For analyzing and comparing the system performance of both a 2×2 MIMO channel and an FD channel, we consider the simplest case of two SUs trying to constantly send data to each other. Both SUs have two antennas that can be used for transmitting or receiving. We compare the case when the SUs use the two antennas

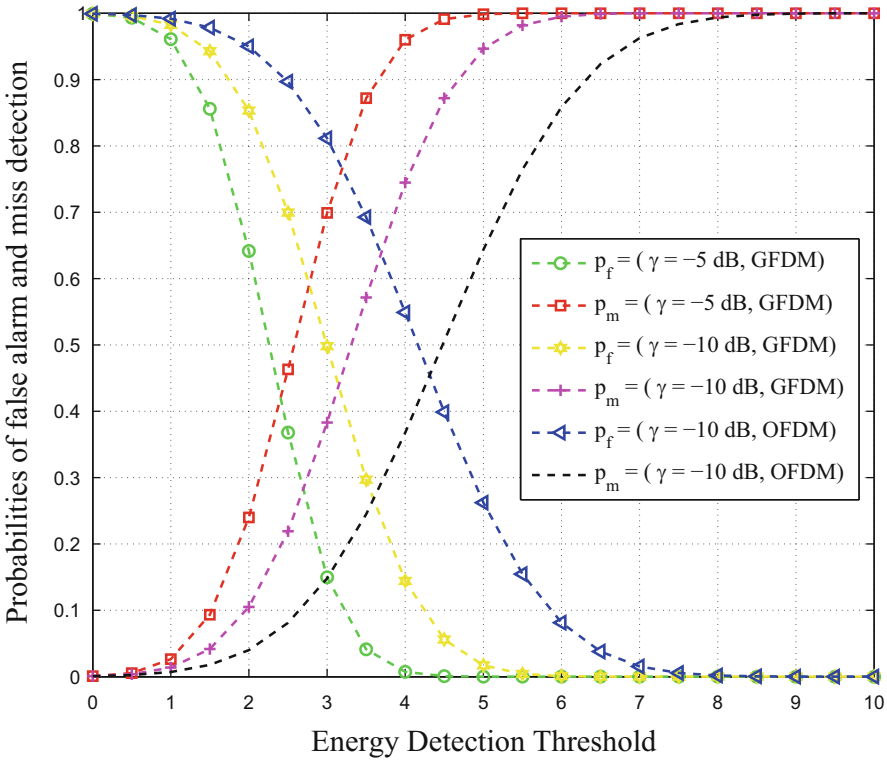

Fig. 6 The probabilities of false alarm and miss-detection with varying SNR over FD CRNs

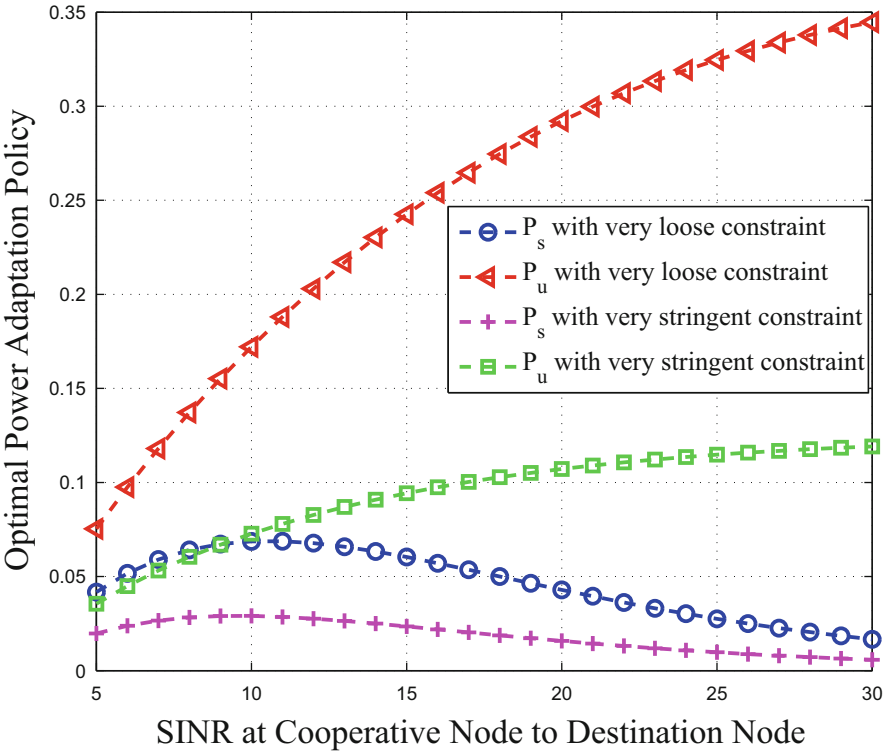

Fig. 7 The comparison of QoS-driven optimal resource allocation policy with different QoS constraints

to implement a 2×2 MIMO system v.s. implement a FD system. We can make two assumptions in this comparison [36]:

- SUs have the same power constraint during the transmission regardless of its duplex mode. This means that an HD SU cannot double its transmit power even though it remains silent half of the time (compared to the FD SU which always transmits). Under this assumption, a 2×2 MIMO system is able to use the maximum power of only a single SU at a given time, since only one of two communicating SUs can transmit at a given time. On the other hand, with FD scheme, the system uses the maximum power of both communicating SUs at the same time, thus allowing the use of more total power in the system.
- The transmitter knows the state of the wireless channel from itself to the receiver perfectly. For a MIMO system, this increases the transmission rate by allowing an additional transmitter processing technique, called MIMO precoding. In case of FD scheme, if both the SUs know the channels between all the antenna pairs, they can agree on the best transmit-receive antenna pair to maximize the transmission rate in both directions.

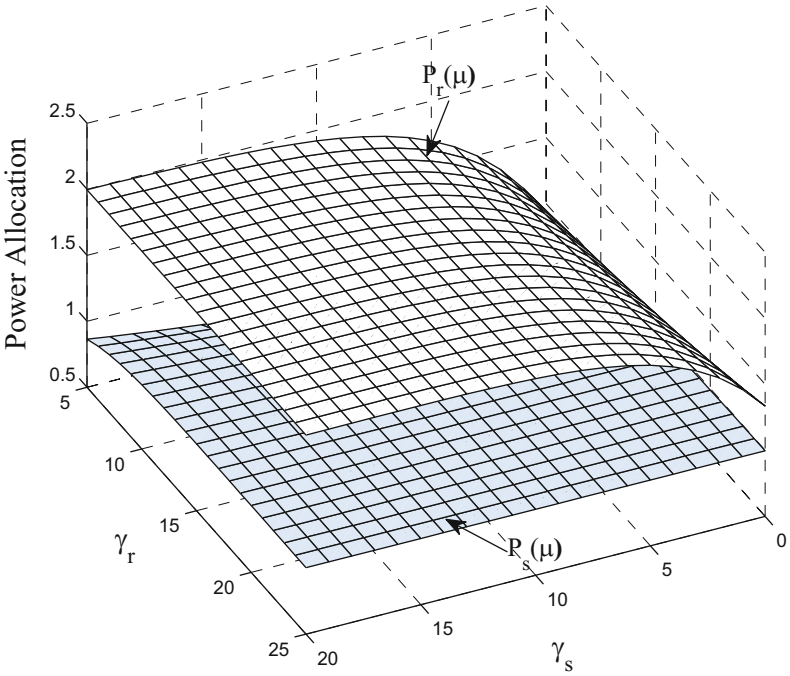

Fig. 8 The optimal power allocation policy for our proposed MIMO-GFDM-based cognitive radio networks

We consider GFDM system and OFDM system with 1024 subcarriers ($P = 1024$) and $Q = 256$. Using Eq. (35), Fig. 6 plots and evaluates the probability of false alarm and the probability of miss-detecting the channel with varying SNR corresponding to GFDM system, compared with the OFDM system. As illustrated in Fig. 6, our proposed GFDM system outperforms OFDM system in terms of the false-alarm probability and miss-detection probability. Figure 6 also shows that the probability of false alarm decreases as the energy detection threshold ε decreases. We can observe from Fig. 6 that the probability of false alarm and the probability of miss-detection both increase as the value of SNR decreases, while the gap between each curve is decreasing as SNR increases. This implies that the energy detection performance of one cognitive node gets worse when the SNR decreases, which is the case when the cognitive node experiences heavy shadowing or fading.

According to the statistical QoS scheme, when $\theta \to \infty$, this implies that the system cannot tolerate any delay, which corresponds to the very stringent statistical delay-bound QoS constraint. On the other hand, when $\theta \to 0$, the system can tolerate an arbitrarily long delay, which corresponds to the very loose statistical delay-bound QoS constraint. Figure 7 depicts the QoS-driven optimal power allocation policy with different QoS constraints, where we plot and compare four curves with very loose constraint ($\theta_1 = \theta_2 = 1 \times 10^{-4}$) and very stringent

constraint ($\theta_1 = \theta_2 = 0.6$). Figure 7 shows that the loose and stringent QoS constraints set the upper bound and lower bound for the power allocation policy, respectively. As illustrated in Fig. 7, we can also observe that for a given SNR, the optimal resource allocation scheme allocates more power for $P_u^{(k)}$ than $P_s^{(k)}$, which implies that the SU consumes more power for LAT mode than HD sensing mode.

Let $\theta_1 = \theta_2 = \cdots = \theta_K = 0.5$, $K = 2$, and $M = 2$. According to Eq. (65), to evaluate the performance of the MIMO-GFDM-based system, Fig. 8 depicts the optimal power allocation policy for our relay-based cognitive radio networks. As illustrated in Fig. 8, the relay station is allocated more power compared with the power allocation policy at the source nodes $P_S^{(k)}$. It makes sense since the average transmit power at the secondary relay station is set larger than the power at the secondary source nodes.

Figure 9 depicts the aggregate effective capacity for the MIMO-GFDM-based cognitive radio networks corresponding to the heterogeneous statistical QoS-driven power allocation scheme compared with the homogeneous QoS-driven power allocation scheme with $K = 2$ and $M = 2$. As shown in Fig. 9, the aggregate effective capacity converges to zero as the statistical QoS constraint becomes more stringent.

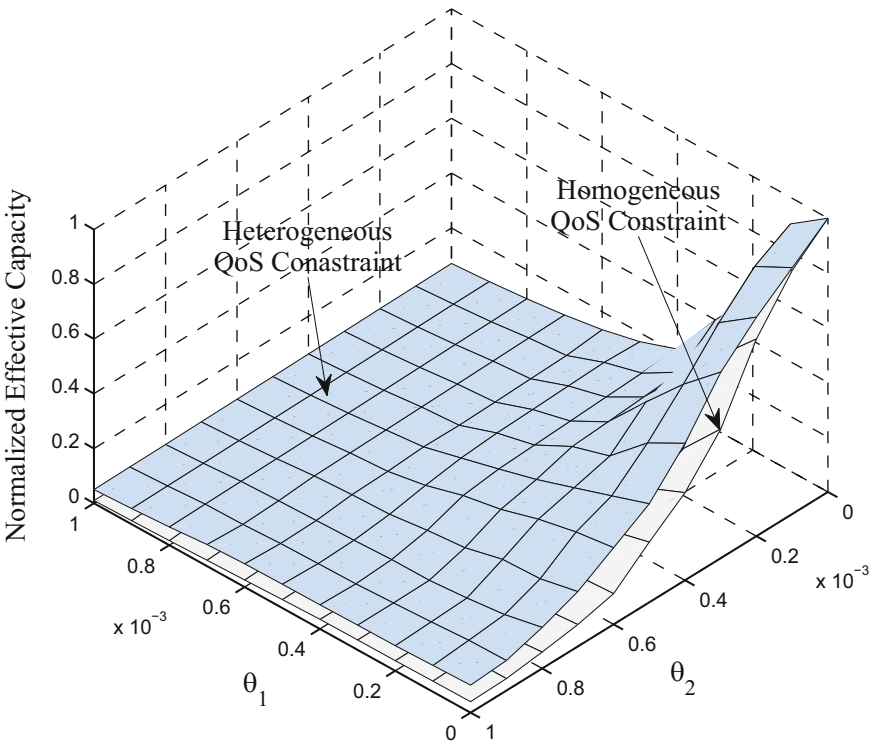

Fig. 9 The heterogeneous statistical QoS-driven power allocation policy v.s. homogeneous QoS-driven power allocation policy

When $\theta_1 = \theta_2$, the aggregate effective capacity for heterogeneous statistical QoS scheme is the same as the homogeneous statistical QoS scheme, which implies that the homogeneous statistical QoS provisioning is a special case of the heterogeneous statistical QoS provisioning. When $\theta_1 \neq \theta_2$, the effective capacity corresponding to the heterogeneous statistical QoS scheme is larger than the effective capacity corresponding to the homogeneous statistical QoS provisioning, implying that the heterogeneous statistical QoS scheme outperforms the existing homogeneous statistical QoS scheme in terms of the aggregate effective capacity for the MIMO-GFDM-based cognitive radio networks.

Set $K = 2$, $\gamma_{S,0}^{(1)} = 10\,\text{dB}$, and $\gamma_{S,0}^{(2)} = 5\,\text{dB}$. Figure 10 plots the aggregate effective capacity for the MIMO-GFDM-based cognitive radio system under different QoS constraints. As shown in Fig. 10, with looser QoS constraint ($\theta = 10^{-2}$), the system can achieve higher aggregate effective capacity, which implies that loose QoS constraint ($\theta = 10^{-3}$) and stringent QoS constraint ($\theta = 10^{-2}$) can set the upper bound and lower bound for the aggregate effective capacity, respectively.

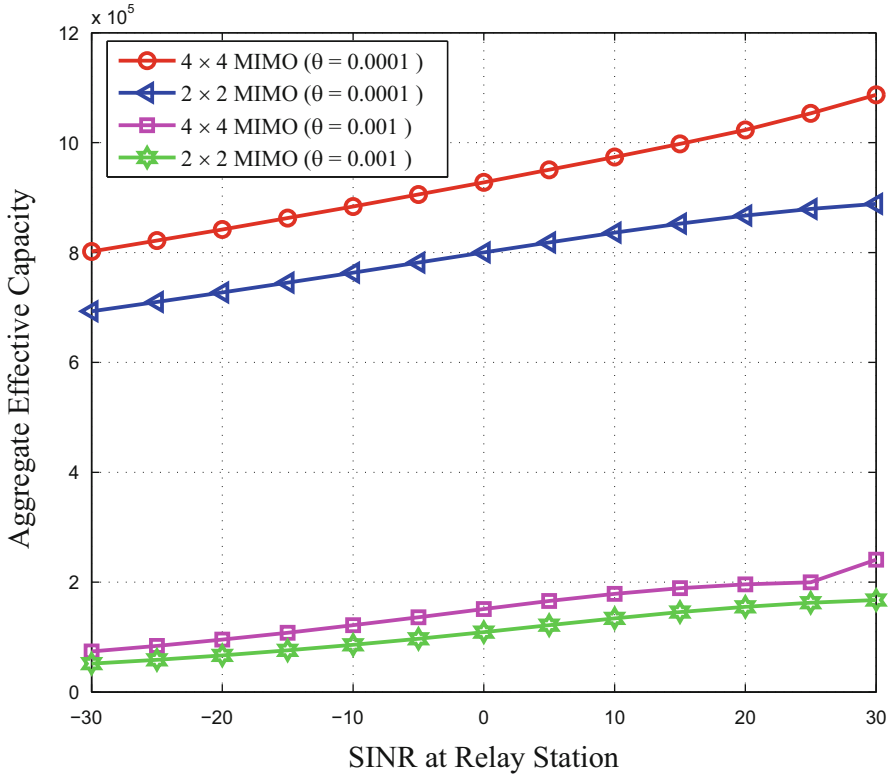

Fig. 10 The aggregate effective capacity under different QoS constraints for our proposed MIMO-GFDM-based cognitive radio networks

Using Eq. (57), Fig. 11 depicts the aggregate effective capacity for the MIMO-GFDM-based cognitive radio system with different number of transmit and receive antennas M compared with single-input single-output (SISO) scheme. As shown in Fig. 11, as the QoS exponent θ becomes larger, the effective capacity decreases. As illustrated in Fig. 11, as the number of transmit and receive antennas increases, the MIMO-based relaying system achieves better aggregate effective capacity over the cognitive radio networks, implying that larger antenna arrays at the relay station can achieve better performance, that is, the MIMO-GFDM-based relaying system can outperform the traditional SISO system in terms of the aggregate effective capacity. From Fig. 11, it is obvious that the gap between the plots becomes smaller as M increases, which implies that the aggregate effective capacity cannot always increase as $M \to \infty$; instead, the transmission rate finally converges to a certain value.

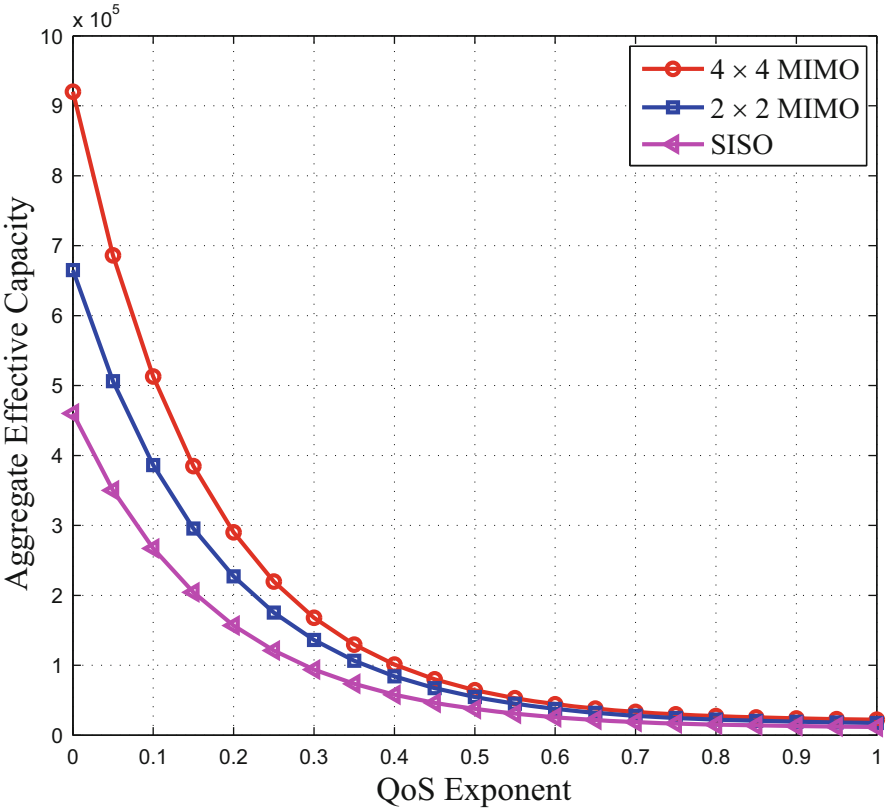

Fig. 11 The aggregate effective capacity with different number of antennas for our proposed MIMO-GFDM-based cognitive radio networks

Conclusions

We proposed the heterogeneous statistical QoS provisioning schemes by applying MIMO-GFDM technique to implement FD-SS-based multimedia services in CRNs. In particular, under the Nakagami-m wireless channels, we established the spectrum sensing model, the MIMO-GFDM-based PHY-layer model, the non-time-slotted CRN model, and the self-interference cancelation model. We developed and analyzed the FD-SS-based MIMO-GFDM scheme to fully utilize the channel spectrum and derived the probabilities of miss-detection and false alarm for the proposed FD-SS-based MIMO-GFDM model over cognitive radio networks. Under the heterogeneous statistical QoS constraints, we developed the Markov chain model to characterize the correctness of detections in channel sensing and then derived and analyzed the aggregate effective capacity under our proposed optimal power allocation policies using the proposed MIMO-GFDM architecture over FD cognitive radio networks. Also conducted was a set of simulations which showed that our proposed scheme outperformed the other existing schemes in terms of aggregate effective capacity to efficiently implement the heterogeneous statistical QoS over cognitive radio-based 5G mobile wireless networks.

Appendix A: Proof of Theorem 1

Proof. The aggregate effective capacity, denoted by $\widetilde{C}_{AF,0}(\theta_1, \theta_2, \ldots, \theta_K)$, for different links in the relay-based cognitive radio networks can be derived as follows:

$$\widetilde{C}_{AF,0}(\theta_1, \theta_2, \ldots, \theta_K) \triangleq -\frac{1}{\theta_o} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\sum_{k=1}^{K} \theta_k T_f B \right. \right. \right.$$
$$\left. \left. \left. \cdot \log_2 \left(1 + \frac{4 P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2 P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2 P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\}. \tag{78}$$

Then, the value of θ_o needs to be derived before solving the optimization problem. The optimal θ_o needs to satisfy the following equation:

$$\sum_{k=1}^{K} -\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \log_2 \left(1 + \frac{4P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\}$$

$$= -\frac{1}{\theta_o} \sum_{k=1}^{K} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \cdot \log_2 \left(1 + \frac{4P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \tag{79}$$

Considering that the effective capacity for one link can be increased when using the QoS-driven power allocation as compared with the effective capacity using the average transmit power control, we have

$$-\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \log_2 \left(1 + \frac{4P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\}$$

$$= -\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \cdot \log_2 \left(1 + \frac{4P_S^{(k)}(\boldsymbol{\mu}) P_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2P_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2P_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} + I_k, \tag{80}$$

for $1 \leq k \leq K$ where I_k represents the increased aggregate effective capacity when using the heterogeneous-statistical-QoS-driven power allocation scheme for the kth downlink. Then, substituting Eq. (80) back into Eq. (79), we can obtain the expression for θ_o in Eq. (81) as follows:

$$\theta_o = \frac{\prod_{n=1}^{K} \theta_n \left[\sum_{k=1}^{K} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu}) \overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \right] - \Lambda_1}{\sum_{k=1}^{K} \left[\left(\prod_{n \neq k}^{K} \theta_n \right) \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu}) \overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \right] - \Lambda_2}, \tag{81}$$

where

$$\begin{cases} \Lambda_1 \triangleq \sum\limits_{k=1}^{K} \theta_k I_k \left(\prod\limits_{n=1}^{K} \theta_n \right); \\ \Lambda_2 \triangleq \prod\limits_{k=1}^{K} \theta_k \left(\sum\limits_{n=1}^{K} I_n \right). \end{cases} \tag{82}$$

According to [7], the approximation of θ_o can be classified into the following four cases based on the values of Nakagami-m channel parameter m:

Case 1: $m \leq 1$. For this case, because the average transmit power is the determining factor for the effective capacity, we have

$$-\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \cdot \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu}) \overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \gg I_k \tag{83}$$

for $1 \leq k \leq K$. Thus, we can omit the terms containing I_k in Eq. (81).

Case 2: $m > 1$ and $\theta_{\max}$ is small ($\theta_{\max} \leq 10^{-2}$). We consider θ is large if $\theta > 10^{-2}$ and if $\theta \leq 10^{-2}$, we claim that θ is small [7]. For small θ, the optimal power-adaptation law allocates more power to worse channel. In contrast, for large θ, the power control assigns less power to the better channel, but more power to the worse channel. Because the average transmit power is the determining factor for the effective capacity, it is the same as **Case 1**.

Case 3: $m > 1$ and $\theta_{\min}$ is large ($\theta_{\min} > 10^{-2}$). For this case, because the QoS-driven power control is the determining factor for the effective capacity, we only need to consider each term containing I_k in Eq. (81), we have

$$-\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \cdot \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu}) \overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} \gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu}) \gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu}) \gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \ll I_k \tag{84}$$

for $1 \leq k \leq K$. Thus, we can obtain

$$\theta_o \approx \frac{\sum_{k=1}^{K} \theta_k I_k}{\sum_{k=1}^{K} I_k} \approx \frac{\sum_{k=1}^{K} \theta_k}{K}. \tag{85}$$

Case 4: $m > 1$, $\theta_{\min}$ is small and $\theta_{\max}$ is large. For this case, because we have

$$-\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \cdot \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu})\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}} \right) \right\} \right] \right\} \gg I_k \quad \text{and} \quad I_n \tag{86}$$

and

$$-\frac{1}{\theta_k} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_k T_f B \log_2 \left(1 + \frac{4\overline{P}_S^{(k)}(\boldsymbol{\mu})\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)}\gamma_{R,0}^{(k)}}{1 + 2\overline{P}_S^{(k)}(\boldsymbol{\mu})\gamma_{S,0}^{(k)} + 2\overline{P}_R^{(k)}(\boldsymbol{\mu})\gamma_{R,0}^{(k)}} \right) \right\} \right] \right\}$$
$$\gg -\frac{1}{\theta_n} \log \left\{ \mathbb{E}_\gamma \left[\exp \left\{ -\theta_n T_f B \cdot \log_2 \left(1 + \frac{4\overline{P}_S^{(n)}(\boldsymbol{\mu})\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)}\gamma_{R,0}^{(n)}}{1 + 2\overline{P}_S^{(n)}(\boldsymbol{\mu})\gamma_{S,0}^{(n)} + 2\overline{P}_R^{(n)}(\boldsymbol{\mu})\gamma_{R,0}^{(n)}} \right) \right\} \right] \right\} \tag{87}$$

where θ_k $(1 \leq k \leq N \leq K)$ is small $(\theta_k \leq 10^{-2})$ and θ_n $((N+1) \leq n \leq K)$ is large $(\theta_n > 10^{-2})$. Then, we can derive Eq. (60).

In order to derive the value of θ_o, we also need to obtain the optimal values of $\overline{P}_S^{(k)}$ and $\overline{P}_R^{(k)}$ $(1 \leq k \leq K)$, which can be obtained by solving the optimization problem $\mathbf{P_2}$. Therefore, the proof for Theorem 1 follows. □

Appendix B: Proof of Theorem 2

Proof. Since $\mathbf{P_4}$ is a strictly convex optimization problem, and thus it has the unique optimal solution. We construct the Lagrangian function for $\mathbf{P_4}$, denoted by J, as follows:

$$J = \left(\frac{MP_R \left(\lambda_R^{(k)}\right)^2}{KP_R(\boldsymbol{\nu}) \left(1 - \left(\lambda_R^{(k)}\right)^2\right) + 1} \right)^{-\beta_2} + \mu \left(\mathbb{E}\left[P_R\right] - \overline{P}_R \right) \tag{88}$$

where μ is the Lagrangian multiplier associated with the constraint specified by Eq. (58). Thus, the optimal solutions for the recourse adaptation law, and the optimal Lagrangian multiplier μ^{opt} of the problem $\mathbf{P_4}$ need to satisfy the following Karush-Kuhn-Tucker (KKT) conditions:

$$\begin{cases} \left.\frac{\partial J}{\partial P_R}\right|_{P_R=P_R^{\text{opt}}} = 0; \\ \mu^{\text{opt}}\left(\mathbb{E}\left[P_R\right] - \overline{P}_R\right) = 0; \\ \mu^{\text{opt}} \geq 0; \\ P_R > 0. \end{cases} \tag{89}$$

Taking derivative of J with respect to P_R, we can obtain

$$\frac{\partial J}{\partial P_R} = \frac{-\beta_2 \left(P_R\right)^{-\beta_2-1}\left(M\left(\lambda_R^{(k)}\right)^2\right)^{-\beta_2}}{\left(KP_R\left(1-\left(\lambda_R^{(k)}\right)^2\right)+1\right)^{-\beta_2+1}} + \mu. \tag{90}$$

Then, for our proposed massive MIMO system ($M \to \infty$), associated with Eq. (89), we can derive the optimal solutions expressed by Eq. (76). Therefore, the proof for Theorem 2 follows. □

Abstract

With the advent of mobile cloud computing, the expectation of the mobile users for anywhere, anytime, content-rich experience will see a significant increase. The users' expectation on quality of experience for content-rich applications can only be met through offloading computationally intensive application tasks to a remote cloud since mobile devices are still constrained by their battery power. This, however, leads to an increase in mobile web traffic. The success of computation offloading techniques, therefore, depends on being able to effectively trade-off resource usage at the mobile device against efficiently managing the spectrum for mobile computing. Hence it is essential for cloud offloading techniques to take advantage of recent advances in cognitive network-

ing and spectrum-aware scheduling of application components. The convergence of cognitive networking and spectrum-aware mobile computing is propelling research in this area. The current state-of-the-art includes techniques that offload application data using all viable multiple radio interfaces (e.g., WiFi, LTE, etc.) in multi-RAT-enabled devices, while being adaptive to the conditions of the mobile network. This chapter presents a survey of the existing spectrum-aware mobile computing techniques and proposes a vision for the future for a 5G-enabled, cognitive mobile computing platform. Implementation setups using real data measurements from an HTC phone running multicomponent applications and using different cloud servers such as Amazon EC2 and NSFCloud over LTE and WiFi are also discussed.

Introduction

The advent of cognitive radio technology, proposed almost two decades ago, has enabled dynamic spectrum access and sharing. Additionally, since 2013, many modern phones have been designed to support multiple radio access technologies (RATs) such as bluetooth, WiFi, and 3G/4G/LTE. The coexistence of these two technologies has spawned a fertile research area in spectrum-aware mobile computing. Furthermore, current and future mobile devices are expected to deliver a lot more than handling basic applications like phone calls, emails, texting, and video sharing. They are expected to run data-intensive and compute-intensive applications such as face recognition software. Users' desired quality of service and experience and resource limitations at the end device will warrant computation offloading to the cloud.

Cloud offloading can be interpreted as (i) data flow offloading in networking applications [8] or (ii) offloading computationally intensive tasks to the cloud [33] or mobile edge devices [67], a self-managing data center in the layer of network infrastructure [53]. The focus of this chapter is on computation offloading to the cloud. State-of-the-art techniques in spectrum-aware mobile computing in this context are presented.

Mobile computation offloading techniques can be classified along four axes as shown in Fig. 1 based on (i) radio access technology (RAT), (ii) time adaptability, (iii) scheduling order of application components, and (iv) extent of offloading. RAT strategies for wireless-aware computation offloading are presented for single-RAT devices (section "Spectrum-Aware Offloading Using Single-RAT Devices") and multi-RAT devices (on/off networking is addressed in section "Spectrum-Aware Cloud Offloading Using On/Off Multi-RAT Networking", and cognitive networking is addressed in section "Spectrum-Aware Cloud Offloading Using Cognitive Networking"). The second classification is based on flexibility of mobile computing

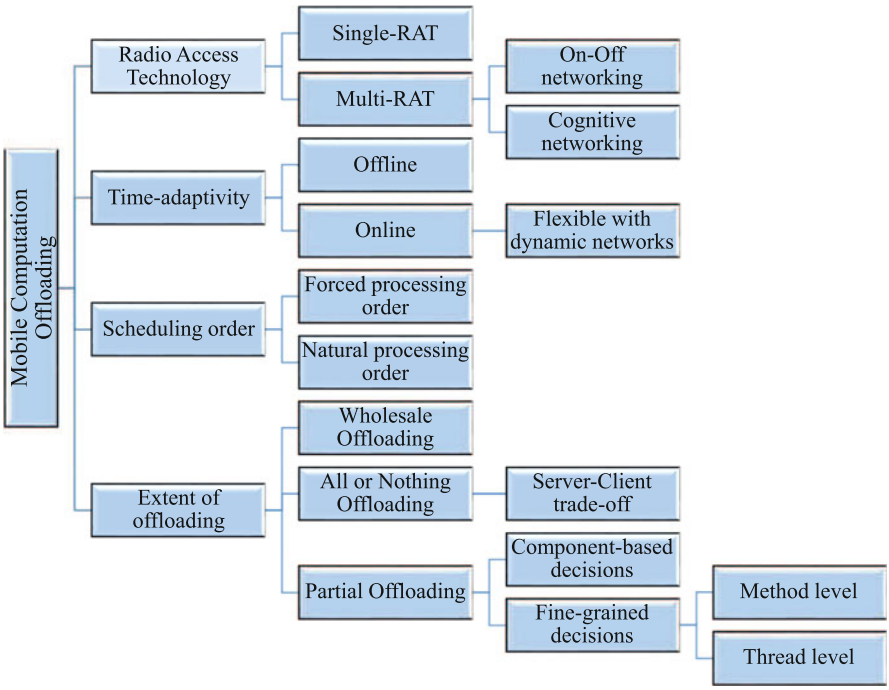

Fig. 1 Classification of mobile computation offloading

techniques with either static variations of wireless network parameters (offline strategies) (sections "Offline Approach", "Offline Approach", "Offline Approach") or dynamic variations of wireless network parameters (online strategies) (sections "Online Approach", "Online Approach", "Online Approach"). The third classification is based on the schedule order of component tasks for spectrum-aware computation offloading – trivial order or nontrivial order. In trivial ordering, the application components are scheduled in a sequential order computed either arbitrarily or based on the compiler-generated call graph. In nontrivial ordering, a sophisticated schedule is computed that allows for simultaneous processing of components on the mobile and the cloud while maintaining the integrity of the application (section "The Effect of Spectrum-Aware Scheduling in Mobile Computing"). Finally, the extent of offloading can be either complete offloading, all-or-nothing offloading, or partial offloading. This chapter focuses only on partial offloading. Hence the different extents of offloading are briefly discussed below.

Extent of offloading: Mobile computation offloading can be classified into three types: (1) complete offloading, where everything is offloaded for remote execution [31, 56]; (2) all-or-nothing offloading, where the required computations for the mobile app are totally offloaded to a cloud server, or everything is

processed in the mobile device [62]; and (3) partial offloading, where the app is partitioned into smaller component tasks, and piecewise decisions are made for individual tasks to be executed either in the mobile device or in the cloud [4, 11, 26, 27, 35, 55].

Partitioning the mobile apps for partial offloading strategies can be divided into two groups: (1) coarse-level partitioning of the applications where the code is pre-partitioned into components [4, 20, 35, 60]; (2) fine-grained offloading using method-level partitioning like MAUI [11] and ThinkAir [26]. ThinkAir focuses on scalability issues and parallel processing of offloaded tasks using multiple virtual machines (VMs). Mobile Augmentation Cloud Service (MACS) [27], which provides an Android service-based mobile computing middleware, allows for seamless offloading of the application component tasks to the cloud. COSMOS [55] is also a new offload platform where fine-grained partial mobile computing of sequential tasks is performed as a service.

Partial offloading can provide more efficient spectrum-aware mobile cloud offloading strategies because decision, for each component task, on whether to offload or execute on the mobile is dynamic with the wireless network parameters such as delay, offloading energy consumption, and queue backlog [4, 11, 26, 27, 35, 55, 65]. The decision for either offloading a component task or executing it on the mobile device can be considered based on the following objectives: minimizing the battery consumption by the mobile device, providing shorter runtimes for the execution of sophisticated mobile apps, and efficiently using the limited spectrum for offloading. Although partial offloading reduces computational burden on the mobile device, it adds to the communication cost on the networks. Therefore, in order to fully harness the power of partial cloud offloading, the resource constraints on the mobile device should be addressed jointly with the recent trends in wireless networking.

For the above reasons, only partial offloading is considered in this chapter. Hence the current research literature in spectrum-aware mobile cloud offloading can be schematically presented along only three axes as shown in Fig. 2.

The existing work can be represented along three axes, namely, the radio access technology (R-axis), time adaptability (T-axis), and scheduling order (S-axis). All the research contributions indicated in this schematic figure are discussed in the following sections. Most of the prior existing work only concerns the radio technology and time adaptability with a predetermined scheduling order (on the R-T plane). The work in [34] was the first to introduce work along the S-axis and the R-T-S-space (addressed in section "Joint Scheduling and Computation Offloading in Time-Adaptive Cognitive Networks").

The rest of this chapter is organized as follows. Section "Spectrum-Aware Cloud Offloading Using Cognitive Radios (Offline/Online Scenarios)" presents the work in the R-T plane. Section "The Effect of Spectrum-Aware Scheduling in Mobile Computing" presents the work along the S-axis. Section "Joint Scheduling and Computation Offloading in Time-Adaptive Cognitive Networks" discusses the work in the R-T-S-space. Finally, section "Summary and Future Directions of Spectrum-Aware Mobile Computing" concludes with future directions.

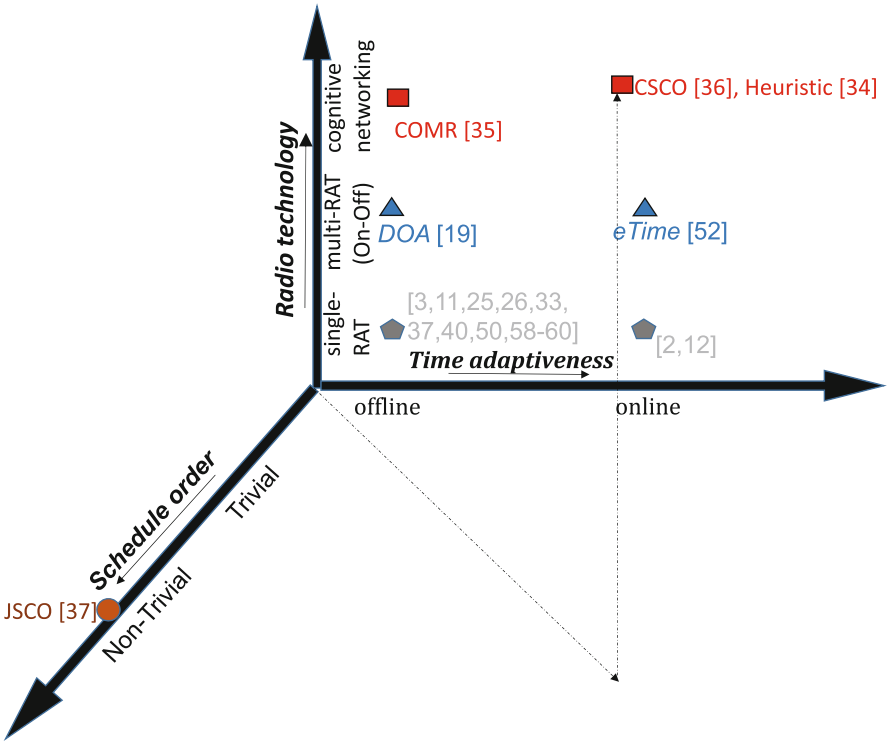

Fig. 2 Schematic of the spectrum-aware mobile computing schemes in context of the state of arts

Spectrum-Aware Cloud Offloading Using Cognitive Radios (Offline/Online Scenarios)

Multiple radio access technology (multi-RAT) is increasingly being supported by mobile devices of today. For example, current iPhones use multipath TCP to create backup connections for iOS [38], and Samsung phones combine WiFi and LTE to provide Gigabit mobile services [45]. Also, exploiting multiple radio interfaces in mobile heterogeneous networks (HetNets) and next-generation cellular networks is necessary to utilize maximum achievable network capacity [24]. Several approaches can be used for multi-RAT networking such as carrier aggregation (CA) and channel bonding (CB) [23, 24, 49]; multipath TCP (MPTCP) protocols that simultaneously access multiple networks [30]; using proper strategies for network selection, which is to select the best network for various communications at any time anywhere [59]; dynamic switching with heterogeneous channels [14]; and concurrent transmission of multi-array antennas [3].

Nowadays, different techniques for aggregation of wireless radio interfaces have been introduced. However, multiple overlapping exists as a main problem in primary

channels (say WiFi) and also uncoordinated frequency bands (e.g., 802.15.4 that uses 2 MHz). Dynamic carrier aggregation between licensed and unlicensed carriers is a technique for multi-RAT networking that has been addressed in [24]. Carrier aggregation is also addressed in [49] where the reference signal design for uplink transmission is based on selections of best combination of distinct sequences and cyclic shifts in each carrier. In [59] the utility function for *network selection* is based on multiple attributes, including bandwidth [21,40], cell radius [28], security [7], battery [51], SNR/ SIR [57], price [40], hand-off failure probability [19,25], data traffic [29], power consumption [1,21], BER [57], delay [28,47], and packet loss and jitter [5]. Another solution for muti-RAT networking is opportunistic channel switching that allows a link to dynamically search for a channel. This technique maximizes the real-time system performance among heterogeneous channels [14].

The emerging technology of cognitive networking is the appropriate solution in the cloud offloading scenario where there is a need for offloading computationally intensive parts of the applications to a resource-rich cloud. Cognitive cloud offloading is a new concept (introduced in [34]) where the computational cloud offloader decides which radio interfaces must be used in the associated data transfers and what percentage of the data should be communicated through each interface, as well as which components of a sophisticated multicomponent application should be offloaded and which should run locally. Cognitive networking and using all the viable networks simultaneously for cloud offloading lead to a higher throughput of the network.

An example of a complex multicomponent mobile application, that is computed through offloading, is shown in Fig. 3. This application consists of ten components, and the dependencies between the components are indicated. A cloud server, such as NSFCloud or Amazon Elastic Compute Cloud (Amazon EC2), is used for cloud computing, scheduling the tasks, and aggregating of the data related to the computations from all the networks. A mobile device with K radio interfaces (networks) is used. In the uplink scenario, at time slot t, $\alpha_k(t)\%$ of the required data for offloading is sent by the mobile device through radio interface k. Similarly in the downlink scenario, $\beta_k(t)\%$ of the data is sent by the cloud to the mobile device using radio interface k $\forall k$. The goal is to find an online scheduling-offloading policy for all components as well as the optimal wireless resource allocation between the multi-RAT networks for two-way data transfers between mobile and cloud.

This section elaborates on research in the R-T plane in the schematic presented in Fig. 2. The R-axis indicates wireless-aware cloud offloading using single radio interface, multiple radio interfaces, and cognitive networking. The cloud offloading algorithms are developed either for single radio access technology (single-RAT) or multiple radio access technology (multi-RAT) devices. Multi-RAT-enabled mobile devices increase the capacity for offloading [30]. In multi-RAT networking, there are two options: the wireless interfaces are used in either an on/off mode or a hybrid mode. In the on/off mode, only one network is offloading at a time, whereas in the hybrid mode *cognitive networking* is applied for cloud offloading.

Recall that offloading with single network can be done using single channel or multiple channels. The multi*channel* single-RAT scenario is totally different from

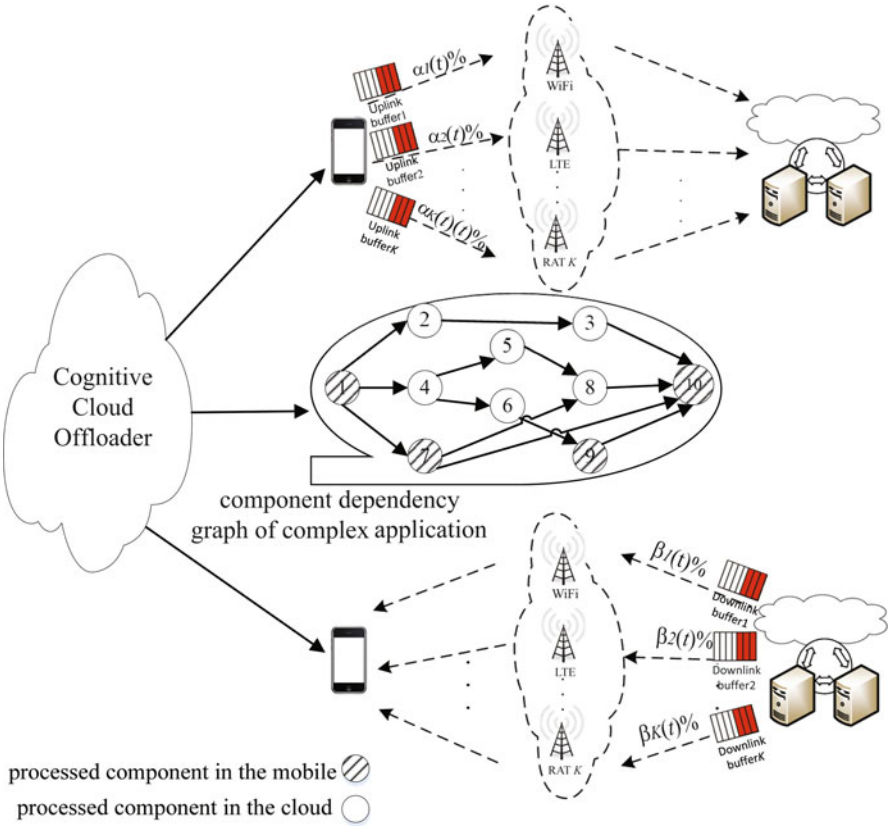

Fig. 3 Cognitive offloading for multi-RAT-enabled wireless devices

the multi-*RAT* scenario. The parameters of *channels* (path characteristics such as rate and delay) in the same radio network vary widely in comparison with radio interfaces such as WiFi and LTE supported by multi-RAT-enabled devices [48]. On the one hand, a multi-RAT system is transparent to underlying wireless network and technology. On the other hand, it makes coarse decision on offloading computation of components from one radio to another unlike multichannel approach which does provide fine grain decisions between different channels. A multi*channel* partial offline offloading solution was proposed in [4] for queue stability. The extension of [4] to joint allocation of transmit power in single and multichannel scenarios in single-RAT devices was studied in [13].

Partial cloud offloading for mobile applications with predetermined compiler-generated call graphs is expressed jointly with allocation of transmit power level, and the constellation size of OFDM subcarriers used for offloading in [13] such that the constraints of latency, packet loss, and execution time are satisfied. The authors of [13] then extended the wireless communication environment of their work to MIMO multiple system where multiple mobile devices demand cloud

offloading [52]. However, decision making is on the CPU cycles/second assigned for the computations on each mobile device by the cloud rather than offloading strategy.

The time (adaptiveness) axis (T-axis) in spectrum-aware cloud offloading indicates that the existing offloading techniques are classified based on offline or online techniques. In the offline approach, the offloading decisions are static and done at the start of processing. In the online approach, the offloading decisions are dynamic and are made on the fly [18].

The research represented in the $R-T$-plane is divided into six categories: (1) offline offloading strategies using single-RAT for networking; (2) online offloading strategies using single-RAT for networking; (3) offline offloading strategies using on/off multi-RAT for networking; (4) online offloading strategies using on/off multi-RAT for networking; (5) offline offloading strategies using cognitive networking; and (6) online offloading strategies using cognitive networking. These 6 classes are discussed below.

Spectrum-Aware Offloading Using Single-RAT Devices

Offline Approach

The offline (static) offloading strategies using single radio includes classic computation offloading approaches such as MAUI [11]. MAUI presented an offline fine-grained partial offloading strategy using WiFi network for communication. This energy-efficient strategy provides minimum burden on the programming support for implementation. It specifies which methods must be offloaded to the cloud using WiFi RAT under the mobile's wireless connectivity constraints at runtime and which methods must be processed in the mobile device. This fine-grained partial offloading scheme maximizes the energy savings. MAUI achieves these advantages using some properties of current code environments for mobile apps as follows:

1. Code portability is used to provide two versions of a mobile app in the infrastructure, one for mobile execution and another one for cloud execution; this flexible code provides adaptability in the instruction set architecture between the mobile app and the cloud servers.
2. Programming reflection is combined with safety to enable the offload scheduler to automatically identify the offloadable methods (tasks) and extract only the program state needed by those methods.
3. Each method of the mobile app is profiled, and *serialization* is used for method processing.

In this work, resources are managed based on the wireless connectivity (bandwidth and latency) using a linear programming formulation of the computation offloading problem. The authors have tested their strategy using several apps including a computationally intensive face recognition mobile application for the specific purpose of energy minimization and a delay-sensitive arcade game application. Other related work on offline single-RAT computation offloading include [2, 26, 27, 33, 36, 41, 55, 62, 63, 66].

In [41], an offline offloading policy is proposed to minimize the energy consumption of the mobile device with overall application deadline constraints. A more precise algorithm for individual deadline constraints on application tasks is also mentioned in [2]. A partial offline computation offloading scheme is used in [54] where a predictive algorithm is used for wireless connectivity. Here, a risk control strategy is used to make the prediction analysis more reliable.

Online Approach

Online (dynamic) computation offloading is fundamentally influenced by instantaneous changes of the data rates, latency, communication power, and buffer queuing at the radio interface. A partial dynamic offloading for frame-based tasks with response time guarantees from the cloud servers is studied in [58]. The server estimates the response time for remote execution of each task based on total bandwidth server model. Also a fault-tolerant strategy for online partial cloud offloading of the mobile applications with sequential component dependency is proposed in [12] such that the trajectory of mobility of users is modeled by random waypoint (RWP). In this fault-tolerant strategy, there is a trade-off to balance waiting for reconnections and restarting failed services from beginning.

Spectrum-Aware Cloud Offloading Using On/Off Multi-RAT Networking

Computation offloading strategies using multi-RAT networking [20, 35, 56] have recently gained interest because of the new features and capabilities in cognitive radio networking [68] and wireless HetNets in the 5G evolution. In the classic multi-RAT offloading [20,56], only one of the radio interfaces, which has the best wireless characteristics, will be selected for offloading. Thus, these schemes use an *on/off* selection model for the networks.

Offline Approach

A classic energy-efficient partial computation offloading algorithm using on/off multi-RAT networking was proposed in [20]. The main objective of this work is to reduce the communication costs (energy and delay) between the mobile device and the cloud server while guaranteeing the given application runtime. Note that although this algorithm works in offline mode, it assumes that the viable wireless networks change over time depending on the current location of the mobile device. However, during the runtime of the application, the parameters of available wireless networks are assumed to not change. Huang et al. [20] considers that cellular network is accessible everywhere while WiFi network is available only in special places. When two networks are available, the controller in the mobile device selects the best RAT based on the higher data rate before making decision on offloading. The offloading decision is obtained based on minimization of the energy consumption by the mobile device (the energy consumed for mobile execution of local tasks of the app plus the energy consumption in the idle mode due to offloading

plus the energy consumed for offloading). The constraints of this optimization problem are designed such that the maximum number of computation requests would not violate a given threshold, and the system stability will also be guaranteed. Lyapunov optimization is applied to solve this problem.

Online Approach

A wholesale offloading strategy is addressed in eTime [56] based on energy and delay trade-off. Although the authors assume a multi-RAT device, only the *best single* wireless interface is used for offloading. This work proposes a strategy for **E**nergy-efficient data **T**ransm**I**ssion from the cloud to **M**obile d**E**vices (eTime) such that online decisions are made for time-adaptive scheduling of the data communication based on wireless connectivity between the two entities. eTime strategy uses the online information of data traffic to specify the amount of data to be transmitted at the current time such that jointly the energy consumed by the mobile device for communication is minimized and the queue of ambient data traffic is stabilized. Therefore, an energy-delay trade-off algorithm was designed to solve the problem using Lyapunov optimization technique. To test the proposed strategy, the authors considered ten applications running in the cloud with specific data-arrival distributions, and the corresponding data of applications were transmitted to the mobile devices based on the current online connectivity through WiFi and cellular networks. The implementation results show that using the eTime strategy, 20–35% less energy was consumed by the mobile device in comparison to a random strategy, where the user may run applications on the mobile device and request data in a random time slot, and the data are offloaded instantly from the cloud to the mobile user without wireless connectivity prediction.

Spectrum-Aware Cloud Offloading Using Cognitive Networking

Offline Approach

Cognitive cloud offloading was first considered in [35] for multi-RAT devices, where all viable networks are simultaneously used to offload. An optimal one shot solution (in offline mode) is used to obtain the percentage of data over each wireless interface. In previous multiple radio-aware computation offloading strategies, including [20], the best of the available wireless interfaces was selected (only one of the wireless interfaces) for computation offloading, rather than a strategy that addresses using all viable radio interfaces simultaneously. In [35], the associated data transfer was optimized over all viable networks at the mobile device transmitter in uplink (not at the cloud transmitter end in downlink scenario). This work assumes one best radio interface for downlink data transfer. The optimization of radio resource allocation for cognitive networking in downlink was addressed in a later work [34]. They also assume that the application components are processed in a predetermined manner like [11, 20].

A comprehensive model is proposed in [35] for energy consumption by the mobile device to run the application component task i, given as $E_i = E_i^{(\mathrm{m})} + E_i^{(\mathrm{c})} + E_i^{(\mathrm{com})}$, where $E_i^{(\mathrm{m})}$ ($E_i^{(\mathrm{c})}$) is defined as the energy consumed by the mobile device to run component i in the mobile (cloud), and $E_i^{(\mathrm{com})}$ is defined as the energy consumed by the mobile for data transfer of component i between cloud and mobile. The energy consumption for mobile execution of component i is expressed as $E_i^{(\mathrm{m})} = (1-I_i)P_{\mathrm{ac}}^{(\mathrm{m})}(i)q_i^{\mathrm{m}}$. I_i is the execution place indicator, assigned 1 if component i is offloaded to the cloud and assigned 0 if processed on the mobile device, $P_{\mathrm{ac}}^{(\mathrm{m})}(i)$ is the power consumed by the mobile device when it is actively processing component i, and q_i^{m} represents the time to process component i in the mobile device. If the component should be offloaded, then the mobile device will spend the idle power for the duration of this execution. The energy consumption by the mobile device when component i is being remotely processed is $E_i^{(\mathrm{c})} = I_i P_{\mathrm{id}} q_i^{\mathrm{c}}$. P_{id} shows the power consumed by the mobile in the idle mode, and q_i^{c} presents the time to process component i in the cloud. $E_i^{(\mathrm{com})}$ comes into play when either the component immediately preceding the component i or immediately succeeding component i is executed in the other entity. $E_i^{(\mathrm{com})}$ is the energy consumed by the mobile device for associated data transfer between the cloud and mobile. $E_i^{(\mathrm{com})}$ represents (1) the energy consumed in transmitting or receiving the relevant data and (2) the idle energy consumption when the relevant computations are being transferred to the cloud (different from $E_i^{(\mathrm{c})}$, which shows the idle energy consumption by the mobile device while component i is running in the cloud). The time to transfer data in the downlink and uplink scenarios are respectively given by $\tau_{ij,k}^{(\mathrm{cm})} = \frac{d_{ij}}{R_k^{(\mathrm{d})}}$ and $\tau_{ij,k}^{(\mathrm{mc})} = \frac{d_{ji}}{R_k^{(\mathrm{u})}}$, where $R_k^{(\mathrm{d})}$ and $R_k^{(\mathrm{u})}$ are the downlink and uplink rates on radio interface k. d_{ij} is the data size that must be transferred from component i to j.

The optimization problem is formulated to minimize the overall energy consumption by the mobile device in processing a sophisticated, multicomponent application under three constraints.

$$\min_{\boldsymbol{\nu},\boldsymbol{I}} E \triangleq \sum_{i=1}^{M} E_i, \tag{1}$$

where M shows the number of components in the application, $\boldsymbol{I} = [I_1 I_2 \ldots I_M]$, $\boldsymbol{\nu}$ is a matrix with entries $\nu_{i,k}$, $\forall i,k$, and $\nu_{i,k}$ is the percentage of data upload using radio interface k, for execution of component i in the cloud. The constraints are given as follows: (1) deadline on the runtime of the application; (2) flow rate control on each network used for cloud offloading; and (3) the overall value of data percentage allocated to the network interface for each offloaded component.

The constraint on the runtime of application is given as

$$\sum_{i=1}^{M} T_i \leq T_{\text{req}}, \tag{2}$$

where T_{req} is the deadline of the application, $T_i = T_i^{(\text{m})} + T_i^{(\text{c})} + T_i^{(\text{com})}, \forall i.\ T_i^{(\text{m})}$, $T_i^{(\text{c})}$ represent the time taken for component i to execute in the mobile device and cloud, respectively, and $T_i^{(\text{com})}$ is the time taken to complete the necessary data transfer for execution of component i. The detailed formulation of these variables is presented in [35]. A solution to the optimization problem indicates where each component should be processed, in the mobile device or in the cloud, and what percentage of data must be allocated to each radio link for necessary uplink data transfer.

In order for the cognitive network model to be stable, the transmit data rate on the radio interfaces must be less than the service rate of each radio interface. Moreover, the overall data allocations to the radio interfaces for each component must sum up to the total data that needs to be transferred. Since this optimization problem is nonlinear and hence computationally intractable, an iterative algorithm that converges to a local optimum is also proposed. Simulations show that the proposed iterative algorithm performs very close to the optimal solution for a significant reduction in complexity.

Online Approach

While [35] was an offline offloading strategy, an online dynamic strategy for cognitive offloading was presented later in [34]. The online strategy addressed both uplink and downlink scenarios and also considered a joint scheduling-offloading policy for applications with arbitrary dependency constraints between components of an application. Moreover, an optimal solution is proposed in [37] for online joint cognitive scheduling and cloud offloading discussed in section "Joint Scheduling and Computation Offloading in Time-Adaptive Cognitive Networks".

The Effect of Spectrum-Aware Scheduling in Mobile Computing

Scheduling of application tasks is studied in [2] and *eTime* [56] where a predetermined compiler-generated order of execution for the application components is used, and all the component tasks are offloaded for cloud execution. *eTime* explores an energy-delay trade-off in scheduling the required data transmissions for wholesale offloading such that offloading is done when the wireless connectivity is sufficiently good. Efficient computing for mobile applications requires spectrum-aware scheduling of the tasks particularly for apps with general arbitrary dependency constraints between components rather than sequential schedule order or predetermined compiler-generated schedule order. Since computation offloading

strategy relies on the task scheduling decisions for the application components, this spectrum-aware scheduling must be considered jointly with the offloading policies.

A joint optimal scheduling and partial offloading solution for sophisticated apps in single-RAT-enabled mobile devices was proposed in [36] where a net utility function was maximized to provide a trade-off between the battery energy saved in the mobile device and the communication costs involved in the offloading. The constraints of the formulation accounted for the precedence ordering for task execution of the application components, the overall execution runtime of the application, and parallel execution of an application between the mobile device and the cloud server. Note that *the accommodation of parallel processing reduces the time to complete the application significantly*. Therefore, efficient task scheduling of the application components in addition to partial cloud offloading decisions provides a more comprehensive solution in comparison with the partial offloading strategies using a predetermined compiler-generated schedule order for processing the individual application components.

Most of the related work on partial computation offloading address mobile applications with forced sequential component dependencies or a scheduling order which is predetermined by a compiler. However in real-life scenarios, applications may have arbitrary dependency constraints between their components. Therefore, efficient strategies for *joint scheduling-offloading* policies must address wireless network aware scheduling order of the components based on the topology of component dependency graphs (CDGs) between the components of the mobile applications.

Component dependency graphs (CDGs) of mobile applications considered in [36] are assumed to have the following properties:

1. All the components, except the first component, must have an in-degree of at least 1.
2. Each component, except the last component which corresponds to the output, must have an out-degree of at least 1.
3. Every component must have at least 1 path from the first component, directly or indirectly. This shows that all the components are dependent on the starting point of the application.
4. Each component must have at least 1 path to the last component. This shows that all the components collaborate in processing the app.
5. There is no self-dependency in the CDG, that is no component must depend on itself. The component dependencies can be represented using an adjacency matrix where entry (i, j) is 1 if component j depends on component i and 0 otherwise.

Since self-dependencies are not allowed, the diagonal entries of the adjacency matrix are all 0.

The sequential and parallel dependency graphs present the two extreme level of dependencies between components. These two CDGs can, therefore, be used

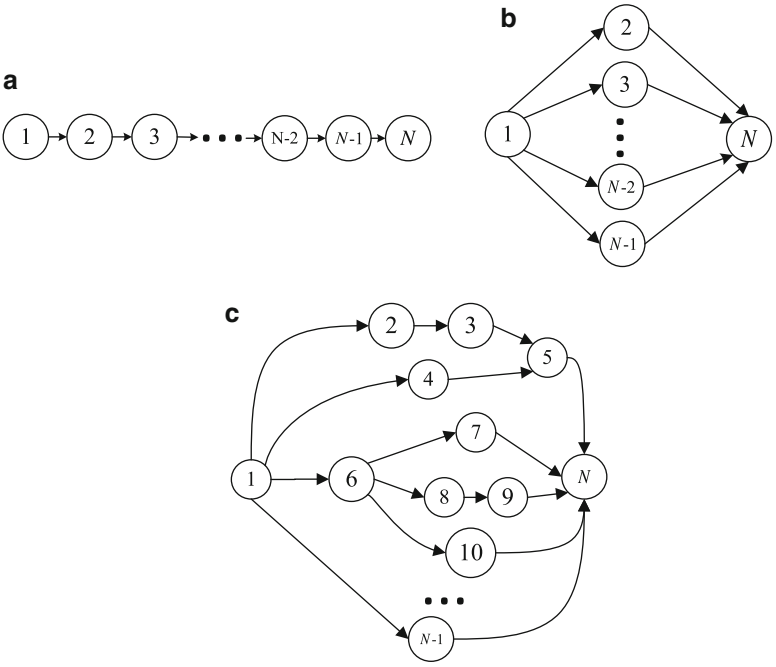

Fig. 4 Examples of various topologies for CDGs of the mobile applications with N components. (**a**) Sequential CDG. (**b**) Parallel CDG. (**c**) Arbitrary CDG

to achieve the upper and lower bounds for the cost of offloading applications. Figure 4 shows different types of CDGs for an N-component application (N=10): (i) sequential dependency graphs where all the components are sequentially dependent (Fig. 4a); (ii) parallel dependency graph where component 1 must be executed before all the other components, and component N must be executed after all the other components (Fig. 4b); and (iii) arbitrary dependency graph, a special class of precedence constraints, where there is a combination of sequential and parallel dependencies between components.

A scheduling scheme for partial cloud offloading is discussed in [66] for a sequence of fine-grained tasks with serial CDG (Fig. 4a) that guarantees the application runtime. A partial mobile offloading strategy based on probabilistic estimations of the offloading effectiveness is proposed in [15] for a variety of mobile applications with serial CDGs. To determine the offloading effectiveness, a semi-Markov framework is used where runtime heterogeneity of application execution characteristics is taken into account. Existing component-based partial cloud offloading strategies use a predetermined compiler-generated serial order that does not lend itself to parallel computation of components in the mobile device and cloud (DOA [20] and MACS [27]). In [4], sequential scheduling of the components is studied in both single-channel and multichannel radio links. The objective is minimization of the energy consumption in the mobile device

while meeting the delay constraints of the application. Another scheduling strategy, designed for energy minimization in a multiuser network, is presented in [41], where a centralized broker partially offloads tasks to the cloud in a serial order. In their work, a centralized strategy is investigated to offload the tasks in two hops where the broker is an intermediary between the mobile user and the cloud. However, the scheme in [36] determines the scheduling decision as well and therefore affords parallel computation of components.

In comparison with the state of the art, joint scheduling and cloud offloading strategies such as [36] have several benefits. These strategies combine computation offloading and task scheduling in the presence of arbitrary component dependencies (precedence constraints between app components) such that parallel execution of components will be possible between the mobile device and the cloud. To achieve this multi-term objective, a holistic optimization problem is solved in [36] for real mobile applications that guarantees deadline for application runtime, ordering of task execution for individual components, and saving of battery energy in the mobile device. The authors of [36] introduced the first energy-efficient joint scheduling and cloud offloading scheme for mobile users running applications with arbitrary component dependency graphs. Earlier state-of-the-art techniques consider either trivial serial ordering of the components or a predetermined compiler-generated ordering, leading to less adaptability with wireless conditions. In [36], real data was measured from an HTC smartphone using real and randomly generated mobile applications, WiFi network was used for partial offloading, and Amazon Elastic Compute Cloud (EC2) was used for remote processing of the application components. The optimal solution is obtained under these real data measurements using IBM CPLEX optimizer [10]. This strategy is analyzed and tested by varying several parameters: the number of application components (up to 150 components), topology of application component dependency graphs (CDGs), application runtime, and wireless parameters such as rates, latencies, and data sizes. The results show that the proposed JSCO reduces energy consumption by 54, 37, 16, 30, and 11% compared to local execution, remote execution, DOA [20], HELVM [43], and RHJS [32], respectively.

Joint Scheduling and Computation Offloading in Time-Adaptive Cognitive Networks

Online cognitive cloud offloading strategies make it possible to realize a more realistic spectrum-aware mobile computing that accommodates (1) arbitrary dependencies between the component tasks of the applications (as opposed to the predetermined schedule order) and (2) online strategies that adapt to the dynamic changes in the mobile networks over time.

The first work in this area of cognitive cloud offloading, [35], proposed an offline optimal solution for applications with predetermined schedule order considering multiple wireless network parameters. Then, a joint scheduling and computation offloading (JSCO) solution was proposed that allows for more degrees of freedom in

the solution by moving away from a predetermined compiler-generated scheduling order for the components toward a more component dependency aware scheduling order [36]. However, this work uses a single-RAT offloader and applies fixed wireless parameters for making decision on offloading and scheduling in the offline mode.

In [34,37], authors move to a more realistic and comprehensive extension of the problem, where an optimal *online* solution (adaptive to changing wireless network parameters) is obtained for applications with *arbitrary component dependencies* over *multi-RAT*-enabled mobile devices. This is indicated schematically, in the context of the existing works in this area, in Fig. 2.

In [34], heuristic strategies are proposed to jointly schedule the application's component tasks for processing and simultaneously optimizing the percentage of the associated data for transferring by the mobile device in uplink and the cloud in downlink via each mobile network. A holistic multi-term net utility function is defined that trades-off costs of resources (energy, memory, and CPU) of the mobile device with the communication costs of offloading including the communication energy and the data queue length at the multiple radio interfaces. Moreover, the offloading strategies for transmission, at the mobile and cloud, use past mobile network data history, queue status, and the current data flow to update the current queue status.

Mahmoodi and Subbalakshmi [34] is implemented in two ways: (i) a fast algorithm with two stages where some of the components are eliminated as unsuitable for offloading at the outset and maximizing the instantaneous utility values in the offline mode (first stage). In the second stage, the selected components for online offloading will be verified for scheduling constraints. (ii) a single stage algorithm (with more complexity but closer to the optimal solution in performance) where all the components are verified for offloading in the online mode. The notations used for the parameters in this work are defined in Table 1.

Consider a scenario as in Fig. 3 where there are K radio interfaces in a wireless network, and a multicomponent app is running on a mobile device with N number of task components. The objective of the algorithm in [34] is to provide an online cognitive offloading and scheduling strategy and an allocation of wireless resource among the multi-RAT interfaces for data transfers of both the uplink and downlink scenarios. Figure 3 shows that at time t, $\alpha_k(t)\%$ of the data for computation offloading is uploaded by the mobile user through network link k. Similarly, $\beta_k(t)\%$ of the data is downloaded from the cloud through network link k. The authors of [34] assume that the battery power and the time required to transfer data between components that are processed in the same place (cloud or mobile device) are negligible in comparison to when the data must be transferred between the mobile device and the cloud. Also, another assumption is that the cloud and the mobile clocks are synchronized (as thoroughly discussed in [9]). Here, the cognitive cloud offloading approach makes a balance in the benefits of cloud execution such as energy and time savings on the mobile device with the costs of cloud offloading including the energy and delay values involved in the associated data transfer. Based on this determination of balance, simultaneous decisions are made on the optimal

Table 1 Parameter definitions

Parameters	Definitions
$A_k^{\mathrm{mc}}(t)(A_k^{\mathrm{cm}}(t))$	Data rate transmitted from the mobile (cloud) to the cloud (mobile) through radio interface k at time slot t
$B_i^{\mathrm{mc}}(t)$ $(B_i^{\mathrm{cm}}(t))$	Arrival data rate at the mobile (cloud), including the ambient traffic as well as the data generated by offloaded component i (arrival data in time slot t)
$c_i(t)$	Indicator function that takes on a value of 1, if the component i has started execution in the cloud at any time between 1 and t
code_i	Code size to launch component i
$E_{\mathrm{com}}^{\mathrm{Tx}}(t)$	Energy consumed for the mobile transmission due to cloud offloading
$I_i(t)$	Offloading indicator: 1 if the mobile starts to offload component i at time slot t
K	Number of wireless radio interfaces
$l_{ji}(t)$	The time slots to process the preceding component j and transfer the output data from component j to i by t
M_i	RAM memory consumed by the mobile device to launch component i
$m_i(t)$	Indicator function that takes on a value of 1, if the component i has started local execution at any time slot between 1 and t
N	Number of components in the application
P_i^{m}	Power consumed by the mobile device when it is actively processing component i
$P_k^{\mathrm{Tx}}(t)$	Transmit power consumed by the mobile device through radio interface k at time slot t
$Q_k(t)$	The transmission queue of data from the mobile (cloud) side for wireless interface k at time slot t
q_i^{m} (q_i^{c})	Number of time slots to process component i in the mobile (cloud)
T	Number of time slots to complete processing the application
$T_{\mathrm{th}}^{\mathrm{Tx}}$	Threshold number of time slots for transmission from mobile to cloud
$U(t)$	Net utility function at time t
V_{mc}	Control parameter in mobile (cloud) transmission for Lyapunov optimization
w_x	Weight factor of function x
$X_i(t)$	Local execution indicator: 1 if the mobile starts to execute component i locally at time slot t
$\alpha_k(t)$	Percentage of allocated uplink (mobile to cloud) rate using radio interface k for communication at t
$\beta_k(t)$	Percentage of allocated downlink (cloud to mobile) rate using radio interface k for communication at t
ε	Mapping factor to relate code size and the CPU instructions [44]
γ	Weight factor (to adjust the wait time for offloading)
μ_{ij}	Dependency indicator: 1 if component i must be processed before j and 0 otherwise
$\Omega_{\mathrm{mc}}(t)$	The objective function for mobile transmission strategy at time t
$\tau_{i,k}^{\mathrm{mc}}(t)$	Delay (in number of time slots) to transmit the output data from component i in the mobile to the cloud at interface k starting by t

percentage of the data to be uploaded and downloaded via each network link. Note that this heuristic cognitive cloud offloading strategy is managed in the cloud, and the feedback decision for offloading will be sent to the mobile user. The mobile user also sends the required information of wireless parameters (delay, rate, queue size, and communication power) to the cloud through control signaling before cognitive cloud offloading. The latency of sending data related to the wireless parameters is negligible in comparison with the computation offloading costs which may require transferring megabytes of data.

An appropriate net utility function is defined based on saving the computational resources of the mobile user and the costs of cloud offloading. To determine the heuristic decision for component task i, two variable parameters must be obtained (at each time slot t) as follows: $I_i(t) = 1$, if component task i starts offloading at t, and otherwise it is assigned 0; $X_i(t) = 1$, if component task i starts processing in the mobile device at t, and otherwise it is assigned 0. This net utility function is defined as a weighted sum of the energy, memory, and CPU cycles saved at the mobile device by cognitive offloading minus the communication costs arising from running some components locally and some remotely. This is given as $U(t) = w_{\text{saved}} E_{\text{saved}}(t) + w_{\text{memory}} M_{\text{saved}}(t) + w_{\text{CPU}} CPU_{\text{saved}}(t) - w_{\text{com}} C_{\text{com}}(t)$. The weight factors for the benefits and costs are chosen such that $w_{\text{saved}} = 1 - w_{\text{com}}$, and $w_{\text{CPU}} = 1 - w_{\text{memory}}$. The weight factors show the relative importance of the utility functions, namely, memory saved, CPU saved, the communication costs, and battery power. The solution can be pre-biased toward different goals by setting weights appropriately. If w_{saved} is assigned a higher value than w_{com}, then it means that saving battery power at the mobile device is preferred; if w_{com} is assigned a higher value, it shows that minimizing the communication costs for cloud offloading is more important. Note that monetary costs of using cloud services could be significant; in which case, this financial cost can be incorporated into the weight factors so that offloading to the cloud is favored a little less.

The overall energy saved by executing the component tasks in the cloud at time t is computed as the energy cost for running it in the mobile device ($P_i^{\text{m}} q_i^{\text{m}}$), and is given by $E_{\text{saved}}(t) = \sum_{i=1}^{N} c_i(t) P_i^{\text{m}} q_i^{\text{m}}$, where $c_i(t) = \sum_{s=1}^{t} I_i(s)$, that is, $c_i(t) = 1$ if component i is processed in the cloud during some time slot s for $s \in \{1, \ldots, t\}$. Similarly, $m_i(t) = \sum_{s=1}^{t} X_i(s)$.

The memory saved in the mobile device by offloading the components to the cloud is illustrated as $M_{\text{saved}}(t) = \sum_{i=1}^{N} c_i(t) M_i$, where M_i is the memory consumed by the mobile device to launch component i. The number of CPU cycles saved is given by $CPU_{\text{saved}}(t) = \sum_{i=1}^{N} c_i(t)(\varepsilon(\text{code}_i))$, where code_i is the code size for instructions that is used for executing component i and ε is the mapping between code size and the CPU instructions. The communication cost at time slot t ($C_{\text{com}}(t)$) will be discussed later.

Besides specifying the components that are selected for computation offloading, the objective of this heuristic strategy is to decide on the time that each component should be scheduled for local or remote processing, and the network link allocation for offloading at each time slot for both uplink and downlink transmission. Accordingly, decision variables are (i) offloading indicator ($I_i(t)$), (ii) local execution

indicator ($X_i(t)$) for component i at time slot t, and, (iii) the percentage of allocated uplink ($\alpha_k(t)$) and downlink ($\beta_k(t)$) rates through network link k at time t.

In the heuristic algorithm, the following two scheduling constraints must be checked to see if a component is eligible for processing at the current time t: First, each component task should be executed only once, either in the mobile device or in the cloud server. This constraint is mathematically written as $m_i(t-1) + c_i(t-1) < 1$, $\forall i$. indicating component i has not started execution by time slot t. Second constraint is to ensure the precedence ordering of component tasks of the application is respected. For running component i at t, it is required that all the components j on which component i depends ($j \prec i$) should have completed processing before starting the offload process for component i or execution of component i (either in the mobile device or in the cloud). If these two constraints are guaranteed, then component i is safe to be executed.

Uplink Transmission Strategy: After the offloading component has been identified and the component is scheduled for execution, the radio allocation for the transmission from the mobile device to the cloud must be calculated. Since the proposed cognitive cloud offloader [34] works with multiple networks at the same time, the queue stability of the uplink data transmission buffers must be monitored to guarantee no buffer overflows. This is stated as follows: $\overline{Q} = \lim_{T\to\infty} \sup \frac{1}{T} \sum_{t=1}^{T} \sum_{k=1}^{K} \mathbb{E}\{|Q_k(t)|\} < \infty$, where $Q_k(t)$ is the transmission queue of radio k at time t in uplink scenario. This problem is cast as a Lyapunov optimization [39] problem. The Lyapunov function is given as $L(Q(t)) = \frac{1}{2} \sum_{k=1}^{K} Q_k^2(t)$ where $Q(t)=[Q_1(t)\ Q_2(t) \ldots\ Q_K(t)]$. When the queue of mobile transmission is updated with time, the Lyapunov drift is given as $\Delta_{\text{mc}}(Q(t)) \triangleq \mathbb{E}\{L(Q(t+1)) - L(Q(t))|Q(t)\}$. The Lyapunov drift is minimized when the cost of the energy consumed for mobile transmission is taken into account: $\Delta_{\text{mc}}(Q(t)) + V_{\text{mc}}\mathbb{E}\{E_{\text{com}}^{\text{Tx}}(t)|Q(t)\}$ [16], where V_{mc} is the control parameter for the queuing of the mobile transmission, considering the balance between the Lyapunov drift and the cost of energy consumed for transmission ($E_{\text{com}}^{\text{Tx}}(t)$), where $E_{\text{com}}^{\text{Tx}}(t) = \sum_{k=1}^{K} P_k^{\text{Tx}}(t) \sum_{i=1}^{N} I_i(t)\alpha_k(t)\tau_{i,k}^{\text{mc}}(t)$,

Following the Lyapunov optimization framework, the upper bound of the objective function must be minimized as:

$$\text{OP1}: \min_{\boldsymbol{\alpha}} \Omega_{\text{mc}}(t) = V_{\text{mc}} E_{\text{com}}^{\text{Tx}} - \sum_{k=1}^{K} \left(Q_k(t) A_k^{\text{mc}}(t)\right), \tag{3}$$

s.t.

$$\sum_{k=1}^{K} \alpha_k(t) \sum_{i=1}^{N} I_i(t)\tau_{i,k}^{\text{mc}}(t) \le T_{\text{th}}^{\text{Tx}}, \tag{4}$$

$$\sum_{k=1}^{K} \alpha_k(t) = 1, \alpha_k(t) \ge 0, \forall k, \tag{5}$$

where $\boldsymbol{\alpha} = [\alpha_1(t)\ \alpha_2(t)\ \ldots \alpha_K(t)]$. Here, V_{mc} is a control-knob parameter that trades-off wireless communication costs with decreasing the uplink communication energy ($E_{\text{com}}^{\text{Tx}}$) and satisfying the queue stability constraint for all the radios. The RHS of the objective function of the optimization problem shows the averaged aggregated queue length ($\overline{Q}$). Reducing V_{mc} emphasizes on reducing the aggregated queue length, while increasing it enforces possible minimization of the uplink transmission energy. Constraint (4) requires that the transmission time lies below a given threshold, $T_{\text{th}}^{\text{Tx}}$. Constraint (5) ensures that the amount of data offloaded at time t does not exceed the transmission capacity of all the multi-RAT interfaces taken together.

The heuristic cognitive offloading strategy (for uplink scenario) in the online stage is as follows. For every qualified component i for processing that meets the scheduling constraints, if there is a feasible solution for OP1 with variable parameter set $\boldsymbol{\alpha}$, then i is offloaded starting at time t ($I_i(t) = 1$) through K radio interfaces at the optimal percentage values $\alpha_k^*(t)\ \forall k$. If there is no feasible solution for optimization problem, OP1, then there are two options: (1) wait for the next time slot; (2) run the component in the mobile device. The difference between the current time slot t and the time slot requested for execution of component i (t_i^{req}) must be much lower than the processing time in the mobile device. This is written as $|t - t_i^{\text{req}}| < \gamma q_i^{\text{m}}$, where γ is the weight factor. If the wait time does not exceed the processing time in the mobile device for component i (q_i^{m}), then $I_i(t)$ gets 0 and the component i is left to await its turn for execution. However, if $|t - t_i^{\text{req}}| \geq \gamma q_i^{\text{m}}$, the component is sent for mobile execution in the next time slot and will not be considered for offloading again.

The transmission queue for the next time slot at radio interface k will be updated as follows: $Q_k(t+1) = \max[Q_k(t) - A_k^{\text{mc}}(t), 0] + \alpha_k(t) \sum_{i=1}^{N} B_i^{\text{mc}}(t)$, where $\max[Q_k(t) - A_k^{\text{mc}}(t), 0]$ shows the data remaining in the queue for interface k, and $\alpha_k(t) \sum_{i=1}^{N} B_i^{\text{mc}}(t)$ represents the data arrival at radio interface k in time slot t. Note that the queue is a function of percentage of allocated uplink. Also, if component i, that is originally scheduled for remote execution, is not offloaded at time t due to not finding a feasible solution for OP1, then the delay values for transmission of the output data from component i in the mobile to the cloud via wireless interface k will be updated to $\tau_{i,k}^{\text{mc}}(t+1) + 1$. Hence, after each time slot, if the scheduled component for cloud execution is not offloaded, the delay cost will be updated by the delay value at the next time slot plus one.

An optimal cognitive scheduling and cloud offloading solution is proposed in [37] that decides on the following features jointly: (1) which application components must be scheduled for offloading and which must be executed locally, (2) which radio interfaces (networks) should be used in the associated data transfers, and (3) what percentage of the associated data must be offloaded through each radio interface (Fig. 3). This work also achieves the optimal solution for online cognitive scheduling and cloud offloading strategies. While the heuristic algorithm in [34] can be implemented in the mobile device, the optimal solution in [37] is managed in the cloud, and the decision on offloading is sent to the mobile device. The mobile device sends the corresponding parameters via control signaling to inform

the cloud. A holistic optimization problem with several constraints is formulated in [37] as a time-indexed mixed-integer linear program (MILP) and is relaxed to a corresponding linear programming problem. The multi-term net utility in [37] is a combination of the cost of mobile resources saved due to cognitive cloud offloading including the energy, memory, and CPU minus the penalty for offloading. This penalty includes the energy consumed for transmission and reception, latencies due to offloading, and the data queue backlog for buffers of uplink and downlink scenarios, using all multi-RAT interfaces. The constraints of this optimization problem take into account: (1) the total deadline of the application; (2) the schedule order of the application components; (3) the percentages of data transferred with each network in uplink and downlink at each time slot; (4) the serial computation of the components for local execution where parallel processing is not feasible; and (5) the completion deadline of application components. This optimal cognitive scheduling and cloud offloading scheme is compared experimentally to the state-of-the-art techniques using real data that includes values for active power, transmission and reception powers of radio interfaces, time to process components in the mobile and cloud, uplink and downlink delays, and queue buffer lengths for wireless interfaces. The real data was obtained from an HTC vivid smartphone and two wireless networks: WiFi and LTE. NSFCloud [42] was used as the cloud server for these comparisons and measurements were taken for both indoor and outdoor environments.

This work [37] proposes a holistic approach for optimal cognitive mobile cloud offloading and scheduling in multi-RAT-enabled mobile devices where the component dependencies are kept intact for partial offloading decisions either on the mobile or on the cloud. Simultaneously, the strategy remains adaptive to the instantaneous changes of wireless network parameters under the presence of several system constraints. The implementation results illustrated that the energy consumed by the mobile device using this approach is 51, 23, 68, and 42% lower in comparison to the best-interface protocol, offline schemes, mobile-only, and cloud-only executions, respectively.

Summary and Future Directions of Spectrum-Aware Mobile Computing

Cognitive radio networking, a relatively newer paradigm in wireless networking, offers among other things a strong feature to opportunistically share spectrum. Using this technology, recent commercial wireless platforms offer bandwidth aggregation services such that the mobile user can use several wireless networks (e.g., WiFi and Cellular) simultaneously to distribute their load and achieve an aggregate throughput. SpiderRadio, a cognitive radio prototype router, developed at Stevens Institute of Technology, offers cloud controlled dynamic spectrum access and management [50]. Among other things, this router can aggregate bandwidth from multiple wireless networks in the licensed as well as unlicensed bands.

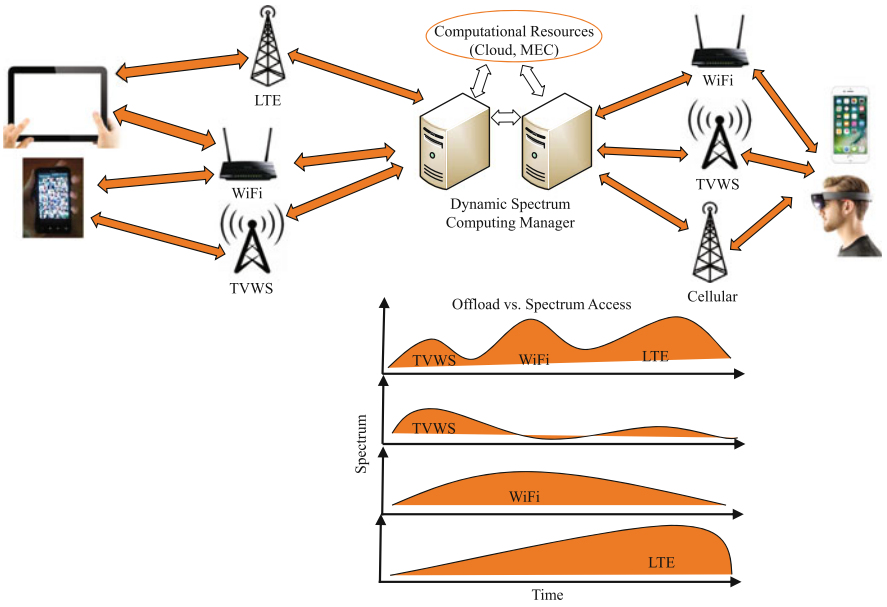

Fig. 5 Cognitive cloud offloader-spectrum manager. The future of mobile computing can apply cognitive radio networking technologies to efficiently use spectrum opportunities when offloading components to the cloud while also being able to aggregate bandwidths from appropriate wireless networks

Given these developments, the future of cloud offloading lies in a holistic approach that will be cognizant of spectrum diversity and opportunity and will be able to access more than one network at a time for offloading needs. We envisage a future as depicted in Fig. 5. The framework will be an integrated cognitive cloud offloader-spectrum manager that is categorized into two parts of dynamic computation offloader that schedules energy and radio spectrum-aware offloaders for application components and the dynamic spectrum manager that will determine spectrum management decisions adaptive with the online network parameters. Therefore, dynamic spectrum management and offloading strategies will be obtained jointly.

As detailed in sections "Spectrum-Aware Offloading Using Single-RAT Devices" and "Spectrum-Aware Cloud Offloading Using On/Off Multi-RAT Networking", there is a good body of work that considers wireless-aware mobile computing. These works have used only *single-RAT* wireless networks at a time or *multichannel* wireless (as opposed to multi-RAT network). In cases where multiple wireless networks have been used [20], the offload scheduler typically only chooses *one* of the available networks for offloading. The first *cognitive computation offloading* strategy for multi-RAT devices, where all viable wireless interfaces are simultaneously used to offload using the optimal distribution of offload data over wireless interfaces, was proposed in [35]. While this strategy was a one-shot (offline) offloading strategy, online (time-adaptive) strategies for cognitive offloading were studied in [34, 37]

where dynamic parameters for wireless environment are considered. These works also remove the assumption of a serial dependency graph and allows for an organic execution order to be determined by the spectrum-aware scheduler. This parallel processing scheme also allows for more degrees of freedom in the solution by moving away from a predetermined compiler-generated scheduling order for the components toward a more wireless-aware scheduling order. A spectrum-aware optimization problem was developed in [37] to determine the best cognitive computation offloading-scheduling policy for multi-radio-enabled mobile devices. The constraints of this offloading-scheduling scheme include overall runtime of the application, precedence of application components, percentages of associated data transfer via each radio, and completion deadline of components. Since the optimization problem is NP-hard and the system complexity will be high, an online heuristic algorithm that converges to a local optimum was studied in [34].

The preliminary results in [34, 37] are encouraging and make a case for the joint design of offloading and spectrum management. Clearly, components of applications can have more complex relationships, which might mean that parts of the program can be parallelized. Taking care of these complex relationships and parallelizing where possible in the joint scheduling-bandwidth management solutions can be expected to pay much better dividends in terms of energy costs as well as better and more informed utilization of the available wireless networks. Looking further into the future, it is possible to imagine that the spectrum-aware cloud offload manager will become spectrum-opportunistic, in the sense that the cognitive cloud offload manager will not only respond to known available wireless networks but will also actively seek spectrum opportunities at runtime to distribute the load more effectively.

Mobility models also can be incorporated to further enhance the understanding of spectrum-aware mobile computing in a mobile multi-network environment. This concept offers new research topics that guarantee promise of 5G technologies such that more resource-aware schemes and faster application runtimes will be provided. The impact of mobility in cloud offloading have been addressed recently in [4, 12, 13, 15, 22, 31, 52, 61, 66]. Some works have addressed this problem for the scenarios where centralized cloud resources are used [4, 12, 13, 52, 66], and the others considered the scenario where computations are offloaded to nearby mobile resource-rich devices (i.e., mobile edge computing (MEC) devices) [6, 22, 61]. There are open problems to be solved in considering the mobile heterogeneous networks such as achieving the capacity of mobile HetNets [24], hand-off [25, 28], impact of geographical and spectral mobility of the users [28, 46], quality of service (QoS)/quality of experience (QoE) [64], and interference between wireless radio interfaces [1].

In heterogeneous delay-tolerant networks (DTNs) (including broadcasting and unicasting routing and distributed systems), a probabilistic epidemic spreading scheme regarding the mobility of the users' neighbors is considered for data offloading [47]. In epidemic spreading, delay is analyzed under a large class of node mobility patterns in a set of fully heterogeneous Poisson processes. A mobile HetNet topology challenges the classic cellular system framework in (i) using uniform

hexagonal grid to model the base station locations (ii) using the concept that a mobile user should generally connect to the one base station providing the strongest signal, which in a HetNet is quite often not the one providing the best rate or network performance [17].

Another approach to monitor the mobility model of the users in HetNets is hierarchical interference management based on clustering and resource allocation for dense cells (especially Femtocells) [1]. In this approach, correlation clustering is used for Femtocell grouping and within each cluster, one Femto access point is elected as a cluster head that is responsible for power and subchannel allocation among the Femtocells in that cluster. Also, joint reduction of mobile data traffic and delay is investigated in [29] where different operation modes are defined depending on the popularity of the data object (e.g., those that are frequently updated such as stock information), and only popular data objects are proactively pushed to the access point to minimize the delay while mitigating the traffic load over the wireless link. A network mobility management framework is introduced in [28] to mitigate heterogeneous spectrum availability such that a target cell and spectrum band for cognitive radio users are dynamically relied on time-varying spectrum opportunities. Also a proper hand-off mechanism to minimize the switching latency at the cell boundary is discussed by considering spatially heterogeneous spectrum availability. Mobility-aware call admission control with hand-off queuing is analyzed in [25] for two vehicular scenarios: (i) when vehicle is static – a hand-off priority scheme with guard channels is studied to protect vehicular hand-off users; (ii) when vehicle is moving: no guard channels for hand-off users are allocated to maximize the channel utilization.

Offloading computations to the nearby mobile resource-rich devices such as MECs [22, 61] and fog services [6] is another research area for mobile computing that has recently been significantly developed. There are two limitations in the approach of using these cloudlets: intermittent connectivity to cloudlet and cloudlet capacity. An optimal partial offloading algorithm, considering the users' mobility patterns and cloudlets' admission control, is proposed in [61]. This algorithm is obtained by deriving the probability of successful offloading actions.

Fog computing is also a framework that uses some end-user clients or near-user edge devices for storage and offloading (rather than routed over the Internet backbone). Using the mobility characteristics, such as edge location, location awareness, and latency, Internet of things (IoT) services will be applicable in this framework [6].

Contents

Abstract

Cognitive radio networks (CRNs) emerge as a possible solution to increase spectrum efficiency by allowing cognitive radios (CRs) to access spectrum in an opportunistic manner. Although security in CRNs has received less attention than other areas of CR technology, the need for addressing security issues is evidenced by two facts. First, as for any other type of wireless network, an open

channel is used for communications that can easily be accessed by attackers. On the other hand, the particular attributes of CRNs raise new opportunities to malicious users, which can disrupt network operation. In this chapter, we provide an overview of those threats that are specific to CRNs. We classify them according to the layer in which the attacks are performed, give an insight of their impact on the network performance, and describe potential countermeasures that can be used to prevent them or mitigate their effect.

Introduction

The proliferation of wireless applications during the last years has led to spectrum shortage. Most of the frequency bands have been assigned by regulator bodies, such as the Federal Communications Commission (FCC) in the USA, to specific services that operate under license. License-free bands, such as the Industrial, Medical and Scientific (ISM) band, rapidly became overcrowded with the explosion of new technologies. However, recent studies show that many licensed spectrum bands are being infra-utilized by their legitimate users, which gives rise to usage of this spectrum in an opportunistic manner.

Cognitive radio networks (CRNs) [4] can improve spectrum utilization by allowing non-licensed users to act as secondary users (SUs) of those portions of the spectrum left unused by the licensed services or primary users (PUs), provided that no interferences are caused to the latter. With the emergence of software-defined radios (SDRs) [15], cognitive radio (CR) systems can become a reality. An SDR can be defined as a radio where transmission frequency, modulation type, and other radio frequency (RF) parameters can be configured and reconfigured by software. As a consequence, they can provide a wide range of services with variable quality of service (QoS) in order to adapt to different network technologies and to the dynamics of radio propagation. The addition of cognition capability to an SDR led to the idea of a CR, an intelligent radio capable of tuning itself based on its own perception of the spectrum availability and the environment conditions, and learn from past experiences.

Consider the network model shown in Fig. 1; a primary network is an existing network infrastructure operating with license in a given spectrum band, such as current cellular or TV broadcast networks and offering its services to incumbents or PUs. In this context, a CRN is allowed to operate in both licensed and unlicensed bands. When using the licensed band, the CRN may coexist with existing primary networks, and thus it is seen as a secondary network, where secondary users are allowed to use the spectrum in an opportunistic manner. Therefore, a CRN must perform spectrum sensing in order to identify the portions of spectrum left unused by primary networks and, among those available, select the channel with best conditions. During its operation in a given channel, a CRN must keep on performing spectrum sensing, and, whenever a primary transmission is detected in the current band of operation, it must immediately vacate the channel and switch to another one, a process known as spectrum handoff. Note that many CRN may overlap

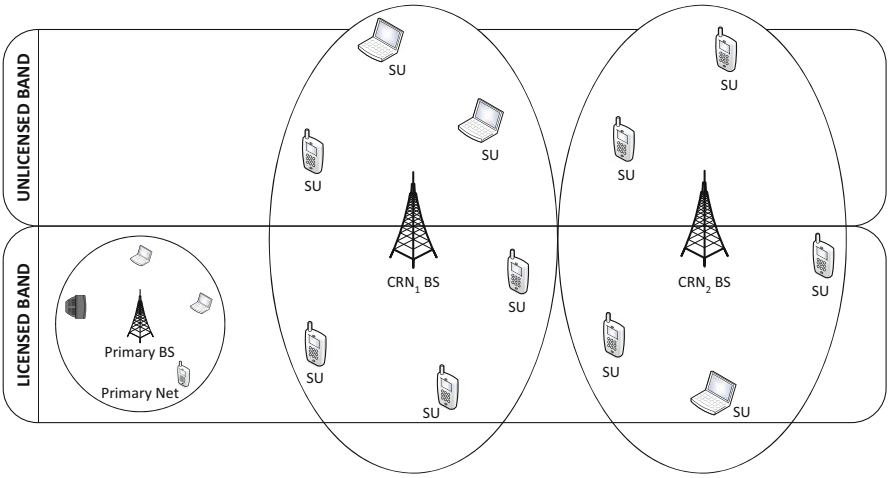

Fig. 1 CRN model

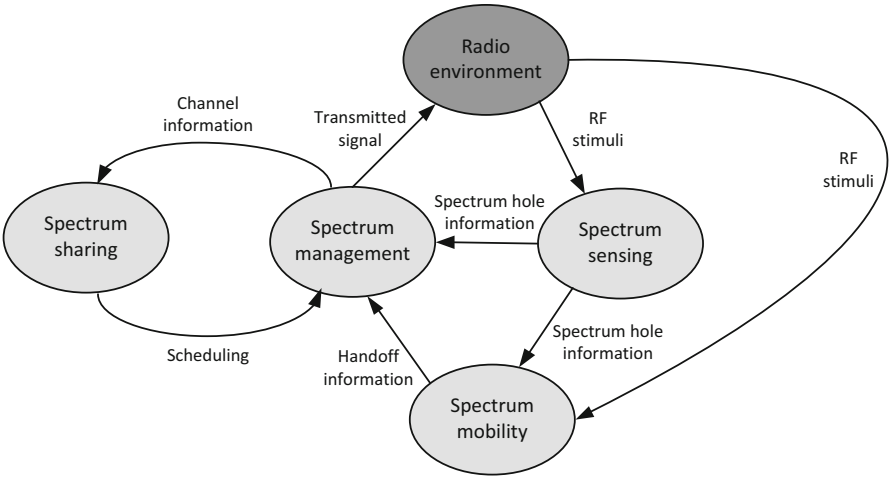

Fig. 2 Cognitive radio cycle

trying to make use of the spectrum left by a primary network, also referred as self-coexistence. As a consequence, there is also a need for mechanisms to enable coexistence among overlapping CRNs. CRs must perform several functions in order to adapt to the environment, known as the cognitive cycle (see Fig. 2):

- Spectrum sensing: it is needed to sense the medium in order to detect unused spectrum and avoid causing harmful interference to legitimate users of the spectrum.

- Spectrum management: a CRN must select the best available channel to meet user communication requirements.
- Spectrum mobility: a channel must be vacated when a licensed user is detected while maintaining seamless communication requirements during the transition to better spectrum.
- Spectrum sharing: a fair spectrum scheduling method among coexisting secondary users must be provided.

Spectrum Sensing in CRNs

Spectrum sensing mechanisms are thus indispensable to prevent harmful interferences to PUs. An SU can use several detection mechanisms in order to detect the existence of PUs [39]:

- Matched filter detection. A matched filter is obtained by correlating the unknown signal with a known signal or a template. When there is prior knowledge of the primary signal, it is the optimal detection method.
- Energy detection. In this approach the received signal strength is measured and compared to a threshold to determine if the channel is idle or not. Its performance is poor under low signal-to-noise ratios (SNRs) and cannot discriminate between signals, i.e., cannot distinguish between a primary signal and interference signals coming from other secondary users. However, it is considered the optimal detection method when there is no a priori knowledge of the primary signal.
- Radio identification-based detection. This category covers a set of techniques which are based on extracting several features from the signal such as frequency, transmission range, modulation technique, etc. One of these techniques is cyclostationary detection, which exploits the periodic properties of the received signal that cannot be found in random noise or interferences signals.

Matched filter detection and radio identification-based detection are more robust to noise uncertainties than energy detection but they are rather complex and require a significantly long observation time. Because of its simplicity and less overhead, energy detection is the most widely used technique in CRNs.

Typically, local sensing for primary signal detection can be formulated as a binary hypothesis problem as in 1.

$$x(t) = \begin{cases} n(t) & H_0 \\ h(t) \cdot s(t) + n(t) & H_1 \end{cases} \tag{1}$$

where $x(t)$ is the received signal at the SU, $s(t)$ is the PU signal, $h(t)$ is the channel gain, $n(t)$ is the zero-mean additive white Gaussian noise (AWGN), and $H0$ and

$H1$ denote the test hypothesis denoting the absence and presence, respectively, of the PU signal. Detection mechanisms are evaluated by means of two parameters: the probabilities of detection P_d and false alarm P_f are defined as in (2) and (3).

$$p_d = \Pr(\text{decision} = H_1|H_1) = \Pr(Y > \lambda|H_1) \tag{2}$$

$$p_{fa} = \Pr(\text{decision} = H_1|H_0) = \Pr(Y > \lambda|H_0) \tag{3}$$

where Y is the decision statistic and λ is the decision threshold. The value of λ is set depending on the requirements of detection performance. Based on an AWGN channel, these values can be computed as in (4) and (5).

$$p_d = Q_m(\sqrt{2\gamma}, \sqrt{\lambda}) \tag{4}$$

$$p_{fa} = \frac{\Gamma(m, \frac{\lambda}{2})}{\Gamma(m)} \tag{5}$$

where $m = TW$, which is the time-bandwidth product of the energy detector, $Q_m(a, b)$ is the generalized Marcum Q-function, $\Gamma(.)$ the complete gamma function and $\Gamma(.,.)$ the upper incomplete gamma function.

Low values for p_d result in missing the presence of a primary user with high probability and can lead to interferences to primary transmissions. On the other hand, a high p_d results in low spectrum utilization, since secondary users miss spectrum opportunities. The probability of misdetection can then be computed as $p_{md} = 1 - p_d$. Typical values are $p_d = 0.1$, $p_{md} = 0.9$, and $p_{fa} = 01$.

A single CR may fail to detect the presence of a primary signal due to fading or shadowing. However, it is unlikely that all secondary users within a CRN experience fading or shadowing concurrently. Therefore, cooperative spectrum sensing (CSS) [5] can help to improve the probability of detection by taking into account sensing reports from several CRs. Cooperation provides with space diversity and overcomes the limitations introduced by bad environment conditions in a particular area of the network.

In CSS, each secondary user takes a measurement and shares its report in order to take a global decision. The combination of all reports, a.k.a. data fusion, can be centralized or distributed; when it is centralized, all CRs sent the reports to a single fusion center (FC), e.g., the BS, which is responsible for taking a global decision and report back the results to the members of the CRN. If it distributed, every CR can act as an FC receiving sensing information from the neighboring nodes and taking a decision locally. Then, individual decisions can be shared among CRs and converge by iterations to a unified decision. On the other hand, sensing reports may contain the observed data by a particular receiver, an approach known as **soft fusion**, or its individual decision about the existence of a primary, known as **hard**

fusion. Soft fusion generally provides better results in terms of primary detection but requires the transmission of a high volume of data. Hard fusion reduces the amount of transmitted data because each node only needs to send one bit of information.

Fusion Data Mechanisms

Hypothesis testing is usually used in soft-fusion mechanisms, which relies on statistical tests used to determine whether there is enough evidence in a sample of data to infer that a certain condition is true for the entire population. In the cooperative spectrum sensing mechanism of CRNs, the sample of data is composed of the set of reports sent by SUs.

The test examines two opposing hypotheses: H_0 or the absence of PU and H_1 or the presence of PU. One of the basic hypothesis testing methods is the Neyman-Pearson (NP) test. The NP test aims at maximizing the detection probability p_d given the constraint $p_{fa} \leq \alpha$, being α is the maximum false alarm probability.

According to the individual signal detection in (1), the NP test is equivalent to the following test:

$$\Lambda(\mathbf{y}) = \frac{f(\mathbf{y}|H_1)}{f(\mathbf{y}|H_0)} = \prod_{k=1}^{N} \frac{f(\mathbf{y}_k|H_1)}{f(\mathbf{y}_k|H_0)} \underset{<H_1}{\geq H_0} \lambda \tag{6}$$

where $\Lambda(\mathbf{y})$ is the likelihood ratio, $f(\mathbf{y}|H_1)$ is the distribution of observations $\mathbf{y}$ under hypothesis H_j, $j \in (0, 1)$, λ is the detection threshold, and N is the number of samples. The likelihood ratio indicates how many times more likely the set of measurements are under one model than the other.

The second equality in (6) holds only if the observations $\mathbf{y}_k$ are independent and identically distributed (i.i.d.) under H_j. As a result, it is the optimal test if the conditional independence is assumed. Another disadvantage of this method is that it requires a fixed number of measurements, which can lead to a large sensing time.

An alternative to reduce the sensing time is the sequential probability ratio test (SPRT). In SPRT, samples are taken sequentially, and the test statistics are compared with two thresholds λ_0 and λ_1, with $\lambda_0 < \lambda_1$, which are determined by detection requirements. If the likelihood ratio is greater than λ_1, the detector outputs $H1$, and H_0 if it is smaller than λ_0. Otherwise, it waits for the next measurement, as more samples are needed in order to take a decision. The main advantage of the SPRT is that it requires fewer samples on the average than those fixed-sample testing methods to achieve the same detection performance, but it also requires a priori knowledge of the distribution probability of measurements and assumes identical probability distributions for all users.

Regarding hard-fusion mechanisms, the OR, AND, and the "k out of N" rules can be used. Q_d and Q_{fa} are then defined, respectively, as the probability of detection and false alarm of the fusion mechanism given the reports of a set of N SUs.

- **OR rule**. The final decision is H_1 if at least one of N SUs reports "1." The probabilities of false detection and false alarm are then given by (7).
- **AND rule**. The final decision is H_1 if all SUs report "1." The probabilities of false detection and false alarm are then given by (8).
- **k out of N rule**. The final decision is H_1 if at least k out of the N SUs report "1." The probabilities of false detection and false alarm are then given by (9).

$$Q_d = \prod_{i=1}^{N}(1 - p_{d,i}) \quad Q_{fa} = \prod_{i=1}^{N}(1 - p_{fa,i}) \tag{7}$$

$$Q_d = \prod_{i=1}^{N} p_{d,i} \quad Q_{fa} = \prod_{i=1}^{N} p_{fa,i} \tag{8}$$

$$Q_d = \sum_{i=k}^{N} \binom{N}{i} p_{d,i}^{i}(1 - p_{d,i})^{N-i} \quad Q_{fa} = \sum_{i=k}^{N} \binom{N}{i} p_{fa,i}^{i}(1 - p_{fa,i})^{N-i} \tag{9}$$

where $p_{d,i}$ and $p_{fa,i}$ are the individual probabilities of detection and false alarm of user i.

The OR rule works best, i.e., maximizes the detection probability and minimizes the false alarm probability, for a large number of cooperative users, while the AND rule presents its best performance for a small number of users. The majority rule can be obtained by means of the k out of N rule, under the condition $k \geq N/2$. In such case, it is important to obtain the value of k for which the detection errors are minimized. It can be shown [5] that this value depends on the individual detection threshold λ (see Eqs. 2 and 3).

Classification of CRNs

CRNs can be classified into **centralized** or **distributed** according to their architecture. In centralized networks there is a single top-level entity in charge of network management, typically a base station (BS). In this type of networks, CSS is performed in a centralized way, and the BS takes decisions about spectrum access.

In a distributed network, management is shared by several entities, and communications takes place in an ad hoc manner. Because of this, distributed CRNs are also known as cognitive radio ad hoc networks (CRAHNs) [3]. When these entities are a subset of SUs, we refer to these networks as partially distributed. SUs are grouped into clusters according to some parameters, such as distance, and a cluster head is selected to be in charge of the cluster management. The CSS in partially distributed CRNs is performed in a centralized way, so members of a given cluster report their measurements to the cluster head, who takes decisions about spectrum availability. Note that the cluster head selection mechanism adds a significant overhead and can pose serious security problems if the cluster head node

is compromised. When the management is shared among all SUs and there is no central entity, then we talk about fully distributed networks. The CSS mechanism is distributed, and SUs exchange their reports among their neighbors in order to reach a joint spectrum decision. Due to the lack of a trusted central entity, management is much more complex, and the design of efficient security policies is hard to achieve. On the other hand, by distributing spectrum decisions among several SUs, the risk of denial of service (DoS) attacks against a single point of failure (i.e., the central entity) is eliminated.

CRNs can also be classified according to what extent they make use of the spectrum:

- **Spectrum interweave networks**. SUs use the spectrum without interfering PUs transmission either by accessing the spectrum in a TDMA (time division multiple access) or FDMA (frequency division multiple access). The goal is to find the spatial, temporal, or spectral gaps and use them for SUs transmission.
- **Spectrum underlay networks**. SUs transmit over the same spectrum as PUs but keeping interferences below a given level by means of spread spectrum techniques. This option requires, however, knowledge of the channel between the CRN transmitters and the PU receivers.
- **Spectrum overlay networks**. This sharing mechanism is similar to spectrum underlay, but in addition it requires the CRN to know about the PU operation. As an example, the CRN should know about the PU's codebooks allowing SUs to decode PU's transmissions.

The type of network plays an important role with regard to security issues. Generally speaking, distributed networks are more likely to be attacked since, due to the lack of a central entity, attack detection and prevention mechanisms are harder to implement. With regard to the use of the spectrum, underlay and overlay networks will require a more precise CSS mechanism in order to prevent harmful interferences to PUs. Thus, attacks to the CSS mechanism in such networks may be easier to implement and have a stronger impact on network performance.

Security in CRNs

Due to the openness of the wireless transmission channel, CRNs are exposed to well- known threats [35] but in addition, their particular features make them vulnerable to new attacks. Security attacks can be implemented against CRN functionalities by altering the radio environment or disrupting CSS mechanisms. CSS is built on the basis that nodes are honest and altruistic, making CRNs vulnerable to security threats such as selfish or malicious behaviors.

As in any other type of wireless network, the following security requirements should be fulfilled:

- Confidentiality, to ensure that data is not accessed by unauthorized users.
- Authentication, in order to verify the identity of the parties involved in a communication, ensure that data comes from a trusted source and prevent unauthorized injection of data.
- Integrity, to prevent an unauthorized user from altering data.
- Availability, to ensure that legitimate users can access network services.

The first three security services can be achieved by means of traditional cryptographic mechanisms, i.e., encryption, message authentication codes, and digital signatures. In fact, the IEEE 802.22 WRAN (wireless rural area networks) standard [1], the first wireless air interface standard based on CR technology, defines a MAC (medium access layer) security sublayer which provides basic security services by applying cryptographic transformations. This security sublayer has two main components: an encapsulation protocol and a PKM (Public Key Management) protocol. The encapsulation protocol defines a set of supported cryptographic suites and the rules for applying these algorithms to data. Confidentiality and integrity is achieved by means of AES-GCM, and network entry authorization is obtained by means of RSA and ECC-based X.509 certificates. On the other hand, the PKM protocol ensures the secure distribution of keying material among the members of the network.

Despite the abovementioned security mechanisms can be efficient to prevent some basic attacks, additional countermeasures are needed to deal with those that are specific to CRNs. As it will be shown in the following sections, most threats to CRNs are targeted to the spectrum sensing process used for detecting portions of free spectrum and selection of channels. These threats may lead to a DoS, thus preventing SUs from accessing network services.

In this chapter we provide an overview of the potential threats to CRNs and focus on those specific to CRNs. We classify them according to the layer in which they are performed, give an insight of their impact on the network performance, and describe potential countermeasures that can be used to prevent them or mitigate their effect.

Physical Layer Security

Eavesdropping

Wireless networks use an open transmission medium, and therefore they are susceptible to eavesdropping, meaning that an unauthorized user can access the

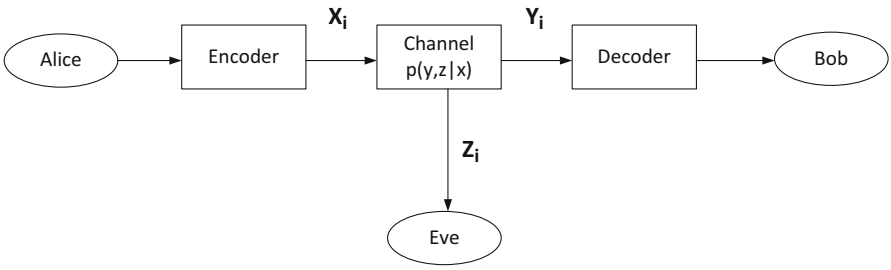

Fig. 3 Wiretap channel model

information transmitted by SUs. Traditionally, this attack has been addressed by means of cryptography implemented at the application level. However, in some scenarios, such as in ad hoc networks, it may be hard to distribute the cryptographic material, i.e., algorithms, keys, etc.

As a consequence, physical-layer security emerges as an effective mean to secure the wireless communications by exploiting the physical-layer characteristics of wireless channels. Wyner proposed the well-known wiretap channel model, a secrecy system consisting of a legitimate transmitter (Alice), a legitimate receiver (Bob), and an eavesdropper (Eve). Wyner showed that Alice can send confidential information to Bob while keeping it secret from Eve if the transmission rate is kept below a given threshold, which is known as **secrecy rate** or **secrecy capacity**. Figure 3 depicts the wiretap channel model. It has been shown that the secrecy capacity is the difference in capacities between the main channel (i.e., the channel from the transmitter to the legitimate receiver) and the eavesdropper channel (i.e., the channel from the transmitter to the eavesdropper) for a degraded discrete memoryless channel (DMC), as in (10).

$$C_s = \max_{p(x)} I(X;Y|Z) = \max_{p(x)}(I(X;Y) - I(X;Z)) \tag{10}$$

where the mutual information $I(X;Y)$ measures how much information the variables X and Y share.

Communication over a discrete memoryless channel, such as an AWGN channel, takes place in a discrete number of channel uses, indexed by a number $i \in N$. Alice sends a message to Bob by transmitting codewords which span n. Bob decodes the received signal, which is often corrupted by noise according to the statistical channel model and recovers the message. A discrete channel has finite input alphabets and output alphabets X_i and Y_i, respectively, which are related through a collection of conditional probability mass functions (pmfs) $p(y|x)$. In its turn, the wiretap channel is modeled by a set of pmfs $p(z|x)$.

Besides secrecy capacity, there are also some other parameters that depict the security of wireless networks. One is the leakage probability, which is the probability that the eavesdropper decodes its received codeword with an error

probability less than its target bit error rate. Another one is the security gap, which is the ratio of two SNRs, the SNR at which a very low-target bit error rate (BER) is achieved at the intended receiver and that at which a high BER is achieved at the eavesdropper. The smaller the security gap, the more likely that the transmitter can transmit over a time-varying wireless channel successfully.

Countermeasures

In order to prevent eavesdropping, it is needed to maximize the secrecy capacity of the main channel (Alice to Bob), while minimizing the capacity of the wiretap channel (Alice to Eve). This can be achieved by means of several techniques [44].

- **Security-oriented beamforming** consists in transmitting a signal in a given direction so that the signal received by the eavesdropper experiences destructive interference and becomes weaker, while the signal received by the legitimate receiver experiences constructive interference. In this way, the capacity of the main channel is higher than the capacity of the wiretap channel.
- **Relay-based techniques**. Relays are cooperative nodes that help the source to relay signals to the destination. The relay selection can also be employed to enhance the physical layer security in the presence of an eavesdropper. In a scenario where multiple relays are available, the relay node with the highest secrecy rate may be invoked if the channel state information (CSI) of both the main channel and the eavesdropper is known. If this information is not available, then the relay with the highest capacity will be chosen. When a relay assists nodes message transmission from a source to a destination, it forwards the signal to the destination by means of a given protocol: amplify and forward (AF) or decode and forward (DF) [23]. With the AF protocol, the relay node just simply retransmits a scaled version of its received noisy signal to the destination. By contrast, the DF protocol enables the relay first to decode its received signal and then forward its decode result to the destination. The AF protocol is simpler, but as a drawback, with this protocol the relay may also amplify and forward the received noise. This may result in a performance degradation at the destination in decoding the signal.
- **Artificial noise aided**. This approach enables the source to generate an interfering signal (referred to as artificial noise) in a such a way that it only interferes the eavesdropper. As a consequence, the capacity of the wiretap channel is decreased, and thus the secrecy capacity is increased. The main drawback of this proposal is that it requires more power consumption to generate the artificial noise and knowledge about the attacker. This strategy is also known as cooperative jamming, and it is usually performed by means of some relays that, instead of forwarding the legitimate signal, jam or generate interferences to prevent an attacker from eavesdropping the legitimate signal.
- **Multi-antenna-Based Techniques**. Multiple-input multiple-out (MIMO) is a method for increasing the capacity of a radio link by taking advantage of the extra degrees of freedom provided by multiple antennas. This technique increases the

capacity of the main channel by using multiple antennas to transmit and receive to exploit multipath propagation.

Jamming

Jamming in wireless networks is defined as the intentional disruption of existing communications by decreasing the signal-to-noise ratio at the receiver through the transmission of interfering wireless signals. In CRNs, a jammer may have two objectives: disrupting all the communications of primary and secondary users or preventing only secondary users from accessing the free spectrum bands. The former goal is a general problem of standard wireless communications, the latter one is specific to CRNs. Note that by disrupting the secondary users communications an attacker increases its chances to use the free spectrum.

Jamming can be achieved by spreading a flat spectrum power in the bandwidth of interest, i.e., band jamming, or by generating a sinusoidal waveform whose power is concentrated on the target carrier frequency, known as tone jamming. The latter might be more expensive and require more specific hardware, but in turn it is more effective and disruptive.

Depending on how a jammer selects the channels to perform the jamming attack, it can be classified into:

- **Sweeping attack**. A malicious node attacks a channel regardless of whether there is activity or not in that channel. In this attack, the jammer may waste resources by transmitting signals on a free channel that do not cause any interference to secondary users.
- **Fixed-strategy jamming**. The jammer senses the spectrum in order to identify the channel being used by the transmitter and the receiver and transmits an interfering signal on that channel. It is thus more efficient than a sweeping attack, since it only generates interfering signals on those channels that are being used by the network. However, because CRNs perform spectrum sensing and may switch to a better channel, such an attack would be inefficient once the CRN has moved to a different channel.
- **Cognitive jamming**. A cognitive jammer is defined in [16] as an adversary equipped with cognitive radio technology, which adapts to the CRN strategy with regard to channel selection in order to maximize the efficiency of the attack.

The impact of the attack will depend on the number of available channels, the number and location of jammers and their capabilities regarding power transmission and channel selection, but in any case it will degrade the overall network performance [36] and can lead to a DoS for some users.

Countermeasures

Traditional jamming countermeasures include the use of directional antennas instead of omnidirectional antennas, or spread spectrum (SS) techniques [18].

Directional antennas are used to improve energy efficiency by only radiating in the sector where the receiver is located, thus reducing the network interference level. In its turn, spread spectrum can be direct sequence (DSSS) or frequency hopping (FHSS) based. The former uses a wider bandwidth for signal transmission, allowing for greater resistance to unintentional and intentional interference. DSSS can be achieved by using the signal to be transmitted to modulate a bit sequence, known as a pseudo noise (PN) code that is much shorter in duration than the original signal. In FHSS, each available frequency band is divided into sub-frequencies, and the signal rapidly changes or hops among them in a predetermined order. In this way, interference at a specific frequency will only affect the signal during a short interval. A major disadvantage of this approach is that the channel switching algorithm, i.e., the sequence of channels that will be followed by the network, must be shared in advance between the sender and receiver. Also, this technique will be only effective provided that such algorithm is kept secret from the attacker.

Channel/frequency hopping has also been proposed as a countermeasure [43] in the context of CRNs. Channel hopping can be performed in a reactive or proactive way, depending on whether the CRN switches to another channel upon detection of the attack or according to a predetermined sequence or algorithm, which is shared in advance among the members of the network. In both cases, the hopping information must be exchanged through a shared control channel. This scheme is time-consuming due to the required frequency synchronization, channel estimation, handshaking for information exchange, and network setup. This approach will be more efficient in preventing jamming attacks, since generally speaking it may be difficult for an attacker to guess the hopping sequence. A major drawback, however, is that in a CRN, the available channels may be time-varying due to PUs activity, and using a fixed channel sequence may greatly reduce the throughput of the CRN.

Some recent works [37] propose to optimize channel selection based on network conditions but also on jammer patterns. The interaction between the CRN and the jammers is modeled as a stochastic game where the CRN goal is to maximize secondary users' throughput. At each stage of the game, secondary users observe the spectrum availability, the channel quality, and the attacker's strategy from the status of jammed channels. According to this observation, they will decide how many channels they should reserve for transmitting control and data messages and how to switch between the different channels. Because these techniques rely on observations of jammers behavior, they are more robust to cognitive jammers than the previous ones. Some works present similar countermeasures but targeted to mitigate the PUE attack (see section "PUE Attack"), which could also be applied to mitigate the effect of jamming.

Finding the location of a jammer is of paramount importance in order to prevent further interferences by, once the jammer is located, taking the appropiate security actions [30]. A CRN can take advantage of its cooperative nature to estimate the position of the attacker by making use of measurements provided by secondary users. This is also one of the countermeasures proposed for the PUE attack and will be discussed in detail in the next section.

Finally, the techniques presented in section "Countermeasures" to prevent eavesdropping can also be applied in order to enhance the throughput of jammed links.

PUE Attack

The primary user emulation (PUE) attack, first presented in [12], can be considered a sophisticated version of a jamming attack. Although both of them can degrade the performance of the network and reduce the throughput, they differ in that:

- While a jammer transmits an interfering signal, a PUE attacker transmits a signal emulating a PU transmission.
- The main goal of a jammer is to disrupt communications, while a PUE attack aims at preventing the CRN from using a free channel due to the (false) detected presence of a PU.

Generally speaking, a PUE attack is less resource-consuming since the transmission power required for a successful attack is lower than in a jamming attack. In particular, it is required that the received power at the secondary users is above the threshold set by the CRN for PU detection. However, it can be more complex depending on the selected detection mechanism (see section "Spectrum Sensing in CRNs"). Mechanisms such as cyclostationary detection will not consider the signal a legitimate PU transmission unless the PUE signal has the same characteristics as a real one in terms of power, modulation, etc. On the other hand, if energy detection is used, an attacker can succeed by transmitting any type of signal with the required transmission power. The ability of the attacker of mimicking a PU transmission is key to the success of a PUE attack. Parameters such as the characteristics of the transmitted signal, transmission power, and location of the attacker will determine the efficiency of the attack.

A PUE attacker can be malicious, if its only purpose is to interrupt the activity of the CRN, or selfish, if it aims at making use of the available bandwidth left by the CRN because of the attack. The PUE attack can be performed against a free channel during sensing period of the CRN or against the channel in use, forcing the CRN to vacate the channel and leading to the interruption of all communications until a new channel is available. In the worst scenario, the attack can lead to a DoS if the CRN fails to get an available channel. This may happen whenever the number of channels left unused by PUs is small or if the attacker resources are enough to perform PUE attacks over several channels simultaneously.

The activity of PUs and channel occupancy is often modeled as a Markov process with arrival rate λ_p and permanence time μ_p, in which every state represents the number of available channels for the CRN. Based on this model and on the attacker model, it is possible to get an estimate of the impact of a PUE attack on the network performance and the probability of a DoS. In [6], a model for the probability of a successful PUE attack is derived, as a function of the distance of the attacker from

the SUs and the energy threshold used during the PU detection. The authors state that under suitable power control and with more than an attacker, it is possible to obtain a probability equal to 1.

Countermeasures

The countermeasures for PUE attacks can be classified into:

- **Channel hopping**. As previously mentioned, channel hopping represents an effective countermeasure to avoid PUE [19] and jamming attacks, provided that the channel sequence cannot be predicted by an attacker. However, it leads the CRN to continuously perform frequency handoffs, implying the interruption of all communications until the CRN is completely operating at a new frequency. CRNs have been designed to deal with mild disruption due to the presence of PUs, and thus they can tolerate PUE attacks that have a similar impact. However, this measure will not be effective when a PUE attack is performed by an intelligent attacker that can guess the next channel to be selected by the CRN, or if the number of available channels is low.
- **Radio fingerprinting** is a process that identifies the device from which a radio transmission originated by looking at the properties of its transmission, including specific radio frequencies. Each signal originator has its own specific "fingerprint" based on the location and configuration of its transmitted signals. Even transmitters of the same type will show different characteristics during a transient period of time due to factors such as age or tolerance levels, which allow to uniquely identify every single transmitter. As a disadvantage, this method requires physical proximity to the PU in order to verify the fingerprints and the use of dedicated nodes to this end, a fact that considerably increases the cost of the method.
- **Cryptographic approaches**. Solutions based on cryptography can be integrated to prevent PUE attacks, such as including cryptographic signatures in PU signals or using integrity and authentication mechanisms for communications between primary and secondary CR users. The main problem with these approaches is that they do not meet the requirement of the FCC, which states that the utilization of available spectrum by SUs should be possible without requiring any modification to the incumbent users and their signals. Therefore, PU authentication is a challenging issue, and existing proposals are subject to practical limitations [24].
- **Location based**. If the location of the true PUs is known in advance, a PUE attacker can be detected by estimating the position of the transmission source and comparing it with the known locations. As an example, in IEEE 802.22 networks, the location of TV broadcast towers (PUs) can be obtained through access to geo-location databases.

The position of an emitter is usually estimated based on measures of certain distance-dependent parameters, such as the received signal strength (RSS), the time it takes to the signal to travel from the emitter to the receiver or time of arrival (ToA), or the angle of arrival (AoA) of the signal. These measurements are performed at

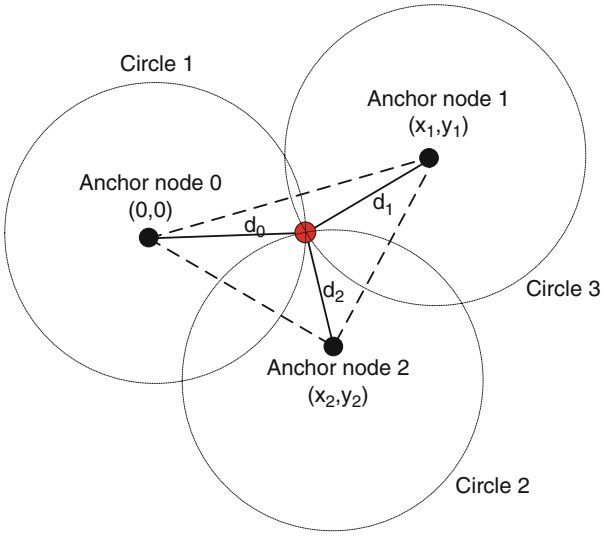

Fig. 4 Trilateration based on RSS/ToA measures

a set of reference nodes whose position is known, which we will refer to as anchor nodes. Distance or angle information is then used to estimate the position of the node, typically by applying a method such as lateration or angulation. Whenever the number of observations is reduced to three, then the process is referred to as trilateration for distance measurements, or triangulation for angles measurements.

Lateration consists in measuring distances between the node to be located and three or more anchor nodes with known positions. When distance measures are obtained by means of ToA or RSS, the position is estimated via the intersection of three circles, as depicted in Fig. 4. Let (x, y) be the 2-D position of the emitter to be located, which is in the range of 3 anchor nodes whose positions (x_i, y_i) are known. Let d_i be the distance from anchor node i to the emitter, which has been derived from a ToA or RSS measurement. Then, the equation of a circle (11) can be derived for each one.

$$d_i = \sqrt{(x - x_i)^2 + (y - y_i)^2} \tag{11}$$

If the transmission time or the transmission power at the sender is not known, the difference in RSS or ToA measurements between pairs of anchor nodes can still be computed. This is known as hyperbolic positioning, as the equation of a hyperbola is derived from each pair of difference measurement. The location of the emitter is then defined by the intersection of three hyperbolas. Regarding angulation, three or more AoA measures (triangulation or multiangulation) are used to obtain a 2-D location estimation, which is given by the intersection of the lines of bearing. For more details on these techniques, we refer the reader to [29].

In practice, measurements are subjected to errors, and the geometrical approaches previously presented lead to position estimation ambiguities. The effect of noisy measures, from the geometric point of view, is that the set of circles defined by equations in (11) rarely intersect. Then, the position estimate is usually approximated by using as many anchor nodes as possible (and therefore more measurements) and applying heuristic approaches which try to minimize the error performed in the estimation.

RSS-based techniques are relatively inexpensive and simple to implement in hardware, but they are susceptible of high errors due to the dynamics of indoor/outdoor environments, mainly due to multipath signals and shadowing. The effect of shadowing is usually modeled as log-normal with standard deviation σ_{dB}. This parameter is relatively constant with distance and typically takes values between 4 and 12 dB depending on the environment considered. This model leads to RSS estimates with variance proportional to their range, i.e., to the distance between the emitter and the node performing the RSS measurement. With regard to time-based techniques, measures may be affected mainly by multipath effect. Because of this, the accuracy of the method strongly depends on the ability to estimate the line-of-sight (LoS) signal. In its turn, angle-based approaches require the use of several antennas, thus increasing the cost and size of nodes.

A number of other methods exist to estimate the position of a node, such location fingerprinting. It consists in storing at a database a set of location signatures, which are built based on the signal characteristics obtained from a set of locations. Then, the position of a given emitter is estimated by comparing its received signal characteristics with those signatures previously stored in a database. This proposal requires being aware of the position of all PUs in advance and also, it may pose scalability problems in large networks.

Attacks to the Learning Engine

One of the key features of CRs is their capability of adapting to changing conditions in order to enhance network performance, based on current observations of the environment and past experiences. Learning from the past requires the introduction of a learning engine that makes use of **machine learning** or **artificial intelligence** (AI) algorithms. The term machine learning refers to the automated detection of meaningful patterns in data, while AI is defined as intelligence exhibited by machines. An intelligent machine perceives its environment and takes decisions that maximize its chance of achieving some goal. Typical algorithms for a learning engine include support vector machines (SVM), reinforcement learning (RL), and neural networks or genetic algorithms.

In the context of CRNs, learning techniques can be a valuable tool to get knowledge about environment conditions and its variability over time, and more specifically about spectrum availability [2]. As an example, knowledge about typical PU activity can reduce the burden of CSS mechanisms and speed up the channel selection process. A CRN may decide not to use a given channel that is available

at some specific time, because it has learned that it is frequently used by PUs that intermittently occupies and vacates the channel. This will prevent the CRN from spending unnecessary time on sensing that channel but also from performing spectrum handoffs whenever that is the channel in use, and it detects the presence of a PU. Recall that spectrum handoffs cause interruption of all communications until a new channel is available, and therefore avoiding spectrum handoffs leads to a higher efficiency in terms of network throughput. Learning machine may also be an aid for other CR functionalities, such as spectrum allocation or even detection of attacks, such as jamming or the PUE attack.

Learning algorithms can be classified into supervised or unsupervised. In supervised learning the algorithm is fed with the input and the desired results during the training phase, while in unsupervised learning it is not provided with the correct results. Usually, this technique is used for classification. When supervised learning is used, input data has already been classified, so that we know how the output of the algorithm should be, and we can modify its internal parameters if the output is not the expected one. In unsupervised learning, the input data has no label yet, and it must be classified according to their statistical properties.

The benefit of applying supervised learning to a CRN is that the algorithm is fed in a controlled environment during the training phase. However, given the dynamics of wireless environments which frequently change due to phenomena such as noise, multipath, etc., it can lead to wrong decisions due to the huge difference between training data and the data acquired during the performance phase. In this sense, unsupervised learning may have a better performance, but it is susceptible to attacks during the training phase. A learning engine attacker could alter the wireless medium by transmitting jamming signals, replaying PU transmissions, or generating interferences to prevent the system from detecting true PU transmissions. This would lead the learning algorithm to a bad classification of environment conditions and thus to take wrong decisions about spectrum availability.

Despite being an important feature of CRs, learning engine issues have received less attention than other areas of CRNs, and, therefore, how to protect the learning phase of such engines still remains an open issue.

Link Layer Security

Byzantine Attack

The need for spectrum sensing mechanisms to protect PU transmissions gives rise to specific threats to CRNs that have been widely studied by the research community [8], such as the Byzantine attack, in which adversaries gain control of one or more authenticated devices with the aim of degrading network performance. In the context of CRNs, this attack is also referred to as spectrum sensing data falsification (SSDF) [11], and it relies on the transmission of false spectrum sensing data by malicious SUs that aim at disrupting the cooperative sensing mechanism of the network.

Recall that in CSS mechanisms, each SU performs energy measurements, and report them to a central entity or FC, or exchange this measurements among its neighboring nodes, depending on whether the network is centralized or distributed.

According to the model of attacker, the Byzantine attack can be classified into [38]:

- Always Yes, if the SU always declares that the primary user is active.
- Always NO, if the SU always reports an absence of primary signal.
- Always FALSE, if the SU always reports the contrary result to its observation.

In addition, when there is more than one compromised or malicious node, attacks can be classified into [32]:

- Independent attack, each attacker forges its sensing result with a given probability regardless of what other attackers do.
- Dependent attack, if the attacker know the sensing reports of other attackers and forges its own reports according to these information in order to minimize the probability of being detected.
- Collaborative attack, if the attackers exchange their sensing information and decide their response in a collaborative way.

The two last attacks might be harder to implement, since they require the set of attackers to exchange their reports in advance, and thus they are more costly. Besides, such an exchange should be done very quickly in order to be able to send the reports to the FC during the sensing period of the CRN. As in other attacks to CRNs, a Byzantine attacker can be malicious or selfish, depending on whether its main goal is to disrupt network performance or make use of the bandwidth left unused by the CRN because of the attack.

Figures 5 and 6 depict the effect of the Byzantine attack, in terms of Q_{md} and Q_{fa}, on the decision of the FC when the fusion mechanism used is the k out of N rule, in a CRN with $N = 100$ SUs and $k = 30$ and $k = 50$, respectively. The number of Byzantine attackers M ranges from 10 to 60, and they forge their report with probability $p_l \in (0, 1)$ in an independent way. Note that for $p_l = 0$, no Byzantine attacker forges its report, and therefore it is equivalent to have a CRN with N honest SUs. As it can be seen, a low threshold ($k = 30$) leads to good performance in terms of misdetections Q_{md}, but also to high values of Q_{fa} for any value of $M > 10$. As a consequence, Byzantine attackers can easily lead the CRN to a wrong decision when there is no PU and take the available bandwidth. In Fig. 6 it can be seen that there is a tradeoff between both metrics Q_{fa} and Q_{md}, so if the threshold k is raised, Q_{fa} decreases but Q_{md} increases.

In [42], a formula is derived for the optimal value of k_{opt} that minimizes $Q_{md} + Q_{fa}$ as a function of the number of users N and the individual probabilities p_{md} and p_{fa}.

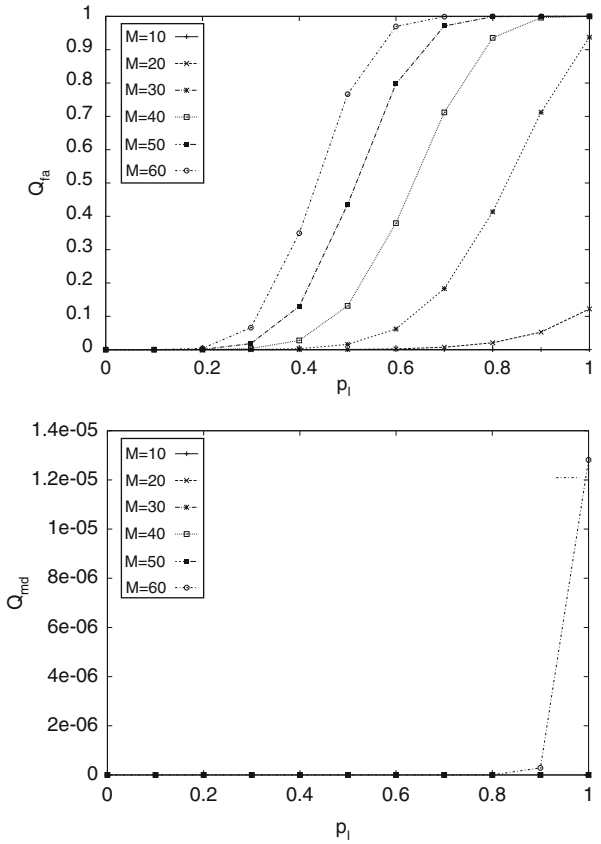

Fig. 5 P_{md} and P_{fa} with $N_{th} = 30$

$$k_{\text{opt}} = \min(N, \lceil \frac{N}{1+\alpha} \rceil) \tag{12}$$

with

$$\alpha = \frac{\log\left(\frac{p_{fa}}{1-p_{md}}\right)}{\log\left(\frac{p_{md}}{1-p_{fa}}\right)} \tag{13}$$

For typical values $p_{fa} = 0.1$ and $p_{md} = 0.1$ and $N = 100$, the optimal value is given by expression (12) is $k_{opt} = 50$.

Countermeasures

Byzantine defense is targeted to detect anomalies in the reported sensing data and discriminate between malicious and honest users. As a consequence, these schemes

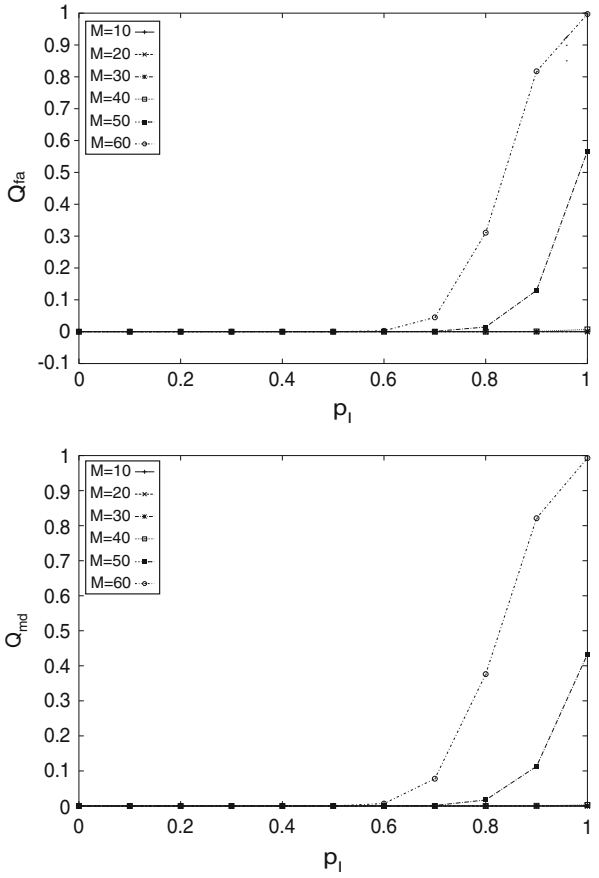

Fig. 6 P_{md} and P_{fa} with $N_{th} = 50$

require references representing normal behavior. In practice, it is hard to get a true reference, since a CRN does not know in advance which of the reports are honest. Besides, the fact that sensing mechanisms are extremely sensitive to the varying channel conditions and even honest users may report incorrect values, makes the task of identifying malicious users more challenging.

The general approach to counteract Byzantine attacks is to identify suspicious reports from potential malicious users and discard or give them a lower weight in the fusion data mechanism [10,31,32]. With that purpose, reputation mechanisms, a.k.a. as trust mechanisms, are typically used. Trust mechanisms have been extensively studied in the context of sensor networks and ad hoc networks [14]. The concept of *trust* has its origin in social sciences and is defined as the degree of subjective belief about the behavior of an entity [22]. Trust in CSS mechanisms is essential in order to ensure the correct detection of PU signals and identify holes in the spectrum.

The rationale behind it is to assign a low trust value to those SUs that deviate from the expected behavior. When an SU joins the network, it is assigned an initial trust value, and it will be updated in each sensing round according to it. Generally, the sensing decision procedure is performed as follows:

- Prefiltering. SUs with low reputation may be excluded from the fusion process.
- Data fusion. A data fusion rule is applied to the remaining reports, which are weighted according to the SU reputation.
- Reputation update. Trust values are updated for the next sensing round.

The way in which trust values are computed can be:

- Global decision based. Trust for a given SU is increased whenever the SUs report matches the final decision and decreased otherwise.
- Outliers detection based. These methods rely on different parameters such as the mean, the standard deviation, or the median, in order to identify those reports which clearly deviated from the data set.
- Correlation based. Relies on the correlation among measurements from neighboring nodes in order to detect abnormal values.

In global decision-based methods, trust is computed by comparing SU reports with the final decision. If a hard-fusion method is used, both SU reports and the final decision are binary variables, and to decide whether there is a match or not is straightforward. When soft fusion is used, however, it is needed to use a threshold. As an example, in [10], trust for a node k, r_k is initially set to zero, and it is incremented or decremented by one whenever the local sensing report is consistent with the final decision or not, respectively. The trust value is mapped to a weight w_k that is used by a SPRT fusion data mechanism (see section "Spectrum Sensing in CRNs") to reach a decision as in (14). This approach is known as weighted SPRT (WPSRT). The mapping between r_k and w_k is done in such a way that $w_i \in (0, 1)$ and ensures that an SU with a slightly negative reputation will have some contribution on the final decision.

$$W_N = \prod_{k=0}^{N} \left(\frac{f(y_k|H_1)}{f(y_k|H_0)} \right)^{w_k} \underset{<H_1}{\geq H_0} \lambda \tag{14}$$

Trust values depend on the report provided by the SU during a sensing round, but also on its past behavior. It is possible, though, to give higher weights to recent behaviors and gradually decrease the influence of older ones by means of a forgetting factor, as in [31]. In this way, an honest SU that reported several erroneous reports in the past due to channel degradation can recover faster.

Outliers detection is a technique that can be used to identify abnormal reports. In statistics, an outlier is an observation that is numerically distant from the rest of the data. When applied to cooperative spectrum sensing, identification of outliers allows

discarding those energy measures which are highly improbable and take a more reliable final decision about the existence of a PU. To this end, different statistical parameters can be used.

The simplest outlier detection technique makes use of the mean and the standard deviation of the set of reported energy values. In [20], an outlier factor is assigned to SU n at the ith sensing round as in (15), where $\sigma_n[i]$ is the outlier factor, $e_n[i]$ represents the reported energy value of a given secondary user, and $\mu[i]$ and $\sigma[i]$ are the sample mean and the sample standard deviation, respectively.

$$\sigma_n[i] = \frac{e_n[i] - \mu[i]}{\sigma[i]} \tag{15}$$

However, as the authors pointed out in [21], this technique does not perform well when the distribution of the energy values is highly skewed. In such case, valid values lying on the heavy-tailed side of the distribution will be assigned a high outlier factor, meaning that they will have a very low impact on the final decision. Other statistical parameters such as the median absolute deviation (MAD) or the bi-weight scale (BWS) are known to be more robust than the mean and the standard deviation. The MAD measures the median of the absolute distances of the data points from the sample median as in (16).

$$\sigma_n[i] = \text{median}_n \left\{ |e_n[i] - \mu[i]| \right\} \tag{16}$$

In its turn, the BWS can be computed as in (17). It has been shown that it is more sensitive to data samples that are at a moderate distance from the estimate and only ignores extremely data points [21]. Given the spatial diversity in CRNs, it makes sense to take into account those measures that slightly differ from the expected and only discard those that extremely deviate.

$$\sigma_n[i] = \sqrt{\left(\frac{N \sum\limits_{u_n^2<1} (e_n[i] - \mu[i])^2 \left(1 - u_n^2\right)^4}{s\,(-1+s)}\right)} \tag{17}$$

where

$$s = \sum_{u_n^2<1} \left(1 - u_n^2\right)\left(1 - 5u_n^2\right) \tag{18}$$

and

$$u_n = \frac{e_n[i] - \mu[i]}{\text{median}_n \left\{ |e_n[i] - \mu[i]| \right\}} \tag{19}$$

with c_2 a tuning constant which can be used to determine the impact of extreme points on BWS estimates.

Correlation between reports can also be applied to detect abnormal reports, under specific circumstances. This method relies on the fact that shadowing correlation decays exponentially with distance, and thus neighboring SUs should report similar values. This approach was followed in [27], where WSPRT is used as data fusion scheme, and the weights assigned to each node are computed according to a shadowing correlation model applied to a two-dimensional area. The authors define the shadowing random field of a given point (x, y) as the shadowing gain at unit grid area, i.e., δm $\times$ δm, centered at the coordinate (x, y). Then, the covariance of the shadowing random field between two different points (x_i, y_i) and (x_j, y_j) is modeled as in (20), with d_{ij} the Euclidean distance between the two nodes, σ the standard deviation of shadow fading. D_{corr} is the decorrelation distance which determines the distance above which the correlation falls to e^{-1} and depends on the environment (urban, suburban...). In suburban areas, it typically takes values between 120 and 200 m.

$$R_p(d_{ij}) = \sigma^2 \cdot e^{-d_{ij}/D_{\text{corr}}} \tag{20}$$

Abnormal reports are then detected by analyzing their similarity (or difference) with reports from neighboring nodes. Note that such an approach can only be applied in small CRNs where all SUs are close to each other, e.g., sensor networks, or in CRNs in rural areas where households tend to be clustered [33]. In the latter case, reports from SUs belonging to the same cluster should be highly correlated. To this end, the set of CR is divided into clusters according to their proximity so that nodes belonging to the same cluster should be highly correlated.

Regardless of the approach followed by the CRN to detect abnormal reports and exclude them from the CSS process, a major concern is to identify Byzantine attackers. Based on outliers detection, global decision-based methods, or correlation, the CRN can compute a trust value and establish a threshold to determine whether a given node is an attacker or a honest node reporting erroneous values due to bad channel conditions. It would be reasonable to penalize those users that are regarded as attackers by denying them access to the network. However, because every detection mechanism exhibits a certain rate of false positives, this would lead to expel some honest users of the CRN.

Utility-based methods circumvent this problem by, rather than identifying malicious users, incentivizing them to behave in an honest way [40]. The utility of a user is an economic term introduced by Daniel Bernoulli referring to the total satisfaction received from consuming a good or a service. When applied to CRNs, the utility may refer, for example, to the bandwidth that a given user is assigned. The key idea is to design the appropriate fusion and resource allocation mechanisms such that the utility of a Byzantine attacker gradually decreases if it keeps forging reports. Note that such approaches can only counteract the Byzantine attack based on selfish profiles, since malicious users do not care about bandwidth, and its only purpose is to disrupt network performance.

The malicious user utility $\hat{U}$ consists of two elements: the utility U acquired by the user as a member of the CRN and the utility achieved by forging reports

(e.g., available bandwidth when the CRN erroneously decides that no PU exists in a channel). The goal is to ensure $\hat{U} < U$ to incentivize SUs to behave honestly and report accurate sensing reports. Utility-based approaches rely on game theory, and some examples of its application to CRNs can be found in [13].

Note that in a centralized CRN, the FC is responsible for computing the trust value for each SU, according to the matches between the reports sent by the SU and the final decisions of the FC regarding the existence of a PU. In a fully distributed network, each SU must compute the trust values for its one-hop neighbors and reach a final decision. This fact increases node complexity due to the computations needed to run the sensing decision procedure and the exchange of reports among neighbors. Besides, it is prone to exhibit a higher error rate due to the lack of a trusted central entity and because the amount of reports combined by fusion data mechanisms is limited to the number of neighbors, and thus lower than in infrastructure-based networks..

Selfish Behavior

In a cooperative framework, selfish behavior refers to a set of actions performed by a node in order to increase its benefit while decreasing the average benefit for the rest of participants. Because CSS is known to improve the performance of PU detection, selfish behaviors may increase the probability of wrong decisions regarding spectrum opportunities. Selfish SUs may not cooperate in the sensing process in order to save energy while still making use of the network resources.

Due to the negative impact of selfish nodes on the CSS mechanisms of a CRN, appropriate strategies are needed in order to enforce cooperation. In wireless networks, this is a hard problem to deal with, since lack of feedback may be either due to selfishness or information loss. The community research has put a big effort on this topic in the context of ad hoc networks [26], mostly regarding routing mechanisms. Although these approaches cannot be directly applied to CRN, they can be used as a basis to develop efficient methods to detect selfish behaviors and to incentivize CR to cooperate. In addition, these methods should be also tailored to the type of CRN: ad hoc or infrastructure based. In ad hoc networks, selfish detection must be performed locally by neighboring nodes, and cooperative enforcement may be achieved by traditional mechanisms that penalize selfish nodes by, for example, not forwarding packets coming from them. On the other hand, in infrastructure-based networks, the FC is responsible for gathering the sensing reports from all CRs and therefore can easily verify which SUs do not report sensing measurement.

Cooperation enforcement can be achieved by means of utility-based methods. As an example, in [34] the CSS process is modeled as an N-player noncooperative, non-zero-sum repeated game. Two different strategies based on game theory are analyzed in order to incentive cooperation: grim trigger and carrot and stick. In grim trigger, cooperation from each node is measured, and all nodes stop cooperation whenever deviation from any node is detected. This technique can effectively motivate nodes to cooperate, but results in poor performance when channel errors

are not negligible. On the other hand, carrot and stick is an iterative approach where, at each step, a given node only cooperates if all nodes cooperated or deviated in the previous step. This approach recovers cooperation when all nodes deviate at the risk of leaving the CRN with no information about spectrum availability.

A more elaborated proposal is presented in [41], where reputation is used as a pricing factor in the spectrum allocation process to incentivize cooperative sensing in distributed CRNs. The reputation values are computed according to the sensing accuracy of the reports and the participation of SUs in the CSS process. SUs with low reputation are allocated bandwidth at the expenses of paying a higher price for it, thus forcing selfish nodes to cooperate if they want to maximize its utility.

Application Layer Security

As previously mentioned, SDRs are key for the deployment of CRNs, as they can provide the flexibility and reconfiguration capability needed by CRs. An SDR must be capable of downloading new software or updates that, once they are activated, may change the radio transmission parameters or implement new learning or decision algorithms. The reconfigurability property gives rise, however, to a number of software-related attacks [17].

The software is downloaded over the air, and therefore an unauthorized user could obtain a copy of the software, modify it, or inject malicious code. On the one hand, knowledge about a CR operation, in terms of channel selection, can be very valuable information to perform a different type of attack, such as a PUE attack. On the other hand, malicious code can lead a CR to behave in an unexpected way and even propagate the attack to other CRs, as it occurs with worms. Overall, the likelihood of causing network disruption because of software attacks is very high.

As a consequence, it is essential to provide confidentiality, authentication, access control and integrity in all communications used to distribute SDR software:

- Confidentiality will prevent unauthorized users to obtain a copy of the software.
- Authentication ensures that the downloaded software comes from a trusted source. Only authorized software should be activated in an SDR.
- Integrity guarantees that the downloaded software has not been altered.

A straightforward solution to provide confidentiality is symmetric encryption, by means of a shared secret key between the network administrator and the device. The key should be unique to each terminal and should be stored in **tamper-proof** hardware on the device [25]. Tamper-resistant devices may be designed to reset to zero, a.k.a. zeroise, sensitive data, such as cryptographic keys, if they detect penetration of their security encapsulation or out-of-specification environmental parameters.

Authentication and integrity can be achieved by means of digital signatures, which are sent together with the software to be downloaded. The main disadvantage of this approach is that it is computationally expensive, and some limited devices

Table 1 Main threats to SDRs

Threat	Security requirement
Insertion of malicious software	Integrity
Alteration or destruction of data	Integrity
Alteration or destruction of software	Integrity
Extraction of data	Confidentiality

may not support them. A lightweight mechanism, such as the one presented in [9], may be more suitable for constraint devices.

A method to ensure a secure execution of downloaded software is the implementation of trusted computing (TC) [28]. TC is a technology aiming at guaranteeing that a device will consistently behave in an expected way, and those behaviors will be enforced by computer hardware and software. This is achieved by loading the hardware with a unique private key that is not accessible to the rest of the system.

In [7] a complete list of threats to SDRs is given. Table 1 show the most relevant ones along with their security requirements.

Conclusions

CR paradigm is considered a key solution to mitigate the spectrum scarcity problem by enabling spectrum access in an opportunistic manner. CRNs are allowed to act as secondary users of the licensed spectrum on a non-interference basis, thus requiring the use of spectrum sensing mechanisms to identify free portions of the spectrum. Detection performance improves by means of spatial diversity and therefore all the members of the network are expected to cooperate by sharing their sensing reports.

The successful deployment of these networks relies on the proper design of mechanisms for cooperative sensing, adapt to changing environment conditions, and manage the available spectrum. However, CRNs use an open transmission medium that open doors to a myriad of attacks that can severely degrade network performance. On the one hand, CRNs are susceptible to well-known attacks that apply to any conventional wireless network. On the other hand, new threats that are based on the specific features or mechanisms of CRNs have been identified.

In this chapter we have provided an overview of the main threats to CRNs, with special emphasis on those inherent to CR functionalities. These threats and their possible countermeasures are summarized in Table 2. Most of the attacks are targeted to disrupt the CSS process of the network, either by altering the medium or by forging sensing reports. The consequences of these attacks are twofold. First, they may cause interference to the legitimate users of the spectrum, thus violating one of the basic principles of CRNs, and, second, they may prevent CRNs from accessing available spectrum, which degrades the quality of the communications. In some extreme situations, these attacks can cause a DoS, meaning that legitimate users will be denied access to network resources.

Table 2 Threats to CRNs and countermeasures

Threat	Layer	Countermeasures
Eavesdropping	Physical	Beamforming/relays/MIMO/artificial noise
Jamming	Physical	Channel hopping/location of attacker
PUE	Physical	Fingerprinting/cryptography/location of attacker
Learning	Physical	Training in a secure environment
Byzantine	Link layer	Trust schemes/utility-based schemes (game theory)
Selfish	Link layer	Utility-based schemes (game theory)
Threats to SDRs	Application	Secure software download and execution

Throughout this chapter we have discussed several countermeasures for each attack and evaluated their pros and cons. Some of them, being effective in mitigating the attack, may not be practical from a deployment point of view. Limitations regarding cost, size of devices, and deployment of additional infrastructure or FCC rules could restrain their realization. Two key aspects make hard the design of efficient countermeasures: first, the lack of real scenarios to evaluate the impact of the attacks with more accuracy and the feasibility of deploying specific countermeasures, and, second, the heterogeneity in CRN architectures and mechanisms to implement all functionalities. Despite the research community has put a big effort in developing the IEEE 802.22 standard, its application is limited to a few scenarios, since it was conceived to be used in large rural areas. As a result, the mechanisms and features defined in IEEE 802.22 may not apply to other CRNs. Therefore, further work in this direction is needed in order to deploy secure CRNs.

Abstract

Spectrum sharing of 802.11 wireless local area network (WLAN) and radars operating in co-/adjacent channel scenarios (notably 5 GHz) is a problem of considerable importance that requires new innovations. The spectrum sharing explored in this chapter is based on unilateral action by Wi-Fi networks to prevent

unacceptable interference to incumbent radar and also mitigating the interference from radar to Wi-Fi. Specifically, the ability of a single Wi-Fi network inside the exclusion region is to *speedily detect* radar operation and to subsequently switch to a clear channel as a means of protecting them. The approach is relied on the opportunistic use of naturally occurring *random* quiet/idle periods in a Wi-Fi network employing distributed coordination function (DCF) to detect the presence of a radar using energy detection. Moreover, the Wi-Fi systems outside the exclusion region are modified to mitigate the interference from a pulsed search radar such that the WLAN continues to operate with no noticeable performance degradation. The radar pulse detection is required to mitigate the radar interference.

Introduction

The fundamental challenge facing mobile network operators is the scarcity of spectrum allocated for civilian use. The demand (and hence the price) for spectrum has skyrocketed as cellular data, and WLAN services have become ubiquitous in response to ever-richer multimedia and interactive applications running on higher-end consumer devices. Acknowledging this recent exponential growth in data traffic on cellular networks, regulatory authorities have aimed at various strategies for systematically increasing the spectral efficiency of wireless networks, as means for alleviating the spectrum crunch.

Looking ahead, the need for coexistence among dissimilar technologies will be a fundamental feature of wireless networks as a broad principle. For example, a significant chunk of Wi-Fi channels in the 5 GHz bands (declared U-NII, i.e., unlicensed, for North America) are utilized by various radar systems worldwide [14,28], in fact, only 36% of 5 GHz channels are unencumbered by radar protection requirements. Hence, 802.11 WLAN networks in the 5 GHz band was the first significant instance of coexistence/spectrum sharing. To that end, dynamic frequency selection (DFS) by Wi-Fi (based on channel sensing and radar avoidance) was the solution proposed to protect radars from WLAN systems [19]. An examination of the 225 MHz–3.7 GHz band assignments shows that 1700 MHz in this range has been set aside for radar and radiolocation operation in the United States [25] making it a virtual certainty that issues of coexistence of radars with civilian systems will recur. In fact, the US Department of Commerce has already recommended that 150 MHz of spectrum between 3550 and 3700 MHz be made available for wireless broadband applications [2,6] which has led to further coexistence studies.

The foundation of protecting radar operation is based on the notion of an *exclusion or protection region* as shown in Fig. 1 – this defines a spatial region centered around the radar location where no co-channel use by WLAN is permitted

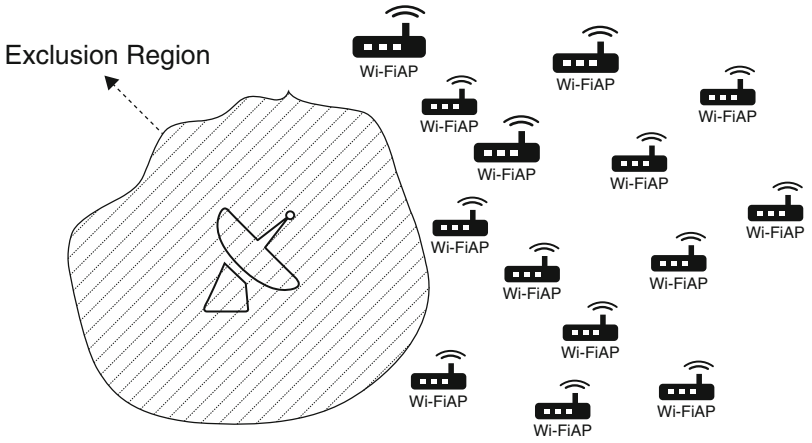

Fig. 1 Wi-Fi access points outside the radar exclusion region that benefit from proposed idea

(and by implication, reuse of the channel is permitted only outside this region). This topic was explored in [18] for a search pulsed radar rotating with a constant angular rotation (speed) and employing a known transmit main beam-pattern in azimuth (For simplicity, the formulation in [18] assumes a 2D model, whereby the radar and Wi-Fi networks operate in the same plane.). Thus the exclusion region is time varying, consist with the current location of the radar beam-pointing angle. Clearly, minimizing the area of the protection region (equivalently, expanding the co-channel reuse opportunities for the secondary Wi-Fi networks) is an appropriate design goal, and a method for achieving this is shown in [18] as a function of the WLAN deployment geometry.

In Fig. 2, the exclusion regions are determined by regulatory organizations (such as the NTIA) under the assumption that secondary networks (e.g., Wi-Fi) do not take any measures to mitigate interference to the radar systems [22]. In such scenarios, these no-go exclusion regions can extend for hundreds of kilometers radially from radar location, which given the proximity of radars to population centers (precisely the places where there is demand for such secondary networks) makes deployment of secondary systems unattractive as a business proposition.

Enabling mitigation between two dissimilar radio networks (such as radar and Wi-Fi) can be accomplished (at a conceptual level) in several ways. The most obvious is for one system to retrofit so as to become more resilient in operation to the presence of the other. This is the methodology which is adopted in this work, i.e., explore enhancements to Wi-Fi system that enable it to (a) rapidly detect the presence of (pulsed) radars and avoid (via evacuating the channel) when it is

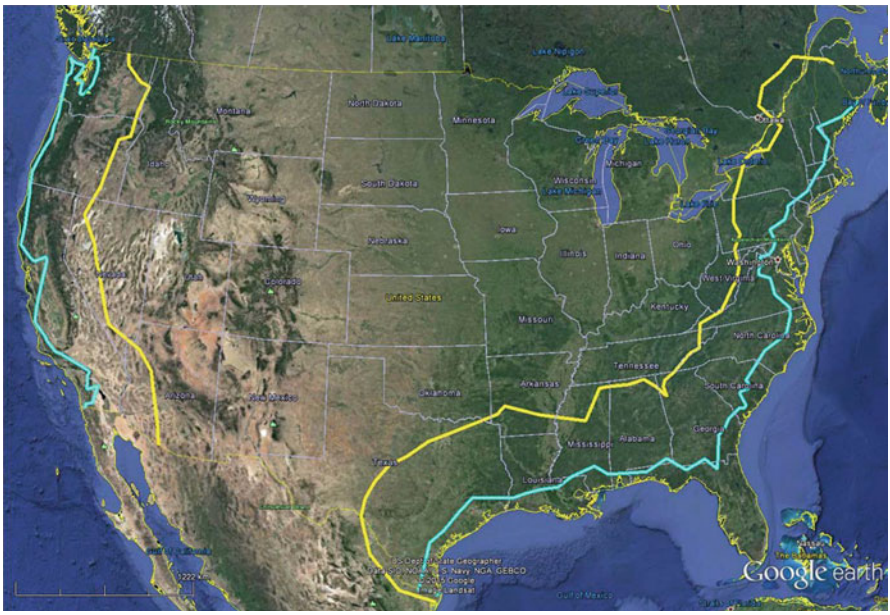

Fig. 2 The original exclusion regions computed by the NTIA (*yellow contours*) were revised recently in [8] (*blue contours*). Even the revised region encompasses many of the major population centers such as Los Angeles and New York City

inside the exclusion region and/or (b) detect and perform interference mitigation during WLAN packet transmission when it is outside the exclusion region. The first conforms to regulatory requirements so as to protect the incumbent radar from undue interference, whereas for WLAN nodes at a distance from the radar (i.e., outside the exclusion region), radar pulses that impact WLAN packets in flight contribute low interference that make (WLAN) packet decoding feasible with suitable interference mitigation.

Inside the exclusion region, it is crucial that communication systems detect active radars *accurately and speedily* in order to limit interference to incumbents. The FCC's current plans for spectrum sharing in the 3.5 GHz band forgo sensing and instead rely solely on a Spectrum Access System to govern usage of the shared spectrum [6]. However, a full coexistence solution will likely employ detect and switch via run-time channel sensing in conjunction with spectrum sharing database assistance. The latter contains all available system information regarding incumbent operation [8] that can assist secondary a priori for interference avoidance; however, in case of any updates to primary operation, such database information may possibly be out of date, and thus run-time sensing will likely be needed.

A traditional approach for a WLAN (inside the protection region) attempting to detect a radar pulse is based on requiring all in-network transmissions to cease (via scheduling) so as to create quiet/idle periods wherein radar pulses that happen to arrive can be accurately detected. In [9], the authors propose periodically

scheduling idle intervals for the purposes of channel sensing. The scheme incurs some complication in implementation due to the increase in packet fragmentation and consequent loss in throughput. In [16], extending (some of) naturally occurring idle periods in the Wi-Fi DCF MAC for the purposes of channel sensing is considered which did not suffer from the complications of [9] and was shown to detect transient out-of-network interference reliably. However, subsequently the requirement for any scheduled quiet period was dropped, and radar detection was based solely on *inherent natural periods of network operation whereby* ***all*** *nodes are backing off*, leading to randomly occurring quiet periods of random duration [24]. However, such naturally occurring idle periods typically comprise only a small portion of channel time on average (This fraction decreases with Wi-Fi node density or traffic load increase, i.e., factors that are beyond direct control.); hence, the chances of detecting the short-duration and low-duty cycle radar pulses within such random quiet intervals reliably is a largely open question. On the other hand, if the number or duration of such quiet intervals is increased (via means to be described later) to improve radar detection probability, it will result in a commensurate loss in communication network throughput, leading to an inherent trade-off that is explored and characterized.

Finally, *outside the exclusion region*, it is possible that a Wi-Fi node is able to detect radar pulses reliably *even during transmission of WLAN packets*, due to the lower interference power at the Wi-Fi receiver. Thus in contrast to the method in [24] that waited for the (probabilistic) event that a pulse falls within a quiet duration, it is proposed to investigate how WLAN may detect the presence of an interfering (narrow) radar pulse while there is a payload on the channel. Accordingly, two modifications to generic Wi-Fi transmitter/receiver chain are suggested toward achieving the goal of radar pulse detection cum interference mitigation.

DFS Requirement in 5 GHz

DFS comprises of a radar detection and avoidance scheme by the secondary (Wi-Fi) network. The detection algorithm has two primary components:

1. **Out-of-service monitoring:** This refers to the period at the start when each access point (AP) must scan the channels to determine if radar is present. The requirement is to detect radar signals above −62 dBm with detection rate of 99.99% within a scan duration of 60 s.
2. **In-service monitoring:** This refers to the ability of an active Wi-Fi network to detect a radar that begins operation after initial setup. DFS requires that during the regular operation, WLANs must detect a radar with a success rate of 60% for radar signals above −62 dBm in 60 s.

The detection rate is determined by the probability that a radar pulse is detected by a Wi-Fi network in each detection phase. Compliance with the radar protection requirements is based primarily on verifying these detection rates under the test scenarios, and example radars are defined in [14]. These DFS rules were aimed specifically at the 5 GHz band (Hence they may be insufficient for protecting radars in other bands.) and will be used as a performance benchmark for the novel schemes. [29] analyzed the radar detection delay in a simple time division duplex (TDD) system.

Radar Pulse Detection Using Quiet Periods in Wi-Fi

Model of Wi-Fi Network

In this work, an isolated Wi-Fi "cell," i.e., a single access point with n connected clients, is considered. In the following sections, the following two cases are studied:

1. Downlink-only traffic from the access point (AP) to the associated stations;
2. Full buffer at *all* nodes in the network.
